Braunwald's Heart Disease

A TEXTBOOK OF CARDIOVASCULAR MEDICINE

ELEVENTH EDITION

Edited by

DOUGLAS P. ZIPES, MD

Distinguished Professor
Division of Cardiology and the Krannert Institute of Cardiology
Indiana University School of Medicine
Indianapolis, Indiana

PETER LIBBY, MD

Mallinckrodt Professor of Medicine
Harvard Medical School
Brigham and Women's Hospital
Boston, Massachusetts

ROBERT O. BONOW, MD

Max and Lilly Goldberg Distinguished Professor of Cardiology
Vice Chairman, Department of Medicine
Director, Center for Cardiac Innovation
Northwestern University Feinberg School of Medicine
Chicago, Illinois

DOUGLAS L. MANN, MD

Lewin Chair and Professor of Medicine, Cell Biology, and Physiology
Chief, Division of Cardiology

Washington University School of Medicine in St. Louis
Cardiologist-in-Chief
Barnes-Jewish Hospital
St. Louis, Missouri

GORDON F. TOMASELLI, MD

Michel Mirowski MD Professor of Cardiology
Professor of Medicine
Chief, Division of Cardiology
Johns Hopkins School of Medicine
Baltimore, Maryland
Founding Editor and Online Editor

EUGENE BRAUNWALD, MD, MD(Hon), ScD(Hon), FRCP

Distinguished Hersey Professor of Medicine
Harvard Medical School
Chairman, TIMI Study Group
Brigham and Women's Hospital
Boston, Massachusetts

Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine, Eleventh Edition
Two-Volume Set ISBN: 978-0-323-46342-3
Single Volume ISBN: 978-0-323-46299-0
International Edition ISBN: 978-0-323-55592-0

Notice
Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment, and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Authors assume any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

Acknowledgments

Creating a 2000-page textbook is a herculean task requiring input from many dedicated and skilled individuals. In addition to thanking the enthusiastic contributors who have written the chapters, at Elsevier we would like to thank Dolores Meloni, executive content strategist, for her resolve in keeping five independently thinking editors on the same path; Anne Snyder, senior content development strategist, for organizing us to make things happen on time; and John Casey, senior project manager. Many others, including copyeditors, artists, and production staff helped make this textbook what it is. Finally, as stated in the preface, we owe an inestimable debt of gratitude to Dr. Braunwald for his vision, integrity, and high standards, which we have tried to emulate.

We would also like to thank our many colleagues from all over the world who have written to us with suggestions on how to improve *Heart Disease*. We consider each recommendation carefully and welcome such input. In particular, we acknowledge the comments on multiple chapters from the following:

Azin Alizadehasl MD *Rajaie Cardiovascular Medical and Research Center, Tehran, Iran*

Arash Hashemi MD *Erfan General Hospital, Tehran, Iran*

Anita Sadeghpour MD *Rajaie Cardiovascular Medical and Research Center, Tehran, Iran*

Leili Pourafkari MD *Razi Hospital, Tabriz, Iran*

Mehran Khoshfetrat MD *Tehran, Iran*

Babak Geraiely MD *Tehran University of Medical Sciences*

Shabnam Madadi MD *Cardiac Imaging Center, Shahid Rajaei Heart Center, Tehran, Iran*

Banasiak Waldemar MD *Centre for Heart Disease, Military Hospital, Wroclaw, Poland*

Carlos Benjamín Alvarez MD, PhD *Sacré Coeur Institute, Buenos Aires, Argentina*

Elias B. Hanna MD *Division of Cardiology, Louisiana State University, New Orleans, Louisiana*

Contributors

Keith D. Aaronson MD, MS
Bertram Pitt MD Collegiate Professor of Cardiovascular Medicine
Professor of Internal Medicine
Division of Cardiovascular Medicine
University of Michigan
Ann Arbor, Michigan

Mechanical Circulatory Support

William T. Abraham MD
Professor of Internal Medicine, Physiology, and Cell Biology
Chair of Excellence in Cardiovascular Medicine
Director, Division of Cardiovascular Medicine
Associate Dean for Clinical Research
Director, Clinical Trials Management Organization
Deputy Director, Davis Heart and Lung Research Institute
The Ohio State University
Columbus, Ohio

Devices for Monitoring and Managing Heart Failure

Michael A. Acker MD
Chief, Division of Cardiovascular Surgery
Director, Penn Medicine Heart and Vascular Center
University of Pennsylvania Health System
Philadelphia, Pennsylvania

Surgical Management of Heart Failure

Michael J. Ackerman MD, PhD
Windland Smith Rice Cardiovascular Genomics Research Professor
Professor of Medicine, Pediatrics, and Pharmacology
Mayo Clinic College of Medicine and Science
Director, Long QT Syndrome/Genetic Heart Rhythm Clinic
Director, Mayo Clinic Windland Smith Rice Sudden Death Genomics Laboratory
Mayo Clinic
Rochester, Minnesota

Genetics of Cardiac Arrhythmias

Philip A. Ades MD
Professor of Medicine
University of Vermont College of Medicine
Burlington, Vermont

Exercise-Based, Comprehensive Cardiac Rehabilitation

Michelle A. Albert MD, MPH
Professor of Medicine
Director, CeNter for the StUdy of AdveRsiTy and CardiovascUlaR DiseasE (NURTURE Center)
University of California at San Francisco
San Francisco, California

Cardiovascular Disease in Heterogeneous Populations

Larry A. Allen MD, MHS
Associate Professor of Medicine
Division of Cardiology
University of Colorado School of Medicine
Aurora, Colorado

Management of Patients with Cardiovascular Disease Approaching End of Life

Elliott M. Antman MD
Professor of Medicine
Associate Dean for Clinical/Translational Research
Harvard Medical School
Senior Investigator
TIMI Study Group
Brigham and Women's Hospital
Boston, Massachusetts

Critical Evaluation of Clinical Trials

Pavan Atluri MD
Assistant Professor of Surgery
Director, Cardiac Transplantation and Mechanical Circulatory Assist Program
Director, Minimally Invasive and Robotic Cardiac Surgery Program
Division of Cardiovascular Surgery
Department of Surgery
University of Pennsylvania
Philadelphia, Pennsylvania

Surgical Management of Heart Failure

Larry M. Baddour MD

Professor of Medicine
Mayo Clinic College of Medicine
Rochester, Minnesota

Cardiovascular Infections

Aaron L. Baggish MD
Associate Professor of Medicine
Harvard Medical School
Director, Cardiovascular Performance Program
Massachusetts General Hospital
Boston, Massachusetts

Exercise and Sports Cardiology

C. Noel Bairey Merz, MD
Director, Barbra Streisand Women's Heart Center
Director, Linda Joy Pollin Women's Heart Health Program
Director, Preventive Cardiac Center
Professor of Medicine
Cedars-Sinai Medical Center
Los Angeles, California

Cardiovascular Disease in Women

Gary J. Balady MD
Professor of Medicine
Boston University School of Medicine
Director, Non-Invasive Cardiovascular Laboratories
Boston Medical Center
Boston, Massachusetts

Exercise Electrocardiographic Testing

David T. Balzer MD
Professor
Division of Pediatric Cardiology
Washington University School of Medicine
St. Louis, Missouri

Catheter-Based Treatment of Congenital Heart Disease

Joshua A. Beckman MD
Professor of Medicine
Division of Cardiovascular Medicine
Director, Vanderbilt Translational and Clinical Cardiovascular Research Center
Vanderbilt University School of Medicine

Nashville, Tennessee

Anesthesia and Noncardiac Surgery in Patients with Heart Disease

Donald M. Bers PhD
Silva Chair for Cardiovascular Research
Distinguished Professor and Chair
Department of Pharmacology
University of California, Davis
Davis, California

Mechanisms of Cardiac Contraction and Relaxation

Sanjeev Bhalla MD
Professor
Mallinckrodt Institute of Radiology
Washington University in St. Louis
Department of Diagnostic Radiology
Section of Cardiothoracic Imaging
St. Louis, Missouri

The Chest Radiograph in Cardiovascular Disease

Aruni Bhatnagar PhD
Professor of Medicine
Division of Cardiovascular Medicine
Department of Medicine
University of Louisville
Louisville, Kentucky

Air Pollution and Cardiovascular Disease

Deepak L. Bhatt MD, MPH
Senior Investigator, TIMI Study Group
Executive Director, Interventional Cardiovascular Programs
Heart and Vascular Center
Brigham and Women's Hospital
Professor of Medicine
Harvard Medical School
Boston, Massachusetts

Percutaneous Coronary Intervention
Treatment of Noncoronary Obstructive Vascular Disease

Surya P. Bhatt MD
Assistant Professor of Medicine
UAB Lung Health Center

Division of Pulmonary, Allergy, and Critical Care Medicine
University of Alabama at Birmingham
Birmingham, Alabama

Chronic Lung Diseases and Cardiovascular Disease

Bernadette Biondi MD
Professor
Department of Clinical Medicine and Surgery
University of Naples Federico II
Naples, Italy

Endocrine Disorders and Cardiovascular Disease

Erin A. Bohula MD, DPhil
TIMI Study Group and Division of Cardiology
Brigham and Women's Hospital
Harvard Medical School
Boston, Massachusetts

ST-Elevation Myocardial Infarction: Management

Marc P. Bonaca MD, MPH
Associate Physician
Division of Cardiovascular Medicine
Brigham and Women's Hospital
Assistant Professor, Harvard Medical School
Investigator, TIMI Study Group
Boston, Massachusetts

Approach to the Patient with Chest Pain
Peripheral Artery Diseases

Robert O. Bonow MD, MS
Max and Lilly Goldberg Distinguished Professor of Cardiology
Vice Chairman, Department of Medicine
Director, Center for Cardiac Innovation
Northwestern University Feinberg School of Medicine
Chicago, Illinois

Nuclear Cardiology
Approach to the Patient with Valvular Heart Disease
Appropriate Use Criteria: Echocardiography
Appropriate Use Criteria: Multimodality Imaging in Stable Ischemic Heart Disease and Heart Failure

Aortic Valve Disease
Mitral Valve Disease
Guidelines: Management of Valvular Heart Disease

Barry A. Borlaug MD
Associate Professor of Medicine
Mayo Medical School
Consultant, Cardiovascular Diseases
Mayo Clinic
Rochester, Minnesota

Mechanisms of Cardiac Contraction and Relaxation

Eugene Braunwald MD, MD(Hon), ScD(Hon), FRCP
Distinguished Hersey Professor of Medicine
Harvard Medical School;
Founding Chairman, TIMI Study Group
Brigham and Women's Hospital
Boston, Massachusetts

Non–ST Elevation Acute Coronary Syndromes

Alan C. Braverman MD
Alumni Endowed Professor in Cardiovascular Diseases
Professor of Medicine
Washington University School of Medicine
Director, Marfan Syndrome Clinic
Director, Inpatient Cardiology Firm
St. Louis, Missouri

Diseases of the Aorta

J. Douglas Bremner MD
Professor of Psychiatry and Radiology
Emory University School of Medicine
and Atlanta Veterans Affairs Medical Center
Atlanta, Georgia

Psychiatric and Behavioral Aspects of Cardiovascular Disease

John E. Brush Jr, MD
Professor of Medicine
Cardiology Division
Eastern Virginia Medical School and Sentara Healthcare
Norfolk, Virginia

Clinical Decision Making in Cardiology

Julie E. Buring MD
Professor of Medicine
Brigham and Women's Hospital
Professor of Epidemiology
Harvard Medical School
Harvard School of Public Health
Boston, Massachusetts

Risk Markers and the Primary Prevention of Cardiovascular Disease

Hugh Calkins MD
Nicholas J. Fortuin Professor of Cardiology
Director, Cardiac Arrhythmia Service
Director, Electrophysiology Laboratory and Arrhythmia Service
The Johns Hopkins Hospital
Baltimore, Maryland

Hypotension and Syncope

John M. Canty Jr., MD
SUNY Distinguished and Albert and Elizabeth Rekate Professor
Chief, Division of Cardiovascular Medicine
Jacobs School of Medicine and Biomedical Sciences
University at Buffalo
Buffalo, New York

Coronary Blood Flow and Myocardial Ischemia

Mercedes R. Carnethon PhD
Associate Professor and Vice Chair
Department of Preventive Medicine
Feinberg School of Medicine
Northwestern University
Chicago, Illinois

Cardiovascular Disease in Heterogeneous Populations

Leslie T. Cooper Jr., MD
Professor of Medicine
Chair, Cardiovascular Department
Mayo Clinic
Jacksonville, Florida

Myocarditis

Mark A. Creager MD
Professor of Medicine and Surgery
Geisel School of Medicine at Dartmouth
Hanover, New Hampshire
Director, Heart and Vascular Center
Dartmouth-Hitchcock Medical Center
Lebanon, New Hampshire

Peripheral Artery Diseases

George D. Dangas MD, PhD
Professor of Medicine (Cardiology)
Zena and Michael A. Wiener Cardiovascular Institute
Icahn School of Medicine at Mount Sinai
New York, New York

Coronary Angiography and Intravascular Imaging

James A. de Lemos MD
Professor of Internal Medicine
Division of Cardiology
UT Southwestern Medical Center
Dallas, Texas

Stable Ischemic Heart Disease
Percutaneous Coronary Intervention

Jean-Pierre Després PhD
Scientific Director
International Chair on Cardiometabolic Risk
Professor, Department of Kinesiology
Faculty of Medicine
Université Laval
Director of Research, Cardiology
Québec Heart and Lung Institute
Québec, Canada

Obesity and Cardiometabolic Disease

Stephen Devries MD
Executive Director
Gaples Institute for Integrative Cardiology
Deerfield, Illinois;
Associate Professor
Division of Cardiology
Northwestern University Feinberg School of Medicine

Chicago, Illinois

Integrative Approaches to the Management of Patients with Heart Disease

Vasken Dilsizian MD
Professor of Medicine and Radiology
University of Maryland School of Medicine
Chief, Division of Nuclear Medicine
University of Maryland Medical Center
Baltimore, Maryland

Nuclear Cardiology
Appropriate Use Criteria: Multimodality Imaging in Stable Ischemic Heart Disease and Heart Failure

Mark T. Dransfield MD
Professor of Medicine
UAB Lung Health Center
Division of Pulmonary, Allergy, and Critical Care Medicine
University of Alabama at Birmingham
Birmingham VA Medical Center
Birmingham, Alabama

Chronic Lung Diseases and Cardiovascular Disease

Dirk J. Duncker MD, PhD
Professor of Experimental Cardiology
Department of Cardiology
Erasmus University Medical Center
Rotterdam, The Netherlands

Coronary Blood Flow and Myocardial Ischemia

Rodney H. Falk MD
Director, Cardiac Amyloidosis Program
Brigham and Women's Hospital
Associate Clinical Professor of Medicine
Harvard Medical School
Boston, Massachusetts

The Dilated, Restrictive, and Infiltrative Cardiomyopathies

James C. Fang MD
Professor of Medicine
Chief, Division of Cardiovascular Medicine

Executive Director
Cardiovascular Service Line
University of Utah Health Sciences Center
Salt Lake City, Utah

History and Physical Examination: An Evidence-Based Approach

Savitri E. Fedson MD
Associate Professor
Center for Medical Ethics and Health Policy
Baylor College of Medicine
Houston, Texas

Ethics in Cardiovascular Medicine

G. Michael Felker MD, MHS
Professor of Medicine
Division of Cardiology
Chief, Heart Failure Section
Duke University School of Medicine
Durham, North Carolina

Diagnosis and Management of Acute Heart Failure

Jerome L. Fleg MD
Medical Officer
Division of Cardiovascular Sciences
National Heart, Lung, and Blood Institute
Bethesda, Maryland

Cardiovascular Disease in the Elderly

Lee A. Fleisher MD
Robert D. Dripps Professor and Chair
Anesthesiology and Critical Care
Professor of Medicine
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania

Anesthesia and Noncardiac Surgery in Patients with Heart Disease

Daniel E. Forman MD
Professor of Medicine
University of Pittsburgh
Section of Geriatric Cardiology
Divisions of Geriatrics and Cardiology
University of Pittsburgh Medical Center

VA Pittsburgh Healthcare System
Pittsburgh, Pennsylvania

Cardiovascular Disease in the Elderly

William K. Freeman MD
Professor of Medicine
Mayo Clinic College of Medicine
Scottsdale, Arizona

Cardiovascular Infections

Chairperson
Department of Cardiovascular Medicine
Morristown Medical Center
Atlantic Health System
Morristown, New Jersey

Echocardiography

Robert P. Giugliano MD, SM
Physician, Cardiovascular Medicine Division
Brigham and Women's Hospital
Associate Professor of Medicine
Harvard Medical School
Boston, Massachusetts

Non–ST Elevation Acute Coronary Syndromes

Ary L. Goldberger MD
Professor of Medicine
Harvard Medical School
Director
Margret and H.A. Rey Institute for Nonlinear Dynamics in Medicine
Associate Chief
Interdisciplinary Medicine and Biotechnology
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Electrocardiography

Jeffrey J. Goldberger MD, MBA
Professor of Medicine and Biomedical Engineering
Chief of the Cardiovascular Division
University of Miami Miller School of Medicine
Miami, Florida

Cardiac Arrest and Sudden Cardiac Death

Samuel Z. Goldhaber MD
Professor of Medicine
Harvard Medical School
Director, Thrombosis Research Group
Senior Staff Physician, Cardiovascular Medicine Division

Brigham and Women's Hospital
Boston, Massachusetts

Pulmonary Embolism

Larry B. Goldstein MD
Ruth L. Works Professor and Chairman
Department of Neurology
Co-Director, Kentucky Neuroscience Institute
University of Kentucky College of Medicine
Lexington, Kentucky

Prevention and Management of Ischemic Stroke

William J. Groh MD, MPH
Clinical Professor of Medicine
Medical University of South Carolina
Chief of Medicine, Ralph H. Johnson VAMC
Charleston, South Carolina

Neurologic Disorders and Cardiovascular Disease

Martha Gulati MD
Division Chief of Cardiology
University of Arizona, Phoenix
Professor of Medicine
Physician Executive Director
Banner University Medical Center Cardiovascular Institute
Phoenix, Arizona

Cardiovascular Disease in Women

Gerd Hasenfuss MD
Professor of Medicine
Chair, Department of Cardiology and Pneumology
Chair, Heart Center
University of Goettingen
Chair, Heart Research Center
DZHK (German Center of Cardiovascular Research)
Goettingen, Germany

Pathophysiology of Heart Failure

Howard C. Herrmann MD
John W. Bryfogle Professor of Cardiovascular Medicine and Surgery
Perelman School of Medicine at the University of Pennsylvania
Health System Director for Interventional Cardiology

Director, Cardiac Catheterization Labs
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

Transcatheter Therapies for Valvular Heart Disease

Joerg Herrmann MD
Associate Professor of Medicine
Department of Cardiovascular Diseases
Mayo Clinic
Rochester, Minnesota

Cardiac Catheterization

Ray E. Hershberger MD
Professor of Medicine
Director, Division of Human Genetics
Division of Cardiovascular Medicine
Section of Heart Failure and Cardiac Transplantation
The Ohio State University Wexner Medical Center
Columbus, Ohio

Preface

This is the 11th edition of the classic textbook, *Heart Disease: A Textbook Of Cardiovascular Medicine*, that Dr. Eugene Braunwald began almost 40 years ago. The editors are pleased and honored to dedicate this edition to him for his extraordinary contributions to the discipline of cardiology, especially this textbook and its companions, and for his unique concept of creating a "living textbook."

In the past several decades, cardiology has advanced at a breakneck pace on many fronts. Knowledge of the diagnosis and management of patients with heart disease, as well as understanding of responsible mechanisms and preventive approaches, advance daily. Genetics, molecular biology and pharmacology, imaging, catheter-based therapy, and cardiac repair are only a sampling of what we encounter daily.

This constant flow of innovative research has generated a proliferation of new cardiovascular journals, cumulatively publishing an unprecedented amount of information. With the rapidly changing cardiovascular knowledge base, an authoritative textbook like *Heart Disease* to which readers can turn, confident that the statements are as accurate and up-to-date as possible, offers even greater value.

As with each edition of this reference work, international experts — household names to many readers — have totally revised *every* chapter. In addition, 14 new chapters have been added to recognize the ever-expanding role of cardiology into areas such as oncology, chronic lung disease, environmental toxins, catheter-based treatments of congenital heart disease, and other topics. Some sections have been revised for clarity, such as arrhythmias; some have been expanded, such as diseases of heart valves; others have had a shift of emphasis, such as congenital heart disease in the adult. Finally, to maintain vitality of standard topics, new authors have replaced more than a third of those who have tirelessly written for previous editions, in chapters on ethics, personalized and precision medicine, imaging, obesity, diabetes, sleep-disordered breathing, autonomic nervous system, and other areas.

In the preface for the 10th edition of *Heart Disease*, we emphasized that the online version contained audio, video, and written information not available in the print edition. We have continued and expanded this practice. To put this 11th edition in perspective, it contains more than 2700 illustrations and 565 tables, while maintaining the number of printed pages near 2000. The eBook includes an additional 400 illustrations, 60 tables, and 300 videos.

We have divided the book into 11 sections, including fundamentals of cardiovascular disease; genetics and personalized medicine; evaluation of the patient; heart failure; arrhythmias, sudden death, and syncope; preventive cardiology; atherosclerotic cardiovascular disease; diseases of heart valves; diseases of the myocardium, pericardium, and pulmonary vasculature bed; cardiovascular disease in special populations; and cardiovascular disease and disorders of other organs. We have continued the tradition of including practice guidelines, and have written the text for all levels of learners and for all specialties in cardiology. As before, information not directly relevant to practicing clinicians is presented in smaller font. More detailed information on many topics can be found in the companions to this book:

Cardiovascular Intervention by Deepak L. Bhatt
Cardiovascular Therapeutics by Elliott Antman and Marc Sabatine

Chronic Coronary Artery Disease by James DeLemos and Torbjorn Omland
Clinical Arrhythmology and Electrophysiology by Ziad Issa, John Miller, and Douglas Zipes
Clinical Lipidology by Christie Ballantyne
Diabetes in Cardiovascular Medicine by Darren McGuire and Nikolaus Marx
Heart Failure by Michael Felker and Douglas Mann
Hypertension by George Bakris and Matthew Sorrentino
Mechanical Circulatory Support by Robert Kormos and Leslie Miller
Myocardial Infarction by David Morrow
Preventive Cardiology by Roger Blumenthal, JoAnn Foody, and Nathan Wong
Valvular Heart Disease by Catherine Otto and Robert Bonow
Vascular Medicine by Marc Creager, Joshua Beckman, and Joseph Loscalzo
Braunwald's Heart Disease Review and Assessment by Leonard Lilly
Atlas of Cardiovascular CT by Allen Taylor
Atlas of Cardiovascular MR by Christopher Kramer and W Greg Hundley
Atlas of Nuclear Cardiology by Amil Iskandrian and Ernest Garcia

In keeping with the revitalization theme noted above, one of us (DPZ) will be leaving after this edition. Beginning with the 2nd edition of Heart Disease in 1984, Dr. Zipes has written the arrhythmia section and, in more recent editions, with co-authors, and has co-edited *Heart Disease* since the 6th edition. Gordon F. Tomaselli will be his very capable replacement.

The editors and authors, along with the Elsevier staff, have endeavored to make *Heart Disease* the go-to source for current cardiology knowledge, maintaining the high standards Dr. Braunwald set many years ago. We hope readers will enjoy reading this edition and learn from it, as we all strive to improve patient care, our ultimate goal.

Preface to the First Edition

Cardiovascular disease is the greatest scourge affecting the industrialized nations. As with previous scourges — bubonic plague, yellow fever, and small pox — cardiovascular disease not only strikes down a significant fraction of the population without warning but also causes prolonged suffering and disability in an even larger number. In the United States alone, despite recent encouraging declines, cardiovascular disease is still responsible for almost 1 million fatalities each year and more than half of all deaths; almost 5 million persons afflicted with cardiovascular disease are hospitalized each year. The cost of these diseases in terms of human suffering and material resources is almost incalculable.

Fortunately, research focusing on the prevention, causes, diagnosis, and treatment of heart disease is moving ahead rapidly. Since the early part of the twentieth century, clinical cardiology has had a particularly strong foundation in the basic sciences of physiology and pharmacology. More recently, the disciplines of molecular biology, genetics, developmental biology, biophysics, biochemistry, experimental pathology and bioengineering have also begun to provide critically important information about cardiac function and malfunction.

In the past 25 years, in particular, we have witnessed an explosive expansion of our understanding of the structure and function of the cardiovascular system—both normal and abnormal—and of our ability to evaluate these parameters in the living patient, sometimes by means of techniques that require penetration of the skin but also with increasing accuracy, by noninvasive methods. Simultaneously, remarkable progress has been made in preventing and treating cardiovascular disease by medical and surgical means. Indeed, in the United States, a steady reduction in mortality from cardiovascular disease during the past decade suggests that the effective application of this increased knowledge is beginning to prolong human life span, the most valued resource on earth.

To provide a comprehensive, authoritative text in a field that has become as broad and deep as cardiovascular medicine, I enlisted the aid of a number of able colleagues. However, I hoped that my personal involvement in the writing of about half of the book would make it possible to minimize the fragmentation, gaps, inconsistencies, organizational difficulties, and impersonal tone that sometimes plague multiauthored texts. Although *Heart Disease: A Textbook of Cardiovascular Medicine* is primarily a clinical treatise and not a textbook of fundamental cardiovascular science, an effort has been made to explain, in some detail, the scientific bases of cardiovascular diseases.

To the extent that this book proves useful to those who wish to broaden their knowledge of cardiovascular medicine and thereby aids in the care of patients afflicted with heart disease, credit must be given to the many talented and dedicated persons involved in its preparation. I offer my deepest appreciation to my fellow contributors for their professional expertise, knowledge, and devoted scholarship, which has so enriched this book. I am deeply indebted to them for their cooperation and willingness to deal with a demanding editor.

Eugene Braunwald

OUTLINE

PART I
Fundamentals of Cardiovascular Disease

OUTLINE

1

Global Burden of Cardiovascular Disease

Thomas A. Gaziano, Dorairaj Prabhakaran, J. Michael Gaziano

Over the last decade, cardiovascular disease (CVD) has become the leading cause of death worldwide. In 2013, CVD caused an estimated 17.3 million deaths and led to 330 million disability-adjusted life-years (DALYs) lost[1]—about 32% of all deaths and 13% of all DALYs lost that year. Overall, these data represent increases in both absolute numbers and percentages of deaths and DALYs compared with 2010 estimates. As with many high-income countries during the last century, low- and middle-income countries are now experiencing an alarming and accelerating increase in CVD.

This chapter reviews the features of the epidemiologic transitions underlying this shift in CVD morbidity and mortality and evaluates the transition in different regions of the world. A survey of the current burden of risk factors and behaviors associated with CVD includes regional variations and trends. A review of the economic impact of CVD highlights the cost-effectiveness of various strategies to reduce it. The chapter ends with a discussion of the diverse challenges that the increasing burden of CVD poses for various regions of the world, along with potential solutions to this global problem.

Shifting Burden

Between 1990 and 2013, deaths from CVD increased from 26% to 32% of all deaths globally, a reflection of the rapid epidemiologic transition, particularly in low- and middle-income countries (LMICs). Although the net percentage of deaths caused by CVD overall has increased, this results from an increase in LMICs and a decline in high-income countries (HICs) (**Fig. 1.1**). CVD now causes the most deaths in all low- and middle-income regions, with the exception of sub-Saharan Africa, where it is the leading cause of death in those older than 45 years. In absolute numbers, CVD causes four to five times as many deaths in LMICs as in HICs. Within the six World Bank–defined low- and middle-income regions, the CVD burden differs vastly (**Fig. 1.2**), with CVD death rates as high as 59% in Eastern Europe and as low as 12% in sub-Saharan Africa. The CVD mortality rate is 38% in HICs.

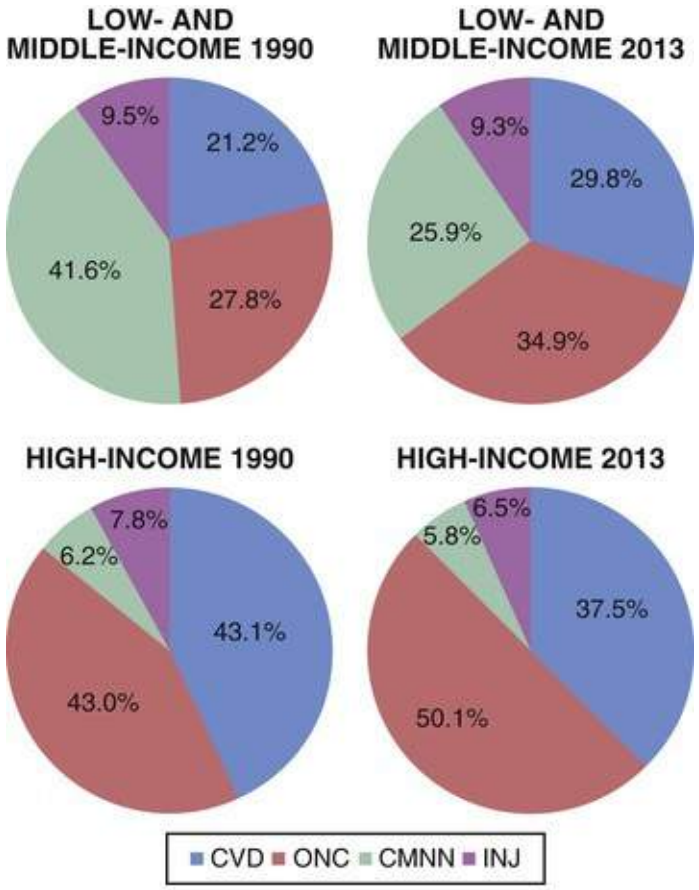

FIGURE 1.1 Changing pattern of mortality, 1990 to 2013. *CVD,* Cardiovascular disease; *ONC,* other noncommunicable diseases; *CMNN,* communicable, maternal, neonatal, and nutritional diseases; *INJ,* injury. (From Global Burden of Disease Study 2013. Age-sex specific all-cause and cause-specific mortality, 1990–2013, Seattle: Institute for Health Metrics and Evaluation; 2014.)

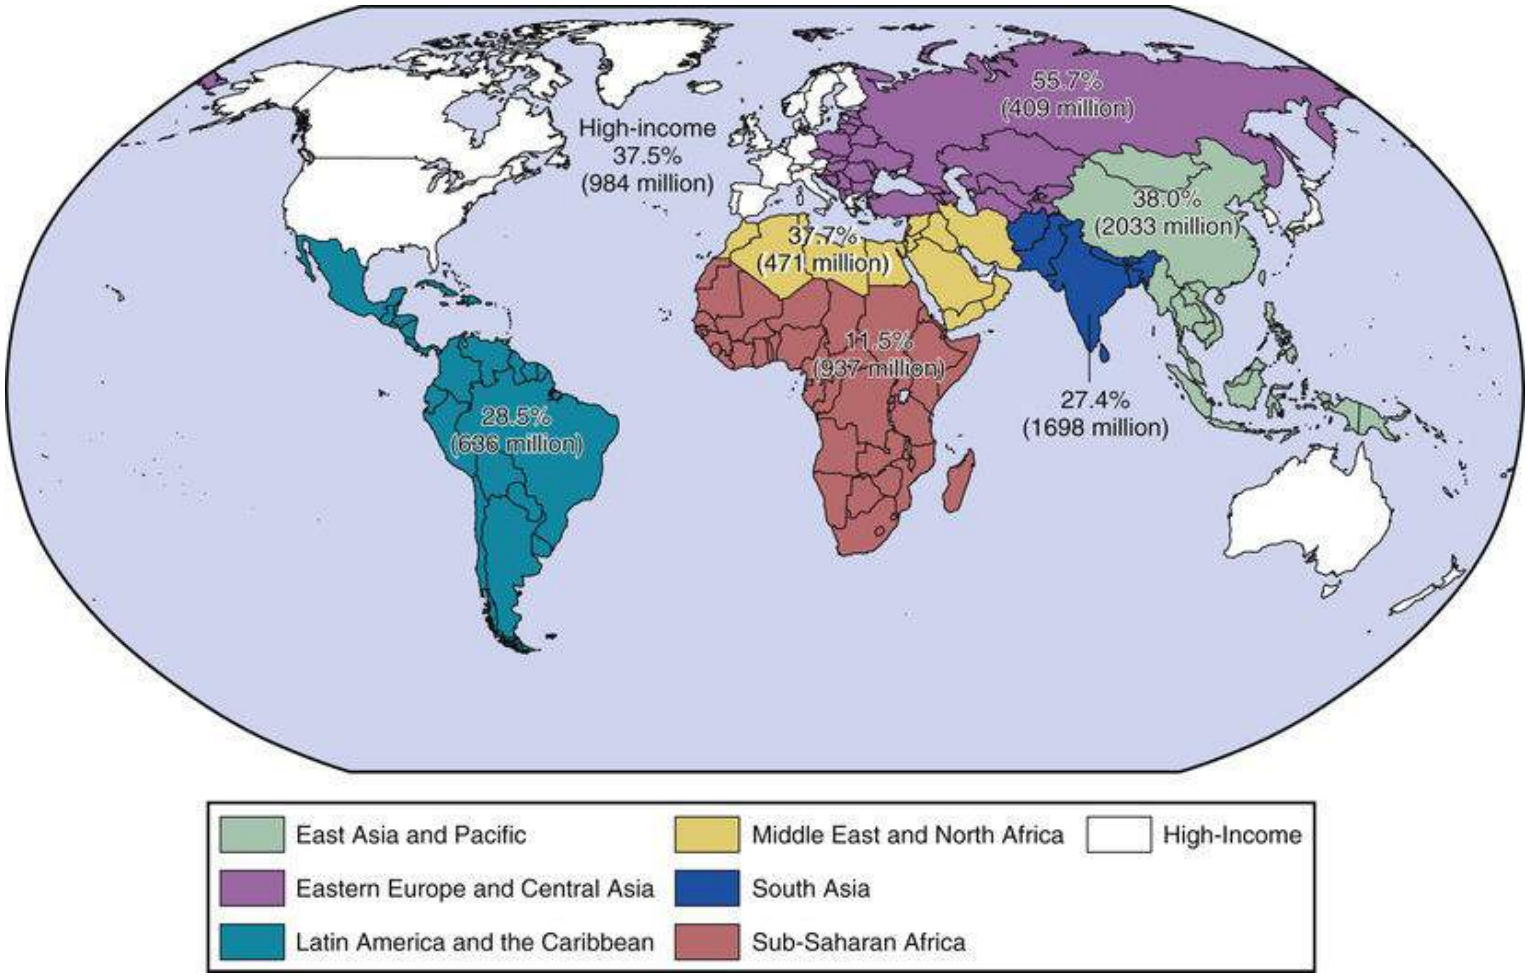

FIGURE 1.2 Cardiovascular disease deaths as a percentage of all deaths in each region and total regional population, 2013. (From Global Burden of Disease Study 2013: Age-sex specific all-cause and cause-specific mortality, 1990–2013. Seattle: Institute for Health Metrics and Evaluation; 2014; and World Health Organization. Global Health Observatory Data Repository. Demographic and socioeconomic statistics: population data by country. http://apps.who.int/gho/data/view.main.POP2040?lang=en.)

Epidemiologic Transitions

The overall increase in the global burden of CVD and the distinct regional patterns result in part from the "epidemiologic transition," which includes four basic stages (**Table 1.1**): Pestilence and Famine, Receding Pandemics, Degenerative and Man-Made Diseases, and Delayed Degenerative Diseases.[2,3] Movement through these stages has dramatically shifted the causes of death over the last two centuries, from infectious diseases and malnutrition in the first stage to CVD and cancer in the third and fourth stages. Although the transition through the age of Pestilence and Famine has occurred much later in LMICs, it has also occurred more rapidly, driven largely by the transfer of low-cost agricultural technologies, the overall globalization of world economies, and public health advances.

TABLE 1.1

Five Typical Stages of Epidemiologic Transition in CVD Mortality and Types

STAGE	DESCRIPTION	TYPICAL PROPORTION OF DEATHS CAUSED BY CVD (%)	PREDOMINANT TYPES OF CVD
Pestilence and Famine	Predominance of malnutrition and infectious diseases as causes of death; high rates of infant and child mortality; low mean life expectancy.	<10	Rheumatic heart disease, cardiomyopathies caused by infection and malnutrition
Receding Pandemics	Improvements in nutrition and public health lead to decrease in rates of deaths caused by malnutrition and infection; precipitous decline in infant and child mortality rates.	10-35	Rheumatic valvular disease, hypertension, CHD, stroke
Degenerative and Man-Made Diseases	Increased fat and caloric intake and decreased physical activity lead to emergency of hypertension and atherosclerosis; with increased life expectancy, mortality from chronic, noncommunicable diseases exceeds mortality from malnutrition and infectious diseases.	35-65	CHD, stroke
Delayed Degenerative Diseases	CVDs and cancer are the major causes of morbidity and mortality; better treatment and prevention efforts help avoid deaths among those with disease and delay primary events. Age-adjusted CVD mortality declines; CVD affects older and older individuals.	40-50	CHD, stroke, congestive heart failure
Inactivity and Obesity	Increasing prevalence of obesity and diabetes; some slowing of CVD mortality rates in women.	38	

CVD, Cardiovascular disease; *CHD,* coronary heart disease.

Modified from Omran AR. The epidemiologic transition: a theory of the epidemiology of population change. Milbank Mem Fund Q 1981;49:509; and Olshanksy SJ, Ault AB. The fourth stage of the epidemiologic transition: the age of delayed degenerative diseases. Milbank Q 1986;64:355.

Humans evolved during the age of **Pestilence and Famine** and have lived with epidemics and hunger for most of recorded history. Before 1900, infectious diseases and malnutrition constituted the most common causes of death in virtually every part of the world, with tuberculosis, pneumonia, and diarrheal diseases accounting for a majority of deaths. These conditions, along with high infant and child mortality rates, resulted in a mean life expectancy of approximately 30 years.

Per capita income and life expectancy increase during the age of **Receding Pandemics** as the emergence of public health systems, cleaner water supplies, and improved food production and distribution combine to reduce deaths from infectious disease and malnutrition. Improvements in medical education follow, and along with other public health changes, contribute to dramatic declines in infectious disease mortality rates. Rheumatic valvular disease, hypertension, and cerebrovascular accident (stroke) cause most CVD. Coronary heart disease (CHD) often occurs at a lower prevalence rate than stroke, and CVD accounts for 10% to 35% of deaths.

During the stage of **Degenerative and Man-Made Diseases,** continued improvements in economic circumstances, combined with urbanization and radical changes in the nature of work-related activities, led to dramatic changes in diet, activity levels, and behaviors such as smoking. For example, in the United States, deaths from infectious diseases decreased to fewer than 50 per 100,000 people per year, and life expectancy increased to almost 70 years. The increased availability of foods high in calories, coupled with decreased physical activity, contributes to an increase in atherosclerosis. In this stage, CHD and stroke predominate, and between 35% and 65% of all deaths are related to CVD. Typically, the ratio of CHD to stroke is 2 : 1 to 3 : 1.

In the age of **Delayed Degenerative Diseases**, CVD and cancer remain the major causes of morbidity and mortality, but CVD age-adjusted mortality rates decline by almost half, accounting for 25% to 40% of all deaths. Two significant advances have contributed to the decline in CVD mortality rates: new therapeutic approaches and prevention measures targeted at people with or at risk for CVD.[4]

Treatments once considered advanced—including the establishment of emergency medical systems, coronary care units, and the widespread use of new diagnostic and therapeutic technologies such as echocardiography, cardiac catheterization, percutaneous coronary intervention (PCI), bypass surgery, and

implantation of pacemakers and defibrillators—have now become the standard of care. Advances in drug development have also yielded major benefits on both acute and chronic outcomes. Efforts to improve the acute management of myocardial infarction (MI) led to the application of lifesaving interventions such as beta-adrenergic blocking agents (beta blockers), PCI, thrombolytics, statins, and angiotensin-converting enzyme (ACE) inhibitors (**see Chapters 58 and 59**). The widespread use of an "old" drug, aspirin, has also reduced the risk of dying of acute or secondary coronary events. Low-cost pharmacologic treatment for hypertension (**see Chapter 47**) and the development of highly effective cholesterol-lowering drugs such as statins have also made major contributions to both primary and secondary prevention by reducing CVD deaths (**see Chapter 48**).

In concert with these advances, public health campaigns have conveyed that certain behaviors increase the risk of CVD and that lifestyle modifications can reduce risk. In this regard, smoking cessation furnishes a model of success. In the United States, for example, 57% of men smoked cigarettes in 1955; in 2012, 20.5% of men smoked. The prevalence of smoking among U.S. women has fallen from 34% in 1965 to 15.8% in 2012.[5] Campaigns beginning in the 1970s dramatically improved the detection and treatment of hypertension in the United States. This intervention likely had an immediate and profound effect on stroke rates and a subtler effect on CHD rates. Public health messages concerning saturated fat and cholesterol had a similar impact on fat consumption and cholesterol levels. Population mean cholesterol levels also declined, from 220 mg/dL in the early 1960s to 192 mg/dL by 2014,[6] with a simultaneous decrease in the prevalence of elevated low-density lipoprotein (LDL) cholesterol.

Age of Inactivity and Obesity: a Fifth Phase?

Troubling trends in certain risk behaviors and risk factors may foreshadow a new phase of epidemiologic transition, the age of **Inactivity and Obesity**[7] (**see Chapters 49 and 50**). In many parts of the industrialized world, physical activity continues to decline while total caloric intake increases at alarming rates, resulting in an epidemic of overweight and obesity. Consequently, rates of type 2 diabetes, hypertension, and lipid abnormalities associated with obesity are rising—a particularly evident trend in children.[6] These changes are occurring while measurable improvements in other risk behaviors and risk factors, such as smoking, have slowed. If these trends continue, age-adjusted CVD mortality rates, which have declined over the past several decades in HICs, could plateau, as they have for young women in the United States, or even increase in the coming years. This trend pertains particularly to age-adjusted stroke death rates. This concerning increase in obesity also applies to LMICs.[8]

Fortunately, recent trends in the first decade of this century suggest a tapering in the increases in obesity among adults, although the rates remain alarmingly high at almost 34%.[9] Furthermore, continued progress in the development and application of therapeutic advances and other secular changes appear to have offset the effects from the changes in obesity and diabetes; cholesterol levels, for example, continue to decline. Overall, in this decade, age-adjusted mortality has continued to decline at about 3% per year, from a rate of 341 per 100,000 population in 2000 to 223 per 100,000 in 2013.[10]

Different Patterns of Epidemiologic Transition

The HICs have followed different patterns of the CVD transition, which differ in both peak death rate from CHD and time of transition. Three patterns emerge that rely on data from countries with an established death certification system[11] (**Fig. 1.3**). One pattern, followed by the United States and Canada, showed a rapid rise and peak in the 1960s and 1970s, followed by a relatively rapid decline through the

end of the 2000s. The peak was 300 to 700 CHD deaths per 100,000 population, with current rates between 100 and 200 per 100,000. This pattern also occurred in the Scandinavian countries, the United Kingdom, Ireland, Australia, and New Zealand. A second pattern showed a peak in the same period but a peak CHD death rate of only 100 to 300 per 100,000. Countries such as Portugal, Spain, Italy, France, Greece, and Japan followed this pattern. Some countries did not have the same rapid rate of decline, with slower rates in central European countries (Austria, Belgium, Germany) compared to northern European countries (Finland, Sweden, Denmark, Norway), but with lower peaks of 300 to 350 per 100,000 in the 1960s and 1970s. Some countries appear to display a third pattern of continued rise (particularly many components of the former Soviet Union), and others have yet to see any significant increase, such as many countries in sub-Saharan Africa (excluding South Africa). Latin America has less longitudinal data, but limited data suggest that many of the countries follow the pattern of either Mediterranean or Southern European countries, with peaks between 50 and 300 deaths per 100,000. Whether other LMICs will follow a “classic” pattern of significant increases then rapidly declining rates (as happened in North America, Australia, and northwestern European HICs), a more gradual rise and fall (as in the southern and central European countries), or some other pattern will depend in part on cultural differences, secular trends, and responses at the country level with regard to both public health and treatment infrastructures.

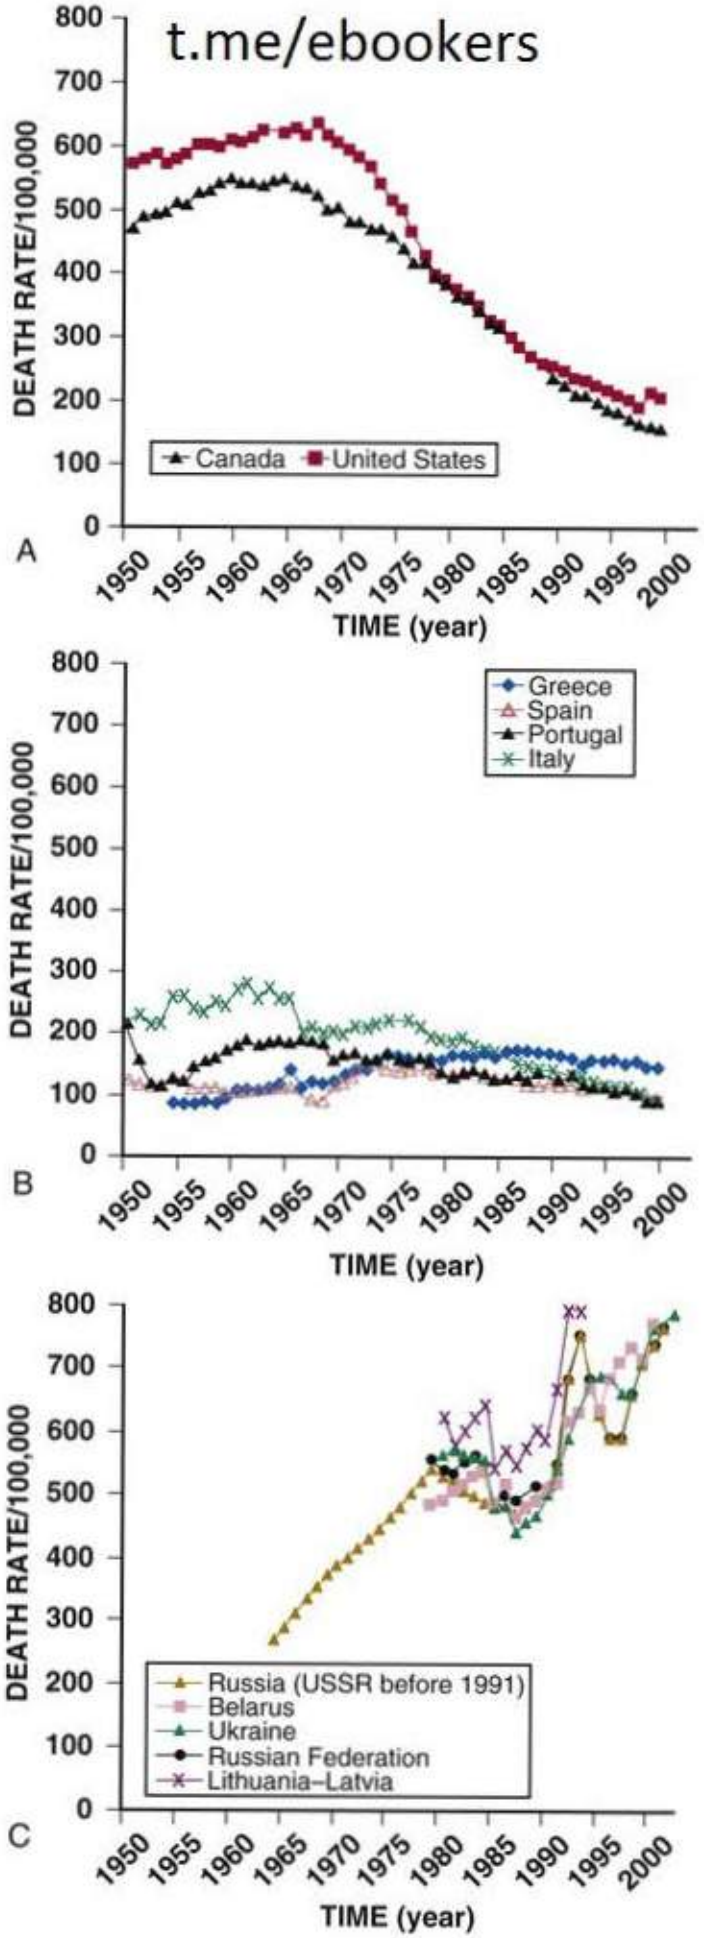

FIGURE 1.3 Differing coronary heart disease mortality patterns. **A,** Rapid rise and decline. **B,** Mild rise and decline. **C,** Continuing rapid rise. (From Mirzaei M, Truswell A, Taylor R, Leeder SR: Coronary heart disease epidemics: not all the same. Heart 2009;95(9):740-6.)

Current Variations in the Global Burden

Three phenomena impact the various metrics for disease burden. First, population growth increases the overall number of deaths caused by CVD globally. Second, a trend in general aging of the population has shifted the proportion of deaths caused by CVD in most regions as a result of better control of many communicable diseases that strike those at early ages. Third, prevention of CVD and treatment for those with CVD have both improved, which reduces age-adjusted mortality rates. We rely on data from the Global Burden of Disease (GBD) study data from 2013. Although extensive, data from GBD 2013 has limitations. The availability and reliability of data on cause of death, especially in LMICs without standardized protocols, are uncertain.

Globally, CVD deaths increased by 46% between 1990 and 2013. The increase in overall CVD deaths results from both increases in CHD and stroke-related deaths. In 2013, CHD accounted for 15% of all deaths worldwide. The second-ranking cause of death was stroke, at 12% (equally split between ischemic stroke and hemorrhagic stroke). An estimated 14.5 million people died from CHD and stroke, which together accounted for almost a quarter of all deaths worldwide in 2013.[1]

Although still substantial, deaths from communicable, neonatal, and maternal diseases are decreasing worldwide,[1,12] with a 27% decrease between 1990 and 2013. Deaths from noncommunicable diseases increased in the same period. In 2013, CHD accounted for the largest portion of global years of life lost (YLLs) and DALYs. Stroke was the third-ranking contributor to global YLLs and DALYs. On the other hand, in 1990, communicable diseases accounted for the largest portion of both YLLs and DALYs.

Despite the increase in overall CVD deaths, age-adjusted death rates decreased by 21.9% in the same period, from 374 to 292 per 100,000 population, suggesting significant delays in age of occurrence and/or improvements in case-fatality rates. Unfortunately, not all countries appear to share in the reductions. Examination of regional trends is helpful in estimating global trends in the burden of disease, particularly CVD. Because 85% of the world's population lives in LMICs, these countries largely drive global CVD rates. These estimates depend on modeling mortality rates in areas where established death certification–based vital registration systems do not cover an entire country. Even as age-adjusted rates have been falling globally, the pattern is different when assessed by income (**Fig. 1.4**) or by region (**Fig. 1.5**).

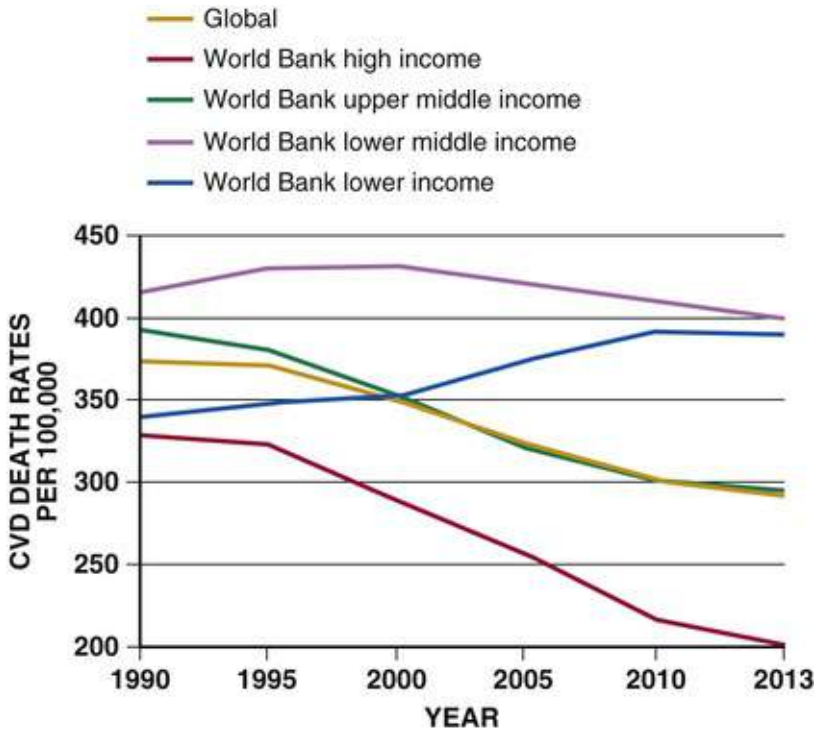

FIGURE 1.4 Cardiovascular disease death rates per 100,000 population from 1990 to 2013, by World Bank income categories. (From Global Burden of Disease Study 2013. Age-sex specific all-cause and cause-specific mortality, 1990–2013. Seattle: Institute for Health Metrics and Evaluation; 2014.)

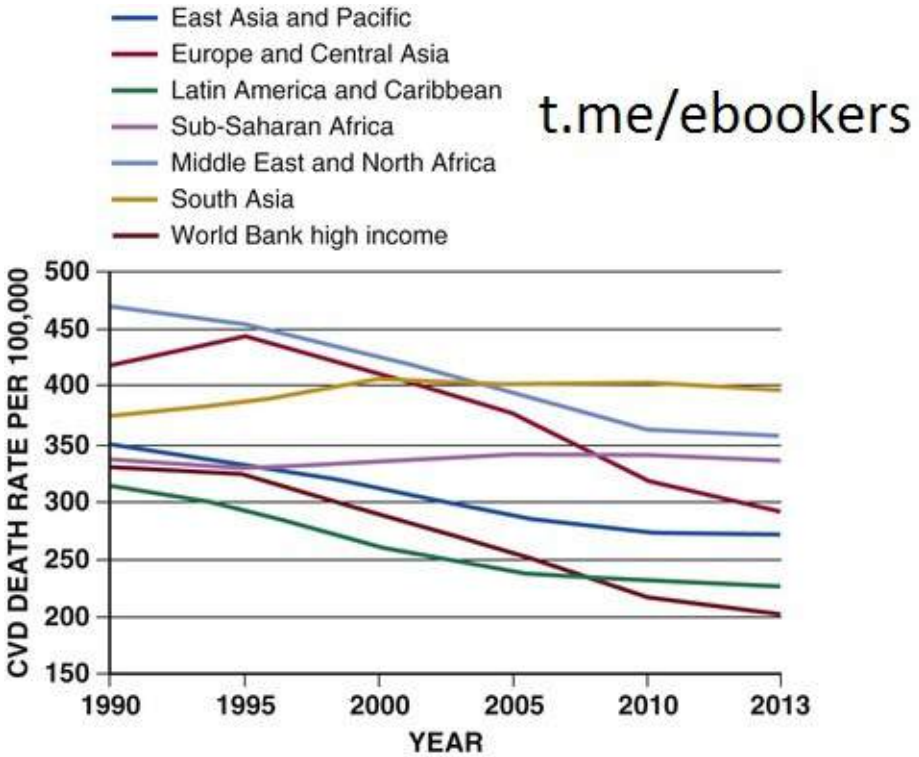

FIGURE 1.5 Cardiovascular disease death rates per 100,000 population from 1990 to 2013 in low- and middle-income countries by region, compared to World Bank high-income countries. (From Global Burden of Disease Study 2013. Age-sex specific all-cause and cause-specific mortality, 1990–2013. Seattle: Institute for Health Metrics and Evaluation; 2014.)

The magnitude of the peak of the CVD epidemic, and whether the peak has arrived at all, has a great range. Here we describe and highlight trends in the seven regions of the world as defined by the GBD project, which includes HICs as one grouping and divides the remaining LMICs into six geographic

regions with a variety of subregions. The East Asia and Pacific, Europe and Central Asia, Latin America and Caribbean, and Middle East and North Africa Regions all saw declines in age-adjusted CVD mortality from 1990 to 2013. Sub-Saharan Africa had little change in its age-adjusted CVD mortality rates. South Asia was the only region that experienced a significant increase in the age-adjusted mortality rates.

Much of the variation appears to relate to income, which is one proxy for the stages of the epidemiologic transition. Looking at age-adjusted CVD death rates by income reveals the different trends over the last two decades. In lower-income regions the death rates have increased from 340 per 100,000 in 1990 to 390 per 100,000 in 2013. Lower middle-income countries saw a small increase (416 to 432 per 100,000 deaths), followed by a decline to 400 per 100,000 population. Upper middle-income countries saw a 25% decline, from 392 per 100,000 in 1990 to 296 per 100,000. High-income countries had a nearly 37% decline, from 330 to 202 CVD deaths per 100,000.

The LMICs have a high degree of heterogeneity with respect to the phase of the epidemiologic transition. First, LMIC subregions differ by age-adjusted CVD death rates, as well as by trends over the last 20 years (**Fig. 1.6**). CVD mortality rates are increasing in most LMICs but are decreasing in HICs. Next, low- and middle-income subregions are unique, as illustrated by the different CVD disease rates by cause in each region (**Fig. 1.7**). Lastly, in the East Asia and Pacific and sub-Saharan Africa regions, stroke still exceeds CHD as a cause of CVD death. Hypertensive heart disease is the largest single contributor among remaining causes of CVD morbidity and mortality.

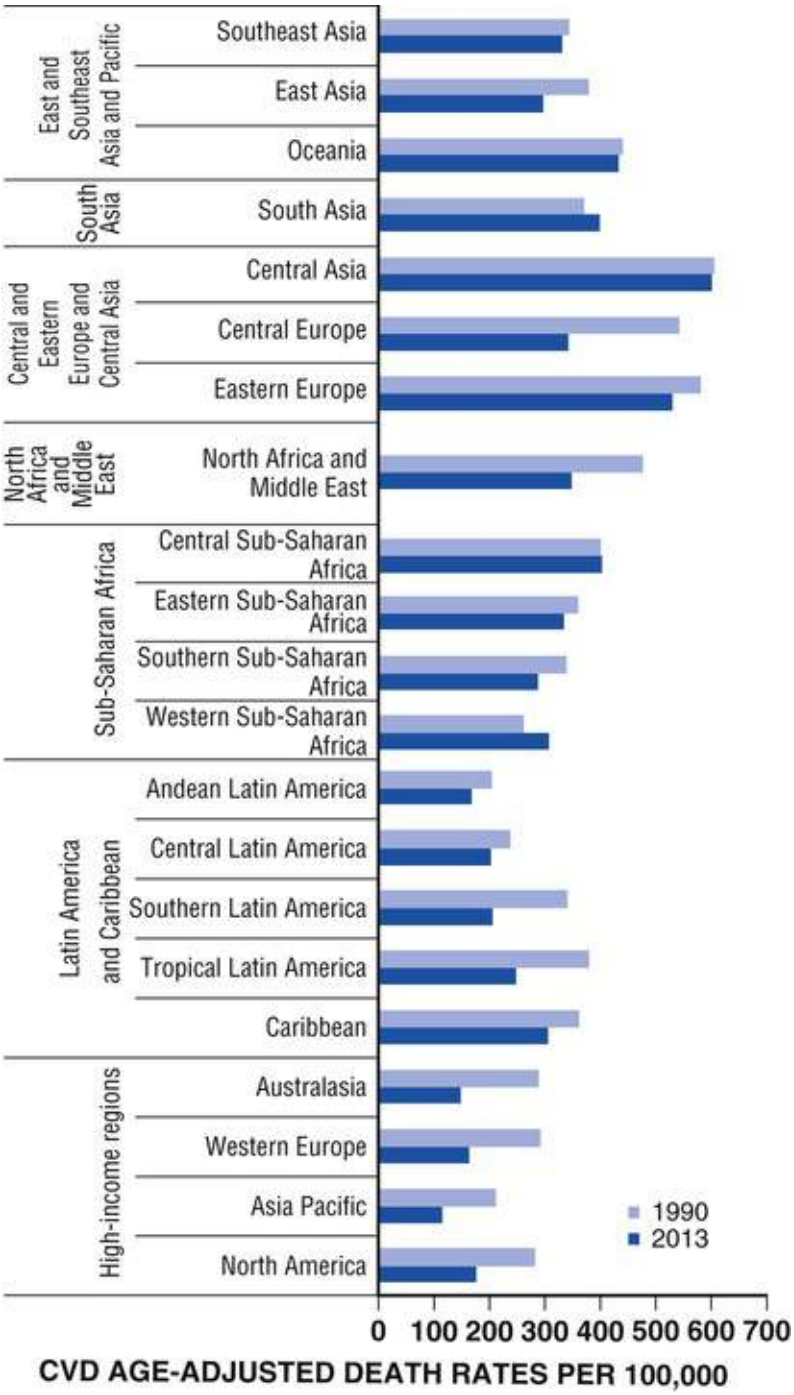

FIGURE 1.6 Age-adjusted death rates per 100,000 population for cardiovascular disease, 1990 and 2013. (From Global Burden of Disease Study 2013. Age-sex specific all-cause and cause-specific mortality, 1990–2013. Seattle: Institute for Health Metrics and Evaluation; 2014.)

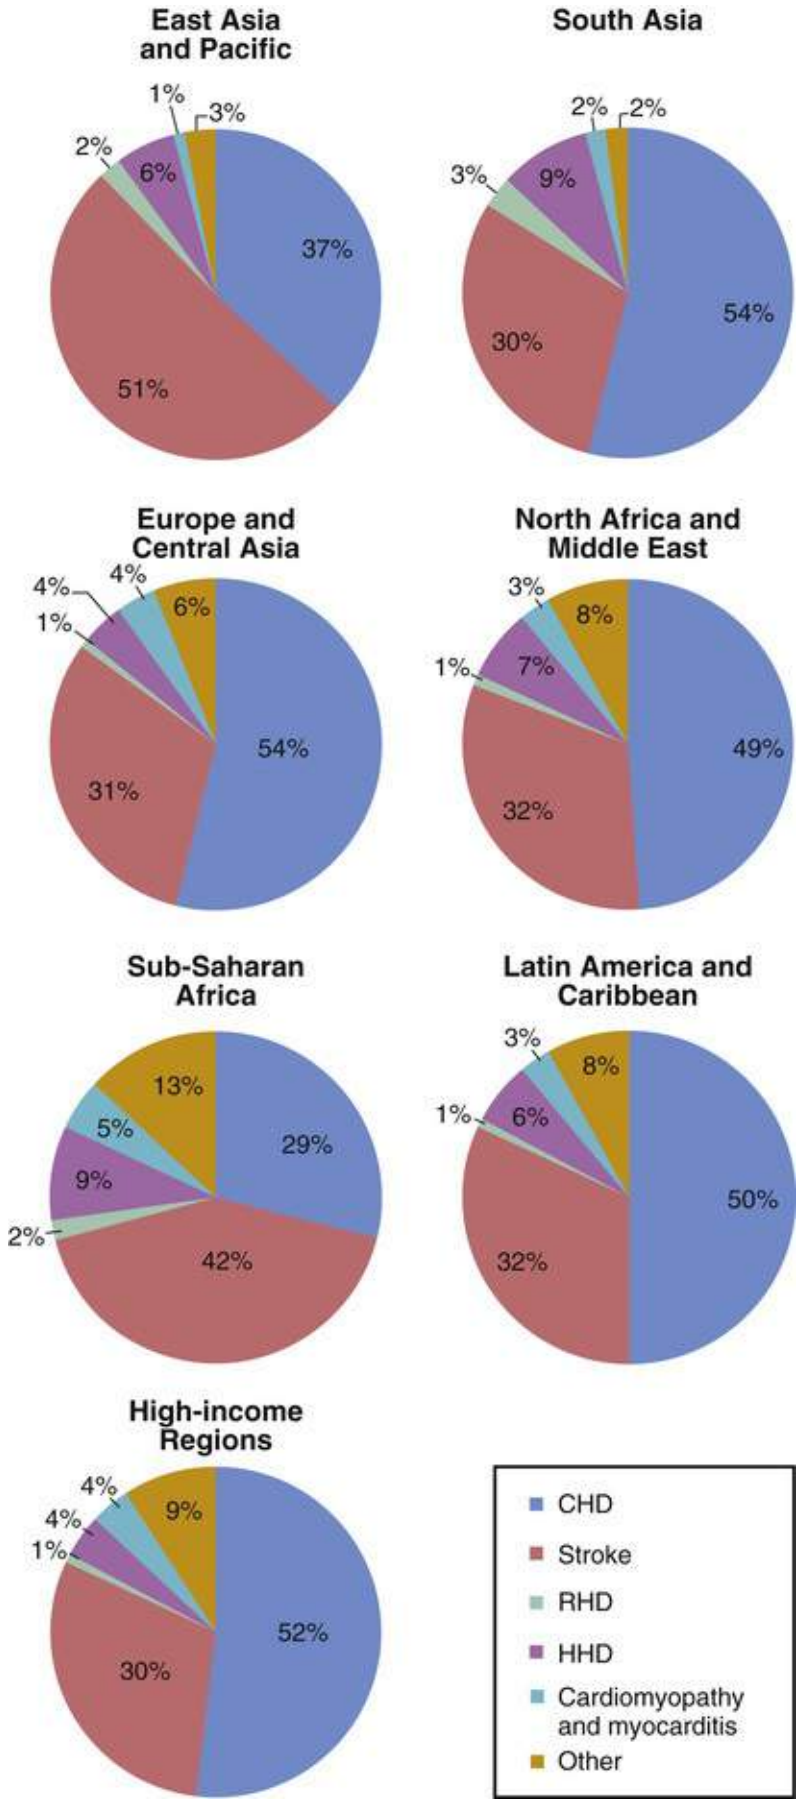

FIGURE 1.7 Cardiovascular disease death by specific cause and region. *CHD,* Coronary heart disease; *RHD,* rheumatic heart disease; *HHD,* hypertensive heart disease. (From Global Burden of Disease Study 2013. Age-sex specific all-cause and cause-specific mortality, 1990–2013. Seattle: Institute for Health Metrics and Evaluation; 2014.)

Variability in disease prevalence among various regions likely results from multiple factors. First, the countries are in various phases of the epidemiologic transition described earlier. Second, the regions may

have cultural and genetic differences that lead to varying levels of CVD risk. For example, per capita consumption of dairy products (and thus consumption of saturated fat) is much higher in India than in China, although it is rising in both countries. Third, certain additional competing pressures exist in some regions, such as war or infectious diseases (HIV/AIDS) in sub-Saharan Africa.

Because CHD affects a younger population in LMICs, the number of deaths is increased in the working population. For some LMICs, the severity of the epidemiologic transition has appeared to follow a reverse social gradient, with members of lower socioeconomic groups having the greatest rates of CHD and the highest levels of various risk factors. Unfortunately, reductions in risk factors do not follow the same trend. Compared with people in the upper and middle socioeconomic strata, those in the lowest stratum are less likely to acquire and apply information on risk factors and behavior modifications or to have access to advanced treatment. Consequently, CVD mortality rates decline later among those of lower socioeconomic status.

High-Income Countries

In 2013, CVD accounted for almost 38% of all deaths in high-income regions, and CHD caused more than half of these deaths (**see Fig. 1.7**). The movement of most HICs through the epidemiologic transition, with rising levels of risk factors and CVD death rates until the 1970s and then declines in both over the next 40 years, resembles what occurred in the United States. CHD is the dominant form, with rates that tend to be twofold to fivefold higher than stroke rates. Two notable exceptions are Portugal, where stroke rates for both men and women exceed CHD rates, and Japan, where stroke causes many more fatalities than CHD. In both these countries, however, the pattern seems to be moving toward that seen in other HICs, with more rapid declines in stroke rates than in CHD rates.

Age-adjusted mortality for CVD declined in all HICs. This age-adjusted decline results largely from preventive interventions that allow people to avert disease, treatments to prevent death during an acute manifestation of disease (particularly stroke or MI), and interventions that prolong survival once CVD is manifest. Thus the average age at death from CVD continues to climb, and as a result, CVD affects a larger retired population.

Western Europe, with an overall CVD mortality rate of 344 per 100,000 in 2013 and an age-standardized rate of 163 per 100,000, had the highest mortality rates, whereas Australasia had the lowest overall (234/100,000) rate, and Japan had the lowest age-adjusted rate (110/100,000). As mentioned, high-income regions have higher mortality rates for CHD than for stroke. The exception is the East Asia and Pacific region, where overall death rates for stroke and CHD are 132 per 100,000 and 88 per 100,000, respectively. Mortality rates and number of deaths attributable to stroke and CHD increased in this region between 1990 and 2010; stroke rates increased by approximately 18%, whereas CHD rates increased by almost 40%.[12] Japan is unique among HICs; as its communicable disease rates fell in the early 20th century, its stroke rates increased dramatically. CHD rates, however, did not rise as sharply in Japan as in other industrialized nations and have remained lower than in any other industrialized country. Overall, CVD rates have fallen 60% in Japan since the 1960s, largely because of a decrease in age-adjusted stroke rates. Japanese men and women currently have the highest life expectancy in the world: 86.4 years for women and 79.6 years for men. The difference between Japan and other industrialized countries may stem in part from genetic factors, although the traditional Japanese fish- and plant-based, low-fat diet and resultant low cholesterol levels may have also contributed. Nevertheless, as in many other countries, dietary habits in Japan are undergoing substantial changes. Since the late 1950s, cholesterol levels have progressively increased in both urban and rural populations. Although the

prevalence of CVD risk factors is increasing in the Japanese population, the incidence of coronary artery disease remains low and even declined.[13] This situation could change, however, because there seems to be a long lag phase before dietary changes manifest as CHD events.

East Asia and Pacific

Demographic and Social Indices

The East Asia and Pacific (EAP) region is the most populated low-income and middle-income region in the world, with almost 2 billion people; approximately 49% of the region is urban. The gross national income (GNI) per capita is $4243, ranging from $4420 in Thailand to $1130 in Laos. In 2004, total health expenditure was 4.8% of total gross domestic product (GDP), or $183 per capita.[14] The region is divided into three distinct subregions: Southeast Asia, East Asia, and Oceania. China is by far the most populated country, representing almost 70% of the region. Life expectancy has risen quickly across the EAP region in past decades, up to an average of 72 years. In China the increase has been dramatic: from 37 years in the mid-1950s to 73 years in 2010.[14] This increase associates with a large rural to urban migration pattern, rapid urban modernization, aging of the population, decreased birth rates, major dietary changes, increasing tobacco use, and a transition to work requiring low levels of physical activity.

Burden of Disease

CVD caused more than 5.2 million deaths in the EAP region in 2013, accounting for 38% of all deaths in the region. More than half of these deaths resulted from stroke, whereas only 31% were caused by CHD (**see Fig. 1.7**). CVD death rates differed significantly between subregions, most notably in Oceania. Age-adjusted mortality rates were highest in Oceania, at 439 per 100,000 in 2010, even though overall mortality for CVD was 205 per 100,000, suggesting that many premature deaths from CVD are occurring in Oceania.

Stroke and CHD lead as causes of death in the East Asia and Southeast Asia subregions. In Oceania, however, lower respiratory infections and diabetes account for the largest proportion of deaths. Whereas stroke and CHD rates increased in both East Asia and Southeast Asia, stroke rates decreased slightly in Oceania, from 40 to 36 per 100,000.[12] China appears to be straddling the second and third stages of a Japanese-like epidemiologic transition. Men in China age 50 to 69 have stroke death rates of 190 per 100,000, versus CHD death rates of 123 per 100,000.[1]

Central and Eastern Europe and Central Asia

Demographic and Social Indices

Of the three subregions that constitute this region—Central Asia, Central Europe, and Eastern Europe—Eastern Europe is the most populated. Russia alone accounts for more than 30% of the region's 404 million inhabitants. Sixty-five percent of the population in the region is urban, with an average life expectancy of 71 years. The average GNI per capita for the region ranges from $870 in Tajikistan to $23,610 in Slovenia. Russia has a GNI of $10,400. On average, the region spends more than 6% of total GDP on public and private health care. Health expenditure per capita ranges from $49 per capita in Tajikistan to $2154 in Hungary. Russia spends about $525 per capita, or 5.1% of its GDP.[14]

Burden of Disease

The highest rates of CVD mortality occur in this region. Overall CVD mortality rates are 793 per 100,000 in Eastern Europe and 547 per 100,000 in Central Europe. Overall rates resemble or exceed those seen in the United States in the 1960s, when CVD peaked. CHD is generally more common than stroke, which suggests that the countries that constitute Eastern Europe and Central Asia remain largely in the third phase of the epidemiologic transition. As expected in this phase, people who develop and die of CVD have a lower average age than that in HICs. In 2013, CVD accounted for almost 60% of all deaths in the region, 55% of which resulted from CHD and 33% from stroke.

A country-level analysis reveals important differences in CHD profiles within the Central and Eastern Europe and Central Asia region (**see Fig. 1.3**). Since the dissolution of the Soviet Union, CVD rates have increased surprisingly in some of these countries, with the highest rates (almost 800 per 100,000 for men) in Ukraine, Bulgaria, Belarus, and Russia.[11] By 2013, this region had the highest CVD mortality rates in the world. Of note, deaths resulting from CHD in these countries affect not only older adults; the GBD study estimates that working-age populations (15 to 69 years) have a significant CHD burden. Almost one third of all deaths in persons age 45 to 49, for example, result from CVD. For people age 60 to 64, CVD accounts for half of all deaths, 27% of which are caused by CHD.[12]

Latin America and the Caribbean

Demographic and Social Indices

The Latin America and Caribbean (LAM) region comprises Andean Latin America, Central Latin America, Southern Latin America, Tropical Latin America, and the Caribbean. The region has a total population of 589 million, 79% of which is urban.[14] Brazil, the region's most populous country, represents one third of the population, with Argentina, Colombia, Mexico, Peru, and Venezuela making up another third. The Caribbean nations, including the Dominican Republic, Jamaica, and Haiti, account for less than 10% of the population in the region. Life expectancy in the LAM region is approximately 74 years but varies greatly. In 2010, for example, Haiti and Cuba had life expectancies of 64 years and 79 years, respectively. Average GNI per capita in the region is about $8544 (purchasing power parity [PPP] of $11,587). The region spends an average of 7.7% of its GDP on health care. This level of spending translates into health care expenditures that range from $46 per capita in Haiti to $1003 per capita in Barbados.[14]

Burden of Disease

The LAM region bears a substantial CVD burden. In 2013, CVD caused 29% of all deaths in the region. As in HICs, CHD dominates among circulatory diseases (**see Fig. 1.7**). Mortality rates vary significantly by subregion. The Caribbean has the highest age-standardized mortality rates for CHD and stroke: 150 deaths per 100,000 and 110 per 100,000, respectively. As with other global trends, overall mortality increased between 1990 and 2013, but age-adjusted mortality declined for this region. Death rates also increased in Central Latin America and Andean Latin America; similar increases in mortality occurred in Tropical Latin America. Together, CHD (14%), stroke (6.9%), and hypertensive heart disease (2.1%) accounted for almost one quarter of all deaths in Central Latin America in 2010. Southern Latin America, which includes Argentina, Chile, and Uruguay, was the only subregion to have declines in both overall and age-adjusted CVD mortality rates. Overall CVD, CHD, and stroke mortality rates decreased in this subregion between 1990 and 2010, but to a lesser extent than for global changes.[12] The lower reductions in the LAM region may result from rapid lifestyle changes: unfavorable dietary changes, increased

smoking, increased obesity, and less exercise.

North Africa and the Middle East

Demographic and Social Indices

The 19 countries of the North Africa and Middle East region represent approximately 5% of the world's population (337 million people). Egypt and Iran are the two most populous countries in the region, with Egypt representing 24% of total inhabitants and Iran, 22%. Approximately 59% of the population is urban, with an average life expectancy of 72 years. The average GNI per capita for the region is $3869, ranging from $1070 in Yemen to $48,900 in Kuwait. Approximately 5.3% of the GDP, or approximately $203 per capita, is expended for health in the region. The per capita health expenditure ranges from $63 in Yemen to $1450 in the United Arab Emirates.[14]

Burden of Disease

Forty-two percent of all deaths in the North Africa and Middle East region result from CVD: 9% from CHD and 32% from stroke. The region has lower CVD mortality rates than global averages. In 2013 the overall death rate per 100,000 for CHD, stroke, and overall CVD were 89, 57, and 180, respectively. The mortality rate for CHD only declined marginally in the region since 1990, when the rates were 88, 62, and 192 deaths per 100,000 population, respectively. However, age-adjusted mortality rates for CVD declined by almost 25% across the region. In 2013, CVD accounted for 20 million DALYs lost, or 21% of all DALYs lost in the region. The DALYs lost were split differently between CHD and stroke, at 9.7 million and 5.7 million, respectively.[12]

South Asia

Demographic and Social Indices

The South Asia region (SAR), one of the world's most densely populated regions, accounts for about 24% of the world's population, with more than 1.6 billion residents. India, home to almost 75% of the region's inhabitants, is the largest country in the region. Only 31% of the region is urban, and life expectancy is approximately 65 years. Average GNI per capita for the region is $1299, ranging from $540 in Nepal to $6530 in Maldives. India's GNI per capita of $1410 sits near the regional average. Countries in the SAR spend an average of 3.9% of their total GDP, or $47 per capita, on health care. Maldives spends the most per capita at $208, and India spends $31, or 5% of its GDP. The lowest expenditures for health care are $22 per capita in Pakistan and $23 in Bangladesh.[14]

Burden of Disease

CVD accounts for 27% of all deaths in the SAR. CHD led causes of mortality in 2013—responsible for 15% of total reported fatalities, or 2 million deaths, and more than half of CVD mortality. Cerebrovascular disease accounted for 6.8% of all deaths and 30% of CVD deaths. The region loses almost 60.5 million DALYs from CVD, accounting for 10% of the total. CHD contributes 4.6% of the DALYs lost because of CVD, nearly twice as high as for stroke.[12] Mortality rates for CVD are increasing in the region.

CVD probably represents 31% of all deaths in India, the largest country in the SAR. Studies also show a higher CHD prevalence in men and in urban residents. The rise in CHD mortality contributes to the

economic burden in the Indian subcontinent. Data indicate that symptoms of CHD arise 5 to 10 years earlier in this region than in Western European and Latin American countries.[15]

Sub-Saharan Africa

Demographic and Social Indices

The GBD study divides sub-Saharan Africa into four subregions: Central Africa, East Africa, Southern Africa, and Western Africa. Approximately 875 million people live in these four regions, with Nigeria being the most populous (163 million) and Cape Verde being the least populous (500,600). Only 36% of the population in the region is urban. The average GNI per capita is $1255, ranging from $250 in Burundi to $7480 in Botswana. Overall, the region also has the lowest average life expectancy—54 years.[14] Average public and private health care expenditures for the region are 6.5% of the total GDP, or $84 per capita. The range of health care expenditures per capita for sub-Saharan Africa is similar to the GDP range for this region, from $3 in Burundi to $511 in Seychelles. Nigeria spends $23 per capita, or 4.6% of the total GDP.[14]

Burden of Disease

In Western Africa, CVD accounts for 7.5% of all deaths. The highest portion of CVD-caused deaths occurred in Southern Africa, where 13% of all deaths were caused by CVD. Mortality rates in the region are lower than global averages and are decreasing, in line with global trends. The exception is Southern Africa, where rates increased from 129 to 136 per 100,000. Communicable, neonatal, and maternal disorders still dominate causes of death in sub-Saharan Africa. Malaria and HIV/AIDS lead as causes of death, accounting for almost half of all deaths in the region.[12]

Risk Factors

Worldwide, CVD is largely driven by modifiable risk factors, such as smoking, lack of physical activity, and diets high in fat and salt (**see also Chapters 45 to 47 and 49 and 50**). Elevated levels of blood pressure (BP) and cholesterol remain the leading causes of CHD; tobacco, obesity, and physical inactivity remain important contributors as well. The GBD project estimated that the population-attributable fraction (PAF) for individual risk factors for CHD in LMICs in 2013 were as follows: high BP, 54%; high cholesterol, 32%; overweight and obesity, 18%; dietary intake, 67%; and smoking, 18%. Because factors may contribute to similar disease mechanisms, the sum exceeds 100%. Unique features regarding some CHD risk factors in LMICs are described next.

Tobacco

By many accounts, tobacco use is the most preventable cause of death in the world. More than 1.3 billion people use tobacco worldwide, with 5.8 trillion cigarettes smoked globally in 2014.[16] More than 80% of tobacco use occurs in LMICs, and if current trends continue unabated, tobacco will cause more than 1 billion deaths during the 21st century.

Tobacco use varies greatly across the world, as do deaths attributable to smoking in both sexes (**Fig. 1.8**). Although historically greatest in HICs, tobacco consumption has shifted dramatically to LMICs in recent decades; some of the highest tobacco use now occurs in the EAP region. Kiribati has the highest

prevalence of age-adjusted tobacco use in the world: 71.0% in men and 42.9% in women. Indonesia has similarly high rates (>60% prevalence in men). China is the largest consumer of tobacco in the world, with an estimated 301 million smokers in 2010 (>50% prevalence in men). Smoking rates have increased in China by 50% since 1980. Several countries in the Central and Eastern Europe regions also have alarmingly high prevalence rates, including Russia (approximately 60.0% in men and 24.3% in women), Ukraine (>50% prevalence in men), and Albania (60% prevalence in men). Latin America, the Middle East, and North Africa have high rates as well, although smoking is not as common among women in these regions as it is in the Pacific region. Countries in sub-Saharan Africa have some of the lowest prevalence rates; Niger and Ethiopia, for example, have less than 10% and 1% prevalence in men and women, respectively.

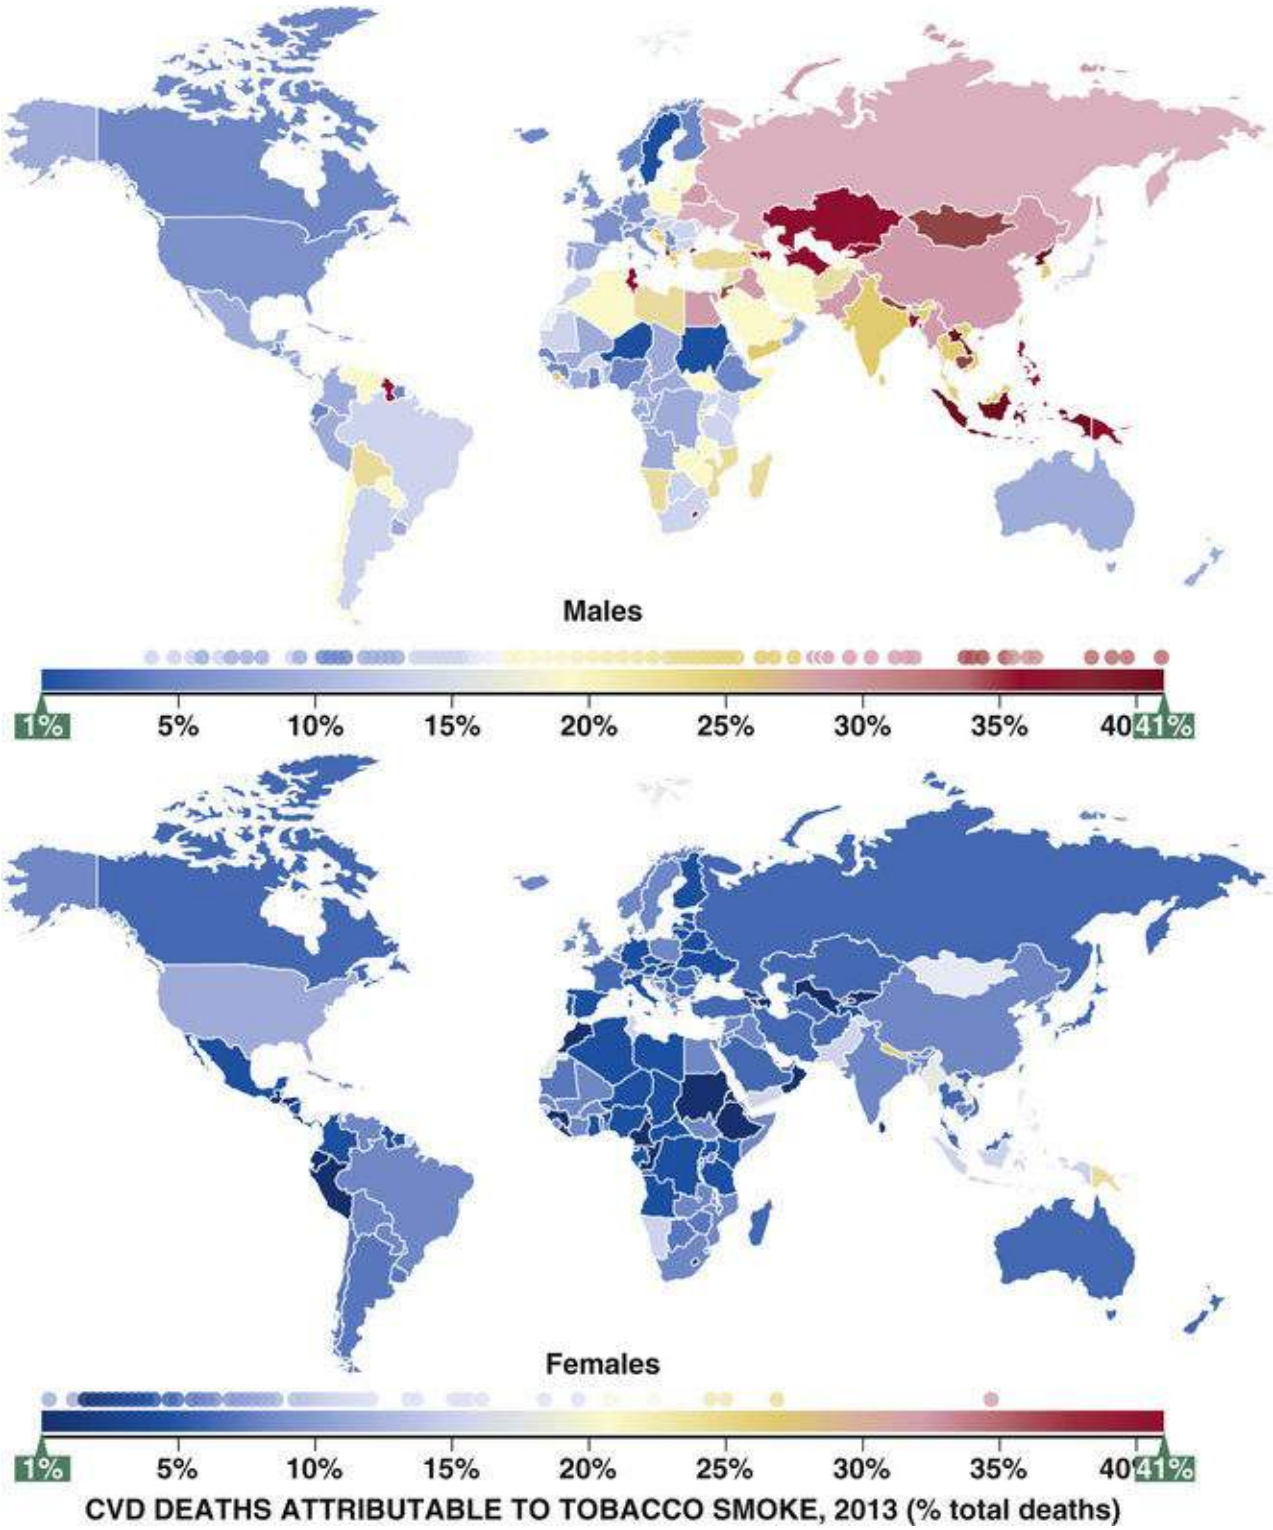

FIGURE 1.8 Cardiovascular disease mortality attributable to tobacco smoke in 2013, percentage of total deaths, males versus females. (From Institute for Health Metrics and Evaluation (IHME). GBD Compare. Seattle: IHME, University of Washington; 2015. http://vizhub.healthdata.org/gbd-compare.)

Women also have a high—and increasing— smoking prevalence in several countries, including Kiribati (42.9%), Austria (45.1%), Nauru (50%), and Greece (41.4%). In general, however, considerably more men than women smoke. Exceptions to this pattern include Nauru and Greece, which have comparable tobacco use prevalence in men and in women. Where they do occur, variations by sex can be substantial. In China, for example, tobacco use prevalence is 50% in men but only 2.2% in women. Indonesia has similarly diverging trends: prevalence in men is 61.3% and only 5.1% in women. Significant variations also occur in North Africa, the Middle East, and some countries in sub-Saharan Africa. Tobacco use is generally less than 1% in women in these regions but is much higher in men.

Other forms of tobacco use increase risk for CHD. Bidis (hand-rolled cigarettes common in South Asia), kreteks (clove and tobacco cigarettes), hookah pipes (water pipes used for smoking flavored tobacco), and smokeless tobacco all link to increased CHD risk.[17] The combined use of different forms of tobacco associates with a higher risk of MI than using one type.

Secondhand smoke also contributes to CHD risk. In 2011, approximately 600,000 nonsmokers died as a consequence of exposure to secondhand smoke. A retrospective analysis of 192 countries found that the largest portion of secondhand smoke–related deaths in 2004 resulted from ischemic heart disease.[18] Smoking bans have both immediate and long-term effects in reducing admissions for acute coronary syndrome (ACS). In Ireland, implementation of a country-wide smoking ban in workplaces decreased ACS-related hospital admissions promptly by 12%, and after 2 years, such admissions decreased by an additional 13%.[19]

Hypertension

Elevated BP is an early indicator of epidemiologic transition. Rising mean population BP occurs as populations industrialize and move from rural to urban settings. Worldwide, approximately 62% of strokes and 49% of CHD cases are attributable to suboptimal (>115 mm Hg systolic) BP, a factor thought to account for more than 7 million deaths annually. The GBD project estimates that 19% of deaths and 9% of DALYs lost globally result from nonoptimal levels of BP.[20] The high rate of undetected, and therefore untreated, hypertension presents a major concern in LMICs. The high prevalence of undetected and untreated hypertension probably drives the elevated rates of hemorrhagic stroke throughout Asia.

The most recent update of the GBD study analyzed mean systolic BP between 1980 and 2008 using multiple published and unpublished health surveys and epidemiologic studies. The analysis, which applied a bayesian hierarchical model to each sex by age, country, and year, found a global decrease in mean systolic BP between 1980 and 2008 in both men and women.[21] Worldwide, the age-standardized prevalence of uncontrolled hypertension has decreased from 33% to 29% in men and from 29% to 25% in women. However, the number of people with uncontrolled hypertension (systolic BP ≥140 mm Hg) has increased; in 1980, 605 million had uncontrolled hypertension, and by 2008, the number increased to 978 million. The trend results largely from population growth and aging. Globally, mean systolic BP has decreased by 0.8 mm Hg per decade among men and by 1.0 mm Hg per decade among women. In 2008, age-standardized mean systolic BP values worldwide were 128.1 mm Hg in men and 124.4 mm Hg in women.

The proportion of CVD deaths attributable to BP by country in 2013 varied by gender (**Fig. 1.9**). The highest mean systolic BP in 2013 occurred in East and West African countries, where both men and women had systolic BP levels that were significantly higher than global averages. In Mozambique and in São Tomé and Príncipe, for example, mean systolic BP in women was 135.4 mm Hg and 136.3 mm Hg, respectively. In men, mean systolic BP was as high as 137.5 mm Hg in Mozambique and 139.4 mm Hg in Niger. Men in Eastern Europe had mean systolic BP levels comparable to those in East and West Africa. Mean systolic BP was lowest in high-income regions such as Australasia (117.4 mm Hg in Australian women) and North America (123.3 mm Hg in U.S. men).

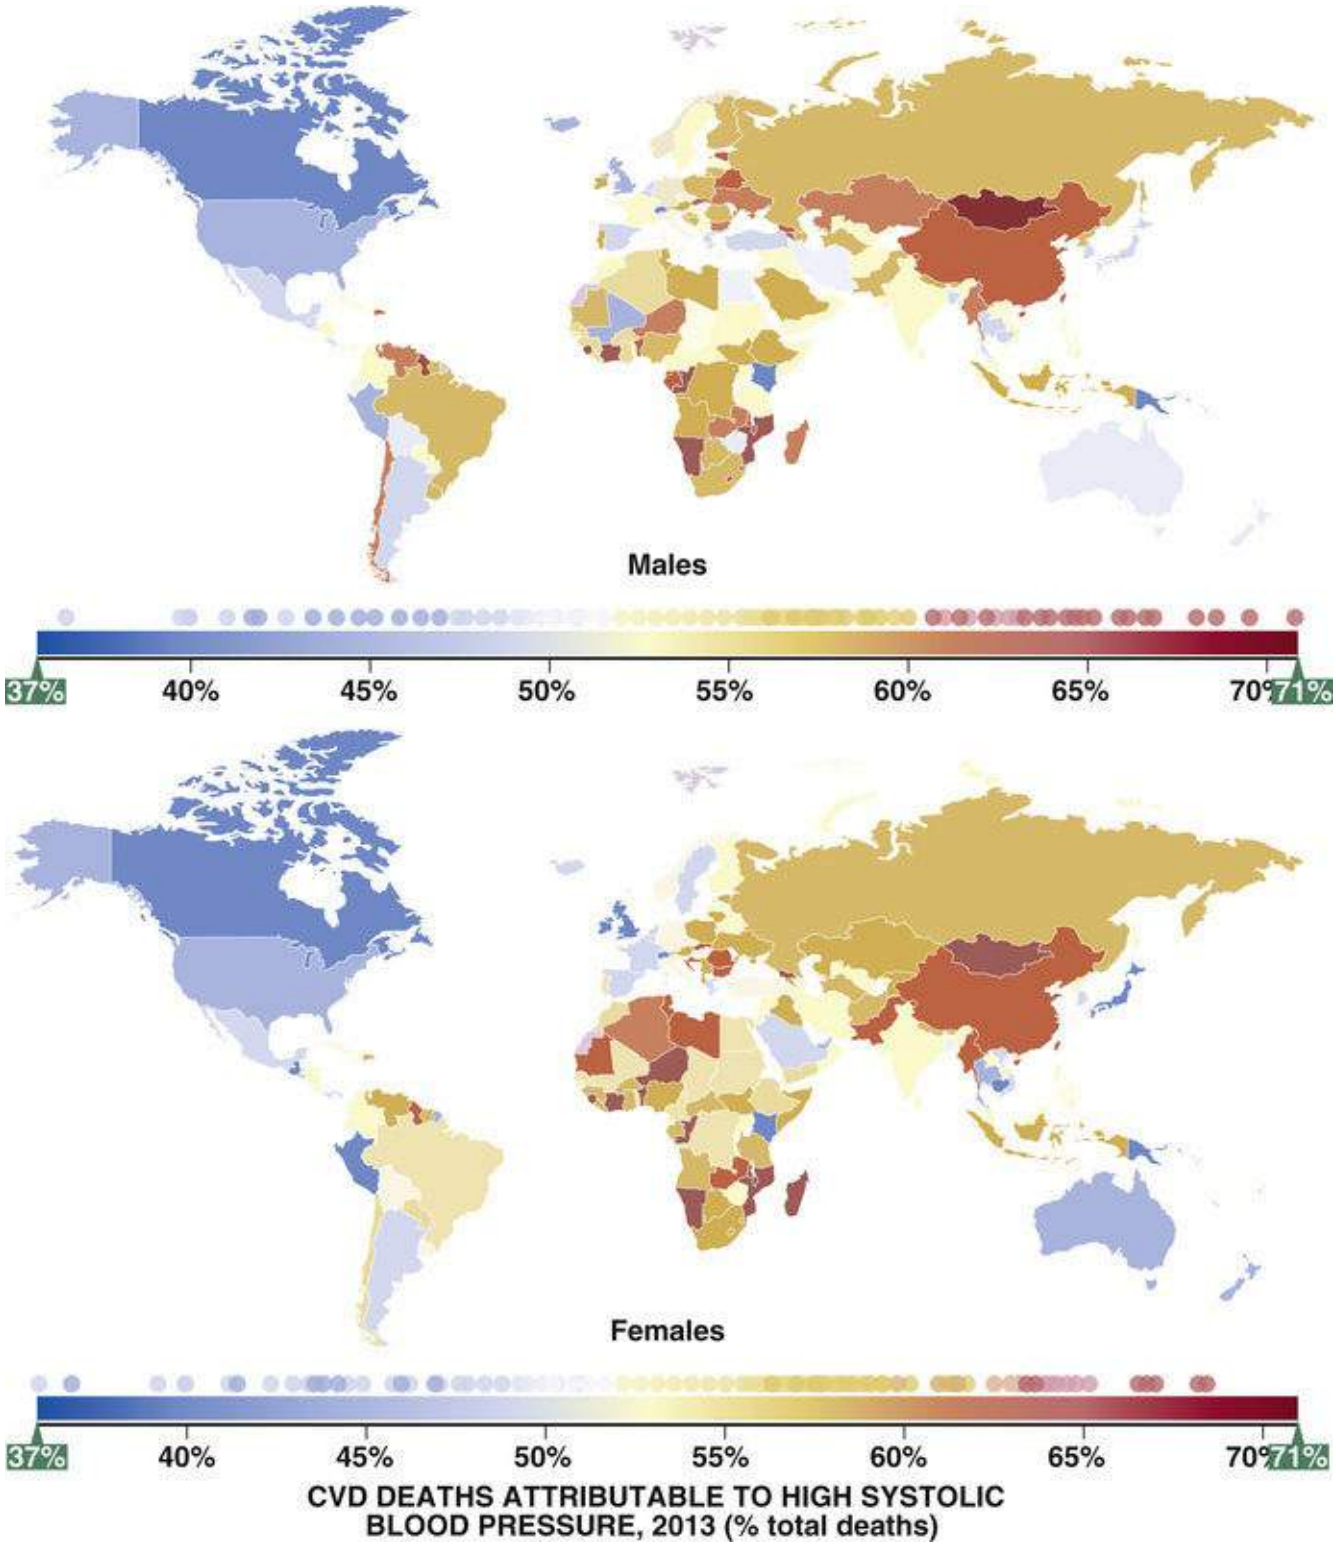

FIGURE 1.9 Cardiovascular disease mortality attributable to high systolic blood pressure in 2013, percentage of total deaths, males versus females. (From Institute for Health Metrics and Evaluation (IHME). GBD Compare. Seattle: IHME, University of Washington; 2015. http://vizhub.healthdata.org/gbd-compare.)

The most significant decreases occurred in high-income regions, where mean systolic BP decreased by 2.4 mm Hg per decade in men and 3.1 mm Hg per decade in women. The decrease in men ranged from 1.7 to 2.8 mm Hg per decade, with the greatest decrease occurring in the North America subregion. The decrease in mean systolic BP in women ranged from 2.3 mm Hg per decade in North America to 3.9 mm Hg per decade in Australasia.

Mean systolic BP increased in several regions. In South Asia, systolic BP increased by 0.8 mm Hg per decade in men and 1.0 mm Hg per decade in women. Southeast Asia saw similar increases: 0.9 mm Hg per decade in men and 1.3 mm Hg per decade in women. In East Africa, mean systolic BP increased by

1.6 mm Hg per decade in men and 2.5 mm Hg per decade in women. The most significant increases in men occurred in East Africa (1.6 mm Hg per decade). In women, mean systolic BP increased the most in Oceania (2.7 mm Hg per decade).

Notable sex differences occurred in Oceania and West Africa. In Oceania, mean systolic BP in women increased by 2.7 mm Hg per decade, the largest increase in any female cohort in the world. In men in this region, however, mean systolic BP increased by only 1.2 mm Hg per decade. Data from West Africa show diverging trends in men and women: although mean systolic BP in men decreased by 0.4 mm Hg per decade, it decreased in women by 2.5 mm Hg.

Lipids

Worldwide, high cholesterol causes about 56% of ischemic heart disease and 18% of strokes, accounting for 4.4 million deaths annually. Unfortunately, most LMICs have limited data on cholesterol levels (often only total cholesterol). In HICs, mean population cholesterol levels are generally decreasing, but in LMICs, these levels vary widely. As countries move through epidemiologic transition, mean population plasma cholesterol levels typically rise. Changes accompanying urbanization clearly play a role, because urban residents tend to have higher plasma cholesterol levels than rural residents. This shift results largely from greater consumption of dietary fats, primarily from animal products and processed vegetable oils, and decreased physical activity.

Globally, mean serum total cholesterol levels have decreased.[22] The GBD study analyzed data between 1980 and 2008 using a bayesian model to estimate mean total cholesterol by age, country, and year. Age-standardized mean total cholesterol was 4.64 mmol/L (179.6 mg/dL) in men and 4.76 mmol/L in women in 2008 (184.2 mg/dL). CVD death rates attributable to cholesterol have changed between 1990 to 2013, with most of the larger LMICs (China, India, Brazil) worsening and most HICs improving (**Fig. 1.10**). In 2008 the combined regions of Australasia, North America, and Western Europe had a mean total cholesterol of 5.24 mmol/L in men and 5.23 mmol/L in women. In Greenland, mean total cholesterol was as high as 5.7 mmol/L for both sexes. Sub-Saharan Africa had the lowest levels for both sexes. Some cohorts, primarily men in Southern African countries such as Liberia, Nigeria, and Burkina Faso, had levels less than 4.0 mmol/L.

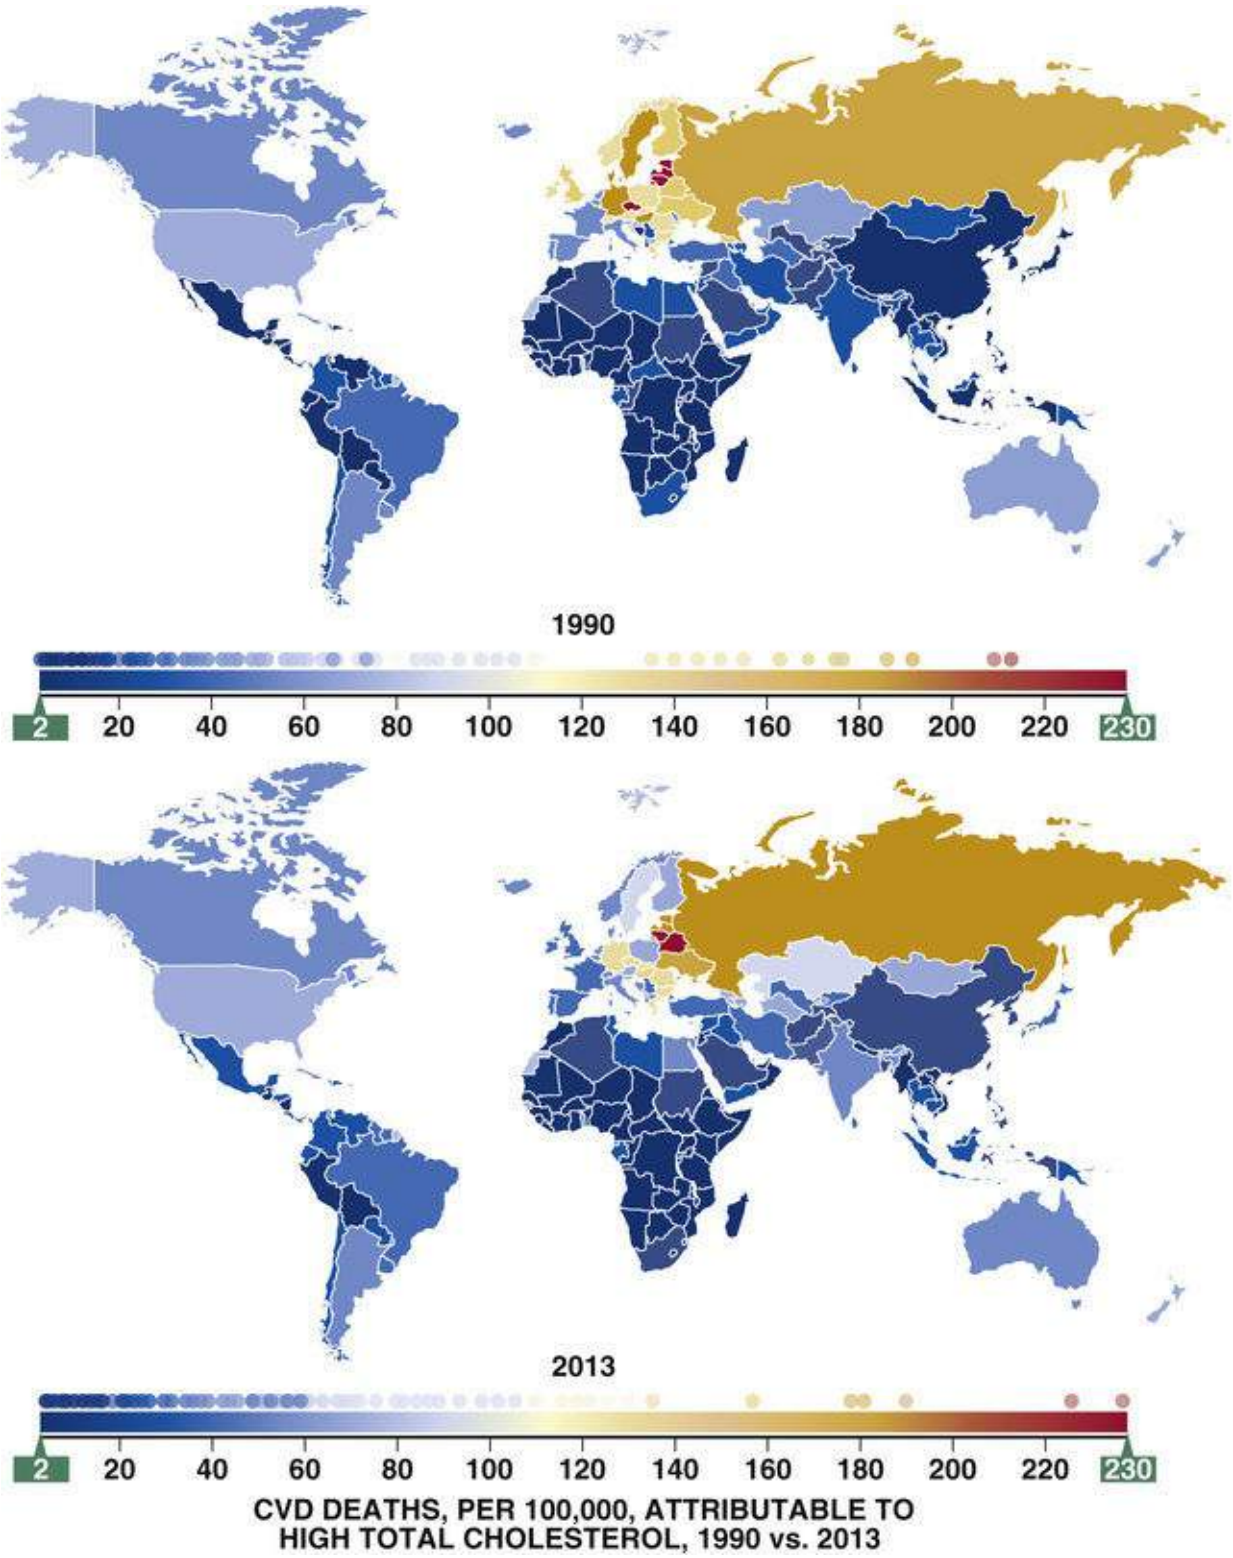

FIGURE 1.10 Cardiovascular disease mortality attributable to high total cholesterol, deaths per 100,000, 1990 versus 2013. (From Institute for Health Metrics and Evaluation (IHME). GBD Compare. Seattle: IHME, University of Washington; 2015. http://vizhub.healthdata.org/gbd-compare.)

Between 1980 and 2008, mean total cholesterol levels decreased by 0.08 mmol/L per decade in men and by 0.07 mmol/L per decade in women. The most significant decreases in cholesterol levels occurred in the Central Europe, Eastern Europe, and Central Asia regions: 0.23 mmol/L per decade in men and 0.24 mmol/L per decade in women. The high-income regions of Australasia, North America, and Western Europe had similarly large decreases in cholesterol levels: 0.19 mmol/L per decade in men and 0.21 mmol/L per decade in women. Countries such as Finland and Sweden had notably faster decreases in cholesterol levels than other Western European countries.

Several exceptions to the worldwide downward trend in cholesterol levels occurred. In the EAP

region, levels increased by 0.08 mmol/L per decade in men and by 0.09 mmol/L per decade in women. The high-income Asia-Pacific subregion showed a similar trend, but the increase was more moderate (≤0.1 mmol/L per decade). South Korea demonstrated no change in cholesterol levels. Singapore data were also notable: In the 1980s, cholesterol levels decreased for both men and women, but beginning in 2000, the downward trend ended in men. In women the trend reversed, increasing from 4.7 mmol/L in 2000 to 5.3 mmol/L in 2008. Several regions, including North Africa and Middle East, sub-Saharan Africa, and South Asia, showed no notable change in cholesterol levels, in part because of a lack of available historical data. In general, women in LMIC subregions had higher total cholesterol than their counterparts in HICs.

Diabetes

Diabetes prevalence has grown rapidly worldwide in the past 30 years. As a result, death rates for CVD attributable to diabetes have increased for many LMICs, particularly in East Asia, South Asia, and Eastern Europe and Central Asia (**Fig. 1.11**). According to the GBD study, an estimated 346 million people worldwide have diabetes.[23] The more expansive International Diabetes Foundation (IDF) definition—which, in addition to fasting plasma glucose (FPG) as in the GBD study, includes oral glucose tolerance and hemoglobin A_{1c} tests—found that 366 million people had diabetes in 2011. Almost 50% of these cases were undiagnosed. By 2030 the number of people with diabetes is expected to increase to 522 million. This rise is estimated to occur at 2.7% annually, a higher growth rate than that of the total world adult population.

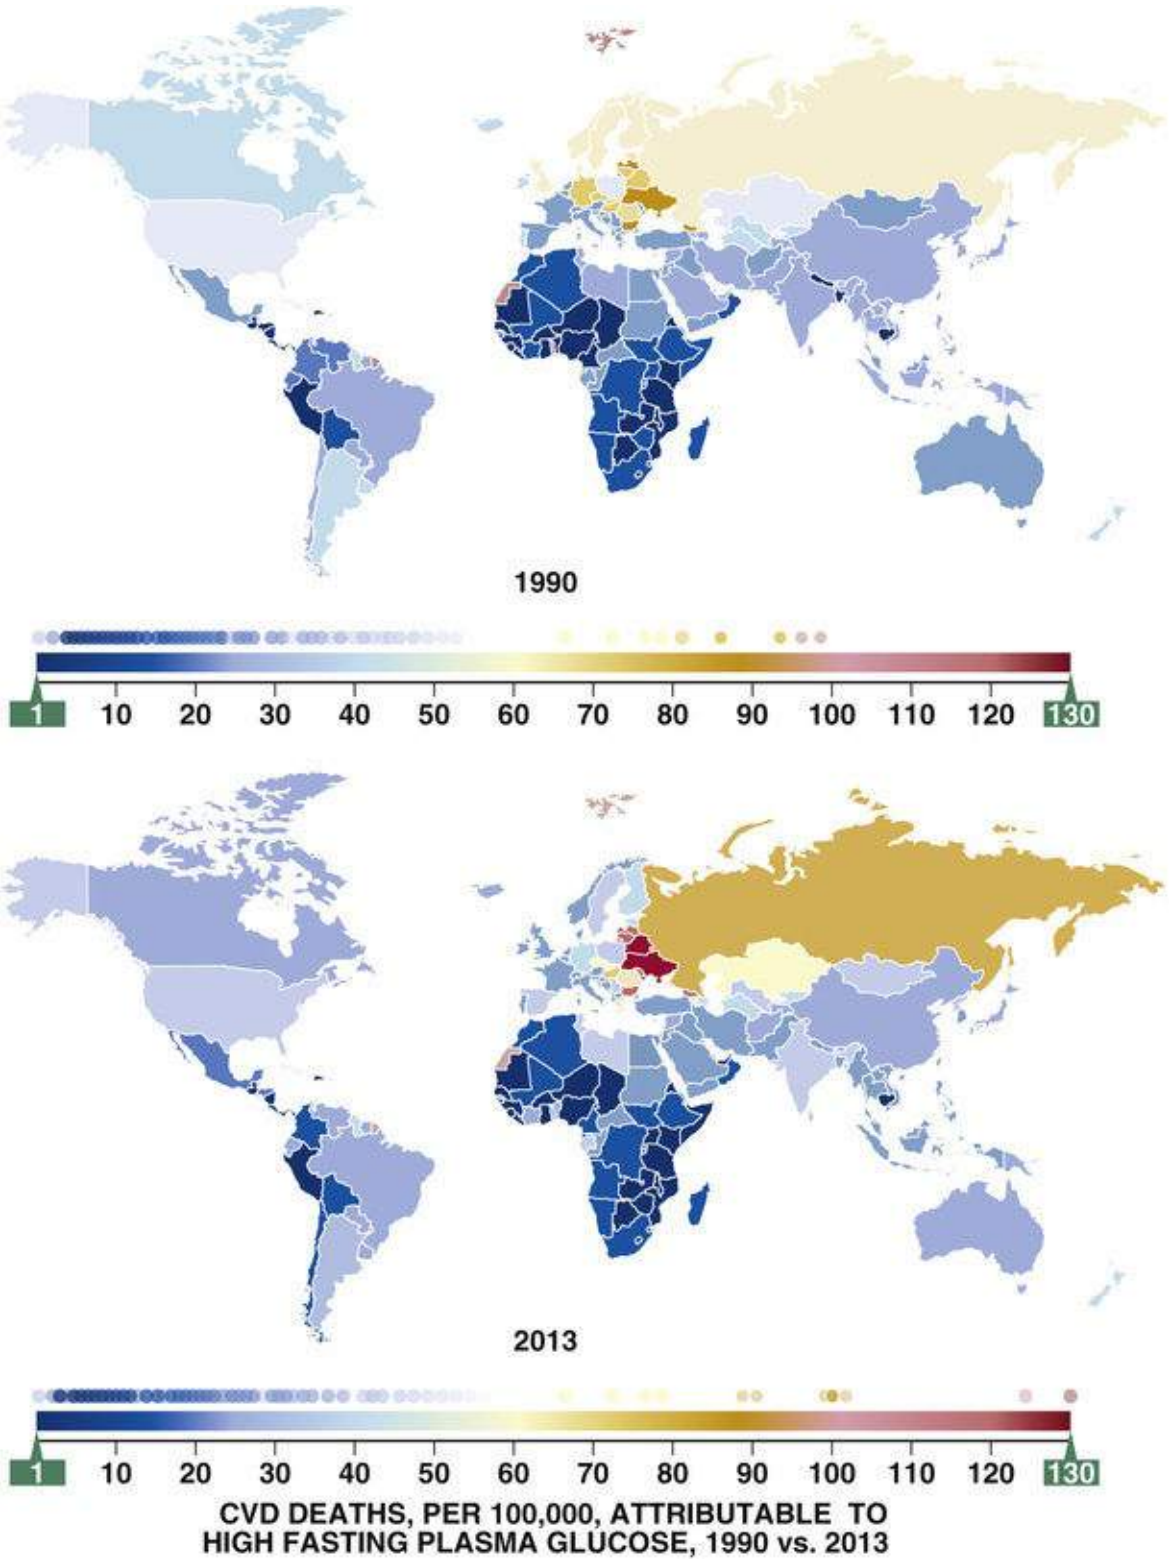

FIGURE 1.11 Cardiovascular disease mortality attributable to high fasting plasma glucose, deaths per 100,000, 1990 versus 2013. (From Institute for Health Metrics and Evaluation (IHME). GBD Compare. Seattle: IHME, University of Washington; 2015. http://vizhub.healthdata.org/gbd-compare.)

Eighty percent of people with diabetes live in LMICs. The highest regional prevalence for diabetes occurs in the Middle East and North Africa, where an estimated 12.5% of the adult population (20 to 79 years of age) has diabetes. Pacific island and Middle Eastern countries have the highest prevalence, with age-adjusted prevalence ranging from 18.8% to 25.4%. Future growth will be concentrated in LMICs, especially in regions such as sub-Saharan Africa, Middle East and North Africa, and Southeast Asia.[24] In addition, a majority of cases will remain within those age 45 to 64 in LMICs, whereas those older than 65 are most affected in HICs. Rising rates of obesity, aging, and urbanization of the population are likely related to the diabetes epidemic. Almost 90% of type 2 diabetes cases are associated with obesity, and

diabetes and its related complications are the costliest consequence of obesity. Mortality from diabetes is also increasing, with approximately 4.6 million deaths in 2011.

Asian countries face a relatively larger burden of diabetes compared with the Europe and Central Asia or Latin America and Caribbean regions. India and China, for example, have the largest numbers of people with diabetes in the world: 61.3 million and 90 million, respectively. Asian populations may have a higher risk for developing diabetes even at a lower body mass index (BMI), because of a greater tendency toward visceral obesity. In addition, this population may experience both undernutrition (during the perinatal period) and rapid weight gain (during childhood), a combination that increases the risk for insulin resistance.[25]

The most recent GBD study found a global increase in mean FPG. The study analyzed multiple published and unpublished health surveys and epidemiologic studies by applying a bayesian hierarchical model for each sex by age, country, and year. Between 1980 and 2008, mean FPG increased by 0.07 mmol/L (1.26 mg/dL) per decade in men and 0.08 mmol/L (1.44 mg/dL) per decade in women. The upward trend in FPG was nearly universal.[23] In almost every region worldwide, mean FPG increased or remained unchanged; regions that displayed apparent decreases (e.g., men in the East Asia and Southeast Asia region) were not statistically different from flat trends (posterior probabilities ≤0.80).

Although some regions had unchanging mean FPG levels, other regions, including southern and tropical Latin America, Oceania, and high-income regions, experienced significant increases. The most notable region is Oceania; between 1980 and 2008, mean FPG increased by 0.22 mmol/L per decade in men and 0.32 mmol/L per decade in women. By 2008, Oceania had the highest mean FPG for both sexes (6.09 mmol/L for men, 6.09 mmol/L for women) and the highest prevalence of diabetes (15.5% in men, 15.9% in women) in the world.

In addition to Oceania, the Caribbean and North Africa and the Middle East have the highest mean FPG levels worldwide: 21% to 25% of men and 21% to 32% of women in these countries have diabetes. By contrast, men in sub-Saharan Africa and women in Asia-Pacific HICs had the lowest mean FPG in 2008: 5.27 mmol/L and 5.17 mmol/L, respectively. The only significant decrease in mean FPG occurred in women in Singapore, where levels fell by 0.21 mmol/L per decade.

Trends in mean FPG also varied by sex. In sub-Saharan Africa, for example, mean FPG increased by 0.05 mmol/L per decade in men, but by 0.13 mmol/L per decade in women. The Central Asia, North Africa, and Middle East region had similar differences in sex: mean FPG increased by 0.06 mmol/L per decade in men and by 0.16 mmol/L per decade in women.

Obesity

Obesity is increasing throughout the world and particularly in LMICs, which have steeper trajectories than in HICs. According to the latest GBD study, almost 1.46 billion adults were overweight (BMI ≥25 kg/m^2) in 2008; of these, approximately 502 million were obese (BMI ≥30 kg/m^2).[26] Explanations for this rapid rise include changes in dietary patterns, physical activity, and urbanization. Popkin and colleagues[27] report that the use of edible oils, caloric sweeteners, and animal-source foods is increasing. Annual animal food consumption tripled in China from the 1950s to 1990s. Physical activity declines as urbanization leads to increased use of motorized vehicles and a change to more sedentary occupations.

Unlike data from the 1980s, which showed that obesity affected predominantly the higher-income group in LMICs, a recent analysis shows a shift to the poor in the burden of overweight and obesity. Although higher-income groups still have the highest prevalence of overweight and obesity, rates are increasing faster in lower-income groups.[28] The poor are relatively more susceptible to obesity as a developing

country's GNP approaches the middle-income range.[28,29] Higher GDP is also associated with faster rates of increase in the prevalence of overweight and obesity in lower-income groups.[28]

Women are more affected than men, with overweight women generally outnumbering underweight women, as indicated by data from LMICs.[26] In the same survey, prevalence of overweight women exceeded 20% in more than 90% of surveyed countries. Even rural areas in half the countries surveyed exhibited such rates. Adolescents are at particular risk: 19% of U.S. adolescents are obese.[30] The number of overweight children is increasing in countries as diverse as China, Brazil, India, Mexico, and Nigeria. According to the most recent World Health Organization (WHO) estimates, 40 million children younger than 5 years are overweight. Brazil saw an alarming rise, from 4% to 14% over a two-decade period. In 1980 the worldwide obesity prevalence rate was 4.8% in men and 7.9% in women. By 2008, prevalence rates had almost doubled, to 9.8% in men and 13.8% in women.

Globally, BMI rose in both men and women. The GBD study analyzed published and unpublished health examination surveys and epidemiologic studies (linear regressions were developed to estimate mean BMI from overweight or obesity prevalence, when available) and found that between 1980 and 2008, global BMI rose by 0.4 kg/m^2 per decade in men and 0.5 kg/m^2 per decade in women.

BMI varied substantially between regions and by sex and over time. In more than two thirds of the countries, the contribution of obesity to attributable burden of CVD death rates worsened. The majority of countries that improved were from HICs, although some were from each of the LMICs that saw improvements except from South Asia (**Fig. 1.12**). In 2008 the age-standardized mean BMI in the United States was 28.5 kg/m^2 in men and 28.3 kg/m^2 in women. In contrast with the United States and other HICs with similarly high BMIs, the sub-Saharan Africa and Asia regions have some of the lowest mean BMIs. Men in Ethiopia, for example, have a mean BMI of 20.2 kg/m^2, and women in Bangladesh have a mean BMI of 20.5 kg/m^2.

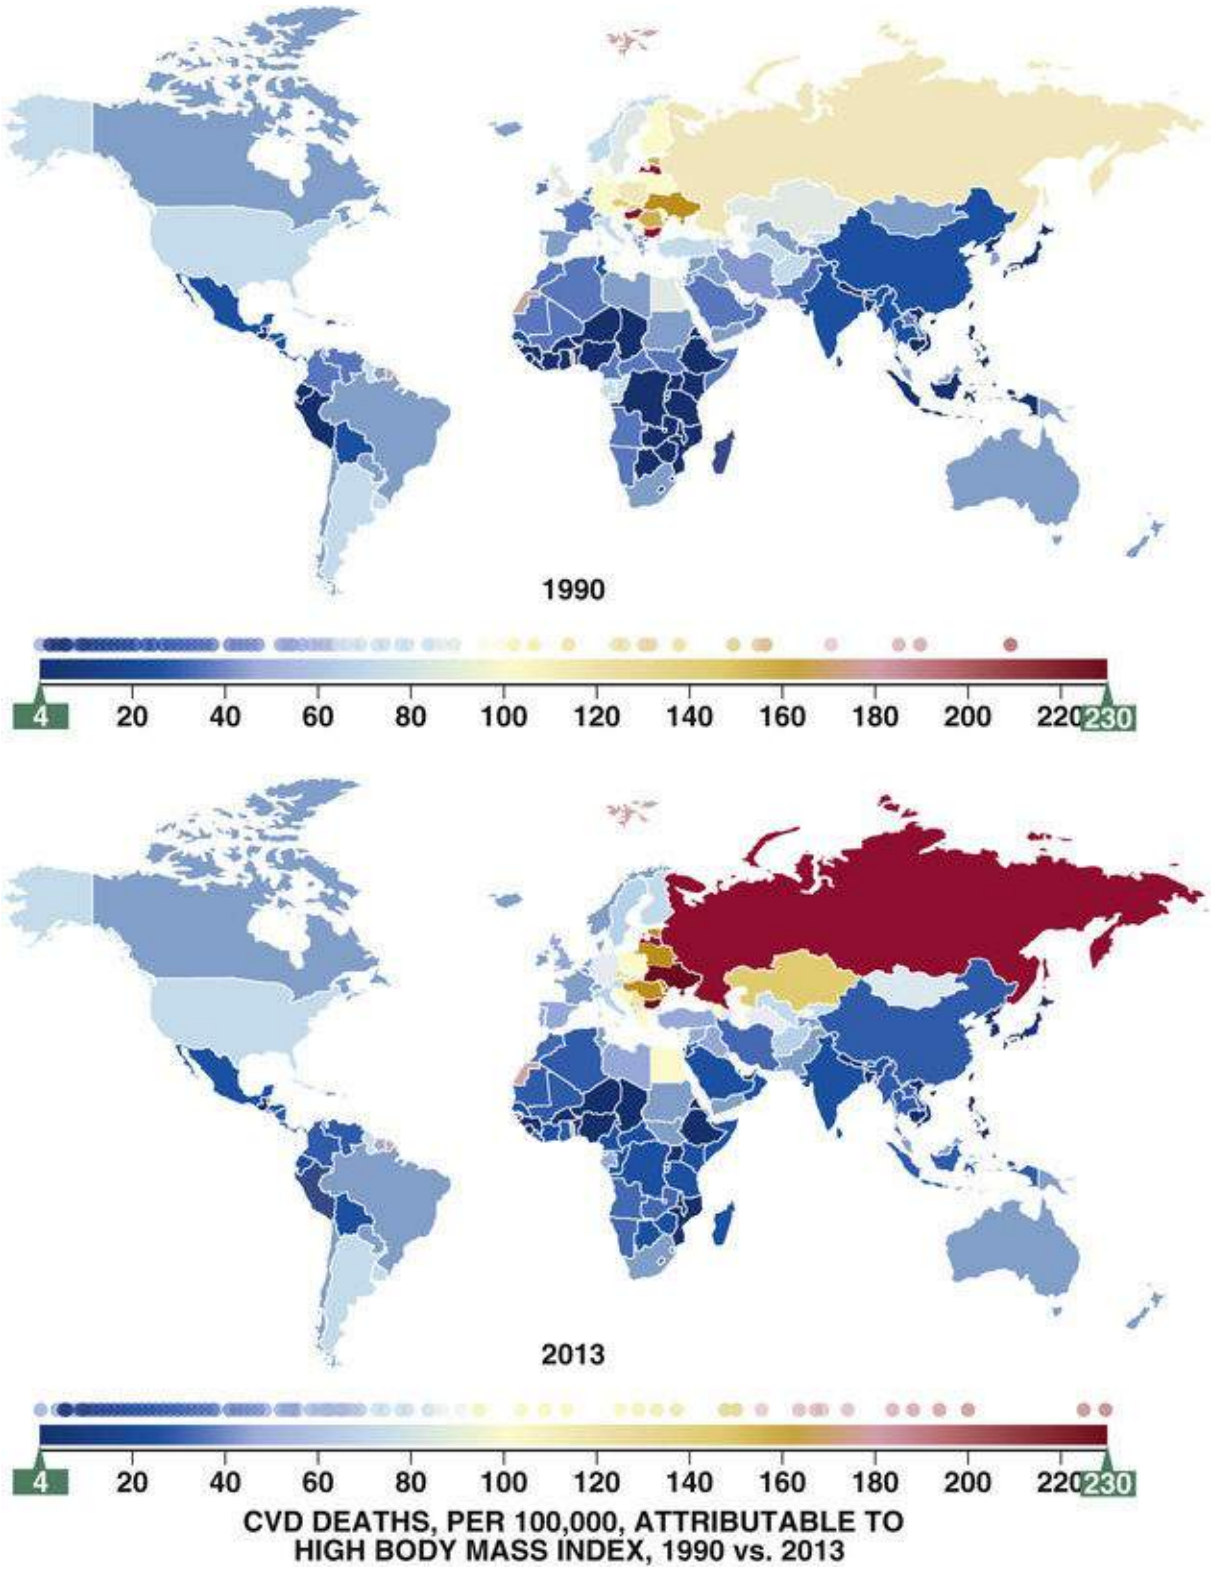

FIGURE 1.12 Cardiovascular disease mortality attributable to high body-mass index, deaths per 100,000, 1990 versus 2013. (From Institute for Health Metrics and Evaluation (IHME). GBD Compare. Seattle: IHME, University of Washington; 2015. http://vizhub.healthdata.org/gbd-compare.)

The largest increase in BMI occurred in Oceania. Between 1980 and 2008, mean BMI rose by 1.3 kg/m^2 per decade in men and 1.8 kg/m^2 per decade in women. Of the islands in the Oceania region, Nauru had the largest BMI increase of more than 2 kg/m^2. BMI trends were similar in the North American high-income region (1.1 kg/m^2 per decade in men and 1.2 kg/m^2 per decade in women). In Latin America and the Caribbean, mean BMI for women increased 0.6 to 1.4 kg/m^2 per decade. By contrast, mean BMI decreased in Central African men by 0.2 kg/m^2 per decade and remained unchanged in South Asian men. In women, mean BMI remained static, with changes less than 0.2 kg/m^2 per decade in Central Asia, Central Europe, and Eastern Europe.

Although regional trends generally showed concordance between sexes, some exceptions occurred. There was no change in mean BMI in South Asian men, but mean BMI in women increased at a rate close to the global average, 0.4 kg/m^2 per decade. The most significant discrepancy in sex trends occurred in Central Africa. BMI in men in Central Africa decreased by 0.2 kg/m^2 per decade, the only significant decrease in any male population in the world. In women in Central Africa, however, mean BMI increased by 0.7 kg/m^2 per decade, a rate greater than the world average.

Diet

As humans have evolved, selective pressures have favored the ability to conserve and store fat as a defense against famine. This adaptive mechanism has become unfavorable in light of the larger portion sizes, processed foods, and sugary drinks that many people now regularly consume. Between 1970 and 2010, the average daily per capita caloric intake in the United States increased from 2076 to 2534 calories.[31] As per capita income increases, so does consumption of fats and simple carbohydrates, whereas intake of plant-based foods decreases. A key element of this dietary change is an increased intake of saturated animal fats and inexpensive hydrogenated vegetable fats, which contain atherogenic *trans* fatty acids. New evidence suggests that high intake of *trans* fats may also lead to abdominal obesity, another risk factor for CVD. (**See Chapters 49 and 50** for further discussion of diet, obesity, and CVD.)

China provides a good example of such a "nutritional transition"—rapid shifts in diet linked to socioeconomic changes. The China Nationwide Health Survey found that between 1982 and 2002, calories from fat increased from 25% to 35% in urban areas and from 14% to 28% in rural areas, as calories from carbohydrates fell from 70% to 47%. As recently as 1980, the average BMI for Chinese adults was about 20 kg/m^2, and less than 1% had a BMI of 30 kg/m^2 or greater. From 1992 to 2002, the number of overweight adults increased by 41%, and the number of obese adults increased by 97%.

China and other countries in transition have the opportunity to spare their populations from the high levels of *trans* fats that North Americans and Europeans have consumed over the past 50 years by avoiding government policies that can contribute to the CVD burden. An estimated 30,000 CVD deaths could be averted over 10 years in the United Kingdom with elimination of *trans* fats, reductions in saturated-fat consumption, reduced salt intake, and increased fruit and vegetable consumption.[32] Another facet of the nutritional transition for countries adopting a Western diet is the introduction of high-sugar beverages associated with weight gain and increased risk for type 2 diabetes. A meta-analysis suggests up to a 16% relative risk increase in CHD per unit of sugar-sweetened beverages consumed daily.[33]

Physical Inactivity

In HICs the widespread prevalence of physical inactivity produces a high population-attributable risk of cardiovascular consequences. Physical inactivity is also increasing in low- and middle-income regions of the world, witnessing a shift from physically demanding, agriculture-based work to largely sedentary, service industry–based and office-based work. A switch to mechanized transportation accompanies this work shift.

Current guidelines call for moderate exercise for at least 30 minutes 5 or more days a week, or vigorous exercise for 20 minutes 3 days a week. Gallup's November 2011 Health and Healthcare poll found that 51.6% of U.S. adults say they exercise three or more times a week. These numbers have remained essentially unchanged since 2008. Physical inactivity levels are similarly high in other regions of the world. In the Middle East and North Africa region, for example, physical inactivity is fairly

common, with a prevalence ranging from 32.9% in Syria to 56.7% in Iraq. In urban China the proportion of adults who participate in moderate- and high-level activity has decreased significantly, whereas participation in low-level activity has increased. The study of about 500,000 adults in China found that a lack of physical activity and an increase in sedentary leisure time were independently associated with greater adiposity.[34]

The Cuban economic crisis that began in 1989, when Cuba lost the Soviet Union as a trading partner, and the resultant hardship for its people improved their overall cardiovascular health. The crisis worsened for the next 5 years, and complete recovery did not take place until 2000. Sustained food rationing led to a reduction in per capita food intake, and the lack of public transportation resulting from fuel shortages meant that more people were walking and riding bikes. During the crisis period, the proportion of physically active adults increased from 30% to 67%, and a 1.5-unit shift in BMI distribution was observed; CHD declined up to 1995. However, a rebound in population weight mirrored a reduction in physical activity and resulted in the cessation of CHD mortality decline from 2000 to 2010.[35]

Aging Populations

Average life expectancy will reach 83 years in developed regions and 75 years in less developed regions by 2025, according to WHO.[36] This increase is associated with a decline in overall infant mortality and fertility rates. Although older adults will constitute a greater percentage of the population in HICs—more than 65 million Americans will be older than 65 by 2025—low- and middle-income regions will see the population over 60 more than double from 1995 to 2025.

The time of transition to an older population is sharply shorter in LMICs. For example, whereas it took the United States and Canada more than 65 years to double their over-65 population, LMICs will do so every 25 years for the next 50 years. Such acute changes in the population structure leave less time to expand an already overburdened health infrastructure to address the chronic diseases of older adults, which prominently include cardiovascular conditions (**see Chapter 88**).

Fetal Influences

Adverse influences such as undernutrition during fetal life (fetal “programming”) and early postnatal life appear to affect the prevalence of adult CVD and contribute to its risk factors. Barker,[37] in his “developmental origins of adult disease” hypothesis, suggested that adverse influences early in development, particularly during intrauterine life, could result in permanent changes in the physiology and metabolism of the pancreas, kidney, muscle, and vascular endothelium, resulting in adult insulin resistance, metabolic syndrome, hypertension, and CHD. Recent evidence indicates that the first 2 years of postnatal life are a sensitive or “critical” period of development, and any stimulus or insult during this period appears to have lasting or lifelong significance for adult-onset CVD.[38] Several epidemiologic studies have demonstrated these associations, and two randomized trials from Guatemala and India on nutritional supplementation for pregnant mothers demonstrated favorable cardiovascular risk profiles among the children of mothers who received such supplementation.[39,40]

The mechanisms of increased risk appear to be both biologic (alterations in fetal tissues and postnatal epigenetic modifications) and social (cognitive impairment, low productivity, and higher prevalence of cardiovascular risk factors among those with lower birth weight and early-life adverse influences), and childhood obesity and sedentary habits aggravate this risk. Thus the prevention of adverse fetal exposures

and subsequent long-term consequences require a holistic approach. An understanding of prenatal risk factors and their early childhood modifiers will provide an opportunity for interventions before the development of risk factors. Remedies include improved maternal nutrition during pregnancy and lactation, emphasis on breastfeeding through early infancy, and ensuring adequate balanced nutrition to infants. On the basis of current understanding, policymakers and health care professionals should design and develop preventive strategies that effectively influence these very early determinants of CVD development.[41]

Environmental Exposures

Environmental pollution, especially both indoor and outdoor air pollution, has emerged as a major cause of death and disease burden[42] (**see Chapter 52**). Exposure to particulate-matter (PM) air pollution,[43] heavy metals (e.g., cadmium, arsenic, lead, mercury),[44] and polyaromatic hydrocarbons[45] is associated with increased risk of mortality and morbidity from CVD. The GBD comparative risk assessments of 2010 and 2013 have shown that more than 30% of all DALYs from ischemic heart disease and about 40% of DALYs from strokes result from environmental risk factors,[46,47] approximately the same as those attributable to tobacco smoke. Of these exposures, air pollution (household and ambient) is the most prominent risk factor, contributing to approximately 7 million premature deaths annually, with a majority occurring in LMICs such as India and China.

In many developing countries, populations experience a continuum of exposure to ambient air pollution (from vehicles, industry, etc.) and household air pollution (from cooking, heating, and lighting), resulting in significant contributions to the health burden, as in India, where it is the second most important risk factor for poor health. More than half of all deaths associated with air pollution exposure are through cardiovascular and cerebrovascular pathways, involving ischemic heart disease,[48] heart failure,[49] stroke,[50] and hypertension.[51] Three pathways, listed below in order of the strength of the evidence base, may contribute to the mechanisms that link PM exposure to CVD and cerebrovascular disease:

1. Particle transport into the lungs provoking inflammatory responses and promoting systemic oxidative stress. This leads to increased risk of thrombosis, endothelial dysfunction, atherosclerosis progression, and dyslipidemia.
2. Particle transport into the lungs promoting autonomous nervous system imbalances. This leads to pathologic alterations in hypertension, endothelial dysfunction, vasoconstriction, and atherosclerosis.
3. Absorption of particles through the lungs into the bloodstream causing tissue-level interactions. This results in platelet aggregation, vasoconstriction, and endothelial dysfunction.

The epidemiologic evidence base suggests that exposure to arsenic,[52] cadmium,[53] and lead[54] follows the common physiologic pathways observed with air pollution. In addition, the mechanistic evidence from animal and human studies indicates that arsenic exposure is associated with carotid intima media thickness, a marker for atherosclerosis, with links to diabetes also observed.[55]

Regardless of the primary route and the pathophysiology involved, short- or long-term exposure to various environmental pollutants is associated with an increased risk of ischemic heart disease, stroke, heart failure, and preclinical conditions such as endothelial dysfunction, thrombosis, atherosclerosis, and hypertension. Although epidemiologic evidence has been well documented for single pollutants, the synergistic impacts are understudied. From a physician's perspective, informing patients on how to avoid

exposure and protect themselves should be part of primary prevention.

Economic Burden

Despite some overlap, at least three approaches can measure the economic burden associated with CHD. The first source of financial burden reflects the costs incurred in the health care system itself and reported in "cost-of-illness" studies. In these studies, the cost of CHD includes the costs of hospitalizations for angina and MI, as well as heart failure attributable to CHD. The cost of specific treatments or procedures related to CVD (e.g., thrombolytics, catheterization, PCI) and the cost associated with outpatient management and secondary prevention (e.g., office visits, pharmaceutical costs) are also included. In addition, nursing home, rehabilitation (inpatient and outpatient), and home nursing costs require consideration.

The second economic assessment is derived from microeconomic studies that assess the household impact of catastrophic health events such as MI. These studies look at out-of-pocket expenses incurred by the individual patient or family that might have other, downstream economic impacts, such as loss of savings or sale of property to cover medical costs. Many LMICs lack an extensive insurance scheme, and health care costs are almost entirely borne by individuals; 150 million people experience financial catastrophe each year because of medical expenditures.[56] Furthermore, the limited data do not confirm the causality between chronic disease and individual or household poverty. However, expenditures for CHD or its addictive risk factors (e.g., tobacco) could lead to substantial and even impoverishing costs.

The third method of determining financial burden from CHD is based on a macroeconomic analysis. These assessments examine lost worker productivity, or the economic growth lost as a result of adults with CHD or their caregivers being partially or completely out of the workforce because of illness. The data for the impact of chronic diseases on labor supply and productivity are more robust. An additional cost usually not accounted for is the intangible loss of welfare associated with pain, disability, or suffering by the affected person. These indirect costs are often addressed by "willingness-to-pay" analyses, asking generally how much would an individual pay to avert suffering or dying prematurely from CHD. The gains are not merely improved work performance, but also enjoying activities beyond productivity. U.S. studies suggest that as much as 1% to 3% of GDP is attributable to the cost of care for CVD, with almost half of that related to CHD.[57] In China, annual direct costs of CVD are estimated at more than $40 billion (U.S.), or about 4% of GNI. In South Africa, 2% to 3% of GNI is devoted to the direct treatment of CVD, which equates to about 25% of South African health care expenditures. The indirect costs are estimated at more than double that of the direct costs. Although few cost-of-illness studies for CHD have been performed in other regions, such studies have reported on the financial burdens attributed to risk factors for CHD. For example, the direct costs caused by diabetes in the Latin American and Caribbean countries were estimated at $10 billion (U.S.). Indirect costs were estimated at more than $50 billion in 2000. The limited studies available suggest that obesity-related diseases account for 2% to 8% of all health care expenditures in HICs. In India and China the costs for obesity are about 1.1% and 2.1% of GDP, respectively.

Recently, the costs attributable to nonoptimal BP levels as mediated through stroke and MI were evaluated for all regions of the world. Globally, the health care costs of elevated BP were estimated at $370 billion (U.S.) for 2001; this amount represented approximately 10% of all global health care expenditures for that year. Regional variations do exist, with hypertension being responsible for up to 25% of health care costs in the Eastern Europe region (**Fig. 1.13**). Over a 10-year period, BP-related

health care costs could equal $1 trillion (U.S.) globally, and indirect health care costs attributed to BP could be nearly four times as much.[58,59]

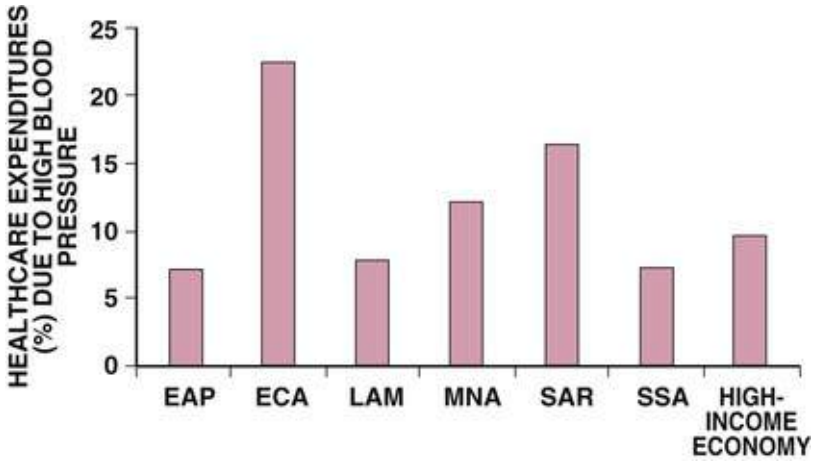

FIGURE 1.13 Percentage of health care expenditures attributed to high blood pressure. *EAP,* East Asia and Pacific; *ECA,* Europe and Central Asia; *LAM,* Latin America and the Caribbean; *MNA,* Middle East and North Africa; *SAR,* South Asia region; *SSA*, sub-Saharan Africa.

The high proportion of CVD burden that occurs earlier among adults of working age augments its macroeconomic impact in LMICs. Under current projections, in LMICs such as South Africa, CVD will strike 40% of adults between ages 35 and 64, compared with 10% in the United States. India and China will have death rates in the same age-group that are two and three times that for most HICs. In view of the large populations in these two rapidly growing economies, this trend could have profound economic effects over the next 25 years, as workers in their prime succumb to CVD.

Cost-Effective Solutions

The large reductions in age-adjusted CVD mortality rates that have occurred in HICs result from three complementary types of interventions. One strategy targets those with acute or established CVD. A second entails risk assessment and targeting persons at high risk because of multiple risk factors for intervention before their first CVD event. The third strategy uses mass education or policy interventions directed at the entire population to reduce the overall level of risk factors. This section reviews various cost-effective interventions (**see Chapter 45**). Much work remains undone in LMICs to determine the best strategies given limited resources, but if implemented, these interventions could help significantly in reducing the burden. **Table 1.2** lists the cost-effectiveness ratios for many high-yield interventions that could be or have been adopted in low- and middle-income regions.

TABLE 1.2

Cost-Effectiveness for a Selection of Coronary Heart Disease (CHD) Interventions in Developing Regions

INTERVENTION	COST-EFFECTIVENESS RATIO ($US/DALY)*
Drug Treatments	
Acute Myocardial Infarction	
ASA, BB (global)	11-22
ASA, BB, SK (global)	634-734
ASA, BB, t-PA (global)	15,860-18,893
Prehospital thrombolysis (Brazil)	457/LY
Secondary Treatment (CHD)	
Multidrug regimen (ASA, BB, ACEI, statin) (global)	1686-2026
Coronary artery bypass graft (global)	24,040-72,345
Primary Prevention	
Cholesterol lowering (Brazil)	441/LY
Multidrug regimen (AR > 20%-25%) (global)	771-1195
Policy Interventions	
Tobacco	
Price increase of 33%	2-85
Nonpolicy Interventions	33-1432
Salt Reduction‡	
2-8 mm Hg reduction	Cost-saving: 250
Fat-Related Interventions§	
Reduced saturated-fat intake	Cost-saving: 2900
Trans fat replacement: 7% reduction in CHD	50-1500
Devices	
Cardioverter-defibrillators: primary prevention (Brazil)	50,345 (US$PPP/QALY)

*Across six World Bank regions; *DALY,* disability-adjusted life-year; *PPP,* purchasing power parity; *QALY,* quality-adjusted life-year.

§Range includes estimates of cost of interventions (<$0.50-$6.00).

ASA, Acetylsalicylic acid (aspirin); *BB,* beta blocker; *SK,* streptokinase; *ACEI,* angiotensin-converting enzyme inhibitor; *t-PA,* tissue plasminogen activator; *AR,* absolute risk.

Data from Gaziano TA. Cardiovascular disease in the developing world and its cost-effective management. Circulation 2005;112:3547; and Gaziano TA, Galea G, Reddy KS. Chronic diseases 2—scaling up interventions for chronic disease prevention: the evidence. Lancet 2007;370:1939.

Established Cardiovascular Disease Management

People at highest risk are those having an MI or stroke; as many as half die before they ever receive medical attention. For those who do reach a hospital, many cost-effective strategies exist.[60] Four incremental strategies were evaluated for the treatment of MI and compared with a strategy of "no treatment" as a control for the six World Bank low- and middle-income regions. The four strategies compared were (1) aspirin; (2) aspirin and atenolol (beta blocker); (3) aspirin, atenolol, and streptokinase; and (4) aspirin, atenolol, and tissue plasminogen activator (t-PA). The incremental cost per quality-adjusted life-year (QALY) gained for the aspirin and beta-blocker interventions was less than $25 for all six regions. Costs per QALY gained for streptokinase were between $630 and $730 across the regions. Incremental cost-effectiveness ratios for t-PA were about $16,000/QALY gained, compared with streptokinase. Minor variations occurred between regions as a result of small differences in follow-up care based on regional costs.

Secondary prevention strategies have equal cost-effectiveness in LMICs. A combination of aspirin, an ACE inhibitor, a beta blocker, and a statin for secondary prevention can lead to acceptable cost-effectiveness ratios in all low- and middle-income regions. Use of currently available generic agents,

even in the absence of the "polypill," could be highly cost-effective, on the order of $300 to $400 per person per QALY gained.

Risk Assessment

Primary prevention is paramount for the large number of people who have high risk for acquiring CVD. In view of limited resources, finding low-cost prevention strategies is a top priority. Using prediction rules or risk scores to identify persons at higher risk to target specific behavioral or drug interventions is a well-established primary prevention strategy and has proved to be cost-effective.[61,62] Most such scoring systems include age, sex, hypertension, smoking status, diabetes mellitus, and lipid values; some also include family history.[63] Other markers of risk, such as C-reactive protein, have been used that improve reclassification and discrimination.[64] Coronary artery calcium scoring may add the most in terms of changes in C-statistic (discrimination) or the net reclassification improvement (NRI) in intermediate-risk populations, but it has limitations as a screening strategy[65] (**see Chapter 45**).

More attention is now focused on developing risk scores that would be easier to use in resource-poor countries, without loss of predictive discrimination. In LMICs with limited testing facilities, a prediction rule that requires a laboratory test may be too expensive for widespread screening, or the cost may preclude its use altogether. In response to this concern, WHO recently released risk-prediction charts for the different regions of the world, with and without cholesterol data. A study based on the U.S. National Health and Nutrition Examination Survey (NHANES) follow-up cohort demonstrated that a non–laboratory-based risk tool that uses information obtained in a single encounter (age, systolic BP, BMI, diabetes status, and smoking status) can predict CVD outcomes as effectively as one that requires laboratory testing, with C-statistics of 0.79 for men and 0.83 for women that were no different from those obtained using the Framingham-based risk tool, and has been shown to correlate with other scores in other countries.[66] Furthermore, the results of "goodness-of-fit" tests suggest that the non–laboratory-based model is well calibrated across a wide range of absolute risk levels and without changes in risk classification. The ankle-brachial index (ABI) also appears to add to risk discrimination and improve the NRI as an alternative noninvasive tool.[65] Furthermore, community health workers can use the simple risk score effectively, decreasing the cost of screening significantly.[67,68]

Policy and Community Interventions

Education and public policy interventions that have reduced smoking rates, lowered mean BP levels, and improved lipid profiles contribute to reduction in CHD rates.[4] Education and policy efforts directed at tobacco consumption have contributed substantially to the reductions in CVD. In addition, salt and cholesterol reduction has been evaluated as a cost-effective strategy to reduce stroke and MI in HICs.[69] Community interventions[70] have reduced levels of multiple risk factors and, in some cases, CHD mortality.

Tobacco Use

Tobacco control can be conceptualized in terms of strategies that reduce the supply of or the demand for tobacco. Most public health and clinical strategies to date focus on reducing demand through economic disincentives (taxes), health promotion (media and packaging efforts), restricted access (to advertising and tobacco), or clinical assistance for cessation. The WHO effort to catalyze the creation of a global treaty against tobacco use was a key milestone. In May 2003 the WHO World Health Assembly

unanimously adopted the WHO Framework Convention in Tobacco Control (FCTC), the first global tobacco treaty. The FCTC had been ratified by 168 countries as of 2016, making it one of the most widely embraced treaties in the United Nations. The FCTC has spurred efforts for tobacco control across the globe by providing both rich and poor nations with a common framework of evidence-based legislation and implementation strategies known to reduce tobacco use.

Jha and colleagues[71] presented a landmark analysis of the cost-effectiveness of tobacco control in 2006, and the findings have led it to be a major focus on noncommunicable diseases.[72] With tax, treatment, and nonprice interventions, a 33% price increase would result in a reduction of 19.7 to 56.8 million (5.4% to 15.9% of total) deaths in smokers in the developing world who were alive in 2000.[72] Calculations show that nicotine replacement therapy (NRT) could reduce the number of deaths by 2.9 to 14.3 million (0.8% to 4.0% of total) in the 2000 cohort. A range of nonprice interventions (e.g., advertising bans, health warnings, smoke-free laws) would reduce deaths by 5.7 to 28.6 million (1.6% to 7.9% of total) in that cohort. These reductions would translate into cost-effectiveness values in the developing world of $3 to $42/QALY saved for tax increases (not including tax revenue), $55 to $761/QALY for NRT, and $54 to $674/QALY for nonprice measures.[72]

Critically important for patients who have had a coronary event, smoking cessation saves lives at a greater rate than any individual medical treatment. Quitting smoking in the Organization to Assess Strategies in Acute Ischemic Syndromes (OASIS) 5 trial was associated with a 40% relative risk reduction for MI. Further studies suggest that varenicline leads to increased smoking cessation rates,[73] although it is unclear whether it is better than traditional NRTs.[74]

Salt and Lipid Reductions

The analyses on salt reduction achieved as a result of public education are quite favorable.[75] The intervention ranges from being cost-saving to $200/DALY averted. A campaign for reducing saturated fat and replacing it with polyunsaturated fat was also likely cost-effective. In the base case, a 3% decline in cholesterol and a $6 per capita education cost were assumed. Findings included a cost as low as $1800/DALY averted in the South Asia region and up to $4000/DALY averted in the Middle East and North Africa region. If the cost for the education plan were halved, however, the ratio would be approximately $900/DALY, which would be cost-saving if the reduction could be achieved for under $0.50 per capita—a possibility in areas with less expensive access to media. Simple measures such as changing prescription length for medications such as statins[76] or training community health workers to do screening for CVD can be cost-effective.[67,77]

Community Interventions

In the 1970s and 1980s, a series of population-based community intervention studies were conducted to reduce risk factors for chronic disease.[78] These studies focused on changes in health behaviors or risk factors such as tobacco use, body weight, cholesterol, and BP, as well as a reduction in CVD morbidity and mortality. In general, they included a combination of community-wide actions and those focused on persons identified as being at high risk for CVD-related health problems.

One of the earliest and most often-cited community interventions is the North Karelia project in Finland, begun in 1972. The community-based interventions included health education, screening, a hypertension control program, and treatment. Over the first 5 years of the study, reductions in risk factors occurred, along with a decline in CHD mortality by 2.9% per year, versus a 1% per year decline in the rest of Finland. During the next 10 years, declines were greater in the rest of Finland. Over a follow-up of

25 years, a large decline in CHD occurred in both the North Karelia region (73%) and the rest of Finland (63%). Although the overall difference in the decline in CHD deaths was not significantly greater in the study area of North Karelia, the reduction in tobacco-related cancers in men was significant. A similar study in the Palo Alto, California, area showed reductions in risk factors—cholesterol (2%), BP (4%), and smoking rates (13%)—compared with sites without the intervention, but no impact on disease endpoints.

Later, community interventions in HICs had mixed results, with some showing improvements in risk factors beyond the secular decline occurring throughout most HICs and others exhibiting no additional decline. A systematic review showed a net reduction in 10-year CVD risk of 0.65%.

Several community intervention studies have been conducted in LMICs, including China, Mauritius, and South Africa. The Tianjin project showed reductions in hypertension and obesity. The Mauritius project, among other interventions, resulted in a government-led program that changed the prime cooking oil from a predominantly saturated-fat palm oil to a soybean oil high in unsaturated fatty acids. Overall total cholesterol levels fell 14% during the 5-year study period (1987 to 1992). Changes in other risk factors were mixed, with declines in BP and smoking rates and increases in obesity and diabetes. The Coronary Risk Factor Study in South Africa compared a control community with two communities receiving interventions at two different levels of intensity. The interventions included mass-media messages, group-sponsored educational sessions, and BP screening and follow-up with the health sector when appropriate. Both high-intensity and low-intensity interventions resulted in improvements in BP, smoking rates, and high-density lipoprotein (HDL)–to–total cholesterol ratio over the control community, but with little difference between the two intervention communities.

Another significant reduction in CHD came not through a concerted community intervention but through changes in fiscal policy. In Poland, reductions in subsidies for animal products such as butter and lard led to a switch from saturated to polyunsaturated fats, mainly rapeseed-based and soybean-based oils. The decrease in CHD mortality by more than 25% between 1991 and 2002 could not be explained by increased fruit consumption or decline in smoking rates.

Success stories such as in Poland and Mauritius are rare, however, suggesting the challenges to achieving meaningful changes targeting single risk factors at a national level.

Summary and Conclusion

Cardiovascular disease remains a significant global problem. The swift pace of economic and social transformation in a postindustrial world with rapid globalization presents a greater challenge for low- and middle-income economies than for high-income economies. Although CVD age-adjusted rates have declined in HICs and some of the LMICs, the number of CVD survivors continues to increase because of aging populations and improvements in case-fatality rates for acute events. From a worldwide perspective, the rate of change in the global burden of CVD is accelerating, reflecting the changes in the low- and middle-income economies, which represent 85% of the world's population. This preventable epidemic will have substantial consequences on many levels: individual mortality and morbidity, family suffering, and staggering economic costs—both the direct costs of diagnosis and treatment and the indirect costs of lost productivity.

Different regions of the world face different stages of the epidemic. In HICs, managing an ever-older population with chronic manifestations of CVD such as heart failure will strain health care budgets. Currently, the Eastern European countries and members of the former Soviet Union face enormous

burdens, with more than half of all deaths attributed to CVD. Meanwhile, countries in sub-Saharan Africa are just beginning to see increases in these chronic illnesses while still grappling with HIV/AIDS. No single global solution to the rising burden of CVD exists, in view of the vast differences in social, cultural, and economic circumstances. HICs must minimize disparities, reverse unfavorable trends in CVD risk factors and behaviors, and deal with the increasing prevalence of CVD in an aging population. The most complex challenges face LMICs, with increasing access to low-cost tobacco products and ready access to less-than-favorable dietary options. Preventing the poverty-inducing effects of catastrophic CVD events will require efforts to improve access to low-cost prevention strategies at both the societal and the individual level and must include improved financing for at least catastrophic health coverage.

A reduction in the disease burden would similarly require both policy and personal changes. In the long term, allocation of resources to lower-cost strategies will likely prove more cost-effective than dedicating resources to high-cost management of CVD. From a societal perspective, efforts to strengthen tobacco-control strategies, improve dietary choices, and increase physical activity will be paramount. At the individual level, risk assessment strategies and treatment modalities require simplification. Furthermore, alternative deployments of allied health workers such as community health workers will need evaluation, in view of the limited human resources in most LMICs. HICs must share with leading and emerging middle-income countries the burden of research and development into every aspect of prevention and treatment. Through further expansion of the knowledge base, particularly regarding the economic consequences of various treatment and prevention strategies, the efficient transfer of low-cost preventive and therapeutic strategies may alter the natural course of epidemiologic transitions in every part of the world, thereby reducing the excess global burden of preventable CVD.

Ethics in Cardiovascular Medicine

Savitri E. Fedson, Laurence B. Mccullough

Ethics continues to provide a bedrock for the practice of modern cardiovascular medicine. While often seen as addressing the distinction between what “can” and what “should” be done in clinical practice, the scope of ethics is much wider, encompassing such diverse topics as genetic testing, appropriateness-based reimbursement policies, and end-of-life decision making. No longer confined to American College of Cardiology (ACC) Bethesda Conferences or joint American Heart Association (AHA) and ACC conferences,[1-3] ethics is now prominently positioned in practice and publication guidelines. This attests to the awareness that, as technology and science have advanced cardiovascular medicine, so too has the need for ethical reasoning and clinically nuanced discussions of ethical challenges.

This chapter focuses on categories within cardiovascular medicine that highlight the need for ethical reasoning: informed consent and decision aids, clinical ethical judgments of futility, conflicts of interest and disclosure, public reporting, social media and mobile health, genetics, and transplantation.

Informed Consent and Decision Aids

One general approach to ethical reasoning is that of *principlism*, deploying the ethical principles, or

guides for clinical ethical judgment and action, of respect for autonomy, beneficence, nonmaleficence, and justice. Respect for autonomy, which has roots in 18th-century medical ethics, emphasizes the role of patient in self-determination, especially informed consent, shared decision making (SDM), and advance care planning. As a consequence, respect for autonomy is often regarded as the most important ethical principle.

Informed consent is often reduced to the verb, *to consent* (a patient consents). The nuances of the conversations that should take place with patients are difficult to master for clinicians and can become time-consuming when caring for patients with complex heart disease but are often relegated to junior staff or extenders. The goal of informed consent is to empower the patient with clinical information relevant to the decision at hand and to support the patient in making a voluntary decision, that is, a decision free of controlling internal influences (e.g., unreasoning fear) and external influences (e.g., well-meaning family members who attempt to usurp the patient's decision-making role). Informed consent has four requirements: (1) a patient with decision-making capacity (or their surrogate), (2) a discussion of relevant facts about the medically reasonable alternatives for managing the patient's condition (i.e., alternatives supported in evidence-based clinical judgment), (3) a determination of the patient's understanding, and (4) a voluntary decision. What constitutes “relevant facts” was established with the “reasonable patient standard” in the 1972 *Canterbury v. Spence* case. This standard requires the physician to provide information that any patient with a specific condition, such as stage C heart failure, needs to know. This is a patient-oriented standard and is the legal standard in the majority of the states in the United States. However, a *meaningful* informed consent additionally should include probable outcomes based on the main risks and benefits of the proposed intervention or procedure in that specific patient *and* a discussion about the patient's preferences. These would be relevant facts for the patient.

Although the accepted legal and ethical standard of practice, informed consent continues to be poorly done and is heavily biased by physician time and preference.[4] The common practice of “discussing” an angiographic finding while a patient is in the cardiac catheterization laboratory and making the decision to intervene is far from ideal; the practical constraints of time often interfere in many settings, as when it would otherwise be reasonable to perform a staged coronary intervention. In some settings, such as emergency care that often includes the presentation of an acute coronary syndrome or aborted sudden death, clinicians practice under the guise of “presumed consent,” and the best interest standard applies to medical care. This standard is based on the ethical principle of *beneficence,* which creates the ethical obligation to provide clinical management that is expected in evidence-based clinical judgment to result in net clinical benefit for the patient.

When patients lack decisional capacity or they are temporarily unable to make decisions, as when sedated, clinicians turn to legally designated surrogate decision makers. Surrogates should act with substituted judgment, making decisions the patient would have made, not necessarily what the surrogates themselves would want or think appropriate. In this situation the process of informed consent often becomes increasingly complicated and time sensitive. If, for example, a patient presents with an acute myocardial infarction and develops cardiogenic shock, the clinician might have to explain the procedure and potential benefit of percutaneous extracorporeal membrane oxygenation (ECMO) as a salvage therapy, while also making sure that the risks of bleeding, infection, and, importantly, lack of recovery are also heard by the surrogate decision maker. The impetus in clinical medicine is to rescue with all tools at hand, whereas the reality may be that rescuing someone from immediate death will only delay more difficult decisions about limiting life-sustaining treatment for only a few days or weeks. This does not mean that no emergency therapies should be performed because of the risk for misunderstanding, but rather that the process of informing patients and their families and updating them with current facts and

probable outcomes is iterative.

It is often in the setting of informed consent that tension between the principles of respect for patient autonomy and beneficence are most acutely experienced. Clinicians may believe that a particular intervention or medication is clearly superior to the alternative, but the patient may not agree. This tests not only respect for autonomy and beneficence, but also strains the fiduciary relationship of physicians and patients, in which the patient's interests (and preferences), as understood from an evidence-based clinical perspective, are given priority. Because of this tension, the use of decision-making aids has been increasingly adopted within cardiology. Meaningfully informed patients are less likely to undergo procedures that have limited benefit or benefits not consistent with their preferences. In addition, what physicians think patients need to know (e.g., clinical risks) and what patients want to know (e.g., costs, lifestyle changes) are often misaligned. Patients who have been meaningfully involved in decisions about their medications are more likely to be compliant with them. Indeed, complying with the 2013 ACC/AHA Guidelines on Cholesterol management will require discussion and shared decision making (SDM) between physician and patient.[5]

The domains of informed consent and end-of-life decision making also come together in the field of mechanical circulatory support (MCS) and ventricular assist device (VAD) technology. The “rise of the machines”[6] (LVADs) has brought the challenges of implantable devices that surpass those of implantable cardioverter-defibrillators (ICDs) and permanent pacemakers (PPMs). MCS, VADs, and to a lesser extent ICDs and PPMs are all forms of life-sustaining treatment undertaken to prevent imminent death and to secure an acceptable outcome: survival without significant morbidity. This especially refers to morbidity that significantly reduces or even eliminates the patient's capacity to engage in valued life tasks and derive satisfaction from them, the formal definition of an acceptable quality of life.

The American Heart Rhythm Society (AHRS) and European Heart Rhythm Association (ERHA) consensus statements in 2010 included a discussion on the deactivation of both ICDs and PPMs[7,8] (**see Chapters 27, 29, and 31**). Although it is well established ethically and legally that deactivation is no different than withdrawing any other life-sustaining therapies and allows a patient to die from underlying disease, there is still substantial physician discomfort in this practice, even with the relatively simple process of reprogramming an ICD/PPM.[9] Although often employed in these same patients, VAD technology is different and more complex. VADs can provide durable improvements in quality of life but can result in significant morbidity, with a predictable incidence of bleeding, cerebrovascular accidents (strokes), and drive-line infections. Unlike other implantable cardiac devices, VADs more completely replace cardiac function and thus are life sustaining. A PPM replaces or augments the conduction system but still requires that the native heart circulate the blood. An ICD is lifesaving for ventricular arrhythmias but is not in cases of progressive pump failure. A VAD requires neither native electrical conduction nor ventricular function to sustain life. In a simple model, a VAD is “cardiac replacement therapy” much as hemodialysis is renal replacement therapy.

Proper discussion about the implantation of a VAD should include patient options, goals of care, and patient preferences about deactivation should the outcome result in a quality of life not acceptable to the patient, a crucial autonomy-based consideration.[10,11] In this setting, use of a decision aid is valuable to allow for the time to discuss these issues. Decision aids or other tools are used to address the medical evidence, consider clinical judgment, and integrate patient preferences. As VAD technology and durability improve, it is increasingly apparent that primary consent is needed for durable VADs. Having a legally designated surrogate make the decision, in the absence of any prior discussion of the ramifications of this life-altering implantation, is not recommended, such as in cases of acute precipitous cardiogenic shock. In the situation of chronic systolic dysfunction where the patient may have had ongoing discussions with the

cardiologist, however, the surrogate might be equipped to make a decision that meets the standard of substituted judgment—a decision based reliably on the patient's values, beliefs, and preferences. The consequences of a durable VAD implant for a patient unaccustomed to chronic disease management or unprepared for the necessary changes in lifestyle can be overwhelming and has led to suicide. Turning off a VAD is also a more complex process than turning off ICD therapies or pacing with a PPM and should entail VAD-specific end-of-life discussions.

As patients survive their immediate cardiovascular disease with VAD implantation, they may develop catastrophic complications such as intracerebral hemorrhage, experience progressive device failure with aortic insufficiency and recurrent heart failure, or have recurrent gastrointestinal bleeding. Even in the setting of perfect VAD functioning, patients may develop dementia or terminal cancer. In a concise summary of patient-centered ethical issues in VAD support, Petrucci and colleagues[12] discuss the development of a withdrawal plan with patient and family. In the case of an ICD, discontinuing therapies will not lead to immediate or even imminent death. Turning off a device allows the patient to die from the underlying disease process, or malignant arrhythmia when and if it occurs (**see Chapter 41**). With a VAD, however, turning off a device can worsen remaining cardiac function (aortic or pump regurgitation) and in most cases will lead rapidly to circulatory death (**see Chapter 29**). The immediate consequences to the patient and surrogate as well as the clinician are inescapable. Although most similar to hemodialysis in replacement of an organ's function, a VAD's discontinuation is most similar to that of mechanical ventilation. A VAD is a *substitution* device rather than a replacement device; therefore discontinuation of an VAD in the patient with other lethal conditions is ethically acceptable, because the VAD support would be futile[13] (see next section). One important distinction is that although there are community-dwelling patients who are chronically supported by mechanical ventilation, their numbers are few and their medical condition usually obvious (e.g., tracheostomy, wheelchair bound). With VAD technology, it is possible to conceal one's dependence on the machine, so the mental and emotional effort to realize this dependency can make discontinuation discussions more difficult.

Clinical Ethical Judgments of Futility

In general, *futility* means that in evidence-based clinical judgment, there is no reasonable expectation that a clinical intervention will result in its usual outcome. When this is the case, the beneficence-based obligation to provide clinical management has reached its limits, and discontinuation should be offered. When continuation of futile treatment results in significant iatrogenic or disease-related burden, there is a beneficence-based obligation to recommend that the intervention be discontinued.[14]

For this general concept of futility to become clinically applicable, the concepts of “no reasonable expectation” and “outcome” must be specified.[15] Because the invocation of futility sets the clinician and patient on a path to limitation of life-sustaining treatment, the concept of “no reasonable expectation” should be specified conservatively. This concern was implicit in Blackhall's landmark article on limited cardiopulmonary resuscitation (CPR), when she set the expectation of failure at 97% to 100%, in the setting of a procedure that results in significant iatrogenic morbidity.[16,17]

There are three beneficence-based specifications of “outcome” and one autonomy-based specification that are clinically distinguishable and applicable. The first beneficence-based specification is physiologic outcome: a clinical intervention should be considered *physiologically futile* when there is no reasonable expectation that its physiologic outcome will occur. The outcome needs to be clearly stated; for example, restoration of spontaneous circulation is the outcome for which CPR is initiated. When CPR is

discontinued because there is no reasonable expectation that spontaneous circulation will be restored, physiologic futility is invoked. The addition of a fifth vasopressor in the setting of critical cardiogenic shock will not reasonably restore cardiac output and can be considered to be physiologically futile. The second beneficence-based specification is the outcome of death during the current admission and no recovery of interactive capacity before death occurs. This is known as *imminent-demise futility*. The third beneficence-based specification is the outcome of survival but with irreversible loss of interactive capacity, such as a permanent vegetative state as determined by American Academy of Neurology criteria.[18] This is known as *interactive capacity futility*. The one autonomy-based specification of the outcome is a functional status that the patient judges to be incompatible with engaging in valued life tasks and deriving satisfaction from doing so. This is known as *quality-of-life futility*.

Whenever one or more of these definitions of futility apply to a clinical intervention, the physician should offer discontinuation of that intervention, or importantly in cardiovascular medicine, the physicians *should not offer* an intervention. When continuation of such an intervention is resulting in significant iatrogenic or disease-related morbidity, the physician should recommend discontinuation of that intervention, such as limb ischemia in the setting of VA-ECMO, or ongoing high-level hemolysis with Impella support. The patient's legally designated surrogate and other involved family members should be provided sustained psychosocial and, for those who want it, spiritual support as they come to terms with the limits of life-sustaining treatment to alter life-taking diseases or injuries.

Conflicts of Interest and Disclosure

The profession of medicine is based on the *fiduciary* relationship, or “putting the patient first”; the maintenance of scientific competency; and being entrusted with the responsibility to improve the health of the public. This ethical concept of medicine as a profession was introduced into the history of medical ethics by two physician-ethicists in the 18th century, John Gregory (1724–1773) of Scotland and Thomas Percival (1740–1804) of England.[19]

The fiduciary relationship and the public trust it generates are part of what underpins the discussion of conflicts of interest. Conflicts of interest (COIs) are circumstances where there is a risk that the self-interest of an individual physician or health care organization will bias professional judgment and action, to the detriment of patient care or research. Not all forms of self-interest are illegal or even unethical. COIs cannot always be avoided, but specific influences can be eliminated, or mitigated and then disclosed. *Disclosure* is the primary method of managing COI in scientific publications, presentations, or committee works but is still limited primarily to financial conflicts, rather than positions on advisory or scientific boards. The Physician Financial Transparency Report, more commonly known as the Sunshine Act, was designed to improve the disclosure of potential financial conflicts, now requiring manufacturers to submit data, which are publically available after a period of review. Although its intent perhaps was to limit the blurring of obligations or undue influence, trainees are now subjected to stricter oversight, because textbooks and other educational material gifts are reported publicly.

The greatest concern with COI is that of undue industry influence on referral or prescription practices and on the use of devices. With the implementation of higher-cost technologies, such as transcatheter valve replacement, implantable hemodynamic monitors, and VADs, the presence or perceived presence of financial COI will become more prominent.[20]

Clinical research also is an increasing area of COI concern. An investigator may have possible financial and academic gains from greater patient enrollment, with authorship on multicenter publications.

The practice of some institutions is to have “neutral” study coordinators approach patients for study enrollment, but it is difficult if not impossible to separate patients from the recommendations of their physicians.

From the perspective of the fiduciary relationship in medical professionalism, the burden of proof is on the physician and the health care organization to permit a COI. Failure to identify a COI and failure to manage it in a professionally responsible way, by eliminating the COI or mitigating and disclosing it, are unacceptable threats to medical professionalism and have the potential to dissuade patient participation in clinical research and erode public trust.

Public Reporting

The development of appropriateness criteria for cardiovascular procedures and imaging is in part a consequence of a mismanaged public trust. Appropriateness of coronary interventions or imaging has been of interest to not only clinicians, but also policymakers and insurers, and has been the subject of quality improvement initiatives at the local and national level.

Cardiovascular medicine has been at the forefront in the movement to create evidence-based practice guidelines to improve patient quality while also reducing health care costs. However, public reporting is now commonplace in medical practice, having arisen from New York State's surgeon-specific reporting of coronary artery bypass grafting results in the late 1980s and 1990s.[21] The Centers for Medicare and Medicaid Services (CMS) publish hospital data for Medicare patients specifically for cardiovascular medicine, addressing acute myocardial infarction (AMI), heart failure hospitalization, stroke hospitalization, and the treatment and prevention of venous thromboembolic diseases. In addition, the CMS Hospital Web Compare site reports publically-accessible 30-day risk-adjusted admission and mortality rates for heart failure and AMI. Although welcomed by policymakers and payers, these data have only received lukewarm public reception and still are under criticism for their lack of uniform risk adjustment.[22] There are risks to this reporting as well, because hospitals may exaggerate their patients' risk or, alternatively, “cherry-pick” patients to improve their reporting statistics.

As part of the system-based measures to improve high value–based care, the efforts to decrease hospital readmission have met with unintended consequences that need to be addressed as the Medicare Access and CHIP (Children's Health Insurance Program) Reauthorization Act of 2015 (MACRA) continues to be implemented. The types of care for patients within the confines of a hospital are changing, challenging the resource and often scope of outpatient care.[23,24] Hospitals are facing what may constitute up to a 9% reduction in CMS reimbursement if they fail to meet quality measures, and those hospitals most affected are typically in underserved areas and are teaching hospitals. The downstream effects of this reduction in reimbursement may lead to worsening of the health care disparities seen among socioeconomic divisions.

This discussion occurs in the context of a larger, economic debate. Health care costs are rising at seemingly logarithmic if not exponential rates. The containment of resources in this way is seen as preferable to the overt concept of “rationing,” the forbidden “R” word in health care. Rationing is occurring without this label. Organ allocation and use of higher technologies for screening are a few examples. If there are a fixed number of slots to schedule patients for nuclear imaging, patients are prioritized, which is acceptable, necessary, and ethical. This can be justified on a beneficence-based approach for patient good, as long as the prioritization does not result in loss of access to clinical management supported by evidence-based clinical judgment. The pressure to discharge a patient earlier

from the hospital does not necessarily share this basis. As MACRA tightens and hospital and payment structure change, it will be the responsibility of the physicians to speak out for their patients for what is appropriate and acceptable care and to give a voice to those who are not empowered to do so.

Social Media and Mobile Health

The professionalism of medicine has also found new challenges with the rise of social media. Applications and programs such as LinkedIn, Twitter, and Facebook are embedded in social culture and are used by patients, providers, and health care systems alike. Patients use social media to participate in support groups and acquire more health information, but they also rely on social media for communication with their physicians. Social media have challenged conventional constructs of confidentiality, professionalism, and both professional and personal boundaries. Previously, episodes of poor judgment might have remained within an institution, but now, posting of comments or photographs about patients to these social media sites has resulted in lost employment, loss of patient trust, and potential harm. Clinicians may find themselves in the social media despite their preference to remain “off-line” and need to be aware of their ability to protect themselves with privacy managers. The American Medical Association (AMA) Council on Ethical and Judicial Affairs has published guidelines on Professionalism and Social Media, recognizing the role of social medial in everyday practice.[25] Similar guidelines have also been published by the British Medical Association.[26]

Image sharing on social media is now common. Pathology associations are using social media to share virtual histology images. Cardiovascular medicine is filled with studies that are as simple to export as image or movie files. Electrocardiograms (ECGs) or similar images are often posted on social media sites to show an interesting case or to ask for diagnostic help and interpretation. It is important to be mindful of the need to preserve patient confidentiality and to maintain professional considerations when engaging in these public conversations. Late-breaking news and trial results are posted on social media minutes after live presentation at conferences, so attention must be paid to conceal patient-specific information because images are disseminated worldwide.

There are also the potential benefits of social media, to help improve public health through information sharing. Hospitals and practices are increasingly using social media to increase their market presence and foothold. Clinical trials can increase recruitment through social media groups that are disease specific and, importantly, are consistent with institutional review board (IRB) guidelines if done correctly. Emerging technology is also improving public health through mobile health applications. Especially in the field of cardiovascular medicine, with devices to recognize common arrhythmias such as atrial fibrillation, patients now have some diagnostic tools available to them. This has potential for better health outcomes but also worse outcomes without the proper discussion and education by providers.

With the increase in a global presence that has accompanied social media, physicians and other providers may find themselves under increasing scrutiny or attack in a public forum. Although often hurtful and even potentially libelous or slanderous, responding to these attacks in the social media in clinical detail would violate the professional obligation of confidentiality. The risk management or legal representation on staff should be informed of these attacks in order to address them without violating patient confidentiality, allowing providers to continue to function in their professional capacity. Similarly, patients often try to connect with physicians through social media. If this link is accepted, the patient can then be “revealed” to all the other contacts, and his or her identity as a patient may no longer be private. Although the patient may have initiated this contact voluntarily, he or she may not be aware of its far-

reaching ramifications and is not “informed.” This highlights the difference between *privacy*, which the patient controls, and *confidentiality*, which is central to maintaining trust as a matter of professionalism. Physicians cannot be too careful in the era of social media in fulfilling this professional responsibility. One practical way to do so is to put a steep burden of proof on use of social media, to prevent breaches of the professional obligation of confidentiality.

Genetics

The role of genetic medicine is increasingly important in cardiovascular medicine. With the growth of personalized medicine and increased capability for both diagnosis and screening, genetic testing is now common. Many diseases have primary genetic origins that are increasingly recognized not only as causative, but as possible targets for therapies.

Personalized medicine, or precision medicine, refers to the practice of specifying as precisely as possible the patient's condition, by sorting patients with a shared diagnosis into clinically significant subgroups, such as based on genomic contributions to the patient's response to medication type or dose (**see Chapter 8**). As genomics moves from the laboratory into routine clinical practice, this increased precision holds the promise of improving the quality of care for patients with cardiovascular diseases.

The most common and traditional use of genetic testing involves the confirmation of a monogenic disease, as with the diagnosis of transthyretin amyloidosis (**Chapter 77**) or familial hypercholesterolemia (**Chapter 44**). This use of genetic testing for a specific diagnosis is well established and is less controversial, often because the phenotype of disease presentation is predictable. While this type of testing does have ramifications for families, because the phenotype is apparent, there is less controversy about discovery of disease.

Testing for genetic susceptibility, or trying to assess a risk profile based on genetic testing, is more challenging because these are *probabilistic* rather than confirmatory tests. The genetic variations associated with dilated cardiomyopathies (**Chapter 77**) or the long-QT syndrome (**Chapter 33**) may be single-gene disorders, occurring in less than 1 in 500 individuals. The presence of a single variation may lead to a diagnosis of risk leading to increased surveillance or even procedures, such as defibrillator placement or surgical intervention for aortic aneurysms. However, the obligations for reporting variations are still unclear and ethically challenging, especially since a “variant of uncertain significance” (VUS) may later prove to have pathologic potential. Because of this uncertainty, genetic testing should be directed toward a clinical phenotype rather than blind screening.[27]

The ethical principle of justice requires that like cases be treated alike, to prevent arbitrary treatment of individual patients. In the health care setting, patients are alike in their diagnoses. Health care justice therefore requires that every patient with a specific diagnosis be offered clinical management that is reliably expected to benefit the patient clinically, thus linking the principle of health care justice to the ethical principle of beneficence and to evidence-based reasoning. From a justice perspective, the accessibility to these tests and to the genetic counseling that should accompany them, as well as inclusion in databases and genetic registries, is limited to genetic evaluation that is reasonably expected to improve the processes of patient care. Insurance coverage may determine whether a patient can have genetic testing or potentially affected family members can be screened. Also, the testing may be feasible, but without the access to trained genetic counselors who can help ascertain the risk and benefits of a screening test. A further consideration is recognized as the “right not to know” (RNTK). Most frequently referenced in the setting of identical twins, genetic information can be a family condition rather than a

sporadic mutation. As such, the labeling of a disease in the proband can ripple through the family tree, with consequences related to family planning, career choices, and even hobbies (e.g., swimming).

In most of cardiovascular medicine, the proportion of attributable risk to monogenic disorders is low. Although genetics clearly influences cardiometabolic disease, environmental exposures have more impact and, importantly, are modifiable and can meaningfully influence health outcomes. As in other fields of medicine, genetic databases are still relatively homogeneous repositories within national and racial populations.[28] As the future of genetic testing evolves to the point of whole-exome and whole-genome sequencing, the responsibility for stewardship of this information and future ramifications is great.

The Genetic Information Nondiscrimination Act of 2008 (GINA) sought to address some of these issues. However, while providing some protection from employment and health insurance discrimination based on genetic information, it provides no assurances against genetic discrimination for either life or disability insurance. Importantly, GINA does not provide protection against phenotypically apparent genetic diseases, such as hypertrophic cardiomyopathy (**Chapter 78**) or against the use of information in a "family history."

Pharmacogenomics is an important component of precision cardiovascular medicine. Genotyping cytochrome P-450 (CYP) 2C9, or *VKORC1* variances to predict and therefore optimize response to warfarin therapy, did indeed have a modest success. Similarly, loss of function in CYP2C19 (*2) is associated with a poorer response to clopidogrel therapy, which has significant racial differences, but was not shown uniformly to affect clinical outcomes.[29] Beta-receptor and G-protein polymorphisms can predict response to therapy in heart failure and pulmonary hypertension and may help explain some of the survival benefits of African American or predominantly Caucasian populations. However, since widespread clinical use of such targeted therapy is still second to guideline-directed medical therapies, it must be recognized that exclusion of population subsets in trials that underpin the guideline-directed therapy, whether intentionally or not, does have social and medical implications. Also, beyond the poor enrollment of racial groups, patients with significant or end-stage renal disease are often excluded from device trials (ICD, PPM, VAD). Clearly, however, these technologies have slowly spread to these excluded populations.

"Big Data"

The near-universal acceptance of electronic health management systems is also changing the role of patients, putting stress on issues of patient confidentiality and autonomy. Patients will no longer be "patient," only subjects of medical care, but have the potential to become active by imputing data about side effects, response to interventions, and other patient-oriented data. The use of health applications in digital media also allows for data gathering on an unrivaled scale. Data regarding health and lifestyle practices are collected by these applications without significant oversight for their use, and fundamentally, with poor public understanding. Other "big data" now almost universally include the electronic health record (EHR), which is being used in "EHR-facilitated" clinical trials. Designed for clinical care and reimbursement, EHRs are heterogeneous and filled with incomplete or duplicated data. In addition to becoming agents in their care, patients may also unwittingly become subjects of research as EHR are mined for patient data to assist with disease modeling.

Machine-learning technology is using not only the databases from clinical trials, but also databases of imaging or laboratory information. These latter data are devoid of protected health information and identifiers; use of data in this way does constitute research, which is categorized as "non–human subjects research."

As more of these EHR-facilitated trials are undertaken, favored because of their ease of use and cost-savings, local IRBs will be responsible for assessing the appropriateness of their use to target potential trial participants.[30] Although it is common practice to use clinical information to screen potential trial participants without their consent, it is the vastness of scale and the potential ease of use that merit further consideration about how patients at institutions might be informed of the potential for being contacted for research purposes. Some institutions have addressed this potential in a transparent and upfront way, at least in spirit, by having a disclosure when one signs for the consent for treatment at a physician's office or hospital. This may meet some of the technical requirements for consent, but certainly fails to meet the requirements for informed consent.

Transplantation

Donation After Circulatory Death

Organ donation still faces the great challenge of supply/demand mismatch. As science and medicine improve the ability to survive illness and end-stage organ disease, the demand for organs has continued to outstrip efforts to increase supply or create alternative replacement strategies. Indeed, within cardiovascular medicine, with the technology of MCS, we are striving to create machines that achieve equipoise with transplantation.

To help meet the demand for organs, there has been increased focus on *controlled donation after circulatory determination of death* (cDCDD). Although death defined by lack of spontaneous circulation constitutes the vast majority of deaths, and before the Uniform Determination of Death Act was the only legally recognized death, organ donation after the common mode of death has its own unique ethical challenges. cDCDD is the process of procuring organs after a donor has been determined to be dead by cardiopulmonary criteria without reference to brain-function criteria, which is how cardiopulmonary criteria for death have always been applied. Circulatory death (i.e., irreversible cessation of circulation) occurs—often after withdrawal of life-sustaining therapies such as mechanical ventilation or ECMO and after a brief period (e.g., 2 to 5 minutes)—when there is no intervention, allowing procurement efforts to commence. An ethical concern arises from discussions about the meaning of “irreversible.” The concern is that if the cessation of cardiac function is truly irreversible, efforts to revive the person 5 minutes later should not succeed. If they do, should the person have been declared dead? The practice of cDCDD has the implicit understanding that if the patient or surrogate understands how death is determined, and the intent is to forgo attempts at resuscitation, after the legally mandated time of 2 minutes of no spontaneous circulation and breathing, a person is legally dead.

The concept of the irreversible is the basis for the ethical concern for the use of cDCDD hearts for transplantation. It should be mentioned that the first heart transplant was performed with what would now be considered a cDCDD heart. The abandonment of this practice coincided with the recognition that recipient outcomes were better with the establishment of *donation after brain death* (DBD). However, as the organ shortage continues and science matures, the outcomes of cDCDD may be viewed as preferable to the clinical alternatives, which may include a higher likelihood of death. For example, a negative cDCDD prospective-crossmatch local heart might be preferable to ongoing chemical desensitization while the patient depends on a left ventricular assist device (LVAD). It will be important to ensure that all parties involved in the process, from the medical and surgical team to especially the potential recipient, are aware of the risks that might accompany use of such organs.[31]

Another aspect of cDCDD distinct from DBD is that the testing to assess organs for donation and the

management to ensure organ viability are often performed on a “live” person rather than a brain-dead donor, simultaneously with end-of-life care. There is not only one patient, but rather a handful more whose interests are of concern. The suggested use of ECMO in the setting of cDCDD has potential conflicts.[32] The use of ECMO before death must be considered in a risk/benefit analysis; if the intention is solely to improve organ viability, then initiation would be inappropriate without clear discussions with the patient or surrogates. Maintaining ECMO or initiating interventions such as placing large-bore catheters or transferring the live patient to an operating room to allow for more controlled procurement is part of many hospital policies on cDCDD and is discussed in length with donor families.

Reinitiating or initiating ECMO after declaration of death might restore cerebral perfusion and stimulate or restore brain functioning. This would be ethically problematic, and the response to this concern has been to make efforts for aortic clamping to prevent cranial perfusion.

Stem Cells

Stem cells have as-yet poorly defined potential within medicine but have been the subject of ethical scrutiny. Leaving aside the challenges of embryonic stem cells, the use of induced pluripotent stem cells (iPSCs) does have ethical implications that will need to be considered as their use increases in research and therapies. As discussed earlier, the use of genetic testing for a discrete diagnosis has different implications from screening. Using iPSCs to redefine what currently may be a VUS through gene-editing techniques has the potential for scientific discovery.[33] However, it is important to remember the legacy of Henrietta Lacks and the HeLa cell controversy. The process of informed consent for research on biobanked specimens is varied.[34] If there is no interaction or intervention with the patient source of the material, this research is often not considered to be “human subjects research” and therefore does not require informed consent. However, if increasingly specific patient information is collected along with the biospecimen, different standards of informed consent, either general research consent or consent specific for a study, might be applicable per local IRB regulations. Clearly, the lesson to remember is to protect not only the individual patient, but also the family and descendants, because genetic information is shared and may have prognostic implications.

The iPSCs may be used to combine the predictive value of gene identification with the phenotypic presentation. They can be used ethically with sufficient forethought and planning of how to maintain public and patient trust while facilitating research.

Conclusion

As medicine and science evolve with emerging technologies and a better understanding of disease, the ethical challenges we face continue to change. At the core, we are still grounded by the fundamental principles of patient care and of professionalism set forth by Percival and Gregory. Research into incorporating mobile technology and its role in both clinical practice and clinical research will be important as the economics of health care delivery and drug development are increasingly stretched. We need to continue to be aware of the implications for progress and for potential harm or misuse as we embrace advancement.

Clinical Decision Making in Cardiology

John E. Brush Jr, Harlan M. Krumholz

Medicine is an information science. Information is being produced at an unprecedented rate and is readily accessible using electronic searches and handheld devices, making skills to parse and use appropriate information ever more important. Memorization of medical facts is less a necessity, while processing knowledge and critical thinking are essential for high-value medical care. Clinical decisions and recommendations define medicine and, in the midst of a rapid expansion of medical knowledge, have never been more challenging. This chapter summarizes some of the core competencies for clinical reasoning that can be learned and should be expected of expert practicing cardiologists.

Clinical Reasoning

Clinical decisions are based on our understanding of medical facts and knowledge of our patients, including their preferences and goals. Good decisions take into account the limits of our information, uncertainty in our measurements, incompleteness of our understanding of human biology, and the play of chance.[1-3] Clinical reasoning is informed by experiential and formal knowledge learned through years of practice and study.[4-6] The translation of medical knowledge into good patient-centered decisions is a key goal of clinical reasoning and is the hallmark of an expert clinician.

Clinical reasoning is often guided by simplified rules. Early in training, physicians are taught how to recognize specific clusters of signs and symptoms, place patients in diagnostic categories, and follow the rules that apply to those categories.[7] For example, patients with particular findings might be labeled as having “acute myocardial infarction,” which would trigger treatment based on studies showing benefit from aspirin and beta-blocking agents. In this context, algorithmic tools are often used to direct actions. For example, guidelines recommend that a patient with a low ejection fraction should be considered for an automated implantable defibrillator, but only after considering the etiology of the systolic dysfunction and the time frame of the disorder. These algorithms are not intended to force actions, but to guide decisions. The best clinicians know when adherence to such algorithms is proper and when exceptions, based on the patient's situation or preferences, can lead to divergence from these algorithms. Divergence from guidelines may be appropriate but requires adequate justification, documentation, and transparency.

Most of medical decision making, however, lies outside of simple algorithms and requires judgment. There are two major settings, related to diagnosis and treatment, where clinical reasoning is critical.

First, there are decisions about classifying an individual who presents with symptoms or signs of disease into the proper diagnostic category. Book chapters and other reference materials are usually organized according to categories, such as a medical diagnosis. The chapter informs the reader about how a particular condition, such as aortic stenosis, might manifest. These labels are useful for understanding mechanism and predicting response to potential therapeutic strategies. However, patients often do not present according to assigned general diagnostic categories. They seek attention for symptoms, which requires the clinician to reverse the order of a typical textbook and to work inductively from a patient's signs and symptoms toward a diagnostic label before a therapeutic plan can be developed. For a patient with dyspnea on exertion and a systolic murmur, aortic stenosis is a possibility, but the diagnosis is not conclusive without further testing. In some cases, uncertainty persists. About one third of patients labeled with a principal discharge diagnosis of heart failure also receive treatments for other causes of dyspnea, such as pneumonia or chronic obstructive pulmonary disease.[8] This is the reality of current practice.

Second, there are decisions about treatments. These decisions are also challenging because they involve weighing risks and benefits, speculating about estimates for these parameters, and aligning choices with the preferences of those being treated. The likelihood of benefit is often probabilistic, because people are pursuing strategies to reduce risk without knowing whether they themselves will benefit. These decisions can occur in prevention, which addresses whether to intervene in the interest of preventing future health problems, based on an estimate of prognosis. In this setting the risks and costs occur immediately, while the benefit is anticipated to be in the future. These decisions can also involve treatments to address symptoms as well as reduce the immediate risk for someone with acute or chronic disease.

Risk stratification is an important application of probability and is often used to estimate patient risk and assist in decision making. This approach generally employs the results of statistical models that have identified prognostic factors and incorporated them into a tool that may assist clinicians. In recent years, many tools have been developed to assist in the rapid assessment of patients.

Recent decades have witnessed the emergence of *cognitive psychology*, a branch of psychology

focused on how people make decisions.[9] The field demonstrated that people frequently develop useful reasoning shortcuts to circumvent the need to explicitly calculate probabilities, but these shortcuts come with biases that can lead decision making to deviate from the rules of logic and probability in predictable ways. Thus a good understanding of clinical reasoning requires knowledge about logic and probability as well as cognitive psychology.

Diagnostic Decisions

Patients often present with descriptions of symptoms such as chest pain. Cues are scattered, like pieces of a jigsaw puzzle. Clinicians, as with all decision makers, often use mental shortcuts called *heuristics* to organize cues and to turn an unstructured problem into a set of structured decisions.[10,11] They are taught to collect the scattered cues of an unstructured clinical problem by using an organized history and physical examination.[12-14] Clinicians are able to reason by analogy by comparing a patient's narrative to prototypic descriptions of diseases. When experts take a history, they use a process known as “early hypothesis generation” to develop a list of three to five possible diagnoses very early in the process.[15] This enables the questioning to become more direct and the clinician to become more engaged in the fact-finding exercise.

After collecting, sorting, and organizing data, clinicians often use a problem list as a tool to list, group, and prioritize clinical findings. With additional information, a *problem statement* can be defined more specifically. For example, “shortness of breath” may be an initial problem statement that is replaced by “acute systolic heart failure,” as further clinical information leads to a more refined problem statement that moves from symptom to diagnosis. Clinicians then use a differential diagnosis to expand the list of possibilities to avoid premature closure of the search for the true diagnosis. This step-by-step process enables the clinician to formulate a set of hypothetical diagnostic possibilities, which can then be tested using iterative hypothesis testing. *Iterative hypothesis testing* allows the clinician to narrow the list of possible diagnoses and hone in on the most plausible hypothesis.[1-3]

Understanding *probability* is essential for clinical decision making.[1-3,16] Probability can be estimated for outcomes that are measured as continuous or categorical variables. **Fig. 3.1** shows how probability of an outcome or event is distributed across a range of possibilities. For example, a laboratory test might be measured in a population of patients resulting in a distribution where most patients are distributed to the middle of the range of possibilities and fewer scatter to the edges of the range, as shown in the probability density curve in the left panel of **Fig. 3.1**. The probability of categories or discrete variables can also be measured, as shown in the probability distribution graph in the right panel. If all the diagnostic possibilities are mutually exclusive and collectively exhaustive, the probability of all of the possibilities will add up to 1, as shown by the red cumulative probability curves in **Fig. 3.1**. Understanding cumulative probability is important for understanding sensitivity and specificity, as discussed later.

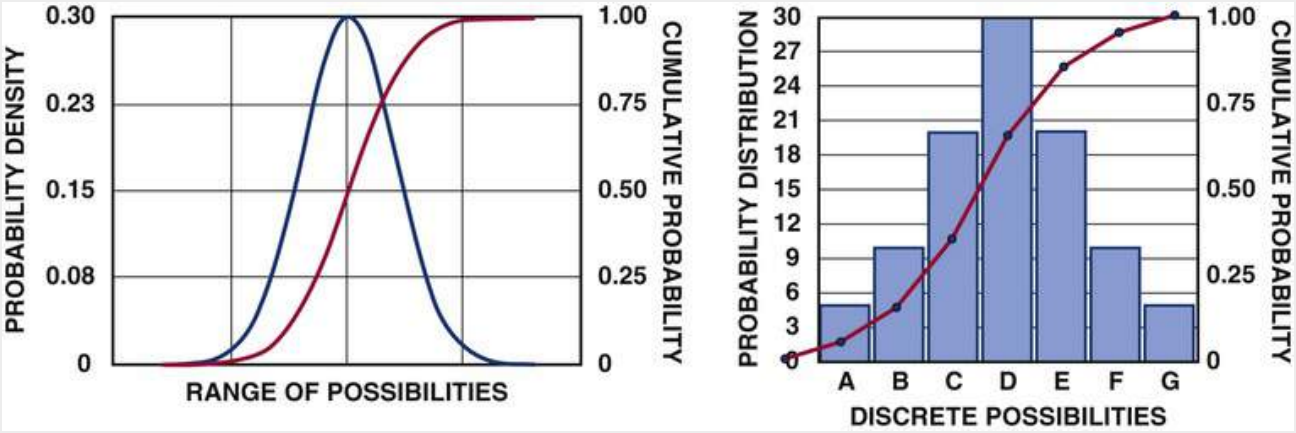

FIGURE 3.1 **Left panel** shows a probability density curve. The *blue curve* shows the probability of an event (left *y* axis), across a range of possibilities (*x* axis). **Right panel** shows a probability distribution. The *blue columns* show the probabilities (left *y* axis) of a variety of discrete possibilities (*x* axis). In both panels the cumulative probability across the range of possibilities (*x* axis) is shown by the *red curves* (right *y* axis).

To test a diagnostic hypothesis, we use *conditional probability*, which is the probability that something will happen, on the condition that something else happened. Conditional probability can tell us the probability of a diagnosis, on the condition of some new information, such as a positive test result. Bayesian reasoning enables us to form a probability estimate and revise that estimate based on new information using conditional probability. For example, a clinician might ask, What is the probability of coronary artery disease in my patient, given a positive stress echocardiogram? What is the probability of pulmonary embolus, given a negative D-dimer test? What is the probability of an acute coronary syndrome, given an abnormal troponin test? The post-test probability depends on a prior estimate of the probability for that particular patient, combined with the strength of the test result. Probability theory helps us understand the question and calculate the answer.

Bayesian reasoning requires both a prior estimate of probability and an estimate of the strength of a test result. Prior estimates can come from experience or published data on the prevalence of a disease. A classic paper by Diamond and Forrester,[17] for example, provides estimates of the prevalence of coronary artery disease in patients depending on age, gender, and symptom features. This type of observational research can be used to provide us with the prior probabilities needed for bayesian reasoning.

Understanding probability is essential to interpreting laboratory tests. A laboratory test might be measured in a population of presumably normal individuals to determine a distribution and to define a normal range, as shown in the probability density curve in the left panel of **Fig. 3.2**. A normal range is usually defined as the inner 95% cumulative probability, and the abnormal range is defined as values falling outside the normal range.

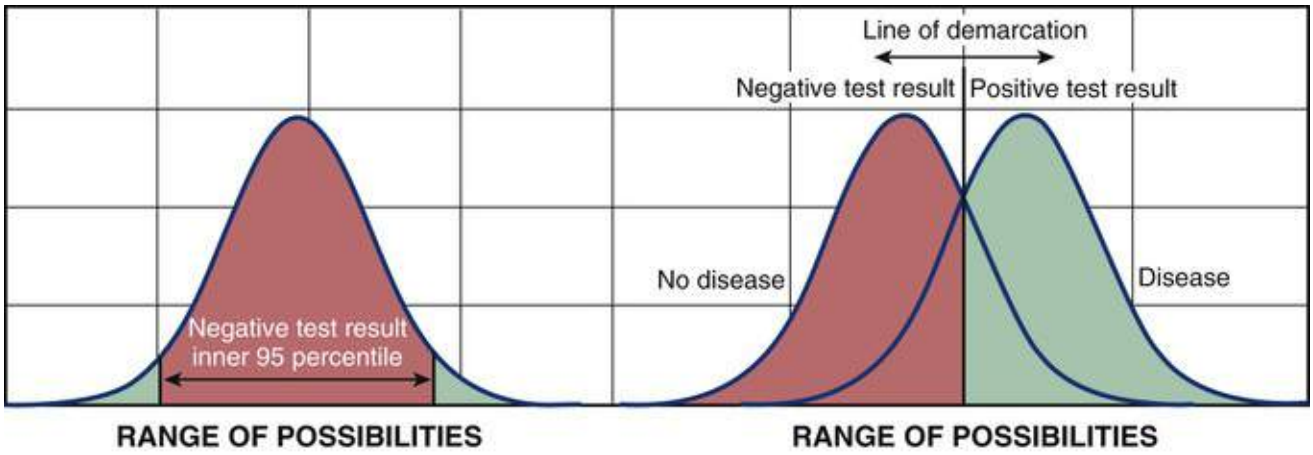

FIGURE 3.2 **Left panel** shows how the normal range of a test result is defined as the inner 95th percentile of a presumably normal population. **Right panel** shows how a normal and abnormal test result is defined by the line of demarcation between distributions of normal and abnormal test subjects, as defined by another, independent "gold standard" test.

Another way of defining a test result is by measuring the test result in a group of individuals who are defined as "normal" and "abnormal" by another, independent "gold standard" test, as shown in the right panel of **Fig. 3.2**. Typically, patients with and without disease will have test results that are distributed as bell-shaped curves. We can draw a line of demarcation to define how a new test would separate patients with positive and negative test results. Because there is overlap in individuals with and without disease, there will be false-positive and false-negative test results, as shown.

Understanding how to use clinical testing is essential to good decision making. The utility of a test result depends in part on the operating characteristics of a test: the *sensitivity* and *specificity*. These are *rates*, meaning the sensitivity and specificity are proportions with different units for the numerator and denominator. The terms *true positive rate* (TPR) for sensitivity and *true negative rate* (TNR) for specificity are alternative labels.

Patients with and without disease are shown separately in **Fig. 3.3** to show the cumulative probabilities of a truly positive result (sensitivity, or TPR) on the right and of a truly negative result (specificity, or TNR) on the left. Sensitivity and specificity are usually shown in a 2 × 2 table, but showing the TPR and TNR in **Fig. 3.3** demonstrates how these rates are variable, depending on the location of the line of demarcation between positive and negative test results.

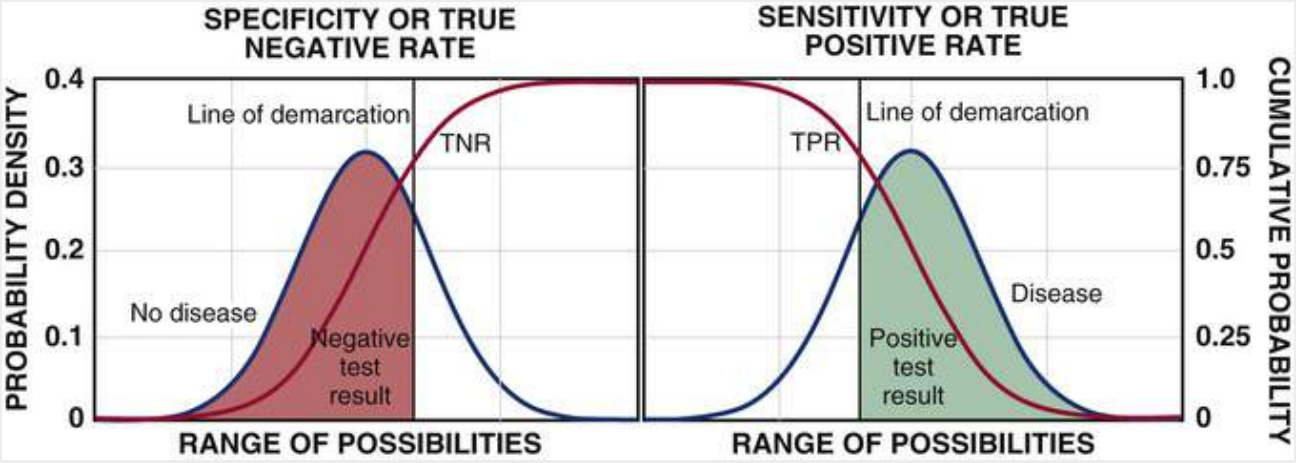

FIGURE 3.3 Distributions of normal and abnormal test subjects are shown separately to demonstrate that the true negative rate (*TNR*, or specificity) is the cumulative probability of a negative test result *(red curve)* in a distribution of subjects without disease *(blue curve,* **left panel***)*, and that the true positive rate (*TPR*, or sensitivity) is the cumulative probability of a positive test result *(red curve)* in a distribution of subjects with disease *(blue curve,* **right panel***)*, depending on the location of the line of demarcation.

The complementary probability of the TNR is the *false-positive rate* (FPR), as shown in the top panel of **Fig. 3.4**. If we create a new graph by plotting the TPR (sensitivity) of a test on the *y* axis and the FPR (1 − specificity) on the *x* axis, we can create a plot called a *receiver operating characteristic* (ROC) *curve*, as shown in the bottom panel of **Fig. 3.4**. ROC curves are useful for determining the optimal cutoff point for the line of demarcation of a test.

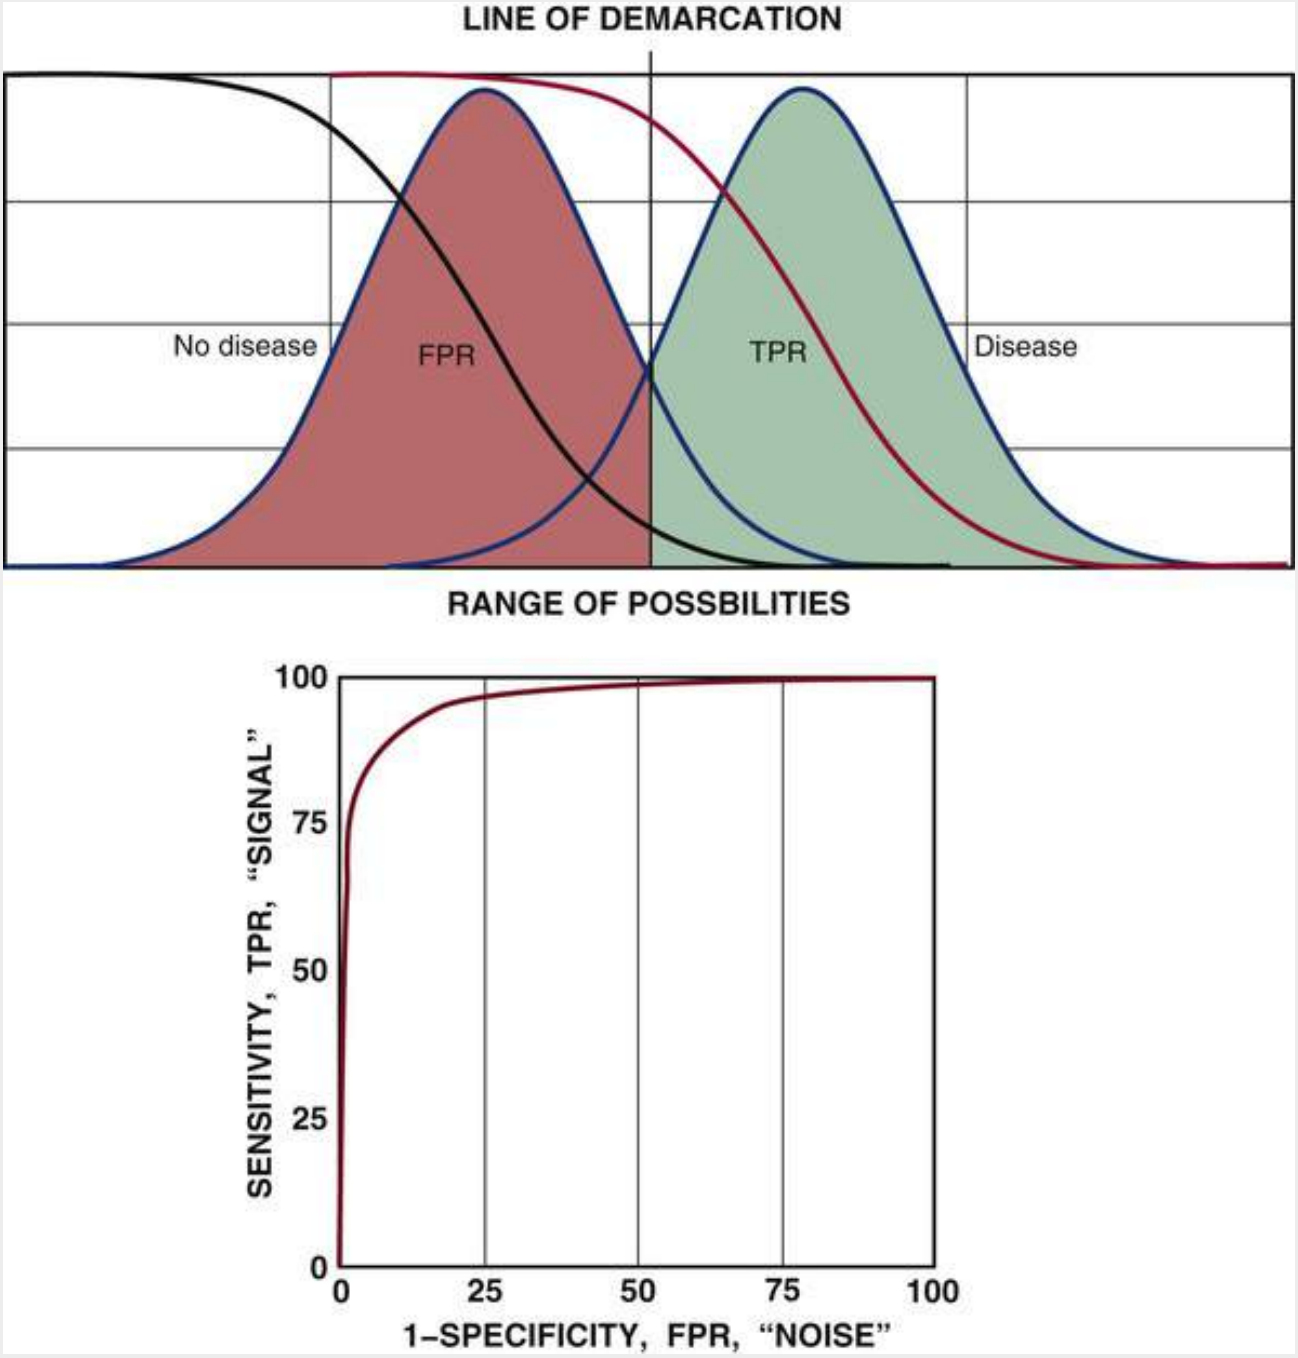

FIGURE 3.4 **Top panel** shows distributions of patients without and with disease *(blue curves)* along with the true positive rate (*TPR,* or sensitivity, *red curve*) and the false positive rate (*FPR,* or [1 − specificity], *black curve*). **Bottom panel** shows the TPR (sensitivity, or "the signal") on the *y* axis plotted against the FPR (1 − specificity, or "the noise") on the *x* axis, across the range of possibilities, depending on the location of the line of demarcation.

The denominators of sensitivity and specificity are patients with disease and patients with no disease, respectively. In clinical practice, when test results are reported as positive or negative, however, the results are reported using terms with different denominators. A clinician wants to know the probability that a positive test result is truly positive, or the *positive predictive value* (PPV), and also the probability of disease given a negative test result, which is 1 minus the *negative predictive value* (NPV). When changing from sensitivity and specificity to the PPV and NPV, the denominators of these rates change, making it difficult for a clinician to estimate these probabilities intuitively. In addition, the PPV and NPV depend not only on the sensitivity and specificity of the test, but also on the prevalence of the target condition in a population of test subjects. The difficulty of keeping track of denominators can be alleviated by using likelihood ratios rather than sensitivity and specificity.

*It should be noted that sensitivity and specificity can change if the spectrum of test subjects that defined them is different from the spectrum of patients for whom the test is used.[2] If the operating characteristics of the test are defined in a narrowly defined population (**Fig. 3.5, left panel**), but the test is used in a broadly defined population and the line of demarcation remains fixed (**Fig. 3.5, right panel**), the specificity, or TNR, will decrease. This frequently occurs with tests such as troponin testing, where the clinical sensitivity and specificity of the test are defined in a research setting, but the test is used indiscriminately in practice. When used as a general screening test in a broadly defined population, the width of the distribution of the individuals with no disease widens, yet the line of demarcation remains fixed, which decreases the TNR, as shown. This issue has also been shown in genetic testing.[18]*

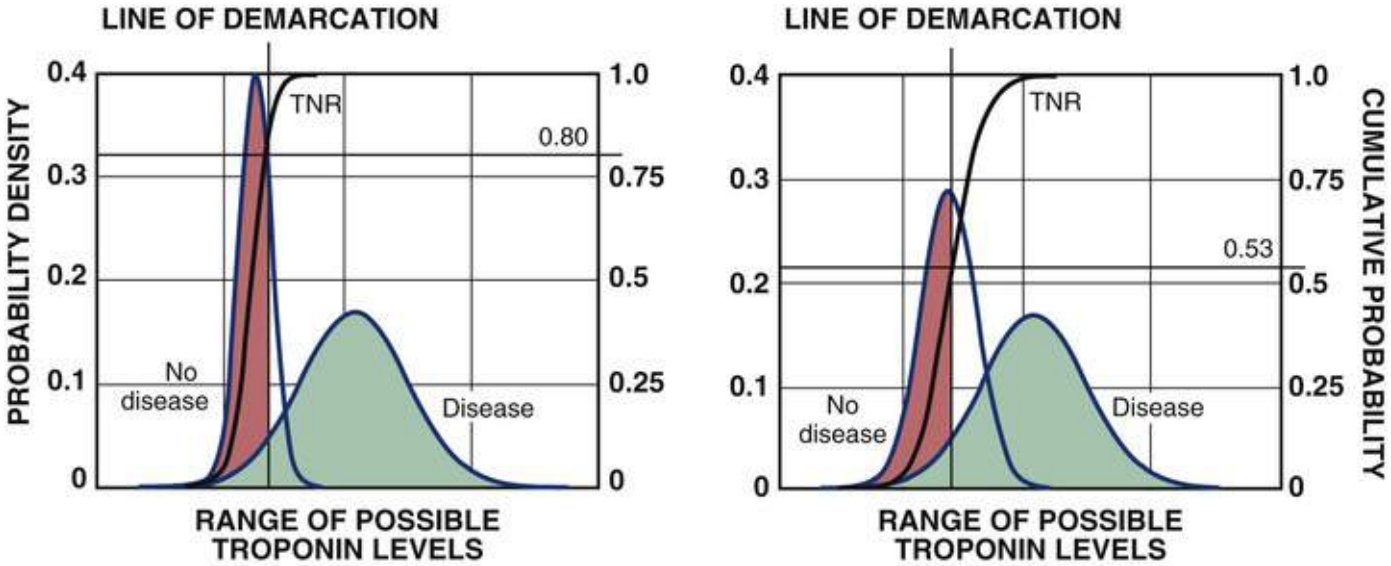

FIGURE 3.5 Distributions of patients without and with disease are shown by the *blue curves.* True negative test results for troponin levels are shown in *red,* and true positive results are shown in *green.* The true negative rates (*TNR,* or specificity) are shown by the *black* cumulative probability curves. **Left panel** shows the results when the test is ordered on a narrowly defined population of test subjects, and **right panel** shows the results when the test is ordered on a broadly defined population of test subjects, resulting in spectrum bias and a marked decrease in specificity of the test (80% to 53% in this example).

In practice, clinicians usually do not calculate bayesian probabilities. Clinicians, as with decision makers in general, use a heuristic that psychologists call "anchoring and adjusting."[3,9] Clinicians estimate a pretest probability (the anchor) and estimate the post-test probability by adjusting the anchor. For a patient with chest pain, for example, the anchor would be an estimate of the pretest probability of coronary artery disease, which would be intuitively adjusted on the basis of new information, such as a stress test result, to estimate a post-test probability. This is an expedient method for intuitively estimating conditional probability. There are two potential problems when using this heuristic. One fallacy, called "anchoring," is when the decision maker becomes too anchored on the pretest probability estimate and does not adequately adjust in estimating the post-test probability. The second fallacy is called "base-rate neglect," when the decision maker overly responds to the new information to estimate a post-test probability, without regard for the pretest probability. For example, troponin tests may be positive because of renal failure or sepsis in patients with a low pretest probability of acute thrombotic myocardial infarction. Taking the test result at face value and initiating therapy (e.g., antithrombotic drugs) in such a patient would be an example of base-rate neglect. Awareness of this heuristic and its

pitfalls can help clinicians avoid this common reasoning error.

Likelihood ratios are useful for bayesian reasoning.[19,20] Their advantage is that, unlike sensitivity and specificity, likelihood ratios are dimensionless numbers, so the need to keep track of the numerator and denominator is alleviated. Likelihood ratios give a measure of the persuasiveness of a positive and negative test result and can be used intuitively or used to calculate post-test odds.

A *likelihood ratio* is defined as the percentage of diseased patients with a given test result divided by the percentage of nondiseased patients with that same test result. Thus a *positive* likelihood ratio is the percentage of diseased patients with a positive test result divided by the percentage of nondiseased patients with a positive test result [TPR/FPR, or sensitivity/(1 − specificity)]. A *negative* likelihood ratio is the percentage of diseased patients with a negative test result divided by the percentage of nondiseased patients with a negative test result [FNR/TNR, or (1 − sensitivity)/specificity]. It is easy to calculate the positive and negative likelihood ratios from sensitivity and specificity. Once calculated, these numbers can be used to multiply the pretest odds to calculate the post-test odds of a diagnosis. They are multipliers, so a higher positive likelihood ratio and a lower negative likelihood ratio (which is a fraction) have stronger multiplying effects. A likelihood ratio that is close to 1 is weak because it would have very weak multiplying effect, meaning it has minimal effect on the pretest assessment.

Some tests are asymmetric, meaning that their positive or negative likelihood ratio is stronger. For example, congestion on a chest x-ray film has a very strong positive likelihood ratio of 13.5 and a relatively weak negative likelihood ratio of 0.48.[20] This reflects that the chest radiograph is highly specific but not very sensitive for heart failure. In other words, congestive findings on a chest radiograph are highly suggestive of heart failure, whereas their absence would not be reassuring about lack of heart failure. Tests that are highly specific are better for ruling in a diagnosis, and this can be remembered using the mnemonic “SpPin” (highly specific tests, if positive, are good for ruling in). On the other hand, a D-dimer for a pulmonary embolus has a very strong negative likelihood ratio of 0.09 and a modest positive likelihood ratio of 1.7.[20] This reflects that a D-dimer is highly sensitive but not very specific for pulmonary embolus. Tests that are highly sensitive are better for ruling out a diagnosis, and this can be remembered using the mnemonic “SnNout” (highly sensitive tests, if negative, are good for ruling out).[19]

The likelihood ratios, however, are only as useful and precise as the sensitivity and specificity that are used to calculate them. They give an approximate quantitative estimate of the strength of new information that provides a mechanism for calibrating intuitive probability estimates. When used with odds, likelihood ratios provide a way to calculate the conditional probabilities that are used for bayesian reasoning. Proceeding through this calculation demonstrates the conceptual framework for reasoning through iterative hypothesis testing.

Test-Ordering Strategies

Clinical reasoning should guide not only test interpretation, but also test ordering. Tests that are ordered for good reasons are more conclusive, and tests that are ordered indiscriminately can cause clinicians to arrive at the wrong conclusions. Ideally, a test should be used to validate or reject an *articulated hypothesis*—a plausible conjecture that is generated by a patient's condition.

To aid with test selection and avoid overtesting, the American College of Cardiology (ACC) and other

organizations have developed appropriate-use criteria to guide clinicians' decisions about ordering cardiac tests.[21] This effort is driven by both the need to avoid excessive false-positive test results and the need to contain the costs of medical care. The goal of appropriate-use guidelines is to reduce overuse errors and maximize the value of diagnostic testing and procedures. The general principle of any test-ordering strategy is that a plausible hypothesis (a provisional diagnosis) should be formulated first, followed by testing. The appropriate-use criteria are designed to avoid testing when the results are unlikely to improve patient care or outcomes.

Predicting Risk

Recent ACC/American Heart Association (AHA) guidelines have promoted the provision of preventive treatments according to an individual's risk of adverse outcomes.[22] These guideline recommendations emphasize the need to consider categories based on estimates of risk and prognosis, rather than diagnostic labels. *Risk* is another word for probability, and when used in this context, risk takes on a meaning of *propensity*, which is probability that has a modifiable tendency or disposition. It is important for clinicians to understand how risk is calculated from long-term observations from pooled cohorts of test subjects, in order to understand the strengths and limitations of these risk calculations. After calculating the risk, the challenge for clinicians is communicating risk to patients in an understandable way. Investigators have provided pictograms that can communicate risk and risk reduction to facilitate a discussion regarding long-term treatment options to diminish risk and to compare the degree of risk reduction with potential side effects and costs of treatment. Some new tools aim to put these risk models into use at the point of care. Since clinicians vary in their use of qualitative terms, such as “high risk,” there is a need to provide clear and understandable quantitative estimates.

Therapeutic Decisions

A preventive or therapeutic decision is a structured choice. For some situations, it is a simple and easy decision, such as deciding to give a diuretic to a patient with acute congestive heart failure. In this case the stakes are not high, the preference of the patient is clear, and the decision is straightforward. In other cases there is a difficult choice between therapeutic options. An elderly patient with moderate to severe mitral regurgitation and comorbid conditions presents a difficult choice based on estimated probabilities of the natural history of the disorder, versus the surgical risks and prospects for an improved outcome with a surgical intervention. These decisions require medical knowledge and a balanced sense of risks and benefits, as well as knowledge of the patient's preferences, to make optimal therapeutic decisions.

The therapeutic effect of a drug is ideally determined by a randomized controlled trial (RCT). Trial results are frequently reported as *relative risk reduction*. Of note, the relative benefit (or risk) of an intervention is often expressed as a relative risk or odds ratio. *Risk* is the probability of an event, and *odds* is the probability an event will occur against the probability that it will not occur. A probability of 25% (1 in 4) represents odds of 1 : 3 or 1/3. The *risk ratio* expresses the relative probability that an event will occur when two groups are compared. The *odds ratio* expresses the odds of the event in one group compared with another.

Despite its widespread use, the odds ratio is less helpful than relative risk in clinical decision making. The expressions are similar when baseline event rates are low (<5%), but deviate with higher risk and larger treatment effects. The odds ratio can express associations but, unlike the risk ratio, cannot express the relative size of the treatment effect; if clinicians assume odds to be equivalent to risk, it may lead to

overestimates of the treatment effect when the outcome is common. The odds ratio is often used in clinical research because of its mathematical properties and its utility for identifying associations in certain situations, but clinicians need to know its limitations for estimates of treatment effect.

Clinical trials report the average risk of an outcome for patients in a treatment group and in a comparison group. There may be heterogeneity of the treatment effect, in which some patients may receive a marked benefit and others receive no benefit at all. Subgroup analysis and tests for interaction can provide hints, but usually heterogeneity of treatment effect is not readily apparent, creating a challenge for clinicians trying to personalize treatment decisions. In a key example of heterogeneity, fibrinolytic therapy was effective in the treatment of suspected acute myocardial infarction (AMI) and subgroup analyses revealed the benefit to be substantial in patients with ST elevation but not in those without it.[23] The challenge is that subgroup analyses introduce the possibility that associations have occurred only by chance. In the Second International Study of Infarct Survival (ISIS-2), the authors provided perspective on subgroup analyses by demonstrating that patients born under the astrological signs of Gemini or Libra were significantly less likely to benefit from fibrinolytic therapy. Thus, subgroup analyses are capable of producing important insights, but must be interpreted with caution.[24]

Risk Stratification

A weakness of *relative benefit* estimates is that they do not convey information about what is achieved for patients at varying levels of risk. A small relative reduction in risk may be meaningful for a high-risk patient, whereas a large relative reduction may be inconsequential for a very-low-risk patient. *Absolute risk reduction,* the difference between two rates, varies with the risk of an individual patient. For example, a risk ratio of 2.0 does not distinguish between baseline risks of 80% and 40% and between 0.08%, and 0.04%. In one case, the absolute difference is 50% (5000 per 10,000), and in the other, 0.05% (5 per 10,000). In one case, 1 person out of 2 benefits, and in the other, 1 out of 2000 benefits. Unfortunately, *absolute benefit* is not emphasized adequately in many articles.[25]

Risk stratification is critically important for calculating the absolute risk reduction. In recent years, many tools have been developed to assist in the rapid assessment of patients, with variable uncertainty about their comparative effectiveness. For example, the Acute Coronary Treatment and Intervention Outcomes Network (ACTION) Registry–Get with the Guidelines (GWTG) model includes eight variables and can differentiate risk from 0.4% to 50%.[26]

In evaluating risk stratification studies, it is important to consider whether the score or approach has been validated in populations similar to the patients to whom it is applied in practice. The predictors should have been collected independently of knowledge of the outcome. The outcome and time frame should be appropriate for clinical decisions. The value of the stratification should also be clear. Improving precision in risk estimates without consequence is like ordering tests that have no implications for treatment. On the other hand, risk stratification can assist in calculation of absolute benefit and put the balance of risks and benefits of an intervention in proper perspective.

Several studies have shown a risk-treatment paradox in which the higher-risk patients are least likely to receive interventions that are expected to provide a benefit.[27,28] This pattern is paradoxical because the high-risk patients would be expected to have the most to gain from an intervention that reduces risk, assuming that the relative reduction in risk is constant across groups defined by their baseline risk. The source of the paradox is not known, although some have suggested that it is related to an aversion to the treatment of patients with a limited functional status, or a concern for greater degree of harm from the same therapy.[29] Another possibility is that concerns about the harm associated with an intervention are

increased in the highest-risk patients.

Cardiovascular drugs and procedures are often double-edged swords, having both benefit and harm. Also, patients may have strong preferences about potential benefit and harm. For example, a patient may have a strong fear of a side effect such as a cerebrovascular accident (stroke) that may overwhelm other considerations about a treatment decision. It is important to engage patients and families in a discussion to explain the considerations that go into therapeutic decisions, particularly for nuanced decisions about treatments that have substantial risks in addition to potential benefits.

Number Needed to Treat

Absolute risk reduction is better than relative risk reduction for estimating a treatment effect. The inverse of the absolute risk reduction, a term called *number needed to treat* (NNT), is even more intuitive.[19]

Consider a trial with a combined event rate of 10% in the treatment group and a 15% risk in the control group, giving an absolute risk reduction of 5%. This means that 5 events are avoided for every 100 patients in the treatment group. The reciprocal of this relationship indicates that there would be 100 patients treated for every 5 events avoided. By dividing 100 by 5, which reduces the denominator to 1, we can say that there would be 20 patients treated per 1 event avoided. Thus the NNT is 20. For NNT, the smaller the number is, the better the result.

NNT and absolute risk reduction depend on both the relative risk reduction and the baseline risk. For conditions with a high baseline risk, the NNT can become very small (desirable). As an extreme example, for a patient with ventricular fibrillation, the baseline risk of dying without defibrillation is 100%, making the NNT for defibrillation (if always effective) equal to 1.

Primary prevention with statin drugs has a relative risk reduction of about 20% over the several-year course of a typical prevention trial.[30] The absolute risk reduction and NNT depend on the baseline risk, which varies depending on a number of factors. At a baseline risk of 7.5%, the absolute risk reduction would be 1.5% and the NNT would be 67, a fairly high number, which suggests marginal benefit at this level of baseline risk.

NNT is a useful intuitive tool for comparing the efficacy of various treatment strategies. NNT is also a useful way to summarize the findings of a clinical trial in a single declarative sentence. For example, the Beta-Blocker Heart Attack Trial (BHAT) had an NNT of 34, meaning you would need to treat 34 patients with AMI with a beta-blocking agent for 25 months to prevent one death.[31] The Survival and Ventricular Enlargement (SAVE) trial had an NNT of 20, meaning you would need to treat 20 patients with heart failure and an ejection fraction of ≤40% with an angiotensin-converting enzyme (ACE) inhibitor for 42 months to prevent one death.[32] With NNT, a single sentence can provide the trial name, the magnitude of the treatment effect, the trial's entry criteria, the study drug, the duration of the trial, and the outcome measure. NNTs of 34 and 20 suggest that these treatments are strongly recommended, and that not treating patients with these drugs, without adequate justification, could be considered an error.

NNT is also a very personal notion of the probability of a treatment effect. Imagine bringing 20 untreated patients with congestive heart failure and an ejection fraction of ≤40% into a room and saying, “If I start all of you on an ACE inhibitor, over the next 42 months, I will save the life of one of you.” Capturing the essence of a treatment effect with NNT is a useful way to intuitively convey the impact of a treatment effect. This knowledge, packaged in a way that is more intuitive, can make it easier for us to combine this medical knowledge with the preferences and values of individual patients to make the best therapeutic decisions.

Nevertheless, there are limitations to NNT. NNT is an index of an average treatment effect over time

and does not provide information about whether the treatment effect is immediate, delayed, or highly variable. NNT does not provide information about whether there is meaningful heterogeneity in effect among different subgroups, because the NNT often is calculated based on an assumption of a uniform effect of the therapy, with the NNT just varying based on the baseline risk.

Changing Clinical Practice Based on New Findings

Science is a quantitative discipline that uses numbers to measure, analyze, and explain nature. *Evidence-based medicine* has been defined as "the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients."[33] To practice evidence-based medicine, clinicians must constantly monitor for new research findings; this vigilance must be accompanied by a basic knowledge of statistics to make proper inferences from clinical research.

When using statistics to compare two groups, the standard method is to assume that there is no difference between the two groups, the so-called null hypothesis. The trial results are reported, along with a *P* value, which is the probability of deriving the difference reported in the trial, or a more extreme difference, given the assumption that the null hypothesis is true (i.e., there is no real difference between the groups).[34] When a trial is designed, the investigators estimate the sample sizes that are required to avoid (1) claiming that there is a difference between treatment groups when there really is no difference (a Type I error, or alpha error) or (2) claiming that there is no difference between treatment groups when there really is a difference (a Type II error, or beta error). Similar to a clinical test (e.g., stress test) that can have false-positive and false-negative test results, clinical trials can have false-positive results (alpha errors) and false-negative results (beta errors). A trial with adequate sample size and rigorous statistical methods should allow investigators to avoid these errors.

When a trial is designed, the alpha level is usually set at 0.05. If the *P* value of the observed data is less than 0.05, one can conclude that a very improbable event occurred, a less than 1 in 20 event, assuming the null hypothesis is valid. According to the "frequentist" notion of statistics, one imagines that repeating a trial many times would create a distribution of possible trial results. The *P* value tells us where the observed results of a particular trial would lie in that imaginary distribution of trial results.

Since the *P* value is so commonly used in clinical research, clinicians need to be aware of several key issues. First, the threshold of 0.05 for statistical significance is arbitrary. A *P* value of 0.04 implies that the data could occur 4% of the time if the null hypothesis is true, and a *P* value of 0.06 would suggest the data would occur 6% of the time. Is the difference between 6% and 4% enough to reject the null hypothesis in one case and accept it in another? Clinicians should understand that *P* values are continuous values and are just one piece of information needed to assess a trial. Second, *P* values do not inform clinical importance. A large study sample can produce a small *P* value despite a clinically inconsequential difference between groups. Clinicians need to examine the size of the effects in addition to the statistical tests of whether the results could have occurred by chance.

Endpoints

In evaluating evidence, clinicians should be particularly attuned to the outcomes that are assessed. Ideally,

interventions are assessed for their effect on a patient's quality or quantity of life. Many studies employ *surrogate outcomes*, measures that are more distally related to the patient experience but might be related to the likelihood that a patient's quality or quantity of life will be affected. These surrogate outcomes often reflect information about a patient's biology, and in epidemiologic studies, these outcomes may have prognostic value. However, it is not possible to know that an intervention that modifies a surrogate outcome has the expected effect on patients. There are many examples in medicine of changes in surrogate measures that did not translate into benefits for patients.

Noninferiority Trials

Most RCTs are designed to show the superiority of a treatment over placebo. However, some conditions already have treatments with proven benefit, making it unethical to design a trial that compares a new treatment with placebo. For example, for chronic atrial fibrillation, it was not possible to test newer oral anticoagulant drugs against a placebo arm that would have withheld the proven benefit of warfarin. For these situations, investigators use a noninferiority trial. The premise is to show that a given treatment is at least no worse than the standard of care by more than a predefined investigator-selected margin (the treatment could be slightly worse, or even be superior for efficacy). However, because the new treatment has other ancillary advantages (e.g., less side effects, better costs or tolerability), it could become a reasonable alternative to the previous standard of care. This trial design requires making assumptions about the margin of decreased efficacy that would be considered acceptable before considering using a new treatment rather than an established treatment with known efficacy. Noninferiority trials are also subject to several other biases that are not seen with typical superiority trials.

Observational Research

There are other situations in which an RCT is impossible, and observational studies such as case-control studies or longitudinal cohort studies are required. RCTs have the advantage of a controlled experiment that eliminates potential biases but have the limitation of narrowly defining a study population, which may affect generalizability. Observational studies have the advantage of observing large groups of unselected individuals in the real-world setting, but have the disadvantage of potentially unrecognized and unmeasured sources of bias that could produce misleading study results. Expert opinion and clinical judgment often require evaluation of a variety of evidence from multiple types of clinical research studies to determine the best clinical practice.

Shared Decision Making

Clinical decisions are not the sole domain of physicians. The principle of autonomy maintains that patients retain control over their bodies and must consent to undergo interventions, except in rare circumstances. Informed consent is the cornerstone of this concept (**see Chapter 2**). Unfortunately, there is little consensus about how best to involve patients actively in decision making. Nevertheless, given the need to align goals of therapy with the patient's preferences and values, it is important to engage them as effectively as possible. This approach is most appropriate for major decisions, those with intermediate or low certainty, and those that are not emergent.

There are many aspects of communicating risks and benefits. First, this information takes many forms. The dimensions of risk and benefit include their identity, permanence, timing, probability, and value to an

individual patient.[35] All these should be considered in decision making. Unfortunately, there is relatively little evidence to guide physicians about how best to convey risks to patients.[36]

It is known that patients do not always understand benefit and risk well. For example, in a study of patients who gave consent for elective routine percutaneous coronary intervention, an intervention that does not improve survival or prevent AMI in this context, 75% thought it would prevent an AMI and 71% believed it would improve survival.[37] Moreover, only 46% could identify at least one possible complication. Among this group, 67% stated that they should be involved at least equally with the physician in making decisions. Other studies have also found that patients often have unrealistic expectations of benefit.[38] These deficiencies in patient understanding need to be addressed for shared decision making to occur.

The manner in which information is presented may influence patients. As with physicians, patients are also susceptible to framing effects.[39] Patients tend to be more likely to choose a therapy that is presented as having an advantage over an alternative in relative rather than absolute terms. The relative effect is almost always much greater than the absolute change. Patients may also be influenced by the order in which information is provided.

Some techniques have been proposed to help clinicians convey risk.[40] First, clinicians should avoid descriptive terms because these may not have a consistent meaning to patients. Terms such as “low risk” may be difficult for people to interpret. If clinicians express risk as ratios, they should use a consistent denominator (e.g., 40 out of 1000 and 5 out of 1000 instead of 1 in 25 and 1 in 200). Clinicians should offer multiple perspectives, revealing multiple ways of thinking about risk. They should use absolute numbers and natural frequencies (e.g., 1 out of 20), not relative risks or percentages. Visual aids are useful, if available, since poor numeracy or literacy skills may be a barrier for many patients. Many patients do not understand risk communication formats.[41] In addition, clinicians should recognize that information and data are not the same, and it is incumbent on the clinician to communicate health information that is meaningful to the patient.

Shared decision making can be understood as having five phases: assess, advise, agree, assist, and arrange, as follows:

1. The clinician must *assess* the patient.
2. The clinician should *advise* the patient of the options, with their benefits and risks.
3. The clinician and patient should *agree* on a plan that is aligned with the patient's preferences and values.
4. The clinician should then *assist* the patient in implementing the plan.
5. The patient and clinician *arrange* follow-up.

Monitoring the Quality of Clinical Decisions

Delivering the right care to the right patient at the right time every time requires good judgment. Learning the basic competencies of good judgment and step-by-step methods of clinical reasoning can help practitioners monitor the quality of their decisions. Knowledge about clinical reasoning is a structural attribute that can lead to more reliable processes and better clinical outcomes. Awareness of the logic, probability theory, and cognitive psychology of clinical reasoning can provide a theoretical foundation for better clinical practice.

Self-monitoring to self-diagnose errors and biases is important, but developing good habits that

systematically prevent cognitive errors may be a more effective strategy. Cognitive science provides justification for many of the good habits that are part of practice, such as consistently performing a standardized history and physical examination and a conscious habit of listing a differential diagnosis. Cognitive psychologists emphasize that measurement and feedback are a crucial process for the development of expert intuition, which is so often necessary for clinical decisions.

System 1 and System 2 Thinking

Cognitive psychologists describe two general thinking modes that people employ to make decisions.[9] *System 1 thinking* is highly intuitive and fast, but prone to jumping to conclusions. *System 2 thinking* is analytic and logical, but slow, effortful, and has difficulty with uncertainty. Used together, System 2 thinking provides a double-check for System 1 thinking, and System 1 thinking provides a work-around when System 2 thinking is constrained by uncertainty. Cardiology decisions require both thinking modes, and expert clinicians are able to use a balance of intuition and critical thinking to make optimal decisions. Calibrating intuitive thinking and organizing thinking by thoughtfully monitoring decisions ("meta-cognition") are key to good clinical practice.

Fallacies

Some psychologists describe three general types of fallacies: hasty judgments, biased judgments, and distorted probability estimates.[9] *Hasty judgments* occur when System 1 thinking is unmonitored. For example, premature closure of a diagnostic exercise, without the use of a differential diagnosis, or becoming anchored on a diagnosis can lead to a misdiagnosis. *Biased judgments* occur when unconscious thoughts influence clinicians' ideas, emotions, and actions. This can take the form of priming, stereotyping, overconfidence, risk aversion, or dread. Emotions can have a "halo effect," influencing clinicians' thinking in imperceptible ways. Exaggerated fear of malpractice, financial incentives, and conflict of interest can adversely affect their decisions. In *distorted probability estimates*, decision makers tend to overweight the probabilities of events or propositions at the extremes. At one end, they can develop an illusion of certainty, which creates certainty about something that, objectively, is not certain at all. At the other extreme is the "possibility effect," which causes them to think that highly improbable events or propositions are quite probable. Knowledge of these fallacies can help clinicians monitor the quality of their clinical reasoning.

Conclusion

Clinical reasoning can be learned and continuously improved through deliberate practice. Logic, probability theory, and cognitive science can provide a framework for good clinical reasoning. The ability to read, understand, and critique the literature is also essential. Knowledge of the components of clinical reasoning is crucial for clinical practice, for team-based care, and for shared decision making. The ability to reason and the ability to use reasoning to stay current and monitor one's performance are the essence of professionalism. Integrating scientific knowledge and calibrated intuition with a patient's personal preferences and values can provide the highest quality of care for our patients.

Measuring and Improving Quality of Care

Relevance to Cardiovascular Clinical Practice

Frederick A. Masoudi, John S. Rumsfeld

The quality of health care is important for all stakeholders; the primary perspective of this chapter is that of cardiovascular clinicians. Our objectives are to provide cardiovascular clinicians with the definition of quality of care and the relevance of quality measurement and improvement in current cardiovascular practice. We focus on measures of health care quality, uses of these measures, and approaches to improving quality of care.

Defining Quality of Care

Quality of care is generally defined as the extent to which health care delivery optimizes the outcomes of care. The U.S. Institute of Medicine (IOM) has more specifically defined quality of care as “the degree to which health care systems, services, and supplies for individuals and populations increase the likelihood for desired health outcomes in a manner consistent with current professional knowledge” (see Classic

References, *Crossing the Quality Chasm*). Key outcomes of care include survival, patient health status (symptom burden, functional status, and health-related quality of life), morbidity (e.g., acute myocardial infarction [MI] or heart failure hospitalization), patient experience (e.g., satisfaction), and cost-effectiveness.

The IOM proposed six domains of quality: effectiveness, safety, equity, timeliness, efficiency, and patient-centeredness (**Table 4.1**). Quality of care can thus be conceptualized as the extent to which these domains are optimized. Accordingly, quality measures should focus on at least one of these six domains of quality or directly measure outcomes of care. *Quality improvement* (QI) is the action undertaken to improve one or more of these six domains to improve health outcomes.

TABLE 4.1

U.S. Institute of Medicine (IOM) Domains of Highest-Quality Health Care

QUALITY DOMAIN	BRIEF DEFINITION
Effective	Providing services based on scientific knowledge to all who could benefit and refraining from providing services to those not likely to benefit (avoiding underuse and misuse, respectively).
Safe	Avoiding harm to patients from the care that is intended to help them.
Equitable	Providing care that does not vary in quality because of personal characteristics such as gender, ethnicity, geographic location, and socioeconomic status.
Timely	Reducing waits and sometimes harmful delays for both those who receive care and those who give care.
Efficient	Avoiding waste, including the waste of resources and patient time, as well as waste of ideas and energy.
Patient centered	Providing care that is respectful of and responsive to individual patient preferences, needs, and values, and ensuring that patient values guide all clinical decisions. Patient-centered care attends to patients' physical and emotional needs, maintaining or improving their quality of life, and gives patients the opportunity to be the locus of control in decision making.

From IOM Committee on Quality Health Care in America. Crossing the Quality Chasm: a New Health System for the 21st Century. Washington, DC: National Academy Press; 2001.

Unfortunately, despite tremendous therapeutic advances in cardiovascular medicine over the last 50 years and the development of evidence-based guidelines that define optimal care, well-recognized deficiencies in health care delivery are manifest, and suboptimal quality and outcomes of care persist in practice. Despite spending more per capita on health care than any other country, the United States does not achieve commensurately high scores on most metrics of quality of care or health outcomes.[1] Further, marked geographic variation in health care spending within the United States does not correlate consistently with health outcomes. For example, significant variation in the use of cardiovascular tests and procedures that is not explained by case-mix does not clearly generate better patient outcomes.[2]

Numerous studies have documented unexplained variation in care delivery that reflect *underuse* of guideline-indicated care, *overuse* of therapies not likely to result in benefits, and *misuse*, including avoidable complications and medical errors, all of which contribute to suboptimal outcomes. Gaps in quality can result from deficiencies in any of the IOM domains of high-quality health care (**see Table 4.1**). For example, effective therapies may not be prescribed for eligible patients (e.g., statin therapy for patient with recent MI). Providers and health care systems may fail to minimize exposure of patients to unnecessary risk (e.g., prescribing drugs that create a high risk of adverse drug-drug interaction). Clinicians may employ ineffective therapies (e.g., primary prevention implantable cardioverter-defibrillator placement in patient with mild left ventricular systolic dysfunction) or may use resource-intensive care for marginal benefit (e.g., routine intra-aortic balloon pump use for high-risk percutaneous coronary intervention [PCI]). Care delivery may be delayed or may be delivered differentially based on patient age, sex, race/ethnicity, or insurance status without adequate clinical justification. Patients may not be optimally engaged in their care, manifested as lower adherence to recommended therapies and lifestyle behaviors.

Deficiencies in any of these areas contribute to observed variation in quality of care and patient

outcomes and generate unnecessary costs. According to the IOM, underuse, overuse, and misuse of medical therapies are estimated to result in excess annual U.S. health care costs of $55 billion, $210 billion, and $130 billion, respectively.[3] Rapidly rising health care costs and the knowledge that substantial proportions of these costs are unnecessary have propelled health care reform, in which measurement and reporting of quality of care are fundamental.

Relevance of Quality of Care in Cardiovascular Practice

Cardiovascular clinicians should play a central role in how quality is measured and how health systems are modified to optimize quality and patient outcomes. Too often, clinicians perceive quality of care as a problem of clinical documentation or "working to the test" of external mandates such as payer requirements. These views are often reinforced in the current health care environment, in which quality measurement and reporting are often placed in a "regulatory" context and are often executed separately from clinician-patient interactions and clinical decision-making. The interaction of patients and clinicians is central to high-quality care, given the impact of clinical decisions (e.g., therapeutics prescribed, procedures done) on patient outcomes.

Indeed, there are several reasons why cardiovascular providers should engage in quality-of-care measurement and improvement. First, quality of care reflects the degree to which clinicians practice *evidence-based medicine*. Inherent in evidence-based medicine is consideration of both the best available scientific evidence and individual patient factors and preferences. Optimally, informed patients, who understand the state of their health and the potential risks and benefits of health interventions ranging from prevention to acute and chronic disease management, interact with clinicians who observe the tenets of evidence-based medicine.

Second, quality of care lies at the center of *health care system improvement*. The outcomes of health decisions by patients and cardiovascular clinicians depend on the environment in which these decisions are made. From the perspective of cardiovascular clinicians, quality of care includes not only their actions, but also patient access, engagement, and behavior; the context and methods of health care delivery; and multiple aspects of the health care system, ranging from information technology and ancillary personnel support to health system policy and incentives. Ultimately, although essential, clinical knowledge and skill are not sufficient for ensuring high-quality health care; another primary driver is the health care delivery system.

Third, quality care provides a means for *professional accountability*. The concept of professionalism includes not only good clinical knowledge but also excellence in the delivery of health care and accountability for that care. Quality of care, through measurement and improvement of the IOM domains of quality and patient outcomes, directly addresses health care delivery and accountability. As such, quality of care is centric to cardiovascular professionalism.

Moreover, quality of care is increasingly tied to certification and licensure, particularly regarding involvement in practice improvement. Medical education is evolving to a model of lifelong learning, in which the principles of quality of care are integrated with clinical knowledge and decision making. Intrinsic to this new framework, cardiovascular clinicians will need to have the skills of quality-of-care measurement and improvement in addition to medical knowledge.

Lastly, major changes in the health care environment bring quality of care to the center of clinical practice. Performance-based reimbursement and public reporting of quality-of-care measures are increasingly prevalent, along with new health care delivery and reimbursement models, such as

accountable care organizations. These invariably emphasize performance on quality measures that reflect one or more of the IOM quality domains and the direct measurement of patient outcomes.

Importantly, reimbursement for medical care is transitioning from payment for quantity to payment for quality, also known as "value-based purchasing" of health services. The Medicare Access and CHIP [Children's Health Insurance Program] Reauthorization Act of 2015 (MACRA), which replaced the Sustainable Growth Rate, represents a dramatic change in the approach of the U.S. Centers for Medicare and Medicaid Services (CMS) to physician payment.[4] MACRA ties reimbursement to the delivery of high-quality care, implementation of electronic health resources, engagement in performance improvement activities, and participation in alternative payment models, which in turn are tied to providing high-quality care at lower cost.

Measuring Health Care Quality and Uses of Quality Measurements

This section describes types of quality measures, uses of measures, common data sources for quality measurement, and limitations of quality measures, including the potential for unintended consequences.

Types of Quality Measures

Fifty years ago, Avedis Donabedian articulated an enduring conceptual framework for measuring health care quality: characterizing quality according to structure, process, and outcome (see Classic References). While contemporary measurement extends beyond these domains, the Donabedian model remains central to understanding the quality of health care. The American College of Cardiology (ACC) and American Heart Association (AHA) have described in detail the methodologic principles of developing various types of measures.[5-8]

Structural measures are specific attributes of the health care delivery system that are considered surrogates for the care delivered; examples include procedural volume and accreditation status. In general, such measures are only weak surrogates and are frequently inadequate if more robust metrics of quality are available.[9,10]

Process measures reflect the actions of clinicians, such as prescribing medication, and are among the most commonly employed metrics of quality. For example, CMS has used processes of care for acute MI and heart failure as part of their Hospital Compare quality reporting system since 1995.[11] ACC/AHA have developed several sets of process measures for specific cardiovascular procedures and conditions (**Table 4.2**). Operationally, process measures are generally selected from among the care processes with strong support in practice guidelines (e.g., class I recommendations in the ACC/AHA guideline recommendation taxonomy). Not all strong guideline recommendations are appropriate for adoption as quality measures, but such measures should possess additional attributes that support their use for quality measurement (**Table 4.3**).

TABLE 4.3

Attributes of Measures of Process, Outcome, and Value in Health Care

MEASURE TYPE	MEASURE ATTRIBUTES
Process[5]	Evidence based Interpretable Actionable Explicit numerator and denominator Valid Reliable Feasible
Outcomes[6]	Clear explicit definition of appropriate patient sample Clinically coherent variables for risk adjustment Sufficiently high-quality and timely data Designated time of covariate and outcome ascertainment Standardized period of outcome assessment Analysis accounting for multilevel organization of data Disclosure of methods employed
Value and efficiency[7]	Integration of both quality and cost Valid cost measurement and analysis No or minimal incentive to provide poor-quality care Proper attribution of the measure

Process measures have “face validity” because they focus on therapies and approaches that have been established in clinical studies and are readily interpretable. However, they generally typically require clinical data, thus requiring resources for data abstraction. The exclusion of individual patients from a process measure “denominator” because of contraindications to treatment is viewed favorably by clinicians but is controversial. Such exclusions further increase the burden of data collection but enhance the clinical validity of these measures. Moreover, there is not always a demonstrated association between higher performance on process measures and better patient outcomes.[12] Lastly, process measures may “top out,” where performance is consistently high and the measures lose the capacity to discriminate meaningfully among institutions. This has been the case with many of the process measures for cardiovascular conditions that have been reported to the public.[13]

Given the limitations of structural and process measures, a greater emphasis has been placed on *outcome measures.* Suitable outcome measures have several important attributes, the most important of

which may be risk adjustment[14] (**Table 4.3**). Risk, or "case-mix," adjustment can help address differences in patient populations receiving care. Robust risk adjustment requires advanced statistical methods and is generally limited by the availability of accurate data variables (e.g., patient characteristics) to include in risk models.

Outcome measures are appealing because they are patient centered, can be applied to all patients (unlike process measures, which apply to only a discrete "denominator" of patients), and reflect the actions of the health care system. However, risk adjustment methods must be valid, and some outcomes of great importance to patients (e.g., health status) are not currently measured systematically in large populations. Furthermore, unlike process measures, outcome measures do not explicitly inform the targets for QI.

Measures of *value*, broadly defined as quality delivered as a function of cost, have emerged as part of the quality measurement portfolio.[15] Importantly, cost alone is not synonymous with value; the easiest way to minimize cost is to withhold care, whereas value explicitly incorporates quality. Attributes of value measures have also been enumerated[14] (**see Table 4.3**). Developing robust measures of value involves the challenges attendant to measuring quality as well as those associated with measuring costs.

In response to evidence that escalating costs in part reflect overuse, the ACC, in conjunction with partner societies, has developed *appropriate use criteria* (AUC). These criteria provide ratings of the appropriateness of care for several cardiovascular diagnostic and therapeutic modalities for a range of commonly encountered clinical scenarios.[16] Because AUC are based on clinical scenarios that may not exactly reflect individual patient situations, and because the criteria are derived from expert consensus, their role in quality measurement and reporting is evolving.

Composite measures, which formally aggregate multiple aspects of quality, are appealing given the various structures, processes, and outcomes that can be measured for a particular condition or procedure.[17] Developing composite measures is complex and should be guided by an explicit methodology.[18] These measures have the advantage of combining various domains of quality but can obscure the impact of component measures and can decrease the understanding of where action for improvement is needed.

Data Sources

In general, quality measures are most useful when compared against an external standard, or "benchmark," of similar practice or national performance. Although single-center data can provide useful insights for local quality assessment and improvement, data used to characterize quality are most useful when compared across patients, providers, and settings. Sources meeting these criteria are often categorized as "claims data" (also known as "administrative data") or clinical data, each of which have distinct strengths and limitations. Ultimately, any measurement of quality will be no more robust than the quality of the data on which it is based.

Insurance payers maintain databases of claims for services as a means of identifying and paying for health services delivered to their members. Claims data have several strengths. First, they tend to include large numbers of patients, although this depends on the payer involved. Second, because these data are already collected for other purposes, there is lower incremental expense to employ claims data for this purpose. Finally, claims data employ a consistent standard (e.g., ICD-9 codes) for each claim.

However, several factors limit the value of claims data. Because their primary purpose is to facilitate billing, claims data are constrained in their capacity to inform clinical inferences. For instance, claims

data are limited with regard to measuring severity of disease, listing indications and results of procedures, and differentiating comorbidities from complications. Moreover, diagnostic codes may lack sensitivity and specificity, resulting in discordance with diagnoses established by clinicians. Claims data are also specific to the population receiving insurance from the entity that creates the database. Furthermore, claims data may require substantial time to elapse before they are adequately complete for use. Thus, measurements with these data will lag with respect to current practice.

The utility of claims data as a component of quality measurement largely depends on the specific use. In some cases, claims and clinical data perform similarly for case-mix adjustment at the institutional or hospital level for cardiovascular conditions. When used for risk adjustment at the patient level, however, clinical data generally provide better calibration and discrimination than claims data alone.[19]

Clinical data are appealing as the foundation of quality measurements for several reasons. The primary advantage of clinical data is their specificity regarding clinical details, such as severity of disease, coexisting conditions, and indications and results of procedures. For example, identifying contraindications to the use of a medication in a quality measure is likely to be incomplete using claims data, whereas clinical data are more likely to include the relevant information. There are also limitations to clinical data. Clinical data are generally more expensive and difficult to obtain on large populations than claims data. Aside from national clinical registry programs (discussed later), there are few sources of clinical data using consistent data standards and adequate in reach and scope to characterize quality on a large scale. Data in medical records, including electronic health records (EHRs), do not employ standardized definitions and may not include the specific elements necessary to compose a quality measure.

National clinical registry programs are currently the most widely used clinical data to measure quality.[20] In the United States the National Cardiovascular Data Registry (NCDR) program of the ACC and partner organizations (www.ncdr.com), the AHA Get With the Guidelines program (www.heart.org), and the Society of Thoracic Surgeons (STS) National Database (www.sts.org) are the most widely implemented cardiovascular registry programs. These programs provide quality measurements with national benchmarks, using detailed standardized clinical data, and can support QI initiatives.[21]

In some cases, clinical and claims data are used together for quality measurement purposes. This approach is often employed to take advantage of the detailed clinical data from a registry program for a specific episode of care (e.g., PCI, hospitalization for heart failure) and the assessment of events after that episode from claims data (e.g. death, rehospitalization). These hybrid data sources, while sharing the advantages and disadvantages of their component sources, allow assessment of longitudinal outcomes with a robust clinical foundation.

The increasing prevalence of EHRs in the U.S. health care system creates both opportunities and challenges for quality measurement. EHRs contain large amounts of clinical data but are currently not a panacea with respect to measuring quality. EHRs are not superior to paper records with respect to data structure and definitions or in ensuring that specific data elements are collected, unless the EHR platforms are specifically modified to do so. Moreover, EHR systems are not necessarily interoperable among institutions, limiting the extent to which they can be used for multi-institutional quality assessment without further efforts. Experience suggests that EHRs must evolve considerably to achieve their full potential as a source of robust, reliable data for quality measurement.[22]

Uses of Quality Measures

Quality measurements serve a range of purposes, but in broad terms they can be considered as supporting

QI or accountability (e.g., public reporting).[23] The distinction between these two uses is important: a broad range of measures may be suitable for the purposes of self-evaluation, benchmarking, and informing QI, but measures that will be used for accountability must withstand the scrutiny of those who are measured and the intended consumers of these measures.[24] The use of measures for accountability requires greater validity, reliability, and reproducibility of the measures, including the quality of the data that underlie the measures, as well as attribution of the measures.[25] The ACC/AHA and other measure developers apply specific standards and nomenclature to identify measures appropriate for accountability purposes (e.g., those designated as "performance measures") or those intended for QI purposes ("quality metrics" or "test metrics").[24] In the United States, most measures intended for the purposes of accountability are reviewed and endorsed by the National Quality Forum (www.nqf.org).

The past two decades have witnessed the evolution of programs that employ quality measures for the purposes of accountability. These include public reporting of quality measures (e.g., CMS Hospital Compare); "pay for reporting," in which participation in reporting efforts (but not specific results) leads to financial incentives; and expanding use of "pay for performance," in which reimbursement is tied to the specific results of outcomes (e.g., MACRA). Professional organizations are also taking leading roles in public reporting efforts based on clinical registry data, such as voluntary hospital programs sponsored by STS and NCDR to promote public reporting of cardiovascular quality.[26]

Ostensibly, accountability programs, including public reporting and pay-for-performance, are intended to incentivize quality improvement. Some evidence indicates that accountability may achieve this objective in some cases,[27-29] but there is no good evidence that it results in better quality of care or influences decisions by the consumers of health care services.[30] The heterogeneity of results likely reflects the variability in these programs in terms of what is measured, the context of implementation, and the incentive structure.

Concerns About Quality Measures: Unintended Consequences

Efforts to measure and improve quality of health care can potentially result in unintended consequences. For example, focusing on one process of care could detract from attention to other processes; incentives to increase rates of treatment could result in overtreatment in some cases; and threats of penalties for providers for adverse procedural outcomes or inadequate risk adjustment methods could result in biases against performing that procedure on high-risk patients.[31] These concerns support the importance of monitoring for potential unintended consequences as part of performance improvement efforts and programs. To date, however, QI and accountability efforts have generally not been evaluated with the rigor and to the extent of other medical interventions. Accountability may also incentivize "gaming" the measurement system, which undermines the credibility regarding meaningful QI and increases the importance of rigorous data quality and audit programs.

Improving Quality of Care

The principal reason to measure quality of care should be to inform meaningful improvement in health care delivery. QI, often also referred to as "performance improvement," is the set of actions undertaken to improve one or more of the six IOM domains of quality to improve health outcomes (**see Table 4.1**). Prior studies have helped identify key components of successful QI efforts, yet several activities familiar

to cardiovascular clinicians have been found to be largely ineffective.

Imploring clinicians to “do more” or “do better” in terms of following guidelines or documenting care is generally ineffective. Perhaps surprisingly, traditional continuing medical education (CME) and didactic lectures, utilization management, and availability of clinical practice guidelines are similarly ineffective.[32] On the other hand, the availability of quality measures with benchmarking (also called “audit and feedback”) can be successful, particularly when tied to health care delivery system improvement.

Successful QI involves identifying suboptimal performance in one or more aspects of care and then matching QI activities to improve performance. Data with benchmarking are central to choosing meaningful targets for improvement (**Fig. 4.1**). Once QI targets are chosen, a primary emphasis should be system changes to support higher-quality care delivery. Examples include using the EHR for computerized order entry to avoid prescription errors and provide automated drug-drug interaction alerts, standardized order sets and care pathways (e.g., for acute MI patients), use of multidisciplinary care teams, efforts to promote care coordination, and effective engagement of patients in decision making.

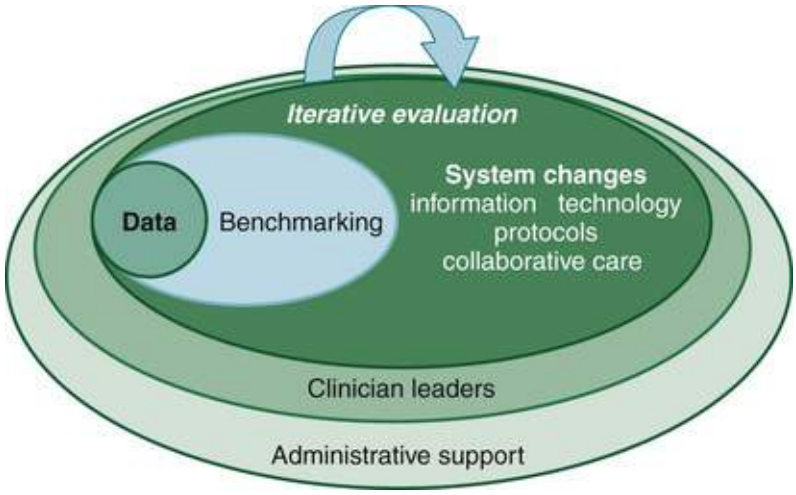

FIGURE 4.1 Key components of quality improvement. (From Rumsfeld JS, Dehmer GJ, Brindis RG. The National Cardiovascular Data Registry: its role in benchmarking and improving quality. US Cardiology 6:11, 2009.)

QI is only successful as a “team sport”; it should not focus on an individual clinician, but on a multidisciplinary team. Moreover, QI should be responsive to specific gaps in performance over time, striving continuously to improve the delivery system. Importantly, QI efforts should be evaluated in an iterative fashion, to assess progress in performance improvement and to monitor for unintended consequences. The measurement of the impact of QI, which can be considered part of “health care delivery research,” should be increasingly important in the future.[33]

Clinical leaders—those who are engaged and committed to quality measurement and improvement—are critical to successful QI efforts. Increasingly, training in quality measurement and QI is available to cardiovascular clinicians. Many hospitals and health systems are training clinical staff in quality. Organizations such as the ACC are embedding quality measurement and performance improvement into educational programs; these programs will increasingly support the performance improvement requirements of maintenance of certification and licensure.

Administrative support is also crucial. This includes not only financial support of quality measurement and improvement efforts, but also clear institutional leadership goals and commitment to achieving the highest quality of care. Indeed, among the most powerful drivers of QI is the *culture* of a practice or

institution. For example, in an evaluation of hospital characteristics associated with 30-day mortality rates after acute MI, hospitals that fostered “an organizational environment in which clinicians are encouraged to solve problems creatively,” in addition to having both physician and nurse “quality champions,” had significantly lower mortality rates.[34]

QI may be carried out at local levels (community, practice, hospital), or at regional, health system, national, or international levels. In other words, QI goals and strategies for performance improvement can be defined as part of local or broader-reaching quality initiatives, although the principles of QI are the same for each of these, and the QI activities ultimately must be executed at the local level following the key factors noted in Fig. 4.1. Several well-known approaches to QI are briefly described next.

Approaches to Quality Improvement

Fruitful QI requires the integration of the components previously described into a specific framework for action (**see Fig. 4.1**). Perhaps the most widely utilized framework in healthcare is Plan-Do-Study-Act (PDSA). This model, developed by Associates in Quality Improvement (www.apiweb.org), has been embraced by the Institute for Healthcare Improvement as the specific means for developing plans for health QI (www.ihi.org). PDSA comprises two interdependent steps: (1) formulating a plan by setting goals, establishing metrics of success, and identifying changes to implement, and (2) testing these changes in an iterative PDSA cycle (**Fig. 4.2**). The goals should be measurable, time delimited, and realistic. The measures should address at least one of the IOM domains of quality (**see Table 4.1**) but should also include measures to characterize possible adverse consequences of the improvement effort. Then, in evaluating changes, each step of the PDSA cycle contributes to the understanding of the impact of the change, both positive and negative, thus informing future cycles of improvement.

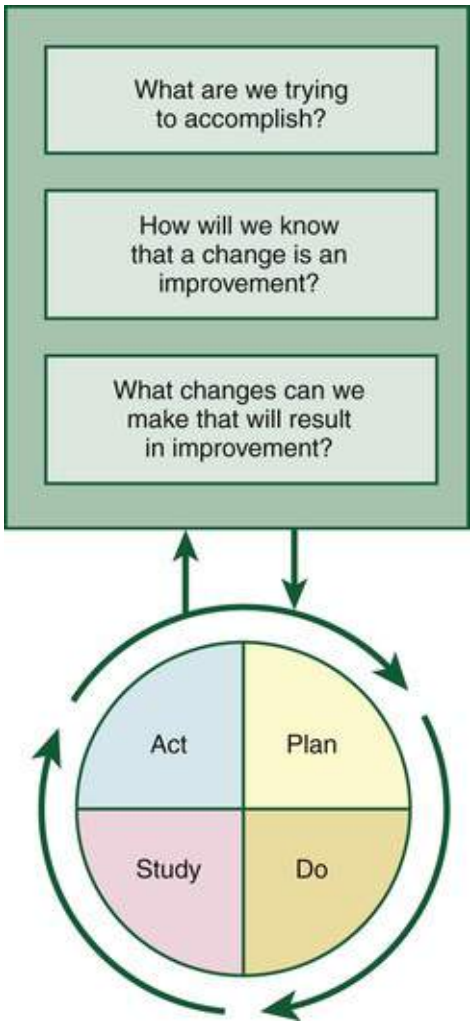

FIGURE 4.2 The PDSA (Plan-Do-Study-Act) cycle of quality improvement. (From Institute of Healthcare Improvement (www.ihi.org), attributed to Langley GL, Nolan KM, Nolan TW, et al. The Improvement Guide: a Practical Approach to Enhancing Organizational Performance. 2nd ed. San Francisco: Jossey-Bass Publishers; 2009).

The Lean approach builds on PDSA by specifically targeting wasteful health care processes. Lean was originally developed at Toyota to improve the efficiency of automobile production. Not surprisingly, with the rapid growth of medical expenditures and the understanding that more spending does not necessarily translate to better quality, the use of Lean in health care settings has expanded rapidly. In essence, the Lean QI approach includes a focus on patient needs, explicit evaluation of complex processes of care delivery in a given setting, and identification and improvement of those components of the process that do not promote one or more of the IOM domains of quality for improvement (**see Table 4.1**). Process-of-care mapping (e.g., the specific steps of how care is delivered in the emergency department, on a ward, or in the office), empowering all members of the health care team to help identify targets, and improving delivery in an iterative fashion are hallmarks of Lean.[35] Studies of the Lean approach suggest that it is an effective means of improving efficiency, both by reducing cost and improving quality.

Another well-known QI approach that builds on PDSA is Six Sigma, which focuses on reduction in unnecessary variation in care delivery. The term *Six Sigma* stems from "statistical process control," in which the goal is to have a care process executed with error rates that are six standard deviations below average. Unfortunately, medical errors generally occur at much higher rates (see Classic References, IOM: *To Err Is Human*). Therefore, Six Sigma emphasizes reducing errors in processes of care such as medication prescriptions or medical procedures (e.g., minimizing unnecessary procedural complications) through five steps (a modification of PDSA): Define, Measure, Analyze, Improve, and Control.[36] The last step emphasizes ongoing monitoring of care processes once error rates/variation has been reduced, such

that additional QI can be applied if variation/error rates increase. Lean and Six Sigma may be combined (Lean Six Sigma) for QI that leverages a PDSA approach to target reductions in wasteful processes of care and minimizes variation/error rates in care delivery.

Conclusion

Quality of care—the extent to which health care delivery optimizes patient outcomes—has become a clinical competency for cardiovascular clinicians. It is the practice of evidence-based medicine as well as accountability of care, both of which help define professionalism. Quality (or performance) improvement is increasingly central to clinical training, lifelong medical education, and reimbursement. Health care reimbursement in the future will reward quality over quantity.

Quality measurement and improvement are now an essential part of cardiovascular practice, as well as for the broader health care system. Quality measures, whether structural, process, outcome, value, or composite, depend on the extent of underlying scientific evidence, the validity of data sources, and clear specification. They can be used for QI as well as in accountability programs, such as public reporting and "pay for performance." Meaningful QI stems from having data with benchmarking to identify targets for improvement, making system changes to support high-quality care delivery, and having clinical leadership as well as administrative support. Robust, iterative evaluation of QI efforts is of critical importance, both to assess the impact of these efforts on intended quality measures and to monitor for unintended consequences.

Ultimately, cardiovascular clinicians should be fully engaged in quality of care, to help ensure that quality measurement, QI, and accountability programs are clinically meaningful, not just a regulatory burden. Only in this way will quality of care efforts truly promote health care that is more effective, safe, equitable, timely, efficient, and patient centered and that translates into improved patient outcomes.

Critical Evaluation of Clinical Trials

Elliott M. Antman

Despite many decades of advances in diagnosis and management, cardiovascular disease (CVD) remains the leading cause of death in the United States and other high-income countries, as well as many developing countries.[1] Managing the burden of CVD consumes substantial portions of health care expenditures globally; interventions to treat CVD are therefore a major focus of contemporary clinical research.[2] Therapeutic recommendations are no longer based on nonquantitative pathophysiologic reasoning but instead are evidence based. Rigorously performed trials are required before gaining regulatory approval and clinical acceptance of new treatments (drugs, devices, biologics) and biomarkers.[3] Thus the design, conduct, analysis, interpretation, and presentation of clinical trials constitute a central feature of the professional life of the contemporary cardiovascular specialist and will need to keep pace with the technology of the future.[3,4] Case-control studies and analyses from registries are integral to epidemiologic and outcomes research but are not strictly clinical trials and are not discussed in this chapter.[5,6]

Constructing the Research Question

Before embarking on a clinical trial, investigators should review the FINER criteria for a good research question (**Table 5.1**) and the phases of evaluation of new therapies (**Table 5.2**). They should also familiarize themselves with the processes of designing and implementing a research project, good clinical practice, and drawing conclusions from the findings[7-10] (**eFig. 5.1**). A clinical trial may be designed to test for superiority of the investigational treatment over the control therapy but also may be designed to show therapeutic similarity between the investigational and the control treatments (noninferiority design) (**Fig. 5.1 and Table 5.3**).[10]

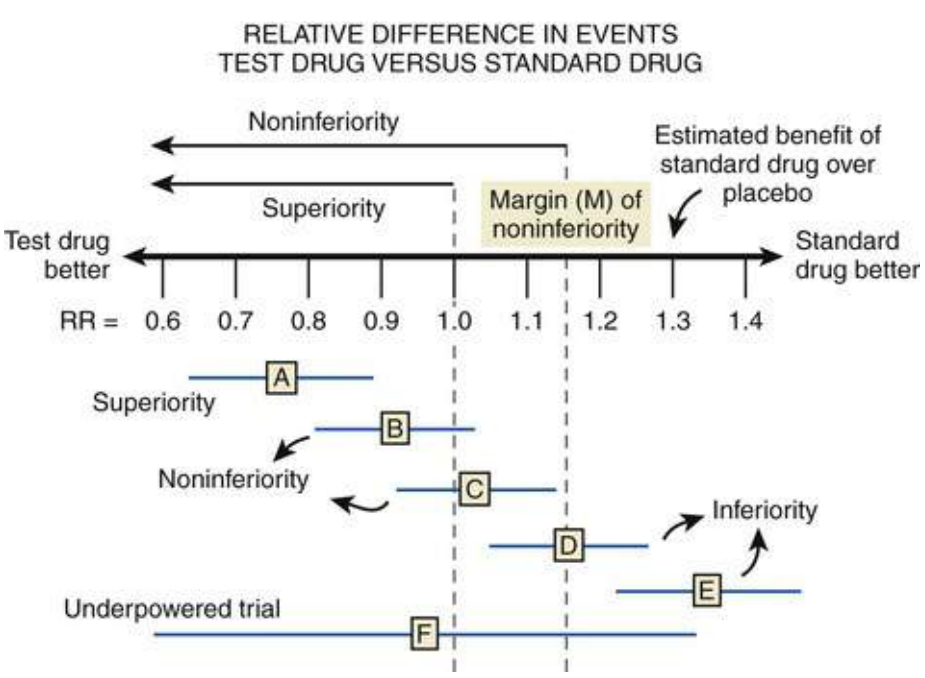

FIGURE 5.1 Example of design and interpretation of noninferiority trials. The margin (*M*) for noninferiority is prespecified based on previous trials comparing the standard drug with placebo. Examples of hypothetical trials A to F are shown, of which some (trials B and C) satisfy the definition of noninferiority. Trial A not only satisfies the criteria for noninferiority but, because the confidence interval is entirely to the left of a relative risk (*RR*) of 1.0, also shows superiority of the test drug over the standard drug.

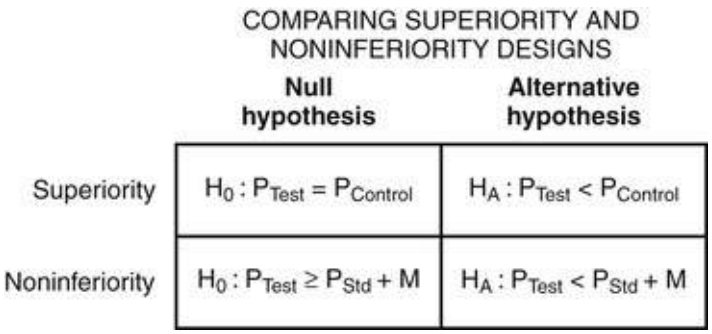
TABLE 5.3

Trial Designs to Replace Standard of Care

PARAMETER	SUPERIORITY	NONINFERIORITY	
		Objective 1	Objective 2
Goal	Test beats control	Test beats placebo	Test as good as standard
H_0 H_A	$P_{test} = P_{control}$ $P_{test} < P_{control}$	Assessment of test made against putative placebo	$P_{test} \geq P_{standard} + M$ $P_{test} < P_{standard} + M$
Source of data	Trial	Historical data	Trial
Type I error	Set by regulatory authorities, typically 0.05	Set by regulatory authorities, typically 0.05	Set by regulatory authorities, typically 0.05
Type II error (power)	Set by investigator	N/A	Set by investigator
Major threats to validity	Assay sensitivity; bias	Assay constancy	Assay sensitivity; bias
Inferential reasoning from trial	Results in study cohort yield estimate of $P_{test} - P_{control}$ in population of patients with same clinical characteristics and disease state.	Combining results from the trial ($P_{test} - P_{standard}$) and historical data ($P_{standard} - P_{placebo}$) yields estimate of ($P_{test} - P_{placebo}$) in population of patients with same clinical characteristics and disease state.	Results in study cohort yield estimate of $P_{test} - P_{standard}$ in population of patients with same clinical characteristics and disease state.
Generalizability to universe of *all* patients with the disease state	Related to enrollment criteria; the more restrictive they are, the less generalizable are the results to the entire universe of patients with the disease state.	Enrollment criteria of prior trials and medical practice concurrent with those trials determine generalizability of estimate of $P_{standard} - P_{placebo}$ to contemporary practice.	Related to enrollment criteria; the more restrictive they are, the less generalizable are the results to the entire universe of patients with the disease state.

H_0, Null hypothesis; H_A, alternative hypothesis; *M*, noninferiority margin; *N/A*, not available.



EFIGURE 5.1 Statistical design of superiority and noninferiority trials. In both superiority and noninferiority trials, the investigators propose a null hypothesis (H_0) with the goal of the trial being to reject H_0 in favor of the alternative hypothesis (H_A). To determine whether the null hypothesis may be rejected, before initiation of the trial, the type I (α) and type II (β) errors are specified (not shown). In superiority trials, α is usually two-sided, whereas it is one-sided in noninferiority trials. The quantity (1 − β) is referred to as the "power" of the trial. *M,* Margin for noninferiority; P_{Std}, and P_{Test}, proportion of subjects experiencing the event of interest in the standard and test treatment groups.

In a noninferiority trial, investigators specify a noninferiority criterion (M) and consider the investigational treatment to be therapeutically similar to control (standard) therapy if, with a high degree of confidence, the true difference in treatment effects is less than M (**see Fig. 5.1**).[11,12] Specification of the noninferiority margin M involves considerable discussion between the investigators (advocating for clinical perception of minimally important difference) and regulatory authorities (advocating for assurance that the investigational treatment maintains a reasonable fraction of the efficacy of the standard treatment based on previous trials).[11-13] The investigational therapy may satisfy the definition of noninferiority and may or may not also show superiority over the control therapy.[14] Thus, superiority can be considered a special case of noninferiority in which the entire confidence interval for the difference in treatments falls in favor of the investigational treatment (**see Fig. 5.1**). Investigators can stipulate that a trial is being designed to test both noninferiority and superiority (**see Table 5.3**). For a trial that is configured as a noninferiority trial, it is acceptable to test for superiority conditional on having demonstrated noninferiority.[15] The reverse is not true—trials configured for superiority cannot later test for noninferiority unless the margin M was prespecified.

Regardless of the design of the trial, it is essential that investigators provide a statement of the hypothesis being examined, using a format that permits biostatistical assessment of the results (**see eFig. 5.1**). Typically, a null hypothesis (H_0) is specified (e.g., no difference exists between the treatments being studied), and the trial is designed to provide evidence leading to rejection of H_0 in favor of an alternative hypothesis (H_A) (a difference exists between treatments). To determine whether H_0 may be rejected, investigators specify Type I (alpha, α) and Type II (beta, β) errors, referred to as the false-positive rate and false-negative rate, respectively. By convention, α is set at 5%, indicating a willingness to accept a 5% probability that a significant difference will occur by chance when there is no true difference in efficacy. Regulatory authorities may on occasion demand a more stringent level of α—for example, when a single large trial is being proposed rather than two smaller trials—to gain approval of a new treatment. The value of β represents the probability that a specific difference in treatment efficacy might be missed, so that the investigators incorrectly fail to reject H_0 when there is a true difference in efficacy. The power of the trial is given by the quantity (1 − β) and is selected by the investigators, typically between 80% and

90%.[16] Using the quantities α, β, and the estimated event rates in the control group, the sample size of the trial can be calculated with formulas for comparison of dichotomous outcomes or for a comparison of the rate of development of events over a follow-up period (time to failure). **Table 5.3** summarizes the major features and concepts for superiority and noninferiority trials designed to change the standard of care for patients with a cardiovascular condition.

Clinical Trial Design

Controlled Trials

Randomized controlled trials (RCTs) are considered the "gold standard" for the evaluation of new treatments (**Fig. 5.2**), but because of their defined structure, RCTs have limitations when used to drive evidence-based practice recommendations.[9,17,18] The allocation of subjects to control and test treatments is not determined but is based on an impartial scheme (usually a computer algorithm). Randomization reduces the likelihood of patient selection bias in allocation of treatment, enhances the likelihood that any baseline differences between groups are random so that comparable groups of subjects can be compared, and validates the use of common statistical tests. Randomization may be fixed over the course of the trial or may be adaptive, based on the distribution of treatment assignments in the trial to a given point, baseline characteristics, or observed outcomes[15,19] (**Fig. 5.2A**). *Fixed* randomization schemes are more common and are specified further according to the allocation ratio (equal or unequal assignment to study groups), stratification levels, and block size (i.e., constraining the randomization of patients to ensure a balanced number of assignments to the study groups, especially if stratification [e.g., based on enrollment characteristics] is used in the trial). During the course of a trial, investigators may find it necessary to modify one or more treatments in response to evolving data (internal or external to the trial) or a recommendation from the trial's data safety monitoring board (DSMB)—that is, to implement an *adaptive* design[15,19] (**Fig. 5.2B**). Adaptive designs are most readily implemented during phase II of therapeutic development. Regulatory authorities are concerned about protection of the trial integrity and the studywise α level when adaptive designs are used in registration pathway trials.[19] The most desirable situation is for the control group to be studied concurrently and to comprise subjects distinct from those of the treatment group. Other trial formats that have been used in cardiovascular investigations include nonrandomized concurrent and historical controls (**Fig. 5.3A, B**), crossover designs (**Fig. 5.3C**), withdrawal trials (**Fig. 5.3D**), and group or cluster allocations (groups of subjects or investigative sites are assigned as a block to test or control). Depending on the clinical circumstances, the control agent may be a placebo or a drug or other intervention used in active treatment (standard of care).

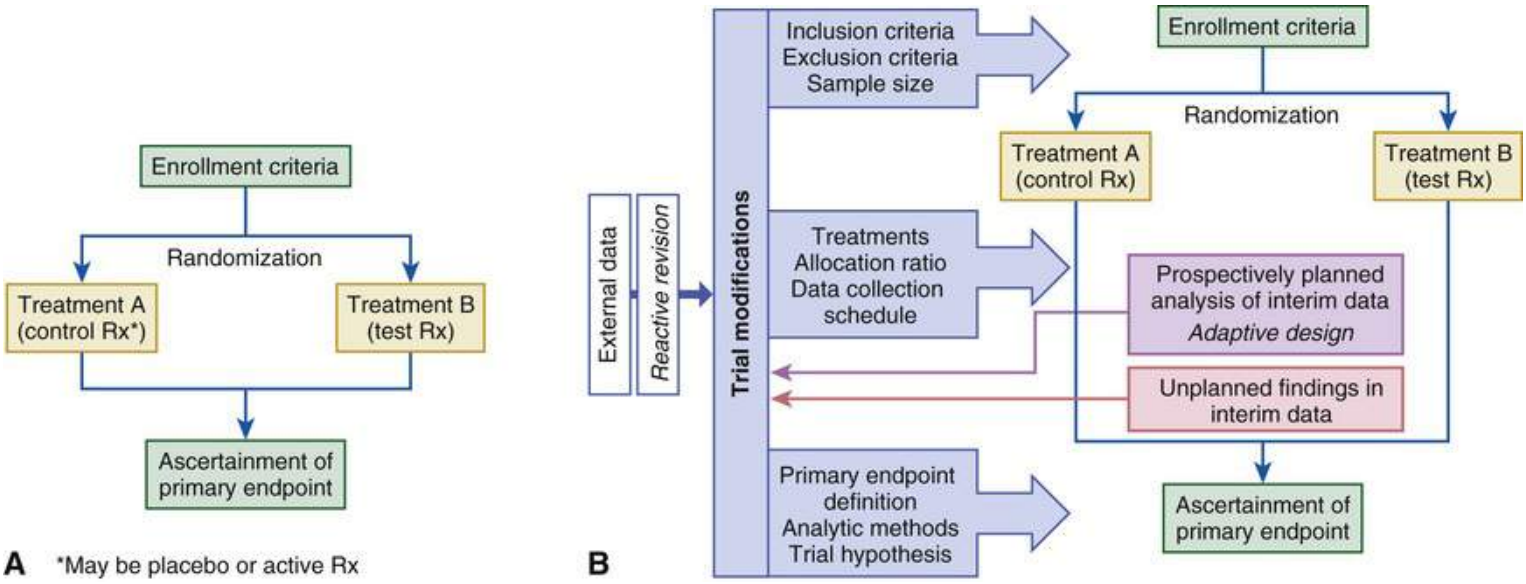


FIGURE 5.2 **A,** Basic structure of a randomized control trial (RCT). The investigators specify the enrollment criteria for the study population. Allocation to the treatment groups occurs through a randomization scheme, subjects are followed, and the primary endpoint is ascertained. **B,** Design of the RCT may be modified at the major levels shown. When the modification is in response to data external to the trial, it is referred to as a "reactive revision" (*left side*). When the investigators prospectively plan an analysis of interim data for the purposes of modifying the trial, it is referred to as an "adaptive design." Unplanned findings in interim data (e.g., data safety monitoring board recommendation) also may provoke a modification of the trial design. (Modified from Antman E, Weiss S, Loscalzo J. Systems pharmacology, pharmacogenetics, and clinical trial design in network medicine. Wiley Interdiscip Rev Syst Biol Med 2012;4:367.)

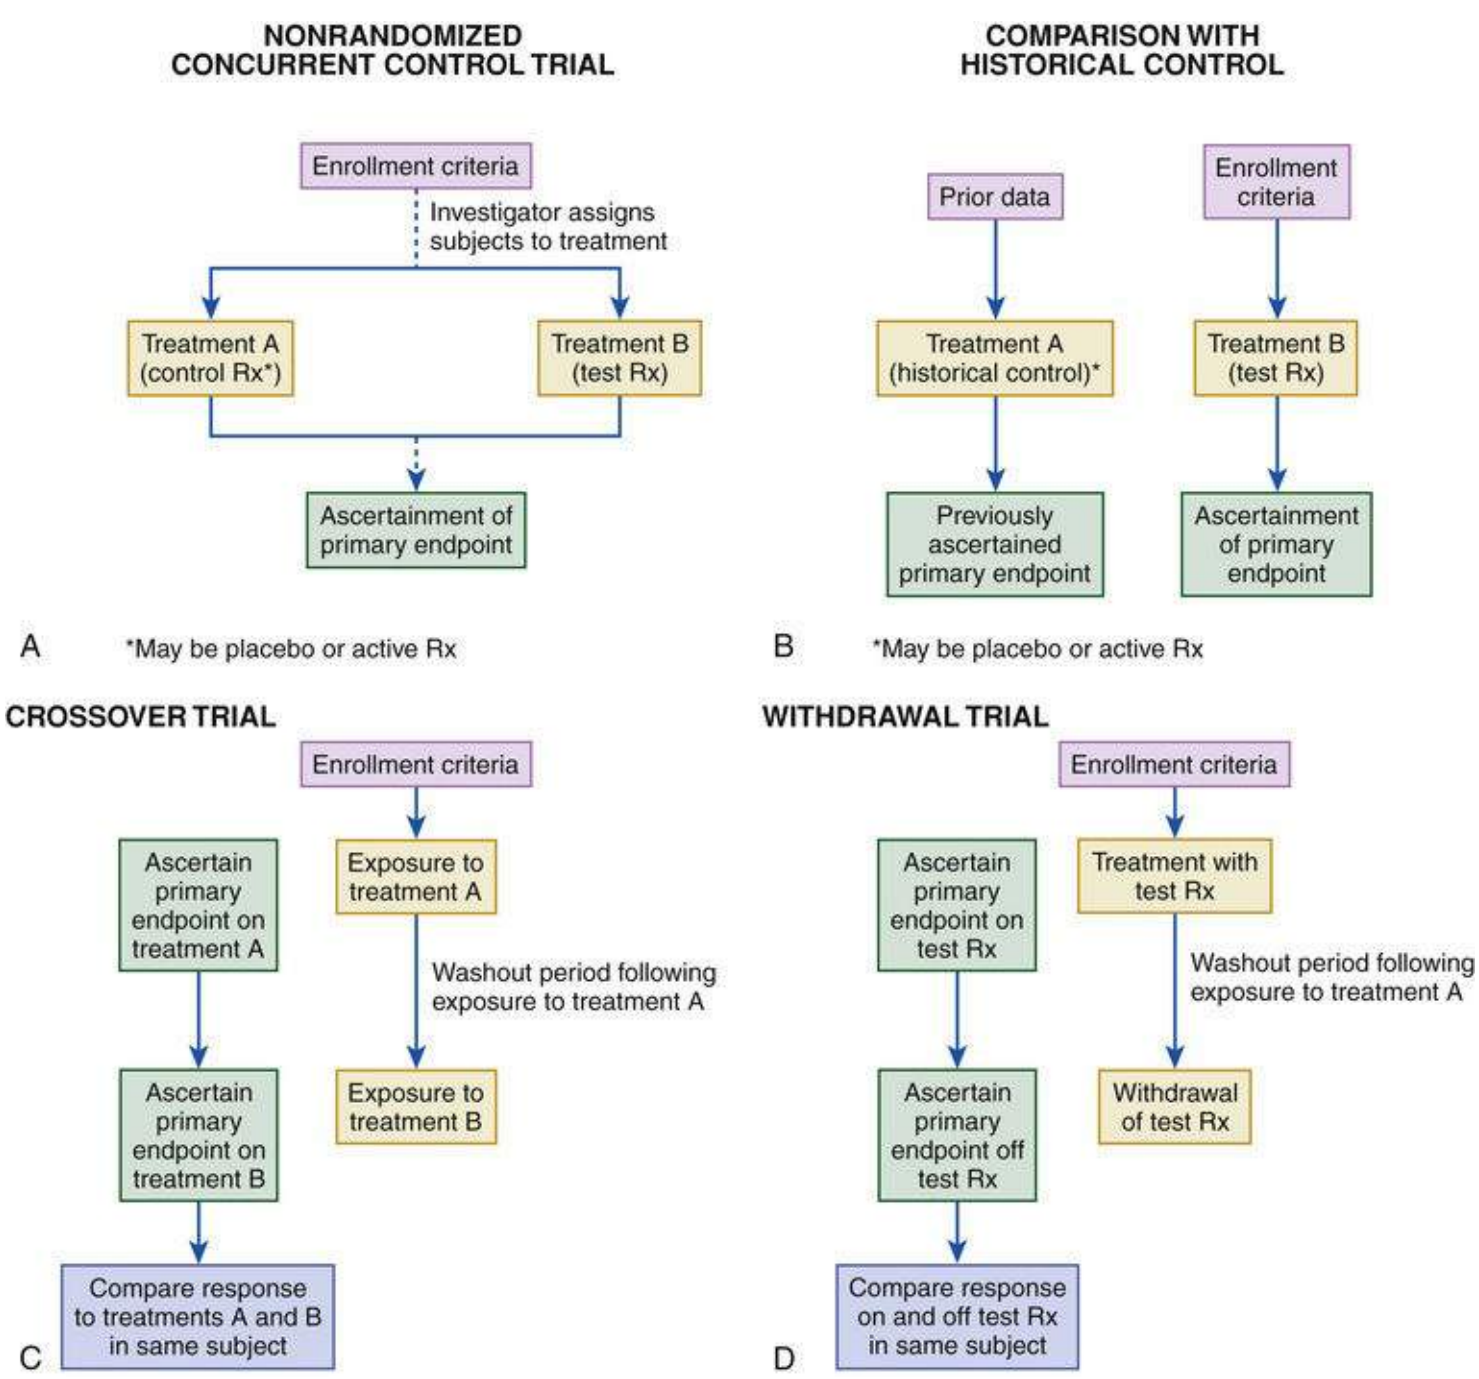

FIGURE 5.3 Other forms of controlled studies. **A,** Features of nonrandomized concurrent control trial. **B,** Design features of a trial using an historical control group. **C,** Design features of a crossover trial. (For an example of this type of trial to evaluate an intervention for angina pectoris, refer to Cole PL, Beamer AD, McGowan N, et al: Efficacy and safety of perhexiline maleate in refractory angina: a double-blind placebo-controlled clinical trial of a novel antianginal agent. Circulation 1990;81:1260.) **D,** Design features of a withdrawal trial. (For an example of the use of this type of trial to evaluate the use of digoxin in patients with chronic heart failure, refer to Packer M, Gheorghiade M, Young JB, et al. Withdrawal of digoxin from patients with chronic heart failure treated with angiotensin-converting-enzyme inhibitors. RADIANCE Study. N Engl J Med 1993;329:1.)

Other Forms of Controlled Studies

Trials in which the investigator selects the subjects to be allocated to the control and treatment groups are *nonrandomized, concurrent control studies* (**see Fig. 5.3A**).[18] In this type of trial design, clinicians do not leave the allocation of treatment in each patient to chance, and patients are not required to accept the concept of randomization. It is, however, difficult for investigators to match subjects in the test and

control groups for all relevant baseline characteristics, introducing the possibility of selection bias, which could influence the conclusions of the trial. Clinical trials that use *historical controls* compare a test intervention with data obtained earlier in a nonconcurrent, nonrandomized control group (**see Fig. 5.3B**). Potential sources for historical controls include previously published trials in cardiovascular medicine and electronic databases of clinic populations or registries. The use of historical controls allows investigators to offer the treatment(s) being investigated to all subjects enrolled in the trial. The major drawbacks are the potential for bias in the selection of the control population and failure of the historical controls to reflect accurately the contemporary picture of the disease under study.

The *crossover* design is a special case of the RCT in that each subject serves as his or her own control (**see Fig. 5.3C**). The appeal of this design is that the same subject is used for both test and control groups, thereby diminishing the influence of interindividual variability and allowing a smaller sample size. However, important limitations to a crossover design are the assumptions that the effects of the treatment assigned during the first period have no residual effect on the treatment assigned during the second period and that the patient's condition does not change during the periods being compared.

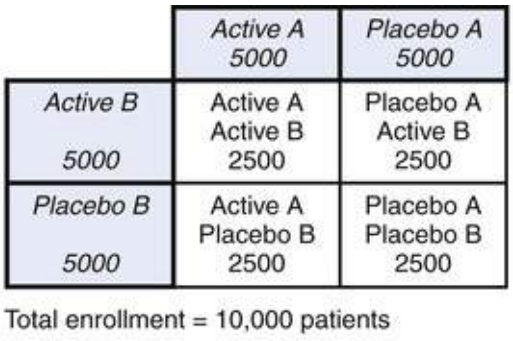
In a *fixed sample size* design, the trialists specify the necessary sample size before patient recruitment, whereas in an *open or closed sequential* design, subjects are enrolled only if the evolving test-control difference from previous subjects remains within prespecified boundaries.[15,19] Trials with a fixed design can be configured to continue until the requisite number of endpoints is reached (event driven), thus ensuring that enough endpoints will occur to provide intended power to evaluate the null (H_0) and alternative (H_A) hypotheses. When both the patient and the investigator are aware of the treatment assignment, the trial is said to be *unblinded*. *Single-blind* trials mask the treatment from the patient but permit it to be known by the investigator. *Double-blind* trials mask the treatment assignment from both the patient and the investigator, and *triple-blind* trials also mask the actual treatment assignment from the DSMB and provide data only in the form of group A and group B categories.

Withdrawal Studies

A withdrawal study evaluates the patient's response to discontinuation of treatment or reduction in the intensity of treatment for a cardiovascular condition (**see Fig. 5.3D**). Because patients previously experiencing incapacitating side effects would have been taken off the test intervention, they are not available for withdrawal. This bias toward selection of patients who tolerate a test intervention can overestimate benefit and underestimate toxicity associated with the treatment. In addition, changes in the natural history of the disease in a given patient may influence the response to withdrawal of therapy.

Factorial Design

In a factorial design, multiple treatments can be compared with control within a single trial through independent randomizations[10] (**eFig. 5.2**). Because patients with CVD typically receive multiple therapies, the factorial design is more reflective of actual clinical practice than trials in which only a single intervention is randomized. Multiple comparisons can be efficiently performed in a single large factorial design trial that is smaller than the sum of two independent clinical trials. Each intervention should be evaluated individually against control, and the possibility of interaction between the factors should be evaluated, because the validity of comparisons within each factor depends on the absence of interaction. Factorial designs may not be appropriate if there is an a priori reason to anticipate interactions (e.g., resulting from related mechanisms of action).



EFIGURE 5.2 Factorial design of clinical trial. In this example, 10,000 patients are randomized to receive or not to receive two interventions (drug A and drug B). Each patient will fall into one of the following four categories: Active A/Active B, Placebo A/Active B, Active A/Placebo B, or Placebo A/Placebo B. *Definitions/equations at bottom:* Differences in event rates for the comparisons permit an assessment of the treatment effect of drug A in the presence and absence of drug B. See text for further discussion. (From Antman E. Medical therapy for acute coronary syndromes: an overview. In Califf R, Braunwald E, editors. Acute Myocardial Infarction and Other Acute Ischemic Syndromes. Philadelphia: Current Medicine; 1996, pp 10.1-10.25.)

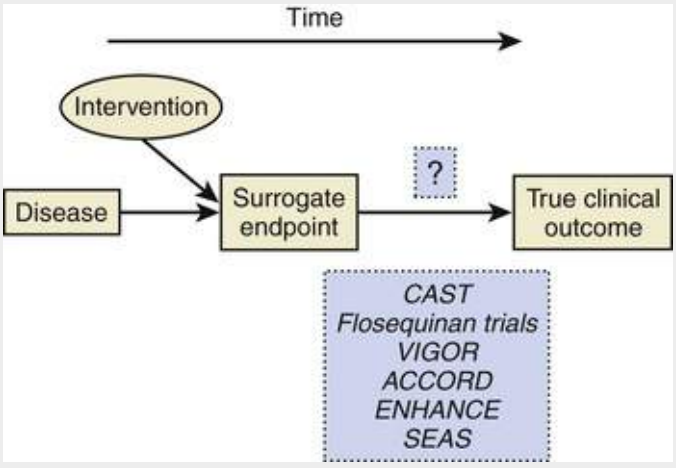
Selection of Endpoint of Clinical Trial

Evaluation of new treatments in the face of rising costs and reduced mortality rates for cardiovascular illnesses has resulted in two major approaches to the selection of endpoints. The first is to use a composite endpoint with a perceived logical grouping of events, whereby each of the elements of the endpoints is believed to be affected by the treatments being studied.[9] During the course of a trial but before unblinding, investigators may assess the aggregate (all treatment groups combined) event rate for the primary endpoint to ascertain whether the initial estimates of the event rate in the control arm and the anticipated treatment effect of the intervention were reasonable.[15] A low aggregate event rate may reflect inaccuracies in the estimated control rate or treatment effect; investigators may respond by modifying the sample size or expanding the definition of the primary endpoint (**see Fig. 5.2B**).

Some investigators use a term such as *MACE* (*m*ajor *a*dverse *c*ardiac *e*vents) to refer to the composite endpoint that they selected, but readers need to evaluate the methods section in clinical trial reports because such phrases may be used differently across trial groups. This situation may improve in the future as a result of a movement toward standardization of the definitions of endpoints in RCTs.[20] Interpretation of composite endpoints is challenging when the various component elements show different quantitative or qualitative responses to a new treatment. For example, the new treatment may reduce a nonfatal element such as hospitalization for heart failure but may increase total mortality. Efforts to address the complexities of composite endpoints include evaluating the total number of endpoints (first element as well as recurrent nonfatal components) as well as novel weighting schemes using matched pairs of patients in the treatment and control groups to calculate a "win ratio."[21,22]

The balance of benefit and risk associated with a new treatment may be described using terms such as *net clinical benefit*, *net clinical outcome*, or *NACE* (*n*et *a*dverse *c*ardiac *e*vents). Such terms typically combine elements of efficacy and safety (e.g., cardiovascular death, nonfatal myocardial infarction [MI], nonfatal stroke, nonfatal major bleed) and provide clinicians with a summary statement about what to expect from a new treatment. Although this is appealing, controversy remains because of a lack of agreement on weighting schemes to interpret composite endpoints, especially when nonfatal safety elements (e.g., bleeding) are combined with efficacy elements (e.g., prevention of MI).

Another approach is to use a surrogate endpoint as a substitute for measuring more traditional clinical outcomes.[23,24] Surrogate endpoints are attractive to investigators because they often are measured on an interval (continuous) scale and can lead to trials with a smaller sample size. However, the field of cardiology is replete with examples of trials configured around surrogate endpoints that not only failed to demonstrate benefit but actually uncovered harm (e.g., increased mortality) associated with a new treatment. Surrogate endpoints are useful if they lie in the causal pathway of a disease and if interventions that affect them are reliably associated with changes in clinical outcomes. **eFig. 5.3** illustrates a range of settings in which surrogate endpoints failed to serve as useful substitutes for measuring "hard" clinical events in cardiovascular trials.



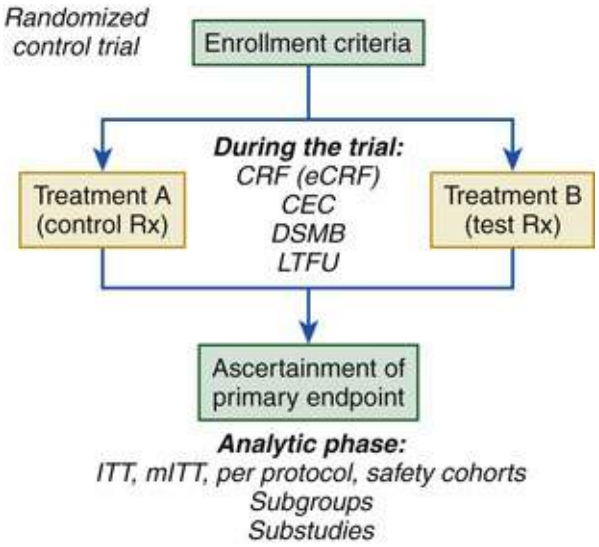
EFIGURE 5.3 Surrogate endpoints. Selection of a surrogate endpoint in a clinical trial provides reliable information for clinicians if the surrogate endpoint is in the causal pathway of the disease with respect to clinical outcomes, and if the intervention acts on the surrogate endpoint so as to truly affect clinical outcome. Some examples of trials in cardiovascular medicine for which this paradigm failed are CAST (Cardiac Arrhythmia Suppressor Trial); studies of flosequinan; VIGOR (Vioxx GI Outcomes Research); ACCORD (Action to Control Cardiovascular Risk in Diabetes); ENHANCE (Ezetimibe and Simvastatin in Hypercholesterolemia Enhances Atherosclerosis Regression); and SEAS (Simvastatin and Ezetimibe in Aortic Stenosis). (Modified from Fleming TR, DeMets DL. Surrogate end points in clinical trials: are we being misled? Ann Intern Med 1996;125:605.)

Key Issues

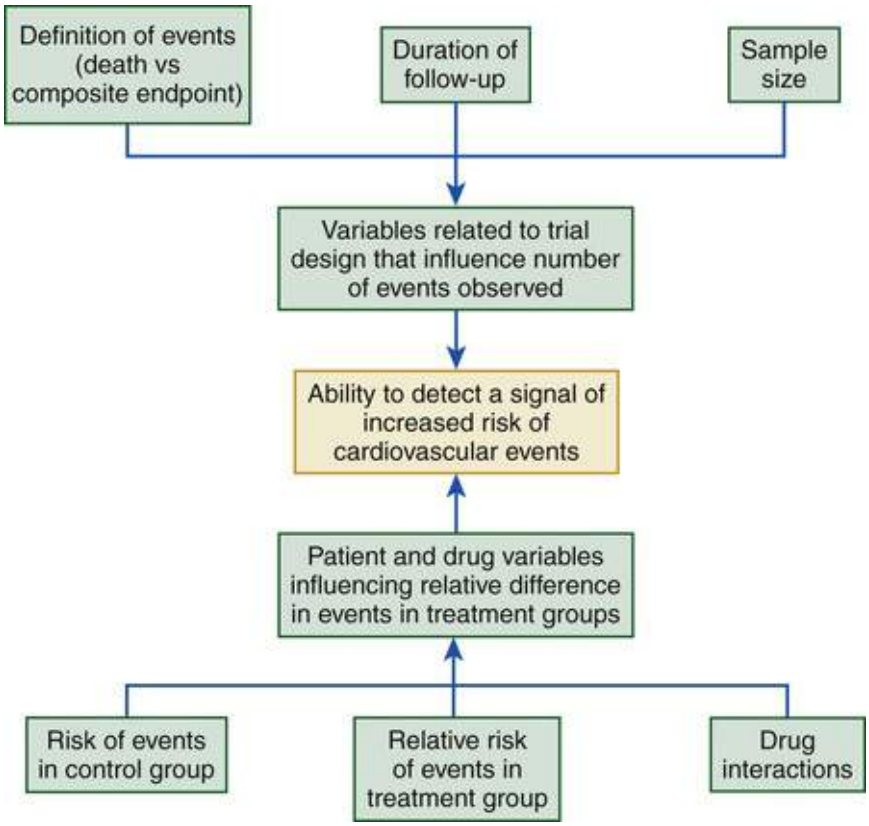
During Course of Trial

Contemporary trials require surveillance of multiple issues on a regular basis (**eFig. 5.4**). The determination as to whether an event (efficacy, safety) has occurred is the responsibility of a clinical events committee (CEC). Members of a CEC typically are experts in the field, remain blinded to the treatment assignment, and adjudicate events according to a charter established before initiation of

enrollment.[20] Because it would not be possible for investigators to maintain equipoise as the events in a trial begin to accumulate, the DSMB assesses the data at prespecified intervals to ascertain whether the accumulating evidence strongly suggests an advantage of one treatment[25] (**eFig. 5.5**).



EFIGURE 5.4 Conduct during recruitment and follow-up of subjects in the trial and during the analytic phase. The case report form (*CRF*) is an important barometer of the quality of the data being collected at investigative sites. Surveillance procedures need to be in place for central review of the data being submitted to trap for key items such as any violations of the enrollment criteria, range check errors (e.g., number of digits or units for age, weight, biomarkers), adequacy of the information being submitted for suspected endpoint events, and timely submission of adverse events (a regulatory reporting responsibility). Many of these tasks are facilitated by the use of an electronic case report form (*eCRF*) that can be completed using an Internet-based interface. The complexity of monitoring the tasks may be handled by a contract research organization (*CRO*) that has a large staff capable of visiting the enrolling sites. Additional quality checks that typically are conducted by a CRO include source document verification (inspection of primary medical record) for suspected endpoint events and random sampling of subjects who did not experience any events. Retention of subjects in the trial and minimizing loss to follow-up (*LTFU*) also are key quality measures. *CEC,* Clinical events committee; *DSMB,* data safety monitoring board; *ITT,* intention to treat; *mITT,* modified intention to treat.



EFIGURE 5.5 Detection of treatment effects in clinical trials. Factors related to trial design (*top*) and to the patient and drug being investigated (*bottom*) are shown. The interplay of these factors influences the ability to detect a treatment effect in a clinical trial. (Reproduced with permission from Antman EM, DeMets D, Loscalzo J. Cyclooxygenase inhibition and cardiovascular risk. Circulation 2005;112:759.)

A critical aspect of a trial that impacts the analysis and interpretation of the findings is *missing data* (see additional content online). Subjects who initially agree to participate in an RCT may decline to continue to take a blinded-study drug at some point during the course of the trial. Rather than ceasing follow-up in such subjects (i.e., censoring the data), trialists should strive to obtain follow-up data by asking subjects who stop taking a study drug to allow the investigators to obtain follow-up on them through office visits, telephone contact, or review of their medical records.[26,27] Every effort also should be made to track patients who move during the trial to avoid "loss to follow-up."[27]

Stopping boundaries to guide the DSMB are usually agreed on before the initiation of enrollment. Such stopping boundaries need to take into account the uncertainty of the evidence at iterative "interim looks" at the data and the play of chance, which may produce a situation in which one treatment appears to be favorable. During these interim looks at the data, DSMB members inspect the differences between treatment groups expressed as a standardized normal statistic (Z_i). Usually, Z_i plots depict evidence of superiority of the test treatment in the upward (positive) direction and inferiority of the test treatment in the downward direction.[25]

Stopping boundaries may be symmetric (**Fig. 5.4**) or asymmetric. Investigators and DSMB members may agree to use an asymmetric stopping-boundary scheme that requires less compelling evidence to cross a lower bound for inferiority of a new treatment when an acceptable standard treatment is clinically available and the new treatment is associated with safety concerns (e.g., intracranial hemorrhage during evaluation of a new fibrinolytic). The DSMB may also be called on to determine whether a particular dose group should be discontinued (adaptive design) (**see Fig. 5.2B**) and whether the trial is futile (e.g., that conditional on the data accumulated at the -*i*th look, there is only a 10% chance that H_0 would be rejected at the end of the trial).[10]

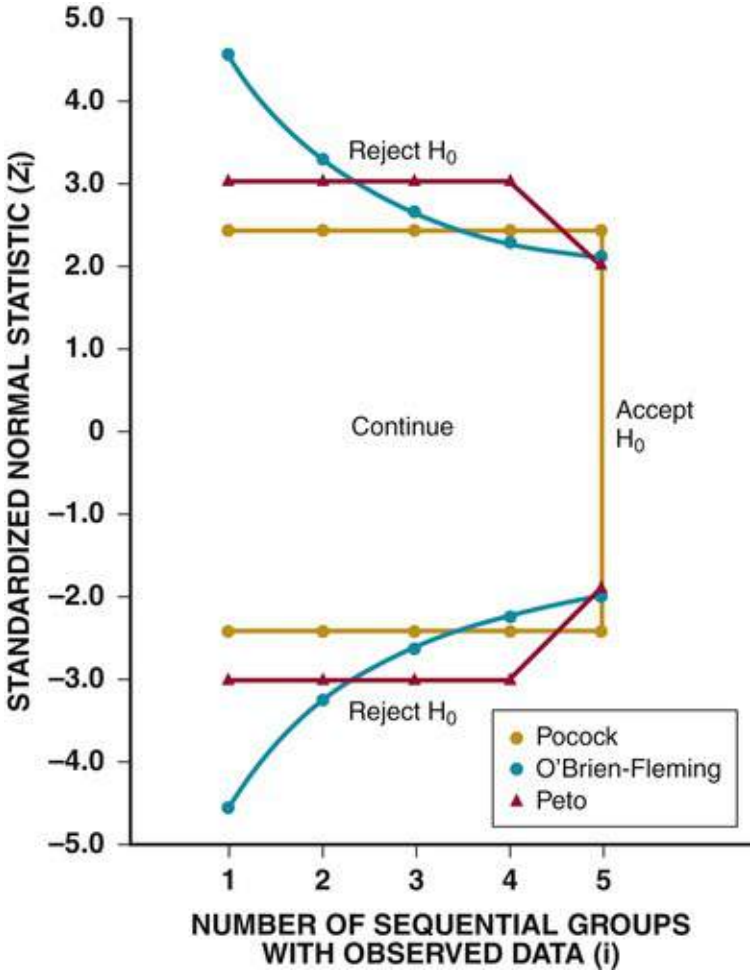


FIGURE 5.4 Sequential stopping boundaries used in monitoring a clinical trial. Shown are three sequential stopping boundaries for the standardized normal statistic (Z_i) for up to five sequential groups (of patients enrolled in the trial by the -*i*th analysis), with a final two-sided significance level of 0.05. (From Friedman LM, Furberg CD, DeMets DL. Fundamentals of Clinical Trials. 4th ed. New York: Springer Verlag; 1998.)

During Analytic Phase of Trial

Before unblinding the results of the trial (i.e., revealing patient outcomes by treatment group to investigators), the investigators should have finalized a statistical analysis plan (SAP). Key features of the SAP include a definition of the cohorts of trial subjects to be analyzed (**Table 5.4**), the statistical test(s) to be used to analyze the primary endpoint (e.g., for comparison of proportions or time to event), conventions for handling missing data,[26,28] time windows for analyzing data (e.g., randomization through common study end date), and subgroups of interest (**see eFig. 5.4**). Depending on the exact definitions used for the analytic cohorts, the denominators may vary; this may lead to slight variations in the estimates of event rates and treatment effects. Ideally, the main results of the trial will be similar in the intention to treatment and per protocol cohorts. If they are not, an explanation should be sought from additional analyses of the data.

TABLE 5.4

Examples of Definitions of Analytic Cohorts in a Clinical Trial

ANALYTIC COHORT	REFERENCE DATE	EXCLUDE IF PROTOCOL VIOLATIONS DISCOVERED	REQUIRE THAT SUBJECT RECEIVED AT LEAST ONE DOSE OF STUDY DRUG	TREATMENT ASSIGNMENT FOR ANALYTIC PURPOSES
Intention to treat	Randomization	No	No	As per randomization
Modified intention to treat	May start at initial dose of study drug	No (may vary)	May introduce this requirement	As per randomization
Per protocol	Initial dose of study drug	Yes	Yes	Usually as per randomization, but sensitivity analyses that account for actual treatment received may be performed
Safety	Usually at time of initial dose of study drug	No	Yes	Usually as per actual treatment received, but sensitivity analyses that use treatment assigned at randomization may be performed

Not all patients will respond to a given treatment in a clinical trial to the same extent. The role of pharmacogenomics in determining the response to therapeutic agents is discussed in **Chapter 8**. Because not all patients will respond to a given treatment, it is of clinical interest to inspect the data stratified by subgroups of interest. Although such an approach initially may seem appealing, a number of considerations limit the investigator's ability to draw conclusions from subgroup analyses. Typically, subgroups involve univariate analyses of the data (e.g., men versus women), but the clinical picture is more complex, such that an individual patient will belong to multiple subgroups. Responses in subgroups should be evaluated by an *interaction test*, which determines whether the relative efficacy of treatments differs among the subgroups being examined. A *quantitative* interaction is said to be present when the treatment effect varies in magnitude but not in direction across subgroups.[29] A *qualitative* interaction is said to be present when the direction of the treatment effect varies among the subgroups. Note that a qualitative interaction also must be a quantitative interaction. Of importance, the multiplicity of subgroup analyses inflates the false-positive rate (**Fig. 5.5**). Rather than relying on a *P* value for a subgroup response, investigators and readers should focus on a graphic display of subgroup data depicting the point estimates and confidence intervals for the treatment effect. Such an approach provides a summary of the range of plausible treatment effects observed in a trial. Ongoing improvements in genotyping and phenotyping subjects offers the potential for more precise definition of subgroups, but statistical complexity may increase as the number of subgroups grows.[3]

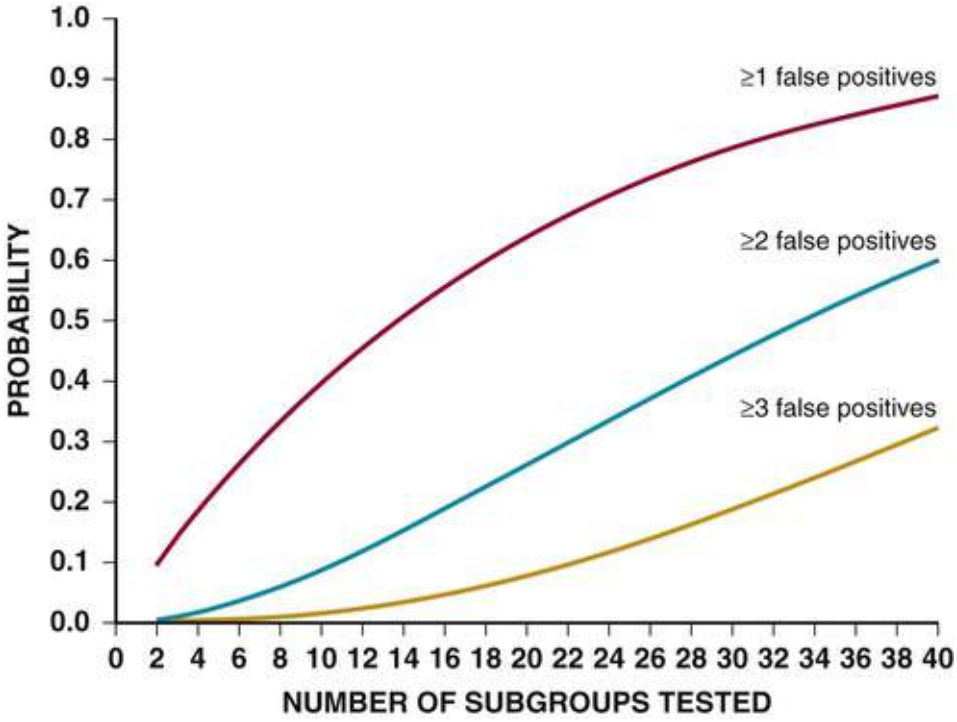

FIGURE 5.5 Probability that multiple subgroup analyses will yield at least one (*red line*), two (*blue line*), or three (*yellow line*) false-positive results. (From Lagakos SW: The challenge of subgroup analyses—reporting without distorting. N Engl J Med 2006;354:1667.)

Measures and Detection of Treatment Effect

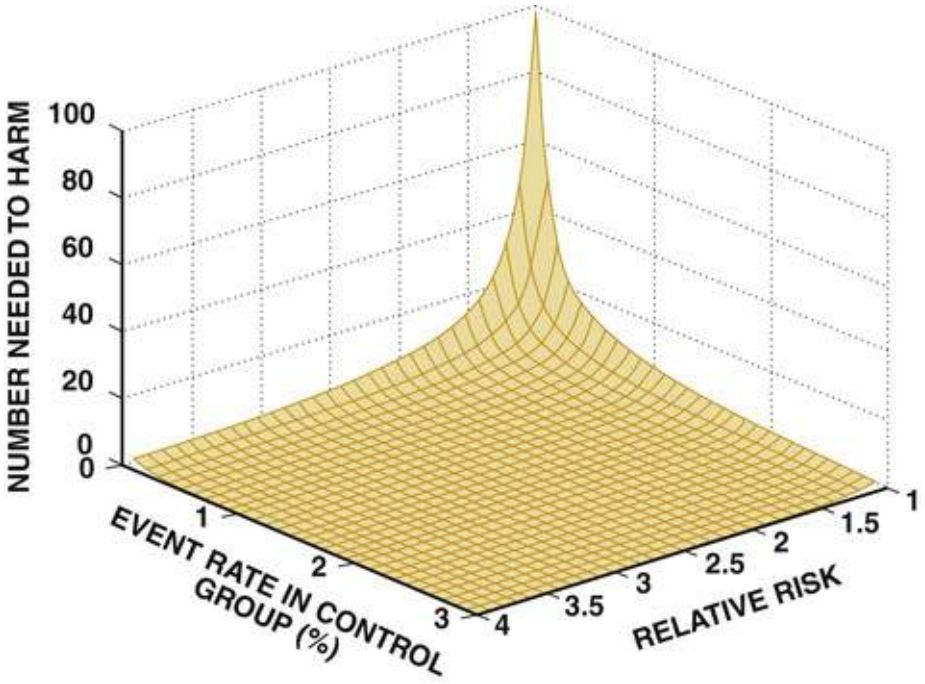
Events in a clinical trial may be measured on a nominal (dichotomous), categorical, or interval (continuous) scale.[30] Clinical trials reports should use descriptive statistics, graphic displays, and estimates of the precision of the observations appropriate for the scale of measurement being used in the trial.[30] A common assessment in a cardiovascular trial is comparison of the proportions of patients experiencing a dichotomous event (e.g., dead versus alive) during the follow-up period of the trial. When the outcome is an undesirable cardiovascular response and the data are arranged as investigational group compared with control group, a *relative risk* (RR) or *odds ratio* (OR) of less than 1 indicates benefit of the investigational treatment (**see Fig. 5.1**).

Interpretation of the treatment effect should take into account the absolute risk of the outcomes. The *absolute risk difference* (ARD) is the difference in events in the treatment group and the control group and is particularly useful when expressed as the number of patients that must be treated ($N = 1/\text{ARD}$), or *number needed to treat* (NNT), to observe the beneficial effect in one patient. Similarly, the *absolute risk increase* (ARI) in adverse events with the investigational treatment can be converted into the *number needed to harm* (NNH). By comparing the NNT and NNH for a given treatment, clinicians can assess the risk-benefit balance and also benchmark the treatment effects of the new therapy against other treatments used in contemporary cardiovascular practice. Another useful metric is to express the outcome for every 1000 patients treated.

The NNT (or NNH) should be interpreted in the context of the time frame of the trial. For example, in patients with an acute coronary syndrome (ACS) undergoing percutaneous coronary intervention (PCI), use of prasugrel instead of clopidogrel over 14.5 months is associated with an NNT of 46 (to prevent one

event of CV death, MI, or stroke) and NNH of 167 (to cause one excess major bleed)[31] (see **Chapter 62**). Use of rosuvastatin (versus placebo) in apparently healthy persons with a low-density lipoprotein cholesterol less than 130 mg/dL but elevated C-reactive protein level is associated with a 5-year NNT value of 20 (to prevent one event of MI, stroke, revascularization, or death)[32] (see **Chapter 45**). In some therapies, the balance of NNT and NNH is even more complex, because a treatment may have an early hazard (e.g., cardiac surgery versus PCI) but may be more effective over time[33]; the balance of NNT and NNH also may vary according to the baseline risk at the time of randomization.[34]

The interplay of variables set by investigators during the design of a clinical trial, the characteristics of the patients studied, and the features of the treatment being investigated influence the relative difference in events in the treatment groups (**see eFig. 5.5**). The interface of the patient and the treatment may change over the course of exposure to the treatment (e.g., lower risk of events over time as the patient moves from the acute to chronic phases of a disease), and background therapy also may change during the course of the trial (e.g., with treatments added or removed or doses modified). Although these considerations can influence the likelihood of a "positive" trial, they also have an impact on the ability to detect a signal of harm (**eFig. 5.6**).



EFIGURE 5.6 Number needed to harm. The relationship of the event rate in the control group and the relative risk of cardiovascular events with the treatment being investigated determines the number of patients who need to be treated with the drug to observe one cardiovascular event (number needed to harm). The surface generated can be used to understand the relative ease or difficulty of detecting a signal of harm with a particular treatment (e.g., cyclooxygenase inhibition). (Reproduced with permission from Antman EM, DeMets D, Loscalzo J. Cyclooxygenase inhibition and cardiovascular risk. Circulation 2005;112:759.)

Future Perspectives

Trialists, peer reviewers, and journal editors now have checklists and templates that codify the reporting of clinical trials (**eTable 5.1**). Clinicians can refer to guides for reading and interpreting clinical trials[35]

(**Table 5.5**). These advances, however, deal only with clinical trials that reach the point at which they are reported in a publicly available format. Considerable concern has been expressed in the past that some clinical trials, especially those with negative results, were never reported. The introduction of a requirement to register clinical trials in an online repository (e.g., Clinical Trials.gov) was an important step forward, but specific details typically are limited on such postings. Requirements that clinical trials post a final study report within a reasonable period after study completion (1 year) will assist investigators planning future trials, clinicians seeking the latest information about treatments, and writing committees charged with creating guidelines documents who need up-to-date and complete data to formulate recommendations.[36]

TABLE 5.5

Questions to Ask When Reading and Interpreting the Results of a Clinical Trial

Are the Results of the Study Valid?
Primary Guides
1. Was the assignment of patients to treatment randomized? 2. Were all patients who entered the trial properly accounted for and attributed at its conclusion? a. Was follow-up complete? b. Were patients analyzed in the groups to which they were randomized?
Secondary Guides
1. Were patients, their clinicians, and study personnel "blind" to treatment? a. Were the groups similar at the start of the trial? b. Aside from the experimental intervention, were the groups treated equally?
What Were the Results?
1. How large was the treatment effect? 2. How precise was the treatment effect?
Will the Results Help Me in Caring for My Patients?
1. Does my patient fulfill the enrollment criteria for the trial? If not, how close is my patient to the enrollment criteria? 2. Does my patient fit the features of a subgroup in the trial report? If so, are the results of the subgroup analysis in the trial valid? 3. Were all the clinically important outcomes considered? 4. Were important concomitant treatments described? 5. Are the likely treatment benefits worth the potential harm and costs?

Modified from material in Guyatt GH, Sackett DL, Cook DJ. The medical literature: users' guides to the medical literature. II. How to use an article about therapy or prevention. A. Are the results of the study valid? JAMA 1993;270:2598; Guyatt GH, Sackett DL, Cook DJ. The medical literature: users' guides to the medical literature. II. How to use an article about therapy or prevention. B. What were the results and will they help me in caring for my patients? JAMA 1994;271:59; and Stanley K. Evaluation of randomized controlled trials. Circulation 2007;115:1819.

ETABLE 5.1

Checklist of Information for Inclusion in Reports of Clinical Trials

Introduction
Clear statement of a priori hypothesis and specific research objective(s)
Methods
Study as designed; include:
1. Planned study population, including controls
2. Inclusion and exclusion criteria
3. Planned subgroup analyses
4. Prognostic factors that may affect study results
5. Outcome measures and minimum difference(s) to be considered clinically important
6. Planned treatment interventions
7. Method of assignment of subjects to treatments (e.g., randomization method, stratification blinding or masking procedure, matching criteria)
8. Planned sample size, power calculations
9. Use of data safety and monitoring board and rules for stopping the study
10. Methods of statistical analysis in sufficient detail to permit replication
Results
Study as conducted; include:
1. Inclusive dates of accrual of study population
2. Sample size achieved
3. Report of extent of follow-up
4. How many subjects were excluded or withdrew and the reasons
5. Demographics and clinical characteristics of the study population, including controls
6. How the study as conducted deviated from the study as planned and the reasons (e.g., compliance)
Study findings; include:
1. Cohorts analyzed (e.g., intention to treat)
2. Estimates of treatment effects, stated as comparisons among treatment groups (e.g., differences in risks, rates, or means of outcome measures, as well as exact *P* values, not just $P < 0.05$)
3. Measures of precision for outcome measures and for estimates of treatment effects (e.g., confidence intervals)
4. Summary data and appropriate descriptive statistics
5. Complications of treatment
6. Repository where original data can be obtained
Discussion
Interpretation of study findings
Results considered in the context of results in other trials reported in the literature

Modified from Working Group on Recommendations for Reporting of Clinical Trials in Biomedical Literature. Call for comments on a proposal to improve reporting of clinical trials in the biomedical literature. Ann Intern Med 1994;121:894; and Stanley K: Evaluation of randomized controlled trials. Circulation 2007;115:1819.

Additional directions for RCTs in the future include (1) involving patients in structuring research questions assessing the value of health care options,[37] (2) engaging community representatives in the planning of trials (community-based participatory research),[38] (3) using a patient's electronic medical record and longitudinal registries to embed randomization between treatment options,[3,7,36] and (4) using biomarkers, enrichment strategies, and adaptive designs more frequently as precision medicine approaches to development of new therapies become more established[3,39] (**Fig. 5.6 and eFig. 5.7**).

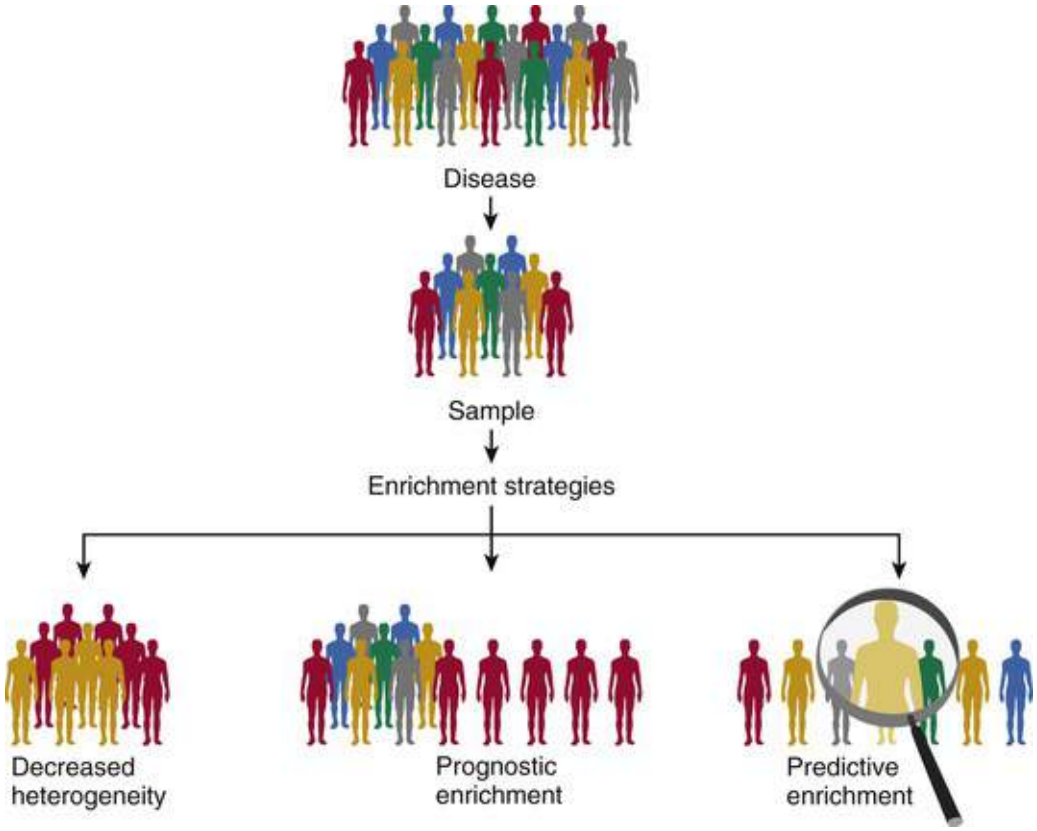


FIGURE 5.6 Enrichment strategies for clinical trials. From the whole population of patients with the disease of interest (e.g., hypertension), the investigators enroll a cohort of subjects (*sample*) that they hope are representative of the distribution of such patients in the broad population. Enrichment strategies to decrease the heterogeneity of the sample or to increase the representation of subjects with a high risk of events (*prognostic enrichment*), although facilitating the conduct of the trial, do not necessarily offer greater precision in matching a prospective treatment response to the clinical profile of the research subject. The predictive enrichment strategy utilizes both the characteristics of the trial subject and the data either from experiments before the trial or from during the trial (adaptive design) to "predict" who is likely to have a more robust response to the treatment(s) being tested. (From Antman EM, Loscalzo J. Precision medicine in cardiology. Nat Rev Cardiol 2016;13:591-602.)

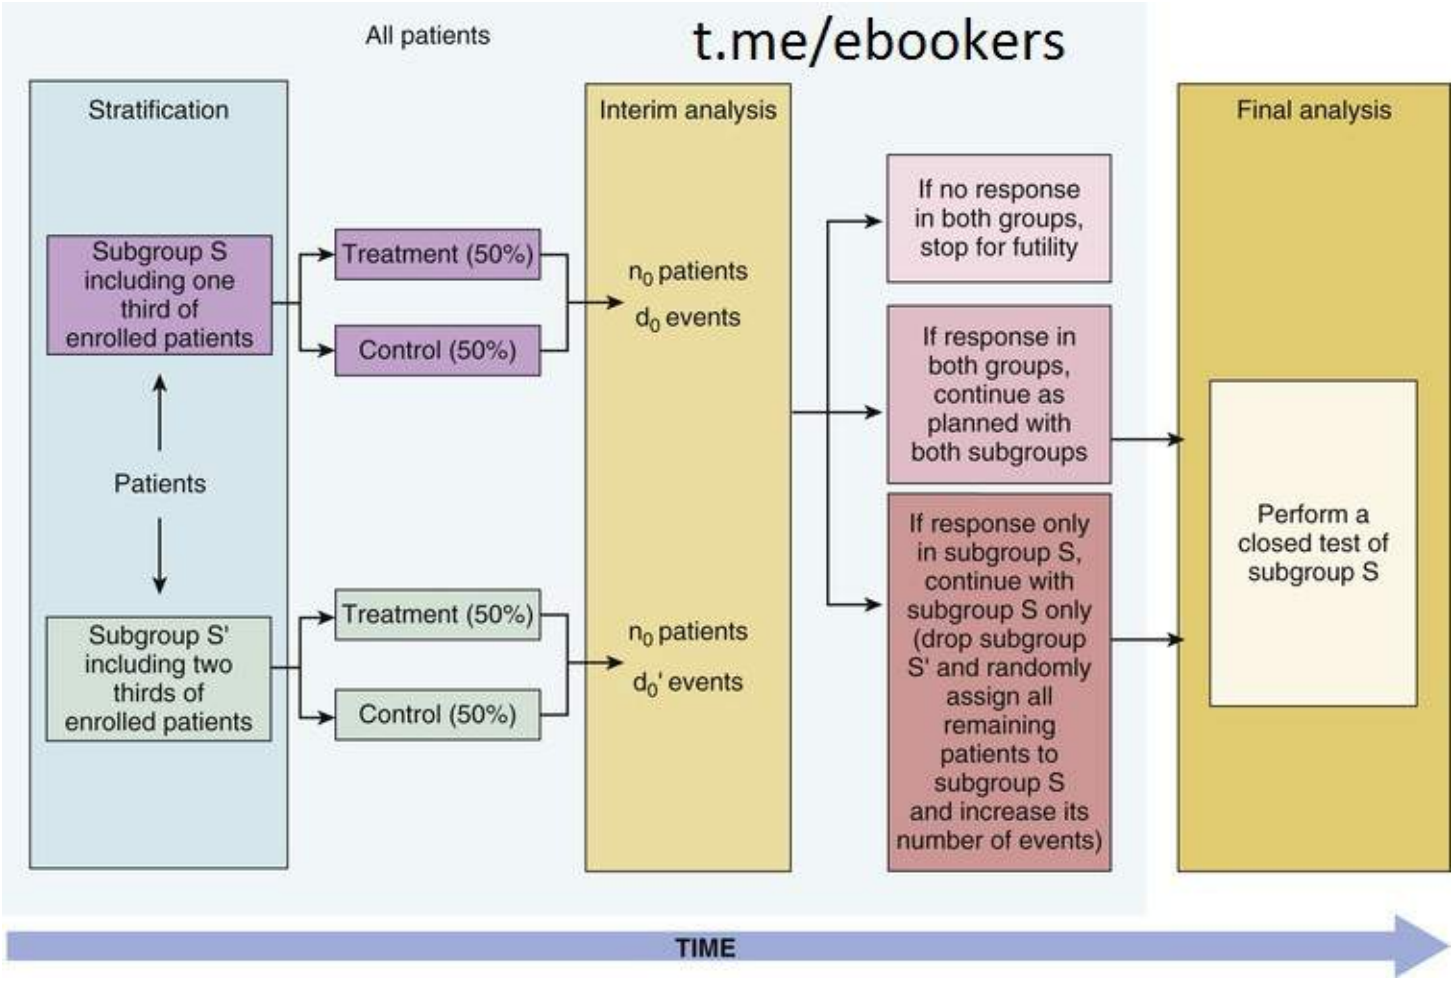

EFIGURE 5.7 Schematic representation of an adaptive two-stage population-enrichment design. The population is stratified before randomization into two subgroups, S and S′, according to a binary biomarker. The interim analysis occurs when a specific number of patients (n_0) have been enrolled in each subgroup. At that time, there will be a specific number of events in each group: d_0 events in subgroup S and d_0' events in subgroup S′. The data are then examined, and the trial may be terminated for futility, continued as planned, or continued by enrolling patients only in subgroup S. In this design, there is a biologic basis for assuming that the biomarker may be predictive of response in subgroup S but not in subgroup S′. The purpose of the interim analysis is to verify whether this assumption is true and if so, to enrich the remainder of the trial with patients from subgroup S only. (From Bhatt DL, Mehta C. Adaptive designs for clinical trials. N Engl J Med 2016;375: 65.)

Missing Data

Missing data present a serious challenge to analysis of trial results. Depending on the mechanism leading to the missing data, the information is considered in one of three categories: (1) missing completely at random, where “missingness” is unrelated to the study (e.g., flood destroys case report forms); (2) missing at random, where the characteristics of the subject can account for differences in the distribution of missing data (e.g., elderly subjects have more missing visits than younger subjects); and (3) missing not at random, where “missingness” depends on the value of the missing observation. The last category is especially problematic because it is likely to be informative and nonignorable—for example, subjects assigned to the test intervention are more likely to have side effects and to drop out of the study.[1] Biostatisticians advise against using simple adjustment methods for dealing with missing data (e.g., analyzing only subjects who complete the trial, or a single imputation such as carrying the last observation forward). They recommend instead using statistical models based on the data and performing sensitivity analyses to examine the robustness of the trial findings.[1]

PART II
Genetics and Personalized Medicine

OUTLINE

6

Personalized and Precision Cardiovascular Medicine

Calum A. Macrae

The Core Concepts of Personalized and Precision Medicine

In many ways, medicine has always been personalized. Every therapeutic relationship has at its core the implicit trust that the outcome will be tailored to the patient's personal needs. At this level, *personalization* incorporates all the nuance and mystery of the patient-healer partnership and is unlikely ever to be replaced by a purely data-driven algorithm.

Over the last few decades, since the advent of molecular medicine, there have emerged several discrete terms for the prevailing vision of therapeutic intervention tailored to the biology of the individual patient. These terms have included *predictive*, *personalized*, *individualized*, and *stratified*, as well as several others.[1] A number of related concepts in which the analytic component is emphasized, such as *P4* (predictive, preventive, personalized, and participatory) *medicine*,[2] *systems medicine*, and *network medicine*, have also gained traction.[3] In essence, these terms all reflect the same fundamental set of goals: medicine that is informed by the biologic state of the individual patient rather than by aggregate or averaged information from a representative population or cohort. The central assumption is that the more

precisely defined the mechanism of any diagnosis or intervention, the more precisely the physician will be able to predict and modify the relevant outcomes. This tenet recently has been embodied in governmental programs, including the President's Precision Medicine Initiative in the United States and Personalized Medicine or Stratified Medicine consortia in other countries.[4,5] Increasingly, these initiatives all recognize that the rigor necessary for such individualized approaches demands active patient engagement at every stage, from data collection and discovery science through intervention and behavioral modification.

Ultimately, the specific terminology employed is less relevant than the goal of the approach: a probabilistic understanding of the fundamental mechanisms of health and disease, with a shared and evolving knowledge base around which patients and their health care teams can maintain wellness and heal disease.

Among the basic requirements for precision medicine are rigorous quantitative models of disease mechanisms, responses to therapy, and outcomes, all at multiple scales.[1,3,6] In current practice, predictive computational models are almost completely restricted to research venues, but as rigorous data accumulate in electronic medical records and other implementation systems, clinical medicine will adopt more of the principles of engineering and related applied sciences.

At present, remarkably few diseases permit generation of quantitative models that fully capture disease causation, diagnosis, and therapeutic outcome.[7] Numerous reasons contribute to this information deficit. In most instances, epidemiologic studies have had to focus on legacy data types defined decades earlier and to study disease entities already known to be aggregates across multiple discrete mechanisms, unified often only by the low biologic resolution of clinical imaging or biomarkers.[8] Although there are general population estimates of the relative contributions of genetic or environmental risk factors and stochastic factors in different disease syndromes, there are few situations where the predictive utility of such estimates is adequate to drive clinical decision making.

The lack of patient-level predictive utility for most modern diagnostic paradigms is a function of the broad range of pretest probabilities in which testing is deployed, the low specificity of most biomarkers outside very specific contexts, and underlying etiologic heterogeneity. Tests with excellent characteristics in one setting are often deployed erroneously in other settings. Genetic studies also support the presence of confounding factors in current diagnoses, with the majority of cardiovascular syndromes exhibiting remarkable *genetic* heterogeneity (multiple different causal genes) and *allelic* heterogeneity (high proportion of new variants in known disease genes).[9] Together, these findings suggest that our etiologic models for many major cardiovascular disorders fail to account for substantial genetic and environmental contributions.[10]

Clinical and translational science has necessarily emphasized later-stage phenotypes that are more readily correlated temporally with outcomes. Even in prevention, however, our ability to move to proximate causes has been limited. Traditional risk factors in many cases may simply reflect early disease manifestations or shared upstream mechanisms rather than true predictive antecedents. The magnitude of the biologic effect size of traditional or genetic biomarkers is probably the most important discriminant of clinical utility but is rarely measured across lifetimes in the general population.[11] Composite genetic risk scores for common disorders such as diabetes and atherosclerosis add only incremental information,[12] whereas even in single-gene disorders with uniform etiologic mechanisms, substantial effect sizes, and high penetrance, it can be difficult to predict discrete, clinically meaningful outcomes such as sudden death. The disconnect between population predictors and individual utility is another consequence of missing data and highlights a central inference of precision medicine: the need to collect biomedical data on a completely different scale. To realize fully the potential benefits of precision medicine, much more

comprehensive datasets must be collected in much larger cohorts and across lifetimes (**Fig. 6.1**).

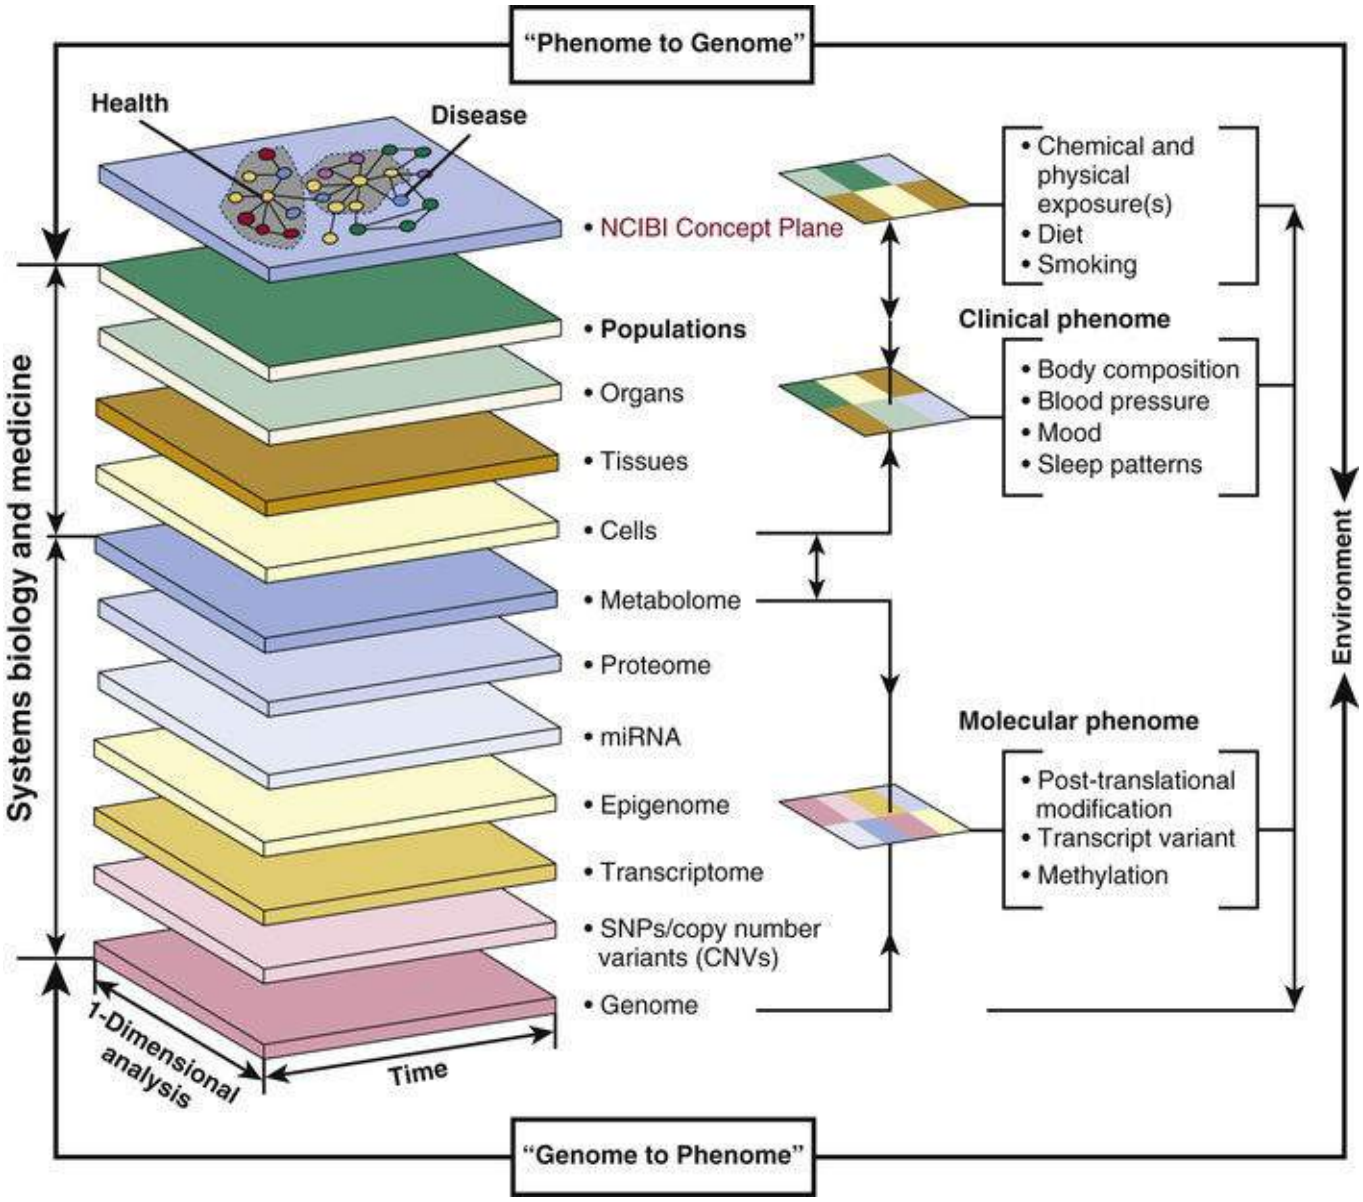

FIGURE 6.1 Systems medicine: layers of data. An infinite number of data layers can likely inform clinical medicine. Creating the informatic frameworks to understand how these datasets interact and how they can impact care, as well as defining those data necessary for decision making, will be a major undertaking that will determine the success of precision medicine. *NCIBI,* National Center for Integrative Biomedical Informatics; *SNPs,* single-nucleotide polymorphisms.

Genetics

The cardiovascular arena has seen much work on the practical application of genetics, including understanding complex paroxysmal phenotypes, such as arrhythmias and sudden death, which have challenged the ability to resolve traits into their constituent components.[13] The long tradition of physiologic measurements and classic risk factor epidemiology in cardiovascular research has also facilitated large genotype-phenotype correlation studies as genomic technologies have become available (**see Chapter 7**).

Large extended families, with what in retrospect seems to be relatively exceptional penetrance, have been the focus of pioneering work in the identification of causative genes and in ongoing efforts to define

disease mechanisms.[9] However, more typical families have inherited contributions to disease that are smaller and considerably less informative. Indeed, spurious "mutations" have proliferated, often in spurious disease genes, based on simple "guilt by association," without rigorous demonstration of mechanistic involvement.[14,15] Even mutations definitively characterized as "causal" in one family may have no discernible phenotype in another family or when seen in the general population, as recently demonstrated in population cohorts.[16,17] Differences in clinical manifestations may reflect differences in sensitizing genetic modifiers or in environmental exposures, but these mechanisms have proved difficult to establish in all but a few cases. Such observations emphasize the importance of developing approaches that allow clinicians to establish a mechanistic role for specific variants in individual patients if genetics is to influence clinical care in precision medicine. Although we have gleaned great etiologic insights from classic mendelian genetics, using simple genotypes to specify diagnoses or to drive therapies in individual patients is, at present, far from reality.

The limits of genotype-phenotype correlation are most obvious in disorders in which profound selection pressures drive elevated de novo mutation rates, often in multiple highly conserved genes, with consequent allelic and genetic heterogeneity. In some cases the imprecise relationship between genotype and phenotype may reflect real differences in the mechanism of action of different variants within the same gene. In severe congenital heart disease, where the survival of the organism during the neonatal period is at risk, despite familial recurrence rates consistent with single genes of large effect size,[18] few if any cases have a "sufficient and necessary" genetic explanation.[19] In this setting, gene-gene or gene-environment interactions are often cited as possible mechanisms for this discordance, but usually without empiric evidence.

Whole-genome or whole-exome approaches reveal the true scale of the genotype-phenotype conundrum, typically generating numerous potential causal variants in the absence of any systematic approaches to understanding which of the variants is causal.[20] Without probabilistic indices of causality, it will be difficult to define disease mechanism, identify novel drugs, and successfully render medicine precise.[6] Conditioning environmental stimuli (intra- and extra-uterine) are almost invariably unknown and unmeasured, which amplifies these limitations.[21] Where genetic selection pressures are less acute (e.g., coronary artery disease, hypertension), in addition to unmeasured environmental factors, the aggregation of different etiologies and the low specificity of negative diagnoses make clinical genetic interpretation challenging.

A rigorous bedside family history can identify potential disease risk and may allow the clinician to discriminate between environment and inheritance from the patterns of transmission. When undertaken systematically across patient cohorts, family history can also assist in the quantitative estimation of heritable and acquired contributions to disease architecture. The advent of the electronic health record (EHR) has diminished the quality of family and exposure data collection, although the success of precision medicine will depend on this information.[5,22] Eventually, relatedness will be estimated on measured genotypes, and heritability could be directly assessed from the EHR.

Similarly, exposures must be measured with quantitative rigor to define fully the role of *environment* in disease causation, prognosis, and therapy. Personal devices, detailed nutritional intake, and microbiota, among many other datasets, will eventually stream into medical records. The scale of investment necessary to capture and integrate this missing information is unlikely to be duplicated outside the EHR, supporting the eventual integration of care and discovery in a single system.

Genomics and Functional Genomics

The development of modern technologies for affordable and efficient genotyping of millions of variants in a single experiment led to the emergence of the *genome-wide association study* (GWAS)[23] (**see Chapters 7 and 45**). Large cardiovascular population studies and clinical trial datasets have been recast in terms of life-long exposure to particular genotypes. These techniques have identified hundreds of loci contributing to numerous continuous traits, from plasma lipids to electrocardiographic parameters. Binary phenotypes such as atrial fibrillation and myocardial infarction have also been successfully studied. Importantly, for the vast majority of identified GWAS loci to date, the underlying mechanism of their contribution to disease is unknown, at least partially reflecting that in most cases these alleles explain only a modest proportion of the observed heritable variance for the trait.[10] Exceptions to this rule typically reflect limited effects of the disease on reproductive efficiency.[11] Gene-gene or gene-environment interactions are rationally invoked as explanations for the "missing heritability," but few efforts have directly tested whether these mechanisms are important for most traits. Ever larger GWASs seem unlikely to address these concerns, not least as a result of the failure to resolve underlying heterogeneity, but also because the scale of study required to understand multiple interacting loci of small effect size is prohibitively expensive. In addition, a plausible alternative model for the source of missing heritability are alleles that are simply unmeasured because of limited phenotyping or a dependence on unknown conditioning variables. The adoption of more rigorous, proximate quantitative phenotypes and an approach to the objective measurement of environmental factors would leverage, through greater cohort homogeneity, much of the unrealized potential of modern genomics.[8]

Genomic measures of common variation have considerably greater predictive rigor than the highly pleiotropic mendelian variation. However, current limitations for this purpose are the lack of lifetime risk prediction models, the incremental nature of the genetic information over traditional risk factors, the very modest effect sizes, and the consequent absence of mechanistic discrimination. GWAS data may be useful for the evaluation of potential therapeutic targets identified by other means or for the assessment of potential pharmacologic safety concerns.[24]

One important attribute of a genome is its *completeness*. Indeed, at present, genomics represents one of the few accessible comprehensive datasets for an organism. As a result, genomics may well prove a useful organizing framework for much of biology and medicine, long before the data are reduced to practice. Genomic sequencing, if performed at birth or even earlier, not only could orchestrate the prioritization of collection for phenotypic data, but also would enable risk-driven preventive care in areas with no biomarkers, the efficient study of disease alleles in relevant model organisms, and the development of patient-specific narratives for lifetime disease.

Other "-Omic" Technologies

Genomic technologies have spawned parallel approaches to the collection of large and unbiased datasets in other areas of biology, including transcriptomics, metabolomics, proteomics, lipidomics, and metagenomics (**see Chapter 9**). Large-scale RNA sequencing has enabled the characterization of the true extent of transcription across the genome.[25] The massive complexity added to the output of each gene through differential splicing of different protein-coding exons or RNA regulatory exons and RNA editing adds new dimensions to the traditional exome.[26] However, the observation that much of the noncoding genome is also actively transcribed and has diverse functions through microRNAs, long intervening noncoding RNAs, and effects on access to DNA or RNA binding sites has changed the conceptual framework of how the genome functions.[25] Other regulatory RNAs, complex intermediates, and

exogenous sequences also exist, although their functions may be less obvious. Some of these represent the products of microbial commensals from skin, gut, or elsewhere, and DNA and RNA sequencing has begun to explore the complexities of the microbiome in health and disease.[27]

Improvements in quantitative mass spectrometry and new technologies such as aptamers (oligonucleotide-based reagents) are beginning to make rigorous proteomics a reality, but the vast differences in relative abundances of some proteins continue to hinder the field. Aptamer technologies may help overcome some of these limitations.[28] Mass spectrometry is also revolutionizing the ability to measure a wide range of physiologic small molecules, lipids, and metabolites.[29] Some of these molecules have been shown to mediate interactions between microbiome and host in the setting of chronic vascular disorders.[27] However, by their nature, each of these datasets remains less comprehensive than a genome.

Avenues already exist to move functional genomic technologies toward diagnostic and therapeutic use, but realizing their full utility requires much more rigorous understanding. As massively parallel datasets are collected and studied, it will also be vital to build dynamic time series in the context of structured perturbations. These perturbations might include standardized environmental, nutritional, or drug challenges. In addition, it will be necessary to understand fluxes between discrete tissue or cellular compartments. In most instances, there are very few data on interacting molecules, highlighting the need for much broader application of identified molecular components in individual classes and emphasizing the central role of systems or network biology in deciphering this new biology.[1,3] Despite some remarkable insights from functional genomics, the incorporation of new profiling technologies into the clinical arena has been slow, largely because of appropriate concerns regarding the need for robust validation through prospective approaches. It is difficult to see how traditional study designs can be appropriately scaled. Full exploitation of these approaches will require building investigative platforms that allow the study of integrative biology in large populations and in multiple different disease states.

Drug Responses and Pharmacogenetics

The effectiveness of a timed and structured challenge to assess the “state” of a complex system has been recognized in cardiology for decades (e.g., fluid challenges to assess hemodynamics). The dynamics of drug responses are among the most rigorously studied inherited traits, since the presence of a perturbation improves the power of most genetic analyses. Moreover, most drugs currently used have known major targets, so pharmacogenetic studies are often more efficiently validated. Despite these observations, the clinical collection of drug response data remains sparse, and the use of pharmacogenetics in clinical practice is rare outside of oncology (**see Chapter 8**).

Several factors have conspired to delay the routine implementation of pharmacogenetics. First, in most cases the drug responses themselves are reasonable surrogates for acute “on-target” efficacy or toxicity, and pharmacogenetic endpoints have not included mortality or morbidity.[30,31] Second, the turnaround time for genetic testing is usually discordant with clinical decision making, as in acute coronary syndromes where the use of higher doses or alternative agents to overcome potential hazards with clopidogrel in specific CYP2C19 genotypes precluded widespread use of genotyping.[32] Obviously, genome sequencing at birth and prospective lifetime analyses would resolve many of these concerns.

The real power of genetics is the unambiguous identification of causal mechanisms. An understanding of “mechanism” transforms the ability to discover and develop new drugs or therapies. Genetic-model organisms have had remarkable success in rare diseases but are not yet available for most common disorders that afflict humans. A major outcome of precision medicine might be the identification of novel

disease biology and thus new therapeutic targets.[8,33]

The identification of new targets through precision medicine would herald the need to transform the current approaches to drug discovery. When integrated with the evolving scientific fields of high-content, phenotype-driven screening and target identification, it will become increasingly feasible to use disease itself as the effective target in drug discovery, rather than one specific pathway downstream in the causal chain.[34,35] Innovation must change the scale and efficiency of drug discovery by almost an order of magnitude if society is to be able to afford precision medicine. Similarly, creative reappraisal of regulatory approaches in drug development would be necessary for the efficient introduction of novel precision therapies.[36] Without precision therapy, precision medicine will have limited effect.

Missing Data: What Is Needed for Precision

A refrain that emerges from precision medicine is the limited nature of data collected in the traditional clinical system. The massive complexity of genomic or functional genomic data contrasts with the modest scale even of the sum of all assays performed in clinical medicine. Deconvoluting the information content embedded in functional genomics requires a substantial change in the scale of modern clinical assessment. However, this shift must not jeopardize the patient-physician interaction (**Table 6.1**).

TABLE 6.1

Data Scales for Clinical Medicine and Genomics

DATA TYPES	DATA SCALE ESTIMATES	METADATA	RELEVANT DATA STANDARDS
History	10^3	No	Tradition but subjective
Physical examination	10^2	No	Largely subjective
Clinical testing	10^4	Few	Objective but few standards
Metabolomics	10^2	No	Emerging
Whole genome	3.0×10^9	N/A	Yes
RNA sequencing	$\approx 10^{18}$	Yes	Yes
Proteomics and post-translational modifications	$\approx 10^{20}$	Yes	Emerging
Cellular connectome	$>10^{69}$	Not yet	None

The clinical history must become more structured, focused on the individual, and rigorously documented. Simply digitizing the traditional cross-sectional retrospective history will not suffice. Ideally, personal histories would include long-term symptom trajectories, symptomatic correlates of objective responses to standardized dynamic challenges, quantitative data on prior exposures, and personal reference data on these same parameters.

In parallel, the core physical examination itself must be modernized. Defining a digital “physical exam” with sufficiently rigorous representation of the core systems and low enough cost for universal implementation is a priority for precision medicine, but has only begun to emerge as a focus through efforts in phenotype ontologies. Genome structure could act as a core comprehensive dataset, but others might include lifetime digital morphometry and wearable or portable technologies focused on quantitative cellular or molecular phenotypes. Ultimately, most data collection will be ambient, with parallel acquisition of metadata, including the administration of specific challenges (e.g., nutritional, pharmacologic). Short-term goals for modern medicine might include detailed lifetime trajectories for a shared set of representative orthogonal phenotypes—a computable physical examination in which deviations from normal would be readily detectable by existing technologies.

Expansion of the scope of phenotyping would extend the power of extant genotypic data and would allow stratification before the introduction of comprehensive functional genomics (**Table 6.2**). Another

rationale for these strategies is the assumption that, in conjunction with complete genomes, more rigorous phenotyping facilitates real-time modeling of disease, whether in silico or in animals. Disease modeling will be further refined by the incorporation of perturbations that can be uniformly applied to model systems and patients alike. A mechanism-centric conceptual framework could facilitate bringing the definition of causation, biomarker, or drug discovery and even drug development to the level of the individual patient or family.[37]

TABLE 6.2

Ideal Phenotype Characteristics

TRADITIONAL PHENOTYPES	PRECISION PHENOTYPES
Intuitive or serendipitous	Unbiased
Qualitative	Quantitative
Static	Dynamic
Few metadata	Dense metadata with translatable stimuli
Cross-sectional	Continuous
Final common pathway	Predisease
Limited translatability	Translatable by design

Integrating Discovery and Care

A major consequence of increasingly comprehensive strategies for the collection of genomic data, phenotypes, and environmental exposures across entire populations and over lifetimes will be the ability to approach gene-gene, gene-environment, and other complex interactions (e.g., host-commensal communication) in a rational manner. This scale of endeavor will require reimagining the clinical and the research enterprise. Indeed, the traditional division between these two spheres of activity will increasingly become blurred in what are currently imagined as “learning health systems.” The prevalent concept is that embedding data collection and data analytics in the EHR would enable real-world experimentation, even including randomization, to explore previously inaccessible questions.[38] Ultimately, the modular addition of new data acquisition tools and new implementation or care delivery platforms might evolve to the point where those elements of care amenable to algorithmic management extend beyond professional involvement, and professional activity would be fully integrated with discovery and translational science. Sharing quantitative genotypic, environmental (including pharmacologic), and phenotypic vocabularies will allow the various communities within biomedical science to work more cohesively.

Barriers to Precision Medicine

Several barriers currently impede the broad implementation of precision medicine, requiring substantive change to realize its full potential (**Table 6.3**). To resolve even one disease with all its complexities to the level of mechanism for a specific patient will require substantial societal changes in attitude toward the use of data in health care. Ultimately, personal control of information may be the most effective solution to many of the extant hurdles.

TABLE 6.3

Barriers to Precision Medicine

AREA OF ACTIVITY	BARRIERS	POTENTIAL OR EMERGING SOLUTIONS
Evidentiary framework	Cost of generating traditional evidence Lack of familiarity with technologies Few RCTs Wide range of risk and benefit	Cost reductions Education Real-world RCTs Alternative trial designs
Phenotypic data collection	Haphazard, serendipitous Legacy data types Few metadata Cross-sectional data collection	Fully embedded in clinical systems Phenomes by design Molecular interventions as metadata Ambient data collection/public engagement
Genomic data collection	Largely research-based reporting Cost Few metadata Limited evidence base	Development of rigorous reporting standards Cost reductions Parallel development of phenome science Development of rigorous evidence base
Data structure	Current EHRs limited in scope Legacy data architecture Data architecture institution-centric	Comprehensive personal records New data types Patient-centric architecture
Data sharing	Security risks Data provenance Privacy/HIPAA Lack of perceived value	Rigorous security and audit Data escrow Reevaluation of privacy trade-offs Objective evidence of value to individual
Analytics	Lack of availability in EHR Limited probabilistic models Lack of provider familiarity Lack of patient engagement	Creation of platforms on top of EHRs Development of probabilistic decision support Adaptive education for patient and provider
Data display	Massive growth in data density and data velocity Legacy data formats Mismatched provider training	Reimagining data display and workflow together across care redesign Investment in user interface development “On the fly” decision support
Clinical adoption and implementation	Legacy workflow Lack of evidence of clinical utility Limited perceived value Limited technical understanding Vested interests Perception of organizational intransigence	Comprehensive care redesign Test genomics in relevant clinical contexts Develop evidence of value Genome as part of the physical exam Care models outside traditional medicine Lay/patient engagement
Education	Rote learning overwhelmed Limited informatics training Decade-scale education cycles	Transition from rote learning to data science Rigorous informatics training Real-time adaptive learning
Regulation	Anchored in traditional evidence base Emphasis on population risk/benefit	Ongoing regulatory innovation Incorporation of individual risk/benefit
Reimbursement and funding	Cost of innovation and new technology Lack of perceived value No rigorous models for comprehensive testing with need for continuous reporting Limited revenue stream diversity	Reduction in cost Definition of added value Moving beyond transactional reimbursement Payment models outside traditional medicine Diversification of revenue streams
Ethics	Caution due to perceived determinism Professional practice restrictions; “turf wars” Archaic innovation cycle	Education for providers and patients Elimination of “genetic exceptionalism” Real-world implementation in clinical context

EHRs, Electronic health records; *HIPAA,* Health Insurance Portability and Accountability Act; *RCTs,* randomized controlled trials.

The goal of any precision medicine platform must be the development of biological frameworks for diagnosis and decision making, which cannot be achieved with the limited information content of the current EHR. Requirements for data collection, aggregation, management, and display will be incorporated in systems focused on the individual, with individual responsibilities, as with most activities outside health care. Data scientists predict that “learning health systems” will extract information from the perturbations of routine care. The deployment of such capabilities will require completely different information systems architecture than current platforms, which focus largely on provider transactions.

Compared with the enormous datasets in almost every other venue of daily life, the identification of environmental factors for understanding health and disease has progressed slowly. Exploiting data from numerous contexts in people's lives may seem like a forceful intrusion, but these approaches are commonplace in commerce or financial security and will be essential to dissect disease mechanisms.[39] Incorporating new data into the health care system will require investment in infrastructure, analytics, and security.

The exponential growth in knowledge implicit in precision medicine will also require new strategies for the management and display of information. One of the most important challenges in precision medicine is the balance between large-scale data collection across time, or across populations, and the highly specific data needed to define the current biological state in an individual. Navigating these distinctions will require a clinical workforce trained in information science.

As clinical care and discovery become more tightly integrated, so too professional and patient education must transform. The need for the collection and display of "just-in-time" information in every encounter will require adaptive learning platforms. Finding ways to incorporate rigorous data collection with high-impact education in the midst of routine care is a central design issue in precision medicine and will require leveraging the EHR for truly meaningful use.[40]

With these disruptive changes, it will be vital not to discard the "ground truth" in medicine painstakingly assembled over the years, while avoiding the urge to uphold the shibboleths of medicalization. Bringing scientific rigor to entire populations will require careful mapping of genomics and novel phenotypes onto existing frameworks. In the clinical arena, it will be important not to replace empathic physician-patient relationships with bland digital encounters. Rather, the seamless upload of objective information at scale will facilitate the elimination of the "provider as data-entry clerk" that has accompanied the implementation of EHRs, thereby promoting true professional-patient interactions.

Many of the hurdles to the implementation of precision medicine result at least in part from the intransigence of different constituencies within the current system. Numerous vested interests must adapt if precision medicine is to succeed, including the organization of the professional workforce. The interdependencies implicit in precision medicine will require the addition of new skills to medicine, new team structures, and new training paradigms.

Future Perspectives

Earlier diagnosis and therapy will lead health systems to reach back into ever-younger populations, with the latest sequencing technologies promising whole-genome coverage before birth. A convergence of technologies, new drugs, big data, and innovation from every other sphere of life together with societal pressures will push medicine to focus on *wellness*, with the goal of detecting and intervening at the first deviation from this state. The discrete steps to achieve broad implementation of precision medicine are not yet obvious. Cardiology, with a long history of successfully pivoting from late-stage disease toward progressively earlier intervention and prevention, is well positioned to lead precision medicine.

Principles of Cardiovascular Genetics

Kiran Musunuru, Sekar Kathiresan

As physicians, we seek to understand the root cause of human disease. Human genetics provides a unique tool for generating new hypotheses about the root causes of disease based on genome-wide searches in the human population that avoid prior assumptions about the underlying pathophysiologic processes. Over the past several decades, application of the principles discussed here has successfully identified the

causative genes for a range of cardiovascular diseases. This information has provided explanations to our patients, improved the ability to predict risk for disease, and most importantly, enabled understanding of the pathophysiology as a foundation for designing rational approaches to improving prevention and therapy.[1] This chapter reviews the principles of human genetics used to make gene discoveries and to translate these findings to improve patient care. We highlight these principles in the context of a clinical case presentation.

Inherited Basis for the Variation in Risk for Cardiovascular Disease

Patient Case, Part I.

A 44-year-old man (JS) presents to a cardiologist's office for a follow-up visit after an ST-segment elevation myocardial infarction (STEMI) and treatment consisting of primary angioplasty and placement of a drug-eluting stent. His cardiovascular risk factors before STEMI included a fasting low-density lipoprotein cholesterol (LDL-C) level of 235 mg/dL and active cigarette smoking. His body mass index (BMI) is 25 kg/m^2, he does not have a history of type 2 diabetes, and he is normotensive. His father died at 45 years of age as a result of myocardial infarction (MI), and his paternal uncle had an MI at age 49. He has two brothers, 43 and 39 years old; both are free of clinical cardiovascular disease. The 43-year-old brother (KS) has an elevated LDL-C level (214 mg/dL). The 39-year-old brother (LS) has an LDL-C level of 130 mg/dL and a high-density lipoprotein cholesterol (HDL-C) level of 29 mg/dL. **Fig. 7.1** shows the family pedigree.

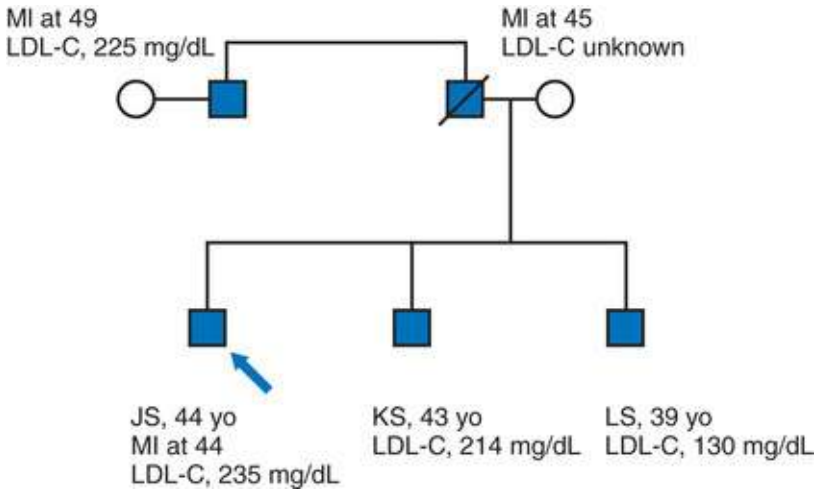

FIGURE 7.1 Pedigree of the case patient JS (indicated by the *arrow*), who had a STEMI when he was 44 years old (yo).

Many cardiovascular diseases cluster within families, and studies of familial aggregation can determine the extent to which inherited DNA sequence variants contribute to these patterns. A family history of premature coronary heart disease (CHD) elevates the risk for CHD in offspring approximately threefold.[2] Family history is an important risk factor for almost every cardiovascular disease, including atrial fibrillation, congenital heart disease, and hypertension, but familial clustering of disease can reflect shared environment in addition to shared genetic sequence.

Heritability—the fraction of interindividual variability in risk for disease attributable to additive

genetic influences—is a commonly used measure for isolating the role of shared genetic sequence. The remaining variability among individuals results from all other contributors: environmental influences on disease, nonadditive (*epistatic*) genetic effects (e.g., gene-gene interactions or gene-environment interactions), error in the measurement of relatedness or disease, and random chance. For most clinically important traits (diseases and risk factors), empiric estimates of heritability range from 20% to 80% (see Online Mendelian Inheritance in Man, available at www.ncbi.nlm.nih.gov:80/entrez/query.fcgi?db=OMIM, for comprehensive information).

A Brief Primer on Molecular Biology

Genes are encoded in DNA, a polymeric molecule with two strands in a configuration known as a double helix. The "code" comprises four different DNA bases—adenine (A), cytosine (C), guanine (G), and thymine (T)—linked together in nonrandom order. The two strands contain redundant information by virtue of complementarity—an adenine on one strand is always paired with a thymine on the other strand, and a cytosine on one strand is always paired with a guanine on the other strand. Thus double-stranded DNA consists of a sequence of A-T, T-A, C-G, and G-C base pairs (**Fig. 7.2**).

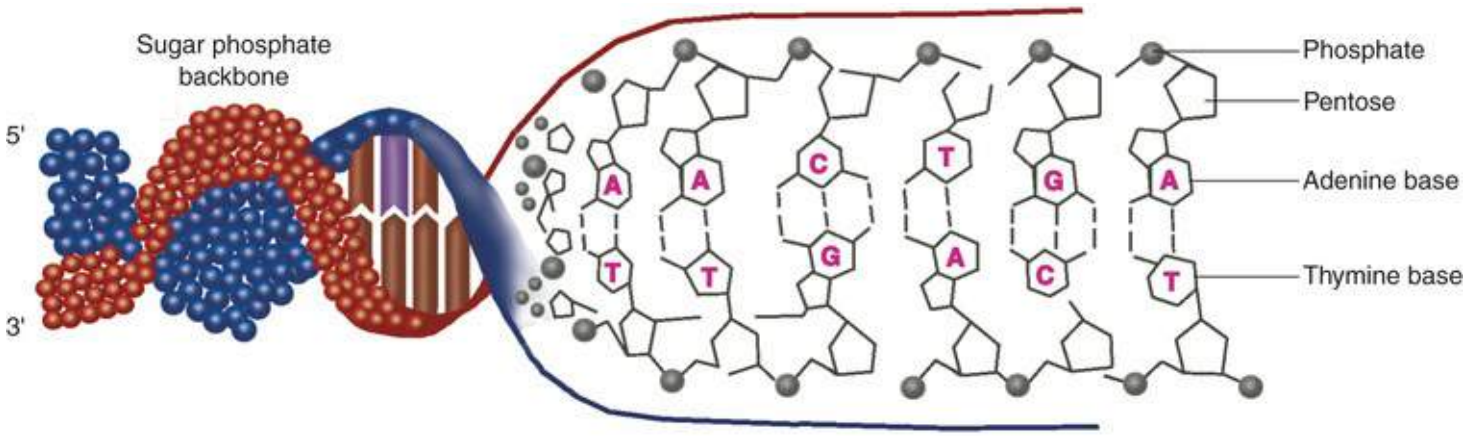

FIGURE 7.2 Schematic representation of the DNA double helix. The specificity of genetic information is carried in the four bases—guanine (G), adenine (A), thymine (T), and cytosine (C)—that extend inward from a sugar phosphate backbone and form pairs with complementary bases on the opposing strand.

Human DNA is organized into a total of 23 pairs of chromosomes, with each chromosome spanning millions of base pairs. The 46 chromosomes in total make up the genome. Each chromosome has numerous genes, which contain so-called coding DNA, separated by large stretches of noncoding DNA. A process called *transcription* copies the information in the DNA sequence into a single-strand coding RNA, also called a messenger RNA or mRNA, a polymer that is structurally similar to DNA but uses uracil (U) in place of thymine (T). Subsequently, the process of translation converts the mRNA sequence into an amino acid sequence that makes up a protein, which can serve in a variety of roles (e.g., structural elements, enzymes, hormones). Thus, genetic information flows from DNA to RNA to protein in what is classically known as the "central dogma" of molecular biology (**Fig. 7.3**).

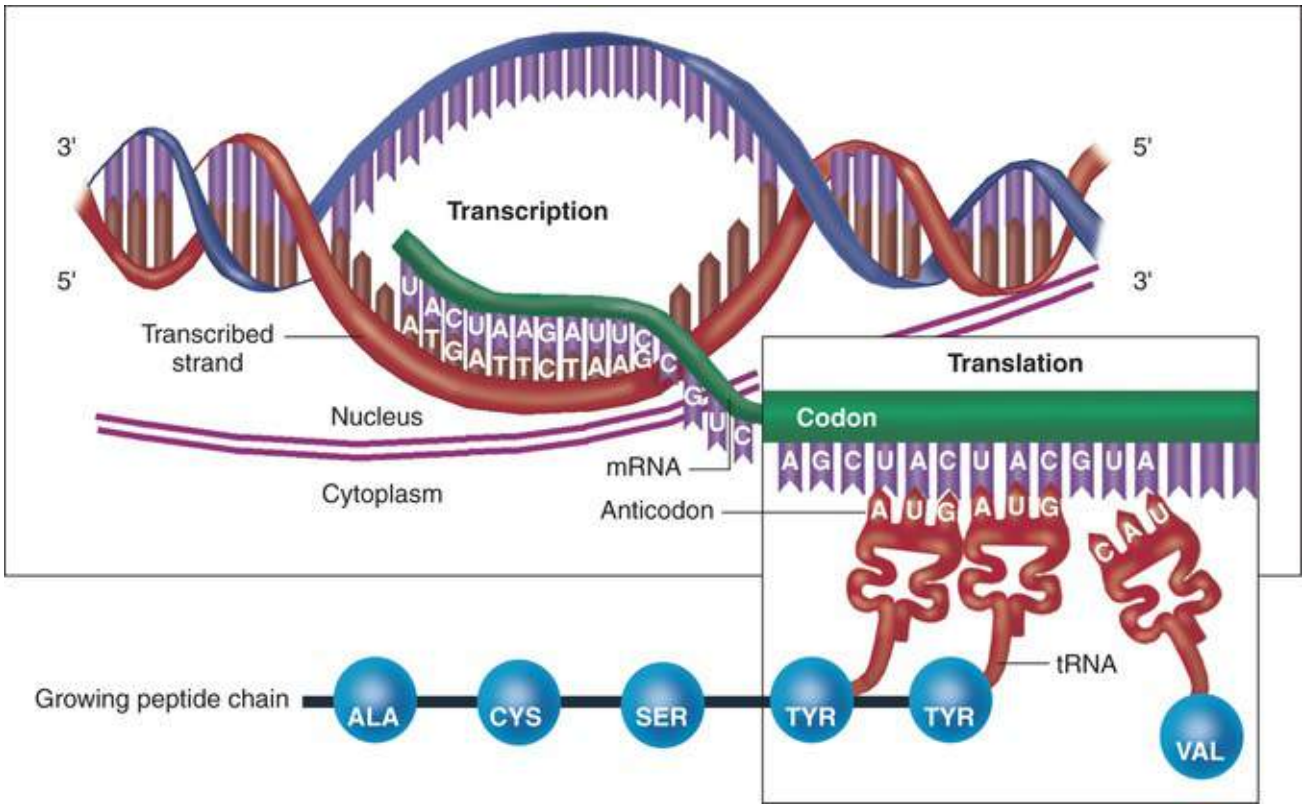

FIGURE 7.3 Flow of genetic information. Transcription in the nucleus creates a complementary RNA copy from one of the DNA strands in the double helix. mRNA is transported into the cytoplasm, where it is translated into protein.

According to the central dogma, a change in the DNA sequence in the genome, if it should occur in or near a gene, can result in a change in the protein encoded by the gene, which in turn can have important consequences on the phenotype of an organism. *Phenotype* refers to any observable characteristic in a human. Changes in DNA sequence leading to phenotypic changes underlie most of the heritability of diseases that have a genetic component.

Epigenetics pertains to phenotypic changes caused by external factors in addition to altered DNA sequence that influence the process of gene transcription. These factors can result in altered levels of RNA being transcribed from the DNA, which in turn result in altered levels of protein. In some cases, parents can transmit the epigenetic changes to offspring and thus represent an additional source of phenotypic heritability. Epigenetic changes include DNA-level modifications that do not involve the DNA sequence itself. The most common such modification is methylation of cytosine bases, which generally results in reduced transcription or “silencing” of a gene.

Within a chromosome, the DNA molecule coils in a complex known as *chromatin*, which includes a group of proteins called *histones*. The configuration of these histones around the DNA molecule can change through structural modifications (e.g., acetylation or deacetylation of certain amino acids), making an area of a chromosome more “open” or “closed” to transcription. Consequently, the genes within that area of the chromosome may undergo increased or decreased transcription.

Epigenetic mechanisms also include factors external to the DNA and chromatin that affect the transcription and translation of genes. In addition to genes, the genome harbors thousands of expressed RNA molecules that do not code for protein; such noncoding RNAs (ncRNAs) include microRNAs and long ncRNAs. The ncRNAs, particularly long ncRNAs, can regulate transcription through several mechanisms, including interactions with the cell's transcriptional machinery and with histone-modifying enzymes. ncRNAs also interact with and modulate the activity of mRNAs, thereby regulating protein amounts. For example, microRNAs physically bind to complementary sequences in mRNA molecules and

result in either suppression of RNA translation into proteins or degradation of the mRNAs.

Modes of Inheritance

The “genetic architecture” of a disease refers to the number and magnitude of genetic risk factors that exist in each patient and in the population, as well as their frequencies and interactions. Diseases can result from a single gene (*monogenic*) in each family or from multiple genes (*polygenic*). Identifying genetic risk factors is easiest when only a single gene is involved and this gene has a large impact on disease in that family. In cases in which a single gene is necessary and sufficient to cause disease, the condition is termed a *mendelian* disorder because the disease tracks perfectly with a mutation (in the family) that obeys Mendel's simple laws of inheritance.

For monogenic disorders, modes of inheritance include autosomal dominant, autosomal recessive, and X-linked. In autosomal dominant disorders, a single defective copy of a gene (either the maternal or paternal copy for every autosomal gene) suffices to cause the phenotype. In autosomal recessive disorders, both copies need to be defective to lead to the phenotype. In X-linked disorders, the defective gene resides on the X chromosome. Given that men have only one X chromosome and women have two X chromosomes, men who carry the defective copy are affected with the disorder, whereas women are unaffected carriers.

Most common cardiovascular diseases, however, do not obey Mendel's simple laws of inheritance but rather are complex—the result of an interplay between multiple genes and the environment. These polygenic disorders require variants in more than one gene to cause a disease. Accordingly, in these cases it becomes difficult to understand a disease by studying a single family. A corollary is that each contributing gene variant may have a small phenotypic effect that is not obvious by comparing a few people with and without that variant. For these reasons, elucidating the genetic architecture of a complex disorder is more feasible by studying a large population.

The patient case presented earlier describes both *discrete* cardiovascular phenotypes (i.e., traits defined by their presence or absence based on a set of criteria) and *quantitative* phenotypes. MI is a discrete (also called *dichotomous*) phenotype, whereas blood pressure, LDL-C, HDL-C, and BMI are continuous cardiovascular traits. In the general population, most of these traits display a complex pattern of inheritance.

For many complex traits, however, some subtypes of the disease are monogenic in inheritance. In our patient case, the co-occurrence of high LDL-C, early-onset MI, and a family history of premature MI suggests a specific mendelian disorder, namely, *familial hypercholesterolemia* (FH).[3] In FH the extremely high LDL-C level and MI result from defects in the LDL receptor gene. Severely high LDL-C and early MI can also be caused by defects in other genes, including proprotein convertase subtilisin/kexin type 9 (*PCSK9*) and apolipoprotein B (*APOB*). Other examples of monogenic subtypes of complex traits include extremely high or low blood pressure caused by rare mutations in genes involved in renal salt handling; extremely low LDL-C as a result of mutations in *APOB*, *PCSK9*, or *ANGPTL3*; and extreme obesity caused by mutations in *MC4R*.

Approaches to Discovering the Inherited Basis for Cardiovascular Disease

Human Genetic Variation

The human genome contains about 6 billion base pairs across the 46 chromosomes. Only about 1% of the genomic DNA actually encodes the estimated 20,000 genes in humans.[4] Although all humans share most of the DNA in the genome, variations in the DNA sequence—occurring in both coding DNA and noncoding DNA—distinguish individuals from one another. These DNA sequence variants partly account for why a disease is more or less likely to develop in some individuals or why some respond more favorably or more adversely to a medication (**see also Chapters 6 and 8**).

As alluded to earlier, some DNA sequence variants have large phenotypic effects, meaning that they can cause disease singlehandedly. These DNA sequence variants tend to be rare (and sometimes unique to a single person or family) because natural selection weeds them out of a population. Classically, they cause monogenic disorders. Other DNA sequence variants commonly occur in a population and tend to have smaller phenotypic effects. Typically, such variants, in combination, cause polygenic disorders. Because of natural selection, in general there is an inverse relationship between the frequency of a DNA sequence variant and the phenotypic effect conferred by that variant. For example, such a relationship applies to gene variants that affect LDL-C in the population[5-8] (**Fig. 7.4**).

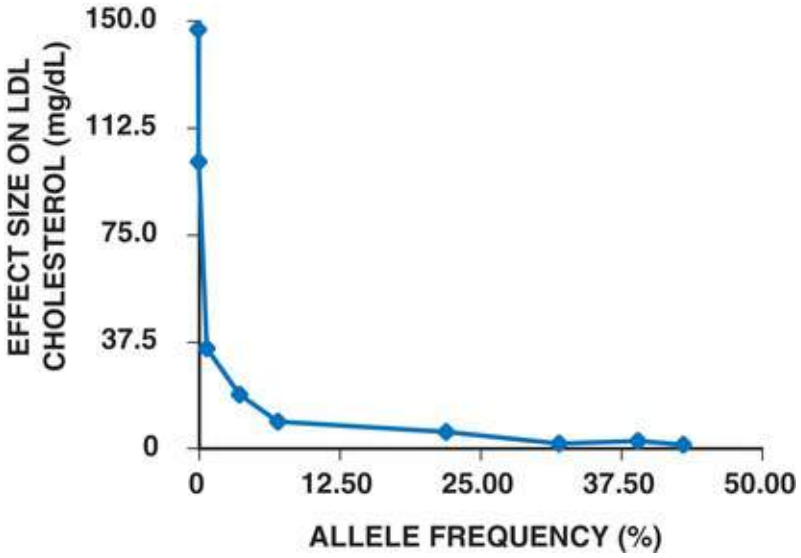

FIGURE 7.4 Effect sizes on LDL-C for DNA sequence variants at a range of allele frequencies. Gene, variant, frequency, and effect size on LDL-C are as follows: *NPC1L1*, rs217386,[5] 43%, 1.2 mg/dL; *HMGCR*, rs12916,[5] 39%, 2.5 mg/dL; *ANGPTL3*, rs2131925,[5] 32%, 1.6 mg/dL; *SORT1*, rs629301,[5] 22%, 5.7 mg/dL; *APOE*, rs429358/C130R,[6] 7.1%, 9.3 mg/dL; *APOE*, rs7412/R176C,[6] 3.7%, 18.8 mg/dL; *APOB*, R3500Q,[7] 0.08%, 100 mg/dL; *LDLR*, W23X or W66G or W556S,[8] 0.03%, 147 mg/dL.

Coding-sequence variants potentially disrupt the function of genes and their protein products[9] (**Fig. 7.5**). Some coding variants do not affect the amino acid sequence of a protein; such "synonymous" variants generally cause no phenotypic consequences. Other coding variants can cause a variety of alterations in a protein—substitution of a single amino acid in a protein with a different amino acid (*missense*), premature truncation of a protein (*nonsense*), scrambling of the amino acid sequence past the site of the variant (*frameshift*), or insertion or deletion of amino acids. Any of these so-called nonsynonymous variants can have phenotypic effects ranging from negligible to profound, although nonsense and frameshift variants tend to be more deleterious than missense variants to protein function. Also, sequence variants at splice sites (the first and second bases after the end of each exon and before the beginning of each exon) can lead to a severely disrupted protein product missing a domain encoded by

an entire exon.

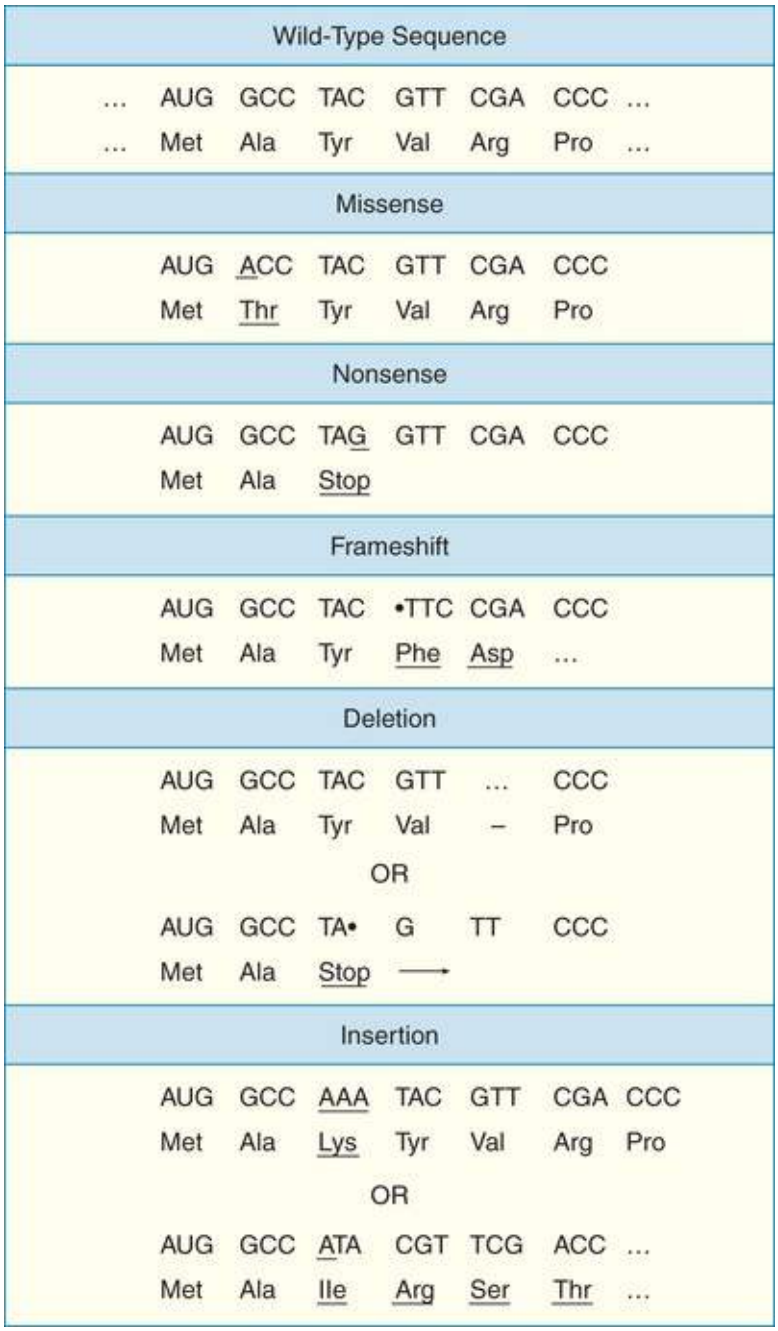

FIGURE 7.5 Different types of mutations that alter the structure and expression of human genes.

Noncoding variants, although they do not directly affect the amino acid sequences of proteins, can cause phenotypic changes in other ways. For example, a noncoding variant near a gene might affect transcription of the gene and result in an increased amount of RNA being produced from a gene, and consequently an increased amount of the protein product.[10] Noncoding variants can affect the processing of RNA in other ways; for example, a noncoding variant that falls in the midst of a microRNA sequence might impair or enhance the microRNA's ability to interact with specific mRNAs and thus result in phenotypic changes.

DNA sequence variants, also known as *polymorphisms* (from the Greek, “multiple forms”), consist of three major classes. *Single-nucleotide polymorphisms* (SNPs) involve the alteration of a single DNA base pair in the genome. SNPs are the most common and best cataloged of the DNA variants, with tens of millions having been identified to date across all human populations. *Variable number tandem repeats*

(VNTRs) involve a variable number of repeats of a short DNA sequence at a genomic location; the number of repeats ranges from very few to thousands. *Copy number variants* (CNVs) involve a variable number of repeats of a long DNA sequence (>1000 base pairs), typically ranging from zero to one or a few repeats. An *indel* (insertion/deletion) is a type of DNA variant in which a sequence is either present (insertion) or absent (deletion); it could be either a special type of a VNTR or a special type of a CNV, depending on the size of the involved sequence.

Characterizing Human Genetic Variation: Genotyping and Sequencing

In most cases a person has two copies of each DNA sequence because of the presence of paired chromosomes (the exceptions are DNA sequences on the X or Y chromosome in men, because these two chromosomes are entirely different). The two copies are known as *alleles*. For a DNA variant, the *genotype* is the identity of the two alleles at the site of the variant. The two alleles may be identical, in which case the person is said to be homozygous for the allele. If the two alleles are different, the person is heterozygous at the DNA variant. A *haplotype* is a series of genotypes at nearby sites of DNA variants. Because the haplotype is located on a single region of the chromosome, it tends to remain linked together as it passes from parents to offspring.

For polymorphisms that are primarily present in just two forms (typical of SNPs, i.e., one DNA base versus another DNA base, but not for VNTRs, which are usually found in at least a few forms, i.e., different numbers of repeats), the allele found more commonly in a given population is termed the *major* allele, with the less common allele being the *minor* allele. Common variants are so defined by virtue of the frequency of the minor allele being greater than 5% in the population. Low-frequency variants have a minor allele frequency of between 0.5% and 5%; rare variants have less than a 0.5% frequency. Rare variants are typically referred to as mutations. In some cases, mutations are so rare that they are found only in one individual or in one family.

Two types of methods can be used to determine genotypes at the sites of DNA variants. In the first type, a genotyping technology directly ascertains the genotype at a single location in the genome. In the second type, polymerase chain reaction (PCR) is used to amplify the region of DNA immediately surrounding the site of the DNA variant (**Fig. 7.6**). The PCR product undergoes DNA sequencing, which indirectly determines the genotype. The first type is generally cheaper—indeed, fabricated “chips” can directly genotype millions of DNA variants at a time—but requires optimization beforehand. Thus direct genotyping is most useful for common and low-frequency variants that have already been cataloged. The second type is more expensive and can be used only at one location at a time, but it can be flexibly adapted to any location in the genome. This approach can be used to discover previously uncataloged, rare DNA sequence variants.

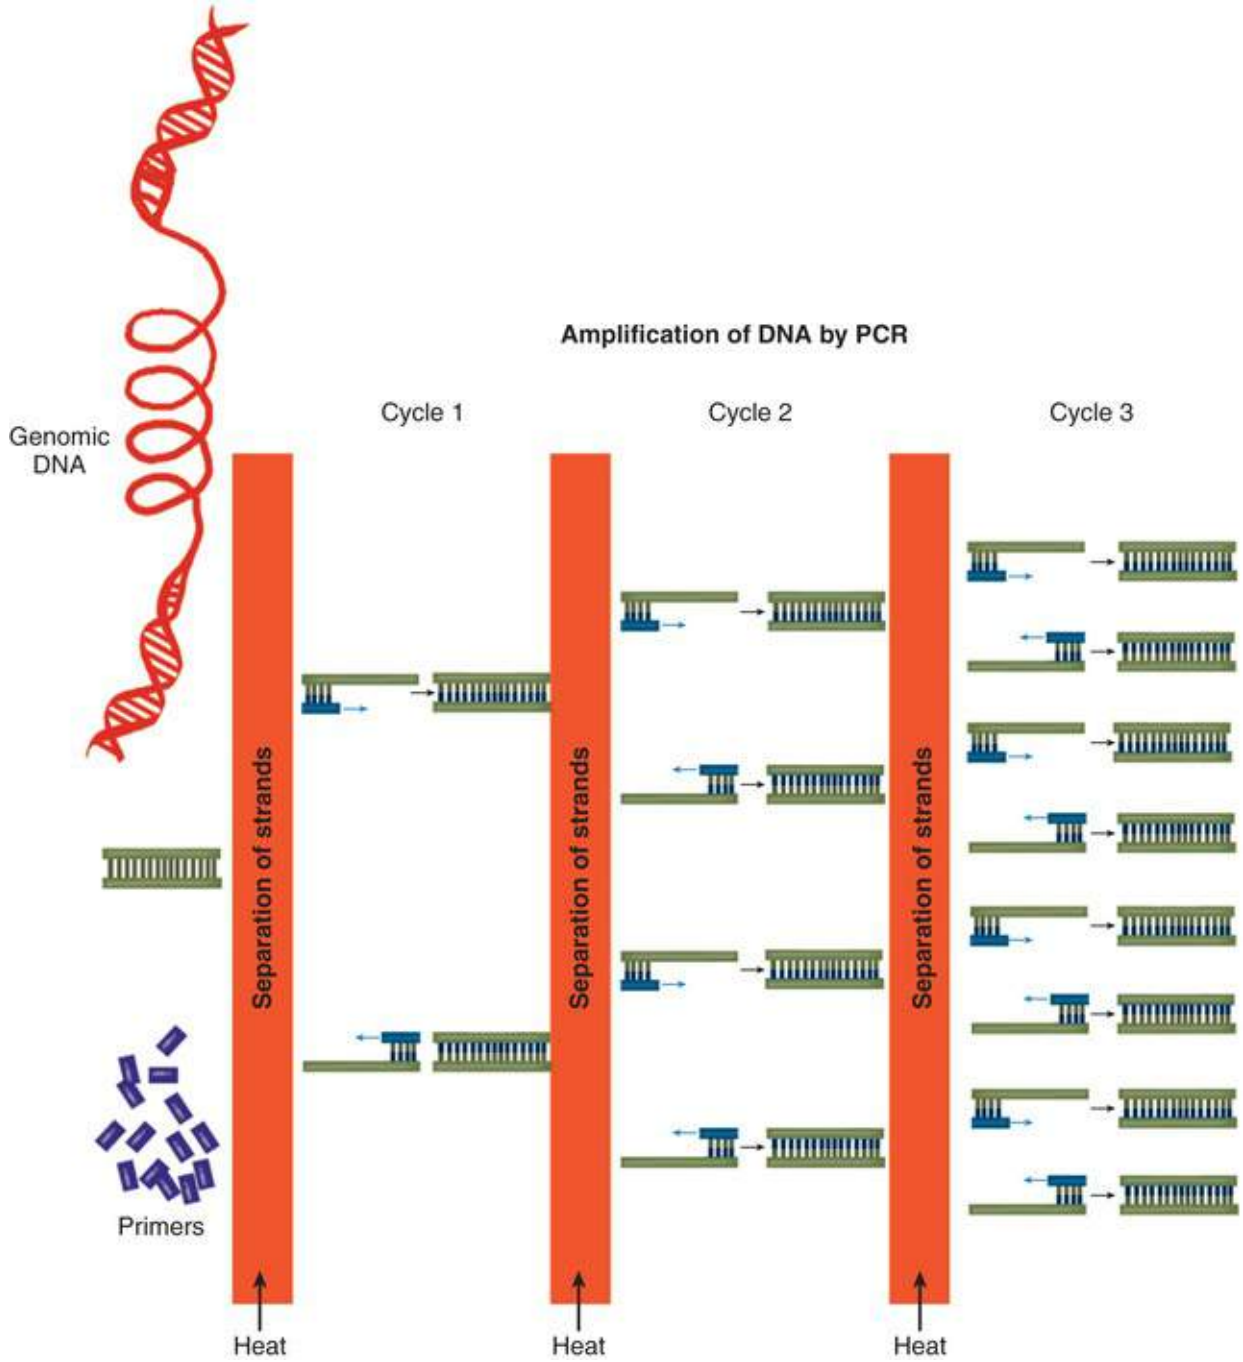

FIGURE 7.6 DNA amplification with PCR. Synthetic primers corresponding to the 5′ and 3′ ends of the DNA sequence are chemically synthesized. The double-stranded DNA is melted by heating to 95°C, followed by cooling to anneal the primers and then setting at 68°C to 72°C for optimal polymerase activity. A heat-stable DNA polymerase amplifies each strand of the target sequence, which produces two copies of the DNA sequence. The process is repeated multiple times to achieve amplification of the target sequence.

In recent years a third type of method has been devised to characterize a person's genetic variation. This method entails the use of any of a group of techniques known as “next-generation DNA sequencing.”[11] Although the operational details differ, these techniques share the ability to sequence billions of DNA base pairs at a time rapidly and at a reasonable cost. The techniques can sequence efficiently the entirety of a patient's coding DNA, known as the *exome*, which accounts for about 1% of the genome.[12,13] More recently, sequencing the entirety of a patient's genome for a few thousand U.S. dollars within 24 hours has become feasible, with the eagerly awaited “thousand-dollar genome” expected to emerge very soon.

Although performing DNA sequencing remains more expensive than direct genotyping, the decreasing cost of whole-genome sequencing will soon enable its application to large cohorts of people. Whole-

genome sequencing offers the advantage of determining genotypes at the locations of all known DNA sequence variants in a single experiment and simultaneously identifying the individual's possibly previously unknown DNA variants.

Study Designs to Correlate Genotype with Phenotype

Fig. 7.7 illustrates approaches to correlate genotype with phenotype. The *x* axis shows the frequency of the allele in the population, from rare to common; the *y* axis shows the size of the phenotypic effect conferred by the DNA sequence variant allele, from small to large. As described earlier, because of evolution and natural selection, an inverse relationship exists between allele frequency and effect size. Typically, to detect common DNA sequence variants of small to modest effect (e.g., increase in risk of 5% to 50%), genotyping characterizes the DNA sequence variation, and population-based association links genotype with phenotype. Rare variants with larger effect are discovered by sequencing to characterize their DNA sequence variation. One of two major approaches—family-based studies or extreme-phenotype studies—can be used to correlate rare variants with phenotype. Variants of low frequency (0.5% to 5%) can be approached by either genotyping or sequencing, and any of the three study designs may be useful in linking genotype with phenotype.

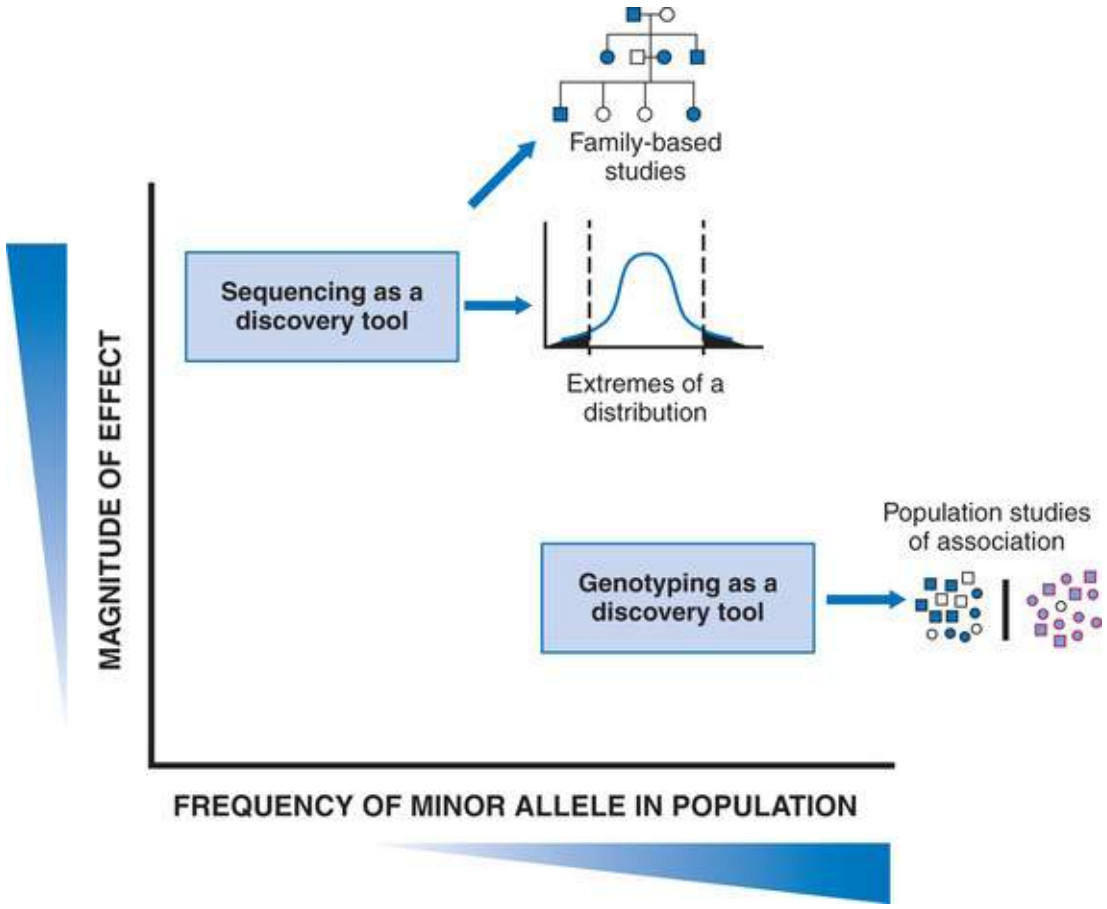

FIGURE 7.7 Approaches to correlate genotype with phenotype.

Family-Based Studies

Patient Case, Part II.

The cardiologist refers the 45-year-old patient (JS), who recently had an MI, to a geneticist for evaluation. The geneticist suspects that the patient has FH and arranges for clinical sequencing of the *LDLR*, *APOB*, and *PCSK9* genes. These tests identify a mutation in the *PCSK9* gene: a T → A substitution in exon 2 at nucleotide 625, which predicts a substitution of arginine at codon 127 for the conserved serine (Ser127Arg). This mutation causes gain of PCSK9 function and autosomal dominant hypercholesterolemia.[14]

Two major study designs serve to identify the gene mutations responsible for monogenic disorders. Both take advantage of family relationships. Classic *linkage* studies entail the genotyping of several hundred or thousand DNA variants (usually VNTRs with repeats that are two to six base pairs in length, also known as microsatellite markers) distributed across the genome. Linkage analysis identifies any markers that are strongly "linked" to the disease. For dominantly inherited disorders, linkage can be observed when one particular allele of the marker is found only in family members with the disease ("affecteds") and not in healthy family members ("unaffecteds"). For recessively inherited disorders, linkage is observed when two copies of a particular allele are found only in family members with the disease and not in healthy family members. The degree of linkage for each genomic marker with affected status is calculated to yield a metric known as the logarithm of odds (LOD) score. A LOD score higher than 3.0 is considered significant evidence of linkage.

As a practical matter, a high LOD score for a particular marker suggests that the causal disease mutation lies within several megabases (i.e., millions of base pairs) of the marker. This region of interest typically harbors dozens, if not hundreds, of candidate genes. The region can sometimes be narrowed further by genotyping a set of markers clustered around the original marker and assessing for linkage, a process called *positional cloning*. Identification of the disease mutation entails sequencing candidate genes in the hope of finding a rare coding variant. Traditionally, cost constraints prohibited sequencing of a large number of genes and forced judicious selection of a limited number of candidate genes thought most likely to have the causal mutation—an often fruitless approach.

Advances in next-generation DNA sequencing technologies have enabled a second study design. Rather than sequencing a few candidate genes, one can now perform *exome sequencing* and capture the coding DNA of all approximately 20,000 human genes in a single, relatively affordable experiment. In this study design, one chooses a few affected family members, performs exome sequencing on their DNA samples, and filters through the sequencing data to identify the handful of rare variants that all affected individuals share.[15] This list of variants can be narrowed down further in several ways, such as confirming that a variant is not present in unaffecteds or simultaneously performing a linkage study and filtering for variants that reside near a marker with a high LOD score.

Once the rare gene variant thought most likely to be the causal mutation is selected, it can be confirmed by sequencing the gene in unrelated individuals who have the same disorder. If some of these individuals have mutations in the same gene (either the same rare variant or, more likely, different variants), it strongly argues that the gene is responsible for the disease.

Extreme-Phenotype Studies

Study of individuals in a population who are at the extremes of a phenotype provides another approach to gene discovery.[16] For a quantitative phenotype such as blood cholesterol level, this undertaking might entail finding a sizable number of people with extremely high cholesterol and people with extremely low cholesterol. For a discrete phenotype such as MI, the desired individuals might be young people with premature disease versus elderly people with multiple risk factors but no evidence of coronary artery disease (CAD).

DNA samples from these extreme cohorts undergo either candidate gene sequencing, exome sequencing, or even whole-genome sequencing. The analysis entails identifying genes that have a preponderance of rare variants in one group versus the other group. For example, if a particular gene were to display a significantly higher frequency of rare variants in young people with MI than in elderly people without CAD, it would argue for that gene being causal for MI. Conversely, if the gene had a higher frequency of rare variants in elderly people without CAD than in young people with MI, the gene might protect against disease.

Population-Based Studies

Family-based studies lend themselves poorly to study polygenic disorders in which each contributing DNA variant has a small or moderate effect. Because these DNA variants tend to be common in a given population, population-based studies can more readily detect their small effects with statistical rigor.

The genome-wide association study (GWAS) is the primary population-based study design.[17,18] In a GWAS, DNA samples from many unrelated individuals in a population—as many as hundreds of thousands of people—undergo genotyping using chips of millions of SNP markers across the genome. The analysis entails a search for SNPs that have robust statistical associations with the phenotype of interest. For a GWAS on a quantitative phenotype such as blood cholesterol level, each SNP undergoes testing to determine whether individuals with one genotype at that SNP have on average a significant difference in cholesterol level from individuals with another genotype.

For a GWAS on a discrete phenotype such as MI, the study compares a group of individuals with the phenotype and a group of individuals without the phenotype (cases versus controls). Each individual SNP is evaluated to determine whether its minor allele frequency differs between the cases and controls (**Fig. 7.8**).

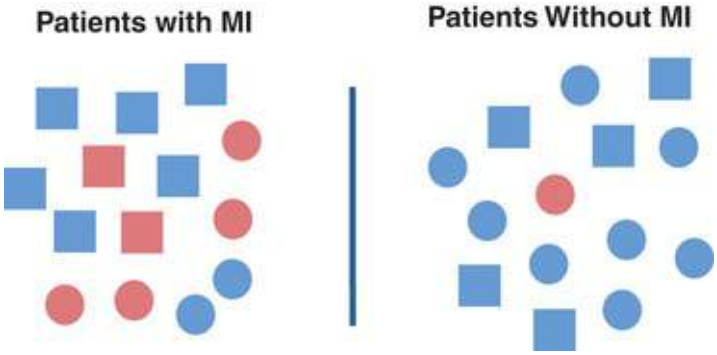

FIGURE 7.8 Analysis scheme for a GWAS involving a dichotomous phenotype. *Step 1:* Compare frequency of genetic variant in cases and controls. Carriers of a variant allele are shown in *pink* and noncarriers in *blue*. *Boxes* represent men and *circles,* women. Here the variant allele occurs more frequently in cases than controls. *Step 2:* For each genetic variant (typically 300,000 to 1 million in each experiment), generate *P* value for the difference in frequency being a chance observation.

Because GWASs evaluate many SNPs independently, the traditional statistical significance threshold of $P < 0.05$ requires adjustment for the number of SNPs tested. A GWAS typically tests about 1 million independent common SNPs. Accordingly, to minimize false-positive results, GWASs usually use a threshold for genome-wide statistical significance of $P < 5 \times 10^{-8}$ (i.e., Bonferroni correction of the traditional *P* value of 0.05 for 1 million independent tests). The need to meet a very rigorous significance threshold, as well as the small effects of most DNA variants that contribute to a polygenic trait, often dictates studying very large numbers of people to carry out a GWAS successfully.

GWASs typically display results in a “Manhattan plot,” with the *x* axis representing each variant in chromosomal order and the *y* axis plotting $-\log_{10}$ of the *P* value associating each variant with the trait of interest. **Fig. 7.9** displays the Manhattan plot from a large-scale GWAS for CAD that identified 25 chromosomal loci that achieved genome-wide significance.

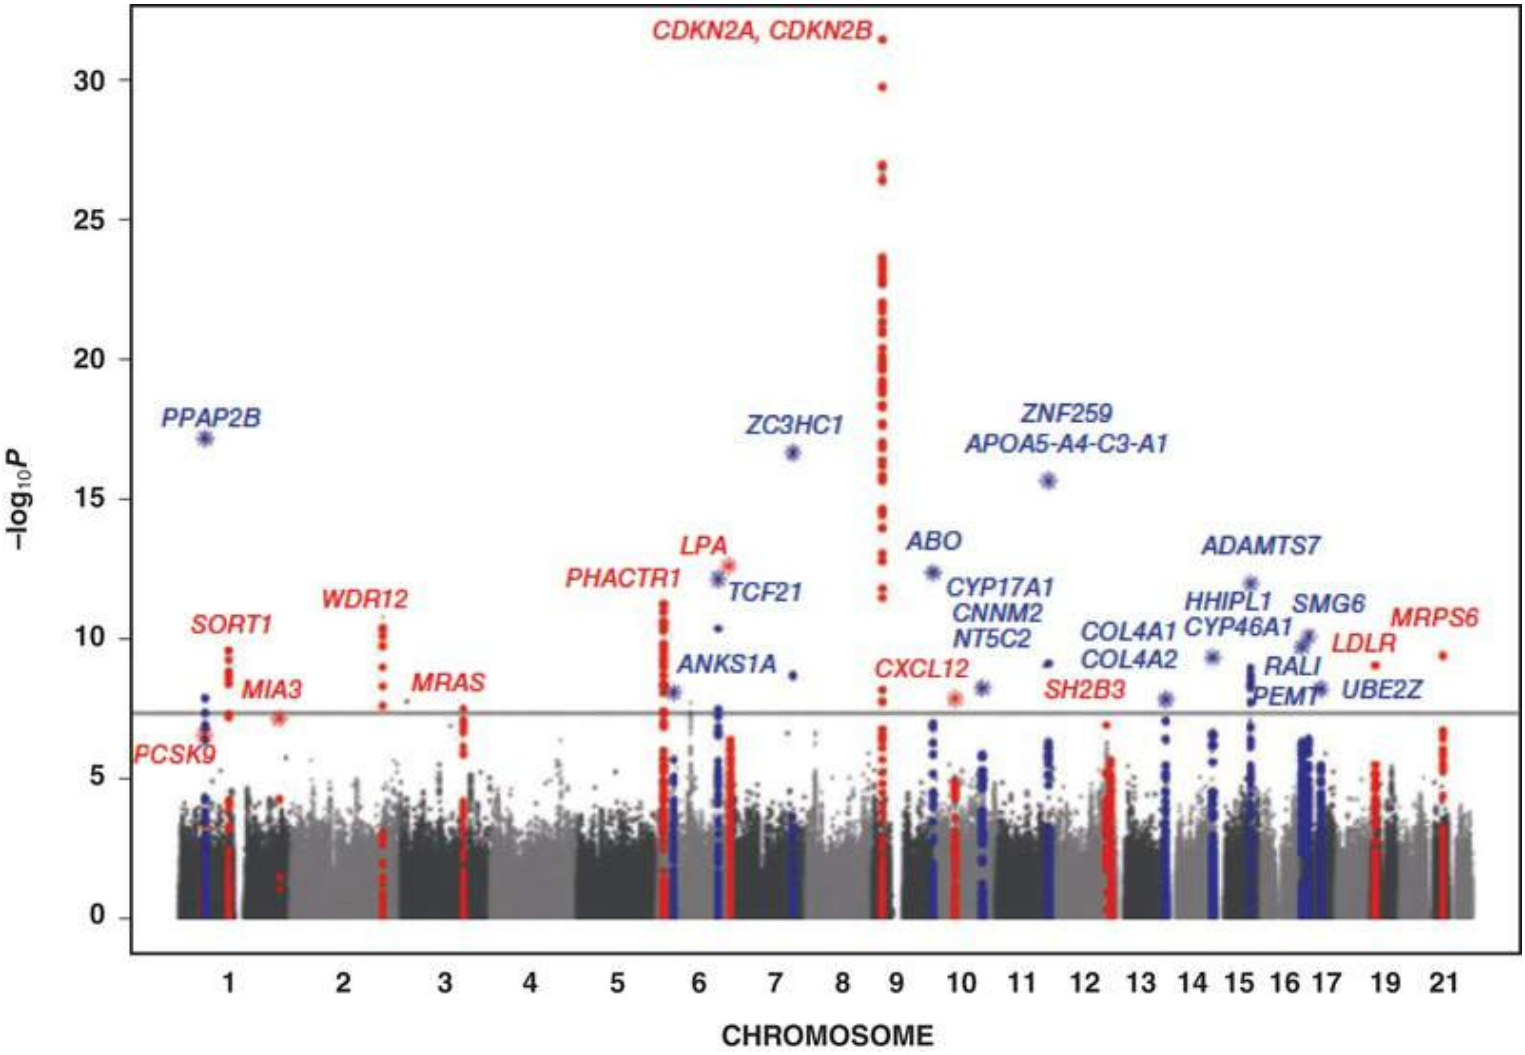

FIGURE 7.9 Graphic summary (Manhattan plot) of genome-wide association results. The *x* axis represents the genome in physical order; the *y* axis shows $-\log_{10}$ *P* for all SNPs. Data from the discovery phase are shown in *circles*, and data from the combined discovery and replication phases are shown in *stars*. Genes at the significant loci are listed above the signals. Known loci (before publication of this work) are shown in *red*, and newly discovered loci from this work are shown in *blue*. (From Schunkert H, Konig IR, Kathiresan S, et al. Large-scale association analysis identifies 13 new susceptibility loci for coronary artery disease. Nat Genet 2011;43:333.)

A GWAS uses a much denser distribution of markers across the genome and data from many more people than a linkage study does. Furthermore, a GWAS takes advantage of the genome's discrete recombination “hot spots,” between which regions of DNA remain relatively intact as they pass from parents to offspring. Consequently, a GWAS has much higher resolution than linkage studies; rather than megabases, the locus of interest is defined by flanking recombination hot spots, which on average occur just tens to hundreds of kilobases apart. For a given SNP with a positive association with a phenotype, this considerably narrows the number of candidate causal genes. Also in contrast to linkage studies, GWASs have successfully pinpointed noncoding causal DNA variants that affect gene expression.

Illustrative Examples

In presenting examples of the various approaches previously described, we focus on LDL-C—whether in the context of monogenic lipid disorders such as FH or in the context of the blood LDL-C level as a polygenic, quantitative trait.

Mendelian Disease Using Classic Linkage

Familial hypercholesterolemia is a monogenic disorder in which patients have extremely high blood LDL-C levels that result in abnormal deposition of cholesterol (xanthomas) and a severely increased risk for premature MI, as early as childhood. Initial studies in the 1970s and 1980s demonstrated that most cases of FH result from mutations in the LDL receptor gene (*LDLR*).[19] In 1989 a subset of cases were found to result from mutations in *APOB*.[20] Following these discoveries, other cases remained in which neither *LDLR* nor *APOB* mutations appeared to be responsible.

Abidfadel and coworkers[14] identified French families affected by FH without apparent *LDLR* or *APOB* mutations and, in performing a linkage study, identified a region on chromosome 1 where markers had strong linkage to the disease. Using positional cloning, they narrowed the region to an interval containing 41 genes. One gene, *PCSK9*, was a strong candidate because a similar gene had previously been reported to be involved in cholesterol metabolism. Sequencing *PCSK9* identified two different rare variants in different families. Subsequent studies in mice supported *PCSK9* as a regulator of blood cholesterol levels and indicated that the mutations discovered were likely to be gain-of-function rather than loss-of-function mutations.[21]

Mendelian Disease Using Direct DNA Sequencing

Musunuru and colleagues[22] identified a family in whom four siblings displayed extremely low blood LDL-C, HDL-C, and triglyceride levels—an apparently recessive disorder termed *familial combined hypolipidemia*. A linkage study could not identify the causal gene because of the prohibitively large number of genes in the linkage region. Years later, following the advent of exome sequencing, DNA samples from two of the siblings underwent such analysis. In a comparison of the siblings' exomes, only one gene harbored rare DNA variants in both alleles in both siblings—the angiopoietin-like 3 (*ANGPTL3*) gene, which had been implicated previously in the metabolism of triglycerides, but not LDL-C. Of note, the siblings had two different mutations, each of which was a nonsense mutation, consistent with total loss of *ANGPTL3* function. Subsequent studies confirmed the presence of various *ANGPTL3* mutations in unrelated individuals with familial combined hypolipidemia.

Complex Trait Using Extremes in a Population

Shortly after the discovery of *PCSK9* as a causal gene in FH, Cohen and colleagues[23,24] hypothesized that loss-of-function variants in *PCSK9* may contribute to differences in blood cholesterol levels in the general population. Reasoning that individuals with low LDL-C levels were more likely to have such loss-of-function variants (because gain-of-function mutations cause increased LDL-C levels in FH), they sequenced *PCSK9* in individuals at the phenotypic extreme in the multiethnic Dallas Heart Study—those with the lowest LDL-C levels. Several of these individuals had one copy of either of two different nonsense variants in the gene. The investigators then specifically genotyped at the sites of the two

nonsense variants in the entire Atherosclerosis Risk in Communities study and found that together, 2.6% of the black subjects in the study had either of the two variants. These individuals had on average a 28% reduction in LDL-C compared with those without *PCSK9* variants. Subsequent work demonstrated that individuals with *PCSK9* nonsense variants have significantly reduced risk for incident CHD (**Fig. 7.10**). Individuals with loss-of-function variants in *PCSK9* did not show adverse consequences, thus suggesting that therapies directed against *PCSK9* would offer beneficial cardiovascular effects without any accompanying undesirable effects.

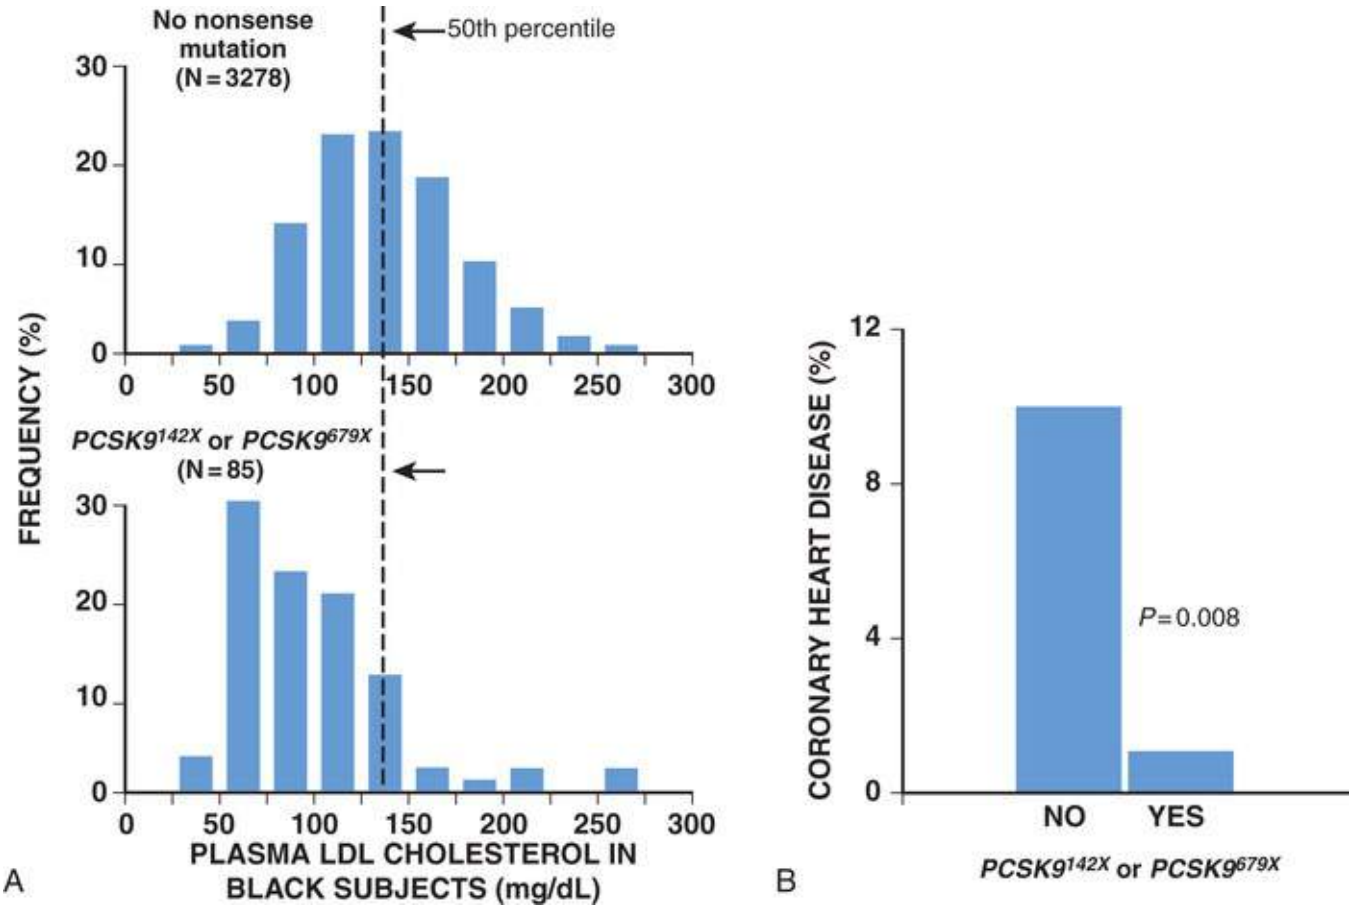

FIGURE 7.10 **A,** Distribution of LDL-C, and **B,** risk for CHD, in carriers versus noncarriers of nonsense mutations in the *PCSK9* gene. (From Cohen JC, Boerwinkle E, Mosley TH Jr, Hobbs HH. Sequence variations in *PCSK9,* low LDL, and protection against coronary heart disease. N Engl J Med 2006;354:1264.)

Complex Trait Using Genome-Wide Association

Starting in 2007, GWASs were performed on collections of individuals of European descent to identify SNPs associated with blood LDL-C, HDL-C, triglycerides, and/or total cholesterol levels. Each year brought a successively larger study and culminated in a collaborative study involving approximately 100,000 people in 2010.[5] This study identified a total of 95 loci associated with one or more of the lipid phenotypes. Remarkably, a third of the loci had genes previously known to be involved in lipid metabolism; indeed, more than a dozen genes had rare DNA variants previously deemed responsible for monogenic lipid disorders, including *LDLR*, *APOB*, *PCSK9*, and *ANGPTL3*. The other two thirds of the loci presumptively harbor novel lipid-regulating genes, inspiring considerable effort to characterize the functions of some of these genes (e.g., *GALNT2*, *SORT1*, and *TRIB1*.)

Clinical Application of Genetic Findings

Risk Prediction

Patient Case, Part III.

The two brothers of the patient JS are referred to a cardiologist for assessment of risk for MI. Both brothers are asymptomatic but are worried about their strong family history and that JS had a coronary event at a similarly young age. They inquire whether they have an increased risk for a coronary event, whether that risk can be quantified, and whether they should be changing their lifestyle or taking any medications. Both patients undergo DNA sequencing to determine whether they carry the *PCSK9* mutation responsible for disease in JS. The 43-year-old brother (KS) carries *PCSK9* Ser127Arg, but the 39-year-old brother (LS) does not.

Identifying individuals at increased risk for cardiovascular disease and implementing preventive interventions to reduce that risk are key goals of biomedicine (**see Chapters 6 and 45**). Genetic markers have long promised to discern patients at increased risk. The use of genetic markers to assess risk entails consideration of two scenarios.

The first is risk prediction in the context of a family with a mendelian disorder. Here, a single defective gene causes disease in the family. The central question is whether the asymptomatic family member carries the causal mutation (or two mutations for a recessive disease). Direct DNA sequencing can determine whether the mutation is present, which typically means a near-certain risk for disease. Yet, complexities may exist in even a single-gene disorder.[1] Among carriers of a mendelian mutation in a given family, some may exhibit the condition and others may not. *Penetrance* refers to the proportion of individuals with a given genotype who exhibit the phenotype associated with the genotype. In many mendelian cardiovascular conditions inherited in an autosomal dominant manner, evidence exists for incomplete penetrance. For example, Hobbs and colleagues[25] reported that in a pedigree with FH caused by a point mutation in *LDLR*, only 12 of 18 heterozygotes had high LDL-C (>95th percentile), whereas some of the remaining 6 heterozygotes had LDL-C as low as the 28th percentile for the population. The lack of a high-cholesterol phenotype given the same genotype may result from influences from modifier genes or from the environment.

The second scenario uses genetics to predict risk for a common, complex disease. Here, disease results from the interplay of multiple genetic and nongenetic factors. The central questions are whether genetic markers can identify a subset of the population at higher risk for disease and whether effective interventions can be allocated to this subset of individuals to reduce their risk. For example, we commonly use a nongenetic marker, the presence of type 2 diabetes mellitus, to identify a subset of the population at higher risk for CHD (those with type 2 diabetes have a twofold increase in CHD).[26] We target statin intervention to this group to reduce their absolute risk for CHD.

Use of the GWAS approach has recently identified 45 common variants for CAD or MI, thereby permitting construction of a genetic risk score using mapped variants.[27] The first 12 common variants mapped for CAD or MI using GWAS led to generation of a simple genetic risk score ranging from 0 to 24 alleles was generated (i.e., each individual can carry 0, 1, or 2 copies of the risk allele at each of these 12 sites), with 0 being ideal and 24 being the most unfavorable.[28] The distribution of this genetic risk score in the population approaches normal. Those in the top quintile of this distribution (the 20% of the population with the highest scores) had an approximately 1.7-fold increased risk for incident CHD, even after accounting for all other cardiovascular risk factors.

Will this information have clinical usefulness? Uncertainty prevails regarding whether young and middle-aged individuals (i.e., men age 30 to 50 and women age 40 to 60 years) should receive a statin to prevent a first MI. A genetic risk score might identify the subset of individuals at highest genetic risk and target statin treatment to these individuals. This hypothesis remains to be tested formally in randomized controlled trials (**see Chapter 45**)

Distinguishing Causal from Reactive Biomarkers

Patient Case, Part IV.

The 39-year-old brother of the patient JS has an HDL-C level of 29 mg/dL. Does his low HDL-C concentration causally contribute to risk for MI?

Hypotheses concerning causative agents for complex diseases have often initially come from observational epidemiology. In a 1961 paper titled "Factors of Risk in the Development of Coronary Heart Disease," Kannel and colleagues[29] in the Framingham Heart Study established an association of total plasma cholesterol with future risk for CHD. Since then, studies have linked hundreds of soluble biomarkers with risk for CAD (**see Chapters 9 and 45**). How many of these biomarkers directly cause CAD, how many simply reflect other causal processes, and why is this question important? Both causal and noncausal biomarkers may help to predict risk for future disease, but only a causal biomarker may be appropriate as a target of therapy. A randomized controlled trial (RCT) testing whether a treatment that alters the biomarker will affect risk for disease can support causality in humans. Because clinical trials are expensive and time-consuming, however, having evidence in humans before engaging in a clinical trial would be helpful.

A technique termed *mendelian randomization* uses DNA sequence variants to address the question of whether an epidemiologic association between a risk factor and disease reflects a causal influence of the former on the latter.[30-32] In principle, if a DNA sequence variant directly affects an intermediate phenotype (e.g., a variant in the promoter of a gene encoding a biomarker that alters its expression) and the intermediate phenotype truly contributes to the disease, the DNA variant should be associated with the disease to the extent predicted by (1) the size of the effect of the variant on the phenotype and (2) the size of the effect of the phenotype on the disease (**Fig. 7.11**). If the predicted association between the variant and disease does not emerge from study of an adequately powered sample, it would argue against a purely causal role for the intermediate phenotype in pathogenesis of the disease.

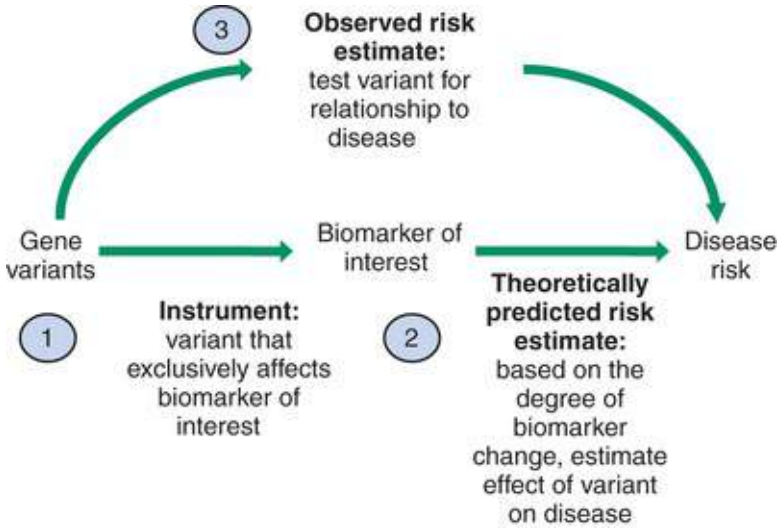

FIGURE 7.11 Design of a mendelian randomization study to test whether a biomarker causally influences risk for disease. The study design has three elements. First, one needs to identify a genetic variant, an instrument that exclusively alters the biomarker of interest. Second, one needs to derive a theoretically predicted estimate of disease risk for the instrument. This estimate is usually derived on the basis of (1) association of the gene variant to the biomarker (i.e., degree of change in biomarker conferred by variant) and (2) association of the biomarker to disease in the population (i.e., extent to which a given change in biomarker is expected to alter risk for disease in the population). Third, one derives an observed disease risk estimate for the instrument after testing the instrument for association with disease in the population. If the observed risk estimate for the instrument is consistent with that predicted theoretically, this supports the notion that the biomarker causally influences risk for disease.

The study design is akin to a prospective RCT in that randomization for each individual occurs at the moment of conception—genotypes of DNA variants are randomly "assigned" to gametes during meiosis, a process that avoids the typical confounders observed in observational epidemiologic studies. For example, a parent's disease status or socioeconomic status should not affect which of the parent's two alleles at a given SNP is passed to a child, with each allele having an equal (50%) chance of being transmitted by the gamete to the zygote. Thus, mendelian randomization should resist confounding or reverse causation. Mendelian randomization has potential shortcomings, however, including that (1) the technique is only as reliable as the robustness of the estimates of the effect sizes of the variant on the phenotype and of the phenotype on disease, and (2) it assumes that the DNA variant does not influence the disease by means other than the intermediate phenotype being studied (pleiotropy), which may not be true. In addition, a potential confounder of mendelian randomization is that, in certain situations, a disease might cause the allele of a DNA variant passed from a parent to an offspring to be expressed in a different way; for example, it could occur through inherited epigenetic effects. Nevertheless, mendelian randomization can prove as informative as a traditional RCT.

Several mendelian randomization studies have confirmed a causal relationship between LDL-C and CHD. Nonsense variants in the *PCSK9* gene that significantly reduce plasma LDL-C concentrations have been associated with a reduced incidence of CHD in a black cohort.[24] Similarly, in white patients, a low-frequency missense variant in *PCSK9* has been associated with lower LDL-C levels, as well as a lower risk for MI. Inactivating mutations in *NPC1L1*, the gene that encodes the drug target of ezetimibe, reduce both LDL-C levels and risk for CHD.[33] These observations suggest that lower LDL-C suffices to provide protection against CHD. Similar to LDL-C, several recent genetic studies have confirmed previous observations that plasma lipoprotein(a) (Lp[a]) relates causally to CHD.[34,35]

Unlike the results with plasma LDL-C and Lp(a) concentrations, a recent large mendelian randomization study of variants that affect plasma HDL-C, performed in more than 100,000 individuals, did not show an association between these variants and MI.[36] The investigators performed two mendelian

randomization analyses. First, an SNP in the endothelial lipase gene (*LIPG* Asn396Ser) served as an instrument, and this SNP was tested in 20 studies (20,913 MI cases, 95,407 controls). Second, a genetic score consisting of 14 common SNPs that associate exclusively with HDL-C provided an instrument, and this score was tested in up to 12,482 MI cases and 41,331 controls. As a positive control, the investigators tested a genetic score of 13 common SNPs exclusively associated with LDL-C. Carriers of the *LIPG* 396Ser allele (2.6% frequency) had higher HDL-C (5.5 mg/dL higher, $P = 8 \times 10^{-13}$) but similar levels of other lipid and nonlipid risk factors for MI compared with noncarriers. This difference in HDL-C was expected to decrease the risk for MI by 13% (odds ratio [OR], 0.87; 95% confidence interval [CI], 0.84 to 0.91), but the 396Ser allele was not associated with risk for MI (OR, 0.99; 95% CI, 0.88 to 1.11; $P = 0.85$) (**Fig. 7.12**). From observational epidemiology, an increase of 1 standard deviation (SD) in HDL-C is associated with a reduced risk for MI (OR, 0.62; 95% CI, 0.58 to 0.66). A 1-SD increase in HDL-C because of genetic score, however, was not associated with risk for MI (OR, 0.93; 95% CI, 0.68 to 1.26; $P = 0.63$). For LDL-C the estimate from observational epidemiology (a 1-SD increase in LDL-C was associated with risk for MI; OR, 1.54; 95% CI, 1.45 to 1.63) agreed with that from the genetic score (OR, 2.13; 95% CI, 1.69 to 2.69; $P = 2 \times 10^{-10}$). These findings indicate that some genetic mechanisms that raise plasma HDL-C do not lower the risk for MI. These data challenge the concept that raising plasma HDL-C therapeutically will uniformly translate into reductions in risk for MI.

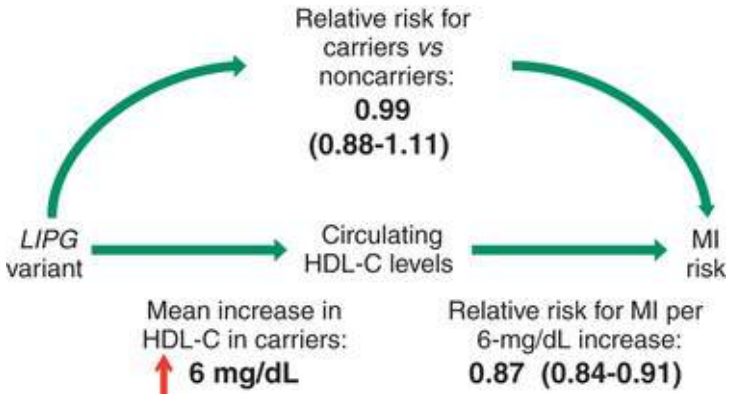

FIGURE 7.12 Mendelian randomization study for plasma HDL-C and risk for MI by using an instrument in the endothelial lipase (*LIPG*) gene. Individuals who carry the serine allele at amino acid 396 of the *LIPG* gene have about 6 mg/dL higher HDL-C. If HDL-C were a causal factor, carriers of the serine allele would be expected to be protected from risk for MI. After association testing in 116,320 individuals, the *LIPG* instrument was not associated with MI. Individuals who carried the HDL-boosting variants had the same risk for MI as did those who did not carry the variant.

A parallel line of clinical trial evidence also casts doubt on the notion that *any* intervention that raises HDL-C will reduce risk for MI. Three different inhibitors of cholesterol ester transfer protein (CETP) substantially raised HDL-C in comparison to placebo. Clinical trials with the three CETP inhibitors were all terminated prematurely because of lack of efficacy.[37-39] When combined, the clinical trial results and the human genetic findings summarized here cast doubt on the notion that raising HDL-C in isolation reduces CHD risk. For several decades the biomedical research community has assumed that if an intervention raises HDL-C, that intervention will reduce risk for CHD. It seems prudent now to rethink this assumption and reevaluate the use of HDL-C as a biomarker predictive of CHD in intervention studies.

In contrast to HDL-C, recent genetic evidence points to triglyceride-rich lipoproteins as a causal risk factor for CHD. Genetic studies have documented that inactivating mutations in the *APOA5*, *APOC3*, *ANPGTL4*, and *LPL* genes are associated with either decreased or increased risk for CHD.[40-44] These four

genes share the common property that each either encodes lipoprotein lipase or encodes a regulator of lipoprotein lipase, an enzyme that metabolizes the triglycerides contained in various lipoprotein particles. These findings suggest that novel therapeutic interventions targeting the lipoprotein lipase pathway will reduce risk for CHD.

Overall, with the recent explosion in our ability to measure soluble biomarkers (including metabolites and proteins; **see Chapter 9**) and genetic variation, mendelian randomization will aid increasingly to distinguish causal from noncausal biomarkers.

Personalized Medicine

Patient Case, Part V.

Shortly after his clinic visit, the 43-year-old brother (KS) goes to the emergency department (ED) because of severe chest pain. He is found to be in the throes of STEMI. He undergoes urgent percutaneous coronary intervention (PCI). The ED physician asks the cardiology consultant which antiplatelet agent in addition to aspirin the patient should receive at this time.

Just as genetic data can be used to predict a patient's risk for development of a disease, it can also be used to predict whether a patient will have a therapeutic response and/or an adverse response to a particular medication. Termed *pharmacogenetics* or, in broader terms, personalized medicine, its goal is to deliver safely the right therapy at the right dose to the right patient (**see also Chapters 6 and 8**).

One example of the emerging use of pharmacogenetics centers on use of the antiplatelet agent clopidogrel. Given routinely to patients after a coronary event, clopidogrel has reduced the risk for future coronary events and, in patients who have undergone coronary stent placement, has decreased the risk for in-stent thrombosis. Common loss-of-function variants in the *CYP2C19* gene, which encodes an enzyme that metabolizes clopidogrel into its active form, reduce the effectiveness of the medication, especially with respect to the prevention of in-stent thrombosis.[45,46] Accordingly, *CYP2C19* genotyping performed at the point of care could guide the choice of therapy. Alternatives for patients found to have loss-of-function *CYP2C19* variants could include an increased dose of clopidogrel or the use of an alternative medication of the same drug class not affected by *CYP2C19* function (**see Chapters 59 and 60**).

Therapeutic Targets: From Gene to Drug in a Decade

The example of *PCSK9* has emerged as a success story for the translation of cardiovascular genetics to the clinic in a relatively short time (**see Chapter 48**). The original report of the involvement of gain-of-function mutations in *PCSK9* in causing FH was published in 2003. Just 10 years later, several companies had developed antibody-based drugs targeting the PCSK9 protein that were being evaluated in clinical trials, with two such drugs, alirocumab and evolocumab, now approved for use in patients.[47,48] Development of these drugs followed directly from the finding that individuals with loss-of-function *PCSK9* mutations are genetically protected from CHD without suffering any known adverse effects. Clinical trials demonstrated a large reduction in blood LDL-C levels with these agents. Definitive outcomes trials remain to be completed.

Genome Editing

Recent advances in the set of technologies known as genome editing, most notably the adaptation of clustered, regularly interspaced, short palindromic repeats (CRISPR)–CRISPR-associated 9 (Cas9)

systems from bacterial species, enable the precise targeting of genes within human cells. Genome-editing tools such as CRISPR-Cas9 can introduce frameshift, nonsense, or missense mutations into a target gene, representing a novel therapeutic approach that is just beginning to be explored.

The recent discoveries that naturally occurring inactivating mutations in genes such as *PCSK9*, *APOC3*, and *ANGPTL4* are associated with decreased risk for CHD provide a rationale for using genome editing to introduce similar inactivating mutations into one or more of these genes in patients at high risk for CHD. In a proof-of-principle study, CRISPR-Cas9 was used to introduce frameshift mutations into the *PCSK9* gene in the liver cells of adult mice.[49] Within several days of administration of the CRISPR-Cas9 therapy, the plasma levels of PCSK9 protein had fallen by 90%, and the plasma cholesterol levels had fallen by 35% to 40%. In principle, one-time genome editing should result in permanent genetic alterations, and thus *PCSK9* targeting in a human should produce a beneficial effects far more enduring than existing medications such as statins and PCSK9 antibody–based drugs. Genome-editing approaches may ultimately prove useful for the prevention and treatment of a variety of cardiovascular disorders.

Future Perspectives

The last 15 years have witnessed remarkable advances in human genetics that promise to continue to transform our understanding of cardiovascular disease, as well as the approaches by which practitioners will prevent and treat disease. Although we remain largely in an information-gathering stage, the first practical applications of the information have begun to emerge, ranging from improvement in cardiovascular risk prediction, to the use of pharmacogenetics to tailor therapy for individual patients, to the development of novel therapies such as the PCSK9 antibody–based drugs. The decade to come should witness substantial progress in all these domains.

Indeed, not too far in the future, the standard of cardiovascular care may look quite different from current practices. Patients would undergo whole-genome sequencing at birth, thereby allowing so-called primordial prevention by assessing the genetic determinants of an individual's lifetime risk for cardiovascular disease and institution of appropriate counseling—starting with lifelong exercise and dietary habits and, as the patient advances in age, individually tailored preventive medications and therapies that address all the individual's various validated, causal genetic risk factors for disease. If cardiovascular disease should nevertheless emerge at some point in the patient's life, he or she would receive the specific therapies that have been demonstrated to be most efficacious and safest for individuals with that genetic profile, both in the acute setting and in the long term for secondary prevention. This standard of care would represent an important step toward ensuring that people everywhere enjoy longer lives free of cardiovascular disease.

Drug Therapeutics and Personalized Medicine

Dan M. Roden

In 2014 the total cost of health care in the United States was approximately $3 trillion, and more than 10% was spent on prescription drugs.[1] Cardiovascular disease makes up the largest subcategory in this spending: In 2016 the American Heart Association estimated that the cost of care for cardiovascular disease was $317 billion/year, and total cost of prescription drugs for cardiovascular care was $33 billion.[2]

Not every patient responds to drug therapy in the same way; efficacy varies, and adverse effects range from minor to potentially fatal. Multiple mechanisms can result in this variability, such as poor

compliance, variable impact of diverse disease mechanisms on drug actions, drug interactions, and the increasingly well-recognized role of genomic variation. Indeed, adverse drug reactions across all therapeutic categories are estimated to be the fourth to sixth most common cause of death in the United States, costing $19 to $27 billion annually, and accounting directly for 3% to 6% of all hospital admissions.[3]

This chapter outlines principles of drug action, the major mechanisms underlying variability in drug effects, and current and future approaches to enable the safest and most effective therapy for an individual patient.

Risk Versus Benefit of Drug Therapy

The fundamental assumption underlying administration of any drug is that the real or expected benefit exceeds the anticipated risk. The benefits of drug therapy are initially defined in small clinical trials, perhaps involving several thousand patients, before a drug's marketing and approval. Ultimately, the efficacy and safety profiles of any drug are determined after the compound has been marketed and used widely in hundreds of thousands of patients.

When a drug is administered for the acute correction of a life-threatening condition, the benefits are often self-evident; insulin for diabetic ketoacidosis and nitroprusside for hypertensive encephalopathy are examples. However, extrapolation of such immediately obvious benefits to other clinical situations may not be warranted.

Clinical Trials Can Define Unexpected Adverse Drug Reactions

The outcome of the Cardiac Arrhythmia Suppression Trial (CAST) highlights the difficulties in extrapolating from an incomplete understanding of physiology to chronic drug therapy. CAST tested the hypothesis that suppression of ventricular ectopic activity, a recognized risk factor for sudden death after myocardial infarction (MI), would reduce mortality; this notion was highly ingrained in cardiovascular practice in the 1970s and 1980s. In CAST, sodium channel–blocking antiarrhythmic drugs did suppress ventricular ectopic beats but also unexpectedly increased mortality threefold. Similarly, with the development of a first-generation cholesterol ester transport protein (CETP) inhibitor, the goal of elevation of high-density lipoprotein (HDL) levels was achieved, but with an accompanying increase in mortality. Thus the use of arrhythmia suppression or HDL elevation as a surrogate marker did not produce the desired drug action—reduction in mortality—probably because the underlying pathophysiology or full range of drug actions were incompletely understood.

Similarly, drugs with positive inotropic activity augment cardiac output in patients with heart failure but also are associated with an increase in mortality, probably because of drug-induced arrhythmias. Nevertheless, clinical trials with these agents suggest symptom relief. Thus the prescriber and the patient may elect therapy with positive inotropic drugs to realize this benefit while recognizing the risk. This complex decision making is at the heart of the broad concept of personalized medicine, which incorporates into the care of an individual patient not only genomic (or other) markers of variable drug responses, but also factors such as patients' understanding of their disease and their willingness to tolerate minor or serious risks of treatment.

Classes of Adverse Drug Reactions

The risks of drug therapy may be a direct extension of the pharmacologic actions for which the drug is actually being prescribed. Hypoglycemia in a patient taking an antidiabetic agent and bleeding in a patient taking an anticoagulant are examples. In other cases, adverse effects develop as a consequence of pharmacologic actions that were not appreciated during a drug's initial development and use in patients. Examples include rhabdomyolysis occurring with HMG-CoA reductase inhibitors (statins), angioedema developing during ACE inhibitor therapy, and torsades de pointes during treatment with noncardiovascular drugs such as methadone. Of importance, these rarer but serious effects generally become evident only after a drug has been marketed and extensively used. Even rare adverse effects can alter the overall perception of risk versus benefit and can prompt removal of the drug from the market, particularly if alternate therapies thought to be safer are available. For example, withdrawal of the first insulin sensitizer, troglitazone, after recognition of hepatotoxicity was further spurred by the availability of other new drugs in this class.

The recognition of multiple cyclooxygenase (COX) isoforms led to the development of specific COX-2 inhibitors to retain aspirin's analgesic effects but reduce gastrointestinal side effects. However, one of these, rofecoxib, was withdrawn because of an apparent increase in cardiovascular mortality. The events surrounding the withdrawal of rofecoxib have important implications for drug development and utilization. First, specificity achieved by targeting a single molecular entity may not necessarily reduce adverse effects; one possibility is that by inhibiting COX-2, the drug removes a vascular protective effect of prostacyclin. Second, drug side effects may include not only readily identifiable events such as rhabdomyolysis or torsades de pointes but also an increase—that may be difficult to detect—in events such as MI that are common in the general population.

Pharmacokinetics and Pharmacodynamics

Two major processes determine how the interaction between a drug and its target molecule(s) can generate variable drug actions in a patient. The first, *pharmacokinetics*, describes drug delivery to and removal from the target molecule and includes the processes of absorption, distribution, metabolism, and excretion—collectively termed *drug disposition*. The second process, *pharmacodynamics*, describes how the interaction between a drug and its molecular target(s) generates downstream molecular, cellular, whole-organ, and whole-body effects.

Genes encoding drug-metabolizing enzymes and drug transport molecules determine pharmacokinetics. Genes encoding drug targets and the molecules modulating the biology in which the drug-target interaction occurs (including those causing the disease being treated) determine pharmacodynamics. *Pharmacogenetics* describes the concept that individual variants in the genes controlling these processes contribute to variable drug actions. *Pharmacogenomics* is often used to describe the way in which variability across multiple genes, up to whole genomes, explains differences in drug response among individuals and populations. The following overview of broad principles of pharmacokinetics, pharmacodynamics, and pharmacogenomics is followed by more detailed discussion of the specific genes, their function, and important variants influencing cardiovascular drug responses.

Pharmacokinetic Principles

Administration of an intravenous (IV) drug bolus results in maximal drug concentrations at the end of delivery of the bolus, followed by a decline in plasma drug concentrations over time (**Fig. 8.1A**),

generally because of drug elimination. In the simplest case this decline occurs monoexponentially over time. A useful parameter to describe this decline is the half-life ($t_{1/2}$), the time in which 50% of the drug is eliminated; for example, after two half-lives, 75% of the drug has been eliminated, and after three half-lives, 87.5%. A monoexponential process can be considered almost complete in four or five half-lives.

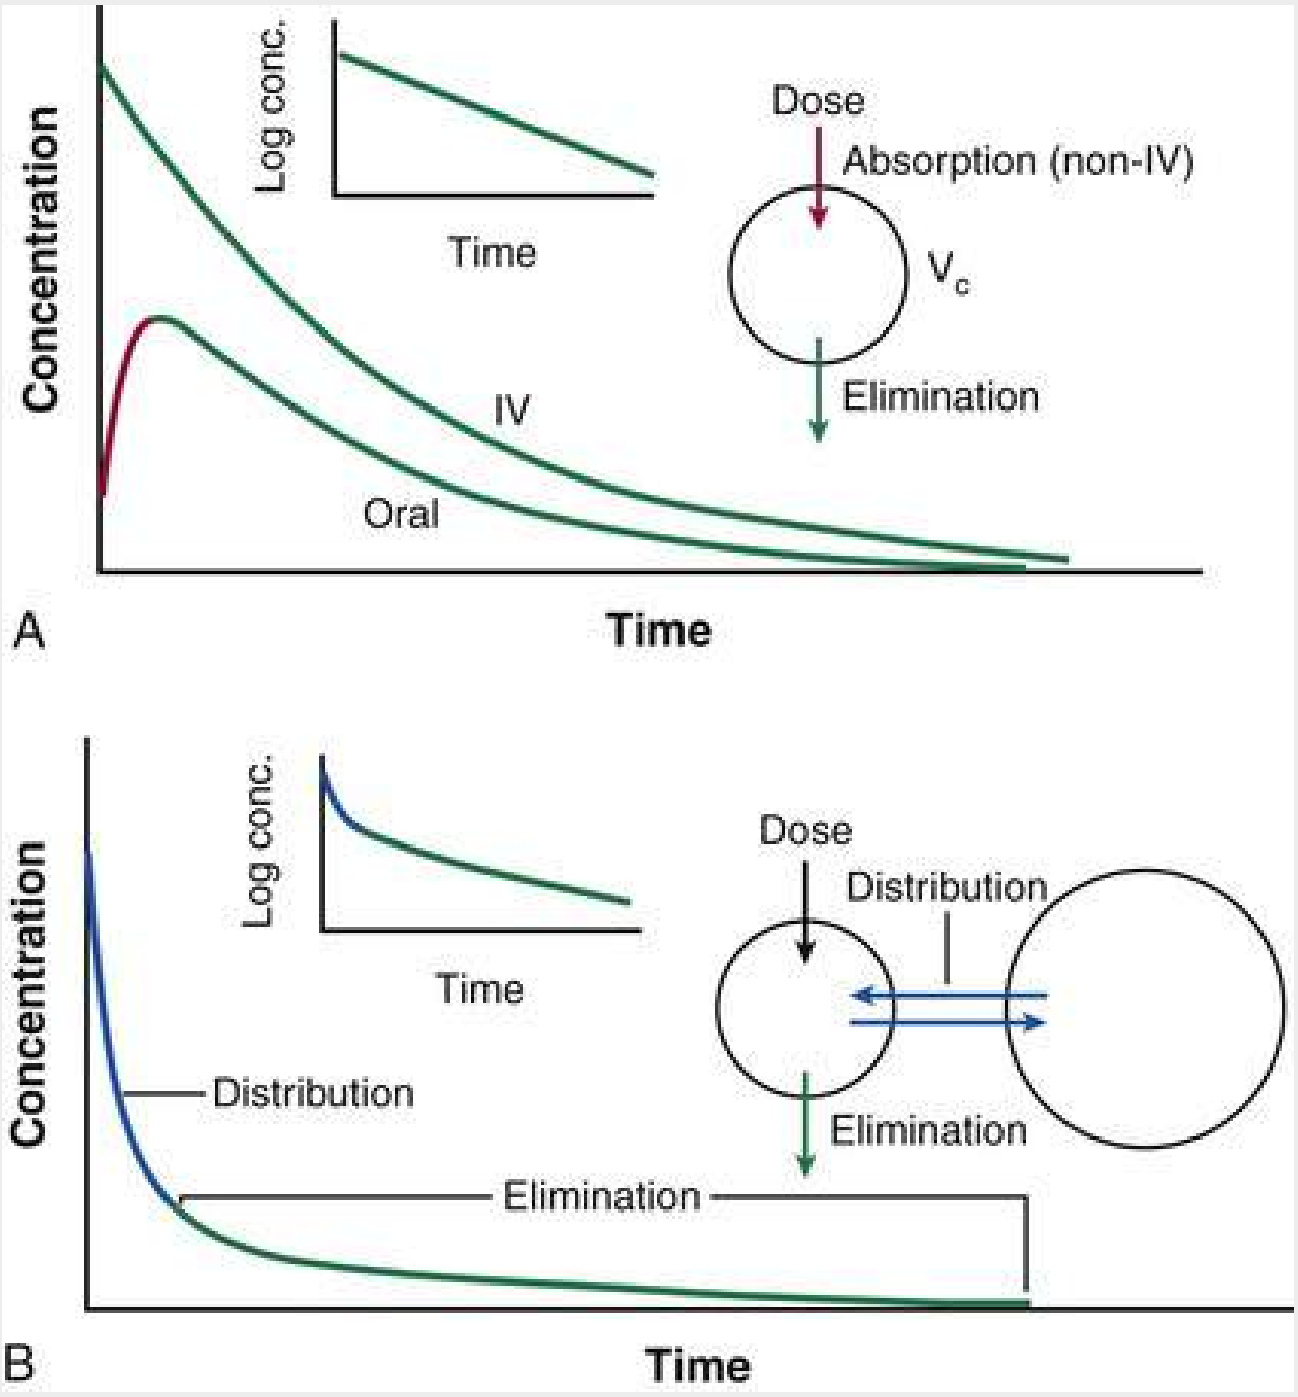

FIGURE 8.1 Models of plasma concentrations as a function of time after a single dose of a drug. **A,** The simplest situation is one in which a drug is administered as a rapid intravenous (IV) bolus into a volume (V_c), where it is instantaneously and uniformly distributed. Elimination then takes place from this volume. In this case, drug elimination is monoexponential; that is, a plot of the logarithm of concentration versus time is linear (*inset*). When the same dose of drug is administered orally, a distinct absorption phase is required before drug entry into V_c. Most absorption (shown here in *red*) is completed before elimination (shown in *green*), although the processes overlap. In this example, the amount of drug delivered by the oral route is less than that delivered by the intravenous route, assessed by the total areas under the two curves, indicating reduced bioavailability. **B,** In this example, drug is delivered to the central volume, from which it is not only eliminated but also undergoes distribution to the peripheral sites. This distribution process (*blue*) is more rapid than elimination, resulting in a distinct biexponential disappearance curve (*inset*).

In some cases the decline of drug concentrations after administration of an IV bolus dose is multiexponential. The most common explanation is that drug is not only eliminated (represented by terminal portion of time-concentration plot) but also undergoes more rapid distribution to peripheral tissues. Just as elimination may be usefully described by a half-life, distribution half-lives also can be derived from curves such as those shown in **Fig. 8.1B**.

The plasma concentration measured immediately after a bolus dose can be used to derive a volume into which the drug is distributed. When the decline of plasma concentrations is multiexponential, multiple distribution compartments can be defined; these volumes of distribution can be useful in considering dose adjustments in cases of disease but rarely correspond exactly to any physical volume, such as plasma or total body water. With drugs that are highly tissue-bound (e.g., some antidepressants), the volume of distribution can exceed total body volume by orders of magnitude.

Drugs are often administered by non-IV routes, such as oral, sublingual, transcutaneous, or intramuscular. Such routes of administration differ from the IV route in two ways (see **Fig. 8.1A**). First, concentrations in plasma demonstrate a distinct rising phase as the drug slowly enters plasma. Second, the total amount of drug that actually enters the systemic circulation may be less than that achieved by the IV route. The relative amount of drug entering by any route, compared with the same dose administered intravenously, is termed *bioavailability*, calculated as the ratio of the area under the time-concentration curves, as shown in **Fig. 8.1A**. Some drugs undergo extensive metabolism before entry into the systemic circulation, and as a result the amount of drug required to achieve a therapeutic effect is much greater (and often more variable) than that required for the same drug administered intravenously. Thus, small doses of IV propranolol (5 mg) may achieve heart rate slowing equivalent to that observed with much larger oral doses (80 to 120 mg). Propranolol is actually well absorbed but undergoes extensive metabolism in the intestine and liver before entering the systemic circulation. Another example is amiodarone; its physicochemical characteristics make it only 30% to 50% bioavailable when administered orally. Thus an IV infusion of 0.5 mg/min (720 mg/day) is equivalent to 1.5 to 2 g/day orally.

Drug elimination occurs by metabolism followed by the excretion of metabolites and unmetabolized parent drug, generally by the biliary tract or kidneys. This process can be quantified as *clearance*, the volume that is cleared of drug in any given period. Clearance may be organ specific (e.g., renal clearance, hepatic clearance) or whole-body clearance. Drug metabolism is conventionally divided into phase I oxidation and phase II conjugation, both of which enhance water solubility and, consequently, biliary or renal elimination.

The most common enzyme systems mediating phase I drug metabolism are those of the cytochrome P-450 superfamily, termed *CYPs*. Multiple CYPs are expressed in human liver and other tissues. A major source of variability in drug action is variability in CYP expression and/or genetic variants that alter CYP activity. **Table 8.1** lists CYPs and other drug-metabolizing enzymes important in cardiovascular therapy. Excretion of drugs or their metabolites into the urine or bile is accomplished by glomerular filtration or specific drug transport molecules, whose level of expression and genetic variation are only now being explored. One widely studied transporter is *P-glycoprotein*, the product of expression of the *MDR1* (or *ABCB1*) gene. Originally identified as a factor mediating multiple drug resistance in patients with cancer, P-glycoprotein expression is now well recognized in normal enterocytes, hepatocytes, renal tubular cells, the endothelium of the capillaries forming the blood-brain barrier, and the testes. In each of these sites, P-glycoprotein expression is restricted to the apical aspect of polarized cells, where it acts to enhance drug efflux. In the intestine, P-glycoprotein pumps substrates back into the lumen, thereby limiting bioavailability. In the liver and kidney, it promotes drug excretion into bile or urine. In central nervous system capillary endothelium, P-glycoprotein–mediated efflux is an important mechanism limiting drug access to the brain. Drug transporters play a role not only in drug elimination but also in drug uptake into many cells, including hepatocytes and enterocytes.

TABLE 8.1

Proteins Important in Drug Metabolism and Elimination

PROTEIN	SUBSTRATES
CYP3A4, CYP3A5*	Erythromycin, clarithromycin; quinidine, mexiletine; many benzodiazepines; cyclosporine, tacrolimus; many antiretrovirals HMG CoA reductase inhibitors: atorvastatin, simvastatin, lovastatin; not pravastatin Many calcium channel blockers; apixaban, rivaroxaban
CYP2D6*	Some beta blockers: propranolol, timolol, metoprolol, carvedilol Propafenone; desipramine and other tricyclics; codeine†; tamoxifen†; dextromethorphan
CYP2C9*	Warfarin, phenytoin, tolbutamide, losartan†, rosuvastatin
CYP2C19*	Omeprazole, clopidogrel†
P-glycoprotein	Digoxin, dabigatran
N-acetyltransferase*	Procainamide, hydralazine, isoniazid
Thiopurine methyltransferase*	6-Mercaptopurine, azathioprine
Pseudocholinesterase*	Succinylcholine
Serine esterase 1 (CES1)	Clopidogrel, dabigatran
Uridine diphosphate-glucuronosyltransferase*	Irinotecan†
SLCO1B1*	Simvastatin, atorvastatin; methotrexate; troglitazone; bosentan

*Clinically important genetic variants described.

†Prodrug bioactivated by drug metabolism.

Pharmacodynamic Principles

Drugs can exert variable effects, even in the absence of pharmacokinetic variability. This can arise as a function of variability in the molecular targets with which drugs interact to achieve their beneficial and adverse effects, as well as variability in the broader biologic context within which the drug-target interaction takes place. Variability in the number or function of a drug's target molecules can arise because of genetic factors (see later) or because disease alters the number of target molecules or their state (e.g., changes in extent of phosphorylation). Simple examples of variability in the biologic context are high dietary salt, which can inhibit the antihypertensive action of beta blockers, and hypokalemia, which increases the risk for drug-induced QT prolongation. In addition, disease itself can modulate drug response. For example, the effect of lytic therapy in a patient with no clot is manifestly different from that in a patient with an acute coronary syndrome, or the vasodilating effects of nitrates, beneficial in patients with coronary disease with angina, can be catastrophic in patients with aortic stenosis. These examples highlight the requirement for precision in diagnosis to avoid situations in which risk outweighs potential benefit. One hope is that emerging genomic or other molecular approaches can add to this precision.

Drug Targets

The targets with which drugs interact to produce beneficial effects may or may not be the same as those with which drugs interact to produce adverse effects. Drug targets may be in the circulation, at the cell surface, or within cells. Many drugs widely used in cardiovascular therapeutics (e.g., digoxin, amiodarone, aspirin) were developed when the technology to identify specific molecular targets was not available. Some drugs (e.g., amiodarone) have many drug targets. In other cases, however, even older drugs are found to have rather specific molecular targets. The actions of digitalis glycosides are mediated primarily by the inhibition of sodium/potassium–adenosine triphosphatase (Na^+,K^+-ATPase). Aspirin permanently acetylates a specific serine residue on the COX enzyme, an effect that is thought to mediate its analgesic effects and its gastrointestinal toxicity. Most newer drugs have been developed to interact with a specific drug target identified in the course of basic mechanistic studies; examples of such targets are 3-hydroxy-3-methylglutaryl–coenzyme A (HMG-CoA) reductase, angiotensin-converting enzyme (ACE), G protein–coupled receptors (GPCRs; e.g., alpha, beta, angiotensin II, histamine), and platelet IIb/IIIa receptors.

An emerging approach is to use modern genetic techniques to identify loss-of-function DNA variants

that are tolerated throughout life and associated with a desired phenotype, such as greatly reduced MI risk. Inhibitors of the corresponding gene products are thus predicted to exert a beneficial effect and lack serious on-target adverse effects. PCSK9 inhibitors are an excellent example[4] (**see Chapter 48**), and other potential drug targets are now being identified using this approach.[5-7]

Time Course of Drug Effects

With repeated doses, drug levels accumulate to a *steady state*, the condition under which the rate of drug administration is equal to the rate of drug elimination in any given period. Drug accumulation to steady state is near-complete in four to five elimination half-lives (**Fig. 8.2**). For many drugs, the target molecule is in plasma or readily accessible from plasma, so this time course also describes the development of pharmacologic effects. In other cases, however, although steady-state plasma concentrations are achieved in four to five elimination half-lives, steady-state drug effects take longer to achieve; there are several possible explanations for this. First, an active metabolite may need to be generated to achieve drug effects. Second, time may be required for translation of the drug effect at the molecular site to a physiologic endpoint. For example, inhibition of synthesis of vitamin K–dependent clotting factors by warfarin ultimately leads to a desired elevation of the international normalized ratio (INR), but the development of this desired effect occurs only as levels of clotting factors fall. Third, penetration of a drug into intracellular or other tissue sites of action may be required before development of a drug effect. One mechanism underlying such penetration is the variable function of specific drug uptake and efflux transport proteins that control intracellular drug concentrations.

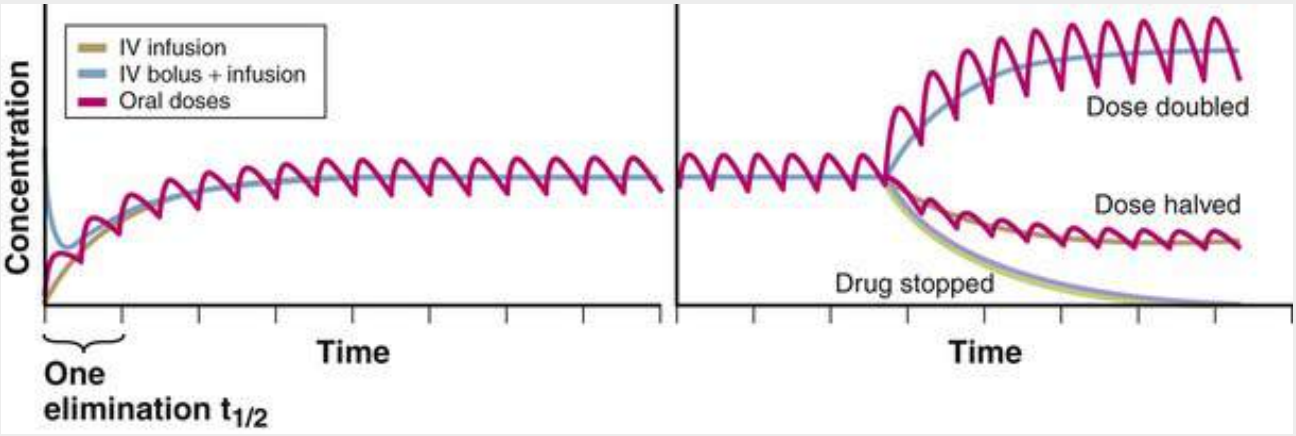

FIGURE 8.2 Time course of drug concentrations when treatment is started or dose changed. **Left,** The *hash lines* on the abscissa each indicate one elimination half-life ($t_{1/2}$). With a constant-rate intravenous (IV) infusion (*gold*), plasma concentrations accumulate to steady state in four or five elimination half-lives. When a loading bolus is administered with the maintenance infusion (*blue*), plasma concentrations are transiently higher but may dip, as shown here, before achieving the same steady state. When the same drug is administered by the oral route, the time course of drug accumulation is identical (*magenta*); in this case the drug was administered at intervals of 50% of a $t_{1/2}$. Steady-state plasma concentrations during oral therapy fluctuate around the mean determined by intravenous therapy. **Right,** This plot shows that when dosages are doubled, or halved, or the drug is stopped during steady-state administration, the time required to achieve the new steady state is four or five half-lives and is independent of the route of administration.

Pharmacogenomic Principles

A range of experimental techniques have been used to establish a role for both common and rare DNA polymorphisms in pharmacokinetic and pharmacodynamic pathways as mediators of variable drug actions. Rare variants associated with mendelian diseases such as familial hypercholesterolemia and

long-QT syndrome are traditionally termed *mutations*, whereas the term *polymorphism* is used more generically to describe variants that may or may not be associated with any human trait. Polymorphism frequency often varies strikingly by ancestry, and with the advent of inexpensive sequencing, it is apparent that the vast majority of DNA polymorphisms in any individual are actually rare (minor allele frequency [MAF] < 1%) across a large population of individuals of the same ancestry. The most common type is a single-nucleotide polymorphism (SNP); SNPs that change the encoded amino acid are termed *nonsynonymous*. Other types are short insertions or deletions (indels) or copy number variations (CNVs), in which large segments of DNA are deleted or duplicated (or more).

One of the great success stories of modern cardiovascular genetics has been the use of linkage analysis in large families to identify disease-causing rare variants (mutations) in familial syndromes with highly unusual clinical phenotypes, such as familial hypercholesterolemia (**see Chapter 48**), hypertrophic cardiomyopathy (**see Chapter 78**), and the ion channelopathies (**see Chapter 33**). Linkage analysis has not been widely applied to study pharmacogenomics because large kindreds with multiple individuals having clearly defined drug-response phenotypes generally are not available. In the syndrome of malignant hyperthermia occurring in response to general anesthetics, it was possible to assign phenotype using functional studies in muscle biopsies and thus identify a linkage signal at chromosomal region 19q, which includes the gene encoding RYR1, the skeletal muscle calcium-release channel in which mutations cause the disease.

DNA variation also contributes importantly to variability in common human traits, such as laboratory values or susceptibility to common disease. Methods are available to establish the extent to which that variability includes a heritable component, often by examining twins, large families, or groups of families; evidence for heritability provides strong justification for pursuing studies to identify contributing genetic variation. Indeed, this general approach has established that common phenotypes such as low-density lipoprotein (LDL) cholesterol, blood pressure, and susceptibility to atrial fibrillation are highly heritable. The extent that rare and common variants contribute to this variability is only now being addressed. Across populations, individual common (MAF > 5%) DNA polymorphisms rarely account for more than even 1% of variability in common traits. Variability in response to drug exposure presents a striking exception to this general rule, where even single common DNA polymorphisms may contribute substantially, 10% or more in many cases, to overall variability in drug response. It has been speculated that common variants with large effects on drug response can persist in a population because there is no evolutionary pressure against such variants since drug exposure is a recent event in human history.

One mechanism accounting for this large effect is that common SNPs in drug metabolism pathways can result in extremely large fluctuations in drug concentration and corresponding effects. Examples of specific cardiovascular phenotypes in which common SNPs have been associated with risk are presented in **Table 8.2** and discussed later. Of note, rarer variants in these (or other) genes are only now being described, so their role in mediating drug response is much less well understood. In addition, virtually all studies to date have focused primarily on populations of European ancestry, and data are only now being generated on specific polymorphisms mediating variable drug actions in other ancestries.

TABLE 8.2

Examples of Common Single-Nucleotide Polymorphisms (SNPs) Mediating Variable Drug Actions

DRUG EFFECT	PATHWAY	GENE	SNP*	dbSNP ID NUMBER	COMMENTS
Adverse outcomes during clopidogrel treatment for acute coronary syndrome	PK	*CYP2C19*	*CYP2C19*2*, *CYP2C19*3*: loss-of-function (LOF) variants *CYP2C19*17*	rs4244285	*2 and *3 result in defective clopidogrel bioactivation and decreased antiplatelet activity. About 3% of European- and 15% of Asian-ancestry individuals carry two LOF alleles. *17 increases *CYP2C19* activity and has been associated with increased bleeding during clopidogrel.
Excess beta-blocker effect: metoprolol, timolol	PK	*CYP2D6*	Many variants		
Warfarin steady-state dose	PK	*CYP2C9*	*CYP2C9*2:* R144C *CYP2C9*3:* I359L (decreased function)	rs1799853 rs1057910	*VKORC1* and *CYP2C9* variants account for ~50% of variability in warfarin steady-state dose. Bleeding risk has been associated with *CYP2C9*3* and variant *CYP4F2*.

The Candidate Gene Approach.

One technique to identify associations between DNA polymorphisms and drug response (or other traits) uses an understanding of the physiology of the trait under question to identify candidate genes modulating the trait. Thus, for example, an investigator interested in variability in the PR interval might invoke polymorphisms in calcium channel genes, or an investigator interested in blood pressure might invoke variation in the ACE gene. The association between polymorphisms in these candidate genes and the phenotype under study is then examined in persons with well-characterized phenotypes. The candidate gene approach is intuitively appealing because it takes advantage of what is known about underlying physiology. Despite this appeal, however, the method is now recognized to carry with it the great potential for false-positive associations, especially when small numbers of participants are studied. An important exception has been in pharmacogenomics, where the candidate gene approach has yielded important and clinically reproducible associations between single common polymorphisms and drug response. This exception probably reflects the unusually high contribution of SNPs to overall variability in drug response previously mentioned.

Unbiased Approaches, Such as Genome-Wide Association.

Another approach to identifying polymorphisms contributing to variable human traits is the genome-wide association study (GWAS). Here, study participants are genotyped at hundreds of thousands or millions of sites known to harbor common SNPs across the genome. Because the GWAS platforms focus on common SNPs, effect sizes for individual SNPs are often small and difficult to identify and validate unless large numbers of participants, thousands or more, are studied. In addition, the SNPs associated

with the trait usually are not themselves functional but rather serve as markers for loci that harbor truly functional variants. The great advantage of the method is that it is unbiased, in that it makes no assumptions about underlying physiology, and one of its major accomplishments has been to identify entirely new pathways underlying variability in human traits.[8] The GWAS approach has been applied to study drug response phenotypes,[9] and even in relatively small sets, it has occasionally been successful in identifying associated common variants. Sometimes these are known from candidate gene studies. In other cases, notably drug hypersensitivity reactions,[10] GWASs in relatively small numbers (tens or hundreds of patients) have identified very strong signals that have then been replicated.

The GWAS paradigm is enabled by technology to generate the dense genotype datasets. New technologies being developed to generate other types of high-dimensional data similarly hold the promise of elucidating new biologic pathways in disease and drug response. Rapid, extremely high-throughput and increasingly inexpensive sequencing technologies are detecting rare DNA sequence variants whose contribution to disease is only now being appreciated.[11,12] RNA sequencing ("RNA-Seq") is replacing microarray analysis as the method of choice for cataloging RNA transcript profiles and abundance by specific cellular subtype and disease. Advances in mass spectrometry are similarly enabling development of catalogs (proteomic and metabolomic profiling) of all proteins or of small-molecule metabolites of cellular processes, including drug metabolites, by cell and disease. Other sources of high-dimensional data include electronic medical record (EMR) systems, as discussed later, and high-density digital images. Integrating these diverse data types into a comprehensive picture of the perturbations that result in disease or variable drug responses is the goal of the evolving discipline of *systems* biology and pharmacology. It has been proposed that future drug development would be better served by a focus on pathways identified by systems approaches rather than single targets.[13]

Molecular and Genetic Basis for Variable Drug Response

Many factors contribute to variable drug responses, including the patient's age, severity of the disease being treated, presence of disease of excretory organs, drug interactions, and poor compliance. This section describes major pathways leading to variable drug responses.

High-Risk Pharmacokinetics

When a drug is metabolized and excreted by multiple pathways, absence of one of these pathways, because of genetic variants, drug interactions, or dysfunction of excretory organs, generally does not affect drug concentrations or actions. By contrast, if a single pathway plays a critical role, the drug is more likely to exhibit marked variability in plasma concentration and associated effects, a situation that has been termed *high-risk pharmacokinetics* (**Fig. 8.3**).

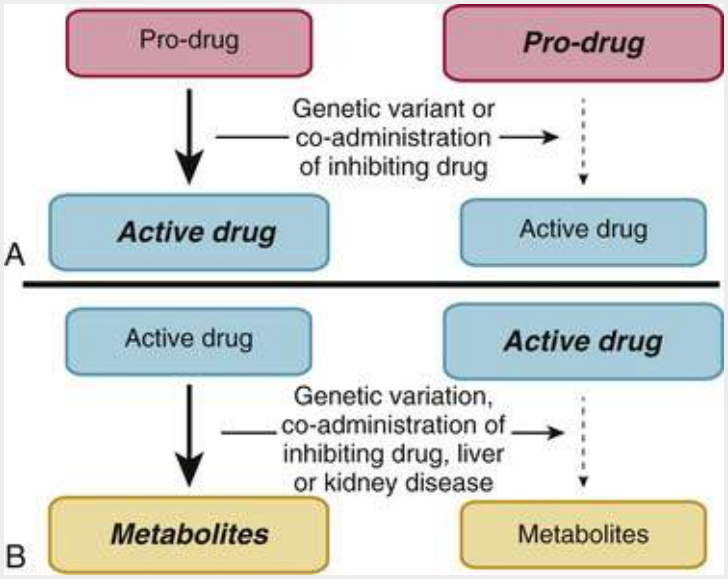

FIGURE 8.3 Two high-risk pharmacokinetic scenarios. **A,** Pro-drug activated by a single drug-metabolizing pathway. In this case, genetic variants or co-administration of a drug that inhibits the pathway will lead to failure of bioactivation and loss of drug effect. **B,** Active drug metabolized by a single pathway. In this case, genetic variants, co-administration of a drug that inhibits the pathway, or the presence of liver or kidney disease can inhibit drug elimination and thus lead to exaggerated drug action. This occurs because clinically important alternate pathways for drug elimination are absent, and increases in plasma parent drug concentrations can translate into serious drug toxicity. Note also that genetic variants or co-administered drugs that increase the rate of elimination will lead to decreased drug action. The overall effect is also modulated by the activity of the metabolites.

One high-risk scenario (**Fig. 8.3A**) involves bioactivation of a drug—that is, metabolism of the drug to active and potent metabolites that mediate pharmacologic action. Decreased function of such a pathway reduces or eliminates drug effect. Bioactivation of clopidogrel by CYP2C19 is an example; persons with reduced CYP2C19 activity (caused by genetic variants or possibly by interacting drugs; see **Tables 8.1** and **8.2**) have an increased incidence of cardiovascular events following coronary stent placement.[14] Similarly, the widely used analgesic codeine undergoes CYP2D6-mediated bioactivation to an active metabolite, morphine, and patients with reduced CYP2D6 activity ("poor metabolizers," PMs) display reduced analgesia. A small group of individuals with multiple functional copies of *CYP2D6*, and thus increased enzymatic activity ("ultrarapid metabolizers," UMs), has been identified; in this group, codeine may produce respiratory depression because of rapid morphine generation. In 2013 the U.S. Food and Drug Administration (FDA) label for codeine was revised to contraindicate its use in children after tonsillectomy, because deaths in UMs had been reported.[15] A third example is the angiotensin receptor blocker losartan, which is bioactivated by CYP2C9; reduced antihypertensive effect is a risk with common genetic variants that reduce CYP2C9 activity or with co-administration of CYP2C9 inhibitors such as phenytoin.

In a second high-risk pharmacokinetic scenario (**Fig. 8.3B**) a drug is eliminated by only a single pathway. In this case, absence of activity of that pathway will lead to marked accumulation of drug in plasma, and for many drugs, such accumulation results in a high risk of drug toxicity. A simple example is the dependence of sotalol or dofetilide elimination on renal function; failure to decrease the dosage in a patient with renal dysfunction leads to accumulation of these drugs in plasma and an increased risk for drug-induced QT prolongation and torsades de pointes. Similarly, administration of a wide range of P-glycoprotein inhibitors will predictably elevate plasma concentration of digoxin, which is eliminated primarily by P-glycoprotein–mediated efflux into bile and urine (see **Table 8.2**). Propafenone is metabolized by CYP2D6 to a metabolite that has some sodium channel–blocking actions but lacks the weak beta-blocking effect of the parent drug. Administration of propafenone to PMs, or co-administration

of CYP2D6 inhibitors (e.g., some SSRI antidepressants) to EMs, can lead to parent drug accumulation, bradycardia, and bronchospasm.

Other Important Pharmacogenetic Effects

Administration of CYP2D6-metabolized beta blockers, including metoprolol and carvedilol, to patients with defective enzyme activity may produce exaggerated heart rate slowing. Some antidepressants are CYP2D6 substrates; for these drugs, cardiovascular adverse effects are more common in CYP2D6 PMs, whereas therapeutic efficacy is more difficult to achieve in UMs.

The risk of aberrant drug responses caused by CYP variants is greatest in persons who are homozygous (i.e., PMs). However, for drugs with very narrow therapeutic margins (e.g., warfarin, clopidogrel), even heterozygotes may display unusual drug sensitivity. Although PMs make up a minority of persons in most populations, many drugs in common use can inhibit these enzymes and thereby "phenocopy" the PM trait. Omeprazole blocks CYP2C19 and in some studies has been associated with an increase in cardiovascular events during clopidogrel therapy; however, this effect is controversial and may not extend to other proton pump inhibitors.[16] Similarly, specific inhibitors of CYP2D6 and CYP2C9 can phenocopy the PM trait when co-administered with substrate drugs (**Table 8.3**).

TABLE 8.3

Drug Interactions: Mechanisms and Examples

MECHANISM	DRUG	INTERACTING DRUG	EFFECT
Decreased bioavailability	Digoxin	Antacids	Decreased digoxin effect secondary to decreased absorption
Increased bioavailability	Digoxin	Antibiotics	By eliminating gut flora that metabolize digoxin, some antibiotics may increase digoxin bioavailability. NOTE: Some antibiotics also interfere with P-glycoprotein (expressed in the intestine and elsewhere), another effect that can elevate digoxin concentration.
Induction of hepatic metabolism	*CYP3A/P-glycoprotein substrates:* Quinidine Mexiletine Verapamil Cyclosporine Apixaban Rivaroxaban	Phenytoin Rifampin Barbiturates St. John's wort	Loss of drug effect secondary to increased metabolism
Inhibition of hepatic metabolism	*CYP2C9:* Warfarin Losartan	Amiodarone Phenytoin	Decreased warfarin requirement Diminished conversion of losartan to its active metabolite, with decreased antihypertensive control
	CYP3A substrates: Quinidine Cyclosporine HMG-CoA reductase inhibitors: lovastatin, simvastatin, atorvastatin; not pravastatin Apixaban Rivaroxaban	Ketoconazole Itraconazole Erythromycin Clarithromycin Some calcium blockers Some HIV protease inhibitors (especially ritonavir)	Increased risk for drug toxicity
	CYP2D6 substrates: Beta blockers (Table 8.2) Propafenone Desipramine Codeine	Quinidine (even ultralow dose), fluoxetine, paroxetine	Increased beta blockade Increased adverse effects Decreased analgesia (due to failure of biotransformation to active metabolite morphine)
	CYP2C19: Clopidogrel	Omeprazole, possibly other proton pump inhibitors	Decreased clopidogrel efficacy
Inhibition of drug transport	*P-glycoprotein transport:* Digoxin, dabigatran	Amiodarone, quinidine, verapamil, cyclosporine, itraconazole, erythromycin, dronedarone	Increased digoxin or dabigatran plasma concentrations, with toxicity
	Renal tubular transport: Dofetilide	Verapamil	Slightly increased plasma concentration and QT effect
	Monoamine transport: Guanadrel	Tricyclic antidepressants	Blunted antihypertensive effects
Pharmacodynamic interactions	Aspirin + warfarin		Increased therapeutic antithrombotic effect; increased risk of bleeding
	Nonsteroidal anti-inflammatory drugs	Warfarin	Increased risk of gastrointestinal bleeding
	Antihypertensive drugs	Nonsteroidal anti-inflammatory drugs	Loss of blood pressure lowering
	QT-prolonging antiarrhythmics	Diuretics	Increased torsades de pointes risk secondary to diuretic-induced hypokalemia
	Supplemental potassium and/or spironolactone	ACE inhibitors	Hyperkalemia
	Sildenafil	Nitrates	Increased and persistent vasodilation; risk of myocardial ischemia

The widely used antirejection drug tacrolimus is bioinactivated by CYP3A5. A variant common in persons of European ancestry reduces enzyme activity. This variant is rare in patients of African ancestry, who therefore often require higher doses to avoid transplant rejection.[17]

An example of variant drug transporter function mediating variable drug actions is provided by *SLCO1B1*, encoding a drug uptake transporter in liver. A common nonsynonymous SNP in this gene has been associated with a greatly increased risk for simvastatin-induced myopathy by candidate studies with variability in simvastatin pharmacokinetics and by GWASs.[18]

The heart rate slowing and blood pressure effects of beta blockers and beta agonists have been associated with polymorphisms in the *drug targets*, the beta-1 and beta-2 receptors. A common variant in *ADRB1*, encoding the beta-1 receptor, has been implicated as a mediator of survival and prevention of atrial fibrillation[19] during therapy with the beta-blocker bucindolol in heart failure. Variability in warfarin dose requirements has been clearly associated with variants in both *CYP2C9*, which mediates

elimination of the active enantiomer of the drug, and *VKORC1*, part of the vitamin K complex that is the drug target. Indeed, these common variants account for up to half of the variability in warfarin dose requirement,[20] illustrating the large impact that common SNPs can exert on drug response phenotypes. Furthermore, allele frequencies vary strikingly by ancestry, probably accounting for warfarin dose requirements being low in Asian patients and high in African patients compared with white patients.[20] Lower rosuvastatin doses are also suggested in patients of Asian ancestry, and variants in multiple genes have been implicated.

Torsades de pointes during QT-prolonging drug therapy has been linked to polymorphisms not only in the ion channel that is the target for most QT-prolonging drugs (Kv11.1, encoded by *KCNH2*, also known as *HERG*) but also to other ion channel genes. A large candidate gene survey reported that a nonsynonymous SNP in *KCNE1*, a subunit for the slowly activating potassium current I_{Ks}, conferred an odds ratio of approximately 10 for torsades risk.[21] In addition, this adverse effect sometimes occurs in patients with clinically latent congenital long-QT syndrome, emphasizing the interrelationship among disease, genetic background, and drug therapy (**see Chapters 33 and 36**). Similarly, sodium channel–blocking drugs also can bring out latent Brugada syndrome. Patients with congenital long-QT syndrome or Brugada syndrome and their practitioners should be aware of websites that list potentially dangerous drugs (www.crediblemeds.org for long QT; www.brugadadrugs.org for Brugada syndrome).

The anticancer drug trastuzumab is effective only in patients with cancers that do not express the Her2/neu receptor. Because the drug also potentiates anthracycline-related cardiotoxicity, toxic therapy can be avoided in patients who are receptor negative (**see Chapter 95**). Indeed, the development of new "targeted" anticancer drugs has seen an increase in multiple types of cardiovascular adverse effects, including arterial and venous thrombosis, cardiomyopathy, myocarditis, and arrhythmias. Understanding the pathways leading to these effects could inform new approaches to prevent treat cardiovascular disease more broadly.[22]

Optimizing Drug Doses

The goals of drug therapy should be defined before the initiation of drug treatment. These may include acute correction of serious pathophysiology, acute or chronic symptom relief, or changes in surrogate endpoints (e.g., blood pressure, serum cholesterol, INR) that have been linked to beneficial outcomes in target patient populations. However, the lessons of CAST and of positive inotropic drugs should make prescribers skeptical about such surrogate-guided therapy in the absence of controlled clinical trials.

When the goal of drug therapy is to correct acutely a disturbance in physiology, the drug should be administered intravenously in doses designed to achieve a therapeutic effect rapidly. This approach is best justified when benefits clearly outweigh risks. Large boluses of IV drugs carry a risk of enhancing drug-related toxicity; therefore, even with the most urgent medical indication, this approach is rarely appropriate. An exception is adenosine, which must be administered as a rapidly delivered bolus because it undergoes extensive and rapid elimination from plasma by uptake into almost all cells. As a consequence, a slow bolus or infusion rarely achieves sufficiently high concentrations at the desired site of action (the coronary artery perfusing the atrioventricular node) to terminate arrhythmias. Similarly, the time course of anesthesia depends on anesthetic drug delivery to and removal from sites in the central nervous system.

The time required to achieve steady-state plasma concentrations is determined by the elimination half-life (see earlier). The administration of a loading dose may shorten this time, but only if the kinetics of

distribution and elimination are known beforehand in an individual patient and the correct loading regimen is chosen. Otherwise, overshoot or undershoot during the loading phase may occur (see **Fig. 8.2**). Thus the initiation of drug therapy by a loading strategy should be used only when the indication is acute.

Two dose-response curves describe the relationship between drug dose and the expected cumulative incidence of a beneficial effect or an adverse effect (**Fig. 8.4**). The distance along the *x* axis describing the difference between these curves, often termed the *therapeutic ratio* (or index, or window), provides an index of the likelihood that a chronic dosing regimen that provides benefits without adverse effects can be identified. Drugs with especially wide therapeutic indices often can be administered at infrequent intervals, even if they are rapidly eliminated (**Fig. 8.4A, C**).

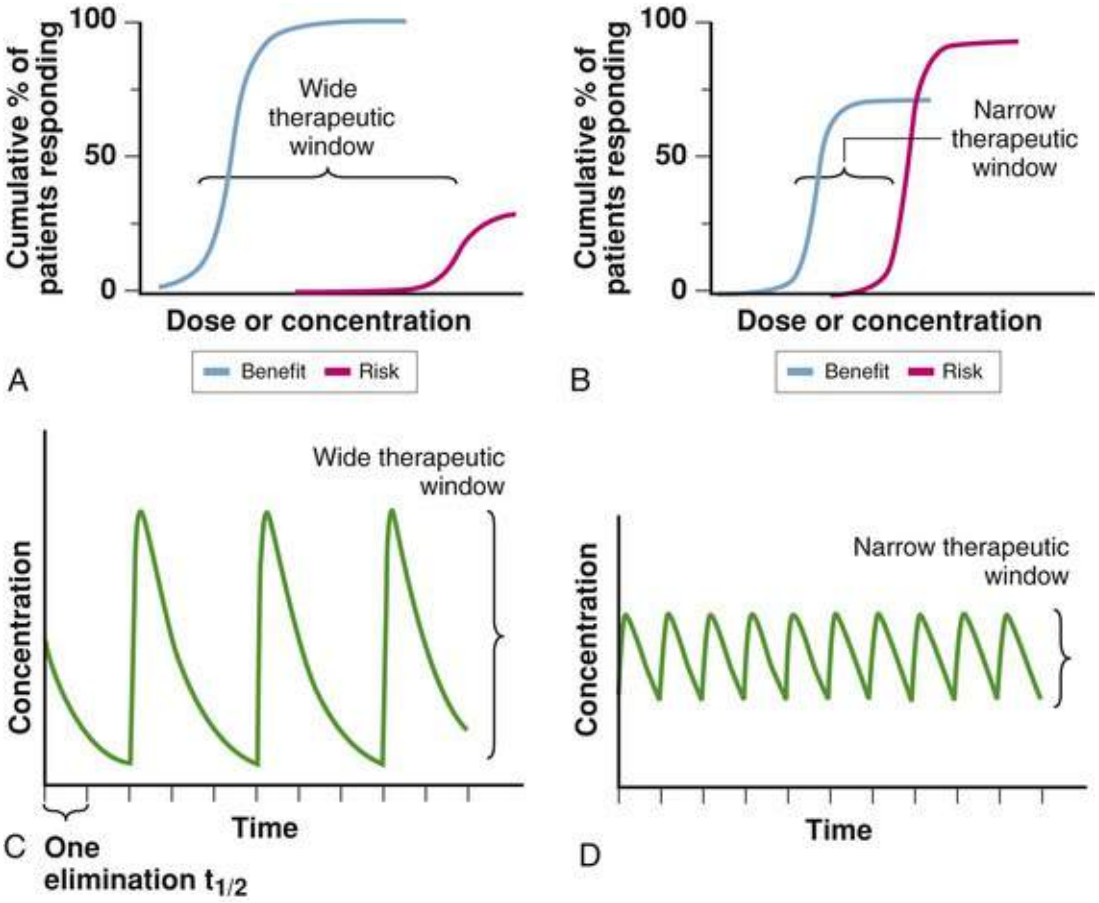

FIGURE 8.4 The concept of therapeutic ratio. **A** and **B,** Two dose-response (or concentration-response) curves. The *blue* lines describe the relationship between dose and cumulative incidence of beneficial effects, and the *magenta* line depicts the relationship between dose and dose-related adverse effects (risk). As depicted in **A,** a drug with a wide therapeutic ratio displays separation between the two curves, a high degree of efficacy, and low degree of dose-related toxicity. Under these conditions, a wide therapeutic ratio can be defined. In **B,** conversely, the curves describing cumulative efficacy and cumulative incidence of adverse effects are positioned near each other, the incidence of adverse effects is higher, and the expected beneficial response is lower. These characteristics define a narrow therapeutic ratio. **C** and **D,** Steady-state plasma concentrations with oral drug administration as a function of time with wide (*left*) and narrow (*right*) therapeutic ratios. The *hash marks* on the abscissae each indicate one elimination half-life ($t_{1/2}$). **C,** When the therapeutic window is wide, drug administration every three elimination half-lives can produce plasma concentrations that are maintained above the minimum for efficacy and below the maximum beyond which toxicity is anticipated. **D,** The opposite situation is illustrated. To maintain plasma concentrations within the narrow therapeutic range, the drug must be administered more frequently.

When anticipated adverse effects are serious, the most appropriate treatment strategy is to start at low doses and reevaluate the necessity for increasing drug dosages once steady-state drug effects have been achieved. This approach has the advantage of minimizing the risk of dose-related adverse effects but

carries with it a need to titrate doses to efficacy. Only when stable drug effects are achieved should increasing drug dosage to achieve the desired therapeutic effect be considered. An example is sotalol: because the risk of torsades de pointes increases with drug dosage, the starting dose should be low.

In other cases, anticipated toxicity is relatively mild and manageable. It may then be acceptable to start at dosages higher than the minimum required to achieve a therapeutic effect, accepting a greater-than-minimal risk of adverse effects; some antihypertensives can be administered in this way. However, the principle of using the lowest dose possible to minimize toxicity, particularly toxicity that is unpredictable and unrelated to recognized pharmacologic actions, should be the rule.

Occasionally, dose escalation into the high therapeutic range results in no beneficial drug effect and no side effects. In this circumstance the prescriber should be alert to the possibility of noncompliance or drug interactions at the pharmacokinetic or pharmacodynamic level. Depending on the nature of the anticipated toxicity, dose escalation beyond the usual therapeutic range may occasionally be acceptable, but only if anticipated toxicity is not serious and is readily manageable.

Plasma Concentration Monitoring

For some drugs, curves such as those shown in **Fig. 8.4A and B**, relating drug concentration to cumulative incidence of beneficial and adverse effects, can be generated. With such drugs, monitoring plasma drug concentrations to ensure that they remain within a desired therapeutic range (i.e., above a minimum required for efficacy and below a maximum likely to produce adverse effects) may be a useful adjunct to therapy. Monitoring drug concentrations also may be useful to ensure compliance and to detect pharmacokinetically based drug interactions that underlie unanticipated efficacy and/or toxicity at usual dosages. Samples for measurement of plasma concentrations generally should be obtained just before the next dose, at steady state. These trough concentrations provide an index of the minimum plasma concentration expected during a dosing interval.

On the other hand, patient monitoring, whether by plasma concentration or other physiologic indices, to detect incipient toxicity is best accomplished at the time of anticipated peak drug concentrations. Thus, patient surveillance for QT prolongation during therapy with sotalol or dofetilide is best timed for 1 to 2 hours after the administration of a dose of drug at a steady state.

A lag between the time courses of drug in plasma and drug effects may exist (see earlier). In addition, monitoring plasma drug concentrations relies on the assumption that the concentration measured is in equilibrium with that at the target molecular site. Of note, it is only the fraction of drug not bound to plasma proteins that is available to achieve such equilibration. Variability in the extent of protein binding can therefore affect the free fraction and anticipated drug effect, even in the presence of apparently therapeutic total plasma drug concentrations.

Dose Adjustments in Disease

Polypharmacy is common in patients with varying degrees of specific organ dysfunction. Although treatment with an individual agent may be justified, the practitioner should also recognize the risk of unanticipated drug effects, particularly drug toxicity, during therapy with multiple drugs.

The presence of renal disease mandates dose reductions (or choosing alternate therapies if renal dysfunction is severe) for drugs eliminated primarily by renal excretion. Examples include dabigatran, rivaroxaban, edoxaban, digoxin, dofetilide, and sotalol. Apixaban can be used even in patients undergoing dialysis, with reduced doses in certain subgroups (e.g., older patients, those weighing <60 kg). A

requirement for dose adjustment in cases of mild renal dysfunction is dictated by available clinical data and the likelihood of serious toxicity if drug accumulates in plasma because of impaired elimination. Renal failure reduces the protein binding of some drugs (e.g., phenytoin); in this case a total drug concentration value in the therapeutic range may actually represent a toxic value of unbound drug.

Advanced liver disease is characterized by decreased hepatic drug metabolism and portacaval shunts that decrease clearance, particularly first-pass clearance. Moreover, affected patients frequently have other profound disturbances of homeostasis, such as coagulopathy, severe ascites, and altered mental status. These pathophysiologic features of advanced liver disease can affect not only the dose of a drug required to achieve a potentially therapeutic effect, but also the perception of risks and benefits, thereby altering the prescriber's assessment of the actual need for therapy.

Heart disease is similarly associated with several disturbances of drug elimination and drug sensitivity that may alter the therapeutic doses or the practitioner's perception of the desirability of therapy based on evaluation of risks and benefits. Patients with left ventricular hypertrophy often have baseline QT prolongation, so risks associated with use of QT-prolonging antiarrhythmics may increase; most guidelines suggest avoiding QT-prolonging antiarrhythmics in such patients (**see Chapters 36, 96, and 98**).

In heart failure (**see Chapter 25**), hepatic congestion can lead to decreased clearance with a corresponding increased risk for toxicity with usual doses of certain drugs, including some sedatives, lidocaine, and beta blockers. On the other hand, gut congestion can lead to decreased absorption of oral drugs and decreased effects. In addition, patients with heart failure may demonstrate reduced renal perfusion and require dose adjustments on this basis. Heart failure also is characterized by a redistribution of regional blood flow, which can lead to reduced volume of distribution and enhanced risk for drug toxicity. Lidocaine probably is the best-studied example; loading doses of lidocaine should be reduced in patients with heart failure because of altered distribution, whereas maintenance doses should be reduced in both heart failure and liver disease because of altered clearance.

Age also is a major factor in determining drug doses, as well as sensitivity to drug effects. Doses in children generally are administered on an mg/kg body weight basis, although firm data to guide therapy are often not available. Variable postnatal maturation of drug disposition systems may present a special problem in the neonate. Older persons often have reduced creatinine clearance, even those with a normal serum creatinine level, and dosages of renally excreted drugs should be adjusted accordingly (**see Chapter 88**). Diastolic dysfunction with hepatic congestion is more common in older adults, and vascular disease and dementia often occur, which can lead to increased postural hypotension and risk of falling. Therapies such as sedatives, tricyclic antidepressants, or anticoagulants should be initiated only when the practitioner is convinced that the benefits of such therapies outweigh this increased risk.

Drug Interactions

As a result of therapeutic successes not only in heart disease but also in other disease areas, cardiovascular physicians are increasingly encountering patients receiving multiple medications for noncardiovascular indications. **Table 8.3** summarizes mechanisms that may underlie important drug interactions. Drug interactions may be based on altered absorption, distribution, metabolism, or excretion. In addition, drugs can interact at the pharmacodynamic level. A trivial example is the co-administration of two antihypertensive drugs, leading to excessive hypotension. Similarly, co-administration of aspirin and warfarin leads to an increased risk for bleeding, although benefits of the combination also can be demonstrated.

The most important principle in approaching a patient receiving polypharmacy is to recognize the high potential for drug interactions. A complete medication history should be obtained from each patient at regular intervals; patients will often omit topical medications such as eye drops, health food supplements, and medications prescribed by other practitioners unless specifically prompted. Each of these, however, carries a risk of important systemic drug actions and interactions. Even high dosages of grapefruit juice, which contains CYP3A and P-glycoprotein inhibitors, can affect drug responses. Beta-blocker eye drops can produce systemic beta blockade, particularly with CYP2D6 substrates (e.g., timolol) in patients with defective CYP2D6 activity. St. John's wort induces CYP3A and P-glycoprotein activity (similar to phenytoin and other drugs) and thus can greatly lower plasma concentrations of substrate drugs such as cyclosporine. As with many other interactions, this may not be a special problem provided both drugs are continued. However, if a patient stabilized on cyclosporine stops taking a concomitantly administered CYP3A inducer, plasma concentrations of the drug can rise dramatically, and toxicity can ensue. Similarly, initiation of an inducer may lead to greatly lowered cyclosporine concentrations and a risk of organ rejection. A number of natural supplements have been associated with serious drug toxicity (e.g., phenylpropanolamine-associated stroke) that has resulted in their withdrawal from the market.

Incorporating Pharmacogenetic Information Into Prescribing

The identification of polymorphisms associated with variable drug responses naturally raises the question of how these data could or should be used to optimize drug doses, avoid drugs likely to be ineffective, and avoid drugs likely to produce major toxicities. Indeed, in 2007 the FDA began systematically including pharmacogenetic information in drug labels.[23] Despite the intuitive appeal of a pharmacogenetically guided approach to drug therapy, however, practitioners wanting to adopt genetic testing to guide drug therapy encounter substantial practical barriers, including cost, varying levels of evidence supporting a role for genetics, and implementation issues such as how fast and accurately a genetic test result can be delivered. The nature of pharmacogenetic variation is that most patients will display average responses to most drugs, so systematically testing every patient in the hopes of finding the minority likely to display aberrant responses is cumbersome and seems inefficient in terms of time and cost unless the benefit for individual patients is large. An example of a large benefit is that routine genotyping of all patients receiving the antiretroviral agent abacavir is now the standard of care because it avoids a potentially life-threatening skin reaction in 3% of patients.[24] By contrast, randomized clinical trials[25-27] suggest either no effect or a modest effect on time within therapeutic range when genotype information is incorporated into warfarin dosing. These trials were underpowered to examine bleeding risk, which has been associated with variants in *CYP4F2*[28] or *CYP2C9*[29] in population- or EMR-based studies.

A difficulty with such drug-specific approaches is that the benefit of the genotype data must be large to justify the cumbersomeness and cost of testing all exposed individuals. Although the probability is small that genetic variation plays an important role in predicting the response of an individual patient to a specific drug, when many drugs are prescribed for a population of patients, each patient will display genetically determined aberrant responses to some drugs. This reasoning underlies the concept of *preemptive genotyping*, in which many genetic variants relevant to many variable drug responses are assayed in patients who have not yet been exposed to the drugs.[30,31] These data are then stored in EMR systems with advanced point-of-care decision support capabilities that deliver instantaneous advice when a drug is prescribed to a patient with known genomic variants.[32] Several technological developments enable this vision, including advanced EMRs and multiplexed inexpensive genotyping assays that

interrogate many polymorphisms for the same cost as a handful relevant to one drug. The concept is now being tested at a few medical centers, with the goals of establishing cost and benefit, understanding how health care providers react,[33] and optimizing decision support to integrate pharmacogenomic information seamlessly into health care.

Future Perspectives

The past 25 years have seen dramatic advances in the treatment of heart disease, in no small part because of the development of highly effective and well-tolerated drug therapies such as HMG-CoA reductase inhibitors, ACE inhibitors, and beta blockers. These developments, along with improved nonpharmacologic approaches, have led to dramatically enhanced survival of patients with advanced heart disease. Thus, polypharmacy in an aging and chronically ill population is becoming increasingly common. In this milieu, drug effects become increasingly variable, reflecting interactions among drugs, underlying disease and disease mechanisms, and genetic backgrounds. Furthermore, despite advances in the Western world, cardiovascular disease is emerging as an increasing problem worldwide as infectious diseases, formerly predominant contributors to morbidity and mortality, are coming under control and smoking and the metabolic syndrome are increasing. Understanding how genetic background plays into disease susceptibility and responses to drug therapy, concepts largely tested in only European-ancestry populations to date, represents a major challenge in cardiovascular medicine.

More generally, genomic medicine—the application of genetic variant information in health care—is still in its infancy, so reported associations require independent confirmation and assessment of clinical importance and cost-effectiveness before they can or should enter clinical practice. Importantly, most pharmacogenomic studies reported to date have focused on common variants, and we now recognize that the vast majority of polymorphisms in any gene, including CYPs and other “pharmacogenes,” are uncommon (MAF < 1%). Developing approaches to establish the clinical impact of such rare variants on drug responses is an emerging challenge.

This challenge is all the more acute because the cost of sequencing has fallen drastically since the completion of the first-draft human genome in 2000, and the under-$1000 whole-genome sequence is now a reality. This may be enabling for the preemptive pharmacogenomic strategy just outlined, as well as a broader vision of genome-guided health care, but presents major challenges in data storage and mining.

The relationship between the prescriber and the patient remains the centerpiece of modern therapeutics. An increasingly sophisticated molecular and genetic view of response to drug therapy should not change this view, but rather complement it. Each initiation of drug therapy represents a new clinical experiment. Prescribers must always be vigilant regarding the possibility of unusual drug effects, which could provide clues about unanticipated and important mechanisms of beneficial and adverse drug effects.

Biomarkers and Use in Precision Medicine

Peter Libby, Robert E. Gerszten, Paul M. Ridker

Clinicians use biomarkers daily in the practice of cardiovascular medicine. Moreover, the use of biomarkers can continue to improve physicians' ability to provide clinically effective and cost-effective cardiovascular medicine in the years ahead.[1] Appropriate risk stratification and targeting of therapies should not only help improve patient outcomes but also assist in responding to the urgent need to “bend the cost curve” of medical care. In particular, excessive use of imaging biomarkers increases the cost of medical care and can jeopardize patient outcomes (e.g., from radiation exposure or complications of administering contrast material or investigating incidental findings). Inappropriate use or interpretation of blood biomarkers (e.g., cardiac troponin levels) can lead to unnecessary hospitalization or procedures as

well.

Despite the current usefulness of biomarkers, their future promise, and the critical need to use them appropriately, much misunderstanding still surrounds their current clinical application.[1] In addition, contemporary technologies can greatly expand the gamut of biomarkers relevant to cardiovascular practice. Emerging genetic, proteomic, metabolomic, and molecular imaging strategies will surely transform the landscape of cardiovascular biomarkers (**see also Chapters 6 to 8 and 45**).

This chapter provides a primer on cardiovascular biomarkers by defining terms and discussing how the application of biomarkers can assist in clinical care, in addition to exploring some emerging technologies. We also discuss an approach to the rigorous evaluation of the clinical usefulness of biomarkers. Advances in cardiovascular biology and the application of novel technologies have identified a plethora of novel cardiovascular biomarkers of potential clinical usefulness—begging the question of whether a novel biomarker adds value to existing and often better-validated biomarkers. Thus, clinicians need tools to evaluate these emerging biomarkers, the adoption of which may elevate clinical practice and improve patient outcomes.

Overview of Biomarkers

For regulatory purposes, the U.S. Food and Drug Administration (FDA) first defined a *biomarker* in 1992 as "a laboratory measure or physical sign that is used in therapeutic trials as a substitute for a clinically meaningful end point that is a direct measure of how a patient feels, functions, or survives and is expected to predict the effect of the therapy." At that time the FDA considered a *surrogate endpoint* as "reasonably likely, based on epidemiologic, therapeutic, pathophysiologic, or other evidence, to predict clinical benefit." The National Institutes of Health (NIH) convened a working group in 1998 that offered some parallel operating definitions to guide the biomarker field (**Table 9.1**). NIH defined a *biologic marker,* or biomarker, as "a characteristic that is objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention." Thus the NIH definition includes not only soluble biomarkers in circulating blood but also "bedside biomarkers," such as anthropomorphic variables obtainable with a blood pressure cuff or a tape measure at the point of care. This broad definition encompasses measurements of biomarkers in blood (**Fig. 9.1A**) as well as measurements from imaging studies (**Fig. 9.1B**). Imaging biomarkers can include those derived from classic anatomic approaches. Imaging modalities now offer functional information, such as estimates of ventricular function and myocardial perfusion. Molecular imaging has the potential to target specific molecular processes. A functional classification of biomarkers helps sort through the plethora encountered by the clinician, in that biomarkers can reflect a variety of biologic processes or organs of origin. For example, as a first approximation, cardiac troponin reflects myocardial injury, brain natriuretic peptide reflects cardiac chamber stretch, C-reactive protein reflects inflammation, and the estimated glomerular filtration rate reflects kidney function.

TABLE 9.1
Biomarker Definitions

Biologic marker (biomarker) A characteristic that is objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention.
Surrogate endpoint A biomarker intended to substitute for a clinical endpoint. A surrogate endpoint is expected to predict clinical benefit (or harm) or lack of benefit (or harm) based on epidemiologic, therapeutic, pathophysiologic, or other scientific evidence.
Clinical endpoint A characteristic or variable that reflects how a patient feels, functions, or survives.

From National Institutes of Health (NIH) Biomarkers Definition Working Group, 1998.

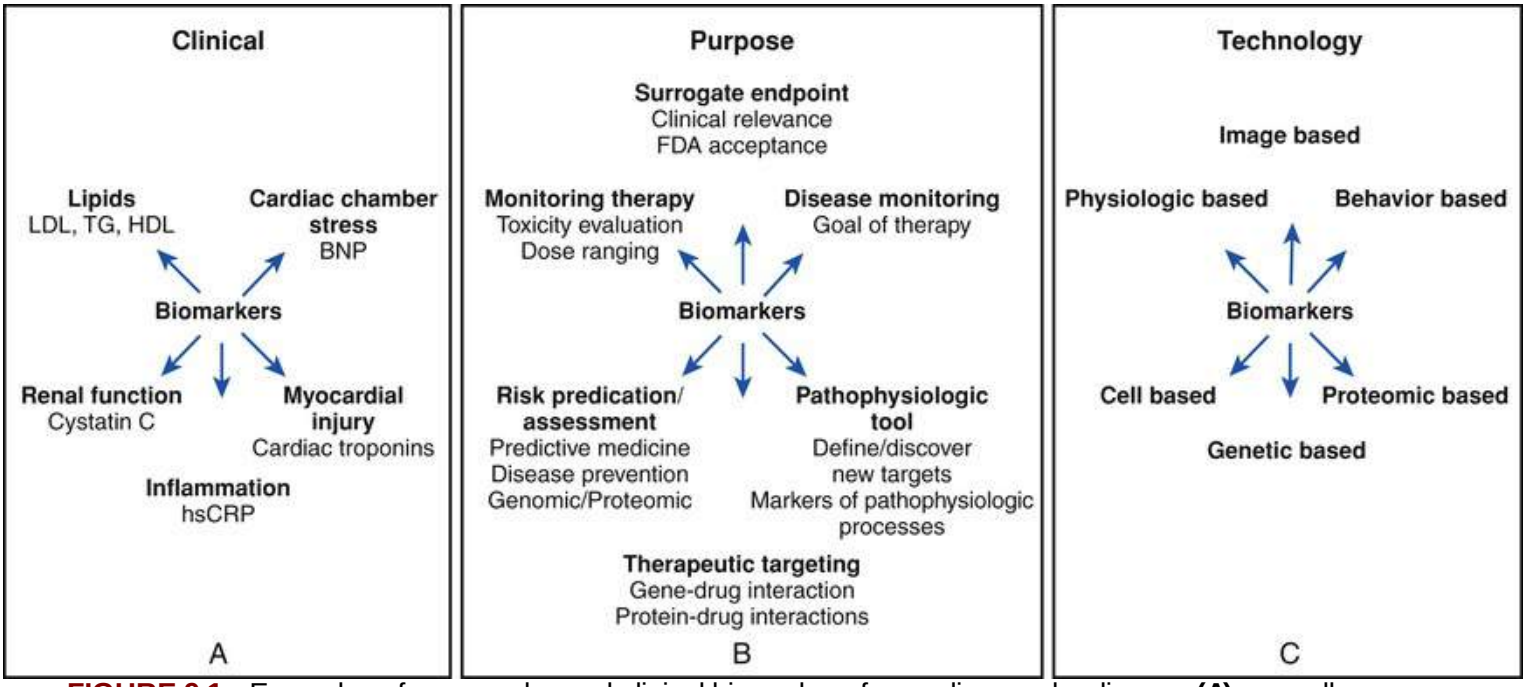

FIGURE 9.1 Examples of commonly used clinical biomarkers for cardiovascular disease **(A),** as well as research-oriented biomarkers categorized according to purpose **(B)** and technology **(C).** *BNP,* Brain natriuretic peptide; *hsCRP,* high-sensitivity C-reactive protein; *TG,* triglyceride.

The NIH working group defined a *surrogate endpoint* as "a biomarker intended to substitute for a clinical endpoint. A surrogate endpoint is expected to predict clinical benefit (or harm) or lack of benefit (or harm) based on epidemiologic, therapeutic, pathophysiologic, or other scientific evidence." (Note that the NIH definitions do not include the commonly used term *surrogate marker.*) Thus a surrogate endpoint is a biomarker that has been "elevated" to surrogate status. This distinction has particular importance in the regulatory aspects of cardiovascular medicine. For example, the FDA previously accepted a certain degree of reduction in hemoglobin A_{1c} (HbA_{1c}) as a criterion for registration of a novel oral hypoglycemic agent; thus HbA_{1c} was considered a biomarker accepted as a surrogate endpoint. Current FDA guidance now requires a cardiovascular safety study for the registration of new medications that target diabetes.[2] This policy indicates regulatory doubts about the fidelity of a decrease in HbA_{1c} as a surrogate endpoint for reduced cardiovascular risk, despite its value as a biomarker of glycemia.

The NIH working group defined a *clinical endpoint* as "a characteristic or variable that reflects how a patient feels, functions, or survives." Pivotal or phase III cardiovascular trials aspire to use clinical endpoints so defined. The distinction among biomarkers, surrogate endpoints, and clinical endpoints has crucial implications as practitioners, regulators, and payers increasingly demand evidence of improvements in actual clinical outcomes rather than mere manipulation of biomarkers as a criterion for

adoption of a treatment in clinical practice.

Clinical Applications of Cardiovascular Biomarkers

Much of the prevailing confusion regarding biomarkers involves framing the question that the clinician wants to answer with the use of a biomarker (**Fig. 9.1C**). We can classify the goals of application of cardiovascular biomarkers into the following rubrics:

1. *Diagnosis.* The use of biomarkers for cardiovascular diagnosis is part of daily medical practice. The current universal definition of myocardial infarction, for example, requires elevation of a biomarker of myocyte injury, such as cardiac-specific isoforms of troponin.
2. *Risk stratification.* Familiar examples of biomarkers used in risk stratification in cardiovascular medicine include systolic blood pressure (SBP) and low-density lipoprotein cholesterol (LDL-C). These biomarkers reliably predict future risk for cardiovascular events on a population basis.
3. *Goals for therapy.* Contemporary guidelines often specify cutoff points for targets of treatment, for example, a specific level of a biomarker (e.g., SBP, LDL-C) in a particular group of individuals. Practitioners of cardiovascular medicine typically use the biomarker international normalized ratio (INR) to titrate the dosage of warfarin administered to an individual patient. Abundant data support the clinical benefit of maintaining the INR within a certain range in various patient groups, an example of a widely used biomarker that has proven clinical usefulness as a goal for therapy.
4. *Targeting of therapy.* In clinical practice, using biomarkers to target therapy has great usefulness and promise as we move toward a more comprehensive "personalized medicine" approach to practice (**see Chapter 6**). Examples of biomarkers used to target therapy include troponin measurements to triage patients with acute coronary syndromes for early invasive management and measurement of high-sensitivity C-reactive protein (hsCRP) to allocate statin treatment to individuals with below-average LDL-C.
5. *Drug development, evaluation, and registration.* Biomarkers have critical importance in the development of new pharmacologic agents. Biomarkers can provide early signals of efficacy that will help prioritize agents more likely to provide benefit on clinical endpoints in large-scale trials. Clinical trials often fail because of inappropriate dose selection. Judicious use of biomarkers can help in selecting an appropriate dose of an agent to study in a large endpoint trial. Biomarkers accepted as surrogate endpoints also prove useful to regulatory agencies in granting approval for novel therapies.

Clinical use of cardiovascular biomarkers requires a clear understanding of *how* they should be used. Many biomarkers provide clinically useful information when measured once at "baseline." A baseline measurement of high-density lipoprotein cholesterol (HDL-C), for example, correlates inversely with future risk for cardiovascular events. However, serial measurement of biomarkers to document a change does not always guarantee a clinical benefit. In the case of HDL-C, recent large-scale trials that have measured clinical endpoints have cast doubt on the fidelity of a rise in HDL-C as a predictor of clinical benefit (**see Chapter 48**). Serial measurements of coronary calcium may prove misleading because statin therapy increases calcification but decreases coronary events.[3,4]

Biomarkers require rigorous validation before adoption into clinical practice. In cardiovascular medicine, LDL-C has high reliability as a biomarker; it satisfies the modified Koch postulates. LDL

levels prospectively predict cardiovascular risk, and decreases in LDL generally correlate with improved outcomes. Not all biomarkers, however, have proved as faithful in predicting clinical events. In the 1960s and 1970s, for example, most of the cardiovascular community considered ventricular premature depolarizations on the electrocardiogram (ECG) as important biomarkers for lethal arrhythmias. Numerous strategies have been aimed at suppressing ventricular ectopy. CAST (Cardiac Arrhythmia Suppression Trial), however, showed that drugs capable of suppressing ventricular premature depolarizations actually worsened clinical endpoints. The short-term improvements in indices of cardiac contractility produced by inotropic agents similarly led to worsened clinical outcomes, including increased mortality. These examples illustrate the necessity of rigorous validation of biomarkers before adoption into clinical practice.

Another important consideration in the use of cardiovascular biomarkers involves the question of *causality*. LDL-C exemplifies a *causal biomarker*, one that clearly participates in the pathogenesis of atherosclerosis. Its levels prospectively correlate with risk for cardiovascular events and the development of atherosclerotic lesions identified by a variety of imaging modalities. A variety of independent manipulations of LDL-C levels correlate with clinical outcomes. In addition, very strong genetic evidence based on mendelian disorders (e.g., familial hypercholesterolemia) and unbiased genome-wide association scans, as well as mendelian randomization analyses, have established LDL-C as a causal risk factor in atherosclerotic cardiovascular disease and as a generally valid surrogate endpoint offering great value in clinical practice[5,6] (**see Chapter 48**). Even a well-validated causal biomarker such as LDL-C, however, may mislead under some circumstances. For example, lowering of LDL-C with certain cholesteryl ester transfer protein inhibitors does not appear to lead to clinical benefit.

Other biomarkers, although clearly clinically useful, do not participate in the causal pathway for disease. For example, fever has served since antiquity as an important biomarker of infection. Resolution of fever correlates with successful resolution of infectious processes. However, fever does not participate causally in the pathogenesis of infection but merely serves as a biomarker of the host defenses against the infectious process. Similarly, the use of hsCRP measurements improves the prediction of cardiovascular risk, and reductions in CRP correlate with clinical benefit in many cases. Regardless, evidence supporting a causal role for CRP in the pathogenesis of cardiovascular disease lacks strength.[7]

These examples illustrate how a biomarker does not need to reside in the causal pathway of a disease to have clinical usefulness. A clear and early exposition of the uses and pitfalls in the application of biomarkers emerged from the landmark work of Fleming and DeMets (**Fig. 9.2**). Biomarkers have the greatest potential for validity when there is one causal pathway and when the effect of intervention on true clinical outcomes is mediated directly through the biomarker surrogate (**Fig. 9.2A**). However, biomarker development can fail when the biomarker is found not to be in the causal pathway, when the biomarker is insensitive to the specific intervention's effect, or when the intervention of interest has a mechanism of action (or a toxicity) that does not involve the pathway described by the biomarker (**Fig. 9.2B-E**). These examples do not mean that biomarkers lack value; few if any novel biologic fields could develop without biomarker discovery and validation. Still, surrogate endpoints probably will not replace large-scale randomized trials that address whether interventions reduce actual event rates.

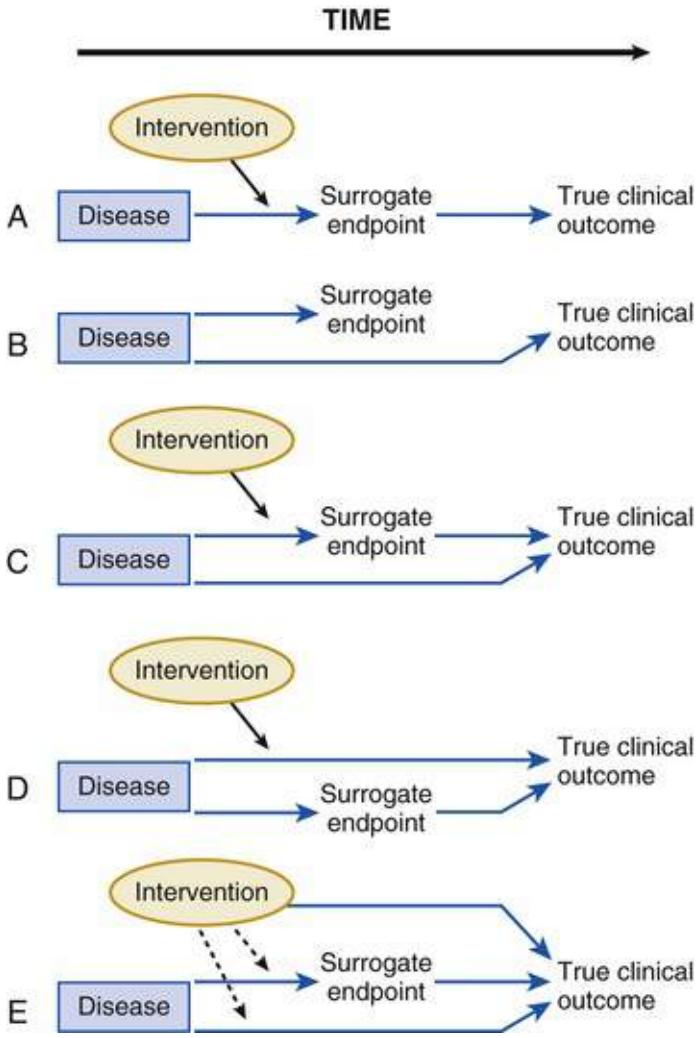

FIGURE 9.2 Biomarkers as surrogate endpoints in clinical research. **A,** The setting that provides the greatest potential for the surrogate endpoint to be valid. **B,** The surrogate is not in the causal pathway of the disease process. **C,** Of several causal pathways of disease, the intervention affects only the pathway mediated through the surrogate. **D,** The surrogate is not in the pathway of the intervention's effect or is insensitive to its effect. **E,** The intervention has mechanisms of action independent of the disease process. *Dotted lines* represent possible mechanisms of action. (Modified from Fleming TR, DeMets DL. Surrogate end points in clinical trials: are we being misled? Ann Intern Med 1996;125:605.)

Novel Technologies in Biomarker Identification

The limitations of currently available biomarkers for screening or prognostic use underscore the importance of identifying “uncorrelated” or “orthogonal” biomarkers associated with novel disease pathways. Most current biomarkers have been developed as an extension of targeted physiologic studies investigating known pathways such as tissue injury, inflammation, or hemostasis. By contrast, emerging technologies now enable the systematic, unbiased characterization of variation in proteins and metabolites associated with disease conditions.

Proteomics and Metabolomics

Of the emerging platforms for biomarker discovery, perhaps none has garnered more recent attention than proteomics and metabolomics. *Proteomics* aims to catalog the entire protein products of the human genome. By contrast, *metabolomics* attempts systemically to capture smaller biochemical compounds, including simple amino acids and related amines, as well as lipids, sugars, nucleotides, and other

intermediary metabolites. Although still less mature than other approaches, proteomics and metabolomics offer insight into the full complexity of a given disease (**Fig. 9.3**). Because proteins and metabolites are downstream of genetic variation and transcriptional changes, they can provide instantaneous "snapshots" of the state of a cell or organism. They can rapidly change in response to environmental stressors such as exercise or directly by the ingestion of foods or other compounds. A growing body of literature suggests unanticipated roles of small proteins and metabolites in the control of biologic functions such as blood pressure and energy homeostasis.[8] Thus, metabolomics and proteomics may not only identify novel biomarkers but also provide information on biology and highlight potential therapeutic targets.

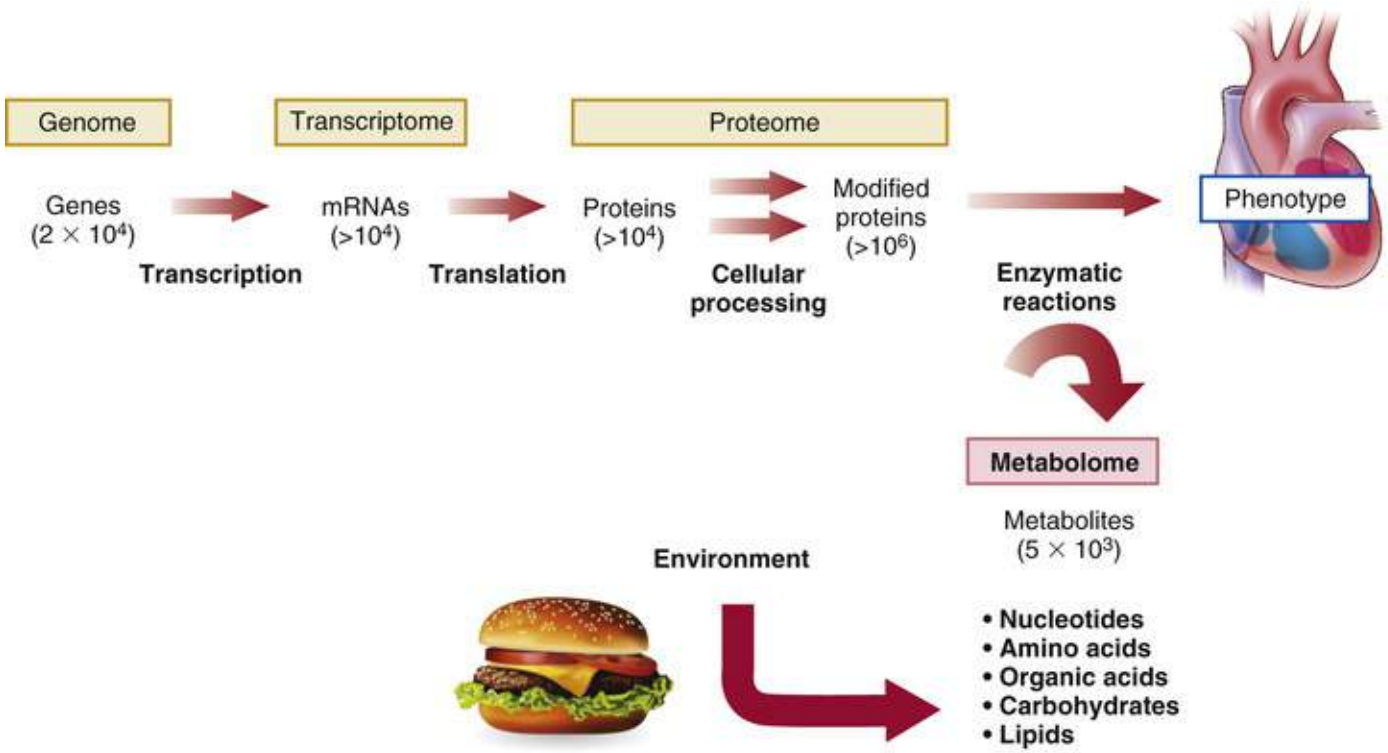

FIGURE 9.3 The conceptual relationship of the genome, transcriptome, proteome, and metabolome. Informational complexity increases from genome to transcriptome to proteome. The estimated number of entities of each type of molecule in humans is indicated in parentheses.

The term *proteome* was coined in the 1990s with the increasing realization that although all cells of a given organism contain an equivalent genomic content, their protein content does not represent all possible proteins that the genome can express. Selective gene expression during development and differentiation and in response to external stimuli results in each cell expressing only a subset of the encoded proteins at any given time. One can speak not only of the general human proteome but also more specifically about the proteome of tissues such as the heart, of specific cells such as cardiac myocytes, and even of subproteomes that correspond to particular organelles or biologic compartments, such as mitochondria.

The proteome provides information beyond the messenger RNA (mRNA) expression profile of a particular genome. Studies suggest that gene expression often correlates poorly with protein levels. Protein expression depends not only on transcription but also on mRNA stability and rates of protein synthesis and degradation, so the presence or absence of mRNA may not accurately reflect levels of the corresponding protein. Following transcription and translation, proteins may undergo one or more of dozens of potential post-translational modifications, which often modulate protein function (e.g., phosphorylation, glycosylation, acetylation, sulfation) at multiple sites. Subsequent enzymatic and

nonenzymatic alterations greatly expand the number of simultaneously existing protein species.

Compared with proteomic techniques, metabolomic technologies focus on smaller compounds, generally less than 2 kDa in size. Metabolites are usually easily separated from protein constituents by simple extraction techniques and precipitation and removal of the proteins. As early as the 1970s, Arthur Robinson and Linus Pauling postulated that the quantitative and qualitative pattern of metabolites in biologic fluids reflected the functional status of the complex biologic system from which they were derived. The term “metabolic profiling” was introduced to describe data obtained from gas chromatographic analysis of a patient sample. This emerging approach to quantitative metabolic profiling of large numbers of small molecules in biofluids was ultimately termed “metabonomics” or “metabolomics” by others.[9] Recently, more focused analyses of specific metabolite families or subsets have given rise to new terms such as “lipidomics.” In terms of applications to human diagnostics, seminal studies of inborn errors of metabolism in infants have served as a key springboard. Mass spectrometry (MS)–based methods permit monitoring of fatty acid oxidation, as well as organic and selected amino acids, enabling neonatal screening for metabolic disorders[9] and thus identification of infants with fatty acid oxidation disorders, organic acidemias, and aminoacidopathies. In certain situations, rapid identification of these disorders triggers intervention such as dietary modulation, with beneficial therapeutic effects. A global metabolomic or proteomic analysis of more common complex diseases might similarly spotlight pathways for dietary or drug modulation.

Analytic Challenges

The many classes of proteins and chemicals present analytic challenges, particularly as applied to searching for biomarkers in blood. Many different types of cells contribute to the plasma proteome and metabolome, thus increasing their complexities and presenting challenges to interpretation of the data that emerge. In the case of the proteome, the 22 most abundant proteins, including albumin and the immunoglobulins, account for 99% of the total proteome mass (**Fig. 9.4**). Many of the biologically interesting molecules relevant to human disease occur in low abundance. Cardiac markers such as troponin circulate in the nanomolar range, insulin in the picomolar range, and tumor necrosis factor in the femtomolar range. Plasma contains tens of thousands of unique protein species in concentrations spanning a range of more than 10 orders of magnitude. Indeed, some suggest that the plasma proteome might encompass the entire set of human polypeptide species resulting from splice variants and post-translational modifications, because the protein content of plasma unexpectedly includes proteins of all functional classes and from apparently all cellular localizations. Most low-abundance proteins in plasma are intracellular, or membrane proteins appear in plasma as a result of cellular turnover. Recent estimates suggest that the human metabolome consists of fewer molecular entities than the human proteome[10] and thus may be somewhat more tractable to analyze and systematize.

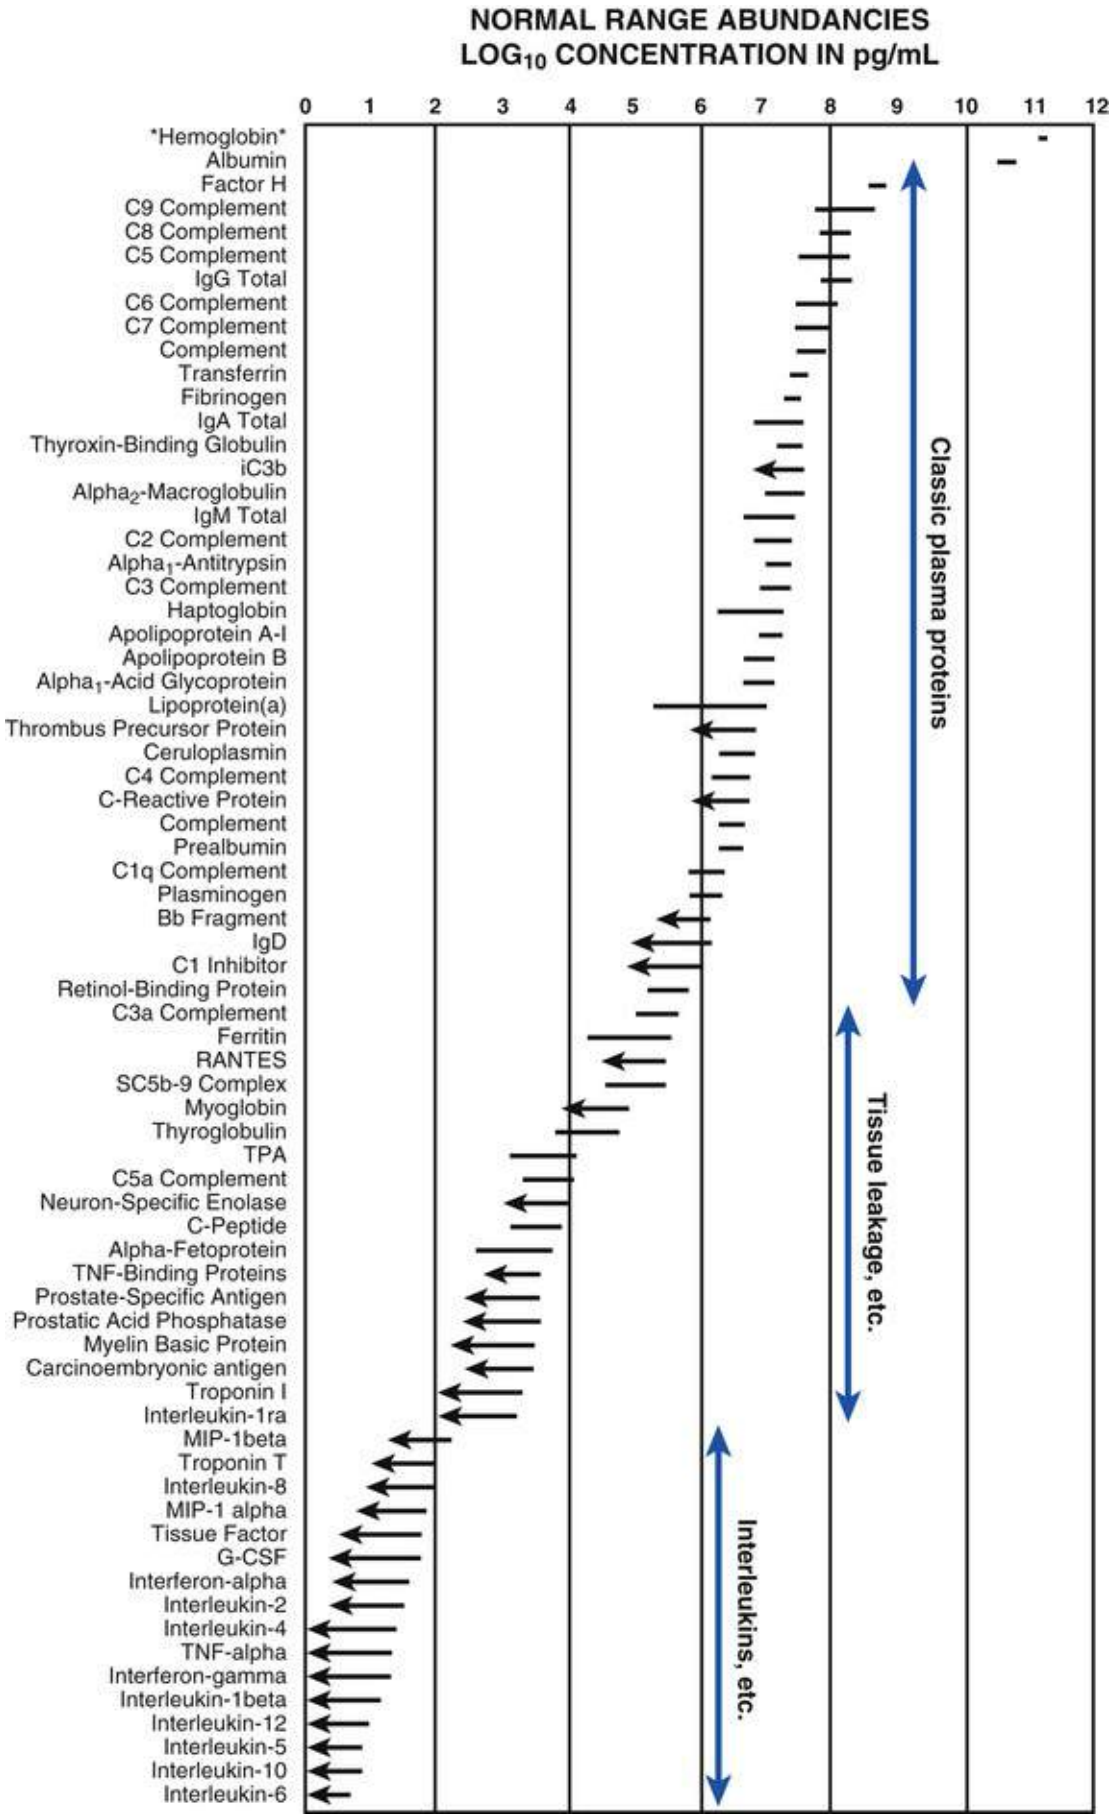

FIGURE 9.4 Reference concentration for representative protein analytes in plasma. Protein abundance is plotted on a log scale spanning 12 orders of magnitude. When only an upper limit is quoted, the lower end of the interval line shows an *arrowhead*. The classic plasma proteins are clustered to the left (high abundance), the tissue leakage markers (e.g., enzymes, troponins) are clustered in the center, and the cytokines are clustered to the right (low abundance). *G-CSF,* Granulocyte colony-stimulating factor; *MIP,* macrophage inflammatory protein; *RANTES,* regulated on activation, T cell expressed and secreted; *TNF,* tumor necrosis factor; *TPA,* tissue plasminogen activator. (From Anderson NL, Anderson NG. The human plasma proteome: history, character, and diagnostic prospects. Mol Cell Proteomics 2003;2:50.)

Several features contribute critically to the success of proteomic or metabolomic technologies. First, the technique must have the capability of identifying a wide breadth of proteins or metabolite analytes within complex biologic samples across a range of physical characteristics, including size and charge. Second, the technologies must be sensitive enough to probe the proteome or metabolome to adequate "depths"—that is, to provide resolution of biologically active compounds of the lowest abundance. Frequently, the least abundant entities play critical regulatory roles in the response to physiologic stressors. Third, tools must also work across a broad dynamic range, a notion underscored in Fig. 9.4—they must be able to simultaneously identify both more abundant and less abundant proteins in the same complex mixture. Unfortunately, most analytic techniques apply well only across concentrations of several orders of magnitude. Fourth, the ideal technology should be stable and reproducible, an attribute necessary for minimizing artifacts during initial discovery, validation, and testing for clinical applications.

Robust, searchable databases for validation of identified proteins or metabolites represent an increasingly crucial support for biomarker discovery. The scope of investigation addressable by these techniques has widened immeasurably since completion of the Human Genome Project. At present, the human databases are the largest and easiest to use, which will help accelerate translational investigation. Genomic databases collectively provide a catalog of all known or theoretical proteins expressed in organisms for which databases exist. Software that can search through databases for identification of candidates has proved essential to interpretation of the data; much of this software is available on the Internet. Collaborative efforts have recently begun to catalog both the human proteome and the plasma metabolome.

The Biomarker Discovery Process

Fig. 9.5 summarizes the essential elements of the discovery approach to biomarkers by using a proteomics experiment as an example. Biologic samples consist of a complex mixture containing intact and partially degraded proteins and metabolites of various molecular weights, modifications, and solubility. The chance of identifying proteins or metabolites in a mixture increases as the complexity of the mixture decreases. As suggested by Liebler,[11] the problem of complexity and how to deal with it resembles the process of printing a book. Printing all the words on a single page could be accomplished quickly, but the resulting page would be illegibly black with ink; dividing the text into multiple pages reduces the complexity to reveal organized text. Analogously, samples can be enriched for certain components through fractionation or affinity depletion columns, but all preparative procedures—including solubilization, denaturation, and reduction processes—should be compatible with the constraints of subsequent analysis steps. The quest to reduce complexity requires careful balance against the possibility that each additional step might also introduce undesired protein or metabolite modifications or loss.

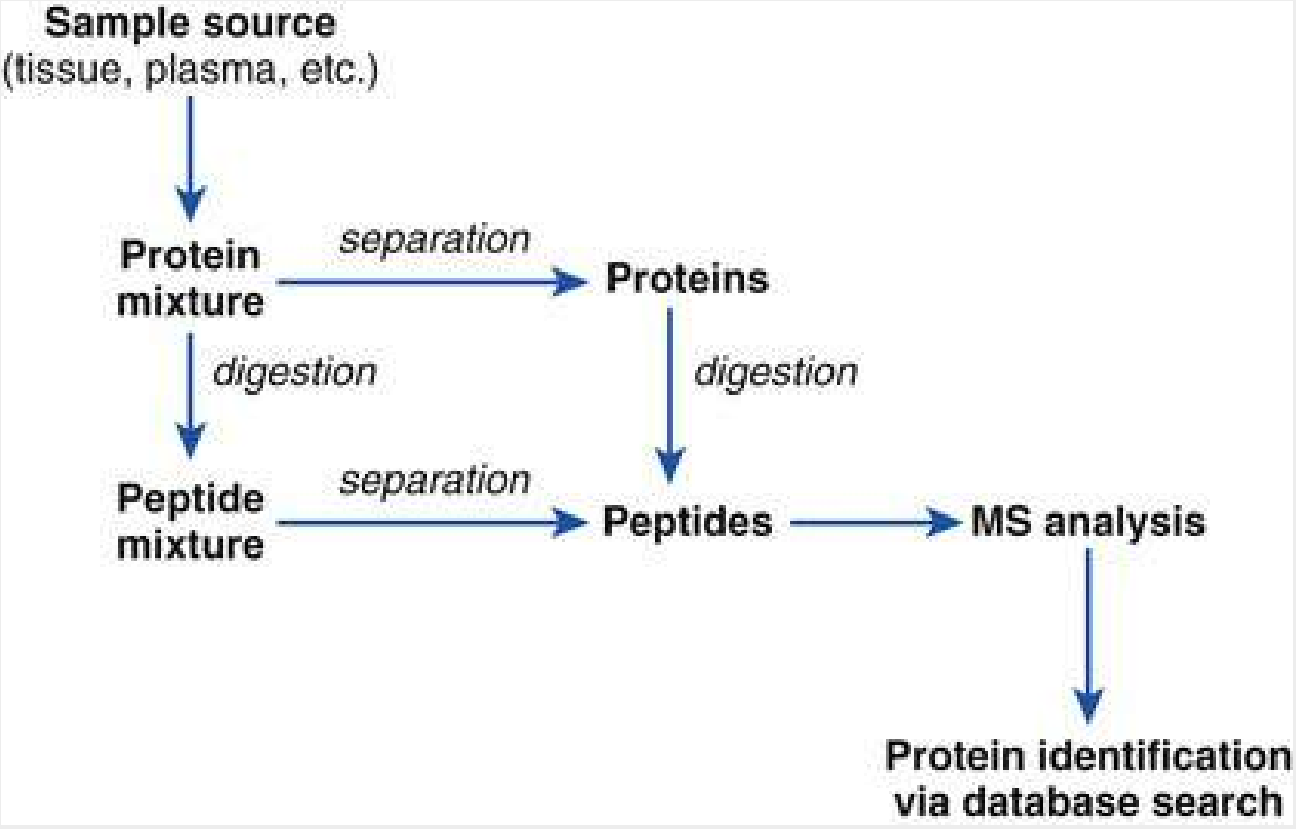

FIGURE 9.5 Overview of a proteomics experiment; *MS,* mass spectrometry.

Several analytic techniques can serve to identify metabolites or proteins, although MS instrumentation offers an unrivaled ability to provide several layers of complementary information, which has benefited tremendously from whole-genome analysis and the genomics revolution. MS provides accurate mass detection of peptides from proteolytic digests of complex protein mixtures or small metabolites derived from tissues or blood. The set of peptide or metabolite mass measurements can be searched in databases to obtain definitive identification of the parent proteins or metabolites of interest. Favorably compared against other proteomics and metabolomics technologies, MS offers high sensitivity and amenability to automation, thus promoting high-throughput processing. MS has a wide range of applicability and not only detects metabolites and proteins but also characterizes any post-translational modifications.

Mass spectrometers contain modular elements, including an ion source, mass analyzer, and a detector/recorder (**Fig. 9.6**). MS instruments differ by ionization source and mass analyzer used, but all process samples as gas-phase ions, the movements of which are measured precisely within an electromagnetic field. An ion source generates these gas-phase ions from the analyte through a variety of available techniques, from either the solid state by matrix-assisted laser desorption/ionization (MALDI) or directly from the liquid phase by electrospray ionization (ESI). A coupled chromatographic separation step fractionates complex sample mixtures before ESI spectroscopic analysis. The gas-phase ions then enter the mass analyzer, which resolves the peptides based on their mass-to-charge (m/z) ratio. Examples of commonly used mass analyzers include the quadrupole mass filter, ion trap mass analyzer, and time-of-flight mass analyzer. Lastly, the detector records the ions with an electronic multiplier and records ion intensity versus the m/z value to create the resulting MS spectra.

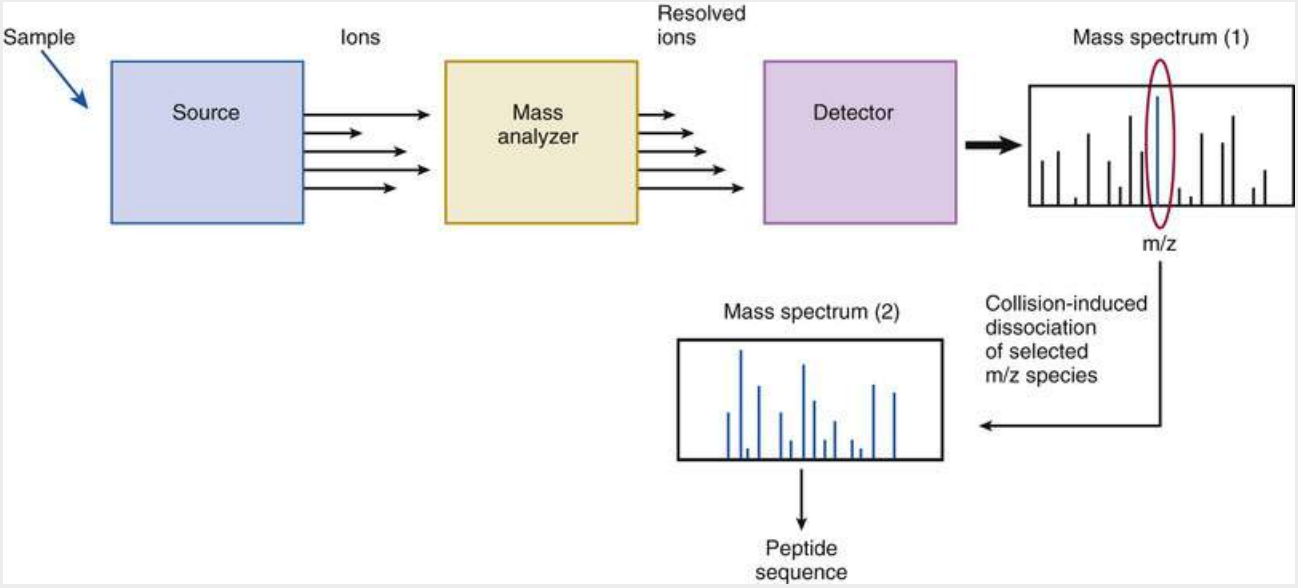

FIGURE 9.6 Schematic of tandem mass spectrometry; *m/z,* mass-to-charge ratio.

These technologies can characterize biologic fluids either in a targeted manner or in a pattern discovery manner. In the *targeted* approach, the investigator targets a predefined set of analytes to be quantitated. For example, libraries of metabolites can be purchased and their chromatographic and MS characteristics determined empirically by "spiking" reference standards into plasma. The information ascertained from the known standards then permits quantification of endogenous metabolites. The targeted approach now readily permits assay of several hundred metabolites in as little as tens of microliters of plasma. In the *pattern discovery* experiment, by contrast, the investigator confronts a complex pattern of peaks, many of which are anonymous—the molecular identities of the species that give rise to the peaks are not generally known. Although the targeted approach is more limiting, the analysis is more straightforward because the analytes yielding the signals are already known. The untargeted or "fingerprint" approach has less inherent bias, but unambiguous identification of the peaks can prove laborious and difficult. Analyses of clinical samples require considerable care to exclude spurious associations, such as confounding related to drug treatment.

Applications of Mass Spectrometry–Based Discovery to Cardiometabolic Disease

In an initial proof-of-principle study using a targeted metabolite profiling approach, Newgard and colleagues[12] profiled obese versus lean humans to gain a broad understanding of the metabolic and physiologic differences in these two disparate groups. Their studies identified a branched-chain amino acid signature that correlated highly with the metrics of insulin resistance. Complementary studies in two large population-based cohorts demonstrated that branched-chain and aromatic amino acid concentrations are significantly associated with incident type 2 diabetes up to 12 years before the onset of overt disease.[13] Adjustment for established clinical risk factors did not substantially attenuate the strength of these associations. Furthermore, the branched-chain amino acid signature also predicts atherosclerosis even after adjusting for the metrics of insulin resistance and diabetes.[14] For those in the top quartile of branched-chain amino acid levels, the odds for development of cardiometabolic disease exceeded any single-nucleotide polymorphism (SNP) identified to date. Taken together, these findings have disclosed dysregulation of amino acid metabolism very early in the development of cardiometabolic diseases. Ongoing studies are examining the relative genetic versus environmental contributions to these findings. A

recent report suggests that genetic variation in enzymes in branched-chain amino acid metabolism is associated with both circulating amino acid levels and diabetes in multiple large-scale human cohorts, suggesting that this class of compounds also contributes to disease pathogenesis.[15]

Using nontargeted liquid chromatography–MS–based metabolite profiling applied to cardiovascular disease, Wang and associates[13] first profiled the plasma of 75 individuals from a hospital-based cohort who experienced a myocardial infarction, stroke, or death in the ensuing 3 years and 75 age- and sex-matched controls who did not.[13] Of 18 analytes that differed significantly between cases and controls, three demonstrated significant correlations among one another, thus suggesting a potential common biochemical pathway. Using complementary analytic methods, these metabolites were identified as betaine, choline, and trimethylamine-*N*-oxide, all metabolites of dietary phosphatidylcholine. Dietary supplementation of choline was sufficient to promote atherosclerosis in mice, and suppression of the intestinal bacteria responsible for the conversion of phosphatidylcholine to choline inhibited this atherogenesis. In addition to reinforcing the interaction among diet, gut bacteria, and the metabolome, this study demonstrated how metabolomic biomarker discovery can elucidate novel pathways to disease.

The previous discussion describes methods of discovery for soluble biomarkers found in body fluids. Analysis of cells also provides another aspect of biomarker use. Fluorescent-activated cell sorting (FACS) has provided a robust method for classifying cells by their cell surface structures.[16] Modifications of this technique can quantify intracellular proteins such as cytokines as well. A recent advance in characterizing cells derived from cytometry and MS is cytometry by time-of-flight mass spectrometry (CyTOF).[17] This technology permits staining of complex cell mixtures with multiple antibodies. Site talk resembles flow cytometry but uses antibodies labeled with rare-earth metal isotopes to resolve as many as 50 cell markers simultaneously. The use of rare-earth tags yields a very low background and permits resolving multiple targets, because the masses of the marked antibodies have minimal overlap. The application of CyTOF promises to permit a deeper immunophenotyping of circulating cells than achievable with traditional fluorescent cell-sorting techniques.[17,18]

Future Directions

Identification of new biomarkers for cardiovascular disease depends on the complementary power of genetics, transcriptional profiling, proteomics, and metabolomics. As discussed in the next section, the clinical usefulness of new biomarkers will require rigorous evaluation of their ability to improve the prediction of risk or to direct and monitor management in an individual, the ultimate goal of personalized medicine. In addition to risk biomarkers, diagnostic biomarkers could help in making challenging acute diagnoses such as reversible myocardial ischemia, pulmonary embolism, and aortic dissection. The evolution of a clinical biomarker requires a long journey and an arduous transition from the research environment to clinical practice. Emerging technologies such as those previously described have the potential to permit systematic assessment of variation in genes, RNA, proteins, and metabolites for identification of “uncorrelated” or “orthogonal” biomarkers that probably would not emerge with a focus on candidates from well-studied pathways.

Aptamer-based technologies are one emerging approach to probe the plasma proteome selectively. *Aptamers*, often considered as “chemical antibodies,” are small RNA or single-stranded (ss) DNA nucleic acids that can bind with great specificity to targeted proteins and related cell targets.[19-22] When

modified with biotin and an activatable fluorophore, aptamers can be incubated with plasma and, using standard bead immobilization techniques, ultimately separated into bound and unbound fractions. Once eluted, these bound aptamers (reflecting their accompanying protein targets) are hybridized to microarrays with complementary ssDNA probes to quantify the specific fluorescent tags.[20] In a recent cardiovascular application of this technology, investigators in the Heart and Soul and HUNT-3 studies used an aptamer-based approach to evaluate 1130 proteins simultaneously. Of these, nine proteins were identified as being predictive of vascular risk, and a risk score derived from these nine proteins was able to separate high from low risk. A second study used a similar aptamer-based platform to identify dozens of novel markers of early myocardial injury. The generalizability of these findings requires much further work to validate clinical utility in terms or early diagnosis or reclassification, and perhaps most importantly, whether the aptamer approach can identify novel therapeutic targets.[21]

Clinical Measures of Biomarker Performance

When considering any biomarker in a clinical setting for risk prediction, physicians should ask two interrelated questions[23]:

- Is there clear evidence that the biomarker of interest predicts future cardiovascular events independent of other already measured biomarkers?
- Is there clear evidence that patients identified by the biomarker of interest will benefit from a therapy that they otherwise would not have received?

If the answer to both these questions is not a clear “yes,” it can be argued that measuring the biomarker will not probably have sufficient usefulness to justify its cost or unintended consequences. Such judgments require clinical expertise and will vary on a case-by-case basis.

Biomarker evaluation also typically involves repeated testing in multiple settings that include varied patient populations and that use different epidemiologic designs. *Prospective* cohort studies (in which the biomarker or exposure of interest is measured at baseline, when individuals are healthy, and then related to the future development of disease) provide a much stronger form of epidemiologic evidence than do data from *retrospective* case-control studies (in which the biomarker of interest is measured after the disease is present in the case participants).

After discovery by the technologies described earlier or identification by a candidate approach, a novel biomarker typically requires development in a translational laboratory for refinement of its assay to address issues of interassay and intra-assay variation before any clinical testing begins. Focused studies in specific patient populations typically follow and eventually broaden to encompass the population of greatest clinical interest. Beyond simple reproducibility, biomarkers under development for diagnostic, screening, or predictive purposes require further evaluation with a standard set of performance measures that include sensitivity, specificity, positive and negative predictive value, discrimination, calibration, reclassification, and tests for external validity.

Sensitivity, Specificity, and Positive and Negative Predictive Value

The validity of a screening or diagnostic test (or one used for prediction) is initially measured by its ability to categorize individuals who have preclinical disease correctly as “test positive” and those without preclinical disease as “test negative.” A simple two-by-two table is typically used to summarize the results of a screening test by dividing those screened into four distinct groups (**Table 9.2**). In this context, sensitivity and specificity provide fundamental measures of the test's clinical validity. *Sensitivity* is the probability of testing positive when the disease is truly present and is defined mathematically as a/(a + c). As sensitivity increases, the number of individuals with disease who are missed by the test decreases, so a test with perfect sensitivity will detect all individuals with disease correctly. In practice, tests with ever-higher sensitivity tend to also classify as “diseased” many individuals who are not actually affected (false positives). Thus the *specificity* of a test is the probability of screening negative if the disease is truly absent and is defined mathematically as d/(b + d). A test with high specificity will rarely be positive when disease is absent and will therefore lead to a lower proportion of individuals without disease being incorrectly classified as test positive (false positives). A simple way to remember these differences is that sensitivity is “positive in disease” whereas specificity is “negative in health.”

TABLE 9.2

Summarizing the Results of Screening, Diagnostic, or Predictive Tests

	DISEASE PRESENT	DISEASE ABSENT	
Test positive	a	b	a + b
Test negative	c	d	c + d
Total	a + c	b + d	
Sensitivity = a/(a + c) Specificity = d/(b + d) Positive predictive value = a (a + b) Negative predictive value = d/(c + d)			

a = Number of individuals for whom the screening test is positive and the individual actually has the disease (true positives).

b = Number of individuals for whom the test is positive but the individual does not have the disease (false positives).

c = Number of individuals for whom the test is negative but the individual actually has the disease (false negatives).

d = Number of individuals for whom the test is negative and the individual does not have the disease (true negatives).

Modified from Biomarkers Definitions Working Group. Biomarkers and surrogate endpoints: preferred definitions and conceptual framework. Clin Pharmacol Ther 2001;69:89-95.

A perfect test has both very high sensitivity and specificity and thus low false-positive and false-negative classifications. Such test characteristics are rare, however, because there is a trade-off between sensitivity and specificity for almost every screening biomarker, diagnostic, or predictive test in common clinical use. For example, although high LDL-C levels usually serve as a biomarker for atherosclerotic risk, up to half of all incident cardiovascular events occur in those with LDL-C levels well within the normal range, and many events occur even when levels are low. If the diagnostic cutoff criterion for LDL-C is reduced so that more people who actually have high risk for disease will be test positive (i.e., increase sensitivity), an immediate consequence of this change will be an increase in the number of people without disease in whom the diagnosis is made incorrectly (i.e., reduced specificity). Conversely, if the criterion for diagnosis or prediction is made more stringent, a greater proportion of those who test negative will actually not have the disease (i.e., improved specificity), but a larger proportion of true cases will be missed (i.e., reduced sensitivity).

In addition to sensitivity and specificity, the performance or yield of a screening, diagnostic, or predictive test also varies depending on the characteristics of the population being evaluated. Positive and negative predictive values are terms used in epidemiology that refer to measurement of whether an individual actually has (or does not have) a disease, contingent on the result of the screening test itself.

The positive predictive value (PPV) is the probability that a person has the disease of interest, given that the individual tests positive, and is mathematically calculated as PPV = a/(a + b). High PPV can be anticipated when the disease is common in the population being tested. Conversely, the negative predictive value (NPV) is the probability that an individual is truly disease free, provided that the test has a negative result, and is mathematically calculated as NPV = d/(c + d). High NPV can be anticipated when the disease is rare in the population being tested. Although sensitivity and specificity are largely performance characteristics of the test itself (and thus tend to be fixed values), PPV and NPV depend in part on the population being tested (and thus tend to vary).

Discrimination, C-Statistics, and Receiver Operating Characteristic Curve

Discrimination is the ability of a test (or prognostic model) to separate those with disease or at high risk for disease (cases) from those without disease or at low risk for disease (controls). The most common method used to measure discrimination has been the *area under the receiver operating characteristic* (ROC) *curve* (AUC), which relates sensitivity (on the *y* axis) to (1 − specificity) (on the *x* axis) across a full range of cutoff values for the test or screening algorithm of interest (**Fig. 9.7**).

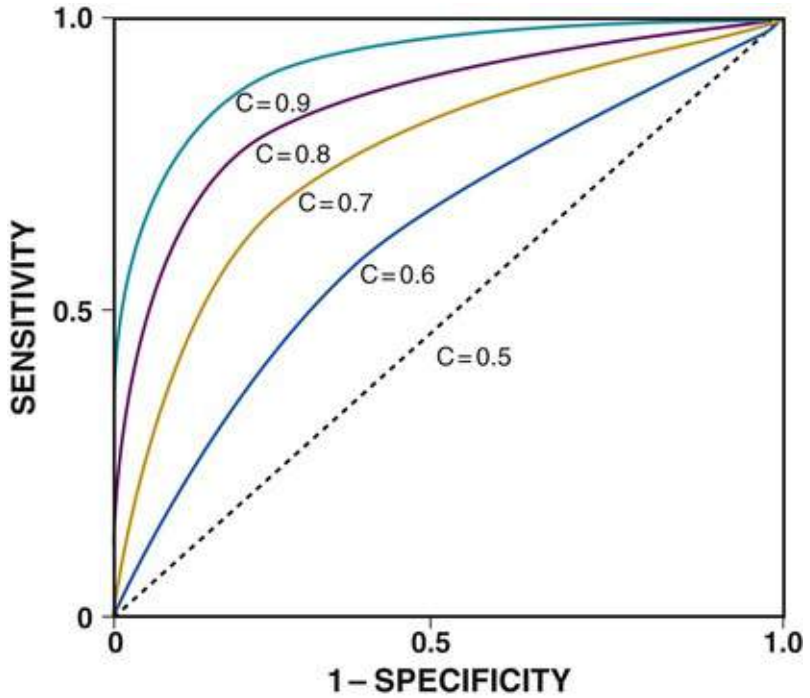

FIGURE 9.7 Receiver operating characteristic (ROC) curves for a series of biomarkers or risk prediction models with incremental improvement. The diagonal line corresponds to a random effect (C-statistic = 0.5), whereas the increasing C-statistic corresponds to improving model discrimination.

Given a population of individuals being evaluated, the area under the ROC curve, also called the *C-statistic*, equals the probability of correctly ranking risk for individuals by using the test or model under evaluation. A random test with no clinical usefulness would have a C-statistic (ROC AUC) of 0.5, which

corresponds to the diagonal line in Fig. 9.7. A perfect test that completely discriminates individuals with disease from those without disease would have a C-statistic that approaches 1.0. As the C-statistic increases from 0.5 to 1.0, model fit (or test accuracy) improves; thus the change in the C-statistic has been used historically to judge whether a new biomarker can "add" significantly to those already in use. This approach permits direct comparison of the relative efficiency of multimarker panels. For example, using comparative C-statistic analyses, investigators in the Emerging Risk Factors Collaboration recently found that the incremental clinical usefulness of CRP has similar magnitude as that of total and HDL-C.[24] Thus, when change in the C-statistic can be demonstrated and the overall power to do so is adequate, this test can assist in understanding the impact of novel pathways and novel risk biomarkers on prediction and prevention.

Unfortunately, as Cook[25,26] has shown in several settings, the traditional C-statistic approach is limited in that biomarkers with large associations may have minimal effect on ROC AUC. For example, a predictor (or set of predictors) would need an odds ratio (OR) as high as 16 (>2 standard deviations [SD]) to lead to a substantial increase in the C-statistic.[27] Almost no test in common use for risk prediction or prognostication in cardiovascular medicine has an OR in this range; high cholesterol, smoking, high blood pressure, and diabetes are all associated with OR of less than 2 and thus have little individual impact at all on ROC AUC. Consequently, sole reliance on the C-statistic as a method for developing and evaluating new biomarkers, at least in the setting of risk prediction, is insufficient.

Accuracy and Calibration

Discrimination is only one measure of model accuracy. The other important measure is *calibration*, or the ability of a predictive model to assign risk estimates accurately compared with the actual observed risk in the population being tested. Unlike discrimination, which is based solely on relative rankings of risk, calibration compares the risk predicted from a model or test with that actually observed.

For *binary* outcomes (e.g., disease or no disease), calibration is often evaluated with the Hosmer-Lemeshow test, which places individuals within categories of estimated risk by using the test biomarker or multivariable model and compares these estimates with the proportions actually observed. These "predicted" and "observed" probabilities can be compared with standard goodness-of-fit tests across categories of risk (e.g., across estimated quintiles or estimated deciles of risk). Calibration becomes particularly important when addressing a biomarker in different populations from the population in whom it was originally developed. A biomarker may calibrate well in men but not in women, or among whites but not among blacks. This consideration also applies to multimarker panels, such as the Framingham Risk Score, which calibrates well in whites but less well in other population groups. Newer risk models such as the Reynolds Risk Score show improved calibration, as well as discrimination, compared with the traditional Framingham model.[28]

Risk Reclassification

To address the shortcoming of biomarker validation via the C-statistic alone, contemporary biomarker development programs for risk prediction now use a series of "reclassification statistics," as initially developed by Cook and Ridker[29] and refined by Pencina[30] and Xanthakis[31] and associates. Rather than addressing whether a new biomarker of interest adds to ROC AUC, reclassification addresses whether the biomarker can shift overall risk estimates upward or downward in a clinically meaningful way. Specifically, reclassification methods compare risk strata formed from prediction models with and

without the new biomarker of interest and then determine which model leads to the most accurate classification of risk. Risk reclassification is particularly useful when actionable and clinically relevant risk categories already exist. For example, in primary cardiovascular prevention, 10-year estimated risk is often categorized as being less than 5%, 5% to 10%, 10% to 20%, or greater than 20%, and those above or below these cut points are frequently targeted for interventions such as aspirin and statin therapy. Thus a biomarker that reclassifies a proportion of individuals upward (or downward) might well be highly effective for targeting (or avoiding) drug therapy, even if the overall effect on discrimination is modest.

Mere reclassification of an individual by a given biomarker does not provide sufficient evidence to support clinical use. Rather, an effective biomarker should correctly reclassify risk higher or lower and thus lead to more accurate overall risk assessment. The *reclassification calibration* (RC) statistic is a tool that tests how well the average predicted risk within a given cell agrees with the observed risk of individuals who actually experience the event. Accordingly, the RC statistic addresses whether the predicted risk estimates after reclassification (using the new biomarker) are more accurate than before reclassification (without the new biomarker). Superior reclassification occurs when the new prediction model places case individuals into higher-risk categories and places control individuals into lower-risk categories, and when the net shift in these two effects is in the overall correct direction. This characteristic can be addressed by using the *net reclassification index* (NRI), analogous to a test of discrimination (the ability to separate cases from controls) in the context of a reclassification table. Broadly, the NRI does not depend as much on the actual predicted probabilities as on movement across a categorical risk border that is the result of the new probabilities predicted. When reclassification is not addressed across categories, an alternative measure is used, called the *integrated discrimination improvement* (IDI), based on the Yates slope, or the difference in predicted probabilities among case and control individuals.[32] Despite their relatively recent introduction, reclassification statistics have rapidly become the standard for clinical evaluation of emerging biomarkers and alternative multibiomarker prediction panels.

External Validation and Impact Studies

A final but important test for any biomarker or biomarker panel when used for prognostication, *external validation* refers to the ability of the panel to function with clinically acceptable levels of sensitivity, specificity, discrimination, and calibration in external populations, distinct from the population used for generation of the panel. As Moons and coworkers[33] note, prognosis research and prognostic biomarkers differ from those used in diagnosis and screening.[33]

Prognostic research involves three distinct phases in the development of multivariable prediction models. The first phase is identification of relevant predictors, assignment of weights to the model, estimation of predictive performance, and optimization of fit. The second phase involves validation or formal testing of calibration and discrimination in new patient groups, which can be similar to those used in the development stage or purposely different. The third phase involves impact studies to quantify directly whether use of a prognostic model in daily practice actually changes physician behavior and decision making, and whether this occurs in a net positive manner and is cost-effective. *Prognostic impact studies* also focus on the incremental usefulness of a given biomarker beyond simple clinical and nonclinical characteristics. Such studies tend to be less biologically driven than biomarker discovery work and recognize that prediction does not necessarily involve a causal pathway.

Practical Example: High-Sensitivity CRP, Lipids, and Reynolds Risk Score

The use of high-sensitivity C-reactive protein (hsCRP) in clinical practice is an example of how biomarker development programs can move from pathophysiologic principles to clinical use and onward to multinational trials evaluating novel targets for vascular risk reduction.[34,35] A prospective cohort of initially healthy individuals showed that hsCRP predicted future risk for a heart attack and stroke in men, an observation externally validated and quickly extended to women. Multiple commercial hsCRP assays —reproducible, internally calibrated, and externally validated to improve assay precision—then became clinically available. Multiple studies have shown that statins reduce hsCRP in a manner largely independent of reduction of LDL-C, thus suggesting that statins have both lipid-lowering and anti-inflammatory effects. The addition of hsCRP to the family history and HbA_{1c} was formally incorporated into the Reynolds Risk Score in 2008. This score was subsequently externally validated and shown to have superior calibration, discrimination, and reclassification over the more traditional Framingham Risk Score. Using hsCRP to define a high-risk population in need of treatment, JUPITER (Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin) reported in 2008 that statin therapy (versus placebo) in those with elevated hsCRP but low levels of LDL-C resulted in a 50% reduction in myocardial infarction and stroke and a 20% reduction in all-cause mortality.[36] By 2010, more than 50 prospective cohort studies evaluating hsCRP were subjected to meta-analysis, which affirmed that the magnitude of vascular risk associated with a change of 1 SD in hsCRP was at least as large as that of a comparable change in cholesterol or blood pressure.[37] An updated 2012 meta-analysis of clinical usefulness and risk prediction found that the change in C-statistic associated with hsCRP was similar to that associated with the use of total and HDL cholesterol.[24] On this basis, several national guidelines incorporated hsCRP screening in primary and secondary prevention,[38] and the FDA approved a labeling claim for the use of statin therapy in those with elevated hsCRP levels.

CRP itself, however, probably does not cause atherothrombosis, but rather serves as a biomarker for the underlying inflammatory process.[39] Thus, as a direct outcome of the hsCRP development program, two randomized trials are now testing directly whether lowering inflammation per se can reduce vascular risk. These two trials—the NIH-funded CIRT (Cardiovascular Inflammation Reduction Trial), which evaluated low-dose methotrexate, and CANTOS (Canakinumab Anti-inflammatory Thrombosis Outcomes Study), which evaluated interleukin-1beta inhibition—are ongoing and, when complete, will have involved more than 18,000 patients worldwide.[35]

Conclusion

We use biomarkers in our daily clinical practice, and cardiovascular journals contain numerous reports regarding biomarkers, new and old, that purport to show how they may aid clinical practice. Moreover, many cardiovascular trials use biomarkers—thus the current practice of cardiovascular medicine requires a firm foundation in understanding and evaluating biomarkers. The road map to the field of biomarkers provided in this chapter, including their use, development, and methods for evaluating their usefulness for various specific applications, should give practitioners tools to sort out the various uses of biomarkers encountered in practice and in the cardiovascular literature. Informed use of biomarkers can aid in decision making in daily patient care. Biomarkers should provide a key for personalized management by directing the right therapy to the right patient at the right time. They can also shed mechanistic insight on

human pathophysiology that is difficult to obtain in other ways. Rigorous and careful use of biomarkers can aid in the development of novel therapies to address the residual burden of cardiovascular risk.

PART III
Evaluation of The Patient

OUTLINE

10

History and Physical Examination

An Evidence-Based Approach

James C. Fang, Patrick T. O'Gara

Evaluation of the patient with known or suspected cardiovascular disease begins with a directed history

and targeted physical examination, the scope and duration of which depend on the clinical context of the patient encounter. Elective, ambulatory investigations allow comparatively more time for the development of a comprehensive assessment, whereas emergency department (ED) visits and urgent bedside consultations necessitate a more focused strategy. The elicitation of the history, with its emphasis on major cardiovascular symptoms and their change over time, demands a direct interaction between the clinician and patient; it should not be delegated to another or inferred from information gleaned from a cursory chart review. The history also affords a unique opportunity to assess the patient's personal attitudes, intelligence, comprehension, acceptance or denial, motivation, fear, and prejudices. Such insights allow a more informed understanding of the patient's preferences and values regarding shared decision-making. The interview also can reveal genetic or familial influences and the impact of other medical conditions on the manifesting illness. Although time constraints have limited the emphasis on careful history taking, the information gathered from the patient interview remains essential to inform the design of a resource-sensitive diagnostic and treatment plan.

Physical examination skills also have declined. Only a minority of internal medicine and family practice residents recognizes classic cardiac findings in relevant diseases. Performance does not predictably improve with experience.[1] Residency work hours and health care system efficiency standards have severely restricted the time and expertise devoted to the mentored cardiovascular examination. In turn, less attention to bedside skills has increased the use of noninvasive imaging, including the use of handheld ultrasound. Educational efforts, which utilize repetition, patient-centered teaching conferences, simulation, and visual display feedback of auscultatory and Doppler echocardiographic findings, can improve performance.[2-6]

The evidence base that justifies correlations between history and physical examination findings and cardiovascular disease severity and prognosis has been developed most rigorously for heart failure, valvular heart disease, and coronary artery disease (CAD). For example, vital signs and detection of pulmonary congestion and mitral regurgitation (MR) contribute importantly to bedside risk assessment in patients with acute coronary syndrome (ACS). The diagnosis of heart failure in ambulatory patients derives from attention to three basic elements of the history—dyspnea at one flight of stairs, orthopnea, and paroxysmal nocturnal dyspnea—and six validated elements of the physical examination—a displaced apex beat, rales, an irregularly irregular pulse, a heart murmur suggestive of MR, a heart rate greater than 60 beats/min, and an elevated jugular venous pressure.[7] Accurate auscultation provides important insight into many valvular and congenital heart lesions. This chapter reviews the fundamentals of the cardiovascular history and physical examination in light of evidence from correlative studies.

The History

The major signs and symptoms associated with cardiac disease include chest discomfort, dyspnea, fatigue, edema, palpitations, and syncope. In most cases, careful attention to the specific characteristics of chest discomfort—quality, location, radiation, triggers, mode of onset, and duration—along with alleviating factors and associated symptoms can narrow the differential diagnosis (**see Chapter 56**). Angina pectoris can usually be differentiated from the pain associated with pulmonary embolism, pericarditis, aortic dissection, esophageal reflux, or costochondritis. Cough, hemoptysis, and cyanosis may provide additional clues as to the cause of chest pain. Claudication, limb pain, edema, and skin discoloration usually indicate a vascular disorder. The cardiovascular clinician also should be familiar with common manifestations of acute cerebrovascular accident (stroke) and transient ischemic attack,

such as sudden weakness, sensory loss, incoordination, and visual disturbance.

Typical angina should satisfy three characteristics: (1) substernal discomfort, (2) initiated by exertion or stress, and (3) relieved with rest or sublingual nitroglycerin. Chest discomfort with two of these three criteria is considered atypical angina; pain with one or none of these features is considered nonanginal. When age and sex are considered, diagnostic accuracy for CAD is reasonable (receiver operating characteristic [ROC] area under the curve [AUC], 0.713). Incorporating a history of diabetes, hypertension, smoking, and dyslipidemia improves the diagnostic accuracy (ROC AUC, 0.791).[8] Several aspects of the presenting symptom of chest pain increase or decrease the likelihood of ACS. For example, pain that is sharp (likelihood ratio [LR], 0.3; 95% confidence interval [CI], 0.2 to 0.5), pleuritic (LR, 0.2; 95% CI, 0.1 to 0.3), positional (LR, 0.3; 95% CI, 0.2 to 0.5), or reproducible with palpation (LR, 0.3; 95% CI, 0.2 to 0.4) usually is noncardiac, whereas discomfort that radiates to both arms or shoulders (LR, 4.1; 95% CI, 2.5 to 6.5) or is precipitated by exertion (LR, 2.4; 95% CI, 1.5 to 3.8) has a higher likelihood of reflecting an ACS. Less classic symptoms (i.e., anginal equivalents), such as indigestion, belching, and dyspnea, also should command the clinician's attention when other features of the presentation suggest ACS, even in the absence of chest discomfort. Women, elderly persons, and patients with diabetes more often present with a less typical clinical picture. A history of a prior abnormal stress test (LR, 3.1; 95%CI, 2.0 to 4.7), known CAD (LR, 2.0; 95% CI, 1.4 to 2.6), or the presence of peripheral arterial disease (LR, 2.7; 95% CI, 1.5 to 4.8) increases the likelihood that the pain indicates an ACS.[9] In general, the accuracy of traditional risk factors and symptoms for the diagnosis of ACS is weak. Clinical prediction tools that incorporate aspects of the history and examination with serum biomarkers of cardiac injury (troponins) and electrocardiographic findings provide better diagnostic accuracy (**Tables 10.1 and 10.2**).

TABLE 10.1

Performance of Chest Pain Characteristics in Diagnosing Acute Coronary Syndrome

SYMPTOM	POSITIVE LR (95% CI)	NEGATIVE LR (95% CI)	PPV (%)	NPV (%)
Radiation to both arms	2.6 (1.8-3.7)	0.93 (0.89-0.96)	28	12
Pain similar to prior ischemia	2.2 (2.0-2.6)	0.67 (0.60-0.74)	25	9
Change in pattern over prior 24 hr	2.0 (1.6-2.5)	0.84 (0.79-0.90)	23	11
“Typical” chest pain	1.9 (0.94-2.9)	0.52 (0.35-0.69)	22	7
Worse with exertion	1.5-1.8	0.66-0.83	18-21	9-11
Radiation to neck or jaw	1.5 (1.3-1.8)	0.91 (0.87-0.95)	18	12
Recent episode of similar pain	1.3 (1.1-1.4)	0.80 (0.71-0.90)	16	11
Radiation to left arm	1.3 (1.2-1.4)	0.88 (0.81-0.96)	16	12
Radiation to right arm	1.3 (0.78-2.1)	0.99 (0.96-1.0)	16	13
Associated diaphoresis	1.3-1.4	0.91-0.93	16-17	12-12
Associated dyspnea	1.2 (1.1-1.3)	0.89 (0.82-0.96)	15	12
Abrupt onset	1.1 (1.0-1.2)	0.75 (0.61-0.91)	14	10
Any improvement with nitroglycerin	1.1 (0.93-1.3)	.90 (0.85-0.96)	14	12
“Typical” radiation	1.0-5.7	0.78-0.98	13-46	10.13
Burning pain	1.0-1.4	0.97-1.0	13-17	13-13
Associated nausea/vomiting	0.92-1.1	0.98-1.0	12-14	13-13
Associated palpitations	0.71 (0.37-1.3)	1.0 (0.98-1.1)	10	13
Associated syncope	0.55 (0.39-0.76)	1.1 (1.1-1.1)	8	14
Pleuritic pain	0.35-061	1.1-1.2	6.6-8.4	14-15

LR, Likelihood ratio; *PPV,* positive predictive value; *NPV,* negative predictive value.

TABLE 10.2

Performance of Physical Examination Findings in Diagnosing Acute Coronary Syndrome

SYMPTOM	POSITIVE LR (95% CI)	NEGATIVE LR (95% CI)	PPV (%)	NPV (%)
Hypotension (SBP <100 mm Hg)	3.9 (0.98-15)	0.98 (0.95-1.0)	37	13
Lung rales	2.0 (1.0-4.0)	0.95 (0.90-1.0)	23	12
Tachypnea	1.9 (0.99-3.5)	0.95 (0.89-1.0)	22	12
Tachycardia (heart rate >120 beats/min)	1.3 (0.42-3.94)	0.99 (0.96-1.0)	16	13
Pain reproduced on palpation	0.28 (0.14-0.54)	1.2 (1.0-1.2)	4.0	15

LR, Likelihood ratio; *PPV,* positive predictive value; *NPV,* negative predictive value; *SBP,* systolic blood pressure.

From Fanaroff AC, Rymer JA, Goldstein SA et al. Does this patient with chest pain have acute coronary syndrome? The rational clinical examination systematic review. JAMA 2015;314:1955-65.

Dyspnea may occur with exertion or in recumbency (orthopnea) or even on standing (platypnea). Paroxysmal nocturnal dyspnea of cardiac origin usually occurs 2 to 4 hours after onset of sleep; the dyspnea is sufficiently severe to compel the patient to sit upright or stand and then subsides gradually over several minutes. The patient's partner should be questioned about any signs of sleep-disordered breathing, such as loud snoring or periods of apnea. Pulmonary embolism often associates with dyspnea of sudden onset.

Patients may use a variety of terms to describe their awareness of the heartbeat (palpitations), such as “flutters,” “skips,” or “pounding.” The likelihood of a cardiac arrhythmia modestly increases with a known history of cardiac disease (LR, 2.03; 95% CI, 1.33 to 3.11) and decreases when symptoms resolve within 5 minutes (LR, 0.38; 95% CI, 0.22 to 0.63) or when associated with panic disorder (LR, 0.26; 95% CI, 0.07 to 1.01). A report of a regular, rapid-pounding sensation in the neck (LR, 177; 95% CI, 25 to 1251) or visible neck pulsations associated with palpitations (LR, 2.68; 95% CI, 1.25 to 5.78) increases the likelihood that atrioventricular nodal reentrant tachycardia (AVNRT) is the responsible arrhythmia. The absence of a regular, rapid-pounding sensation in the neck makes detecting AVNRT much less likely (LR, 0.07; 95% CI, 0.03 to 0.19). Cardiac syncope occurs suddenly, with rapid restoration of full consciousness thereafter. Patients with neurocardiogenic syncope may experience early warning signs (nausea, yawning), appear ashen and diaphoretic, and revive more slowly, although without signs of seizure or a prolonged postictal state. The complete history consists of information pertaining to traditional cardiovascular risk factors, a general medical history, occupation, social habits, activities, medications, drug allergies or intolerance, family history, and systems review.

It is important to obtain a semiquantitative assessment of symptom severity and to document any change over time. The New York Heart Association (NYHA) and the Canadian Cardiovascular Society (CCS) functional classification systems are useful for both patient care and clinical research, despite their inherent limitations.

The General Physical Examination

The physical examination can help determine the cause of a given symptom, assess disease severity and progression, and evaluate the impact of specific therapies. It also can identify the presence of early-stage disease in patients without signs or symptoms.

General Appearance

The examination begins with an appreciation of the general appearance of the patient, including age,

posture, demeanor, and general health status. Is the patient in pain, resting quietly, or visibly diaphoretic with a foreboding sense of doom? Does the patient choose to avoid certain positions to reduce or eliminate pain? The pain of acute pericarditis, for example, often diminishes with sitting up, leaning forward, or breathing shallowly. Pursing of the lips, a breathy quality to the voice, and an increased anteroposterior chest diameter would favor a pulmonary rather than a cardiovascular cause of dyspnea, although disorders in both etiologic categories may contribute in an individual patient. *Pallor* suggests anemia as a possible underlying disorder in patients with exercise intolerance or dyspnea, independent of cardiovascular disease. Cyanosis and jaundice also bear noting. Specific genetic cardiovascular disorders may be discernible from the patient's appearance. *Emaciation* suggests chronic heart failure or another systemic disorder (e.g., malignancy, infection).

The vital signs, including height, weight, temperature, pulse rate, blood pressure (in both arms), respiratory rate, and peripheral oxygen saturation, dictate the pace and scope of the evaluation and provide initial clues as to the presence of a cardiovascular disorder. The height and weight permit calculation of body mass index (BMI) and body surface area (BSA). Waist circumference (measured at the iliac crest) and waist-to-hip ratio (using the widest circumference around the buttocks) powerfully predict long-term cardiovascular risk. In patients with palpitations, a resting heart rate less than 60 beats/min may increase the likelihood of a clinically significant arrhythmia (LR, 3.00; 95% CI, 1.27 to 7.08). Observation of the respiratory pattern may reveal signs of disordered breathing (e.g., Cheyne-Stokes respirations, obstructive sleep apnea), a finding associated with reduced survival in patients with severe systolic heart failure.[10] Mental status should be assessed and is an important gauge of adequate cerebral and systemic perfusion. Finally, *frailty* should be specifically addressed and recognized. Several scales are available that incorporate quantifiable criteria such as unintentional weight loss, grip strength, and gait speed (**Table 10.3**). Frailty assessment, a common tool in the evaluation of patients with heart failure, has also entered into the preprocedural appraisal of patients referred for heart valve replacement or repair.

TABLE 10.3

The Fried Criteria for Frailty

CHARACTERISTIC	METRICS
Shrinking (Unintentional weight loss)	>10 pounds or >5% of total body weight in past year
Weakness (Reduced handgrip strength)	Maximum isometric contraction in dominant hand over 3 attempts using hand dynamometer
Exhaustion (Self-reported exhaustion)	Questions from the Center for Epidemiologic Studies—Depression Scale
Slowness (Slow gait speed)	Slowest quintile according to gender/height based on time to walk 15 feet
Inactivity (Low self-reported physical activity)	Lowest quintile of expended kcal/week using activity questionnaire

Frail: Three or more criteria present.

Intermediate/Prefrail: One or two criteria present.

From Joyce E. Frailty in advanced heart failure. Heart Fail Clin Adv Heart Fail 2016;12:363-74.

Skin

Central cyanosis is present with significant right-to-left shunting at the level of the heart or lungs. It also is a feature of hereditary methemoglobinemia. Peripheral cyanosis or acrocyanosis of the fingers, toes, nose, and ears is characteristic of the reduced blood flow that accompanies small-vessel constriction seen in

severe heart failure, shock, or peripheral vascular disease. Differential cyanosis affecting the lower but not the upper extremities occurs with a patent ductus arteriosus (PDA) and pulmonary artery (PA) hypertension with right-to-left shunting at the great vessel level.

Hereditary telangiectases on the lips, tongue, and mucous membranes (a finding in Osler-Weber-Rendu syndrome) resemble spider nevi; when present in the lungs, they can cause right-to-left shunting and central cyanosis. Telangiectasias also are seen in patients with scleroderma with or without pulmonary hypertension. Tanned or bronze discoloration of the skin in unexposed areas can suggest iron overload and hemochromatosis. With jaundice, often first appreciated in the sclerae, the differential diagnosis is broad in scope. *Ecchymoses* often occur with either anticoagulant and/or antiplatelet use, whereas *petechiae* characterize thrombocytopenia, and purpuric skin lesions can be seen with infective endocarditis and other causes of leukocytoclastic vasculitis. Various lipid disorders can manifest with *xanthomas*, located subcutaneously, along tendon sheaths, or over the extensor surfaces of the extremities. Xanthomas within the palmar creases are specific for type III hyperlipoproteinemia.

The leathery, cobblestone, "plucked chicken" appearance of the skin in the axillae and skinfolds of a young person is characteristic of pseudoxanthoma elasticum, a disease with multiple cardiovascular manifestations, including premature atherosclerosis. Extensive *lentiginoses* (freckle-like brown macules and café au lait spots over the trunk and neck) may be part of developmental delay–associated cardiovascular syndromes (LEOPARD, LAMB, and Carney) with multiple atrial myxomas, atrial septal defect (ASD), hypertrophic cardiomyopathy, and valvular stenoses. In a patient with heart failure or syncope, cardiovascular sarcoid should be suspected in the presence of lupus pernio, erythema nodosum, or granuloma annulare. Certain vascular disorders, such as erythromelalgia, chilblain, frostbite, and lymphangitis, also may be readily apparent from examination of the skin in the appropriate context.

Head and Neck

All patients should undergo assessment of the state of dentition, both as a source of infection and as an index of general health and hygiene. A high-arched palate is a feature of Marfan and other connective tissue disease syndromes. A large protruding tongue with parotid enlargement may suggest amyloidosis. Patients with Loeys-Dietz syndrome characteristically have a bifid uvula. Orange tonsils are typical of Tangier disease. Ptosis and ophthalmoplegia suggest muscular dystrophies, and congenital heart disease often is accompanied by hypertelorism, low-set ears, micrognathia, and a webbed neck, as with Noonan, Turner, and Down syndromes. Proptosis, lid lag, and stare point to Graves hyperthyroidism. Patients with osteogenesis imperfecta have blue sclerae, MR or aortic regurgitation (AR), and a history of recurrent nontraumatic skeletal fractures.

Attention to the extraocular movements and the size and symmetry of the pupils may reveal a neurologic disorder. The oft-omitted funduscopic (ophthalmoscopic) examination can aid in the evaluation of patients with hypertension, atherosclerosis, diabetes, endocarditis, neurologic signs or symptoms, or known carotid or aortic arch disease. Lacrimal gland hyperplasia is sometimes a feature of sarcoidosis. The "mitral facies" of rheumatic mitral stenosis (pink-purplish patches with telangiectasias over the malar eminences) also can accompany other disorders associated with pulmonary hypertension and reduced cardiac output. Relapsing polychondritis is suggested by inflammation of the pinnae and nasal cartilage in association with a saddle-nose deformity. Palpation of the thyroid gland assesses its size, symmetry, and consistency.

Extremities

Inspection can quickly ascertain the temperature of the extremities and the presence of clubbing, arachnodactyly, and nail changes . Clubbing implies the presence of central shunting (**Fig. 10.1**). An unopposable “fingerized” thumb occurs in Holt-Oram syndrome. Arachnodactyly characterizes Marfan syndrome. Janeway lesions (nontender, slightly raised areas of hemorrhage on the palms and soles), Osler nodes (tender, raised nodules on the pads of the fingers or toes), and splinter hemorrhages (linear petechiae in the mid-nailbed) may be signs of infective endocarditis. Ulcerations and tissue loss of the fingertips may suggest thromboangiitis obliterans in the appropriate context.

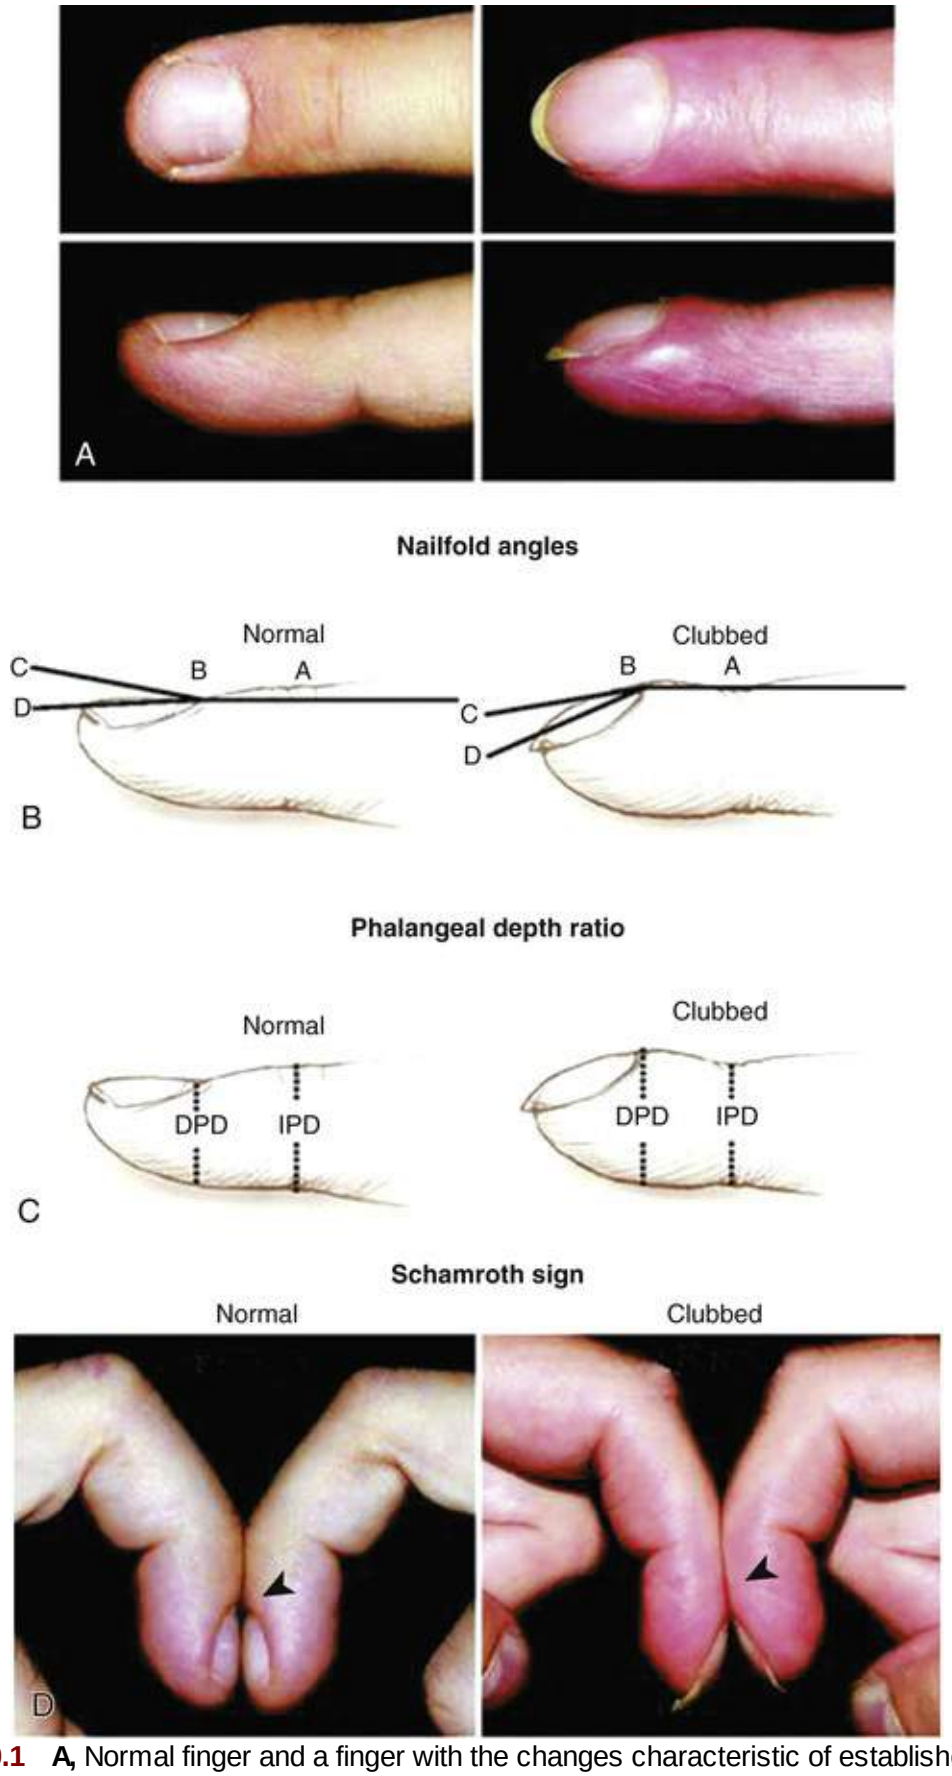

FIGURE 10.1 **A,** Normal finger and a finger with the changes characteristic of established clubbing, viewed from above and in profile. **B**, The finger on the *left* demonstrates normal profile (ABC) and normal hyponychial (ABD) nailfold angles of 169 degrees and 183 degrees, respectively. The clubbed finger on the *right* shows increased profile and hyponychial nailfold angles of 191 degrees and 203 degrees, respectively. **C**, Distal phalangeal finger depth (DPD)/interphalangeal finger depth (IPD) represents the phalangeal depth ratio. In normal fingers the IPD is greater than the DPD. In clubbing this relationship is reversed. **D**, Schamroth sign. In the absence of clubbing, nail-to-nail opposition creates a diamond-shaped window (*arrowhead*). In clubbed fingers, the loss of the profile angle with the increase in tissue at the nailbed causes obliteration of this space (*arrowhead*). (From Myers KA, Farquhar DR. Does this patient have clubbing? JAMA 2001;286:341.)

Lower extremity or presacral edema with elevated jugular venous pressure (JVP) occurs in many volume-overloaded states, including heart failure. With a normal JVP, additional signs of venous disease, such as extensive varicosities, medial ulcers, or brownish pigmentation from hemosiderin deposition, suggest chronic venous insufficiency. A history of lower extremity vein ligation and "stripping" should be recognized. Edema also can occur with dihydropyridine calcium channel blocker therapy. Anasarca seldom occurs in heart failure, unless the condition is longstanding, untreated, and accompanied by severe hypoalbuminemia. Asymmetric swelling can reflect local or unilateral venous thrombosis, the sequelae of previous vein graft harvesting, or lymphatic obstruction. Homans sign (calf pain elicited by forceful dorsiflexion of the foot) is neither specific nor sensitive for deep vein thrombosis. Muscular atrophy and the absence of hair in an extremity should suggest chronic arterial insufficiency or a neuromuscular disorder. Redistribution of fat from the extremities to central/abdominal stores (lipodystrophy) in some patients with HIV infection may relate to antiretroviral therapy and also is associated with insulin resistance and several features of the metabolic syndrome.

Chest and Abdomen

Cutaneous venous collaterals over the anterior chest suggest chronic obstruction of the superior vena cava (SVC) or subclavian vein, especially in the presence of indwelling catheters or leads from cardiac implantable electrical devices (CIEDs). Asymmetric breast enlargement or arm swelling ipsilateral to a CIED also may be present. Thoracic cage abnormalities, such as pectus carinatum (pigeon chest) or pectus excavatum (funnel chest), may accompany connective tissue disorders; the barrel chest of emphysema or advanced kyphoscoliosis may be associated with cor pulmonale. The severe kyphosis of ankylosing spondylitis should prompt careful auscultation for AR and scrutiny of the electrocardiogram (ECG) for first-degree atrioventricular block. The "straight back syndrome" (loss of normal kyphosis of the thoracic spine) can accompany mitral valve prolapse (MVP). A thrill may be present over well-developed intercostal artery collaterals in patients with aortic coarctation.

Patients with emphysema may exhibit prominence of the cardiac impulse in the epigastrium. The liver often is enlarged and tender in heart failure; systolic hepatic pulsations signify severe tricuspid regurgitation (TR). Patients with infective endocarditis of long duration may have splenomegaly. Ascites can develop with advanced and chronic right heart failure or constrictive pericarditis. The abdominal aorta normally may be palpated between the epigastrium and the umbilicus in thin patients and in children. The sensitivity of palpation for the detection of abdominal aortic aneurysm (AAA) disease increases as a function of aneurysm diameter and varies inversely with body size. Arterial bruits in the abdomen should be sought.

Careful chest auscultation is an essential component of the cardiovascular examination and is of prime importance when the presenting complaint is dyspnea. Technological advances have provided important insights into often-underappreciated pulmonary auscultatory phenomena that are frequently encountered in the evaluation of patients with cardiovascular disease[11] (**Fig. 10.2**).

Respiratory sound	Amplitude–Time plot	
Acoustics	Unexpanded time	Expanded time
A Tracheal sound White noise Typical frequency, 100–5000 Hz Drop of energy at 800 Hz		B Normal (vesicular) lung sound Low-pass-filtered noise Typical frequency, 100–1000 Hz Drop of energy at 200 Hz		C Bronchial breathing Strong expiratory component An intermediate sound between tracheal and normal breathing		D Stridor Sinusoid Fundamental frequency, >500 Hz		
E Wheeze Sinusoid Typical frequency, >100–5000 Hz Typical duration, >80 msec		F Rhonchus Sinusoid Typical frequency, about 150 Hz Typical duration, >80 msec		G Fine crackle Rapidly dampened wave deflection Typical frequency, about 650 Hz Typical duration, about 5 msec		H Coarse crackles Rapidly dampened wave deflection Typical frequency, about 350 Hz Typical duration, about 15 msec		
I Pleural friction rub Rhythmic succession of short sounds Typical frequency, <350 Hz Typical duration, >15 msec		
J Squawk Sinusoid Typical frequency, 200–300 Hz Typical duration, about 200 msec Followed or preceded by crackles		
FIGURE 10.2 Respiratory sounds and the acoustic waveforms. (From Bohadana A, Izvicki G, Kraman SS. Fundamentals of lung auscultation. N Engl J Med 2014;370:2053.)

The Cardiovascular Examination

Jugular Venous Pressure and Waveform

The JVP aids in the estimation of volume status. The external (EJV) or internal (IJV) jugular vein may be used, although the IJV is preferred because the EJV is valved and not directly in line with the SVC and right atrium. The EJV is easier to visualize when distended, and its appearance can help to discriminate between low and high central venous pressure (CVP). An elevated left EJV pressure may also signify a persistent left-sided SVC or compression of the innominate vein from an intrathoracic structure. If an elevated CVP is suspected but venous pulsations cannot be appreciated, the patient should be asked to sit upright with the feet dangling. With subsequent pooling of blood in the lower extremities, venous pulsations may be evident. SVC syndrome should be suspected if the venous pressure is elevated, pulsations are still not discernible, and the skin of the head and neck appears dusky or cyanotic. When hypovolemia is suspected as a cause of hypotension, the patient may need to be lowered to a supine position to assess the waveform in the right supraclavicular fossa.

The venous waveform can sometimes be difficult to distinguish from the carotid artery pulse. The venous waveform has several characteristic features (**Fig. 10.3** and **Table 10.4**), and its individual components can usually be identified. The *a* and *v* waves, and *x* and *y* descents, are defined by their temporal relation to electrocardiographic events and heart sounds (S_1 and S_2, plus S_3 and S_4, as defined later). The estimated height of the venous pressure indicates the CVP or right atrial pressure. Although observers vary widely in their estimates of the CVP, knowledge that the pressure is elevated, and not its specific value, can inform diagnosis and management.

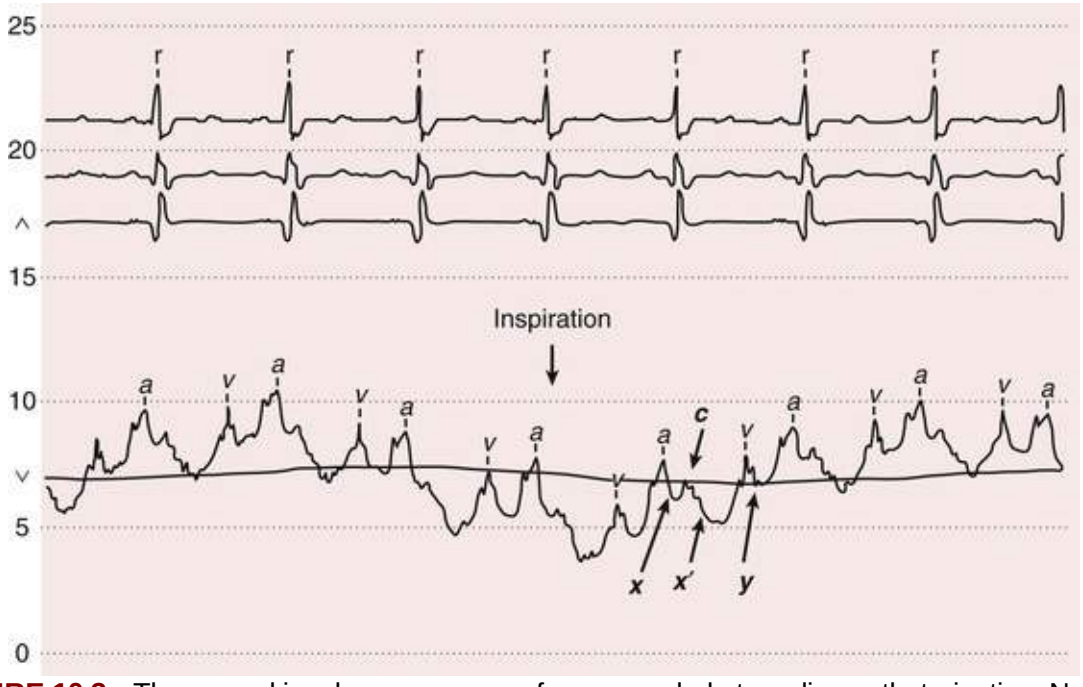

FIGURE 10.3 The normal jugular venous waveform recorded at cardiac catheterization. Note the inspiratory fall in pressure and the dominant *x*/*x*′ descent.

TABLE 10.4

Distinguishing Jugular Venous Pulse from Carotid Pulse

FEATURE	INTERNAL JUGULAR VEIN PULSE	CAROTID ARTERY PULSE
Appearance of pulse	Undulating two troughs and two peaks for every cardiac cycle (biphasic)	Single brisk upstroke (monophasic)
Response to inspiration	Height of column falls and troughs become more prominent	No respiratory change to contour
Palpability	Generally not palpable (except in severe TR)	Palpable
Effect of pressure	Can be obliterated with gentle pressure at base of vein/clavicle	Cannot be obliterated

TR, Tricuspid regurgitation.

The venous pressure is measured as the vertical distance between the top of the venous pulsation and the sternal inflection point, where the manubrium meets the sternum (angle of Louis). A distance of greater than 3 cm (1.2 inches) is considered abnormal, but the distance between the angle of Louis and the mid–right atrium varies considerably, especially in obese patients. On chest computed tomography (CT) scans in 160 consecutive patients, this distance varied considerably in accordance with body position. In general, use of the sternal angle as a reference leads to systematic underestimation of venous pressure. In practice, however, it is difficult to use even relatively simple landmarks, and on attempts to locate an external reference point to determine the CVP, measurements obtained by critical care nurses vary by several centimeters. Venous pulsations above the clavicle with the patient in the sitting position are clearly abnormal, because the distance from the right atrium is at least 10 cm (4 inches). Estimated CVP correlates only modestly with direct measurement. Measurements made at the bedside, in units of centimeters of blood or water, require conversion to millimeters of mercury (1.36 cm H_2O = 1.0 mm Hg), for comparison with values measured with catheterization.

The venous waveforms include several distinct peaks: *a*, *c*, and *v* (**see Fig. 10.3**). The *a* wave reflects right atrial presystolic contraction, occurs just after the electrocardiographic P wave, and precedes the first heart sound (S_1). Patients with reduced right ventricular (RV) compliance from any cause can have a prominent *a* wave. A cannon *a* wave occurs with atrioventricular dissociation and right atrial contraction against a closed tricuspid valve (**Fig. 10.4**). The presence of cannon *a* waves in a patient with wide-complex tachycardia identifies the rhythm as ventricular in origin. The *a* wave is absent with atrial fibrillation (AF). The *x* descent reflects the fall in right atrial pressure after the *a* wave peak. The *c* wave interrupts this descent as ventricular systole pushes the closed valve into the right atrium. In the neck the carotid pulse also may contribute to the *c* wave. As depicted in **Fig. 10.4**, the *x* descent follows because of atrial diastolic suction created by ventricular systole pulling the tricuspid valve downward. In normal persons the *x* descent is the predominant waveform in the jugular venous pulse. The *v* wave represents atrial filling, occurs at the end of ventricular systole, and follows just after S_2. Its height is determined by right atrial compliance and by the volume of blood returning to the right atrium from any source. The *v* wave is smaller than the *a* wave because of the normally compliant right atrium. In patients with ASD, the *a* and *v* waves may be of equal height; in TR, the *v* wave is accentuated (Video 10.1). With TR, the *v* wave will merge with the *c* wave because retrograde valve flow and antegrade right atrial filling occur simultaneously. The *y* descent follows the *v* wave peak and reflects the fall in right atrial pressure after tricuspid valve opening. Resistance to ventricular filling in early diastole blunts the *y* descent, as with pericardial tamponade or tricuspid stenosis. The *y* descent will be steep when ventricular diastolic filling occurs early and rapidly, as with pericardial constriction or isolated, severe TR.

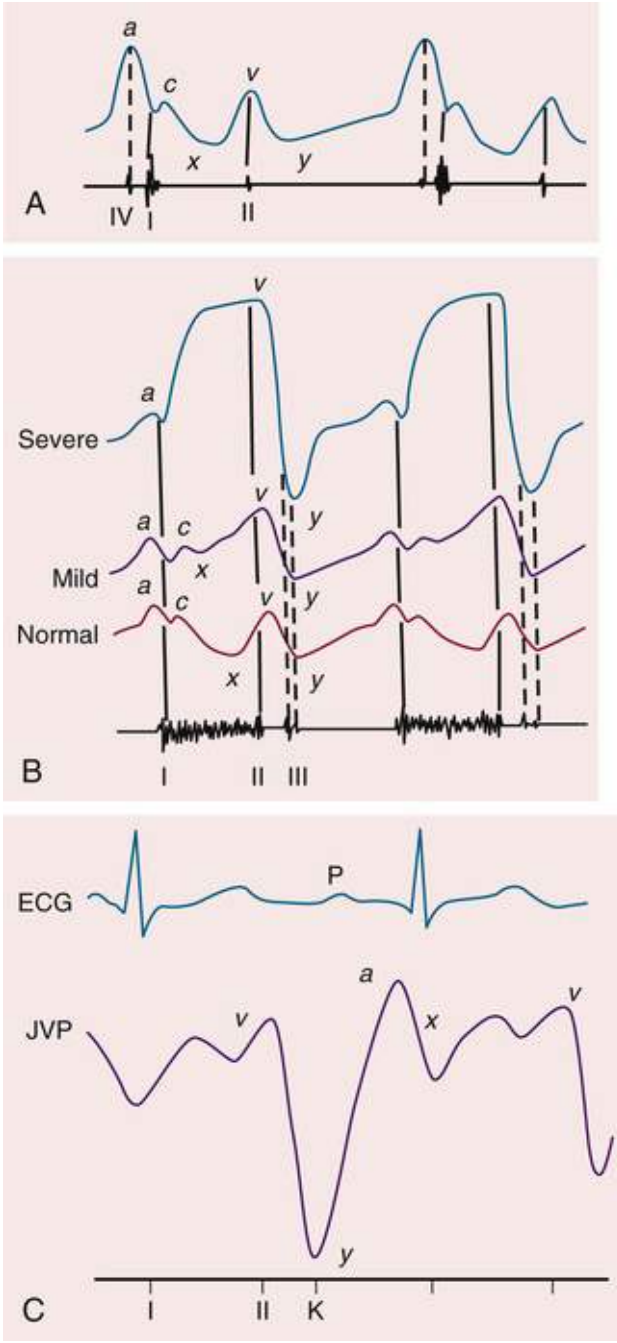

FIGURE 10.4 Abnormal jugular venous waveforms. **A,** Large *a* waves associated with reduced RV compliance or elevated RV end-diastolic pressure. Phonocardiographic tracing (*below*) shows timing of the corresponding right-sided S_4. **B,** Normal jugular venous waveform (*bottom*), mild tricuspid regurgitation (TR) (*middle*), and severe TR (*top*), with corresponding phonocardiogram. With severe TR, "ventricularization" of the jugular venous waveform is seen, with a prominent *v* wave and rapid *y* descent. The *x* descent is absent. **C,** Jugular venous waveform in constrictive pericarditis with a prominent *y* descent. Note the timing of the pericardial knock (*K*) relative to S_2. The abrupt rise in pressure after the nadir of the *y* descent is caused by the rapid rise in venous pressure with ventricular filling. *JVP,* Jugular venous pressure. (From Abrams J. Synopsis of Cardiac Physical Diagnosis. 2nd ed. Boston: Butterworth Heinemann; 2001, pp 25-35.)

The normal venous pressure should fall by at least 3 mm Hg with inspiration. A rise in venous pressure (or its failure to decrease) with inspiration (Kussmaul sign) is associated with constrictive pericarditis and also with restrictive cardiomyopathy, pulmonary embolism, RV infarction, and advanced systolic heart failure. A Kussmaul sign is seen with right-sided volume overload and reduced RV compliance (Video 10.2). Normally, the inspiratory increase in right-sided venous return is accommodated by increased RV ejection, facilitated by an increase in the capacitance of the pulmonary vascular bed. In states of RV diastolic dysfunction and volume overload, the right ventricle cannot accommodate the

enhanced volume, and the pressure rises.

The abdominojugular reflux maneuver or passive leg elevation can elicit venous hypertension. The abdominojugular reflux maneuver requires firm and consistent pressure over the upper abdomen, preferably the right upper quadrant, for at least 10 seconds. Classically, a positive abdominojugular reflux sign has been defined as a rise of more than 3 cm in the venous pressure sustained for at least 15 seconds, although in practice a shorter duration is usually accepted. The patient should be coached to refrain from holding the breath or performing a Valsalva-like maneuver, which can falsely elevate the venous pressure. A positive abdominojugular reflux sign can predict heart failure in patients with dyspnea as well as a PA wedge pressure higher than 15 mm Hg.

Measuring the Blood Pressure

Auscultatory measurement of blood pressure (BP) yields lower systolic and higher diastolic values than direct intra-arterial recording (**see Chapters 46 and 47**). Nurse-recorded BP usually is closer to the patient's average daytime BP than physician measured BP. BP should be measured with the patient in the seated position, with the arm at the level of the heart, using an appropriate-size cuff (**Table 10.5**). The use of an inappropriately small cuff can result in overestimation of the true BP, an issue of particular relevance in obese patients.

TABLE 10.5

Important Aspects of Blood Pressure Measurement

• Patient should be seated comfortably, with back supported and legs uncrossed, and the upper arm bared.
• Upper arm should be at heart level.
• Cuff length and width should be 80% and 40% of arm circumference, respectively.
• Cuff should be deflated at <3 mm Hg/sec.
• Column or dial should be read to nearest 2 mm Hg.
• First audible Korotkoff sound is systolic pressure; last sound, diastolic pressure.
• There should be no talking between subject and observer (or other person).

From Daskalopolou SS et al. The 2015 Canadian Hypertension Education Program recommendations for blood pressure measurement, diagnosis, assessment of risk, prevention, and treatment of hypertension. Can J Cardiol 2015;31:549-68; and Ringrose JS et al. Effect of cuff design on auscultatory and oscillometric blood pressure measurements. Am J Hypertens 2016;29:1063-9.

On occasion, the Korotkoff sounds may disappear soon after the first sound, only to recur later before finally disappearing at phase 5. This auscultatory gap is more likely to occur in older, hypertensive patients with target organ damage. The systolic BP should be recorded at the first Korotkoff sound and not when the sound reappears. This finding should be distinguished from pulsus paradoxus (see later). Korotkoff sounds may be heard all the way down to 0 mm Hg with the cuff completely deflated in children, in pregnant patients, in patients with chronic severe AR, or in the presence of a large arteriovenous fistula. In these cases, both the phase 4 and phase 5 pressures should be noted.

Blood pressure should be measured in both arms either in rapid succession or simultaneously; normally the measurements should differ by less than 10 mm Hg, independent of handedness. As many as 20% of normal individuals, however, exhibit a left-right arm BP differential of more than 10 mm Hg in the absence of symptoms or other examination findings. A BP differential of more than 10 mm Hg can be associated with subclavian artery disease, supravalvular aortic stenosis, aortic coarctation, or aortic dissection. Systolic leg pressures may exceed arm pressures by as much as 20 mm Hg; greater leg-arm systolic BP differences are seen in patients with severe AR (Hill sign) and patients with extensive and calcified (noncompressible) lower extremity peripheral arterial disease (PAD). Leg BP should be

measured using large thigh cuffs with auscultation at the popliteal artery or using a standard large arm cuff on the calf with simultaneous auscultation or palpation at the posterior tibial artery. Measurement of lower extremity BPs constitutes the basis of the ankle-brachial index (ABI) (**see Chapter 64**).

Consideration should be given to ambulatory BP monitoring when uncertainty exists about the significance of recordings obtained in the clinic. This approach is especially useful for the patient with suspected "white coat hypertension"[12] (**see Chapters 46 and 47**). Measurement of normal or even low BP with evidence of hypertensive end-organ damage should suggest masked hypertension caused by severe PAD. Masked hypertension occurs more often than clinicians appreciate and may present in the absence of severe PAD.[13]

Orthostatic hypotension (a fall in blood pressure of more than 20 mm Hg systolic and/or more than 10 mm Hg diastolic in response to moving from the supine to the standing position within 3 minutes) may be accompanied by a lack of compensatory tachycardia, a response suggestive of autonomic insufficiency, as can occur in patients with diabetes or Parkinson disease. The heart rate–blood pressure response to standing also depends on age, hydration, medications, food, conditioning, and ambient temperature and humidity.

An increase in pulse pressure can represent increased vascular stiffness, usually secondary to aging or atherosclerosis. Aortic stiffness is increased in patients with Marfan syndrome and other connective tissue disorders and may contribute to risk for dissection. Peripheral indices may not correlate well with central aortic stiffness, which is a primary determinant of ventricular-vascular coupling.

Assessing the Pulses

The carotid artery pulse wave occurs within 40 milliseconds of the ascending aortic pulse and reflects aortic valve and ascending aortic function. The temporal arteries can be easily palpated to aid in the diagnosis of temporal arteritis. One of the two pedal pulses may not be palpable in a normal person because of unusual anatomy (posterior tibial, <5%; dorsal pedis, <10%), but each pair should be symmetric. True congenital absence of a pulse is rare, and in most cases, pulses can be detected with a handheld Doppler device when not palpable. Simultaneous palpation of the brachial or radial pulse with the femoral pulse should be performed in patients with hypertension to screen for aortic coarctation.

The contour of the pulses depends on the stroke volume, ejection velocity, vascular capacity and compliance, and systemic resistance. The palpable pulse reflects the merging of the antegrade pulsatile flow of blood and the propagated pulse returning from the periphery. The amplitude of the arterial pulse increases with distance from the heart. Normally, the incident (percussion) wave begins with systolic ejection (just after S_1) and is the predominant monophasic pulse appreciated at the bedside (**Fig. 10.5**). The incisura or dicrotic notch identifies aortic valve closure. A *bounding* pulse may occur in hyperkinetic states, such as fever, anemia, and thyrotoxicosis, or in pathologic states such as severe bradycardia, AR, or arteriovenous fistula. A *bifid* pulse is created by two distinct pressure peaks. This phenomenon may occur with fever or after exercise in a normal person and is consistent with increased vascular compliance. With chronic severe AR, a large stroke volume ejected rapidly into a noncompliant arterial tree produces a reflected wave of sufficient amplitude to be palpated during systole, rendering the pulse bifid. Hypertrophic obstructive cardiomyopathy (HOCM) can rarely produce a bifid systolic pulse with percussion and tidal waves (**Fig. 10.5**). Diastolic augmentation of pressure with an intra-aortic balloon pump also results in a bifid pulse, although with the two components separated by aortic valve closure.

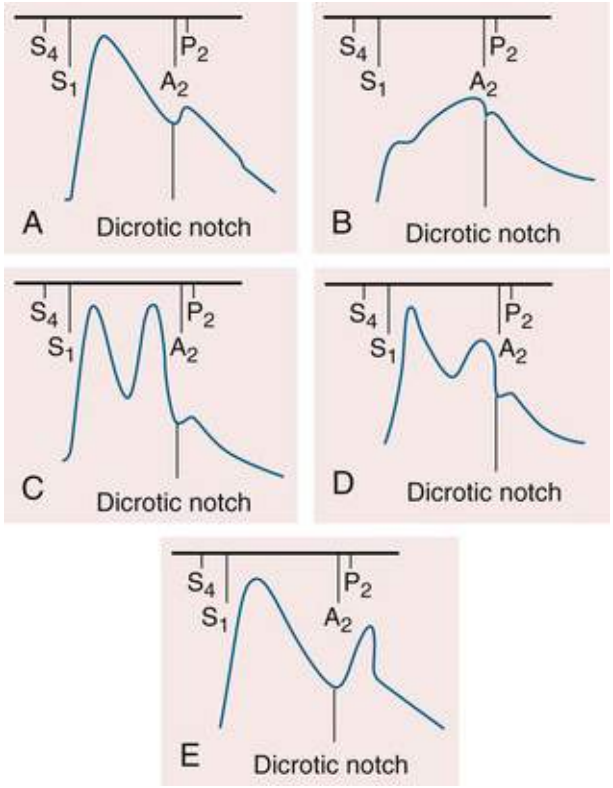

FIGURE 10.5 Carotid pulse waveforms and heart sounds. **A,** Normal. **B,** Aortic stenosis. Anacrotic pulse with slow upstroke and peak near S_2. **C,** Severe AR: bifid pulse with two systolic peaks. **D,** Hypertrophic obstructive cardiomyopathy (HOCM): bifid pulse with two systolic peaks. The second peak (tidal or reflected wave) is of lower amplitude than the initial percussion wave. **E,** Bifid pulse with systolic and diastolic peaks as may occur with sepsis or intra-aortic balloon counterpulsation. A_2, Aortic component of S_2; P_2, pulmonic component of S_2. (From Chatterjee K. Bedside evaluation of the heart: the physical examination. In Chatterjee K, Parmley W, editors. Cardiology: an Illustrated Text/Reference. Philadelphia: Lippincott; 1991, pp 3.11-3.51; and Braunwald E. The clinical examination. In Braunwald E, Goldman L, editors. Primary Cardiology. 2nd ed. Philadelphia: Saunders; 2003, p 36.)

Pulsus paradoxus, a fall in systolic pressure of more than 10 mm Hg with inspiration, is considered pathologic and a sign of pericardial tamponade or pulmonary disease. This phenomenon also can occur in obesity and pregnancy without clinical disease. Pulsus paradoxus is detected by noting the difference between the systolic BP at which the Korotkoff sounds are first heard (during expiration) and the systolic BP at which the Korotkoff sounds are heard with each beat, independent of respiratory phase. Between these two pressures, the sounds will be heard only intermittently (during expiration). Appreciation of this finding requires a slow decrease of the cuff pressure. Conditions such as tachycardia, AF, and tachypnea make its assessment difficult. Pulsus paradoxus may be palpable when the BP difference exceeds 15 to 20 mm Hg (**see Chapter 83**). Pulsus paradoxus is not specific for pericardial tamponade and can accompany massive pulmonary embolus, hemorrhagic shock, severe obstructive lung disease, or tension pneumothorax.

Pulsus alternans is defined by the beat-to-beat variability of the pulse amplitude (**Fig. 10.6**). It is present when only every other phase 1 Korotkoff sound is audible as the cuff pressure is slowly lowered, in a patient with a regular heart rhythm, independent of the respiratory cycle. Pulsus alternans generally occurs in severe heart failure, in severe AR, hypertension, and hypovolemic states. It is attributed to cyclic changes in intracellular calcium and action potential duration. Association with electrocardiographic T wave alternans appears to increase arrhythmic risk.

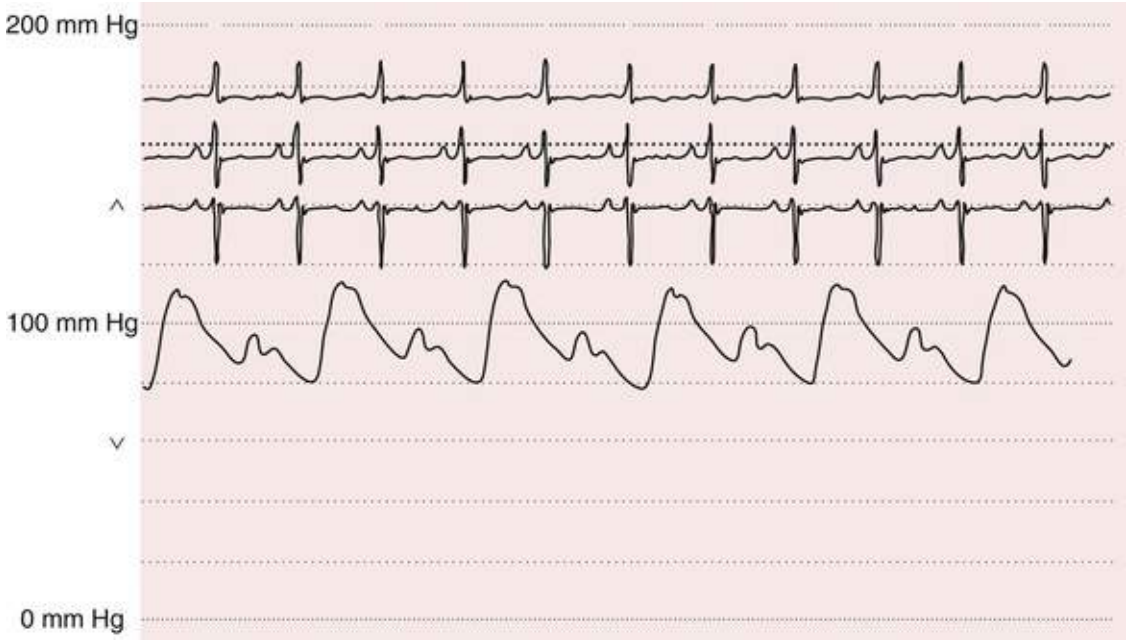

FIGURE 10.6 Pulsus alternans in a patient with severe left ventricular systolic dysfunction. The systolic pressure varies from beat to beat, independent of the respiratory cycle. The rhythm is sinus throughout.

Severe aortic stenosis may be suggested by a weak and delayed pulse *(pulsus parvus et tardus)*, and is best appreciated by careful palpation of the carotid arteries (**see Fig. 10.5** and **Chapter 68**). The delay is assessed during simultaneous auscultation of the heart sounds; the carotid upstroke should coincide with S_1. This finding is less specific in older, hypertensive patients with reduced vascular compliance and stiffer carotid arteries. An abrupt carotid upstroke with rapid falloff characterizes the pulse of chronic AR (Corrigan or water-hammer pulse). The carotid upstroke also is rapid in older patients with isolated systolic hypertension and wide pulse pressures.

Pulsation of the abdominal aorta can be appreciated in the epigastric area. Femoral and popliteal artery aneurysms should be sought in patients with AAA disease or underlying connective tissue disease.

The history and physical examination findings can help assess the level of arterial obstruction in patients with lower extremity claudication (**see Chapter 64**). Auscultation for aortic and femoral artery bruits should be routine. The correlation between the presence of a bruit and the degree of vascular obstruction is weak. Extension of a bruit into diastole or a thrill generally indicates severe obstruction. Other causes of a bruit include arteriovenous fistulas and enhanced flow through normal arteries, as in a young patient with fever.

Integrating the clinical history and presence of atherosclerotic risk factors improves the accuracy of the examination for the identification of lower extremity PAD. In an asymptomatic patient the presence of a femoral bruit (LR, 4.8; 95% CI, 2.4 to 9.5) or any abnormality of the pulse (LR, 3.1; 95% CI, 3.1 to 6.6) increases the likelihood of PAD. The likelihood of significant PAD increases when there are lower extremity symptoms and cool skin (LR, 5.9; 95% CI, 4.1 to 8.6), pulse abnormalities (LR, 4.7; 95% CI, 2.2 to 9.9), or any bruit (LR, 5.6; 95% CI, 4.7 to 6.7). Abnormal pulse oximetry, defined by a more than 2% difference between finger and toe oxygen saturation, can also indicate lower extremity PAD and is comparable to the ABI (LR, 30.0; 95% CI, 7.6 to 121 versus LR, 24.8; 95% CI, 6.2 to 99.8).

Inspection and Palpation of the Heart

The apical heartbeat may be visible in thin-chested adults. The left anterior chest wall may heave in patients with enlarged and hyperdynamic left ventricles. Right upper parasternal and sternoclavicular

pulsations suggest ascending AAA disease. A left parasternal lift indicates RV pressure or volume overload. A pulsation in the third intercostal space to the left of the sternum can indicate PA hypertension. In very thin, tall patients, or in patients with emphysema and flattened diaphragm, the RV impulse may be visible in the epigastrium and should be distinguished from a pulsatile liver edge.

Palpation of the heart should begin with the patient in the supine position inclined at 30 degrees. If the heart is not palpable in this position, the patient should be examined either in the left lateral decubitus position with the left arm above the head or in the seated position, leaning forward. The point of maximal impulse normally is over the left ventricular (LV) apex beat and should be located in the midclavicular line at the fifth intercostal space. It is smaller than 2 cm (0.8 inch) in diameter and moves quickly away from the fingers. It is best appreciated at end-expiration, when the heart is closest to the chest wall. The normal impulse may not be palpable in obese or muscular patients or in those with thoracic cage deformities. LV cavity enlargement displaces the apex beat leftward and downward. A sustained apex beat is a sign of LV pressure overload (as in aortic stenosis or hypertension). A palpable, presystolic impulse corresponds to a fourth heart sound (S_4) and reflects the atrial contribution to ventricular diastolic filling of a noncompliant left ventricle. A prominent, rapid early filling wave in patients with advanced systolic heart failure may result in a palpable third sound (S_3), which may be present when the gallop itself is not audible (Video 10.3). A large ventricular aneurysm may yield a palpable and visible ectopic impulse discrete from the apex beat. HOCM rarely may cause a triple-cadence apex beat, with contributions from a palpable S_4 and the two components of the systolic pulse.

A *parasternal lift* occurs with RV pressure or volume overload. Signs of TR (jugular venous *cv* waves) and PA hypertension (loud, single, or palpable P_2) should be sought. An enlarged right ventricle can give rise to a *precordial lift* that can extend across the precordium and obscure left-sided findings. Rarely, patients with severe MR will have a prominent left parasternal impulse because of systolic expansion of the left atrium and forward displacement of the heart. Lateral retraction of the chest wall may be present with isolated RV enlargement secondary to posterior displacement of the systolic LV impulse. Systolic and diastolic thrills signify turbulent, high-velocity blood flow. Their locations help to identify the origins of heart murmurs.

Auscultation of the Heart

Heart Sounds

First Heart Sound (S_1)

The normal S_1 comprises mitral (M_1) and tricuspid (T_1) valve closure. The two components usually are best heard at the lower left sternal border in younger individuals. Normal splitting of S_1 is accentuated with complete right bundle branch block (RBBB). S_1 intensity increases in the early stages of rheumatic mitral stenosis when the valve leaflets are still pliable, in hyperkinetic states, and with short P-R intervals (<160 msec). S_1 becomes softer in the late stages of stenosis, when the leaflets are rigid and calcified, with contractile dysfunction, beta-adrenergic receptor blockers, and long P-R intervals (>200 msec). Other factors that can decrease the intensity of the heart sounds and murmurs include mechanical ventilation, obstructive lung disease, obesity, pendulous breasts, pneumothorax, and pericardial effusion.

Second Heart Sound (S_2)

S_2 comprises aortic (A_2) and pulmonic (P_2) valve closure. With normal, or *physiologic*, splitting, the A_2-P_2 interval increases during inspiration and narrows with expiration. The individual components are best heard at the second left interspace with the patient in the supine position. The A_2-P_2 interval widens with complete RBBB because of delayed pulmonic valve closure, and with severe MR because of premature aortic valve closure. Unusually narrow but physiologic splitting of S_2, with an increase in the intensity of P_2 relative to A_2, indicates PA hypertension. With *fixed* splitting the A_2-P_2 interval is wide and remains unchanged during the respiratory cycle, indicating ostium secundum ASD. Reverse, or *paradoxical*, splitting occurs as a consequence of a pathologic delay in aortic valve closure, as may occur with complete left bundle branch block, RV apical pacing, severe aortic stenosis, HOCM, and myocardial ischemia. A_2 normally is louder than P_2 and can be heard at most sites across the precordium. When both components can be heard at the lower left sternal border or apex, or when P_2 can be palpated at the second left interspace, PA hypertension is present. The intensity of A_2 and P_2 decreases with aortic and pulmonic stenosis, respectively. A single S_2 may result.

Systolic Sounds

An *ejection sound* is a high-pitched, early systolic sound that coincides in timing with the upstroke of the carotid pulse and usually is associated with congenital bicuspid aortic or pulmonic valve disease, or sometimes with aortic or pulmonic root dilation and normal semilunar valves. The ejection sound accompanying pulmonic valve disease decreases in intensity with inspiration, the only right-sided cardiac event to behave in this manner. Ejection sounds disappear as the culprit valve loses its pliability over time. They often are better heard at the lower left sternal border than at the base of the heart. *Nonejection clicks*, which occur after the upstroke of the carotid pulse, are related to MVP. A systolic murmur may or may not follow. With standing, ventricular preload and afterload decrease, and the click (and murmur) move closer to S_1. With squatting, ventricular preload and afterload increase, the prolapsing mitral valve tenses later in systole, and the click (and murmur) move away from S_1 (**Fig. 10.7**).

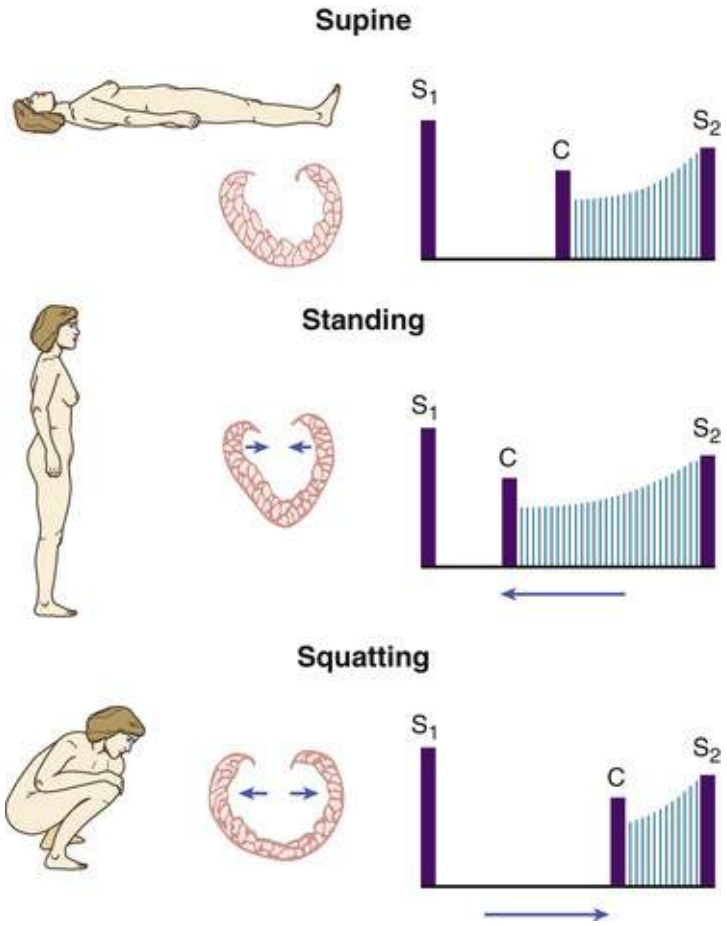

FIGURE 10.7 Behavior of the nonejection click (*C*) and systolic murmur of mitral valve prolapse. With standing, venous return decreases, the heart becomes smaller, and prolapse occurs earlier in systole. The click and murmur move closer to S_1. With squatting, venous return increases, causing an increase in left ventricular chamber size. The click and murmur occur later in systole and move away from S_1. (From Shaver JA, Leonard JJ, Leon DF. Examination of the Heart. Part IV. Auscultation of the heart. Dallas: American Heart Association; 1990, p 13. Copyright 1990, American Heart Association.)

Diastolic Sounds

The high-pitched *opening snap* (OS) of mitral stenosis occurs a short distance after S_2; the A_2-OS interval is inversely proportional to the height of the left atrial (LA)–LV diastolic pressure gradient. The intensity of both S_1 and OS decreases with progressive calcification and rigidity of the anterior mitral leaflet. A *pericardial knock* (PK) is a high-pitched early diastolic sound that corresponds in timing to the abrupt cessation of ventricular expansion after atrioventricular valve opening and to the prominent *y* descent seen in the jugular venous waveform in patients with constrictive pericarditis. A tumor "plop" rarely is heard with atrial myxoma; it is a low-pitched sound sometimes only heard in certain positions that arises from the diastolic prolapse of the tumor across the mitral valve. A diastolic murmur may be present, although most myxomas cause no sound.

A third heart sound (S_3) occurs during the rapid filling phase of ventricular diastole. An S_3 may be normally present in children, adolescents, and young adults but indicates systolic heart failure in older adults and carries important prognostic weight. A left-sided S_3 is a low-pitched sound best heard over the LV apex with the patient in the left lateral decubitus position, whereas a right-sided S_3 is usually heard at the lower left sternal border or in the subxiphoid position with the patient supine and may become louder with inspiration. A fourth heart sound (S_4) occurs during the atrial filling phase of ventricular diastole and is thought to indicate presystolic ventricular expansion. An S_4 is especially common in patients with

accentuated atrial contribution to ventricular filling (e.g., LV hypertrophy).

Cardiac Murmurs

Heart murmurs result from audible vibrations caused by increased turbulence and are defined by their timing within the cardiac cycle (**Table 10.6** and **Fig. 10.8**). Not all murmurs indicate valvular or structural heart disease. The accurate identification of a functional (benign) systolic murmur can obviate the need for echocardiography in many healthy individuals. The magnitude, dynamic change, and duration of the pressure difference between two cardiac chambers, or between the ventricles and their respective great arteries, dictate the duration, frequency, configuration, and intensity of murmurs. Intensity is graded on a scale of 1 to 6; a *palpable thrill* characterizes murmurs of grade 4 or higher intensity. Other important attributes that aid in identification include location, radiation, and response to bedside maneuvers, including quiet respiration.

TABLE 10.6

Principal Causes of Heart Murmurs

Systolic Murmurs
Early Systolic
Mitral—acute mitral regurgitation (MR)
Ventricular septal defect (VSD)
Muscular
Nonrestrictive with pulmonary hypertension
Tricuspid—tricuspid regurgitation (TR) with normal pulmonary artery pressure
Midsystolic
Aortic
Obstructive
Supravalvular—supravalvular aortic stenosis, coarctation of the aorta
Valvular—aortic stenosis and sclerosis
Subvalvular—discrete, tunnel, or HOCM
Increased flow, hyperkinetic states, aortic regurgitation (AR), complete heart block
Dilation of ascending aorta, atheroma, aortitis
Pulmonary
Obstructive
Supravalvular—pulmonary artery stenosis
Valvular—pulmonic valve stenosis
Subvalvular—infundibular stenosis (dynamic)
Increased flow, hyperkinetic states, left-to-right shunt (e.g., ASD)
Dilation of pulmonary artery
Late Systolic
Mitral—mitral valve prolapse (MVP), acute myocardial ischemia
Tricuspid—tricuspid valve prolapse
Holosystolic
Atrioventricular valve regurgitation (MR, TR)
Left-to-right shunt at ventricular level (VSD)
Diastolic Murmurs
Early Diastolic
Aortic regurgitation
Valvular—congenital (bicuspid valve), rheumatic deformity, endocarditis, prolapse, trauma, postvalvulotomy
Dilation of valve annulus—aortic dissection, annuloaortic ectasia, cystic medial degeneration, hypertension, ankylosing spondylitis
Widening of commissures—syphilis
Pulmonic regurgitation
Valvular—postvalvulotomy, endocarditis, rheumatic fever, carcinoid
Dilation of valve annulus—pulmonary hypertension; Marfan syndrome
Congenital—isolated or associated with tetralogy of Fallot, VSD, pulmonic stenosis
Mid-Diastolic
Mitral
Mitral stenosis
Carey Coombs murmur (mid-diastolic apical murmur in acute rheumatic fever)
Increased flow across nonstenotic mitral valve (e.g., MR, VSD, PDA, high-output states, complete heart block)
Tricuspid
Tricuspid stenosis
Increased flow across nonstenotic tricuspid valve (e.g., TR, ASD, anomalous pulmonary venous return)
Left and right atrial tumors (myxoma)
Severe or eccentric AR (Austin Flint murmur)
Late Diastolic
Presystolic accentuation of mitral stenosis murmur
Austin Flint murmur of severe or eccentric AR
Continuous Murmurs
Patent ductus arteriosus (PDA)
Coronary arteriovenous fistula
Ruptured sinus of Valsalva aneurysm
Atrial septal defect (ASD)
Cervical venous hum
Anomalous left coronary artery
Proximal coronary artery stenosis
Mammary souffle of pregnancy
Pulmonary artery branch stenosis
Bronchial collateral circulation
Small (restrictive) ASD with mitral stenosis
Intercostal arteriovenous fistula

(Modified from Wood P. Diseases of the Heart and Circulation. Philadelphia: Lippincott; 1968; and O'Rourke RA, Braunwald E. Physical examination of the cardiovascular system. In Kasper D, Braunwald E, Fauci A, et al, editors. Harrison's Principles of Internal Medicine. 16th ed. New York: McGraw-Hill; 2005, p 1309.)

Systolic Murmurs

Systolic murmurs are early, midsystolic, late, or holosystolic in timing. Acute severe MR results in a decrescendo, early systolic murmur because of the steep rise in pressure within the noncompliant left atrium (**Fig. 10.9**). Severe MR associated with posterior mitral leaflet prolapse or flail radiates anteriorly and to the base; MR caused by anterior leaflet involvement radiates posteriorly and to the axilla. With acute TR in patients with normal PA pressures, an *early* systolic murmur, which increases in intensity with inspiration, may be audible at the lower left sternal border, and regurgitant *cv* waves may be visible in the jugular venous pulse.

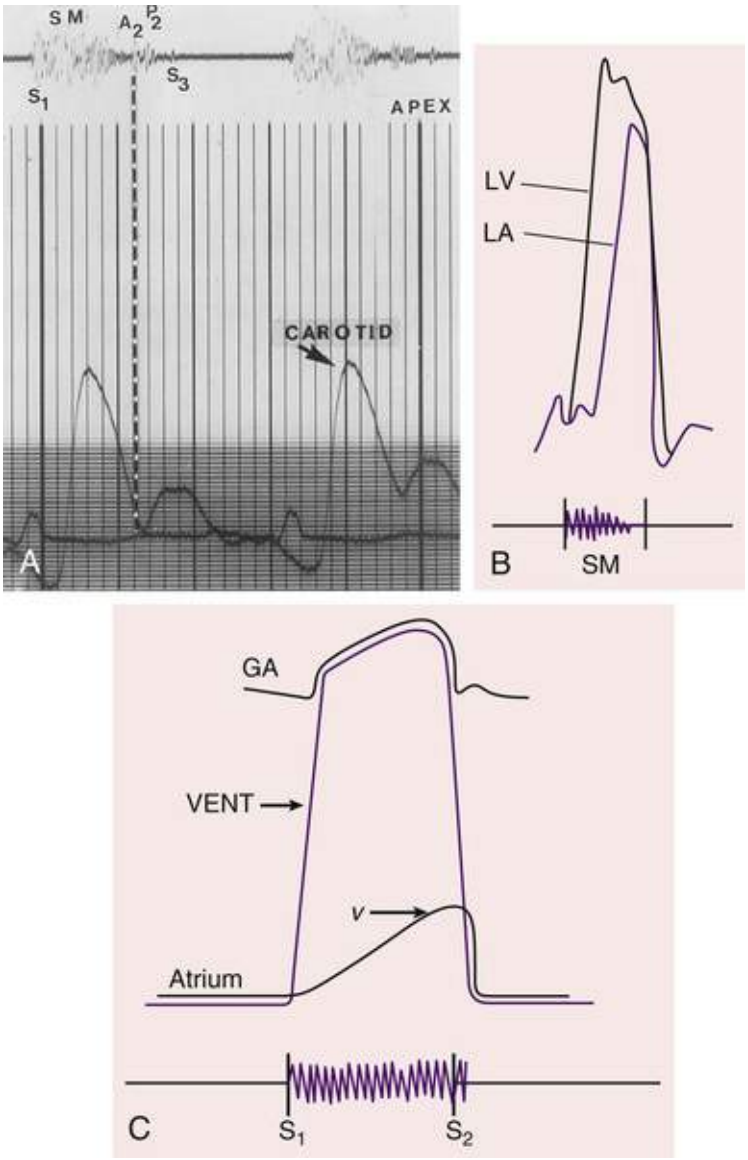

FIGURE 10.9 **A,** Phonocardiogram (*top*) obtained in a patient with acute severe mitral regurgitation (MR) showing a decrescendo early systolic murmur (*SM*) and diastolic filling sound (S_3). **B,** Left ventricular (LV) and left atrial (LA) pressure waveforms demonstrating the abrupt rise in LA pressure and attenuation of the LV-LA pressure gradient, resulting in the duration and configuration of the SM. **C,** Illustration of great artery (*GA*) and ventricular (*VENT*) and atrial pressures with corresponding phonocardiogram in chronic MR or TR. Note the holosystolic timing and plateau configuration of the murmur, both of which derive from the large ventricular-atrial pressure gradient throughout systole; *v, v* wave. (From Braunwald E, Perloff JK. Physical examination of the heart and circulation. In Zipes D, Libby P, Bonow RO, Braunwald E, editors. Braunwald's Heart Disease: a Textbook of Cardiovascular Medicine. 7th ed. Philadelphia: Saunders; 2005, p 97.)

Midsystolic murmurs begin after S_1 and end before S_2; they usually are crescendo-decrescendo in configuration. Aortic stenosis or sclerosis causes most midsystolic murmurs in adults. Accurate characterization of the severity of aortic stenosis at the bedside depends on cardiac output, stiffness of the carotid arteries, and associated findings. Other causes of a midsystolic heart murmur include HOCM, pulmonic stenosis, and increased pulmonary blood flow in patients with a large ASD and a left-to-right shunt. An isolated grade 1 or 2 midsystolic murmur in the absence of symptoms or other signs of heart disease is a benign finding that does not warrant further evaluation, including echocardiography.

A *late,* apical systolic murmur usually indicates MVP; one or more nonejection clicks may be present. A similar murmur may be heard transiently during an episode of acute myocardial ischemia. In this setting the MR is caused by apical tethering and mal-coaptation of the leaflets in response to structural and functional changes of the ventricle and mitral annulus. The intensity of the murmur will vary with LV afterload.

Holosystolic murmurs, which are plateau in configuration, derive from the continuous and wide pressure gradient between two cardiac chambers—the left ventricle and left atrium with chronic MR, the right ventricle and right atrium with chronic TR, and the left ventricle and right ventricle with membranous ventricular septal defect (VSD) without PA hypertension. MR is best heard over the cardiac apex, TR at the lower left sternal border, and a VSD murmur at the mid-left sternal border, where a thrill is palpable in most patients. TR most frequently is secondary to annular dilation from RV enlargement with papillary muscle displacement and failure of tricuspid leaflet coaptation. PA hypertension also may be present.

Diastolic Murmurs

Diastolic murmurs invariably signify cardiac disease. Chronic AR causes a high-pitched, decrescendo, early to mid-diastolic murmur. With primary aortic valve disease, the murmur is best heard along the left sternal border, whereas with root enlargement and secondary AR, the murmur may radiate along the right sternal border. A midsystolic murmur caused by augmented and accelerated blood flow is also present with moderate to severe AR and need not signify valve or outflow tract obstruction. The diastolic murmur is both softer and of shorter duration in acute AR, as a result of the rapid rise in LV diastolic pressure and the diminution of the aortic-LV diastolic pressure gradient. Additional features of acute AR include tachycardia, a soft S_1, and the absence of peripheral findings of significant diastolic runoff.

The murmur of pulmonic regurgitation (PR) is heard along the left sternal border and most often is caused by annular enlargement from chronic PA hypertension (*Graham Steell murmur*). Signs of RV pressure overload are present. PR also can occur with a congenitally deformed valve and is invariably present after repair of tetralogy of Fallot. In these settings the murmur is relatively softer and lower pitched. The severity of PR after surgical repair can be underappreciated.

Mitral stenosis is the classic cause of a mid- to late diastolic murmur (**see Fig. 10.8A, F**). The stenosis also may be "silent," as in patients with low cardiac output or large body habitus. The murmur is best heard over the apex with the patient in the left lateral decubitus position, is low pitched (rumbling), and is introduced by an OS in the early stages of the disease. Presystolic accentuation (an increase in the intensity of the murmur in late diastole following atrial contraction) occurs in patients in sinus rhythm. Left-sided events usually obscure findings in patients with rheumatic tricuspid stenosis. Functional mitral stenosis or tricuspid stenosis refers to mid-diastolic murmurs created by increased, accelerated transvalvular flow, without valvular obstruction, in the setting of severe MR or TR, respectively, or ASD with a large left-to-right shunt.

The low-pitched mid- to late apical diastolic murmur sometimes associated with AR (*Austin Flint murmur*) can be distinguished from mitral stenosis on the basis of its response to vasodilators and the presence of associated findings. Less common causes of a mid-diastolic murmur include atrial myxoma, complete heart block, and acute rheumatic mitral valvulitis (*Carey Coombs murmur*).

Continuous Murmurs

The presence of a continuous murmur implies a pressure gradient between two chambers or vessels during both systole and diastole. These murmurs begin in systole, peak near S_2, and continue into diastole. They can be difficult to distinguish from systolic and diastolic murmurs in patients with mixed aortic or pulmonic valve disease. Examples are the murmurs associated with PDA, ruptured sinus of Valsalva aneurysm, and coronary, great vessel, or hemodialysis-related arteriovenous fistulas. The cervical venous hum and mammary souffle of pregnancy are two benign variants.

Dynamic Auscultation

Simple bedside maneuvers can help identify heart murmurs and characterize their significance (**Table 10.7**). Right-sided events, except for the pulmonic ejection sound, increase with inspiration and decrease with expiration; left-sided events behave oppositely (100% sensitivity, 88% specificity). The intensity of the murmurs associated with MR, VSD, and AR will increase in response to maneuvers that increase LV afterload (e.g., handgrip, vasopressor administration) and decrease after exposure to vasodilating agents (e.g., amyl nitrite). The response of the murmur associated with MVP to standing and squatting has previously been described. The murmur of HOCM behaves in a directionally similar manner, becoming softer and shorter with squatting (95% sensitivity, 85% specificity) and longer and louder on rapid standing (95% sensitivity, 84% specificity). The intensity of the murmur of HOCM also increases with the Valsalva maneuver (65% sensitivity, 95% specificity). A change in the intensity of a systolic murmur in the first beat after a premature beat, or in the beat after a long cycle length in patients with AF, suggests aortic stenosis rather than MR, particularly in an older patient, in whom the murmur of aortic stenosis is well transmitted to the apex (*Gallavardin effect*). Systolic murmurs caused by LV outflow obstruction, including those caused by aortic stenosis, will increase in intensity in the beat following a premature beat because of the combined effects of enhanced LV filling and postextrasystolic potentiation of contractile function. Forward flow accelerates, causing an increase in the gradient and a louder murmur. The intensity of the murmur of MR does not change in the post–premature beat, because relatively minimal further increase occurs in mitral valve flow or change in the LV-LA gradient.

TABLE 10.7

Interventions for Altering Intensity of Cardiac Murmurs

Respiration: Right-sided murmurs generally increase with inspiration. Left-sided murmurs usually are louder during expiration.
Valsalva maneuver: Most murmurs decrease in length and intensity. Two exceptions are the systolic murmur of HOCM, which usually becomes much louder, and that of MVP, which becomes longer and often louder. After release of the Valsalva maneuver, right-sided murmurs tend to return to baseline intensity earlier than left-sided murmurs.
Exercise: Murmurs caused by blood flow across normal or obstructed valves (as in pulmonic and mitral stenosis) become louder with both isotonic and isometric (handgrip) exercise. Murmurs of MR, VSD, and AR also increase with handgrip exercise.
Positional changes: With standing, most murmurs diminish; two exceptions are the murmur of HOCM, which becomes louder, and that of MVP, which lengthens and often is intensified. With squatting, most murmurs become louder, but those of HOCM and MVP usually soften and may disappear. Passive leg raising usually produces the same results as squatting.
Post–ventricular premature beat or atrial fibrillation: Murmurs originating at normal or stenotic semilunar valves increase in intensity during the cardiac cycle after a ventricular premature beat or in the beat after a long cycle length in AF. By contrast, systolic murmurs caused by atrioventricular valve regurgitation do not change, diminish (papillary muscle dysfunction), or become shorter after a premature beat (MVP).
Pharmacologic interventions: During the initial relative hypotension after amyl nitrite inhalation, murmurs of MR, VSD, and AR decrease in intensity, whereas the murmur of AS increases in intensity because of increased stroke volume. During the later tachycardia phase, murmurs of mitral stenosis and right-sided lesions also become louder. This intervention may help distinguish the murmur of the Austin Flint phenomenon from that of mitral stenosis. The response in MVP often is biphasic (softer and then louder than control).
Transient arterial occlusion: Transient external compression of both brachial arteries by bilateral cuff inflation to 20 mm Hg greater than peak systolic pressure augments the murmurs of MR, VSD, and AR, but not murmurs from other causes.

Integrated, Evidence-Based Approach to Specific Cardiac Disorders

Heart Failure (see also Part IV)

History

Both exertional and resting symptoms should be investigated. Common signs and symptoms include dyspnea, fatigue, exercise limitation, orthopnea, and edema. In a review of 22 studies of adult patients presenting to an ED with dyspnea, the probability of heart failure (HF) was best predicted by a past history of HF (LR, 5.8; 95% CI, 4.1 to 8.0), paroxysmal nocturnal dyspnea (LR, 2.6; 95% CI, 1.5 to 4.5), a third heart sound (LR, 11; 95% CI, 4.9 to 25), or AF (LR, 3.8; 95% CI, 1.7 to 8.8).[14] An initial clinical impression of HF as noted by a physician was one of the stronger clinical predictors of this diagnosis (LR, 4.4; 95% CI, 1.8 to 10.0). With the exception of paroxysmal nocturnal dyspnea, these same features also predicted HF when there was concomitant pulmonary disease. The addition of testing for N-terminal pro–B-type natriuretic peptide (NT-proBNP) increases diagnostic accuracy only modestly (C-statistic, 0.83 versus 0.86).[7]

Severe and sudden-onset dyspnea indicates acute pulmonary edema, typically precipitated by ischemia, arrhythmia, sudden left-sided valvular regurgitation, and accelerated hypertension. It is important to exclude other causes, such as pulmonary embolism and pneumothorax. The extent of limitation also should be defined because functional capacity, as assessed by NYHA classification, strongly and independently predicts the risk of death for HF patients. Self-reported functional capacity and objectively measured cardiovascular performance can differ substantially. Symptoms that occur at rest may have greater predictive value for the diagnosis of HF than exertional symptoms. Orthopnea is not specific for HF and can occur in patients with asthma, ascites, or gastroesophageal reflux. *Trepopnea*, which is dyspnea or discomfort experienced in the lateral decubitus position, also may be present. Patients with HF prefer sleeping on their right side, and trepopnea probably accounts for the predominance of right-sided pleural effusions in this population. Shortness of breath may be particularly noticeable when bending forward, termed *bendopnea*. It is associated with higher supine right atrial and pulmonary capillary wedge pressures and is mediated by further elevations in these pressures with bending over. It is even more likely present when the resting cardiac index is low.[15] Paroxysmal nocturnal dyspnea also is common in HF patients. Cheyne-Stokes respirations may be apparent when the patient is awake.[16] The prevalence of central sleep apnea or Cheyne-Stokes respirations ranges from 20% to 62% in various HF studies,[10] and either of these disorders is associated with an increased mortality risk.

Clinically evident edema or weight gain over days indicates volume excess but lags behind the clinical redistribution of intravascular volume from the splanchnic beds to the central veins. In patients with advanced right-sided heart failure, uncomfortable hepatomegaly and ascites may predominate. Patients with chronic HF often lack pulmonary rales or lower extremity edema. Gastrointestinal symptoms such as early satiety, nausea, vomiting, and belching are also common and are related to decreases in GI blood flow and bowel edema, particularly in those with cardiac cachexia.[17]

Few studies have explored the predictive values of various signs and symptoms of HF. In a systematic review, orthopnea only modestly predicted increased filling pressures.[18] Dyspnea and edema were similarly useful but were most predictive when combined with physical examination findings (S_3, tachycardia, elevated JVP, low pulse pressure, rales, abdominojugular reflux sign). When combined with other findings, a total of three or more symptoms or signs predicted a greater than 90% likelihood of increased filling pressures if severe LV dysfunction was not known. By contrast, if one or no findings or symptoms were present, the likelihood of increased filling pressures was less than 10%. The commonly used Framingham criteria for HF diagnosis in patients with reduced ejection fraction (EF) have only modest specificity (63%) and sensitivity (63%). The distinction between HF with reduced EF and HF with preserved EF can be made at the bedside with modest accuracy. Systolic function is more likely to be preserved when patients are female or older and have an increased BMI, but such findings lack adequate specificity or sensitivity to guide therapy. Furthermore, diastolic dysfunction does not exclude

systolic dysfunction.

Physical Examination

In most patients with HF who require hospitalization, the reason for admission is volume overload; failure to relieve it has negative prognostic impact. Four signs are commonly used to predict elevated filling pressures: jugular venous distention/abdominojugular reflux sign, presence of an S_3 and/or S_4, rales, and pedal edema. In general, the use of a combination of findings, rather than reliance on isolated clinical findings, improves diagnostic accuracy. Some clinicians advocate assessment of the HF patient along two basic axes—volume status ("dry" or "wet") and perfusion status ("warm" or "cold")—as a useful guide to therapy (**see Fig. 21.3**). This approach has prognostic usefulness, particularly in assessing patients at discharge after admission for HF. For example, such patients discharged with a "wet" or "cold" profile experience worse outcomes (hazard ratio [HR], 1.5; 95% CI, 1.1 to 12.1; $P = 0.017$) compared with those discharged "warm and dry" (HR, 0.9; 95% CI, 0.7 to 2.1; $P = 0.5$).[18] Advanced training may be required to achieve this level of diagnostic precision with the physical examination.

Jugular Venous Pressure

The JVP provides the readiest bedside estimate of LV filling pressure. In the Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE) trial, 82% of patients whose estimated right atrial (RA) pressure was higher than 8 mm Hg (10.5 cm H_2O) had a measured RA pressure higher than 8 mm Hg. The same investigators also identified 9 of the 11 patients with RA pressures lower than 8 mm Hg.[18] Although the JVP estimates RV filling pressure, it has a predictable relationship with PA wedge pressure. Drazner and colleagues[18] found that the RA pressure reliably predicted the PA wedge pressure; the positive predictive value of RA pressure higher than 10 mm Hg for PA wedge pressure higher than 22 mm Hg was 88%. In addition, the PA systolic pressure could be estimated as twice the wedge pressure. In the ESCAPE trial, an estimated RA pressure higher than 12 mm Hg and two-pillow orthopnea were the only bedside parameters that provided incremental value to the prediction of a PA wedge pressure higher than 22 mm Hg, and compared favorably with BNP levels.[18] Echocardiography and BNP determinations may not always provide incremental value to the clinical assessment of HF by experienced observers.[19]

An elevated JVP has prognostic significance. Drazner and associates[18] demonstrated that the presence of jugular vein distention signifying elevated pressures at enrollment in a large clinical HF trial (11% of the Studies of Left Ventricular Dysfunction [SOLVD] treatment study participants), after adjustment for other markers of disease severity, predicted HF hospitalizations (relative risk [RR], 1.32; 95% CI, 1.08 to 1.62), death from pump failure (RR, 1.37; 95% CI, 1.07 to 1.75), and death plus HF hospitalization (RR, 1.30; 95% CI, 1.11 to 1.53) (**Fig. 10.10**). The investigators extended these observations to asymptomatic individuals enrolled in the SOLVD prevention study, among whom jugular vein distention was less common (1.7% of the study population).[18] In patients presenting with dyspnea, the abdominojugular reflux sign is useful in predicting HF (LR, 6.0; 95% CI, 0.8 to 51) and suggests a PA wedge pressure higher than 15 mm Hg (LR, 6.7; 95% CI, 3.3 to 13.4). The presence of jugular vein distention, either at rest or induced, had the best combination of sensitivity (81%), specificity (80%), and predictive accuracy (81%) for elevation of the PA wedge pressure. Ultrasound assessment of internal jugular vein dimension, both at rest and during the Valsalva maneuver, is independently associated with prognosis in ambulatory HF patients with reduced EF.[20]

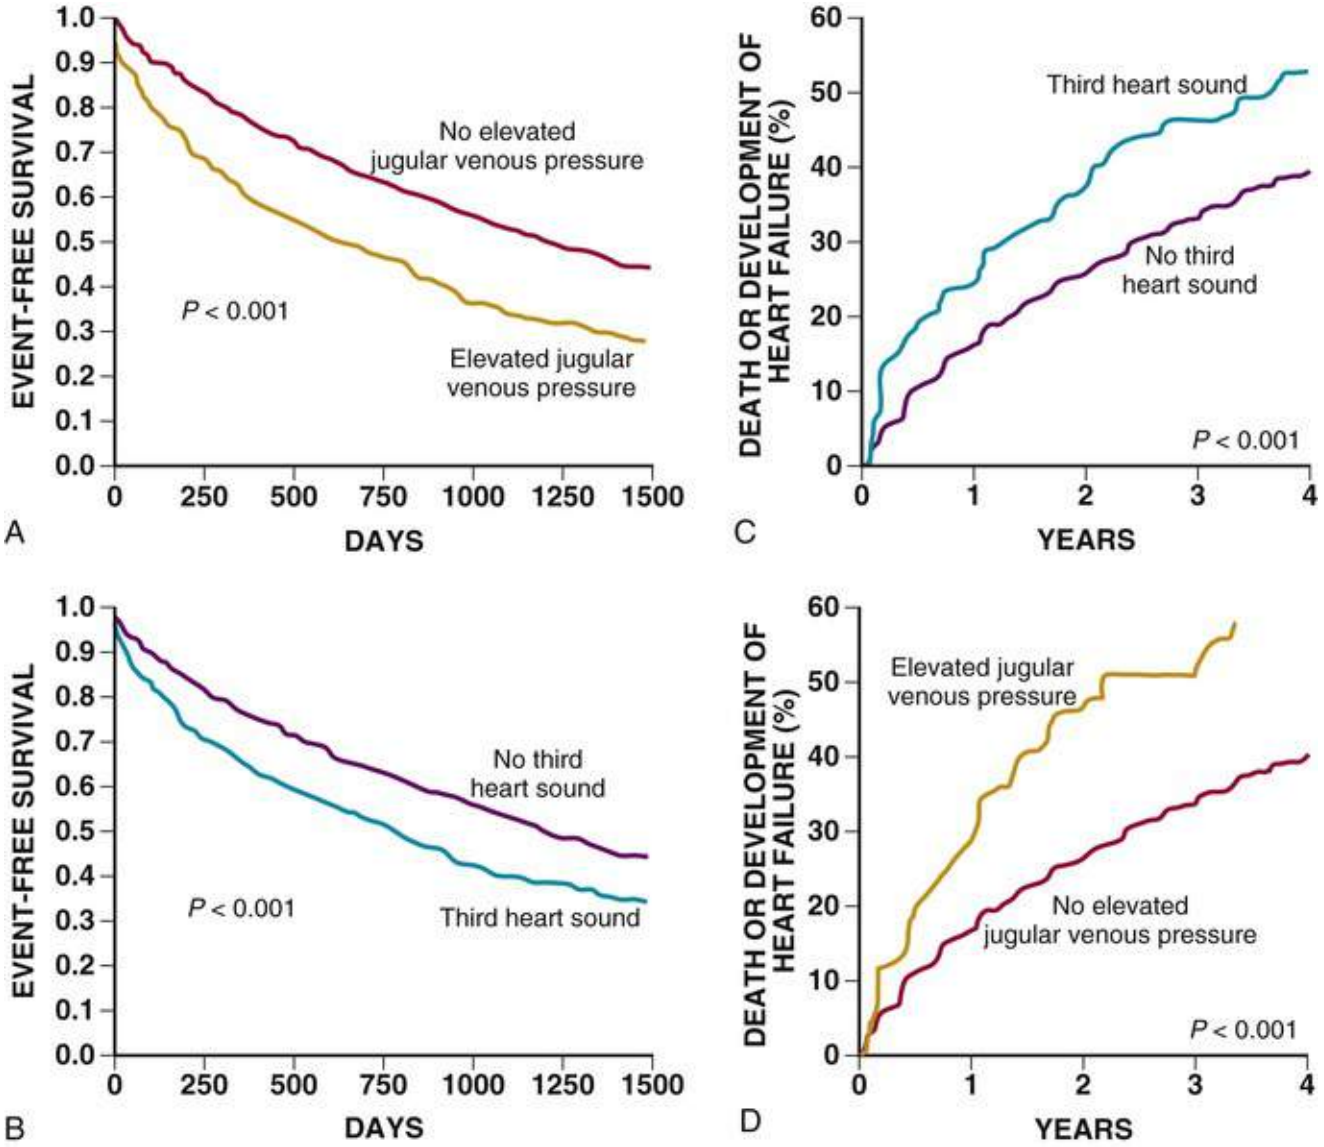

FIGURE 10.10 Kaplan-Meier plots demonstrating prognostic value of an elevated jugular venous pressure and third heart sound (S_3) in symptomatic (**A** and **B**) and asymptomatic (**C** and **D**) patients with heart failure who also had systolic dysfunction. (**A, B,** From Drazner MH, Rame JE, Stevenson LW, Dries DL. Prognostic importance of elevated jugular venous pressure and a third heart sound in patients with heart failure. N Engl J Med 2001;345:574; **C, D,** from Drazner MH, Rame JE, Dries DL. Third heart sound and elevated jugular venous pressure as markers of the subsequent development of heart failure in patients with asymptomatic left ventricular dysfunction. Am J Med 2003;114:431.)

Third and Fourth Heart Sounds

The third heart sound (S_3) predicts EF poorly because it reflects primarily diastolic rather than systolic performance. In HF patients an S_3 is equally prevalent in those with and without LV systolic dysfunction. Marcus and colleagues conducted a rigorous assessment of S_3 in 100 patients with various cardiovascular conditions undergoing elective cardiac catheterization (see online References). Cardiology fellows (n = 18; K statistic, 0.37; $P < 0.001$) and faculty (n = 26; K statistic, 0.29; $P = 0.003$) performed better than residents (n = 102; no significant agreement) in the identification of a phonocardiographically confirmed S_3. Furthermore, an S_3 predicted an increase in both LV end-diastolic pressure (LVEDP) (>15 mm Hg) and BNP (>100 pg/mL) and depressed ventricular systolic function (EF <0.50), although sensitivities were low (32% to 52%) (**Fig. 10.11**). An S_4 had comparable sensitivity (40% to 46%) but inferior specificity (72% to 80% for S_4 versus 87% to 92% for S_3) (**Table 10.8**). S_3 frequently may be heard in patients referred for cardiac transplant evaluation but is a poor predictor of elevated filling pressures.

Alternatively, the lack of an S_3 cannot exclude a diagnosis of HF, but its presence reliably indicates ventricular dysfunction.

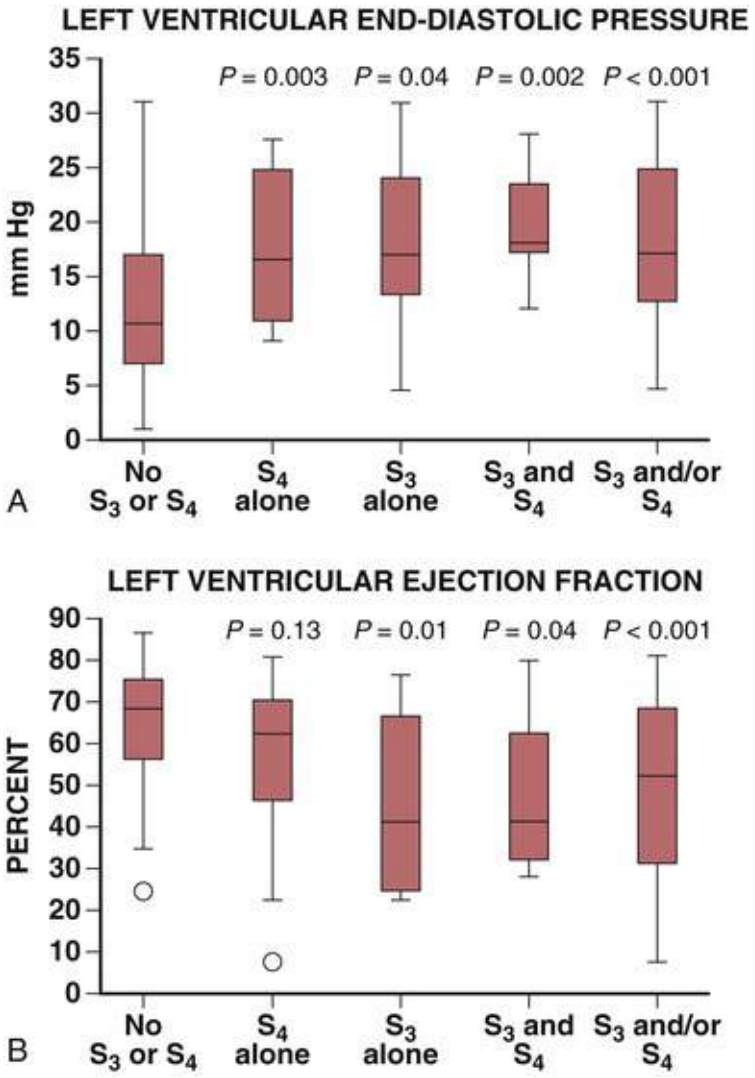

FIGURE 10.11 **A,** Median left ventricular end-diastolic pressure, and **B,** left ventricular ejection fraction, in patients in whom the phonocardiographic tracing demonstrated the presence of a third and/or fourth heart sound. Median and interquartile ranges, error bars, and outlier values (*circles*) are shown; *P* values are compared with data in the first column. (From Marcus GM, Gerber IL, McKeown BH, et al. Association between phonocardiographic third and fourth heart sounds and objective measures of left ventricular function. JAMA 2005;293:2238.)

Test Characteristics in Computerized Detection of Heart Sounds*

CHARACTERISTIC	LVEDP > 15 mm Hg (%)	LVEF < 50% (%)	BNP > 100 pg/mL (%)
Third Heart Sound (S_3)			
Sensitivity	41 (26-58)	52 (31-73)	32 (20-46)
Specificity	92 (80-98)	87 (76-94)	92 (78-98)
PPV	81 (58-95)	57 (34-78)	85 (62-97)
NPV	65 (53-76)	84 (73-92)	48 (36-60)
Accuracy	69 (58-78)	78 (68-86)	56 (45-67)
Fourth Heart Sound (S_4)			
Sensitivity	46 (31-63)	43 (23-66)	40 (26-54)
Specificity	80 (66-90)	72 (59-82)	78 (61-90)
PPV	66 (46-82)	34 (18-54)	72 (52-87)
NPV	64 (51-76)	79 (66-88)	47 (34-60)
Accuracy	64 (54-74)	64 (54-74)	55 (44-66)
S_3 and/or S_4			
Sensitivity	68 (52-82)	74 (52-90)	57 (42-70)
Specificity	73 (59-85)	64 (52-76)	72 (55-86)
PPV	68 (52-82)	42 (26-58)	75 (59-87)
NPV	73 (59-85)	88 (75-95)	53 (38-67)
Accuracy	71 (61-80)	67 (56-76)	63 (52-73)

*Data are presented as percentages (with 95% confidence interval).

LVEDP, Left ventricular end-diastolic pressure; *LVEF,* left ventricular ejection fraction; *BNP,* brain (B-type) natriuretic peptide; *PPV,* positive predictive value; *NPV,* negative predictive value.

Modified from Marcus GM, Gerber IL, McKeown BH, et al. Association between phonocardiographic third and fourth heart sounds and objective measures of left ventricular function. JAMA 2005;293:2238.

The prognostic value of an S_3 in chronic HF was established in the SOLVD treatment and prevention studies.[18] The investigators found that an S_3 predicted cardiovascular morbidity and mortality (**see Fig. 10.10**). The relative risk for HF hospitalization and death in patients with an S_3 was of comparable magnitude in the prevention and treatment cohorts. These observations remained significant after adjustment for markers of disease severity and were even more powerful when combined with presence of elevated JVP. An S_3 also predicts a higher risk of adverse outcomes in other settings, such as myocardial infarction (MI) or noncardiac surgery.

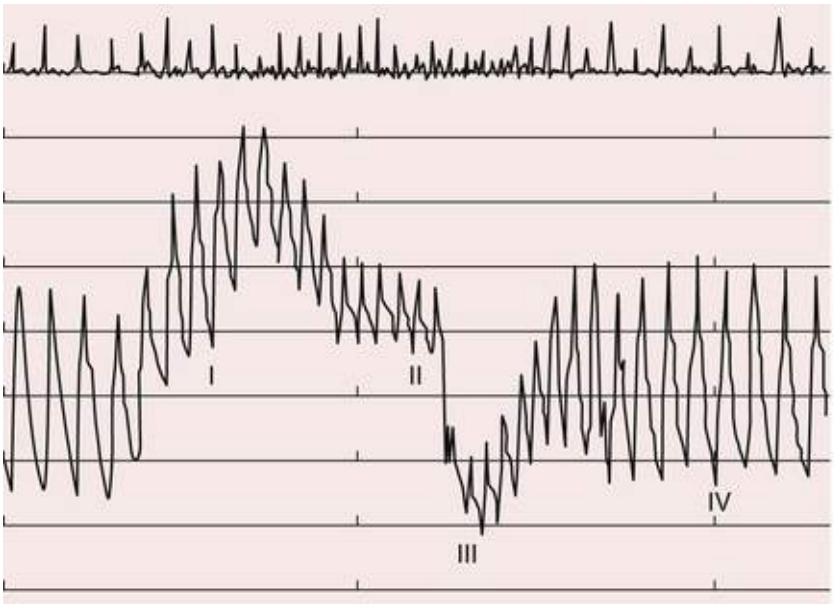
Rales and Edema

In patients with chronic HF, approximately 75% to 80% of participants lacked rales despite elevated PA wedge pressures, presumably because of enhanced lymphatic drainage. Recent studies have incorporated the findings from lung ultrasound (LR, 7.4; 95% CI, 4.2 to 12.8) in the assessment of ED patients with acute HF[21] and in ambulatory heart failure patients.[22] In the latter setting, lung ultrasound findings can identify patients with worse prognosis. When pulmonary adventitious sounds are present, specific characteristics may help elucidate a pulmonary rather than cardiac disorder (**see Fig. 10.2**). The chest radiograph similarly lacked sensitivity for increased filling pressures in these studies. Pedal edema is neither sensitive nor specific for the diagnosis of HF and has low predictive value as an isolated variable.

Valsalva Maneuver

The BP response to the Valsalva maneuver can be measured noninvasively using a BP cuff or commercially available devices. The Valsalva maneuver consists of four phases (**Fig. 10.12**). In a normal response, Korotkoff sounds are audible only during phases I and IV, because the systolic pressure

normally rises at the onset and release of the strain phase. Two abnormal responses to the Valsalva maneuver in HF are recognized: (1) absence of the phase IV overshoot and (2) the square-wave response (**Fig. 10.13**). The absent overshoot pattern indicates decreased systolic function; the square-wave response indicates elevated filling pressures and appears to be independent of EF. The responses can be quantified using the pulse amplitude ratio if the pulse pressure is measured during the maneuver. This ratio compares the minimum pulse pressure at the end of the strain phase against the maximum pulse pressure at the onset of the strain phase; a higher ratio is consistent with a square-wave response.



Phase I: Increase in systolic pressure with initial strain due to increase in intrathoracic pressure

Phase II: Decrease in stroke volume and pulse pressure and reflex tachycardia with continued strain due to decrease in venous return and increase in vascular resistance

Phase III: Brief, sudden decrease in systolic pressure due to sudden decrease in intrathoracic pressure

Phase IV: Overshoot of systolic pressure and reflex bradycardia due to increased venous return and decreased systemic vascular resistance

FIGURE 10.12 The normal Valsalva response. (From Nishimura RA, Tajik AJ. The Valsalva maneuver—3 centuries later. Mayo Clin Proc 2004;79:5774.)

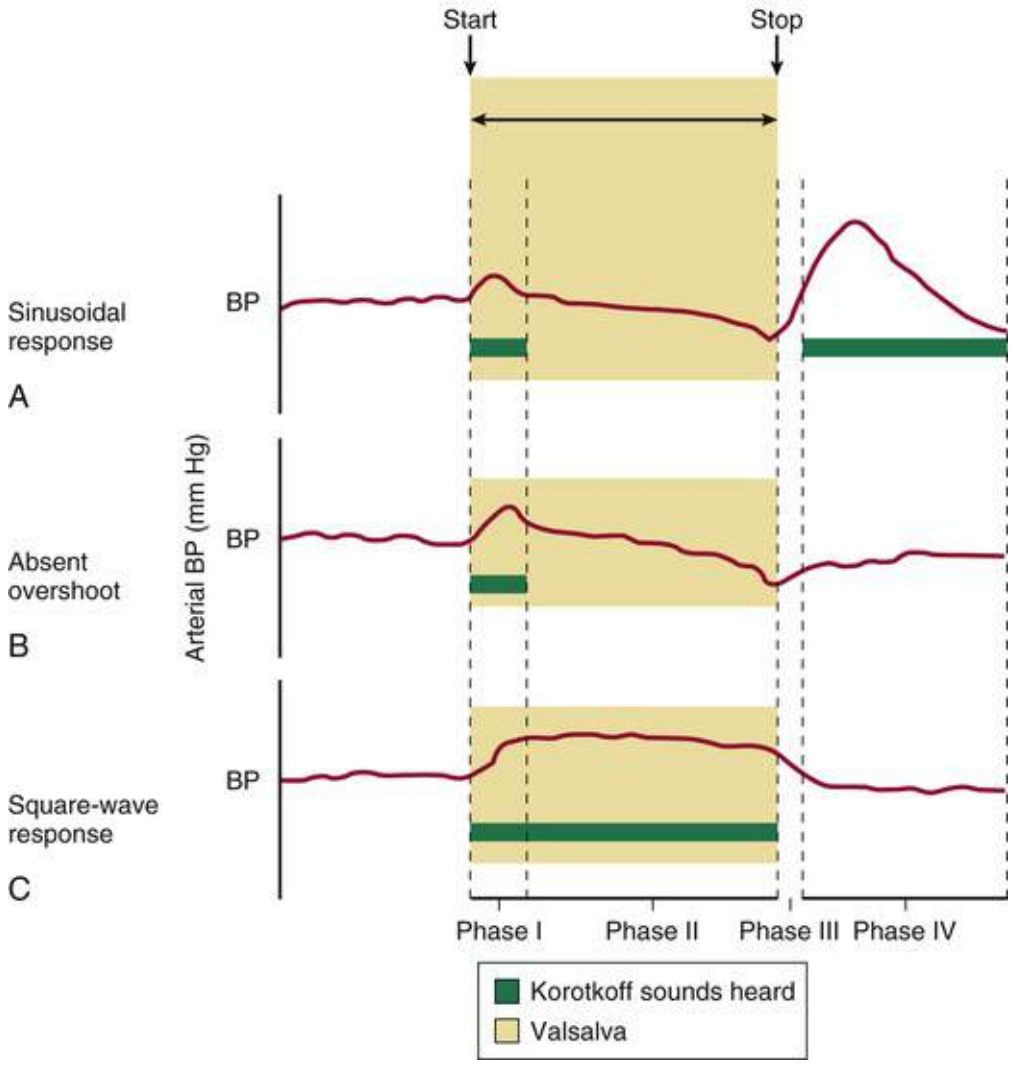


FIGURE 10.13 Abnormal Valsalva responses assessed using the pattern of Korotkoff sounds. **A,** Normal, sinusoidal response with sounds intermittent during strain and release. **B,** Briefly audible sounds during initial strain phase suggests only impaired systolic function in absence of fluid overload. **C,** Persistence of Korotkoff sounds throughout strain phase suggests elevated left ventricular filling pressures. *BP,* Blood pressure. (From Shamsham F, Mitchell J. Essentials of the diagnosis of heart failure. Am Fam Physician 2000;61:1319.)

Other Findings

In the absence of hypertension, the pulse pressure is determined by the stroke volume and vascular stiffness and can be used to assess cardiac output. In a cohort of patients with chronic systolic HF, the proportional pulse pressure ([systolic − diastolic]/systolic) correlated well with cardiac index (correlation coefficient [r] = 0.82; $P < 0.001$), stroke volume index ($r = 0.78$; $P < 0.001$), and the inverse of systemic vascular resistance ($r = 0.65$; $P < 0.001$). Using a proportional pulse pressure of 25%, the cardiac index could be predicted: if the value was lower than 25%, the cardiac index was less than 2.2 L/min/m^2 in 91% of patients; if the value was higher than 25%, the cardiac index was greater than 2.2 L/min/m^2 in 83% of patients.[23] Circulation time has also been used to assess the cardiac output. Using oxygen as the indicator, a time from a breath-hold to the nadir of finger oximetry of greater than 34 seconds has been associated with a cardiac output of less than 4 L/min.[24]

Heart rate is also a powerful indicator of prognosis in HF. A resting heart rate (in sinus rhythm) greater than 70 to 75 beats/min is an independent predictor of mortality. When the heart rate is decreased by ivabradine on a background of beta-blocker therapy, HF hospitalizations are decreased.[25] An attenuated heart rate increase with immediate standing (e.g., ≤3 beats/min) may also reflect the dysautonomia of HF

and has been associated with death or HF hospitalization. A greater increase of heart rate with standing over time is associated with longer HF hospitalization–free survival.[26]

Clinical experience may be the most helpful in assessing hemodynamic status. A good assessment for systemic perfusion and cardiac index appears to be overall clinical impression, the "cold" profile (**see Fig. 21.3**). The gestalt of specialized HF clinicians performed better than proportional pulse pressure, systolic blood pressure, cool extremities, or fatigue in predicting an invasively measured cardiac index lower than 2.3 L/min/m^2.[18] This prediction rule has not been reported in other patient groups, in larger cohorts, or in more contemporary studies. Pleural effusions also are common in patients with HF, in whom effusions typically are right sided, as noted previously. Dullness to percussion is the simplest finding to elicit in identifying a pleural effusion and is superior (LR, 8.7; 95% CI, 2.2 to 33.8) to auscultatory percussion, decreased breath sounds, asymmetric chest expansion, increased vocal resonance, crackles, or pleural friction rubs. By contrast, absence of reduced tactile vocal fremitus makes a pleural effusion less likely (negative LR, 0.21; 95% CI, 0.12 to 0.37).

Valvular Heart Disease (see also Part VIII)

A careful history and physical examination can reveal much regarding lesion severity, natural history, indications for intervention, and outcomes in patients with valvular heart disease. The history in patients with known or suspected valvular heart disease should rely on the use of a functional classification scheme and assessment of patient frailty when appropriate (**see Table 10.3**). Onset of even mild functional limitation is generally an indication for mechanical correction of the responsible valve lesion. Valvular heart disease most often is first suspected because of a heart murmur, but many patients go undetected until presentation with symptoms.[27,28] Cardiologists can detect systolic heart murmurs with fair reliability (interobserver kappa coefficient, 0.30 to 0.48) and usually can confirm or rule out aortic stenosis, HOCM, MR, MVP, TR, and functional murmurs. The use of handheld ultrasound devices may improve detection and accuracy rates.[29]

Mitral Stenosis

In patients with mitral stenosis, survival declines after symptom onset and worsens with increasing degrees of functional limitation (NYHA class) and as PA hypertension increases. Findings on physical examination vary with the chronicity of the disease, heart rate, rhythm, and cardiac output. It can be difficult to estimate the severity of the valve lesion in older patients with less pliable valves, rapid AF, or low cardiac output. Severe mitral stenosis is suggested by (1) a long or holodiastolic murmur, indicating a persistent LA-LV gradient; (2) a short A_2-OS interval, consistent with higher LA pressure; (3) a loud P_2 (or single S_2) and/or an RV lift, suggestive of pulmonary hypertension; and (4) elevated JVP with *cv* waves, hepatomegaly, and lower extremity edema—all signs of right heart failure. Neither the intensity of the diastolic murmur nor the presence of presystolic accentuation in patients with sinus rhythm accurately reflects lesion severity.

Mitral Regurgitation

The symptoms associated with MR depend on its severity and time course of development. Acute severe MR that occurs with papillary muscle rupture or infective endocarditis usually results in sudden and profound dyspnea from pulmonary edema. Examination findings may be misleading because the LV impulse usually is neither enlarged nor displaced, and the systolic murmur is early in timing and

decrescendo in configuration (**see Fig. 10.9**). The murmur also may be louder at the lower left sternal border or in the axilla than at the apex. A new systolic murmur developing early after an MI may not be audible in a ventilated or obese patient.

Several findings suggest chronic severe MR: (1) an enlarged, displaced, but dynamic LV apex beat; (2) an apical systolic thrill (murmur intensity of grade 4 or greater); (3) a mid-diastolic filling complex comprising an S_3 and a short, low-pitched murmur, indicative of accelerated and enhanced diastolic mitral inflow; (4) wide but physiologic splitting of S_2 caused by early aortic valve closure; and (5) a loud P_2 or RV lift. The findings in patients with MVP can vary, depending on LV loading conditions. The combination of a nonejection click and mid- to late systolic murmur predicts MVP best, as confirmed by transesophageal echocardiography (TTE) criteria (LR, 2.43). Dynamic auscultation should be performed.

Aortic Stenosis

A slowly rising carotid upstroke *(pulsus tardus),* reduced carotid pulse amplitude *(pulsus parvus),* reduced intensity of A_2, and mid- to late peaking of the systolic murmur help gauge the severity of aortic stenosis. The intensity of the murmur depends on cardiac output and body size (peak momentum transfer) and does not reliably reflect stenosis severity. In a 35-year follow-up study of 2014 apparently healthy middle-aged Norwegian men, the presence of even a low-grade systolic murmur was associated with an almost fivefold increased age-adjusted risk for aortic valve replacement.[30]

No single physical examination finding has both high sensitivity and high specificity for the diagnosis of severe aortic stenosis, and only a reduced carotid upstroke amplitude may independently predict outcome. Clinical experience has established the difficulty of assessing carotid upstroke characteristics in older patients, in patients with hypertension, and in low-output states. Distinguishing the murmur of hemodynamically significant aortic stenosis from that caused by lesser degrees of stenosis is also challenging. Even with aortic sclerosis, the murmur can be of grade 2 or 3 intensity, although it peaks in midsystole. The carotid upstroke should be normal, A_2 should be preserved, and the ECG should lack evidence of LV hypertrophy. Nevertheless, TTE often is necessary to clarify this distinction, especially in older patients with hypertension. Signal analysis of digitally captured cardiovascular sounds using spectral display can distinguish the murmur of aortic sclerosis from a murmur resulting from hemodynamically significant aortic stenosis.

The differential diagnosis of a systolic murmur related to LV outflow obstruction includes valvular aortic stenosis, HOCM, discrete membranous subaortic stenosis (DMSS), and supravalvular aortic stenosis (SVAS). The presence of an ejection sound indicates a valvular cause. HOCM can be distinguished on the basis of the response of the murmur to the Valsalva maneuver and standing or squatting. Patients with DMSS will usually have a diastolic murmur indicative of AR but not an ejection sound, whereas in patients with SVAS, the right arm BP is more than 10 mm Hg greater than the left arm BP. The increasing use of transcatheter aortic valve replacement (TAVR) for the treatment of prohibitive–, high–, or intermediate–surgical risk patients with symptomatic severe AS, many of whom are elderly, has obligated multidisciplinary heart teams to assess frailty status (**see Table 10.3**).

Aortic Regurgitation

Patients with acute severe AR present with pulmonary edema and symptoms and signs of low forward cardiac output. Tachycardia is invariably present, systolic BP is not elevated, and the pulse pressure is not significantly widened. S_1 is soft because of premature closure of the mitral valve. The intensity and

duration of the diastolic murmur are attenuated by the rapid rise in LV diastolic pressure and diminution of the aortic-LV diastolic pressure gradient. In patients with acute type A aortic dissection, the presence of a diastolic murmur (present in almost 30% of cases) does little to change the pretest probability of dissection. Acute severe AR is poorly tolerated and mandates emergency surgery. Typical symptoms associated with chronic, severe AR include dyspnea, fatigue, chest discomfort, and palpitations. A decrescendo diastolic blowing murmur suggests chronic AR. A midsystolic murmur indicative of augmented LV outflow is invariably heard at the base. Aortic stenosis may coexist. The absence of a diastolic murmur significantly reduces the likelihood of moderate or greater AR (LR, 0.1), whereas the presence of a typical diastolic murmur increases the likelihood of moderate or greater AR (LR, 4.0 to 8.3). In addition, in patients with chronic AR, the intensity of the murmur correlates with the severity of the lesion. A grade 3 diastolic murmur has an LR of 4.5 (95% CI, 1.6 to 14.0) for distinguishing severe AR from mild or moderate AR. Data conflict regarding the significance of an Austin Flint murmur. Little evidence supports the historical claims of the importance of almost all the eponymous peripheral signs of chronic AR, which number at least 12. The *Hill sign* (brachial-popliteal systolic BP gradient >20 mm Hg) may be the single exception (sensitivity of 89% for moderate to severe AR), although its supporting evidence base also is weak.

Tricuspid Valve Disease

Left-sided valve lesions often obscure the symptoms and signs of tricuspid stenosis. An elevated JVP together with a delayed *y* descent, abdominal ascites, and edema suggests severe tricuspid stenosis. Auscultatory findings are difficult to appreciate but mimic those in mitral stenosis and may worsen during inspiration. The symptoms of TR resemble those of tricuspid stenosis. Severe TR causes elevated JVP with prominent *cv* waves, a parasternal lift, pulsatile liver, ascites, and edema. The intensity of the holosystolic murmur of TR increases with inspiration (*Carvallo sign*). Murmur intensity does not accurately reflect the severity of the valve lesion. Primary and secondary causes of TR should be distinguished.

Pulmonic Valve Disease

Pulmonic stenosis may cause exertional fatigue, dyspnea, lightheadedness, and chest discomfort (“right ventricular angina”). Syncope denotes severe obstruction. The midsystolic murmur of pulmonic stenosis is best heard at the second left interspace. With severe pulmonic stenosis, the interval between S_1 and the pulmonic ejection sound narrows, and the murmur peaks in late systole and may extend beyond A_2. P_2 becomes inaudible. Signs of significant RV pressure overload include a prominent jugular venous *a* wave and a parasternal lift. Pulmonic regurgitation (PR) occurs most often as a secondary manifestation of significant PA hypertension and annular dilation, but it may also reflect a primary valve disorder (e.g., congenital bicuspid valve) or develop as a complication of RV outflow tract surgery, in which case characteristics of the murmur and Doppler echocardiographic signs differ. Symptoms vary as a function of the severity of PA hypertension and the level of RV compensation. The diastolic murmur of secondary PR (Graham Steell) can be distinguished from that caused by AR on the basis of its increase in intensity with inspiration, its later onset (after A_2 and with P_2), and its slightly lower pitch. When a typical murmur is audible, the likelihood of PR increases (LR, 17), but the absence of a murmur does not exclude PR (LR, 0.9). With severe PA hypertension and PR, P_2 is usually palpable and there are signs of RV pressure and volume overload on examination.

Prosthetic Heart Valves

The differential diagnosis of functional limitation after valve replacement surgery includes prosthetic valve dysfunction, arrhythmia, and impaired ventricular function. Prosthetic valve dysfunction can result from thrombosis, pannus ingrowth, infection, or structural deterioration. Symptoms and signs mimic those of native valve disease and may arise acutely or develop gradually. The first clue suggesting prosthetic valve dysfunction often is a *change* in the quality of the heart sounds or the appearance of a new murmur.

The heart sounds with a bioprosthetic valve resemble those generated by native valves. A bioprosthesis in the *mitral* position usually is associated with a midsystolic murmur (from turbulence created by systolic flow across valve struts that project into LV outflow tract) and a soft, mid-diastolic murmur that occurs with normal LV filling. The diastolic murmur usually is heard only in the left lateral decubitus position at the apex. A high-pitched or holosystolic apical murmur signifies para- or transvalvular regurgitation that requires echocardiographic verification and careful follow-up evaluation. Depending on the magnitude of the regurgitant volume, a diastolic murmur may be audible. Clinical deterioration can occur rapidly after initial manifestation of bioprosthetic failure.

A bioprosthesis in the *aortic* position is invariably associated with a midsystolic murmur at the base of grade 3 or less intensity. A diastolic murmur of AR is abnormal under any circumstance and merits additional investigation. A decrease in the intensity of either the opening or the closing sounds of a mechanical prosthesis, depending on its type, is a worrisome finding. A high-pitched apical systolic murmur in patients with a mechanical mitral prosthesis, or a decrescendo diastolic murmur in patients with a mechanical aortic prosthesis, indicates paravalvular regurgitation or prosthetic dysfunction. Signs of hemolysis should be sought. Patients with prosthetic valve thrombosis may present with signs of shock, muffled heart sounds, and soft murmurs. Pannus ingrowth is usually associated with an increase in the intensity of a systolic murmur and other signs indicative of prosthetic valve stenosis.

Acute Coronary Syndrome

Risk stratification of patients with ACS informs decision making regarding the intensity and pace of management and is recommended by international guidelines.[31-33] Clinical findings indicative of high risk of short-term death or MI in patients with non–ST-segment elevation ACS include older than age 75, tachycardia, hypotension, signs of pulmonary congestion, and a new or worsening murmur of MR (**see Chapters 56, 58, and 60**).

Pericardial Disease (see Chapter 83)

Pericarditis

The typical pain of acute pericarditis starts abruptly, is sharp, and varies with position. It can radiate to the trapezius ridge. Associated fever or history of a recent viral illness may provide additional clues. A pericardial friction rub is almost 100% specific for the diagnosis, although its sensitivity is not as high, because the rub may wax and wane over the course of an acute illness or may be difficult to elicit. This leathery or scratchy, typically two- or three-component sound also may be monophasic. It usually is necessary to auscultate the heart with the patient in several positions. The ECG may provide additional clues related to concave upward ST-segment elevation and P-R–segment deviation (elevation in lead aVR, depression in lead II). A transthoracic ECG is routinely obtained to assess the volume and appearance of any effusion and to look for early signs of hemodynamic compromise.

Pericardial Tamponade

Pericardial tamponade occurs when intrapericardial pressure equals or exceeds RA pressure. The time course of its development depends on the volume of the effusion, the rate at which it accumulates, and pericardial compliance. The most common associated symptom is dyspnea (sensitivity, 87% to 88%). Hypotension (sensitivity, 26%) and muffled heart sounds (sensitivity, 28%) are relatively insensitive indicators of tamponade. A pulsus paradoxus greater than 12 mm Hg in a patient with a large pericardial effusion predicts tamponade with sensitivity of 98%, specificity of 83%, and positive LR of 5.9 (95% CI, 2.4 to 14). Echocardiography is indicated in all patients with suspected pericardial tamponade.

Constrictive Pericarditis

Constrictive pericarditis is an uncommon clinical entity that occurs with previous chest irradiation, cardiac or mediastinal surgery, chronic tuberculosis, or malignancy. Dyspnea, fatigue, weight gain, abdominal bloating, and leg swelling dominate the clinical presentation. The diagnosis most often is first suspected after inspection of the JVP and waveforms, with elevation and inscription of the classic M or W contour caused by prominent *x* and *y* descents and a Kussmaul sign. Evidence of pleural effusions and ascites often can be found. On rare occasion, a PK is audible. Distinction from restrictive cardiomyopathy often is not possible on the basis of the history and physical examination alone.

Future Perspectives

The history and physical examination play an invaluable role in the initial assessment of the patient with known or suspected cardiovascular disease. Concerns regarding the escalating costs of medical care may reinforce the value of these time-honored traditions to guide appropriate use of imaging and invasive diagnostic modalities. Patients' perceptions of the quality of the care they receive may be influenced by the interactions associated with the performance of the history and examination. These considerations should spur additional efforts to establish the accuracy and predictive value of bedside findings across a spectrum of cardiovascular disorders. Recognition of the need to reestablish the mentored patient evaluation as a dedicated component of training programs, along with mechanisms to allow practice, repetition, and feedback, is essential. Improved teaching methods using simulation-based training aids are effective.[5] Electronic and digital stethoscopes may allow for computer automation and spectral display not only to enhance learning but also to improve the accuracy of diagnosis, while maintaining the physical link between the patient and provider.[6,34,35] The addition of handheld ultrasound may also improve learner performance, but whether it should replace the stethoscope controversial.[3,36-39] Continued improvements in the technical performance characteristics and declining costs of these devices are attractive features, as is the possibility of initiating treatment at the point of care without the need for additional testing in many patients.[39,40] Handheld ultrasound is a useful adjunct to screen for the presence of rheumatic heart disease in vulnerable populations and should be used routinely when available.[41]

Acknowledgments

The authors wish to acknowledge the previous contributions of Drs. Eugene Braunwald, Joseph Perloff, Robert O'Rourke, and James A. Shaver, which laid the foundation for this chapter.

Anesthesia and Noncardiac Surgery in Patients with Heart Disease

Lee A. Fleisher, Joshua A. Beckman

Cardiovascular morbidity and mortality represent a special concern in patients with known (or with risk factors for) cardiovascular disease who undergo noncardiac surgery. The cost of perioperative myocardial injury adds substantially to the total health care expenditure, with an average increased length of stay of 6.8 days for patients with perioperative myocardial ischemic injury. Perioperative cardiovascular complications not only affect the immediate period but may also the influence outcome over subsequent years. The evidence base for managing patients with cardiovascular disease in the context of noncardiac surgery has grown in recent decades, beginning with identification of those at greatest risk and progressing to randomized trials to identify strategies for reducing perioperative cardiovascular complications. Guidelines provide information for the management of high-risk patients and disseminate best practices. Indeed, over the last decade, mortality rates for all major surgeries have decreased in parallel with implementation of these practices. This chapter distills this information by incorporating guidelines available from the American College of Cardiology and American Heart Association (ACC/AHA) and the European Society of Cardiology (ESC).[1,2] The ACCF/AHA guideline was updated in 2014, with a focused update on dual-antiplatelet therapy in 2016. (An update on this guideline is available online at ExpertConsult.)

Additionally, controversy surrounds research conducted at Erasmus University by Don Poldermans, the DECREASE (Dutch Echocardiographic Cardiac Risk Evaluation Applying Stress Echocardiography) studies, in which an investigative committee found serious shortcomings in the procedure used to record patient consent, submission of publications based on unreliable data, and scientifically inaccurate data collection. Since none of his perioperative papers was withdrawn, the committee chose to include the published papers in the discussion, but studies by Poldermans were not used to make formal recommendations.

Assessment of Risk

Numerous points of entry lead to evaluation of patients before they undergo noncardiac surgery. Primary physicians or cardiologists may examine such patients. History and physical examination represent the cornerstone of surgical risk evaluation, but risk assessment testing is rarely performed unless it changes management. Many patients undergo evaluation only immediately before surgery by the surgeon or anesthesiologist. Importantly, several cardiovascular conditions require assessment independent of the time before surgery.

Ischemic Heart Disease

The stress related to noncardiac surgery increases metabolic requirements and activates the sympathetic nervous system and may raise the heart rate preoperatively, which is associated with a high incidence of symptomatic and asymptomatic myocardial ischemia. Preoperative clinical evaluation of patients may

therefore identify stable or unstable coronary artery disease (CAD). Patients with acute manifestations of CAD such as unstable angina or decompensated heart failure have a high risk for the development of further decompensation or myocardial infarction (MI) and death during the perioperative period. Such patients clearly warrant further evaluation and medical stabilization. If the noncardiac surgery is truly an emergency, several older case series have shown that intra-aortic balloon pump counterpulsation can provide short-term myocardial protection beyond that afforded by maximal medical therapy, although this measure is seldom used today.

If the patient is not clinically unstable, identification of known or symptomatic stable CAD or risk factors for CAD can foster the implementation of guideline-based risk reduction therapies. In determining the extent of preoperative evaluation, it is important not to perform testing unless the results will affect perioperative management. In addition, the use of medications or interventions should mirror those that would be implemented in the absence of surgery. Infrequently, these changes in management may include cancellation of surgery (if the risk-benefit ratio is prohibitive) and consideration of palliative therapy, delay of surgery for further medical management, coronary interventions before surgery, use of an intensive care unit (ICU), and changes in monitoring. As discussed later, few evidence-based therapies are available independent of treating the underlying atherosclerotic risk, and except in the case of left main coronary artery stenosis, current data challenge the benefit of preoperative coronary revascularization. Thus, the primary reason to perform risk assessment is to determine clinical cardiovascular instability.

Over the last two decades, there has been a secular decrease in the rates of perioperative type 1 MI and mortality. Finks and colleagues[3] reported a 36% decrease in death after open abdominal aortic aneurysm repair from 2000 to 2008, to a risk-adjusted mortality of 2.8%. More recent data substantiate a decreasing frequency of type 1 and increasing rate of type 2 MI, indicating a predominance of subendocardial ischemic events resulting from hemodynamic challenge.[4] Although these events, characterized by increases in troponin, are strongly associated with death, the interval between troponin elevation and adverse events and the higher rate of nonvascular than cardiovascular mortality suggest that this is a marker of illness rather than a mechanism of mortality.

Traditionally, assessment of the coronary risk associated with noncardiac surgery in patients with previous MI was based on the time between the MI and surgery. Multiple studies have demonstrated an increased incidence of reinfarction after noncardiac surgery if the previous MI had occurred within 6 months of the operation. Improvements in MI management and perioperative care have shortened this interval. Although in some patients after a recent MI the myocardium may still be at risk for subsequent ischemia and infarction, most patients in the United States will have had critical coronary stenoses identified and revascularized when appropriate and should receive maximal medical therapy. The AHA/ACC Task Force on Perioperative Evaluation of the Cardiac Patient Undergoing Noncardiac Surgery has suggested that the highest-risk patients are those within 30 days of MI, during which time plaque and myocardial healing occur. After this period, risk stratification is based on the features of the disease (i.e., those with active ischemia are at highest risk). However, a study using administrative data from California demonstrated that the rate of perioperative cardiac morbidity and mortality remained elevated for at least 60 days after an MI, and the current iteration of the guidelines supports such a time frame.[5]

Hypertension

In the 1970s a series of case studies changed the prevailing thought that the use of antihypertensive agents

should be discontinued before surgery. The reports suggested that poorly controlled hypertension was associated with untoward hemodynamic responses and that antihypertensives should be continued perioperatively. However, several large prospective studies were unable to establish mild to moderate hypertension as an independent predictor of postoperative cardiac complications such as cardiac death, postoperative MI, heart failure, or arrhythmias. The approach to patients with hypertension therefore relies mostly on management strategies from the nonsurgical literature.

Blood pressure (BP) excursions in the operative and postoperative period portend worsening outcome. A hypertensive crisis in the postoperative period—defined as diastolic BP higher than 120 mm Hg and clinical evidence of impending or actual end-organ damage—poses a definite risk for MI and cerebrovascular accident (CVA, stroke). Iatrogenic precipitants of hypertensive crises include abrupt withdrawal of clonidine or beta-blocker therapy before surgery, chronic use of monoamine oxidase inhibitors with or without sympathomimetic drugs, and inadvertent discontinuation of antihypertensive therapy. Similarly, intraoperative hypotension is associated with both type 2 MI and increases in postoperative mortality.[6]

Although postulated to predict an increased rate of myocardial ischemia, none of the recent large clinical trials has shown that chronic hypertension predisposes patients to perioperative cardiovascular events.[4] This finding likely reflects the excellent perioperative management of hypertension in the current era. The pharmacologic management of patients with hypertension should be continued perioperatively, and BP should be maintained near preoperative levels to reduce the risk for myocardial ischemia. In patients with more severe hypertension, such as a diastolic BP higher than 110 mm Hg, little evidence suggests a benefit of delaying surgery to optimize antihypertensive medications in the absence of a hypertensive urgency or emergency. Currently, debate surrounds the optimal decision on withholding angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) on the day of surgery. Studies support both continuation and withholding, although continuation may require treatment with vasopressin for intractable hypotension. It is important to restart these agents as soon as possible postoperatively.

Heart Failure

Heart failure (HF) is associated with perioperative cardiac morbidity after noncardiac surgery in virtually all studies. Since the early work of Goldman and colleagues, who identified signs of HF as a significant risk of adverse events perioperatively, HF has become a more common problem with more varied presentations, including the presence or absence of ischemia and of reduced left ventricular ejection fraction. The underlying causes in patients with signs or symptoms of HF who are scheduled for noncardiac surgery require characterization. HF may eclipse CAD as a cause of postoperative adverse events. The 30-day postoperative mortality rate was significantly higher in patients with both nonischemic (9.3%) and ischemic (9.2%) HF compared to those with CAD (2.9%) in a population-based data analysis of 38,047 consecutive patients.[7]

The preoperative evaluation should aim to identify the underlying coronary, myocardial, and valvular heart disease and assess the severity of the systolic and diastolic dysfunction. Hammill and associates used Medicare claims data to evaluate short-term outcomes in patients with HF, CAD, or neither who underwent major noncardiac surgery. Elderly patients with HF who underwent major surgical procedures had substantially higher risk for operative mortality and hospital readmission than other patients, including those with CAD, admitted for the same procedures. In the absence of a surgical emergency, patients with decompensated HF should be treated to achieve a euvolemic, stable state before operation.

Ischemic cardiomyopathy is of greatest concern because the patient has substantial risk for the development of further ischemia, which can lead to myocardial necrosis and potentially a downward spiral.

Treatment of decompensated hypertrophic cardiomyopathy differs from that of dilated cardiomyopathy, and thus the preoperative evaluation can influence perioperative management. In particular, this assessment may influence perioperative fluid and vasopressor management. Obstructive hypertrophic cardiomyopathy was formerly regarded as a high-risk condition associated with high perioperative morbidity. A retrospective review of perioperative care in 35 patients, however, suggested low risk related to general anesthesia and major noncardiac surgery in such patients. This study also suggested that spinal anesthesia was a relative contraindication in view of the sensitivity of cardiac output to preload in this condition. Haering and colleagues studied 77 patients with asymmetric septal hypertrophy identified retrospectively from a large database; 40% had one or more adverse perioperative cardiac events, including one patient with MI and ventricular tachycardia who required emergency cardioversion. Most of the events consisted of perioperative congestive heart failure, and no perioperative deaths occurred. Unlike the finding in the original cohort of patients, the type of anesthesia was not an independent risk factor. Important independent risk factors for an adverse outcome (as seen generally) included major surgery and increasing duration of surgery.

Valvular Heart Disease (see also Part VIII)

Aortic stenosis places patients at increased risk. Critical stenosis is associated with the highest risk for cardiac decompensation in patients undergoing elective noncardiac surgery. Thus, the presence of any of the classic triad of angina, syncope, and HF in a patient with aortic stenosis should prompt further evaluation and potential interventions (usually valve replacement). Preoperative patients with aortic systolic murmurs warrant a careful history and physical examination—and often further evaluation. Several recent case series of patients with critical aortic stenosis have demonstrated that when necessary, noncardiac surgery can be performed with acceptable risk. In a matched-sample study using the Danish Health Care System, Andersson and colleagues demonstrated that patients with asymptomatic aortic stenosis did not experience a higher rate of major adverse cardiovascular events (MACE) or mortality in elective surgery. Emergency surgery type and symptomatic aortic stenosis increased both MACE and mortality. Aortic valvuloplasty is a bridging option for some patients who cannot undergo valve replacement or percutaneous intervention in the short term. The substantial risk for procedure-related morbidity and mortality and little evidence to demonstrate a perioperative risk reduction mandate careful consideration before recommending this strategy.

Mitral valve disease is associated with a lower risk for perioperative complications than aortic stenosis, although occult rheumatic mitral stenosis can sometimes lead to severe left-sided heart failure in patients with tachycardia (e.g., uncontrolled atrial fibrillation) and volume loading. In contrast to aortic valvuloplasty, mitral valve balloon valvuloplasty often yields both short- and long-term benefit, especially in younger patients with predominantly mitral stenosis but without severe mitral valve leaflet thickening or significant subvalvular fibrosis and calcification.

In perioperative patients with a functioning prosthetic heart valve, antibiotic prophylaxis and anticoagulation are major issues. All patients with prosthetic valves who undergo procedures that can cause transient bacteremia should receive prophylaxis. In patients with prosthetic valves, the risk for increased bleeding during a procedure while receiving antithrombotic therapy must be weighed against the increased risk for thromboembolism caused by stopping the therapy. Common practice in patients undergoing noncardiac surgery with a mechanical prosthetic valve in place is cessation of warfarin 3 days before surgery. This allows the international normalized ratio (INR) to fall to less than 1.5 times normal; oral anticoagulants can then be resumed on postoperative day 1. An alternative approach in patients at high risk for thromboembolism is conversion to heparin during the perioperative period, which can then be discontinued 4 to 6 hours before surgery and resumed shortly thereafter. A multicenter, single-arm cohort study of 224 high-risk patients (prosthetic valves, atrial fibrillation, and a major risk factor) investigated the use of low-molecular-weight heparin (LMWH) as a preoperative bridge to warfarin anticoagulation in which warfarin was withheld for 5 days and LMWH was given 3 days preoperatively and at least 4 days postoperatively. The overall rate of thromboembolism was 3.6% and of cardioembolism, 0.9%. Major bleeding was seen in 6.7% of patients, although only 8 of 15 episodes occurred during the administration of LMWH. LMWH is cost-effective because it helps reduce the duration of the hospital stay, but two studies have shown a residual anticoagulation effect in as many as two thirds of patients.

Many current prosthetic valves have a lower risk for valve thrombosis than the older designs, so the risk associated with heparin may outweigh its benefit in the perioperative setting. According to the AHA/ACC guidelines, heparin can usually be reserved for high-risk patients. *High risk* is defined by the presence of a mechanical mitral or tricuspid valve or a mechanical aortic valve and by certain risk factors, including atrial fibrillation, previous thromboembolism, hypercoagulable condition, older-

generation mechanical valves, an ejection fraction lower than 30%, or more than one mechanical valve. Subcutaneous LMWH or unfractionated heparin offers an alternative outpatient approach but has received only a tentative recommendation. Discussion between the surgeon and cardiologist regarding optimal perioperative management is critical. The ACC/AHA guidelines on valvular heart disease are being revised, and newer data questioning the value of bridge therapy in the atrial fibrillation setting are being incorporated into the recommendations.[8]

Congenital Heart Disease in Adults (see also Chapter 75)

Congenital heart disease afflicts 500,000 to 1 million adults in the United States. The nature of both the underlying anatomy and any anatomic correction affects the perioperative plan and incidence of complications, which include infection, bleeding, hypoxemia, hypotension, and paradoxical embolization. In a study using the National Surgical Quality Improvement Program (NSQIP) database, prior cardiac surgery in a population age 19 to 39 years significantly increased the risk of death, MI, stroke, reoperation, and length of stay.[9] Pulmonary hypertension and Eisenmenger syndrome present a major concern in patients with congenital heart disease. Regional anesthesia has traditionally been avoided in these patients because of the potential for sympathetic blockade and worsening of the right-to-left shunt. However, a review of 103 cases found that overall perioperative mortality was 14%; patients receiving regional anesthesia had a mortality of 5%, whereas those receiving general anesthesia had a mortality of 18%. The authors concluded that most deaths probably resulted from the surgical procedure and the disease rather than from anesthesia. Although perioperative and peripartum mortality was high, many anesthetic agents and techniques have been used with success. Patients with congenital heart disease are at risk for infective endocarditis and should receive antibiotic prophylaxis.

Arrhythmias (see Part V)

Cardiac arrhythmias frequently occur in the perioperative period, particularly in older adults or patients undergoing thoracic surgery. Predisposing factors include previous arrhythmias, underlying heart disease, hypertension, perioperative pain (e.g., hip fractures), severe anxiety, and other situations that heighten adrenergic tone. In a prospective study of 4181 patients 50 years or older, supraventricular arrhythmia occurred in 2% during surgery and in 6.1% after surgery. Perioperative atrial fibrillation (AF) raises several concerns, including the incidence of stroke (**see Chapters 38 and 65**). Winkel and colleagues evaluated 317 patients without AF who were undergoing major vascular surgery to determine the incidence of new-onset AF and its association with adverse cardiovascular outcomes. They reported an incidence of 4.7% and more than a sixfold increase in cardiovascular death, MI, unstable angina, and stroke in the first 30 days and a fourfold increase over the next 12 months. Early treatment to restore sinus rhythm or control the ventricular response and initiate anticoagulation is therefore indicated. Prophylactic use of intravenous (IV) diltiazem in randomized, placebo-controlled trials of patients undergoing high-risk thoracic surgery reduced the incidence of clinically significant atrial arrhythmias. Balser and colleagues studied 64 cases of postoperative supraventricular tachyarrhythmia. After the administration of adenosine, patients who remained in supraventricular tachyarrhythmia were prospectively randomly assigned to receive either IV diltiazem or IV esmolol for control of the ventricular rate; esmolol produced a more rapid (2-hour) conversion to sinus rhythm than diltiazem.

Although older studies identified ventricular arrhythmias as a risk factor for perioperative morbidity, recent studies have not confirmed this finding. O'Kelly, as cited in the guidelines, studied a consecutive sample of 230 male patients with known CAD or at high risk for CAD who underwent major noncardiac surgical procedures. Preoperative arrhythmias were associated with intraoperative and postoperative arrhythmias, but nonfatal MI and cardiac death were not substantially more common in those with previous perioperative arrhythmias. Recent data suggest otherwise. In a population-based study from Alberta, Canada, the risk of mortality at 30 days was 6.4% in patients with AF preoperatively compared with 2.9% for patients with CAD.[7] Despite this finding, a preoperative arrhythmia should provoke a search for underlying cardiopulmonary disease, ongoing myocardial ischemia or infarction, drug toxicity, or electrolyte or metabolic derangements.

Conduction abnormalities can increase perioperative risk and may require placement of a temporary or permanent pacemaker. On the other hand, patients with intraventricular conduction delays, even in the presence of a left or right bundle branch block but without a history of advanced heart block or symptoms, rarely progress to complete heart block perioperatively. The availability of transthoracic pacing units has decreased the need for temporary transvenous pacemakers.

The Decision to Undergo Diagnostic Testing

The ACC/AHA and ESC proposed algorithms for CAD evaluation based on the available evidence and incorporated the class of recommendations and level of evidence into each step (**Figs. 11.1 and 11.2**). Current algorithms use a stepwise bayesian strategy that relies on assessment of clinical markers, previous coronary evaluation and treatment, functional capacity, and surgery-specific risk, Successful use of the ACC/AHA algorithm requires an appreciation of the different levels of risk attributable to the combination of clinical circumstances and type of surgery, levels of functional capacity, and how the information from any diagnostic testing will influence perioperative management.

Multiple studies have attempted to identify clinical risk markers for perioperative cardiovascular morbidity and mortality. As described earlier, patients with unstable coronary syndromes and severe valvular disease have active cardiac conditions. Risk can be divided into low (<1%) and elevated clinical risk. The 2014 ACC/AHA guidelines advocate using a risk index. This includes either the American College of Surgeons (ACS) NSQIP risk calculator or myocardial infarction and cardiac arrest (MICA) risk calculator, which incorporates both surgical and clinical risk. Alternatively, the clinician can incorporate the revised cardiac risk index with the estimated surgical risk to differentiate low from elevated risk (**Table 11.1**). Cardiovascular disease also has clinical risk markers classified as "low-risk factors," each of which is associated with variable levels of perioperative risk. The previous classification of perioperative, active clinical risk markers to assess the need for further testing includes issues beyond ischemic heart disease (**Table 11.2**).

TABLE 11.1

Cardiac Risk* Stratification for Noncardiac Surgical Procedures

RISK STRATIFICATION	EXAMPLES OF PROCEDURES
High (reported cardiac risk often >5%)	Aortic and other major vascular surgery Peripheral vascular surgery
Intermediate (reported cardiac risk generally 1%-5%)	Intraperitoneal and intrathoracic surgery Carotid endarterectomy Head and neck surgery Orthopedic surgery Prostate surgery
Low† (reported cardiac risk generally <1%)	Endoscopic procedures Superficial procedure Cataract surgery Breast surgery Ambulatory surgery

*Combined incidence of cardiac death and nonfatal myocardial infarction.

†These procedures do not generally require further preoperative cardiac testing.

J Am Coll Cardiol 2009;54(22):e13.

As described for the anginal pattern, exercise tolerance is one of the strongest determinants of perioperative risk and the need for invasive monitoring. In one study of outpatients referred for evaluation before major noncardiac procedures, patients were asked to estimate the number of blocks that they could walk and flights of stairs that they could climb without experiencing cardiac symptoms. Patients who could not walk four blocks and could not climb two flights of stairs were considered to have poor exercise tolerance and had twice as many perioperative cardiovascular complications as those with better functional status. The likelihood of a serious complication is inversely related to the number of blocks that could be walked or flights of stairs climbed. Several scales based on activities of daily living have been proposed to assess exercise tolerance; current guidelines advocate the Duke Activity Scale Index (**Table 11.3**).

TABLE 11.3

Estimated Energy Requirements for Various Activities

	CAN YOU …
1 MET	Take care of yourself? Eat, dress, or use the toilet? Walk indoors around the house? Walk a block or two on level ground at 2-3 mph (3.2-4.8 kph)?
4 METs	Do light work around the house such as dusting or washing dishes? Climb a flight of stairs or walk up a hill? Walk on level ground at 4 mph (6.4 kph)? Run a short distance? Do heavy work around the house such as scrubbing floors or lifting or moving heavy furniture? Participate in moderate recreational activities such as golf, bowling, dancing, doubles tennis, or throwing a baseball or football?
>10 METs	Participate in strenuous sports such as swimming, singles tennis, football, basketball, or skiing?

MET, Metabolic equivalent; *mph,* miles per hour; *kph,* kilometers per hour.

Modified from Hlatky MA, Boineau RE, Higgenbotham MB, et al. A brief self-administered questionnaire to determine functional capacity (the Duke Activity Status Index). Am J Cardiol 1989;64:65; and Fleisher LA, Beckman JA, Brown KA, et al. 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2009;54(22):e13.

The type of surgical procedure significantly impacts perioperative risk and the amount of preparation required to perform anesthesia safely. For surgical procedures not associated with significant stress or a high incidence of perioperative myocardial ischemia or morbidity, the cost of the evaluation often exceeds any benefit from the information gained by preoperative assessment. Outpatient procedures, for example, cause minimal morbidity and mortality; in such patients, cardiovascular status rarely changes perioperative management unless the patient has unstable angina or overt congestive heart failure. In fact, 30-day mortality after outpatient surgery may actually be lower than that expected if the patient did not undergo surgery. In contrast, open surgery for vascular disease entails a high risk for morbidity and the potential for ischemia. Intra-abdominal, thoracic, and orthopedic procedures are associated with elevated risk, which can then be combined with clinical risk factors to determine overall perioperative risk. Endovascular procedures fall into this intermediate-risk category because of their associated perioperative morbidity and mortality, although long-term survival appears to be similar to that in patients who undergo open procedures.

In addition to the risk related to the surgical procedure itself, risk is also correlated with the surgical volume in a given center. Several studies have demonstrated differential mortality rates in both cancer and vascular surgery, with higher mortality occurring in low-volume centers, although recent studies have demonstrated that low-volume centers may also have low mortality rates if proper care systems are in place. Surgical mortality rates may therefore be institution specific, which may influence the decision to perform further perioperative evaluations and interventions.

Risk Calculators

Much of the contemporary study of perioperative cardiac risk has focused on the development of clinical risk indices. The most widely used index was developed in a study of 4315 patients age 50 or older undergoing elective major noncardiac procedures in a tertiary care teaching hospital. The index includes six independent predictors of complications in a *revised cardiac risk index* (RCRI): high-risk type of surgery, history of ischemic heart disease, history of congestive heart failure, history of cerebrovascular disease, preoperative treatment with insulin, and preoperative serum creatinine concentration greater than 2.0 mg/dL. Cardiac complication rates rise with an increasing number of these risk factors. Patients are

stratified into low, intermediate, or high cardiovascular risk on the basis of having 0, 1 or 2, or 3 or more factors included in the RCRI, respectively. The RCRI has become the standard tool for assessing the probability of perioperative cardiac risk in a given individual and serves to direct the decision to perform cardiovascular testing and implement perioperative management protocols. The RCRI has undergone validation in vascular surgery populations and serves to predict long-term outcome and quality of life, although one group has advocated inclusion of age as a risk factor.

Additional risk indices were developed from the ACS-NSQIP database. Gupta and colleagues[10] developed a risk calculator for predicting perioperative *myocardial infarction and cardiac arrest* (MICA). In a study of 211,410 patients, perioperative MI or cardiac arrest developed in 1371 (0.65%). Multivariate logistic regression analysis identified five predictors of perioperative MI or cardiac arrest: type of surgery, dependent functional status, abnormal creatinine level, American Society of Anesthesiologists class, and increasing age.

A universal risk calculator recently developed to predict multiple outcomes was based on 1,414,006 patients encompassing 1557 unique surgical procedure codes, which had excellent performance for mortality (C-statistic = 0.944) and morbidity (C-statistic = 0.816) (any of the following intraoperative or postoperative events: surgical site infection [SSI], wound disruption, pneumonia, unplanned intubation, pulmonary embolism, on ventilator >48 hours, progressive renal insufficiency, acute renal failure, urinary tract infection [UTI], stroke/CVA, cardiac arrest, MI, deep venous thrombosis [venous thromboembolism, VTE], systemic sepsis), pneumonia, cardiac event (cardiac arrest or MI), SSI, UTI, VTE, and renal failure (progressive renal insufficiency or acute renal failure) (http://riskcalculator.facs.org). The risk calculator incorporates 21 preoperative risk factors and therefore has more discriminative ability than the MICA-specific risk calculator.

The Guidelines Approach

The ACC/AHA Task Force for Guidelines for Perioperative Cardiovascular Evaluation and Management for Noncardiac Surgery presented their recommendations in algorithmic form as a framework for determining which patients are candidates for cardiac testing (**see Fig. 11.1**). Given the availability of the evidence, the writing committee included the level of the recommendations and strength of evidence for each of the pathways. The current algorithm focuses exclusively on the evaluation for CAD. Valvular or other forms of heart disease are not included in the current algorithm.

Step 1: The consultant should determine the urgency of performing noncardiac surgery. In many cases, patient- or surgery-specific factors dictate an obvious strategy (e.g., emergency surgery) that may not allow further cardiac assessment or treatment.

Step 2: Does the patient have an acute coronary syndrome? Acute coronary syndromes include previous MI with evidence of substantial ischemic risk as determined by clinical symptoms or noninvasive study, unstable or severe angina, and new or poorly controlled ischemia-mediated HF. Depending on the results of tests or interventions and the risk inherent in delaying surgery, it may be appropriate to proceed to the planned surgery with maximal medical therapy.

Step 3: What is the estimated perioperative risk of a major adverse cardiac event (MACE) based on the combined clinical and surgical risk? The use of a validated risk index is advocated, either one of the ACS-NSQIP risk indices or combining the RCRI with the estimated surgical risk.

Step 4: Does the patient have low perioperative risk (<1%)? In such cases, no further testing is required.

Step 5: Does the patient have elevated risk? Such circumstances merit assessment of functional capacity. If the patient has at least moderate exercise capacity (≥4 metabolic equivalents [METs]), management rarely changes on the basis of the results of any further cardiovascular testing, and it is therefore appropriate to proceed with the planned surgery. The strength of the evidence and the recommendation depends on the degree of exercise capacity, with excellent capacity having stronger evidence and recommendation.

Step 6: In patients with poor (<4 METs) or unknown functional capacity, the physicians and patient should jointly determine if further testing will impact decision making or perioperative care. If not, proceeding to surgery with goal-directed medical therapy is appropriate. In the current guidelines, the identification of elevated risk with poor functional capacity may also lead to the decision to proceed with alternative strategies, such as noninvasive treatment or palliation.

Tests to Improve Identification and Definition of Cardiovascular Disease

Several noninvasive diagnostic methods can evaluate the extent of CAD before noncardiac surgery. The exercise electrocardiogram (ECG) has traditionally served to evaluate individuals for the presence of CAD, but as outlined earlier, patients with excellent exercise tolerance in daily life will rarely benefit from further testing. Patients with poor exercise capacity, in contrast, may not achieve an adequate heart rate and blood pressure for diagnostic purposes on electrocardiographic stress tests. Such patients often require concomitant imaging.

Many high-risk patients either cannot exercise or have limitations to exercise (e.g., patients with claudication or an abdominal aortic aneurysm who are undergoing vascular surgery, both of which have a high rate of perioperative cardiac morbidity). Pharmacologic stress testing has therefore become popular, particularly as a preoperative test in patients undergoing vascular surgery. Several studies have shown that the presence of a redistribution defect on dipyridamole or adenosine thallium or sestamibi imaging in patients undergoing peripheral vascular surgery predicts postoperative cardiac events. Pharmacologic stress imaging is best used in patients at moderate clinical risk. Several strategies may increase the predictive value of such tests. The redistribution defect can be quantitated, with larger areas of defect being associated with increased risk. Additionally, either increased lung uptake or dilation of the left ventricular cavity indicate ventricular dysfunction with ischemia. Several investigative groups have demonstrated that delineation of low-risk and high-risk myocardial perfusion scans (larger area of defect, increased lung uptake, and dilation of the left ventricular cavity) greatly improves the test's predictive value. Patients with high-risk scans have a particularly increased risk for perioperative morbidity and long-term mortality.

Stress echocardiography has also been used widely as a preoperative test. One advantage of this test is that it dynamically assesses myocardial ischemia in response to increased inotropy and heart rate, stimuli relevant to the perioperative period. The presence of new wall motion abnormalities occurring at a low heart rate is the best predictor of increased perioperative risk, with large areas of contractile dysfunction having secondary importance. As part of the DECREASE studies, Boersma and colleagues (as cited in the guidelines) assessed the value of dobutamine stress echocardiography with respect to the extent of wall motion abnormalities and the ability of preoperative treatment with beta blockers to attenuate risk in patients undergoing major aortic surgery. They assigned 1 point for each of the following characteristics: age older than 70 years, current angina, MI, congestive heart failure, previous cerebrovascular disease,

diabetes mellitus, and renal failure. As the total number of clinical risk factors increases, perioperative cardiac event rates also increase. Furthermore, with a high-risk score, abnormal findings on an echocardiogram predict higher risk.

Several groups have published meta-analyses examining various preoperative diagnostic tests. Such studies report good predictive values for ambulatory electrocardiographic monitoring, radionuclide angiography, dipyridamole-thallium imaging, and dobutamine stress echocardiography. Shaw and colleagues also demonstrated excellent predictive values for dipyridamole thallium imaging and dobutamine stress echocardiography.[2] Beattie and colleagues performed a meta-analysis of 25 stress echocardiography studies and 50 thallium imaging studies.[2] The likelihood ratio for stress echocardiography was more indicative of a postoperative cardiac event than that for thallium imaging (likelihood ratio [LR], 4.09; 95% confidence interval [CI], 3.21 to 6.56; versus LR, 1.83; 95% CI, 1.59 to 2.10; $P < 0.001$). The difference was attributable to fewer false-negative stress echocardiograms. A moderate to large abnormality found by either test predicted postoperative MI and death.

Institutional expertise should guide the choice of preoperative testing. The relevant clinical questions also influence the choice of test. For example, if valve function or myocardial thickness is of interest, echocardiography has advantages over perfusion imaging. Stress nuclear imaging may have slightly higher sensitivity, but stress echocardiography may have fewer false-positive results. The role of newer imaging modalities such as magnetic resonance imaging, multislice computed tomography, coronary calcium scores, and positron emission tomography in preoperative risk assessment is rapidly evolving.

Over the past decade, cardiopulmonary exercise testing (CPET) has been used as a preoperative test, particularly in Great Britain. A consistent finding of the studies was that a low anaerobic threshold was predictive of perioperative cardiovascular complications, postoperative death, or midterm and late death after surgery. An anaerobic threshold of approximately 10 mL O_2/kg/min was proposed as the optimal discrimination point, with a range in these studies of 9.9 to 11 mL O_2/kg/min. CPET is being evaluated as a means of determining the need for “prehabilitation,” in which a strategy of exercise is advocated to increase aerobic capacity before surgery.[12] Current research is determining if such strategies improve outcome. Additionally, several groups are studying the value of CPET in determining the appropriateness of surgery given the intermediate- and long-term outcome in high-risk patients and helping to inform shared decision making.

Overview of Anesthesia for Cardiac Patients Undergoing Noncardiac Surgery

Three classes of anesthetics exist: general, regional, and local/sedation or monitored anesthesia care (MAC). General anesthesia can be defined best as a state that includes unconsciousness, amnesia, analgesia, immobility, and attenuation of autonomic responses to noxious stimulation, and it can be achieved with inhalational agents, intravenous agents, or a combination of these (frequently called a “balanced technique”). Contemporary general anesthesia does not always require an endotracheal tube. Laryngoscopy and intubation were traditionally considered the time of greatest stress and risk for myocardial ischemia, but extubation may actually engender greater risk. Alternative methods for delivering general anesthesia use a mask or a laryngeal mask airway—a device that fits above the epiglottis and does not require laryngoscopy or intubation.

Five inhalational anesthetic agents (in addition to nitrous oxide) are currently approved in the United States, although enflurane and halothane are rarely used today. All inhalational agents have reversible myocardial depressant effects and lead to decreases in myocardial oxygen demand. The degree to which they depress cardiac output depends on their concentration, their effects on systemic vascular resistance, and their effects on baroreceptor responsiveness; agents therefore differ in their specific effects on heart rate and blood pressure. Isoflurane causes negative inotropic effects and potent vascular smooth muscle relaxation and has minimal effects on baroreceptor function. Desflurane has the fastest onset and is commonly used in the outpatient setting. The onset and offset of action of sevoflurane are intermediate to those of isoflurane and desflurane; the major advantage of sevoflurane is an extremely pleasant smell, which makes it the agent of choice in children.

Issues have arisen regarding the safety of inhalational agents in patients with CAD. Several large-scale, randomized and nonrandomized studies of patients undergoing coronary artery bypass grafting (CABG), however, demonstrated no increased incidence of myocardial ischemia or infarction in patients receiving inhalational agents versus narcotic-based techniques. The use of inhalational anesthetics in patients with CAD also has theoretical advantages. Several investigative groups demonstrated in vitro and in animals that inhalational agents have protective effects on myocardium similar to ischemic preconditioning, although the clinical relevance of this remains unclear.[13]

High-dose narcotic techniques offer the advantages of hemodynamic stability and lack of myocardial depression. Narcotic-based anesthetics were frequently considered the “cardiac anesthesia” and were advocated for use in all high-risk patients, including those undergoing noncardiac surgery. The disadvantage of these traditional high-dose narcotic techniques is the requirement for postoperative ventilation. The ultrashort-acting narcotic remifentanil obviates the need for prolonged ventilation but provides hemodynamic stability. This agent can assist in early extubation of patients undergoing cardiac surgery and may aid in managing short periods of intense intraoperative stress in high-risk patients.

Despite the theoretical advantages of a high-dose narcotic technique, large-scale trials in patients undergoing CABG showed no difference in survival or major morbidity compared to the inhalation-based technique. This observation has contributed to the abandonment of high-dose narcotics in much of cardiac surgery and to an emphasis on early extubation. Most anesthesiologists use a balanced technique involving the administration of lower doses of narcotics with an inhalational agent. This approach allows the anesthesiologist to derive the benefits of each of these agents while minimizing side effects.

The IV agent propofol is an alternative mode of delivering general anesthesia. An alkyl phenol that can be used for both induction and maintenance of general anesthesia, propofol can cause profound hypotension because of reduced arterial tone with no change in heart rate. Its major advantage is rapid clearance with few residual effects on awakening, but because it is expensive, its current use tends to be limited to operations of brief duration. Despite its hemodynamic effects, propofol has been used extensively to assist in early extubation after CABG.

Current evidence indicates that there is no single “best” general anesthetic technique for patients with CAD who are undergoing noncardiac surgery, which has led to abandonment of the concept of a cardiac anesthetic.

Regional Anesthesia

Regional anesthesia includes spinal, epidural, and peripheral nerve blocks, and each technique has advantages and risks. Peripheral techniques, such as brachial plexus or Bier blocks, offer the advantage

of causing minimal or no hemodynamic effects. In contrast, spinal or epidural techniques can produce sympathetic blockade, which can reduce blood pressure and slow the heart rate. Spinal anesthesia and lumbar or low thoracic epidural anesthesia can also evoke reflex sympathetic activation mediated above the level of blockade, which might lead to myocardial ischemia.

The primary clinical difference between epidural and spinal anesthesia is the ability to provide continuous anesthesia or analgesia with placement of an epidural catheter, as opposed to a single dose with spinal anesthesia, although some clinicians will place a catheter in the intrathecal space. Even though the speed of onset depends on the local anesthetic agent used, spinal anesthesia and its associated autonomic effects occur sooner than when the same agent is administered epidurally. A catheter, usually left in place for epidural anesthesia, permits titration of the agent. Epidural catheters can also be used postoperatively to provide analgesia.

Extensive research has compared regional with general anesthesia for patients with CAD, particularly in those undergoing infrainguinal bypass surgery. In one meta-analysis, overall mortality was reduced by approximately one third in patients allocated to neuraxial blockade, although the findings were controversial because most of the benefit was observed in older studies. Reductions in MI and renal failure also occurred. A large-scale study of regional versus general anesthesia in noncardiac surgery patients did not demonstrate a difference in outcome.

Regional anesthesia has become very common with recent advances in ultrasound-guided administration and development of *enhanced recovery after surgery* (ERAS) protocols. Regional anesthesia offers the opportunity to provide excellent pain relief after surgery, which has proved advantageous and reduces perioperative cardiac stress.[14]

Monitored Anesthesia Care

MAC encompasses local anesthesia administered by the surgeon, with or without sedation. In a large-scale cohort study, MAC was associated with increased 30-day mortality compared with general anesthesia in a univariate analysis, although it did not remain significant in multivariate analysis once patient comorbidity was taken into account. The major issue with MAC is the ability to block the stress response adequately, because the tachycardia associated with inadequate analgesia may be worse than the potential hemodynamic effects of general or regional anesthesia. Since the introduction of newer, short-acting IV agents, general anesthesia can now be administered essentially without an endotracheal tube. This approach allows the anesthesiologist to provide intense anesthesia for short or peripheral procedures without the potential effects of endotracheal intubation and extubation and therefore blurs the distinction between general anesthesia and MAC. An analysis of closed insurance claims demonstrated a high incidence of respiratory complications with MAC.

Intraoperative Hemodynamics and Myocardial Ischemia

Over the last two decades, numerous studies have explored the relationship between hemodynamics and perioperative ischemia and MI. Tachycardia is the strongest predictor of perioperative ischemia. Although traditionally a heart rate (HR) greater than 100 beats/min defines tachycardia, slower HRs may result in myocardial ischemia. As described later, control of HR with beta blockers decreases the incidence of myocardial ischemia and infarction. In the DECREASE studies, HR control reduced the incidence of perioperative MI, with the greatest benefit achieved if HR was controlled to less than 70 beats/min. Although some are concerned about beta blockers causing intraoperative hypotension in

patients with CAD, no evidence supports this contention. However, the Perioperative Ischemic Evaluation (POISE) trial demonstrated that an acute beta blockade protocol was associated with hypotension and a higher rate of stroke in the metoprolol arm. During CABG, the vast majority of episodes of intraoperative ischemia are not correlated with hemodynamic changes. In the absence of tachycardia, hypotension is not associated with myocardial ischemia.

Postoperative Management

Postoperative Response to Surgery

Understanding the pathophysiology of perioperative cardiac events helps in determining the best approach to preoperative testing. A full discussion of the pathophysiology of perioperative MI has been published.[15] All surgical procedures cause a stress response, although the extent of the response depends on the extent of the surgery and the use of anesthetics and analgesics to reduce the response. The stress response can increase heart rate and blood pressure, which can precipitate episodes of myocardial ischemia in areas distal to coronary artery stenoses. Prolonged myocardial ischemia (either prolonged individual episodes or prolonged cumulative duration of shorter episodes) can cause myocardial necrosis and perioperative MI and death. Identification of patients at high risk for coronary artery stenosis, through either the history or cardiovascular testing, can lead to the implementation of strategies to reduce morbidity as a result of supply-demand mismatches. Recent work with highly sensitive markers of myocardial damage has shown a high rate of cardiac injury even in the absence of frank infarction. In the POISE trial, 8.3% of the patients had an elevated cardiac biomarker without other evidence of infarction, whereas 5% also had a second confirmatory marker of MI.

A major mechanism of MI in the nonoperative setting is plaque rupture with subsequent coronary thrombosis (**see Chapters 44 and 58**). Inasmuch as the perioperative period is marked by tachycardia and a hypercoagulable state, plaque disruption and thrombosis may occur quite often. Because noncritical stenosis can furnish the nidus for coronary artery thrombosis, preoperative cardiac evaluation may fail to identify patients at risk before surgery. The areas distal to the noncritical stenosis might not have developed collateral coronary flow, and therefore any acute thrombosis may have a greater detrimental effect than it would in a previously severely narrowed vessel. If a prolonged increase in myocardial oxygen demand in a patient with one or more critical fixed stenoses provoked postoperative MI, preoperative testing would probably identify such a patient.

Evidence from several autopsy and postinfarction angiography studies after surgery supports both mechanisms. Ellis and colleagues demonstrated that one third of all patients sustained events in areas distal to noncritical stenoses. Dawood and associates, as cited in the guidelines, demonstrated that fatal perioperative MI occurs predominantly in patients with multivessel coronary disease, especially left main and three-vessel disease, but the severity of preexisting stenosis did not predict the infarct territory. This analysis suggested that fatal events occurred primarily in patients with advanced fixed stenoses, but that the infarct may result from plaque rupture in a mild or only moderately stenotic segment of the diseased vessel. Duvall and colleagues reviewed hospital records and coronary angiograms from patients who underwent noncardiac surgery complicated by perioperative MI from 1998 to 2006. The distribution of demand, thrombotic, and nonobstructive MI was 55%, 26%, and 19%, respectively. In contrast, Gualandro and colleagues found that almost 50% of patients with perioperative acute coronary syndromes have evidence of ruptured coronary plaque. The evidence therefore shows that several mechanisms may cause perioperative MI.

Postoperative Intensive Care

Provision of intensive care by intensivists has now become a patient safety goal. Pronovost and coworkers performed a systematic review of the literature on physician staffing patterns and clinical outcomes in critically ill patients. They grouped ICU physician staffing into low-intensity (no intensivist or elective intensivist consultation) and high-intensity (mandatory intensivist consultation or closed ICU [all care directed by an intensivist]) groups. High-intensity staffing was associated with lower hospital mortality in 16 of 17 studies (94%) and with a pooled estimate of the relative risk for hospital mortality of 0.71 (95% CI, 0.62 to 0.82). High-intensity staffing was associated with lower ICU mortality in 14 of 15 studies (93%) and with a pooled estimate of the relative risk for ICU mortality of 0.61 (95% CI, 0.50 to 0.75). High-intensity staffing reduced hospital length of stay (LOS) in 10 of 13 studies and reduced ICU LOS in 14 of 18 studies without case-mix adjustment. High-intensity staffing was associated with reduced hospital LOS in two of four studies and lowered ICU LOS in both studies that adjusted for case-mix. No study found increased LOS with high-intensity staffing after case-mix adjustment. High-intensity versus low-intensity ICU physician staffing was associated with reduced hospital and ICU mortality and LOS.

Postoperative Pain Management

Postoperative analgesia may reduce perioperative cardiac morbidity. Because postoperative tachycardia and catecholamine surges probably promote myocardial ischemia and/or rupture of coronary plaque, and because postoperative pain can produce tachycardia and increase catecholamines, effective postoperative analgesia may reduce cardiac complications. Postoperative analgesia may also reduce the hypercoagulable state. Epidural anesthesia may decrease platelet aggregability compared with general anesthesia. Whether this decrease relates to intraoperative or postoperative management is unclear. In an analysis of Medicare claims data, the use of epidural analgesia (as determined by billing codes for postoperative epidural pain management) was associated with decreased risk for death at 7 days. As previously noted, regional anesthesia may be advantageous for postoperative pain relief. Future research will focus on how best to deliver postoperative analgesia to maximize the potential benefits and reduce complications.[14]

Surveillance and Implications of Perioperative Cardiac Complications

The optimal and most cost-effective strategy for monitoring high-risk patients for major morbidity after noncardiac surgery is unknown. Myocardial ischemia and infarctions that occur postoperatively are usually silent, most likely because of the confounding effects of analgesics and postoperative surgical pain. Intraoperative hypotension confers a fourfold increase in the risk of troponin elevation.[6] Most perioperative MIs do not cause ST-segment elevation, and less specific ST-T wave changes are common after surgery with or without MI. These considerations therefore render the diagnosis of perioperative MI particularly difficult to make.

A marked elevation in mortality associated with postoperative MI provides continuing impetus for improved methods of detection. Biomarkers may help identify myocardial necrosis. Lee and colleagues found that troponin T had similar efficacy as creatine kinase (CK) MB in diagnosing perioperative MI but significantly better correlation with major cardiac complications developing after acute MI. Mohler and

colleagues evaluated troponin I (cTnI) and CK-MB in 784 high-risk vascular surgery patients on the day of surgery and at 24 hours, 72 hours, and 120 hours postoperatively. They reported a sensitivity of 51% and a specificity of 91% for the defined cardiovascular event by using a receiver operating characteristic (ROC)–defined cutoff point for CK-MB of 3.1 ng/mL.

In the VISION (Vascular Events in Noncardiac Surgery Cohort Evaluation) study, 15,133 participants undergoing noncardiac surgery had troponin T measurements performed between 6 and 12 hours postoperatively and on postoperative days 1, 2, and 3.[4] Troponin T levels above the baseline level of 0.01 ng/mL or lower were associated with increased rates of 30-day mortality. Indeed, a troponin T level of 0.02 ng/mL was associated with more than a twofold risk for death. With a troponin T level of 0.3 ng/mL or higher, the hazard ratio for death increased to more than 10-fold above that in patients without any elevation in troponin. Mortality was 16.9% with a troponin T level of 0.3 ng/mL or higher, versus 1% in the group without troponin elevation. Although troponin T levels stratified the rate of mortality across a low spectrum of positive levels, it could not predict the cause of death. Both vascular and nonvascular death increased similarly with increasing troponin T levels, and more than half of all deaths were from nonvascular causes. An elevated troponin T level thus provides adverse prognostication without direction for appropriate therapy.

Three important points can be made from these data: First, noncardiovascular causes of mortality outnumber cardiovascular causes, indicating important new areas for research. Second, even if there is evidence of troponin elevation, the death is remote from the event, suggesting it is not an immediate cause but a marker of illness. Third, true type 1 MI is rare. In the POISE trial, 7521 participants were screened to find 697 (9.2%) with troponin elevations, but only two individuals of the total cohort were referred for coronary revascularization.[16] In our opinion, troponin measurement should be avoided in the asymptomatic patient without hemodynamic embarrassment or ischemic ECG change. Troponin elevations in this setting provide neither diagnostic direction nor specific management to implement. Should future trials identify management strategies for troponin elevations, we would reconsider routine troponin measurement in high-risk patients.

Several studies have evaluated brain (B-type) natriuretic peptide (BNP) in the perioperative period. In a meta-analysis of seven prospective observational studies, BNP or N-terminal (NT)–pro-BNP above the ROC-determined optimal threshold was associated with marked increases in 30-day and intermediate-term cardiac death, nonfatal MI, and major adverse cardiac events. One meta-analysis demonstrated that preoperative BNP measurement independently predicted perioperative cardiovascular events in studies that considered only the outcomes of death, cardiovascular death, or MI (odds ratio [OR], 44.2; 95% CI, 7.6 to 257.0; I[2] = 51.6%), and in studies that included other outcomes, the OR was 14.7 (95% CI, 5.7 to 38.2; I[2] = 62.2%). A subsequent meta-analysis showed that the addition of postoperative BNP measurements to a risk prediction model of 30-day death and MI had a net reclassification index of 20%. Moreover, elevated postoperative BNP increased the rate of death and MI by 3.7-fold.[17]

Traditionally, perioperative MI has been associated with 30% to 50% short-term mortality, but recent series have reported a fatality rate of less than 20% for perioperative MI. Studies from the 1980s suggested a peak incidence on the second and third postoperative days. Badner and colleagues, using troponin I as a marker for MI, suggested that the highest incidence occurred during the immediate and first postoperative days, as confirmed in other studies. The finding that hypotension in the postanesthetic care unit best predicted release of troponin suggests a hemodynamic consequence rather than plaque rupture event (type 2 versus type 1 MI). Thus the change is probably related to more robust surveillance methods, not to a fundamental shift in how or when myocardial ischemia or infarction occurs.

Increasing evidence has associated perioperative MI or biomarker elevation with worse long-term

outcome. Oberweis and colleagues[18] studied 3050 patients who underwent orthopedic surgery. Of the 179 in whom myocardial necrosis occurred, mortality was 16.8% in patients with biomarker elevation at a mean follow-up of 3 years compared to 5.8% in patients without elevation.[18] Landesberg and coworkers, as cited in the guidelines, demonstrated that postoperative CK-MB and troponin, even at low cutoff levels, are independent and complementary predictors of long-term mortality after major vascular surgery. Mahla and colleagues have also shown that elevations in BNP are associated with a fivefold increased long-term risk for cardiac events. The appropriate use of screening biomarkers in current preoperative risk assessment algorithms remains unstudied because there is no evidence-based intervention to apply in response to a biomarker elevation.

Recent evidence has suggested that biomarker elevation before surgery identifies a population at particularly high risk. Maile and coworkers reviewed 6030 patients with troponin measured in the 30 days before nonemergent noncardiac surgery and found a 30-day mortality of 4.7% in the group without detectable troponin levels, but a 12.7% mortality in the group with the highest tercile of troponin elevation. The closer in time that an elevated troponin was drawn to the date of surgery, the higher the risk. Similar results are reported with BNP. A meta-analysis of 15 studies reported that preoperative BNP elevation was associated with approximately a 20-fold increase in major adverse cardiovascular events, ninefold increase in all-cause mortality, and 24-fold increase in cardiac death. These data suggest future avenues for identification of high-risk noncardiac surgical patients in the study of risk reduction therapies.

Strategies to Reduce the Cardiac Risk Associated With Noncardiac Surgery

Coronary Artery Revascularization

The treatment of patients before noncardiac surgery should follow the same trajectory in the absence of impending surgery. Over optimum medical treatment, coronary revascularization in stable patients has limited value.[19] Despite this evidence and recent data that the postoperative incidence of type 1 MI requiring revascularization is 0.3% to 0.5%,[15,16] some have suggested coronary revascularization as a means of reducing the perioperative risk related to noncardiac surgery. This view is derived from retrospective evidence such as the Coronary Artery Surgery Study (CASS) registry, which enrolled patients from 1978 to 1981, an era that antedates almost all the current therapies shown to be effective for reducing coronary events. This observational analysis did not randomly assign patients, however, and reflects a different era in preventive strategies and higher rates of adverse outcomes after noncardiac surgery.

Several cohort studies have examined the benefit of percutaneous coronary intervention (PCI) before noncardiac surgery. Posner and colleagues, as cited in the guidelines, used an administrative dataset of patients who underwent PCI and noncardiac surgery.[2] They matched patients with coronary disease undergoing noncardiac surgery with and without previous PCI and examined cardiac complications. In this nonrandomized analysis, they noted a significantly lower rate of 30-day cardiac complications in patients who underwent PCI at least 90 days before the noncardiac surgery. PCI within 90 days of noncardiac surgery did not improve outcomes. The advent of drug-eluting stents requiring prolonged antiplatelet therapy may promote operative bleeding complications or increase subacute stent thrombosis if antiplatelet treatment is stopped perioperatively.

Several randomized trials have now addressed the value of both CABG and PCI in a subset of patients.

McFalls and coauthors reported the results of a multicenter randomized trial in the Veterans Affairs Health System in which patients with documented CAD on coronary angiography, excluding those with left main coronary artery disease or a severely depressed ejection fraction (≤20%), were randomly assigned before elective major vascular surgery to CABG (59%) or PCI (41%) versus routine medical therapy. At 2.7 years after randomization, mortality in the revascularization group did not differ significantly (22%) from that in the no-revascularization group (23%). Within 30 days after the vascular operation, postoperative MI, defined as elevated troponin levels, occurred in 12% of the revascularization group and in 14% of the no-revascularization group ($P = 0.37$). The authors suggested that coronary revascularization is not indicated in patients with stable CAD and that PCI or CABG for one- or two-vessel disease before noncardiac surgery does not prevent perioperative MI. A reanalysis of the data found that the completeness of revascularization affects the rate of perioperative MI, with CABG being more effective than PCI. Most recently, Garcia and colleagues analyzed both randomly and nonrandomly assigned patients who underwent coronary angiography before vascular surgery in the CARP trial registry; 4.6% of these patients had unprotected left main CAD. Only this subset of patients showed a benefit of preoperative coronary artery revascularization.

Monaco and associates studied 208 patients at moderate clinical risk who underwent major vascular surgery and were randomly allocated to either a “selective strategy” group, in whom coronary angiography was performed on the basis of noninvasive test results, or to a “systematic strategy” group, in whom preoperative coronary angiography was systematically performed. The strategy of routine coronary angiography had no effect on the short-term outcome, but the long-term outcome was improved in surgical patients with peripheral arterial disease at medium to high risk.

One issue in interpreting the results is that the length of time between coronary revascularization and noncardiac surgery most likely affects its protective effect and potential risks. Back and colleagues studied 425 consecutive patients undergoing 481 elective major vascular operations at an academic Veterans Affairs Medical Center. Coronary revascularization was classified as “recent” (CABG, <1 year; percutaneous transluminal coronary angioplasty [PTCA], <6 months) in 35 cases, as “previous” (CABG, 1 to 5 years; PTCA, 6 months to 2 years) in 45 cases, and as “remote” (CABG, >5 years; PTCA, >2 years) in 48 cases. Patients with previous PTCA had similar outcomes as those after CABG. Significant differences in adverse cardiac events and mortality were found between patients with CABG performed within 5 years or PTCA within 2 years (6.3% and 1.3%, respectively), individuals with remote revascularization (10.4% and 6.3%, respectively), and nonrevascularized patients stratified at high risk (13.3% and 3.3%, respectively) or intermediate to low risk (2.8% and 0.9%, respectively). The authors concluded that previous coronary revascularization (CABG, <5 years; PTCA, <2 years) provides only modest protection against adverse cardiac events and mortality following major arterial reconstruction.

In our opinion, the randomized controlled trials provide strong evidence of the limited benefit in preoperative coronary artery revascularization to reduce cardiovascular risk. In the absence of unusual circumstances, percutaneous and surgical revascularization should not be pursued before noncardiac surgery.

Coronary Stenting and Noncardiac Surgery

PCI using coronary stenting poses several special issues.[20] Kaluza and colleagues reported the outcome of 40 patients who underwent prophylactic coronary stent placement less than 6 weeks before major noncardiac surgery requiring general anesthesia. They reported seven MIs, 11 major bleeding episodes, and eight deaths. All the deaths and MIs, as well as 8 of the 11 bleeding episodes, occurred in patients subjected to surgery less than 14 days after stenting. Four patients died after undergoing surgery 1 day

after stenting. Wilson and colleagues, as cited in the guidelines, reported on 207 patients in whom noncardiac surgery was performed within 2 months of stent placement. Eight patients died or had an MI, and all of them were among the 168 patients who underwent surgery 6 weeks after stent placement. Vincenzi and coworkers studied 103 patients and reported that the risk for a perioperative cardiac event was 2.11-fold greater in patients with recent stents (<35 days before surgery) than in those undergoing PCI more than 90 days before surgery. These data point to the importance of delaying surgery after stenting, even though the investigators either continued antiplatelet drug therapy or only briefly interrupted it, and all patients received heparin.

Drug-eluting stents may represent an even greater problem during the perioperative period. Emerging data from a series of recent analyses in the nonoperative setting and several perioperative case reports suggest that the risk for thrombosis continues for at least 1 year after insertion. Several reports suggest that drug-eluting stents may represent an additional risk over a prolonged period (up to 12 months), particularly if the use of antiplatelet agents is discontinued.

Schouten's group retrospectively evaluated 192 patients who underwent noncardiac surgery after successful PCI for unstable CAD within 2 years of the procedure. Drug-eluting stents accounted for 52% of the stents placed. Of the 192 patients, 30 underwent surgery before the recommended discontinuation of dual-antiplatelet therapy for the particular stent (30 days for bare-metal stents and up to 6 months for sirolimus-eluting stents). In patients in whom antiplatelet therapy was stopped before the required time for use of clopidogrel (early-surgery group), the incidence of death or nonfatal MI was 30.7% compared with 0% in patients who continued antiplatelet therapy. The elevated risk for stent thrombosis and cardiovascular events, however, seems to abate over time. In the EVENT (Evaluation of Drug-Eluting Stents and Ischemic Events) registry of 4637 consecutive patients, 4.4% underwent major noncardiac surgery in the ensuing year. A relative 27-fold increased rate of cardiovascular events occurred in the week after surgery versus any other week after stent implantation, but the absolute rate was only 1.9%.

Wijeysundera and colleagues[21] evaluated 8116 patients who underwent noncardiac surgery in Ontario, Canada, and found that 34% had a coronary stent implanted within the 2 years before surgery. Drug-eluting stents represented one third of the stents placed. Patients with bare-metal stents implanted less than 45 days before surgery had a 6.7% cardiovascular event rate, which dropped to 2.6% with a stent implanted 45 to 180 days before surgery. Patients with a drug-eluting stent had a 20.2% cardiovascular event rate in the first 45 days after stent implantation, and the rate became similar to that in patients without stenting when the stent was implanted more than 180 days before surgery. Bangalore and colleagues[22] studied the impact of drug-eluting stents compared with bare-metal stents placed preoperatively in 8415 patients in Massachusetts. In this cohort the death, MI, and bleeding event rate was 8.6% in the first 30 days after PCI, dropping to 5.2% when surgery was performed more than 90 days after coronary revascularization. Using propensity matching to compare the bare-metal stent and drug-eluting stent populations, the death and MI rate was higher in the bare-metal stent cohort.

In a Scotland-wide retrospective cohort analysis, perioperative death and ischemic cardiac events were much more common within the first 6 weeks after stent implantation than after 6 weeks, 42.4% versus 12.8%, respectively. Forty-five percent of the revascularizations in this cohort were performed for an acute coronary syndrome, increasing the baseline risk of the cohort. The event rate was higher in patients who underwent revascularization because of acute coronary syndromes within 6 weeks, in whom it reached 65%. In contrast to other reports, no temporal differences were noted between the bare-metal and drug-eluting stent groups.

Data from more recent large observational studies suggest that the time frame of increased risk of stent thrombosis is on the order of 6 months, regardless of stent type (bare metal or drug eluting). In a large

cohort of patients from the Veterans Health Administration hospitals, the increased risk of surgery for the 6 months after stent placement was most pronounced in patients in whom the indication for PCI was an MI.[23,24]

In 2016, ACC/AHA published a focused update on duration of dual-antiplatelet therapy in CAD patients, including revising the perioperative guidelines.[20] The current recommendations for delay after coronary stent placement include 30 days for bare-metal stent implantation and 6 months after drug-eluting stent placement (**Fig. 11.3**). The guidelines writing committee noted that elective noncardiac surgery may be considered more than 180 days after drug-eluting stent implantation if the risk of delay is thought to be greater than the risk of stent thrombosis. The guideline committee gave a class IIb recommendation that elective surgery may be considered after 3 months for patients in whom the P2Y12 inhibitor needs to be discontinued if further delay of surgery is greater than the risk of stent thrombosis. In patients with illness requiring more timely surgery, strategies for bridging the cessation of antiplatelet therapy until the procedure include the use of IV eptifibatide and tirofiban, but these strategies lack outcomes data.

J Am Coll Cardiol 2016;68:1082-115.)

Pharmacologic Interventions

Beta-Adrenergic Blocking Agents

Beta-adrenergic blocking agents have undergone extensive study in perioperative risk management. As noted earlier, some of the trial data used to support recent recommendations on the titrated use of beta blockers from Poldermans and colleagues have become uncertain. A recent meta-analysis of all the beta-

blocker trials demonstrates that beta blockers decrease nonfatal MI but increase stroke and death.[25] As a result, ACC/AHA guidelines suggest that perioperative beta blockers can be considered on a case-by-case basis in patients with significant myocardial ischemia, three or more RCRI risk factors, or a compelling long-term indication for beta blockers. Aggregate impact of beta blockers seems to be low. Of the more than 10,000 participants in the trials, 75 nonfatal MIs were prevented and 19 strokes and 35 deaths instigated (**Table 11.4**).

TABLE 11.4

Recommendations for Perioperative Therapy with Beta Blockers

Class I
• Continue beta blockers in patients who are receiving beta blockers chronically.
Class IIa
• Guide management of beta blockers after surgery by clinical circumstances.
Class IIb
• In patients with intermediate- or high-risk preoperative tests, it may be reasonable to begin beta blockers. • In patients with ≥3 Revised Cardiac Risk Index (RCRI) factors, it may be reasonable to begin beta blockers before surgery. • Initiating beta blockers in the perioperative setting as an approach to reduce perioperative risk is of uncertain benefit in those with a long-term indication but no other RCRI risk factors.* • It may be reasonable to begin perioperative beta blockers long enough in advance to assess safety and tolerability, preferably >1 day before surgery.
Class III
• Beta-blocker therapy should not be started on the day of surgery

*Clinical risk factors include a history of ischemic heart disease, history of compensated or previous heart failure, history of cerebrovascular disease, diabetes mellitus, and renal insufficiency (defined in the RCRI as a preoperative serum creatinine level of 2 mg/dL).

From Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2014;64:e77-137.

Most of these trials did not titrate beta blockers in the same manner as they are used in other conditions, such as heart failure or hypertension. For example, in the POISE trial, Devereaux and colleagues randomly assigned 8351 high-risk patients undergoing noncardiac surgery to metoprolol succinate, 200 mg daily, or matching placebo. The use of high-dose, long-acting medications may have worsened outcomes by limiting the physician's flexibility to modify treatment on the basis of the rapidly shifting perioperative environment. Other trials used lower doses without titration to hemodynamic parameters as well. Administration of beta blockers as performed in the clinical trials clearly does not provide a benefit sufficient for their routine use.

Current guidelines suggest that beta blockade may be reasonable in patients with intermediate- or high-risk myocardial ischemia reported in preoperative noninvasive testing or patients with three or more RCRI risk factors, although there is no direct evidence to support routine use even in this higher-risk population.[1] If beta blockers are to be used, it is recommended that initiation begin 1 day or more before surgery. Initiation on the day of surgery has been associated with an increase in stroke and mortality.[26] In hospital, short-acting oral or IV beta blockers should be used to permit titration to hemodynamics. No specific blood pressure or heart rate targets have been validated, although blood pressure control to less than 140/90 mm Hg and heart rates of 60 to 80 beats/min may be reasonable when beta blockers are used.

Statin Therapy

Statins are routinely recommended for patients with atherosclerosis and diabetes (**see Chapters 45 and 48**). Their role in surgery is less well defined. In a retrospective analysis of 750 patients, 10% of whom had the composite outcome (30-day death, MI, and AF), statin use was associated with a 45% reduction in adverse events, including a 5% absolute reduction in 30-day mortality. In addition to their cholesterol-

lowering properties, statins have anti-inflammatory actions that may provide benefit as well. In an NSQIP study of 7777 patients undergoing various surgeries, statin use was associated with reductions in noncardiac events, including a 47% reduction in respiratory complications, 59% reduction in VTE, and 35% reduction in infectious complications.[27] The evidence suggests that statin therapy should be continued during the perioperative period. Le Manach and associates evaluated the effect of statin discontinuation in a vascular surgery population. When compared with a control population, discontinuation of statins was associated with more than a twofold increase in troponin elevation, whereas continuation reduced the rate of troponin release by more than 40%. In patients already receiving statins, a prospective randomized trial of 500 patients with stable CAD about to undergo emergency surgery randomly received placebo or atorvastatin (80 mg) 2 hours before surgery. In the group who received the statin, cardiac death, MI, or unplanned revascularization occurred in 2.4% of patients compared with 8% in the placebo arm.[28] Indeed, starting statin therapy should be considered in patients who meet ACC/AHA lipid guideline recommendations and in high-risk patients, because they probably merit this treatment even without surgery.

Perioperative Ischemic Evaluation 2 (POISE 2), a blind randomized trial with a 2 × 2 factorial design, allowed separate evaluation of low-dose clonidine versus placebo and low-dose aspirin versus placebo in 10,010 patients with, or at risk for, atherosclerotic disease who were undergoing noncardiac surgery. Low-dose clonidine did not reduce the rate of death or nonfatal MI but was associated with an increased risk of clinically important hypotension and nonfatal cardiac arrest.[29] Administration of aspirin was not associated with any difference in the rate of death or nonfatal MI but increased the risk of major bleeding.[30]

Two small randomized trials have evaluated the potential protective effect of prophylactic nitroglycerin in reducing perioperative cardiac complications after noncardiac surgery. Neither established a benefit for the prophylactic use of nitroglycerin. Because prophylactic nitroglycerin has considerable hemodynamic effects and is not known to prevent MI or cardiac death, the data do not support its routine use.

One large trial currently in progress may affect the management of patients during noncardiac surgery in the near future. The Management of Myocardial Injury after Noncardiac Surgery Trial (MANAGE) has a 2 × 2 factorial design testing the efficacy of dabigatran and omeprazole in patients undergoing noncardiac surgery who develop an elevated troponin or CK-MB level with evidence of an ischemic event or no alternative explanation for biomarker elevation.

Nonpharmacologic Interventions

Temperature

Frank and colleagues, as cited in the guidelines, completed a randomized trial of regional versus general anesthesia for lower extremity vascular bypass procedures and noted an association between hypothermia (temperature <35°C) and myocardial ischemia. They subsequently performed a trial in 300 high-risk patients undergoing a diverse range of intermediate- and high-risk procedures and randomly assigned to maintenance of normothermia or routine care. They observed a significantly reduced incidence of perioperative cardiac morbidity and mortality within 24 hours of surgery in the normothermic group.

Electrocardiographic, Hemodynamic, and Echocardiographic Monitoring

Multiple studies have demonstrated the predictive value of correlating perioperative ST-segment changes

and major cardiac events, as described earlier. Furthermore, the duration (cumulative or continuous) of perioperative ST changes strongly predicts poor outcomes. ST-segment monitoring has therefore become standard during the intraoperative and ICU periods for high-risk patients. However, ST-segment changes may also develop in patients at low to moderate risk. These changes may not reflect true myocardial ischemia, as suggested in a recent series.

Postoperative patients may have the greatest risk for a cardiac event when on the ward and unmonitored. Few studies have tested the efficacy of ST-segment telemetric monitoring during the perioperative period. The issue of whether early treatment of prolonged ST-segment changes improves outcomes in this situation remains unresolved.

Much controversy surrounds the value of pulmonary artery (PA) catheterization for noncardiac surgery. Several small, randomized trials did not demonstrate a significant reduction in major cardiac morbidity and mortality in patients so monitored during aortic surgery. In a large-scale cohort study, Polanczyk and colleagues[31] found that patients with PA catheters who were matched to those without catheters by a propensity score also failed to demonstrate significant benefit. In fact, they observed an increased incidence of congestive heart failure and untoward noncardiac outcomes in the catheter group. A total of 1994 patients were randomly allocated to goal-directed therapy guided by a PA catheter or to standard care without the use of a PA catheter in patients undergoing urgent or elective major surgery. No difference in survival occurred, but pulmonary embolism developed at a higher rate in the catheter group than in the standard-care group. Current evidence therefore does not support the routine use of PA catheterization for high-risk patients undergoing major noncardiac surgery. Determining whether these results apply to the high-risk vascular surgical population and whether use of a PA catheter provides benefit in specific clinical situations will require further work.

Transesophageal echocardiography (TEE) represents another means of assessing intraoperative cardiac function. This tool sensitively monitors intraoperative wall motion abnormalities and fluid status. In patients undergoing aortic cross-clamping, TEE showed significantly better sensitivity in detecting intraoperative ischemia than electrocardiographic monitoring. For noncardiac surgery, a study of TEE, 2-lead electrocardiography, and 12-lead electrocardiography demonstrated minimal additive value of TEE over 2-lead electrocardiography. TEE monitoring may nonetheless prove valuable in guiding treatment in patients with unstable hemodynamics who have uncertain fluid status and myocardial function.

Transfusion Threshold

Much controversy surrounds the optimal hemoglobin level at which transfusion is indicated in high-risk noncardiac surgical patients. No randomized trials have evaluated the optimal transfusion threshold, although much anecdotal evidence exists. A large-scale trial of transfusion triggers in the ICU did not document increased morbidity or mortality when a hemoglobin concentration lower than 7 g/dL was used as a transfusion threshold, but trends toward increased morbidity emerged in the subset of patients with ischemic heart disease. In the FOCUS (Transfusion Trigger Trial for Functional Outcomes in Cardiovascular Patients Undergoing Surgical Hip Fracture Repair) trial, Carson and colleagues[32] randomly assigned hip fracture patients to a liberal transfusion strategy (hemoglobin threshold of 10 g/dL) or a restrictive transfusion strategy (symptoms of anemia or at physician's discretion for hemoglobin level <8 g/dL). A liberal transfusion strategy, compared with a restrictive strategy, did not reduce rates of death or inability to walk independently on 60-day follow-up and did not reduce in-hospital morbidity in elderly patients at high cardiovascular risk. The impact of transfusion may depend on the severity of the precipitating anemia. Smilowitz and coworkers[33] followed 3050 patients after orthopedic surgery. In this cohort the presence of anemia, hemorrhage, and transfusion were independently associated with long-term

mortality. Interestingly, the effect of transfusion was attenuated by the severity of anemia. For patients with no anemia, transfusion increased the hazard ratio (HR) 4.4-fold; for those with mild anemia, HR was only 2.3-fold; and for those with moderate/severe anemia (hemoglobin <11 g/dL), there was benefit, with HR of 0.81. These data suggest a restrictive policy of transfusion may be the most beneficial for patients undergoing noncardiac surgery.

Conclusion

Three trends are notable in the perioperative management of patients undergoing noncardiac surgery: (1) the rate of myocardial infarction and cardiovascular death are declining; (2) noncardiovascular death now accounts for the majority of perioperative mortality; and (3) the evidence base supporting current management practices continues to grow rapidly. As overall mortality risk declines over time, the future goal of preoperative assessment will be to identify patients at clinically inapparent increased risk and devise and test interventions to reduce this risk. Additionally, preoperative risk assessment will increasingly serve to determine if the long-term benefits of surgery outweigh the perioperative risks. The predictive value of biomarkers and treatment of biomarker elevations, novel medications, and presurgical rehabilitation (prehabilitation) are currently under investigation and may represent the next frontier in perioperative management.

Electrocardiography

David M. Mirvis, Ary L. Goldberger

The technology and the clinical value of the electrocardiogram (ECG) have continuously evolved since the invention of the string galvanometer by Einthoven in 1901. By 1910, the ECG had emerged from the research laboratory into the clinic and soon became the most commonly used cardiac diagnostic test. Although other techniques have evolved to assess cardiac structure and mechanical function, the ECG remains the fundamental method to assess the heart's electrical activity. This chapter outlines the criteria for and the utility of the most common ECG diagnoses in adults.

Fundamental Principles

The ECG is the final outcome of a complex series of physiologic and technologic processes. First, transmembrane ionic currents are generated by ion fluxes across cell membranes and between adjacent cells (**see Chapter 34**). These currents are synchronized during cardiac activation and recovery sequences to generate a physiologically meaningful time-varying electrical field in and around the heart. This field is altered as it passes through numerous other structures, including the lungs, blood, and skeletal muscle.

Electrodes placed in specific locations on the extremities and torso detect the currents reaching the skin. These electrodes (sensors) are configured to produce leads (also called “derivations”). The outputs of these leads are then amplified, filtered, digitized, stored, and displayed to produce an electrocardiographic (ECG) recording. These signals are typically processed by pattern recognition software to provide a preliminary interpretation, subject to careful clinician review.

Genesis of Cardiac Electrical Fields

Ionic Currents and Cardiac Electrical Fields During Activation.

Transmembrane ionic currents (**see Chapter 34**) are ultimately responsible for the potentials recorded as an ECG. As sites along a cardiac fiber are activated, the polarity of the transmembrane potential converts from negative to positive, as represented in the typical cardiac action potential. Thus, sites on a cardiac fiber that have already undergone excitation have positive transmembrane potentials (i.e., the inside of the cell is positive relative to the outside of the cell), whereas more distal sites still in a resting state have negative transmembrane potentials (i.e., the inside of the cell is negative relative to the outside).

This reversal of polarity along a fiber creates a flow of positively charged current from the already activated to the more distal, inactivated portions of the fiber. As activation of multiple adjacent fibers proceeds, an activation *wavefront* is produced that moves in the direction of activation and that generates an electrical field characterized by positive potentials ahead of the front and negative potentials behind it.

An electrode senses positive potentials when an activation front is moving toward it and senses negative potentials when the activation front is moving away from it. The magnitude of the potential recorded by an electrode at any site is directly proportional to the average rate of change of intracellular potential, as determined by action potential shapes; directly proportional to the size of the wavefront; inversely proportional to the square of the distance from the activation front to the recording site; and

directly proportional to the cosine of the angle between the direction of activation spread and a line drawn from the site of activation to the recording site. Thus, if activation proceeds directly toward an electrode such that the angle between the direction of activation to the location of the electrode equals zero (and its cosine equals 1), the voltage sensed by the electrode will be maximal. In contrast, if activation proceeds in a direction perpendicular to that direction (cosine equals 0), the sensed potential will be zero.

Cardiac Electrical Field Generation During Recovery.

The cardiac electrical field during recovery phases differs in several important ways from that during activation. First, the gradient of intercellular potentials and thus the direction of current flow during recovery are the opposite of those described for activation. As a cell undergoes recovery, its intracellular potential becomes progressively more negative. For a cardiac fiber, the intracellular potential of the region whose recovery has progressed further is more negative than that of the adjacent, less recovered region. Intracellular currents then flow from the less recovered toward the more recovered portion of the fiber. That is, recovery wavefronts will have an orientation opposite that of activation wavefronts.

The strength of the recovery front also differs from that of the activation front. As noted, the strength of a wavefront is proportional to the rate of change in transmembrane potential. Rates of change in transmembrane potential during the recovery phases of the action potential are considerably slower than during activation, and thus the strength of the recovery wavefronts during recovery is less than during activation.

The rate of movement of the activation and recovery wavefronts is a third difference between activation and recovery. Activation is rapid (as short as 1 millisecond in duration) and occurs over only a small distance along the fiber. Recovery, by contrast, lasts 100 milliseconds or longer and occurs simultaneously over extensive portions of the heart.

These features result in ECG differences between activation and recovery patterns. All other factors being equal (an assumption that often is not true, as described later), ECG waveforms generated during recovery of a fiber with uniform recovery properties would be of opposite polarity, lower amplitude, and longer duration than those generated by activation.

Role of Transmission Factors.

The activation and recovery fields are perturbed by the complex three-dimensional physical environment in which they are generated. These transmission factors include the biophysical characteristics of the heart itself as well as those of the surrounding organs and tissues.

The most important *cardiac factor* is the presence of connective tissue between cardiac fibers that disrupts efficient electrical coupling of adjacent fibers. Waveforms recorded from fibers with little or no intervening connective tissue are narrow in width and smooth in contour, whereas those recorded from tissues with abnormal fibrosis are prolonged and sometimes exhibit prominent notching.

Extracardiac factors include the effects of all the tissues and structures that lie between the activation region and the body surface, including intracardiac blood, lungs, skeletal muscle, subcutaneous fat, and skin. These tissues alter the intensity and the orientation of the cardiac field because of differences in the electrical resistivity of adjacent tissues within the torso. For example, intracardiac blood has much lower resistivity (approximately 160 Ω cm) than the lungs (~2150 Ω cm).

Physical factors also reflect basic laws of physics. Potential magnitudes change in proportion to the square of the distance between the heart and recording electrode. One consequence of this principle is that eccentricity of the heart within the chest affects the surface waveforms. The right ventricle and

anteroseptal aspect of the left ventricle are closer to the anterior chest wall than are other parts of the left ventricle and atria. Therefore, ECG potentials will be higher on the anterior than on the posterior chest, and the amplitudes of waveforms projected from the anterior left ventricle to the chest wall will be greater than those generated by posterior regions.

An additional physical factor affecting the recording of cardiac signals is *cancellation*. When two or more wavefronts are simultaneously active during activation (or repolarization) and have different orientations, the vectorial components of the wavefronts may augment (if oriented in the same directions) or cancel (if oriented in opposite directions) each other when viewed from remote electrode positions. The magnitude of this effect is substantial. During the inscription of both the QRS and the ST-T waves, as much as 90% of cardiac activity is obscured by cancellation effects.

As a result of these transmission factors, body surface potentials (1) have an amplitude of only 1% of the amplitude of transmembrane potentials, (2) are smoothed in detail so that they have only a general spatial relationship to the underlying cardiac events, (3) preferentially reflect electrical activity in some cardiac regions over others, and (4) represent only limited amounts of total cardiac electrical activity.

Recording Electrodes and Leads Systems

Electrode Characteristics.

The standard clinical ECG is recorded from electrodes placed on each of the four extremities and six placed on the chest.[1] These electrodes are connected to form *leads* that record the potential difference between two electrodes. One electrode is designated as the positive input. The potential at the other (negative) electrode is subtracted from the potential at the positive electrode to yield the *bipolar potential*. The actual potential at either electrode is not known; only the difference between them is recorded.

In some cases, as described later, multiple electrodes are electrically connected together to form the negative member of the bipolar pair. This electrode network is commonly referred to as a *compound* or *reference electrode*. The lead then records the potential difference between a single electrode serving as the positive input (the *exploring electrode*) and the potential in the reference electrode.

The clinical ECG is performed using 12 leads: three standard *limb leads* (leads I, II, and III), six *precordial leads* (leads V_1 through V_6), and three *augmented limb leads* (leads aVR, aVL, and aVF). Specifics of electrode placement and definitions of the positive and negative inputs for each lead are presented in **Table 12.1**.

TABLE 12.1

Location of Electrodes and Lead Connections for the Standard 12-Lead ECG and Additional Leads

LEAD TYPE	POSITIVE INPUT	NEGATIVE INPUT
Standard Limb Leads*		
I	Left arm	Right arm
II	Left leg	Right arm
III	Left leg	Left arm
Augmented Limb Leads		
aVR	Right arm	Left arm plus left leg
aVL	Left arm	Right arm plus left leg
aVF	Left leg	Left arm plus right arm
Precordial Leads†		
V_1	Right sternal margin, fourth intercostal space	Wilson central terminal
V_2	Left sternal margin, fourth intercostal space	Wilson central terminal
V_3	Midway between V_2 and V_4	Wilson central terminal
V_4	Left midclavicular line, 5th intercostal space	Wilson central terminal
V_5	Left anterior axillary line at same horizontal plane as for V_4 electrode	Wilson central terminal
V_6	Left midaxillary line at same horizontal plane as for V_4 electrode	Wilson central terminal
V_7	Posterior axillary line at same horizontal plane as for V_4 electrode	Wilson central terminal
V_8	Posterior scapular line at same horizontal plane as for V_4 electrode	Wilson central terminal
V_9	Left border of spine at same horizontal plane as for V_4 electrode	Wilson central terminal

*Limb electrodes should be placed near the wrists and ankles or, at a minimum, distal to the shoulders and hips.

†The right-sided precordial leads V_3R to V_6R are placed in mirror-image positions on the right side of the chest.

Standard Limb Leads.

The standard limb leads record the potential differences between two limbs, as detailed in **Table 12.1** and illustrated in **Fig. 12.1 (top)**. Lead I registers the potential difference between the left arm (positive electrode) and right arm (negative electrode); lead II displays the potential difference between the left leg (positive electrode) and right arm (negative electrode); and lead III records the potential difference between the left leg (positive electrode) and left arm (negative electrode). The electrode on the right leg serves as an electronic reference that reduces noise and is not included in these lead configurations.

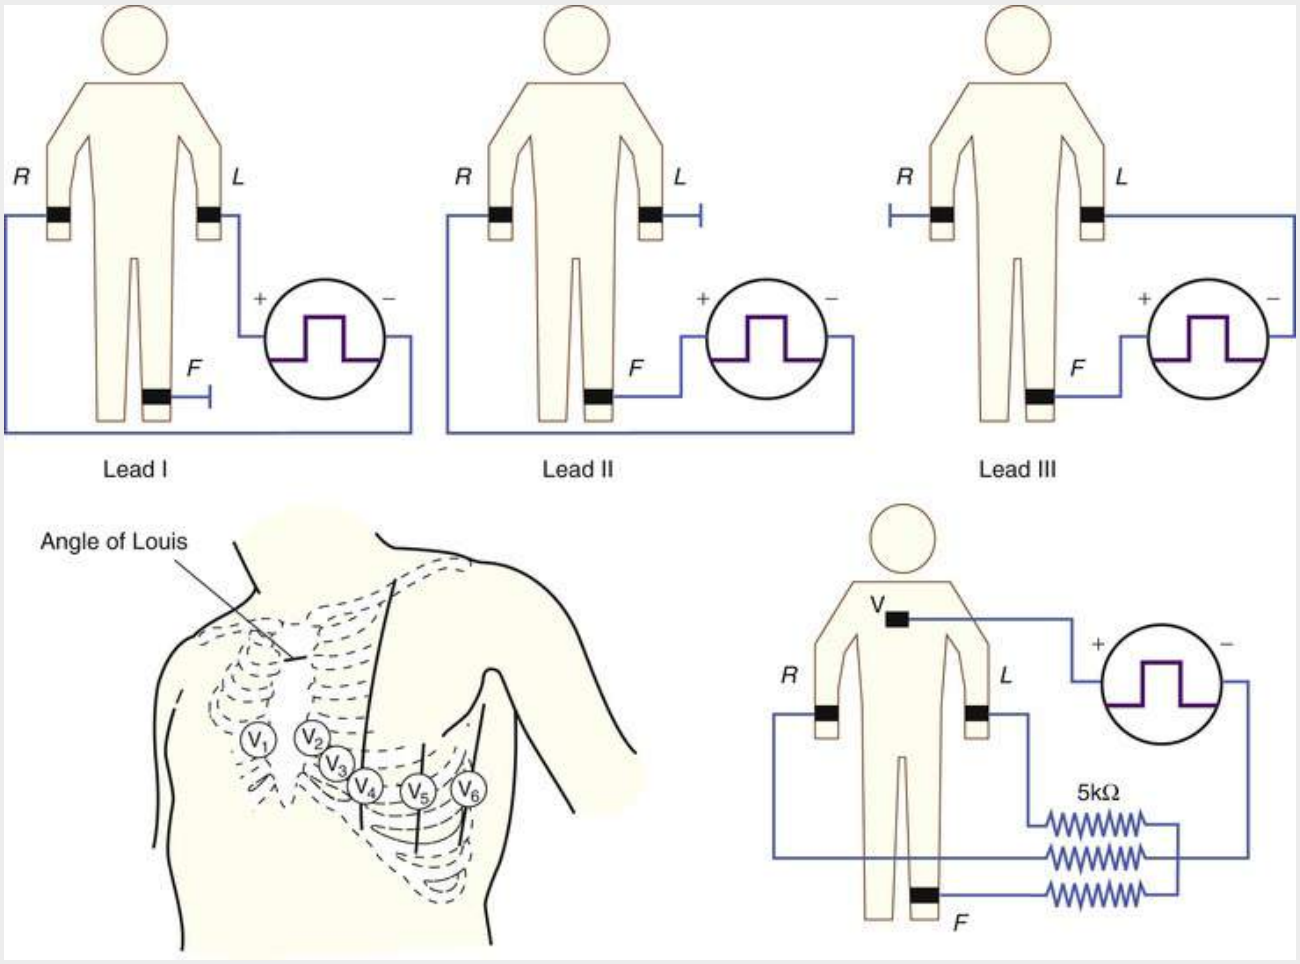

FIGURE 12.1 **Top,** Electrode connections for recording the standard limb leads I, II, and III and the augmented limb leads aVR, aVL, and aVF, with electrodes on the right arm, left arm, and left foot. **Bottom,** Electrode locations and electrical connections for recording a precordial lead. *Left,* The positions of the exploring electrode (V) for the six precordial leads. *Right,* Connections to form the Wilson central terminal for recording a precordial (V) lead. Five-thousand ohm resistors (5kΩ) are connected to each limb electrode when constructing the Wilson central terminal.

The electrical connections for each of these leads can be represented as a vector oriented from its negative toward the positive pole. These vectors form a triangle, known as the *Einthoven triangle,* in which the potential in lead II equals the vectorial sum of potentials sensed in leads I and III, that is:

$$I + III = II$$

Precordial Leads and the Wilson Central Terminal.

The precordial leads register the potential at each of the six specific torso sites (**see Fig. 12.1, bottom left panel**) in relation to a reference potential. For this purpose, an exploring electrode is placed at each of six specific precordial sites and connected to the positive input of the recording system (**see Fig. 12.1, bottom right**). The negative input is the mean value of the potentials recorded at each of the three limb electrodes, referred to as the *Wilson central terminal* (WCT).

The potential in each V lead can be expressed as:

$$V_i = E_i - WCT$$

where

$$WCT = (LA + LL + RA)/3$$

and V_i is the potential recorded in precordial lead i, E_i is the voltage sensed at the exploring electrode for lead V_i, and WCT is the potential in the composite Wilson central terminal.

The potential recorded by the Wilson central terminal remains relatively constant during the cardiac cycle, and the output of a precordial lead is determined predominantly by time-dependent changes in the potential recorded at that site.* Thus the potentials registered by these leads preferentially reflect activity in cardiac regions near the electrode, with lesser contributions by potential generated from more distant cardiac sources.

Augmented Limb Leads.

The three augmented limb leads are designated aVR, aVL, and aVF. For lead aVR, the exploring electrode (**Fig. 12.2**) that forms the positive input is the right arm electrode, for lead aVL it is the left arm electrode, and for aVF it is the left leg electrode. The reference potential for these leads is formed by connecting the two limb electrodes that are not used as the exploring electrode. For lead aVL, for example, the exploring electrode is on the left arm, and the reference electrode is the combined output of the electrodes on the right arm and the left foot.

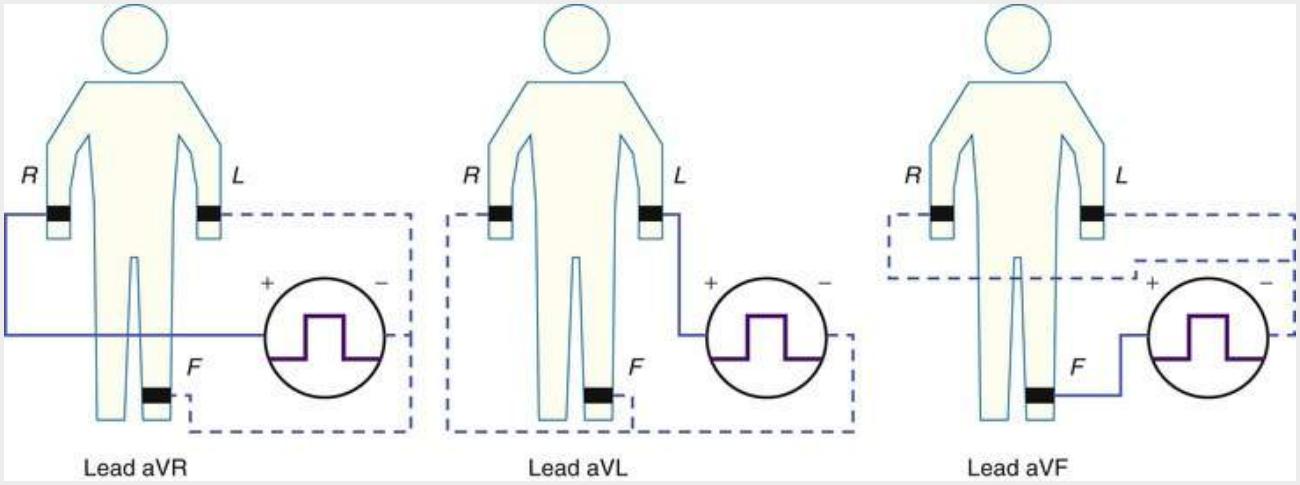

FIGURE 12.2 Electrode locations and electrical connections for recording the augmented limb leads aVR, aVL, and aVF. *Dotted lines* indicate connections to generate the reference electrode potential.

Thus,

$$aVR = RA - (LA + LL)/2$$

$$aVL = LA - (RA + LL)/2$$

and

$$aVF = LL - (RA + LA)/2$$

This modified reference system produces a larger-amplitude signal than if the full Wilson central terminal were used as the reference electrode. When the Wilson central terminal was used, the output was small, in part because the same electrode potential was included in both the exploring and the reference potential inputs. Eliminating this duplication results in a theoretical 50% increase in amplitude.

The three standard limb leads and the three augmented limb leads are aligned in the *frontal plane* of the torso. The six precordial leads are aligned in the *horizontal plane* of the chest.

The 12 leads are usually divided into subgroups corresponding to the cardiac regions to which they may be most sensitive. Various definitions of these groupings have been offered in the literature. For example, anterior lead groups have been defined as including V_1 through V_4 or only V_2 and V_3, and leads I and aVL have been described as being lateral or anterobasal. These designations are nonspecific, and the recommendation of expert committees has been not to use them in ECG interpretation, except in the case of estimating the location of certain types of myocardial infarction.[2]

Other Lead Systems.

Expanded lead systems that are frequently used include recordings from additional electrodes placed on the right precordium to assess right ventricular abnormalities such as right ventricular infarction,[2] and on the left posterior torso (**see Table 12.1**) to detect acute posterolateral infarctions. Electrodes placed higher on the anterior torso than normal may also help detect abnormalities such as the Brugada pattern and its variants (**see Chapters 33 and 37**).

Other lead sets have sought to minimize movement artifacts during exercise and long-term monitoring (**see Chapters 13 and 35**) by placing limb electrodes on the torso rather than near the ankles and wrists as recommended. The resulting waveforms may differ substantially from those recorded from the standard ECG sites with altered QRS and ST-T wave patterns in all 12 leads. These differences change the mean QRS axis and may impact the diagnostic accuracy of criteria of, for example, ventricular hypertrophy and myocardial infarction.[1] Thus these alternative lead sets should not be used to record a diagnostic ECG.

Less frequently used lead systems include those designed to record a *vectorcardiogram* (VCG), which depicts the orientation and strength of a single cardiac vector representing overall cardiac activity throughout the cardiac cycle. Electrode sets including 80 or more electrodes that sense cardiac potentials over large portions of the torso have been used to display the spatial distributions as well as the amplitudes of potentials throughout the cardiac cycle. Also, electrodes may be passed into the esophagus to enhance detection of atrial activity in, for example, the diagnosis of various arrhythmias (**see Chapter 35**).

Hexaxial Reference Frame and the Electrical Axis

Each ECG lead can be represented as a vector, which is referred to as the *lead vector*. As previously noted, for leads I, II, and III, the lead vectors are directed from the negative electrode toward the positive one, as from the right arm to the left arm for lead I (**Fig. 12.3, left**). For an augmented limb and for a precordial lead, the origin of the lead vector passes through the midpoint of the axis connecting the electrodes that comprise the reference electrode. That is, for lead aVL, the vector points from the midpoint of the axis connecting the right arm and left leg electrodes toward the left arm (**Fig. 12.3, left**). For each precordial lead, the lead vector points from the center of the triangle formed by the three standard limb leads to the precordial electrode site (**Fig. 12.3, right**).

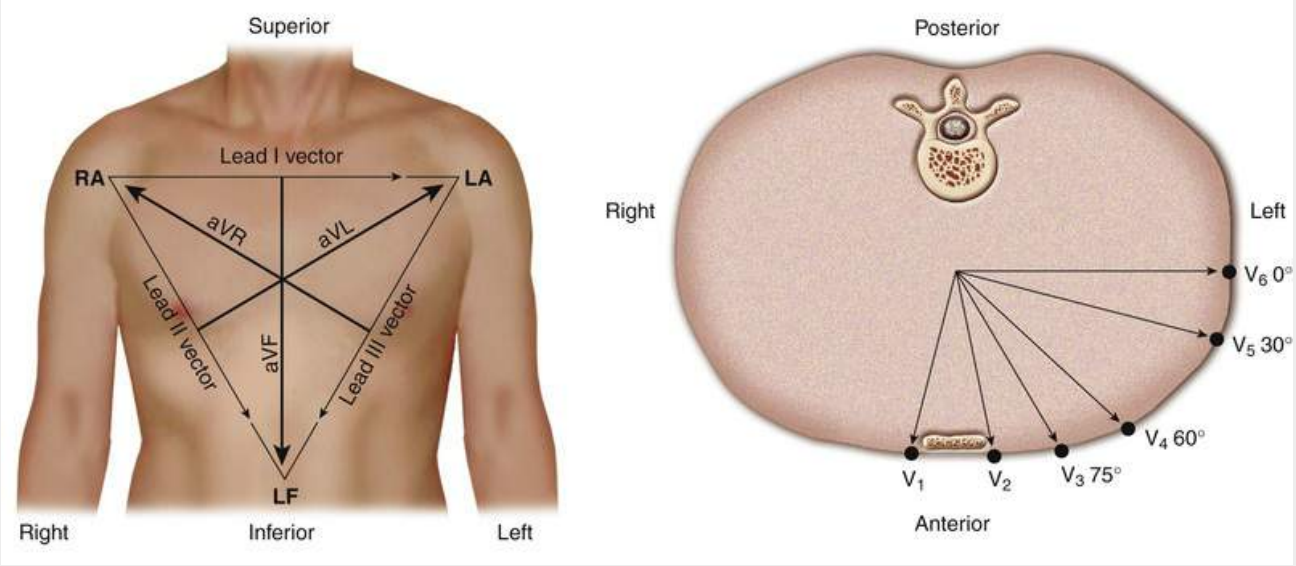

FIGURE 12.3 Lead vectors for the three standard limb leads, the three augmented limb leads (*left*), and the six unipolar precordial leads (*right*). *LA,* Left arm; *LF,* left foot; *RA,* right arm.

Instantaneous cardiac activity also can be approximated as a single vector, the *heart vector,* representing the vectoral sum of the activity of all active wavefronts. This vector's location, orientation, and intensity vary from instant to instant as cardiac activation proceeds. The amplitude of the recorded waveform in a lead then equals the length the projection of the heart vector onto the lead vector.

The lead axes of the six frontal plane leads can be superimposed to produce the *hexaxial reference system.* As depicted in **Fig. 12.4**, the six lead axes divide the frontal plane into 12 segments, each subtending 30 degrees.

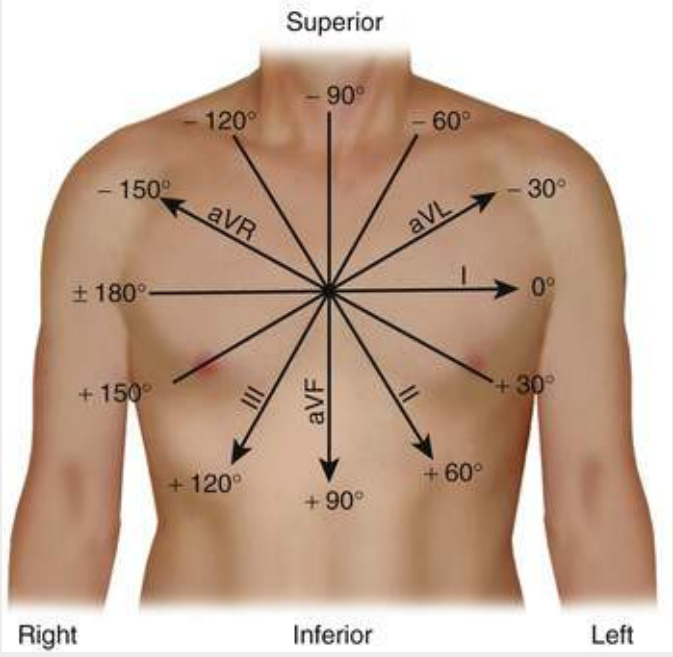

FIGURE 12.4 The hexaxial reference system constructed from the lead axes of the six frontal plane leads. The lead axes of the six frontal plane leads have been rearranged so that their centers overlie one another. Positive ends of each axis are labeled with the name of the lead.

This presentation allows calculation of the *mean electrical axis* of the heart. The orientation of the mean electrical axis represents the direction of activation in a theoretical “average” cardiac fiber. This direction is determined by the properties of the cardiac conduction system and properties of the

myocardium. Differences in the relation of cardiac to torso anatomy contribute relatively little to shifts in the axis.

The process for computing the mean electrical axis during ventricular activation in the frontal plane is illustrated in **Fig. 12.5**. First, the mean electrical force (i.e., the heart vector) as recorded in each lead is estimated by computing the area under the QRS waveform, measured as millivolt-milliseconds, in that lead. Areas above the baseline (the TP segment; see later) are assigned a positive polarity, and those below the baseline are assigned a negative polarity. The overall area equals the sum of the positive and the negative areas.

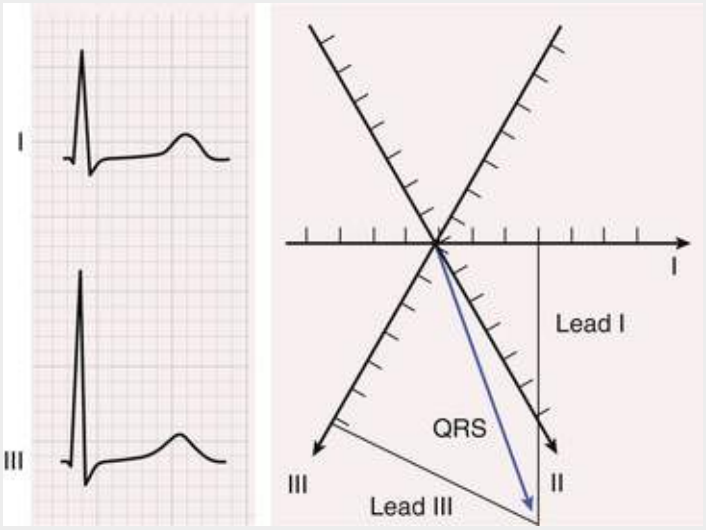

FIGURE 12.5 Calculation of the mean electrical axis during ventricular depolarization from the areas under the QRS complex in leads I and III. Magnitudes of the areas of the two leads are plotted as vectors on the appropriate lead axes, and the mean QRS axis is the sum of these two vectors. (From Mirvis DM. Electrocardiography: a Physiologic Approach. St Louis: Mosby–Year Book; 1993.)

Second, the area in each lead (typically, two are chosen) is represented as a vector oriented along the appropriate lead axis in the hexaxial reference system. The mean electrical axis equals the resultant sum of the (two) vectors.

An axis directed toward the positive end of the lead axis of lead I, that is, oriented directly away from the right arm and toward the left arm, is designated as being directed at 0 degrees. Axes oriented in a clockwise direction from this arbitrary zero level are assigned positive values, and those oriented in a counterclockwise direction are assigned negative values, as discussed further below.

The mean electrical axis during ventricular activation in the horizontal plane can be computed in an analogous manner by using the areas under and lead axes of the six precordial leads (**see Fig. 12.3, right**). A horizontal plane axis located along the lead axis of lead V_6 is assigned a value of 0 degrees; axes directed more anteriorly have positive values.

This approach can also be applied to compute the mean electrical axis for other phases of cardiac activity. Thus the mean force during atrial activation is represented by the areas under the P wave and the mean force during ventricular recovery by the areas under the ST-T wave.

Electrocardiographic Processing and Display Systems

ECG recording using computerized systems involves several steps: (1) signal acquisition, (2) data transformation, waveform recognition, and feature extraction, (3) diagnostic classification, and (4) display of the final ECG.

Signal Acquisition.

Signal acquisition includes amplifying the recorded signals, converting the analog signals into digital form, and filtering the signals to reduce noise. The standard amplifier gain for routine electrocardiography is 1000. Lower (e.g., 500, or *half-standard*) or higher (e.g., 2000, or *double-standard*) gains may be used to compensate for unusually large or small signals, respectively.

Analog signals are converted to a digital form at rates of 1000 samples per second (1000 hertz, Hz) to as high as 15,000 Hz. Too low a sampling rate may miss brief, high-frequency signals, such as notches in QRS complexes or pacemaker spikes, and may result in altered waveform morphologies. Too fast a sampling rate may introduce artifacts, including high-frequency noise, and will generate excessive amounts of data necessitating extensive digital storage capacity.

ECG potentials are filtered to reduce unwanted, distorting signals. Low-pass filters reduce the distortions caused by high-frequency interference from, for example, muscle tremor and nearby electrical devices; high-pass filters reduce the effects of body motion or respiration. For routine electrocardiography, the standards set by professional groups require an overall bandwidth of 0.05 to 150 Hz for adults.[1] Narrower filter settings, such as 1 to 30 Hz, as typically used in rhythm monitoring, will reduce baseline "wander" related to motion and respiration but may result in significant distortion of both the QRS complex (including width, amplitude, and Q wave patterns) and the ST-T wave.

ECG amplifiers include a capacitor stage between the input and output; they are *capacitor-coupled*. The ECG may be modeled as a time-varying or alternating current (AC) signal producing the waveforms superimposed on a fixed direct current (DC) baseline. Capacitor-coupling blocks unwanted DC potentials, such as those produced by the electrode interfaces, while permitting flow of AC signals, which account for the waveform shape. The elimination of the DC potential from the final product, however, means that ECG potentials will not be calibrated against an external reference level (e.g., a ground potential). Clinical ECG potentials are measured in relation to another portion of the waveform that serves as a baseline. The TP segment, which begins at the end of the T wave of one cardiac cycle and ends with the onset of the P wave of the next cycle (as detailed later), usually is the most appropriate internal ECG baseline (e.g., for measuring ST-segment deviation).

Data Transformation, Waveform Identification, and Feature Extraction.

The multiple cardiac cycles are recorded for each lead and are overlaid electronically to form a single representative beat for each lead. This reduces the effects of minor beat-to-beat variation in the waveforms and random noise. In addition, the averaged waveforms from each lead are overlaid on each other to measure intervals.[1]

Diagnostic Classification.

These measurements are then compared with specific diagnostic criteria to establish the interpretation of the ECG. A lexicon of preferred diagnostic statements has been proposed.[3] In some cases the criteria are derived from physiologic constructs and constitute the sole basis for a diagnosis, with no anatomic or functional correlation. For example, the criteria for intraventricular conduction defects are diagnostic without reference to an anatomic standard.

For other diagnoses, criteria are based on statistical correlations between anatomic or physiologic findings and ECG measurements in large populations (e.g., criteria for ECG diagnosis of ventricular hypertrophy). For such population-based criteria, the diagnosis is not absolute but represents a statistical probability that a structural abnormality exists based on the presence or absence of a specified set of ECG findings. Because different populations may be studied and different ECG and structural measurements may be included in the analyses, numerous criteria with highly varying accuracies have

been developed for common clinical conditions.

Display.

Cardiac potentials are most often displayed as the classic scalar ECG, which depicts the potentials recorded from each lead as a function of time. Amplitudes are displayed on a scale of 0.1 mV/mm on the vertical axis and time as 40 msec/mm on the horizontal scale. Leads generally are displayed in three groups—the three standard limb leads, followed by the three augmented limb leads, followed by the six precordial leads.

Alternative display formats have been proposed in which the six limb leads are displayed in the sequence of the frontal plane reference frame[4] (**see Fig. 12.4**). In addition, the polarity of lead aVR is reversed. Based on this scheme, waveforms are ordered as follows: lead aVL, lead I, negative lead aVR, lead II, lead aVF, and lead III. Advantages of this system may include facilitating estimation of the electrical axis by presenting the leads in the order in which they appear on the frontal plane reference frame and emphasizing the relevance of abnormalities in lead aVR by reversing its polarity.

*The precordial electrodes and the augmented limb leads have often been referred to as "unipolar" leads. However, true unipolar leads register the potential at one site in relation to an absolute zero potential. Referring to these leads as unipolar leads is based on the imprecise notion that the Wilson central terminal represents a true zero potential. Classifying these leads as "bipolar" more rigorously reflects the recognition that the reference electrode is not at exactly zero potential.

The Normal Electrocardiogram

The waveforms and intervals that make up the standard ECG are displayed in **Fig. 12.6**, and a normal 12-lead ECG is shown in **Fig. 12.7**. The *P wave* is generated by activation of the atria, the *PR interval* corresponds to the duration of atrioventricular conduction, the *QRS complex* is produced by the activation of the two ventricles, and the *ST-T wave* reflects ventricular recovery.

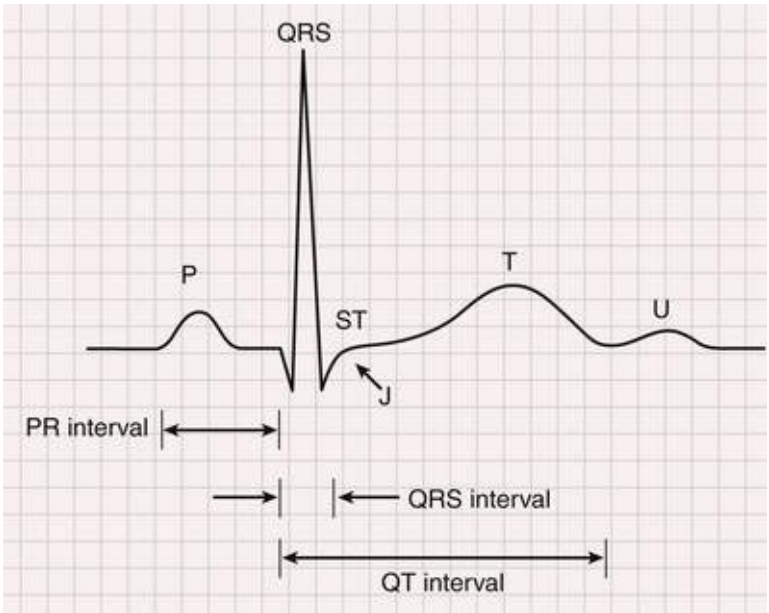

FIGURE 12.6 The waves and intervals of a normal electrocardiogram. (From Goldberger AL, Goldberger ZD, Shvilkin S. Goldberger's Clinical Electrocardiography: a Simplified Approach. 9th ed. Philadelphia: Saunders; 2017.)

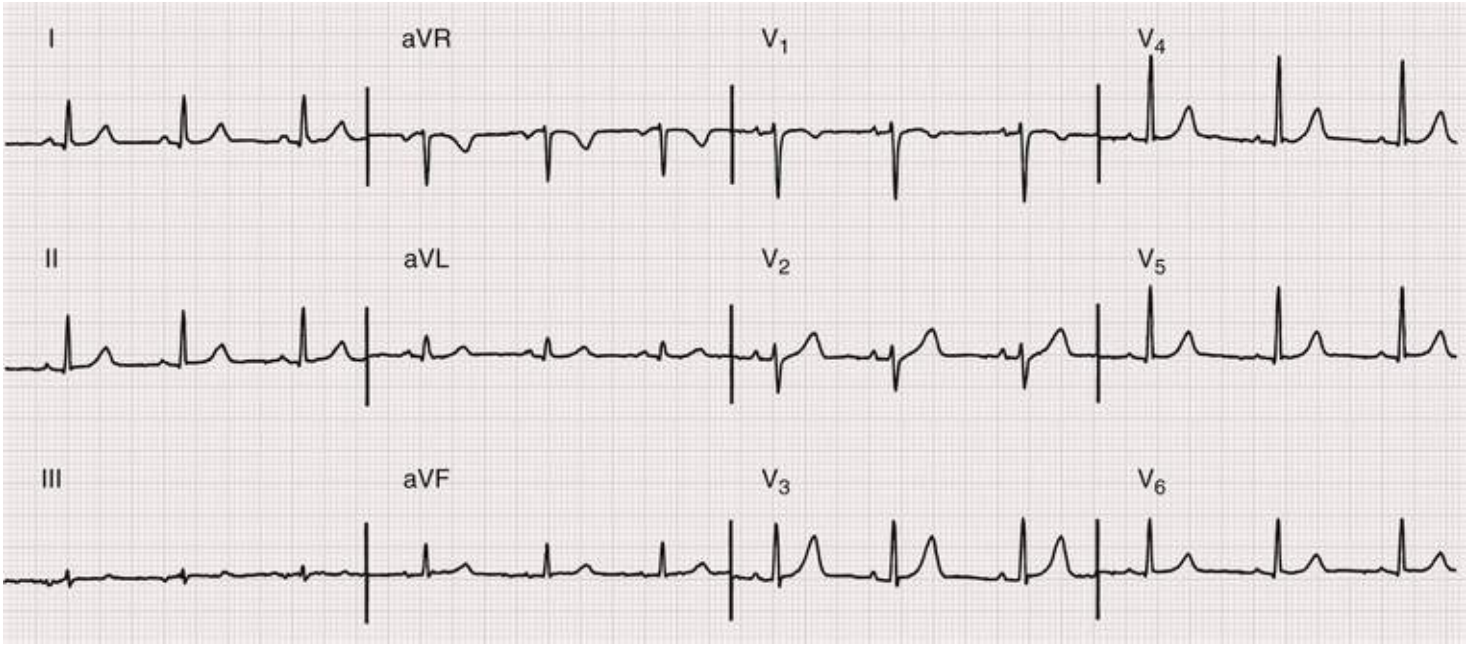

FIGURE 12.7 Normal ECG recorded from a 48-year-old woman. The *vertical lines* of the grid represent time intervals, with lines spaced at 40-millisecond intervals. *Horizontal lines* represent voltage amplitude, with lines spaced at 0.1 mV intervals. Every fifth line on each axis is darkened. The heart rate is approximately 76 beats/min (with physiologic variations due to respiratory sinus arrhythmia); the PR interval, QRS, and QTc durations measure approximately 140, 84, and 400 milliseconds, respectively; and the mean QRS axis is approximately +35 degrees.

Table 12.2 lists the classic normal values for the various intervals and waveforms of the ECG. The range of normal values of these measurements reflects the substantial intra- and interindividual variability in ECG patterns. Intraindividual differences in ECG patterns may even occur between ECGs recorded days, hours, or even minutes apart because of technical issues (e.g., changes in electrode position) or the biophysical effects of changes in, for example, posture, temperature, eating, or heart rate.

TABLE 12.2

Normal Values for Durations of ECG Waves and Intervals in Adults

WAVE OR INTERVAL	DURATION (msec)
P wave duration	<120
PR interval	<200
QRS duration	<110-120*
QT interval (corrected)	≤440-450*

*See text for further discussion.

Variability between individuals may reflect differences in age, sex, race, body habitus, heart orientation, and physiology. For example, in the Atherosclerosis Risk in Communities (ARIC) Study, the normal range for measures of ventricular repolarization, including both duration (QT interval) and magnitude (ST-segment amplitude) varied substantially between males and females and between white and African American cohorts.[5] The observed upper limits for ST-segment elevation (see later) in leads V_1 and V_2 were 50 microvolts (μV) higher in white men than in white women and almost 100 μV higher in African American men than in white men.

The observed differences among various subpopulations suggests that a single range of normal values for all individuals may be inappropriate and may lead to errors in diagnosis. Computerized ECG interpretation may facilitate the identification and use of different criteria for various population subgroups based on, for example, age, sex, and race.

Atrial Activation and the P Wave

Atrial Activation.
Atrial activation begins with impulse generation in the atrial pacemaker complex in or near the sinoatrial node (**see Chapter 34**). Once the impulse leaves this pacemaker site, atrial activation proceeds anteriorly toward the lower portion of the right atrium and inferiorly toward the atrioventricular (AV) node and the top of the interventricular septum.

The left atrium is most frequently activated after the onset of right atrial activation by propagation across Bachmann's bundle, which extends from the anterior right atrium to the left atrium near the right upper pulmonary vein. Activation continues in both atria during much of the middle of the overall atrial activation period, with left atrial activation continuing after the end of right atrial activation.

The Normal P Wave

The normal P wave reflects these activation patterns. Thus, P waves are positive in lead II and usually in leads I, aVL, and aVF, reflecting the leftward and inferior direction of activation during sinus rhythm. This corresponds to a mean frontal plane P wave axis of approximately 60 degrees. The pattern in leads aVL and III may be upright or downward, depending on the exact orientation of the mean P wave axis.

In the horizontal plane, atrial early activation of the right atrium generates a P wave that is oriented primarily anteriorly. Later, it shifts leftward and posteriorly as activation proceeds over the left atrium. Thus the P wave in the right precordial leads is typically upright. In lead V_1 and occasionally in lead V_2, the P wave may be biphasic with an initial positive deflection followed by a later negative wave. The P wave in the more lateral leads is upright and reflects continual right-to-left spread of the activation fronts. Variations in this pattern may reflect differences in pathways of interatrial conduction, described later.

The upper limit for a normal P wave duration is conventionally set at 120 milliseconds, as measured in the lead with the widest P wave. The amplitude in the limb leads normally is less than 0.25 mV, and the terminal negative deflection in the right precordial leads normally is less than 0.1 mV in depth.

Atrial Repolarization

The potentials generated by atrial repolarization are not usually seen on the surface ECG because of their low amplitude (usually <100 µV) and because they may be superimposed on the much higher-amplitude QRS complex. They may be observed as a low-amplitude wave with a polarity opposite that of the P wave (T_a *wave*) during AV block. Deviation of the PR segment has special significance in influencing ST-segment patterns during exercise testing and as an important marker of acute pericarditis (**see Chapter 83**) or atrial infarction (**see Chapters 58 and 59**).

Heart Rate Variability

Analysis of beat-to-beat changes in heart rate and related dynamics, termed *heart rate variability*, can provide insight into neuroautonomic control mechanisms and their perturbations with aging, disease, and drug effects (**see Chapters 35 and 36**). For example, relatively high-frequency (0.15 to 0.4 Hz) fluctuations are mediated primarily by vagus nerve traffic, such that heart rate increases during inspiration and decreases during expiration. Attenuation of this respiratory sinus arrhythmia at rest is a marker of physiologic aging and also occurs with diabetes mellitus, congestive heart failure, and a wide range of

other conditions that alter autonomic tone modulation. Relatively lower-frequency (0.05 to 0.15 Hz) physiologic oscillations in heart rate appear to be jointly regulated by sympathetic and parasympathetic interactions. A variety of complementary signal-processing techniques have been developed to analyze heart rate variability and its interactions with other physiologic signals, including time domain statistics, frequency domain techniques based on spectral methods, and newer computational tools derived from nonlinear dynamics and complex systems theory.[6] However, the relationship between specific autonomic effects (e.g., sympathovagal balance) cannot be reliably inferred from the ratio of relatively low- to higher-frequency components.

Atrioventricular Node Conduction and the PR Segment

The *PR segment* is the usually isoelectric region beginning with the end of the P wave and ending with the onset of the QRS complex. It forms part of the *PR interval* that extends from the onset of the P wave to the onset of the QRS complex. The normal PR interval measures 120 to 200 milliseconds in duration in adults and is best determined from the lead with the shortest PR intervals (to avoid missing various preexcitation syndromes) (**see Chapter 37**).

The PR segment serves as the temporal bridge between atrial activation and ventricular activation. This time period includes atrial repolarization and slow conduction within the AV node plus the more rapid conduction through the ventricular conduction system. The segment ends when enough ventricular myocardium has been activated to initiate the QRS complex.

The PR segment appears isoelectric because the potentials generated by atrial recovery and transmission through the conduction system structures are too small to be detected on the body surface at amplifier gains used in clinical electrocardiography. Signals from elements of the conduction system can be recorded from intracardiac recording electrodes placed against the base of the interventricular septum near the bundle of His (**see Chapter 35**).

Ventricular Activation and the QRS Complex

Normal ventricular activation is a complex process that depends on interactions between the physiology and anatomy of both the specialized ventricular conducting system and the ventricular myocardium.

Ventricular Activation.

Ventricular activation (and thus the QRS complex) is the net product of two events: endocardial activation and transmural activation of the two ventricles. *Endocardial* activation is guided by the anatomic distribution and physiology of the His-Purkinje system. The rapid conduction within the broadly dispersed ramifications of this treelike (*fractal*) system results in the rapid, synchronized activation of multiple endocardial sites and the depolarization of most of the endocardial surfaces of both ventricles within several milliseconds.

The sequence of left ventricular endocardial activation, depicted in **Fig. 12.8**, begins at three sites: (1) the anterior paraseptal wall of the left ventricle, (2) the posterior paraseptal wall of the left ventricle, and (3) the center of the left side of the septum. These loci generally correspond to the sites of insertion of the fascicles of the left bundle branch.

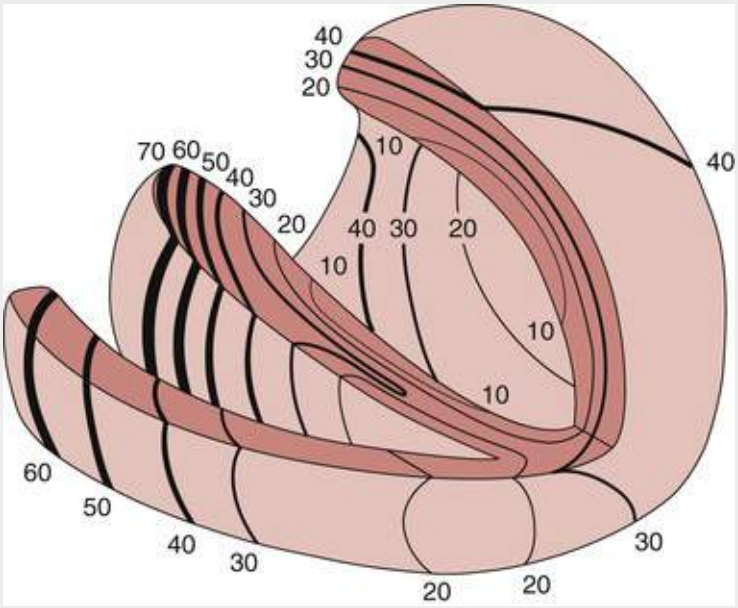

FIGURE 12.8 Activation sequence of the normal right and left ventricles. Portions of the left and right ventricles have been removed so that the endocardial surfaces of the ventricles and the interventricular septum can be seen. *Isochrone lines* connect sites that are activated at equal instants after the earliest evidence of ventricular activation. (From Durrer D. Electrical aspects of human cardiac activity: a clinical-physiological approach to excitation and stimulation. Cardiovasc Res 1968;2:1.)

Septal activation begins on the left side and spreads across the septum from left to right and from apex to base. Wavefronts sweep from these initial sites of activation in anterior and inferior and then superior directions to activate the anterior and lateral walls of the left ventricle. The posterobasal areas of the left ventricle are the last to be activated.

Excitation of the right ventricular endocardium begins near the insertion point of the right bundle branch near the base of the anterior papillary muscle and spreads to the free wall. The final areas to be activated are the pulmonary conus and the posterobasal right ventricular areas.

Thus, in both ventricles, the overall endocardial excitation pattern begins on septal surfaces and sweeps down toward the apex and then around the free walls to the basal regions, in an apex-to-base direction.

Activation then moves across the ventricular wall from endocardium to epicardium. Excitation of the endocardium begins at sites of Purkinje–ventricular muscle junctions and proceeds by muscle cell–to–muscle cell conduction in an oblique direction toward the epicardium. Multiple regions of both ventricles are usually activated simultaneously, resulting in substantial cancellation of the electrical forces that are generated, as previously described.

Normal QRS Complex

QRS patterns are described by the sequence of waves constituting the complex. An initial negative deflection is called the *Q wave*, the first positive wave is the *R wave*, and the first negative wave after a positive wave is the *S wave*. A second upright wave following an S wave, when present, is an *R′ wave*. Tall waves are denoted by uppercase letters and smaller ones by lowercase letters. A monophasic negative complex is referred to as a *QS complex*. Thus, for example, the overall QRS complex may be described as qRS if it consists of an initial small negative wave (q) followed by a tall upright one (R) and a deep negative one (S). In an RSr′ complex, initial tall R and S waves are followed by a small positive wave (*r′*). In each case, the deflection must cross the baseline to be designated a discrete wave.

Changes in waveform patterns that do not cross the baseline result in notches or slurs. A *notch* is an

abrupt change in waveform direction similar to the underlying wave but that does not cross the baseline. A *slur* is a more gradual change in the slope or rate of change in waveform amplitude. These patterns may reflect disruptions in the normally smooth patterns of activation by scarring, as with ventricular hypertrophy or infarction. Slurring of the initial QRS is caused by anomalous ventricular activation via a bypass tract with Wolff-Parkinson-White preexcitation (**see Chapter 37**).

Early QRS Patterns.

The complex pattern of activation described earlier may be simplified into two forces, the first representing septal activation and the second representing left ventricular free wall activation (**Fig. 12.9**). Initial activation of the interventricular septum is oriented from left to right in the frontal plane and anteriorly in the horizontal plane, corresponding to the anatomic position of the septum within the chest. This wavefront produces an initial positive wave in leads with axes directed to the right (lead aVR) or anteriorly (lead V_1). Leads with axes directed to the left (leads I, aVL, V_5, and V_6) will register initial negative waves known as *septal q waves*. These initial forces are normally of low amplitude and are brief (<30 msec in duration). The absence of these septal q waves, with QS complexes evident in the right precordial leads or with initial R waves in leads I, V_5, and V_6, is a common normal variant and not associated with any specific cardiac disease.

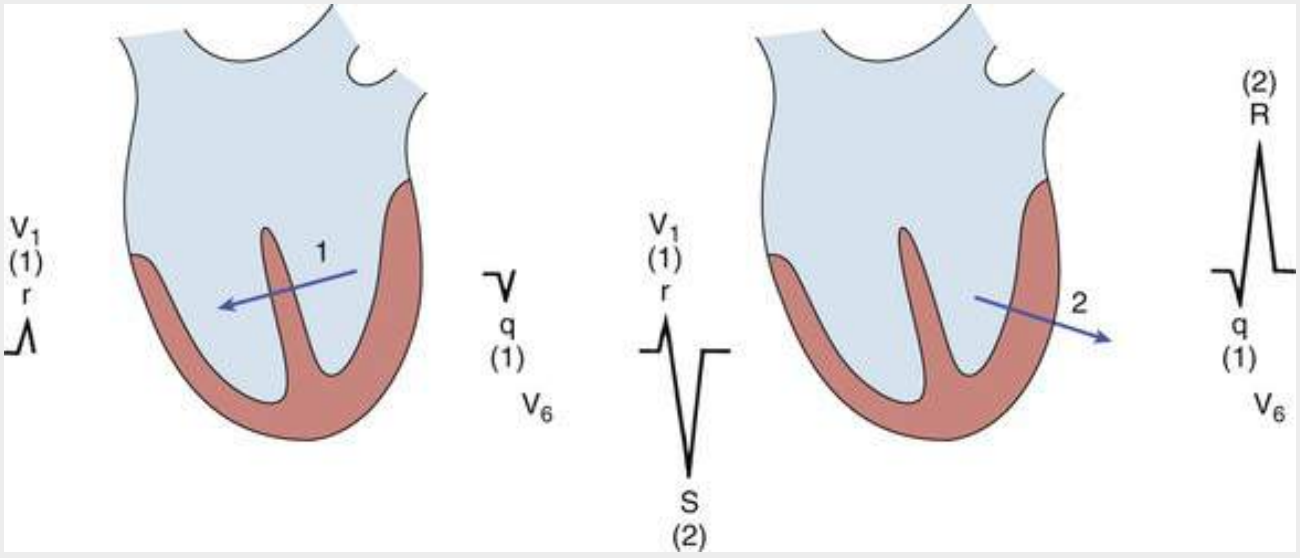

FIGURE 12.9 Schematic representation of ventricular depolarization as two sequential vectors representing septal (*left*) and left ventricular free wall (*right*) activation. QRS waveforms generated by each stage of activation in leads V_1 and V_6 are shown.

Mid- and Late QRS Patterns.

Subsequent parts of the QRS complex reflect activation of the free walls of the left and right ventricles. Because right ventricular muscle mass is considerably smaller than that of the left ventricle, most of the electrical activity it generates in canceled by the much greater forces from the left ventricle so that it contributes little to normal QRS complexes. Thus, the normal QRS can be considered to represent only septal and left ventricular activity with little meaningful oversimplification, as depicted in **Fig. 12.9**.

The complex interrelationships among cardiac position, conduction system function, and ventricular geometry result in a wide range of normal QRS patterns in the limb leads. The QRS pattern in leads II,

III, and aVF may be predominantly upright, with qR complexes, or these leads may show rS or RS patterns. Lead I may record a qR pattern or an isoelectric RS pattern.

Electrical Axis.

The wide range of QRS patterns can be interpreted by referring to the hexaxial reference system in **Fig. 12.4**. The normal mean QRS axis in adults lies between −30 degrees and +90 degrees. If the mean axis is near 90 degrees, the QRS complex in leads II, III, and aVF will be predominantly upright, with qR complexes; lead I will record an isoelectric RS pattern because the heart vector lies perpendicular to the lead axis. If the mean axis is nearer 0 degrees, the patterns will be reversed; leads I and aVL will register a predominantly upright qR pattern, and leads II, III, and aVF will show rS or RS patterns. This variation largely reflects physiologic differences in conduction system; the anatomic position of the heart within the torso has a minor role.

Mean QRS axes more positive than +90 degrees (usually with an rS pattern in lead I) represent *right axis deviation*. Axes between +90 and +120 degrees are referred to as *moderate right axis deviation*, and those between +120 and +180 degrees, *marked right axis deviation*. Axes more negative than −30 degrees (with an rS pattern in lead II) represent *left axis deviation*, with axes between −30 and −45 degrees called *moderate* and those between −45 and −90 degrees called *marked left axis deviation*.

Mean axes lying between −90 degrees and −180 degrees (or, equivalently, between +180 degrees and +270 degrees) are referred to as *extreme axis deviations* or, alternatively, as *right superior axis deviations*. The term *indeterminate axis* is applied when all six extremity leads show biphasic (QR or RS) patterns, indicating a mean axis that is perpendicular to the frontal plane. This finding may occur as a normal variant or may be seen in a variety of pathologic conditions discussed later.

Normal QRS patterns in the precordial leads follow an orderly progression from right (V_1) to left (V_6). In leads V_1 and V_2, initial r waves generated by septal activation are followed by S waves (an rS pattern) reflecting leftward and posterior activation of the left ventricular free wall (i.e., proceeding away from the precordial electrode).

Patterns in midprecordial leads V_3 and V_4 reflect the movement of the activation front in the ventricular free wall. It first approaches the exploring electrode and then moves leftward and posteriorly to more remote regions of the left ventricle and away from the exploring electrode. This sequence generates an R or r wave as it moves toward the electrode, followed by an S wave as it moves away from the electrode to produce rS or RS complexes.

As the exploring electrode moves further to the left, the R wave becomes more dominant and the S wave becomes smaller (or is totally lost) because of the longer time period during which the activation front moves toward the positive end of the electrode. In the leftmost leads (i.e., leads V_5 and V_6), the normal pattern also includes the septal q wave, to produce a qR (or qRs) pattern.

Thus, in the precordial leads, the QRS complex usually is characterized by a consistent progression from an rS complex in the right precordial leads, to an RS pattern in the midprecordial leads, and to a qR pattern in the left precordial leads. The site at which the pattern changes from a dominant S wave to a dominant R wave pattern is known as the *transition zone*. It normally occurs between lead V_3 and V_4. Transition zones that are shifted to the right (e.g., to lead V_2) are *early transitions*, and those shifted leftward (e.g., to V_5 or V_6) are *delayed transitions*.

Normal variability in QRS amplitudes, axes, and QRS duration are related to demographic and physiologic factors. QRS amplitudes are greater in men than in women and higher in African Americans than in those of other races. In addition, left ventricular mass (within the normal range) affects both QRS amplitude and duration. Higher-than-normal amplitudes are characteristic of chamber hypertrophy and

conduction defects. Low-amplitude QRS complexes, that is, complexes with overall amplitudes of less than 0.5 mV in all frontal plane leads and less than 1.0 mV in the precordial leads, may occur as a normal variant or as a result of cardiac (e.g., multiple infarctions, infiltrative cardiomyopathies, myocarditis) or extracardiac (e.g., pericardial effusion, anasarca, chronic obstructive pulmonary disease, pneumothorax) conditions.

QRS Duration

The upper normal value for QRS duration traditionally is set at less than 120 milliseconds, measured in the lead with the widest QRS complex. Recent epidemiologic studies have suggested that the median QRS duration may be shorter, as low as 100 milliseconds in men and 92 milliseconds in women.[7]

The Intrinsicoid Deflection.

As previously described, an electrode overlying the ventricular free wall will record a rising R wave as transmural activation proceeds toward it. Once the activation front reaches the epicardium, the full thickness of the wall under the electrode will be in an active state. After that moment, the electrode will register negative potentials as activation proceeds in remote cardiac areas. The sudden reversal of potential produces a sharp downslope, the *intrinsicoid deflection,* that approximates the timing of activation of the epicardium under the electrode. The term *R wave peak time* is sometimes used with reference to this subinterval on the surface ECG.

Ventricular Recovery and the ST-T Wave

Genesis of Ventricular Recovery Potentials.

The ST-T wave reflects activity during the plateau phase (the *ST segment)* and the later repolarization phases (the *T wave*) of the cardiac action potential.

ST-T wave patterns depend on the interaction of two factors: (1) the direction of intracellular current flow in cardiac fibers during repolarization and (2) the sequence of recovery within the ventricles. As described earlier, cellular current flow during recovery phases is directed away from less recovered to more recovered regions, that is, in a direction opposite to that during activation.

Ventricular repolarization, like activation, occurs in characteristic geometric patterns, with differences in recovery times between regions of the left ventricle and across the ventricular wall. In general, the repolarization sequence is the opposite of the activation sequence; that is, regions activated later have shorter action potentials and begin to repolarize before areas activated early. Thus, action potential durations are shorter in the anterobasal region than in the posteroapical region of the left ventricle. Similarly, action potential durations are shorter and repolarization begins earlier in the epicardium than in the endocardium.

In each case, the shortening of recovery time is greater than the delay in onset of activation so that the net resulting current flow will then be directed away from the basal left ventricle and the endocardium toward the apex and the epicardium. That is, repolarization current flow will be in the same direction as during activation.

The final result is that, in normal persons, QRS and ST-T wave patterns are relatively concordant. That is, the ST-T wave has approximately the same polarity as that of the QRS complex.

Evidence suggests that the regional differences in action potential duration are the major cause of ST-T wave,[8] with lesser contributions by transmural forces. Transmural differences may be augmented by the

presence of putative *midwall* or *M cells* that have action potentials longer than those of endocardial or epicardial cells.[9] In this model the ST-T wave begins when epicardial cells begin to recover ahead of both M cells and endocardial cells, with current flowing from midmyocardial and endocardial regions toward the epicardium. This initiates the rising portion of the ST-T wave, with the peak of the T wave corresponding to the end of epicardial repolarization.

The Normal ST-T Wave

The normal ST-T wave begins as a low-amplitude, slowly changing wave (the *ST segment*) that gradually evolves into a larger wave, the *T wave*. The onset of the ST-T wave is the *junction* or *J point*, and it is normally at or near the isoelectric baseline of the ECG (**see Fig. 12.7**). The level of the ST segment generally is measured at the J point or, in some applications such as exercise testing, 40 or 80 milliseconds after the J point.

The polarity of the ST-T wave generally is the same as the net polarity of the preceding QRS complex. Thus, T waves usually are upright in leads I, II, aVL, and aVF and the lateral precordial leads. T waves are normally negative in lead aVR and variable in leads III, V_1, and V_2.

The amplitude of the normal J point and ST segment varies with race, sex, and age.[5,10] It typically is greatest in lead V_2, and it is higher in young men than in young women and higher in African Americans than in whites. Recommendations[10] for the upper limits of normal J point elevation in leads V_2 and V_3 are 0.2 mV for men age 40 or older, 0.25 mV for men younger than 40, and 0.15 mV for women. In other leads the recommended upper limit is 0.1 mV for men and women. Higher levels, however, are common in normal persons, especially among athletes; in one report, 30% of athletes had ST elevation exceeding 0.2 mV in the anterior precordial leads.[11]

The J Wave

A *J wave* is a dome- or hump-shaped wave or notch that appears at the end of the QRS complex and that has the same polarity as the preceding QRS complex. It may be prominent as a normal variant (see later) and in certain pathologic conditions, such as systemic hypothermia (sometimes referred to as an *Osborn wave*) and in a set of conditions commonly referred to as the *J wave syndromes*. These syndromes include the *Brugada patterns* (**see Chapters 33 and 35**) and the *early repolarization pattern* (discussed later and in **Chapter 39**). Its origin has been postulated to be associated with a prominent notch in phase 1 of the action potentials on the epicardium (related to an augmented net outward current, I_{to}) but not on the endocardium, creating a transmural potential gradient leading to QRS notching and ST elevation.[12]

The U Wave

The T wave may be followed by an additional low-amplitude wave known as the *U wave*. This wave, usually less than 0.1 mV in amplitude, normally has the same polarity as the preceding T wave. The U wave is largest in the leads V_2 and V_3 and is most often seen at slow heart rates. Its electrophysiologic basis is uncertain. Suggestions include delayed repolarization in areas of the ventricle that undergo late mechanical relaxation, late repolarization of the Purkinje fibers, and long action potentials of (putative) midmyocardial M cells.

The QT Interval

The QT interval extends from the onset of the QRS complex to the end of the T wave. Thus, it includes the

total duration of ventricular activation and recovery and, in a general sense, reflects the duration of the ventricular action potential.

Accurately measuring the QT interval is challenging. Difficulties include identifying the beginning of the QRS complex and especially the end of the T wave, determining which lead(s) to use, and adjusting the measured interval for rate, QRS duration, and sex. Because the onset of the QRS and the end of the T wave do not occur simultaneously in every lead, the QT interval duration will vary from lead to lead by as much as 50 to 65 milliseconds (*QT dispersion*). In automated ECG systems, the QT interval typically is measured from a composite of all leads, with the interval beginning with the earliest onset of the QRS in any lead and terminating with the latest end of the T wave in any lead. When the interval is measured from a single lead, the lead in which the interval is the longest (most frequently lead V_2 or V_3) and in which a prominent U wave is absent (usually aVR or aVL) is preferred.

The normal QT interval is rate dependent, decreasing as heart rate increases. This corresponds to rate-related changes in the duration of the normal ventricular action potential. Numerous formulas have been proposed to correct the measured QT interval for this rate effect,[13] including one proposed by Bazett in 1920. The result is the *corrected QT interval*, or *QTc*, defined by the following equation:

$$QTc = QT/\sqrt{RR}$$

where the QT and RR intervals are measured in seconds. (The latter is considered as unitless for the calculation and the index is first calculated in seconds and often reported in milliseconds.) A joint report of the American Hospital Association (AHA), American College of Cardiology (ACC), and other professional organizations[10] suggested that the upper limit for QTc be set (in milliseconds) at 460 for women and 450 for men, and that the lower limit be set at 390 (although 360 for the latter has been suggested elsewhere).

The Bazett formula has limited accuracy in correcting for the effects of heart rate on the QT interval. Large database studies have shown that the QTc interval based on the Bazett formula remains significantly affected by heart rate, and that as many as 30% of normal ECGs may be diagnosed as having a prolonged QT interval when this formula is used.[14] The formula, in general, overcorrects the QT interval at high heart rates and undercorrects it at low rates.

Many other formulas and methods for correcting the QT interval for the effects of heart rate have been proposed, including linear, logarithmic, hyperbolic, and exponential functions. The AHA/ACC joint committee suggested using a linear regression function.[10] Several linear models have been proposed. One linear formula has been shown to be relatively insensitive to heart rate,[13] as follows:

$$QTc = QT + 1.75(HR - 60)$$

where HR is heart rate and the intervals are measured in milliseconds. Another commonly used correction is Fridericia's formula:

$$QT/(RR)^{0.33}$$

Other approaches include regression analyses based on the specific population being studied or computing individual-specific corrections to assess serial changes.

QT prolongation and shortening occur in numerous syndromes associated with tachyarrhythmias and sudden death (**see Chapters 37, 39 and 42**). A meta-analysis of 23 studies demonstrated that a 50-millisecond increase in the QT interval is associated with a relative risk (RR) of 1.20 for all-cause mortality and 1.29 for cardiovascular mortality.[14] Drug-induced prolongations and its relation to sudden death have made assessment of QT interval responses to new drugs an important topic for manufacturers and regulatory agencies.

Other Measures of Ventricular Recovery

The QRST Angle.

The concordance between the orientation of the normal QRS complex and the normal ST-T wave described earlier can be expressed vectorially. An angle can be visualized in three-dimensional space between the vector representing the mean QRS force and the vector representing the mean ST-T force. This angle is the *spatial QRST angle*. The angle between the two vectors in the frontal plane represents a reasonable simplification and normally is less than 90 degrees for women and 107 degrees for men.[15] Abnormalities of the QRST angle reflect abnormal relationships between the properties of activation and recovery. An analysis of the Third National Health and Nutrition Examination Survey (NHANES III) reported a significant increase in both all-cause and cardiovascular mortality over a 14-year period in persons with increased QRST angles.[15]

The Ventricular Gradient.

If the two vectors representing mean activation and mean recovery forces are added, a third vector known as the *ventricular gradient* is created. This vector represents the net area under the QRST complex. The ventricular gradient was originally conceptualized to assess the variability that exists in regional repolarization properties; the greater these differences, the larger will be the ventricular gradient. In addition, because changes in activation patterns produced by bundle branch block, for example, cause corresponding changes in recovery patterns (see later), no change in the ventricular gradient would be expected. The ventricular gradient should thus allow a measure of regional recovery properties that is independent of the activation pattern. This measurement has possible although unproven relevance to the genesis of reentrant arrhythmias that may be caused in part by abnormal regional variations in refractory periods.

Normal Variants

Numerous variations of these normal ECG patterns frequently occur in persons without heart disease. The presence of such findings without coexistent cardiac pathology is particularly common among athletes (**see Chapter 53**). These variations are important to recognize because they may be mistaken for significant abnormalities, leading to erroneous and potentially harmful diagnoses of heart disease.

T waves usually are inverted in all precordial leads at birth and become upright as time passes. However, T waves can remain inverted in the right precordial leads in normal adults (**Fig. 12.10**). This *persistent juvenile pattern*, with inverted T waves in leads to the left of V_1, occurs in 1% to 3% of adults and is more common in women than in men and more common in African Americans than in other racial or ethnic groups.

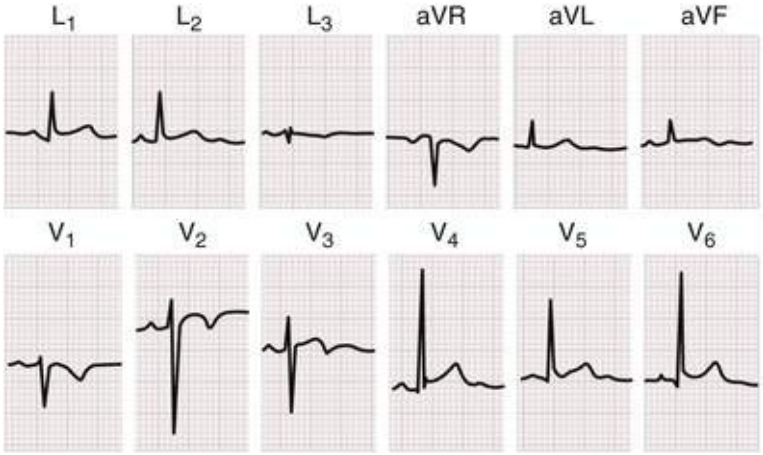

FIGURE 12.10 Normal tracing with a juvenile T wave inversion pattern in leads V_1, V_2, and V_3, as well as early repolarization pattern manifested by ST-segment elevation in leads I, II, aVF, V_4, V_5, and V_6. A J point notch is present in lead V_4. (Courtesy Dr. C. Fisch.)

Elevation of the J point and the following ST segment is common in normal persons. The pattern typically has a rapidly upsloping shape and is most prominent in the right and midprecordial leads (**Fig. 12.11**). This pattern occurs in as many as 30% of the general population[16] and is most prevalent in young adults, especially African American men and those who are athletically active. Its appearance is labile, being most prominent under conditions of increased vagal tone.

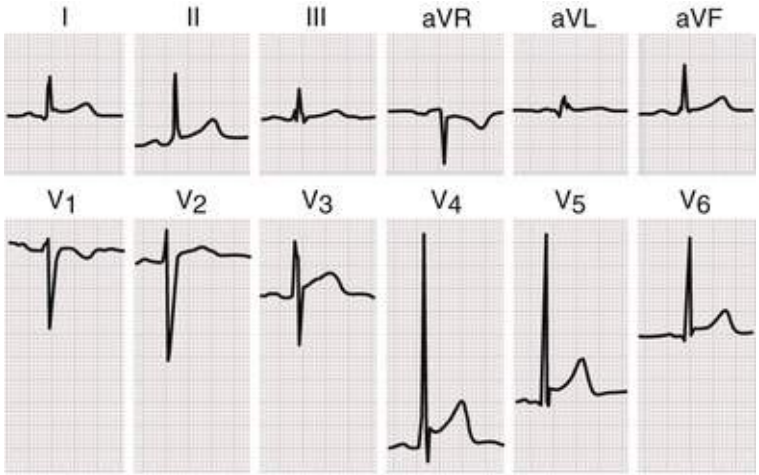

FIGURE 12.11 Normal variant pattern with the "early repolarization" pattern of a J point notch and ST-segment elevation. The ST-segment elevation and a J point notch are most marked in the midprecordial lead V_4. Reciprocal ST-segment depression and PR-segment depression are absent (except in lead aVR). (From Goldberger AL, Goldberger ZD, Shvilkin A. Goldberger's Clinical Electrocardiography: a Simplified Approach. 9th ed. Philadelphia: Elsevier; 2017.)

J point elevation is also often considered to represent the *early repolarization pattern* (**see Chapter 39**). Although diagnostic criteria for this pattern vary widely, recent recommendations by an expert panel[12] have suggested that this ECG diagnosis may be diagnosed if (1) there is a notch at the end of QRS complex or slur on the downstroke of the R wave, (2) the peak of the notch or J wave is 0.1 mV or greater in amplitude in two or more contiguous leads, excluding V_1 to V_3, and (3) the QRS duration is normal. Although commonly associated with these findings, ST-segment elevation is not required. The identification and the clinical significance of benign and potentially malignant variants of early repolarization patterns continue to be a subject of ongoing controversy and study (**see Chapters 33 and**

39).

The Abnormal Electrocardiogram

The prevalence of abnormal ECGs in the general population is substantial and increases progressively with age and in certain population groups. For example, screening ECGs revealed abnormalities requiring follow-up investigation in 2.5% of more than 32,000 high school students.[17] In contrast, abnormal ECGs were recorded in 36% of adults 70 to 79 years of age without overt cardiovascular disease.[18] Many of these abnormalities have prognostic as well as diagnostic import; a review of reports that included more than 173,000 persons demonstrated the prognostic value of six ECG abnormalities (ST-segment abnormalities, T wave abnormalities, combined ST-segment and T wave abnormalities, left ventricular hypertrophy, bundle branch block, and left axis deviation), with RR factors for subsequent cardiovascular events of 1.5 to 1.9.[19]

Atrial Abnormalities

Various pathophysiologic events can produce P wave abnormalities reflecting changes in (1) the origin of the initiating sinus node impulse that may affect atrial activation sequences, (2) conduction from the right to the left atrium that determines left atrial activation, or (3) the size and shape of the atria that determine the duration and path of atrial activation. These may result in abnormal patterns of activation and conduction, left atrial abnormalities, and right atrial abnormalities.

Abnormal Atrial Activation and Conduction.

Small shifts in the site of initial activation within or near the sinoatrial (SA) node or to ectopic sites within the atria can lead to major changes in the pattern of atrial activation and thus in the morphology of P waves. These shifts may occur as *escape rhythms* if the normal SA nodal pacemaker fails or as *accelerated atrial rhythms* if the automaticity of an ectopic site is enhanced (**see Chapter 37**).

P wave patterns may suggest the site of impulse formation and the path of subsequent activation. A negative P wave in lead I suggests activation beginning in the left atrium, and an inverted P wave in the inferior leads generally corresponds to a posterior atrial activation site. However, the correlations of P wave patterns with the location of origin are highly variable. Accordingly, these patterns, as a group, may be referred to as *atrial rhythms*, rather than assigned anatomic terms inferring a specific site of origin.

Interatrial block, with conduction delay between the atria, alters the duration and pattern of P waves.[20] When conduction from the right to the left atrium is delayed, the normal lag in left atrial activation relative to that of the right atrium increases. P wave duration is prolonged beyond 120 milliseconds, and P waves typically have two humps in lead II, with the first representing right atrial and the second reflecting left atrial activation.

With more advanced block, the sinus node impulses reach the left atrium only after passing inferiorly toward the atrioventricular junction and then superiorly through the left atrium. In such cases, P waves are wide and biphasic (an initial positive wave followed by a negative deflection) in the inferior leads.

Interatrial block is common, being found in approximately 10% of young adults and in as many as 60% of hospitalized adults. Although often associated with left atrial enlargement, it also is seen as an isolated conduction defect without concomitant structural abnormalities. It is an independent predictor of atrial fibrillation and other supraventricular tachyarrhythmias, and it has been associated with left atrial

thrombi and systemic embolization.

Left Atrial Abnormality

Anatomic abnormalities of the left atrium that alter the P waves include atrial dilation, atrial muscular hypertrophy, and elevated intra-atrial pressures. Because these pathophysiologic abnormalities often coexist and produce similar ECG effects, the resulting patterns are often referred to as *left atrial abnormality* (or *abnormalities*).[21]

Diagnostic Criteria.

Abnormalities in left atrial structure and function produce wide and notched P waves, with prominent terminal negative deflections in the right precordial leads. The most common criteria for diagnosing left atrial abnormality are listed in **Table 12.3** and illustrated in **Figs. 12.12 and 12.13**.

TABLE 12.3

Common Diagnostic Criteria for Left and Right Atrial Abnormalities

LEFT ATRIAL ABNORMALITY	RIGHT ATRIAL ABNORMALITY*
Prolonged P wave duration to >120 msec in lead II	Peaked P waves with amplitudes in lead II to >0.25 mV ("P pulmonale")
Prominent notching of P wave, usually most obvious in lead II, with interval between notches of >40 msec ("P mitrale")	Prominent initial positivity in lead V_1 or V_2 >0.15 mV
Ratio between duration of P wave in lead II and duration of PR segment >1.6	Increased area under initial positive portion of P wave in lead V_1 to >0.06 mm-sec
Increased duration and depth of terminal-negative portion of P wave in lead V_1 (P terminal force) so that area subtended by it >0.04 mm-sec	Rightward shift of mean P wave axis to >+75 degrees
Leftward shift of mean P wave axis to between −30 and −45 degrees	

*In addition to criteria based on P wave morphologies, right atrial abnormality is suggested by QRS changes as described in the text.

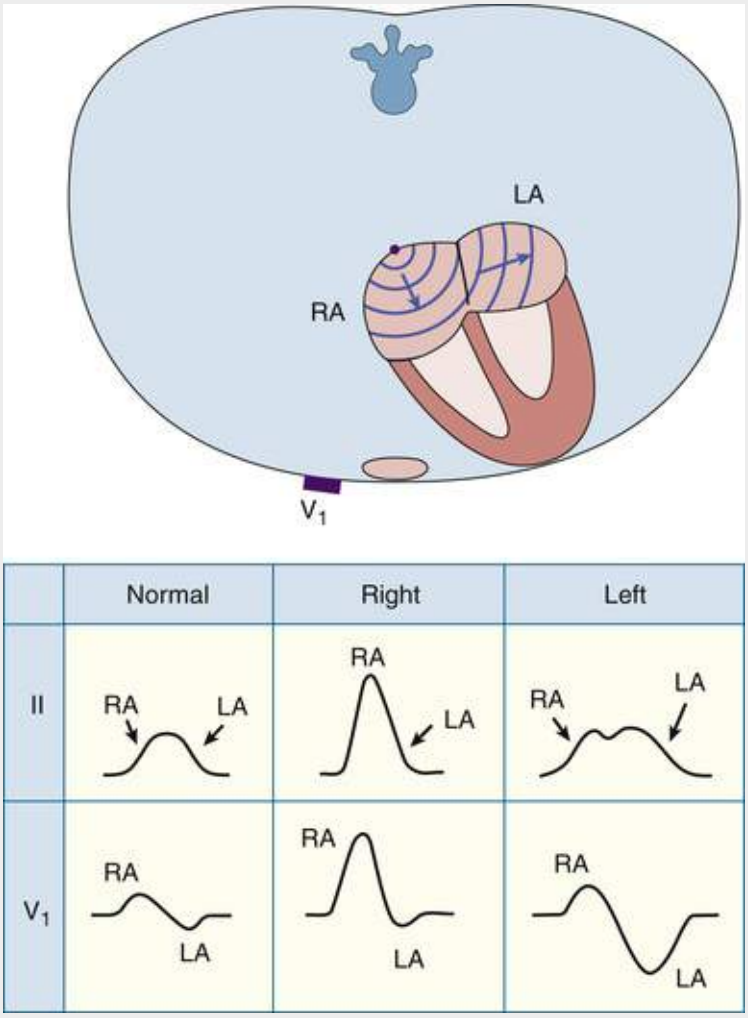

FIGURE 12.12 **Top,** Schematic representation of atrial depolarization. **Bottom,** P wave patterns associated with normal atrial activation (*left*) and with right atrial (*middle*) and left atrial (*right*) abnormalities. (Modified from Park MK, Guntheroth WG. How to Read Pediatric ECGs. 4th ed. St Louis: Mosby; 2006.)

FIGURE 12.13 Biatrial abnormality, with tall P waves in lead II (right atrial abnormality) and an abnormally large terminal negative component of the P wave in lead V_1 (left atrial abnormality). The P wave also is notched in lead V_5.

Mechanisms for the ECG Abnormalities.

Enlargement and prolonged activation time of the left atrium that is located posteriorly in the chest produces prolonged P wave duration, notching of P waves that is most prominent in inferolateral leads, and increased amplitude of terminal negative P wave forces in the right precordial leads. Widening of the P wave has also been associated with abnormal levels of fibrosis and fatty infiltration of the major atrial conduction pathways.[22]

Diagnostic Accuracy.

Recent studies correlating these ECG criteria with left atrial volumes determined by magnetic resonance imaging (MRI)[23] have demonstrated the limited accuracy of the criteria. A prolonged P wave duration has a high sensitivity (84%) but low specificity (35%). By contrast, bifid P waves and increased negative terminal P wave amplitude in lead V_1 have low sensitivities (8% and 37%, respectively) and high specificities (90% and 88%, respectively).

Clinical Significance.

The ECG features of left atrial abnormality are associated with more severe left ventricular dysfunction in patients with ischemic heart disease (**see Chapter 61**) and with more severe valve damage in patients with mitral or aortic valve disease (**see Chapters 68 to 70**). Patients with left atrial abnormalities also have a higher-than-normal incidence of atrial tachyarrhythmias, including atrial fibrillation, cerebrovascular accident (stroke), and all-cause and cardiovascular mortality[24] (**see Chapter 38**).

Right Atrial Abnormality

The ECG features of right atrial abnormality are illustrated in **Figs. 12.12 and 12.13**. As in the case of left atrial abnormality, the term *right atrial abnormality* may be used rather than designations such as "right atrial enlargement" that suggest a particular underlying pathophysiology.[21]

Diagnostic Criteria.

P wave amplitudes in the limb and right precordial leads typically are abnormally high, with normal durations. Criteria commonly used to diagnose right atrial abnormality are listed in **Table 12.3**. In addition to criteria based on P wave morphology, right atrial abnormality is suggested by certain QRS changes, including a qR-type pattern in the right precordial leads without evidence of myocardial infarction or low-amplitude QRS complexes in lead V_1 together with a threefold or greater increase in lead V_2.

Mechanisms for the ECG Abnormalities.

Greater right atrial mass and size generate greater electrical force early during atrial activation, producing taller P waves in limb leads and increasing the initial P wave deflection in leads such as lead V_1 that face the right heart. Because right atrial activation occurs early during the P wave, P wave duration is not prolonged, in contrast to the pattern with left atrial changes. It has also been suggested that downward displacement of the heart may be responsible for the increase in P-terminal force and tall P waves in patients with emphysema.[25]

Diagnostic Accuracy.

Imaging studies have shown that the ECG features of right atrial abnormality have limited sensitivity (7% to 17%) but high specificity (96% to 100%) for detecting anatomic right atrial enlargement.[25]

Clinical Significance.

Patients with chronic obstructive pulmonary disease and this ECG pattern (often referred to as P pulmonale) have more severe pulmonary dysfunction, with significantly reduced survival, than in others (**see Chapters 85 and 86**). However, comparison of ECG and hemodynamic parameters has not demonstrated a close correlation between P wave patterns and right atrial hypertension.

Other Atrial Abnormalities.

Patients with biatrial abnormalities may have ECG patterns reflecting each defect. Findings suggestive of biatrial abnormalities include large, biphasic P waves in lead V_1 and tall, broad P waves in leads II, III, and aVF (**see Fig. 12.13**).

Ventricular Hypertrophy

Left Ventricular Hypertrophy

Left ventricular hypertrophy (LVH) produces changes in the QRS complex, the ST segment, and the T wave. QRS changes include increased QRS amplitudes often with prolonged QRS durations, left axis deviation, notching or slurring of R waves, and patterns suggesting intraventricular conduction defects. The most characteristic finding is increased amplitude of the QRS complex. R waves in leads facing the left ventricle (i.e., leads I, aVL, V_5, and V_6) are taller than normal, and S waves in leads overlying the opposite side of the heart (i.e., V_1 and V_2) are deeper than normal. These changes are illustrated in **Fig. 12.14**.

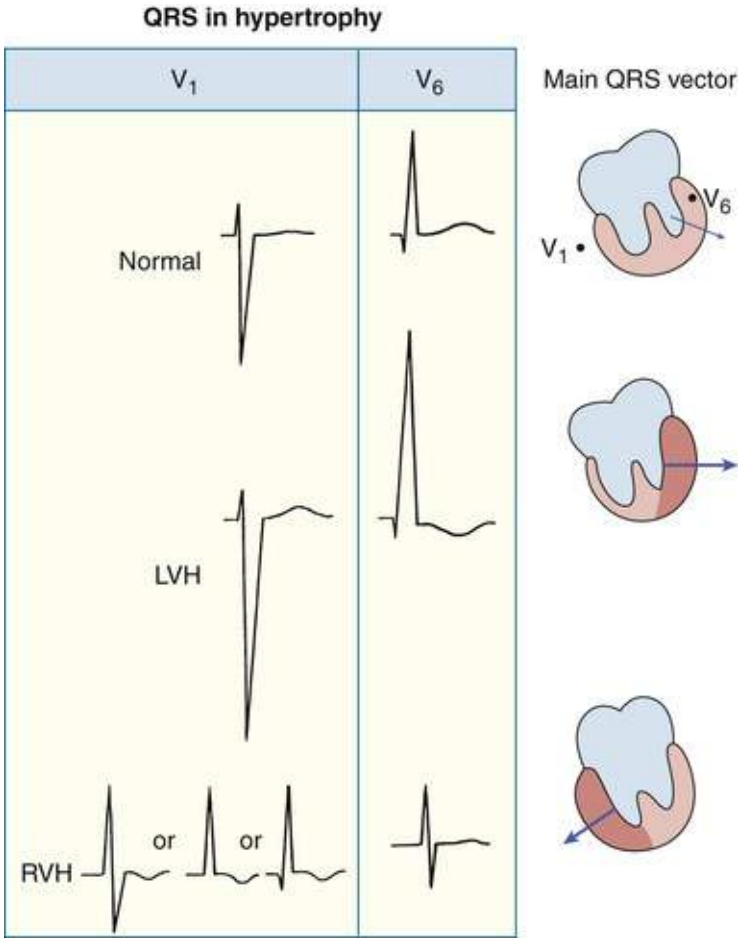

FIGURE 12.14 LVH increases the amplitude of electrical forces directed to the left and posteriorly. In addition, repolarization abnormalities can cause ST-segment depression and T wave inversion in leads with a prominent R wave. RVH can shift the QRS vector to the right, usually with an R, RS, or qR complex in lead V_1, especially when caused by severe pressure overload. T wave inversions may be present in the right-mid precordial leads. (From Goldberger AL, Goldberger ZD, Shvilkin A. Goldberger's Clinical Electrocardiography: a Simplified Approach. 9th ed. Philadelphia: Saunders; 2017.)

The ST segment may be normal or somewhat elevated in leads with tall R waves. In many patients, however, the ST segment is depressed and followed by an inverted T wave (**Fig. 12.15**) in leads I, II,

aVL, and V_5-V_6. In these cases the depressed ST segment is typically either flat or slopes downward from a depressed J point, and the T wave is asymmetrically inverted. These LVH-related repolarization changes usually occur in patients with QRS changes but may appear alone. Additional abnormalities may include prolongation of the QT interval and evidence of left atrial abnormality.

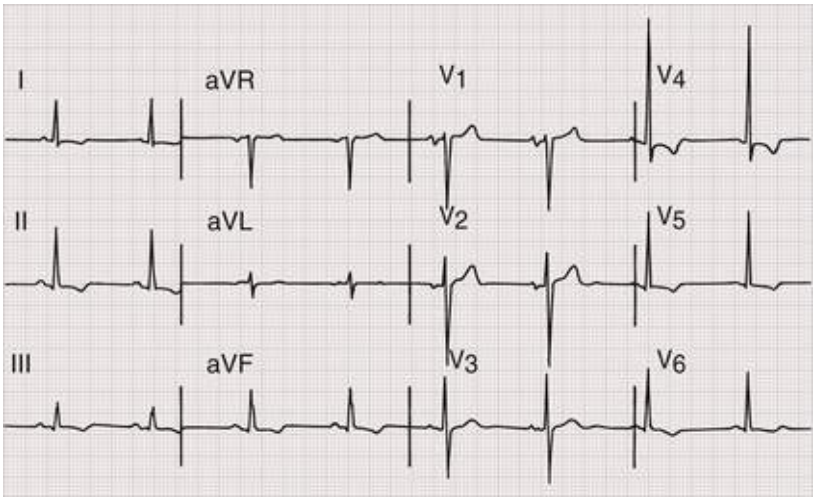

FIGURE 12.15 Marked LVH pattern with prominent precordial lead QRS voltages, ST-segment depression, and T wave inversion (compare with **Fig. 12.16**). Left atrial abnormality also is present.

These ECG features are most typical of LVH induced by pressure overload of the left ventricle, such as hypertension (**see Chapter 46**). Volume overload may produce a somewhat different pattern, including tall upright T waves, and sometimes narrow (<25 msec) but deep (≥0.2 mV) Q waves in leads I, aVL, and $V_{4\text{-}6}$ (**Fig. 12.16**) (**see Chapter 77**). These distinctions have limited value in identifying hemodynamic conditions, and their diagnostic use has been discouraged.[21]

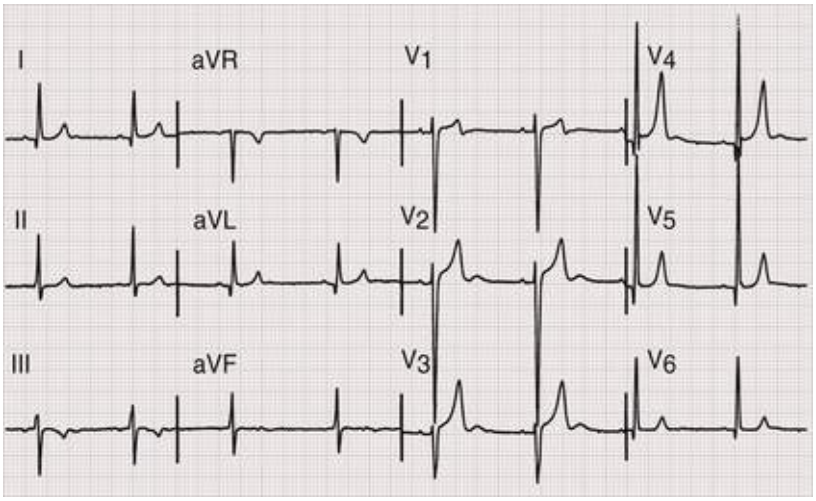

FIGURE 12.16 LVH pattern with prominent positive anterior T waves on an ECG from a patient with severe aortic regurgitation.

Mechanisms for the ECG Abnormalities.

ECG changes of LVH result from interrelated structural, biochemical, and bioelectric changes.[26,27]

Structural abnormalities include (1) an increase in the size of activation fronts moving across the thickened wall that generate higher body surface voltages, (2) thickened walls that require more time to fully activate, and (3) an increase in fibrosis resulting in fragmented and slower-than-normal conduction within the myocardium.

At the cellular level, hypertrophy is associated with a form of electrical remodeling.[27] This includes biochemical changes in gap junctions and ion channels that alter the intensity of current flow. Changes in fiber diameter and length and changes in myocyte branching patterns alter impulse propagation. The heterogeneous distribution of these abnormalities and intramural scarring associated with hypertrophy can disrupt smooth propagation of wavefronts to produce notching of the QRS complex.[28]

ST-T abnormalities may reflect any of several phenomena related to ventricular hypertrophy. These include primary disorders of repolarization that accompany the cellular processes of hypertrophy, and myocardial ischemia related to inadequate compensatory dilation of coronary arteries, inadequate growth of arterioles and capillaries in relation to the increased muscle mass, greater oxygen demand related to increased wall stress, and underlying coronary artery disease.

Diagnostic Criteria

Many sets of criteria to detect anatomic LVH have been developed based on these ECG abnormalities. Widely used criteria are listed in **Table 12.4**; Hancock and colleagues[21] have presented a comprehensive list.

TABLE 12.4

Common Diagnostic Criteria for Left Ventricular Hypertrophy (LVH)

MEASUREMENT	CRITERIA
Sokolow-Lyon voltages	$SV_1 + RV_5 > 3.5$ mV
	RaVL > 1.1 mV
Romhilt-Estes point score system*	Any limb lead R wave or S wave > 2.0 mV (3 points)
	or SV_1 or $SV_2 \geq 3.0$ mV (3 points)
	or RV_5 to $RV_6 \geq 3.0$ mV (3 points)
	ST-T wave abnormality, no digitalis therapy (3 points)
	ST-T wave abnormality, digitalis therapy (1 point)
	Left atrial abnormality (3 points)
	Left axis deviation ≥ −30 degrees (2 points)
	QRS duration ≥ 90 msec (1 point)
	Intrinsicoid deflection in V_5 or $V_6 \geq 50$ msec (1 point)
Cornell voltage criteria	SV_3 + RaVL > 2.8 mV (for men)
	SV_3 + RaVL > 2.0 mV (for women)
Cornell regression equation	Risk of LVH = $1/(1 + e^{-exp})$†
Cornell voltage duration measurement	QRS duration × Cornell voltage > 2436 mm-sec‡
	QRS duration × sum of voltages in all leads > 1742 mm-sec

*Probable LVH is diagnosed with totals of 4 points, and definite LVH is diagnosed with totals of 5 or more points.

†For persons in sinus rhythm, exp = 4.558 − 0.092 (SV_3 + RaVL) − 0.306 TV_1 − 0.212 QRS − 0.278 $PTFV_1$ − 0.559 (sex). Voltages are in mV, QRS is QRS duration in msec, $PTFV_1$ is the area under the P terminal force in lead V_1 (in mm-sec), and sex = 1 for men and 2 for women. LVH is diagnosed as present if exp < −1.55.

‡For women, add 8 mm.

PTF, P terminal force; *$PTFV_1$,* P terminal force in lead V_1.

Most methods assess the presence or absence of LVH as a binary function, indicating that structural LVH either does or does not exist, based on an empirically determined set of criteria. For example, the widely used Sokolow-Lyon and Cornell voltage criteria require that voltages in specific leads exceed certain values. The Romhilt-Estes point score system assigns point values to amplitude and other criteria,

including QRS axis and P wave patterns; definite LVH is diagnosed with a score of 5 points or more and probable LVH with a score of 4 points. The Cornell voltage duration method includes measurement of QRS duration as well as amplitudes. Other methods seek to quantify left ventricular mass as a continuum. Diagnosis of LVH can then be based on a computed mass that exceeds an independently determined threshold. One set of criteria applying this approach is used for the Cornell regression equation, shown in **Table 12.4**.

Diagnostic Accuracy.

The accuracy of these criteria depend on the ultimate outcome being predicted. This may be, as most frequently practiced, the presence or absence of structural left ventricular hypertrophy or enlargement. Alternatively, as recently emphasized,[27,28] the ECG criteria may be applied to predict clinical outcomes, as discussed later.

The reported diagnostic accuracies of these ECG criteria to detect structural LVH are highly variable, differing with the specific criteria tested, the imaging method used to determine anatomic measurements, and the population studied. Most studies have reported low sensitivity and high specificity. One review of 21 studies relying on echocardiographic measures reported a median sensitivity for six commonly used criteria ranging from 10.5% to 21% and a median specificity of 89% to 99%.[29]

More recent studies relying on cardiac MRI have similarly reported low sensitivities and high specificities of standard ECG criteria for detecting structural LVH. An analysis of the Multi-Ethnic Study of Atherosclerosis (MESA) results demonstrated sensitivities of 5.7 to 26.0% and specificities of 88.7 to 99.2% for commonly applied ECG measures.[23] Because of the variability in the accuracy of the various criteria from one trial to another, no single criterion can be established as the preferred method.[21]

Accuracy also varies with sex (with women having lower QRS amplitudes than men), race (with African Americans having higher QRS amplitudes than whites), age (with lower voltages with increasing age), and body habitus (with obesity reducing QRS amplitudes).[21]

Clinical Significance

Although the low sensitivities of ECG measurements limit the value of these criteria as screening tools for structural LVH in both the general population and cohorts with a higher prevalence of LVH, the significance of an ECG diagnosis of LVH may also be measured by its ability to identify patients at high risk for future cardiac clinical events.[27,28] Thus, ECG findings may provide independent, clinically important information that reflect the underlying cellular abnormalities that may impact prognosis.[27]

The presence of ECG criteria for LVH identifies a subset of the general population and of those with hypertension, aortic stenosis, and other conditions with a significantly increased risk for cardiovascular morbidity, including new-onset heart failure, atrial and ventricular arrhythmias, and cardiovascular and all-cause mortality. For example, data from the ARIC study demonstrated that the incidence of all-cause mortality in the general population rose progressively with increasing scores using the Romhilt-Estes criteria; rates increased from 13.8 per 1000 person-years with a score of zero to 60.5 per 1000 person-years with a score of 5 or greater.[30] Findings that the ECG abnormalities are associated with increased risk whether they represent true or false-positive results in relation to MRI-determined left ventricular mass, and that the risks posed by ECG and imaging evidence of LVH are complementary,[27,28] suggest the structural and electrical changes of hypertrophy have additive value and reflect different although overlapping consequences of the hypertrophic process on outcomes.

The clinical significance of ST-T wave changes has been demonstrated in, for example, the Losartan Intervention for Endpoint Reduction in Hypertension (LIFE) study.[31] The presence of ST-T changes by the Sokolow-Lyon or Cornell voltage criteria among hypertensive patients increased the 5-year risk of heart failure by more than threefold and the risk of heart failure–related mortality by more than fourfold. In addition, the onset of ST-T changes during the first year of follow-up was associated with a three- to fivefold increase in clinical events. Conversely, regression of ST-T changes during treatment was associated with reduced risk of cardiovascular death, nonfatal infarction, and other outcomes.

In addition to these clinical impacts, the ECG changes of LVH may confound or obscure ECG changes of other common conditions.[21] The widened, notched, and leftward QRS complex may mimic intraventricular conduction defects, and the ST-T wave changes may suggest myocardial ischemia or infarction (see later). Similarly, the ECG changes of other conditions may confound the value of ECG criteria for LVH. These include left anterior fascicular block, left bundle branch block, and right bundle branch block, as discussed later.

Right Ventricular Hypertrophy

Right ventricular hypertrophy (RVH), especially when resulting from pressure overload, changes fundamental aspects of the ECG, whereas an enlarged left ventricle produces predominantly quantitative changes in underlying normal waveforms. The ECG changes associated with moderate to severe concentric RVH most often include abnormally tall R waves in anteriorly and rightward-directed leads (leads aVR, V_1, and V_2) and deep S waves and abnormally small r waves in leftward-directed leads (I, aVL, and lateral precordial leads) (**Fig. 12.17**). These changes result in a reversal of normal R wave progression in the precordial leads, a shift in the frontal plane QRS axis to the right, and the presence of S waves in leads I, II, and III (the *$S_1S_2S_3$ pattern)* (**see Chapters 84 to 86**).

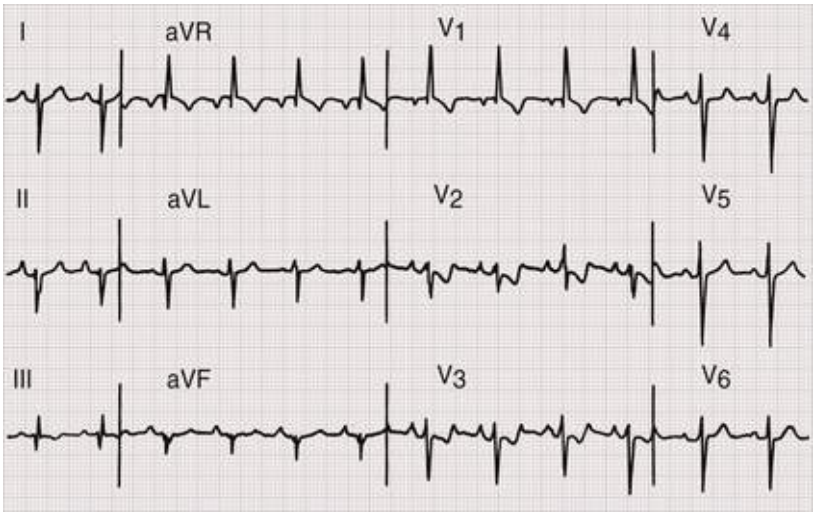

FIGURE 12.17 RVH pattern most consistent with severe pressure overload of the right ventricle. Findings include (1) a tall R wave in V_1 (as part of the qR complex), (2) right axis deviation, (3) ST-segment depression and T wave inversion in V_1 through V_3, (4) delayed precordial transition zone (rS in V_6), (5) right atrial abnormality, and (6) an $S_1Q_3T_3$ pattern.

Less severe hypertrophy, especially when limited to the outflow tract of the right ventricle that is activated late during the QRS complex, produces less marked changes. Abnormalities may be limited to an rSr′ pattern in V_1 and persistence of s (or S) waves in the left precordial leads. This pattern is typical

of right ventricular volume overload, such as that produced by an atrial septal defect and is also seen in persons without manifest cardiac abnormalities.

Diagnostic Criteria

Commonly relied-on criteria for the ECG diagnosis of RVH are listed in **Table 12.5**. Other criteria that have been used recently include the Butler-Leggett score (maximum R_{V1-2} + Max $S_{I,V6} - S_{V1} > 6$ mV) and the Lewis criterion ($R_I + S_{III} - [S_I + R_{III}] < 1.5$ mV). Although right axis deviation is not listed as a diagnostic criterion, it is present in most cases of significant structural RVH.[21]

TABLE 12.5

Common Diagnostic Criteria for Right Ventricular Hypertrophy (RVH)

Tall R in $V_1 > 0.6$ mV
Increased R/S in $V_1 > 1$
Deep S in $V_5 > 1.0$ mV
Deep S in $V_6 > 0.3$ mV
Tall R in aVR > 0.4 mV
Small S in $V_1 < 0.2$ mV
Small R in $V_{5-6} < 0.3$ mV
Reduced R/R ratio in $V_5 < 0.75$
Reduced R/S ratio in $V_6 < 0.4$
Reduced R/S ratio in $V_1 < 0.04$
$(R_I + S_{III}) - (S_I + R_{III}) < 1.5$ mV
Max R_{V1-2} + Max $S_{I, aVL} - S_{V1} > 0.6$ mV
$RV_1 + S_{V5-6} > 1.05$ mV
R peak $V_1 > 0.035$ msec
QR in V_1 present

Data from Hancock EW, Deal B, Mirvis DM, et al. Recommendations for the standardization and interpretation of the electrocardiogram. Part V. ECG changes associated with cardiac chamber hypertrophy. J Am Coll Cardiol 2009;53:982.

In addition, other ECG findings have been considered supportive of a diagnosis of RVH, although not by themselves diagnostic. These include an RSR′ pattern in V_1 with a QRS duration longer than 120 milliseconds, positive S/R ratio in I, II and III, an S_IQ_{III} pattern, R/R ratio in V_1 greater than in V_{3-4}, negative T waves in V_{1-3}, and evidence of left atrial abnormality.[21]

Diagnostic Accuracy.

The diagnostic accuracies of these criteria, as with those of LVH, typically show low sensitivities and high specificities. Recent studies using cardiac MRI to assess right ventricular structure have reported sensitivities of most criteria in populations without clinical heart disease to be less than 10%,[32] although higher sensitivities (as high as 74%) have been reported in patient cohorts with pulmonary hypertension.[33] Accuracies have been reported to be greatest in congenital heart disease, intermediate with acquired heart disease, and pulmonary hypertension, and lowest with chronic lung disease.[21]

The normal right ventricle is considerably smaller than the left ventricle and produces electrical forces largely canceled by those generated by the left ventricle. Thus, for RVH to be manifest on the ECG, it must be severe enough to overcome the masking effects of the larger left ventricular forces.

Mechanisms for the ECG Abnormalities.

As in LVH, RVH increases current fluxes between hypertrophied cells and the size of activation fronts moving through the enlarged and thickened right ventricle to produce higher-than-normal voltages on the

body surface. In addition, the activation time of the right ventricle is prolonged. Right ventricular activation now ends after activation of the left ventricle is completed. As a result, cancellation of forces generated by the right ventricle by the more powerful forces of the left ventricle is reduced, so that right ventricular forces become manifest late in the QRS complex (e.g., generation of S waves). Because the right ventricle is located anteriorly and to the right of the left ventricle, these changes are most prominent in leads directed anteriorly and to the right, that is, in the right precordial leads.

Clinical Significance

Chronic obstructive pulmonary disease (**see Chapter 86**) can induce ECG changes by producing RVH, by changing the position of the heart within the chest, and by hyperinflation of the lungs (**Fig. 12.18**). QRS changes caused by the insulating and positional changes produced by pulmonary hyperinflation include reduced amplitude of the QRS complex, right axis deviation in the frontal plane, and delayed transition in the precordial leads. Evidence of true RVH includes right axis deviation, deep S waves in the lateral precordial leads, and an $S_1Q_3T_3$ pattern, with an S wave in lead I (as an RS or rS complex), an abnormal Q wave in lead III, and an inverted T wave in the inferior leads.

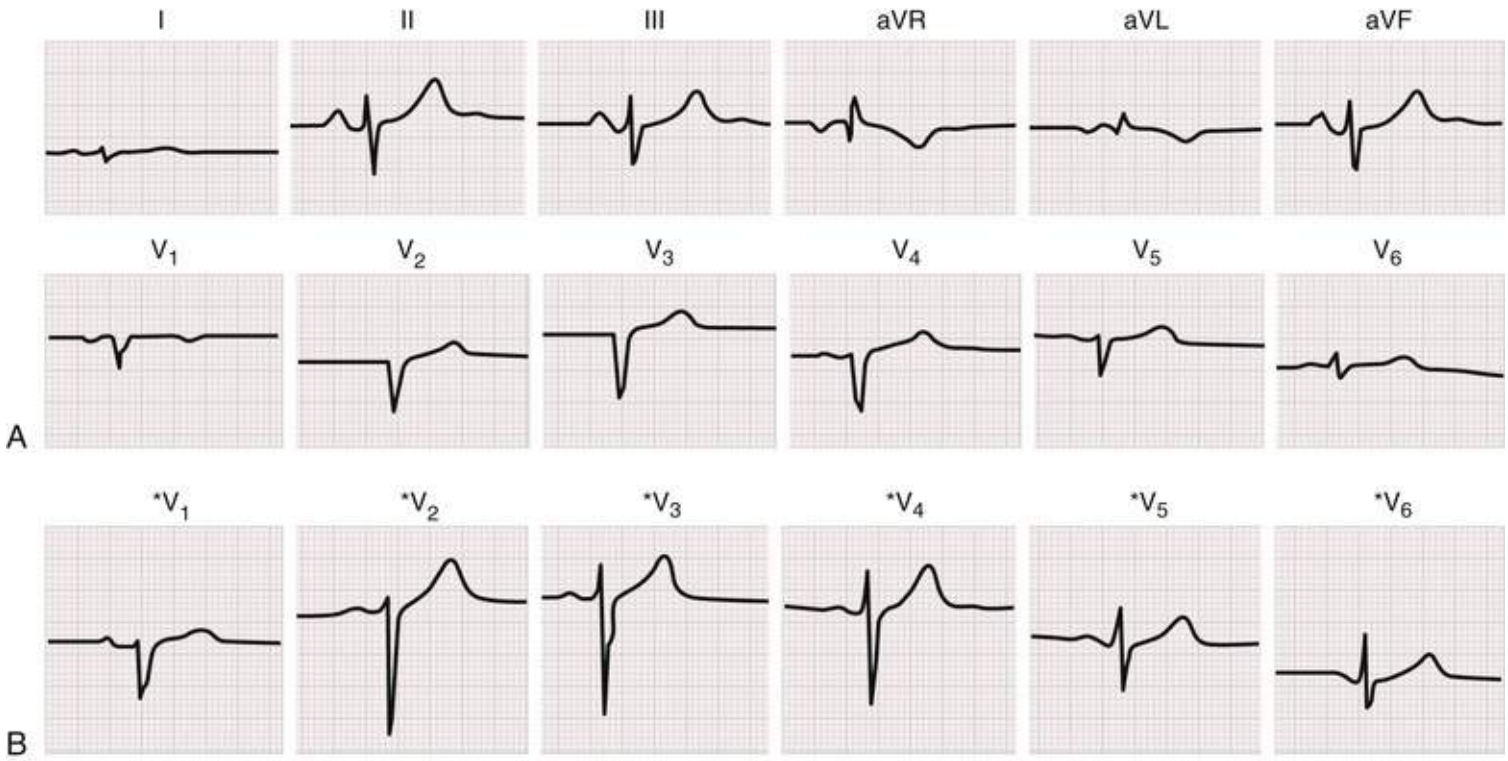

FIGURE 12.18 Pulmonary emphysema simulating anterior infarction in a 58-year-old man with no clinical evidence of coronary disease. In the tracing in **A,** note the loss of anterior R waves in the precordial leads. In **B**, the tracing shows relative normalization of R wave progression with placement of the chest leads an interspace below their usual position (e.g., $*V_1$, $*V_2$). (Modified from Chou TC. Pseudo-infarction (noninfarction Q waves). In Fisch C, editor. Complex Electrocardiography. Vol 1. Philadelphia: FA Davis; 1973.)

Conventional ECG evidence of RVH, however, has limited value in assessing the severity of pulmonary hypertension or lung disease. QRS changes generally do not appear until ventilatory function is significantly depressed, and the correlation with ventilatory function or hemodynamics is low.

Pulmonary embolism causing acute right ventricular pressure overload may generate characteristic ECG patterns (**Fig. 12.19**) (**see Chapter 84**). These include a QR or qR pattern in the right ventricular

leads, an $S_1Q_3T_3$ pattern, ST-segment deviation and T wave inversions in leads V_1 to V_3, and incomplete or complete right bundle branch block. Sinus tachycardia usually is present. Occasionally, with massive pulmonary arterial obstruction, ST-segment elevations may be seen in the right midprecordial leads. Even with major pulmonary artery obstruction, however, the ECG may show little more than minor or nonspecific waveform changes or may be normal in appearance. Thus the ECG changes are of limited clinical value.

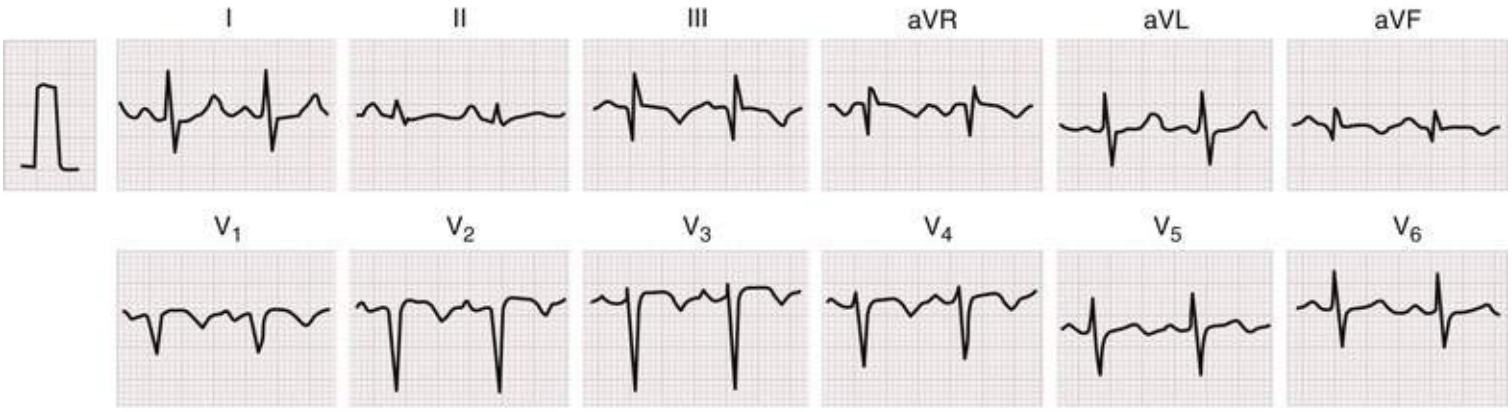

FIGURE 12.19 Acute cor pulmonale secondary to pulmonary embolism simulating inferior and anterior infarction. This tracing exemplifies the classic pseudoinfarction patterns sometimes seen with an $S_1Q_3T_3$ pattern, a QR in lead V_1 with poor R wave progression in the right precordial leads (clockwise rotation), and right precordial to midprecordial ST elevation and T wave inversion (V_1 to V_4). (From Goldberger AL, Goldberger ZD, Shvilkin A. Goldberger's Clinical Electrocardiography: a Simplified Approach. 9th ed. Philadelphia: Elsevier; 2017.)

Biventricular Hypertrophy

Hypertrophy of both ventricles produces complex ECG patterns. In contrast to biatrial enlargement, the result is not the simple sum of the two sets of abnormalities. The effects of enlargement of one chamber may cancel the effects of enlargement of the other. The greater left ventricular forces generated in LVH increase the degree of RVH needed to overcome the dominance of the left ventricle, and the anterior forces produced by RVH may cancel the enhanced posterior forces generated by LVH.

Because of these factors, specific ECG criteria for either RVH or LVH are seldom observed with biventricular enlargement. Rather, ECG patterns usually are a modification of the features of LVH, such as tall R waves in the right and left precordial leads, vertical heart position or right axis deviation, deep S waves in the left precordial leads, or a shift in the precordial transition zone to the left—all with evidence of LVH. The presence of prominent left atrial abnormality or of atrial fibrillation with evidence of right ventricular or biventricular enlargement (especially LVH with a vertical or rightward QRS axis) should suggest chronic rheumatic valvular disease (**Fig. 12.20**).

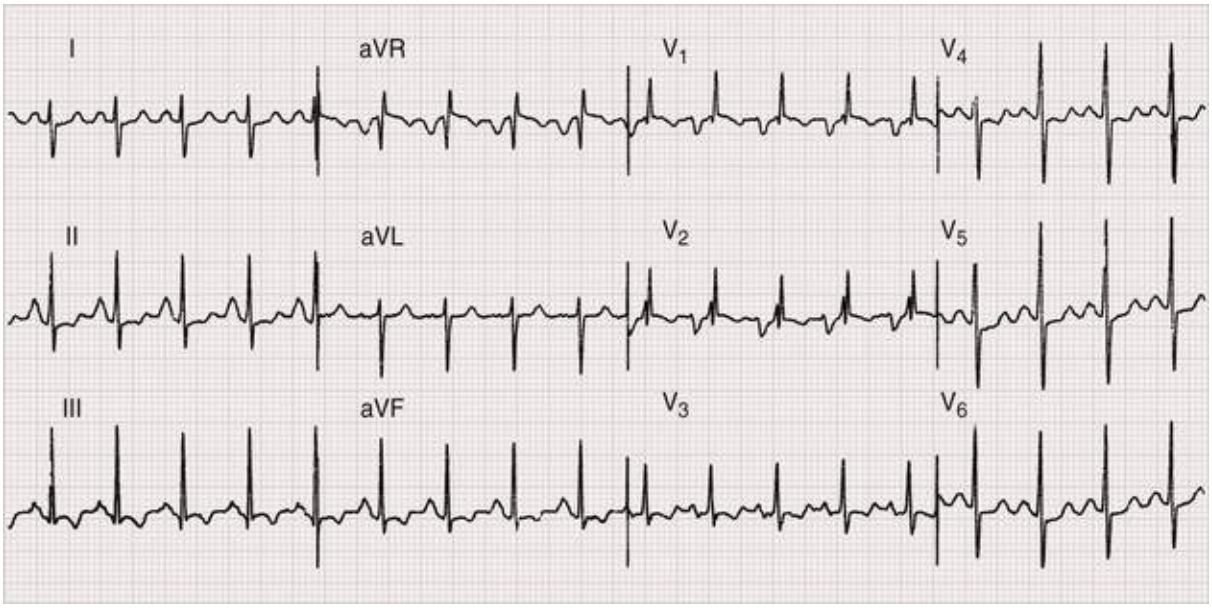

FIGURE 12.20 ECG from a 45-year-old woman with severe mitral stenosis showing multiple abnormalities. Right axis deviation and a tall R wave in lead V_1 are consistent with RVH. The very prominent biphasic P wave in lead V_1 indicates left atrial abnormality. The tall P waves in lead II suggest concomitant right atrial abnormality. Nonspecific ST-T changes and incomplete RBBB also are present. The combination of RVH and marked left or biatrial abnormality is highly suggestive of mitral stenosis. (From Goldberger AL, Goldberger ZD, Shvilkin A. Goldberger's Clinical Electrocardiography: a Simplified Approach. 9th ed. Philadelphia: Elsevier; 2017.)

Intraventricular Conduction Delays or Defects

Intraventricular conduction delays or defects (IVCDs) may result from permanent structural abnormalities in the specialized conducting tissues of the atria or ventricles or in cardiac muscle. IVCDs also may result from transient functional abnormalities in conduction in the major structures of the conduction system[34] (**see Chapters 37, 39, and 40**).

Fascicular Blocks

Absolute or relative delays in conduction in one fascicle of the left bundle system, *fascicular block*, result in an abnormal sequence of early left ventricular activation and lead to characteristic ECG patterns. Only modest delays in conduction are enough to alter ventricular activation patterns sufficiently to produce characteristic ECG patterns; a complete block of conduction is not required.

Left Anterior Fascicular Block (LAFB)

With LAFB, the regions of the left ventricular activated by the left anterior fascicle (i.e., uppermost portion of septum, anterosuperior portion of left ventricle, and left anterior papillary muscle) are activated later than normal. This results in unbalanced inferior and posterior forces early during ventricular activation (activated by the normal left posterior fascicle) followed by unopposed anterosuperior forces later during the QRS complex (the region activated late).

The resulting ECG features of LAFB are listed in **Table 12.6** and illustrated in **Fig. 12.21**. The most characteristic finding is marked left axis deviation, with a shift of the mean frontal plane QRS axis to

between −45 and −90 degrees. Lesser degrees of block may cause lesser shifts of the mean axis from previous values toward the left without exceeding the normal limits.

TABLE 12.6
Common Diagnostic Criteria for Fascicular Blocks

Left Anterior Fascicular Block
Frontal plane mean QRS axis between −45 and −90 degrees
qR pattern in lead aVL
QRS duration < 120 msec
Time to peak R wave in aVL ≥ 45 msec
Left Posterior Fascicular Block
Frontal plane mean QRS axis between +90 and +180 degrees
rS pattern in leads I and aVL with qR patterns in leads III and aVF
QRS duration < 120 msec
Exclusion of other factors causing right axis deviation (e.g., right ventricular overload patterns, lateral infarction)

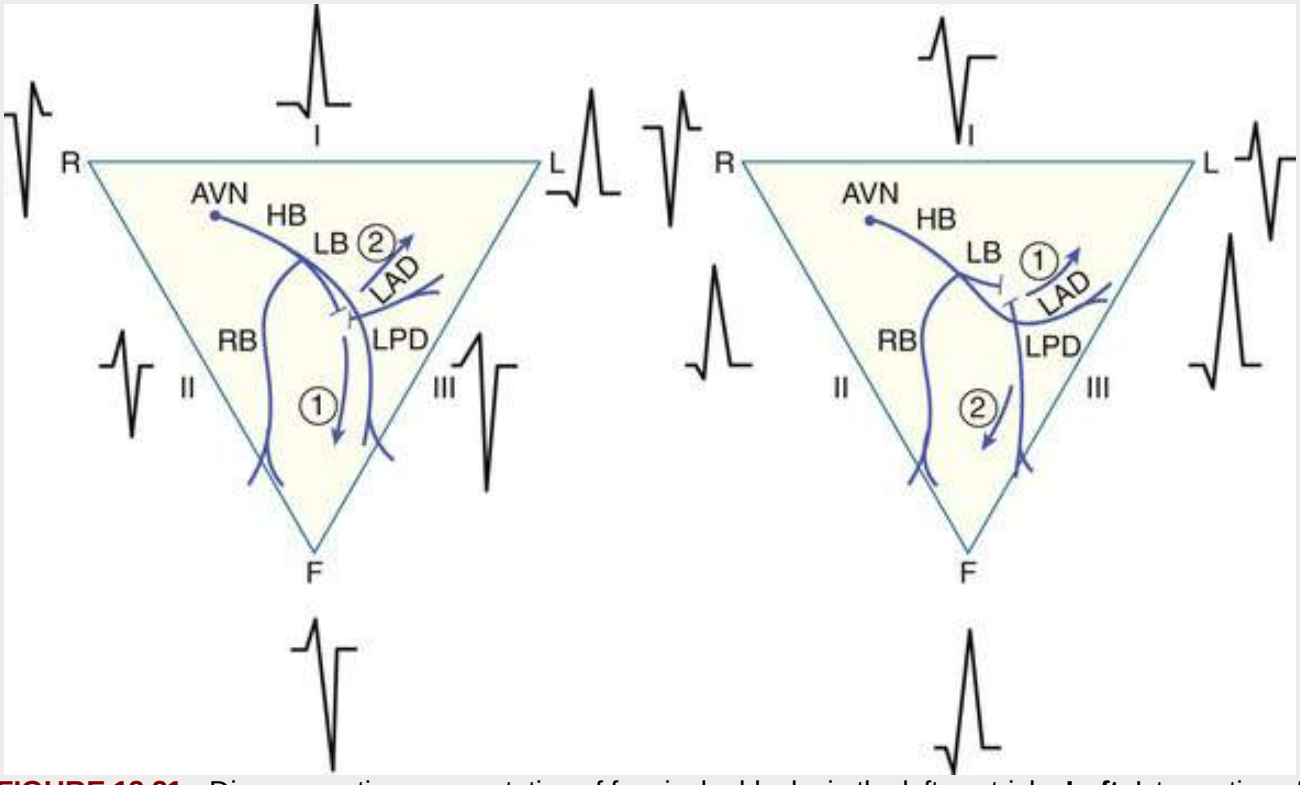

FIGURE 12.21 Diagrammatic representation of fascicular blocks in the left ventricle. **Left,** Interruption of the left anterior fascicle or division (here labeled *LAD*) results in an initial inferior (*1*) followed by a dominant superior (*2*) direction of activation. **Right,** Interruption of the left posterior fascicle or division (here labeled *LPD*) results in an initial superior (*1*) followed by a dominant inferior (*2*) direction of activation. *AVN,* Atrioventricular node; *HB,* His bundle; *LB,* left bundle; *RB,* right bundle. (Courtesy Dr. C. Fisch.)

The resulting QRS pattern in the inferior leads includes initial r waves (caused by early unopposed activation of the inferoposterior left ventricle) followed by deep S waves (caused by late unopposed activation of the anterosuperior left ventricle). Therefore, leads II, III, and aVF show rS patterns. Leads I, aVL, V_5, and V_6 show small q waves and qR patterns.

LAFB can also produce prominent changes in the precordial leads. Leads V_4 through V_6 typically show deep S waves (i.e., a delayed transition zone pattern), produced by the late activation of the anterosuperior left ventricle. The overall QRS duration is not prolonged; fascicular blocks alter the sequence but not the overall duration of left ventricular activation.

LAFB probably is the most common cause of marked left axis deviation, although it is not synonymous with it. Lesser axis shifts to between −30 and −45 degrees usually reflect other conditions, such as LVH.

LAFB is common in persons without overt cardiac disease and in a variety of cardiac conditions, reflecting the delicate nature of the structure. Some evidence indicates that this finding has a negative impact on prognosis or on progression of conduction system disease. A review in support of U.S. Preventive Services Task Force data reported a pooled adjusted hazard ratio for mortality of 1.5 based on three studies.[19]

LAFB can mask or mimic ECG changes from other conditions. The development of rS complexes in leads II, III, and aVF can mask the Q waves of an inferior myocardial infarction. Conversely, concomitant inferior infarction may cause a loss of inferior lead r waves that are expected with LAFB, instead producing QS patterns in II, III, and aVF. The larger R waves in leads I and aVL and smaller R waves but deeper S waves in leads V_5 and V_6 also make LVH criteria relying on R wave amplitude less accurate.

Left Posterior Fascicular Block (LPFB)

LPFB is caused by damage to the left posterior fascicle of the left bundle branch. It is less common than injury in the anterior fascicle because of its thicker structure and more protected location near the left ventricular inflow tract. Conduction delay results in early unopposed activation of the anterosuperior left ventricular free wall, followed by late activation of the inferoposterior aspect of the left ventricle—that is, the reverse of the pattern observed with LAFB.

The ECG features of LPFB (**see Table 12.6 and Fig. 12.21**) reflect this altered activation pattern. Right axis deviation, with rS patterns in leads I and aVL as well as qR complexes in the inferior leads, is the result of early unopposed activation forces from the anterosuperior aspect of the left ventricle (activated normally via the left anterior fascicle and producing the initial q and r waves) and late unopposed forces from the inferoposterior free wall (activated late via the left posterior fascicle and generating the late S and R waves). As in LAFB, the overall activation time of the ventricles is not prolonged, and the QRS duration remains normal.

LPFB can occur in patients with any cardiac disease but is unusual in otherwise healthy persons. The specific diagnosis of LPFB requires first excluding other causes of right axis deviation and including right ventricular overload syndromes and extensive high or anterolateral infarction.

Other Forms of Fascicular Block

An estimated one third of people have an anatomic third branch of the left bundle system: the *left median* or *septal fascicle*. ECG patterns that suggest left septal or median fascicular block include the absence of septal q waves. However, this term is not currently recommended for use in clinical diagnosis because clear diagnostic criteria have not been generally accepted.[34]

Left Bundle Branch Block (LBBB)

LBBB results from conduction delay or block in any of several sites in the intraventricular conduction system, including the main left bundle branch or in each of its two major fascicles; the distal conduction system of the left ventricle; the fibers of the bundle of His that become the main left bundle branch; or in the ventricular myocardium.

LBBB causes extensive reorganization of the activation and recovery patterns of the left ventricle to produce a widened QRS complex with characteristic changes in the shape of the QRS complex and ST-T wave (**Fig. 12.22**). Commonly relied-on diagnostic criteria for LBBB are listed in **Table 12.7**. Basic requirements include QRS duration of 120 milliseconds or more; broad and, typically, notched R waves in leads I and aVL and the left precordial leads; narrow r waves followed by broad and deep S waves in the right precordial leads; and, in most cases, absence of septal q waves. The mean QRS axis may be normal, deviated to the left, or rarely, deviated to the right.

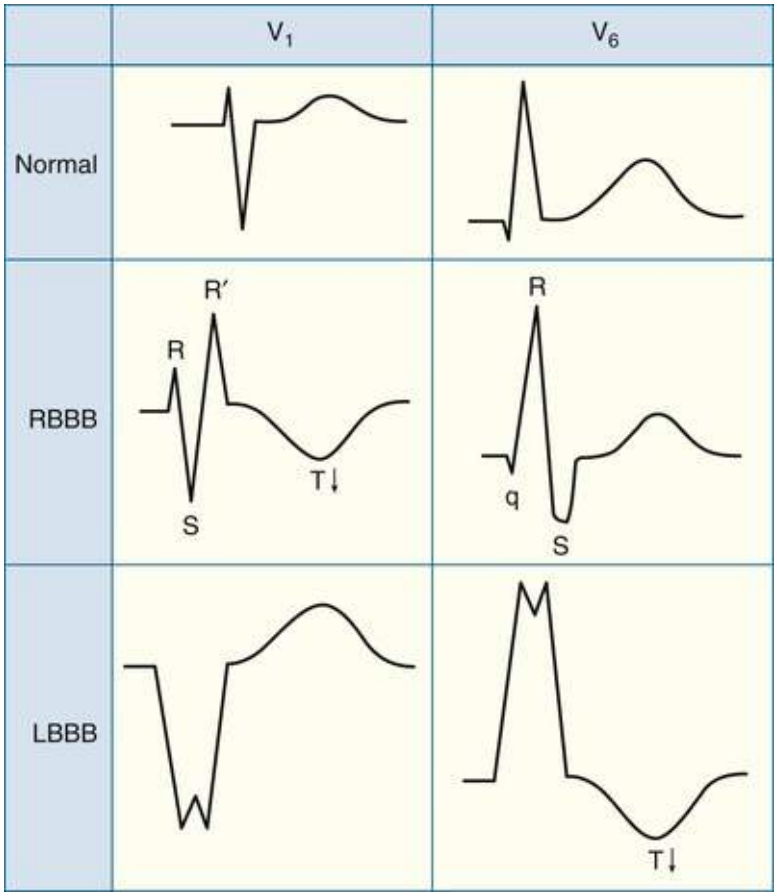

FIGURE 12.22 Comparison of typical QRS-T patterns in RBBB and LBBB with the normal pattern in leads V_1 and V_6. Note the secondary T wave inversions (*arrows*) in leads with an rSR′ complex with RBBB and in leads with a wide R wave with LBBB. (From Goldberger AL, Goldberger ZD, Shvilkin A. Goldberger's Clinical Electrocardiography: a Simplified Approach. 9th ed. Philadelphia: Elsevier; 2017.)

TABLE 12.7

Common Diagnostic Criteria for Bundle Branch Blocks

Complete Left Bundle Branch Block
QRS duration ≥ 120 msec
Broad, notched, or slurred R waves in leads I, aVL, V_5, and V_6
Small or absent initial r waves in leads V_1 and V_2 followed by deep S waves
Absent septal q waves in leads I, V_5, and V_6
Prolonged time to peak R wave (>60 msec) in V_5 and V_6
Complete Right Bundle Branch Block
QRS duration ≥ 120 msec
rsr′, rsR′, or rSR′, patterns in leads V_1 and V_2
S waves in leads I and V_6 ≥ 40 msec wide
Normal time to peak R wave in leads V_5 and V_6 but > 50 msec in V_1

Recently proposed, stricter criteria mandate a QRS duration of 140 milliseconds or more and mid-QRS notching in left-facing leads. These criteria may have better correlation with disordered endocardial activation patterns (see later) and higher predictive value of benefit from resynchronization pacemaker therapy[35] (**see Chapters 27 and 41**). Other criteria require a prolonged time to the peak of the R wave (≥60 msec) in the left precordial leads to diagnose LBBB.[34]

The ST segment and T wave are discordant with the QRS complex in most cases. The ST segments are depressed and T waves inverted in leads with positive QRS waves (e.g., leads I, aVL, V_5, and V_6). ST segments are elevated and T waves upright in leads with predominantly negative QRS complexes (e.g., leads V_1 and V_2).

Incomplete LBBB may result from lesser degrees of conduction delay in the left bundle branch system. Features include modest prolongation of the QRS complex (100 to 119 msec); loss of septal q waves; slurring and notching of the upstroke of tall R waves; and delay in time to peak of the R wave in left precordial leads.

Mechanisms for the ECG Abnormalities.

LBBB causes extensive reorganization of left ventricular activation. Initial septal activation with LBBB typically occurs on the right (rather than on the left as in normal conditions) septal surface, leading to right-to-left (rather than left-to-right) activation of the septum; as a result, normal septal q waves are absent. Left ventricular activation follows slow transseptal spread from the right ventricular side of the septum and is substantially delayed.

In as many as one third of cases, however, earliest septal activation occurs in the left midseptal region. This suggests activation by the left bundle system rather than by transseptal spread. In these cases the LBBB pattern may reflect damage to the distal left bundle system or primarily delays in intramuscular conduction within the ventricular myocardium.[36] In such cases, septal q waves may persist.

The subsequent activation of the ventricular free wall is highly variable, depending on the type, location, and extent of the underlying cardiac disease. Spread is disrupted by regions of block, forcing activation to maneuver around the block through slowly conducting, working myocardium to activate the more distal portions of the ventricle. This results in a prolonged QRS complex with prominent notching and slurring. Overall activation may require more than 180 milliseconds, depending on the functional status of the distal left bundle and Purkinje systems and on the speed of propagation through working cardiac muscle. Studies have suggested that LBBB patterns may develop solely from disordered conduction within ventricular walls even without disordered ventricular endocardial activation.[36]

The discordant ST-T wave pattern is a reflection of the altered pattern of ventricular activation. With LBBB, the right ventricle is activated and recovers earlier than the left so that recovery currents are directed toward the right and away from the left ventricle. Therefore, positive ST-T waves will be registered in leads over the right ventricle that show S waves and negative ones are detected over the left ventricular leads showing prominent R waves. These ST-T wave changes are referred to *secondary ST-T abnormalities* because they are generated predominantly by abnormalities in conduction. As discussed later, ST-T wave changes produced by direct abnormalities of the recovery process (e.g., ischemia, drug effects, electrolyte abnormalities) are referred to as *primary ST-T abnormalities*.

Clinical Significance.

LBBB occurs in fewer than 1% of the general population but in more than one third of patients with heart failure. As many as 70% of persons in whom LBBB develops have preceding ECG evidence of LVH. Fewer than 10% of patients with LBBB have no clinically demonstrable heart disease.

In persons with or without overt heart disease, LBBB is associated with a higher-than-normal risk of mortality and morbidity from infarction, heart failure, and arrhythmias, including high-grade atrioventricular block. In two recent population-based studies, LBBB was significantly related to an increase in new onset of heart failure (with a RR of 2.8 to 3.0) and in cardiovascular death (with a RR of 2.2).[37,38] Among patients with coronary artery disease, including acute myocardial infarction, the presence of LBBB is associated with more extensive disease, more severe left ventricular dysfunction, and reduced survival rates.

Patients with LBBB and either left or right axis deviation have more extensive cardiac disease and more severe clinical manifestations. Left axis deviation is associated with more severe conduction system disease that involves the fascicles and the main left bundle, whereas right axis deviation suggests dilated cardiomyopathy with biventricular enlargement.

The abnormal ventricular activation pattern of LBBB itself induces hemodynamic changes that are superimposed on the abnormalities caused by the underlying heart disease. Whereas normal left ventricular contraction is highly synchronized and begins in all sites within 40 milliseconds, the pattern with LBBB is less coordinated and requires much more time. The result is asynchronous and prolonged left ventricular contraction that causes regional differences in workload, regional changes in blood flow and metabolism, structural remodeling, and functional mitral valve regurgitation.[39] These perturbations may lead to or exacerbate clinical heart failure and serve as a basis for resynchronization cardiac therapy, especially with greatly prolonged QRS duration (**see Chapters 27 and 41**).

A major impact of LBBB lies in obscuring or simulating other ECG patterns. The diagnosis of LVH is complicated by the increased QRS amplitude intrinsic to LBBB, and the very high prevalence of anatomic LVH in patients with LBBB makes defining criteria with high specificity difficult. Patterns suggestive of coexistent LVH include left atrial P wave abnormalities, greatly prolonged QRS duration (>155 msec), and precordial voltage criteria.[34] The diagnosis of myocardial infarction may be obscured, as discussed in detail later.

The diffuse ST-T wave abnormalities associated with LBBB also render detection of ischemia at rest and on standard exercise testing unreliable. This clinical problem is compounded by the frequency of reversible myocardial perfusion defects in the septal and anteroseptal left ventricle during exercise stress testing in the absence of significant disease of the left coronary system, reflecting functional abnormalities in regional myocardial blood flow rather than ischemia related to fixed coronary artery lesions.

Right Bundle Branch Block (RBBB)

RBBB is a result of conduction delay in any portion of the right-sided intraventricular conduction system. The delay is most common in the main right bundle branch itself and may also occur in the bundle of His or in the distal right ventricular conduction system, such as after right ventriculotomy.

ECG Abnormalities.

Major features of RBBB are illustrated in **Fig. 12.22**, and common diagnostic criteria are listed in **Table 12.7**. As with LBBB, the QRS complex duration exceeds 120 milliseconds. The right precordial leads show prominent and notched R waves with rsr′, rsR′, or rSR′ patterns, whereas leads I and aVL and the left precordial leads demonstrate S waves that are wider than the preceding R wave. As in LBBB, the ST-T waves are discordant with the QRS complex; T waves are inverted in the right precordial leads and upright in the left precordial leads and in leads I and aVL.

The mean QRS axis is not altered by RBBB. Axis shifts can occur, however, as a result of the simultaneous occurrence of left fascicular block along with RBBB (see later).

Incomplete RBBB, produced by lesser delays in conduction in the right bundle branch system, is characterized by an rSr′ pattern in lead V_1 with a QRS duration between 100 and 120 milliseconds. These changes also may reflect underlying RVH (especially with a rightward QRS axis) without intrinsic dysfunction of the conduction system or as a manifestation of the Brugada pattern (**see Chapters 33 and 37**). An rSr′ morphology in lead V_1 (and sometimes V_2) with a normal QRS duration is also a common finding in patients without cardiovascular disease, especially in athletes or in association with pectus excavatum, and may normalize when the right precordial electrodes are placed one interspace lower than usual.[40]

Mechanisms for ECG Abnormalities.

With delay or block in the proximal right bundle branch system, activation of the right side of the septum is initiated only after slow transseptal spread of activation from the left septal surface. The right ventricular anterior free wall is then excited slowly, followed by activation of the remaining right ventricle.

The delayed and slowed activation of the right ventricle causes much or all of the right ventricle to activate after depolarization of the left ventricle has been completed. This reduces the cancellation of right ventricular activation forces by the more powerful left ventricular activation forces. The late unopposed emergence of right ventricular forces then produces increased anterior and rightward voltage observed in the latter half of the QRS, as well as a prolonged QRS duration.

Discordant ST-T wave patterns are generated by the same mechanisms as for LBBB. With RBBB, recovery forces are directed away from the right and toward the earlier activated left ventricle. The result is inverted T waves in the right precordial leads and positive ones in the left precordial leads.

Clinical Significance.

RBBB is a common finding in the general population, and many persons with RBBB have no clinical evidence of structural heart disease. The high prevalence of RBBB is attributable to the relative fragility of the right bundle branch, as suggested by the development of RBBB after the minor trauma produced by

right ventricular catheterization.

In patients without manifest cardiac disease, RBBB or incomplete RBBB patterns generally are not associated with increased risk of cardiac morbidity or mortality,[37,38,41] although right ventricular dilation and reduced function may be present. When cardiac disease is present, the coexistence of RBBB suggests advanced disease with more extensive multivessel disease and reduced long-term survival in patients with ischemic heart disease. An RBBB-like pattern with persistent ST-segment elevation in the right precordial leads may indicate the Brugada pattern, with susceptibility to ventricular tachyarrhythmias and sudden cardiac death (Brugada syndrome; **see Chapters 33 and 37**). Patterns of complete or incomplete RBBB are also common among trained athletes (**see Chapter 53**).

RBBB interferes with other ECG diagnoses, although to a lesser extent than for LBBB. The diagnosis of RVH is more difficult to make with RBBB because of the accentuated positive potentials in lead V_1. RVH is suggested, although with limited accuracy, by the presence of an R wave in lead V_1 that exceeds 1.5 mV and a rightward shift of the mean QRS axis.

The usual criteria for LVH can be applied but have lower sensitivities than with normal conduction. RBBB reduces the amplitude of (or eliminates) the S wave in the right precordial leads and that of the R waves in the left precordial leads, thus reducing the accuracy of ECG criteria for LVH. The combination of left atrial abnormality or left axis deviation with RBBB also suggests underlying LVH. Ventricular dyssynchrony also occurs with RBBB but to a lesser extent than with LBBB.

Multifascicular Blocks

The term *multifascicular block* refers to conduction delay or block in more than one of the structural components of the specialized conduction system, including the main left bundle and its major fascicles and the right bundle branch.

Bifascicular block involves delay or block in any two of these structures. It may have several forms depending on the sites of conduction delay. Delay in the RBBB and LAFB is characterized by RBBB plus left axis deviation beyond −45 degrees (**Fig. 12.23**). RBBB with LPFB produces a pattern of RBBB and a mean QRS axis deviation to the right of +120 degrees (**Fig. 12.24**). LBBB alone, which may be caused by delay in both the anterior and the posterior fascicle, is also usually considered a form of bifascicular block, even though the site or sites of delay are not known.

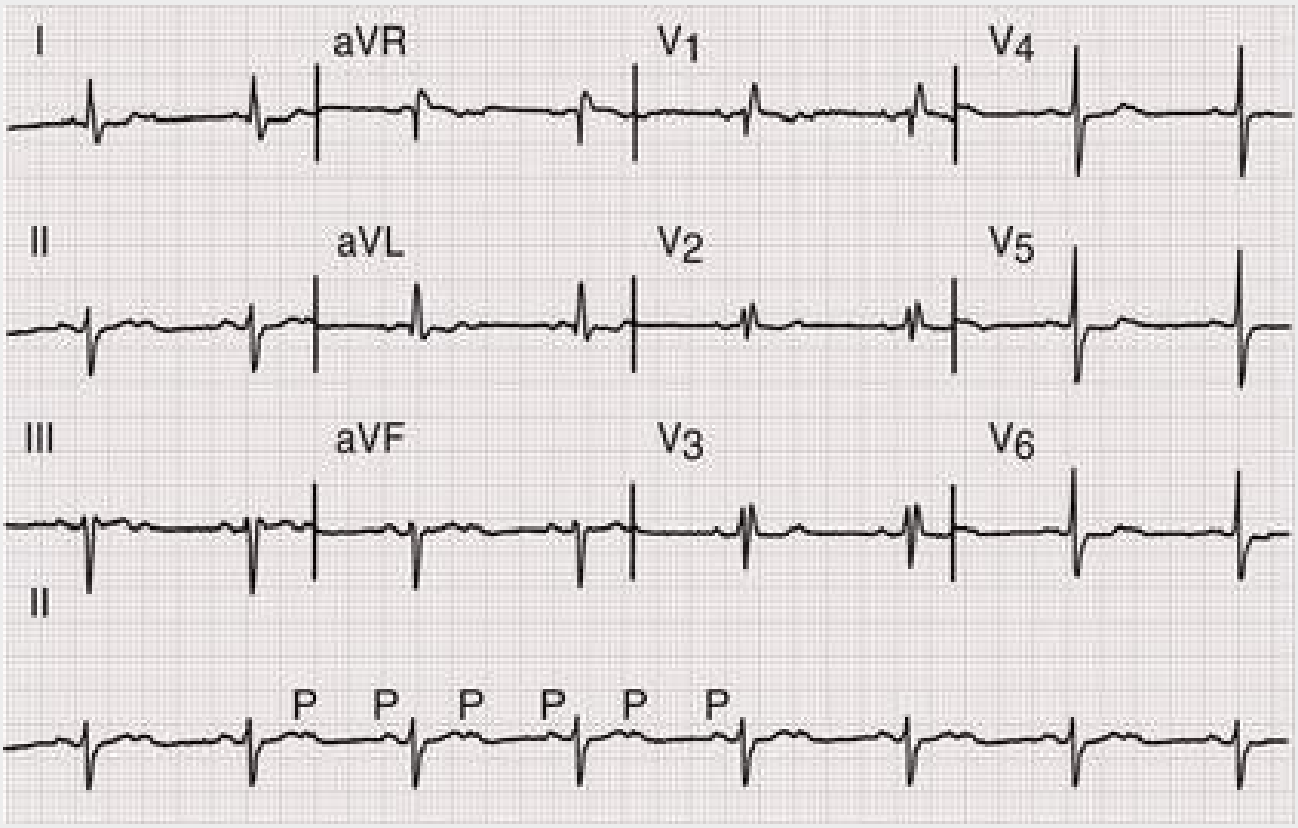

FIGURE 12.23 Sinus rhythm at 95 beats/minute with 2 : 1 atrioventricular block. Conducted ventricular beats show a pattern consistent with bifascicular block with delay or block in the right bundle and left anterior fascicle. The patient underwent pacemaker implantation for presumed infra-Hisian block, which was symptomatic.

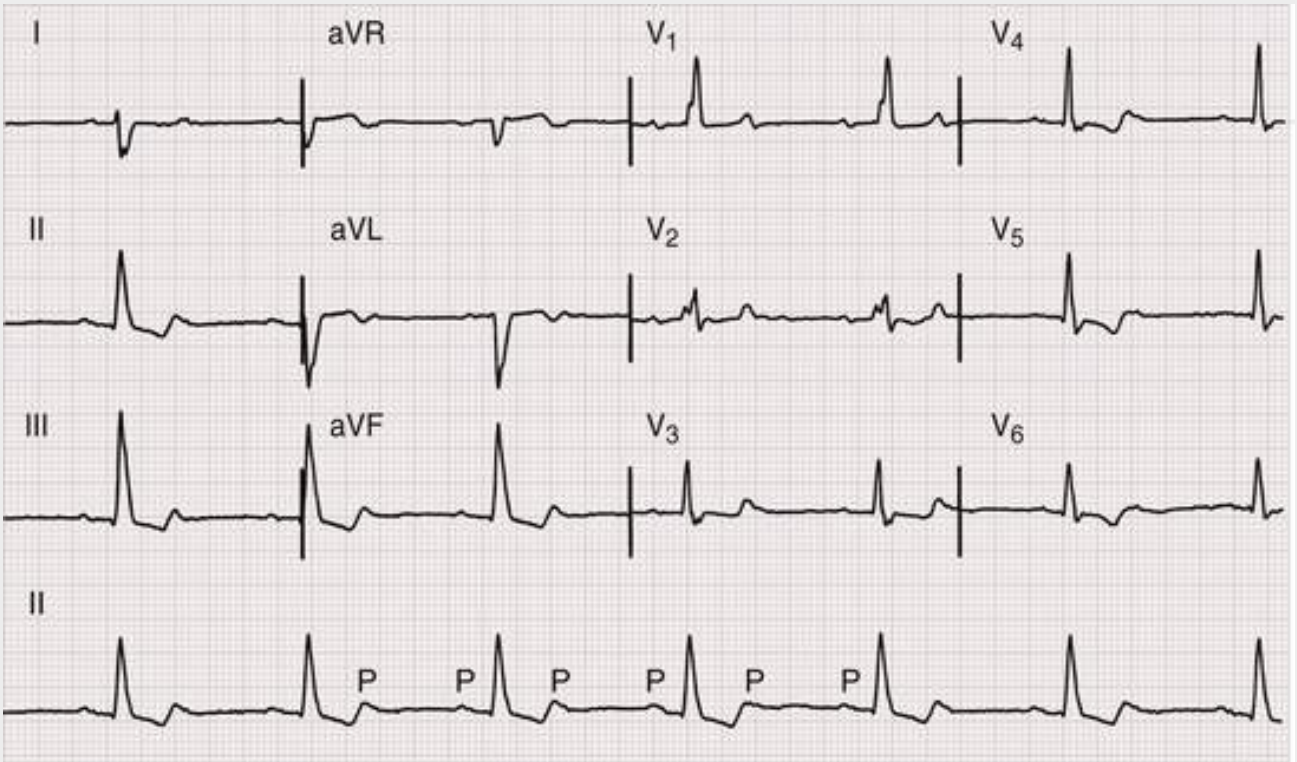

FIGURE 12.24 Sinus rhythm with 2 : 1 atrioventricular block. QRS morphology in the conducted beats is consistent with bifascicular block with delay or block in the right bundle and left posterior fascicle. Subsequently, complete heart block was noted. The patient underwent pacemaker implantation.

Trifascicular block involves conduction delay in the right bundle branch plus delay in either the main

left bundle branch or in both the left anterior and the left posterior fascicle. The resulting ECG pattern depends on the relative degree of delay in the affected structures. If conduction delay exists in both the right and the left bundle branch and the delay in the right bundle branch is less than the delay in the left bundle branch, activation will begin in the right ventricle, and the QRS pattern will resemble that of LBBB. If the delay is greater in the right bundle branch than in the left bundle branch, the ECG pattern will be that of RBBB.

A diagnosis of trifascicular block requires an ECG pattern of bifascicular block plus evidence of prolonged conduction below the atrioventricular (AV) node. In bifascicular block, conduction time through the unaffected fascicle (and thus minimum conduction time) is normal, and conduction time from the AV node to ventricular muscle is normal. Accordingly, the PR interval will be normal (in the absence of AV nodal conduction delay). In trifascicular block, however, the delay in conduction through even the least affected path is abnormally prolonged so that the minimal conduction time from the AV node to the ventricular myocardium also is prolonged. Only delay, not block, of conduction in at least one of the conduction pathways is required. If complete block were present in the right bundle branch and in the left bundle or in of its fascicles, conduction would fail and complete heart block would result.

In some cases the path with the longest delay can vary with the heart rate. In these cases, conduction patterns vary or alternate between two or more IVCD types to produce *alternating bundle branch block* (**Fig. 12.25**).

FIGURE 12.25 Multifascicular block manifested by alternating bundle branch blocks and PR intervals (sections *A-C*), recorded on separate days. *A,* Lead V_1 recording shows a RBBB with a prolonged PR interval of 280 milliseconds. *B,* Lead V_1 shows LBBB with a PR of 180 milliseconds. *C,* Leads I, II, III, and V_1 show alternating RBBB and LBBB patterns, along with PR alternation. The limb leads also show left anterior fascicular block (with subtle alternation of the QRS morphology). (From Fisch C. Electrocardiography of Arrhythmias. Philadelphia: Lea & Febiger; 1990.)

On the surface ECG, the delay in conduction may be manifested as a prolonged PR interval. However, the PR interval in mostly determined by the conduction time through the AV node with a lesser contribution by the conduction time in the infranodal conduction system. Prolonged intraventricular conduction may be insufficient to extend the PR interval beyond normal limits, whereas a greatly prolonged PR interval most often reflects delay in the AV node rather than in all three intraventricular fascicles. *Thus the finding of a prolonged PR interval in the presence of an ECG pattern consistent with bifascicular block is not diagnostic of trifascicular block, whereas the presence of a normal PR interval does not exclude it.* This delay in conduction is most specifically observed as a prolongation of the His-ventricular (HV) time in intracardiac recordings (**see Chapter 34**).

The major clinical implication of a multifascicular block is its relation to advanced conduction system disease. It may be a marker for severe myocardial disease and may identify patients at risk for heart block (**see Fig. 12.23**), as discussed in **Chapter 40**.

Other Forms of Conduction Abnormalities

Rate-Dependent Conduction Blocks

Rate-dependent block usually occurs as a transient IVCD pattern (**see Chapter 34**). In *acceleration (tachycardia)-dependent block*, conduction delay occurs when the heart rate exceeds a critical value. This form of rate-related block is relatively common and can have the ECG pattern of RBBB or LBBB (**Fig. 12.26**). In *deceleration (bradycardia)-dependent block*, conduction delay occurs when the heart rate falls below a critical level. Deceleration-dependent block is less common than acceleration-dependent block and usually is seen only in patients with advanced conduction system disease (**Fig. 12.27**). The electrophysiologic bases for these patterns are discussed in **Chapter 34**.

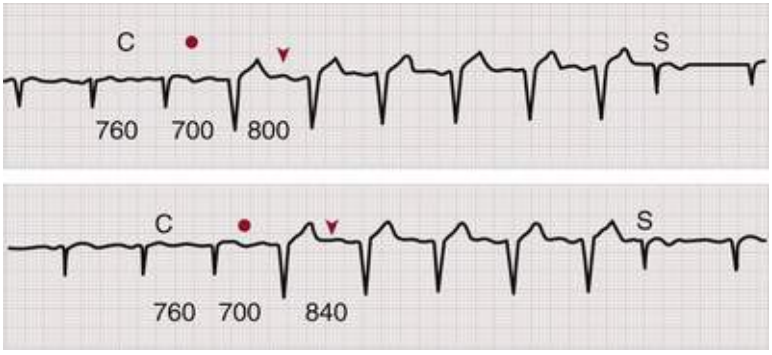

FIGURE 12.26 Acceleration-dependent QRS aberration with the persistence at a longer cycle and normalization at a shorter cycle than that initiating the aberration, indicating conduction hysteresis in the conduction system. The basic duration of the basic cycle (*C*) is 760 milliseconds. LBBB appears at a cycle length of 700 milliseconds (*dot*) and is perpetuated at cycle lengths (*arrowhead*) of 800 and 840 milliseconds; conduction normalizes after a cycle length of 600 milliseconds. Perpetuation of LBBB at cycle lengths of 800 and 840 milliseconds is probably caused by transseptal concealment. Unexpected normalization of the QRS (*S*) after the atrial premature contraction probably is caused by equalization of conduction in the two bundles. (From Fisch C, Zipes DP, McHenry PL. Rate dependent aberrancy. Circulation 1973;48:714.)

FIGURE 12.27 Deceleration-dependent aberration. The basic rhythm is sinus with a Wenckebach (type I) atrioventricular block. With 1 : 1 atrioventricular conduction, the QRS complexes are normal in duration; with a 2 : 1 atrioventricular block or after the longer pause of a Wenckebach sequence, LBBB appears. (Courtesy Dr. C. Fisch).

Other mechanisms of ventricular aberration include concealed conduction in the bundle branches, preexcitation syndromes, depressed myocardial conduction from drugs or hyperkalemia, and the effect on refractoriness of abrupt changes in cycle length (the basis of the *Ashman phenomenon*) and are discussed in **Chapters 34 and 37**. **Table 12.8** summarizes the major causes of a wide QRS occurring at physiologic heart rates. The more specific topic of wide complex tachycardias is discussed in **Chapters 35 and 37**.

TABLE 12.8

Major Causes of a Wide QRS (at Physiologic Rates)

Chronic (intrinsic) intraventricular conduction delays or defects (IVCDs)
Right bundle branch block (RBBB)
Left bundle branch block (LBBB)
"Nonspecific" IVCDs
Transient IVCDs
Rate related
Acceleration dependent
Deceleration dependent
Retrograde (transseptal) activation
Ashman type
"Toxic" (extrinsic) conduction delays
Hyperkalemia
Drugs (especially those with class I activity)
Ventricular-originating complexes
Premature ventricular complexes (PVCs)
Ventricular escape beats
Ventricular paced beats
Ventricular preexcitation (WPW and related patterns)

For causes of wide-complex tachycardias, see **Chapters 34 and 37**.

WPW, Wolff-Parkinson-White.

Peri-Infarction Block.

Peri-infarction block refers to conduction delay in the region of a myocardial infarction. It is manifested in ECG leads by pathologic Q waves when the terminal portion of the QRS complex is wide and directed opposite to the Q wave, such as a QR complex in leads III and aVF. A related abnormality is *peri-ischemic block,* with reversible widening of the QRS complex in leads with ST-segment elevation caused by acute injury.

Nonspecific Intraventricular Conduction Defect (Delay).

This term is often used to refer to patterns with a widened QRS complex (>120 msec) but without the specific patterns characteristic of RBBB or LBBB.

Myocardial Ischemia and Infarction

The ECG remains a key test for the diagnosis and management of acute and chronic coronary syndromes.[2,42-50] The waveform findings vary considerably depending on four major factors: (1) the duration of the ischemic process (acute versus evolving versus chronic), (2) its extent (size and degree of transmural involvement), (3) its topography (anterior versus inferior-posterior-lateral or right ventricular), and (4) the presence of other underlying abnormalities (e.g., prior infarction, LBBB, Wolff-Parkinson-White syndrome, or pacemaker patterns) because they can alter or mask the classic patterns. A critical clinical distinction is between *ST-segment elevation myocardial infarction* (or ischemia) (STEMI) and *non-STEMI infarction* (or ischemia) syndromes. With STEMI, an invasive approach aimed toward immediate reperfusion therapy with a percutaneous coronary intervention is the goal, unless contraindicated. With non-STEMI, urgent diagnostic angiography with revascularization, if feasible, is indicated by the presence of refractory angina, or hemodynamic or electrical instability (**see Chapters 59 and 60**).

Repolarization (ST-T Wave) Abnormalities

The earliest and most consistent ECG finding during acute severe ischemia is deviation of the ST segment occurring as a result of complicated current of injury mechanisms (**see Chapter 59**). Under normal

conditions, the ST segment usually is nearly isoelectric, because almost all healthy myocardial cells attain approximately the same potential during the plateau phase of the ventricular action potential.

Ischemia, however, produces complex time-dependent effects on the electrical properties of myocardial cells. Severe acute ischemia can reduce the resting membrane potential, shorten the duration of the action potential, and decrease the rate of rise and amplitude of phase 0 in the ischemic area (**Fig. 12.28**). The key concept is that these perturbations cause a *voltage gradient* between normal and ischemic zones that leads to current flow between these regions. The resulting *injury currents* are represented on the surface ECG as deviations of the ST segment.

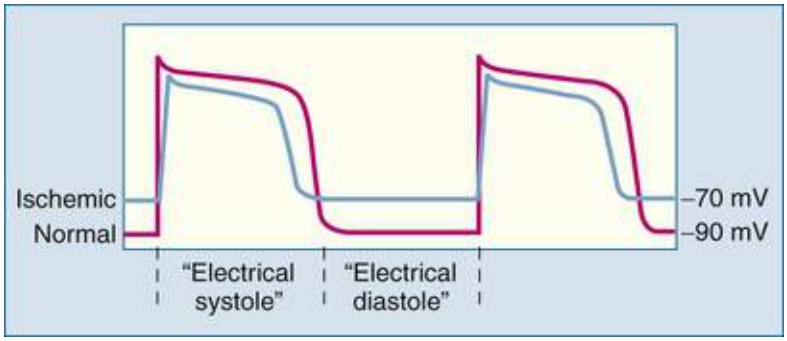

FIGURE 12.28 Acute ischemia may alter ventricular action potentials in a number of ways that result in lower resting membrane potential, decreased amplitude and velocity of phase 0, and an abbreviated action potential duration (a pathologic form of early repolarization). These electrophysiologic effects, singly or in combination, create a voltage gradient between ischemic and normal cells during different phases of the cardiac electrical cycle. The resulting currents of injury are reflected on the surface ECG by deviation of the ST segment (**see Fig. 12.29**).

The precise electrophysiologic mechanisms underlying injury currents and their directionality with ischemia and related conditions remains an area of active research and some controversy even after decades of study. Both "diastolic" and "systolic" injury currents have been proposed, based primarily on animal studies, to explain ischemic ST-segment elevations[2,46,48] (**Fig. 12.29**). According to the "diastolic current of injury" hypothesis, ischemic ST-segment elevation is attributable to negative (downward) displacement of the electrical diastolic baseline (the TQ segment of the ECG). Ischemic cells remain relatively depolarized, probably related importantly to potassium ion leakage, during phase 4 of the ventricular action potential (i.e., lower membrane resting potential; **see Fig. 12.28**) and depolarized muscle carries a negative extracellular charge relative to repolarized muscle. Therefore, during electrical diastole, current (the diastolic current of injury) will flow between the partly or completely depolarized ischemic myocardium and the neighboring, normally repolarized, uninjured myocardium. The injury current vector will be directed away from the more negative ischemic zone toward the more positive normal myocardium. As a result, leads overlying the ischemic zone will record a negative deflection during electrical diastole and produce depression of the TQ segment.

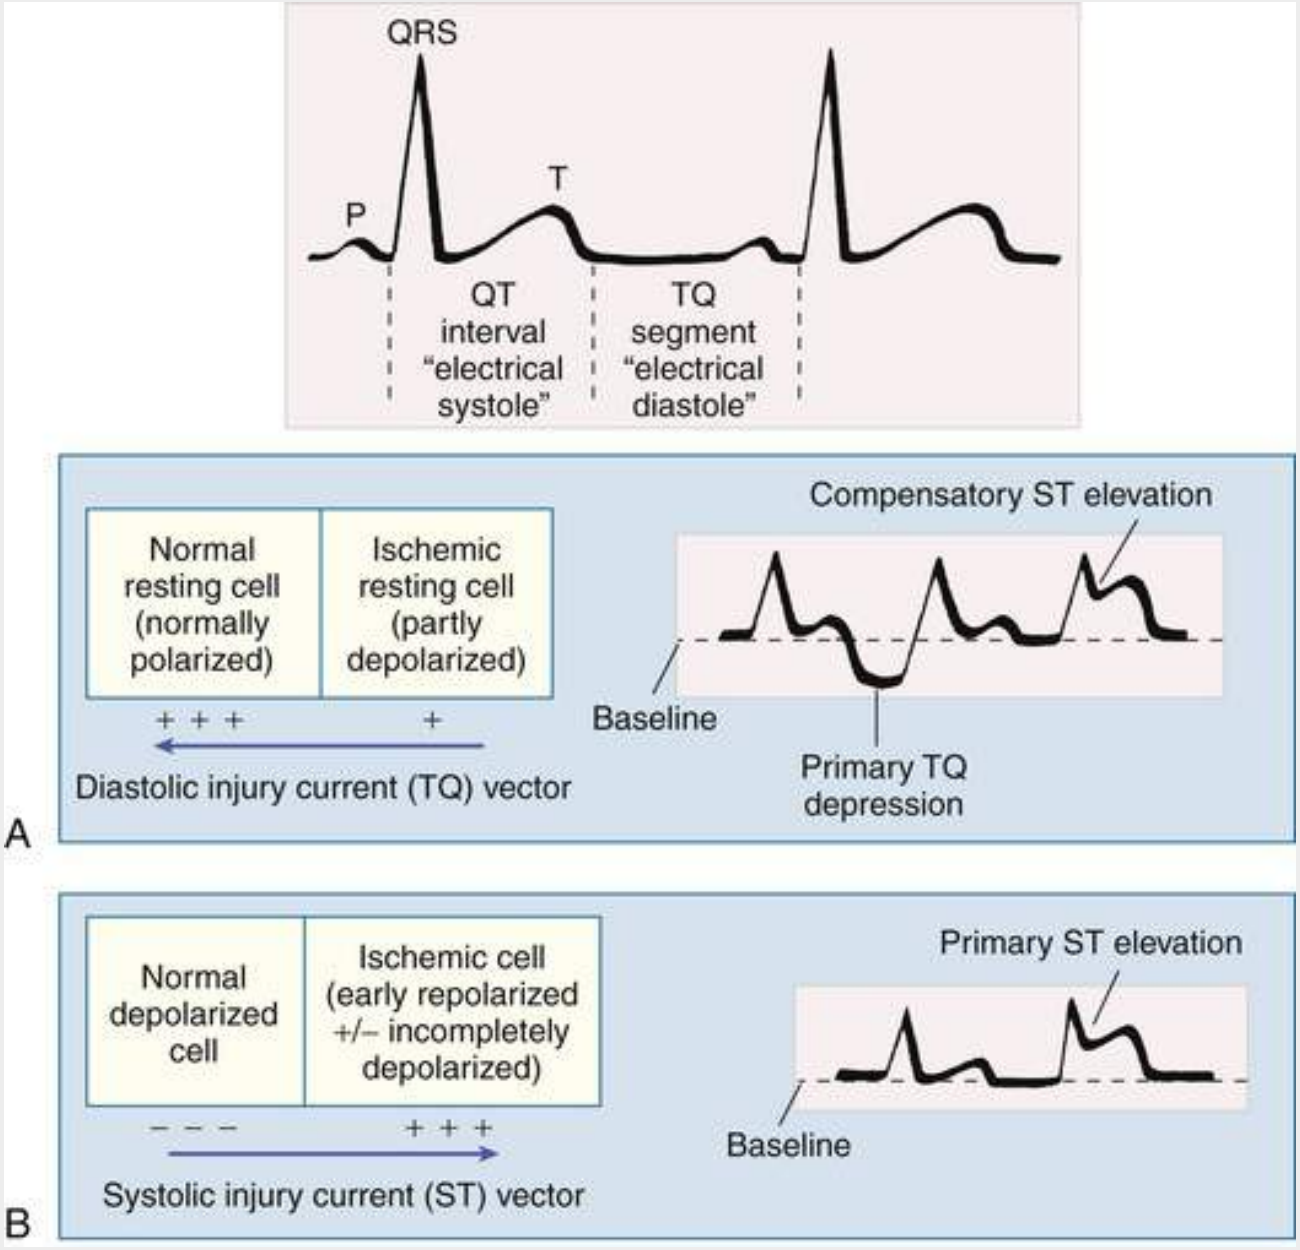

FIGURE 12.29 A simplified scheme of the pathophysiology of ischemic ST elevation. Two basic mechanisms have been advanced to explain the ST elevation seen with acute myocardial injury. **A,** Diastolic current of injury. In this case (first QRS-T complex), the ST vector will be directed away from the relatively negative, partly depolarized ischemic region during electrical diastole (TQ segment), and the result will be primary TQ depression. Conventional alternating current ECGs "compensate" for the baseline shift, and apparent ST-segment elevation (second QRS-T complex) results. **B,** Systolic current of injury. In this scenario, the ischemic zone will be relatively positive during electrical systole because the cells are repolarized early, and the amplitude and upstroke velocity of their action potentials may be decreased. This so-called systolic injury current vector will be oriented toward the electropositive zone, and the result will be primary ST-segment elevation. In clinical recordings, the contributions of diastolic and systolic injury currents to the observed ST-segment elevation cannot be determined (see text).

TQ-segment depression appears as ST-segment elevation, because the ECG recorders in clinical practice use AC-coupled amplifiers that automatically "compensate" or adjust for any negative shift in the TQ segment. As a result of this electronic effect, the ST segment will be proportionately elevated. Therefore, according to the diastolic current of injury theory, ST-segment elevation represents an apparent shift. The true shift, observable only with DC-coupled ECG amplifiers, is the negative displacement of the TQ baseline.

Evidence also suggests that ischemic ST-segment elevations (and hyperacute T waves) may also be related to systolic injury currents. Three pathologic factors may make acutely ischemic myocardial cells relatively positive compared with normal cells in regard to their extracellular charge during electrical

systole (QT interval): (1) abbreviation of action potential duration, (2) decreased action potential upstroke velocity, and (3) decreased action potential amplitude (**see Fig. 12.28**). The presence of one or more of these effects will establish a voltage gradient between normal and ischemic zones during the QT interval such that the current of injury vector will be directed toward the ischemic region. This systolic current of injury mechanism, also probably related in part to potassium leakage, will result in primary ST-segment elevation, sometimes with tall positive (*hyperacute*) T waves.

When acute ischemia is transmural (or nearly so), the overall ST vector (whether caused by diastolic or systolic injury currents, or both) usually is shifted in the direction of the outer (epicardial) layers, and ST-segment elevation and sometimes tall, positive (hyperacute) T waves are recorded over the ischemic zone (**Fig. 12.30**). Reciprocal ST-segment depression can appear in leads reflecting the contralateral surface of the heart. Occasionally, the reciprocal changes can be more apparent than the primary ST-segment elevations.

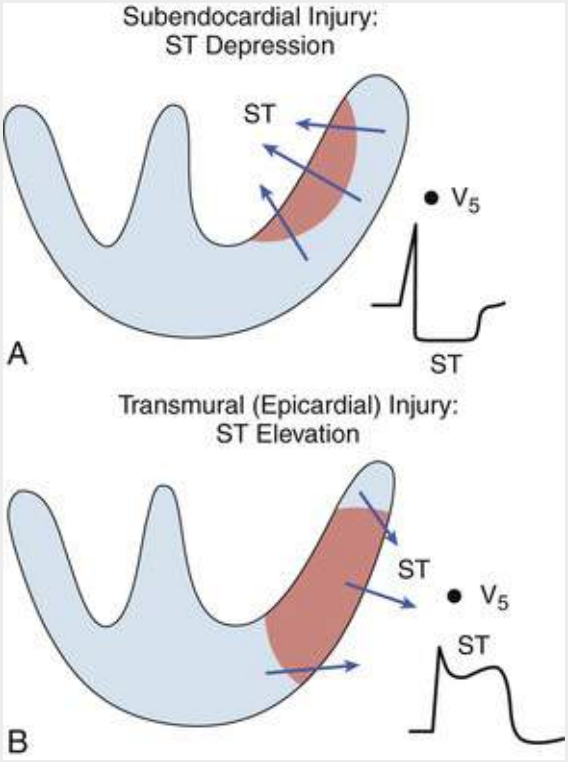

FIGURE 12.30 Directionality of current of injury patterns (ST vectors) with acute ischemia. **A,** With predominant subendocardial ischemia, the resultant ST vector is directed toward the inner layer of the affected ventricle and the ventricular cavity. Overlying leads therefore record ST depression, as may be seen during abnormal exercise stress tests or with spontaneous angina pectoris. **B,** With ischemia involving the outer ventricular layer (transmural or epicardial injury), the ST vector is directed outward. Overlying leads record ST-segment elevation. Reciprocal ST-segment depression can appear in contralateral leads.

When ischemia is confined primarily to the subendocardium (approximately the inner half of the ventricular wall), the overall ST vector typically shifts toward the inner ventricular layer and the ventricular cavity such that the overlying (e.g., anterior precordial) leads show ST-segment depression, with ST-segment elevation in lead aVR (**Fig. 12.30**). This subendocardial ischemia pattern is the typical finding during spontaneous episodes of angina pectoris or during symptomatic or asymptomatic (silent) ischemia induced by exercise or pharmacologic stress tests (**see Chapter 13**). However, inspection of the surface ECG, with either ST elevation or ST depression ischemia, cannot differentiate between the contributions of systolic and diastolic currents of injury. Furthermore, associated alterations in

myocardial conduction and action potential properties may contribute to the ST deviations observed on the ECG.[48]

Multiple factors can affect the amplitude of acute ischemic ST-segment deviations. Profound ST-segment elevation or depression in multiple leads usually indicates very severe or widespread ischemia. Conversely, prompt resolution of ST-segment elevation after reperfusion with percutaneous coronary interventions or thrombolytic therapy is a useful marker of successful reperfusion.[49] These relationships are not universal, however, because severe ischemia or even infarction can occur with slight or absent ST-T changes. Furthermore, a relative increase in T wave amplitude (hyperacute T waves) can accompany or precede the ST-segment elevations with ischemia with or without infarction (**Fig. 12.31**).

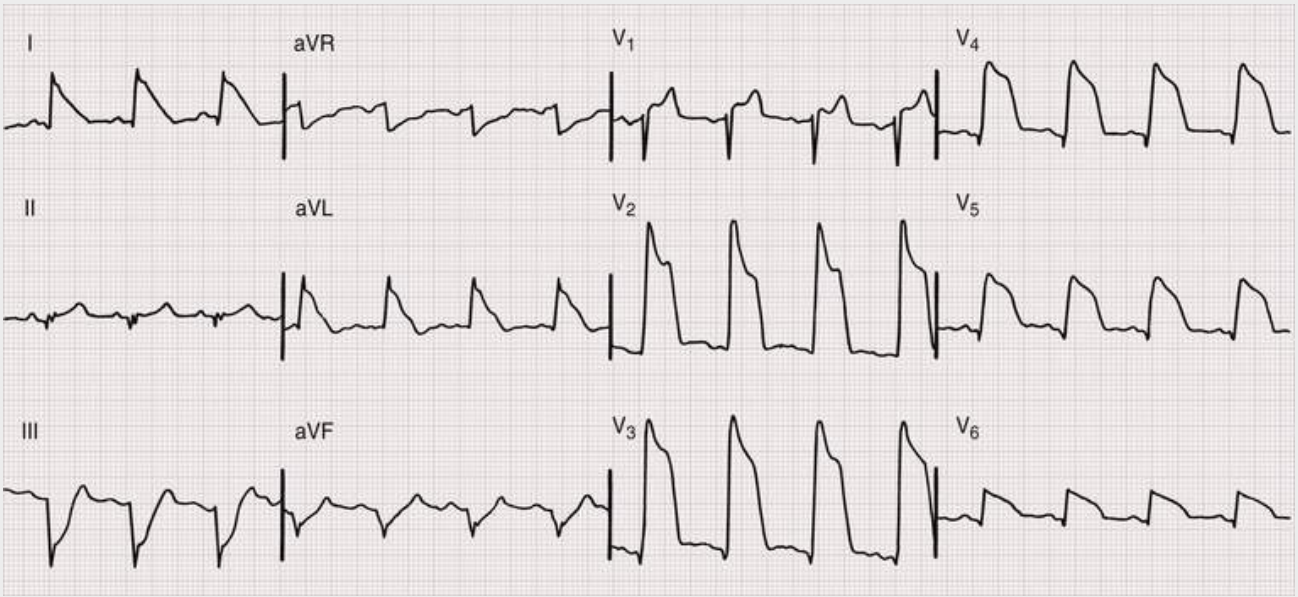

FIGURE 12.31 Hyperacute phase of extensive anterolateral myocardial infarction. Marked ST-segment elevation melding with prominent T waves is present across the precordium, as well as in leads I and aVL. ST-segment depression, consistent with a reciprocal change, is seen in leads III and aVF. Q waves are present in leads V_3 through V_6. Marked ST-segment elevations with tall T waves caused by severe ischemia are sometimes referred to as a "monophasic current of injury pattern." A paradoxical increase in R wave amplitude (V_2 and V_3) may accompany this pattern. This tracing also shows left axis deviation with small or absent inferior R waves, which raises the possibility of a previous inferior infarct.

QRS Changes

With actual infarction, depolarization (QRS) changes often accompany repolarization (ST-T) abnormalities (**Fig. 12.32**). Necrosis of sufficient myocardial tissue can lead to decreased R wave amplitude or Q waves in the anterior, lateral, or inferior leads as a result of loss of electromotive forces in the infarcted area. Local conduction delays caused by acute ischemia also can contribute to Q wave pathogenesis in selected cases.

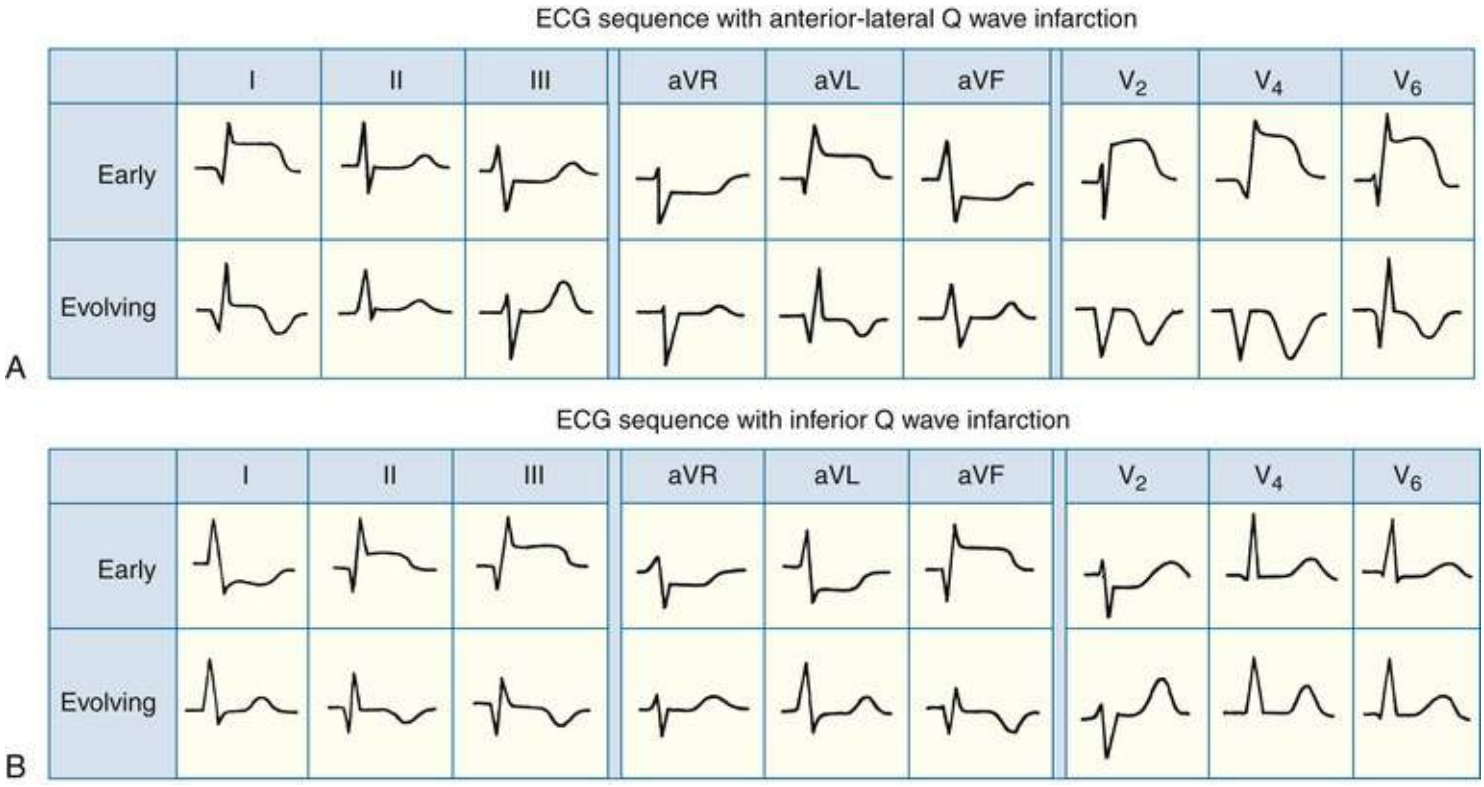

FIGURE 12.32 Sequence of depolarization and repolarization changes with acute anterior-lateral and inferior wall Q wave infarctions. **A,** With anterior-lateral infarcts, ST-segment elevation in leads I, aVL, and the precordial leads can be accompanied by reciprocal ST-segment depression in leads II, III, and aVF. **B,** Conversely, acute inferior (or posterior) infarcts can be associated with reciprocal ST-segment depression in leads V_1 to V_3. (From Goldberger AL, Goldberger ZD, Shvilkin A. Goldberger's Clinical Electrocardiography: a Simplified Approach. 9th ed. Philadelphia: Elsevier; 2017.)

Abnormal Q waves were once considered markers of transmural myocardial infarction, whereas subendocardial (*nontransmural*) infarcts were thought not to produce Q waves. However, careful experimental and correlative studies based on necropsy and imaging findings have convincingly indicated that transmural infarcts can occur without Q waves and that subendocardial or other nontransmural infarcts can be associated with Q waves.[2,42,46] Accordingly, evolving or chronic infarcts are more appropriately designated by ECG as "Q wave" or "non–Q wave," rather than as "transmural" or "nontransmural."

The QRS findings may also be somewhat different with posterior or lateral infarction (**Fig. 12.33**). Loss of depolarization forces in these regions can reciprocally increase R wave amplitude in lead V_1 and sometimes V_2, rarely without causing diagnostic Q waves in any of the conventional leads. The differential diagnosis for major causes of prominent right precordial R waves is presented in **Table 12.9**. In certain patients, fragmentation of the QRS complex, even without Q waves, may be a marker of myocardial scarring from ischemic or nonischemic causes.[51]

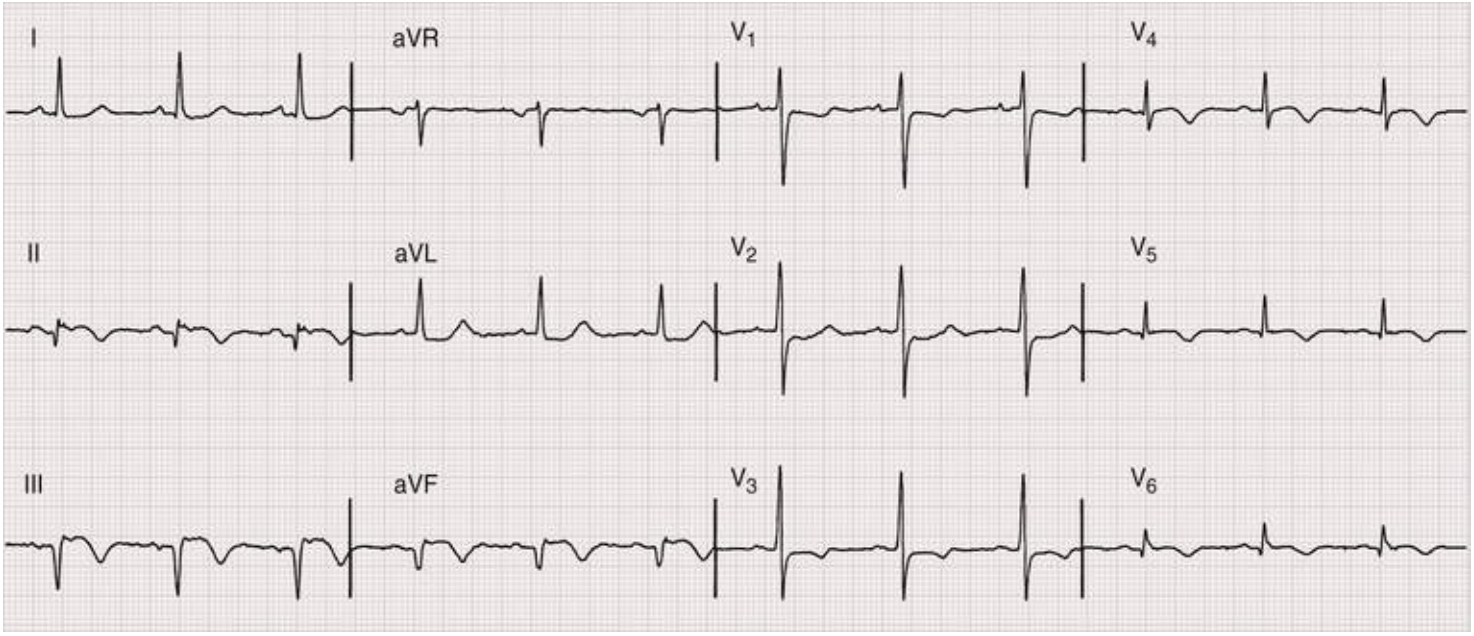

FIGURE 12.33 Evolving infero-posterolateral infarction. Note the prominent Q waves in II, III, and aVF, along with ST-segment elevation and T wave inversion in these leads, as well as V_3 through V_6. ST depression in I, aVL, V_1, and V_2 is consistent with a reciprocal change. Relatively tall R waves also are present in V_1 and V_2.

TABLE 12.9

Differential Diagnosis of Tall R Waves in Leads V_1 and V_2

Physiologic and Positional Factors
Misplacement of chest leads Normal variants Displacement of heart toward right side of chest (dextroversion), congenital or acquired
Myocardial Injury
Lateral or "true posterior" myocardial infarction Duchenne muscular dystrophy (**see Chapter 97**)
Ventricular Enlargement
RVH (usually with right axis deviation) Hypertrophic cardiomyopathy
Altered Ventricular Depolarization
Right ventricular conduction abnormalities WPW patterns (caused by posterior or lateral wall preexcitation)

Modified from Goldberger AL, Goldberger ZD, Shvilkin A. Goldberger's Clinical Electrocardiography: a Simplified Approach. 9th ed. Philadelphia: Elsevier; 2017.

Evolution of ECG Changes

Ischemic ST-segment elevation and hyperacute T wave changes may occur as the earliest ECG manifestations of STEMI. These are typically followed within hours to days by evolving T wave inversion and sometimes Q waves in the same lead distribution (**see Fig. 12.32 and Chapter 59**). T wave inversion from evolving or chronic ischemia correlates with increased ventricular action potential duration, and these ischemic changes are often associated with QT prolongation. The T wave inversions can resolve after days or weeks or may persist indefinitely.

The extent of the infarct may be an important determinant of T wave evolution. In one series, T waves that were persistently negative (inverted) for more than 1 year in leads with Q waves were associated with transmural infarction; by contrast, T waves that were positive in leads with Q waves correlated with nontransmural infarction, with viable myocardium within the wall.[52]

In the days to weeks or longer after infarction, the QRS changes can persist or begin to resolve.[46,53] Complete normalization of the ECG after Q wave infarction is uncommon but can occur, particularly with smaller infarcts, and with subsequent improvement of the left ventricular ejection fraction and regional wall motion. This development usually is associated with spontaneous recanalization or good collateral circulation and is a positive prognostic sign. By contrast, persistent Q waves and ST-segment elevation seen several weeks or more after infarction correlate strongly with severe underlying wall motion disorders (akinetic or dyskinetic zone), although not necessarily a frank ventricular aneurysm. The presence of an rSR′ or similar type of complex in the mid-left chest leads or lead I is another reported marker of a left ventricular aneurysm.

Other Ischemic ST-T Patterns

Reversible transmural ischemia, such as that caused by coronary vasospasm, may result in transient ST-segment elevation[42,44,46] (**Fig. 12.34**). This pattern is the classic ECG marker of *Prinzmetal variant angina* (**see Chapter 60**). Depending on the severity and duration of such noninfarction ischemia, the ST-segment elevation either can resolve within minutes or can be followed by T wave inversion that can persist for hours or even days.

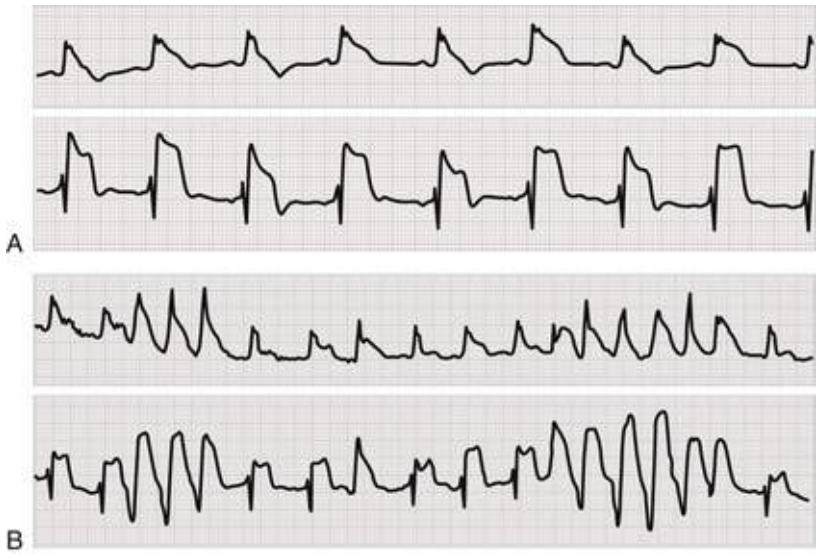

FIGURE 12.34 **A,** ECG tracing from a patient with Prinzmetal angina with ST-segment elevation and ST-T wave (repolarization) alternans. **B,** ECG shows ST segment elevation and T wave alternans associated with nonsustained ventricular tachycardia. (Courtesy Dr. C. Fisch.)

Some patients with ischemic chest pain exhibit deep coronary T wave inversion in multiple precordial leads (e.g., V_1 through V_4), with or without cardiac enzyme level elevations. This finding typically is the result of severe ischemia associated with a high-grade stenosis in the proximal left anterior descending (LAD) coronary artery system (referred to as the LAD–T wave or *Wellens' pattern*). These T wave inversions may be preceded by transient ST-segment elevations that resolve by the time the patient arrives at the hospital. Furthermore, T wave inversions of this type, especially in the setting of unstable angina, can correlate with segmental hypokinesis of the anterior wall and suggest a myocardial stunning syndrome. The natural history of this syndrome is unfavorable, with a high incidence of recurrent angina and myocardial infarction.[42-44]

On the other hand, patients whose baseline ECG shows abnormal T wave inversion can experience paradoxical T wave normalization (*pseudonormalization*) during episodes of acute transmural ischemia

(**Fig. 12.35**). In summary, there are four major classes of acute coronary artery syndrome in which myocardial ischemia is associated with distinct ECG findings (**Fig. 12.36**).

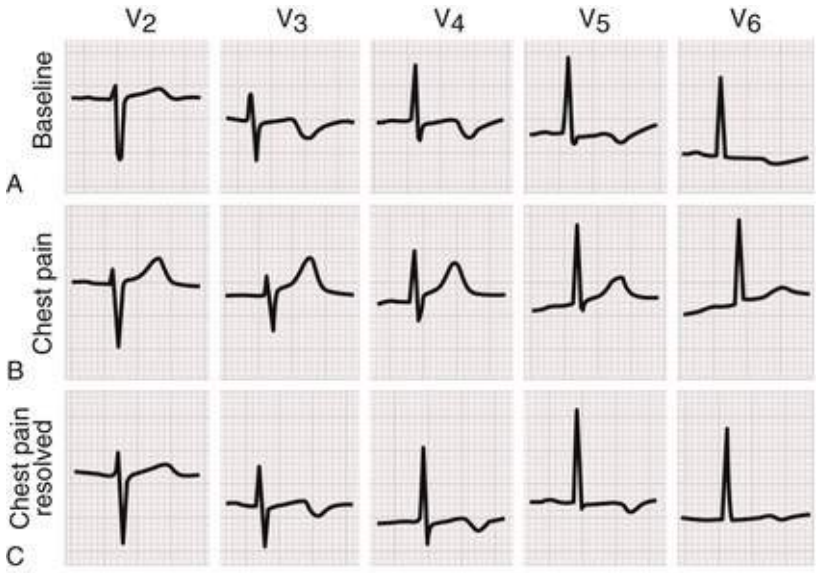

FIGURE 12.35 Pseudo– (paradoxical) T wave normalization. **A,** Baseline ECG of a patient with coronary artery disease shows ischemic T wave inversion. **B,** T wave "normalization" during an episode of ischemic chest pain. **C,** Following resolution of the chest pain, the T waves reverted to their baseline appearance. (**A, B,** From Goldberger AL, Goldberger ZD, Shvilkin A. Goldberger's Clinical Electrocardiography: a Simplified Approach. 9th ed. Philadelphia: Elsevier; 2017.)

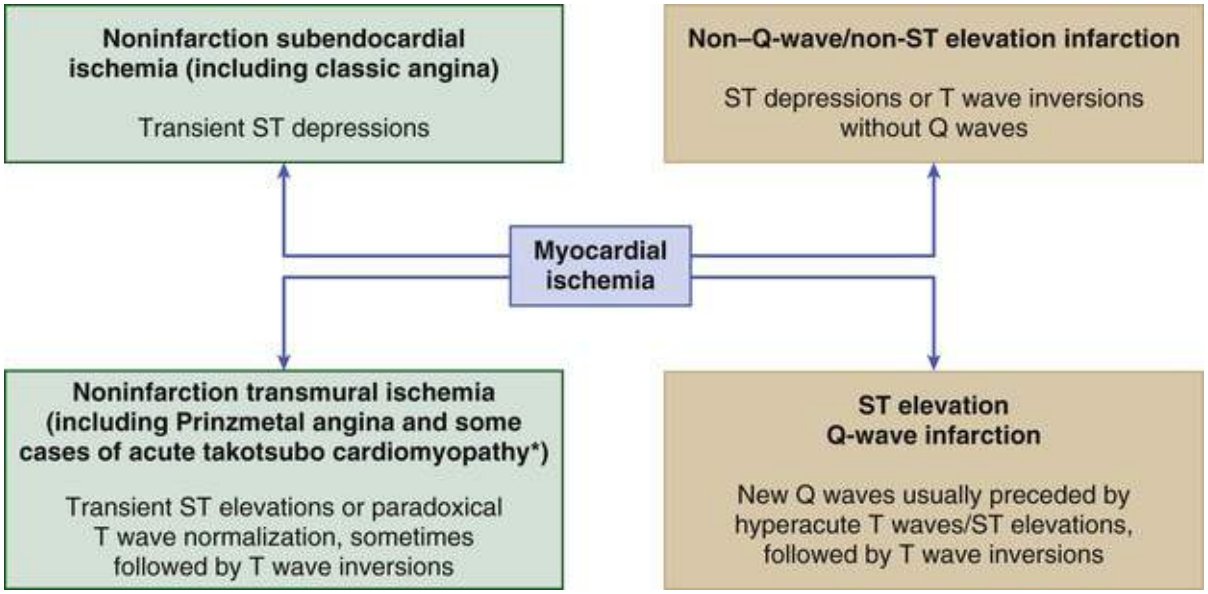

FIGURE 12.36 Variability of ECG patterns with acute myocardial ischemia. The ECG also may be normal or nonspecifically abnormal. Furthermore, these categorizations are not mutually exclusive. For example, a non–Q-wave infarct can evolve into a Q wave infarct, ST-segment elevation can be followed by a non–Q-wave infarct or ST-segment depression, and T wave inversion can be followed by a Q wave infarct. *May exactly mimic acute infarction. (From Goldberger AL, Goldberger ZD, Shvilkin A. Goldberger's Clinical Electrocardiography: a Simplified Approach. 9th ed. Philadelphia: Elsevier; 2017.)

Ischemic U Wave Changes

Alterations in U wave amplitude or polarity have been reported with acute ischemia or infarction.[54] For example, exercise-induced transient inversion of precordial U waves has been correlated with severe stenosis of the LAD coronary artery. Rarely, U wave inversion can be the earliest ECG sign of an acute coronary syndrome.

ECG Localization of Myocardial Ischemia and Infarction

The ECG leads are more helpful in localizing regions associated with ST-segment elevation than with ST-segment depression. ST-segment elevation and hyperacute T waves are seen in the following: (1) two or more contiguous precordial leads (V_1 through V_6) and/or in leads I and aVL with acute transmural anterior or anterolateral wall ischemia; (2) leads V_1 to V_3 with anteroseptal or apical ischemia; (3) leads V_4 to V_6 with apical or lateral ischemia; (4) leads II, III, and aVF with inferior wall ischemia; and (5) right-sided precordial leads with right ventricular ischemia.

In addition, posterior or posterolateral wall infarction induce ST-segment elevation in leads placed over the back of the heart, such as leads V_7 to V_9 (**see Table 12.1**), can be produced by lesions in the right coronary artery (RCA) or the left circumflex artery. Such blockages can produce both inferior and posterolateral injuries, which may be indirectly recognized by reciprocal ST-segment depression in leads V_1 to V_3. Similar ST changes also can be the primary ECG manifestation of anterior subendocardial ischemia. Posterolateral or inferolateral wall infarction with reciprocal changes can sometimes be differentiated from primary anterior wall ischemia by the presence of ST-segment elevations in posterior leads, although these are not routinely recorded.[55]

The ECG also can suggest specific information about the location of an acute occlusion within the coronary system (the “culprit lesion”).[2,42,47,50,56-59] With an inferior wall myocardial infarction, ST-segment elevation in lead III exceeding that in lead II, particularly combined with ST-elevation in lead V_1 (and other right-sided chest leads), is a reliable predictor of occlusion in the proximal to midportion of the RCA (**Fig. 12.37**). By contrast, the presence of ST-segment elevation in lead II equal to or exceeding that in lead III, especially in concert with ST-segment depression in leads V_1 to V_3 or ST-segment elevation in leads I and aVL, suggests occlusion of the left circumflex artery or a distal occlusion of a dominant RCA.

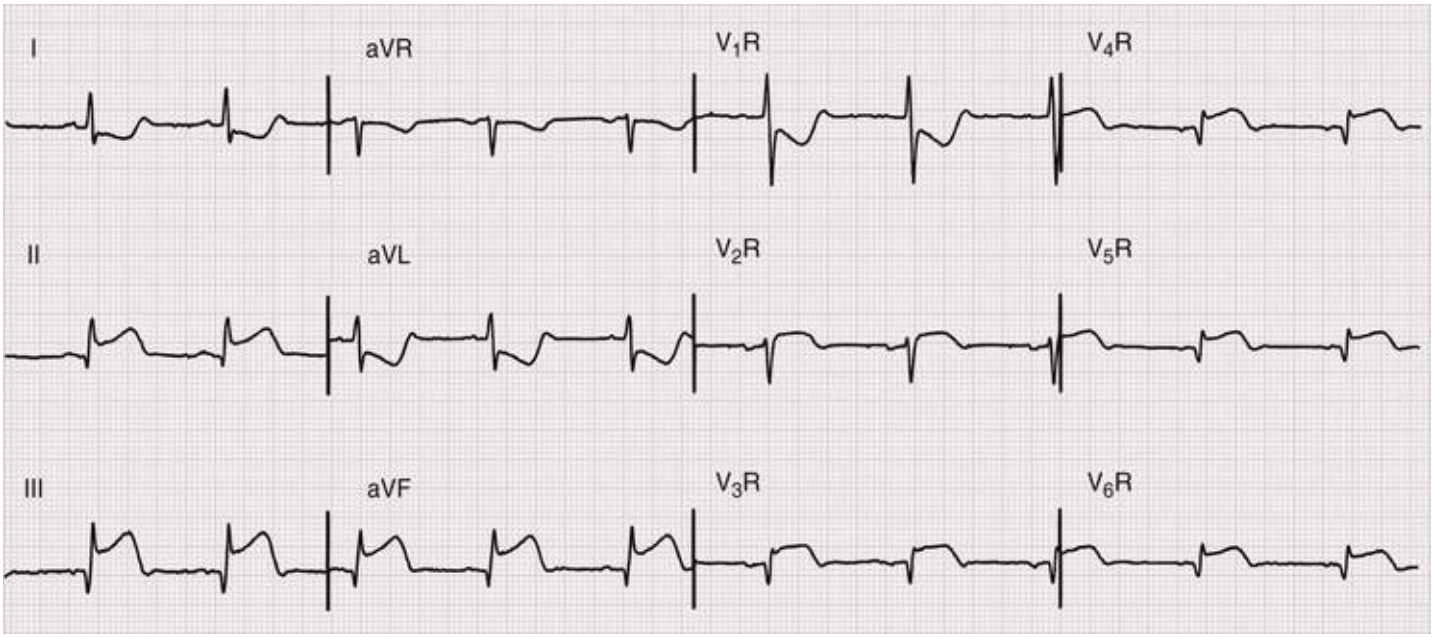

FIGURE 12.37 Acute right ventricular infarction in concert with an acute inferior wall ST-segment elevation infarction. Note the ST-segment elevation in the right precordial leads, as well as in leads II, III, and aVF, with reciprocal changes in leads I and aVL. ST-segment elevation in lead III greater than in lead II and right precordial ST-segment elevation are consistent with proximal to middle occlusion of the right coronary artery. The combination of ST-segment elevation in conventional lead V_1 (note: V_2R here) juxtaposed with ST-segment depression in lead V_2 (note: lead V_1R here) also has been reported with acute right ventricular ischemia or infarction.

Right-sided ST-segment elevation is indicative of acute right ventricular injury and usually indicates occlusion of the proximal RCA. Of note is the finding that acute right ventricular infarction can project an injury current pattern in leads V_1 through V_3 or even V_4, thus simulating anterior infarction. In other cases, simultaneous ST-segment elevation in V_1 (V_2R) and ST-segment depression in V_2 (V_1R) can occur (**Fig. 12.37**).

Lead aVR[56,57] may provide important clues to the location of artery occlusion in acute myocardial infarction. Left main (or severe multivessel) coronary artery disease should be considered when leads aVR and V_1 show ST-segment elevation, especially in concert with diffuse prominent ST-segment depression in other leads.

These and multiple other criteria proposed for localization of the site of acute coronary occlusion based on the initial ECG still require additional validation in larger populations. Current and future criteria will always be subject to limitations and exceptions based on interindividual variations in coronary anatomy, the dynamic nature of acute ECG changes, the presence of multivessel involvement, collateral flow, and the presence of ventricular conduction delays.

For example, in some cases, ischemia can affect more than one region of the myocardium (e.g., inferolateral; **see Fig. 12.32**). The ECG may show the characteristic features of involvement in each region. Sometimes, however, partial normalization can result from cancellation of opposing vectorial forces. Similarly, inferior lead ST-segment elevation accompanying acute anterior wall infarction suggests either occlusion of a left anterior descending artery that extends onto the inferior wall of the left ventricle (the wraparound vessel) or multivessel disease with jeopardized collaterals.

ECG Diagnosis of Myocardial Infarction with Bundle Branch Blocks

The diagnosis of myocardial infarction (MI) often is more difficult when the baseline ECG shows a bundle branch block pattern or when bundle branch block develops as a complication of the MI. The

diagnosis of Q wave infarction usually is not impeded by the presence of RBBB, which affects primarily the terminal phase of ventricular depolarization (see earlier). The net effect is that the criteria for the diagnosis of a Q wave infarct in a patient with RBBB are the same as in patients with normal conduction (**Fig. 12.38**).

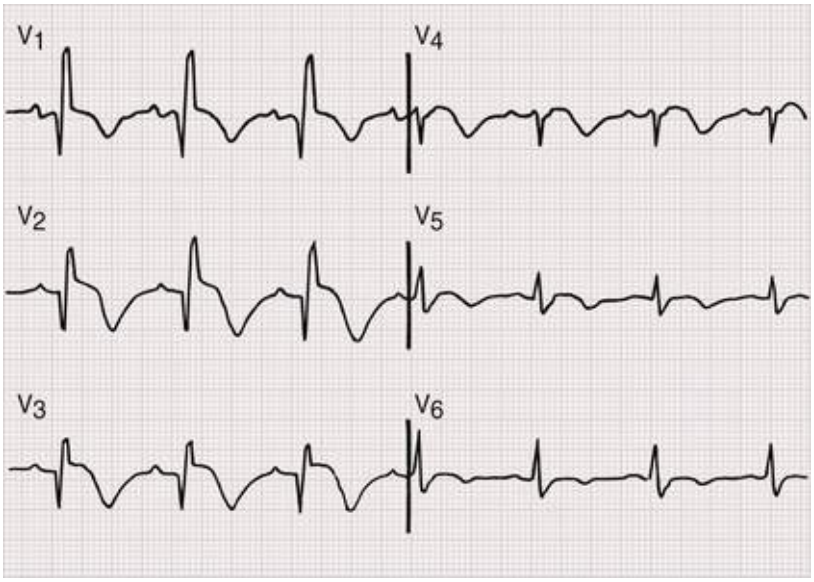

FIGURE 12.38 RBBB with acute anterior infarction. Loss of anterior depolarization forces results in QR-type complexes in the right precordial to midprecordial leads, with ST-segment elevations and evolving T wave inversions (V_1 through V_6).

The diagnosis of infarction in the presence of LBBB is considerably more complicated and confusing, because LBBB alters the early and the late phases of ventricular depolarization and produces secondary ST-T changes. These changes may mask and/or mimic MI findings. As a result, considerable attention has been directed to the problem of diagnosing acute and chronic MI in patients with LBBB[60] (**Fig. 12.39**).

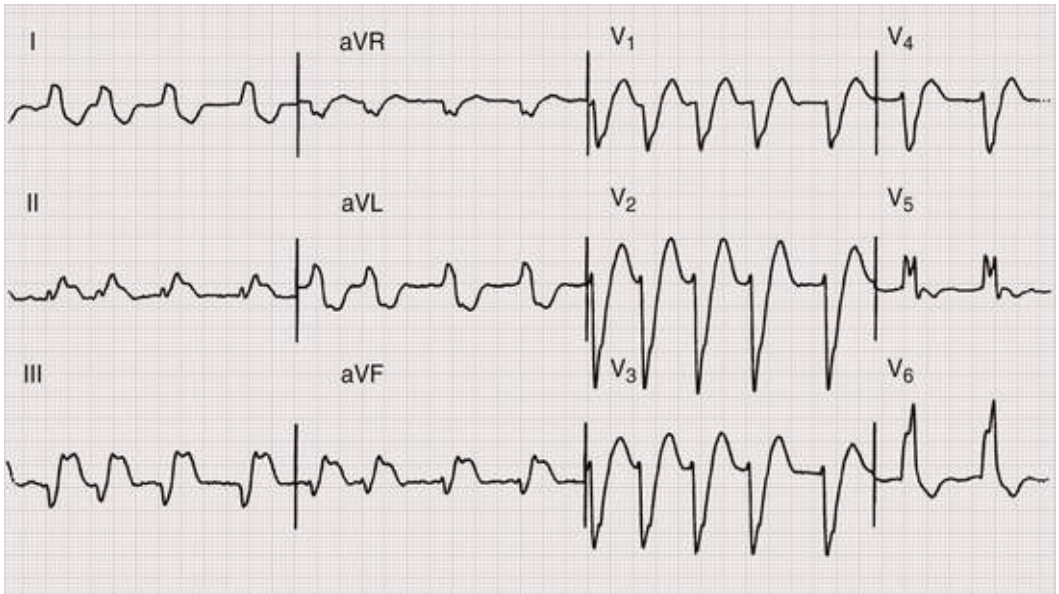

FIGURE 12.39 Complete LBBB with acute inferior myocardial infarction. Note the prominent ST-segment elevation in leads II, III, and aVF, with reciprocal ST-segment depression in leads I and aVL superimposed on secondary ST-T changes. The underlying rhythm is atrial fibrillation.

Infarction of the left ventricular free (or lateral) wall ordinarily results in abnormal Q waves in the midprecordial to lateral precordial leads and in selected limb leads. However, the initial septal depolarization forces with LBBB are directed from right to left. These leftward forces produce an initial R wave in the midprecordial to lateral precordial leads, usually masking the loss of electrical potential (Q waves) caused by the MI. Therefore, acute or chronic left ventricular free wall infarction by itself will not usually produce diagnostic Q waves in the presence of LBBB. Acute or chronic MI involving both the free wall and septum (or the septum itself) may produce abnormal Q waves (usually as part of QR-type complexes) in leads V_4 to V_6. These initial Q waves probably reflect posterior and superior forces from the spared basal portion of the septum (**Fig. 12.40**). Thus a wide Q wave (40 milliseconds) in one or more of these leads is a reliable sign of underlying MI. The sequence of repolarization also is altered in LBBB, as described earlier, and these changes can mask or simulate the ST-segment changes of actual ischemia.

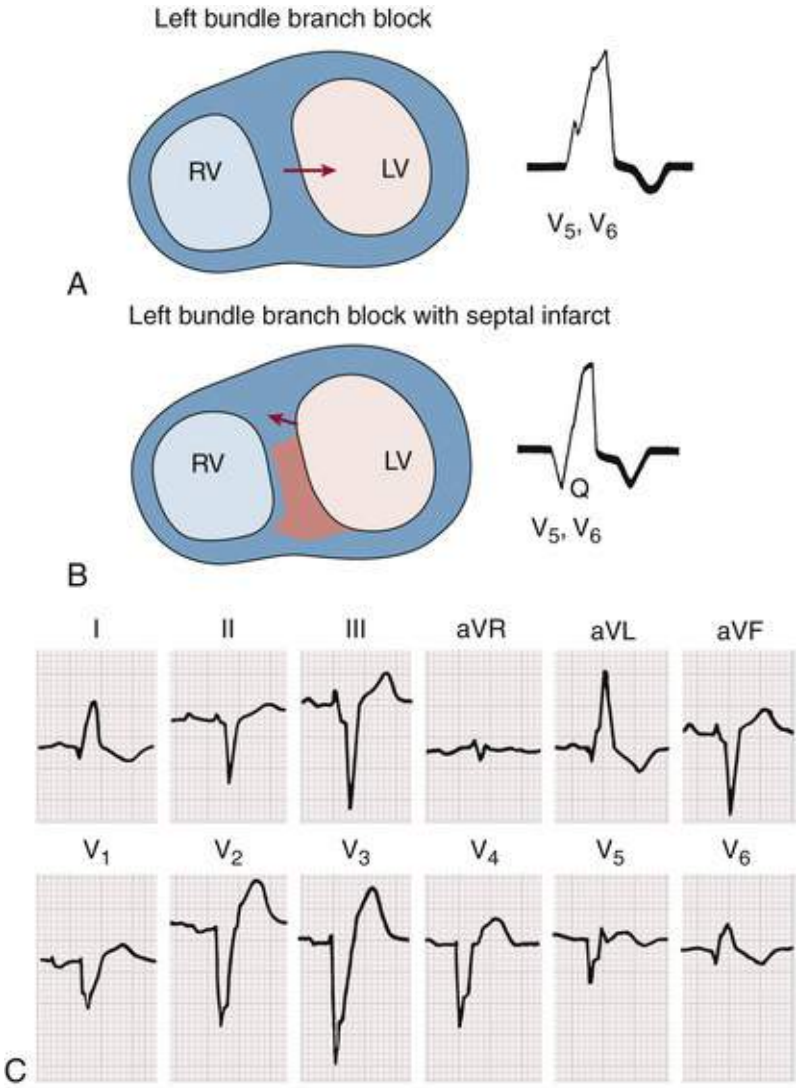

FIGURE 12.40 **A,** With uncomplicated LBBB, early septal forces are directed to the left (*arrow*). Therefore, no Q waves will be seen in V_5 and V_6 on the ECG tracing. **B,** With LBBB complicated by anteroseptal infarction, early septal forces can be directed posteriorly and rightward (*arrow*). Therefore, prominent Q waves may appear in leads V_5 and V_6 as a paradoxical marker of septal infarction. **C,** ECG from patient with anterior wall infarction (involving septum) with LBBB. Note the presence of QR complexes in leads I, aVL, V_5, and V_6. *LV,* Left ventricle; *RV,* right ventricle. (**A, B,** Modified from Dunn MI, Lipman BS. Lipman-Massie Clinical Electrocardiography. 8th ed. Chicago: Year Book; 1989.)

The following points summarize the ECG signs of MI in LBBB:

1. ST-segment elevation with tall, positive T waves frequently is seen in the right precordial leads with uncomplicated LBBB. Secondary T wave inversions are characteristically seen in the lateral precordial leads. However, the appearance of ST-segment elevations in the lateral leads or ST-segment depressions or deep T wave inversions in leads V_1 to V_3 strongly suggests underlying ischemia. More marked ST-segment elevations (>0.5 mV) in leads with QS or rS waves also may be caused by acute ischemia, but false-positive findings occur, especially with large-amplitude negative QRS complexes. Use of the ratio of the *absolute* amplitude of the ST-segment to S wave, determined in any relevant lead of greater than 0.25 has been proposed as having greater accuracy than that of the original criterion.[59] Further studies are needed to confirm this finding and test other proposed criteria.
2. The presence of QR complexes in leads I, V_5, or V_6 or in II, III, and aVF with LBBB strongly suggests underlying MI.
3. Chronic MI also is suggested by notching of the ascending part of a wide S wave in the midprecordial leads or the ascending limb of a wide R wave in lead I, aVL, V_5, or V_6.

Similar principles can apply to the diagnosis of acute and chronic MI in the presence of right ventricular pacing. Comparison between an ECG exhibiting the LBBB before the infarction and the present ECG often is helpful to show these changes.

The diagnosis of concomitant LAFB and inferior wall MI also can pose challenges. This combination can result in loss of the small r waves in the inferior leads, so leads II, III, and aVF show QS, not rS, complexes.

However, LAFB may also hide the diagnosis of inferior wall MI. The inferior orientation of the initial QRS forces caused by the fascicular block can mask inferior Q waves, with resultant rS complexes in leads II, III, and aVF. In other cases, the combination of LAFB and inferior wall MI will produce qrS complexes in the inferior limb leads, with the initial q wave the result of the infarct and the minuscule r wave the result of the fascicular block.

Atrial Infarction

A number of ECG clues to the diagnosis of atrial infarction have been suggested. These include localized deviations of the PR segment, such as PR elevation in lead V_5 or V_6 or the inferior leads,[60,61] changes in P wave morphology, and atrial arrhythmias. The sensitivity and specificity of these signs are limited, however.

ECG Differential Diagnosis of Ischemia and Infarction

The ECG has important limitations in sensitivity and specificity in the diagnosis of coronary syndromes.[42,43,46] A normal or nondiagnostic ECG does not exclude ischemia or even acute infarction.[62,63] If the initial ECG is not diagnostic, but the patient remains symptomatic, with a clinical picture strongly suggestive of acute ischemia, the ECG should be repeated at 15- to 30-minute intervals or shorter.[45] However, a normal ECG throughout the course of an acute infarction is distinctly uncommon. As a result, prolonged chest pain without suggestive or diagnostic ECG changes on repeat ECGs should always prompt a careful search for noncoronary causes of chest pain (**see Chapter 56**).

Noninfarction Q Waves and Related Depolarization Changes

Loss of electromotive force associated with myocardial necrosis contributes to R wave loss and Q wave formation in MI. This mechanism of Q wave pathogenesis, however, is not specific for coronary artery disease with infarction. Any process, acute or chronic, that causes sufficient loss of regional electromotive potential can result in Q waves. For example, replacement of myocardial tissue by electrically inert material such as amyloid or tumor can cause noninfarction Q waves (**see Chapters 77 and 95**). A variety of dilated cardiomyopathies associated with extensive myocardial fibrosis can cause pseudoinfarction patterns. Ventricular hypertrophy also can contribute to the appearance of Q waves.

Q waves simulating the ECG pattern of coronary artery disease can be related to one (or a combination) of the following four factors[46] (**Table 12.10**): (1) physiologic or positional variants, (2) altered ventricular conduction, (3) ventricular enlargement, and (4) myocardial damage or replacement.

TABLE 12.10

Differential Diagnosis of Noninfarction Q Waves (With Select Examples)

Physiologic or Positional Factors
Normal variant "septal" Q waves
Normal variant Q waves in V_1-V_2, III, and aVF
Left pneumothorax or dextrocardia—loss of lateral R wave progression
Myocardial Injury or Infiltration
Acute processes—myocardial ischemia without infarction, takotsubo cardiomyopathy myocarditis, hyperkalemia (rare cause of transient Q waves)
Chronic myocardial processes—idiopathic cardiomyopathies, myocarditis, amyloid, tumor, sarcoid
Ventricular Hypertrophy or Enlargement
Left ventricular (slow R wave progression)*
Right ventricular (reversed R wave progression† or slow R wave progression, particularly with chronic obstructive lung disease)
Hypertrophic cardiomyopathy (can simulate anterior, inferior, posterior, or lateral infarcts
Conduction Abnormalities
LBBB (slow R wave progression*)
WPW patterns

*Small or absent R waves in the right precordial to midprecordial leads.

†Progressive decrease in R wave amplitude from V_1 to the midlateral precordial leads.

Modified from Goldberger AL, Goldberger ZD, Shvilkin A. Goldberger's Clinical Electrocardiography: a Simplified Approach. 9th ed. Philadelphia: Elsevier; 2017.

Prominent Q waves can be associated with a variety of positional factors that alter the orientation of the heart vis-à-vis a specific lead axis. Depending on the electrical axis, prominent Q waves (as part of QS- or QR-type complexes) can appear in the limb leads (aVL with a vertical axis and III and aVF with a horizontal axis). A QS complex can appear in lead V_1 as a normal variant but rarely in leads V_1 and V_2. Slow R wave progression, sometimes with actual QS waves, can be caused solely by improper placement of chest electrodes above their usual position. With dextrocardia (**see Chapter 75**), in the absence of underlying structural abnormalities, normal R wave progression can be restored by recording leads V_2 to V_6 on the right side of the chest (with lead V_1 placed in the V_2 position). A rightward mediastinal shift with left pneumothorax can contribute to the apparent loss of left precordial R waves. Other positional factors associated with slow R wave progression include pectus excavatum and congenitally corrected transposition of the great vessels.

An intrinsic change in the sequence of ventricular depolarization can lead to pathologic, noninfarct Q waves. The two most important conduction disturbances associated with pseudoinfarction Q waves are LBBB and the Wolff-Parkinson-White (WPW) preexcitation patterns. With LBBB, QS complexes can appear in the right precordial to midprecordial leads and occasionally in leads II, III, and/or aVF. Depending on the location of the bypass tract, WPW preexcitation can mimic anteroseptal, lateral, or

inferior-posterior infarction.

LAFB is sometimes cited as a cause of anteroseptal infarct patterns; however, LAFB usually has only minor effects on the QRS complex in horizontal plane leads. Probably the most common findings are relatively prominent S waves in leads V_5 and V_6. Slow R wave progression is not a consistent feature of LAFB, although minuscule q waves in leads V_1 to V_3 have been reported in this setting. These small q waves can become more apparent if the leads are recorded one interspace above their usual position and disappear in leads that are one interspace below their usual position. As a general clinical rule, however, prominent Q waves (as part of QS or QR complexes) in the right precordial to midprecordial leads should *not* be attributed to LAFB alone.

Q waves caused by myocardial injury, whether ischemic or nonischemic in origin, can appear transiently and do not necessarily signify irreversible heart muscle damage. Severe ischemia can cause regional loss of electromotive potential without actual cell death (*electrical stunning* phenomenon). Transient conduction disturbances also can cause alterations in ventricular activation and result in noninfarctional Q waves. In some cases, transient Q waves may represent unmasking of a previous Q wave infarct. New but transient Q waves have been described in patients with severe hypotension from a variety of causes, as well as with tachyarrhythmias, myocarditis, Prinzmetal angina, protracted hypoglycemia, phosphorus poisoning, and hyperkalemia.

Slow ("poor") R wave progression is a nonspecific finding and is frequently observed with LVH and with acute or chronic right ventricular overload. Q waves in such settings can reflect a variety of mechanisms, including a change in the balance of early ventricular depolarization forces and altered cardiac geometry and position. A marked loss of R wave voltage, sometimes with frank Q waves from lead V_1 to the lateral chest leads, can be seen with chronic obstructive pulmonary disease (**see Fig. 12.18**). The presence of low limb voltage and signs of right atrial abnormality (P pulmonale) can serve as additional diagnostic clues. This loss of R wave progression in part may be related to right ventricular dilation and downward displacement of the heart in an emphysematous chest, as discussed earlier. Partial or complete normalization of R wave progression can be achieved in some of these cases by recording the chest leads an interspace lower than usual.

Other ventricular overload syndromes, acute or chronic, can also mimic ischemia and infarction. Acute cor pulmonale caused by pulmonary embolism (**see Chapter 84**) can cause a variety of pseudoinfarct patterns. Acute right ventricular overload in this setting can cause slow R wave progression and sometimes right precordial to midprecordial T wave inversion (sometimes still referred to as right ventricular "strain"), mimicking anterior ischemia or infarction. The classic $S_1Q_3T_3$ pattern can occur but, as noted, is neither sensitive nor specific. A prominent Q wave (usually as part of a QR complex) also can occur in lead aVF along with this pattern (**see Fig. 12.19**). However, acute right overload by itself does not cause a pathologic Q wave in lead II. Right-sided heart overload, acute or chronic, also may be associated with a QR complex in lead V_1, simulating anteroseptal infarction.

Pseudoinfarction patterns are important findings in patients with hypertrophic cardiomyopathy, and the ECG changes can simulate those in anterior, inferior, posterior, or lateral infarction. The pathogenesis of depolarization abnormalities in this cardiomyopathy is not certain. Prominent inferolateral Q waves (leads II, III, aVF, and V_4 to V_6) and tall, right precordial R waves probably are related to increased depolarization forces generated by the markedly hypertrophied septum (**Fig. 12.41**). Abnormal septal depolarization also can contribute to bizarre QRS complexes.

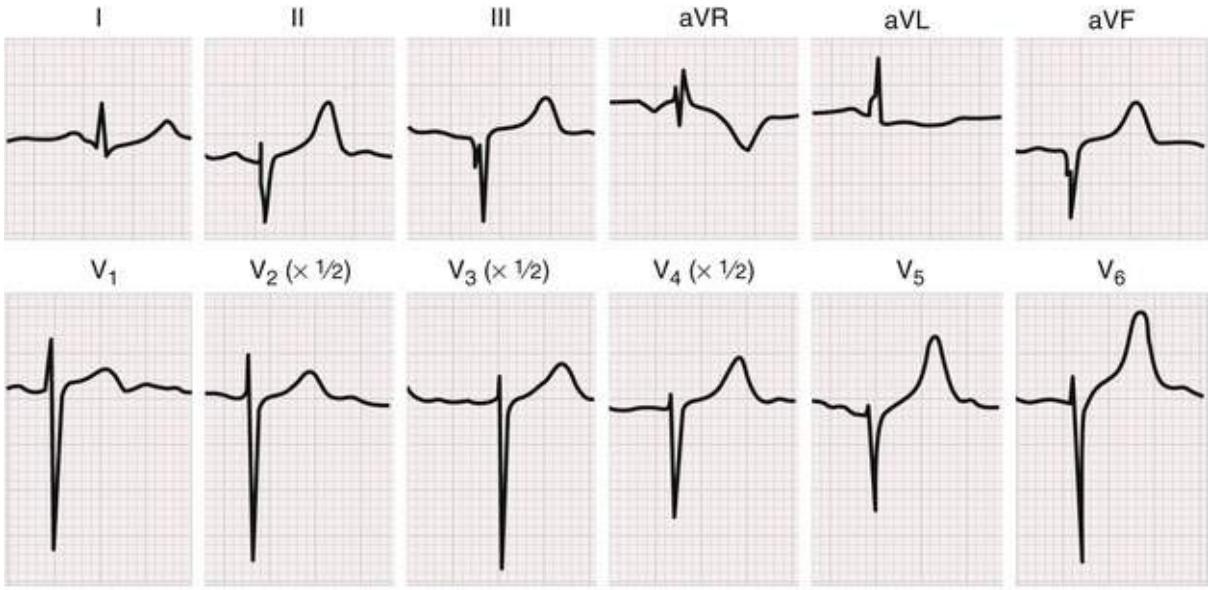

FIGURE 12.41 Hypertrophic cardiomyopathy simulating inferolateral infarction. This ECG was obtained in an 11-year-old girl who had a family history of hypertrophic cardiomyopathy. Note the W-shaped QS waves and the qrS complexes in the inferior and lateral precordial leads. (From Goldberger AL, Goldberger ZD, Shvilkin A. Goldberger's Clinical Electrocardiography: a Simplified Approach. 7th ed. Philadelphia: Elsevier; 2017.)

ST-T Changes Simulating Ischemia and Infarction

The differential diagnosis of STEMI (or ischemia)[44-50] caused by obstructive coronary disease encompasses a wide variety of clinical entities, including acute pericarditis (**Fig. 12.42**) (**see Chapter 83 and Fig. 83.2**), acute myocarditis (**Chapter 79**), normal variants, including classic "early repolarization" patterns (**see Fig. 12.11**), takotsubo (stress) cardiomyopathy,[64,65] Brugada patterns (**Chapters 33 and 39**), and other conditions (**Table 12.11**). Acute pericarditis, unlike MI, typically induces diffuse ST-segment elevation, usually in most of the chest leads and also in leads I, aVL, II, and aVF. Reciprocal ST-segment depression is seen in lead aVR. An important clue to acute pericarditis, in addition to the diffuse nature of the ST-segment elevation, is the frequent presence of PR-segment elevation in aVR, with reciprocal PR-segment depression in other leads, caused by a concomitant atrial current of injury (**see Fig. 12.42**). Abnormal Q waves do not occur with acute pericarditis, and the ST-segment elevation may be followed by T wave inversion after a variable period. Severe acute myocarditis can produce identical ECG patterns of acute myocardial infarction (AMI), including ST-segment elevations and Q waves. These findings can be associated with a rapidly progressive course and increased mortality.

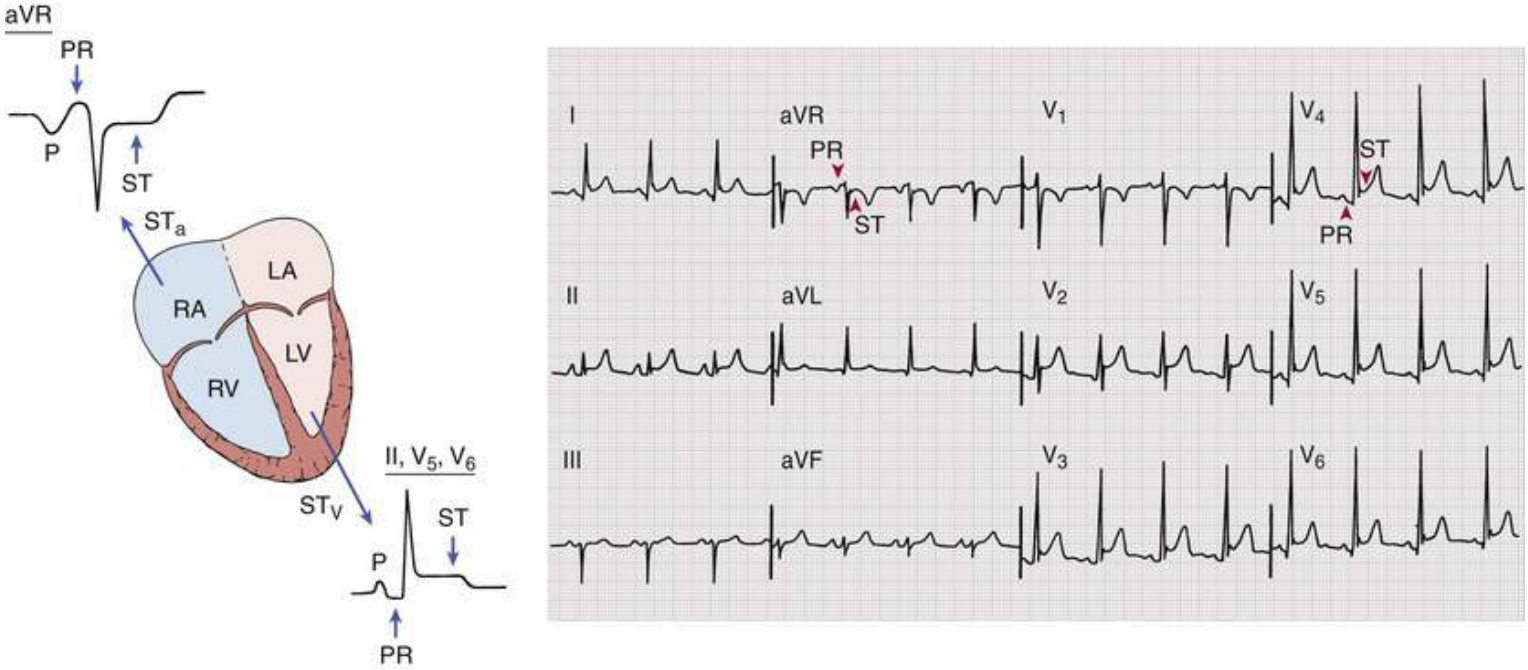

FIGURE 12.42 Acute pericarditis often is characterized by two apparent injury currents, one atrial and the other ventricular. The atrial injury current vector (ST_a) usually is directed upward and to the right (see diagram at *left*) and produces PR-segment elevation in aVR, with reciprocal PR depression in II, V_5, and V_6. The ventricular injury current (ST_V) is directed downward and to the left, associated with ST-segment elevation in leads II, V_5, and V_6. This characteristic PR-ST segment discordance is illustrated in the bottommost tracing. Note the diffuse distribution of ST-segment elevation in acute pericarditis (e.g., I, II, and V_2 through V_6, with reciprocal changes in aVR and perhaps minimally in V_1). *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. (From Goldberger AL. Myocardial Infarction: Electrocardiographic Differential Diagnosis. 4th ed. St Louis: Mosby–Year Book; 1991.)

TABLE 12.11
Differential Diagnosis of ST-Segment Elevation

Myocardial ischemia or infarction
Noninfarction, transmural ischemia (e.g., Prinzmetal angina pattern, takotsubo syndrome)
Acute myocardial infarction (caused by obstructive coronary occlusion or other causes)
Post–myocardial infarction (ventricular aneurysm pattern)
Acute pericarditis
Normal variants (including the classic "early repolarization" pattern)
LVH, LBBB (V_1-V_2 or V_3 only)
Other (rarer) causes
Acute pulmonary embolism (right to mid-chest leads)
Brugada pattern (RBBB-like pattern and ST-segment elevations in right precordial leads)*
Class IC antiarrhythmic drugs*
Hypercalcemia*
DC cardioversion (immediately after procedure)
Hyperkalemia*
Hypothermia (J or Osborn wave)
Intracranial hemorrhage
Myocardial injury (e.g., caused by trauma)
Myocarditis (may resemble myocardial infarction or pericarditis)
Tumor invading the left ventricle

*Usually most apparent in leads V_1 to V_2.

Modified from Goldberger AL, Goldberger ZD, Shvilkin A. Goldberger's Clinical Electrocardiography: a Simplified Approach. 9th ed. Philadelphia: Saunders; 2017.

Takotsubo cardiomyopathy (**see Chapter 77**), also called *transient left ventricular apical ballooning syndrome* or *stress cardiomyopathy*, is characterized by reversible wall motion abnormalities of the left ventricular apex and midventricle.[65,66] Patients, usually postmenopausal women, may present with chest pain, ST-segment elevations, and elevated cardiac enzyme levels, mimicking AMI caused by obstructive

coronary disease. The syndrome typically is reported in the setting of emotional or physiologic stress.

Fixed epicardial coronary disease is absent. The exact pathophysiology is not known but may relate to coronary vasospasm or adrenergically mediated myocardial damage,[65] resulting in a variety of ST-T elevation (or depression) changes simulating coronary occlusion.

A number of factors, such as digitalis, ventricular hypertrophy, hypokalemia, secondary ST-T changes, and hyperventilation, can cause *ST-segment depression* mimicking that in non–ST-segment elevation ischemic syndromes. Similarly, *tall positive T waves* do not invariably represent hyperacute ischemic changes but can reflect normal variants, hyperkalemia, cerebrovascular injury, and left ventricular volume loads resulting from mitral or aortic regurgitation (**see Fig. 12.16**), among other causes. ST-segment elevation, J point elevations, and tall positive T waves also are common chronic findings in leads V_1 and V_2 with LBBB or LVH patterns, which may simulate acute ischemia.

As noted, a variety of other factors, pathologic and sometimes physiologic, can alter repolarization, causing prominent T wave inversion, sometimes simulating ischemia or evolving MI. For example, prominent primary T wave inversions also are a well-described feature of the ECG in cerebrovascular accidents (strokes), particularly with subarachnoid hemorrhage. The so-called *cerebrovascular accident (CVA) T wave pattern* characteristically is seen in multiple leads, with a widely splayed appearance usually associated with marked QT prolongation (**Fig. 12.43; see also Chapters 33 and 39**). Some studies have implicated structural damage (termed *myocytolysis*) in the hearts of patients with such T wave changes, probably induced by excessive sympathetic stimulation mediated through the hypothalamus. A role for concomitant vagal hyperactivation has also been postulated in the pathogenesis of such T wave changes, which usually are associated with bradycardia. Similar T wave changes have been reported after truncal vagotomy, radical neck dissection, and bilateral carotid endarterectomy. In addition, the massive diffuse T wave inversion seen in some patients after Stokes-Adams syncope may be related to a similar neurocardiogenic mechanism. Patients with subarachnoid hemorrhage also can show transient ST-segment elevation, as well as arrhythmias, including torsades de pointes. Ventricular dysfunction can even occur and may be related to takotsubo cardiomyopathy[64,65] or neurogenic stress–type syndromes (**see Chapters 65 and 99**).

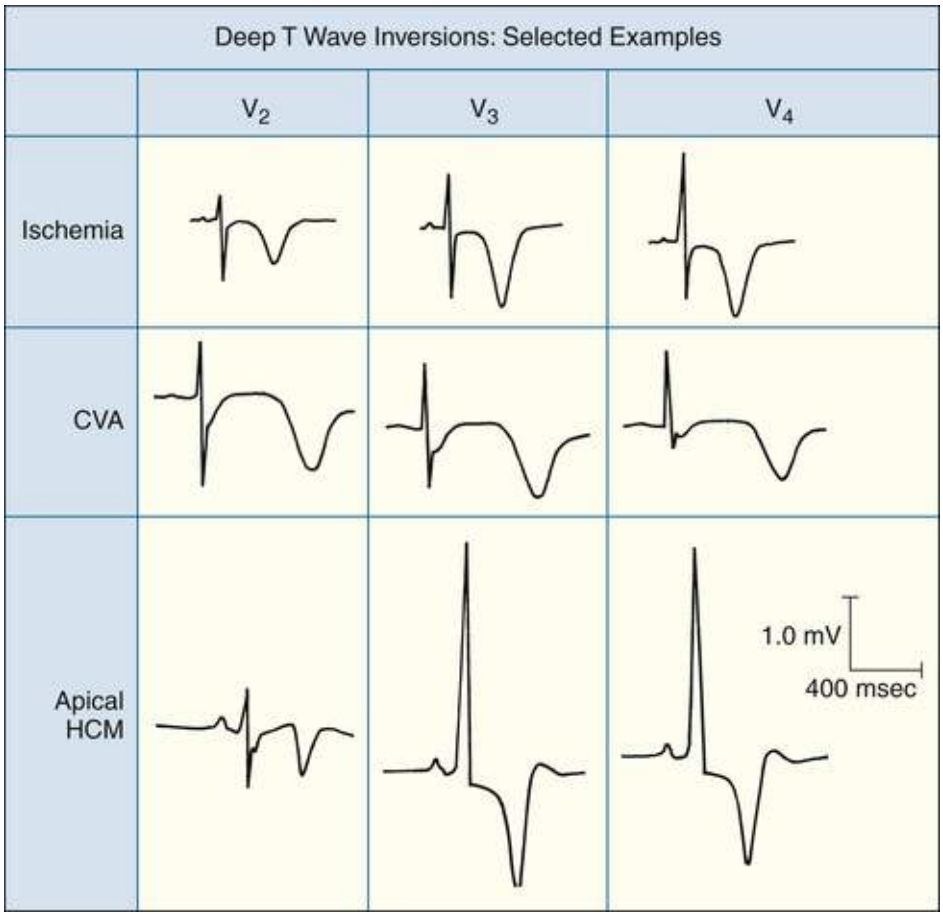

FIGURE 12.43 Deep T wave inversion can have various causes. In the *middle* tracing, note the marked QT prolongation in conjunction with the cerebrovascular accident (*CVA*) T wave pattern, caused here by subarachnoid hemorrhage. Apical hypertrophic cardiomyopathy (*HCM*), "memory T waves," and takotsubo syndrome are other causes of deep T wave inversion that can be mistaken for ischemia from acute/evolving or chronic obstructive coronary disease. (From Goldberger AL. Deep T wave inversions. ACC Curr J Rev 1996;5:28.)

In contrast to these primary ST-T wave abnormalities, secondary ST-T wave changes are caused by altered ventricular activation, without changes in action potential characteristics (discussed earlier). Examples include bundle branch block, WPW preexcitation, and ventricular ectopic or paced beats. In addition, transiently altered ventricular activation (associated with QRS interval prolongation) can induce T wave changes which can persist for hours to days after normal ventricular depolarization has resumed. The term *cardiac memory T wave changes* has been used in this context to describe repolarization changes after depolarization changes caused by ventricular pacing, intermittent LBBB, intermittent WPW preexcitation, and other alterations of ventricular activation[66] (**see Chapters 37 and 40**). T wave inversions also may occur. The term *idiopathic global T wave inversion* has been applied in cases in which no identifiable cause for prominent diffuse repolarization abnormalities can be found. Some of these cases may represent unrecognized takotsubo cardiomyopathy.

When caused by physiologic variants, T wave inversion is sometimes mistaken for ischemia. T waves in the right precordial leads can be slightly inverted, particularly in leads V_1 and V_2. Some adults show persistence of the juvenile T wave pattern (**see Fig. 12.10**), with more prominent T wave inversion in right precordial to midprecordial leads showing an rS or RS morphology. Such patterns, especially associated with LBBB-type premature ventricular beats or relevant family history, also raise strong consideration of *arrhythmogenic right ventricular cardiomyopathy* (formerly "dysplasia").[67] The other major normal variant that can be associated with notable T wave inversion is the so-called early repolarization pattern (**see Fig. 12.11**). As described earlier, some persons, especially athletes, with this

variant have prominent, biphasic T wave inversion in association with the ST-segment elevation. This pattern, which may simulate the initial stages of an evolving infarct, is most prevalent in young black men and endurance athletes. These functional ST-T changes probably are the result of regional disparities in repolarization and usually can be “normalized” by exercise. An important consideration in the differential diagnosis for such changes, especially in athletes, is apical hypertrophic cardiomyopathy.

Drug Effects

Numerous drugs can affect the ECG and often are associated with nonspecific ST-T alterations.[42,43] More marked changes, as well as atrioventricular and intraventricular conduction disturbances, can occur with select agents (**see Chapters 33 and 36**).

The term *digitalis effect*[68] refers to the relatively distinctive “scooped” appearance of the ST-T complex and shortening of the QT interval, which correlates with abbreviation of the ventricular action potential duration (**Fig. 12.44**). Digitalis-related ST-T changes can be accentuated by an increased heart rate during exercise, with consequent false-positive results on stress testing (**see Chapter 13**), and can occur with therapeutic or toxic doses of the drug. *Digitalis toxicity* refers specifically to systemic effects (e.g., nausea, anorexia) or conduction disturbances and arrhythmias caused by drug excess or increased sensitivity.

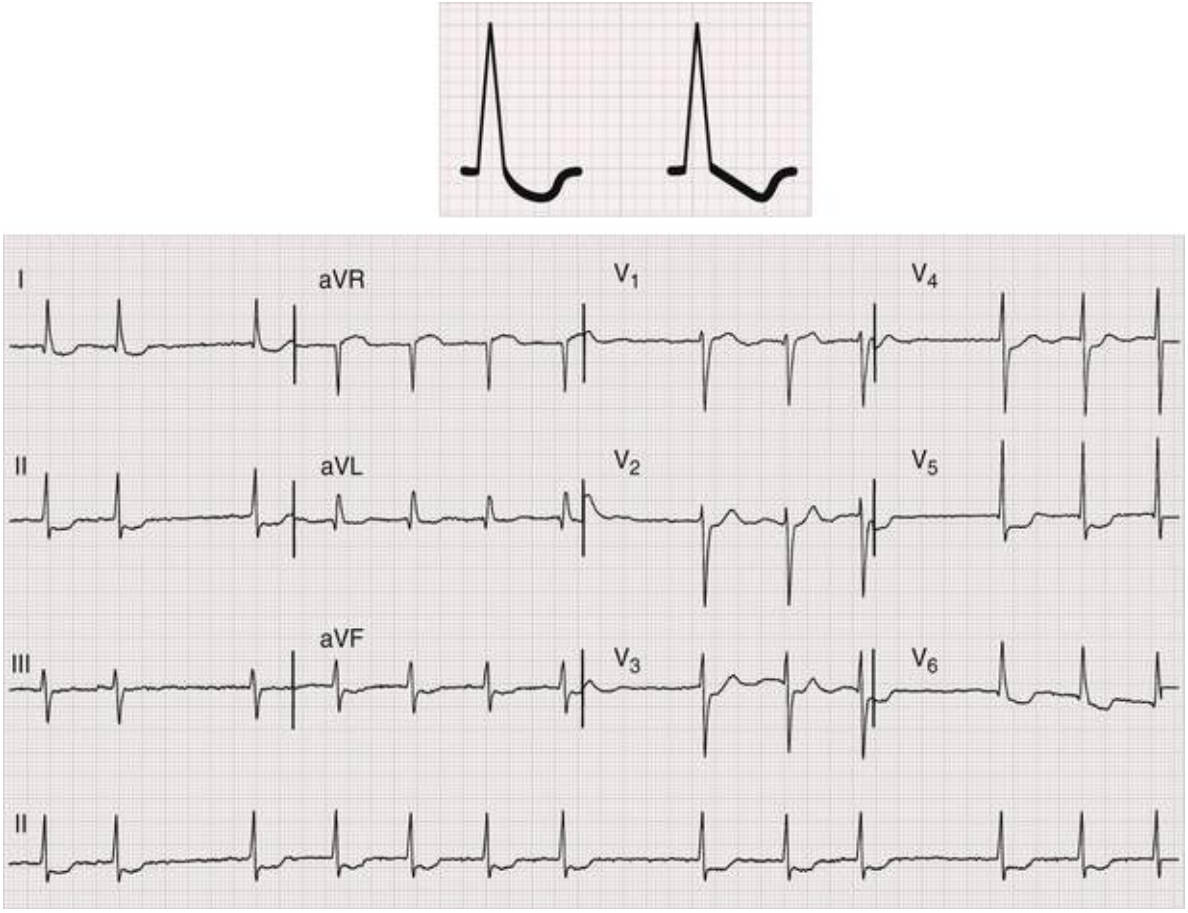

FIGURE 12.44 **Top,** Digitalis effect. Digitalis glycosides characteristically produce shortening of the QT interval with a scooped or downsloping ST-T complex. **Bottom,** Digitalis effect in combination with digitalis toxicity. The underlying rhythm is atrial fibrillation. A group beating pattern of QRS complexes with shortening of the R-R intervals is consistent with nonparoxysmal junctional tachycardia with probable exit (block atrioventricular Wenckebach) variant. ST-segment depression and scooping (lead V_6) are consistent with the digitalis effect, although ischemia or LVH cannot be excluded. These ECG findings are strongly suggestive of digitalis excess; the serum digoxin level was higher than 3 ng/mL. Note that digitalis effect (ST-T changes) does not necessarily imply digitalis toxicity. Most patients with digitalis toxicity, however, do show digitalis effect on the ECG. (**Top,** From Goldberger AL, Goldberger ZD, Shvilkin A. Goldberger's Clinical Electrocardiography: a Simplified Approach. 9th ed. Philadelphia: Elsevier; 2017.)

The ECG effects and toxicities of other cardioactive agents can be anticipated in part from ion channel effects (**see Chapter 33**). Inactivation of sodium channels by class I agents (e.g., quinidine, procainamide, disopyramide, flecainide) can cause QRS prolongation. Class IA (e.g., quinidine) and class III (e.g., amiodarone, dronedarone, dofetilide, ibutilide, sotalol) agents can induce an *acquired long QT(U) syndrome* (**see Chapters 34 and 36**). Psychotropic drugs (e.g., tricyclic antidepressants, phenothiazines), which have class IA–like properties, also can lead to QRS and QT(U) prolongation (**see Chapter 96**). Toxicity can produce asystole or torsades de pointes. Right axis shift of the terminal 40-millisecond frontal plane QRS axis may be a helpful additional marker of tricyclic antidepressant overdose. QT prolongation has been reported with methadone. Cocaine (**see Chapter 80**) can cause a variety of ECG changes, including those of STEMI, as well as life-threatening arrhythmias.

Electrolyte and Metabolic Abnormalities

In addition to the structural and functional cardiac conditions already discussed, numerous systemic metabolic aberrations may affect the ECG, including electrolyte abnormalities and acid-base disorders, as well as systemic hypothermia.[12,42,43]

Calcium

Hypercalcemia and hypocalcemia predominantly alter the action potential duration. An increased extracellular calcium concentration shortens the ventricular action potential duration by shortening phase 2. By contrast, hypocalcemia prolongs phase 2. These cellular changes are reflected in abbreviation or prolongation of the QT interval (ST-segment portion) with hypercalcemia or hypocalcemia, respectively (**Fig. 12.45**). Severe hypercalcemia (e.g., serum Ca^{2+} > 15 mg/dL) also can be associated with decreased T wave amplitude, sometimes with T wave notching or inversion. Hypercalcemia sometimes produces a high takeoff of the J point/ST segment in leads V_1 and V_2 and can thus simulate acute ischemia (**see Table 12.11**).

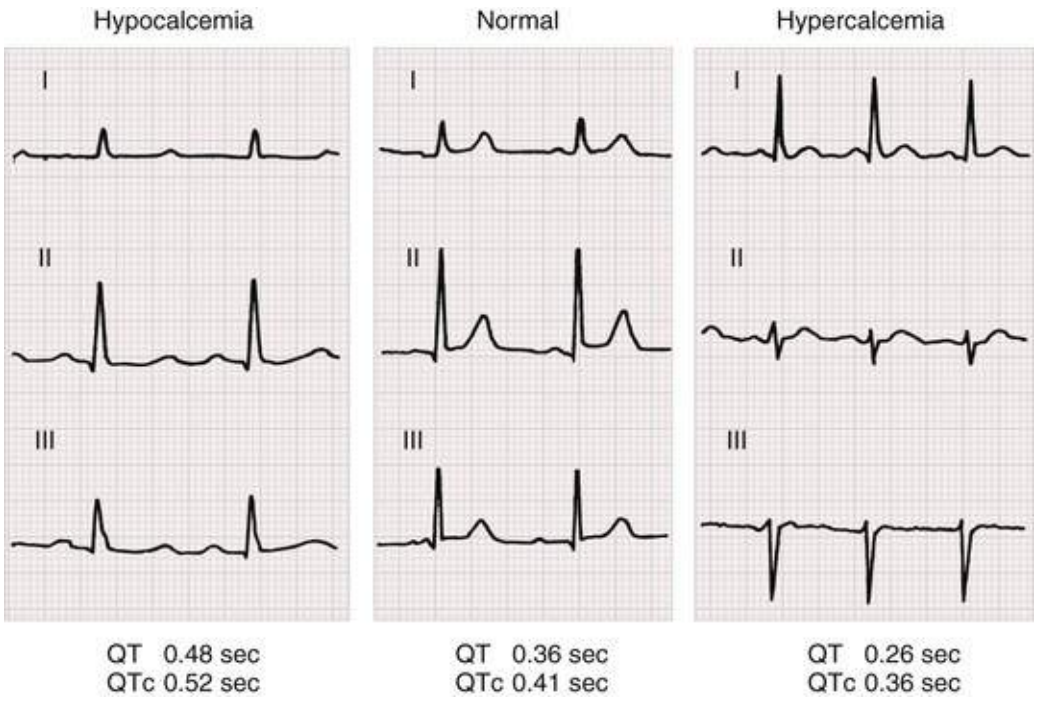

FIGURE 12.45 Prolongation of the QT interval (ST-segment portion) is typical of hypocalcemia. Hypercalcemia may cause abbreviation of the ST segment and shortening of the QT interval. (From Goldberger AL, Goldberger ZD, Shvilkin A. Goldberger's Clinical Electrocardiography: a Simplified Approach. 9th ed. Philadelphia: Elsevier; 2017.)

Potassium

Hyperkalemia is associated with a distinctive sequence of ECG changes (**Fig. 12.46A**). The earliest effect usually is narrowing and peaking (or *tenting*) of the T wave. The QT interval is shortened at this stage, reflecting a decreased action potential duration.

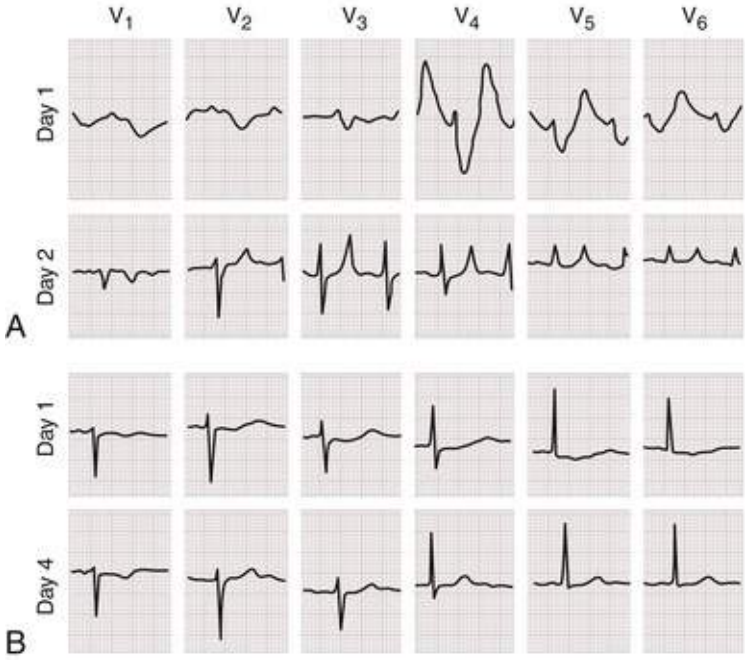

FIGURE 12.46 ECG changes in hyperkalemia **(A)** and hypokalemia **(B). A,** On day 1, at a K^+ level of 8.6 mEq/liter, the P wave is no longer recognizable and the QRS complex is diffusely prolonged. Initial and terminal QRS delays are characteristic of K^+-induced intraventricular conduction slowing and are best illustrated in leads V_2 and V_6. On day 2, at a K^+ level of 5.8 mEq/liter, the P wave is recognizable, with a PR interval of 0.24 second; the duration of the QRS complex is approximately 0.10 second, and the T waves are characteristically "tented." **B,** On day 1, at a K^+ level of 1.5 mEq/liter, the T and U waves are merged. The U wave is prominent and the QU interval is prolonged. On day 4, at a K^+ level of 3.7 mEq/liter, the tracing is normal. (**A, B,** Courtesy Dr. C. Fisch.)

Progressive extracellular hyperkalemia reduces atrial and ventricular resting membrane potentials, thereby inactivating sodium channels, which decreases Vmax and conduction velocity. The QRS begins to widen, and P wave amplitude decreases. PR interval prolongation can occur, followed sometimes by second- or third-degree atrioventricular block. Complete loss of P waves may be associated with a junctional escape rhythm or putative *sinoventricular rhythm*. In the latter, sinus rhythm persists with conduction (possibly over internodal tracts or muscle bundles) between the sinoatrial and atrioventricular nodes, but without producing an overt P wave.

Moderate to severe hyperkalemia occasionally induces ST elevations in the right precordial leads (V_1 and V_2), simulating an ischemic current of injury or Brugada-type patterns. Even severe hyperkalemia, however, can be associated with atypical or nondiagnostic ECG findings. Marked hyperkalemia leads to eventual asystole, sometimes preceded by a slow undulatory (or *sine wave*) ventricular flutter-like pattern. The ECG triad of peaked T waves (from hyperkalemia), QT (ST portion) prolongation (from hypocalcemia), and LVH (from hypertension) is strongly suggestive of chronic renal failure (**see Chapter 98**).

Electrophysiologic changes associated with hypokalemia, by contrast, include hyperpolarization of myocardial cell membranes and increased action potential duration. The major ECG manifestations are ST depression with flattened T waves and increased U wave prominence (**Fig. 12.46B**). U waves can exceed the amplitude of T waves, and distinguishing T waves from U waves can be difficult or impossible from the surface ECG. Indeed, apparent U waves in hypokalemia and other pathologic settings may actually be part of T waves whose morphology is altered by the effects of voltage gradients between M, or midmyocardial, cells and adjacent myocardial layers.[10,13] The prolongation of repolarization with hypokalemia, as part of an acquired long QT(U) syndrome, predisposes to the development of torsades de

pointes (**see Chapter 39**) and to tachyarrhythmias during digitalis therapy.

Magnesium.
Specific ECG effects of mild to moderate isolated abnormalities in magnesium ion concentration are not well characterized. Severe hypermagnesemia (serum Mg^{2+} > 15 mEq/L) can cause atrioventricular and intraventricular conduction disturbances that may culminate in complete heart block and cardiac arrest. Hypomagnesemia usually is associated with hypocalcemia or hypokalemia and can potentiate certain digitalis toxic arrhythmias The role of magnesium deficiency in the pathogenesis and treatment of the acquired long QT(U) syndrome with torsades de pointes is discussed in **Chapters 36 and 39**.

Other Factors.
Isolated hypernatremia or hyponatremia does not produce consistent effects on the ECG. Acidemia and alkalemia are often associated with hyperkalemia and hypokalemia, respectively. Systemic hypothermia may be associated with the appearance of a distinctive convex elevation at the junction (J point) of the ST segment and QRS complex (J wave or Osborn wave)[9,12] (**Fig. 12.47**). The cellular mechanism of this type of pathologic J wave appears to be related to an epicardial-endocardial voltage gradient associated with the localized appearance of a prominent epicardial action potential notch.

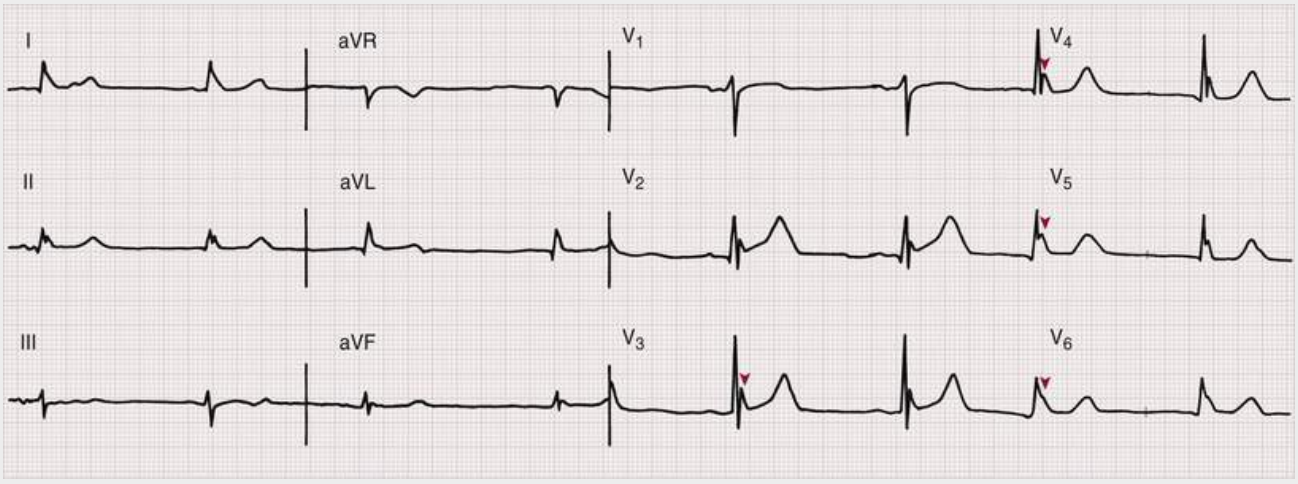

FIGURE 12.47 Systemic hypothermia. The *arrowheads* (leads V_3 through V_6) point to the characteristic convex J waves, termed *Osborn waves.* Prominent sinus bradycardia is also present, along with QT prolongation.

Nonspecific QRS and ST-T Changes

Low QRS voltage is considered to be present when the total (positive-to-negative peak) amplitude of the QRS complexes in each of the six extremity leads is 0.5 mV or less or 1.0 mV or less in leads V_1 through V_6. Low QRS voltage, as described earlier, can be caused by a variety of mechanisms, including increased insulation of the heart by air (chronic obstructive pulmonary disease) or adipose tissue (obesity); replacement of myocardium by fibrous tissue (ischemic or nonischemic cardiomyopathy), amyloid, or tumor; and possibly to short-circuiting (shunting) effects resulting from low resistance of fluids (especially with pericardial or pleural effusions, or anasarca). The combination of relatively low limb voltage (QRS voltage < 0.8 mV in each of the limb leads), relatively prominent QRS voltage in the chest leads (SV_1 or SV_2 + RV_5 or RV_6 > 3.5 mV), and slow R wave progression (R wave < S wave

amplitude in V_1 through V_4) has been reported as a relatively specific but not sensitive sign of dilated-type cardiomyopathies (sometimes referred to as the ECG "congestive heart failure triad").[42]

Ventricular repolarization is particularly sensitive to the effects of many factors in addition to ischemia (e.g., postural changes, meals, drugs, hypertrophy, electrolyte and metabolic disorders, central nervous system lesions, infections, pulmonary diseases) that can lead to a variety of *nonspecific ST-T changes*. The term usually is applied to slight ST-segment depression or T wave inversion or to T wave flattening without evident specific cause. Care must be taken not to overinterpret such changes, especially in persons with a low previous probability of heart disease. At the same time, subtle repolarization abnormalities can be markers of coronary or hypertensive heart disease or other types of structural heart disease; these probably account for the association of relatively minor but persistent nonspecific ST-T changes with increased cardiovascular mortality in middle-aged and older men and women.[69]

Alternans Patterns

The term *alternans* applies to conditions characterized by the sudden appearance of a periodic beat-to-beat change in some property of cardiac electrical or mechanical behavior. These abrupt changes (AAAA → ABAB pattern) are reminiscent of a generic class of patterns observed in perturbed nonlinear control systems. Many different forms of electrical alternans have been described clinically. Most familiar is total electrical alternans with sinus tachycardia, a specific but not highly sensitive marker of pericardial effusion with tamponade physiology (**Fig. 12.48**) (**see Chapter 34**). This finding is associated with an abrupt transition from a 1 : 1 to a 2 : 1 pattern in the "to-and-fro" swinging motion of the heart in the effusion.

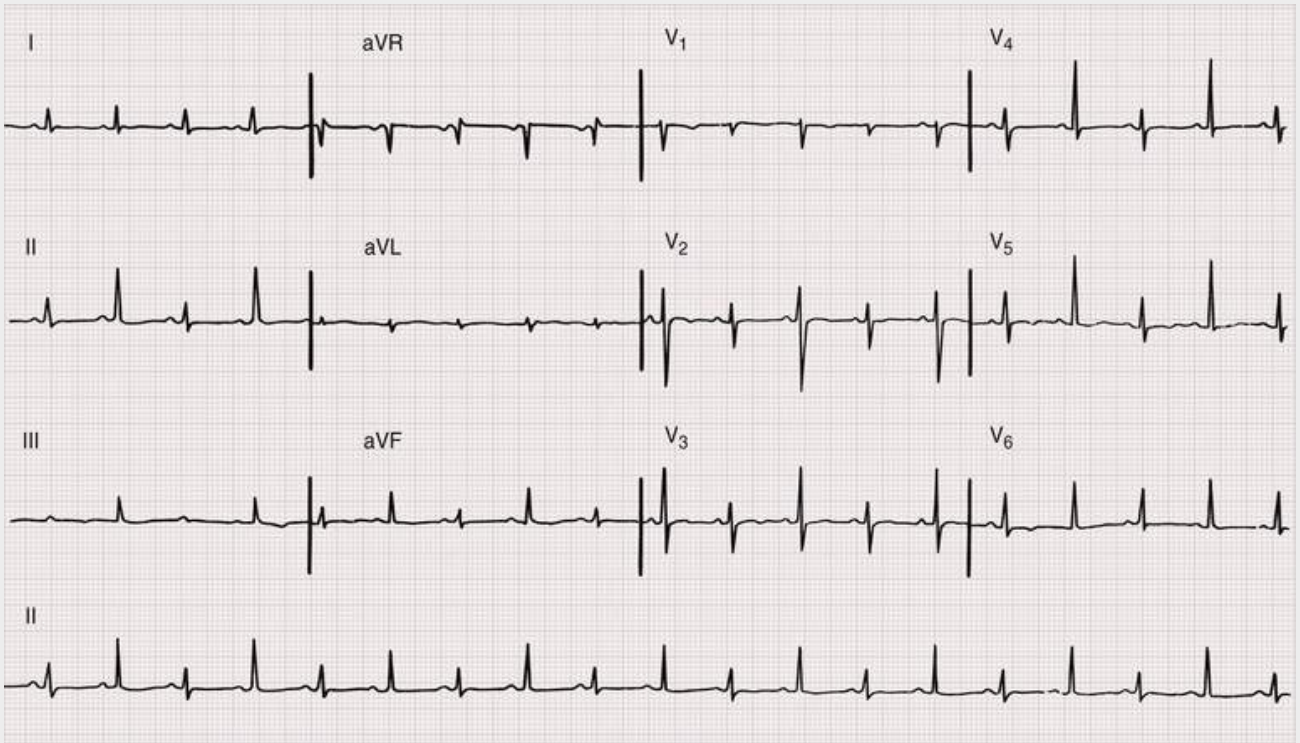

FIGURE 12.48 Total electrical alternans (P-QRS-T) caused by pericardial effusion with tamponade. This finding, particularly in concert with sinus tachycardia and relatively low voltage, is a highly specific, although not sensitive, marker of cardiac tamponade.

Other alternans patterns have primary electrical rather than mechanical causes. QRS (and sometimes R-R) alternans may occur with a number of different types of supraventricular tachycardias.[70] Alternans

has long been recognized as a marker of electrical instability of repolarization in cases of acute ischemia, in which it may precede ventricular tachyarrhythmia (**see Fig. 12.34**). Therefore, considerable interest continues to be directed at the detection of microvolt T wave (or ST-T) alternans as a noninvasive marker for increased risk of ventricular tachyarrhythmias in patients with chronic heart disease[71-73] (**see Chapter 39**). Similarly, T-U wave alternans (**Fig. 12.49**) may be a marker of imminent risk of torsades de pointes in hereditary or acquired long QT syndromes.

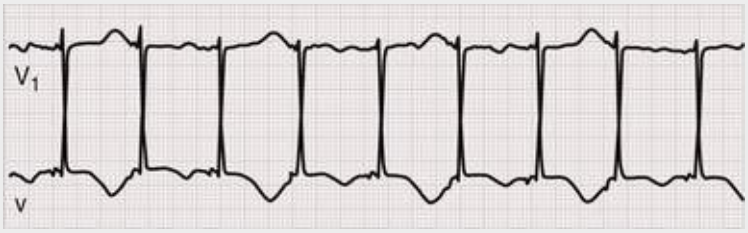

FIGURE 12.49 The QT(U) interval is prolonged (approximately 600 milliseconds) with T-U wave alternans. The tracing was recorded in a patient with chronic renal disease shortly after dialysis. This type of repolarization alternans may be a precursor to torsades de pointes. (Courtesy Dr. C. Fisch.)

Clinical Issues in Electrocardiographic Interpretation

The clinical effectiveness of the ECG as a diagnostic tool depends on numerous "real world" factors such as the appropriateness of the procedure, proper recording technique, and the skills of the interpreter.

Indications and Clinical Value

Relatively limited attention has been paid to the indications for an ECG, probably because of its seeming simplicity, safety, and low cost. However, direct out-of-pocket costs to patients and the potential risks and costs to the patient of both false-negative and false-positive diagnoses of cardiac disease can be substantial.[74] Recommendations for performing ECGs have been proposed by various organizations (see Guidelines supplement for chapter online).

Concerns appropriately include both overuse and underuse of the ECG. The American College of Physicians,[74] American Heart Association,[75] U.S. Preventive Services Task Force,[21] and other professional groups recommend that routine ECGs not be used as a screening approach in asymptomatic persons in an effort to reduce overuse. On the other hand, fewer than two-thirds of emergency medical services record and interpret on-site 12-lead ECGs in cases of suspected STEMI,[76] a procedure accepted to improve outcomes (**see Chapter 42**).

The clinical value of the ECG is optimized when a technically adequate recording is interpreted by a skilled professional who has knowledge of the accuracy of the various ECG diagnoses and who integrates findings from prior ECG recordings, clinical information, and the results of other cardiac and noncardiac tests. Key factors include reader competency and interobserver variability in ECG interpretation, technical issues in ECG recording that impact reliability and consistency, and the appropriate application of computer technology and interpretation.

Reading Competency

Developing and maintaining competency in interpretation of the ECG are critical to successful clinical practice. The American College of Cardiology (ACC) recommends supervised and documented interpretation of a minimum of 3500 ECGs, covering a broad spectrum of diagnoses and clinical settings, over the training period for cardiology fellows.[77] In addition, follow-up assessment of interpretation accuracy has been recommended to maintain skills and to assess updated knowledge of new criteria and applications. Both the ACC and the American College of Physicians[78] have provided lists of patterns to be recognized and recommend knowledge of basic electrophysiology and electrocardiology as well as in waveform analysis.

The actual adequacy of training and the level of competency of trainees remain limited. In one study, cardiology fellows at an academic institution correctly interpreted only 58% of a test set of ECGs and missed 36% of potentially life-threatening abnormalities.[79] The challenge of adequate training is compounded by the number of physician specialties as well as nonphysicians with various modes and intensity of training in interpretation of ECGs.

Various tools are available to assess and improve proficiency. Programs such as the ECG Self-Assessment Program of the ACC are useful for identifying knowledge levels of proficiency and areas of specific weakness. A number of websites feature ECGs for self-assessment and clinical instruction. For example, ECG Wave-Maven (http://ecg.bidmc.harvard.edu) provides free access to more than 490 case studies of ECGs, with answers and multimedia adjuncts.

A related issue is the common phenomenon of differing diagnoses even among expert readers, that is, inter-reader variability. One recent study reported that, based on a test set of 20 ECGs read by 21 experts, agreement occurred in 79% of tracings with evidence of STEMI and in only 37% of cases showing chamber hypertrophy.[80] These issues can lead to clinical mismanagement, including failure to identify and appropriately triage patients with AMI eligible for urgent revascularization.[81] A set of common pitfalls in the ECG diagnosis of MI has recently been published.[82]

Technical Errors

Technical errors can lead to clinically significant diagnostic mistakes. Artifacts that may interfere with interpretation can result from movement of the patient, misplacement of electrodes or poorly secured electrodes, electrical disturbances related to current leakage and grounding failure, and external interference from nearby electrical sources, such as stimulators or cauteries. Electrical or motion (e.g., parkinsonian tremor) artifacts can simulate life-threatening arrhythmias (**Fig. 12.50**). Body motion can cause excessive baseline wander that may simulate or obscure ST-segment shifts of myocardial ischemia or injury.

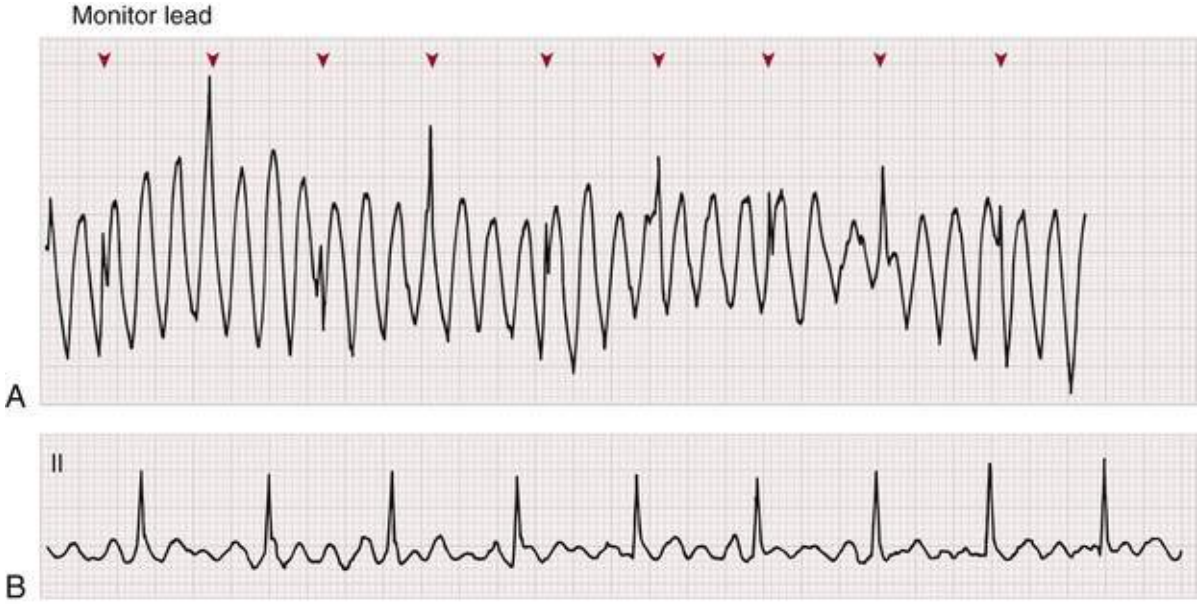

FIGURE 12.50 Artifacts simulating serious arrhythmias. **A,** Motion artifact mimicking ventricular tachyarrhythmia. Partly obscured normal QRS complexes (*arrowheads*) can be seen with a heart rate of approximately 100 beats/min. **B,** Parkinsonian tremor causing baseline oscillations mimicking atrial fibrillation. The regularity of QRS complexes may provide a clue to the source of this artifact.

Misplacement of one or more electrodes is a common cause for errors in interpretation of the ECG. Many limb lead switches produce ECG patterns that can aid in their identification. Reversal of the two arm electrodes, for example, results in an inverted P and QRS waveforms in lead I but not in lead V_6, two leads that would normally be expected to have similar polarities.

The most common precordial electrode misplacements are placement of V_1 and V_2 electrodes in the second or third rather than in the fourth intercostal place and placement of the V_5 and V_6 electrodes above or below the horizontal line of V_4. These misplacements may be more difficult to detect but may result in changes in R wave progression, accentuation of r' waves, and ST-segment elevation in the right precordial leads simulating IVCDs or MI. In addition, variation in placement of electrodes between recordings, even to a small extent, may cause diagnostically confusing changes in waveform patterns, especially when relying on serial changes to detect acute ischemia or infarction.

Similarly, ECGs recorded using nonstandard electrode locations or altered filter settings often lead to clinically important waveform changes. Recordings from electrode subsets, such as used for exercise testing or in intensive care settings, are significantly different from those recorded using standard electrode sets and should not be used for diagnostic purposes. Increasing the low-frequency cutoff to reduce baseline wander and respiratory effects can produce a range of artifactual ST-segment abnormalities. Lowering the high-frequency cutoff to reduce motion and tremor artifacts reduces R wave amplitudes and Q wave measurements and decreases the accuracy of diagnoses of hypertrophy and infarction.[1]

Computer Interpretation

Other technical issues reflect characteristics of computerized systems. Computerized recording and interpretation systems have become the norm and have many clinical and technical advantages. However, important distinctions and challenges remain. Whereas intervals and amplitudes measured in manual systems are typically based on features of individual leads, those reported by computerized systems are based on measurements from an overlay of averaged beats from all leads. As a result, computerized

measurements are usually longer than those from manual readings because they include portions of the ECG waveform that appear to be isoelectric in some leads but not in others. Differences in the duration of the Q wave, the QRS complex, or the QT interval may be sufficient to meet criteria for infarction, conduction defects, and repolarization abnormalities that were based on manual recordings.

An ongoing concern is overreliance on computerized interpretations. Although computerized diagnostic algorithms have become more accurate and serve as important adjuncts to the clinical interpretation of ECGs, such measurements and diagnoses are currently not sufficiently accurate to be relied on in critical clinical environments without expert review. Reports have described limited accuracies for computerized systems, with error rates as high as 30% for pattern-based diagnoses and as high as 40% for arrhythmias.[83] In addition, clinically relevant discrepancies in measurements and interpretation terminology may be reported by systems from different manufacturers and even by different software versions from the same manufacturer.[84]

Future Perspectives

Clinical electrocardiography represents a mature cardiovascular methodology based on extensive electrophysiologic and clinical correlates that have evolved over more than a century of study. Although recent and future advances in other imaging techniques provide a more direct assessment of cardiac structural abnormalities, the ECG uniquely provides essential information about the electrical properties of the heart with potentially life-threatening conditions such as brady- and tachyarrhythmia, ischemia, and hyperkalemia.

Several areas for expanded knowledge and clinical relevance may be suggested. Advances in computerized diagnostic criteria stratified for race, age, and sex as well as other demographic and clinical variables may improve the value of the standard ECG. Incorporating ECG findings into broader electronic medical record and database systems may facilitate automated interpretation of serial ECG recordings as well as linkage to other clinical information, leading to more relevant interpretations. Development of meticulously annotated, open-access databases of high-resolution digital ECGs with detailed clinical correlates will help refine current diagnostic criteria.

Other advances may represent major changes in approach. Examples are mathematical analysis of body surface potentials, such as those that estimate direct cardiac potentials from surface recordings,[85] and the assessment of genomic and biomarker patterns that permit more direct understanding of the abnormal physiology[86] underlying ECG patterns (**see Chapters 8 and 34**).

Guidelines

Electrocardiography

David M. Mirvis and Ary L. Goldberger

The clinical uses of the electrocardiogram (ECG) include both (1) the identification and characterization of existing or suspected cardiovascular disease and (2) the prediction of future clinical events related to cardiac function, that is, risk stratification. To meet these goals with maximal efficiency and efficacy, numerous professional organizations have proposed appropriateness guidelines for recording an ECG. These may be considered for several different populations—persons with known heart

disease, those with suspected heart disease or at high risk for heart disease, and those without evidence of heart disease. In addition, more specific recommendations have been proposed for the use of the ECG in special groups, including preoperative patients, persons with dangerous occupations, athletes, and patients taking medications with electrophysiologic effects.

Patients With Known Cardiovascular Disease

Guidelines published jointly by the American College of Cardiology (ACC) and the American Heart Association (AHA)[1-3] are summarized in **Tables 12G.1 to 12G.3**. **Table 12G.1** summarizes the ACC/AHA guidelines in patients with known cardiovascular disease. They support the use of ECGs as part of the baseline evaluation of all patients with known cardiovascular disease after initiating therapy known to produce ECG changes that correlate with therapeutic responses, progression of disease, or adverse effects; for intermittent follow-up evaluations for investigation of new or changes in signs or symptoms of cardiovascular disease or relevant laboratory findings; and after significant intervals (usually 1 year or longer) in the absence of clinical changes. Follow-up ECGs are not considered appropriate for patients with mild chronic cardiovascular conditions that are not deemed likely to progress (e.g., mild mitral valve prolapse) and are not considered to be appropriate at each visit for patients with stable heart disease who are seen frequently (e.g., within 4 months) without evidence of clinical change.

TABLE 12G.1

ACC/AHA Guidelines for Electrocardiography in Patients with Known Cardiovascular Disease or Dysfunction*

INDICATION	CLASS I† (INDICATED)	CLASS II (EQUIVOCAL)	CLASS III (NOT INDICATED)
Baseline or initial evaluation	All patients	None	None
Response to therapy	Patients in whom prescribed therapy is known to produce changes in the ECG that correlate with therapeutic responses or progression of disease or adverse effects	Patients prescribed drugs known to alter serum electrolyte concentrations	Patients receiving pharmacologic or nonpharmacologic therapy not known to produce changes in the ECG or to affect conditions that may be associated with such changes
Follow-up evaluation	Patients with a new or a change in symptoms, signs, or laboratory findings related to cardiovascular status Patients with an implanted pacemaker device Patients with cardiovascular disease in the absence of new symptoms or signs after an interval of time appropriate for the condition or disease	None	Adult patients whose cardiovascular condition is usually benign and unlikely to progress (e.g., patients with asymptomatic mild mitral valve prolapse or mild hypertension) Adult patients with chronic stable heart disease seen at frequent intervals (e.g., 4 months) without unexplained findings

*Based on published recommendations of the AHA/ACC.[1-3]

†Classifications are based on those used by Schlant and colleagues.[1]

TABLE 12G.2

ACC/AHA Guidelines for Electrocardiography in Patients Suspected of Having or at Increased Risk for Cardiovascular Disease or Dysfunction*

SETTING	CLASS I (APPROPRIATE)	CLASS II (EQUIVOCAL)	CLASS III (NOT INDICATED)
Baseline or initial evaluation	All patients suspected of having or being at increased risk for cardiovascular disease Patients who may have used cocaine, amphetamines, or other illicit drugs known to have cardiac effects	None	None
Response to therapy	Patients in whom prescribed therapy is known to produce changes in the ECG that correlate with therapeutic responses or progression of disease or adverse effects	Patients prescribed drugs known to alter serum electrolyte concentrations	Patients receiving pharmacologic or nonpharmacologic therapy not known to produce changes in the ECG or to affect conditions that may be associated with such changes
Follow-up examination, once	Presence of any change in clinical status or laboratory findings suggesting interval development of cardiac disease or dysfunction Periodic follow-up examination of patients (e.g., every 1 to 5 years) known to be at increased risk for cardiac disease	None	Follow-up ECGs more often than yearly for patients who remain clinically stable

*Based on published recommendations of the AHA/ACC.[1-3]

TABLE 12G.3

ACC/AHA Guidelines for Electrocardiography in Patients with No Apparent or Suspected Heart Disease or Dysfunction*

Setting	Class I (Appropriate)	Class II (Equivocal)	Class III (Not Indicated)
Baseline or initial evaluation	Before administration of pharmacologic agents known to be associated with a high incidence of cardiovascular effects (e.g., antineoplastic agents) People of any age in special occupations that require very high cardiovascular performance (e.g., firefighters, police officers) or whose cardiovascular performance is linked to public safety (e.g., pilots, air traffic controllers, critical process operators, bus or truck drivers, railroad engineers)	Initial evaluation of patients with risk factors such as diabetes and hypertension	Routine screening, risk assessment, or as a baseline in asymptomatic, low-risk persons
Response to therapy	To evaluate patients in whom prescribed therapy (e.g., doxorubicin) is known to produce cardiovascular effects	None	To assess treatment not known to produce any cardiovascular effects
Follow-up	To evaluate interval changes in symptoms or signs	None	To evaluate asymptomatic adults who have had no interval change in symptoms, signs, or risk factors
Before surgery	Patients being evaluated as donor for heart transplantation or as recipient of noncardiopulmonary transplant	Patients undergoing vascular or other high-risk procedures	Asymptomatic persons undergoing low-risk procedures

*Based on published recommendations of the AHA/ACC,[1-3] and other groups as described in the text.

Patients Suspected of Having Cardiovascular Disease

Table 12G.2 summarizes the AHA/ACC recommendation for patients suspected of having cardiac disease or those at high risk for cardiac disease. An ECG is appropriate as part of an initial evaluation in the presence of signs or symptoms suggesting cardiac disease; in patients with important risk factors such as cigarette smoking, diabetes mellitus, peripheral vascular disease, or a family history of cardiac disease; during therapy with cardioactive medications; and during follow-up if new clinical findings or events develop or at prolonged intervals if the patient is clinically stable. In follow-up evaluation of patients at increased risk for heart disease, ECGs every 1 to 5 years are considered appropriate, but routine ECGs more frequently than yearly are not supported for patients who remain clinically stable.

Patients Without Known or Suspected Cardiovascular Disease

The ECG in persons without known or suspected cardiovascular disease has been discouraged by major

professional groups. Although they recognize that certain ECG findings do have prognostic value, and that the impetus to identify these abnormalities in the general population to reduce the risk of cardiovascular morbidity and mortality is understandable, they conclude that there is inadequate evidence that the ECG has the practical ability to accurately identify persons at high risk within the general, seemingly healthy population; that adding an ECG to the standard risk assessment approach based on history and physical examination improves risk stratification, alters the risk management approach, or improves outcome; and that high rates of false-positive results in this population have significant consequences, including unnecessary, expensive and potentially hazardous noninvasive and invasive diagnostic testing, overtreatment, and labeling.

Based on these concepts, recommendations for routine clinical screening by numerous organizations, including the AHA/ACC[1-3] U.S. Preventive Services Task Force (USPSTF)[4] and the American College of Physicians discourage the use of the ECG as part of a routine health or risk factor assessment.

The 2010 ACC/AHA guidelines (**Table 12G.3**) do suggest that an ECG is reasonable for cardiovascular risk assessment in asymptomatic persons with diabetes or hypertension (a Class IIa recommendation, with benefits substantially exceeding risk). The AHA/ACC recommendations are based on information from limited population studies and relied on consensus opinions and existing standards of care (Level C). The USPSTF[4] similarly concluded that for persons with moderate to high risk of events (>10% likelihood within 10 years, based on other risk factor analyses) the existing data are insufficient to make a definitive recommendation about the relative benefits and risks of a routine ECG.

Special Populations

Persons with Dangerous Occupations

Recommendations for screening of persons with dangerous jobs or jobs that place other people at risk—for example, airline pilots and bus drivers—also are controversial. Although no specific data defining the value of routine screening are available, some groups, including USPSTF[4] and AHA,[1] recognize the potential for benefit in relation to the possible risk to others. The U.S. Federal Aviation Administration currently requires an ECG at age 35 and annually after age 40 (for first-class airline transport pilots) for commercial pilots.

Preoperative Evaluation

The common practice of routinely recording an ECG before noncardiac surgery in patients without other indications has been based on the putative value of the ECG in predicting intraoperative or postoperative events and as a baseline for comparison if a later event occurs. However, most (although not all) studies have documented the absence or limited value of the routine preoperative ECG in identifying patients with coronary artery disease and in predicting postoperative outcomes.[5-7]

Thus the ACC/AHA[5] concluded that a routine preoperative ECG is reasonable (Class IIa recommendation based on limited randomized or nonrandomized studies [Level B]) for patients with known coronary heart, peripheral vascular, or cerebrovascular disease; significant arrhythmias; or other structural heart disease, except for those undergoing low-risk procedures.

These groups also concluded that a preoperative ECG (within 1 to 3 months of the procedure) may be considered for other asymptomatic patients without coronary artery disease except those undergoing low-risk procedures (Class IIb recommendation, Level B evidence). However, routine ECGs for patients undergoing low-risk procedures are determined not to be beneficial and are deemed to be inappropriate

(Class III recommendation).

Likewise, the European Society of Cardiology[6] and the American Society of Anesthesiologists Task Force on Preanesthesia Evaluation[7] have concluded that a preoperative ECG is not indicated for patients undergoing low-risk procedures who do not have risk factors. They do suggest that preoperative testing may be performed on a selective basis based on the clinical features of individual patients. Important clinical characteristics may include cardiovascular or respiratory disease, known cardiovascular risk factors, or risk factors and the patient's age.

Screening of Athletes

The requirement for an ECG as part of the preparticipation clinical evaluation of competitive athletes remains very controversial[8] (**see Chapter 53**). Both the European Society of Cardiology[9] and the International Olympic Committee[10] recommend including the ECG as part of preparticipation medical assessment. These recommendations are based on some studies that have reported an added diagnostic value and high sensitivity of the ECG for detecting the most common underlying causes of athlete deaths, such as hypertrophic cardiomyopathy and the long-QT interval syndromes, and the experience of the 30-year national screening program in Italy to prospectively identify these abnormalities and greatly reduce the occurrence of sudden death by facilitating the disqualification of high-risk affected persons.[11]

The AHA, in contrast, does not recommend routine ECG screening.[8,12] Rather, they recommend a complete 14-point clinical evaluation based on history and physical examination. Reasons for this position include the limited and conflicting data on the benefits, the significant false-positive rate leading to the inappropriate disqualification of many athletes and the need for unnecessary secondary testing (and logistical) manpower, and financial and resource limitations within the U.S. health care system. Rather, the AHA recommends an ECG only if suggestive abnormalities are revealed in the personal and family history or found on physical examination.

Similarly, a multidisciplinary task force convened by the National Collegiate Athletic Association (NCAA)[13] did not recommend a mandatory preparticipation ECG based on their conclusion that the evidence that the has a substantially positive risk/benefit ratio was lacking. The NCAA as well as the AHA do support local, community, or institutional efforts to provide screening ECGs if (1) athletes are well informed about the potential benefits and limits of the test, (2) tests are performed by adequately trained staff and interpreted based on accepted criteria for abnormalities in athletic hearts, and (3) appropriate cardiologic oversight and backup provide secondary testing if ECG abnormalities are found. The NCAA also recommends that ECG testing be accompanied by establishment of registries to expand knowledge about the value of such testing.

Recommendations do support a standard 12-lead ECG as part of routine evaluation for all athletes older than 40 seeking to engage in competitive sports. No conclusive data exist on the value of ECG screening for recreational athletes of any age.

Cardioactive Drug Administration

Numerous drugs have potentially harmful electrophysiologic effects that may be associated with ECG changes, including antiarrhythmic agents, methadone, tricyclic antidepressants and other psychotropic agents, stimulants, and illicit drugs. The role of the ECG as a baseline examination and in follow-up evaluation of patients taking such drugs remains poorly defined and, in some cases, controversial.

Although definitive data are not yet available, the AHA[14] has recommended that it would be “prudent” to obtain a baseline ECG before beginning tricyclic antidepressant or phenothiazine treatment in children

and adolescents and another ECG once steady-state dosage has been reached. They likewise suggest that an ECG may be reasonable (Class IIA recommendation, Level C evidence) in children and adolescents before initial therapy for attention-deficit hyperactivity disorder (ADHD) as part of a complete clinical assessment.[15] The American Pain Society and the Heart Rhythm Society[16] have also published recommendations that patients receiving methadone who have risk factors for prolonged QTc intervals or a history of ventricular arrhythmias have a baseline ECG before beginning therapy and periodically during therapy based on the baseline ECG, dosage changes, and other risk factors.

Exercise Electrocardiographic Testing

Gary J. Balady, Anthony P. Morise

Exercise electrocardiographic testing is among the most fundamental and widely used tests for the evaluation of patients with cardiovascular disease (CVD). It is easy to administer, perform, and interpret; it is flexible and adaptable; and it is reliable, inexpensive, and readily available in hospital or practice settings. The exercise test has been used by clinicians for more than half a century, and its durability can be attributed to its evolution over time. Initially developed to detect the presence of myocardial ischemia secondary to coronary artery disease (CAD), the exercise electrocardiogram (ECG) is now recognized for its power in predicting prognosis. Exercise test variables beyond the ST segment yield important information, particularly when used in combination with clinical information, to predict outcomes and guide therapy in a broad range of individuals, from the healthy to those crippled by heart disease. Emerging applications of exercise electrocardiography have demonstrated its usefulness in the evaluation and management of patients with a wide variety of cardiovascular conditions, including valvular heart disease, congenital heart disease, genetic cardiovascular conditions, arrhythmias, and peripheral artery disease. When used appropriately with adjunctive modalities to measure gas exchange and ventilation or with imaging techniques such as echocardiography or nuclear perfusion imaging (**see Chapters 14 and 16**), the power of the exercise ECG is greatly enhanced. The exercise ECG is the clinician's beacon that can guide optimal care for a great majority of patients with known or suspected CVD. This chapter provides a detailed foundation of information on the exercise ECG. Other chapters address adjunctive imaging techniques and further discuss the use of exercise testing in patients with specific cardiovascular conditions.

Exercise Physiology

Total-Body Oxygen Uptake

Exercising muscles require energy to contract and relax. Most of this energy is derived from oxidative metabolism to generate adenosine triphosphate; thus energy requirements at rest and for any given amount of physical activity (*work rate*) can be estimated from measurements of total-body oxygen uptake (V_{O_2}). The Fick equation (**Fig. 13.1**) demonstrates that V_{O_2} is equal to the product of cardiac output and oxygen extraction at the periphery (i.e., arteriovenous oxygen difference). V_{O_2} is easily expressed in multiples of resting oxygen requirements (metabolic equivalents [METs]), with 1 MET being resting energy

expenditure and defined as approximately 3.5 mL O_2/kg body weight/min. This convenient system indexes the amount of energy used during any given physical activity against that used at rest. Accordingly, 5-MET activity requires five times the energy expenditure at rest. VO_2max is the peak oxygen uptake achieved during performance of the highest level of dynamic exercise involving large muscle groups and by definition cannot be exceeded despite increases in work rate. It is related to age, sex, heredity, exercise habits, and cardiovascular status. Cardiac output can increase as much as four to six times resting levels in the upright position. Maximum cardiac output is the result of a twofold to threefold increase in heart rate from resting levels and an increase in stroke volume. Stroke volume in healthy persons generally plateaus at 50% to 60% of VO_2max. Oxygen extraction at the periphery can increase as much as threefold, and the maximum arteriovenous O_2 difference has a physiologic limit of 15 to 17 mL O_2/100 mL blood. During clinical exercise testing, patients are prompted to exercise not until they attain VO_2max but rather to the VO_2 that is attained during symptom-limited, maximum tolerated exercise; this level is termed the VO_2 peak.[1]

$$\text{Resting } VO_2 = \text{C.O.} \times \text{A-}VO_2 \text{ Difference}$$

$$\text{Maximal Exercise } VO_2 = \text{C.O.} \times \text{A-}VO_2 \text{ Difference}$$

$$= \text{HR (2-3x resting)} \times \text{SV (2x resting)} \times \text{A-}VO_2 \text{ Difference (3x resting)}$$

FIGURE 13.1 Fick equations at rest and during exercise; see text for details. *A-VO_2 Difference,* Arteriovenous oxygen difference; *C.O.,* cardiac output; *HR,* heart rate; *SV,* stroke volume; *VO_2,* total body oxygen uptake.

Myocardial Oxygen Demand and Supply Relationships During Exercise

Myocardial ischemia occurs when the supply of oxygenated blood to myocardial cells is inadequate to meet demands. Many factors affect the delicate balance of supply and demand (**Fig. 13.2**). Exercise testing is performed to stress these relationships and observe the physiologic responses that ensue. This enables the clinician not only to assess for the development of myocardial ischemia, but also to evaluate at what level of myocardial oxygen demand and physical activity (work rate) ischemia occurs.[1]

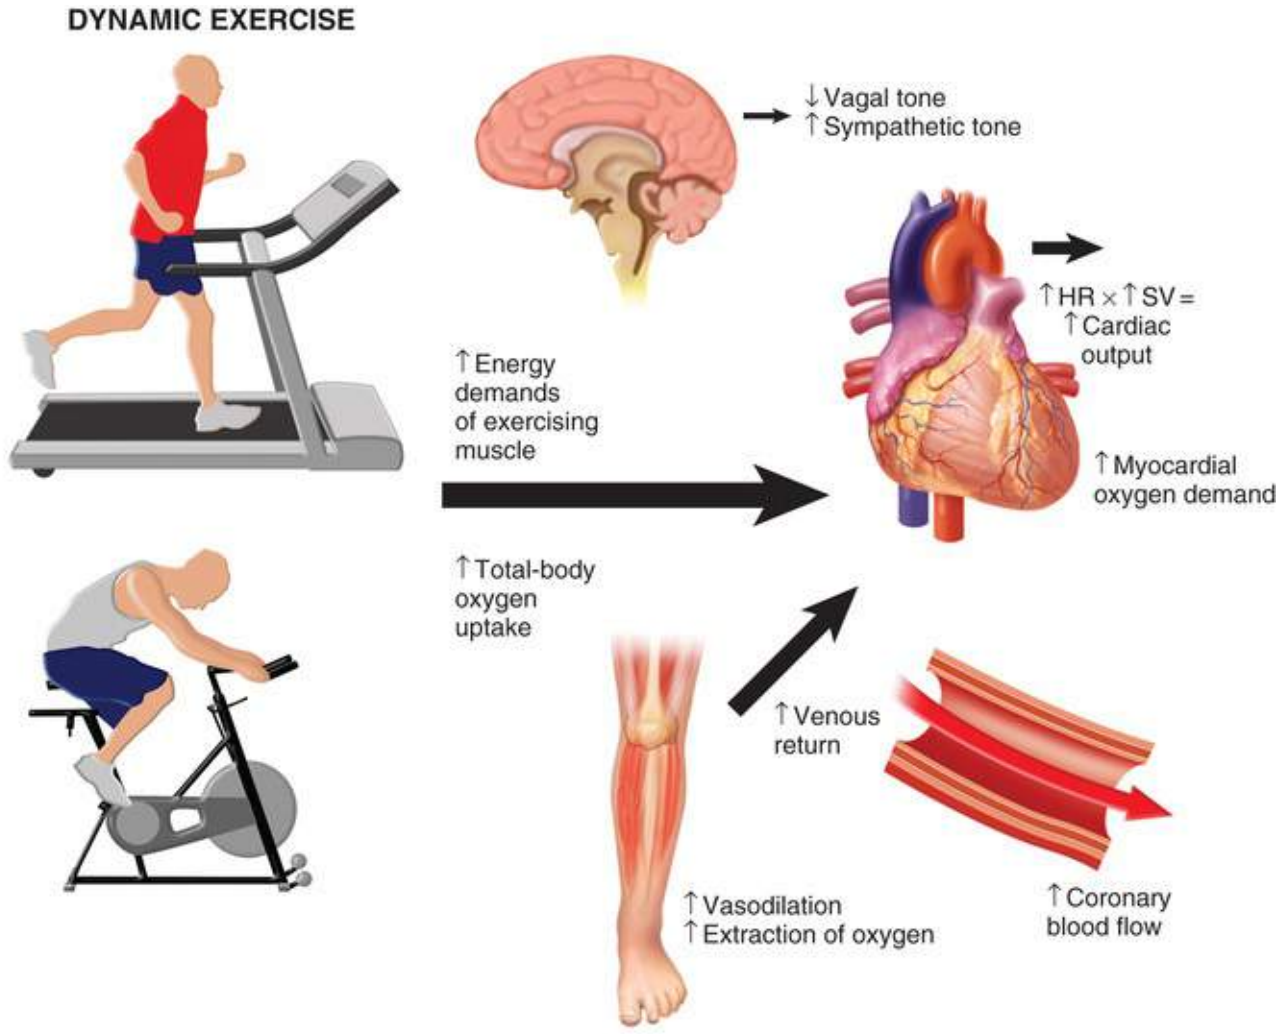

FIGURE 13.2 Physiologic responses to acute exercise. (See text for details.)

Myocardial Oxygen Demand.

Myocardial oxygen demand is related to heart rate (HR), blood pressure (BP), left ventricular (LV) contractility (myocardial shortening per beat), and LV wall stress. The latter is related to LV pressure, wall thickness, and cavity size. Changes in any of these interdependent factors can affect myocardial need for oxygenated blood. Of these parameters, HR and BP are the easiest to measure and monitor. The product of HR and systolic BP, termed the *rate-pressure product*, is a reliable index of myocardial oxygen demand and can be readily assessed clinically.

During acute endurance (high-repetition/low-resistance) exercise (e.g., walking or cycling), cardiac output rises in response to the metabolic needs of the exercising muscles (estimated by measured V_{O_2}). Diminution of vagal tone and a rise in sympathetic tone lead to an increase in HR and LV contractility. Stroke volume also rises because of increases in venous return of blood from exercising muscles, and blood flow is redistributed from the renal, splanchnic, and cutaneous circulation to the exercising muscles. Accumulation of metabolites in the actively contracting muscles causes vasodilation of muscle arterioles, which increases skeletal muscle blood flow up to four times that of resting levels and results in a reduction in aortic outflow impedance. This in turn allows more complete systolic ejection, thereby further increasing stroke volume. Systolic BP increases mostly because of the rise in cardiac output, whereas diastolic BP either remains constant or falls as a result of the reduction in vascular resistance. The size and location of the exercising muscle groups will have different effects on the hemodynamic

response to exercise. Dynamic arm exercise elicits higher HR and BP responses at any given work rate than does dynamic leg exercise. Arm work yields differences in sympathetic output, peripheral vasodilation, venous return, and metabolic requirements, which are influenced not only by the exercising muscle mass but also by the stabilizing muscles recruited during arm exercise.[1]

Resistance (low-repetition/high-load) exercise (e.g., weightlifting) is not generally used during graded exercise testing but may be used in work simulation testing or exercise training regimens. This type of exercise generates an increased sympathetic response, leading to an increase in HR; however, venous return, especially during straining, may decrease. Therefore the rise in cardiac output is relatively small in comparison to that achieved with endurance exercise and is primarily caused by increases in HR. Muscle contraction during resistance exercise generates compressive force on muscle capillaries that leads to elevated peripheral resistance. This rise in vascular resistance coupled with an increase in cardiac output yields an increase in both systolic and diastolic BP. Elevations in systolic BP from rest to exercise are proportionally greater than the elevations in HR during resistance exercise than during endurance exercise. Therefore, both endurance exercise and resistance exercise increase myocardial oxygen demand because of increases in HR, BP, LV contractility, and LV wall stress (the latter caused by increases in LV pressure and volume during exercise).[1]

Myocardial Oxygen Supply.

Coronary blood flow increases during exercise in response to neurohumoral stimulation (primarily sympathetic beta receptor stimulation) and as a result of the release of endothelial substances, including nitric oxide. In healthy persons during acute exercise, coronary arteries dilate and coronary blood flow rises in response to the increases in myocardial oxygen demand. Most often, coronary flow is compromised as a result of atherosclerotic plaque within the lumen of the coronary artery (**see Chapter 44**). Plaque may cause minimal stenosis or complete occlusion of the artery. Several factors influence the significance of a given luminal stenosis, including the degree of luminal obstruction, the length of the obstruction, the number and size of functioning collateral vessels, the magnitude of the muscle mass supplied, the shape and dynamic properties of the stenosis, and the autoregulatory capacity of the vascular bed. In general, a 50% to 70% reduction in luminal diameter will impair peak reactive hyperemia, whereas 90% or greater stenosis will reduce resting flow. However, exercise stimulates local changes in vasomotor tone as a result of neuromodulation, endothelial dysfunction, and local factors, and these changes can further influence the supply of oxygenated blood to the myocardium. Atherosclerotic arteries often fail to dilate and may actually constrict with exercise, thus further reducing the supply of blood in the setting of increased demand.[1]

Technical Components of Exercise Testing

Patient Preparation

Patient Assessment

It is important to assess the patient before performing the exercise test to evaluate the indications for the test, the appropriateness of the specific test that has been ordered to answer the question posed, the ability of the patient to perform exercise, and whether the patient has any contraindications to exercise testing (**Table 13.1**). Information from the medical history as provided by the patient, chart review, and the ordering provider and/or the patient's primary care physician or cardiologist can be most useful in this pretest evaluation. A brief physical examination that addresses the components outlined in **Table 13.2** can

also be helpful. A current standard resting 12-lead ECG is useful in assessing heart rate, rhythm, conduction abnormalities, and evidence of previous myocardial infarction (MI) and should be compared with the most recent previous ECG, if available.

TABLE 13.1
Contraindications to Exercise Testing

Absolute Contraindications
Acute myocardial infarction, within 2 days
High-risk unstable angina
Uncontrolled cardiac arrhythmia with hemodynamic compromise
Active endocarditis
Symptomatic severe aortic stenosis
Decompensated heart failure
Acute pulmonary embolism or pulmonary infarction
Acute myocarditis or pericarditis
Physical disability that precludes safe and adequate testing
Relative Contraindications
Known left main coronary artery stenosis
Moderate aortic stenosis with uncertain relation to symptoms
Tachyarrhythmias with uncontrolled ventricular rates
Acquired complete heart block
Hypertrophic cardiomyopathy with severe resting gradient
Mental impairment with limited ability to cooperate

From Fletcher GF, Ades PA, Kligfield P, et al. Exercise standards for testing and training: a scientific statement from the American Heart Association. Circulation 2013;128:873.

Patient Assessment for Exercise Testing

History
1. **Medical diagnoses and past medical history:** A variety of diagnoses should be reviewed, including cardiovascular disease (known existing coronary artery disease [CAD], previous myocardial infarction, or coronary revascularization); arrhythmias, syncope or presyncope; pulmonary disease, including asthma, emphysema, and bronchitis or recent pulmonary embolism; cerebrovascular disease, including stroke; peripheral artery disease; current pregnancy; and musculoskeletal, neuromuscular, or joint disease.
2. **Symptoms:** Angina; chest, jaw, or arm discomfort; shortness of breath; and palpitations, especially if associated with physical activity, eating a large meal, emotional upset, or exposure to cold
3. **Risk factors for atherosclerotic disease:** Hypertension, diabetes, obesity, dyslipidemia, and smoking
4. If patient is without known CAD, determine the pretest probability of CAD (see Table 13.11).
5. Recent illness, hospitalization, or surgical procedure
6. Medication dose and schedule
7. Ability to perform physical activity
Physical Examination
1. Pulse rate and regularity
2. Resting blood pressure sitting and standing
3. Auscultation of the lungs, with specific attention to uniformity of breath sounds in all areas, particularly in patients with shortness of breath, a history of heart failure, or pulmonary disease
4. Auscultation of the heart, particularly in patients with heart failure or valvular disease
5. Examination related to orthopedic, neurologic, or other medical conditions that might limit exercise

Although diagnostic exercise tests in patients without known CAD are best performed by withholding cardioactive medications on the day of the test to better assess for an ischemic response, functional testing in patients with known CAD might best be performed with patients having taken their usual medications to evaluate the effects of the medications on HR, BP, symptoms, and ischemia during exercise (see later, Pharmacologic Influences on Interpretation).

In patients with permanent cardiac pacemakers, it is important to obtain information from the patient's cardiologist regarding the type of pacemaker (single or dual chamber), programmed mode, rate responsiveness, and pacing HR limits before the test. Similarly, in patients with implantable cardioverter-defibrillators (ICDs), information regarding ICD rhythm detection and treatment algorithms should be obtained so that the peak HR during the exercise test is maintained at least 10 beats/min below the programmed HR threshold for antitachycardia pacing and defibrillation.[2] Additional details of patient

assessment are provided elsewhere.[1]

Symptom Rating Scales

Before exercising, patients should be made familiar with the symptom rating scales that might be used during testing. These are described further elsewhere[2] and may include the Borg Scale of Perceived Exertion.[1]

Electrocardiographic Lead Systems

As the technology of exercise electrocardiographic testing has evolved, several different types of lead systems have been developed and used. Details regarding these lead systems, along with skin preparation techniques, are provided elsewhere.[1,3] The importance of adequate skin preparation cannot be overstated; this is essential to optimize the quality of the exercise ECG. To obtain a high-quality 12-lead ECG during testing, electrode placement on the torso is standard for routine testing. Torso electrodes are placed under the lateral aspect of the clavicles for the arm leads and on the lower end of the rib cage or high under the rib cage for the leg leads. A standard 12-lead ECG should be performed before placement of the torso limb leads because such lead placement may alter the inferior lead complexes and result in previous Q waves being either mimicked or hidden.

Exercise Test Modality and Protocols

The testing modality and protocol should be selected in accordance with the patient's estimated functional capacity based on age, estimated physical fitness from the patient's history, and underlying disease. Several exercise test protocols are available for both treadmill and stationary cycle ergometers. Patients who have low estimated fitness levels or are deemed to be at higher risk because of underlying disease (e.g., recent MI, heart failure) should be tested with a less aggressive exercise protocol. Treadmill and cycle ergometers may use stepped or continuous ramp protocols. Work rate increments (stages) during stepped protocols can vary from 1 to 2.5 METs. Ramp protocols are designed with stages that are no longer than 1 minute and for the patient to attain peak effort within 8 to 12 minutes. Accordingly, ramp protocols must be individualized and selected to accommodate the patient's estimated exercise capacity. Because there are no widely published or standard sets of ramp protocols, individual exercise testing laboratories usually develop their own customized protocols that accommodate a wide range of fitness levels. **Table 13.3** provides examples of such protocols.[4,5] The American College of Sports Medicine (ACSM)[2] details a variety of treadmill and cycle ergometer testing protocols.

TABLE 13.3

Boston Medical Center Treadmill Ramp Protocols

STAGE*	VERY LOW RAMP			LOW RAMP			MODERATE RAMP			HIGH RAMP			ATHLETE'S RAMP

*Stages are each 30 seconds in duration.

Exercise tests may be submaximal or maximal relative to the patient's effort. In addition to common indications for stopping the exercise test (**Table 13.4**), submaximal exercise testing has a predetermined endpoint, often defined as a peak heart rate (e.g., 120 beats/min or 70% of predicted maximum HR) or an arbitrary MET level (e.g., 5 METs). Submaximal tests are used in patients early after MI before discharge from the hospital because they can provide prognostic information to guide management. They can also be useful in the evaluation of a patient's ability to engage in daily activities after discharge and can serve as a baseline for cardiac rehabilitative exercise therapy (see later, Physical Activity and Exercise Prescription). Symptom-limited tests are designed to continue until the patient demonstrates signs and/or symptoms necessitating termination of exercise (**Table 13.4**). Whatever modality or protocol is used, standard patient monitoring and measurements are made during and early after exercise (**Table 13.5**).

TABLE 13.4

Indications for Terminating the Exercise Test

Absolute Indications
ST-segment elevation (>1.0 mm) in leads without Q waves caused by prior myocardial infarction (other than aVR, aVL, or V_1)
Drop in systolic blood pressure of >10 mm Hg, despite an increase in workload, when accompanied by any other evidence of ischemia
Moderate to severe angina
Central nervous system symptoms (e.g., ataxia, dizziness, or near-syncope)
Signs of poor perfusion (cyanosis or pallor)
Sustained ventricular tachycardia or other arrhythmia that interferes with normal maintenance of cardiac output during exercise
Technical difficulties monitoring the ECG or systolic blood pressure
Patient's request to stop
Relative Indications
Marked ST-segment displacement (horizontal or downsloping of >2 mm) in a patient with suspected ischemia
Drop in systolic blood pressure of >10 mm Hg (persistently below baseline) despite an increase in workload, in the absence of other evidence of ischemia
Increasing chest pain
Fatigue, shortness of breath, wheezing, leg cramps, or claudication
Arrhythmias other than sustained ventricular tachycardia, including multifocal ectopy, ventricular triplets, supraventricular tachycardia, atrioventricular heart block, or bradyarrhythmias
Exaggerated hypertensive response (systolic blood pressure >250 mm Hg and/or diastolic blood pressure >115 mm Hg)
Development of bundle branch block that cannot be distinguished from ventricular tachycardia

From Fletcher GF, Ades PA, Kligfield P, et al. Exercise standards for testing and training: a scientific statement from the American Heart Association. Circulation 2013;128:873.

TABLE 13.5

Patient Monitoring During Exercise Testing

During the Exercise Period
12-lead ECG during last minute of each stage, or at least every 3 minutes
Blood pressure during last minute of each stage, or at least every 3 minutes
Symptom rating scales as appropriate for the test indication and laboratory protocol
During the Recovery Period
Monitoring for a minimum of 6 minutes after exercise in sitting or supine position, or until near baseline heart rate, blood pressure, ECG, and symptom measures are reached. A period of active cool-down may be included in the recovery period, particularly following high levels of exercise, to minimize the postexercise hypotensive effects of venous pooling in the lower extremities.
12-lead ECG every minute
Heart rate and blood pressure immediately after exercise, then every 1 or 2 minutes until near-baseline measures are reached
Symptomatic ratings every minute as long as they persist after exercise. Patients should be observed until all symptoms have resolved or returned to baseline levels.

Treadmill.

Treadmill testing provides a more common form of physiologic stress (i.e., walking) in which patients are more likely to attain a higher oxygen uptake and peak heart rate than during stationary cycling. Cycling may be preferable when orthopedic or other specific patient characteristics limit treadmill testing or during exercise echocardiographic testing to facilitate acquisition of images at peak exercise. The most frequently used stepped treadmill protocols are the Naughton, Bruce, and modified Bruce[2] (**Table 13.6**).

TABLE 13.6

Bruce Protocol for Treadmill Testing

STAGE	TIME	SPEED (mph)	GRADE (%)	METs
Rest	00.00	0.0	0.0	1.0
1	03.00	1.7	10.0	4.6
2	03.00	2.5	12.0	7.0
3	03.00	3.4	14.0	10.1
4	03.00	4.2	16.0	12.9
5	03.00	5.0	18.0	15.1
6	03.00	5.5	20.0	16.9
7	03.00	6.8	22.0	19.2

The modified Bruce protocol employs 2 initial low level 3-minutes stages at a speed of 1.7 mph and grades 0 % and 5%, respectively, and then continues into the full Bruce protocol. *METs,* Metabolic equivalents.

From American College of Sports Medicine Guidelines for Exercise Testing and Prescription. 9th ed. Philadelphia: Lippincott, Williams & Wilkins; 2013.

During treadmill exercise, patients should be encouraged to walk freely and use the handrails for balance only when necessary. Excessive handrail gripping and support alter the BP response and decrease the oxygen requirement (METs) per given workload, thereby resulting in an overestimation of exercise capacity and an inaccurate HR- and BP-to-workload relationship. Exercise capacity (peak METs) can be reasonably estimated for treadmill exercise by using common equations provided by ACSM,[2] as long as the equipment is calibrated regularly. When precise determination of oxygen uptake is necessary, such as assessment of patients for heart transplantation (**see Chapter 28**), evaluation by expired gas analysis is preferred over estimation (see Cardiopulmonary Exercise Testing). Normal values for exercise capacity in healthy adults at different ages are available and may serve as a useful reference in the evaluation of a patient's exercise capacity.[6]

Stationary Cycle.

A cycle ergometer is smaller, quieter, and less expensive than a treadmill. Because a cycle ergometer requires less movement of the arms and thorax, quality electrocardiographic recordings and BP measurements are easier to obtain. However, stationary cycling may be unfamiliar to many patients, and its success as a testing tool is highly dependent on patient skill and motivation. Thus the test may end before the patient reaches a true cardiopulmonary endpoint. Unlike treadmill testing, in which the work being performed involves movement of the patient's body weight at a given pace, stationary cycle work involves cycling at a given pace against an external force and is generally independent of the patient's body weight, which is supported by the seat. As shown in **Table 13.7**, the MET level attained at a given work rate varies with the patient's body weight. Accordingly, at the same given cycle ergometer work rate, a lighter person will attain higher METs than will a heavier person. Mechanically braked ergometers require that the patient's cycling speed be kept constant. Electronically braked cycle ergometers automatically adjust external resistance to the cycling speed to maintain a constant work rate at a given stage. Electronically braked cycle ergometers allow simple programming of ramp protocols. As with treadmill ramp protocols, customized cycle ergometer ramp protocols that accommodate a wide range of fitness levels need to be established by individual exercise testing laboratories.

TABLE 13.7

Approximate MET Levels During Cycle Ergometer Testing

BODY WEIGHT		EXERCISE RATE (kpm • min^{-1} and watts)						
kg	lb	kpm • min^{-1} 300 Watts 50	450 75	600 100	750 125	900 150	1050 175	1200 200
50	110	5.1	6.9	8.6	10.3	12.0	13.7	15.4
60	132	4.3	5.7	7.1	8.6	10.0	11.4	12.9
70	154	3.7	4.9	6.1	7.3	8.6	9.8	11.0
80	176	3.2	4.3	5.4	6.4	7.5	8.6	9.6
90	198	2.9	3.8	4.8	5.7	6.7	7.6	8.6
100	220	2.6	3.4	4.3	5.1	6.0	6.9	7.7

MET, Metabolic equivalent; *kpm,* kilopond-meter.

Arm Cycle Ergometry.

Arm ergometry is an alternative method of exercise testing for patients who cannot perform leg exercise. Although this test has diagnostic usefulness, it has been largely replaced by nonexercise pharmacologic stress techniques.

Six-Minute Walk Test.

The 6-minute walk test can be used as a surrogate measure of exercise capacity when standard treadmill or cycle testing is not available. Distance walked is the primary outcome of the test. It is not useful in the objective determination of myocardial ischemia and is best used in a serial manner to evaluate changes in exercise capacity and the response to interventions that may affect exercise capacity over time. The 6-minute walk test protocol is discussed in detail elsewhere[7] (**Table 13.8**).

TABLE 13.8
Six Minute Walk Test Protocol

Testing Site
• The Six Minute Walk Test Protocol should be performed indoors, along a long, flat, straight, enclosed corridor with a hard surface that is seldom traveled. The walking course must be 30 m in length. • A 30-m (100-ft) hallway is required, and its length should be marked every 3 m. • The turnaround points should be marked with a cone (e.g., orange traffic cone). • A starting line, which marks the beginning and end of each 60-m lap, should be marked on the floor using brightly colored tape.
Measurements
• Assemble all necessary equipment (lap counter, timer, clipboard, worksheet) and move to the starting point. • Set the lap counter to zero and the timer to 6 minutes. Position the patient at the starting line. • You should also stand near the starting line during the test. • Do not walk with the patient. • As soon as the patient starts to walk, start the timer. • Do not talk to anyone during the walk. • Use an even tone of voice when voicing the standard phrases of encouragement. • Each time the patient returns to the starting line, click the lap counter once (or mark the lap on the worksheet). • At the end of 6 minutes, tell the patient to stop walking, and measure the total distance traveled (meters).
Patient Instructions
Standardized scripted patient instructions should be used, and are provided elsewhere.

Data from American Thoracic Society. ATS statement: Guidelines for the six-minute walk test. Am J Respir Crit Care Med 2002;166:111.

Cardiopulmonary Exercise Testing (Exercise Testing with Gas Exchange Analysis).

Because of the inaccuracies associated with estimating oxygen uptake (V_{O_2}) and METs from work rate with the treadmill or cycle ergometer, many laboratories perform cardiopulmonary exercise testing (CPX), which uses ventilatory gas exchange analysis during exercise to provide a more reliable and reproducible measure of V_{O_2}. Peak V_{O_2} is the most accurate measure of exercise capacity and is a useful reflection of overall cardiopulmonary health. Measurement of expired gases is not necessary for all clinical exercise testing, but the additional information can provide important physiologic data that can be useful in both clinical and research applications. Measures of gas exchange primarily include V_{O_2}, carbon dioxide output (V_{CO_2}), and minute ventilation. Use of these variables in graphic form provides further information on the ventilatory threshold and ventilatory efficiency.[6,8]

CPX is well established as useful in the following situations[6,8,9]:

- Evaluation of exercise capacity in selected patients with heart failure, to assist in estimation of prognosis, evaluate the response to medications and other interventions, and assess the need for cardiac transplantation.
- Evaluation of exertional dyspnea. Such testing can provide useful information for differentiating cardiac from pulmonary limitations as a cause of exercise-induced dyspnea or impaired exercise capacity when the cause is uncertain.
- Evaluation of the patient's response to specific therapeutic interventions in which improvement in exercise tolerance is an important goal or endpoint.

Emerging evidence demonstrates that CPX can provide valuable clinical information in patients with hypertrophic cardiomyopathy (HCM), suspected or confirmed pulmonary hypertension, suspected myocardial ischemia, suspected mitochondrial myopathy, and confirmed chronic obstructive pulmonary disease or interstitial lung disease. More recently, utility of CPX has been demonstrated in the assessment of perioperative risk and valvular heart disease.[9]

The technical aspects of CPX have become simplified with contemporary systems, but meticulous maintenance and calibration of these systems are required for optimal use. The personnel involved in

administering and interpreting the test must be trained and proficient in this technique. The test also requires additional time, as well as patient cooperation.[6,9] CPX used in combination with Doppler echocardiography can provide complementary information regarding cardiac output, myocardial contractile function, and valvular function.[9]

Exercise Test Supervision

Over the past 30 years since the American Heart Association (AHA) published its first set of *Standards for Adult Exercise Testing Laboratories*, the role of the physician in ensuring that the exercise laboratory is properly equipped and appropriately staffed with qualified personnel who adhere to a written set of policies and procedures specific to that laboratory has not changed. In subsequent iterations of their respective guidelines, the AHA, ACSM, American College of Cardiology (ACC), and American Association of Cardiovascular and Pulmonary Rehabilitation (AACVPR) have consistently addressed this issue. In 2000 the ACC/AHA/American College of Physicians/American College of Sports Medicine Competency Task Force focused its efforts on outlining the specific cognitive and training requirements for personnel involved in supervising and interpreting exercise ECGs and was the first to look beyond the specific professional type (e.g., physician, nurse, exercise physiologist) and focus on specific competencies of the individual staff member.[10] In 2014 these recommendations were updated to define further the roles of each staff member involved with exercise testing.[11] This statement clearly defined different levels of supervision as follows: (1) “personal supervision” requires a physician's presence in the room; (2) “direct supervision” requires a physician to be in the immediate vicinity, on the premises or the floor, and available for emergencies; and (3) “general supervision” requires the physician to be available by phone or by page. Common to every guideline is the recommendation that patients be screened before exercise testing to assess their risk for an exercise-related adverse event so that the most appropriate personnel to supervise the test can be provided. Exercise testing may be supervised by nonphysician staff members who are deemed competent according to the criteria outlined in the ACC/AHA statement.[11] In all such cases the physician should be immediately available to assist as needed (i.e., provide direct supervision). In high-risk patients the physician should personally supervise the test (i.e., provide personal supervision).

Risks of Exercise Testing

Exercise is associated with increased risk for an adverse cardiovascular event, and details regarding the safety of exercise testing and emergency preparedness in exercise laboratories are addressed in depth in guidelines from the AHA[1,3] and the ACSM.[2] Nonetheless, the safety of exercise testing is well documented, and the overall risk for adverse events is quite low. In several large series of individuals with and without known CVD, the rate of major complications (including MI and other events requiring hospitalization) was less than 1 to as high as 5 per 10,000 tests, and the rate of death was less than 0.5 per 10,000 tests. The incidence of adverse events depends on the study population.[6] Patients with recent MI, reduced LV systolic function, exertion-induced myocardial ischemia, and serious ventricular arrhythmias are at highest risk.[1] In more than 2000 participants with New York Heart Association (NYHA) Functional Class II to IV systolic heart failure who completed exercise testing in the HF-ACTION (Heart Failure: A Controlled Trial Investigating Outcomes of Exercise Training) study, there were no deaths, and the rate of nonfatal major cardiovascular events was lower than 0.5 per 1000 tests.[12] A recent report of 5060 CPX studies performed in patients with severe functional impairment and a variety of high-risk cardiac

diseases, including heart failure, HCM, pulmonary hypertension, and aortic stenosis, further supports the safety of exercise testing. The adverse event rate was 0.16%, and the most common adverse event was sustained ventricular tachycardia. No fatal events were reported.[13]

Maintenance of appropriate emergency equipment, establishment of an emergency plan, and regular practice in carrying out the plan are fundamental to ensuring safety in an exercise testing laboratory.[3]

Exercise Testing in Coronary Artery Disease

Exercise-Induced Symptoms

Any chest pain produced during the exercise test needs to be factored into the exercise test conclusion and report.

First, are the symptoms reported during the test the same or similar to the reported historical symptoms that prompted the exercise test? If the answer is yes, the provider can assess the objective test responses and discern whether they support the presence of CAD. If the answer is no, differences between the produced and historical symptoms need to be clarified. In addition, the symptoms produced need to be categorized according to whether they are consistent with angina. Distinguishing anginal from nonanginal chest pain is important at the time of occurrence of the chest pain. Angina is not well localized, pleuritic, or associated with palpable tenderness (**see Chapters 56 and 61**), and the only opportunity to define these qualities may be after the exercise test.

Second, exercise-induced angina is an important clinical predictor of the presence and severity of CAD, equal to or greater than ST-segment depression. Consideration of limiting versus nonlimiting chest pain, in addition to any induced angina, has been incorporated into the Duke treadmill score, as well as into other treadmill scores (see later). These factors will have an impact on the prognostic and diagnostic assessment of the test results and ultimately the next step in the clinical evaluation.

Third, exercise-induced angina predicts an adverse prognosis and is worthy of further evaluation regardless of the ST-segment response or the exercise capacity. In a series of 3270 patients without known coronary disease referred for exercise testing, Christman and colleagues[14] found that typical angina defined by physicians and exercise physiologists at the exercise test was a predictor of adverse events, including death, nonfatal MI, and revascularization. This was found irrespective of the absence of a positive ST-segment response or good exercise capacity.[15]

Lastly, if the patient stops exercise earlier than anticipated because of dyspnea, careful consideration should be given as to whether an anginal equivalent is present. If the presenting symptom was dyspnea with exertion, this becomes even more relevant.

Functional Capacity

Functional capacity is a strong predictor of mortality and nonfatal cardiovascular outcomes in both men and women with and without CAD.[16] Even though exercise capacity is most accurately measured by CPX, a reasonable estimate can be obtained from treadmill testing alone. The best methods for estimating predicted METs are the following simple regression equations[1]:

$$\text{Men: Predicted METs} = 18 - (0.15 \times \text{Age})$$

$$\text{Women: Predicted METs} = 14.7 - (0.13 \times \text{Age})$$

The reported exercise time can be translated into metabolic equivalents or METs based on the exercise test protocol. The reported METs can then be expressed as a percentage of the predicted METs. **Table 13.9** provides an alternative qualitative classification of functional capacity[1] that adjusts for age and sex.

TABLE 13.9

Estimated Functional Capacity Relative to Age and Sex

AGE (yr)	ESTIMATED FUNCTIONAL CAPACITY (METs)				
	Poor	Fair	Average	Good	High
Women					
≤29	<7.5	8-10	10-13	13-16	>16
30-39	<7	7-9	9-11	11-15	>15
40-49	<6	6-8	8-10	10-14	>14
50-59	<5	5-7	7-9	9-13	>13
≥60	<4.5	4.5-6	6-8	8-11.5	>11.5
Men					
≤29	<8	8-11	11-14	14-17	>17
30-39	<7.5	7.5-10	10-12.5	12.5-16	>16
40-49	<7	7-8.5	8.5-11.5	11.5-15	>15
50-59	<6	6-8	8-11	11-14	>14
≥60	<5.5	5.5-7	7-9.5	9.5-13	>13

1 metabolic equivalent (MET) = 3.5 mL/kg/min of oxygen consumption.

From Snader CE, Marwick TH, Pashkow FJ, et al. Importance of estimated functional capacity as a predictor of all-cause mortality among patients referred for exercise thallium single-photon emission computed tomography: report of 3,400 patients from a single center. J Am Coll Cardiol 1997;30:641.

In addition to clinical factors, functional capacity can be related to familiarity with the exercise equipment, level of training, and environmental conditions in the exercise laboratory. Patients who cannot perform an exercise test or who undergo a pharmacologic stress test have a worse prognosis than do those who can perform an exercise test.

Functional capacity should always be incorporated into the results, conclusions, and/or recommendations of the exercise test report. Functional capacity can be incorporated into available multivariable scores such as the Duke treadmill score or the method of Lauer (see later) to classify the prognosis as low, intermediate, or high risk (**Fig. 13.3**).

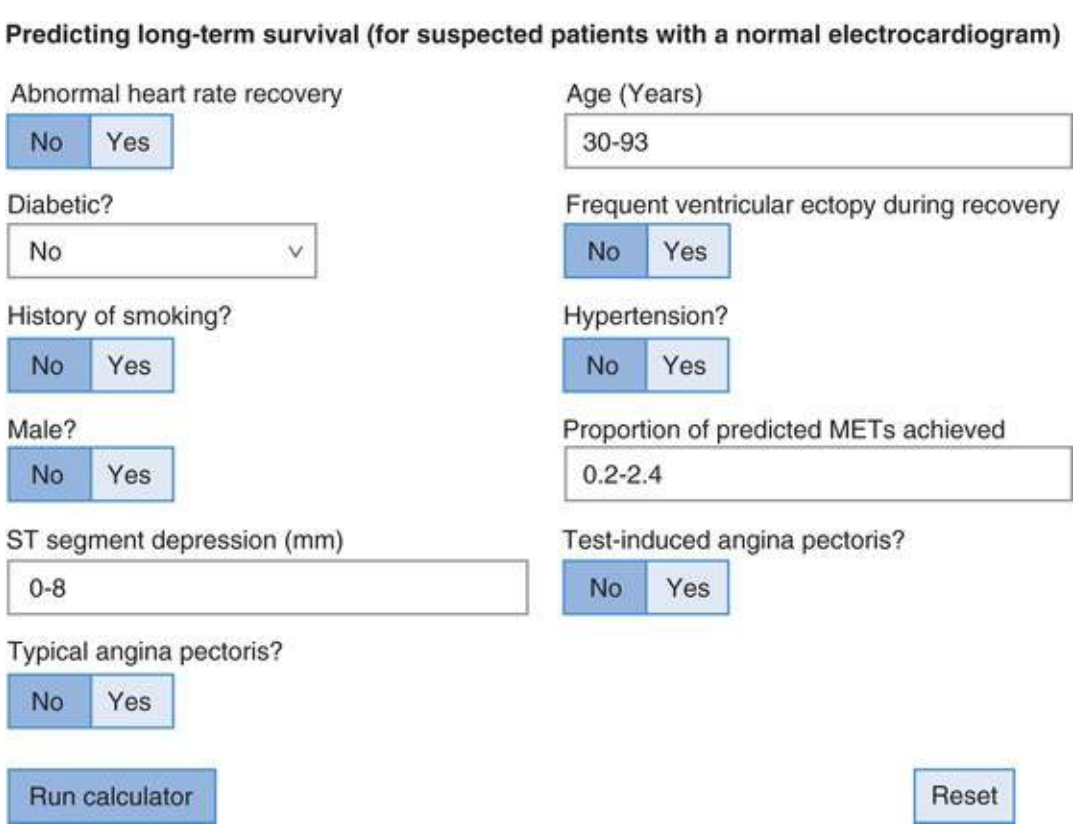

FIGURE 13.3 Cleveland Clinic Score. The Cleveland Clinic Score Calculator is available at https://apervita.com/community/clevelandclinic. Entering this URL will bring you to the site listing many scores developed at the Cleveland Clinic. Choose "Coronary Artery Disease." You will need to register one time at no cost. Once the score is open, you can create a shortcut to your desktop. The score will then always be open and ready for use. Definition of terms used in this calculator follow. *Typical angina*: chest discomfort that is substernal, is brought on by physical or mental exertion, and is relieved within minutes by rest or nitroglycerin. *Smoking*: regular smoking now or within the past year. *Hypertension:* resting systolic BP ≥140 mm Hg, resting diastolic BP ≥90 mm Hg, or use of medications for treatment of hypertension. *Proportion of predicted METs* (metabolic equivalents) *achieved*: in men, predicted METs = [14.7 − (0.11 × age)]; in women, [14.7 − (0.13 × age)]. *ST depression:* only count horizontal or downsloping ST depression that it at least 1 mm; otherwise record as 0. *Exercise-induced angina:* any angina is included, whether or not it is test terminating. *Abnormal heart rate recovery:* calculated as HR at the end of graded exercise minus HR 1 min later; for upright cool-down, consider abnormal if ≤12 beats/min; for supine cool-down, consider abnormal if ≤18 beats/min. *Frequent ventricular ectopy in recovery:* includes at least 7 premature ventricular beats/min, frequent ventricular couplets, any ventricular triplets, nonsustained or sustained ventricular tachycardia or torsade des pointes, or ventricular fibrillation occurring in the first 5 minutes of recovery.

Heart Rate Responses

Peak Heart Rate.

The maximum heart rate with exercise is a fundamental physiologic parameter that provides the provider relevant information concerning the intensity of exercise, the adequacy of the exercise test, the effect of medications that influence heart rate, the potential contribution to exercise intolerance, and the patient's prognosis.[17] The maximum achievable heart rate (HRmax) is unique for each patient but can be estimated by using regression equations that adjust for the patient's age. The most familiar equation, which was developed principally in middle-aged men, is:

$$\text{HRmax} = 220 - \text{Age}$$

Although easy to apply and calculate, there is considerable variability with this equation, especially in patients with CAD who are taking beta blockers. Newer equations[2,17] have been proposed to replace the "220 – age" rule to generate the maximum age-predicted heart rate (MPHR):

$$\text{Men: HRmax} = 208 - (0.7 \times \text{Age})$$

$$\text{Women: HRmax} = 206 - (0.88 \times \text{Age})$$

$$\text{CAD with beta blockers: HRmax} = 164 - (0.7 \times \text{Age})$$

Chronotropic Incompetence.

The inability of the heart to increase its rate to meet the demand placed on it is termed chronotropic incompetence. It is considered an independent predictor (including the well-established Duke treadmill score) of cardiac or all-cause mortality, as well as other adverse other adverse cardiovascular outcomes.[17]

A *submaximal* study is assigned when the peak HR achieved is below the MPHR. An *inadequate* study is defined by failure to achieve a predefined goal, such as 85% of MPHR. If a patient without known CAD has an inadequate study, the term *nondiagnostic* study is often applied. As usual, this "nondiagnostic" status is relative. In the presence of any other diagnostic endpoints, such as 2-mm or greater ST-segment depression, exercise-induced hypotension, or exercise-induced anginal chest pain, the heart rate adequacy question becomes irrelevant.

Chronotropic incompetence typically has been defined by the adjusted heart rate reserve, which incorporates both resting and peak HRs, as well as the age-adjusted HRmax. However, before "chronotropic incompetence" is applied, consideration should be given to the effort exerted in performing exercise, present medications, and the reason for termination of the exercise test. Effort applied to the exercise is often defined by the symptoms produced or by indices of perceived exertion (e.g., Borg scale).[1] These work well in most settings but can also be defined quantitatively by using CPX parameters such as the respiratory exchange ratio. For the usual non-CPX application, the following formula[17] defines the chronotropic index:

$$[(\text{HRmax} - \text{HRrest})/(220 - \text{Age} - \text{HRrest})] \times 100$$

Failure to achieve a chronotropic index higher than 80% defines the presence of chronotropic incompetence.[17] In patients taking nontrivial doses of beta blockers who are compliant with their medication, a value lower than 62% is considered chronotropic incompetence.[1] Criteria for assessing chronotropic incompetence in patients with atrial fibrillation (AF) have not been established.

Heart Rate Recovery.

The HR increases during exercise because of an increase in sympathetic tone and a decrease in

parasympathetic tone. At the cessation of exercise, under normal circumstances, the reverse process occurs. In athletes and normal persons, there is a biexponential response, with an initial steep 30-second fall in HR followed by a more shallow decline thereafter. This biexponential response disappears with the administration of atropine and becomes similar to the response in patients with heart failure. Abnormal *heart rate recovery* (HRR) has been defined by many methods, but the most commonly accepted include less than 12 beats/min after 1 minute with postexercise cool down, less than 18 beats/min after 1 minute with immediate cessation of movement into either the supine or sitting position, and less than 22 beats/min after 2 minutes. In healthy individuals, short-term reproducibility has been demonstrated.[17]

Abnormal HRR is associated with an increase in all-cause mortality in both asymptomatic individuals and patients with established heart disease. This association is independent of the chronotropic index, beta blockade, CAD severity, LV function, Duke treadmill score, and ST-segment depression. HRR adds to the prognostic ability of peak V_{O_2}. When considered in a multivariable format assessing prognosis, HRR has been found to be an independent predictor of adverse outcomes even when combined with nuclear variables.[18]

Most of the literature focuses on the early phase of HRR, but later HRR, expressed as a percentage of change in cycle length, may be independently predictive of adverse cardiovascular outcomes.[19] This aspect requires further investigation.

Blood Pressure Responses

Exercise BP responses, as with those for HR, reflect the balance between sympathetic and parasympathetic influences. Systolic blood pressure, pulse pressure (difference between systolic and diastolic BP), HR-BP product (also called the *double product*), and double-product reserve (change in double product from peak to rest) all increase steadily as workload increases. Diastolic BP increases only minimally or may fall. In most normal individuals, systolic BP will increase to higher than 140 mm Hg and the double product to higher than 20,000.

Hypertensive Systolic Pressure Response.

This response is usually defined as greater than 210 mm Hg in men and greater than 190 mm Hg in women. Even though these exercise responses are considered abnormal, they are not generally reasons to terminate exercise. Such responses may be indicative of the future development of hypertension or adverse cardiac events.[20]

Exercise-Induced Systolic Hypotension.

This has been variably defined but most frequently as systolic pressure during exercise falling below resting systolic pressure.[1] Another definition is a 20 mm Hg fall after an initial rise. Either of these definitions would be an absolute reason to terminate the exercise test. The former definition is more predictive of a poor prognosis and is usually related to severe multivessel CAD with LV dysfunction, especially when noted with other signs of ischemia, such as ST depression or angina at a low workload. Its positive predictive value is higher in men than in women. Its presence usually warrants consideration of prompt invasive evaluation. Exercise-associated hypotension may also be seen in patients with cardiomyopathy, LV outflow tract obstruction, enhanced vagal tone, hypovolemia, antihypertensive medications, and arrhythmias. In addition, one study of 57,442 patients suggests that exercise-induced hypotension may be a predictor of future AF.[21]

One systolic BP response that needs to be appreciated might be called “pseudo–exercise-induced hypotension.” This response occurs in patients who are anxious about the exercise study and begin exercise with a somewhat elevated systolic pressure. As exercise proceeds in the first stage, this

elevated BP usually settles down or “falls” toward its customary resting level. As exercise continues, continued observation reveals a gradual upward trend in BP. Considerable judgment needs to be used when interpreting this response.

Low Maximum Systolic Pressure Peak.
This is defined as a rise to less than 140 mm Hg or a lower than 10 mm Hg rise overall. After excluding poor exercise effort, this response is often associated with severe CAD and worse cardiovascular outcomes in persons with and without known CAD and warrants further evaluation.[2]

ST-Segment Changes

For decades, the change in ST segments was the principal factor considered in the analysis of exercise ECG results (**Fig. 13.4**). However, the diagnostic value of ST-segment depression has been recognized to be mediocre by current noninvasive test standards, with a sensitivity and specificity of 60% to 70% and 70% to 80%, respectively, based on coronary angiography. When adjusted for referral or workup bias, its sensitivity is lower (45% to 50%) and specificity higher (85% to 90%).[1] Accordingly, the prognostic value of ST-segment changes has been appropriately placed behind the prognostic value of non–ST-segment variables, such as functional capacity and heart rate responses. Despite these issues, it is still appropriate to consider ST-segment changes, but only in the context of other clinical and non–ST-segment data.

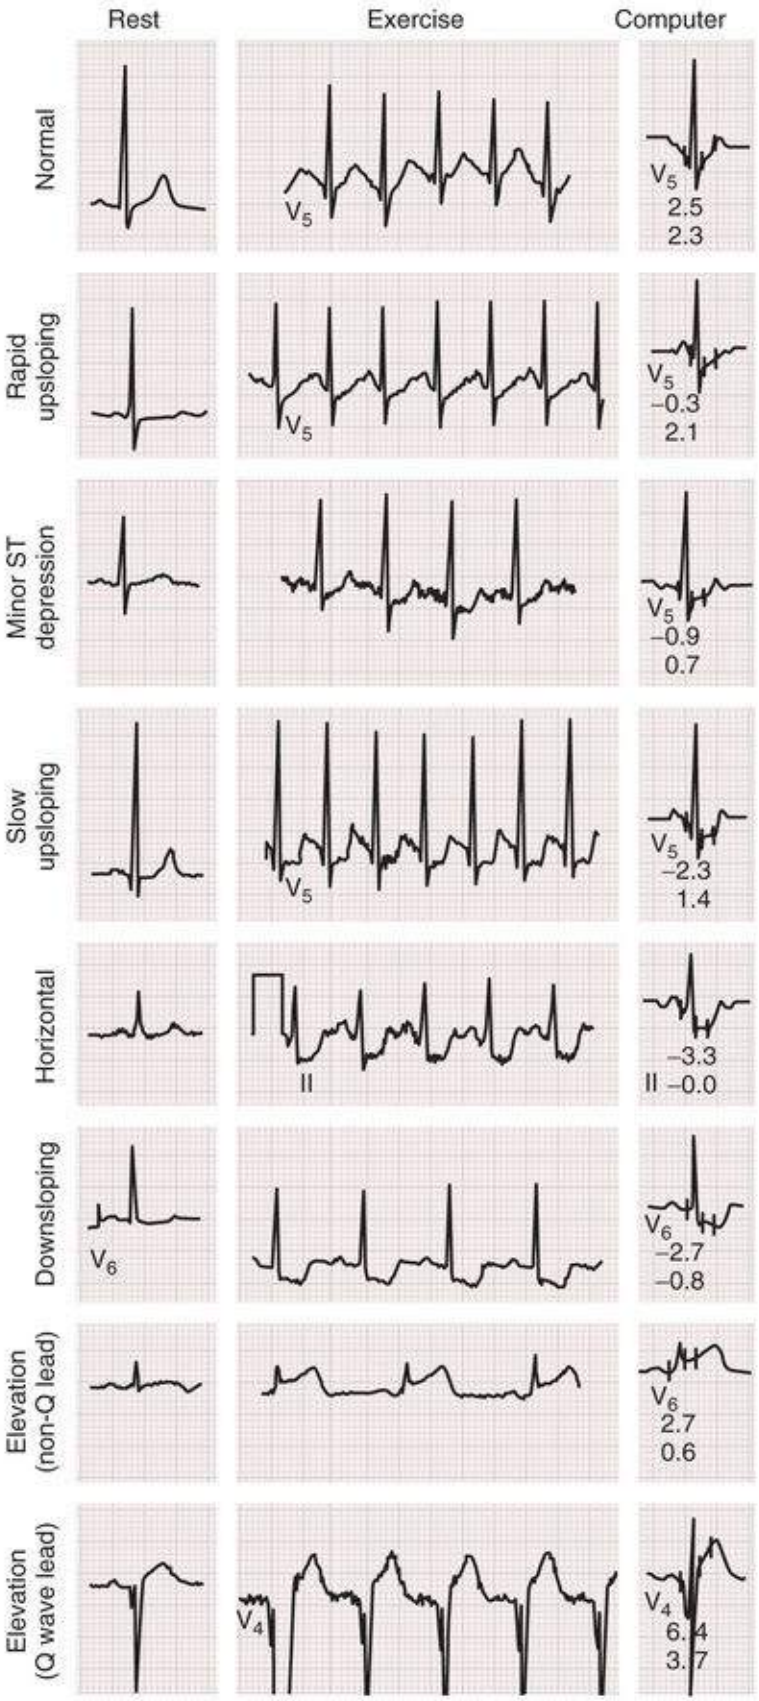

FIGURE 13.4 Eight typical exercise electrocardiographic patterns at rest and at peak exertion. The computer-processed incrementally averaged beat corresponds with the raw data taken at the same time point during exercise and is illustrated in the last column. The patterns represent worsening ECG responses during exercise. In the column of computer-averaged beats, ST80 displacement (*top* number) indicates the magnitude of ST-segment displacement 80 milliseconds after the J point relative to the PQ junction or E point. ST-segment slope measurement (*bottom* number) indicates the ST-segment slope at a fixed time point after the J point to the ST80 measurement. At least three non–computer-averaged complexes with a stable baseline should meet criteria for abnormality before the exercise ECG result can be considered abnormal. The *normal* and *rapid upsloping ST-segment* responses are normal responses to exercise. J point depression with rapid upsloping ST segments is a common response in an older, apparently healthy person. *Minor ST-segment depression* can occur occasionally at submaximal

workloads in patients with CAD; in this figure, the ST segment is depressed 0.09 mV (0.9 mm) 80 milliseconds after the J point. The *slow upsloping ST-segment pattern* may suggest an ischemic response in patients with known CAD or those with a high pretest clinical risk of CAD. Criteria for slow upsloping ST-segment depression include J point and ST80 depression of 0.15 mV or more and ST-segment slope of more than 1.0 mV/sec. This pattern may also precede horizontal or downsloping ST-segment depression that will occur in recovery. *Classic criteria for myocardial ischemia* include horizontal ST-segment depression observed when both the J point and ST80 depression are 0.1 mV or more and the ST-segment slope is within the range of 1.0 mV/sec. Downsloping ST-segment depression occurs when the J point and ST80 depression are 0.1 mV and the ST-segment slope is −1.0 mV/sec. *ST-segment elevation in a non–Q wave noninfarct lead* occurs when the J point and ST60 are 1.0 mV or higher and represents a severe ischemic response. *ST-segment elevation in an infarct territory (Q wave lead)* indicates a severe wall motion abnormality and, in most cases, is not considered an ischemic response. (From Chaitman BR. Exercise electrocardiographic stress testing. In Beller GA, editor. Chronic Ischemic Heart Disease. In Braunwald E, series editor. Atlas of Heart Diseases. Vol 5. Philadelphia: Current Medicine; 1995, pp 2.1-30.)

ST Depression

When considering ST-segment depression, it is important to use standards that allow application of uniform criteria. The usual criterion applied to raw data is 1 mm or greater or 0.1 mV or greater of horizontal or downsloping (i.e., <0.5 mV/sec) ST-segment depression in three consecutive beats. This assumes that the PQ point (not the TP segment) is used as the isoelectric reference and that the point of ST-segment measurement is 60 to 80 milliseconds after the J point. The 60-millisecond post–J point criterion is used at HR higher than 130 beats/min. This criterion should be added to and not included with existing resting ST-segment depression. ST-segment changes in the presence of early repolarization should be measured from the isoelectric line and not the baseline ST elevation. Unlike ST-segment elevation, exercise-induced ST-segment depression does not localize ischemia to a precise region or vascular bed. The lateral precordial leads are the best for defining positive responses. However, the inferior leads can be helpful in assessing the extent of ischemia when the lateral leads are abnormal as well. Isolated inferior ST depression is frequently falsely abnormal because of the influence of atrial repolarization in these leads.

Although raw data should always be examined, the use of signal-averaged data can be useful, especially when moderate baseline wandering or motion artifact is present. Particular care must be taken to avoid signal averaging that incorporates gross distortions as a result of motion and transient ventricular aberrations such as premature ventricular contractions and intraventricular conduction defects.

Postexercise recovery responses are also important to assess. First, positive responses are occasionally limited to the recovery period, and these have equal significance to changes that occur at peak exercise. Second, positive changes during exercise that resolve within 1 minute of recovery are associated with a favorable prognosis and low downstream diagnostic test yield.[14] In addition, compared to ST changes longer than 1 minute, early-recovery ST changes are associated with significantly smaller summed stress scores on myocardial perfusion imaging and a lower prevalence of CAD.[22]

Upsloping ST Depression

Rapidly upsloping ST depression that resolves quickly is rarely a true-positive response. However, ST-segment depression that is slowly upsloping (0.5 to 1.0 mV/sec) may be considered abnormal, especially if it occurs at low workloads. Its presence during exercise may presage horizontal or downsloping depression in recovery. HR adjustment can be applied to upsloping ST segments (see later).

Lead aVR ST Elevation

Emerging literature suggests that 1-mm or greater ST-segment elevation in lead aVR may be a significant predictor of left main coronary artery disease, proximal left anterior descending (LAD) artery disease, or at least multivessel CAD.[23] As an isolated marker, it appears to be sensitive and has moderate specificity and a high negative predictive value. What is yet unclear is where it fits into the multivariate approach for assessing prognosis.

ST Adjustments

Heart rate adjustments of ST segments have been proposed as an alternative way to analyze ST-segment depression.[1] However, comparative studies have not shown an increase in accuracy. Nevertheless, HR adjustments can be helpful for borderline cases in which ST depression is upsloping or barely abnormal, or traditional criteria and other clinical or exercise data suggest a false-positive result (e.g., low pretest probability or very high HR or workload achieved during exercise). HR adjustment can be accomplished by two methods (complicated and simple). The complicated method, known as *ST/heart rate slope*, is automated and available on most stress testing machines as an option to be toggled on or off. It plots ST depression as a function of HR at numerous points during exercise and generates the terminal ST/HR slope for each lead. The criterion for abnormality is 2.4 µV/beat/min. Depending on the protocol used and the duration of exercise, the ST/HR slope will not always be calculated because of insufficient data points. The developers of the method proposed a modification of the standard Bruce protocol to increase the points available for analysis. The slightly less intensive Cornell protocol uses 2-minute rather than 3-minute stages and is useful in patients who are not anticipated to exercise beyond stage 2 of the Bruce protocol. The simple method, known as *ST/heart rate index*, can easily be calculated by dividing the maximum ST-segment depression in microvolts by the difference in resting and peak HR. The criterion for abnormality is 1.6 µV/beat/min.

ST Elevation

The usual criterion applied to raw data is 1 mm or greater or 0.1 mV of ST-segment elevation above the PQ point at 60 milliseconds after the J point in three consecutive beats. The J point may or may not be elevated as well. Without pathologic Q waves, exercise-induced ST elevation usually indicates either significant proximal coronary stenosis or epicardial coronary spasm. In either case the ST-segment elevation precisely localizes the transmural ischemia to a particular vascular region (e.g., anterior = LAD, and thus coronary angiography is an appropriate next step). In contrast, when pathologic Q waves are present, ST-segment elevation is usually indicative of an LV aneurysm or significant wall motion change. Ischemia may be involved in this process, and myocardial perfusion imaging is generally required to determine this.

Quantitative QRS Changes

R Wave Amplitude.

Precordial R waves normally increase during exercise. They peak before achieving maximal exercise and decrease as maximal exercise is achieved. If exercise is limited to a submaximal level by any cause, the R waves will appear to increase in height at peak exercise. This increase in R wave height has not been found to have predictive power.[1]

QRS Duration.

During exercise there is a normal shortening of the QRS complex, as well as the PR and QT intervals. Exercise-induced bundle branch block (BBB) is rare and occurs at a frequency of 0.5% or less. Exercise-induced left BBB (EI-LBBB) has been reported.[1] When EI-LBBB occurs at HRs higher than 125 beats/min, significant CAD is unlikely. The incidence of CAD does increase when it occurs at progressively lower HRs. One study suggested an increased association of EI-LBBB with death and major cardiac events. The ST-segment changes before onset of the LBBB are still interpretable, but they become uninterpretable once the LBBB begins. Onset and offset of the LBBB usually occur at different heart rates.

In contrast, exercise-induced right BBB (EI-RBBB) from one recent large Veterans Affairs series correlated with age and was not associated with added incremental risk.[24] Limited data are available in women. EI-RBBB does not invalidate interpretation of the ST segment for the inferior (II, III, aVf) and lateral leads (V_5, V_6). However, ST-segment changes limited to V_1 to V_4 are nondiagnostic.

Exercise-Induced Rhythm Changes

Ventricular ectopic activity is noted in up to 20% of patients during exercise testing. It varies from isolated premature ventricular beats (PVBs) to nonsustained ventricular tachycardia. However, frequent ventricular ectopy occurs during exercise or recovery in only 2% to 3% of patients. Suppression of resting ventricular ectopic activity during exercise is a nonspecific finding that can occur with or without CAD.

In clinical populations referred for testing because of symptoms, ventricular ectopic activity during exercise was predictive of mortality in most studies. In addition, ventricular ectopic beats occurring during exercise or recovery increase the likelihood of future cardiac death.[1] For asymptomatic populations, one study of 2099 participants followed for 13 years found no correlation between nonsustained ventricular arrhythmias and mortality.[25]

Exercise-induced supraventricular arrhythmias are not predictive of ischemia or any cardiovascular endpoint. However, they may be a marker for the later occurrence of AF or supraventricular tachycardia.

Miscellaneous Electrocardiographic Changes

The following factors have been reported to improve the accuracy of the exercise ECG[1] but have not been studied in large, unselected populations.

Duration of the P Wave.

The duration of the P wave in lead V_5 has been reported to increase sensitivity. A duration of 20 milliseconds or less is considered normal, whereas 30 milliseconds or longer is considered abnormal. From a practical standpoint, it is more realistic to expect that these changes would be easier to appreciate with signal-averaged complexes.

ST Changes in Premature Ventricular Beats.

Comparing the ST segments of PVBs before and during exercise has been reported to increase sensitivity.

T Wave Amplitude Increase.

An increase in T wave height by more than 2.5 mV in leads V_2 to V_4 in patients with exercise-induced chest pain has been noted as a highly specific finding of ischemia.

Pharmacologic Influences on Interpretation

Digitalis Glycosides

That digitalis can have an adverse effect on ST-segment interpretation is generally common knowledge. The principal issue has been false-positive results and reduced specificity. The absence of ST-segment change at rest does not eliminate the effect occurring during exercise. Sensitivity is not affected by digitalis. Therefore a negative ST-segment response with digitalis is still reliable.

However, this issue arises much less frequently in the current era. Although still used, digitalis has become a secondary drug for both HR control for patients in AF and treatment of symptomatic heart failure. Its use for the treatment of other supraventricular arrhythmias is virtually nonexistent. For many if not most patients taking digitalis, stress imaging with or without pharmacologic stress is appropriate for reasons other than the presence of digitalis. For the relatively few patients who are taking digitalis and qualify for a simple exercise ECG, individualized decision-making can obviate the need for a general policy statement, beyond repeating the exercise ECG with imaging if the ST-segment response is abnormal while taking digitalis.

Beta Adrenoreceptor Blockers

Beta blockers clearly reduce the rate-pressure product in most patients receiving proper doses. Evidence indicates that the diagnostic sensitivity and negative predictive value of exercise testing are adversely affected.

For those without established CAD who are undergoing a diagnostic-level exercise ECG, beta blockers should ideally be withheld to allow an adequate HR response. For those undergoing supplemental stress imaging, the issue is less critical given the availability of conversion to pharmacologic stress if the patient fails to achieve the desired HR response.

For those with established CAD, the situation is less clear. For most patients with CAD, beta blockers are part of their standard medical therapy and have significant effects on both quality and quantity of life (i.e., their prognosis). Many laboratories routinely have patients discontinue beta blockers before stress testing of all sorts without apparent harm. The principal justification for this seems to be to enhance diagnostic sensitivity (e.g., with myocardial perfusion imaging, to allow a larger defect size). Conversely, many laboratories do not discontinue these medications. Discontinuing beta blockers in patients with CAD creates a clinical state that is unlike their usual day-to-day existence. We are unaware of any reported studies in patients with established CAD indicating that beta blockers adversely affected the ability of exercise testing (with or without imaging) to detect prognostically important myocardial ischemia such that it would have significantly altered their clinical management. Therefore, discontinuation of beta blockers before exercise testing may be left to the discretion of the referring provider.

Diagnostic Value

Sensitivity and Specificity

Table 13.10 outlines the diagnostic characteristics of stress testing. Sensitivity and specificity define how effectively a test discriminates individuals with disease from those without disease. *Sensitivity* is the percentage of individuals with a disease who have abnormal test results and, in the case of CAD, is influenced by disease severity, effort level, and the use of anti-ischemic drugs. *Specificity* is the percentage of those without disease who have normal test results, and it may be affected by resting ECG patterns (e.g., LV hypertrophy, ST-T abnormalities, interventricular conduction delay) and drugs such as digoxin. All tests have a range of inversely related sensitivities and specificities such that when

sensitivity is the highest, specificity is lowest, and vice versa. These can be selected by specifying a *discriminant* or diagnostic cut point.[26] The standard exercise test cut point of 0.1 mV (1 mm) of horizontal or downsloping ST-segment depression in three consecutive beats of at least a single lead has been selected as the discriminating cut point and has a sensitivity of 68% and specificity of 77%.[27]

TABLE 13.10

Diagnostic Characteristics of the Exercise ECG Test

TERM	DEFINITION
True positive (TP)	Abnormal test result in individual with disease
False positive (FP)	Abnormal test result in individual without disease
True negative (TN)	Normal test result in individual without disease
False negative (FN)	Normal test result in individual with disease
Sensitivity	Percentage of patients with CAD who have an abnormal result = TP/(TP + FN)
Specificity	Percentage of patients without CAD who have a normal result = TN/(TN + FP)
Predictive value of a positive test	Percentage of patients with an abnormal result who have CAD = TP/(TP + FP)
Predictive value of a negative test	Percentage of patients with a normal result who do not have CAD = TN/(TN + FN)
Test accuracy	Percentage of true test results = (TP + TN)/total number tests performed

CAD, Coronary artery disease; *ECG,* electrocardiogram.

Modified from Chaitman BR. Exercise stress testing. In Bonow RO, Mann DL, Zipes DP, Libby P, editors. Braunwald's Heart Disease. 9th ed. Saunders: Philadelphia; 2012.

Once a discriminant value that determines a test's specificity and sensitivity is chosen, the population tested must be considered. If the population is skewed toward individuals with a greater severity of disease, the test will have higher sensitivity. Thus the exercise test has higher sensitivity in individuals with triple-vessel disease than in those with single-vessel disease.[1] The sensitivity and specificity of stress testing are limited by the use of angiographic CAD as the diagnostic "gold standard," so most data are derived from studies in which patients underwent both exercise testing and cardiac catheterization. The data are therefore subject to workup bias, which inflates the estimated sensitivity and deflates the specificity, because patients selected for coronary arteriography are more likely to have obstructive CAD,[1] and in some studies, patients with a positive test result were more likely to be referred for angiography.

The *diagnostic accuracy* of a test is the percentage of true test results (total true positives plus total true negatives) among all tests performed. Diagnostic accuracy is additionally influenced by the criteria used to determine whether an adequate level of stress has been achieved. This is currently defined as having attained 85% of the maximum age-predicted heart rate, with HRmax estimated as "220 − age" (see earlier, Heart Rate Responses). Despite many limitations in using this equation for diagnostic purposes, it remains a standard criterion for test adequacy but should not be used as a reason to terminate the test.

Positive and Negative Predictive Values

Predictive values further define the diagnostic value of a test (**Table 13.10**). The predictive value of a test is heavily influenced by the prevalence of disease in the group being tested. Bayes' theorem states that the probability of a person having the disease after the test is performed is the product of the probability of the disease before testing and the probability that the test provided a true result. Thus a test has a higher positive predictive value (PPV) and lower negative predictive value (NPV) when used in a population with a high prevalence; conversely, a higher NPV and lower PPV occur in a population with a lower prevalence. For example, an exercise ECG that demonstrates ST depression in an elderly person with typical anginal symptoms is most likely a true-positive result, whereas that in a young asymptomatic person without cardiac risk factors is most likely a false-positive result.

Pretest and Post-Test Probability of Disease

Table 13.11 demonstrates the pretest probability of obstructive CAD based on age, sex, and symptoms. However, these can be refined further with knowledge of the presence and extent of traditional atherosclerotic risk factors (e.g., hypertension, hyperlipidemia, smoking, diabetes).[28,29] Using exercise ST-segment criteria, the post-test likelihood of obstructive CAD can be estimated for a given individual if an ischemic response was demonstrated at any HR or if the patient attained HR of 85% or greater of the predicted maximum without an ischemic response.

TABLE 13.11

ACC/AHA Practice Guidelines on Exercise Testing: Pretest Probability of Coronary Artery Disease by Age, Sex, and Symptoms

AGE (yr)	TYPICAL/DEFINITE ANGINA PECTORIS	ATYPICAL/PROBABLE ANGINA PECTORIS	NONANGINAL CHEST PAIN	ASYMPTOMATIC
30-39	Intermediate	Very low	Very low	Very low
40-49	Intermediate	Low	Very low	Very low
50-59	Intermediate	Intermediate	Low	Very low
60-69	High	Intermediate	Intermediate	Low
≥70	High	Intermediate	Intermediate	Low

Modified from Gibbons RJ, Balady GJ, Bricker JT, et al. ACC/AHA 2002 guideline update for exercise testing: summary article. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to Update the 1997 Exercise Testing Guidelines). Circulation 2002;106:1883-92.

Assessment of Anatomic and Functional Extent of Disease

As discussed earlier, several factors influence the significance of a given coronary artery luminal stenosis, and these factors may affect the presence and extent of myocardial ischemia relative to exercise-induced increases in myocardial oxygen demand. Furthermore, exercise-induced ST-segment depression does not provide a reliable assessment of the extent of disease or the specific coronary vessel or vessels involved. ST-segment elevation in leads without Q waves, although an uncommon response, generally reflects transmural ischemia that can be localized by the leads involved: leads V_2 to V_4 reflect LAD disease; lateral leads reflect left circumflex and diagonal vessel disease; and leads II, III, and AVF reflect right coronary artery disease (in a right-dominant circulation).[27] Other factors related to the probability and severity of CAD include the degree, time of appearance, duration, and number of leads with ST-segment depression or elevation. It is important to realize, however, that prognostically important CAD may be present in the absence of obstructive lesions. Therefore the use of diagnostic ST-segment analysis alone during exercise testing is inadequate and should be done with consideration of several non–ST-segment variables, as discussed later (see Prognostic Value).

Testing in Women

Identification of ischemic heart disease in women can be a diagnostic challenge because of several factors, including the lower prevalence of obstructive CAD in women younger than 65, more atypical manifestations of ischemic symptoms, and more frequent resting ST changes. In women with a low pretest likelihood of CAD, exercise electrocardiographic testing results in a minimal change in assessment from pretest levels. Premenopausal women with one or fewer risk factors for CAD and with nonanginal or atypical symptoms will have a high rate of false-positive tests. Thus the exercise ECG in such women is

of little value, except perhaps in selected cases to reassure women with atypical symptoms regarding their low likelihood of obstructive CAD when they have no exercise-induced ischemic ST changes and a low-risk Duke treadmill score.

The reported sensitivity and specificity of exercise electrocardiographic testing in symptomatic women vary greatly depending on the study characteristics and range from 31% to 71% and 66% to 86%, respectively.[30] However, exercise testing has similar diagnostic characteristics in women with an intermediate probability of CAD as it does for men. Thus, exercise testing has the greatest incremental value in intermediate-risk women, particularly when coupled with the Duke treadmill score. In a series of 976 symptomatic women referred for exercise testing and coronary angiography, a low-, intermediate-, and high-risk score was associated with obstructive CAD (>75% luminal narrowing) in 19%, 35%, and 89% of women, respectively. Moreover, 2-year cardiac mortality rates in this same cohort of women with low-, moderate-, and high-risk Duke treadmill scores were 1%, 2%, and 4%, respectively. Non–ST-segment variables, including peak exercise capacity (METs), chronotropic response, HRR, and BP response, have prognostic value in women[30,31] (**Table 13.12**) and are most useful when incorporated into the prognostic scores discussed next. The usefulness of exercise stress testing in the assessment of ischemic heart disease in women has been reviewed and updated in detail by the AHA[31] (**Fig. 13.5**). The exercise ECG remains the recommended test of first choice for the assessment of symptomatic, intermediate-risk women who can exercise and have normal findings on a resting ECG. A negative and diagnostically adequate test, particularly when associated with low risk scores, makes the likelihood of obstructive CAD very low. A positive or inconclusive test generally requires further evaluation with either a stress imaging test or coronary angiography.

TABLE 13.12

ECG and Non-ECG Variables Associated with Elevated Ischemic Heart Disease Risk from Exercise Testing in Women

STRESS TESTING VARIABLES	METHOD OF ASSESSMENT	HIGH-RISK VALUE
Exercise capacity	Estimated by ETT protocol (speed and grade)	<5 METs <100% Age-predicted METs = 14.7 − (0.13 × age)
HR recovery	Difference between peak HR at 1 min of recovery	≤12 beats/min after 1 min of recovery (upright cool-down period)
ST-segment changes	Difference in ST-segment changes (at 60 msec after the J point) between peak exercise (or recovery) and rest ECG	ST-segment depression ≥2 mm ST-segment depression ≥1 mm at <5 METs or >5 min into recovery ST-segment elevation ≥2 mm (not in q wave lead or aVR)
Duke treadmill score (DTS)	DTS = Exercise time − (5 × ST change) − (4 × angina index)	High-risk DTS: −11 or less
BP response	Assessment of BP response to exercise, change in SBP from rest to peak exercise	Decrease in SBP >10 mm Hg from rest
Ventricular arrhythmias		Persistent ventricular tachycardia/fibrillation

BP, Blood pressure; *ETT,* exercise treadmill testing; *HR,* heart rate; *METs,* metabolic equivalents; *SPB,* systolic blood pressure.

(From Mieres JH, Gulati M, Bairey Merz N, et al. Role of noninvasive testing in the clinical evaluation of women with suspected ischemic heart disease: a consensus statement from the American Heart Association. Circulation 2014;130:350-79.)

Prognostic Value

Predictive Variables

The strongest predictor of prognosis derived from the exercise test is functional capacity. The weakest predictor is ST-segment depression. All other variables, such as the heart rate achieved, HRR, BP response, ventricular arrhythmias, and exercise-induced angina, fall between these two extremes. This prognostic hierarchy is similar in both men and women.

Multivariable Scores

Multivariable scores are the best way to distill the relative prognostic values of many variables into a single indicator of risk that can be expressed as both continuous (e.g., 0 to 100) and ordinal variables (e.g., low, intermediate, and high). To date, three scores have been developed and validated and are worthy of consideration in analyzing exercise tests.[1]

Duke Treadmill Prognostic Score.

This score has been available since the early 1990s and is the most widely recognized, used, and

validated score. It was cited in the 1997 and subsequent updates of the ACC/AHA exercise test guidelines. It incorporates three treadmill variables: exercise time (Bruce protocol), millimeters of any ST-segment deviation (except aVR), and angina score index (1 = nonlimiting angina and 2 = exercise-limiting angina). It is simple enough to present as the following equation:

$$\text{Score} = \text{Exercise time} - (5 \times \text{ST deviation}) - (4 \times \text{Angina index})$$

ST deviation is the largest net ST-segment displacement in any lead. It is equally valid in men and women, and its prognostic value is independent of clinical, coronary anatomic, and LV function data. The principal criticism of the Duke score is the absence of consideration of clinical variables, especially age, or other exercise test variables such as HR.

Separate Scores for Men and Women.

These scores were developed and validated in the early 2000s. Separate scores for men and women incorporate three standard exercise test variables (ST-segment depression, peak HR, exercise angina score) and several other clinical variables (**Fig. 13.6**). These scores are not as simple as the Duke treadmill score but lend themselves to easy clinical application.

VARIABLE	CHOOSE RESPONSE	SUM	Exercise test score
Maximal heart rate	Less than 100 bpm = 30		MEN
	100 to 129 bpm = 24		Choose one per group
	130 to 159 bpm = 18		
	160 to 189 bpm = 12		
	190 to 220 bpm = 6		<40 = low probability
Exercise ST depression	1 to 2 mm = 15		
	Greater than 2 mm = 25		40-60 = intermediate probability
Age	Greater than 55 yr = 20		
	40 to 55 yr = 12		>60 = high probability
Angina history	Definite/typical = 5		
	Probable/atypical = 3		
	Noncardiac pain = 1		
Hypercholesterolemia?	Yes = 5		
Diabetes?	Yes = 5		
Exercise test: induced angina	Occurred = 3		
	Reason for stopping = 5		
	Total score:		

A

VARIABLE	CHOOSE RESPONSE	SUM	Exercise test score
Maximal heart rate	Less than 100 bpm = 20		WOMEN
	100 to 129 bpm = 16		Choose one per group
	130 to 159 bpm = 12		
	160 to 189 bpm = 8		
	190 to 220 bpm = 4		<40 = low probability
Exercise ST depression	1 to 2 mm = 6		
	Greater than 2 mm = 10		40-60 = intermediate probability
Age	Greater than 65 yr = 25		
	50 to 65 yr = 15		>60 = high probability
Angina history	Definite/typical = 10		
	Probable/atypical = 6		
	Noncardiac pain = 2		
Smoking?	Yes = 10		
Diabetes?	Yes = 10		
Exercise test: induced angina	Occurred = 9		
	Reason for stopping = 15		
Estrogen status	Positive = –5, Negative = 5		
	Total score:		

B

FIGURE 13.6 Exercise test scores for men **(A)** and women **(B)**; *bpm,* beats per minute. To determine risk group, total points for the appropriate choice for each clinical and exercise test variable. If there is no appropriate choice for a particular variable, score points as zero for that variable. *Exercise ST depression* is only horizontal or downsloping. *Diabetes* is insulin or noninsulin requiring. *Smoking* is any current or prior cigarette smoking. *Estrogen status* positive includes women who are premenopausal, receiving hormone replacement therapy, or with intact ovaries under age 50. Otherwise, women are estrogen status negative. (From Morise AP, Jalisi F. Evaluation of pretest and exercise test scores to assess all-cause mortality in unselected patients presenting for exercise testing with symptoms of suspected coronary artery disease. J Am Coll Cardiol 2003;42:842-50.)

Cleveland Clinic Prognostic Score.

This score was initially reported in 2007. It incorporates most of the important prognostic exercise test variables, as well as other important clinical variables. The originally published nomogram is more

difficult to apply in routine clinical settings, but it is available in a more user-friendly, free, online software application (**see Fig. 13.3**).

Newer Scores and Observations.

Several published scores and methods for patients with and without CAD emphasize non–ST-segment variables. None of these has been validated outside the derivation institution or compared to other scores (e.g., Duke treadmill) but nevertheless demonstrate the prognostic power of the non–ST-segment variables in a variety of populations.

The FIT treadmill score was derived using more than 58,000 adults without established heart disease (about half women) to assess for all-cause mortality.[16] Patients were followed 10 years on average. The maximum predicted HR and functional capacity were the best exercise predictors. The score equation is:

$$\text{Maximum heart rate (\%)} + 12\,(\text{METs}) - 4\,(\text{Age}) + 43\,(\text{if female})$$

Score ranges of greater than 100, 0 to 100, −1 to −100, and less than −100 yielded mean survival at 10 years of 98%, 97%, 89%, and 62%, respectively.

Investigators in Finland proposed the SCOREexe, which included functional capacity and HR responses to exercise and recovery.[32] In a population of 1531 patients with stable CAD taking beta blockers, these three variables had significant independent prognostic value over other clinical data on cardiovascular death and heart failure admissions. This score is not yet easily applied in the clinical setting.

Park and colleagues[33] followed 898 adults without cardiac disease prospectively for up to 27 years after undergoing treadmill exercise testing. Main outcome measures were silent and overt MI. They found that ST-segment change, inability to achieve target HR, abnormal HRR, and chronotropic incompetence were independent predictors of the outcomes. An integrated scoring model using these four parameters demonstrated a stepwise increase in risk as the number of abnormal parameters increased.

Arbit and associates[18] analyzed 11,218 patients with and without CAD not receiving beta blockers and demonstrated that reduced functional capacity (<7 METs), HRR less than 22 beats after 2 minutes, and chronotropic index less than 80 added significant incremental prognostic value to myocardial perfusion imaging for cardiac death and all-cause mortality. As the number of these three abnormal treadmill variables increased, the risk of mortality increased regardless of the scan interpretation. A patient with a normal scan but two or three variables that were abnormal had the same all-cause mortality risk as a patient with a severely abnormal scan but two or three variables that were normal. This study provides a simple method to incorporate non–ST-segment variables into the interpretation of both stand-alone exercise ECGs and myocardial perfusion studies.

Post–Myocardial Infarction Evaluation

Since 2002, when the last full set of exercise testing guidelines was updated, treatment of MI and evaluation of post-MI patients have evolved greatly. In the original guidelines, exercise testing carried class I indications before hospital discharge (submaximal, 4 to 7 days), 14 to 21 days after discharge (symptom limited if not performed before discharge), and 3 to 6 weeks after discharge (symptom limited if predischarge submaximal exercise performed). These recommendations were based largely on the existing ACC/AHA guidelines for the management of acute MI. In this setting the exercise test was found to be safe, with a reported mortality rate of 0.03% and a nonfatal event rate of 0.09%.

Since 1997, the use of coronary angiography as part of the diagnostic evaluation and treatment of MI has taken priority. This evolution has limited the role of exercise testing in the stratification of post-MI patients. The most recent guidelines for both ST-segment elevation MI (STEMI)[34] and non-STEMI[35] state that the role of the simple exercise ECG is limited to patients who did not undergo coronary angiography following thrombolytic therapy, or patients who did not receive reperfusion therapy. In addition, these patients should have LV ejection fractions greater than 40% and no other high-risk features, should be able to exercise, and should have interpretable ECGs. This subset of patients is likely to be a small percentage of the total postinfarction group. In addition, it is highly likely that many of these patients will undergo stress imaging rather than a simple exercise test. Nevertheless, when exercise testing is performed, the variables of prognostic importance are the same as in all other settings: functional capacity, HR, systolic BP, and ventricular arrhythmias.

In the present clinical environment, realistic goals of exercise testing in the post-MI setting, whenever it is performed, should be threefold: to provide (1) a functional evaluation to guide the exercise rehabilitation prescription, (2) a basis for advice concerning return to work and other physical activities, and (3) an evaluation of present therapy.

Preoperative Evaluation in Noncardiac Surgery

Published guidelines for the preoperative evaluation of patients undergoing noncardiac surgery indicate a limited role for simple exercise testing in this process[36] (**see Chapter 11**). For patients with low preoperative cardiac risk or who are undergoing low-risk surgery, no exercise testing is indicated (class III, level of evidence B). Likewise, for patients with increased risk and excellent functional capacity (i.e., >10 METs, defined primarily by history), no further exercise testing with imaging is required (class IIa, level of evidence B). For patients with increased risk and more moderate functional capacity (i.e., 4 to 10 METs), it may be reasonable to forego further exercise imaging (class IIb, level of evidence B). Finally, for those with increased risk and poor or unclear functional capacity, it may be reasonable to perform stress imaging, especially if it will alter management (class IIb, level of evidence C). In most if not all patients who are candidates for stress imaging, this will be done with (or with the potential to convert to) pharmacologic stress.

Assessment of Therapy

The exercise ECG can be applied to assess the efficacy of therapy, whether medication, revascularization, ablation, or other. Serial exercise testing can be performed to assess HR and double product at the onset of ischemia (i.e., angina or ST-segment depression). These parameters are generally chosen because of their reproducibility. Peak V_{O_2} is the most reproducible measure, but CPX is not performed routinely. Exercise time is not generally chosen because of the influence of exercise training on the peripheral musculature with serial testing.

Exercise Testing in Nonatherosclerotic Heart Disease

The latest iteration of ACSM guidelines on exercise testing is dominated by diagnostic and prognostic assessments of atherosclerotic CAD.[2] Less prominent are applications that pertain to certain nonatherosclerotic conditions. In each case, exercise imaging, especially with echocardiography, provides important information for evaluation of these conditions. This section emphasizes and expands

on the value of the simple exercise test.[37]

Valvular Heart Disease

The role of exercise ECG testing in patients with valvular heart disease is best exemplified in the current valvular heart disease guidelines from AHA/ACC,[38] which were updated in 2017 (**see Chapter 67**). Exercise testing also has a role in patients with valvular heart disease who want to participate in competitive athletic activity.[39] Frequently, exercise testing is combined with echocardiography to assess structural and physiologic responses. This is the preferred approach in evaluating patients with mitral stenosis and disparate clinical and resting echocardiographic data, such as severe stenosis without symptoms or symptoms with mild to moderate stenosis. In patients with chronic severe mitral or aortic regurgitation, the diagnostic role of exercise testing is limited to the evaluation of functional capacity in patients with equivocal symptoms. The only valve lesion in which the simple exercise ECG still has a significant role in management is aortic stenosis.

Aortic Stenosis

It is universally agreed that exercise testing is absolutely contraindicated in patients with symptomatic severe valvular aortic stenosis.[38,40] However, for asymptomatic patients, exercise testing has found a role in two specific scenarios (**see Chapter 68**).

Severe Acquired Aortic Valve Stenosis

The first scenario is asymptomatic patients with severe acquired valvular aortic stenosis, defined as a peak Doppler velocity of 4 m/sec or greater, valve area less than 1 cm^2, or a mean valve gradient greater than 40 mm Hg with associated normal LV systolic function.[37] Patients with more moderate stenosis but suspected symptoms might also be considered. When peak aortic velocity exceeds 5.5 m/sec, exercise testing should not be done even in the absence of symptoms.[40,41] In addition, patients with severe aortic stenosis and high-gradient and normal LV function are to be distinguished from those with low-gradient stenosis and either normal or reduced LV systolic function.

Customary practice is to defer aortic valve replacement until symptoms develop (**see Chapter 67**). However, some patients with asymptomatic severe aortic stenosis who do not undergo early aortic valve replacement are still at increased short- and longer-term risk. The purpose of exercise testing in this setting is to induce either symptoms or an abnormal BP response (class IIa, level of evidence B). The class IIa indication clearly places it in the “it is reasonable” category. The intent is to provide a basis for a recommendation for valve replacement in patients who do not report any of the expected symptoms of severe aortic stenosis. The safety of exercise testing in this setting is established within the guidelines provided later.

Exercise testing in this scenario should be performed only in those with no reported symptoms or with symptoms that are equivocal at worst, such that aortic valve surgery is not indicated on that basis. They should have no extracardiac factors that limit exercise and no contraindications to aortic valve replacement. Considering that replacement of the aortic valve can currently be performed surgically or percutaneously, absolute contraindications for replacement are evolving. Protocols less intense than the standard Bruce protocol should be used, especially in elderly or untrained individuals. A modified Bruce or other low-level protocol can be used for patients who might manifest an earlier-than-anticipated adverse response. Special emphasis should be placed on the minute-by-minute BP response, patient

symptoms, and heart rhythm. Exercise should be terminated for limiting dyspnea and fatigue at a low workload, any angina or dizziness, any decrease in systolic BP, and complex ventricular ectopy. All these should be considered abnormal responses, placing the patient in a higher-risk group. Limiting dyspnea and fatigue must be interpreted carefully according to what is appropriate for age- and sex-based expectations. Isolated ST-segment depression (i.e., >2 mm of horizontal or downsloping depression) is very prevalent but is rarely an indication to stop the exercise test. If possible, termination should include a 2-minute cool-down walk and avoidance of the supine position to obviate acute LV volume overload. The average follow-up in exercise studies was approximately 1 year, suggesting a potential warranty period for favorable exercise test results. Magne and colleagues[40] review further application of exercise echocardiography to this setting.

Moderate to Severe Congenital Valvular Aortic Stenosis

The second scenario consists of young or adolescent patients with congenital aortic valve stenosis that is moderate to severe, defined as a mean Doppler gradient greater than 30 mm Hg or a peak Doppler gradient greater than 50 mm Hg (class IIa, level of evidence B).[42] Exercise testing in this specific scenario is done to provide advice for patients wanting to participate in athletic activities, as well as to evaluate asymptomatic patients with severe stenosis to assess the BP response and exercise tolerance, as with acquired stenosis. The testing procedure is similar to that for acquired aortic stenosis.

Hypertrophic Cardiomyopathy

Exercise testing in HCM has been historically considered a relative contraindication (**see Chapter 78**). In the 2011 ACC/AHA guidelines on HCM,[43] the exercise test carries a class IIa indication for assessing response to therapy (level of evidence C), for risk stratification (i.e., rhythm and blood pressure; level of evidence B), and for the decision concerning placement of a defibrillator when other sudden cardiac death (SCD) risk factors are present (class IIb without other SCD risk factors). On the issue of safety, several reported series have indicated a low and acceptable incidence of fatal and nonfatal complications.

Exercise testing in patients with HCM appears to have clinical value in three clinical situations.[37] The first is defining the presence of exercise-induced outflow tract obstruction with Doppler echocardiography in patients with no gradient at rest. The second is identifying patients with coexistent CAD, and the third is detecting patients with the high-risk indicator of an abnormal BP response.

The first two questions require exercise testing with imaging. Exercise testing in symptomatic patients with no significant resting peak outflow tract gradient (<50 mm Hg) appears to be safe and useful for detecting an exercise-induced gradient (class IIa, level of evidence B). A positive gradient response indicates obstructive rather than nonobstructive HCM. When the presence of significant CAD is being considered, LV hypertrophy and associated ST-segment changes at rest contribute to the reduced specificity of the exercise ST-segment response in this setting. In actual practice, when upright treadmill exercise is performed to address this question, imaging will be used with careful assessment of the BP response.

An abnormal BP response during maximal upright treadmill exercise is a risk factor for SCD in patients with HCM (**see Chapter 78**). It is of greater predictive value in patients younger than 50 years. An abnormal BP response is defined as either an initial increase in systolic pressure with a subsequent fall of greater than 20 mm Hg or a continuous fall from the start of exercise of greater than 20 mm Hg. Patients with abnormal BP responses tend to have more frequent exercise-induced ST-segment depression. The

NPV for SCD is reported to be in the mid-90% range, whereas the PPV is low. According to the HCM guidelines,[43] patients are considered low risk if they demonstrate eight characteristics, including a normal exercise BP response. Therefore, although a normal BP response can be reassuring, an abnormal response only places the patient into a high-risk cohort. The implication is that further stratification is required beyond the abnormal BP response. It is considered reasonable to reassess the BP response after therapy to reduce the outflow tract obstruction, but no data exist on this issue.

Adult Congenital Heart Disease

The 2010 European Society of Cardiology (ESC) guidelines for the management of adult congenital heart disease outline the role of the simple exercise test for the evaluation of patients with selected congenital defects[42] (**see Chapter 75**). In each case a specific class recommendation was given. The following recommendations do not include assessment of exercise capacity with CPX or assessment of ischemia with stress imaging. A more recent review indicates no significant change to these recommendations.[44]

For patients with outflow tract obstruction, the exercise test has a role with or without consideration of athletic participation (class IIa, level of evidence C). For valvular aortic stenosis, see the previous section on valvular heart disease. Similar recommendations are found for discrete subaortic and supravalvular aortic stenosis.

In patients with coarctation of the aorta, exercise testing should be done to assess for exercise-induced hypertension (peak systolic pressure >230 mm Hg). All patients with a noninvasive pressure difference greater than 20 mm Hg between upper and lower limbs, regardless of symptoms but with upper limb hypertension (>140/90 mm Hg in adults), pathologic BP response during exercise, or significant LV hypertrophy, should have intervention (class Ic).

Exercise testing plays a critical role in patients with repaired coronary anomalies and residual coronary abnormalities associated with Kawasaki disease, but stress imaging is recommended concomitantly.

A 2015 scientific statement from ACC/AHA addressed the selective use of simple exercise testing in individuals with congenital heart disease who want to participate in athletics. This does not include the individualized exercise prescription that could be done on any patient in this scenario. The specific entities where the simple exercise test has a role include repaired and unrepaired aortic coarctation, repaired tetralogy of Fallot, surgically and congenitally corrected transposition of the great arteries, and coronary artery anomalies. Van Hare and colleagues[45] address sport-specific intensity levels and recommendations.

Cardiac Rhythm Disturbances

Exercise testing can be used in the evaluation of suspected cardiac arrhythmias, premature ventricular complexes (PVCs), or nonsustained ventricular tachycardia (VT).[1,46] **Table 13.13** summarizes indications for exercise testing in the evaluation of arrhythmias. In addition, concerning the eligibility recommendations for competitive athletes with cardiac arrhythmias, an ACC/AHA statement covers the role of exercise testing in the settings of sinus bradycardia, heart block, isolated ventricular ectopic beats, nonsustained VT, and sustained monomorphic VT.[47]

TABLE 13.13

Guideline Recommendations for Exercise-ECG Testing in Heart Rhythm Disorders

Class I
Exercise testing is recommended for adult patients with ventricular arrhythmias who have an intermediate or greater probability of having coronary heart disease by age, gender, and symptoms to provoke ischemic changes or ventricular arrhythmias. *(Level of evidence: B)*
Exercise testing, regardless of age, is useful for patients with known or suspected exercise-induced ventricular arrhythmias, including catecholaminergic ventricular tachycardia, to provoke the arrhythmia, achieve a diagnosis, and determine the patient's response to tachycardia. *(Level of evidence: B)*
In asymptomatic patients with preexcitation, the findings of abrupt loss of conduction over a manifest pathway during exercise testing in sinus rhythm. *(Level of evidence: B-NR)*
In symptomatic patients with preexcitation, the findings of abrupt loss of conduction over the pathway during exercise testing in sinus rhythm. *(Level of evidence: B-NR)*
Class IIa
Exercise testing can be useful for evaluating response to medical or ablation therapy in patients with known exercise-induced ventricular arrhythmias. *(Level of evidence: B)*
Class IIb
Exercise testing may be useful in patients with ventricular arrhythmias and a low probability of coronary heart disease by age, gender, and symptoms. *(Level of evidence: C)*
Exercise testing may be useful in the investigation of isolated premature ventricular complexes in middle-aged or older patients without other evidence of coronary heart disease. *(Level of evidence: C)*
Class III
Routine investigation of isolated ectopic beats in young patients.
Uncontrolled cardiac arrhythmias causing symptoms or hemodynamic compromise.
High-degree atrioventricular block.
Atrial Fibrillation
The following are included as indications for exercise testing in atrial fibrillation, but are not given a recommendation class or level of evidence:
• If adequacy of rate control is in question.
• To reproduce exercise-induced atrial fibrillation.
• To exclude ischemia before treatment of selected patients with a class IC antiarrhythmic drug.

From Zipes DP et al. ACC/AHA/ESC 2006 guidelines for management of patients with ventricular arrhythmias and the prevention of sudden cardiac death. Circulation 2006;114:e385; January CT et al. 2014 AHA/ACC/HRS guideline for the management of patients with atrial fibrillation. Circulation 2014;130:e199-267; and Page RL et al. 2015 ACC/AHA/HRS guideline for the management of adult patients with supraventricular tachycardia. Circulation 2016;133;e506-74.

Atrial Fibrillation.

The AF guidelines state that exercise testing should be performed for three specific scenarios[48] (**see Chapter 38**). The first indication is when myocardial ischemia is suspected and initiation of type IC antiarrhythmic drug therapy is being considered. The second indication involves assessing the adequacy of HR control across a full spectrum of activity in patients with persistent or permanent AF (class Ic). No standard method for assessment of HR control has been established to guide management in patients with AF. Criteria for HR control vary with patient age but usually involve achieving ventricular rates between 90 and 115 beats/min during moderate exercise. Lastly, exercise testing may be used to induce possible exercise-induced AF.

Ventricular Preexcitation.

Exercise testing carries a class Ib recommendation in either symptomatic or asymptomatic patients with preexcitation.[49] Identifying accessory pathways that are at risk of developing rapid conduction and life-threatening ventricular arrhythmias in response to AF is an important consideration. The abrupt loss of preexcitation during exercise testing identifies a low-risk patient in this respect. Care should be taken to ensure that the delta wave is truly absent.

Ventricular Arrhythmias.

The 2014 European Heart Rhythm Association, Heart Rhythm Society, and Asia Pacific Heart Rhythm Society (EHRA/HRS/APHRS) Expert Consensus on Ventricular Arrhythmias recommend that exercise testing be performed for known or suspected exercise-induced ventricular arrhythmias to provoke and diagnose the arrhythmia and determine response to the tachycardia.[46] Exercise-induced ventricular arrhythmias can be associated with CAD. Therefore, detection of ischemia with or without associated ventricular arrhythmias defines a role for the exercise test.

With respect to patients with known or suspected exercise-induced ventricular arrhythmias, it should be understood that exercise testing in this high-risk cohort is not a low-risk endeavor. However, an exercise test may assist in uncovering significant arrhythmias in a controlled clinical environment rather

than in the patient's everyday setting.

Catecholaminergic Polymorphic Ventricular Tachycardia.

This arrhythmia occurs in genetically predisposed individuals when they are subjected to intense emotional or physical stress.[37] Standard cardiac testing, including the ECG at rest, usually produces normal results. The arrhythmia is almost always inducible by a maximal exercise test and is frequently not inducible with programmed electrical stimulation. Catecholaminergic polymorphic VT generally appears in HRs above 120 to 130 beats/min and begins with polymorphic ventricular premature beats progressing to nonsustained VT and eventually to bidirectional or polymorphic VT. The purpose of the exercise test, therefore, is to achieve a diagnosis and determine the patient's response to treatment, namely, beta blockade.[46]

Long-QT Syndrome.

When LQTS is suspected and the rest QTc is borderline, exercise testing can be performed safely given that arrhythmias do not usually develop in patients with LQTS during exercise (**see Chapter 33**). In addition, changes in the QT interval with exercise can be useful in identifying and stratifying patients with LQTS.[46] Further prolongation of (or failure to shorten) an already prolonged QT interval with exercise is typical of LQT1. LQT2 has normal shortening, whereas LQT3 has supranormal shortening of the QT interval with exercise. Beta blockade normalizes these responses. These responses can be useful in predicting and directing genetic testing in patients with LQTS.

Arrhythmogenic Right Ventricular Cardiomyopathy.

Even though arrhythmias and SCD can occur during exercise in patients with arrhythmogenic right ventricular cardiomyopathy, exercise testing has no significant role in the management of these patients. Serious ventricular arrhythmias that do occur during exercise usually take the form of monomorphic VT with an LBBB pattern.[44]

Brugada Syndrome.

Exercise testing generally plays little role in the diagnosis of this condition but might have a role in risk-stratifying patients who are asymptomatic. A recent report suggested that augmentation of early precordial ST-segment elevation early in recovery from exercise is both specific to Brugada syndrome and a predictor of a poor prognosis.[50]

Assessment of Therapy.

Assessing the response to medical, ablative, or surgical therapy for exercise-induced ventricular arrhythmias is a class IIa, level of evidence B indication. Unlike anti-ischemic therapy, the endpoint is the presence or absence of significant ventricular arrhythmias with reasonable levels of exercise, depending on patient-specific factors.

Assessment of Pacemaker Function

Even though earlier guidelines endorse exercise testing with rate-adaptive pacemakers to fine-tune or maximize the physiologic response, the 2012 guidelines regarding device-based treatment of cardiac arrhythmias do not even mention the use of exercise testing with implanted pacemakers.[51] This discrepancy raises a practical question. Despite the original endorsement of exercise testing in patients with rate-adaptive pacemakers, do pacemaker physicians actually use exercise testing in clinical decision making for rate-adaptive pacemakers? Exercise testing could play a role with rate-adaptive pacemakers when exercise intolerance is not completely relieved by factory settings or empiric adjustments. This would be especially true in patients involved in significant physical activities or athletic participation.[37]

Additional Uses for Exercise Testing

Chest Pain Units

Chest pain units are designed to assist in the triage and management of low-risk patients among the more than 8 million patients evaluated in emergency departments annually. Low-risk patients have stable hemodynamic signs, no arrhythmias, normal or near-normal findings on the ECG, and negative cardiac injury biomarkers and are appropriate for admission and observation in a chest pain unit. Such units are designed to provide an integrated approach to further risk stratification by short-term observation, repeated ECGs, and serial cardiac injury biomarkers. In patients without further chest pain and no objective evidence of ischemia, an exercise test can be performed after 8 to 12 hours of observation. Such testing is often performed with a symptom-limited treadmill protocol. Several studies encompassing more than 3000 such patients have demonstrated that a negative test has a high NPV for subsequent cardiac events (**Table 13.14**). No adverse events during exercise testing have been reported. Those with a positive test are admitted for further evaluation, whereas those with a negative test can be discharged safely with outpatient follow-up. This strategy has been shown to be cost-effective compared with usual care in which such patients are admitted to the hospital.[52] Patients who are unable to exercise or who have baseline electrocardiographic abnormalities can undergo stress imaging tests or computed tomographic angiography. The usefulness of such tests is discussed in detail elsewhere[52] (**see Chapters 14, 16, and 18**).

TABLE 13.14

Chest Pain Unit: Patient Selection, Testing Procedure, and Endpoints

Patient Selection Criteria
Able to exercise ECG: Normal or minor ST-T changes Hemodynamically stable, no arrhythmia Negative cardiac injury markers
Procedure
Bruce or modified Bruce protocol
Endpoints
Symptom-limited Ischemia (≥0.10 mV of horizontal ST depression or elevation) Decreased blood pressure (≥10 mm Hg systolic) during exercise test
Result
Positive: ≥0.10 mV of horizontal ST-segment depression Negative: No exercise-induced abnormalities at 85% MPHR Nondiagnostic: <85% MPHR with no ECG evidence of ischemia

MPHR, Maximum age-predicted heart rate.

Physical Activity and Exercise Prescription

Data derived from the exercise test can yield valuable objective information to assist in providing physical activity recommendations for patients with CVD, specifically regarding domestic, occupational, recreational, and athletic activities. The 2011 Compendium of Physical Activities: a Second Update of Codes and MET Values[53] and its associated web link (http://links.lww.com/MSS/A82) provide 821 codes that reflect 21 major headings, numerous specific activities and their detailed descriptions, and associated MET values that can be used to identify the energy cost associated with a given activity. By

using the exercise test to measure peak exercise capacity in METs and evaluate the HR, BP, and symptomatic responses to peak and submaximal MET levels, the clinician can combine this information with that derived from the compendium to counsel patients on their ability to perform a broad spectrum of activities and tasks. It is important to realize, however, that the exercise test does not yield information regarding the patient's ability to perform sustained tasks for long periods or take into account the environmental conditions (e.g., temperature, humidity, altitude, wind) where the activity is performed. Therefore, data from the exercise test and the compendium can serve only as a guide to prudent activity counseling. Patients must be made aware of these other factors and instructed to use subjective symptoms scales (e.g., Borg Scale of Perceived Exertion)[1,2] to further tailor their activity performance.

Exercise training programs are designed to maintain or improve fitness and include the prescriptive components of intensity, duration, frequency, and modality. Details regarding the exercise prescription for patients with CVD are provided elsewhere.[1,2] For patients with CVD, the *intensity* of dynamic aerobic exercise is usually determined from the results of a pretraining exercise test by using either of two methods: 40% to 80% of peak exercise capacity using the *heart rate reserve* method ([peak HR− resting HR] × [percent intensity] + [resting HR]), and in patients who have performed a CPX, the heart rate at 40% to 80% of the measured peak V_{O_2}. Intensity may be modified further by using the subjective perceived exertion scale at a rating of 11 to 16 on a scale of 6 to 20.[1] In patients with an ischemic response during exercise, the intensity should be prescribed at a heart rate that is at least 10 beats below the ischemic threshold (i.e., the HR at which ischemic ST depressions and typical angina begin to occur). The goal *duration* of exercise at the prescribed intensity is generally 20 to 60 minutes per session at a *frequency* of 3 to 5 days per week. Training *modalities* should ideally incorporate exercises that include rhythmic, large muscle group activities of both the upper and the lower extremities with varying types of exercise equipment.

Emerging data on aerobic interval training (AIT) offer promise for patients with CVD. AIT involves alternating 3- to 4-minute periods of exercise at very high intensity (90% to 95% of peak HR) with exercise at moderate intensity (60% to 70% of peak HR). When such training is performed for approximately 40 minutes, three times per week, studies demonstrate greater improvements in peak V_{O_2}, endothelial function, and metabolic parameters than with standard continuous, moderate-intensity exercise.[54,55] A large cross-sectional study has found that the cardiovascular risks of AIT are low in a supervised cardiac rehabilitation setting. Although more such studies are needed, AIT should be considered in select patients as an alternative training modality for those with CVD enrolled in cardiac rehabilitation programs.[56]

Disability Assessment

The U.S. Social Security Administration defines disability as “the inability to engage in any substantial gainful activity by reason of any medically determinable physical or mental impairment(s) which can be expected to result in death or which has lasted or can be expected to last for a continuous period of not less than 12 months.”[57] In several cardiovascular conditions, disability is not based solely on the diagnosis but also on the functional limitations imposed by the condition. Thus, exercise testing plays an integral role in the determination of disability for several cardiovascular conditions, including chronic heart failure, ischemic heart disease, congenital heart disease, peripheral artery disease (PAD), and valvular heart disease. The Institute of Medicine (IOM) convened a panel of experts to provide recommendations for updating the Social Security listings for cardiovascular conditions. Although each

of the previous conditions have specific criteria to define the condition, functional disability in almost all of them is defined by the inability to attain a peak VO_2 of 15 mL/kg/min (or 5 METs) on a symptom-limited treadmill or stationary cycle test. **Table 13.15** outlines details regarding exercise test criteria for specific cardiovascular conditions as recommended by IOM.

TABLE 13.15

Exercise Test Criteria for Disability Determination in Specific Cardiovascular Conditions

CARDIOVASCULAR CONDITION	SOCIAL SECURITY CRITERIA	IOM RECOMMENDATIONS
Chronic heart failure	Inability to attain 5 METs due to symptoms of dyspnea, fatigue, palpitations, or chest discomfort; frequent or complex ventricular ectopy >10 mm Hg decrease in SBP during graded exercise; signs due to inadequate cerebral perfusion	Exercise testing in chronic heart failure is safe. CPX testing requires less subjective endpoint interpretation, using criteria of peak VO_2 <15 mL/kg/min with RER >1.1, or <5 METs on standard treadmill test without gas exchange. Frequent exercise-induced ventricular ectopy alone should not be listed as a criteria.
Ischemic heart disease	Exercise tolerance testing that demonstrates ischemia, or ≥10 mm Hg fall in SBP at ≤5 METs	Additional specific criteria when stress imaging tests are used
Peripheral artery disease	≥50% decrease in SBP at the ankle from resting levels that requires ≥10 minutes to recover	
Congenital heart disease (adults)	Intermittent right-to-left shunting leading to cyanosis and arterial PO_2 of ≤60 mm Hg at ≤5 METs.	Intermittent right-to-left shunting with pulse oximetry ≤85% at ≤5 METs Exercise capacity with peak VO_2 <15 ml/kg/min or <5 METs
Pulmonary hypertension	No previous criteria	Exercise capacity <5 METs
Valvular heart disease	No previous criteria	Exercise capacity <5 METs

CPX, Cardiopulmonary exercise testing; *METs,* metabolic equivalents; *RER,* respiratory exchange ratio; *SBP,* systolic blood pressure; VO_2, oxygen uptake.

Data from the Institute of Medicine (IOM) of the National Academies. Cardiovascular Disability. Updating the Social Security Listings. Washington, DC: National Academies Press; 2010.

Evaluation of Peripheral Artery Disease

Exercise testing can be performed in patients with PAD to establish further the diagnosis by noninvasive techniques, particularly in patients with calf pain and borderline ankle-brachial indices (ABIs: 0.91 to 1.0), and objectively evaluate functional limitations imposed by PAD and the subsequent response to therapies (**see Chapter 64**). Assessment of the time to initial claudication symptoms (*claudication onset time*) and the *peak exercise time* to maximum tolerated calf pain should be done by using a gradual graded exercise treadmill, such as the Gardner protocol (**Table 13.16**). For functional assessment, the 6-minute walk test (**see Table 13.8**) can also be used; during this test, both time and distance are measured to onset and to peak calf pain.

Table 13.16

Gardner Testing Protocol for Patients with Peripheral Artery Disease

STAGE	SPEED/GRADE	METs
1	2 mph/0%	2.5
2	2 mph/2%	3.1
3	2 mph/4%	3.6
4	2 mph/6%	4.2
5	2 mph/8%	4.7
6	2 mph/10%	5.3
7	2 mph/12%	5.8
8	2 mph/14%	6.4
9	2 mph/16%	6.9
10	2 mph/18%	7.5

Each stage is 2 minutes in duration. *METs,* Metabolic equivalents.

From Gardner AW, Skinner JS, Cantwell BW, Smith LK. Progressive vs single-stage treadmill tests for evaluation of claudication. Med Sci Sports Exerc 1991;23:402.

The postexercise ABI can provide additional diagnostic information and is done by measuring the ABI in both ankles at rest and again immediately after exercise (**see Chapters 10 and 64**). During leg exercise, systolic BP normally increases in the arms but decreases in the ankles because of the peripheral vasodilation that occurs in exercising leg muscles. This leads to a mild decrease in the ABI in healthy patients that returns to normal within 1 to 2 minutes of recovery. In patients with PAD, ankle pressure decreases even more, thereby leading to a further decrease in the ABI and also a prolonged recovery time. Several diagnostic criteria have been proposed and include greater than a 5% drop in postexercise ABI from resting levels, postexercise ABI lower than 0.9, greater than a 30 mm Hg drop in systolic BP at the ankle, and recovery time to baseline ABI longer than 3 minutes.[58] Details regarding the use of exercise testing are also discussed in the ACC/AHA guidelines for the management of patients with PAD[59] (**Table 13.17**).

TABLE 13.17

ACC/AHA Guidelines for Exercise Testing in Peripheral Artery Disease (PAD)

Class I
Exercise treadmill tests are recommended to provide the most objective evidence of the magnitude of the functional limitation of claudication and to measure the response to therapy. *(Level of evidence: B)*
A standardized exercise protocol (either fixed or graded) with a motorized treadmill should be used to ensure reproducibility of measurements of pain-free walking distance and maximal walking distance. *(Level of evidence: B)*
Exercise treadmill tests with measurement of preexercise and postexercise ankle-brachial index (ABI) values are recommended to provide diagnostic data useful in differentiating arterial claudication from nonarterial claudication ("pseudoclaudication"). *(Level of evidence: B)*
Exercise treadmill tests should be performed in individuals with claudication who are to undergo exercise training (lower extremity PAD rehabilitation) so as to determine functional capacity, assess nonvascular exercise limitations, and demonstrate the safety of exercise. *(Level of evidence: B)*
Class IIa
An exercise ABI measurement can be useful to diagnose lower extremity PAD in individuals who are at risk for lower extremity PAD and who have a normal ABI (0.91 to 1.30), are without classic claudication symptoms, and have no other clinical evidence of atherosclerosis. *(Level of evidence: C)*
Long-term patency of infrainguinal bypass grafts may be considered for evaluation in a surveillance program, which may include conducting exercise ABIs and other arterial imaging studies at regular intervals. *(Level of evidence: B)*
Long-term patency of endovascular sites may be evaluated in a surveillance program, which may include conducting exercise ABIs and other arterial imaging studies at regular intervals. *(Level of evidence: B)*
Class IIb
A 6-minute walk test may be reasonable to provide an objective assessment of the functional limitation of claudication and response to therapy in elderly individuals or others not amenable to treadmill testing. *(Level of evidence: B)*

Patients with Diabetes

CAD remains the most common cause of morbidity and mortality in patients with diabetes mellitus (**see Chapter 51**). In recent years, strategies for the treatment of CAD in patients with diabetes have undergone much evolution such that regardless of symptoms or documented CAD, diabetic patients are treated with preventive therapies. In this context, the ability to specifically identify diabetic patients with disease who will benefit from more aggressive and, perhaps, invasive therapies remains a challenge. A comprehensive review of screening methods to detect CAD in patients with diabetes is found elsewhere.[60] Exercise electrocardiographic testing has similar diagnostic sensitivity (approximately 60%) and specificity (80%) for diabetic patients with angina as for nondiabetic patients. It can also identify a subgroup of asymptomatic diabetic patients who have significant CAD as defined by angiography and, more importantly, in lower-risk asymptomatic diabetic cohorts may offer short-term prognostic reassurance to those with negative test results. However, considerable prognostic power of the exercise ECG test lies beyond the ST-segment response. Poor exercise capacity and slow HRR in diabetic patients are markers of an adverse outcome. The value of the Duke prognostic score in patients with diabetes has not been well studied, and unlike the Morise score[28] and the Cleveland Clinic Foundation risk score,[29] it did not specifically address the presence of diabetes in the original cohort study. Therefore, at present, the Morise and Cleveland Clinic scores are more appropriate to apply in patients with diabetes who have normal resting ECG findings and undergo exercise electrocardiography.

At present, evidence is inadequate for recommending routine screening of asymptomatic diabetic patients with an exercise ECG. The American Diabetes Association standards of medical care conclude that in asymptomatic patients, routine screening for CAD is not recommended, even before initiation of an exercise training program, because it does not improve outcomes as long as risk factors for CVD are treated.[61] They recommend that diabetic persons who might be considered for advanced or invasive cardiac testing include those with (1) typical or atypical cardiac symptoms and (2) an abnormal resting ECG. Exercise ECG testing without or with echocardiography may be used initially. Pharmacologic stress echocardiography or nuclear imaging should be considered in diabetic persons in whom resting ECG abnormalities preclude exercise stress testing (e.g., LBBB or ST-T abnormalities) or in those who are not able to exercise.

These recommendations have arisen from the observation that intensive medical therapy, which would be indicated in any case for diabetic patients at high risk for CVD, appears to provide similar outcomes as invasive revascularization, raising the question of how the results of screening would change management. This position is supported by data from the DIAD (Detection of Ischemia in Asymptomatic Diabetics) study, which evaluated 1123 patients with type 2 diabetes and no symptoms of CAD. They were randomly assigned to be screened with adenosine stress radionuclide myocardial perfusion imaging or not to be screened. Cardiac death and nonfatal MI event rates were low in both groups (2.7% versus 3%) over 4.8 years and not significantly reduced by myocardial perfusion imaging (MPI) screening for myocardial ischemia. Importantly, during the course of this study, there was a significant and similar increase in primary medical prevention in both groups.[62]

Acknowledgment

The authors wish to acknowledge the previous contributions of Dr. Bernard R. Chaitman, which have laid the foundation for this chapter.

Echocardiography

Scott D. Solomon, Justina C. Wu, Linda Gillam

Illustrated by, Bernard Bulwer

Echocardiography remains the most commonly used comprehensive cardiac imaging modality and is often the first test of choice for assessing cardiac structure and function. When compared with other imaging methods, echocardiography can be performed quickly, with minimal patient inconvenience or risk, and provides immediate clinically relevant information at relatively low cost. Echocardiography provides detailed data on cardiac structure, including the size and shape of cardiac chambers, as well as the morphology and function of cardiac valves. Furthermore, the real-time nature of echocardiography makes it uniquely suited to immediate noninvasive assessment of systolic and diastolic function and intracardiac hemodynamics. In most echocardiography laboratories, standard *transthoracic echocardiography* (TTE) is complemented by *transesophageal echocardiography* (TEE), which offers improved resolution, and by *stress echocardiography,* which is routinely used to assess myocardial ischemia and valvular function with exercise. Technical advancements in echocardiography over the past several decades have led to progressively improved diagnostic capabilities; these include advances in three-dimensional (3D) and tissue strain imaging, miniaturization of equipment, and contrast echocardiography for better cavity visualization and assessment of myocardial perfusion.

Because two-dimensional (2D) echocardiography is not a tomographic technique such as cardiac computed tomography (CT) or cardiac magnetic resonance (CMR) imaging (**see Chapters 17 and 18**), acquisition of ultrasound images is dependent on an operator—either a sonographer or a physician—applying an ultrasound transducer to a patient's chest. Both acquisition and interpretation of echocardiograms require substantial training and skill. Thus echocardiography is best described as an "examination" rather than a "test." Although cardiologists receive this training routinely, a growing number of noncardiologists, including emergency physicians, anesthesiologists, intensivists, and inpatient hospital staff, are increasingly using echocardiography in their practice, in some cases with small, handheld ultrasound devices. Knowledge of the basic principles, utility, and limitations of echocardiography is becoming essential for all physicians who care for patients with cardiovascular problems.

Principles of Ultrasound and Instrumentation

Principles of Image Generation

Echocardiography is based on the standard principles of ultrasound imaging in which high-frequency sound waves in the 1- to 10-MHz range are emitted from piezoelectric crystals housed in a transducer, traverse through internal body structures, interact with tissues, reflect back to the transducer, and are then processed by microcomputers to generate an image. An understanding of the physical principles that underlie echocardiography is essential to understanding its usefulness and limitations.[1]

Ultrasound machines calculate the time required for sound waves to reflect from structures and return to the transducer, thereby determining the depth of reflecting structures. This information is used to generate scan lines that comprise data on both *location* (depth of reflection) and *amplitude* (intensity of reflection). Early ultrasound equipment projected a single beam of ultrasound, which resulted in a single scan line that could be "painted" across a moving paper or screen, with depth being depicted on the vertical axis and time on the horizontal axis. This method, known as *M-mode* (for motion) echocardiography (**Fig. 14.1, lower right**), has largely been replaced by 2D imaging (**Fig. 14.1, lower left**). However, M-mode is still used routinely and is particularly useful for making linear measurements and assessments that require precise timing with respect to the cardiac cycle.

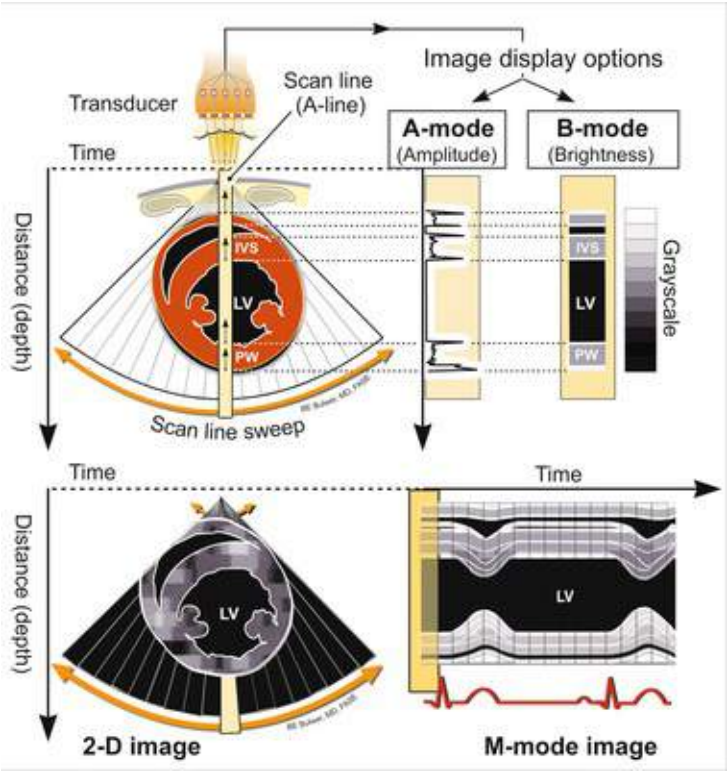

FIGURE 14.1 Generation of ultrasound images. An ultrasound pulse transmitted from piezoelectric elements housed in a transducer **(upper left)** reflects off structures and returns to the transducer. These signals are processed and displayed based on their amplitudes **(upper right)**. Echoes with the highest amplitudes emerge from tissue interfaces such as the pericardial-pleural and endocardial-blood borders. In original A-mode scans, such signals are visualized as amplitude spikes. On B-mode, the echo amplitudes are displayed via gray scale. B-mode images can then be displayed in one dimension over time, i.e., M (motion)–mode **(bottom right),** or as a two-dimensional cross-sectional image **(bottom left)**. *IVS,* Interventricular septum; *LV,* left ventricle; *PW,* posterior wall. (Modified from Bulwer BE, Rivero JM, editors. Echocardiography Pocket Guide: The Transthoracic Examination. Burlington, Mass: Jones & Bartlett Learning; 2011, 2013. Reprinted with permission.)

Current 2D imaging uses phased-array transducers, in which the piezoelectric crystal is precisely diced into multiple (currently up to 512) elements that emit and receive sonar pulses elements; the beam is electronically steered through an arc side-to-side to create a scan plane (**Fig. 14.2**). The transducer emits pulses of ultrasound in an ordered sequence and sequentially "listens" for returning echoes, referred to as the *pulse-echo principle*. Repetition of this sequence generates the moving images. The rate at which these pulses are emitted is termed the *pulse repetition frequency* (PRF). Proper interpretation of returning signals is physically limited by the speed of sound in tissues (approximately 1540 m/sec) and the depth of the tissues being interrogated, which dictates the time it takes for the ultrasound signal to return to the transducer. Nevertheless, improvements in processing speed have allowed "frame" rates, a major determinant of temporal resolution, to reach speeds higher than 100 image frames per second. In practice, the echo machine operator can increase frame rate by narrowing the scan sector, imaging at shallower depths, and reducing scan line density. 3D echocardiography extends the phased-array concept to make use of a planar waffle-like grid or matrix-array of elements (2500+), which allows both simultaneous multiplanar 2D imaging and true volumetric 3D imaging and rendering (see Three-Dimensional Echocardiography).

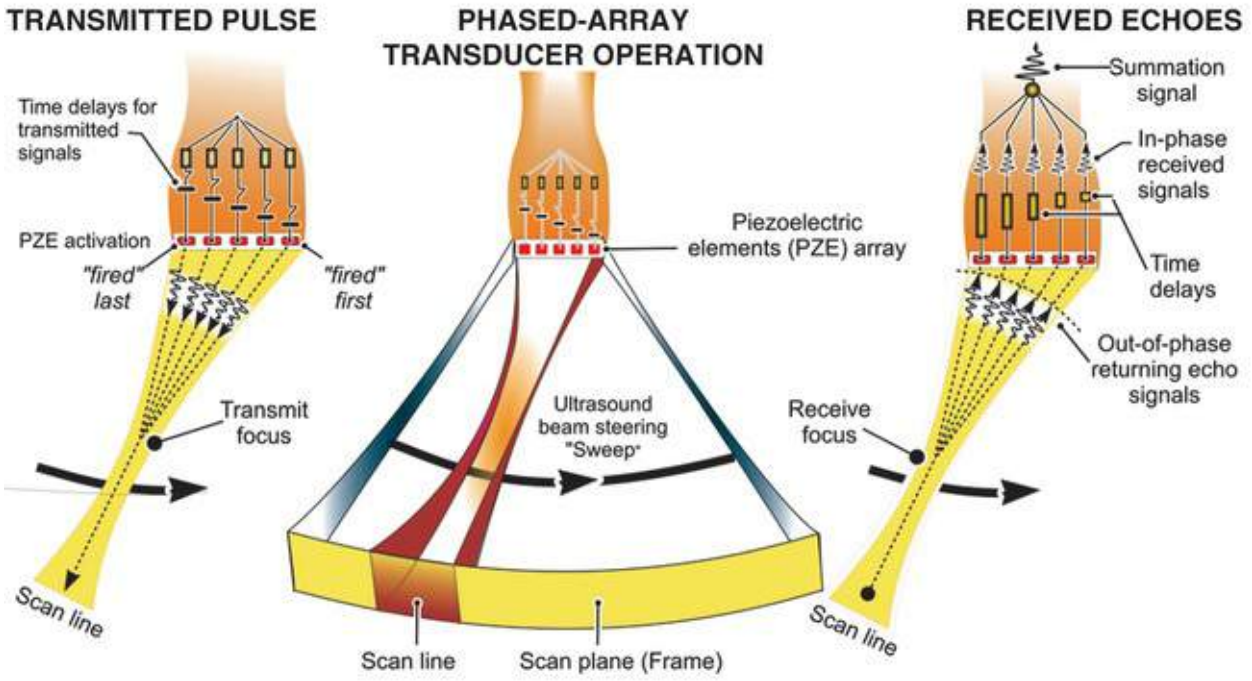

FIGURE 14.2 Phased-array transducer operation. Modern echocardiography transducers scan through a relatively wide scan sector by steering the electronic beam across the scan plane **(center)**. During transmission **(left)**, electronic time delays in firing the piezoelectric elements of the transducer cause the scan line to sweep in an arc. During reception **(right),** the returning echo signals received by each transducer element must be time-shifted or phased before being summated and processed. (Modified from Bulwer BE, Shernan SK, Thomas JD. Physics of echocardiography. In Savage RM, Aronson S, Shernan SK, editors. Comprehensive Textbook of Perioperative Transesophageal Echocardiography. Philadelphia: Wolters Kluwer: Lippincott, Williams & Wilkins; 2009, pp 1-41.)

Physical Principles of Ultrasound

The physical characteristics of ultrasound are exploited to generate images representative of the heart. The wavelength of the ultrasound used, which is inversely related to ultrasound frequency, is the principal determinant of axial imaging resolution, which equals approximately half the wavelength. The higher the ultrasound frequency (i.e., shorter the wavelength), the higher is the spatial resolution. Imaging resolution is also dependent on the depth of the structure being interrogated. Therefore, the choice of imaging frequency involves a trade-off between image resolution and target tissue depth: higher frequencies are capable of increased resolution, but at the expense of reduced tissue penetration. Most TTE machines operate across frequencies of 2.5 to 5 MHz. Higher frequencies up to 7 to 10 MHz can be used in pediatric imaging, in TEE where the transducer is closer to the heart, or when interrogating near-field structures, such as the apex of the heart from the apical window.

The speed of ultrasound through body tissues averages 1540 meters per second (m/sec), essentially the speed of sound through water, but varies minutely as ultrasound waves traverse various body constituents. These slight differences in ultrasound speed through different media (e.g., blood, muscle, fat, air) result in impedance mismatches at the tissue interfaces, which produces the *specular reflections* that mark the boundaries between different tissues. The most intense reflections occur when ultrasound strikes these interfaces perpendicularly and when the tissues differ greatly in density. When ultrasound encounters inhomogeneous tissue regions, such as myocardium, liver, or other tissues, multidirectional reflection, or *backscatter*, occurs and results in speckled-appearing images. The combination of specular reflections and backscatter, together with the unique interactions between ultrasound and tissue such as refraction, interference, and attenuation, contributes to the characteristic gray-scale appearance of ultrasound images.

Ultrasound penetrates poorly through air and bone, which is one of the greatest challenges to echocardiography because the heart is surrounded by the lungs and the rib cage. The ability to circumvent these limitations during image acquisition underscores the importance of the operator's skill and the advantages of a TEE approach in specific clinical situations.

Several advances in the past decade have improved the quality of ultrasonic imaging. The higher number of elements in phased-array transducers has increased the number of scan lines and thus lateral resolution. *Tissue harmonic imaging* is now the norm, in which the receiver "listens" for returning second-harmonic ultrasound signals that are twice the fundamental frequency of the emitted ultrasound. By doing so, it effectively filters out the weaker noisy signals from cardiac chambers and has substantially improved the definition of tissue interfaces, in particular that of the endocardial borders (**Fig. 14.3**), when compared to fundamental imaging.

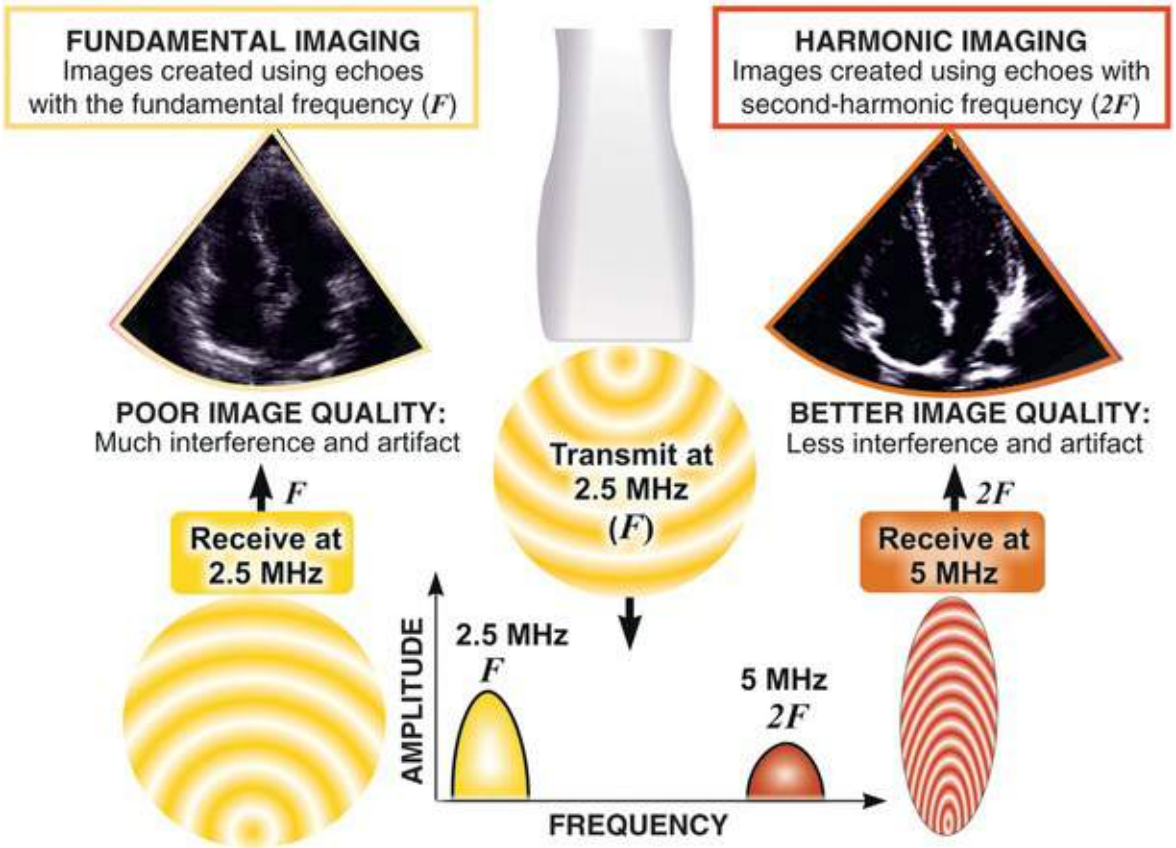

FIGURE 14.3 Tissue harmonic imaging. Tissue harmonic imaging improves image quality by using second-order harmonics. Ultrasound causes tissues to vibrate at a the fundamental frequency **(left)** but also multiples (harmonics) of that frequency. By listening for the higher (second-order) frequency returning echoes, signal-to-noise ratio and tissue definition are dramatically improved **(right)**. (Modified from Bulwer BE, Shernan SK, Thomas JD. Physics of echocardiography. In Savage RM, Aronson S, Shernan SK, editors. Comprehensive Textbook of Perioperative Transesophageal Echocardiography. Philadelphia: Wolters Kluwer: Lippincott, Williams & Wilkins; 2009, pp 1-41.)

Principles of Doppler Imaging

In addition to generating images of cardiac structures, ultrasound can be used to interrogate the velocity of blood flow through the heart and to quantify myocardial motion. These techniques are based on the Doppler principle, which states that the frequency of a waveform bounced back from a moving object

will be altered (shifted) from the emitting frequency, depending on whether the object is moving toward or away from the observer. Ultrasound that is reflected from red blood cells moving toward the emitter will return at higher frequency, whereas blood flow away from the transducer will cause a lower-frequency waveform to return (**Fig. 14.4**). This difference between the frequency emitted and that received is termed the *Doppler frequency shift* and is dependent on the speed of ultrasound through the medium and the velocity of blood flow. The basic equation for Doppler shift (f_d) is $f_d = f_t V/c$, where f_t is the transmitted ultrasound frequency, V is the velocity of blood flow, and c is the speed of ultrasound in the tissue. For cardiac ultrasound, multiplication by a factor of 2 occurs because the Doppler shift occurs twice (when the wave goes to and from the moving object). Notably, the velocity information obtained is most accurate when the ultrasound beam is aligned parallel to the direction of blood flow (i.e., an optimal angle of insonation is 0 degrees). When the angle of insonation (θ) cannot be physically corrected, the correction factor *cos*θ may be applied. Thus the refined formula for Doppler shift is:

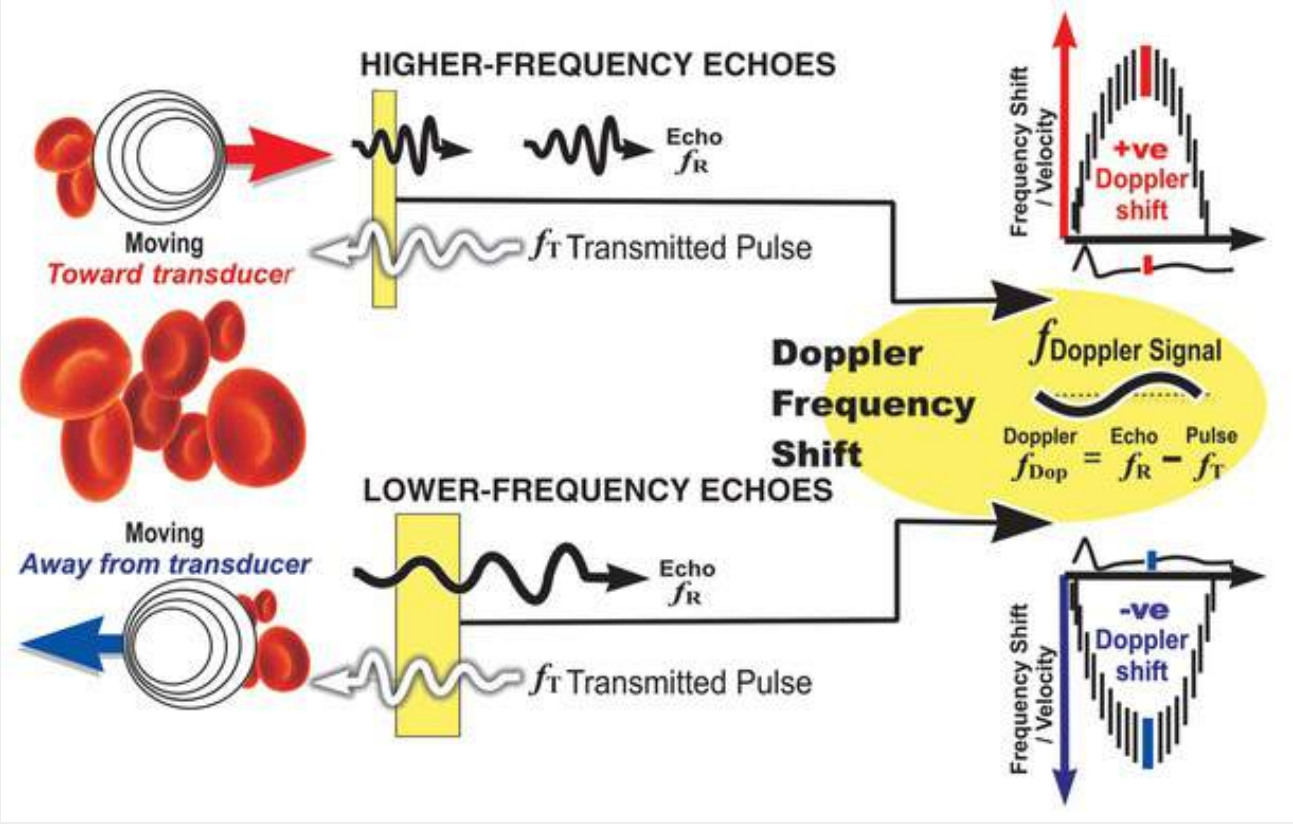

FIGURE 14.4 The Doppler frequency shift. Echoes reflected from blood cells moving toward the transducer will return at a higher frequency than the transmitted ultrasound pulse **(upper panels)**. The opposite is seen with blood moving away from the transducer **(lower panels)**. Doppler echocardiography instruments harness this shift in frequency to derive blood flow velocities. The direction of flow is displayed graphically as a time-velocity spectrum above or below the baseline (in spectral Doppler) or as color-coded velocities with color flow Doppler.

$$F_d = 2f_t V(\cos\theta)/c$$

Ultimately, the equation above is used to solve for velocity, V, of blood flow.

Pulsed-Wave and Continuous-Wave Doppler

The two principal types of Doppler imaging are pulsed-wave (PW) and continuous-wave (CW) Doppler. In PW Doppler (**Fig. 14.5, left panel**), discrete pulses of ultrasound reflect off moving structures (i.e., red blood cells moving through the heart) and return to the transducer. By *gating*, or defining a specific time window during which the machine "listens" for reflected signal, this technique can be used to ascertain the velocity of blood flow at a prespecified depth within the heart. Thus, when an operator places the cursor (sample volume) on the 2D ultrasound image at a particular location, the equipment will assess the velocity at that point. Because it takes time for the pulses to reflect and return to the transducer, they cannot be transmitted too frequently, or the equipment will fail to discern whether a given pulse has returned, and the velocity information obtained at that depth will be ambiguous. The PRF is essentially the sampling rate; the higher the blood flow velocity, the higher is the frequency of the Doppler shift and thus the higher the sampling rate needed to accurately sample that shift (**eFig. 14.1**). These physical principles limit the upper range of velocities that can be interrogated with PW Doppler. The *Nyquist limit* refers to the maximum velocity that can be accurately quantified within a given sample volume and is directly related to the PRF (the numeric value equals ½ the PRF). PRF in turn is inversely related to the distance from the sample volume to the transducer. The machine is unable to assess velocities that are higher than the Nyquist limit, because the values will go off-scale and appear to "alias" (wrap around) in the generated spectrogram; adjusting the Nyquist limit setting on the machine upward effectively adjusts the PRF upward until the physical limit is reached.

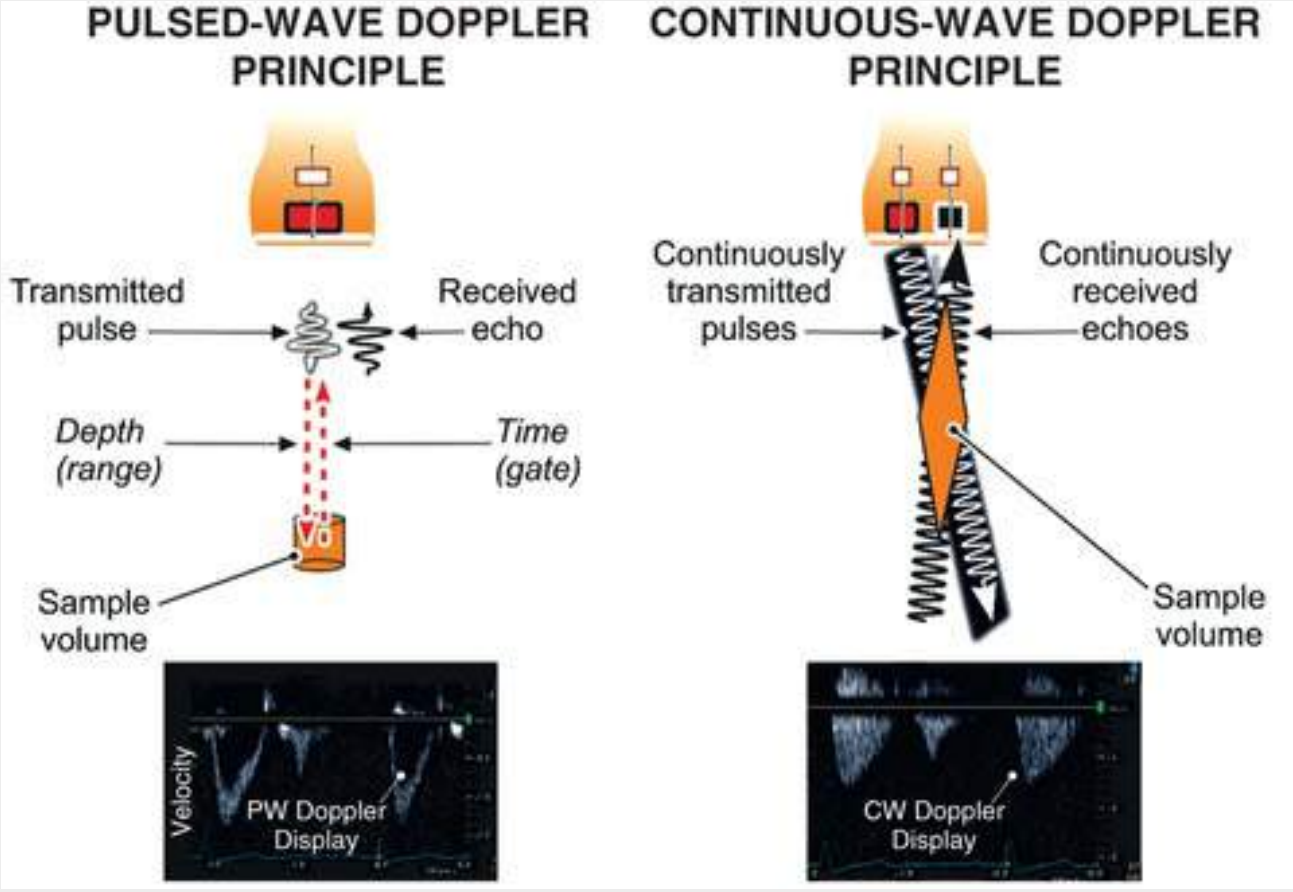

FIGURE 14.5 Pulsed-wave (PW) versus continuous-wave (CW) Doppler. **Left,** PW Doppler technique uses a single piezoelectric element that generates the pulse, interrogates a small sample volume at a specific depth, and receives the emerging echoes within the specified time window. **Right,** CW Doppler technique uses two separate transducer elements, one continuously transmitting pulses and the other receiving echoes across a large sample volume, and thus cannot localize the depth of the site with highest velocity.

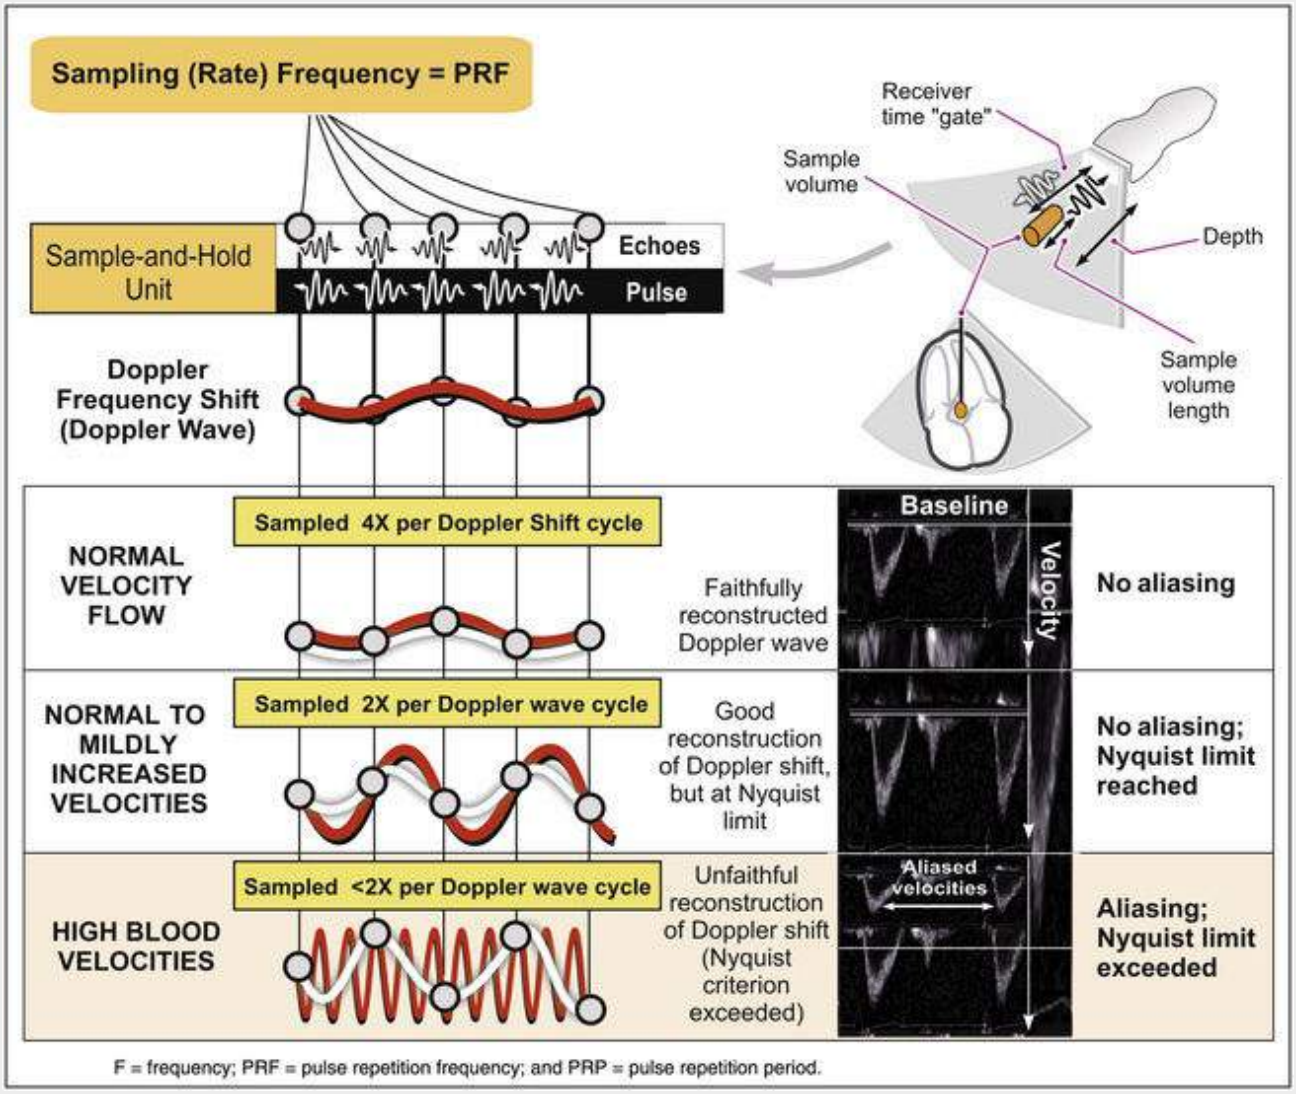

EFIGURE 14.1 Velocities derived from Doppler frequency shifts are extracted through sampling and transformation (Fourier) before being graphically displayed. PW Doppler is subject to the limitation of aliasing when the Nyquist criterion or limit is exceeded, thus limiting the velocities that can be accurately depicted with this modality. The sampling frequency (pulse repetition frequency, PRF) must be at least twice the frequency of the sampled waveform. In Doppler ultrasound, the sampling rate must be high enough to sample the Doppler shift, which is the difference between the ultrasound frequency emitted by the transducer and the ultrasound frequency returning to the transducer. As shown by the Doppler equation, $f_d = \frac{2f_t V \cos\theta}{C}$, this difference, the Doppler frequency shift, is directly related to the velocity of the flow being assessed. PW Doppler can accurately sample and reconstruct lower blood velocities (from the Doppler shift) with no ambiguity (aliasing) **(upper panels)**. The frequency at which waveform sampling will become ambiguous is referred to as the Nyquist limit and is half the PRF. When velocities being assessed exceed the Nyquist limit, the system cannot accurately determine these velocities, and aliasing occurs **(lower panels)**. These higher aliased velocities will appear on the opposite side of the baseline on the spectral Doppler display or will result in mosaic patterns in color flow Doppler imaging. How can this problem be minimized? Simply increasing the PRF works only up to a certain point because the farther the ultrasound pulse has to travel, the greater the time delay must be between pulses to avoid ambiguity. Newer ultrasound machines can perform high-PRF Doppler imaging, in which pulses are emitted without waiting for the original pulses to return to the transducer. This allows an unaliased signal at the expense of some range ambiguity. The technique is meant to be used in conjunction with standard PW Doppler, with the operator determining the region of highest velocity along a scan line with color Doppler and then switching to the high-PRF mode to determine this velocity.

With CW Doppler (**Fig. 14.5, right panel**) a dedicated piezoelectric element continuously emits ultrasound, and a separate element simultaneously continuously receives the returning signals. Because the ultrasound tone is continuous rather than pulsed, depth of the target cannot be determined from the signal received. However, unlike the situation with PW Doppler, no limit is imposed on the velocities

discernible with this technique. *Thus PW Doppler is primarily used to assess flow with relatively low velocity (typically ≤1.5 m/sec) present at a specific location, whereas CW Doppler is used to assess higher velocities (typically ≥1.5 m/sec) along the transducer beam, but cannot specify at what location the highest velocity occurs.* Note that PW Doppler envelopes have a linear "hollowed-out" profile because the blood within the small sample volume tends to travel at similar velocities (laminar flow), whereas CW Doppler envelopes are "filled in" because all the varying velocities along the ultrasound beam are received and recorded.

Color Flow Doppler

Color flow Doppler is a PW Doppler–based technique in which the velocities in a region of interest are encoded with colors that represent both mean velocities and directionality of the flow, which are superimposed on a 2D image in the region of interest (**Fig. 14.6**). By convention, flow moving away from the transducer is encoded in blue, and flow toward the transducer is encoded in red. Because color flow Doppler is a form of PW Doppler, it is subject to aliasing, such that high velocities (greater than the Nyquist limit) demonstrate "wraparound" in the color coding to the color of the opposite direction. Turbulent flow, in which a wide range of velocities exist, appears as a multicolored mosaic pattern (usually green and yellow). In some systems the variance in the velocities relative to the mean is color-coded in superimposed shades of green. Color flow Doppler allows direct real-time visualization of the movement of blood in the heart and is particularly useful for identifying blood flow acceleration and turbulence. Therefore, this technology is useful for delineating both regurgitant lesions, in which blood moves rapidly and opposite to the expected direction of flow, and discrete stenoses in which there is flow acceleration.

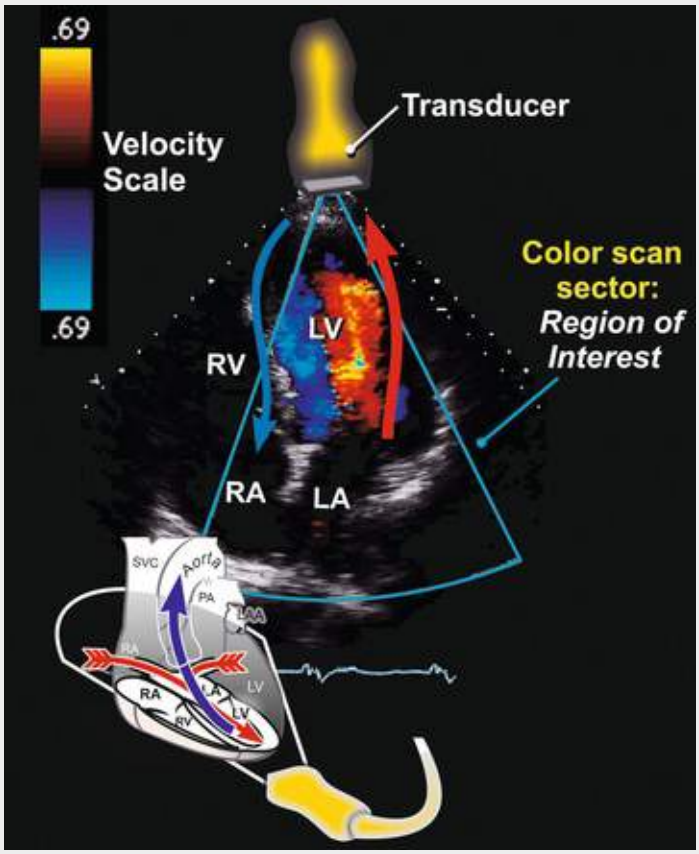

FIGURE 14.6 Color flow Doppler. By convention, blood flow moving toward the transducer is color-coded *red* and flow away from the transducer is shown in *blue*. The color velocity scale (*upper left vertical bar*) represents increasing velocities in either direction. with higher velocities depicted in progressively brighter hues. Note the Nyquist limit (69 cm/sec) displayed above and below the color scale bar. Velocities greater than the Nyquist limit cause aliasing, i.e., an apparent wraparound in the color-coding to that of the opposite direction. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. Reprinted with permission.)

Blood Flow Profiles and Doppler Signals

Laminar Versus Turbulent Flow.

Blood flow through the normal heart and great vessels is predominantly *laminar,* meaning that the direction and velocity of flow are streamlined and uniform, even across valves. **Fig. 14.7** shows that the spectral Doppler flow signal observed when interrogating laminar flow is characterized by a hollowed-out waveform with a narrow outline, indicating that flow velocities throughout the sample are similar. In a Doppler assessment of the left ventricular outflow tract (LVOT), for example, the Doppler profile represents the velocity of blood flow throughout systole and is usually laminar. In contrast, valvular or vessel stenoses or obstructive lesions often cause turbulent flow, in which blood moves at different velocities and in multiple directions. In these cases the displayed spectrum of velocities will be wider on PW Doppler, a phenomenon termed *spectral broadening.* On color Doppler, turbulent flow appears brighter with mixture of colors.

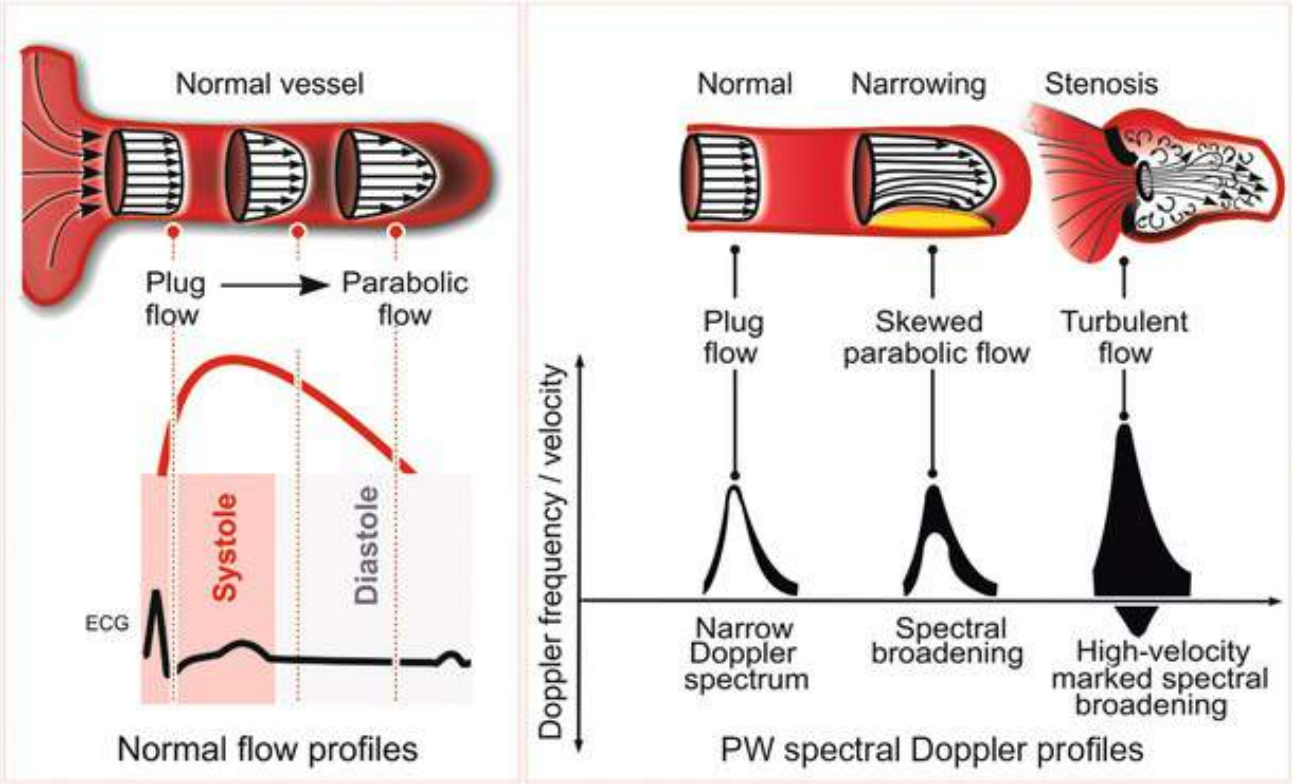

FIGURE 14.7 Flow velocity profiles on spectral Doppler. **Left,** During the cardiac cycle, most intracardiac and large arterial flows exhibit a laminar flow profile termed "plug flow" proximally that progresses distally to a more parabolic profile because of drag force and blood viscosity. **Right,** The narrowest range or spectrum of flow velocities is seen during the initial phases of systole or when valves open (plug flow). As the vessel becomes stenotic, the turbulence causes progressively wider variation in flow velocities and directions. On spectral Doppler this manifests as a splay in velocities both above and below the baseline. (Modified from Bulwer BE, Shernan SK, Thomas J. Physics of echocardiography. In Savage RM, Aronson S, Shernan SK, editors. Comprehensive Textbook of Perioperative Transesophageal Echocardiography. Philadelphia: Wolters Kluwer: Lippincott, Williams & Wilkins; 2009, p 23.)

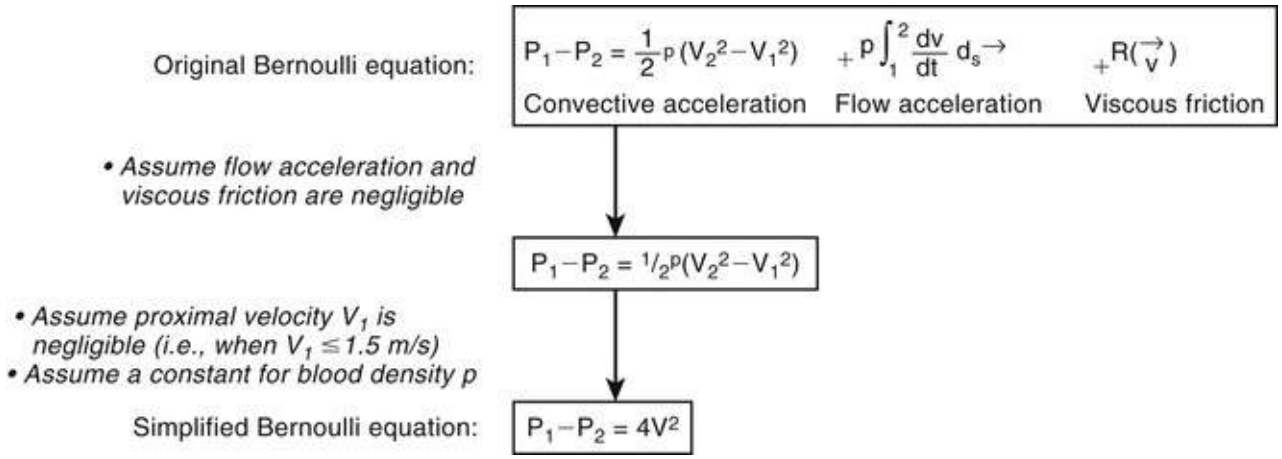
As illustrated by the Doppler equation and discussed earlier, the velocity of blood flow determined from the Doppler shift will change with the angle of insonation. If the vector of flow is not directly in line with the ultrasound beam, the velocities calculated by the Doppler shift will be underestimated. This problem can be corrected by applying an angle adjustment that is computed in at the machine level. However, the further the angle of flow deviates from the angle of the beam, the greater the likelihood for error in the calculation. In practice, for cardiac ultrasound it is recommended simply to minimize the angle of insonation as much as possible by probe and patient positioning and to avoid Doppler assessments that are substantially off-angle. It is for this reason that multiple windows are used in assessing peak flow velocities of aortic stenosis and tricuspid regurgitation, so that the lowest angle of insonation can be selected to avoid underestimation. In specific cases where flow is very laminar and insonation angles are unavoidable, such as in vascular ultrasound, the correction factor proves to be useful.

Doppler Echocardiography in Practice

Doppler echocardiography is used primarily to assess blood flow velocity in the heart and blood vessels. Within the heart the velocity of blood flow is itself dependent on the pressure gradient between cardiac chambers, with higher gradients resulting in higher velocities. This relationship can be described by the Bernoulli equation, which estimates the pressure gradient (ΔP) between two chambers separated by an orifice based on the velocity of flow through the orifice. The original Bernoulli equation (**eFig. 14.2**) is

complex and includes variables for flow acceleration and viscous friction and a constant for fluid density. The clinical equation used in echocardiography assumes that these two factors are negligible, and that the velocity (V_1) proximal to an orifice is relatively low in comparison to that distal velocity. This leaves the vastly simplified equation for use in clinical echocardiography for ΔP:

$$\mathbb{P}_1 - \mathbb{P}_2 = 4\mathbb{V}^2$$



EFIGURE 14.2 The Bernoulli equation. Derivations of the Bernoulli equation as applied to echocardiography. This equation is used to estimate the pressure difference $\Delta P = P_1 - P_2$ across orifices or stenoses in the heart. Simply put, the narrower the orifice, and the higher the change in velocity (and thus the higher the pressure gradient).

For example, the peak flow velocity of a tricuspid regurgitant jet can be used to calculate the pressure gradient ΔP between the right ventricle and the right atrium, which when added to an estimate of right atrial (RA) pressure, provides an estimate of right ventricular systolic pressure (and hence pulmonary artery systolic pressure in most cases). Similarly, the blood flow velocity difference between the LVOT and the aorta can be used to calculate the peak instantaneous pressure gradient across a stenotic aortic valve. It is important to appreciate that Doppler echocardiography measures *velocity* but neither pressure nor flow directly. Pressure gradients are inferred from velocities based on the Bernoulli equation, but the absolute pressure within chambers cannot be directly measured as in cardiac catheterization. Similarly, the amount of flow cannot be measured directly, although there are Doppler-based methods that permit fairly accurate estimation of flow volumes (see later).

Assessment of Flow and Continuity Equation

Doppler methods are used to assess blood flow velocities, but the magnitude of flow can also be inferred by multiplying the *velocity-time integral* (VTI; i.e., integrated velocity throughout the cardiac interval) by the cross-sectional area (CSA) of the region being interrogated (**Fig. 14.8**). For example, stroke volume (SV) can be estimated by interrogating the LVOT region with PW Doppler and multiplying the VTI by the CSA (calculated by measuring the diameter of the LVOT and assuming a circular area = πr^2):

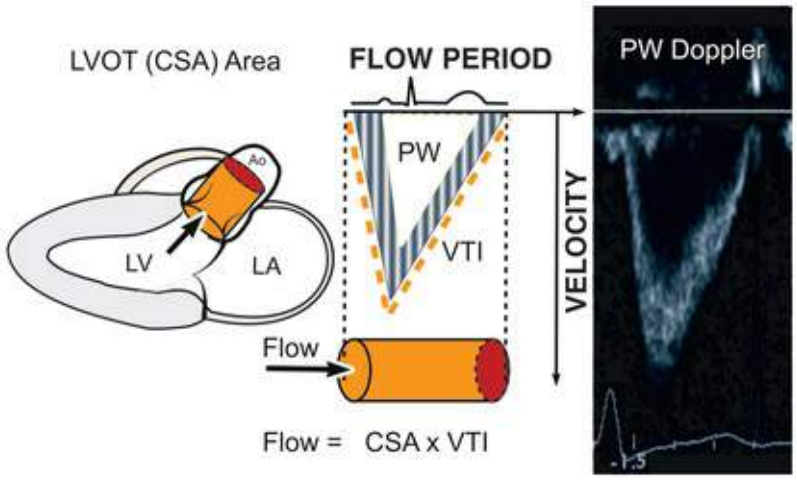


FIGURE 14.8 Volumetric flow assessments using spectral Doppler. The volume of a cylinder is cross-sectional area (CSA) multiplied by length. Using this geometric assumption and assuming constant flow during systole, stroke volume (SV) can then be derived from the CSA of the left ventricular outflow tract (LVOT) measured on the parasternal long-axis view. This is then multiplied by the Doppler velocity-time integral (VTI) measured on apical windows. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle.

$$SV = VTI_{LVOT} \times Area_{LVOT}$$

The continuity principle is based on conservation of mass and states that flow in one region of the heart should be equivalent to flow in another region (assuming no intervening shunt). It can be used together with Doppler analysis to determine an unknown area, such as that of a stenotic valve. The CSA of a stenotic valve can be difficult to measure directly (i.e., by planimetry) if image quality is suboptimal. By measuring the CSA and VTI proximal to the valve and the VTI at the valve itself with 2D and Doppler imaging, the area of stenosis can be calculated. Since velocities through stenotic valves are usually too high to assess with PW Doppler, CW Doppler is usually used, assuming that the highest attained velocities correspond to the narrowest region along the ultrasound beam. Because the continuity principle states that flow through the LVOT must equal flow through the aortic valve (AV),

$$VTI_{LVOT} \times Area_{LVOT} = VTI_{AV} \times Area_{AV}$$

rearranging the equation to solve for $Area_{AV}$ will give the desired valve CSA. The accuracy of this estimate depends on the accuracy of the LVOT CSA calculation (and thus LVOT diameter measurement) and optimal positioning of the PW and CW Doppler cursor.

The Standard Adult Transthoracic Echocardiographic Examination

The standard adult TTE examination consists of a combination of 2D, M-mode, and Doppler imaging. The recommended comprehensive examination protocol involves a series of views, each of which is described in terms of three principal components: (1) the standard transducer position or “window,” (2) the orthogonal imaging planes, and (3) the anatomic region of interest (**Figs. 14.9 and 14.10**). At each

transducer position the operator optimally acquires 2D images with M-mode images, spectral Doppler, and color flow Doppler as indicated.

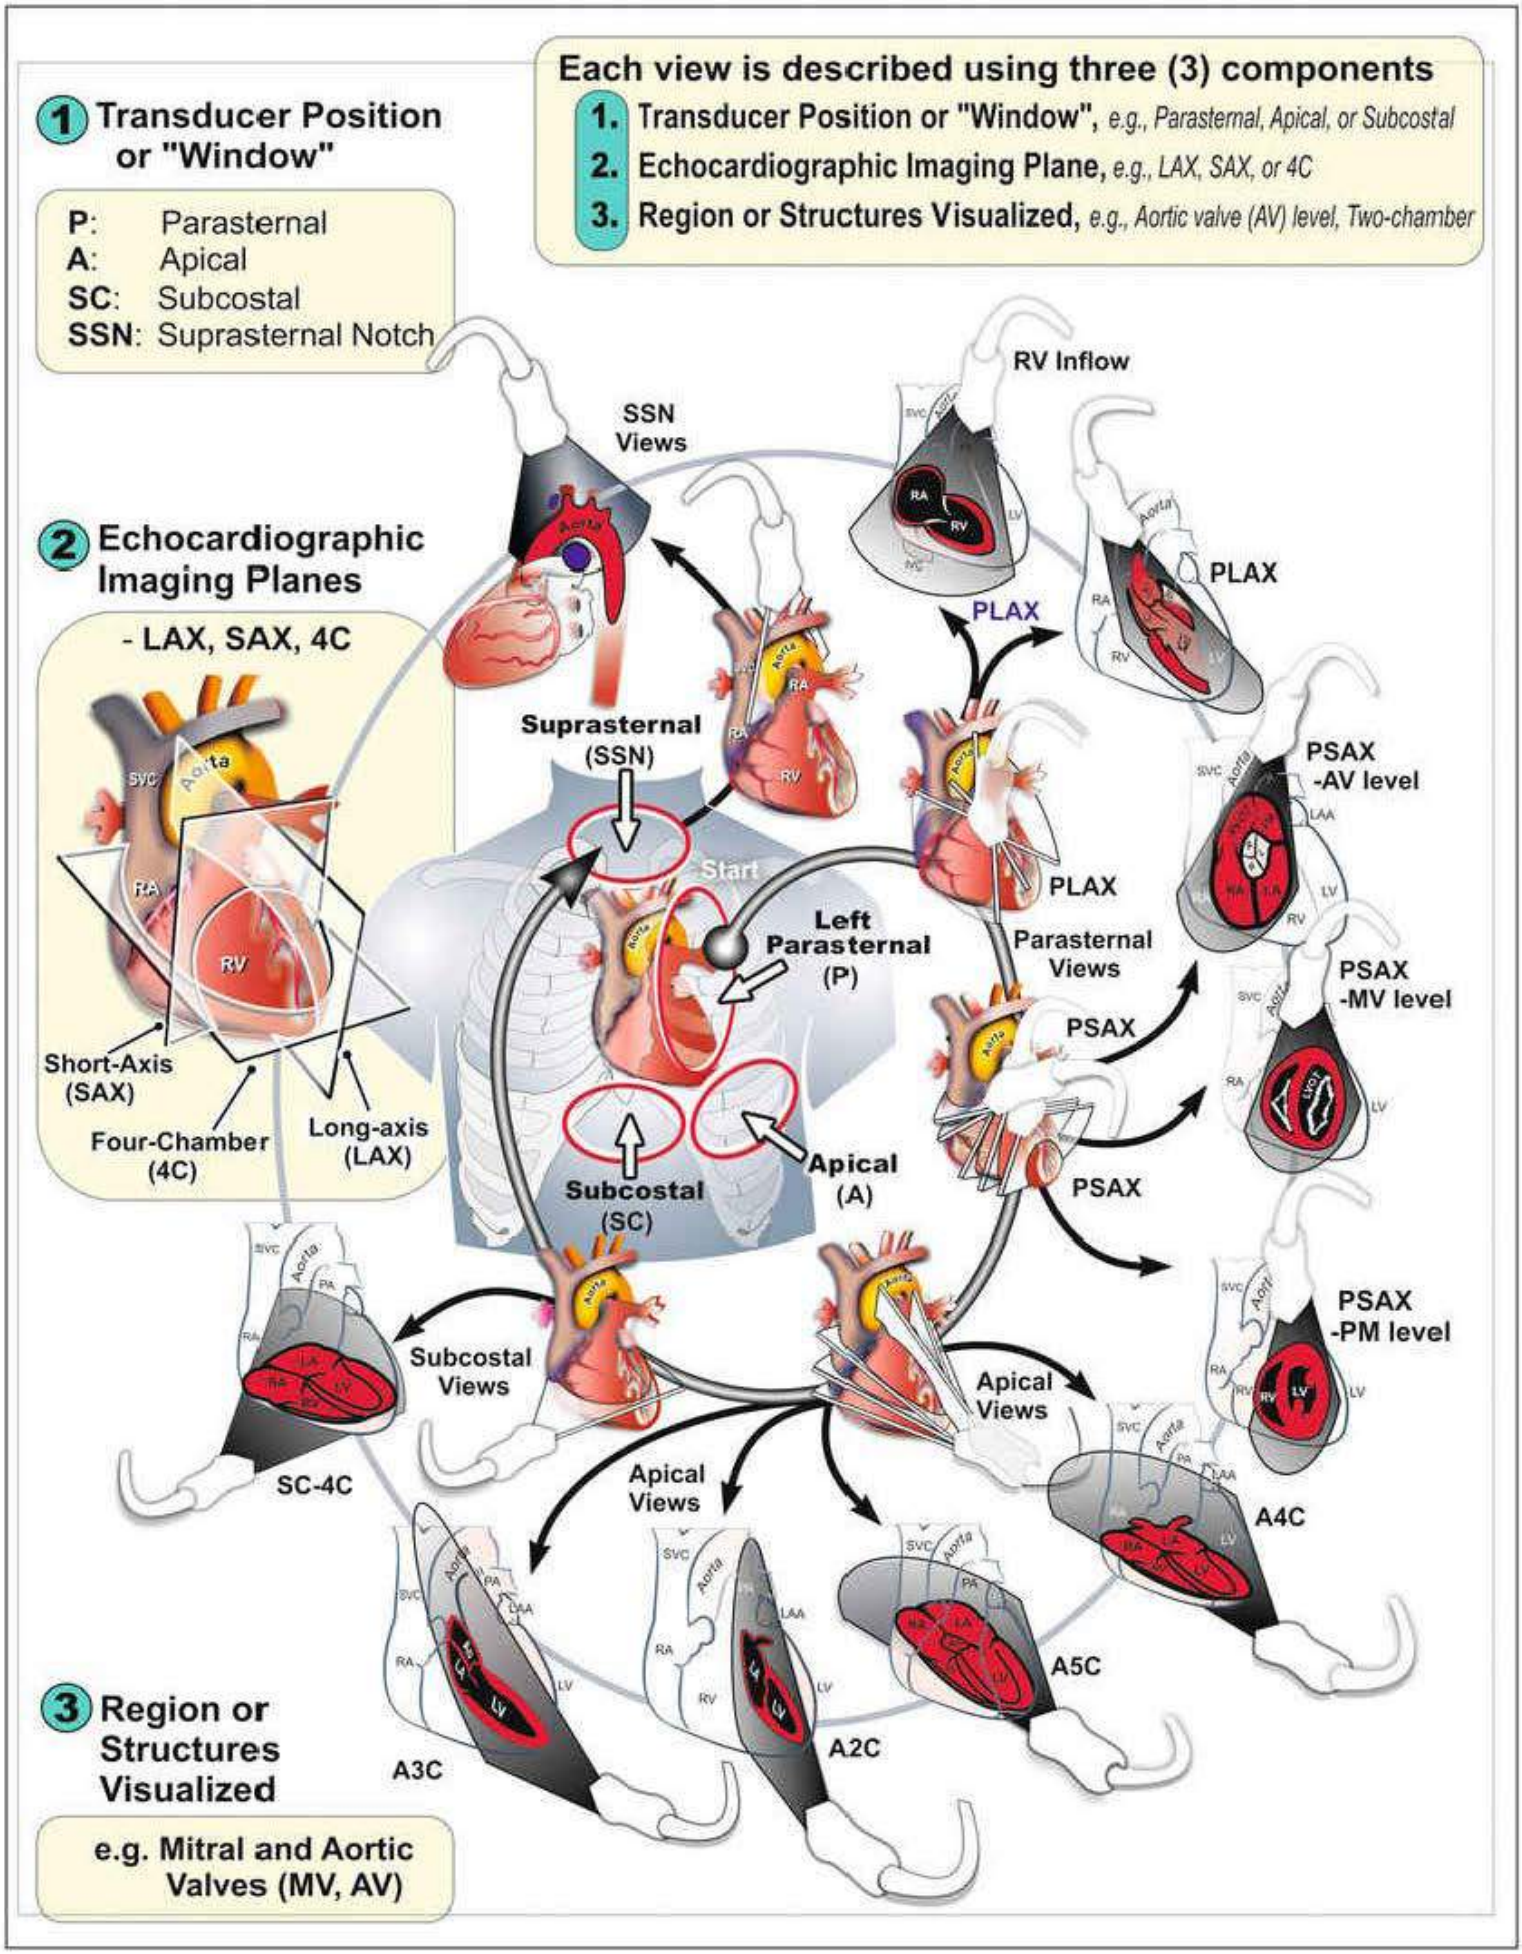

FIGURE 14.9 Standard adult transthoracic echocardiography imaging planes, protocol, and nomenclature recommended by the American Society of Echocardiography (ASE). Each echocardiographic view can be described by three parameters: window, plane, and structure visualized.

See Fig. 14.10 for abbreviations. (Modified from Bulwer BE, Shernan SK, Thomas JD. Physics of echocardiography. In Savage RM, Aronson S, Shernan SK, editors. Comprehensive Textbook of Perioperative Transesophageal Echocardiography. Philadelphia: Wolters Kluwer: Lippincott, Williams & Wilkins; 2009, pp 1-41.)

M-Mode Echocardiography

M-mode echocardiography provides greater temporal resolution than does standard 2D imaging and remains the method of choice for certain linear measurements, particularly those that are collinear with the ultrasound beam. Standard reports will include measurements of septal and posterior wall thickness and left ventricular (LV) chamber dimensions on parasternal views by convention (**Fig. 14.11A** shows a normal M-mode at the basal left ventricle). Because M-mode echocardiography is essentially a one-dimensional imaging technique, it has several limitations that should be recognized. For accurate measurements the cursor scan line must be oriented perpendicular to the long axis of the left ventricle or left atrium, which may require operator or machine correction to achieve. M-mode–based estimates of LV volume, mass, and function can be inaccurate in patients with LV geometries that deviate substantially from normal, such as those with aneurysms or focal wall motion abnormalities. M-mode of valvular leaflets is of historical importance for diagnosis and still remains useful for demonstrating abnormalities in valvular motion, including rheumatic mitral stenosis, mitral valve prolapse, and systolic anterior motion of the mitral valve as occurs in obstructive hypertrophic cardiomyopathy (HCM) (**Fig. 14.11**). M-mode can also be combined with 2D imaging to reveal subtle changes in interventricular septal motion and chamber wall movement in pericardial disease. In combination with color flow Doppler (color M-mode), accurate information about the timing and direction of flow and assessment of diastolic function can also be augmented.

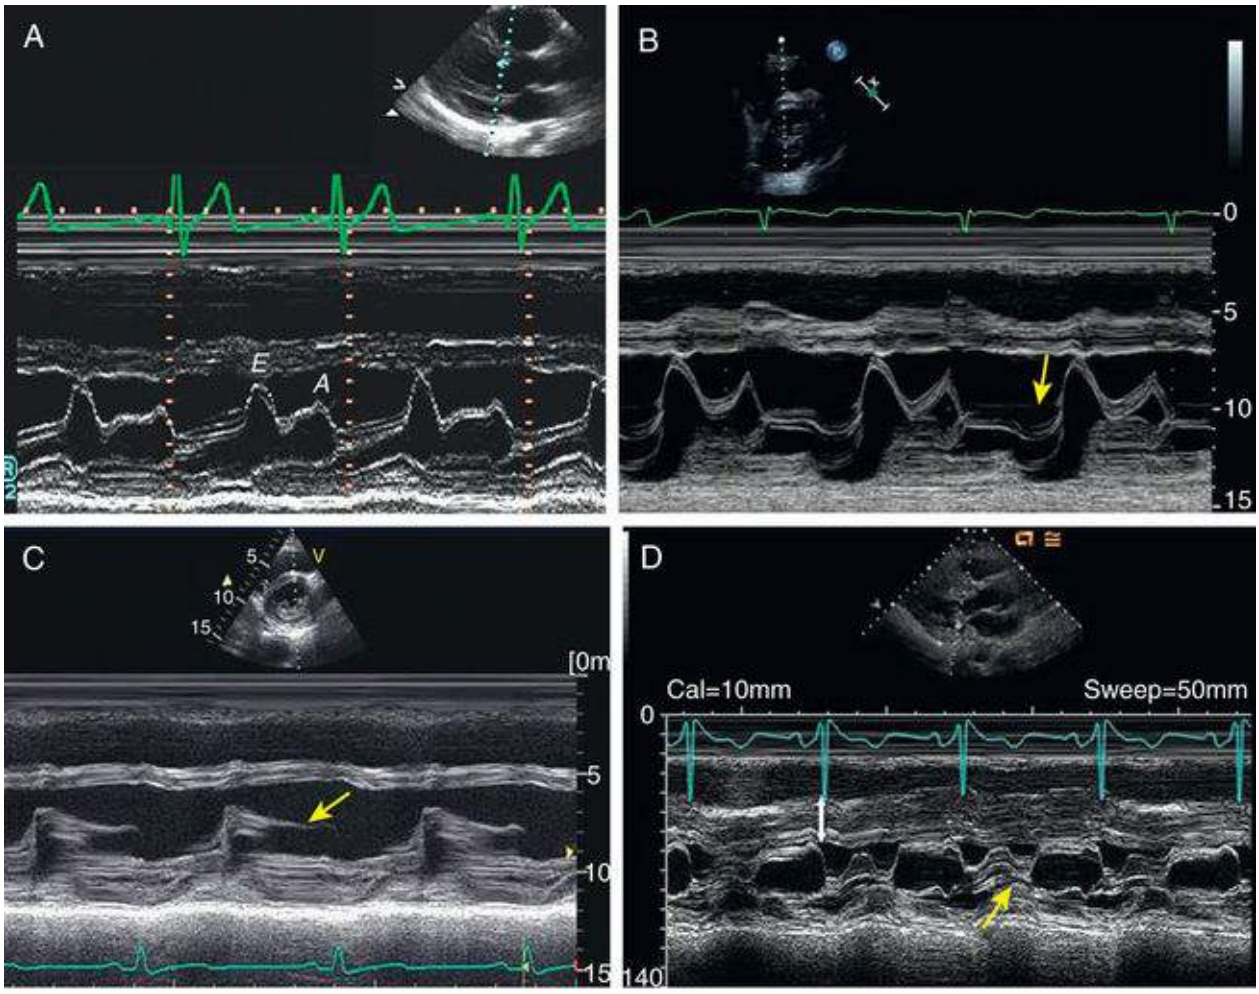

FIGURE 14.11 M-mode tracings. **A**, Normal M-mode across the base of the left ventricle at the level of the mitral leaflet tips. Note the E and A waves corresponding to the anterior mitral leaflet motion in early diastole (E) and with atrial contraction (A), respectively. Compare with **B,** which shows a patient with mitral valve prolapse, where there is late systolic posterior bowing (*arrow*) of the mitral leaflets on M-mode. **C,** Rheumatic mitral stenosis, with thickened mitral leaflets that move parallel to each other, straightening of the slope after the E wave (E-F slope), and reduced leaflet opening in diastole. **D,** Hypertrophic obstructive cardiomyopathy, displaying a very thickened interventricular septum (*white double-headed arrow*) and systolic anterior motion of the mitral valve leaflets (*yellow arrow*).

Imaging Artifacts

Ultrasound imaging artifacts are ubiquitous in echocardiography and are incurred by the physical principles of ultrasound. Artifacts can include the resemblance of structures that do not exist or that can be caused by real structures, such as the ribs obscuring visualization of the heart. Most artifacts are caused by physical interactions between ultrasound and tissue. Common artifacts include (1) *attenuation artifacts*, which result in "shadowing" typically caused by ribs or bony structures; (2) *side lobe artifacts*, which occur when lower-energy side beams (side lobes) aside from the main ultrasound beam reflect off of lateral structures and are mapped onto the central image; (3) *multiple reflection artifacts*, in which the sound waves bounce between a strong reflector, often the pericardium, pleura, or aortic wall, and the transducer more than once, giving rise to mirror images (Video 14.1) or near-field clutter; and (4) *reverberation artifacts*, which are caused by continuing repetition of internal reflections, often seen behind mechanical valve prostheses or left ventricular assist device (LVAD) cannulas (**Fig. 14.12**). One type of reverberation artifact, the *comet-tail artifact*, can be useful diagnostically to detect interstitial fluid in the lungs.

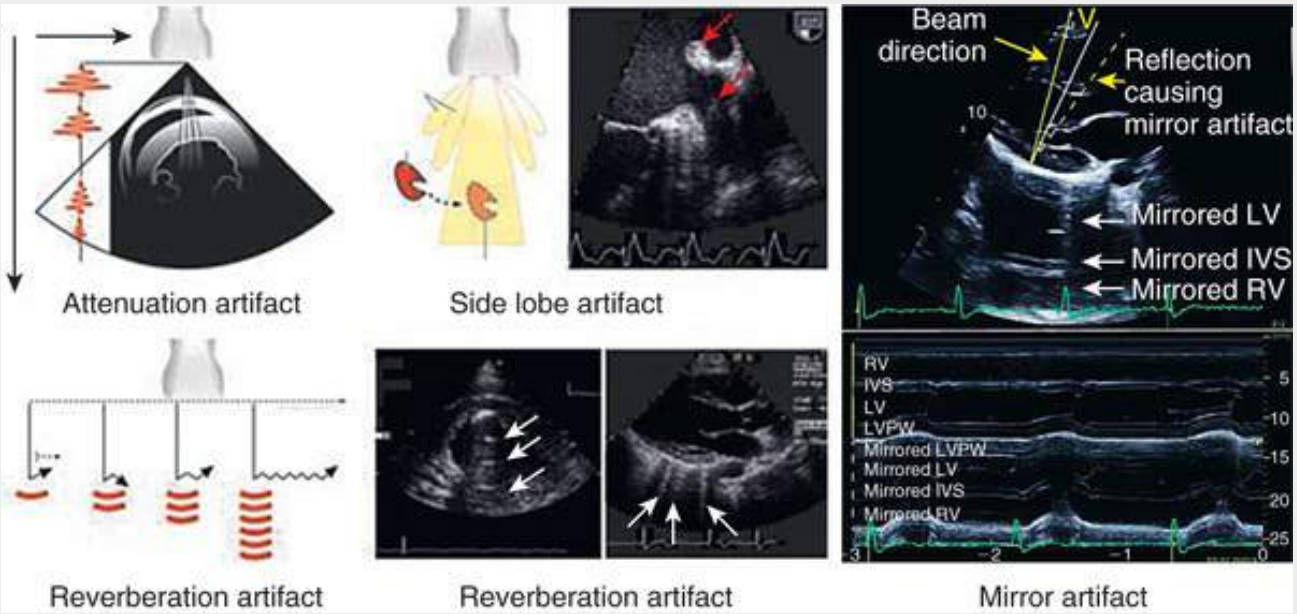

FIGURE 14.12 Common imaging artifacts seen in echocardiography. Attenuation artifacts, caused by diminution in ultrasound beam intensity with increasing depth, resulting in fading and dropout **(upper left)**. Side lobe artifacts occur when structures in the path of the side lobe beams are erroneously mapped into the image **(upper middle)**. Reverberation artifacts are common **(lower left and middle panels)**. They may be large, as in the case of reflections from the inflow tube of an LVAD (three parallel *arrows,* below center), or appear as fine comet-tail or "ring-down" artifacts because of multiple reverberations that invariably occur at the highly specular epicardial-pleural interface **(lower right)**. **Right panels,** Mirror artifact, caused by reflection between tissue interfaces and the transducer.

Assessment of Cardiac Structure and Function

The primary goal of the echocardiographic examination remains assessment of cardiac structure and function. Each chamber, valve, and great vessel can be assessed qualitatively and quantitatively to define any alterations in size, geometry, and patency. Measurements of cardiac structures are typically made in various locations throughout the heart, and linear, area, or volumetric measures can be obtained. These methods are often complementary to one another. For example, although volumetric measurements of the left ventricle (see later) are generally considered best suited to characterize LV size, many laboratories continue to record linear cavity measurements, because there is extensive literature correlating these measures with outcomes in numerous disease states. Moreover, linear measures may be subject to less variability than area- or volume-based measures and therefore may be more reliable for assessing changes over time.

Tables 14.1 to 14.3 show established normal values on echocardiography. For LV linear dimensions and volume, **Table 14.1** gives the normal ranges for the general population, but ideally one should take into account not only sex, but also body surface area (BSA) and age[2] (**eFigs. 14.3 and 14.4**). Current American Society of Echocardiography (ASE) consensus statements also provide partition values—that is, mild, moderate, and severely abnormal ranges—for LV size, mass, and ejection fraction and left atrial (LA) volume, but caution that the ranges were arrived at by experience-based consensus only, and that degree of abnormality does not necessarily connotate a direct correlation with outcomes or prognosis (**Table 14.2**). Normal values for LV parameters obtained with 3D echocardiography also exist and appear accurate and reproducible when image quality is good. In general, LV volumes calculated by 3D imaging are smaller than data generated from CMR data, but correlations with trends in sex and body surface area hold true.[2]

TABLE 14.1

Normal Values for Two-Dimensional Echocardiographic Parameters of Left Ventricular Size and Function According to Sex

Parameter	MALE		FEMALE	
	Mean ±SD	2-SD Range	Mean ±SD	2-SD Range
Left Ventricular (LV) Internal Dimension				
Diastolic dimension (mm)	50.2 ±4.1	42.0-58.4	45.0 ±3.6	37.8-52.2
Systolic dimension (mm)	32.4 ±3.7	25.0-39.8	28.2 ±3.3	21.6-34.8
LV Volumes (Biplane)				
LV EDV (mL)	106 ±22	62-150	76 ±15	46-106
LV ESV (mL)	41 ±10	21-61	28 ±7	14-42
LV Volumes Normalized by Body Surface Area				
LV EDV (mL/m^2)	54 ±10	34-74	45 ±8	29-61
LV ESV (mL/m^2)	21 ±5	11-31	16 ±4	8-24
LV EF (biplane)	62 ±5	52-72	64 ±5	54-74

Left Ventricular Structure: Size and Mass

Historically, LV volumes can be estimated from one of several formulas that use either linear or 2D measurements to calculate a volume based on the assumption that the left ventricle approximates a prolate ellipsoid or cylinder hemiellipsoid shape (**Fig. 14.13**). These approaches had the advantages of being relatively reproducible and simple to calculate. Much published research relies on M-mode data, but the estimation of LV volume is less accurate when ventricular geometry deviates from normal because of wall motion abnormalities or remodeling. For all LV geometries, the modified biplane Simpson method of discs has been demonstrated to be the most accurate method and is recommended (**Fig. 14.14**). This method requires tracing the endocardial border in the apical four- and two-chamber views with computerized assistance to measure the diameter and height of equally distributed slices along the ventricle. With these measurements, the volume of each axial slice can be calculated, and the volume of all the slices summed to give the total chamber volume. The method is very accurate when image quality is good. However, in actual practice, suboptimal image quality can make definition of the endocardial border challenging. Moreover, foreshortening of the ventricle in one of the apical views, which can occur simply by minor changes in the transducer angle, can dramatically reduce the measured volume. The development and utilization of LV echocardiographic contrast, 3D echocardiography, and strain analysis can mitigate the impact of these limitations (see later) and appear to permit greater accuracy and reproducibility.

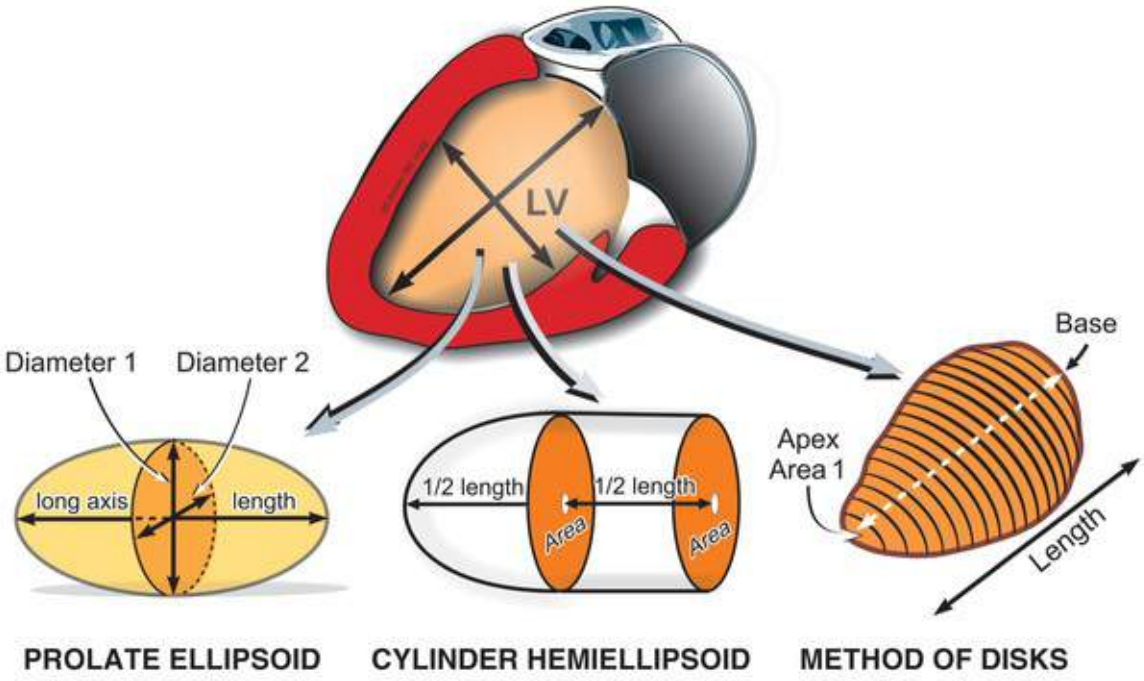

FIGURE 14.13 Geometric models and assumptions used in quantification of volumes of the left ventricle (*LV*) in two-dimensional echocardiography. (Modified from Bulwer BE, Rivero J, Solomon SD. Philadelphia: Current Science/Springer Science; 2009, pp 1-24.)

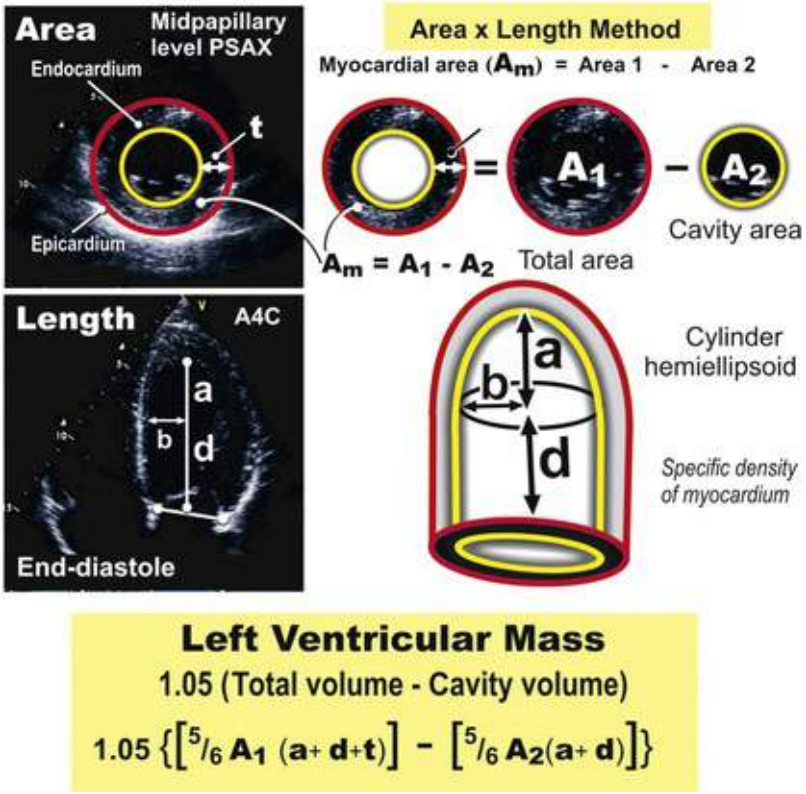
Left ventricular mass may be calculated by using one of several formulas that take into account both wall thickness and chamber size,[2] typically using either linear (M-mode) or 2D measurements together with geometric modeling of the shape of the LV myocardial "shell" (**eFig. 14.5**). These formulas have been validated in normal ventricles; however, as in volume calculations, accuracy suffers when applied to abnormally shaped ventricles. 3D datasets, in which wall thicknesses are measured at a multitude of points and mass is calculated without assumptions about cavity geometry, appear more accurate but again depend on image quality. Normal values are also less well established for 3D data.



EFIGURE 14.5 LV mass calculation in 2D echocardiography using an area-length method for a cylinder hemiellipsoid. Area 1 (A_1) is the total planimetered area at the mid-LV level on the parasternal short-axis (PSAX) view in diastole; area 2 (A_2) is the planimetered LV cavity area; A_m is the myocardial "shell" area; *b,* minor axis radius; *t,* wall thickness. (Modified from Bulwer BE, Rivero J, Solomon SD. Basic principles of echocardiography and tomographic anatomy. In Solomon SD, editor. Atlas of Echocardiography. 2nd ed. Philadelphia: Current Science/Springer Science; 2009, pp 1-24.)

With all methods, care must be taken to measure the walls at end-diastole, because small errors may be exponentially multiplied depending on the calculation used; **Table 14.3** shows currently accepted normal values. An LV mass index (derived from 2D measurements) of greater than 95 g/m^2 for women or more than 115 g/m^2 for men is considered abnormally high. Pathologically, LV *hypertrophy* is defined as increased overall LV mass and is distinct from wall thickness per se. However, in general, if LV diameter is not decreased, wall thicknesses of 12 mm or more correlates with LV hypertrophy. Alterations in LV size and mass can be categorized based on the ratio of relative wall thickness to the total LV mass index (**Fig. 14.15**). The specific pattern of ventricular remodeling has been related to prognosis in a variety of diseases, of both myocardial and valvular etiology.[3]

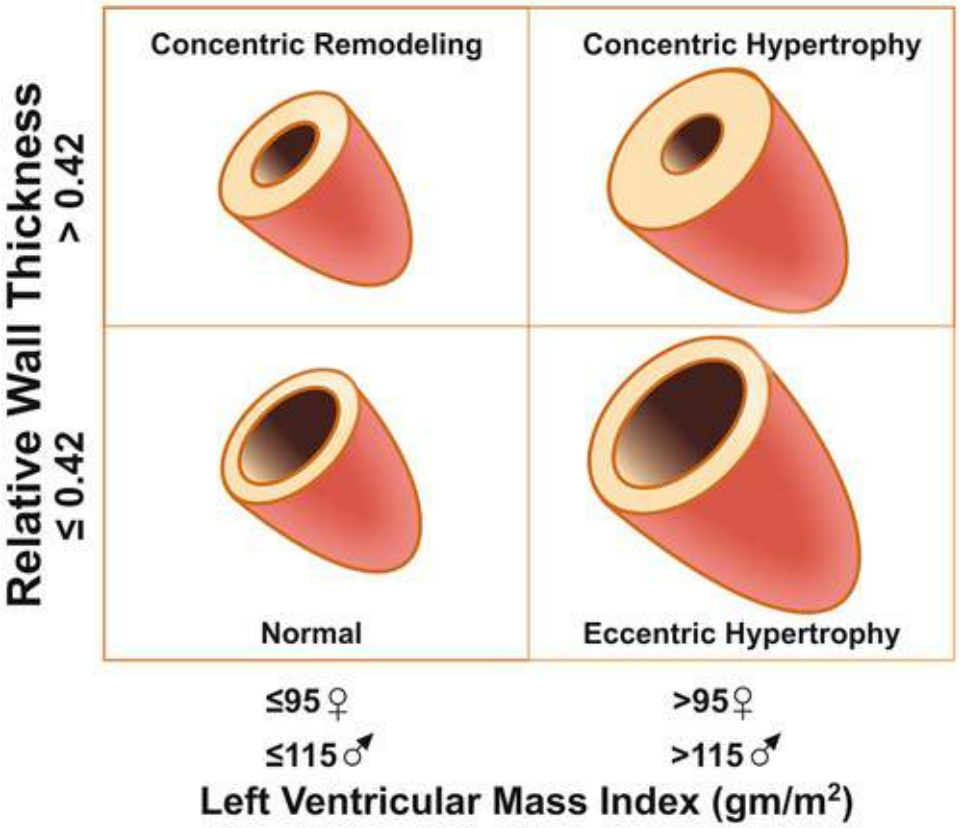


FIGURE 14.15 Patterns of left ventricular (LV) remodeling. Three patterns of LV remodeling can be defined based on measurement of left ventricular mass index (LVMI) and relative wall thickness (RWT): concentric remodeling (normal LVMI and increased RWT), eccentric hypertrophy (increased LVMI and normal RWT), and concentric hypertrophy (both LVMI and RWT are increased). (Modified from Konstam MA, Kramer DG, Patel AR, et al. Left ventricular remodeling in heart failure. current concepts in clinical significance and assessment. J Am Coll Cardiol Imaging 2011;4:98.)

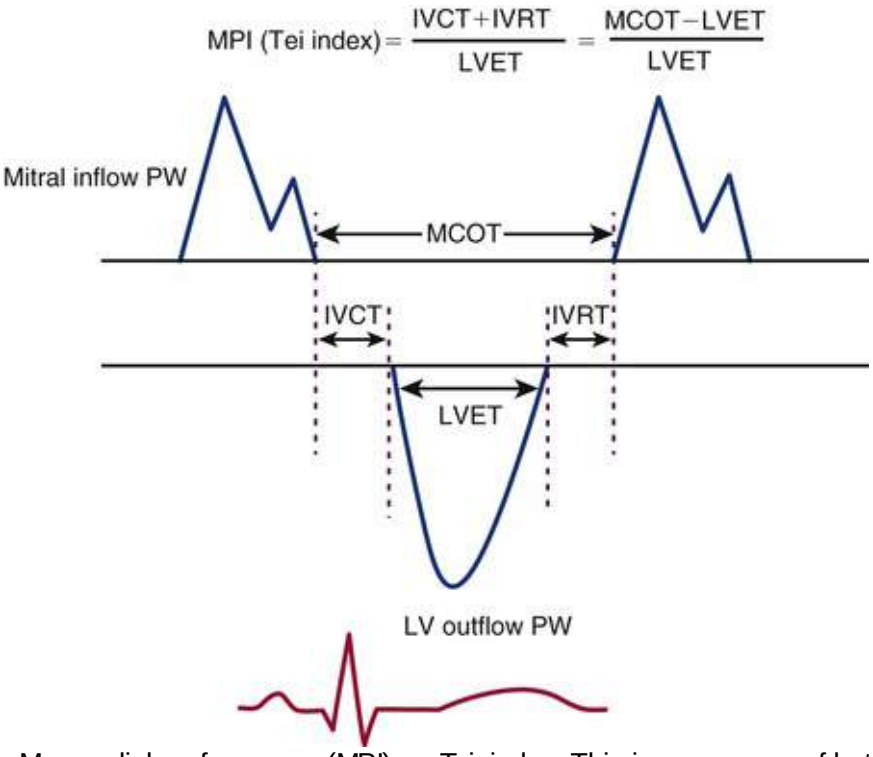
Left Ventricular Systolic Function

Echocardiography offers several methods for assessment of systolic function. The most common remains left ventricular ejection fraction (LVEF), calculated as the difference between end-diastolic volume and end-systolic volume divided by end-diastolic volume (**see Fig. 14.14**). LVEF is one of the best-studied measures in cardiovascular medicine for diagnosis and risk stratification. In echocardiography the volumes are preferably calculated by the modified Simpson formula (see earlier), and normal values are greater than 50%. Most echocardiography machines have basic analysis packages for automatically estimating the LVEF based on linear measurements at the base of the heart (e.g., Teicholz and Quinones formulas), which are helpful for a quick approximation but are less accurate in remodeled ventricles. In reality, the accuracy of all methods is affected by image quality, endocardial border definition, ventricular geometry, and imaging plane. When one or more of these factors are suboptimal, a visual “eyeball” estimation by experienced echocardiographers can be reliable and sufficient for most clinical scenarios. Although this is common practice and can actually be more accurate than mathematical computation in many cases, the presence of intra- and interobserver variability needs to be acknowledged, and reproducibility should be monitored.[4]

Other approaches are commonly used in addition to LVEF to assess systolic function. Stroke volume can be determined from 2D images by subtracting end-systolic volume from end-diastolic volume. An alternative method is to use Doppler data (discussed earlier), in which the VTI within the LVOT is multiplied by the LVOT CSA to calculate SV (**see Fig. 14.8**). Multiplication of SV by the heart rate gives the cardiac output.

Several other methods have been proposed for assessment of both LV and right ventricular (RV) function. The *myocardial performance index* (MPI), also known as the Tei index, is defined as the sum of isovolumic relaxation time and isovolumic contraction time divided by ejection time, and this method takes into account both systolic and diastolic performance (**eFig. 14.6**). A higher index is associated with worse function.[2] In adults, values of LV MPI greater than 0.40 and RV MPI greater than 0.43 are considered abnormal. This measure has been related to outcomes in a variety of conditions, including heart failure and following myocardial infarction (MI). *Doppler tissue imaging* (DTI) can be used to assess myocardial contraction velocity, or S′, although this technique has proved to be more useful for assessment of diastolic function (see later).



EFIGURE 14.6 Myocardial performance (MPI), or Tei, index. This is a measure of both global systolic and diastolic ventricular function and can be calculated from spectral Doppler tracings of mitral valve inflow and left ventricular (LV) outflow. *IVCT,* Isovolumetric contraction time, *IVRT,* isovolumetric relaxation time, *LVET,* LV ejection time, *MCOT,* mitral closure time. See also **eFig. 14.11** to correlate hemodynamics over the cardiac cycle. Alternatively, it can be measured by tissue Doppler. For above spectral Doppler method: normal LV Tei index is ≤0.40. Similar calculations can be performed for the right heart, and normal RV Tei index is ≤0.43.

Myocardial Strain Imaging.

Myocardial deformation, or strain imaging, has evolved to become a sensitive method for assessment of cardiac function. *Strain* refers to the percent deformation between two regions, such as shortening of myocardial muscle in systole or lengthening in diastole.[2] Myocardial strain can be assessed by Doppler methods in which myocardial tissue velocities are integrated to obtain the change in distance between points, but these are relatively noisy, require dedicated acquisition, and are angle dependent. In contrast, strain imaging based on 2D speckle-tracking techniques has proved to be much more robust and reliable (but with poorer temporal resolution) and thus has virtually replaced Doppler-based strain assessments for most applications. The technique has been validated by sonomicrometry and takes advantage of the

coherent speckle within the myocardial tissue signature (**eFig. 14.7**) to determine regions that are contracting versus those that are moving passively. Strain can be estimated in the longitudinal, circumferential, and radial directions by using the appropriate imaging plane (**Fig. 14.16**).

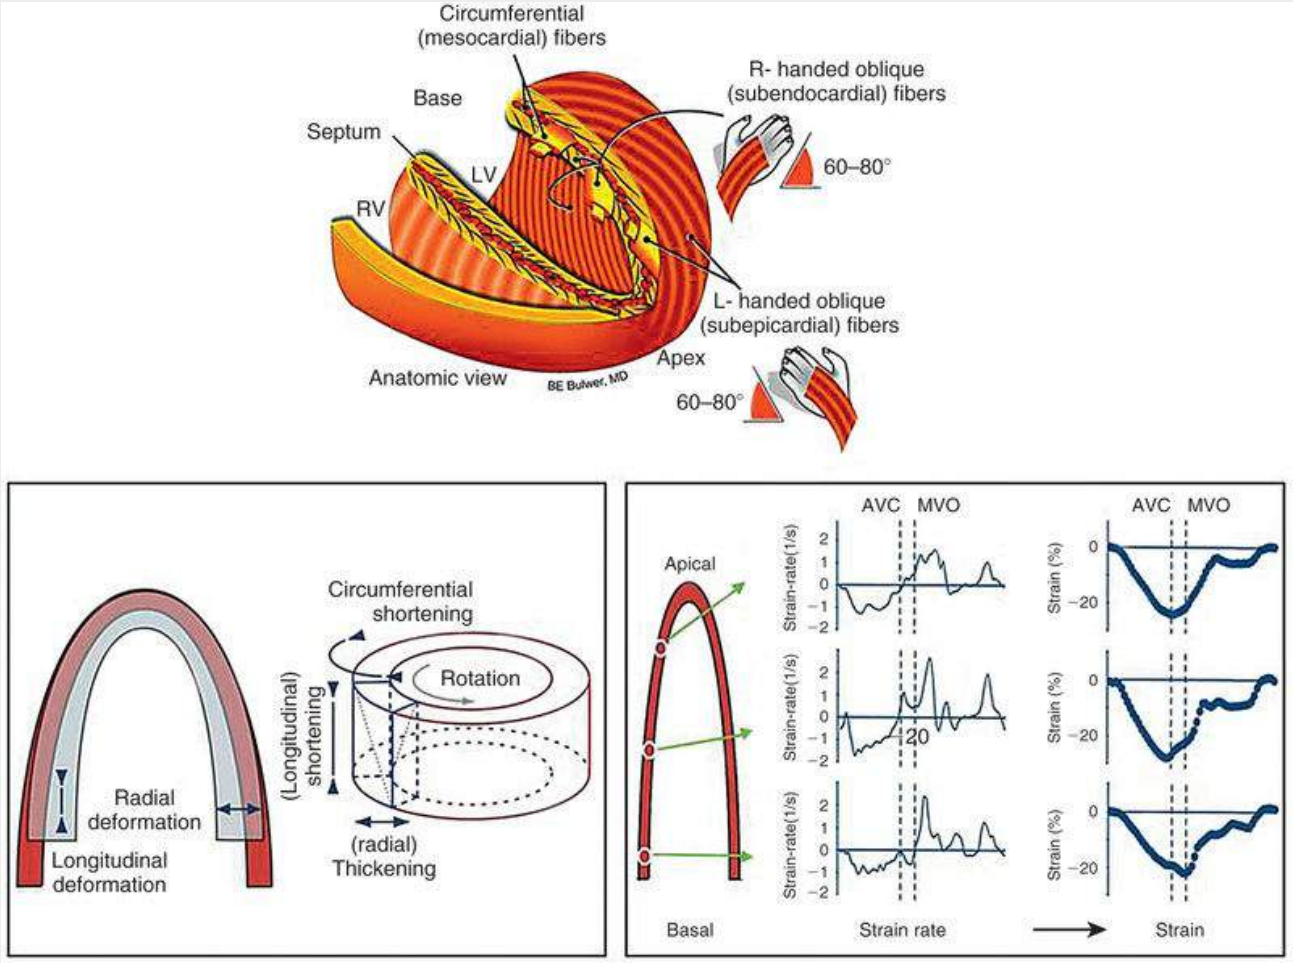


FIGURE 14.16 Normal myocardial fiber orientation, deformation planes, and typical longitudinal strain rate and strain traces. **Upper panel,** Left ventricular endo- and epicardial longitudinal fibers and their opposing oblique directions, midmyocardial circumferential fibers. **Lower panel: Left,** The three planes of myocardial motion and deformation at systole: longitudinal shortening, radial thickening, and circumferential shortening. **Right,** Typical traces of longitudinal strain rate and strain from a healthy adult. *AVC,* Aortic valve closure; *AVO,* aortic valve opening; *MVO,* mitral valve opening. (From Cikes M, Solomon SD. Beyond ejection fraction: an integrative approach for assessment of cardiac structure and function in heart failure. Eur Heart J 2016;37:1642.)

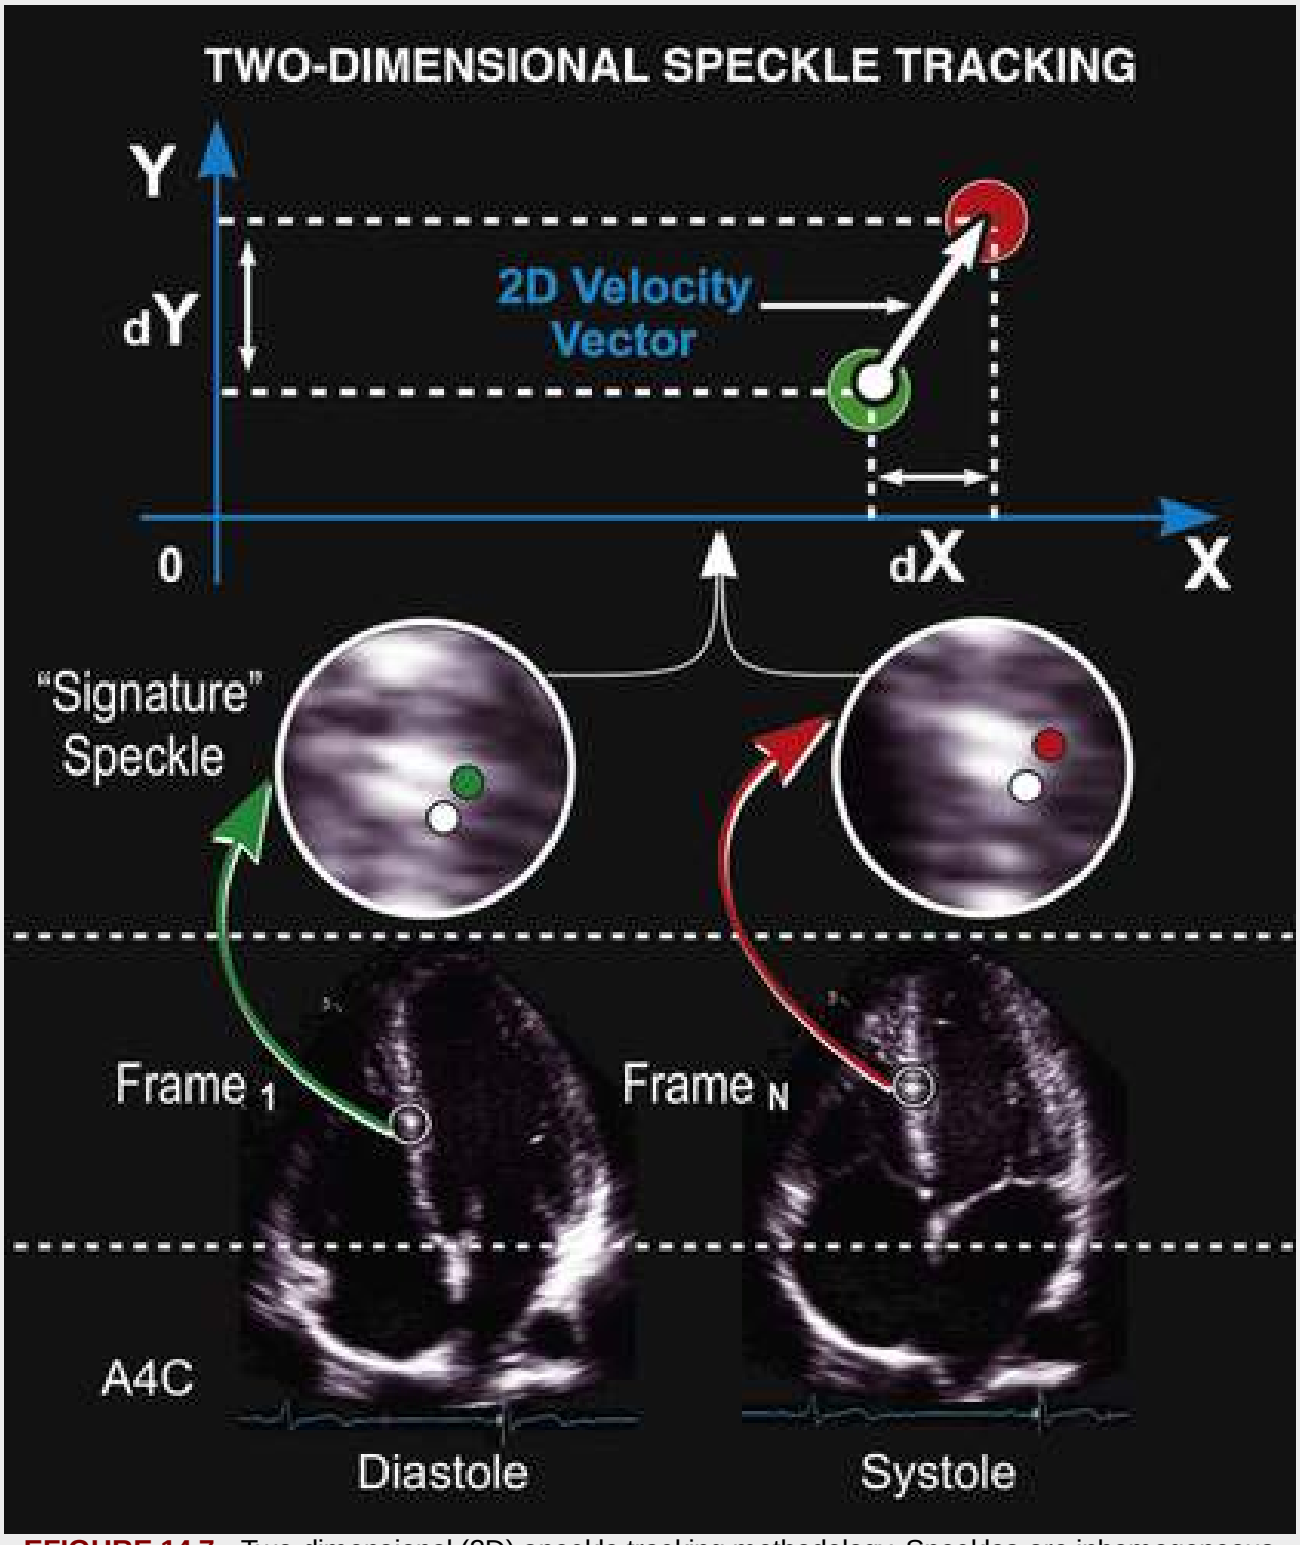


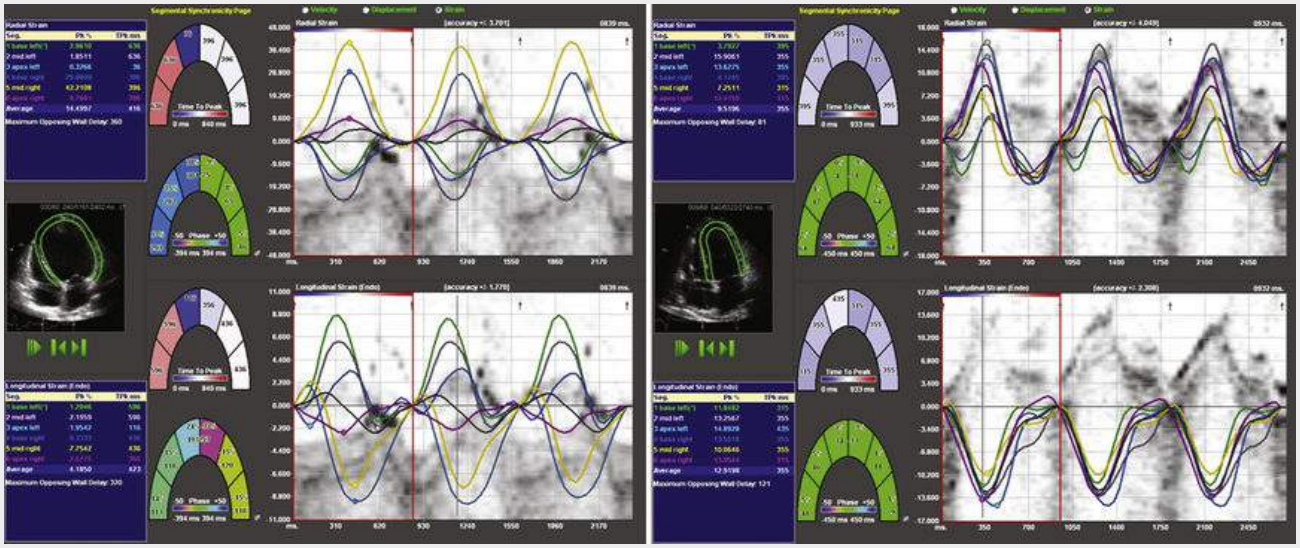
EFIGURE 14.7 Two-dimensional (2D) speckle tracking methodology. Speckles are inhomogeneous interference patterns that result from the interaction of ultrasound with the myocardium. Each area of myocardium, with its unique signature speckle, can be tracked during the myocardial deformation cycle. Unlike Doppler-based deformation imaging measures, speckle tracking–derived deformation measures are angle independent. *A4C,* Apical four-chamber view.

Current equipment can assess regional strain and then calculate global longitudinal strain either by averaging regional strain values or by determining the percent difference in the endocardial perimeter between systole and diastole. Longitudinal deformation reflects function of the subendocardial myocardial fiber bands primarily, whereas circumferential deformation, best assessed on short-axis views, may reflect the function of more epicardial layers.

Global strain, particularly *global longitudinal strain* (GLS, or the relative change in length of myocardium during systole), has emerged as an important measure of cardiac performance that has been

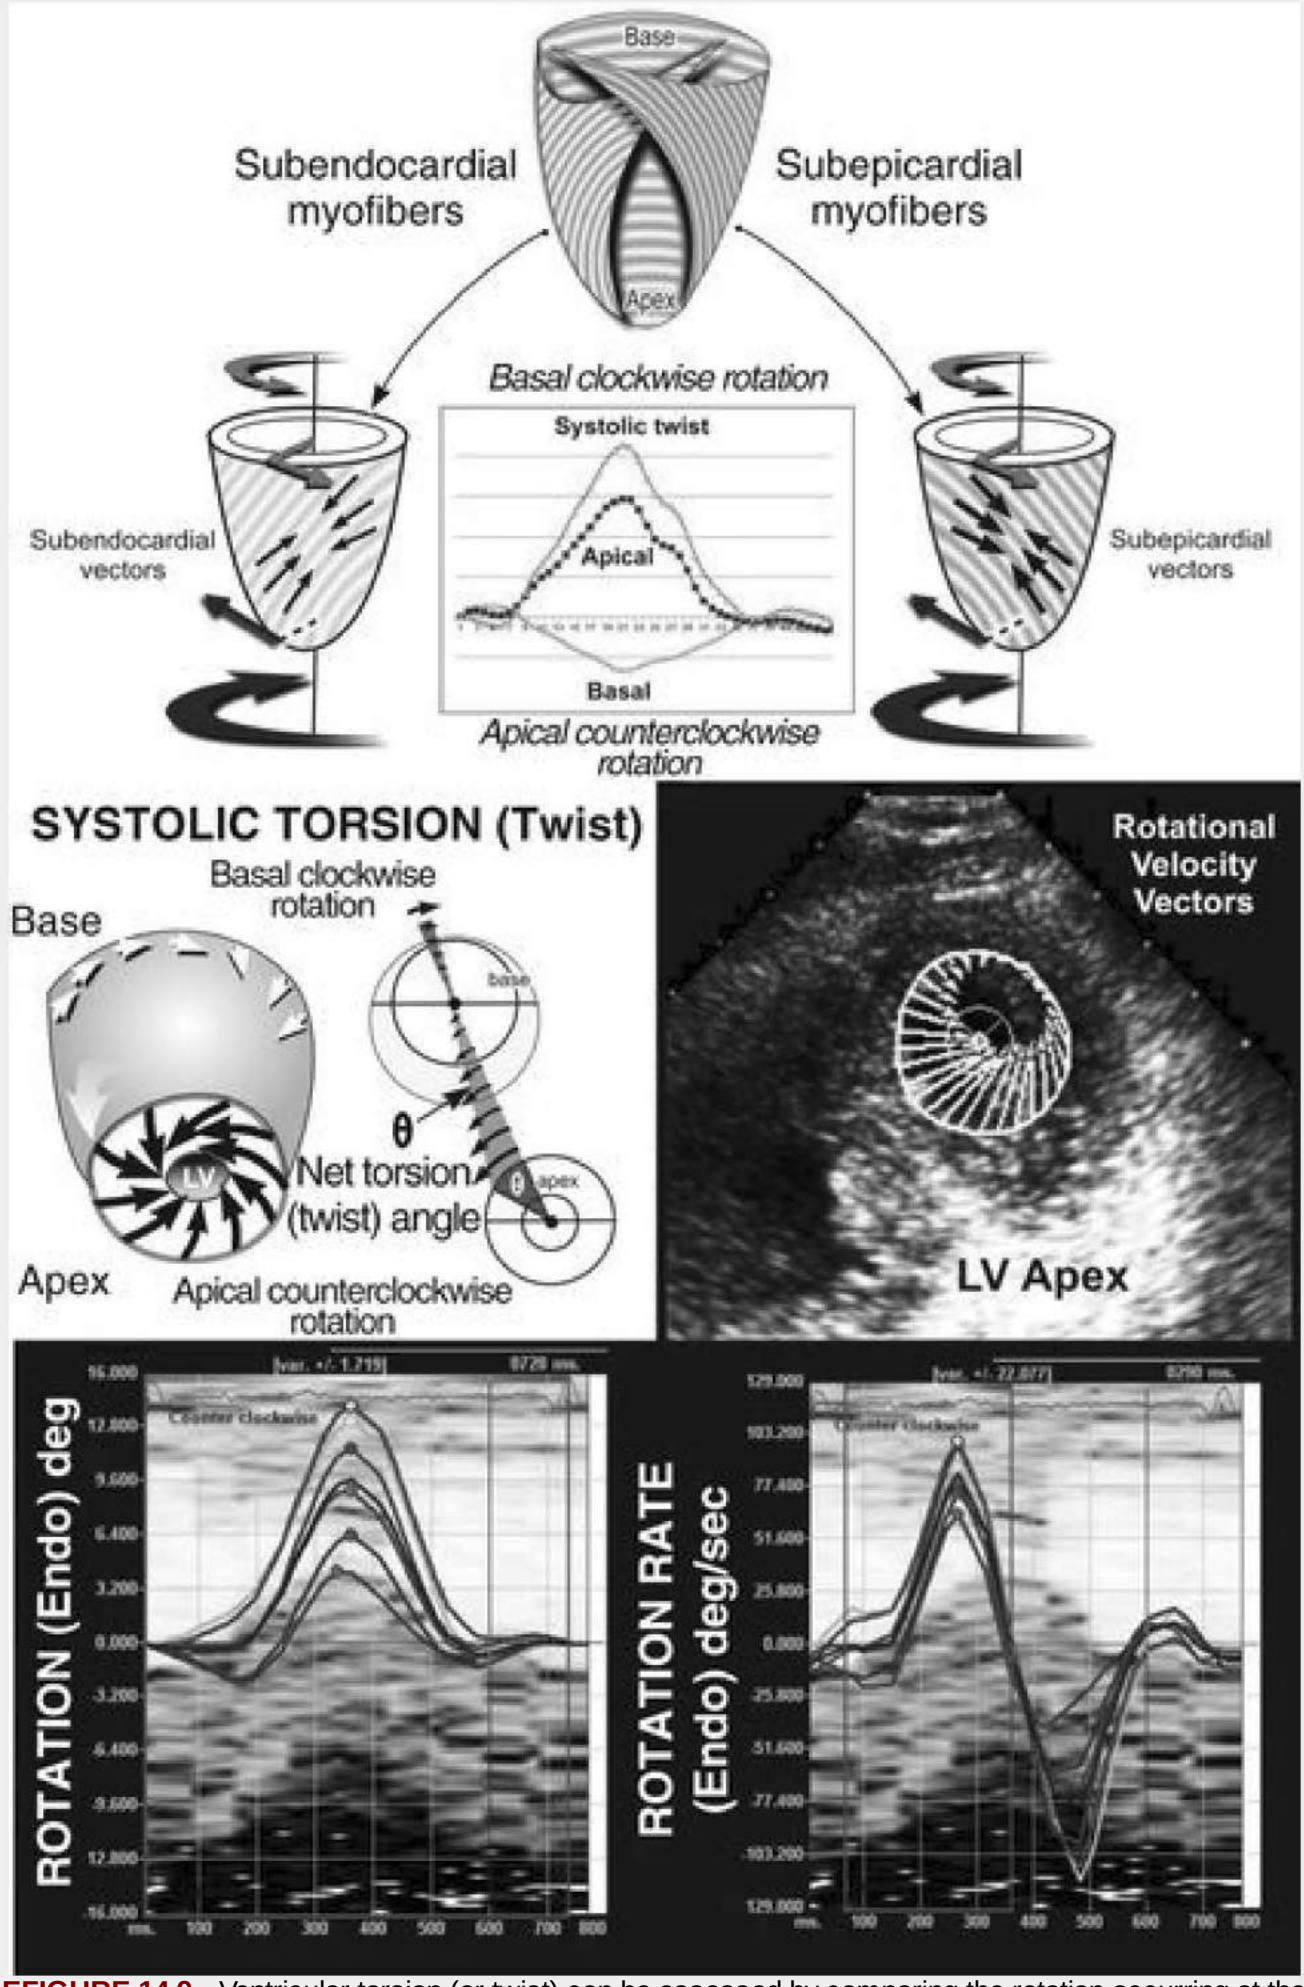
shown to add incremental predictive value to standard measures such as the LVEF.[5] Several diseases have been associated with a reduction in GLS, including hypertension, diabetes mellitus, renal insufficiency, infiltrative cardiomyopathies, HCM, and valvular heart disease. This measure also appears to predict survival or the development of heart failure in patients following MI. Global strain measurements are also useful in assessing the effect of cardiotoxic chemotherapies on individual patients over time.

Myocardial deformation imaging has been used for the evaluation of cardiac synchrony by assessing the time to peak strain (maximal contraction) across many cardiac regions (**eFig. 14.8**). Both regional timing, reflecting synchrony, and myocardial peak strain, reflecting contractile function, have prognostic significance in patients undergoing cardiac resynchronization therapy (CRT) (**see Chapters 25 and 41**) and may be used to stratify those who will benefit most from CRT.[6,7]



EFIGURE 14.8 Dyssynchrony versus synchrony, as assessed by myocardial strain before and after CRT. Average radial and longitudinal strain is calculated from six different regions in the ventricle on apical four-chamber views. The waveforms depicted demonstrate both timing and magnitude of peak strain in these regions. **Left panel** shows a patient with cardiomyopathy before therapy with a cardiac resynchronization device. **Right panel** shows same patient after 12 months of CRT with dramatic improvement in ventricular synchrony.

In addition to assessment of global function, strain imaging can be used to assess and quantify regional function. Regional strain correlates with the degree of myocardial scar in patients with ischemic heart disease (**see Chapter 17**) and in HCM[8,9] (**Chapter 78**). These measures can also be used to assess ischemia during stress echocardiography. An offshoot of myocardial strain imaging has been the quantitative assessment of ventricular twist and torsion, or the wringing motion of the heart during contraction and relaxation (**eFig. 14.9**).

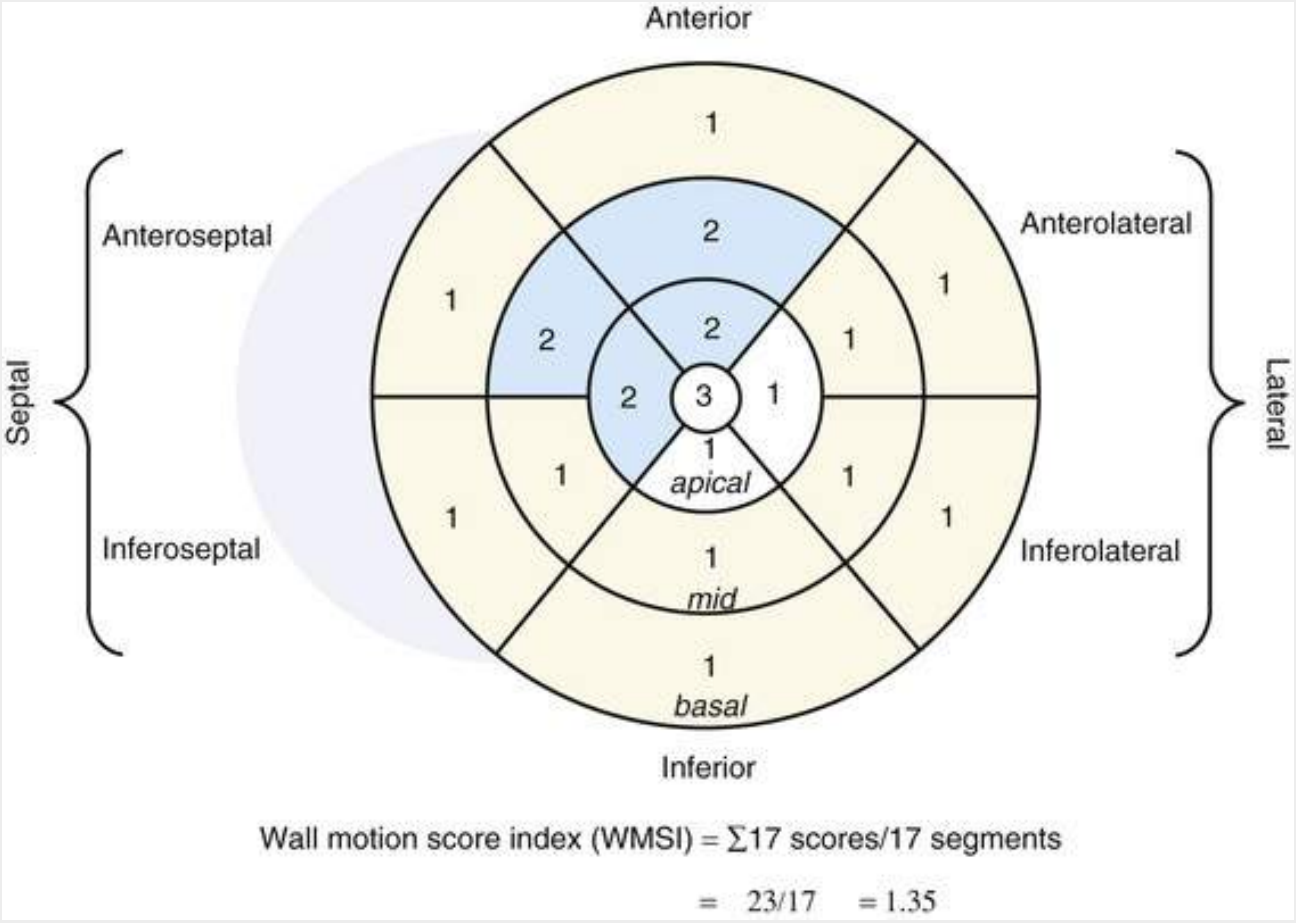


EFIGURE 14.9 Ventricular torsion (or twist) can be assessed by comparing the rotation occurring at the base of the heart with that occurring at the apex using speckle tracking. Rotation and the rate of rotation can be assessed and displayed. (Modified from Bulwer BE, Solomon SD. Assessment of systolic function. In Solomon

There are several limitations of strain imaging based on 2D echocardiography. First, myocardial deformation occurs in three dimensions, and out-of-imaging plane movement is lost. Second, these measures are subject to the same limitations as conventional ultrasound images, including frame rate and image quality, with limited time resolution at high heart rates. Third, the technique, data acquisition and calculations, and normal values still remain to be standardized among the many vendors. Until this is achieved, it is highly recommended that the same vendor equipment and software be used to follow strain in a given individual. As strain techniques become more standardized, refined, and automated, their usefulness and applicability will increase.

Left Ventricular Regional Function.

Even though measures of global LV function provide quantification of overall cardiac performance and have prognostic value, regional function can vary substantially, such as in ischemic heart disease or other focal processes. Acute MI can cause regional wall motion abnormalities: each specific myocardial region is supplied by a respective coronary artery (see later, Myocardial Infarction). Regional wall motion may be assessed qualitatively or semiqualitatively with a scoring system (**eFig. 14.10**). The most popular current scoring system is based on a 17-segment model advocated by the ASE in which each segment is scored as normal (1 point), hypokinetic (2 points), akinetic (3 points), or dyskinetic (4 points). The *wall motion score index* (WMSI) is equal to the sum of these grades divided by the number of segments visualized, so a normally contracting ventricle should have a score of 1.0. A WMSI of 1.7 or higher is usually associated with the physical examination findings of heart failure. A higher score is also an independent predictor of mortality and morbidity, including increased hospitalization for heart failure, following MI.



EFIGURE 14.10 Wall motion score index (WMSI). A polar map or "bulls-eye" view, one way to schematically depict the area of regional wall motion abnormalities (WMA) and calculation of the wall motion score index. Scores are 1 = normokinetic, 2 = hypokinetic, 3 = akinetic, and 4 = dyskinetic. The example displayed here is of mid-to-distal anteroseptal and anterior hypokinesis with an akinetic apex, giving a WMSI of 1.35. See **Fig. 14.28** in text for coronary distributions.

The main goal of detecting regional myocardial dysfunction is to identify patients with coronary artery disease (CAD). Assessment of regional wall motion cannot easily distinguish between old and new wall motion abnormalities, although local myocardial thinning and increased brightness would be suggestive of chronic infarction and scar tissue. Typically, MI is associated with discrete regions of severe hypokinesis, akinesis, or even dyskinesis. Focal wall motion abnormality can be apparent even within the first few minutes of acute MI, thus making assessment of regional wall motion particularly suited for diagnosis in the acute setting, for example, in patients with acute chest pain and equivocal abnormalities on the electrocardiogram (ECG) in whom a new discrete wall motion abnormality might argue for early intervention (**see Chapters 58 and 59**). Although MI, either acute or old, is the most likely reason for regional wall motion abnormalities, other conditions such as myocarditis or sarcoidosis can affect the myocardium regionally, but generally not in a clear coronary distribution. The LV dysfunction that can accompany valvular or hypertensive heart disease may also have some minor regional variability.

Assessment of regional wall motion is particularly important in stress echocardiography, in which induced regional wall motion abnormalities in the setting of exercise-induced or pharmacologic stress indicate myocardial ischemia. For stress echocardiography, regions are compared before and after stress in a side-by-side fashion, and wall segments with unchanged or worsening systolic function are compared qualitatively and scored (see later).

Left Ventricular Diastolic Function

Diastolic dysfunction is extremely prevalent in patients with hypertension and in older adults (**see**

Chapter 26). It is described mechanistically as impaired LV relaxation and increased LV stiffness. The "gold standard" for assessment of diastolic function has been the invasively obtained pressure-volume loop, in which diastolic function is assessed as the instantaneous relationship between pressure and volume. Noninvasively, several echo-based methods can be used to assess cardiac diastolic performance and estimate LV end-diastolic pressure (LVEDP). The more commonly used variables are summarized in **Figs. 14.17 and 14.18**, with age-adjusted reference values in **eTable 14.1**.[10] Analysis of diastolic dysfunction must be carried out with acknowledgment that (1) there are overlapping spectra of both echo values and degrees of diastolic dysfunction at any LVEF; (2) a patient's age, hemodynamics, and presence of disease (particularly mitral disease) may affect many values; and (3) no single index is accurate in isolation.

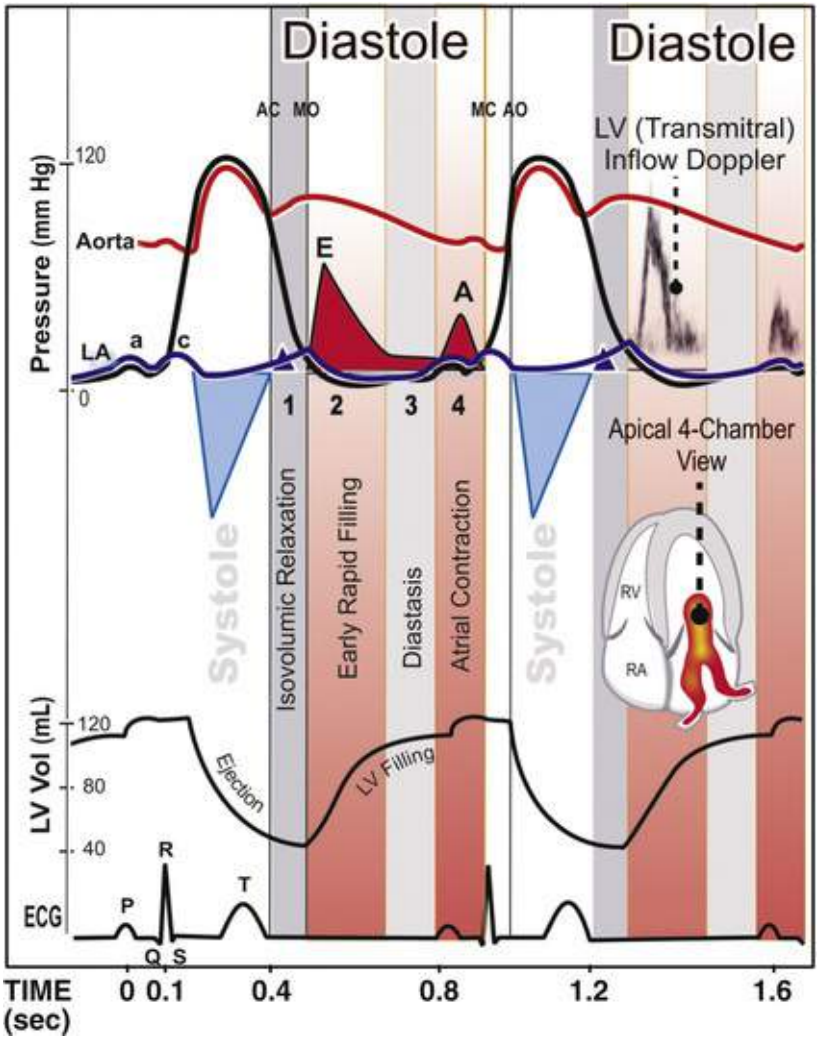
Mitral Inflow Patterns

Mitral inflow Doppler can be used to assess flow from the left atrium to the left ventricle during diastole (**eFig. 14.11**). The transmitral inflow velocity at a given point in time correlates with the pressure gradient between the chambers. The E wave occurs during early diastole when the ventricle is filling actively. The A wave represents the velocity of blood flow during late diastole during atrial contraction. Initial classification of diastolic function has been based on the pattern (i.e., relative heights) of the E and A waves (**Fig. 14.17**). E wave velocity is dependent on the transmitral pressure gradient and is thus directly related to LA pressure and inversely related to LV compliance. The height of the A wave is additionally dependent on the strength of atrial contraction. Normally in individuals younger than 65, E wave height is greater than A wave height, with ratios of 1.0 or higher. LV compliance declines with age, and so the E wave generally diminishes. Simultaneously, the A wave typically increases as atrial contraction augments to compensate for the reduced LV compliance. Moreover, the deceleration time of the E wave increases as compliance worsens initially. However, as diastolic function continues to worsen and LA pressures rises, the E wave will heighten again, and the size of the A wave declines as LV pressure rises and LA function begins to worsen, so the E/A ratio may revert to relatively normal (*pseudonormalization*). Because pseudonormal patterns can appear similar to normal patterns, E and A measures alone can be misleading. Further worsening of diastolic function leads to the so-called restrictive pattern, in which the descending slope of the E wave becomes very steep (rapid deceleration time) because of abrupt cessation of mitral inflow. Thus, both the pattern of the E and the A waves and the mitral deceleration time follow a biphasic course as diastolic function worsens, which limits the usefulness of these measures alone in assessment of diastolic function.



EFIGURE 14.11 The cardiac cycle and phases of diastole. *AC,* Aortic closure; *AO,* aortic opening; *MC,* mitral closure; *MO,* mitral opening; *RA,* right atrium; *RV,* right ventricle.

Doppler Tissue Imaging

DTI applies Doppler imaging principles to the assessment of myocardial contraction and relaxation. Rather than assessing signals from rapidly moving red blood cells, DTI uses filters to optimize reception of the higher-amplitude signals that arise from the much slower-moving myocardium. When applied to assess myocardial motion at the mitral annulus (typically at both medial and lateral sampling points), the Doppler velocities are recorded over the cardiac cycle. Three distinct waveforms are seen: systolic contraction (the S′ wave) toward the relatively fixed apex, followed by early (e′) and late relaxation (a′) signals in diastole. The timing of the e′ and a′ waves is coincident and analogous in many ways to standard Doppler of mitral inflow, but the movement is in the opposite direction to blood flow and of much lower velocity. The e′ peak value is inversely related to tau (τ), the time constant of ventricular relaxation. The e′ velocity ranges up to greater than 20 cm/sec in children and young adults but declines rapidly in early adulthood and beyond. Values less than 5 cm/sec are seen in patients with severe diastolic dysfunction (e.g., amyloidosis).

Because E velocity reflects the atrial-to-ventricular pressure gradient, it is dependent on both LV compliance and LA pressure (i.e., preload dependent). In contrast, DTI e′ in principle is a measure of LV compliance alone. Therefore, dividing E by e′ yields a measure that reflects LA pressure, which usually approximates LVEDP. An E/e′ ratio greater than 14 is considered abnormally high at any age and is usually indicative of elevated LVEDP. However, this ratio may be insensitive to acute changes and thus

may not be suitable for monitoring patients during therapy.[11]

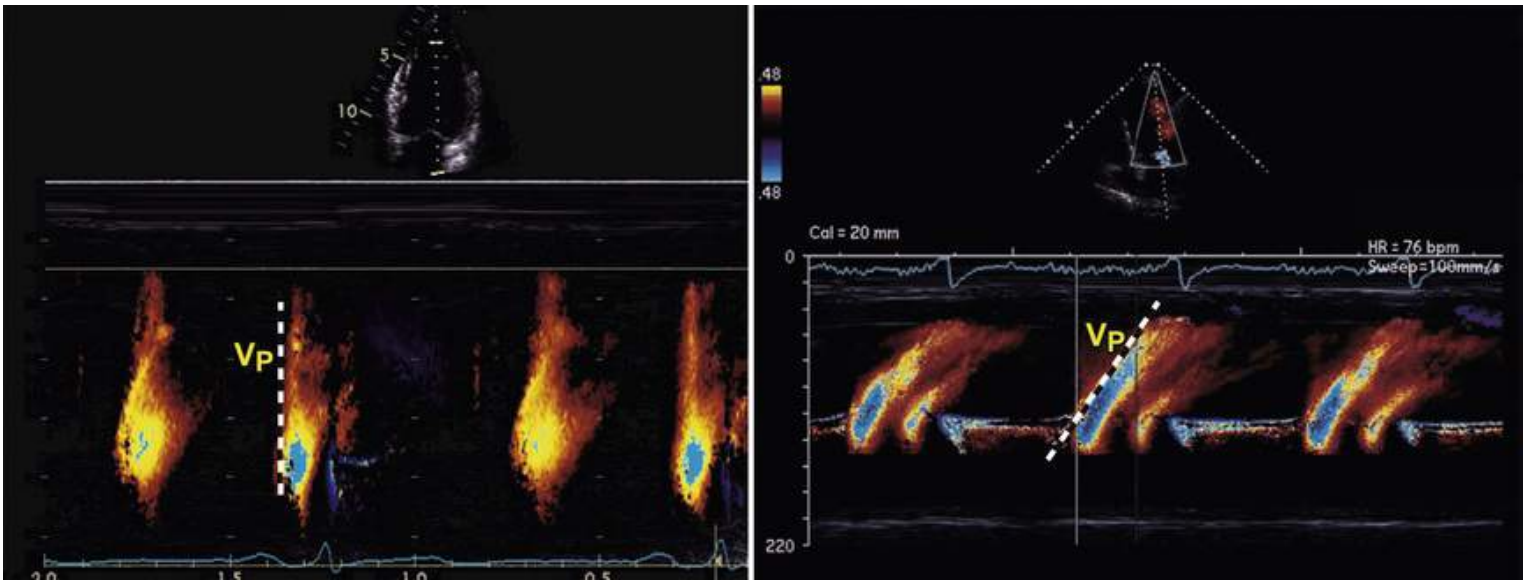
Pulmonary Venous Doppler Flow Patterns

Pulmonary flow patterns are complementary to mitral inflow Doppler patterns for assessment of diastolic function. Pulmonary vein flow has three components: (1) the S wave, which consists of forward flow from the pulmonary veins to the left atrium during ventricular systole; (2) the D wave, which consists of passive flow during ventricular diastole; and (3) the AR wave, which is the slight flow reversal into the pulmonary veins during atrial contraction (**see Fig. 14.18**). Patients with impaired LV relaxation will demonstrate blunting of the S wave relative to the D wave. Reduced LV compliance may also result in greater flow into the pulmonary veins during atrial contraction (broader A wave).

A number of other Doppler parameters change with declining diastolic function. The *isovolumic relaxation time* (IVRT) represents the period between closure of the aortic valve and the start of ventricular filling (i.e., end of LVOT flow and beginning of mitral inflow E wave; **see eFig. 14.6**). Prolongation of the IVRT is associated with abnormal relaxation, and shortening of the IVRT can occur in patients with restrictive LV filling. Mitral E wave deceleration time (DT; **see Fig. 14.17**) is the interval from peak to no mitral inflow in early diastole. In early diastolic dysfunction, deceleration time can actually increase. However, in patients with severe restrictive physiology where the stiff ventricle reaches its volume limit suddenly, the DT will be very rapid (<140 msec). This has been associated with an adverse prognosis in patients with heart failure and after MI (i.e., in patients with both systolic and advanced diastolic dysfunction).[12]

Color M-Mode and Flow Propagation

Color M-mode can be used to assess transmitral flow propagation velocity (Vp). While performing color flow Doppler through the mitral valve in apical windows, one can initiate the M-mode function to superimpose the color flow information onto the M-mode image (**eFig. 14.12**). The slope of the E wave flow (Vp) represents flow propagation, which correlates inversely with tau, the time constant of relaxation. Patients with impaired active relaxation will have a reduced “suction” action of the left ventricle, with abrupt slowing of blood once it enters the ventricle. On color M-mode, this manifests as a more shallow slope of Vp (abnormal is considered <0.45 in middle-aged adults, and <0.55 in younger adults). In practice, despite refinements in calculation of parameters based on flow propagation, Vp measures have lower reproducibility and appear reliable only in patients with depressed LVEF.[10]



EFIGURE 14.12 Transmitral flow propagation demonstrated by color M-mode. Flow propagation velocity is assessed as the linear slope of the isovelocity contour (the aliasing portion) of the mitral inflow pattern at 4 cm into the LV cavity. This slope will be more shallow when velocity is impaired (as in **right panel**). Vp is transmitral flow propagation velocity. Determination of Vp is often more difficult when the early diastolic flow velocities form a curved isovelocity inflow pattern, rather than a single straight slope.

Assessing Diastolic Function in Clinical Practice

In clinical practice, assessment of diastolic function requires an integrated approach. Main parameters and rough cutoffs for initial assessment include mitral inflow Doppler (particularly E/A ratio) and tissue Doppler (e′ and E/e′ ratio) criteria, but also estimation of pulmonary artery systolic pressure and LA volume (**Table 14.4**). A majority of evidence (initially at least two of four) of abnormal parameters is required to parse diastolic dysfunction, with use of additional parameters as needed for corroboration.[10] Several schemes have been developed to grade diastolic function based on these parameters (as in **Fig. 14.18 and Table 14.4**). Although these schemes allow for some standardization in description of diastolic dysfunction, data on the relationship between specific grades, resting hemodynamics, and clinical outcomes remain limited. Abnormalities in diastole are extremely prevalent in patients with hypertension and in elderly patients, but are not necessarily associated with clinical symptoms or overt heart failure.[10,13] Assessment of diastolic function during exercise, termed the “diastolic stress test,” may help unmask abnormalities that contribute to symptoms only during exertion.[14]

Right Ventricular Structure and Function

Assessment of the right ventricle has proved especially challenging for 2D echocardiography. Even though the left ventricle is relatively easily characterized as a prolate ellipsoid, the odd crescentic shape of the right ventricle makes modeling of volumes considerably more complex. Moreover, because visualization of the entire right ventricle is not encompassed by any single 2D plane, multiple measurements from multiple views are necessary to fully assess this chamber (**eFig. 14.13**). Normal linear RV measurements are shown in **Table 14.5**. The normal right ventricle is accustomed to low pulmonary vascular resistance (PVR) and is thus extremely sensitive to changes in afterload. Conditions that increase PVR acutely, such as pulmonary embolism (**see Chapter 84**), will cause marked RV dilation and dysfunction. Conditions that cause a chronic increase in PVR will lead to RV hypertrophy and dilation, but RV function is usually maintained until the late stages of disease (**see Chapter 85**).

TABLE 14.5

EFIGURE 14.13 Right ventricular linear and area measurements on 2D echocardiography. The right ventricle is a tripartite shape, with a half-crescent shape in long-axis windows and a crescentic cross section in short-axis views. As a rough guide, from RV-focused apical views (which display the largest basal RV diameter but still center the LV apex at the top of the scanning sector) an RV basal diameter >41 mm and midlevel diameter >35 mm is indicative of RV enlargement (**see Table 14.5**). *LA,* Left atrium; *LV,* left ventricle; *PA,* pulmonary artery; *RA,* right atrium; *RV,* right ventricle. (Modified from Bulwer BE, Solomon SD. Assessment of systolic function. In Solomon SD, editor. Atlas of Echocardiography. 2nd ed. Philadelphia: Current Science/Springer Science; 2009, p 65.)

Several methods are commonly used to assess global RV function initially on conventional echocardiography (**Table 14. 6**).[2] RV fractional area change (FAC) (**Fig. 14.19**) is easily determined by calculating the RV area in diastole (RVAd) and systole (RVAs) on the apical four-chamber view:

TABLE 14.6

Normal Values for Parameters of Right Ventricular (RV) Function

PARAMETER	MEAN ±SD	ABNORMALITY THRESHOLD
TAPSE (mm)	24 ±3.5	<17
Pulsed Doppler S wave (cm/sec)	14.1 ±2.3	<9.5
Color Doppler S wave (cm/sec)	9.7 ±1.85	<6.0
RV fractional area change (%)	49 ±7	<35
RV free wall 2D strain* (%)	−29 ±4.5	>−20†
RV 3D EF (%)	58 ±6.5	<45
Pulsed Doppler MPI	0.26 ±0.085	>0.43
Tissue Doppler MPI	0.38 ±0.08	>0.54
E wave deceleration time (msec)	180 ±31	<119 or >242
E/A	1.4 ±0.3	<0.8 or >2.0
e′/a′	1.18 ±0.33	<0.52
e′	14.0 ±3.1	<7.8
E/e′	4.0 ±1.0	>6.0

*Limited data; values may vary depending on vendor and software version.

†<20 in magnitude with the negative sign.

MPI, Myocardial performance (Tei) index; *TAPSE,* tricuspid annular plane systolic excursion.

From Lang RM, Badano LP, Mor-Avi Victor, et al. Recommendations for cardiac chamber quantification by echocardiography in adults: an update from the American Society of Echocardiography and the European Association of Cardiovascular Imaging. J Am Soc Echocardiogr 2015;28:1.

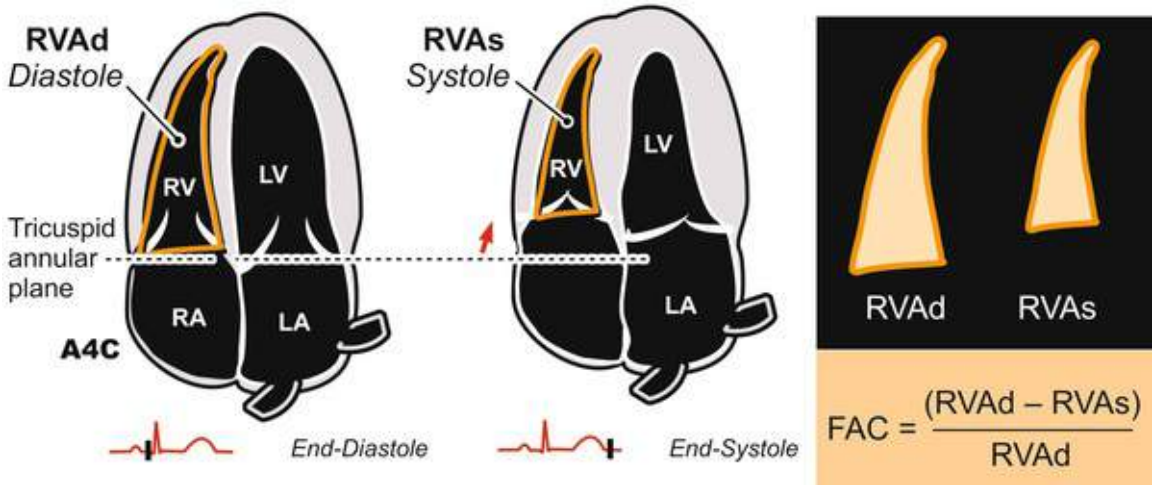

FIGURE 14.19 Right ventricular area (*RVA*) measurement and fractional area change (*FAC*) used to assess RV function with the apical four-chamber view (*A4C*). *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

$$FAC = (RVAd) - RVAs)/RVAd$$

Assessment of RV function by FAC has been shown to provide incremental prognostic value in patients with heart failure and following MI.[15] *Tricuspid annular plane systolic excursion* (TAPSE) is a measure of RV contractility that is usually measured with M-mode imaging (**Fig. 14.20**). This longitudinal motion

of the tricuspid annulus can similarly be assessed with pulsed or tissue Doppler as the peak velocity of the systolic wave, S′ (**Fig. 14.20, right**). Also exactly analogous to the left ventricle, an RV Tei index and RV GLS values can similarly be obtained. RV regional, as opposed to global, dysfunction has particular importance in conditions in which RV afterload increases abruptly, such as pulmonary embolism (see later), in which regional RV function is often preserved in the apical and basal free wall segments but dyskinetic or akinetic in the midregion. Both global and segmental RV wall motion abnormalities also notably occur in RCA infarcts.

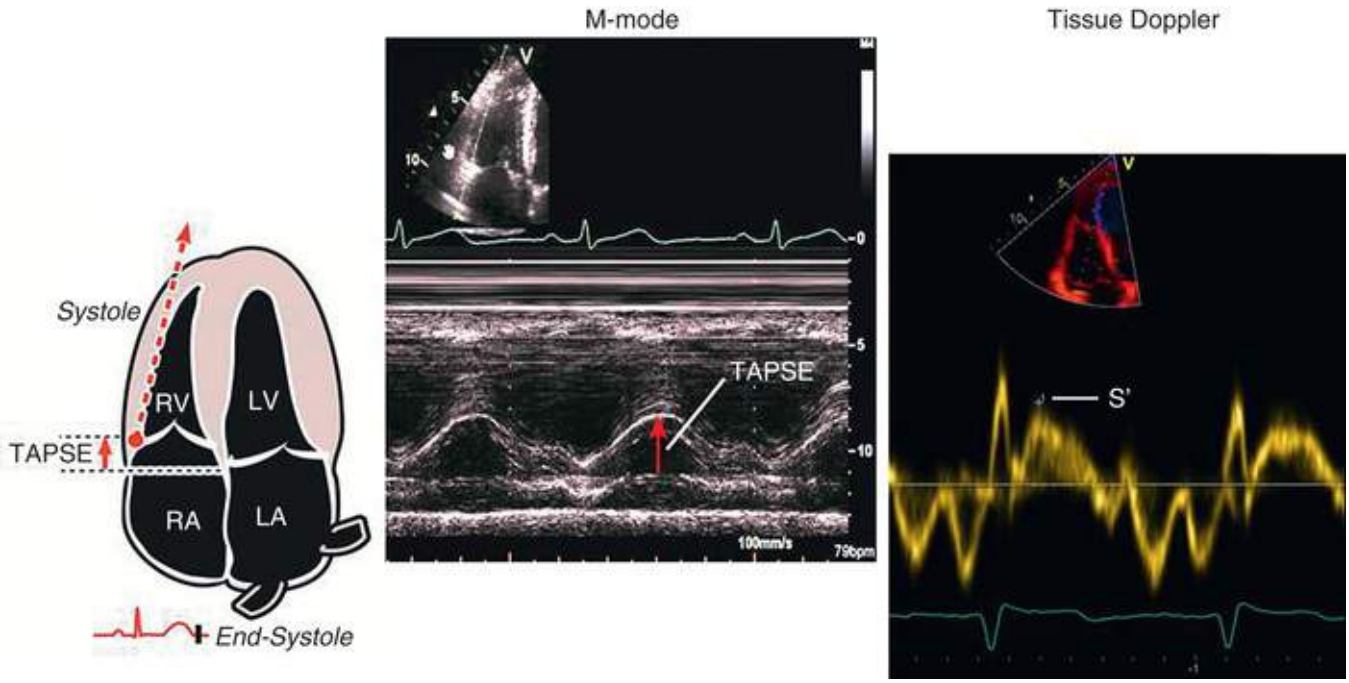

FIGURE 14.20 M-mode and Doppler tissue imaging (DTI) measurements of RV systolic function. **Left and middle panels,** On M-mode, the tissue annular plane systolic excursion (TAPSE) can be measured. **Right,** DTI is used to map tricuspid annular motion, where S′ is the analogous measurement to TAPSE.

Three-dimensional imaging of the right ventricle is now available, and reconstructed views beautifully illustrate its geometric complexity (**Fig. 14.21**). 3D imaging allows for calculation of volumes that are not as angle dependent as all the measures previously discussed. Image acquisition still relies on an experienced sonographer, and the volume measurements require additional training, are only semiautomatic, and must to be done off-line. However, normal reference values for RV volumes and RV ejection fractions now exist (**see Tables 14.5 and 14.6**).[2] Similar to LV volume data, the accuracy appears comparable with that of CMR imaging, although volumes tend to be lower on echocardiography.

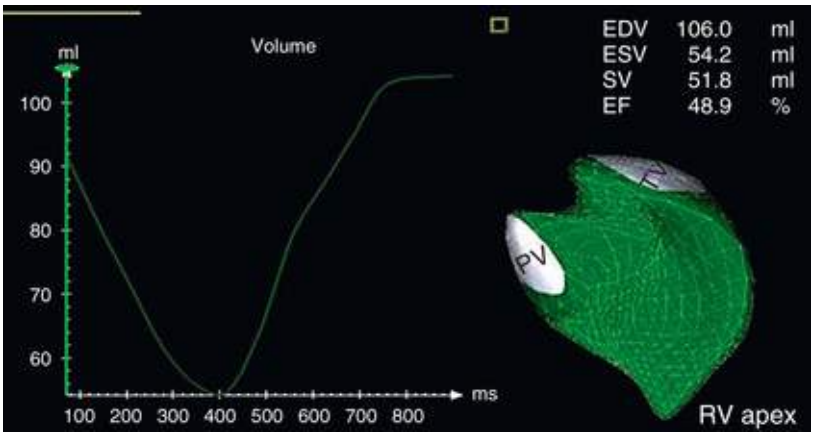

FIGURE 14.21 Three-dimensional measurements of right ventricular (RV) volume and function. A 3D echocardiographic reconstruction of the RV shape and volume, as viewed from the septal surface. The graph at *left* shows RV volumes plotted against time over the cardiac cycle, with data obtained from RV-focused apical four-chamber windows. RV stroke volume (SV) = EDV − ESV. RV ejection fraction (EF) =SV/EDV. *EDV,* end-diastolic volume; *ESV,* end-systolic volume; *PV,* pulmonic valve; *TV,* tricuspid valve.

Left and Right Atria

LA enlargement has been associated with adverse cardiovascular outcomes. The left atrium enlarges under several pathologic conditions, including LV systolic and diastolic dysfunction and atrial fibrillation (AF). Other frequent causes of LA enlargement include hypertension and mitral valve regurgitation or stenosis. LA size is thought to reflect LV filling pressure and thus has been considered a useful indicator of diastolic function over time. Several methods can be used to quantify LA size. A linear measurement of the left atrium is traditionally obtained on the parasternal and in the early days of echocardiography was the initial screen of LA size. A longstanding reference standard for parasternal long-axis LA dimension has been 3.8 cm as the upper limit of normal in women and 4.0 cm in men (or 2.3 cm/m^2 BSA for both). Other axes in the apical windows may also be measured. However, any single linear measurement is inadequate, and LA area is more fully assessed from orthogonal apical views, with volume subsequently calculated by applying the Simpson biplane method. Volumes are typically indexed to body surface area (BSA; **see Table 14.2**). LA function contributes to overall cardiac performance and is itself also affected by LV compliance.

Assessment of the right atrium is best performed from the apical and subcostal views. Right atrial (RA) size is a reflection of right-sided filling pressure and volume. The most frequent causes of RA enlargement are AF and tricuspid regurgitation. Isolated right heart enlargement should always raise the question of whether interatrial (left-to-right) shunting is occurring, and a search for an atrial septal defect should be undertaken with intravenous saline contrast if necessary. Biatrial enlargement can occur with AF or with restrictive cardiomyopathy.

Indexed RA volumes based on volumetric assessment are similar to LA volumes in healthy men and are slightly smaller in healthy women (**eTable 14.2**). Assessment of both the right atrium and the inferior vena cava (IVC) is important in the estimation of RA pressure, which is essential for calculating pulmonary artery systolic pressure from tricuspid regurgitant velocity. Qualitative evidence of elevated RA pressure includes a dilated right atrium, dilation of the IVC, or attenuation of IVC collapse during inspiration. Several methods have been used to estimate RA pressure by echocardiography, but most involve a combination of IVC size and the amount that the IVC collapses with inspiration. A rough scale of RA pressure has been developed that combines assessment of IVC size and respirophasic collapse (**Table 14.7**): complete (>50%) collapse, RA pressure of 0 to 5 mm Hg; partial collapse, 5 to 10 mm Hg; and no (<50%) collapse, 15 mm Hg.[16] Notably, the IVC is occasionally dilated in healthy young individuals and

in athletes, particularly when imaged completely supine.

TABLE 14.7

Estimation of Right Atrial Pressure Based on Inferior Vena Cava (IVC) Diameter and Collapse

VARIABLE	NORMAL (0-5 [3] mm Hg)	INTERMEDIATE (5-10 [8] mm Hg)		HIGH (15 mm Hg)
IVC diameter	≤2.1 cm	≤2.1 cm	>2.1 cm	>2.1 cm
Collapse with sniff	>50%	<50%	>50%	<50%
Secondary indices				Restrictive filling by tricuspid valve inflow Tricuspid E/e′ >6 Diastolic flow predominance in hepatic veins (systolic filling <55%)

Ranges are provided for low and intermediate categories, but for simplicity, midrange values of 3 mm Hg for normal and 8 mm Hg for intermediate are suggested. Intermediate (8 mm Hg) RA pressures may be downgraded to normal if no secondary indices of elevated RA pressure are present, upgraded to high if minimal collapse with nasal inhalation (<35%) and secondary indices of elevated RA pressure are present, or left at 8 mm Hg if uncertain.

ETABLE 14.2

Normal Right Atrial (RA) Size Obtained From Two-Dimensional (2D) Echocardiographic Studies

	WOMEN	MEN
RA minor axis dimension (cm/m^2)	1.9 ±0.3	1.9 ±0.3
RA major axis dimension (cm/m^2)	2.5 ±0.3	2.4 ±0.3
2D echocardiographic RA volume (mL/m^2)	21 ±6	25 ±7

Data are expressed as mean ±SD.

Transesophageal Echocardiography

TEE is an alternative method to obtain ultrasound images of the heart in which a smaller ultrasound transducer is introduced into the patient's esophagus through a manipulable flexible probe. Similar to transthoracic scanning, multiplane 2D and 3D, color flow, and spectral Doppler imaging can be performed at the bedside, but with a higher-frequency transducer and from a position that is posterior and closer to the heart than can be achieved with TTE. The result is superior image quality and spatial resolution with less artifact with TEE, particularly when assessing the left atrium and left-sided valves, which are directly adjacent to the esophagus. Because it is semi-invasive, TEE is generally used as an adjunctive or follow-up test to an initial TTE if additional information is sought or the TTE images are inconclusive. **Table 14.8** summarizes the advantages and disadvantages of TTE versus TEE.

TABLE 14.8

Advantages and Disadvantages of Transesophageal Echocardiography (TEE) Relative to Transthoracic Echocardiography (TTE)

ADVANTAGES	DISADVANTAGES
Useful in percutaneous and surgical procedures, as well as at the bedside	Semi-invasive—usually requires sedation, hence associated risks with probe intubation (gastrointestinal and pulmonary implications) and sedation effects (hypotension). Long procedures may necessitate general anesthesia. Generally a minimum of two staff members required: one operator and one person to monitor the sedation needed
Higher resolution: better to definitively detect vegetations, thrombi, masses, and intracardiac shunts. Superior imaging of valves, especially the mitral and aortic, left atrium and appendage, left ventricle, thoracic aorta and arch, and interatrial septum, as well as the pulmonary veins	May not view the LV apex or right-sided structures well (structures that are further from probe, particularly in large patients)
"Continuous" acoustic window when compared with TTE (no ribs to cause acoustic shadowing)	"Blind spot" of acoustic shadowing where the trachea is interposed between the esophagus and heart Much of the abdominal aorta is out of range
Superior imaging of the mitral valve and mitral prostheses in general, with the ability to precisely localize valvular and paravalvular defects	Mechanical aortic prostheses can cause excessive shadowing May be technically difficult to achieve the best angle of insonation (i.e., less reproducible and accurate) for assessing aortic stenosis gradients Maneuvers to increase or decrease preload may be more difficult (e.g., Valsalva maneuver), although most patients can cooperate Real-time 3D imaging and reconstruction dependent on a slow regular heart rate and "stable" window (i.e., still patient)

TEE is particularly useful in the evaluation of valve dysfunction, diagnosis or follow-up of endocarditis (**see Chapter 73**), searching for potential causes of stroke, and better characterization of cardiac masses and congenital heart disease. In some circumstances, TEE is appropriately the first test of choice, such as evaluation of aortic pathology and assessment for LA appendage thrombi[17] (see Diseases of the Aorta and Cardiac Masses). TEE can be used to determine the presence of thrombus in patients in whom rapid cardioversion of AF is necessary (**see Chapter 38**) or when elective atrial arrhythmia ablation/cardioversion is planned, particularly in the patient found to be underanticoagulated or at high risk for stroke[18] (**eTable 14.3**). In addition, TEE has a major role in optimizing and evaluating cardiac surgical and percutaneous procedures, particularly with respect to valvular procedures, closure of intracardiac shunts, and implantation of LVADs.[19-21]

ETABLE 14.3

Indications for Transesophageal Echocardiography–Guided Cardioversion

APPROPRIATE	INAPPROPRIATE
CHF exacerbation or hemodynamic compromise	Stable with therapeutic anticoagulation >3 weeks
Symptomatic from AF	AF <48 hours (insufficient time for thrombus to form)
Hospitalized and symptomatic	Permanent AF (sinus rhythm unable to be sustained after cardioversion)
New-onset AF (first-time diagnosis)	Hospitalized but asymptomatic
High stroke risk (including history of stroke or TIA, previous history of LA thrombus, rheumatic heart disease, HOCM)	
Subtherapeutic anticoagulation (INR <2) within preceding 3 weeks, or significant interruption in NOAC therapy	
Miscellaneous (including need for TEE unrelated to AF but otherwise appropriate, such as evaluation of valve function or endocarditis, with timing of TEE coincidentally helpful for expediting cardioversion)	

AF, Atrial fibrillation; *CHF,* congestive heart failure; *HOCM,* hypertrophic obstructive cardiomyopathy; *INR,* international normalized ratio; *TIA,* transient ischemic attack; *NOAC,* non–vitamin K antagonist oral anticoagulant.

TEE may be performed on an inpatient or outpatient basis, and most patients require topical anesthesia and/or intravenous (IV) conscious sedation for comfort. This is usually achieved with IV midazolam and fentanyl or alternatively with propofol if issues with respiratory or hemodynamic stability or patient comfort are anticipated. Risks are relatively low but include trauma to the oropharynx and esophagus, aspiration, bronchospasm or laryngospasm, accidental tracheal intubation, and arrhythmia, as well as risks associated with sedation (transient hypotension).[19,22] General anesthesia is used for patients in the

operating room and appears associated with higher complication rates (as high as 1.2% for major complications). The most serious complication is upper gastrointestinal perforation, which typically occurs in the esophagus or hypopharynx. Patients with esophageal diverticular strictures, significant thoracic radiation-induced fibrosis, distorted anatomy of the mediastinal organs, or difficult probe placement are at higher risk. TEE may also cause bleeding (0.02% to 1.0%) from direct abrasion of the mucosa, esophageal varices, or tumor. The overall risk for major adverse events with TEE is 0.2% to 0.5% in the nonsurgical setting, and the overall mortality rate is exceedingly low (0.0004%). These risks may be minimized by screening patients for potential contraindications (**eTable 14.4**); if one is found, TEE is best deferred until the situation can be better assessed or ameliorated. Alternatively, another imaging modality (e.g., intravascular ultrasound or epiaortic scanning, CT, CMR) or strategy could be considered if an underlying risk factor cannot be mitigated.

ETABLE 14.4

Relative Contraindications to Transesophageal Echocardiography and Potential Strategies

RELATIVE CONTRAINDICATION	POTENTIAL STRATEGIES
Esophageal strictures or diverticula	GI consultation to evaluate, consider use of a pediatric TEE probe or limited TEE only to a depth proximal to the lesion
Esophagitis, especially radiation induced	GI consultation to evaluate, consider alternative procedure
Esophageal varices or recent UGI bleeding	GI consultation to evaluate, correct any coagulopathy, limit TEE only to a depth proximal to the lesion, avoid unnecessary probe manipulation
Recent esophageal dilation or UGI surgery	GI/surgery consultation, consider delaying TEE to at least 4-6 weeks, consider limited TEE proximal to the intervention
Unstable airway and/or hemodynamically tenuous or unstable	Consider intubation and pressors
Unstable cervical spine (e.g., after trauma)	Stabilize with a cervical spine collar, consider paralysis, neurologic and/or orthopedic consultation to clear
Uncooperative patient, restricted cervical mobility	Anesthesia consultation for intravenous propofol, consider higher levels of sedation or general anesthesia
History of significant opioid use/abuse	Anesthesia consultation for intravenous propofol
Severe coagulopathy or thrombocytopenia	Consider correction with blood products and vitamin K

GI, Gastrointestinal; *UGI,* upper GI.

The Standard Transesophageal Echocardiographic Examination

Fig. 14.22 shows a standard TEE examination. It is usually prudent to address the main indication first in the event that the examination must be aborted because of clinical instability. If the patient remains stable, a comprehensive examination is performed, with the majority of the images at the midesophageal level (probe tip approximately 35 cm from the incisors). For a frame of reference with respect to the imaging planes, at midesophageal level when the transducer angle set at 0 to 30 degrees and flexed, the imaging plane cuts the heart in a short-axis (transverse) plane. A TEE transducer angle of 90 to 120 degrees corresponds to a long-axis (longitudinal, or sagittal) plane.

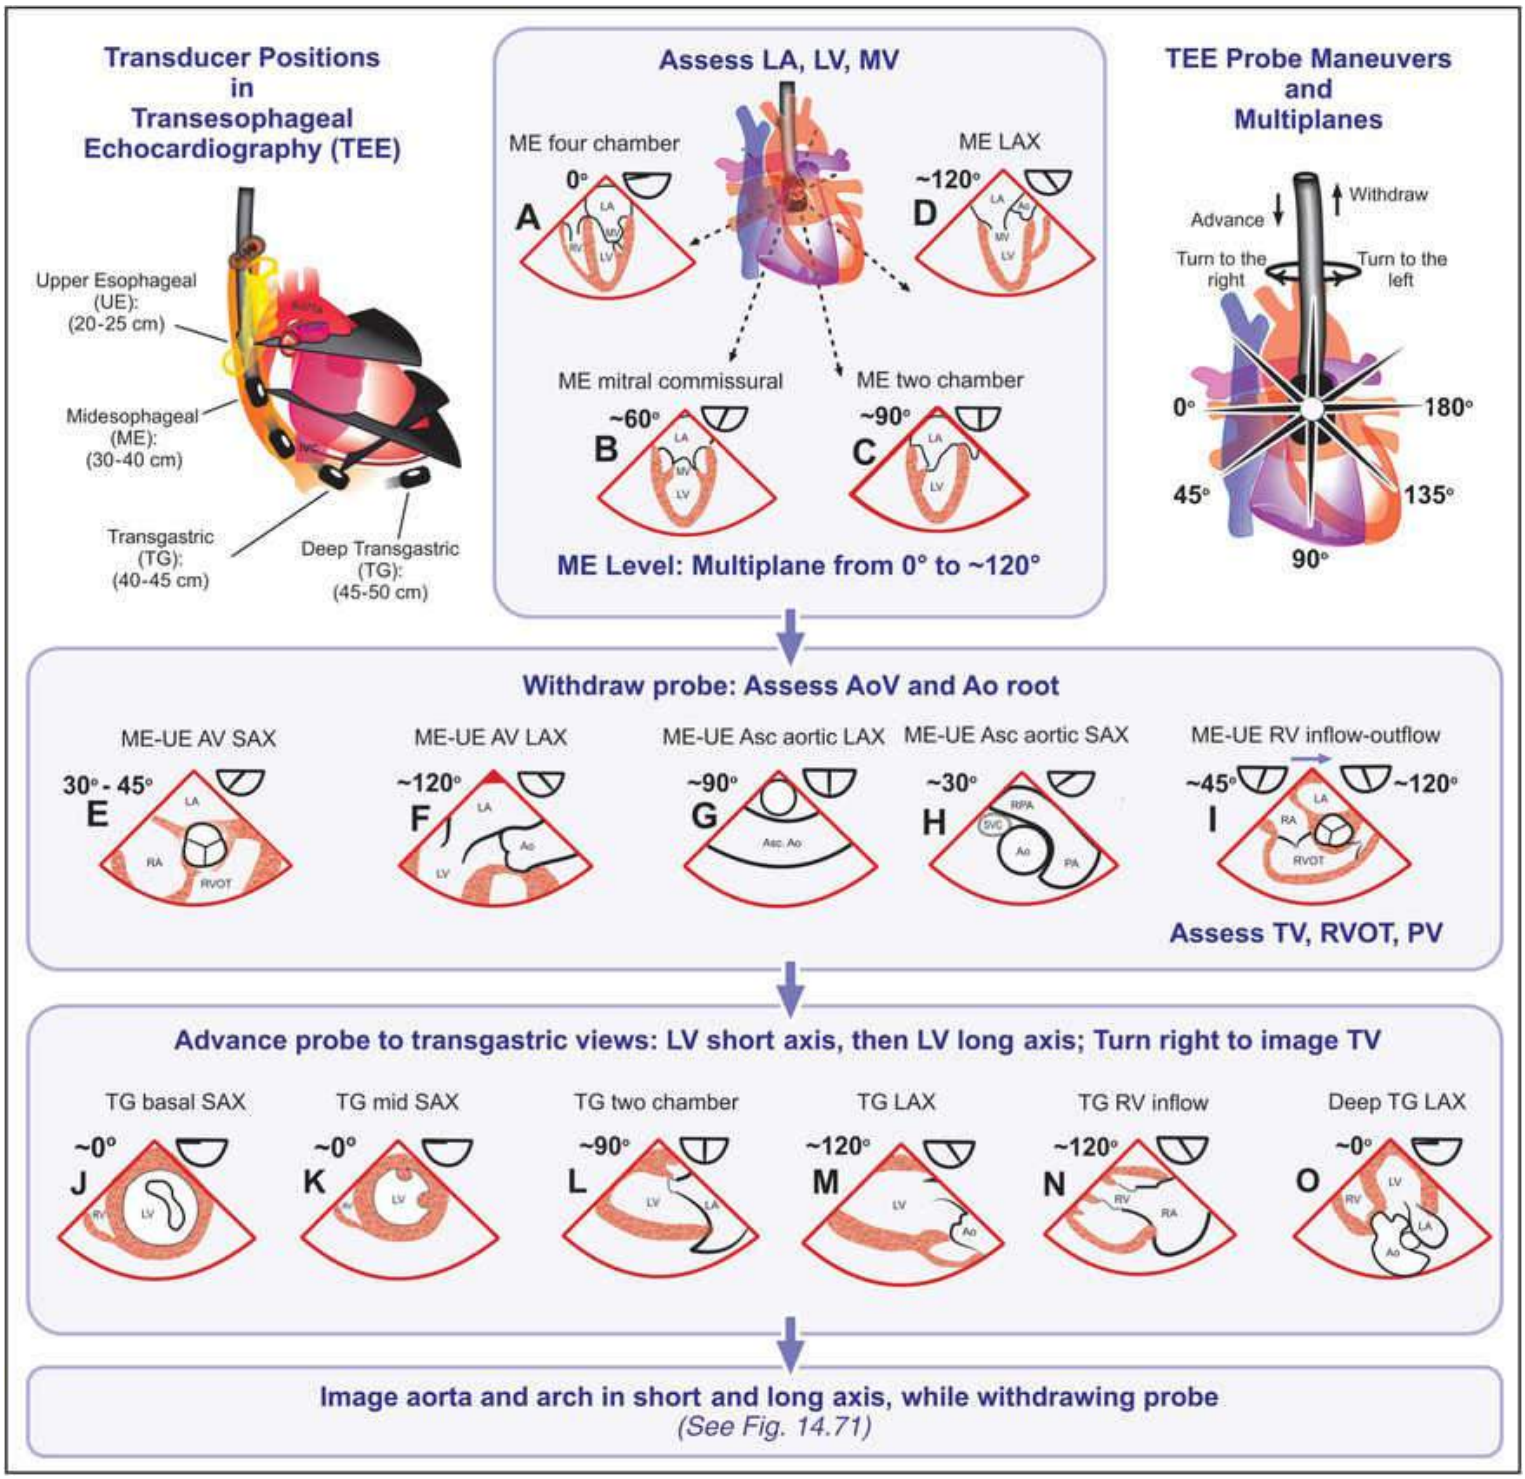

FIGURE 14.22 A suggested standard TEE examination, showing basic probe positioning, manipulations, and views. The sequence illustrated allows a basic survey of all the cardiac chambers and valves. Additional views are obtained as required for the specific indication. *Ao,* Aorta; *AoV,* aortic valve; *Asc,* ascending; *AV,* aortic valve; *Desc,* descending; *LAX,* long axis; *ME,* midesophageal; *PV,* pulmonic valve; *SAX,* short axis; *TG,* transgastric; *TV,* tricuspid valve; *UE,* upper esophageal.

Most transesophageal examinations start with the standard four-chamber view of the heart, similar to the transthoracic apical four-chamber view. At midesophageal level, 0 degrees, this is achieved by slight retroflexion of the probe to tilt the imaging plane in order to include the cardiac apex. At this level the multiplane "omni" controller is used to rotate the scanning plane counterclockwise to slice the left ventricle into two-chamber (approximately 90-degree) and then three-chamber (long-axis or 120-degree) views. These views are optimal for assessing the left ventricle, left atrium, and mitral valve structure and function. If desired, the LA appendage may be thoroughly examined by withdrawing the probe slightly cephalad, centering the image sector on the appendage, and scanning from 30 to 150 degrees. To examine

the aortic valve, the operator retracts the probe slightly, and the aortic valve should be imaged just superior to the mitral valve, at approximately 30 degrees for short-axis images and 120 degrees for long-axis views. The tricuspid valve may be examined at approximately 45 degrees, with subsequent views of the right ventricular outflow tract (RVOT), pulmonary artery and valve, and pulmonary bifurcation sought by gradually increasing the omni angle up toward 120 degrees again. Minor additional manipulations of the TEE probe and transducer angle will provide views of the pulmonary veins, right atrium, interatrial septum, superior vena cava (SVC), IVC, coronary sinus, and abdominal aorta. For transgastric windows, the TEE probe is advanced gently past the gastroesophageal sphincter with the transducer plane reset back to 0 degrees. One can view the left ventricle and mitral valve in the short axis and also obtain transaortic gradients from an apical five- or three-chamber view if needed. By increasing the omni angle up to 90 degrees and rotating the transducer plane to the right, more detailed views of the tricuspid valve and right side of the heart are attainable. Lastly, the thoracic aorta is usually examined in cross-sectional and longitudinal views as the probe is withdrawn, to document any significant atherosclerosis or other pathology.

Three-Dimensional Echocardiography

Acquisition and display of 3D images have been a long-term goal of echocardiography. Although 3D datasets can be obtained from transthoracic or transesophageal rotational acquisition, true 3D echocardiography is accomplished by using a matrix-array transducer that emits and receives beams of ultrasound in two dimensions (**Fig. 14.23**), which results in the acquisition of a pyramidal dataset in three dimensions. Matrix-array probes for both transthoracic and transesophageal use are available. The 3D datasets can be used to display simultaneous orthogonal 2D images (e.g., four- and two-chamber apical views) or a 3D-rendered image. 3D echocardiography offers the potential to better orient valvular structures (see Valvular Heart Disease) or congenital abnormalities and can be particularly useful in planning surgical and percutaneous interventions. As discussed earlier, 3D echocardiography can also improve the accuracy of quantification of LV and RV volume and function. Useful 3D imaging depends heavily on good 2D images, and in fact there is some loss of spatial and temporal resolution in comparison. However, 3D echocardiography has become extremely useful as a way to delineate complex structures that extend beyond one plane or to find and localize measurements and abnormalities that are difficult to encompass using 2D images. Examples include finding clefts and localizing prolapsed segments in the mitral valve, delineating paravalvular leaks, measuring the distance of the coronary artery origins from the aortic valve, and providing comprehensive quantitative analysis of the valve leaflets and annuli (**Fig. 14.24** and Video 14.2), as well as guiding percutaneous device implantation (see Cardiac Procedures). As technologic advances improve 3D image quality and the ability to interpret these images in real time, 3D acquisition is becoming standard in echocardiography and in the operating room.

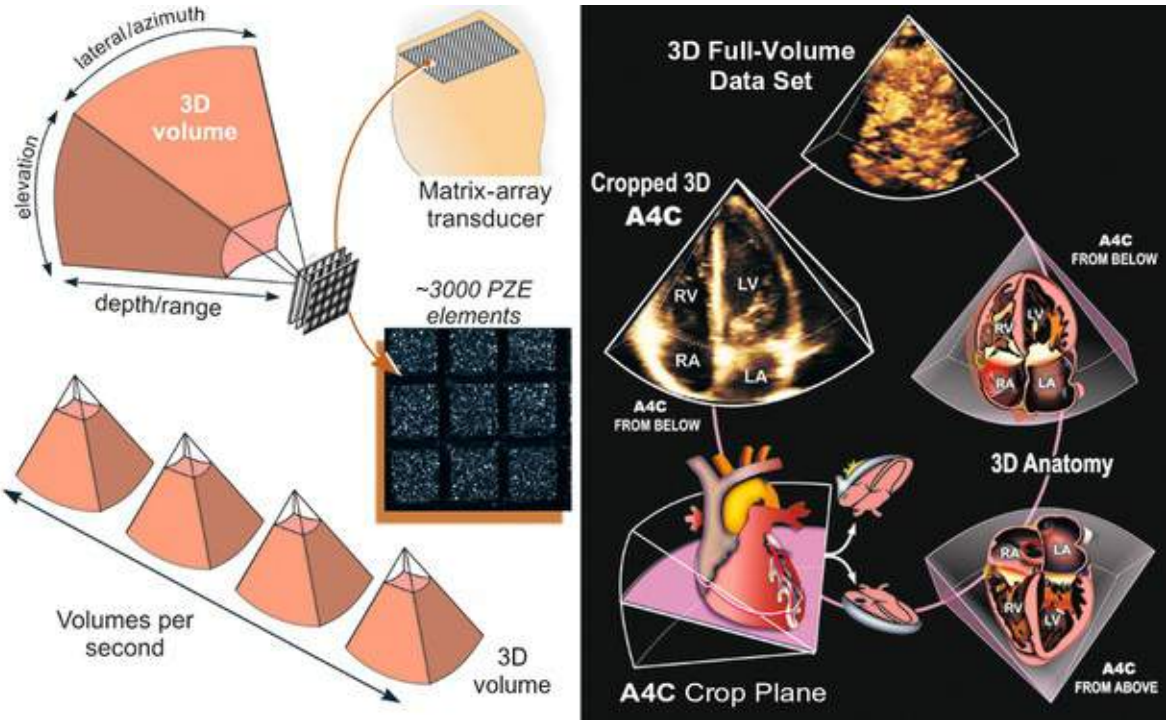

FIGURE 14.23 Three-dimensional echocardiography using a matrix-array transducer. A waffle-like matrix array **(left panel)** is used to obtain pyramidal "volumes" for real-time 3D data sets that can be cropped **(right panel)** and rendered in three dimensions. Alternatively, two-dimensional planes can be "cut" through any part of the 3D data set. *A4C,* Apical four-chamber view. (Modified from Bulwer BE, Rivero JM, editors. Echocardiography Pocket Guide: The Transthoracic Examination. Burlington, Mass: Jones & Bartlett Learning, 2011, 2013, p 208. Reprinted with permission.)

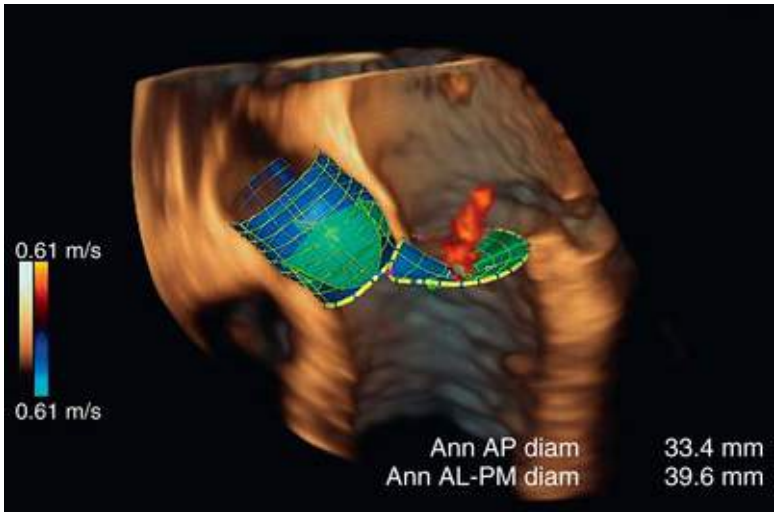

FIGURE 14.24 Three-dimensional TEE reconstructed view of the heart, showing the aortic and mitral valve geometry with mitral regurgitant jet (*red*) originating between the midscallops of the mitral valve. (See Video 14.2 for corresponding 4D images.)

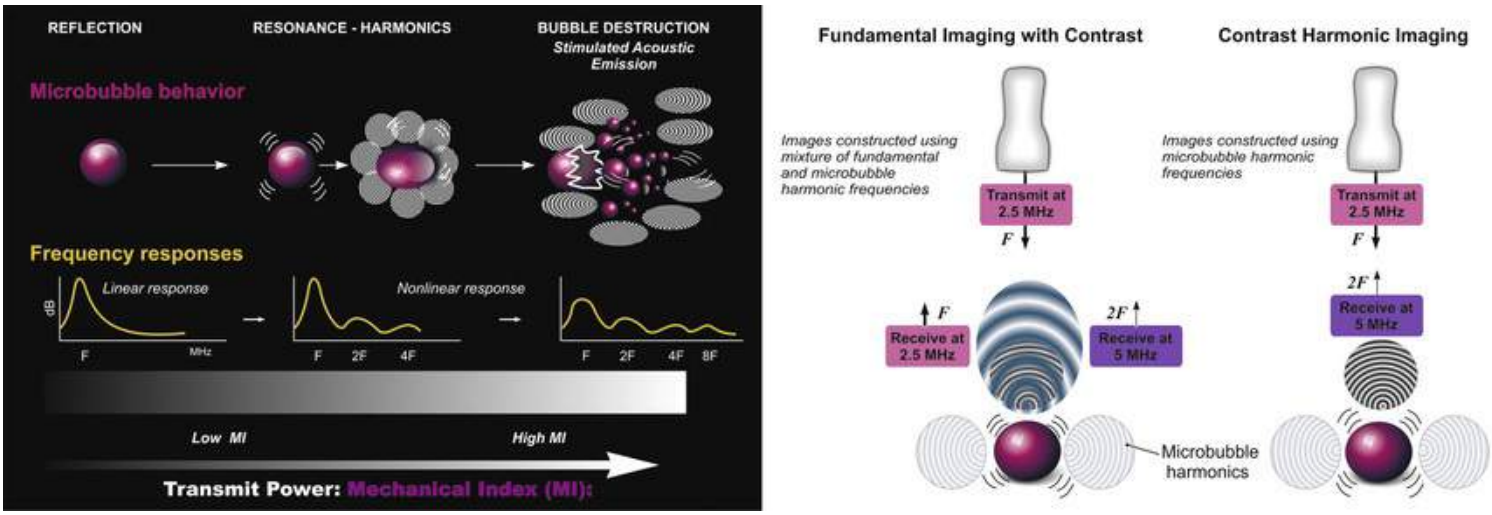
Contrast Echocardiography

Contemporary echocardiographic contrast agents are stabilized gas microspheres of 2 to 8 µm, similar in size to red blood cells, and can move through the circulatory system accordingly after IV injection. Currently approved agents consist of perfluorocarbon gases, chosen because of their resistance to diffusion into the blood, which are enclosed within either albumin or phospholipid shells. Unlike the larger bubbles created by agitating saline, commercial contrast bubbles are small enough to transit the pulmonary vascular bed and are therefore capable of opacifying the left side of the heart.

Because their shells are not rigid, contrast bubbles will contract in response to the peak acoustic pressure of the sinusoidal ultrasound wave and expand when acoustic pressure is at its trough. Optimal imaging of contrast agents capitalizes on the way in which this oscillation in size varies with ultrasound system transmit powers (mechanical index). When exposed to sound waves at lower mechanical indices, the bubbles will undergo resonant oscillation in a linear fashion and reflect sound at the same fundamental frequency. With higher transmit frequencies, the bubbles will resonate in a nonlinear fashion and reflect sound at both fundamental frequency and harmonic frequencies, multiples of the fundamental frequency. At even higher transmit powers, the bubbles will be destroyed, thereby generating very strong nonlinear backscatter of extremely short duration (**eFig. 14.14**). Therefore, to distinguish bubbles from surrounding tissue, ultrasound systems are set at mechanical indices (0.15 to 0.3) that will generate nonlinear resonance without bubble destruction and then selectively "listen" only at harmonic frequencies, thereby improving the strength of the bubble signal relative to that of tissue.



EFIGURE 14.14 Principles of contrast-enhanced imaging.

By opacifying the blood pool, contrast agents improve detection of the endocardial–blood pool interface and thus facilitate assessment of ventricular volume, as well as global and regional ventricular function[23,24] (**Fig. 14.25**). It has been demonstrated that contrast agents can convert nondiagnostic (defined as inadequate visualization of two or more of six LV segments seen on apical views) to diagnostic studies in up to 90% of patients. This can be particularly helpful in the intensive care unit (ICU), as well as with stress echocardiography, in which obtaining adequate images in the immediate postexercise period may be challenging. By better delineating the cardiac anatomy, contrast agents facilitate the discovery of aneurysms and diverticula, mechanical complications of MI such as free wall rupture and

pseudoaneurysms (Video 14.3), apical hypertrophy, transient apical ballooning, endomyocardial fibrosis, and the spongelike trabeculations of noncompaction cardiomyopathy. Contrast is also helpful in detecting intracardiac masses such as thrombi and tumors and assessing their vascularity. In addition, contrast agents may help distinguish imaging artifact from pathology (**Fig. 14.26**). Despite being considered off-label use, contrast agents may be used to intensify spectral Doppler signals, which may be particularly helpful in delineating transvalvular gradients in aortic stenosis (**eFig. 14.15**), and can delineate extracardiac pathology such as vascular dissection. Finally, in patients undergoing alcohol septal ablation for obstructive HCM (**see Chapter 78**), contrast agents are used to delineate the perfusion bed of target septal perforators.

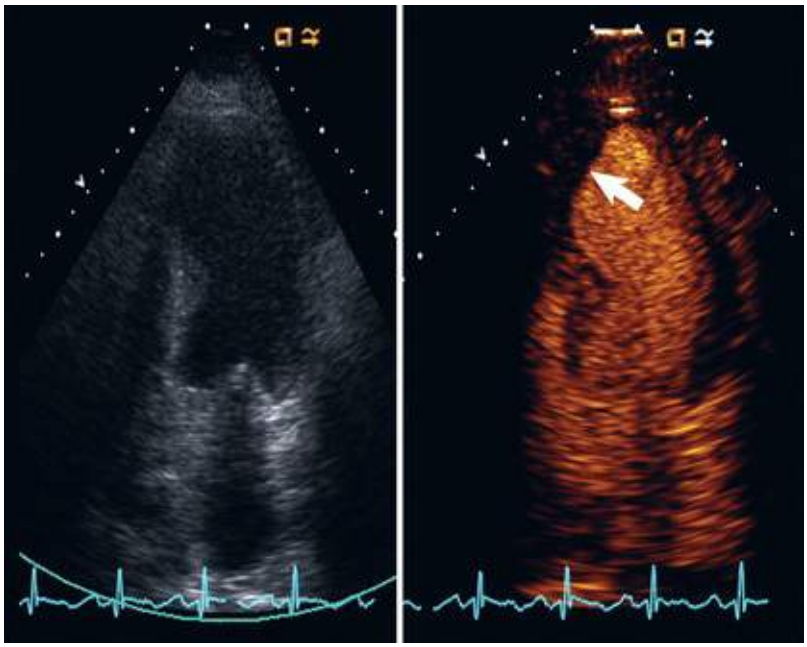


FIGURE 14.25 Unenhanced **(left)** and contrast-enhanced **(right)** apical four-chamber systolic images. In the unenhanced image it is impossible to define the endocardium, whereas with contrast enhancement the endocardium is clearly delineated and the straight margin characteristic of a sessile apical thrombus (*arrow*) is appreciated.

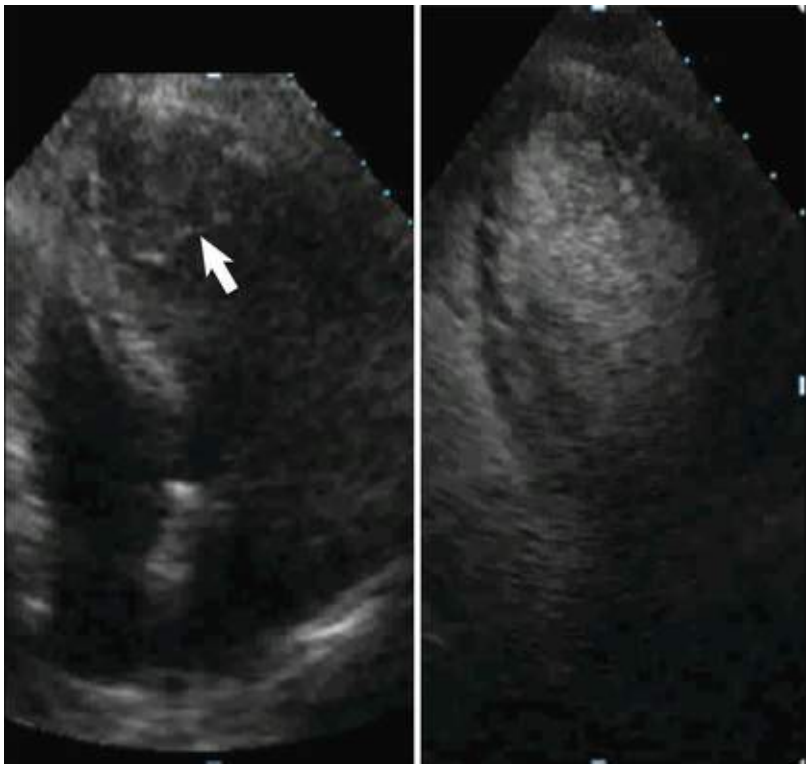

FIGURE 14.26 Apical four-chamber unenhanced **(left)** and contrast-enhanced **(right)** images. In the unenhanced image a thrombus-like structure is visualized in the apical region (*arrow*). The enhanced version shows that there is no filling defect, thus suggesting that this was an acoustic artifact and not a true thrombus.

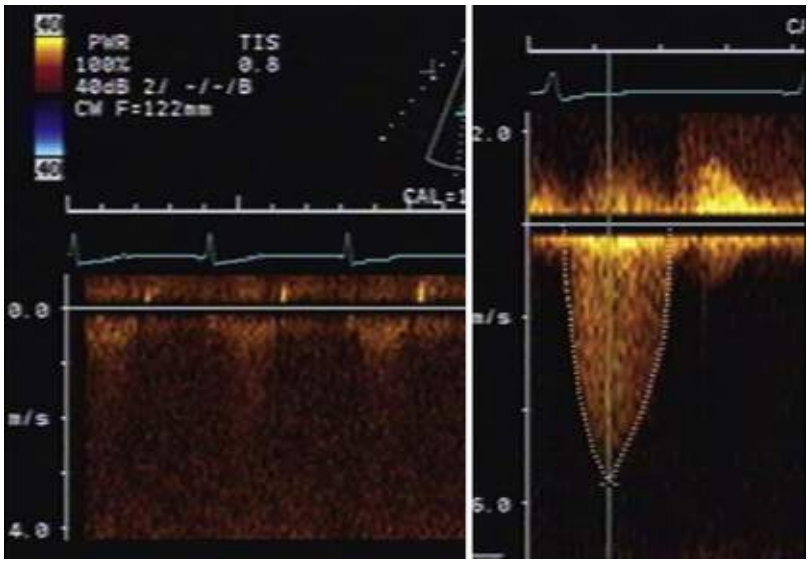

EFIGURE 14.15 Use of echocardiographic contrast to enhance CW envelopes. Baseline unenhanced Doppler spectra **(left panel)** in this patient with valvular aortic stenosis are indistinct. Following administration of contrast material **(right panel)**, the CW spectra are clearly defined.

Myocardial perfusion contrast-enhanced echocardiography is another application that is based on the ability of ultrasound to detect contrast bubbles within the myocardial vasculature. Approaches depend on the fact that a burst of ultrasound with a high mechanical index “flash” will predictably destroy all microbubbles in the sector, and the rate at which myocardial contrast will subsequently be replenished depends on myocardial blood flow (**Fig. 14.27**). There are two options for imaging protocols following the high–mechanical index flash: continuous low–mechanical index real-time imaging, which preserves the ability simultaneously to see wall motion in the segment, versus a higher–mechanical index approach

with progressively longer intervals between ultrasound frames, which enhances the perfusion signal but at the expense of attaining wall motion information. Although myocardial perfusion imaging has been shown to be of value in both rest and stress imaging for detecting ischemia (**eFig. 14.16**) and identifying viable but stunned or hibernating myocardium,[24] contrast perfusion imaging requires expertise to optimize and is not yet in mainstream use.

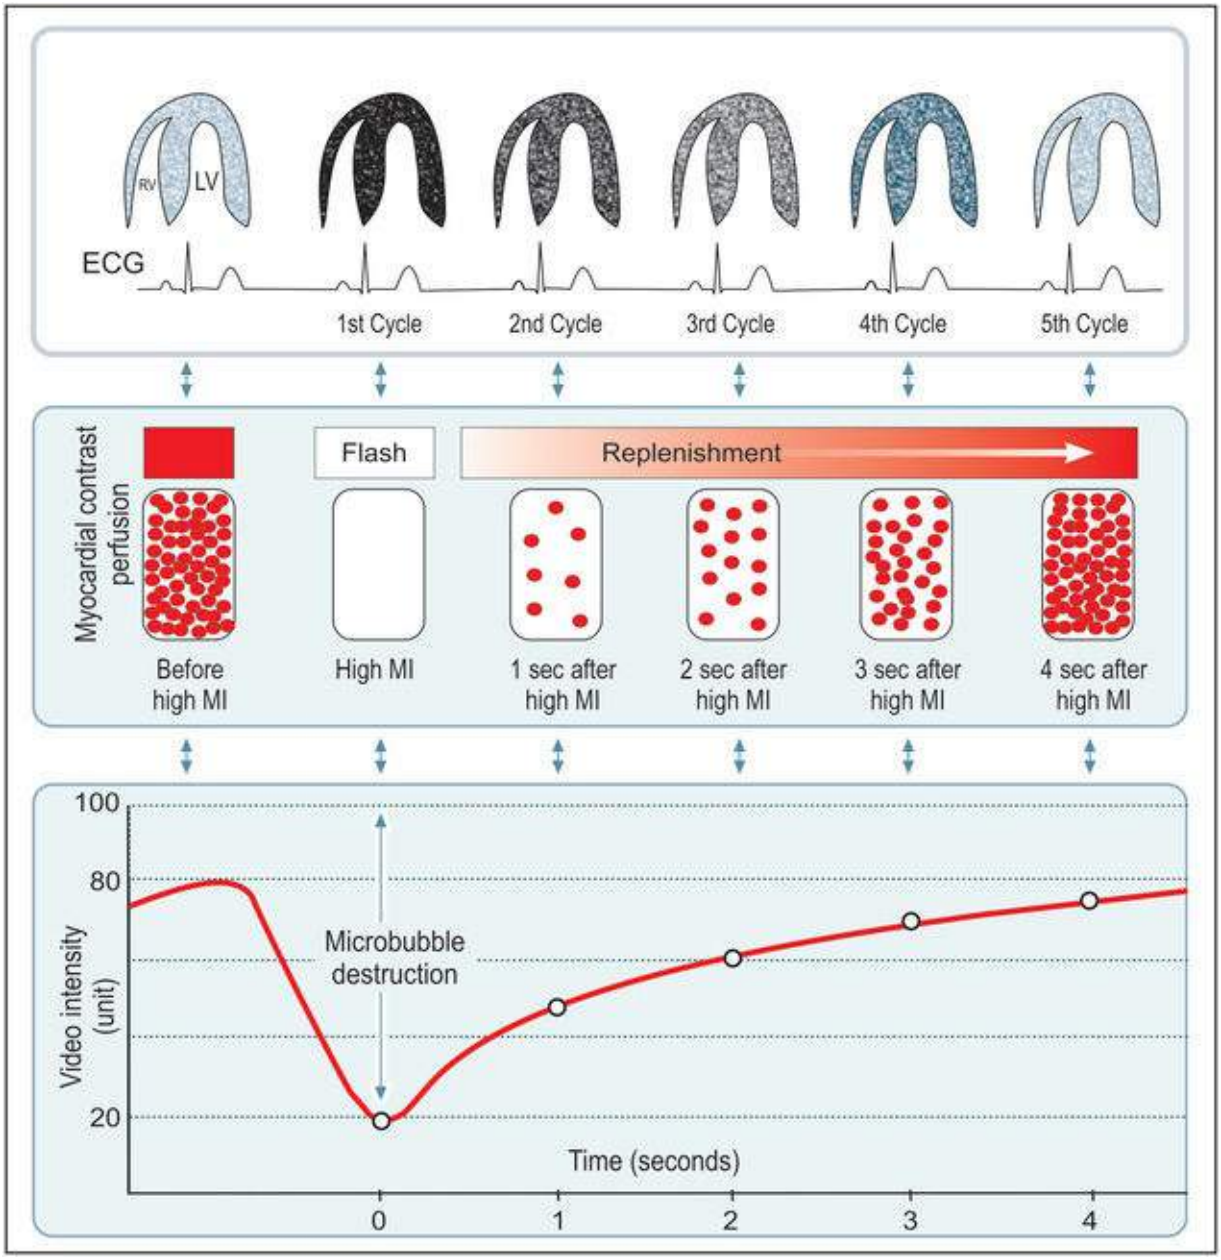

FIGURE 14.27 Myocardial contrast-enhanced echocardiography: schematic demonstrating the approach to myocardial perfusion imaging during steady-state infusion of a contrast agent. A high–mechanical index impulse (MI) destroys all the intramyocardial bubbles to yield an unenhanced image that will serve as the reference baseline. Subsequently, bubbles will return by coronary perfusion and progressively enhance the myocardium until a steady-state concentration is reached. This may be monitored by either a triggered approach in which imaging is performed on end-systolic images at increasing numbers of beats after the flash (1, 2, 3, 4, etc.) or by using low-MI continuous imaging. Enhancement will increase until a steady-state level is achieved (in this hypothetical example, at a five-beat pulsing interval or after 4 seconds of low-MI imaging). The rate at which replenishment occurs and the degree of enhancement under steady-state conditions, as quantitated by video intensity, reflect myocardial perfusion. (Modified from Wei K, Jayaweera AR, Firoozan S, et al. Quantification of myocardial blood flow with ultrasound-induced destruction of microbubbles administered as a constant venous infusion. Circulation 1998;97:473.)

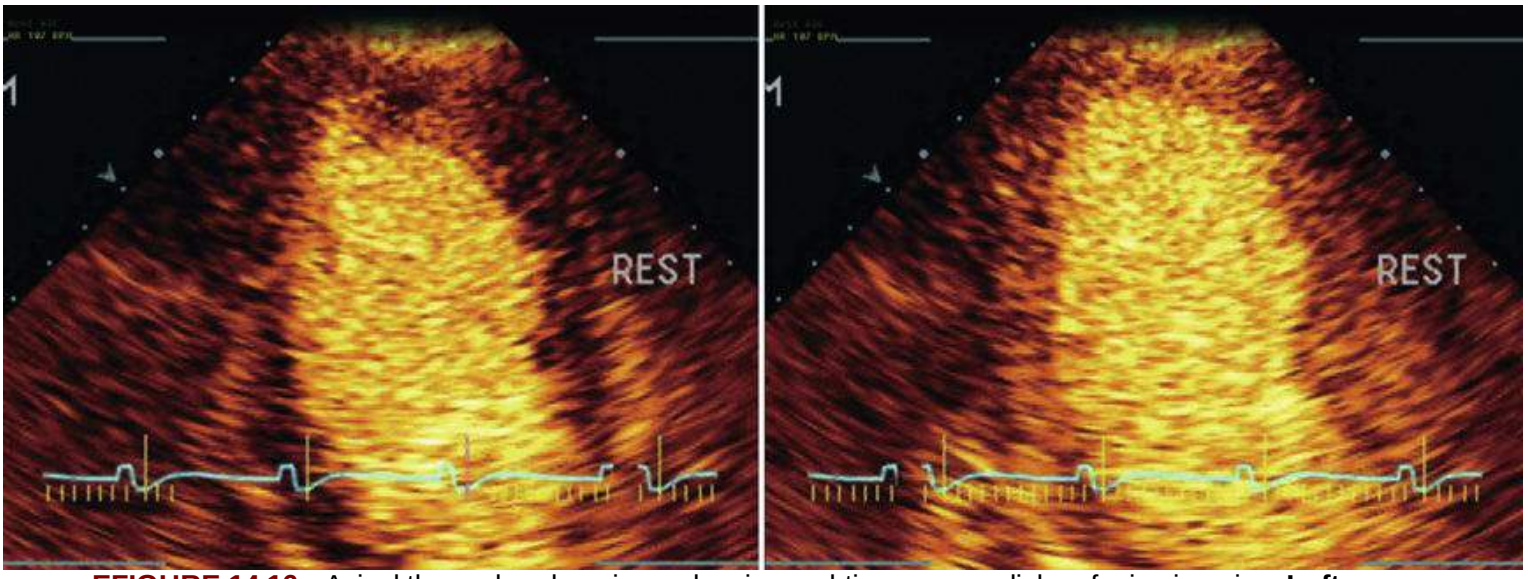

EFIGURE 14.16 Apical three-chamber views showing real-time myocardial perfusion imaging. **Left,** Unenhanced baseline immediately after a high–mechanical index impulse flash. **Right,** Uniform enhancement consistent with normal perfusion. (Courtesy F. Xie and T. Porter, University of Nebraska Medical Center.)

Echocardiography in the Context of Cardiac Imaging

The arsenal of noninvasive cardiovascular imaging modalities includes nuclear imaging (single-photon emission computed tomography [SPECT] and positron emission tomography [PET]), cardiac CT, and CMR (**see Chapters 16, 17, and 18**) and will undoubtedly continue to expand. Of these choices, echocardiography continues to hold the major advantage of being the most rapid, portable, and real-time imaging modality available today. Therefore, TTE or TEE is often the first tool used in emergency situations such as cardiac tamponade, aortic dissection, peri-infarct or postoperative complication, and shock, in which rapid assessment of a very unstable patient may be carried out at the bedside. When a large number of patients need to be screened or patients need to be monitored long term with serial examinations, the fact that ultrasound imaging involves no ionizing radiation or nephrotoxic dye is a particularly important consideration. It is thus ideal for monitoring valvular dysfunction, cardiotoxic chemotherapy, and cardiomyopathies. Although the spatial resolution of other modalities such as CMR or CT may be greater than that of echocardiography, the superior temporal resolution of TTE and TEE render these techniques ideal for detection of small mobile vegetations, thrombi, and fibrinous strands in the heart, which move too rapidly to be easily visualized by techniques with slower frame rates. On the other hand, PET with ^{18}F-fluorodeoxyglucose (FDG) has emerged as a sensitive method for detecting inflammation and abscesses (**see Chapter 73**) when suspicion of endocarditis and intracardiac abscess is high but TEE is nondiagnostic.[25] Use of contrast-enhanced CT for diagnosis of aortic dissections has increased over the past two decades, largely because of the increasing accessibility of high-speed scanners and their ability to scan the entire aorta expeditiously.

Stress echocardiography using either treadmill, bicycle, or pharmacologic (dobutamine or vasodilator) stress has proved to be more accurate than the exercise ECG alone for diagnosing flow-limiting CAD, particularly in women and patients with LV hypertrophy.[26] When compared with nuclear imaging, stress echocardiography is equally sensitive and specific. It also has the advantage of allowing simultaneous assessment of hemodynamics, valvular disease (particularly aortic and mitral stenosis), and estimation of pulmonary artery systolic pressures in the same examination. However, the presence of previous

infarcted segments, known multivessel CAD, and a left bundle branch block may decrease the sensitivity and specificity of stress echocardiography because of difficulty interpreting wall thickening in the presence of resting regional dysfunction and translational motion.

In addition to diagnosing structural abnormalities of the myocardium, pericardium, valves, and vessels, echocardiography can directly demonstrate the consequent physiologic and hemodynamic derangements. This is particularly true for pericardial effusions (**see Chapter 83**), in which echocardiography can demonstrate impending or actual tamponade in real time within seconds. For more refined tissue characterization, CMR often offers higher resolution and specificity in defining tumor characteristics such as tissue density and vascularity, infiltrative/inflammatory processes, and nontransmural fibrosis. CT is particularly useful in defining calcified cardiac structures, and CT angiography is capable of imaging the coronary arteries along their full extent much more reliably than echocardiography (provided that the patient has a relatively slow and regular heart rate). Defining the thickness of the pericardium is also another "Achilles heel" of echocardiography. Cardiac ultrasound is poorly sensitive for pericardial thickening, and CT and CMR provide a more sensitive and comprehensive method of evaluation. However, echocardiography remains the first-line modality for detecting the characteristic respirophasic septal bounce and respiratory variations in cardiac output caused by constriction and continues to be the mainstay of follow-up regardless of treatment.[27]

Acoustic shadowing from prosthetic valves, ventricular assist devices (VADs), calcification, or air between the transducer and the far-field portions of the heart can preclude adequate visualization of portions of the heart by echocardiography. In these cases, fluoroscopy and CT are useful alternative or adjunctive modalities. A common example would be the dysfunctional mechanical aortic prosthesis, which can be difficult to visualize directly on TEE because of acoustic shadowing. However, the valve discs and disc excursion are easily visible on fluoroscopy or CT angiography. Similarly, because the sternum and ribs impede transthoracic ultrasound imaging and the air-filled trachea produces a "blind spot" on TEE, echocardiographic evaluation of the aorta is limited to the proximal root, arch, and segments of the thoracic and abdominal aorta. However, for unstable patients (e.g., after a motor vehicle accident or those in profound shock), TTE or TEE is often the only suitable bedside tool and is sufficient rapidly to diagnose or rule out most type A dissections (**see Chapter 63**). With TEE one can also expeditiously determine whether the proximal coronary arteries and arch vessels are patent without the use of nephrotoxic contrast material.

It should be emphasized that in many cases the use of two or more modalities is appropriate and complementary to diagnose more definitively the nature and extent of a pathology and plan appropriate treatment. This is particularly true in cases of ischemic and nonischemic cardiomyopathy,[28] for which CMR and SPECT/PET and FDG methods can more clearly define the locations of hypertrophy, fibrosis, or inflammation. Extensive aortic dissections in which one needs to define precisely the extent to which major coronary, head, and systemic arteries are involved also often calls for multimodality imaging. Nuclear molecular imaging is also useful for confirming or refuting suspected diagnoses of sarcoidosis and ATTR amyloidosis (**see Chapter 77**) made initially on clinical and echocardiographic grounds.

Echocardiography can unfortunately render a variety of artifacts that mimic masses, thrombi, tumors, or mobile tissue flaps. Although most can be discerned as false findings by experienced sonographers, a minority may require additional tailored echocardiographic views in varying tissue planes to put the question to rest. The adjunctive use of 3D echocardiography and echocardiographic contrast can reveal the true nature of these artifacts without the nephrotoxic effects of the iodinated and gadolinium agents used in radiologic imaging.

Currently, the newer techniques for assessing tissue strain, dyssynchrony, and diastolic function have

evolved in almost parallel fashion in echocardiography and CMR.[29] These techniques have been used extensively in research and are being validated in a clinical setting with larger populations. In summary, although ultrasound and radiology continue to advance, familiarity with the relative advantages and limitations of each imaging modality greatly assists in determining which tool is best suited to answer the clinical question at hand.

Myocardial Infarction

Echocardiography plays an essential diagnostic and prognostic role in assessing patients during and after acute MI. Normal wall contractility (normokinesis) is seen as wall thickening caused by the contraction of individual myocardial fibers during systole. On echocardiography the radial distance between the epicardial and endocardial borders normally increases by at least 20% during systole. Global LVEF, as calculated by 2D echocardiography and preferably by the 2D biplane method of discs, provides an indication of overall infarct size and location. It has remained the single measure with the greatest prognostic and clinical significance during and after MI.

Myocardial ischemia affects LV systolic function both focally and globally. Focal hypokinesis—decreased systolic thickening—occurs within seconds of the onset of myocardial ischemia, before chest pain and changes on the ECG. This pathognomonic finding will occur in the region of the left and/or right ventricle supplied by the compromised artery (at least 70% stenosis) and give the appearance of a hinge point compared with adjacent perfused segments (Video 14.4). Ischemia may also manifest as delayed contractility of a segment. Ischemia is a dynamic condition, and if sufficient blood flow is restored in time, either through a decrease in metabolic demand (as when a stress test ends) or through reperfusion, contractility of the affected segment can recover rapidly. However, after reperfusion, a marked reduction in LVEF during the initial few days after MI can be secondary to myocardial stunning rather than permanent myocardial dysfunction and can improve substantially over days to weeks[30,31] (**see Chapter 57**).

Persistence or increasing severity of the wall motion abnormality after the initial insult implies that the tissue is becoming nonfunctional (i.e., not metabolically active or hibernating) or nonviable (infarcted). Akinetic myocardial segments do not thicken at all, and dyskinetic segments bulge paradoxically outward in systole, thus implying that no functioning myocardium is present. Thinning of the walls to less than 6 mm, echo brightness, and dyskinesis usually indicate scar. Sudden dilation of the left ventricle and a decrease in the LVEF are predictive signs of larger areas of ischemia (more proximal and/or multivessel disease). More refined techniques, including IV echocardiographic contrast enhancement to examine myocardial perfusion, low-dose dobutamine echocardiography, or regional strain analysis, may be useful in demonstrating whether segments that are still akinetic after reperfusion remain viable but hibernating.[31]

Specific regions in the heart can be mapped to specific coronary artery territories (**Fig. 14.28**), thereby allowing determination of the infarct-related vessel in patients with MI or detection of ischemic territory during stress echocardiography (see later, Stress Echocardiography). Very proximal CAD can actually be detected by examining the ostia of the coronary arteries with TEE. A proximal coronary artery stenosis will cause wall motion abnormality in a large territory (i.e., an entire wall from base to apex), whereas more distal blockage will affect only more apical segments. An acute left main occlusion will result in such extensive dysfunction (anterior septum, anterior and lateral walls) that if untreated, is usually lethal. Proximal right coronary artery (RCA) lesions can additionally cause RV dysfunction and infarction (Video 14.5). The presence of previously existing CAD can modify the extent of new wall motion

abnormalities seen during acute MI. Small collateral vessels from other unobstructed coronary arteries can develop and perfuse the peripheral territory of affected vessels, thus diminishing the dysfunctional territory. Wall motion scoring can be used as a complementary tool to the ejection fraction for quantifying the extent and severity of LV systolic function (**see eFig. 14.10**).

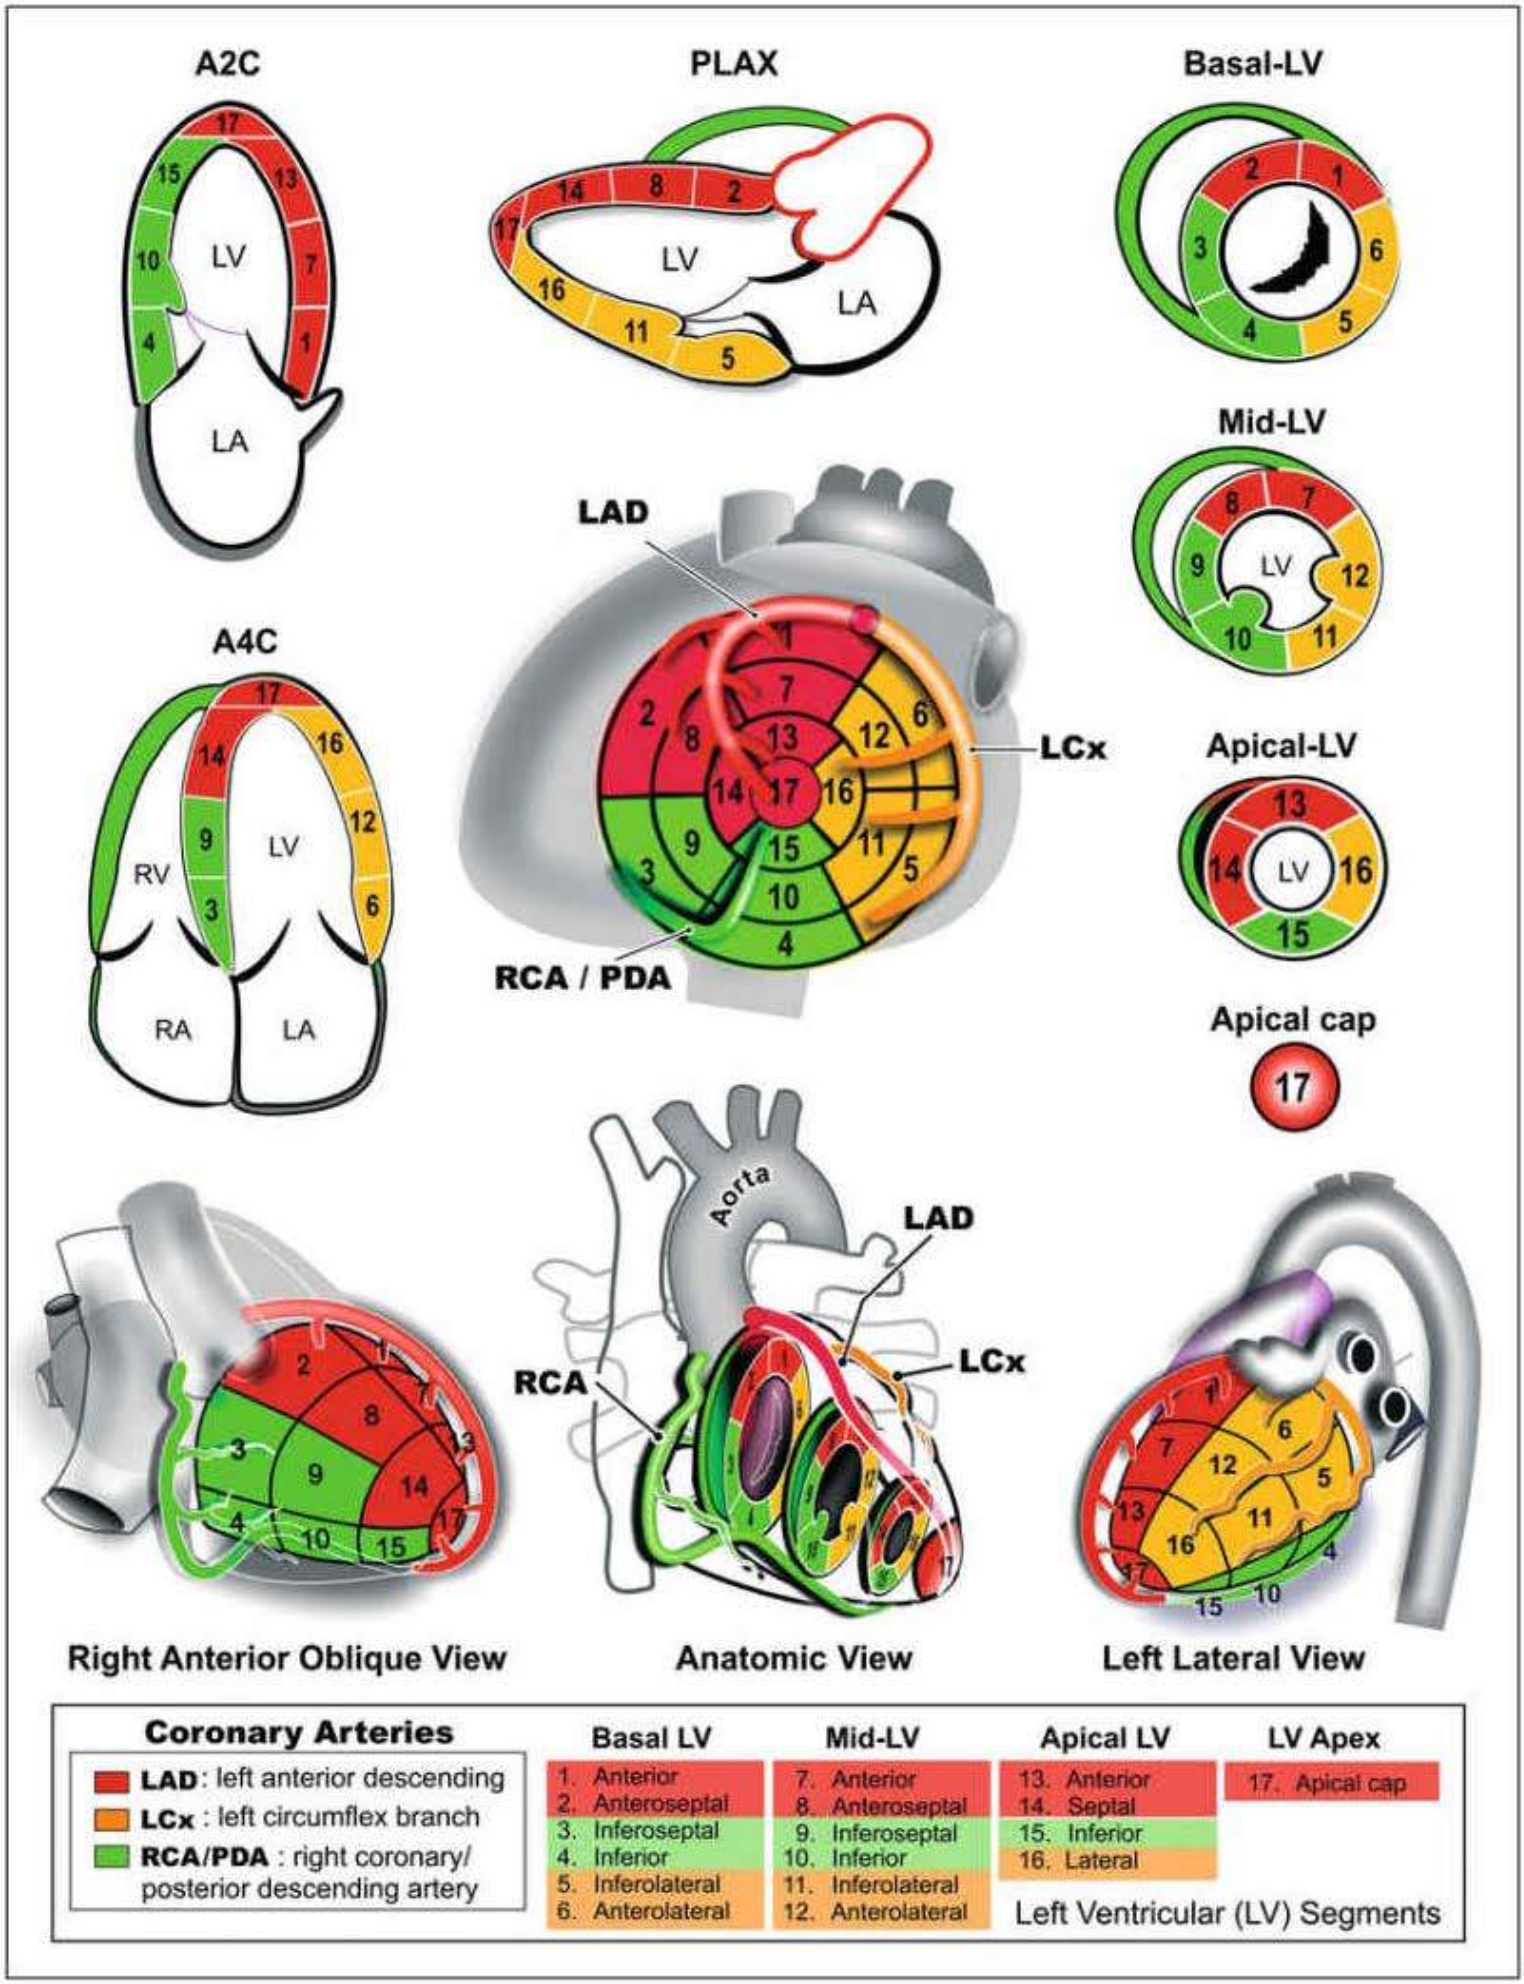

FIGURE 14.28 Coronary artery territories. The main epicardial coronary arteries each supply distinct myocardial territories, which may be mapped and evaluated during the ultrasound examination. For standardization, the left ventricle (LV) is divided along the long axis into anterior, inferior, septal, and lateral

quadrants. At the basal and midventricular levels, the septal and lateral walls are further subdivided into anterior and inferior segments. Each wall is further sectioned in short-axis planes into basal, middle, and apical thirds, with the distal apex beyond the LV cavity forming a cap segment, to yield a total of 17 wall segments. Most of the blood supply to the heart is from the left main coronary artery, which divides into the left anterior descending (LAD) and left circumflex (LCx) arteries. The LAD supplies most of the anterior ventricular wall, and its septal branches supply the anterior two thirds of the septum. In addition, diagonal branches of the LAD supply the anterolateral wall. Large LADs may wrap around the apex of the heart and supply the distal-most portion of the inferior wall. The LCx runs in the atrioventricular groove, and its obtuse marginal branches supply the inferolateral wall. The right coronary artery (RCA) supplies blood to the inferior third of the septum and the inferior wall. The RCA also supplies the right ventricle. *A2C,* apical two-chamber view; *A4C,* apical four-chamber view; *LA,* left atrium; *PDA,* posterior descending artery; *PLAX,* parasternal long axis; *RA,* right atrium; *RV,* right ventricle. Reprinted with permission.)

Practical Considerations in Assessment of Regional Wall Motion

It is important to distinguish carefully between wall thickening as opposed to just epicardial or endocardial border movement during systole. The many pitfalls in diagnosing wall motion abnormalities include false positives because of poor visualization of the endocardium, superior angulation of the probe such that the membranous nonmuscular portion of the upper interventricular septum is misinterpreted as a nonmoving myocardial segment, extracardiac compression of the inferior wall by ascites or abdominal contents (“pseudodyskinesis”), and paradoxical or dyssynchronous septal motion as a result of bundle branch block or the postsurgical state. False negatives, such as missing a wall motion abnormality that is present, can also occur because of poor image quality or off-axis imaging. Injection of an IV contrast agent can often help delineate the endocardial borders.

Notably, echocardiography in a patient who is free of chest pain at the time of imaging may not reveal a resting wall motion abnormality (because of decreased demand or reperfusion at that point in time). Furthermore, this technique is relatively insensitive for small areas of subendocardial or microvascular ischemia. Nevertheless, when a patient has ongoing acute chest pain but echocardiography does not reveal new wall motion abnormalities, a broader differential diagnosis than epicardial coronary artery occlusion must be entertained. Possible nonischemic cardiac causes of chest pain that can be also diagnosed by cardiac ultrasound include pericarditis, aortic or coronary aneurysm or dissection, myocarditis, cardiac contusion, and ruptured mitral chordae. Noncardiac causes include pulmonary emboli (which can cause acute right-sided heart dysfunction in a distinctive pattern), as well as gastroenterologic processes (e.g., reflux, peptic ulcer disease, esophageal spasm), pleuritis, and costochondritis.

Mechanical Complications After Myocardial Infarction

MI can cause serious collateral damage from tissue necrosis and bleeding, which is often heralded by cardiogenic shock (**see Chapter 59**). These events may appear within days of the initial infarct or may be delayed by years. All cardiologists should be familiar with causes of infarct-related shock and their appearance on echocardiography (**Fig. 14.29**). Indications for echocardiography after MI are detailed in the appropriate use criteria developed by the American College of Cardiology and other societies (**see Table 14G.1**).[17]

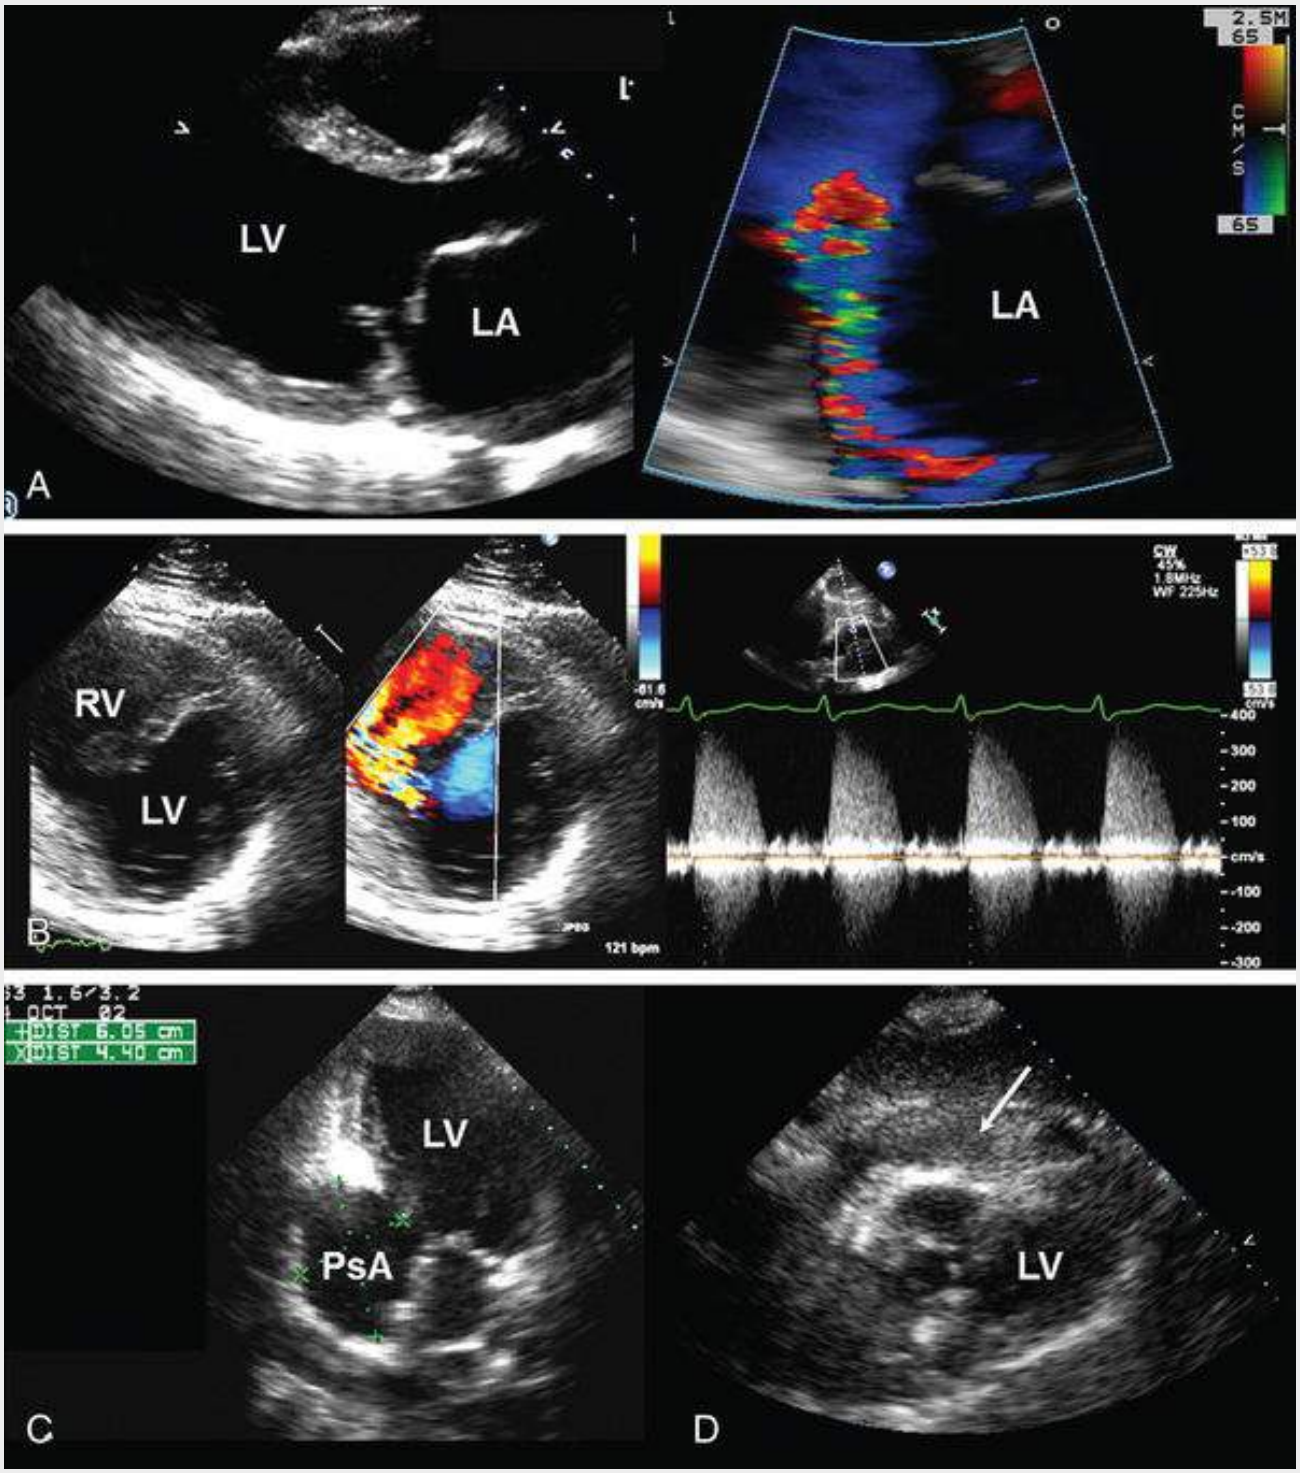

FIGURE 14.29 Acute complications of myocardial infarction. **A,** Flail mitral leaflet **(left panel)** with severe mitral regurgitation **(right panel). B,** Ventricular septal defect **(left panel)** in the basal inferoseptum with **(right panel)** an intraventricular pressure gradient of 58 mm Hg by spectral Doppler. **C,** Pseudoaneurysm (*PsA*) of the basal inferior wall. **D,** Hemopericardium (*arrow*) caused by free wall rupture. *LA,* Left atrium; *LV,* left ventricle; *RV,* right ventricle.

Mitral Regurgitation.

Acute severe mitral regurgitation (MR) is most often caused by infarction and consequent rupture of a papillary muscle. It results in "flail" of the associated mitral leaflet into the left atrium during systole with valve incompetence (**Fig. 14.29A** and Videos 14.6 and 14.7). The anterolateral papillary muscle receives dual blood supply from both the left anterior descending (LAD) coronary artery and its diagonals and the left circumflex artery (**see Chapter 20**); thus a very large infarct would be required to disrupt this papillary muscle, which supports more of the anterior mitral leaflet. In contrast, the posterior descending artery, which arises from the RCA in right-dominant individuals, supplies solely the

posteromedial papillary muscle. For this reason, papillary muscle rupture and flail posterior leaflet occur more frequently with inferior infarcts. There is, however, overlap between the papillary muscle support of the leaflets, and only one head or a tip of a papillary muscle may be disrupted rather than the entire trunk. Thus, in small infarcts there may be a focally flail segment or just the tip of an opposing mitral leaflet affected. The jet of MR is eccentric and directed *away* from the affected mitral leaflet; that is, posterior leaflet flail directs the MR jet anteroseptally, whereas anterior leaflet flail directs the regurgitant jet posterolaterally (**Fig. 14.30**). *If clinical suspicion for acute infarct-related MR is high and TTE is not definitive, proceeding expeditiously to surgical consultation and TEE is recommended.*

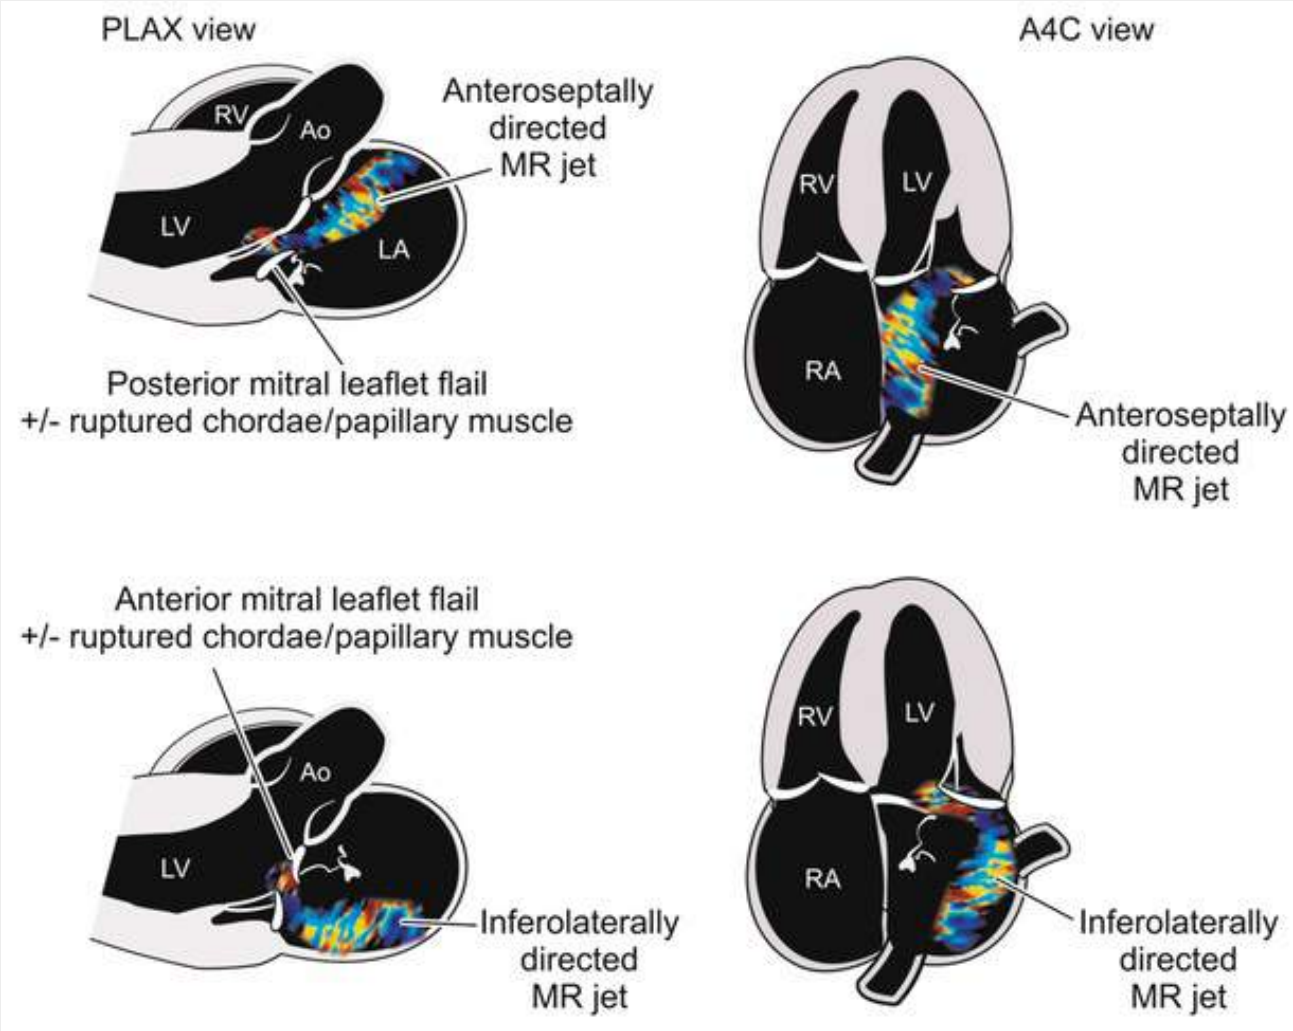

FIGURE 14.30 Acute structural mitral regurgitation (MR). The consequences of rupture of the posterior papillary muscle and chordae **(upper figure)** versus the anterior papillary muscle and chordae **(lower figure)** are shown with respect to the direction of the MR jet. Posterior mitral leaflet flail will cause a very eccentric jet to be directed anteroseptally, and this can occasionally cause clinicians to erroneously detect a "new aortic stenosis" murmur. Anterior mitral leaflet flail will cause the MR jet to be directed inferolaterally, and this murmur may be missed unless one auscultates the back. *A4C,* Apical four-chamber; *Ao,* aorta; *LA,* left atrium; *LV,* left ventricle; *PLAX,* parasternal long axis; *RA,* right atrium; *RV,* right ventricle.

Ventricular Septal Defect (VSD).

Defects in the ventricular septum may appear as discrete areas of echo dropout with interventricular flow coursing through, as demonstrated by color Doppler (**Fig. 14.29B** and Video 14.8). Echocardiography should define the location, type (simple or complex), and size of the defect. Anterior VSDs tend to be simple (i.e., direct slitlike perforations through both sides of the septum at the same level) and are

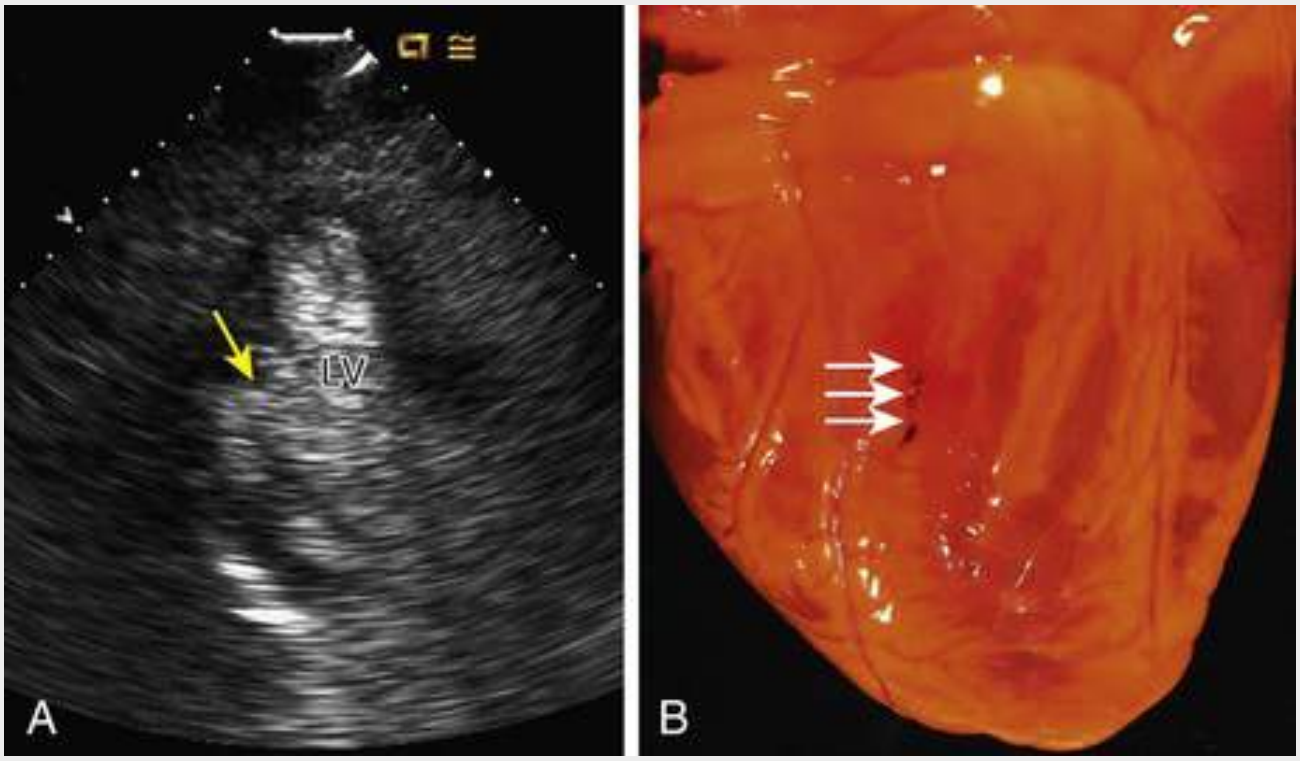
usually located more apically. In contrast, inferior infarctions often involve the adjacent basal inferior septum or even the right ventricle and can be complex (with serpiginous or multiple fissures). Unless the defect is very large, 2D echocardiographic images alone may only be suggestive of thinned or focally absent myocardium, but color flow Doppler can definitively demonstrate both location and extent of the shunt at the "break" area (Video 14.9). A small (restrictive) VSD will have a high interventricular pressure gradient, whereas a large (unrestrictive) VSD will have lower gradients and is more likely to be associated with further tissue damage, including even papillary muscle rupture or free wall rupture in catastrophic cases. By applying the Bernoulli equation, the pressure gradient across a restrictive VSD can be calculated. RV systolic pressure should be equal to systolic blood pressure minus the interventricular pressure gradient. Significant and prolonged shunting across the VSD can lead to biventricular failure and eventually cause right-sided pressures to increase and the amount of left-to-right shunting paradoxically to decrease over time.

Pseudoaneurysm.

A pseudoaneurysm is a ventricular free wall perforation that is locally contained by adjacent pericardium and adhesions. Pseudoaneurysms appear more often after inferior MI, although they may arise in the lateral and apical regions. On echocardiography, pseudoaneurysms appear as echo-free spaces or extra chambers adjacent to and continuous with the LV cavity (**Fig. 14.29C** and Video 14.10). The appearance can be similar to that of a true LV aneurysm or diverticulum, but unlike these two pathologies, the definitive feature of a pseudoaneurysm is disruption of all three layers: endocardium, myocardium, and epicardium. Thus a pseudoaneurysm is more likely to have distinguishing traits such as a narrower neck with more ragged edges and turbulent bidirectional flow (as opposed to the smoother margins and flow pattern typically seen with true aneurysms). However, no single echocardiographic criterion is specific enough to distinguish false from true LV aneurysms accurately. IV echocardiographic contrast agents can be very helpful in delineating the area of the perforation and extravasation into the pericardial space if the patient is sufficiently stable (see Video 14.3). Although pseudoaneurysms are typically subacute complications of MI and may hemorrhage suddenly, a fair percentage of pseudoaneurysms are surprisingly stable and go undetected for months and even years. In stable patients, CMR or even angiography is often useful in distinguishing pseudoaneurysm from aneurysm.

Free Wall Rupture.

Free wall rupture is usually so acutely lethal that it is rarely imaged, but findings consist of a sudden new pericardial effusion in a patient with marked thinning and akinesis at the terminal myocardial territory of the occluded artery. Echocardiographic features of tamponade are usually present. The pericardial effusion may contain spontaneous echocardiographic contrast or organized clot (*hemopericardium*) (Video 14.11). Demonstration of low-velocity color Doppler flow or extravasation of intravenous echocardiographic contrast from the LV cavity into the effusion (**eFig. 14.17**) would confirm wall rupture, but care must be taken not to confuse rupture with the low-velocity color signal generated within pericardial fluid by the adjacent moving heart.



EFIGURE 14.17 LV wall rupture, as demonstrated by **A,** extravasation of intravenous echo contrast from the LV cavity through a slitlike orifice (*yellow arrow*) into the pericardium inferolaterally, on this apical three-chamber view. **B,** Posterior view of the heart, with the site of rupture (*white arrows*) at the posterolateral left ventricle, causing this patient's demise 5 days after diagnosis of a large posterolateral myocardial infarction.

Tamponade.

Mechanical causes of tamponade related to infarcts include pseudoaneurysm and free wall rupture, as previously described, but also aortic dissection (in some cases caused iatrogenically by percutaneous intervention). All cause frank bleeding into the pericardial sac. Hemopericardium is associated with a distinctive gel-like appearance of pericardial fluid on echocardiography (**Fig. 14.29D** and Video14.11). Fully organized thrombus found in otherwise echolucent pericardial effusions may be indicative of past wall rupture that has been sealed off in the interim (i.e., intermittent bleeding).

Other Causes of Cardiogenic Shock in Myocardial Infarction.

In addition to the mechanical complications described earlier, there are other potential explanations for hypotension in the setting of acute MI. Simple loss of pump function in large infarcts is probably the most common reason. RV infarction can occur concomitantly with inferoposterior injury or as isolated RV injury in a patient with occlusion of a nondominant RCA (**see Chapter 59**). It may reveal itself when nitroglycerin is administered and decreases preload. The most reliable echocardiographic sign of RV infarction is new dilation and hypokinesis of the right ventricle. Typically, the lateral or posterior RV walls are most affected (the posterior wall represents the distalmost RCA territory), with sparing of the apex (which is also supplied by the distal LAD). Depressed RV function can often be illustrated by a low tissue Doppler peak velocity of the tricuspid annulus at systole or by a slow upstroke to the tricuspid regurgitant (TR) Doppler envelope (low dP/dT) and can be quantified by a low RV ejection fraction or FAC.[15] Annular dilation may cause associated TR and RA dilation with relatively low or normal peak TR flow velocity (because of low or normal RV systolic pressure). Because RV walls are thinner than those of the left ventricle, the right ventricle can recover relatively quickly from ischemic insults and return to normal function after revascularization. Other potential causes of hypotension and cardiogenic shock include reocclusion of coronary arteries with infarct expansion, related effusive pericarditis

(Dressler syndrome), and acute dynamic LVOT obstruction with mitral systolic anterior motion, when the basal portion of the heart becomes hypercontractile in response to more apical wall motion abnormalities in patients with upper septal hypertrophy.

Late Complications of Myocardial Infarction

Even after a MI is completed, ongoing changes in heart structure and function can cause negative sequelae that can be clinically silent. *Left ventricular aneurysms* are discrete dyskinetic outpouchings of the left ventricle with preservation of the integrity of the three heart layers (endocardium, myocardium, and epicardium). The most common locations of LV aneurysms are the basal inferior wall and the apex, where they may grow to a size that rivals the other cardiac chambers (Video 14.12). Spontaneous echocardiographic contrast within the aneurysms signifies local stasis of blood flow.

In the absence of anticoagulation, ongoing sluggish flow within an LV aneurysm may lead to the formation of *left ventricular thrombus* (**Fig. 14.31A**). Patients with large aneurysms, anterior MIs, or LVEF less than 40% are at particular risk for LV thrombus. Intracavitary thrombi may be detected within the first 1 to 2 weeks after MI and appear as discrete, homogeneously echogenic, deformable masses abutting the endocardial border of an akinetic or dyskinetic wall segment. Earlier studies indicated that the sensitivity and positive predictive value (PPV) of echocardiography for LV thrombus were 95% and 86%, respectively, compared with surgical/pathologic or radionuclide imaging. However, compared more recently with CMR, the sensitivity (60%) and PPV (75%) appear to be significantly less than originally assumed. Accuracy is undoubtedly affected by pretest probability, image quality, and the size and type of thrombus (the mural type being more difficult to detect).[32] The use of IV echocardiographic contrast material can double the detection rate of intracavitary thrombi and is highly recommended (**see Fig. 14.25**). Thrombi may appear mural (i.e., fixed, flattened, and adherent to the endocardial wall, as in **Fig. 14.31A**) or may have independently mobile and protuberant portions (Video 14.13). Larger and more mobile thrombi, as well as those residing adjacent to hyperkinetic myocardial segments, are more likely to embolize. As the thrombi age, they tend to become less mobile, more compact, and echobright in appearance. With anticoagulation, LV thrombi have been observed to resolve in almost 50% of patients by 1 year and in approximately 75% by 2 years of follow-up.

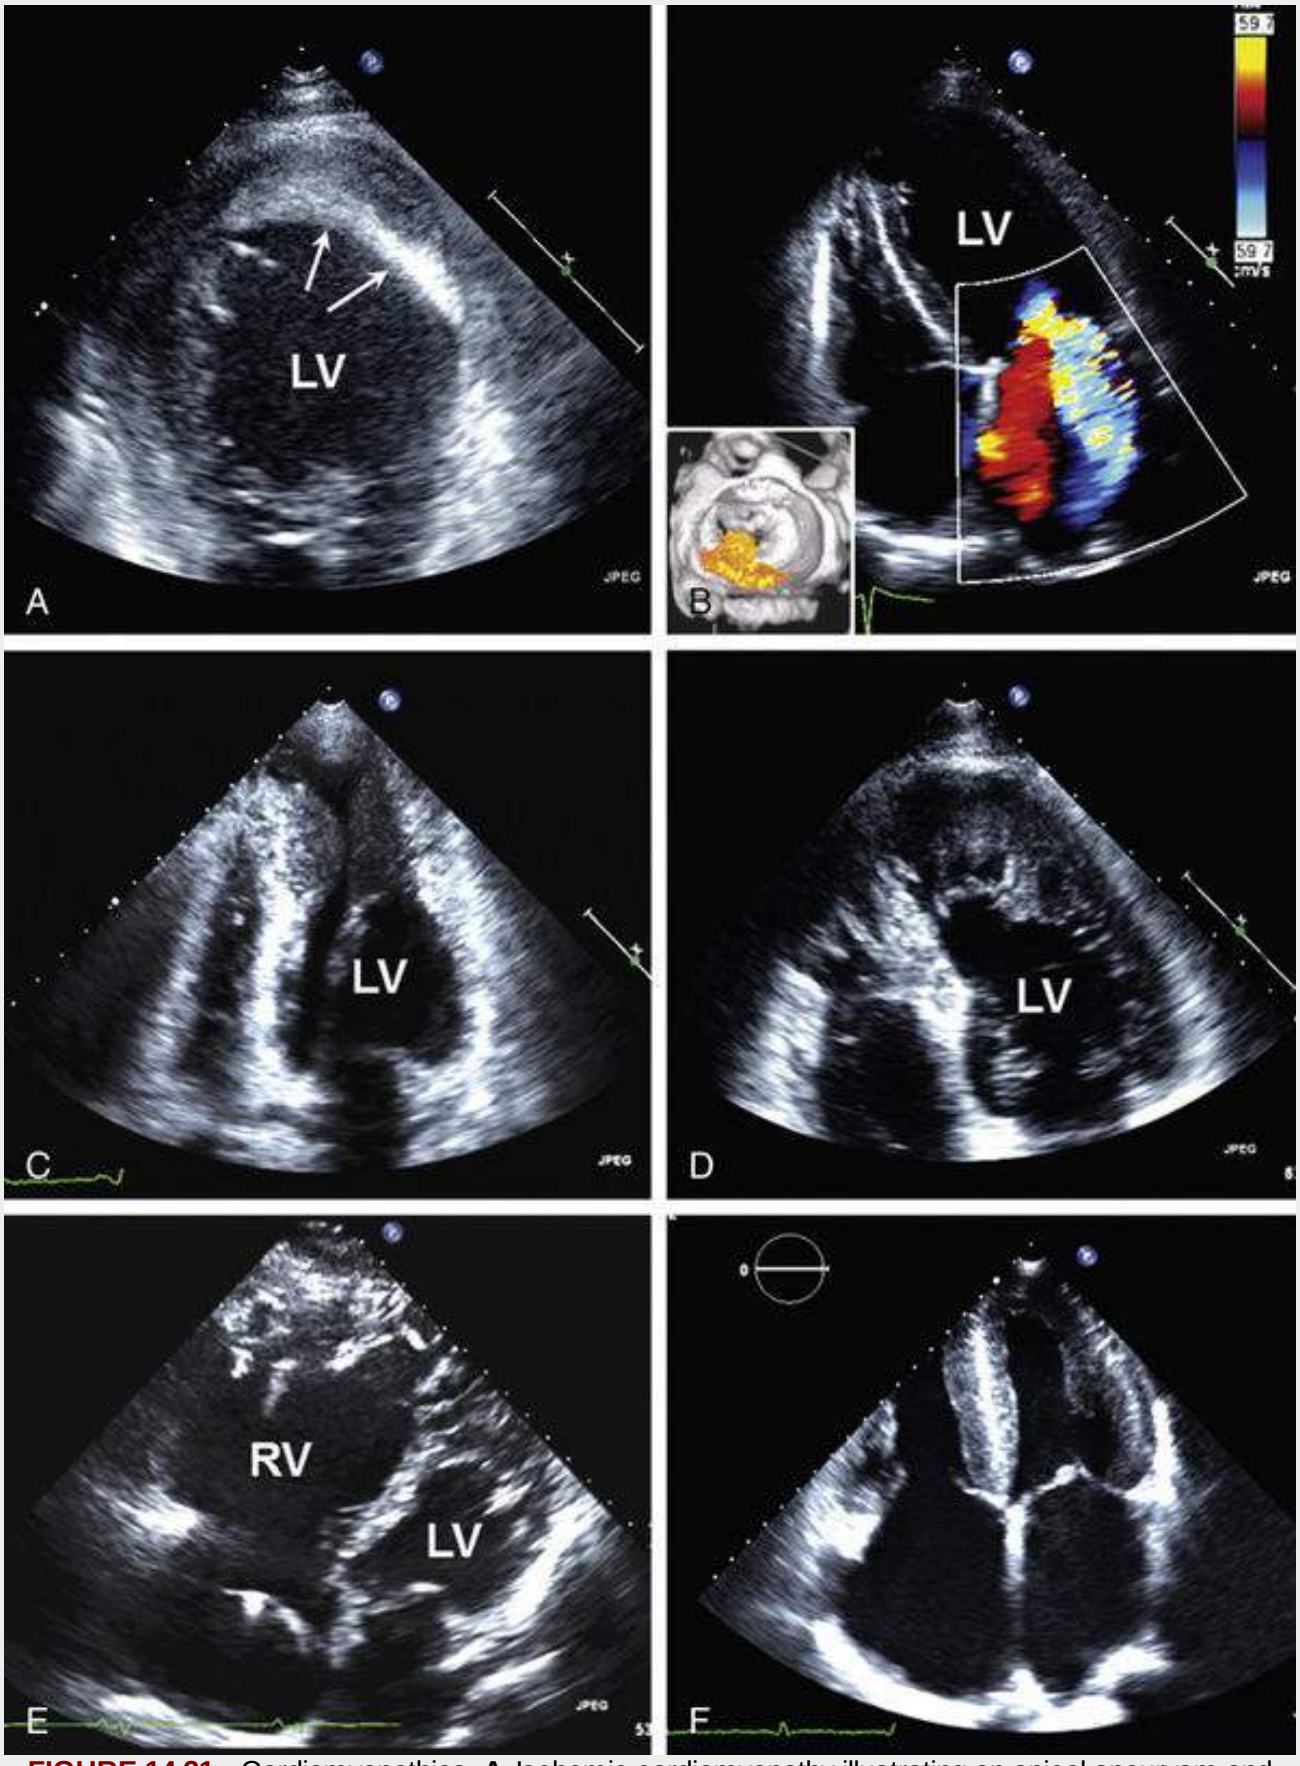


FIGURE 14.31 Cardiomyopathies. **A,** Ischemic cardiomyopathy illustrating an apical aneurysm and thrombus (*arrows*). **B,** Ischemic cardiomyopathy illustrating severe functional MR. **C,** Apical hypertrophic cardiomyopathy with midcavity systolic obliteration and an apical aneurysm. **D,** LV noncompaction. **E**, Arrhythmogenic RV dysplasia. **F,** Amyloid heart disease. *LV,* Left ventricle; *RV,* right ventricle. (See accompanying Videos 14.15 to 14.22.)

The left ventricle can continue to expand in size and mass and display hypokinesis in noninfarcted areas, even after the initial insult has ended, a process termed *left ventricular remodeling*. In the

broadest context, remodeling is defined as an increase in LV volume, but concomitant changes in the geometry of the ventricle are also frequently observed. An increase in the globular shape of the heart is quantified by the *sphericity index*. On 2D echocardiography, this is the ratio of the long-axis dimension to the short-axis dimension. Sphericity index is 1.5 or higher in normal hearts but approaches 1.0 in globular hearts (see later, Dilated Cardiomyopathy).

Ischemic MR refers to mitral incompetence in the setting of ischemic LV dysfunction and in the absence of structural abnormalities, such as prolapse, thickening, or calcification, that would otherwise cause regurgitation (**see Chapter 69**). This process has been intensively studied, and there appears to be interplay between the LV, mitral, and subvalvular components, as well as the left atrium, all of which contribute to the pathophysiology of MR. Displacement of the papillary muscle positions inferiorly and toward the apex contributes to tethering of the mitral leaflets at abnormal angles that restrict leaflet closure. Mitral annular and LA dilation, as well as insufficient mitral leaflet area to compensate for the enlarged orifice, appears to play a role in enhancing ischemic MR as well[33] (**Fig. 14.31B**). The *effective regurgitant orifice area* (EROA) is a simple measure of the degree of mitral insufficiency derived from color and spectral Doppler measurements and has a direct correlation with overall mortality (see later, Mitral Regurgitation).

Echocardiographic Prognostic Indicators After Myocardial Infarction

After acute MI, echocardiography can assist in assessing (1) the prognosis for patients at risk for recurrent ischemia and heart failure and (2) overall risk for morbidity and mortality. LVEF is one of the most important predictors of overall morbidity and mortality after acute MI and is used as a surrogate endpoint in most major clinical trials of medical and procedural interventions. As LVEF declines, the rate of sudden cardiac death (SCD) increases. Based on current evidence the incidence of SCD at an LVEF of 35% or less is high enough to consider implantation of an implantable cardioverter-defibrillator (ICD) for primary prevention in selected patients with intraventricular conduction delay and heart failure[34] (**see Chapters 25 and 27**). As mentioned previously, after reperfusion, stunned or hibernating myocardium may recover function days to weeks later, so it is generally recommended that one wait at least 40 days after acute MI, or as long as 3 months after coronary artery bypass graft (CABG) or percutaneous revascularization, to reevaluate LVEF before making a decision on ICD implantation for primary prevention. Reduced global longitudinal (GLS) and circumferential strain have emerged as important risk indicators for death or heart failure after MI. A high degree of dyssynchrony, quantitated by the same technique, is also a risk factor.[2,5,35] In addition to LVEF, overall LV size (as assessed by LV end-diastolic diameter and volume) and sphericity are important prognostic indicators. Other measures independently predictive of heart failure in patients with stable CAD include increasing LV mass index (LVMI >90 g/m^2), a pseudonormalized or restrictive pattern of diastolic dysfunction, an LVOT VTI less than 22 mm, and an LA volume index greater than 29 mL/m^2. The presence of even mild MR (especially if EROA ≥20 mm^2 or regurgitant volume ≥30 mL) is now well established as an independent predictor of cardiac mortality, as well as heart failure or recurrent MI.[36]

The WMSI may be a more discriminatory measure than LVEF (as measured by echocardiography or nuclear methods) in predicting cardiac events, in particular, rehospitalization for heart failure. On resting echocardiography, WMSI higher than 1.7 that persists after treatment of MI suggests a substantial (>20%) perfusion defect and increased risk for complications. In stress echocardiography, WMSI higher than 1.7 at peak stress and LVEF of 45% or less are independent markers of patients at high risk for recurrent MI

or cardiac death. When there is a question of whether revascularization will improve akinetic but viable areas, dobutamine or contrast-enhanced echocardiography may delineate the extent of myocardium that is hibernating (hypocontractile yet viable and still perfused)[37] (see later, Stress Echocardiography).

Finally, it should be noted that wall motion abnormalities are indicative of focal myocardial dysfunction but are not entirely specific for atherosclerosis-related MI. Vasospasm, inflammation, or fibrosis secondary to myocarditis; swelling from intramural hematoma or edema; takotsubo cardiomyopathy (**see Chapter 77**); and any focal myocardial insult are also causes of wall motion abnormality. A comprehensive synthesis of the history, clinical and physical examination findings, and ECG together with appropriate cardiac imaging will allow the clinician to narrow down the differential diagnoses and pursue appropriate therapy.

Cardiomyopathies

Dilated Cardiomyopathy

Dilated cardiomyopathies share the common characteristics of an enlarged LV and/or RV cavity with systolic dysfunction (**see Chapter 77**). Left ventricular end-diastolic (LVED) and end-systolic volumes, as well as LVED dimensions and overall LV mass, are increased (with normal or thinned walls), and the overall LVEF is subnormal. With persistence of the underlying condition, the left ventricle becomes less ellipsoid and more globular in shape, and the sphericity index decreases toward 1. The actual SV and cardiac output may remain preserved because of increased overall intraventricular volumes, as well as increased heart rate.

Dilated cardiomyopathies caused by processes such as viral, postpartum, genetic, chemotherapy, tachycardia, and toxic-metabolic causes typically display diffuse LV hypokinesis; those caused by more focal processes such as sarcoidosis are more likely to have discrete areas of hypokinesis or akinesis (Video 14.14). Ischemic heart disease is often accompanied by focal wall motion abnormalities in a coronary distribution, as well as visible atherosclerotic plaque in the aortic root and other portions of the aorta. One clue to the presence of focal inflammatory processes is wall motion abnormalities that do not follow a coronary distribution and associated thickening secondary to edema. Approximately half of symptomatic patients with Chagas disease classically have an apical or inferobasal aneurysm, but more advanced cases feature global hypokinesis.[38] *Takotsubo cardiomyopathy,* which appears to be a stress- or neuroendocrine-mediated process, is unique in displaying a distinctive pattern of apical ballooning and basal hyperkinesis in the majority (>80%) of patients[39] (see Video 14.13). Although the degree of dysfunction can be impressive in stress cardiomyopathy, remarkable and complete resolution can take place within days to weeks. Rarer “reverse” or alternate patterns of stress cardiomyopathy have also been encountered, in which basal or midventricular wall motion abnormalities occur with preservation of apical function. With sustained left-sided heart failure (and thus secondary pulmonary hypertension) or systemic causes of myocardial dysfunction, the right ventricle may also become dilated and hypokinetic, and enlargement of both atria—and thus four-chamber enlargement—is also common.

The degree of impairment in LV contractility is quantifiable by several means (see earlier, Assessment of Cardiac Structure and Function, and later, Echocardiography in Heart Failure). Historically, M-mode findings such as increased separation of the mitral E point from the interventricular septum, decreased mitral leaflet opening, and early closure of the aortic valve are known to correlate with poor cardiac output. A universally used measure of systolic function is LVEF, which is considered subnormal if less than 50%. The total SV of the ventricle (reflected by VTI_{LVOT}) may be diminished, and tissue Doppler S′

(systolic) excursion is diminished. RV size and contractility may be assessed by parallel means (**see Tables 14.5 and 14.6**), although it is more difficult to assess RV volume without the use of 3D echocardiography. One easily obtainable measure of RV function is TAPSE, which reflects shortening in the long-axis dimension of RV myocardial fibers; a TAPSE of less than 17 mm is considered abnormal, and 14 mm or less confers a worse prognosis in patients with dilated cardiomyopathy.

Functional (secondary) MR with incomplete leaflet coaptation, caused by multiple processes similar to that seen with ischemic cardiomyopathy, often accompanies and exacerbates dilated cardiomyopathy[33] (**see Fig. 14.31B** and Videos 14.15 and 14.16). If the patient begins to experience right-sided heart failure because of left-sided heart failure (i.e., elevated LVED pressure), the pulmonary venous inflow patterns will show diminution of systolic inflow (the S wave) in the pulmonary venous waveforms because of elevated atrial pressure, and this may precede a rise in estimated pulmonary artery systolic pressure (as reflected by TR velocity).

Regardless of cause, a worse prognosis is associated with declining LVEF and elevated end-diastolic and end-systolic volume, increasing LV mass, the development of restrictive physiology by Doppler indices, and the presence of right-sided heart failure, pulmonary hypertension, and severe TR.[10,40] If the LVEF is 35% or lower and the patient has an intraventricular conduction delay and clinical heart failure, CRT (**see Chapters 27 and 41**) may improve pump cardiac output, reverse the LV remodeling, and improve functional MR[41] (see later, Echocardiography in Heart Failure). Whereas chamber enlargement and systolic dysfunction are the prominent features in dilated cardiomyopathies, in *hypertrophic* and *restrictive cardiomyopathies* the ventricles are not dilated, but diastolic filling of the ventricle is impaired. Declining systolic function typically appears only very late in the process. Both cardiomyopathies typically have thickened LV walls, caused by infiltration, myocyte hypertrophy, or both. Biatrial enlargement is frequent because the atria become the low-compliance reservoirs for cardiac inflow, particularly if AF is present.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy is a primary, genetic disease of the sarcomere in which the ventricular walls are inappropriately hypertrophied and frequently asymmetrically thickened (**see Chapter 78**). HCM should be distinguished from the more common *focal upper septal hypertrophy,* a discrete septal bulge frequently observed in older adults, not usually associated with significant LVOT obstruction, and with a benign prognosis. In contrast, the most common forms of HCM of the obstructive type show these echocardiographic features (**Fig. 14.32**): a small, hyperdynamic left ventricle with a thick sigmoid septum and/or banana-shaped cavity, asymmetric septal hypertrophy (septal thickness ≥1.6 times the thickness of the posterior wall), a relatively small LVOT, elevated flow velocity in the LVOT that peaks in late systole (when the LVOT is smallest), systolic anterior motion of the mitral valve, and often a significant amount of posteriorly directed MR (Videos 14.17 and 14.18). The LVOT gradient (ΔP) is calculated from PW Doppler LVOT peak velocity by the Bernoulli equation $\Delta P = 4(V_{LVOT})^2$. It reflects the degree of outflow obstruction caused by altered LV and mitral valve geometry. The combination of small LVOT area and motion of a relatively large, anteriorly positioned, slack mitral apparatus causes the mitral leaflets to be pushed into the LVOT in early systole by flow drag forces and, to a lesser extent, by suctioning via the LVOT gradient and Venturi effect. A maximum wall thickness greater than 30 mm or a resting LVOT gradient greater than 30 mm Hg is associated with increased risk for SCD and progression to New York Heart Association (NYHA) Functional Class III heart failure. The LVOT obstruction is highly dynamic, and in some individuals the LVOT obstruction and gradient can be significantly augmented by conditions

that decrease preload and consequently also diminish LVOT size. Such movements include the Valsalva maneuver, sudden standing, and exercise, all of which may be performed during echocardiographic evaluation of these patients.

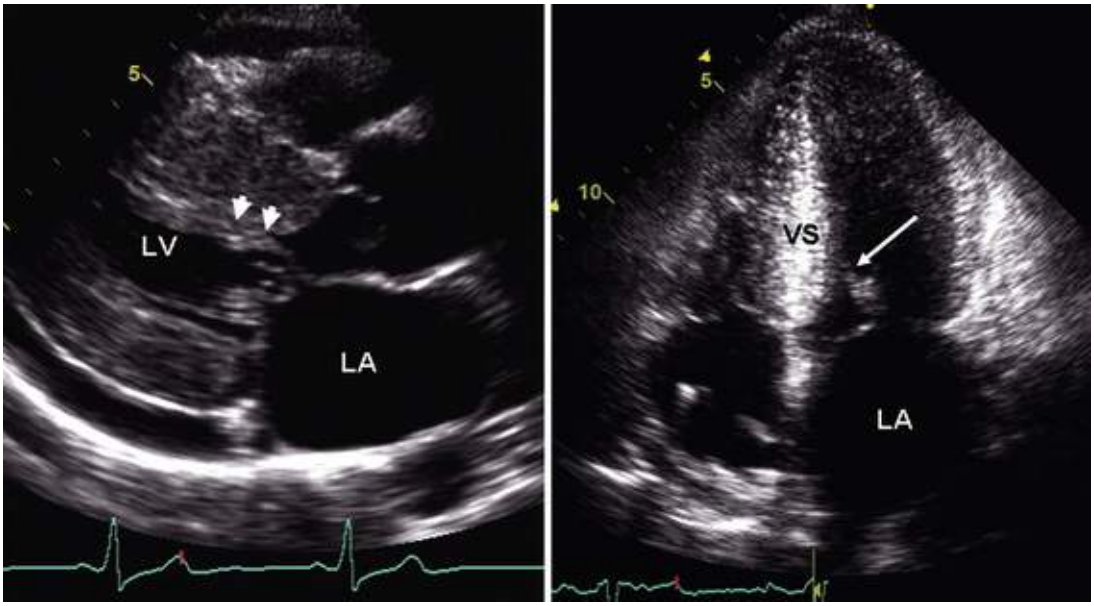

FIGURE 14.32 Hypertrophic cardiomyopathy. A parasternal long-axis view **(left)** shows markedly increased septal wall thickness and systolic anterior motion of the mitral valve (*arrows*), also visualized in the apical four-chamber view **(right)**. Note the sigmoid, banana-shaped septum. *LA,* Left atrium; *LV,* left ventricle; *VS,* interventricular septum. (See Videos 14.17 and 14.18.)

Other forms of HCM may easily be recognized by echocardiography. In *apical* HCM, basal wall thickness may be normal, but the midventricular and apical portions are unusually thickened, and a midcavity gradient may exist; in more advanced cases, a distal apical aneurysmal area may develop (**see Fig. 14.31C** and Video 14.19) and may be associated with a higher incidence of arrhythmias, stroke, and SCD.[42] In a minority (10% to 15%) of patients with HCM, systolic dysfunction ultimately develops, and the heart becomes progressively more dilated and globally hypokinetic. For screening purposes, it is important to keep in mind that some patients with HCM by genotype may have normal or only slightly increased wall thickness or may not manifest hypertrophy until late in adulthood.[43]

Other Cardiomyopathies With Regional or Global Variations in Myocardial Composition

Left Ventricular Noncompaction

LV noncompaction is also thought to be a genetic abnormality and is characterized by abundant trabeculations and deep endothelial-lined recesses extending into the myocardial layer that have failed to compact. On echocardiography this confers a “spongy” appearance to the inner layer of the myocardium, whereas the outer layer has the normal “compacted” morphology (**see Fig. 14.31D** and Video 14.20). Using color flow Doppler and/or echocardiographic contrast enhancement, blood perfusion between the intratrabecular recesses and the LV cavity can be demonstrated. With noncompaction there is a spectrum of expression: the condition may affect the entire mid- and apical ventricle or merely a portion of the apicolateral wall in less affected individuals, and the severity of trabeculation may vary. Because of this variable expression and rising awareness of this entity, definitive imaging and clinical criteria continue to

be refined. In general, a ratio of trabeculated/compacted layer thickness of greater than 2, as measured on short-axis views at the mid- and apical levels, is considered to be consistent with noncompaction.[44] A more specific echocardiographic criterion may be a maximal systolic compacta thickness of less than 8 mm (in the segment with the most prominent recesses), which appears to better discriminate noncompaction from normal patients and those with pressure overload hypertrophy.[45]

Arrhythmogenic Cardiomyopathy

Previously called "arrhythmogenic right ventricular dysplasia" (ARVD), arrhythmogenic cardiomyopathy is distinct from the other nonischemic cardiomyopathies in that often primarily the right ventricle is usually affected (**see Chapter 77**). However, as use of CMR and familial screening has increased, we now know that biventricular or even LV-predominant expressivity occurs. In the most classic form, RV dilation (RVOT long-axis dimension >30 mm) is the most commonly associated abnormality, and RV global hypokinesis (FAC <32%) is present in most (**see Fig. 14.31E** and Video 14.21). Segmental wall motion abnormalities, including thinning and aneurysms, may be present and are caused by fibrofatty infiltration. The inferoposterior wall of the RV inflow tract is the most frequent segment affected. RV trabecular derangement and subsequent tricuspid regurgitation (TR) secondary to annular dilation is common.[46] Echocardiography alone is insufficiently sensitive or specific for the diagnosis of arrhythmogenic cardiomyopathy, and other causes of right-sided heart dilation and arrhythmia need to be excluded.

Restrictive Cardiomyopathies

Systemic diseases that can infiltrate the heart may lead to restrictive cardiomyopathies (**see Chapter 77**); the most common is *amyloidosis*. Deposition of amyloid proteins in the heart causes a very distinct appearance on echocardiography, including increased LV and RV wall thickness in association with a very finely granular or "scintillating" echobright appearance of the myocardium and initially a preserved LVEF (**see Fig. 14.31F** and Video 14.22). Advanced diastolic dysfunction is manifested both by Doppler indices and by worsening longitudinal strain measured by speckle tracking. Features that distinguish infiltrative cardiomyopathy from true LV hypertrophy include the concomitant presence of diffusely thickened valves, biatrial enlargement ("owl eyes" pattern), RV hypertrophy, pericardial effusion, and low voltage on the ECG. Although LVEF can appear to be normal even in clinically affected individuals, there is often marked systolic dysfunction in the longitudinal axis, as detected by both tissue Doppler and strain imaging. Amyloidosis in particular has a characteristic regional pattern of severely reduced longitudinal strain at the base of the left ventricle, but relatively preserved apical strain.[47]

Apart from amyloid heart disease, echocardiography is frequently used to screen for cardiac involvement by other infiltrative diseases.[48] It may reveal abnormalities ranging from dilated to restrictive phenotypes, but no specific pattern is pathognomonic of any single cause. Heart failure develops in more than one third of patients with idiopathic or hereditary *hemochromatosis*, and their echocardiograms reveal LV and LA dilation and global hypokinesis with normal LV wall thickness. A restrictive filling pattern may occur earlier than the manifestations of systolic heart failure. All these parameters of function have been shown to improve with iron removal therapy. *Fabry disease* is associated with accumulation of glycosphingolipid in the heart and a high incidence of cardiovascular signs and symptoms in addition to renal, dermatologic, and neurologic abnormalities. More than 80% of individuals with Fabry disease will display concentric hypertrophy, although concentric remodeling and asymmetric hypertrophy occur in a smaller proportion. The presence of LV hypertrophy is associated with lower alpha-galactosidase activity

and more cardiovascular symptoms. Mitral leaflet thickening and significant MR are common, and focal or global LV systolic dysfunction occurs in a minority of patients.

Endomyocardial fibrosis, also termed Löffler endocarditis, is a rare restrictive cardiomyopathy frequently accompanied by peripheral eosinophilia, which may be idiopathic or associated with helminthic infection in the tropics. Eosinophilic endocarditis and infiltration of the myocardium lead to changes that can be striking on echocardiography. LV size and systolic function may be preserved, but a hallmark of this condition is the formation of prominent diffuse thrombi along the endocardium in one or both LV apices that may embolize and can grow large enough to actually obliterate the cavities (Video 14.23). The ventricular cavities themselves are small with restrictive physiology because of the fibrotic process. Patients may display retracted and incompetent atrioventricular valves and marked biatrial enlargement. Because most patients are identified relatively late in the disease, the time course of development of these changes is unclear.

Heart Failure

Echocardiography is key in the diagnosis and management of patients with heart failure (**see Chapters 25 and 26**). Determination of LVEF is the primary method to distinguish heart failure with reduced ejection fraction (HFrEF) from HFpEF, with the latter generally being considered when the LVEF is 45% or greater. Echocardiography can help distinguish among the different types and narrow down the potential causes of heart failure from the main categories discussed earlier. Abnormalities in diastolic function are common in patients with heart failure and either reduced or preserved LVEF and may have prognostic implications. MR can occur in heart failure patients secondary to apical displacement of the papillary muscles, annular dilation, or both, and progressive ventricular dilation can develop in patients with primary valvular MR (**see Chapter 69**). Increasing degrees of MR are associated with a poor outcome in patients with heart failure.

Assessment of Ventricular Synchrony

Cardiac resynchronization therapy has been associated with a reduction in heart failure and death in patients with reduced LV function and a wide QRS complex in several outcomes trials[49] (**see Chapters 27 and 41**). Use of CRT appears to reverse ventricular remodeling and improve pump performance; in numerous studies it has also been associated with marked improvement in LV end-diastolic and end-systolic volume, ejection fraction, RV function, and LA size.[50] While the benefit of CRT is seen most often in patients with LVEF less than 35%, wide QRS, and heart failure symptoms, it is estimated that 30% to 40% are nonresponders. The ability of echocardiography to predict which patients will or will not benefit remains to be proved. After numerous single-center studies reported a variety of M-mode, conventional Doppler, and DTI parameters that appeared to discriminate for dyssynchrony and CRT response, the PROSPECT multicenter prospective trial concluded that of the dozen echocardiographic measures implemented, none was able to reliably predict clinical or echocardiographic response to CRT in a generalized setting. Thus, at present, echocardiography is not recommended for assessing candidates for CRT.[51,52]

However, in this cautionary background, *speckle tracking* has emerged over the past decade as the most broadly used technique for measuring strain (tissue deformation) and dyssynchrony, in large part because it appears to be more angle- and operator-independent, robust, and reliable than prior techniques (**see eFig. 14.8**). Speckle tracking has been validated with sonomicrometry and tagged magnetic resonance angiography (MRA) data and can now be measured in three dimensions simultaneously within

one heartbeat.[2,5,6] Data using this technique are accumulating, but standardization is needed among vendors and researchers. In the meantime, echocardiographic dyssynchrony studies are useful on a case-by-case basis and for tailoring CRT, particularly regarding lead placement in the cardiac veins relative to scar to increase cardiac output, but should not be used at present to select which patients are candidates for CRT.[41]

Assessment After Orthotopic Heart Transplantation

Echocardiography is used both to certify that cardiac structure and function are normal in potential heart donors and to monitor for rejection in cardiac transplant recipients[53] (**see Chapter 28**). After uncomplicated orthotopic heart transplantation, the "normal" transplanted heart should display normal LV size, wall thickness, and systolic function, although RV size and function can be abnormal. In patients who have undergone the standard Shumway-Lower technique of transplantation, the resultant atria are very enlarged and deformed because of the retained upper portion of the dilated native heart. In these patients the anastomosis between the donor and recipient heart may be visible as a thickened ridge of plicated tissue that encircles the atria. The ridge may be mistaken for thrombus by inexperienced observers. There is a trend toward newer surgical methods that either retain no recipient myocardium (i.e., total atrioventricular transplantation) or retain only a limited cuff of LA wall with pulmonary vein ostia (in the bicaval technique) and thus preserve more normal atrial architecture with less obvious suture lines. A "normal" transplanted heart often has slight paradoxical septal motion—anterior motion of the septum in systole and a slight decrease in septal systolic thickening—that persists in the postoperative state. Over time, in part because of distortions in atrial geometry, supraventricular arrhythmias, and repeated endomyocardial biopsies causing incidental damage to the tricuspid valve, significant TR and MR, as well as atrial thrombi, may develop in the allograft heart.

Cardiac allograft dysfunction may result from acute rejection, coronary artery vasculopathy, myocardial fibrosis, acute myocarditis from opportunistic infections, or tachycardia-mediated cardiomyopathy. Cardiac ultrasound may detect the "downstream" effects of these pathologic mechanisms. Acute cellular rejection, which results in edema and interstitial infiltrates in the myocardium, has been shown to cause detectable increases in LV wall thickness and mass, systolic dysfunction, and Doppler indices of elevated LA pressure and restrictive physiology (increased E wave velocity, decreased IVRT and mitral deceleration time), but these changes are of insufficient sensitivity and specificity to rely on for routine clinical screening. Speckle tracking, used for global LV and RV strain and LV torsion measurements, may have a potential role in serial monitoring for rejection, but wider validation and outcome-based studies are required.[54] For now the gold standard for detecting acute rejection remains endomyocardial biopsy, although echocardiography has an appropriate supplementary role in monitoring for rejection and other complications after transplantation.

For detecting cardiac allograft vasculopathy, coronary intravascular ultrasound (IVUS) is the gold standard, although coronary angiography is used more routinely for practical reasons. Among noninvasive imaging techniques, echocardiography is the most widely investigated and used. The presence of depressed LVEF or focal wall motion abnormalities on a *resting* echocardiogram is relatively specific (>80% in multiple studies) for allograft vasculopathy but has poor (<50%) sensitivity. Some centers use dobutamine stress echocardiography (DSE), which is preferred over exercise stress echocardiography because denervation of the allografted heart blunts the heart rate response to exercise. Meta-analysis of the published data on the accuracy of DSE indicates a mean specificity of 88% and a sensitivity of 72%. The use of longitudinal strain rate imaging or myocardial echocardiographic contrast enhancement with DSE may increase the sensitivity, but again, more validation is needed. For prognostic purposes,

however, normal findings on DSE have been shown to have a high negative predictive value for adverse cardiac events (0.6% incidence) over short-term follow-up. Conversely, worsening findings on serial DSE confer increased risk in comparison to stable findings. Currently, therefore, DSE (as well as SPECT) is considered by the International Society of Heart and Lung Transplantation[55] as possibly being useful (class IIa, level of evidence B) in transplant recipients who are unable to undergo invasive evaluation. Some centers use DSE to minimize exposure of transplant patients to coronary angiography, although currently no noninvasive imaging modality is sufficiently accurate to supplant it.

Assessment of Left Ventricular Assist Devices.

The advent and increasing use of a variety of VADs for both bridge and destination therapy (**see Chapter 29**) have mandated that echocardiography play an integral role in assisting in the optimal selection of patients for left and right VADs, implantation, optimization, and troubleshooting. Here we address the principles for the more widely used HeartMate devices, which are now continuous-flow pumps.

All LV assist devices (LVADs) work by unloading the ventricle (i.e., removing some or all of the inflow and pumping it to the aorta). Echocardiography is useful for evaluation of the patient *preoperatively* for VAD implantation and for evaluating LV as well as RV function.[53] If RV failure is too severe, as may be indicated by a number of parameters such as RV FAC, TAPSE, and the RV Tei index (see earlier), there will be insufficient preload to fill the VAD and left ventricle. The incidence of right-sided heart failure is 20% to 30% in patients implanted with an isolated LVAD, and a preoperative RV FAC less than 20% is associated with RV failure on activation of the LVAD. In addition, echocardiography (TTE and/or TEE) can identify aortic insufficiency, intracardiac shunting, thrombi in the LV or LA appendage, or structural problems with inflow and outflow site cannulation such as excessive necrosis or atherosclerotic plaque, which are detrimental to proper LVAD function. *Intraoperatively*, TEE is used to ensure proper LV apical coring, de-airing, and cannula position and to reassess RV function on initial start-up of the LVAD. Extreme RV failure may mandate placement of an RV assist device (RVAD) as well.

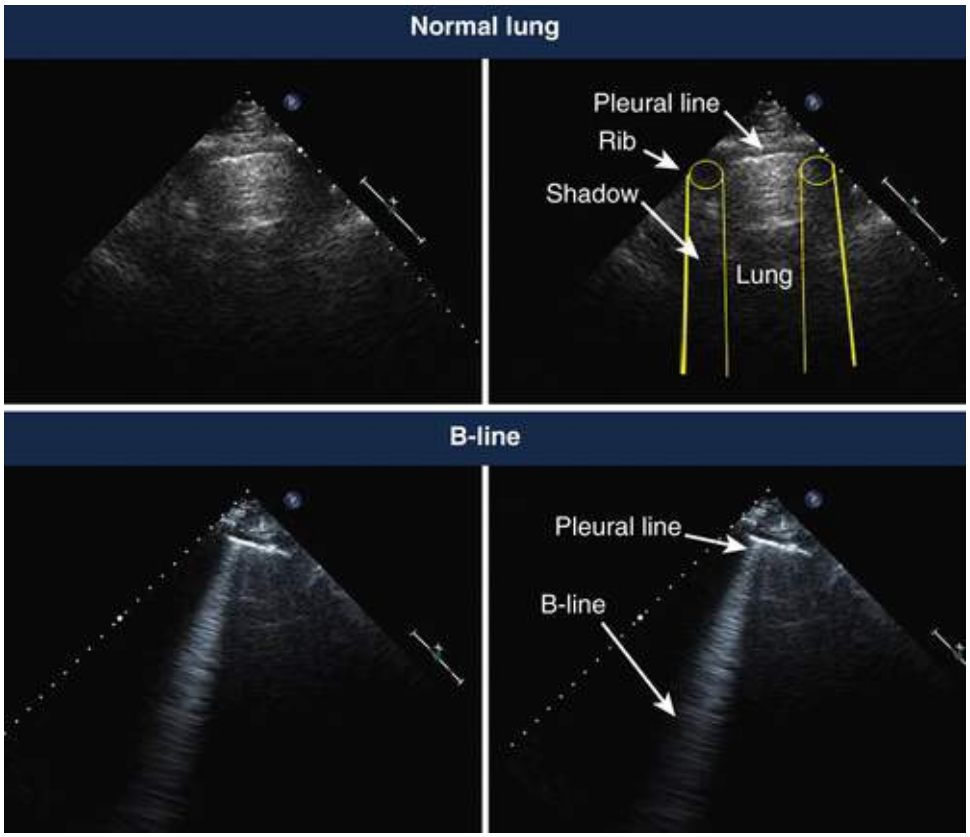
Postoperatively the echocardiogram may be used to identify causes of LVAD dysfunction and fine-tune its operation. When the LVAD is working properly, the ventricle should be “decompressed,” that is, smaller than its original dilated size with the interventricular septum in a neutral position. The aortic valve in a completely decompressed heart stays completely closed throughout the cardiac cycle. Thickening and fusion of the aortic valve may occur over time, particularly in nonpulsatile LVADs; growing experience with these continuous-flow devices supports a rationale for adjusting flow settings to permit at least occasional opening of the aortic valve (i.e., on a 1 : 3 or smaller cyclic ratio) to avoid this valvulopathy and associated aortic regurgitation (AR). This is ideally assessed with both M-mode and 2D imaging of the aortic valve over multiple beats. Enlargement of the left ventricle, distention of the interventricular septum rightward, and rising estimated pulmonary artery systolic pressure are signals of a relatively underfunctioning device that may be caused by an inadequate pump rate, worsening ventricular function, AR, volume overload, or systemic factors (e.g., sepsis). If the left ventricle appears small with a left-shifted interventricular septum, this indicates inadequate preload to the ventricle, and factors such as RV failure, pulmonary embolus, tamponade, hypovolemia (e.g., bleeding), or obstruction of the inflow cannula should be sought. Obstruction may be caused by LV thrombus, a papillary muscle or chorda, or bending or slippage of the cannula or outflow graft. Such abnormalities may be demonstrated by 2D echocardiography or by increased velocities and turbulence seen with Doppler evaluation at the

cannula/graft orifices. The LVAD inflow cannula should be visible at the apex, and the outflow graft/cannula can occasionally be detected by angling into the ascending aorta with a right parasternal view. Occasionally, positional kinks in the LVAD cannulas or the aortic outflow graft, which tend to occur in smaller patients, can be demonstrated by scanning the patient in the supine, sitting, and standing positions. Many centers now perform echocardiography "ramp" studies for continuous-flow LVADs, where many of the previous parameters (LV and RV dimensions, septal position, aortic valve opening, valvular insufficiency, and calculated pulmonary artery systolic pressure) are tracked at incrementally varying rpm settings, with the aim of optimizing LVAD function and diagnosing malfunction.[53]

Percutaneously implanted ventricular assist devices (PVADs) are often used to provide temporary or partial support for the left ventricle. Echocardiography is useful for confirming that the cannulas are positioned appropriately across the interatrial septum (in the case of the TandemHeart PVAD, CardiacAssist, Pittsburgh, Pa) or the aortic valve/LVOT (for the Impella).[53]

Lung Ultrasound in Heart Failure

Lung ultrasound is a technique that can provide semiquantitative assessment of lung fluid in patients with heart failure. *B-lines* are vertical echogenic reverberation artifacts that arise from the pleural line and extend raylike with respirophasic movement and are markers of increased extravascular lung water (**eFig. 14.18**). B-lines are most frequently seen in pulmonary edema but also in other processes such as acute respiratory distress syndrome and pulmonary fibrosis. In patients with heart failure, the number of B-lines within prespecified thoracic segments correlates with chest x-ray findings and N-terminal pro–brain natriuretic peptide (NT-proBNP) levels, clears contemporaneously with treatment, and is a prognostic marker for short-term (3 to 6 months) hospital readmission and death. B-lines are relatively sensitive and specific for cardiogenic dyspnea in the emergency department setting, and the simplicity and availability of the technique makes it attractive for early diagnosis and monitoring of therapy, particularly in limited-resource environments.[56]



EFIGURE 14.18 B-lines on lung ultrasound. For studies, typically the number of B-lines are summed from two to eight segments of the chest using a 1.5- to 7.5-mHz transducer. **Top panels,** Normal lung. **Bottom panels,** Example of B-line. Annotated images are on the right. (Courtesy Dr. Elke Platz, Brigham and Women's Hospital.)

The Athlete's Heart

Physiologic changes, including enlargement of the heart and bradycardia, can be induced in the heart through intensive athletic training. Echocardiography, along with ECG and ECG exercise testing, is often used to distinguish the athlete's beneficial cardiac adaptive changes from pathologic entities such as hypertrophic, arrhythmogenic, or other cardiomyopathies that are associated with SCD. Different forms of exercise are hypothesized to favor different remodeling patterns: endurance athletes have been well documented to develop LV (and RV) dilation and a proportionate increase in wall thickening (eccentric hypertrophy), whereas strength/isometric training has long been thought to predispose toward concentric hypertrophy (LV walls thickened relative to LV diameter, or RWT >0.42), although this latter trend is less well supported by data.[57] Although “cutoff” values for normal LVED diameter are less helpful for distinguishing physiologic from pathologic remodeling (a variable percentage of athletes have diameters >60 mm), absolute wall thicknesses greater than 15 mm are unusual even in elite athletes and should trigger further investigation for HCM, especially if the hypertrophy is asymmetric. Typically, the resting LVEF is in the low-normal (approximately 50%) range in trained athletes. The standard flow and tissue Doppler metrics of diastolic dysfunction are normal or even supranormal (higher E' velocities and transmitral E/A >2) in athletes compared with HCM patients, and speckle-based local and global longitudinal strain parameters are generally higher as well. Further CMR testing, exercise testing to confirm LV augmentation and document high exercise capacity and in “gray-zone” cases, and even a period of detraining to see if LV hypertrophy regresses may be necessary to distinguish the athlete's heart from a true cardiomyopathy.[58]

Stress Echocardiography

Stress echocardiography is a well-validated tool for the evaluation of ischemia. In particular, it is an appropriate first-line test in patients who have baseline abnormalities on the ECG that preclude interpretation of exercise ECGs, and it is both time- and cost-efficient. The accuracy of stress echocardiography is similar to that of stress radionuclide perfusion imaging (**see Chapter 16**). From meta-analyses, as well as from comparisons of the accuracy of stress echocardiography and nuclear imaging in the same patient population, the sensitivity of stress echocardiography for significant CAD (generally defined as >50% coronary artery stenosis by angiography) averages approximately 88% (range, 76% to 94%), and its specificity is 83%.[59] The specificity of stress echocardiography appears to be higher than that of nuclear imaging for left main and triple-vessel CAD. As with other tests, stress echocardiography is best used for diagnosis or to identify the extent, severity, and location of ischemia in patients with an intermediate pretest probability of disease.

The Stress Echocardiographic Protocol.

In the standard stress protocol, baseline images are obtained at rest, before the patient exercises on either a treadmill or stationary bicycle. The same Bruce protocol used for routine (ECG only) exercise stress tests is standard (**see Chapter 13**), with echocardiographic imaging performed at rest and during immediate recovery as close to the peak exercise time as possible. If a stationary (upright or supine) bicycle is used, the workload is increased by 25 W every 2 or 3 minutes, and echocardiographic images can be obtained on the cycle precisely at the time of peak stress. Patients who cannot exercise can undergo pharmacologic stress with a graded dobutamine infusion of up to 40 µg/kg/min (and added atropine, if necessary, to achieve the target heart rate), which increases the heart rate and myocardial contractility. This method, although less physiologic than exercise, produces a smaller rise in blood pressure and also allows imaging exactly at time of peak stress. Vasodilator stress with dipyridamole and pacing stress—via a preexisting permanent pacemaker or a transesophageal pacing catheter—are also possible but less widely used. The test endpoint is completed by exercise-limiting symptoms or completion of the protocol (reaching at least 85% of the age-predicted maximal heart rate).

Absolute indications to terminate the test early include moderate to severe angina, ST-segment elevation, sustained ventricular tachycardia, near-syncope or signs of poor perfusion, a drop in systolic blood pressure of more than 10 mm Hg from baseline when accompanied by any other evidence of ischemia, and patient request to stop (intolerable symptoms). Relative indications to stop early include a hypertensive response (systolic blood pressure >250 mm Hg and/or diastolic blood pressure >115 mm Hg).[59] The risks associated with exercise echocardiography or DSE are very low. In the largest survey to date, the overall rate of life-threatening events was 1 per 1000 examinations (0.015% for exercise and 0.18% for dobutamine).[60] The most frequent complications were acute MI or ventricular tachycardia or fibrillation.

If a previous echocardiogram has not been performed, a brief survey of the ventricular chambers, valves, and aortic root should be performed to screen for significant pathology or contraindications to stress and to ensure adequate image quality (usually obtainable in at least 90% of patients with harmonic imaging). If endocardial resolution is poor in two or more segments, IV echocardiographic contrast enhancement should be used to improve accuracy.[31] Images of the left ventricle are then obtained in the parasternal long, parasternal short, and apical windows at rest and then with stress. Side-by-side

comparison of the baseline versus stress digitized images, which are gated by the ECG and synchronized in systole, allows quantification of overall LV size and systolic function, as well as identification of regional wall motion abnormalities. The standard 17-segment ASE model is used as the guide for grading function in each segment as normal, hyperkinetic, hypokinetic, akinetic, or dyskinetic at rest and with stress or increasing doses of dobutamine. A normal ventricle has normal size and wall thickness and an ejection fraction of 50% or higher with no focal wall motion abnormalities (WMSI = 1.0); with stress the ventricle should become hypercontractile and the cavity size should shrink. The presence of baseline wall motion abnormalities that remain "fixed" (unchanged) with stress is indicative of a previous infarct. The development of a new or worsening wall motion abnormality indicates a flow-limiting stenosis in the coronary artery supplying the abnormal segment or segments (**Fig. 14.33** and Video 14.24). A large ischemic territory (i.e., left main or multivessel disease) will be manifested as diminished global LVEF and chamber dilation with stress.

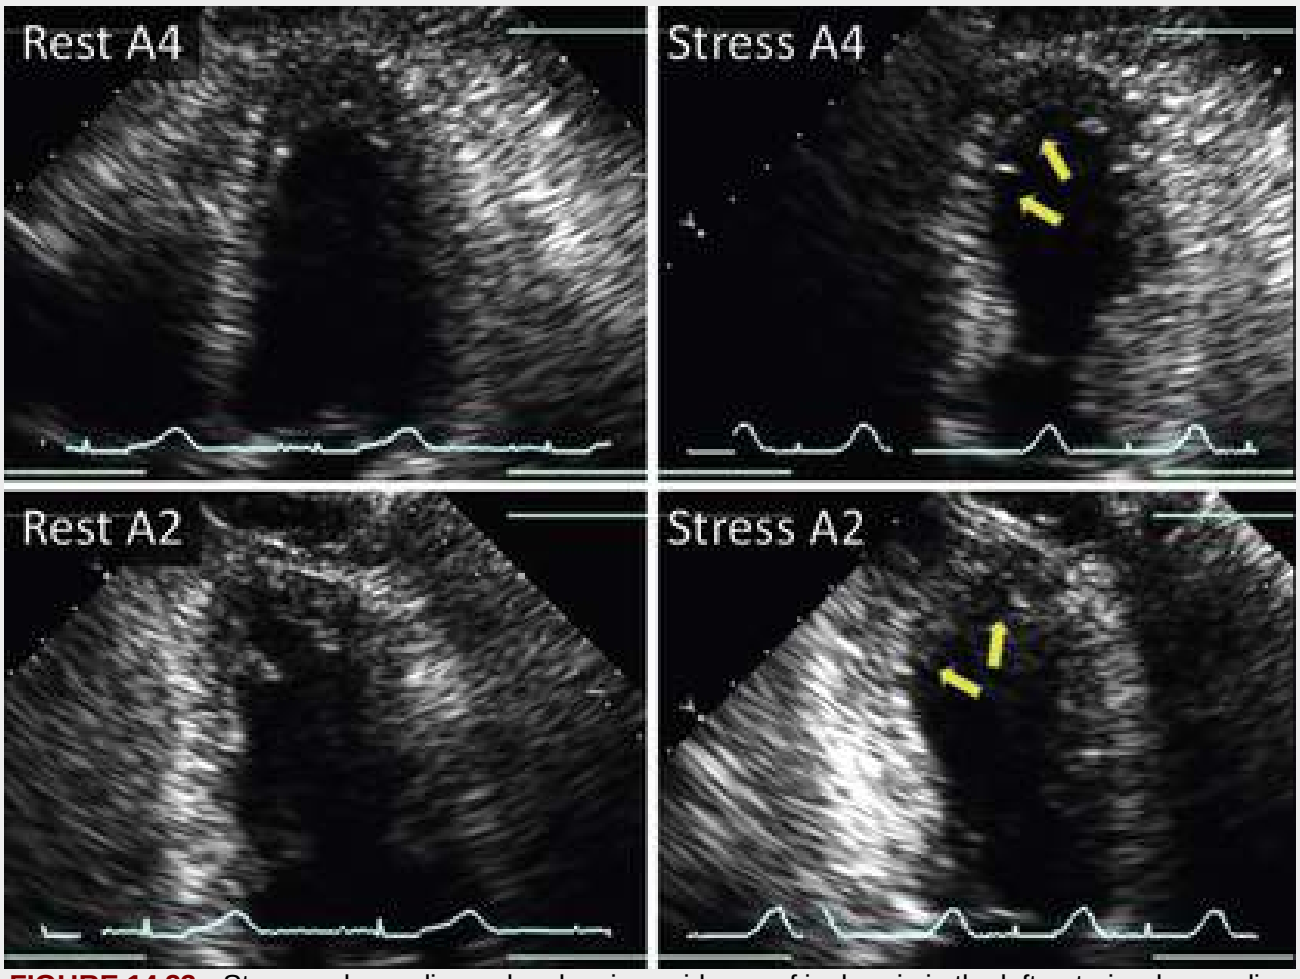


FIGURE 14.33 Stress echocardiography showing evidence of ischemia in the left anterior descending (LAD) distribution. Resting and stress echocardiograms in the apical four-chamber (*A4*) and apical two-chamber (*A2*) views reveal new severe middle to distal septal, apical, and distal inferior LV hypokinesis (*arrows*). This patient was found to have greater than 90% mid-LAD stenosis on cardiac catheterization. (See Video 14.24.)

Limitations of Stress Echocardiography

When compared with the gold standard of coronary angiography, the results of stress echocardiography can be discrepant.[61] When false-negative results occur, primary causes include a suboptimal level of

stress (from inadequate exercise capacity or beta-blocker use), limited image quality, a small area of ischemia (particularly for single-vessel or left circumflex disease), or preexisting conditions such as marked LV hypertrophy or a hyperdynamic state. False-positive results may also occur, particularly when the pretest probability is low. Diagnosis of wall motion abnormalities is particularly challenging in patients with left bundle branch block or septal dyssynchrony (e.g., as a result of pacing or the postoperative state). In these patients, because exercise can exaggerate the abnormal septal motion and thereby obfuscate interpretation, DSE is recommended. A focus on wall thickening rather than on endocardial excursion may also be helpful in such situations. Other conditions that can cause nonspecific or nondiagnostic findings include the presence of preexisting wall motion abnormalities that tether adjacent segments, severe hypertension, HCM, and other cardiomyopathies in which myocardial perfusion reserve is diminished as a result of microvascular disease.[31]

Risk Stratification with Stress Echocardiography

Numerous studies have demonstrated that in patients who complete normal exercise or pharmacologic stress echocardiograms (reaching good exercise capacity and the target heart rate), the risk for cardiac events is very low and at or close to that of a "normal" population (<1% per year for exercise and <2% per year for pharmacologic tests). In patients with suspected or known CAD, both the extent of resting wall motion abnormalities and the extent of ischemia—specifically quantified by the change in WMSI, four or more LV wall segments affected, and/or no change or decrease in exercise LVEF—correlate with a fourfold or greater increased risk for cardiac death or MI.[31]

Assessment of Myocardial Viability

DSE can also be used to quantify viability (contractile reserve) and thus functional recovery after reperfusion,[61] although its overall sensitivity appears to be lower than that of nuclear and CMR studies. A biphasic response, in which improvement in wall thickening occurs at low-dose dobutamine but then deteriorates with high-dose dobutamine, is the most specific sign. However, any improvement in wall motion abnormality by at least one grade in two or more segments during stress is likely to signify viability (either stunned or hibernating myocardium).

Coronary Flow Reserve and Perfusion

It is feasible to assess coronary flow and flow reserve (**see Chapter 57**), most reliably in the LAD territory, by using Doppler TTE and vasodilators (adenosine or dipyridamole) to provide additional prognostic information. Coronary flow reserve reduced to less than 1.9 to 2.0 in the LAD territory correlates with greater than 70% angiographic stenosis and is a predictor of future adverse cardiac events. Microperfusion to the myocardium at rest and with stress echocardiography may also be demonstrated with the use of IV echocardiographic contrast enhancement on 2D and 3D images (see Contrast Echocardiography and **Fig. 14.27**). In laboratories with expertise, both techniques of assessing myocardial perfusion appear to have acceptable agreement compared with angiography and nuclear stress tests. However, technical challenges and a learning curve presently exist, which has currently limited widespread adoption of these methods.[61]

Stress echocardiography is also used to assess factors beyond LV systolic function, particularly in patients who are dyspneic for unclear reasons. Valvular disease, diastolic function, pulmonary hypertension, and hemodynamics may all be assessed under stress conditions.[62]

Stress Echocardiography in Valvular Heart Disease

Resting echocardiography may lead to conflicting interpretations of the degree of aortic stenosis (AS) in patients with very calcified valves and low LVEF, because leaflet excursion and both the LVOT and the aortic gradients are diminished simply by low forward flow (**see Chapter 68**). In patients with "low-gradient, low-output aortic stenosis" and LV dysfunction (defined classically as a calculated aortic valve area by Doppler <1.0 cm^2 [0.6 cm^2/m^2], mean transaortic gradient <30-40 mm Hg, and LVEF ≤40%), DSE can be used to assess both the true severity of AS and the amount of LV contractile reserve (see later, Valvular Aortic Stenosis). In this test, dobutamine is infused in graded doses from 5 to 20 µg/kg/min, typically for longer stages than used for ischemia testing, to allow for steady-state measurements of spectral Doppler of the LVOT and CW Doppler across the aortic valve. SV is calculated from VTI_{LVOT}. An increase of 20% or higher in SV is indicative of significant contractile reserve. The test is indeterminate if little or no augmentation of LV function takes place (no contractile reserve, or SV <20%). Aortic valve area is calculated at both baseline and with dobutamine; in true AS, the ratio of aortic/LVOT velocity will increase, whereas in "pseudosevere" or "functional" AS, the LVOT and aortic gradients change relatively little, and the calculated valve area remains the same or increases as the leaflets open more. Patients with true severe AS generally benefit from aortic valve replacement, but if contractile reserve is absent or concomitant CAD is present, surgical mortality is high.[62,63]

A subset of patients, often women with small ventricles and hypertension, with advanced AS have been described who have low-gradient/low-flow states despite preserved LVEF[63] (**see Chapter 68**). On DSE these "paradoxical low-flow low-gradient AS" patients usually appear to have low aortic valve areas consistent with true severe AS even with stress, but only modest gradients despite preserved LVEF. These patients have a poor prognosis, which is improved by aortic valve replacement. The explanation appears to be pronounced LV concentric remodeling and myocardial fibrosis that results in severe restrictive physiology and low SV (not reflected by the LVEF because of small total chamber size and reduced LV systolic longitudinal contractility). If this state is suspected, it may be useful to further elucidate the degree of AS and restrictive pathophysiology by indexing measurements to body size (SV ≤35 mL/m^2 is considered low) and measuring GLS. Optimizing antihypertensive therapy may be useful, and the aortic valve may also be evaluated directly with CT for aortic valve calcium scores.

Patients with rheumatic or calcific mitral stenosis (MS) may have severe exertional symptoms despite relatively modest gradients on the resting echocardiogram. Conversely, sedentary patients with severe MS may be relatively asymptomatic because they are inactive. Valve gradients are notoriously dependent on the flow rate and heart rate. Stress echocardiography can define the true exercise capacity and quantitate the degree of valvular stenosis and regurgitation. A rise in the mean transmitral pressure gradient greater than 15 mm Hg or an increase in calculated pulmonary artery systolic pressure greater than 60 mm Hg is correlated with significant MS, and such patients should be considered for valvotomy (if the cause is rheumatic and there is no more than mild MR) or mitral valve replacement[31,62] (**see Chapter 69**). Mitral valve surgery should also be considered if severe MR occurs with stress. If symptoms and pulmonary artery systolic pressure increase markedly while transmitral gradients remain low, however, a pulmonary cause should be sought.

In patients with MR, stress echocardiography may be instrumental in revealing acute reversible ischemic MR caused by inferior wall ischemia (**Fig. 14.34** and Video 14.25). This would characteristically be associated with stress-induced inferior wall motion abnormalities and improvement in both abnormalities during recovery. In chronic severe MR, even if the LVEF is preserved, demonstration of a rise in pulmonary artery systolic pressure to greater than 60 mm Hg with exercise and

reduced LV contractile reserve are reasonable indications for mitral valve surgery.[31,62]

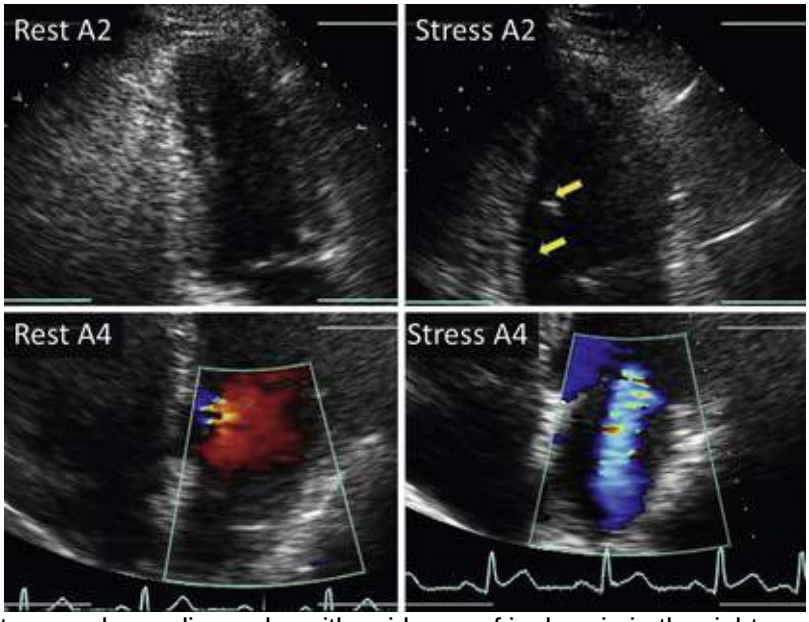

FIGURE 14.34 Stress echocardiography with evidence of ischemia in the right coronary artery (RCA) territory and acute ischemic MR. Resting and stress echocardiograms in the apical two-chamber (*A2*) and apical four-chamber (*A4*) views with color Doppler reveal new stress-induced inferior hypokinesis (*arrows*) in the area containing the posteromedial papillary muscle and increased MR. This patient was found to have 90% stenoses of the RCA and left circumflex artery on cardiac catheterization. (See Video 14.25.)

Stress echocardiography may be refined or tailored in other conditions. In patients with HCM, exercise can bring out latent gradients and is also used to monitor response to therapy and assess symptoms such as syncope (**see Chapter 78**). In conjunction with cardiopulmonary testing, stress echocardiography may aid in identifying other causes of dyspnea and fatigue, such as diastolic dysfunction. Delayed diastolic relaxation, as measured by strain and strain rate imaging, may also be a more sensitive and persistent indicator of exercise-induced ischemia than wall thickening. With the advent of real-time 3D and four-dimensional (4D) imaging, automatic endocardial border tracking, and volumetric imaging, there is now the capability to capture images of LV systolic and diastolic function simultaneously at peak exercise, thereby potentially improving the sensitivity, accuracy, and reproducibility of this test for ischemia.

Valvular Heart Disease (See Chapters 67 Through 72)

Mitral Valve

Mitral Valve Anatomy.
The mitral valve apparatus is a complex structure consisting of two leaflets attached to the left atrium by the mitral annulus and to the left ventricle through the mitral chordae and papillary muscles. The posterior leaflet is divided naturally into three scallops termed P1, P2, and P3 (using the Carpentier nomenclature), with P1 being lateral and P3 being medial. Opposing scallops of the anterior leaflet are termed A1, A2, and A3. Localization of pathology to specific scallops is important, particularly in surgical decision making for degenerative MR. The annulus is a nonplanar saddle-shaped structure, with

its highest points seen on the parasternal long-axis view and its nadir seen in the apical four-chamber view (**see Fig. 14.24**). The chordae consist of a complex arcade of primary (first-order) and secondary (second-order) chordae radiating from both papillary muscles, with the former being inserted along free margin of both leaflets and the latter serving as strut supports to the leaflet undersurfaces. Tertiary (third-order) chordae arise from the ventricular wall and insert into the base of the posterior leaflet only (**Fig. 14.35 and eFig. 14.19**).

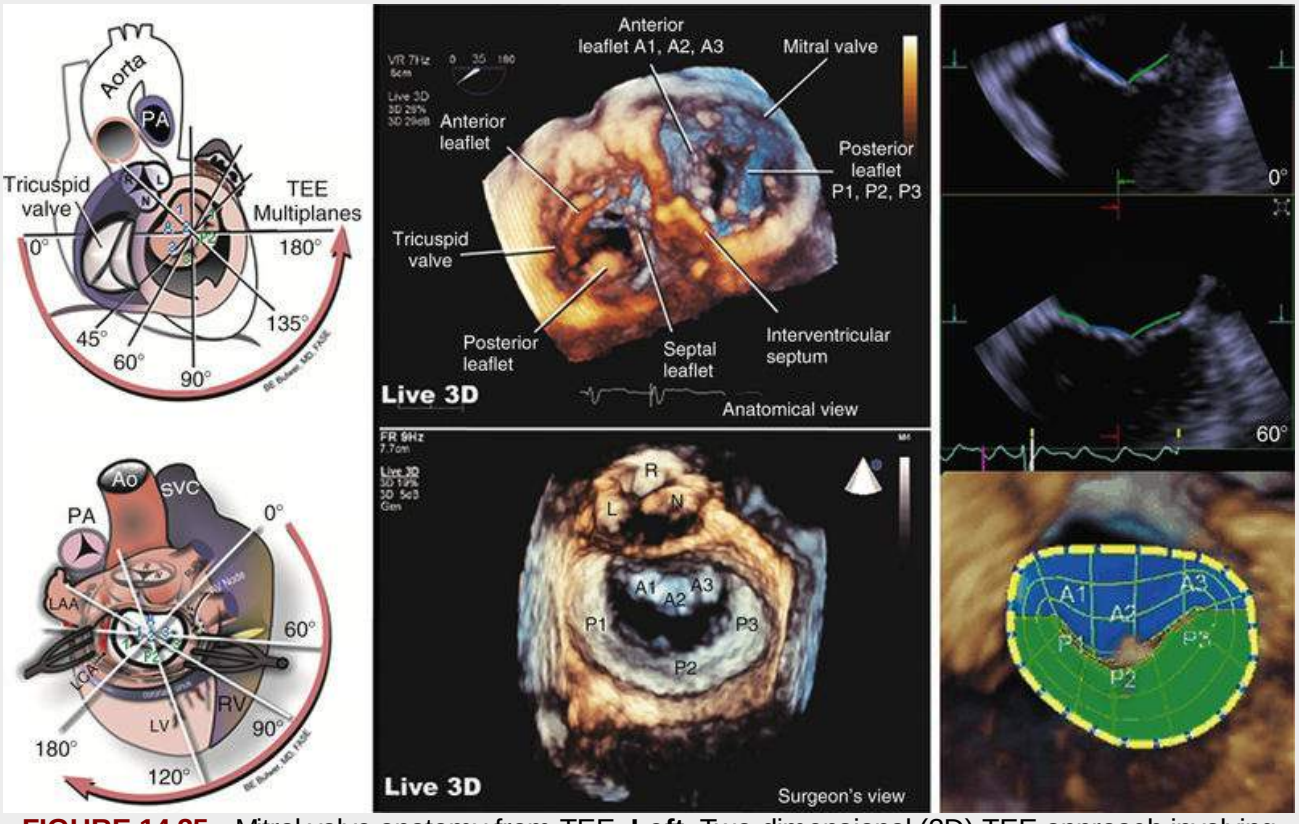

FIGURE 14.35 Mitral valve anatomy from TEE. **Left,** Two-dimensional (2D) TEE approach involving adjustment of probe position and omni orientation (degrees), sweeping to image all scallops. **Middle,** Three-dimensional (3D) appearance of the valve from the TEE view **(upper)** and surgeon's view **(lower)** with the mitral leaflet scallops labeled. **Right,** 3D TEE images delineating the mitral valve scallops at 0 degrees (four-chamber) and 60 degrees (two-chamber) planes, and below superimposed 3D analysis of leaflet areas from the left atrial aspect. *Ao,* Aorta; *PA,* pulmonary artery, *LAA,* left atrial appendage. The aortic valve right (*R*), left (*L*), and non- (*N*) coronary cusps are also shown. (See Video14.26.)

(Modified from Bulwer BE, Rivero JM, editors. Echocardiography Pocket Guide: The Transthoracic Examination. Burlington, Mass: Jones & Bartlett Learning; 2011, 2013, p 132. Reprinted with permission.)

Although it is possible to identify each of the scallops with 2D TTE on the parasternal short-axis view at the level of the mitral valve, it may be challenging to identify the scallops in the other views. Consequently, TEE plays a particularly important role in assessment of the mitral valve. 3D TEE has rapidly become an essential tool because of its ability to provide images that replicate the surgeon's view of the valve (**Fig. 14.35**), as well as improved methods for assessing mitral pathophysiology in a variety of disease states. Leaflet morphology, focal disruptions, and detailed measurements can now be made virtually real-time (Video 14.26). Congenital anomalies of the mitral valve are unusual, but those that might be newly diagnosed in adulthood include double-orifice and parachute mitral valve.

Mitral Stenosis

Echocardiographic Features

The commissural fusion, chordal thickening and fusion, and leaflet thickening and calcification that develop in patients with rheumatic MS result in narrowing of the mitral orifice, classically with a fish-mouth configuration (**Fig. 14.36**). Other pathognomonic echocardiographic features of rheumatic mitral disease are best appreciated on the parasternal long- and short-axis views and apical views. Commissural fusion results in restricted diastolic excursion of the tips of the leaflets, with relatively preserved mobility of the belly of the leaflet, particularly in early or milder forms of the disease. The result is a pattern of opening in which excursion of the midsection of the leaflet exceeds that of the leaflet tips. This pattern, also encountered in rheumatic tricuspid stenosis and congenital anomalies of the aortic valve (discussed later), is termed *doming*. In rheumatic mitral disease, anterior leaflet doming is more readily appreciated because the posterior leaflet is shorter and tends to become immobilized early in the rheumatic process (Videos 14.27 and 14.28). Leaflet and chordal thickening with or without calcification is also seen. Despite the fact that degenerative mitral annular calcification is a common anomaly that occurs with aging and renal disease, it infrequently causes MS unless very severe.

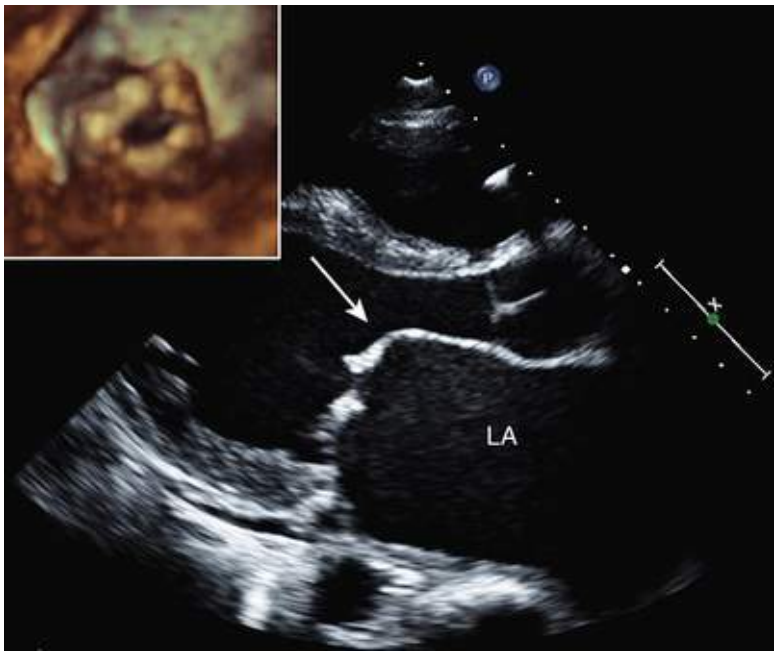

FIGURE 14.36 Rheumatic mitral stenosis. Parasternal long-axis view (diastolic frame) of a rheumatic mitral valve. Diastolic doming of the anterior mitral leaflet (*arrow*) is present, as well as a fixed posterior leaflet. *Inset,* Doming and fish-mouth appearance of the valve, as seen by 3D TTE from the LV aspect. *LA,* Left atrium. (See Videos 14.27 and 14.28.)

Quantification of Severity

The normal mitral valve area (MVA) is 4 to 5 cm^2. Direct planimetry of the orifice area from a parasternal short-axis view was first validated in the pre-Doppler era. It relies on meticulous positioning of the imaging plane at the level of the flow-limiting orifice; misleadingly larger-appearing "orifices" will be captured if the plane used is at the level of more mobile leaflet segments. It is equally important for the gain to be set at the lowest possible setting that will provide a complete orifice. Overgained images will also underestimate the true MVA. 3D echocardiography has proved to be a valuable tool because it provides a robust means of precisely identifying the valve orifice (**Fig. 14.37**).

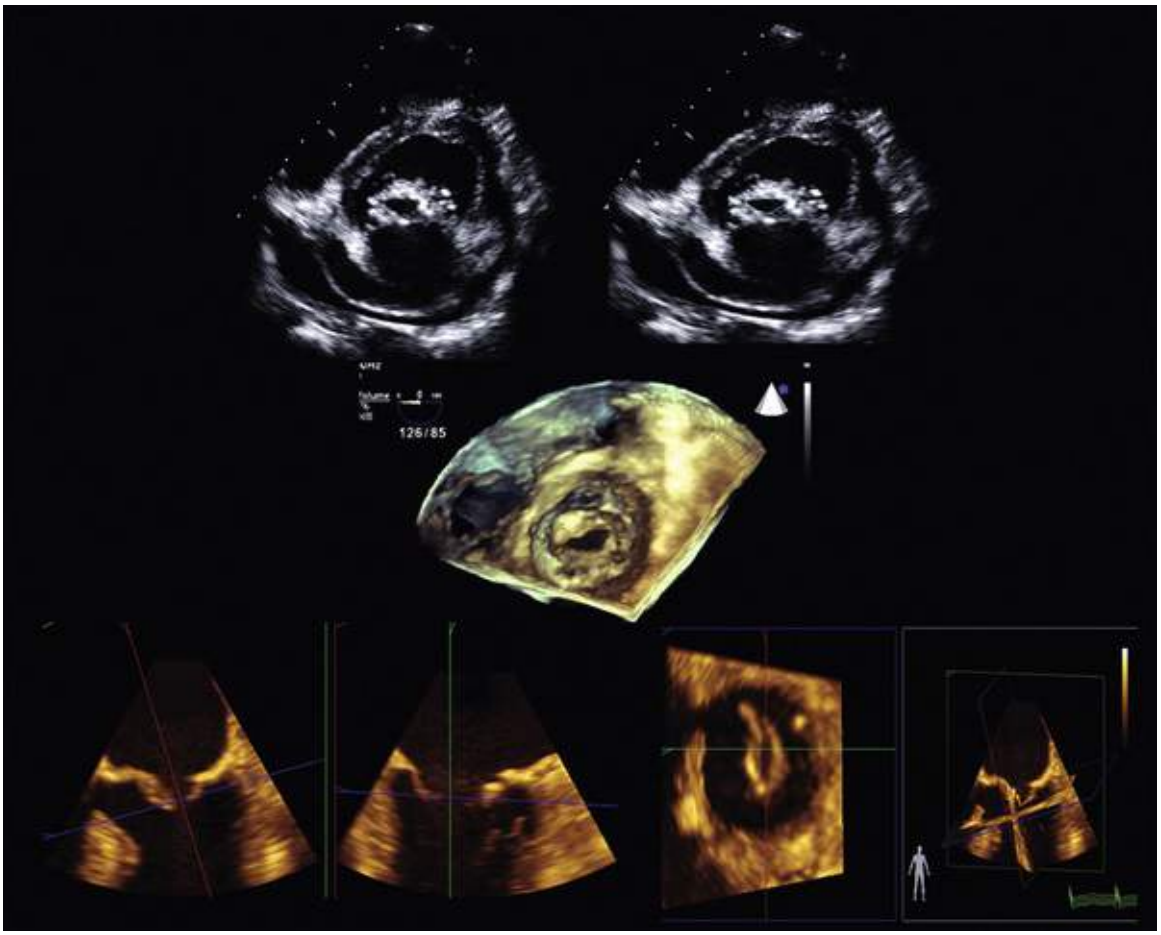

FIGURE 14.37 Approaches to planimetry of the mitral valve area (MVA) in rheumatic mitral stenosis. **Top panel,** Planimetry of 2D parasternal short-axis images. **Middle panel,** 3D TEE view of the stenotic orifice from the perspective of the left ventricle, which can be directly planimetered. **Lower panel,** Multiplanar reconstruction of 3D TEE volumes can ensure that a short-axis view precisely at the level of the limiting orifice is selected for planimetry.

Determination of the mean gradient is the simplest Doppler method for assessing the severity of MS. Given the degree to which gradients are influenced by flow rate, it is important to report the heart rate at which the gradient was determined and to know the impact of concomitant MR, which can increase transmitral flow. Abnormalities that increase LVED pressure independent of transmitral flow, such as reduced LV compliance and AR, can attenuate the transmitral gradient and result in underestimation of the severity of MS.

Doppler echocardiography also provides alternative methods to planimetry for determining MVA. The most widely used approach is the pressure half-time method, which relies on the rate at which LA and LV pressures equalize. Using a simplified derivation of a catheterization laboratory–validated method, MVA is calculated as 220 divided by pressure half-time, with 220 being an empirically derived constant. Pressure half-time is the time that it takes the initial transvalvular gradient to fall to half its initial value. This calculation can rapidly be done online with the basic analysis packages available on echocardiographic machines (**Fig. 14.38**). The pressure half-time method should not be used in the immediate postvalvuloplasty setting because acute changes in the LA-LV compliance relationship and in the initial transmitral gradient may have occurred. As discussed, it may also be invalid in the setting of significant AR and reduced LV compliance, each of which will result in overestimation of MVA. Additionally, the pressure half-time may be indeterminate when the mitral inflow Doppler spectrum has a biphasic contour. Finally, this method has not been validated for other causes of MS, such as mitral annular calcification, or for prosthetic valves.

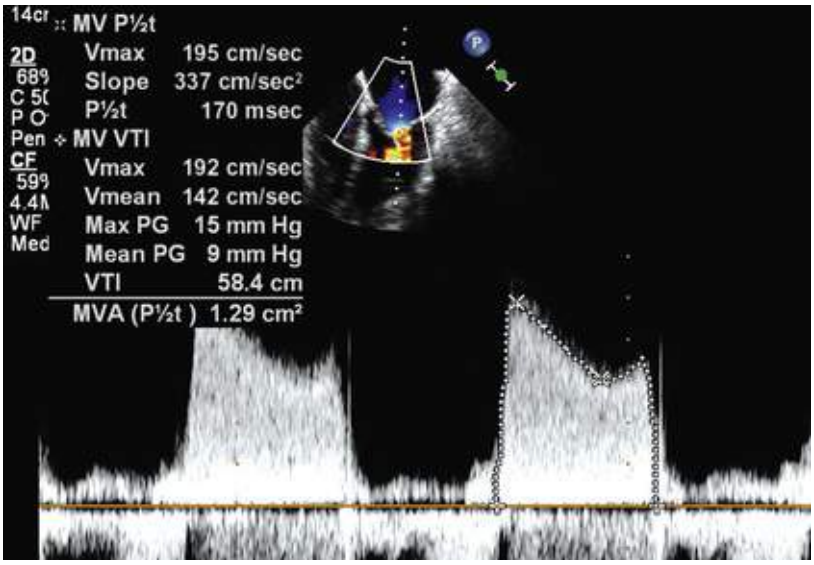

FIGURE 14.38 Tracing the CW mitral stenotic spectrum (*dotted line*) for VTI provides the mean transvalvular gradient, whereas assessment of the rate at which the gradient between the left atrium and left ventricle falls (marked by the two Xs) can be used to calculate valve area from the pressure half-time method ($P_{½t}$). *MV,* Mitral valve; *MVA,* MV area; *PG,* pressure gradient.

An alternative method is the *proximal isovelocity surface area* (PISA) approach (**Fig. 14.39**), in which $MVA = 2(\pi r^2)(V_{aliasing})/(\text{Peak } V_{mitral}) \times \alpha/180$, where α is the angle formed by the doming cusps, or a simplification of this equation in which α is assumed to be 100 degrees. A continuity-based method has also been proposed whereby $MVA = \pi(D_{LVOT}/2)^2(VTI_{LVOT}/VTI_{MV})$, where D is the diameter of the LVOT measured on the parasternal long-axis view. As with other forms of valvular heart disease, an approach that integrates imaging and Doppler findings will optimize assessment of mitral stenotic severity.[64]

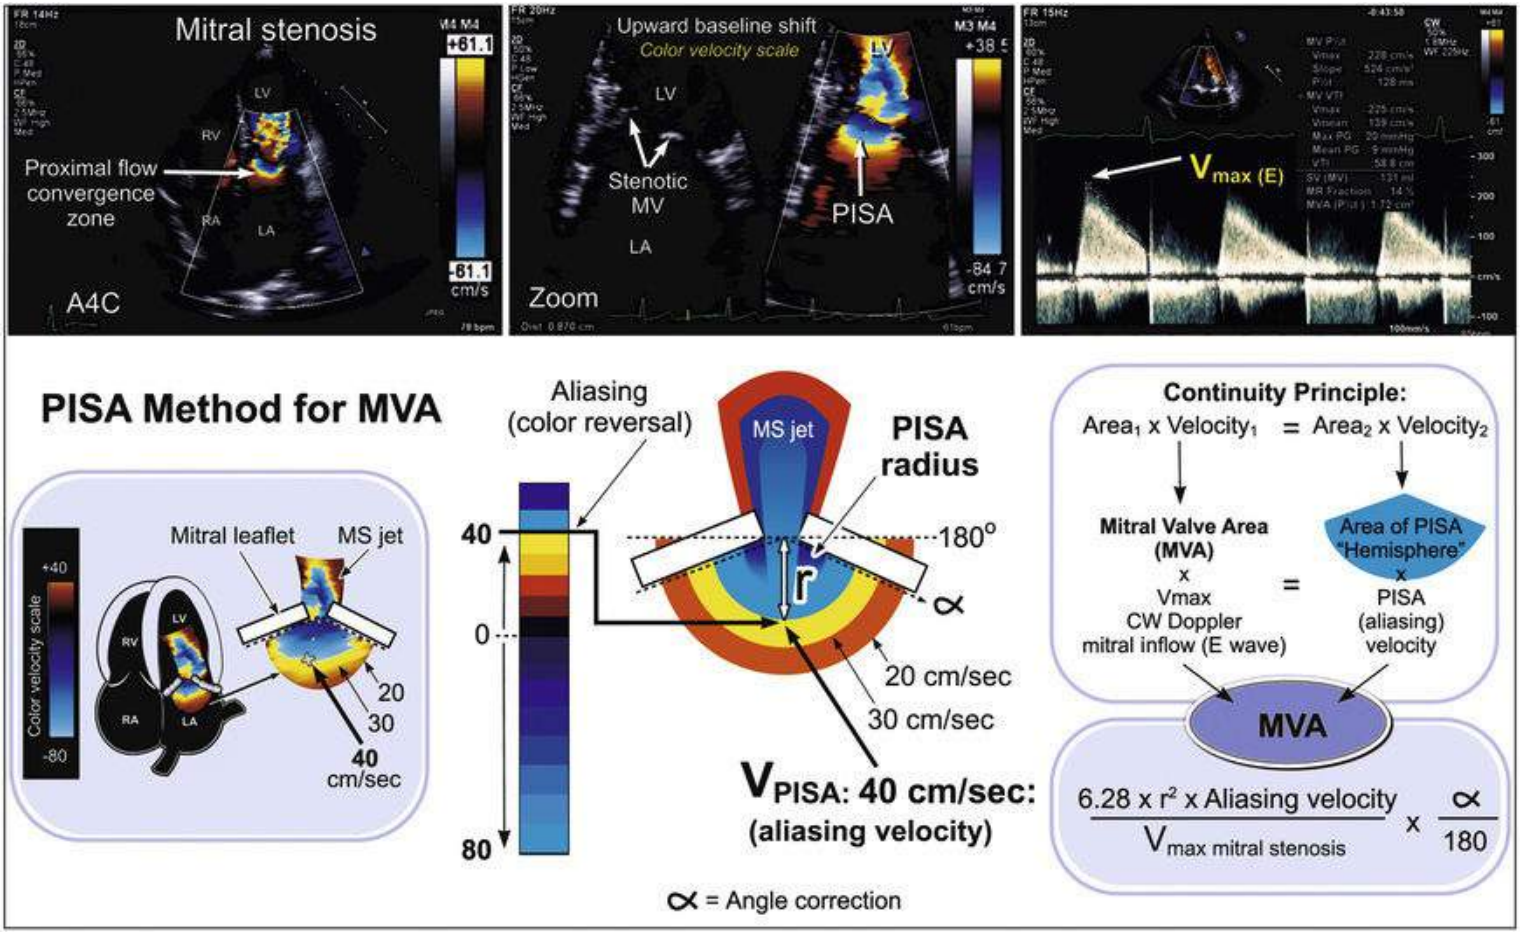

FIGURE 14.39 Proximal isovelocity surface area (PISA) method for calculation of MVA. In patients with mitral stenosis (MS), flow acceleration proximal to the stenotic orifice will result in a flow convergence zone that is characterized by color aliasing and a PISA shell **(upper left)**. The definition of the PISA shell and thus accuracy of the PISA radius measurement can be improved by shifting the baseline Nyquist limit in the direction of flow **(upper middle)**. In the **lower left** and **middle panels,** the aliasing velocity is 40 cm/sec. Application of the continuity equation allows MVA to be calculated as MVA = $[2(\pi r^2)(V_{aliasing})/(\text{Peak } V_{mitral})] \times \alpha/180$. The angle correction is used to correct for deviation of the shell from hemisphericity. *A4C,* Apical four-chamber view.

Patient Selection for Balloon Valvuloplasty

In patients with severe MS in whom transcatheter intervention is planned, the Wilkins echocardiographic scoring system is useful in determining the likelihood of overall procedural success (**Table 14.9**); the less widely used Padial scoring system is useful in predicting freedom from severe MR. A Wilkins score greater than 8 or Padial score of 10 or more are predictors of poorer outcomes. It is also important to determine the amount of associated MR on echocardiography, because percutaneous balloon mitral valvotomy will increase the severity of regurgitation by at least one grade; thus the presence of moderate or greater MR should deter one from pursuing a percutaneous approach. The presence of LA appendage thrombus, which must be ruled out by TEE, is also a contraindication to percutaneous intervention because of the risk of embolization from guidewires and catheters.

TABLE 14.9

Wilkins Scoring System for Mitral Valvuloplasty

GRADE	LEAFLET MOBILITY	VALVE THICKENING	CALCIFICATION	SUBVALVULAR THICKENING
1	Highly mobile	Minimal thickening	Single area of brightness	Minimal chordal thickening
2	Reduced mobility	Thickened tips	Scattered areas at leaflet margins	Chordal thickening up to one-third
3	Basal leaflet motion only	Entire leaflet thickened	Brightness extends to mid leaflets	Distal third of chordae thickened
4	Minimal motion	Marked leaflet thickening	Extensive leaflet brightness	Extensive thickening to papillary muscles

A desirable score is 8 or lower.

Mitral Regurgitation

Causes of Mitral Regurgitation.
Minor leakage of the mitral valve is a common physiologic finding. There are many causes of pathologic regurgitation, and echocardiography should be used not only to diagnose and quantify MR, but also to determine the underlying functional disturbance and, when possible, to identify the disease causing the disturbance (**see Chapter 69**). Carpentier proposed a useful classification system based on the pathophysiology of MR that lends itself to an echocardiographic approach. In type I, leaflet motion is normal, and the most common abnormalities are leaflet perforation, alteration in coaptation because of bulky vegetation, or annular dilation secondary to chronic atrial fibrillation. In type II, at least one leaflet overrides the most superior plane of the annulus, that is, mitral prolapse or flail on the basis of either intrinsic valvular abnormality or rupture of either the chordae or papillary muscles. In type IIIA, leaflet motion is restricted during both systole and diastole, usually because of rheumatic disease, whereas in type IIIB, motion is limited in systole because of pathologic tethering on the basis of LV systolic dysfunction and remodeling, so-called functional MR.

Primary (Degenerative) Mitral Regurgitation

Mitral prolapse or flail that is attributable to primary leaflet and/or chordal pathology is termed *degenerative* MR. Echocardiography is the gold standard for the diagnosis of mitral prolapse or flail, distinguished as follows: in mitral flail, the unsupported free edge of the mitral leaflet extends into the left atrium because of loss of chordal support, whereas in mitral prolapse, the free edge remains tethered by chordae, and the leaflet billows pathologically into the left atrium. The diagnosis of prolapse is made from the parasternal long-axis view when any part of the leaflet extends 2 mm above a line drawn from the insertion of the anterior and posterior leaflets (**Fig. 14.40** and Video 14.29). This line represents the most superior aspect of the saddle-shaped annulus (**see Fig. 14.24** for 3D mitral valve shape). In the apical four- and two-chamber views, some extension of leaflet tissue above the annular boundaries is a normal variant and in most cases is not diagnostic of prolapse, although these views may demonstrate the classic billowing motion of a truly prolapsing mitral valve. It may be difficult to differentiate between mitral prolapse and flail with TTE alone, but TEE can assist in making the correct diagnosis.

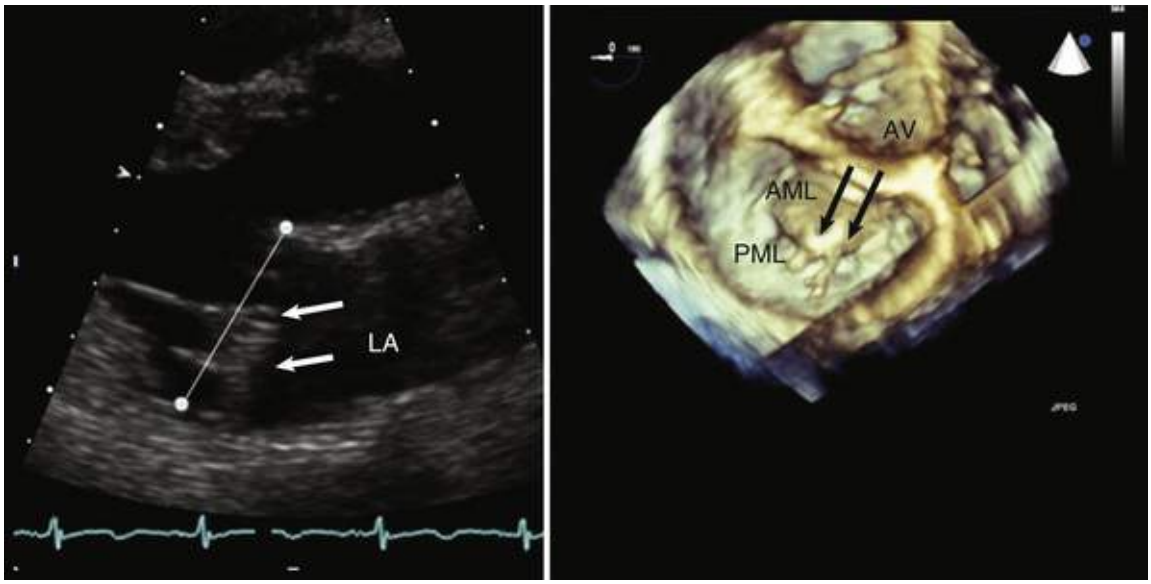

FIGURE 14.40 Degenerative MR. **Left,** Parasternal long-axis view showing bileaflet prolapse, as evidenced by billowing of both leaflets (*arrows*) above the annular plane, defined by the insertion of the anterior and posterior leaflets (*line*). **Right,** 3D TEE image of the mitral valve from the left atrial perspective. There is a large flail segment of the anterior mitral leaflet (*AML*). *Arrows* point to ruptured chordae. *AV,* Aortic valve; *LA,* left atrium; *PML,* posterior mitral leaflet.

The anatomic substrate for degenerative MR spans the spectrum from diffuse myxomatous change (Barlow) to localized abnormalities characterized as fibroelastic deficiency. Mitral valve prolapse is more prevalent in patients with Marfan syndrome, Ehlers-Danlos syndrome, osteogenesis imperfecta, and other connective tissue disorders. 3D echocardiographic assessment of the extent of billowing has been reported to be useful in characterizing the nature of the pathology but, more importantly, has assumed a key role in determining precisely which scallop or scallops are prolapsing or flail. This information is essential in predicting the likelihood of successful repair. There is a high probability of successful repair for isolated P2 pathology, which is fortunately the most common pattern. Next in frequency and ease of repair is A2 disease, followed by abnormalities in the medial and lateral scallops. 3D TEE (see Video 14.26) is also helpful in identifying involvement of multiple scallops or unexpected associated anomalies such as localized mitral valve clefts. In the absence of 3D capability, a systematic approach to assessment of all three scallops via 2D TEE can be used (**see Fig. 14.35**). Complete assessment of the mitral scallops is difficult with TTE, although when achievable, high-quality 3D TTE images may be used for this purpose.

Secondary (Functional) Mitral Regurgitation

The term *functional MR* refers to MR that has as its root cause LV systolic dysfunction and remodeling. When the dysfunction is on the basis of CAD, the term *ischemic MR* is used. 3D echocardiography has shown that functional/ischemic MR reflects an imbalance between the forces that close versus those that tether the mitral leaflets (**Fig. 14.41**). The end result is pathologic tethering seen as apical displacement of leaflet coaptation. This pattern, which is appreciable on parasternal long-axis or apical views, is the echocardiographic hallmark of functional/ischemic MR (see Video 14.15). Reduced closing forces are attributable to impaired LV systolic function, whereas pathologic tethering forces can occur because of traction on the mitral leaflets from either their annular insertion (as a result of annular dilation and/or reduced annular contraction) or from their chordal connection to the papillary muscles. The latter has been shown to result from geometric displacement of the papillary muscles because of global or regional remodeling. It has been shown convincingly that papillary muscle contractile dysfunction per se does not

cause functional/ischemic MR.

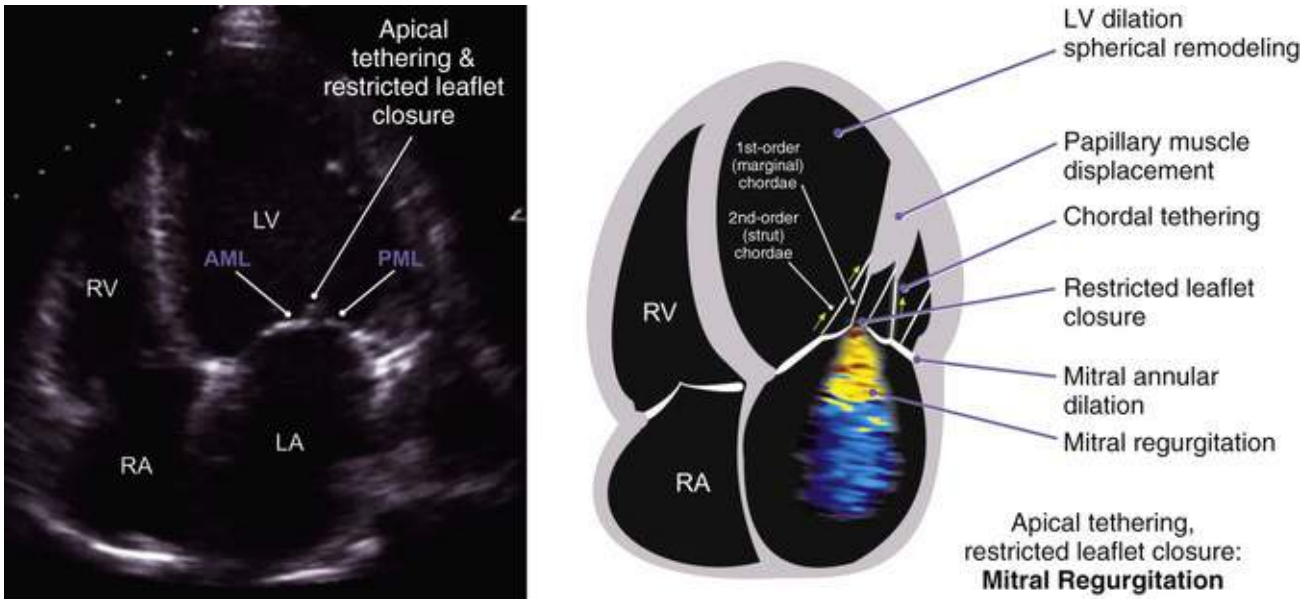

FIGURE 14.41 Functional/ischemic MR. Mitral tethering forces are increased because of both annular dilation and papillary muscle traction, which occur as a result of LV remodeling. Closing forces are reduced because of impaired LV systolic function. The end result is apical displacement of leaflet coaptation, as shown in the apical four-chamber view on the **left.** *AML,* Anterior mitral leaflet; *LA,* left atrium; *LV,* left ventricle; *PML,* posterior mitral leaflet; *RA,* right atrium; *RV,* right ventricle.

Quantitation of Mitral Regurgitation

The ASE recommends an integrated approach to the quantitation of MR[65] that incorporates semiquantitative measures such as assessment of jet area (ratio of jet area to LA area), the size of the peak mitral E wave, vena contracta diameter, and pulmonary venous flow patterns (**eFig. 14.20**). The peak E velocity reflects the initial diastolic gradient between the left atrium and left ventricle and will be elevated when MR has resulted in elevation of LA pressure. The vena contracta is the narrowest region of a jet and is best assessed in zoom mode on the parasternal long-axis view. Pulmonary venous flow patterns reflect the impact of the MR jet on flow into the left atrium with, in some cases, severe regurgitant systolic flow reversal. Quantitation of regurgitant volume and the EROA is possible with the PISA approach, which is based on the concept of acceleration of flow proximal to the regurgitant orifice (**Fig. 14.42**). The quantitative Doppler approach that uses the continuity equation provides a means of calculating regurgitant volume and fraction by comparing the total antegrade flow across the mitral valve with that across a nonstenotic nonregurgitant reference valve, typically the aortic valve (**Fig. 14.43**). In general, an EROA of 0.4 cm^2 or greater and RV volume of 60 mL is indicative of severe primary MR.

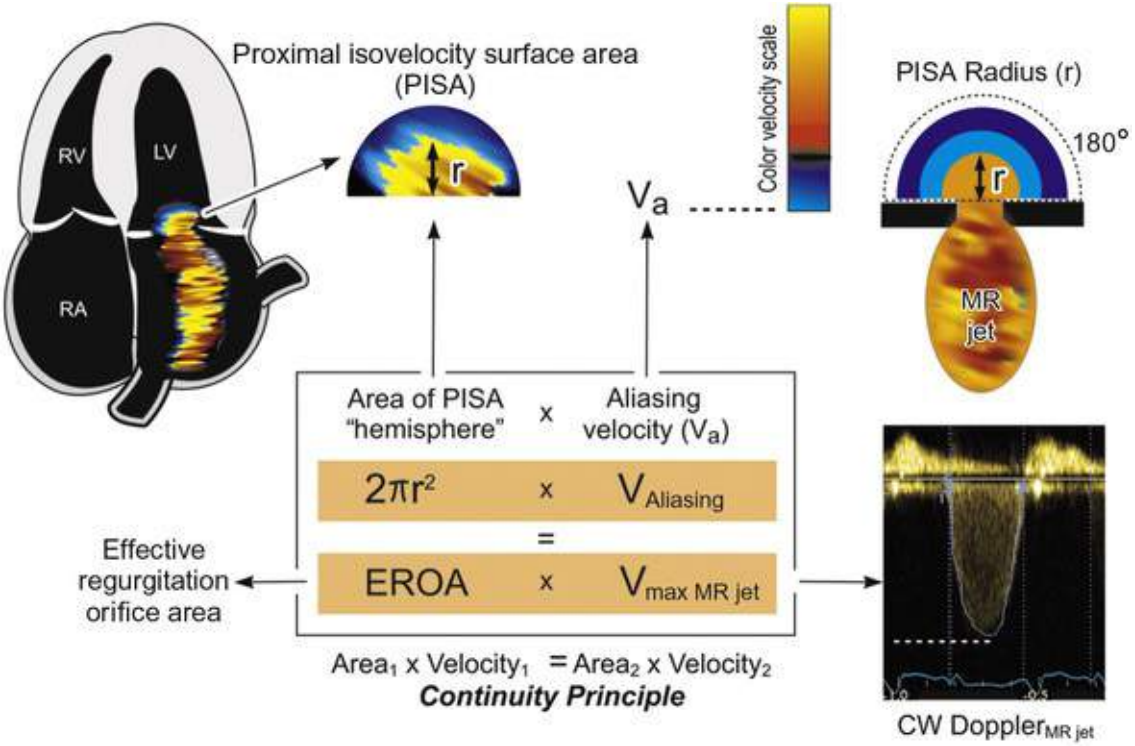

FIGURE 14.42 PISA approach to quantitating the aortic regurgitant orifice area (EROA) for MR. To optimize the PISA shell, the baseline is shifted in the direction of the jet. EROA is computed as EROA = $2(\pi r^2)(V_{aliasing})/(V_{MaxMR})$. Regurgitant volume can be calculated as EROA × VTI_{MR}, where VTI_{MR} is the velocity-time integral of the MR spectrum.

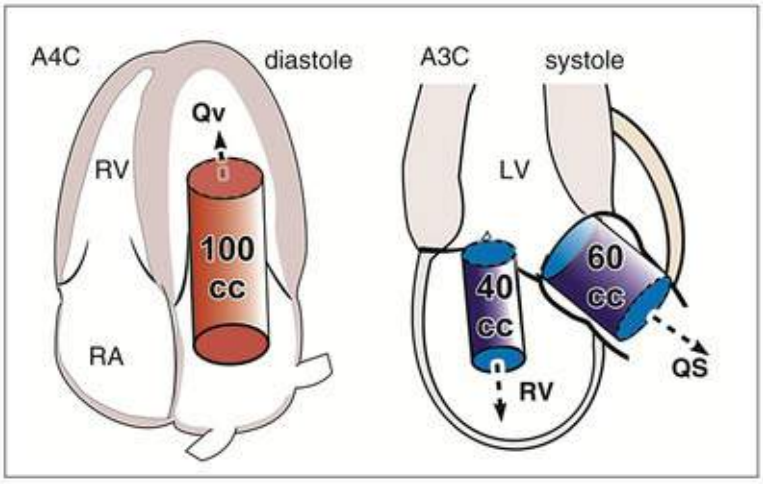

FIGURE 14.43 Quantitative Doppler approach to assessing the severity of MR. Regurgitant volume (RV) is calculated as the difference between total transmitral flow (Qv) and antegrade flow across the LVOT (Qs). Qv and Qs are calculated via the continuity method approach (CSA × VTI). Alternatively, Qv, which is identical to LV SV in the absence of a ventricular shunt or aortic regurgitation, may be calculated as LVEDV − LVESV, where LVEDV and LVESV are the LV end-diastolic and end-systolic volumes, respectively. *A4C,* Apical four-chamber view; *ALAX,* apical long axis; *RA,* right atrium.

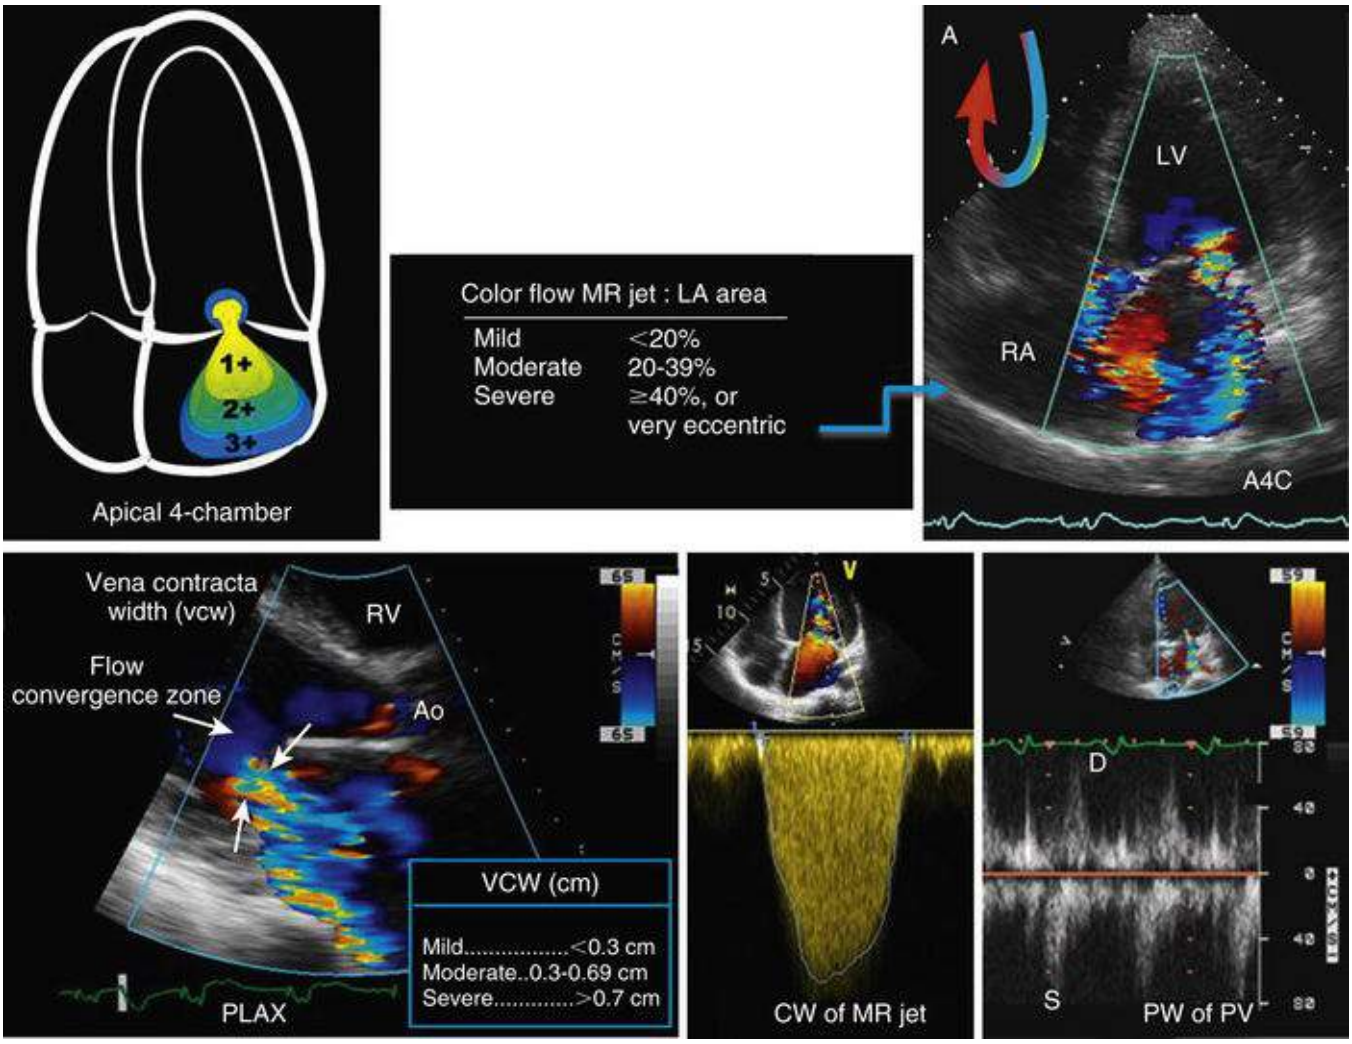

EFIGURE 14.20 Mitral regurgitation (MR) grading by semiquantitative parameters. **Top panels,** A time-honored technique of grading simple central mitral regurgitant jets by freezing the apical window when the color flow jet is greatest (at usual Nyquist limits of 50 to 70 cm/sec), then tracing the area of the jet and expressing it as a ratio to the area of the left atrium. Ideally this is done in two orthogonal planes and the results averaged. If the jet is very eccentric (i.e., "hugs a wall"), the grade is generally increased by one grade in this scale. **Bottom panels: Left**, Vena contracta, or "neck," of color flow Doppler is measured ideally in the parasternal long-axis window (or alternatively, apical three-chamber window), and is a linear estimate that correlates with the actual orifice size of the mitral valve during systole. **Middle,** MR CW Doppler jet is very dense, consistent with more severe mitral regurgitation. **Right,** There is systolic flow reversal (the S wave is negative, or below the baseline) in the right upper pulmonary vein on PW Doppler.

Even though the color jet size approach is easy and widely utilized, it is influenced by machine settings and many other factors.[66] It underestimates MR severity with eccentric jets and overestimates severity with nonholosystolic MR. The PISA method is limited in situations where the assumption of a hemispheric PISA shell and circular regurgitant orifice is invalid; this is often true for eccentric jets caused by degenerative MR, as well as for functional MR cases where the PISA shell is flatter and hemi-elliptical. In fact, for functional ischemic MR, the values that suggest severe regurgitation and that correlate with poor clinical outcome are lower than the same cutoffs used for organic MR, possibly because the PISA method underestimates the true EROA; in this population, a calculated EROA of 0.2 cm^2 or greater and RV volume of 30 mL or more is considered severe.[66] Conversely, in nonholosystolic MR (e.g., late systolic MR that frequently occurs in MV prolapse), the EROA calculated with the PISA approach will overestimate severity because it reflects the maximum rather than the EROA averaged over all of systole. The major limitation of the quantitative Doppler technique lies in the assumption of circular or oval mitral orifice geometry in calculating transmitral flow. The use of LV SV calculated from echocardiographically measured LV volume versus aortic outflow has been suggested as an alternative

approach. The advent of 3D echocardiography has provided methods for direct planimetry of regurgitant orifices and has optimized assessment of nonhemispheric PISA shells, but these methods are not yet widely used clinically.

It is important to recognize that functional MR, and to a lesser degree MR of other causes, is afterload dependent, and thus determination of severity must take into account LV systolic pressure. Clinical decision making based on echo parameters made under general anesthesia is to be avoided, because anesthesia is associated with a predictable fall in systemic vascular resistance, which may dramatically reduce the degree of regurgitation.

Aortic Valve

Aortic Valve Anatomy.
The normal aortic valve consists of three symmetric cusps that are supported by the aortic annulus and extend into the aortic root. The right and left coronary cusps lie within the sinuses of Valsalva that give rise to the corresponding coronary arteries, and the remaining cusp is termed the *noncoronary* cusp. The ideal views for assessing aortic valvular anatomy are the parasternal short- and long-axis views (**see Fig. 14.10**) and their comparable views on TEE (**see Fig. 14.22E, F**). The short-axis view shows all three cusps, which when open create a triangular-shaped orifice and when closed have a Y-shaped appearance. The long axis typically displays the right and noncoronary cusps, which when normally open will flatten against the walls of the aortic root and with normal closure will meet centrally without prolapse below the plane of the aortic annulus.

The most common congenital abnormalities of the aortic valve result from failure of cusp development and include, in order of decreasing frequency, bicuspid, unicuspid, and quadricuspid valves (**Fig. 14.44**). Bicuspid valves can be distinguished on the basis of the position of the coronary arteries relative to the line of closure. When both arteries arise on the same side, the commissure is termed *horizontal*, whereas with a *vertical* commissure the arteries arise on opposite sides. Because of the inability of bicuspid valves to open fully, the systolic orifice of a bicuspid aortic valve is oval when seen in short axis, whereas the long-axis view demonstrates convex bulging of the leaflet midportions into the aortic lumen (doming) (Videos 14.30 and 14.31). Although bicuspid aortic valves classically have a single line of closure, many such valves additionally have an echogenic ridge or raphe that represents a vestigial commissure. The closed appearance of such valves may be echocardiographically indistinguishable from a tricuspid valve. Thus, bicuspid aortic valve is a systolic diagnosis. Unicuspid valves (Video 14.32) typically have circular openings that may be central or asymmetrically positioned, and quadricuspid valves (Video 14.33) have a square appearance in systole and a crosslike appearance in diastole.

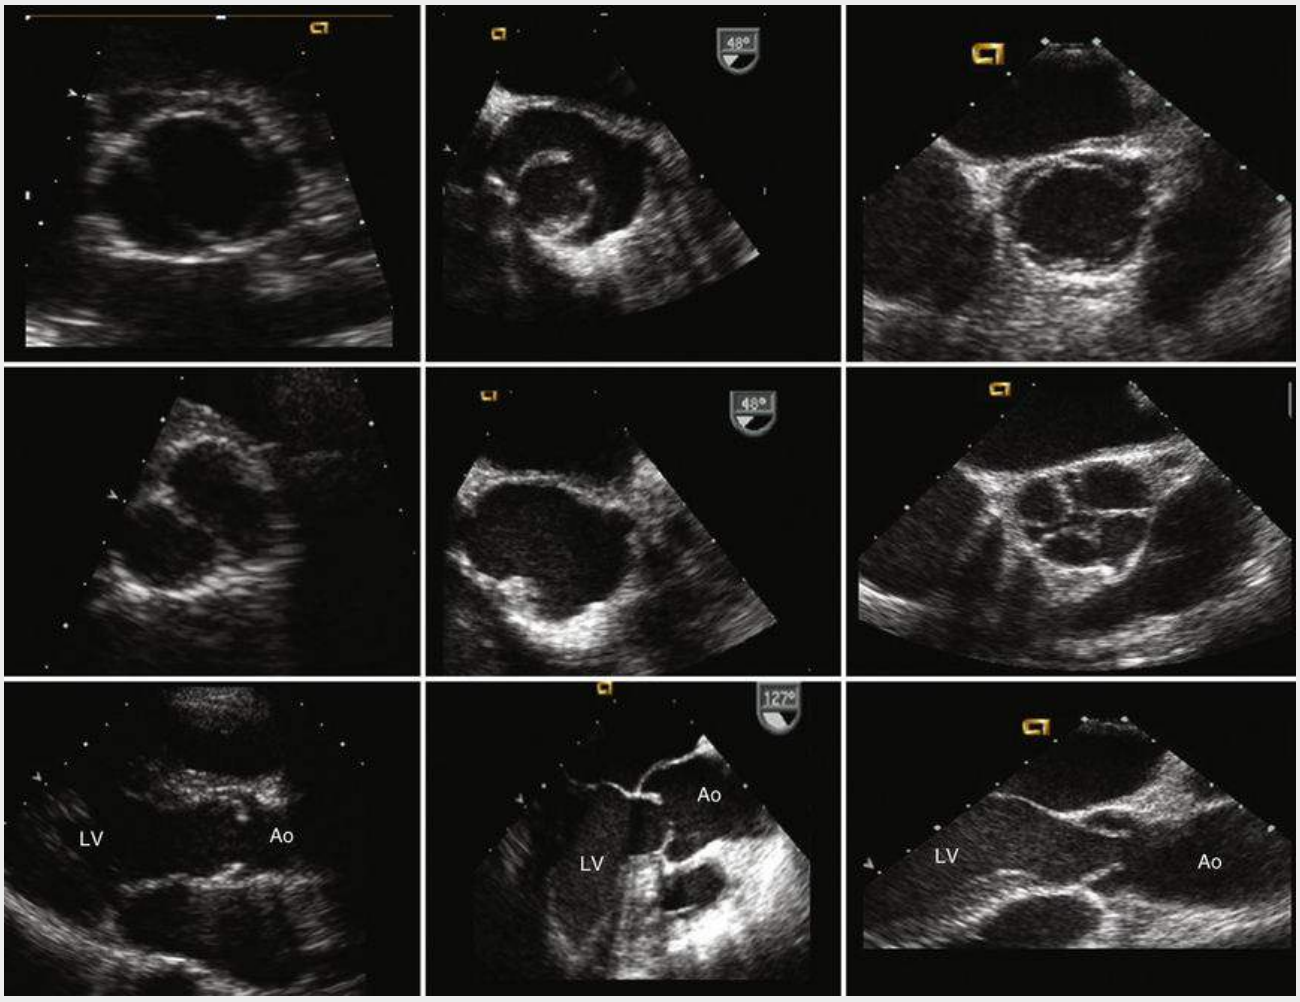

FIGURE 14.44 Congenital abnormalities of the aortic valve with (*top to bottom*) systolic short-axis, diastolic short-axis, and systolic long-axis views. **Left panels,** Bicuspid aortic valve. **Middle panels,** Unicuspid unicommissural aortic valve. **Right panels,** Quadricuspid aortic valve. *Ao,* Aorta; *LV,* left ventricle.

Congenital abnormalities of the LVOT include subaortic membranes, characterized by linear echoes extending from the anterior mitral leaflet to the septum or fibromuscular tunnels in which there is an echogenic ridge extending into the LVOT (**Fig. 14.45**). The presence of subaortic systolic turbulence on color Doppler should prompt close inspection of the LVOT for evidence of obstruction. Associated valvular AR is seen frequently and results from valve trauma caused by the subaortic stenotic jet. Supravalvular AS is a rare phenomenon that consists of localized or diffuse narrowing of the ascending aorta distal to the sinuses of Valsalva.

FIGURE 14.45 Nonstandard parasternal long-axis view demonstrating a subaortic membrane (*arrow*). The image is angled to show the membrane well with the result that the aortic valve (*AV*) is not well seen. *LA,* Left atrium.

Valvular Aortic Stenosis

Although the impeded cusp excursion of a bicuspid or unicuspid aortic valve may alone result in AS, calcium deposition on a congenitally normal tricuspid aortic valve is a common cause of AS in adults. The echocardiographic appearance is restricted cusp excursion with irregular nodular cusp thickening (**Fig. 14.46**).

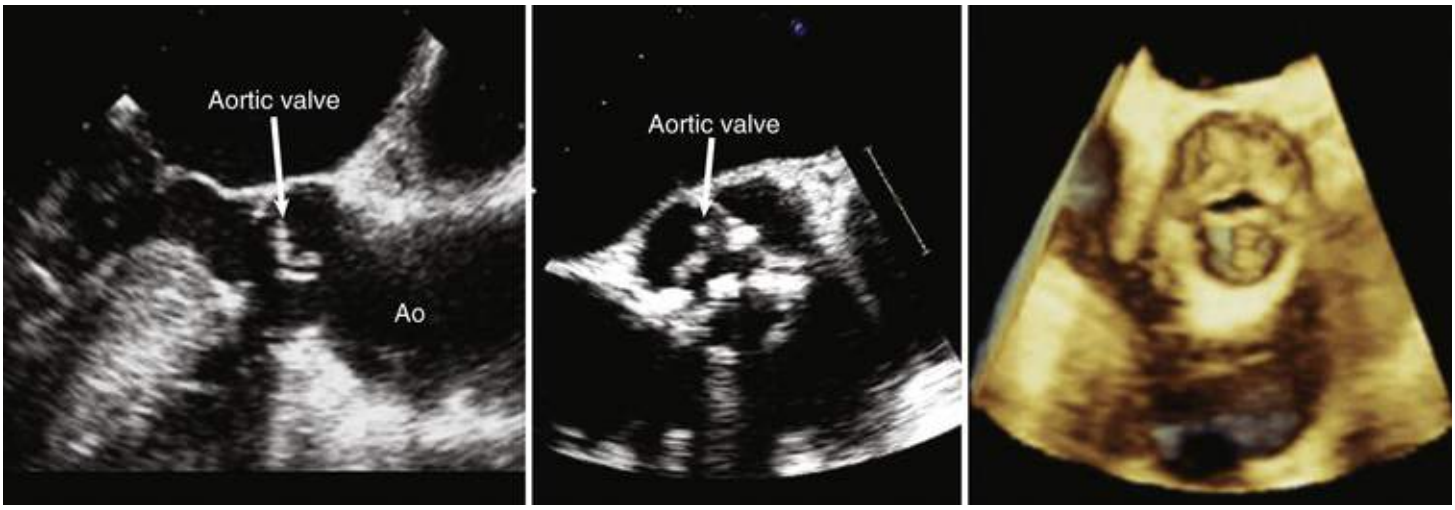

FIGURE 14.46 Systolic TEE images of calcific aortic stenosis in a patient with a tricuspid valve. **Left,** Two-dimensional long axis. There is minimal opening of the valve. *Ao,* Aorta. **Middle,** Short axis. **Right,** Three-dimensional image. The latter two views better demonstrate the distribution of calcium.

Quantitation of Severity

The normal aortic valve area (AVA) is 3 to 4 cm^2. Application of the Bernoulli equation to CW Doppler interrogation of transvalvular flow provides accurate measures of the mean and peak instantaneous gradients in aortic stenosis. Typically, the simplified form of the equation ($\Delta P = 4\ V^2$) may be used, but when LVOT velocity significantly exceeds 1 m/sec, the expanded version, $\Delta P = 4\ (V_2^2 - V_1^2)$, where V_2 is transaortic velocity and V_1 is LVOT velocity, should be used.

In recognition of the importance of recording Doppler signals parallel to flow, aortic gradients are best recorded from the apical five- or three-chamber, suprasternal notch, and right parasternal windows; typically, the highest velocities are found on the right parasternal view. The nonimaging Pedoff probe has a smaller footprint, making it essential for optimal assessment of patients with AS. When TEE is used, velocities are recorded from the deep transgastric views (**see Fig. 14.22, position O**). It should be noted that although echocardiographically derived mean gradients are generally identical to those obtained invasively, the echocardiographically derived peak *instantaneous* gradient is typically higher than the *peak-to-peak* gradient calculated in the catheterization laboratory (**see Chapter 19**). The latter is the arithmetic difference between peak LV and aortic pressure (**Fig. 14.47**), which may not be coincident in time.

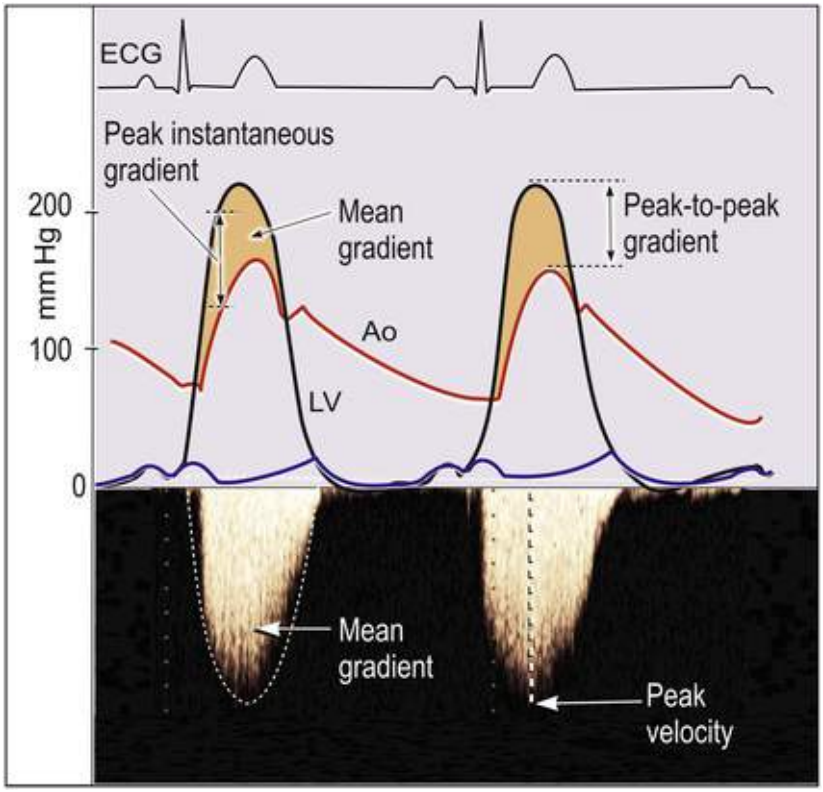

FIGURE 14.47 Doppler methods provide peak instantaneous and mean gradients. The peak instantaneous gradient is typically higher than the peak-to-peak gradient calculated from invasively measured peak left ventricular (*LV*) and aortic (*Ao*) pressure, which is not instantaneous, although mean gradients measured with both techniques are identical.

Although gradients alone provide a reasonable assessment of the severity of AS when transaortic flow is normal, they may underestimate severity in the setting of low-flow states and overestimate severity when flow is elevated (e.g., high-output states such as those caused by sepsis and anemia). For this reason it is important to determine AVA. Direct planimetry of TEE images may be used for this purpose, but TTE planimetry is not sufficiently accurate. The most common approach is therefore by application of the continuity equation (**Fig. 14.48**). AVA is calculated as follows:

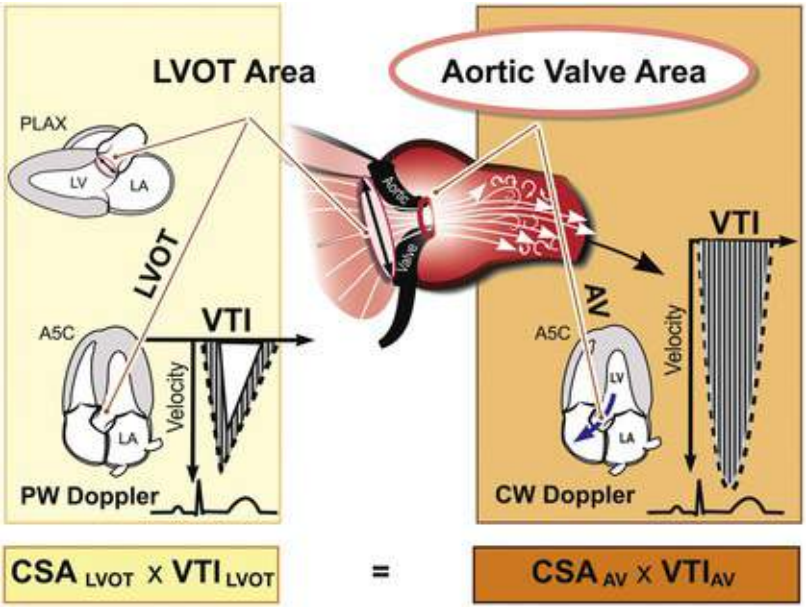

FIGURE 14.48 Continuity equation approach to calculating aortic valve area. The cross-sectional area (CSA) of the aortic valve (CSA_{AV}) is calculated as ($CSA_{LVOT} \times VTI_{LVOT}$)/$VTI_{AV}$). LVOT CSA is calculated as $\pi(D/2)^2$, where *D* is LVOT diameter. LVOT VTI should be measured from the modal rather than the maximal velocity (**see Fig. 14.49**).

$$AVA = (CSA_{LVOT} \times VTI_{LVOT})/VTI_{AV}$$

Less desirable is the simplified version:

$$AVA = (CSA_{LVOT} \times V_{LVOT})/V_{AV}$$

where V represents peak velocity. The CSA of the LVOT is typically calculated by assuming circular geometry with the formula $CSA = \pi(D/2)^2$, where D is the systolic LVOT diameter measured on the parasternal or TEE-equivalent long-axis view. According to the ASE convention, the diameter is measured just proximal to the aortic annulus. It is cautioned that because the LVOT velocity incorporated into the calculation is the *modal* velocity, displayed as the densest part of the pulsed Doppler envelope, the VTI should not be traced by using the outer edge of the spectrum, which represents the maximal (not modal) velocity at each time point (**Fig. 14.49**). Optimal sample volume placement is in the LVOT immediately proximal to the site of subvalvular flow acceleration, typically 1 to 2 mm proximal to the valve on the apical five- or three-chamber (TTE) or deep transgastric (TEE) views.

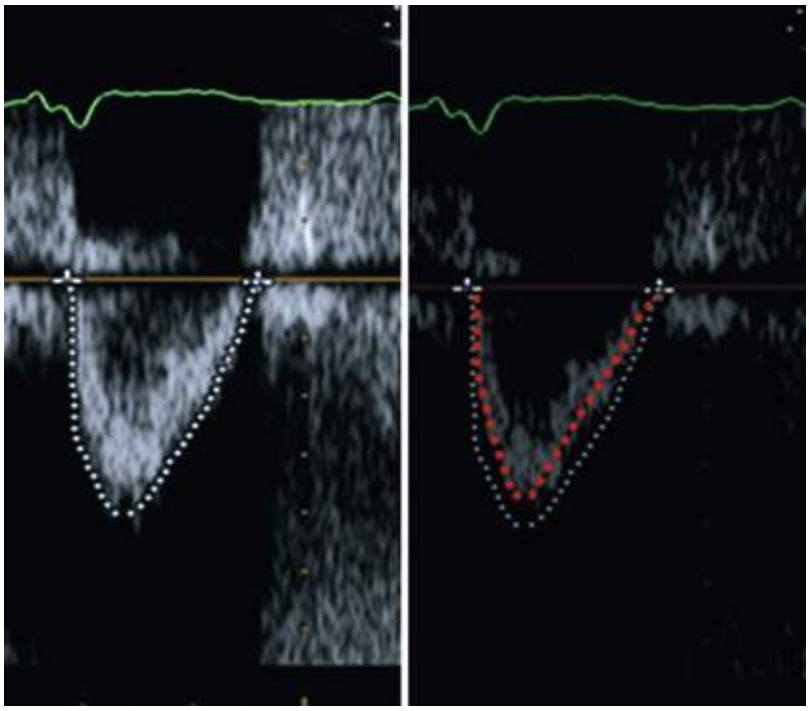

FIGURE 14.49 Doppler spectra demonstrating the error that may be introduced if the maximal (*white dotted line*) rather than the modal (*red dotted line*) velocity is measured. The modal velocity (the most commonly occurring velocity) corresponds to the brightest portion of the Doppler spectrum.

Low-Gradient Severe Aortic Stenosis

In the setting of reduced SV because of LV systolic dysfunction, leaflet excursion may appear reduced and calculated effective orifice area may be small despite low gradients, and it becomes important to determine whether the valve obstruction is fixed (true severe AS) or the valve is intrinsically capable of opening more fully at higher flow rates (pseudosevere aortic stenosis). As noted previously, DSE is routinely used in this setting, typically with close physician supervision to evaluate the true AVA, as well as LV contractile reserve. The effective orifice area may also be severely reduced despite low gradients when the LVEF is within the normal range but SV is impaired, so-called paradoxical low-gradient, preserved–ejection fraction, severe AS (discussed earlier).

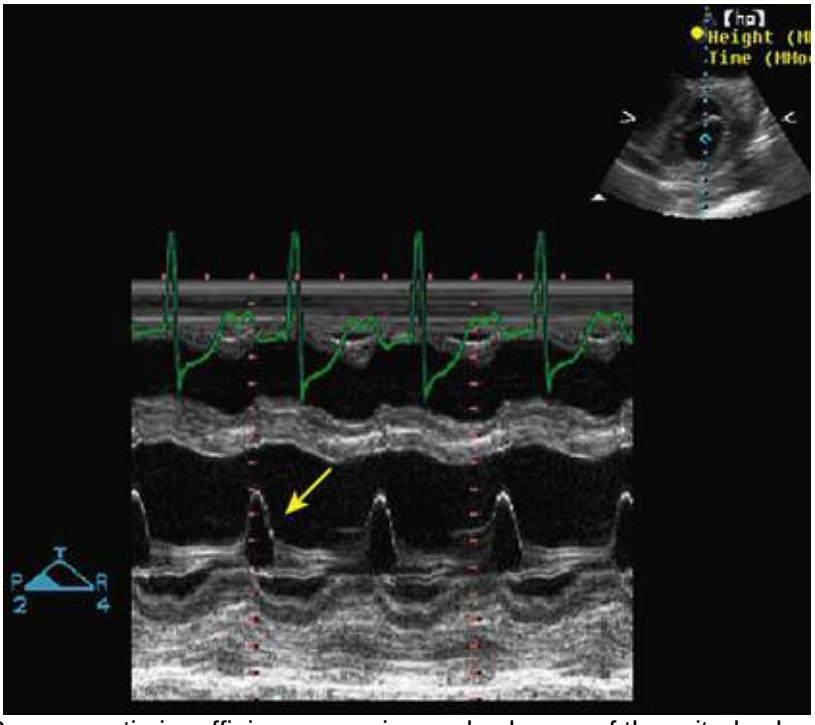
Subvalvular or Supravalvular Aortic Stenosis.

CW Doppler echocardiographic assessment of peak and mean gradients is the cornerstone in evaluating patients with LVOT obstruction below or above the valve. However, by demonstrating the site of flow acceleration relative to the 2D images, color Doppler may provide a clue that the obstruction is not at the level of the valve and prompt the more detailed imaging investigation of the pathophysiology. In some patients, evaluation is complicated by the presence of obstruction at multiple levels, such as the presence of both subaortic and valvular AS. In such cases, because of the trade-off between range resolution and the inability to measure accurately the high velocities inherent in the PW Nyquist limit, it may be impossible to discern accurately the gradients created at each level of obstruction.

Aortic Regurgitation

Aortic regurgitation (AR) may result from abnormalities in the valve cusps, normal cusps whose coaptation is altered by enlargement of the annulus and/or sinuses, or rarely, prolapse of an aortic

dissection flap through the valve (see Diseases of the Aorta). Echocardiographic imaging (TTE and TEE) will establish a causative diagnosis and typically demonstrates LVED enlargement if the regurgitation is hemodynamically significant. High-frequency fluttering of the anterior mitral leaflet caused by the impact of the regurgitant jet may be evident on M-mode, and in cases of acute severe regurgitation, the mitral valve may close prematurely before ventricular systole because of a rise in LV pressure exceeding the LA pressure before ventricular contraction (**eFig. 14.21**).



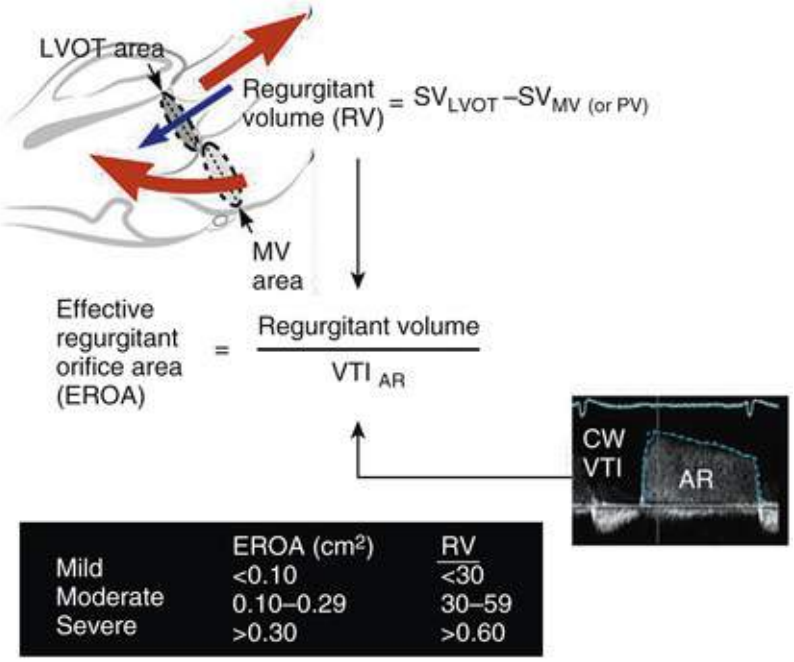
EFIGURE 14.21 Severe aortic insufficiency causing early closure of the mitral valve (*arrow*) on M-mode.

The diagnosis of AR is most easily made when a diastolic color Doppler jet is seen in the LVOT. Small transient jets can be normal variants. Again, an integrated approach is best for determining the severity of AR, with elements including evidence of LV enlargement, color jet dimensions, spectral Doppler signal intensity, pressure half-time, vena contracta, and diastolic flow reversal in the descending thoracic or abdominal aorta (**eFig. 14.22**). Regurgitant volume and fraction can be calculated using a continuity-based approach (**eFig. 14.23**), or alternatively, both measures and EROA may be calculated with the PISA approach. A regurgitant volume of 60 mL or more and EROA of 0.30 cm^2 or greater are consistent with severe AR.[65,66]

	Jet: LVOT width ratio	Vena contracta (mm)	Jet: LVOT area ratio
Mild	<25%	<3	<5%
Moderate	25-64%	3-6	5-60%
Severe	>65%	>6	>60%

Mild | Moderate to severe | Moderate to severe AR

EFIGURE 14.22 Aortic regurgitation (AR) grading by semiquantitative parameters. **Top panel,** Color Doppler zoomed in on the parasternal long axis (*left*) view of the aortic valve showing the AR jet. Parameters that correlate roughly with grades of AR are shown chart below each measurement. The jet height and left ventricular outflow tract (LVOT) height are measured directly on the images. The jet area can be traced by planimetry. LVOT area is calculated as 0.785 × (LVOT diameter/2)^2. **Bottom: Left panels,** CW Doppler of the jet in apical five-chamber view, showing that the density of the CW jet in diastole, relative to the forward-flow envelope, correlates roughly with the severity of AR. **Right panel,** PW Doppler with the pulse sample volume placed in the descending thoracic aorta near the origin of the left subclavian artery, showing that there is diastolic flow reversal suggestive of at least moderate AR. If diastolic flow reversal is seen even more distally, in the abdominal aorta, the AR is likely severe.



EFIGURE 14.23 Calculation of the aortic effective regurgitant orifice area (EROA), using quantitative Doppler methods based on the continuity equation. The EROA represents the average size of the defect in the aortic valve during diastole and is proportional to regurgitant severity. The regurgitant volume (RV) across the aortic valve may be calculated as the difference between the LVOT volume (SV_{LVOT}) and the transmitral volume (SV_{MV}) or transpulmonic volume (SV_{PV}), assuming there is no significant mitral (or pulmonic) regurgitation. Alternatively SV_{LVOT} may be calculated as LVEDV − LVESV, where LVEDV and LVESV are the LV end-diastolic and endsystolic volumes traced from endocardial borders and calculated by modified Simpson's equation, respectively.

Color jet dimensions should be assessed with Nyquist settings of 50 to 60 cm/sec. The best dimensional predictors of angiographic severity are the jet area/LV short-axis area ratio (parasternal short-axis view) and jet diameter indexed to LVOT diameter immediately proximal to the valve (parasternal long-axis view). Jet length is not a reliable index of severity. The pressure half-time reflects the rate at which aortic and LV pressures equalize and is most reliable in the setting of acute AR, as long as care is taken to ensure that the early diastolic velocity is captured accurately (**Fig. 14.50**). The vena contracta is the waist (smallest diameter) of the regurgitant flow jet at the level of the valve measured in zoom mode on a parasternal long-axis or TEE-equivalent view. A measurement greater than 6 mm generally correlates with severe AR. Holodiastolic flow reversal in the descending thoracic aorta as detected with the pulsed Doppler is a marker of at least moderate AR (**see Fig. 14.50 and eFig. 14.22**). Reversal of comparable duration as measured in the abdominal aorta generally reflects severe AR. Although the PISA approach that is widely used to assess the severity of MR has similarly been used to calculate EROA and regurgitant volume for AR, it may be challenging to measure accurately the PISA radius when only mild regurgitation is present (particularly with TTE). The quantitative Doppler approach (**eFig. 14.23**) that calculates regurgitant volume by comparing flow through the LVOT with that across a competent nonstenotic valve is most robust when the pulmonic valve is used as the reference for normal flow (image quality permitting). The mitral valve can theoretically be used as the reference but is more geometrically complex and thus more prone to error.

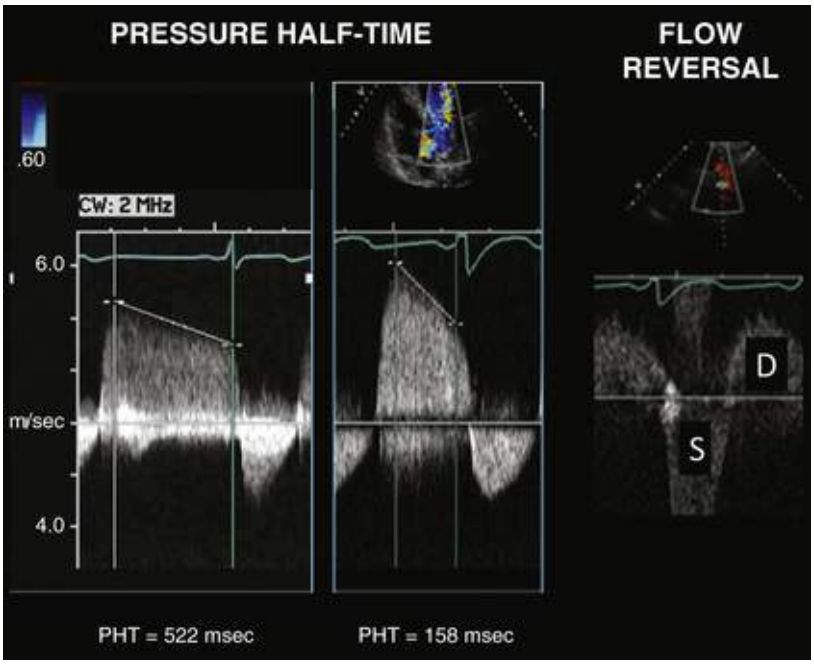


FIGURE 14.50 Doppler methods of quantitating aortic regurgitation (AR). A pressure half-time (PHT) greater than 500 milliseconds suggests mild AR, 200 to 500 milliseconds suggests moderate AR, and less than 200 milliseconds suggests severe AR. Holodiastolic flow reversal in the descending thoracic aorta, as shown here, is consistent with at least moderate AR. *S,* Systole; *D,* diastole.

Tricuspid Valve

Tricuspid Valve Anatomy.
The tricuspid valve is anatomically complex, with anterior, posterior, and septal leaflets extending from the tricuspid annulus to chordae and variable papillary muscle/trabecular attachments. Even though the anterior and septal leaflets are well seen on multiple echocardiographic views, the posterior leaflet is visualized only on the RV inflow tract view and on short-axis views of the right ventricle (which can display all three leaflets). Because of its importance in imaging the tricuspid valve, the RV inflow tract view must be acquired in a manner that displays the inferior (diaphragmatic) wall but avoids the interventricular septum and septal leaflet of the tricuspid valve (**see Fig. 14.10**).

Acquired Disorders of the Tricuspid Valve

Tricuspid stenosis occurs in approximately 11% of patients with rheumatic mitral disease and is characterized by diastolic leaflet doming, as well as by leaflet and chordal thickening (**Fig. 14.51** and Video 14.34). Severity is best assessed by Doppler-derived mean gradients. Methods for calculating valve area, including the pressure half-time approach, have not been validated for tricuspid stenosis (**see Chapter 70**).

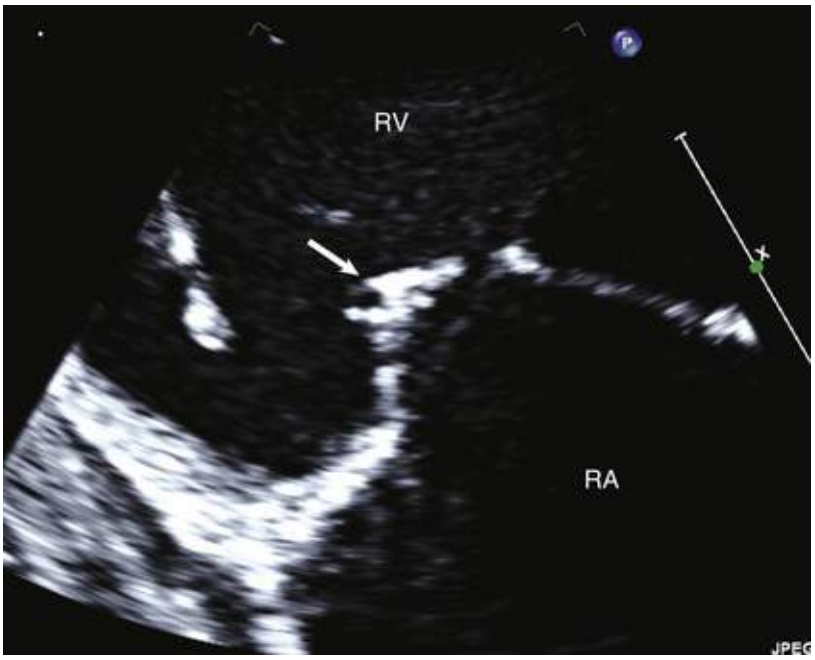

FIGURE 14.51 Right ventricular inflow tract view demonstrating diastolic doming of the posterior leaflet (*arrow*) characteristic of rheumatic tricuspid valve disease. *RA,* Right atrium; *RV,* right ventricle.

Pathologic tricuspid regurgitation (TR) most frequently occurs on a functional basis, that is, attributable to RV enlargement or dysfunction. RV abnormalities may be primary or secondary to pulmonary hypertension and left-sided cardiac abnormalities. The echocardiographic hallmark of functional TR is apical tethering, which when severe may result in a visible regurgitant orifice (noncoaptation of the leaflets) (**Fig. 14.52**). Under these conditions the regurgitant jet could be laminar and relatively low velocity because of the almost complete equalization of pressures between the right ventricle and the right atrium and could lead to underestimation of the severity of the TR. Similarly, estimation of pulmonary artery systolic pressure from TR jet velocity will be inaccurate in this situation.

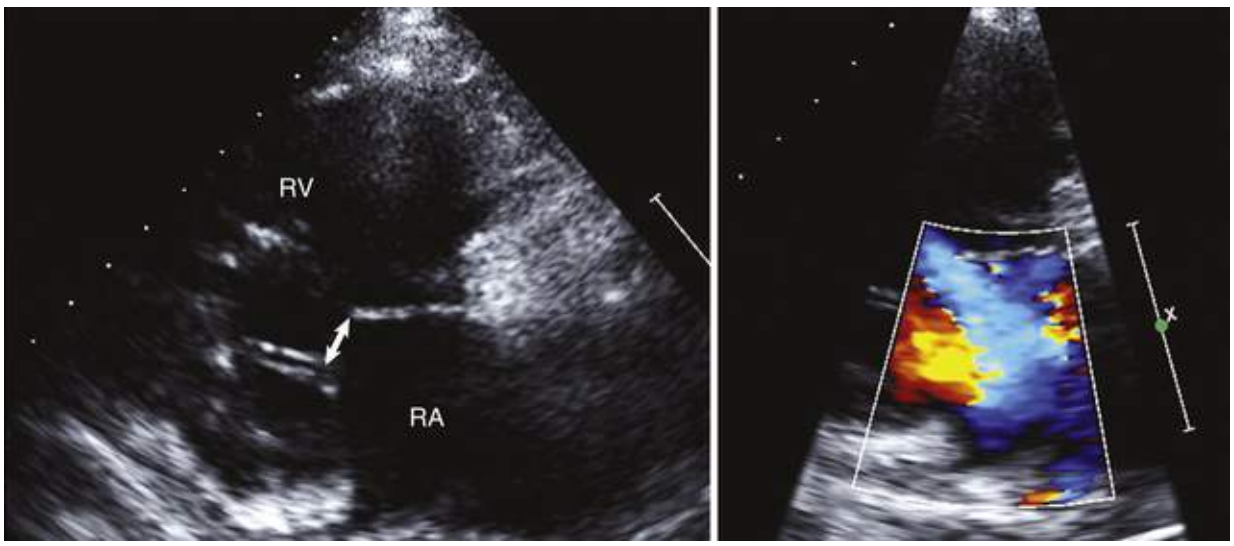

FIGURE 14.52 **Left,** Right ventricular inflow tract view showing failure of coaptation of the anterior and posterior leaflets (*arrow*) in a patient with severe functional tricuspid regurgitation. *RA,* Right atrium; *RV,* right ventricle. **Right,** Severity may be underestimated because of its low velocity and monochromatic appearance.

Less common acquired causes of TR include carcinoid, rheumatic disease, endocarditis, trauma (including iatrogenic injury to the valve during RV biopsy), pacemaker and defibrillator wires, and

myxomatous disease with prolapse. The characteristic echocardiographic appearance of carcinoid heart disease is drumstick-like, rigid, and shortened leaflets with at times a visible regurgitant orifice (**Fig. 14.53** and Video 14.35). Spontaneous flail of the tricuspid valve virtually never occurs but is precipitated by the previous causes. Myxomatous tricuspid valve disease has been less well studied than mitral disease, with less clear-cut criteria for the diagnosis of prolapse. It frequently accompanies myxomatous mitral disease.

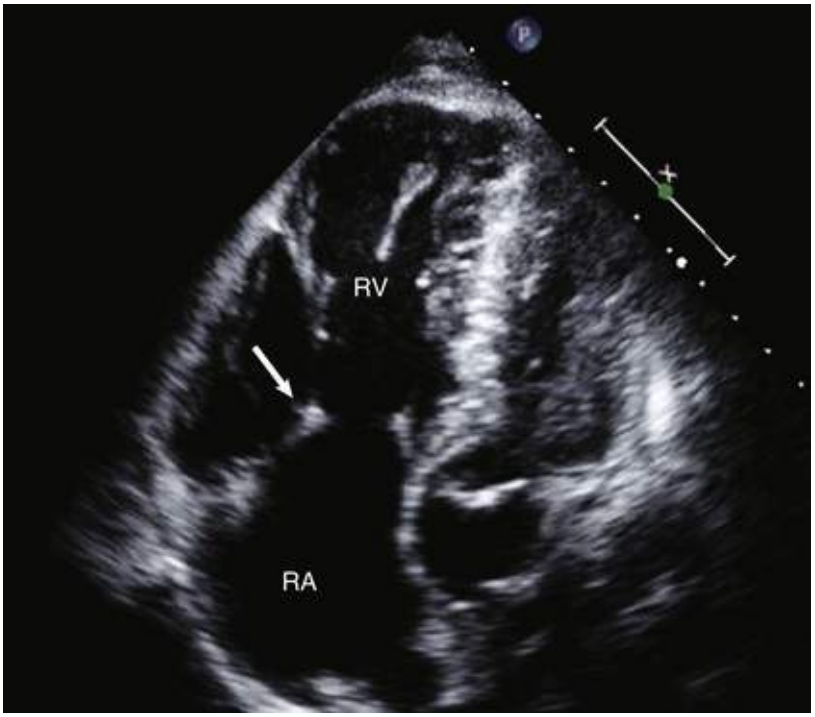

FIGURE 14.53 Apical four-chamber view showing the drumstick appearance of the tricuspid valve (*arrow*), which is characteristic of carcinoid valvopathy. *RA,* Right atrium; *RV,* right ventricle.

Quantitation of Tricuspid Regurgitation

Quantitation of TR is similar to that for MR and consists of an integrated approach,[65,66] including measures of jet size, vena contracta, and PISA-derived regurgitant volume and EROA. Systolic flow reversal into the hepatic veins is specific for severe TR.

Pulmonic Valve

Pulmonic Valve Anatomy.

The normal pulmonic valve is tricuspid with a structure that is similar to that of the aortic valve. The cusps are named right, left, and anterior, although it is unusual to be able to see all three cusps simultaneously with 2D imaging. The pulmonic valve can be seen on parasternal and subcostal views, as well as on anteriorly oriented apical views. TEE windows include the midesophageal, deep transgastric, and high esophageal (at the level of the aortic arch). The most common congenital anomaly is valvular stenosis, based on developmental abnormalities that mimic those of a bicuspid aortic valve (**eFig. 14.24**). It is characterized by systolic doming and a jump rope–like appearance of the valve (Video 14.36

). Congenital pulmonic stenosis may be isolated or may occur as a feature of more complex congenital anomalies. Acquired pulmonic disease is rare and includes carcinoid and endocarditis, as well as iatrogenic disruption of the valve because of balloon or surgical valvuloplasty for congenital stenosis.

EFIGURE 14.24 Systolic parasternal short-axis view demonstrating systolic doming of this congenitally stenotic pulmonic valve (*arrow*). In real time the valve has a jump rope appearance.

Quantitation of Valve Dysfunction

Pulmonic stenosis is most reliably quantitated with mean and peak gradients, although the continuity equation provides a means of calculating valve area. Pulmonic regurgitation is usually graded on the basis of jet dimensions, with the caveat that there may be little turbulence in the setting of severe regurgitation with normal pulmonary pressure, which can lead to inadvertent underestimation of the true severity. Laminar regurgitant flow is a clue to severe regurgitation (**Fig. 14.54**).

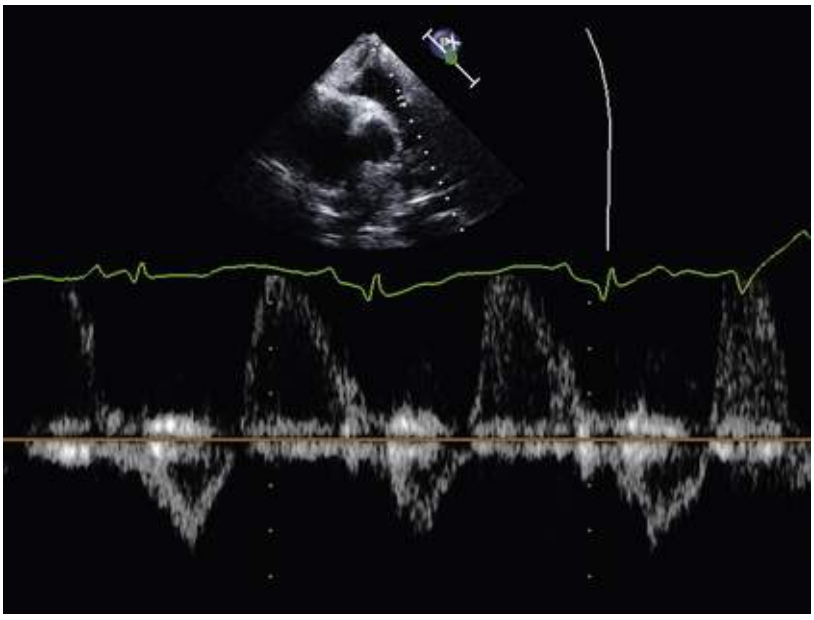

FIGURE 14.54 PW Doppler interrogation of the RVOT in a patient who has undergone pulmonary valvotomy. There is severe pulmonic regurgitation resulting in a laminar regurgitant signal.

Prosthetic Valves

Echocardiographic assessment of prosthetic valves requires an understanding of valve design, normal functional characteristics, and the imaging artifacts introduced by valve elements (**see Chapter 71**).

The most commonly encountered mechanical valves are bileaflet or single, tilting disc valves. Ball-and-cage valves, which are no longer implanted, are becoming increasingly rare. Most bioprosthetic valves are stented porcine or bovine pericardial valves, although freestyle (stentless) xenograft, cadaveric homograft, autograft (Ross procedure), and transcatheter and sutureless surgical valves are also available. Prosthetic annular rings are also often used for mitral and tricuspid repair. The sewing rings of all valves, as well as the occluders of mechanical valves, may cause acoustic shadowing that limits imaging and Doppler assessment; the exceptions to this are the stentless, homograft, and autograft valves, which may be indistinguishable from that of native valves. Additionally, the material of the ball in ball-and-cage valves transmits sound more slowly than human tissue does, with the result that the ball appears much larger than its actual size when imaged echocardiographically.

Even normally functioning prostheses tend to be intrinsically stenotic, with the degree of stenosis inversely related to valve size. Additionally, trivial degrees of valvular regurgitation are normal findings, and although not normal, trivial paravalvular regurgitation is not uncommon. Intraventricular microcavitations (apparent “microbubbles”) are often seen in the left heart in the presence of mechanical valves and are not considered abnormal. **Figs. 14.55 to 14.57** and Video 14.37 demonstrate the normal echocardiographic appearance of the most common prostheses. **eTable 14.5** provides normal echocardiographic values for the most common implanted valves.[67] More current data, including recently introduced prostheses, are collated from the literature and valve manufacturers at www.valveguide.ch.[68] A helpful rule of thumb when valve size is unknown is that for common-size prostheses in patients with physiologic heart rates and SV, the peak transaortic velocity should be less than 3 m/sec and the mean transmitral gradient 5 mm Hg or lower. Stentless bioprosthetic valves, which have little or no acoustic shadowing due to lack of a rigid annulus, are designed to have lower hemodynamic profiles (i.e., lower gradients) than their equivalently sized first-generation predecessors and appear useful for implantation in patients with a small annulus or severely reduced LV function.

From Zoghbi WA et al. Recommendations for evaluation of prosthetic valves with echocardiography and Doppler ultrasound. A report from the American Society of Echocardiography's Guidelines and Standards Committee and the Task Force on Prosthetic Valves. J Am Soc Echocardiogr 2009;22:975.

The echocardiographic approach to prosthetic valves is similar to but often more challenging than that

of native valves. Peak and mean gradients are calculated by using the conventional application of the Bernoulli equation, and effective orifice area may be calculated with the continuity equation. Additionally, the Doppler velocity or "dimensionless" index, defined as the ratio of the VTI (or peak velocity) proximal to the valve to that distal to the valve, provides an alternative metric of aortic prosthetic function that is useful when LVOT diameter cannot be measured. As for native valves, it is critical that LVOT sampling be proximal to the site of flow acceleration; in the case of transcatheter or sutureless valves, the sampling volume should be proximal to the inlet of the metal frame because in these valves there is acceleration of flow at the inlet, as well as at the level of the cusps. For mitral prostheses, the comparable measure is the ratio of mitral to aortic VTI. In the patient with AF, matching of cycle lengths for beats used for LVOT and valvular VTIs is preferred to averaging over multiple beats. Beats corresponding to physiologic heart rates should be used if available. Although the pressure half-time may be useful in a relative sense in patients with mitral prostheses, it does not provide a valid measure of effective orifice area.

In many centers, intraoperative TEE is performed routinely during valve procedures, and these studies can both alert the surgeon to remediable complications before chest closure and serve as reference studies for follow-up evaluation. It is also recommended that TTE be performed soon after implantation to define the baseline appearance and structure with this modality and under more physiologic conditions than those present in the immediate postpump period (**see Chapter 67**). For all studies, chamber dimensions and function and estimated pulmonary artery systolic pressure, as well as heart rate, blood pressure, and BSA, should be included in the report. Before postoperative echocardiographic evaluation, it is important to obtain information on valve type and size and details of the valve implantation when possible.

Abnormalities in Valve Appearance.

Abnormalities in valve appearance include evidence of an unusual implantation position or valvular dehiscence, which when extensive is characterized by pathologic valve rocking (Video 14.38). Although extensive bioprosthetic cusp thickening is typically associated with functional disturbance (see later), mild abnormalities may not affect valve function. Similarly, valve vegetation and thrombus may be functionally silent. Therefore, echocardiographic evaluation must focus on structure even when function is normal, with ensuing TEE planned if TTE images are nondiagnostic.

Approach to Assessing Elevated Prosthetic Gradients.

The diagnosis of prosthetic stenosis is suggested when gradients are elevated and the effective orifice area is reduced relative to published norms. For aortic prostheses, a Doppler velocity index less than 0.25 or a ratio of acceleration to ejection times greater than 0.4 supports the diagnosis. For mitral prostheses, a pressure half-time longer than 200 milliseconds, peak E wave greater than 1.9 m/sec, or VTI_{MV}/VTI_{LVOT} of 2.2 or greater is considered abnormally high. As with native valves, gradients must be interpreted in the context of heart rate. Causes of prosthetic stenosis include restricted leaflet/disc motion because of thrombus (**Fig. 14.58** and Video 14.39), pannus ingrowth (**Fig. 14.59**), vegetation, or in the case of bioprostheses, cusp degeneration often with calcification (**Fig. 14.60**). Differentiation between pannus and thrombus may be challenging, although thrombi tend to have a softer echotexture than pannus and may be larger with extension beyond the sewing ring. Clinical factors suggesting thrombus include the acuity of symptom onset and a history of inadequate anticoagulation. Because the restricted motion may be intermittent, it is important to capture multiple beats if prosthetic dysfunction is clinically

suspected. TEE is frequently required to image valves optimally, and fluoroscopy may be helpful when abnormal occluder motion is suspected in mechanical valves.

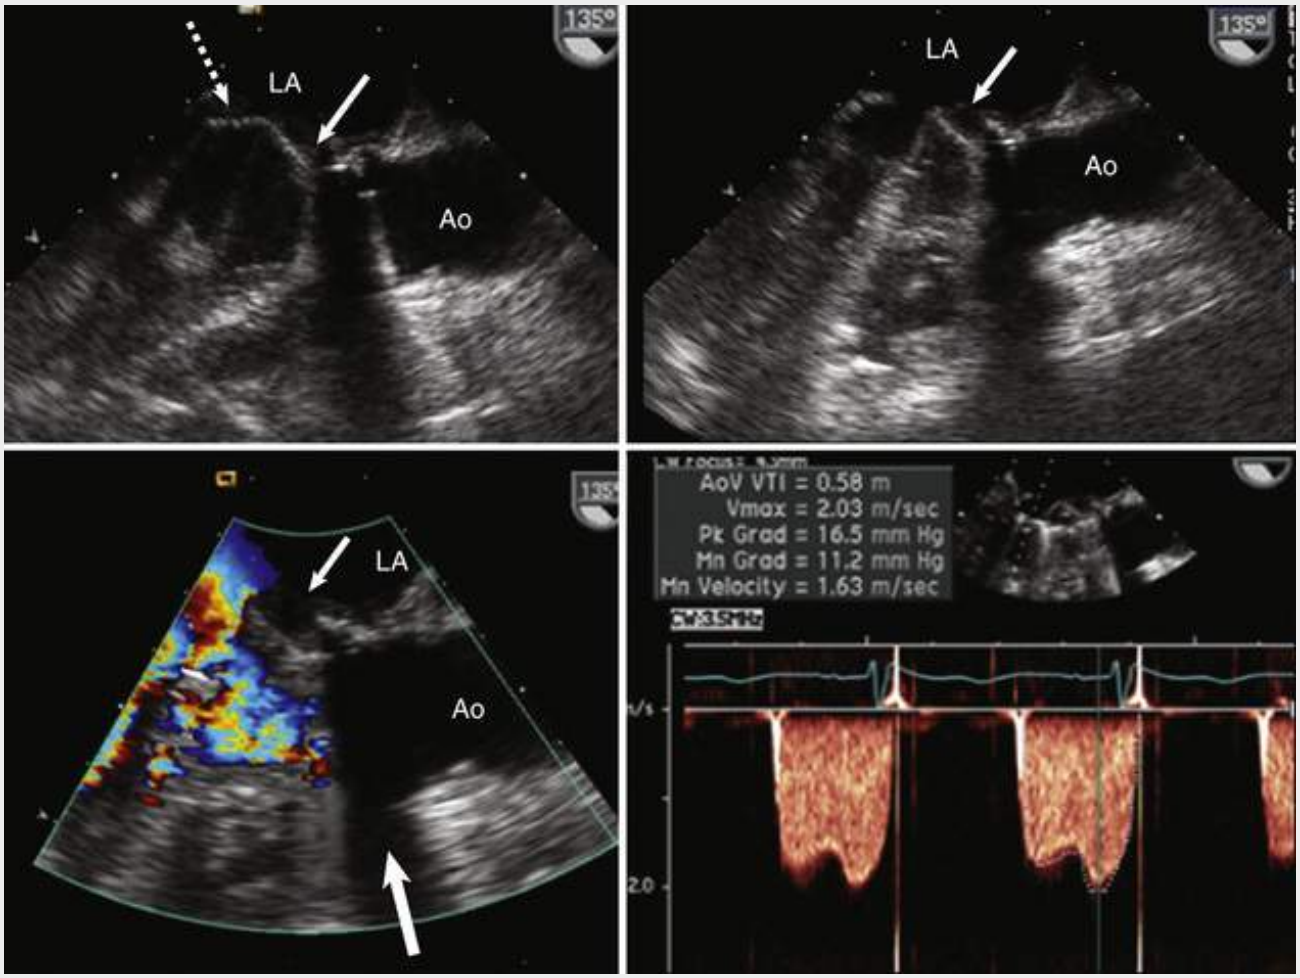

FIGURE 14.58 TEE showing a bileaflet mechanical mitral prosthesis in which one disc is immobilized because of thrombus. **Upper left,** Systolic frame showing that neither disc (*arrows*) closes completely. **Upper right,** While the left disc opens fully, the right disc is immobile. **Lower left,** Color flow Doppler demonstrating high-velocity flow through a single orifice. The *large arrow* indicates acoustic shadowing because of the mitral sewing ring. **Lower right,** Doppler demonstrating an elevated transmitral gradient (11 mm Hg at a heart rate of 65 beats/min). *Ao,* Aorta; *LA,* left atrium.

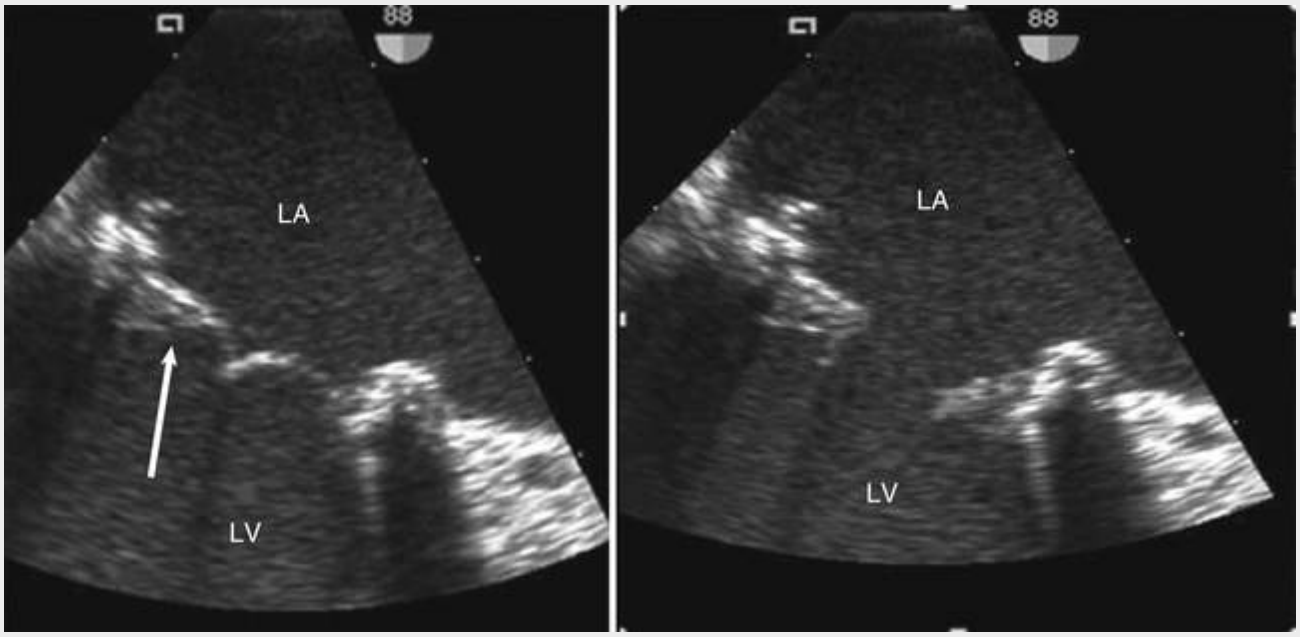

FIGURE 14.59 TEE appearance of pannus ingrowth (*arrow*) in a mitral bioprosthesis. **Left,** Systole. **Right,** Diastole. The pannus has immobilized the base of the left-sided cusp and created a hinge point midway along the cusp and an narrow orifice. *LA,* Left atrium; *LV,* left ventricle.

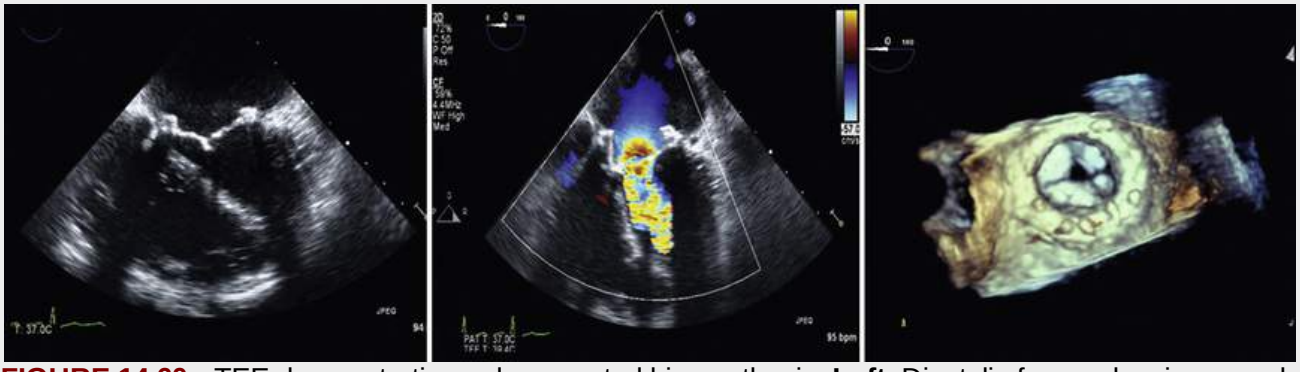

FIGURE 14.60 TEE demonstrating a degenerated bioprosthesis. **Left,** Diastolic frame showing grossly restricted cusp motion. **Middle,** Color Doppler demonstrating turbulent transmitral flow and an easily identifiable proximal isovelocity hemispheric surface area shell. **Right,** 3D TEE view of the prosthesis from the left atrial perspective. The mitral orifice is greatly restricted.

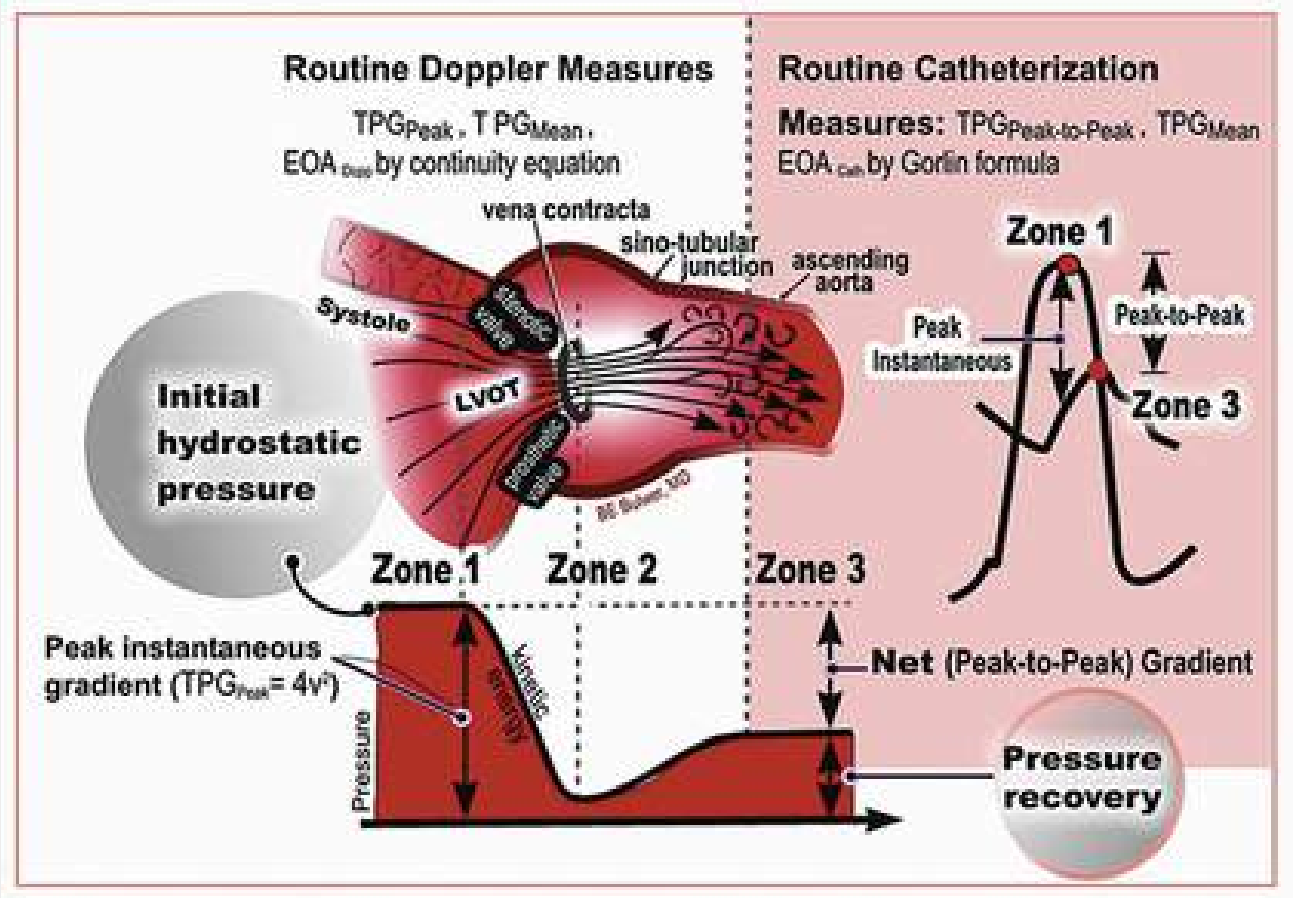
Notably, elevated gradients do not always reflect prosthetic stenosis. *Patient-prosthesis mismatch* (PPM) refers to the situation in which the implanted valve, although functioning normally, has elevated gradients (**see Chapter 71**). This occurs when patient anatomy results in the implantation of a smaller-than-ideal valve. The diagnosis is made by confirming that the calculated effective orifice area is consistent with normal function, but the indexed orifice area is 0.85 cm^2/m^2 or less for aortic prostheses and less than 1.2 cm^2/m^2 for mitral prostheses. For aortic prostheses an indexed effective orifice area less than 0.65 cm^2/m^2 is considered severe PPM, a phenomenon encountered in 2% to 11% of patients. PPM is best studied for the aortic valve and is reportedly associated with poorer outcomes,[69] although in obese patients it is unclear whether the indexed effective orifice area should be calculated on the basis of lean rather than actual body mass.

Elevated gradients may also be a consequence of significant regurgitation, which when paravalvular may be underappreciated on initial evaluation. A final important cause of elevated gradients in aortic prostheses, *pressure recovery*, refers to the tendency for Doppler-derived gradients to overestimate those registered invasively. This occurs because Doppler measures the largest gradient, typically encountered

at the vena contracta, whereas invasive measurements reflect pressure distal to the valve where there has been recovery either because blood has moved from the narrow valve orifice into the wider aorta (i.e., a flask-shaped aortic root, which is a significant factor only in the setting of aortas measuring <3 cm) or, in the case of bileaflet mechanical valves, because the lower pressure encountered in the central orifice is augmented by higher pressure caused by eddies at the lateral orifices (**eFig. 14.25**). Pressure recovery is most important clinically in the setting of small (≤19 mm) bileaflet valves in the aortic position. As demonstrated, the measurements most representative of invasive gradients is obtained by carefully interrogating the lateral orifices, but this generally requires TEE. Alternatively, it has been suggested that gradients recorded through the central orifice may be corrected by applying the pressure loss coefficient of 0.64. (Of note, the reported normal values in **eTable 14.5** are uncorrected.)



EFIGURE 14.25 The pressure recovery phenomenon.

Prosthetic Regurgitation.

Trivial degrees of valvular regurgitation are normal findings, although the location of normal jets varies depending on the valve type. Pathologic regurgitation may be valvular and may arise within the sewing ring or may be paravalvular, exterior to the sewing ring. *Valvular* regurgitation in mechanical valves typically reflects occluder malfunction as a result of pannus, thrombus, vegetation, or rarely, retained mitral valve apparatus, whereas in bioprostheses, this is typically a result of cusp degeneration or disruption from endocarditis. *Paravalvular* regurgitation may be a residual finding resulting from suboptimal implantation or may develop de novo from endocarditis or spontaneous valve dehiscence. Some degree of paravalvular regurgitation is a common finding after transcatheter aortic valve implantation (**see Chapter 72**), but moderate or greater degrees appear to be associated with a worse prognosis (**Fig. 14.61**).

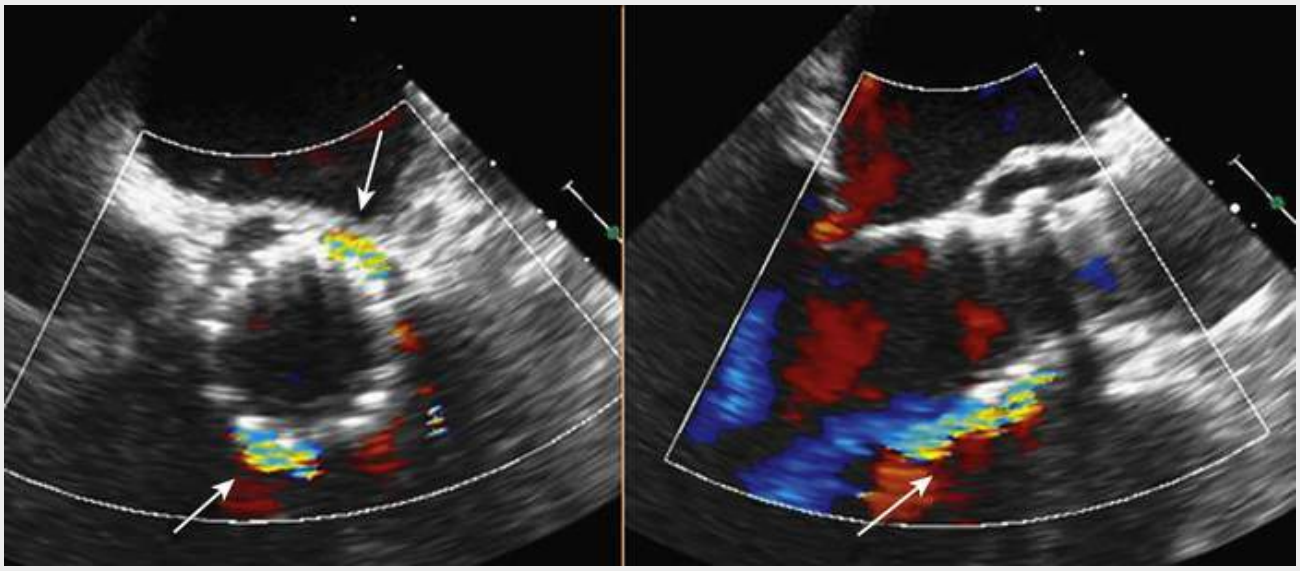


FIGURE 14.61 Orthogonal TEE views of a balloon-expandable aortic prosthesis (TAVI, CoreValve) with at least two sites of significant paravalvular regurgitation (*arrows*), seen as turbulent diastolic flow on **left panel** (45 degrees) and **right panel** (120 degrees).

Detection of prosthetic regurgitation may require nonstandard views. Quantitation of prosthetic regurgitation may be challenging because jets frequently are highly eccentric and may be multiple, thus limiting the value of approaches based on jet dimensions. For mechanical valves the acoustic shadowing cast by mitral prostheses can greatly limit detection of MR, because the shadowing predictably falls directly over the left atrium in TTE views. The use of TEE is extremely advantageous in this respect since it insonifies the valve from an aspect posterior and directly adjacent to the left atrium. Assessment of paravalvular regurgitation in transcatheter or sutureless valves is particularly difficult because multiple pinhole jets may be present.[70] As in native AR, the presence of a shortened pressure half-time (<200 msec) and holodiastolic flow reversal in the descending thoracic or abdominal aorta are clues to significant regurgitation. For mitral prostheses, VTI_{MV}/VTI_{LVOT} of 2.2 or greater (as seen in stenotic valves as well), but in particular an elevated E wave (i.e., peak gradient elevated out of proportion to the mean gradient) and pulmonary venous flow reversal in systole, should raise suspicion for significant regurgitation. The quantitative Doppler approach using the pulmonic valve as the reference may also be helpful for aortic prostheses. As in native valvular regurgitation, regurgitant volume values less than 30 mL, 30 to 59 mL, and 60 mL or more and regurgitant fraction values less than 30%, 30% to 50%, and more than 50% are consistent with mild, moderate, and severe prosthetic AR, respectively. For mitral valves the presence of well-defined flow convergence suggests significant regurgitation, and the PISA approach may be used to quantitate central valvular or well-defined single paravalvular jets. 3D TEE approaches that allow direct planimetry of regurgitant orifices and better localization of paravalvular leaks facilitate these tasks and may be more accurate.

Prosthetic tricuspid and pulmonic valves are much less common than their left-sided counterparts. In general, methods developed for assessment of the mitral and aortic valves are extrapolated to the tricuspid and pulmonic valves, although the evidence base for their use is less robust.

Pericardial Disease

Echocardiography is the imaging modality of choice for the identification of pericardial effusion and is an important tool in the diagnosis of tamponade and pericardial constriction (**see Chapter 83**).

Pericardial Effusion

Identification of pericardial effusion was one of the earliest applications of echocardiography. The diagnosis is made when an echo-free space separates the visceral and parietal pericardial echoes throughout the cardiac cycle, including diastole (**Fig. 14.62**). Systolic separation alone may be a normal finding. In most cases the diagnosis of pericardial effusion is straightforward because the parietal pericardium is a strong echo reflector and the visceral pericardium is adherent to the epicardial surface of the heart. “Echo free” is defined as having an echotexture that is equivalent to that of the intracardiac blood pool. Although it is typically black, in some cases suboptimal image quality results in both blood pool and pericardial effusion with a grayish or intermediate echotexture. In such cases it may be difficult to differentiate a small pericardial effusion from epicardial fat, although the latter typically has a more reticulated inhomogeneous appearance than a fluid effusion.

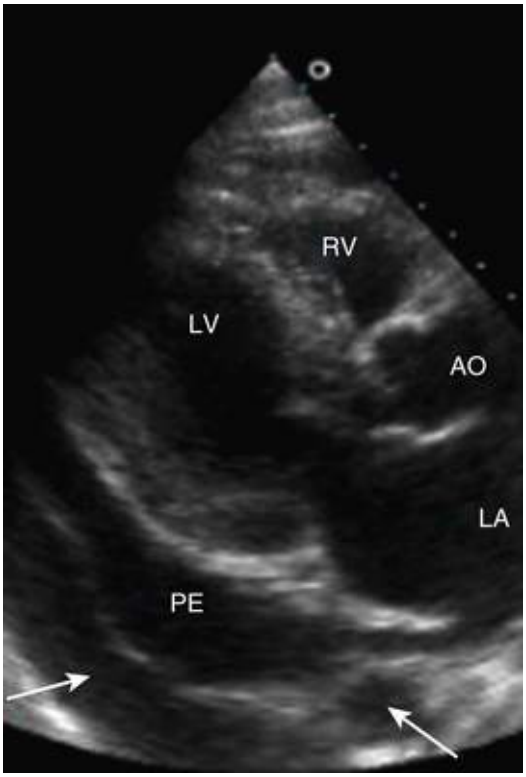

FIGURE 14.62 Pericardial effusion. A parasternal long-axis view shows both pericardial effusion (*PE*) and pleural effusion (*short arrow*). Note that the descending thoracic aorta (*long arrow*) is displaced from the heart by the pericardial effusion. With isolated pleural effusion, the descending aorta (*Ao*) remains immediately posterior to the heart. In this case the pericardial effusion extends posterior to the left atrium (*LA*), although this is not always the case. *LV,* Left ventricle; *RV,* right ventricle.

Another source of confusion may be left pleural effusion. Differentiating features include displacement of the aorta from the heart by pericardial (but not pleural) fluid and extension of pleural (but not pericardial) fluid behind the left atrium (**Fig. 14.62**). Of the two features, the relative position of the aorta

is the most definitive because the position of the pericardial reflection is somewhat variable. Pericardial effusions may extend cephalad beyond the atrioventricular groove. It is therefore essential that sonographers routinely provide views that demonstrate the descending thoracic aorta and its position relative to the heart. Multiple windows—particularly the subcostal view, because fluid is gravity dependent and thus tends to collect inferiorly—are essential to rule out localized effusions.

Sizing of pericardial effusions is typically somewhat subjective, with the terms *trace*, *small*, *medium*, and *large* being used. For reporting the size of effusions when longitudinal comparison will be important, it is helpful to report the maximal diameter of the effusion while noting the view(s) and time of the cardiac cycle (systole versus diastole) when the measurement is taken. Earlier estimates of the volume of the effusion, calculated using linear measures of pericardial and epicardial diameter, relied on a symmetric distribution of fluid and assumptions on the shape of the pericardial sac and heart. In a small case series, tracing pericardial and epicardial borders at end-diastole, and using the biplane Simpson method of discs instead to calculate the difference between the two volumes, has been shown to correlate much better with volumes drained by pericardiocentesis, underestimating the pericardial effusion by a mean of 9%.[71]

Pericardial Hematoma

Pericardial hematoma results from bleeding into the pericardial space and may be caused by bleeding along suture lines after open heart surgery, trauma, myocardial rupture, or aortic dissection or may occur as a complication of catheter-based or surgical intervention. Hematomas typically have an echotexture that is more coalescent and echodense than that of free fluid. They may be unevenly distributed and localized to the bleeding site, such as the anterior mediastinum post-CABG. When images are obtained in the acute setting, there may be evidence of both clot and free fluid (**Fig. 14.63**).

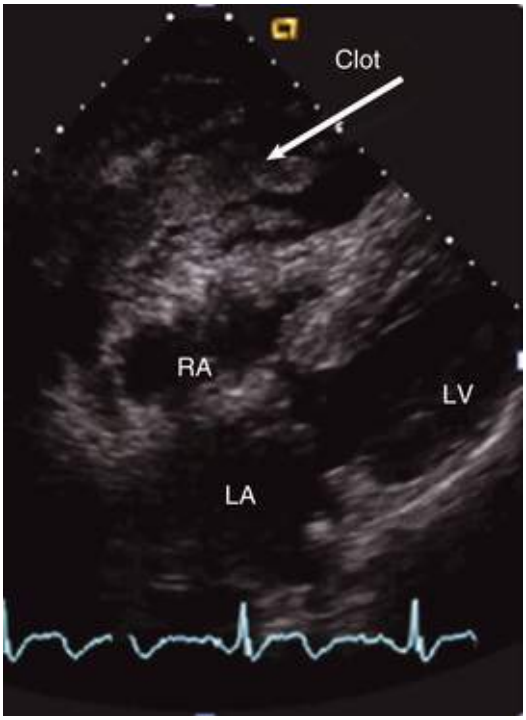

FIGURE 14.63 Pericardial hematoma. A subcostal view shows clotted (*arrow*) and free blood (black echotexture) within the pericardial space. In this patient the cause was acute aortic dissection. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium.

Echocardiographic Markers of Tamponade.

Echocardiographic markers of cardiac tamponade fall into two categories: (1) cardiac chamber invagination reflecting *elevated intrapericardial pressure* and the resultant pressure gradients across the chamber walls and (2) echocardiographic markers of pulsus paradoxus, which reflect exaggerated respiratory variation in left-sided heart filling and ejection relative to that of the right side of the heart (*ventricular interdependence*).

Right atrial inversion is a dynamic phenomenon with onset when RA volume and pressure are lowest: in late ventricular diastole immediately after atrial contraction (**Fig. 14.64, left panel**, and Video 14.40). Inversion continues through a variable portion of ventricular systole and resolves as the right atrium fills and RA pressure rises. This sign can be detected in any view where the RA wall and adjacent effusion are well seen, typically the parasternal short-axis view at the level of the great vessels and the apical four-chamber and subcostal four-chamber views. This sign is highly sensitive (100%) but may be present when hemodynamic disturbances are invasively detectable but fall below the threshold for the clinical diagnosis of tamponade, resulting in a specificity for clinical tamponade of 82%. Empirically, an RA inversion time index (readily calculated as number of frames during which the right atrium is inverted divided by number of frames per cardiac cycle) of at least 0.33 is associated with clinically evident tamponade (100% specificity, 95% sensitivity). *Left atrial inversion* as a marker of tamponade is rare and typically occurs in the setting of loculated effusions or those in which the pericardial reflection is relatively high and the left atrium is exposed to the effects of intrapericardial pressure.

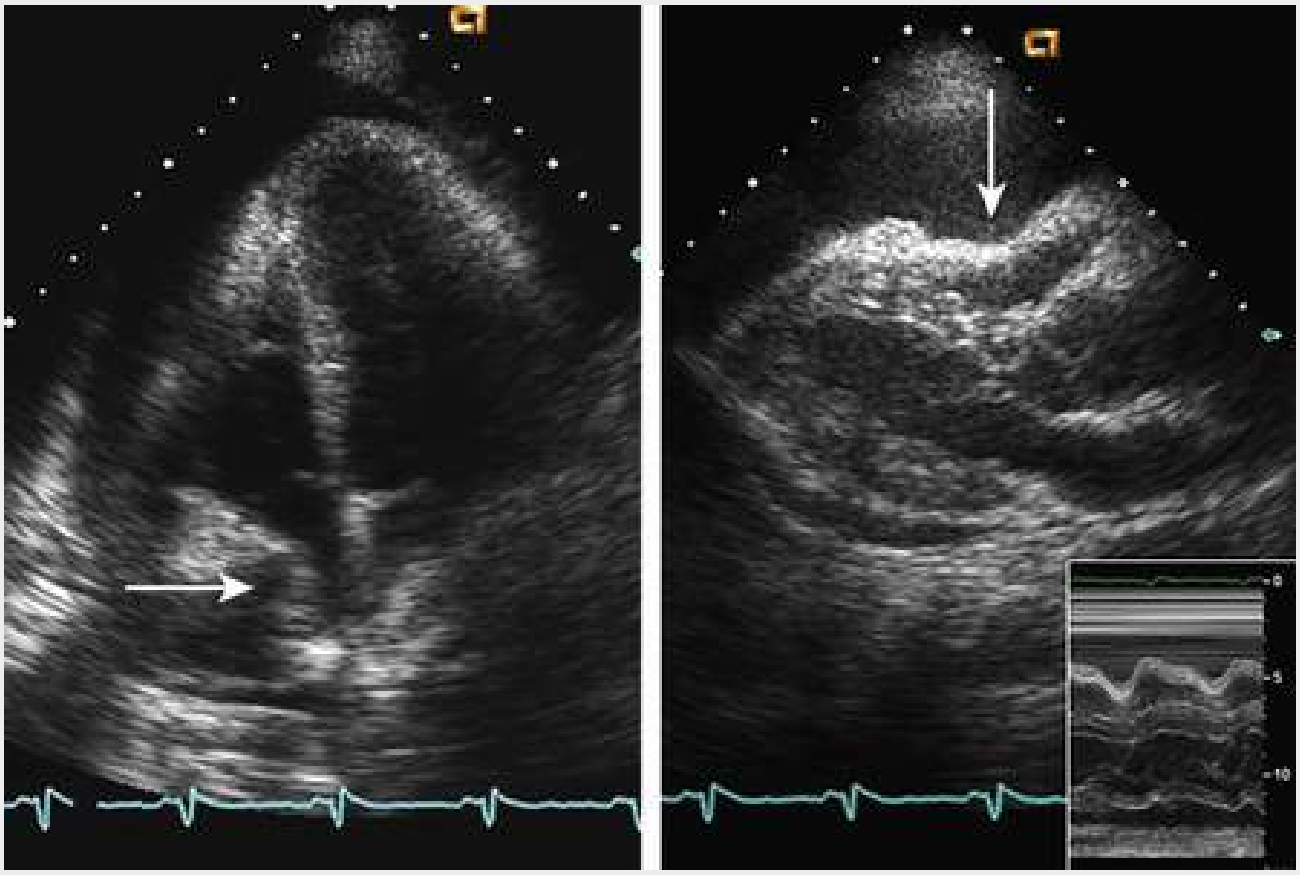

FIGURE 14.64 Signs of cardiac tamponade. **Left,** Apical four-chamber view showing RA inversion (*arrow*), a marker of tamponade. In this case, inversion, which is initiated in late ventricular diastole, has persisted well into ventricular systole. **Right**, Parasternal long-axis view showing RV collapse in diastole (*arrow*). *Inset,* An M-mode cursor placed down the RVOT shows diastolic inversion of the RV wall (note timing with respect to the ECG, closed aortic valve, and open mitral valve). (See Videos 14.40 and 14.41 .)

Right ventricular inversion has its onset when RV volume and pressure are lowest: during isovolumic relaxation (**Fig. 14.64, right panel**). It continues through a variable portion of ventricular diastole, with the RV contour normalizing as the ventricle fills and RV pressure rises. This sign is most easily detected on the parasternal long-axis view, which displays the RVOT (Video 14.41). Its reported sensitivity is 82% to 94%, with a specificity of 88% to 100%.

It is important to note that RA inversion and RV inversion are defined by actual wall invagination rather than by the normal flattening that may occur with respective chamber systole. RA or RV inversion may also be absent (i.e., false negative) in the setting of underlying right-sided heart dysfunction associated with elevated intracavitary pressure. With pericardial hematoma in which no free blood is present, dynamic inversion of the chambers will not be observed, but the presence of fixed compression and underfilling of the cardiac chambers may be clues to the presence of tamponade physiology.

There is an echocardiographic correlate to the clinical phenomenon of pulsus paradoxus. In the normal state, a slight increase (up to 17%) in flow velocities through the right heart occurs on inspiration, and a reciprocal but smaller decrease (up to 10%) in flow velocities through the left heart occurs during expiration. These tendencies are exaggerated when a tense, fluid-filled pericardium constrains the overall heart size and increases interdependence between the right and left ventricles. The most widely used signs are an exaggerated (>25%, and often >60% in frank tamponade) increase in the tricuspid inflow Doppler E wave peak velocities with a reciprocal decrease (of >30%) in the mitral E wave velocities (**Fig. 14.65**), as well as corresponding changes in the pulmonic and aortic (or LVOT) systolic Doppler spectra. Additional signs of tamponade include the characteristic appearance of the heart oscillating or “swimming” in the pericardial fluid (see Video 14.41), which has its counterpart in

electrical alternans on ECG, and a dilated IVC consistent with elevated RA pressures.

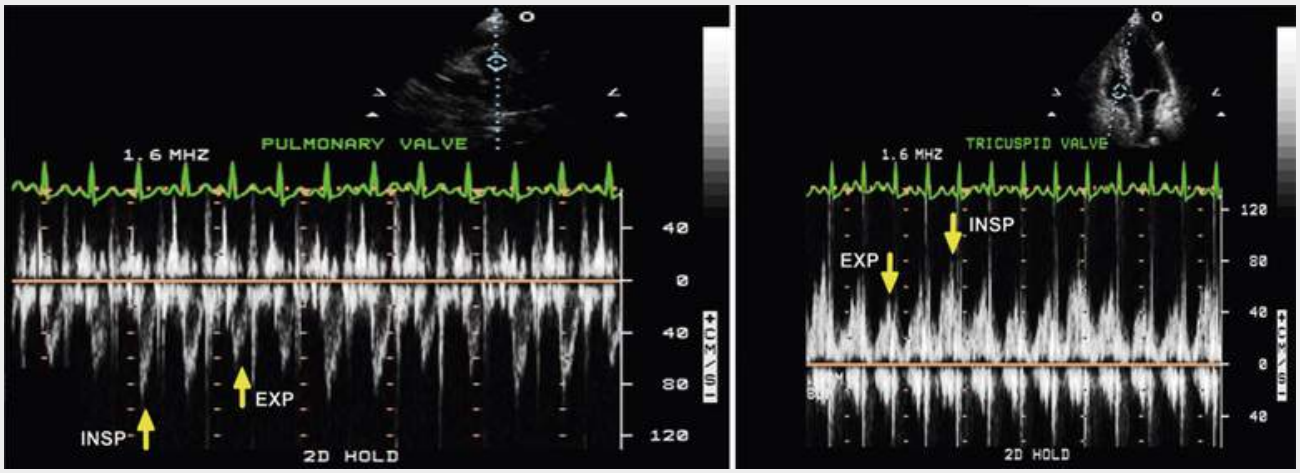

FIGURE 14.65 Doppler spectra showing the characteristic exaggerated respiratory variation in right-sided pulmonary valve outflow **(left panel)** and tricuspid valve inflow **(right panel)** peak flow velocities. On inspiration, right-sided flow increases. In the left heart, PW tracings of LVOT outflow and mitral valve inflow (not shown) would demonstrate reciprocal reductions in left-sided flow on inspiration. *EXP,* Expiration; *INSP,* inspiration.

Pericardiocentesis.

Echocardiography may also be useful in guiding needle pericardiocentesis, particularly in the setting of loculated effusions. Imaging may help identify the best puncture site and angle of needle introduction, then confirm that the needle has entered the pericardial space. The latter is accomplished by the injection of a small amount of agitated saline, which will opacify the pericardial effusion with proper needle placement, but this will result in intracardiac contrast bubbles if the needle inadvertently penetrates the heart. Echocardiography is used to document the reduction in effusion size that should occur with successful drainage.

Constrictive Pericarditis

Pericardial constriction occurs when there is thickening, with or without calcification, of the pericardium that results in impaired cardiac diastolic filling, particularly during inspiration (**Fig. 14.66**). The clinical features mimic those of biventricular heart failure, although the presence of a pericardial knock and Kussmaul sign (inspiratory increase in jugular venous pressure) should raise suspicion for constriction. Frequently, when the patient is referred for echocardiographic evaluation, the clinical differential diagnosis is “restrictive cardiomyopathy” versus pericardial constriction, since ejection fraction (EF) is generally preserved in both. Pericardial thickening is a hallmark of constriction but is a relatively insensitive finding; furthermore, echocardiography can be relatively insensitive for detecting pericardial thickening compared with CT and CMR. When the pericardial space is expanded because of adhesions and fibrous tissue, the visceral and parietal pericardia are separated by tissue of variable echogenicity, unlike the echolucent appearance of pericardial effusion. Also, with effusion the parietal pericardial echo will be relatively stationary, whereas with pericardial thickening, visceral and parietal pericardial echoes will move in tandem. Calcification will result in acoustic shadowing.

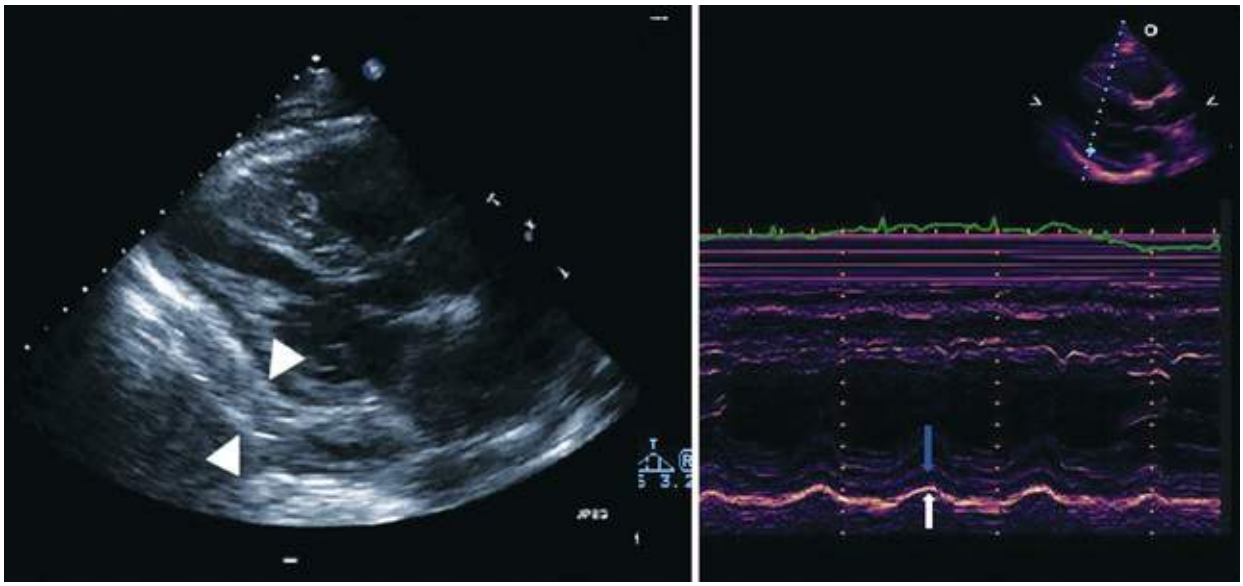

FIGURE 14.66 **Left,** Parasternal long-axis view demonstrating thickened pericardium (between the *arrowheads*). **Right,** M-mode echocardiogram. The bright posterior echo (*white arrow*) representing the parietal pericardium moves in parallel with the visceral pericardial/epicardial echoes (*blue arrow*), a finding indicative of adhesion between the two layers. If the pericardial space were expanded by free fluid (pericardial effusion), the parietal pericardial echo would be relatively stationary (compare with the M-mode *inset* of **Fig. 14.64**).

Restrictive and constrictive physiology share a mitral diastolic filling pattern characterized by a prominent E wave (E/A ratio >2) and shortened deceleration time caused by rapid early filling, biatrial enlargement, and a fixed dilated IVC that does not change size with a sniff. However, the two may be distinguished by tissue and color Doppler diastolic indices, as well as respirophasic effects on septal motion (interventricular interdependence and septal bounce) that are specific to constriction. Mitral annular DTI waves generally have normal or increased amplitude in constriction (peak e′ of ≥8 cm/sec is reported to be 89% sensitive and 100% specific for constriction), reflecting compensatory exaggerated longitudinal motion of the heart, in contrast to the reduced e′ seen with restriction. Notably, the peak e′ of the lateral site may be smaller than that of the medial annulus, which is the opposite of the normal pattern; this phenomenon is termed *annulus reversus* and is believed to result from calcification and tethering effects of the pericardium on the lateral heart wall. Color M-mode propagation velocity is typically normal or even increased in constriction, but reduced in restriction. In addition, pulmonary artery systolic pressure rarely exceeds 50 mm Hg in constriction.

In constriction the rigid pericardium abruptly limits filling to a fixed volume. When inspiration causes increased venous return to the right side of the heart, there is a sudden leftward septal shift and thus obligatory reduction in the amount of blood that the left ventricle can accommodate. The leftward septal shift may be seen on echocardiography during inspiration (**Fig. 14.67** and Video 14.42), and often a transient left-right septal “bounce” occurs in early and late diastole. There are also exaggerated respirophasic changes in the magnitude of the mitral and tricuspid E waves (in opposing directions, similar to the patterns in tamponade). Additional markers of constriction include premature opening of the pulmonic valve, which is most pronounced with inspiration (reflecting a rapid rise in end-diastolic RV pressure that exceeds pulmonary artery pressure), diastolic MR, and expiratory diastolic hepatic vein flow reversal (**Fig. 14.68**).

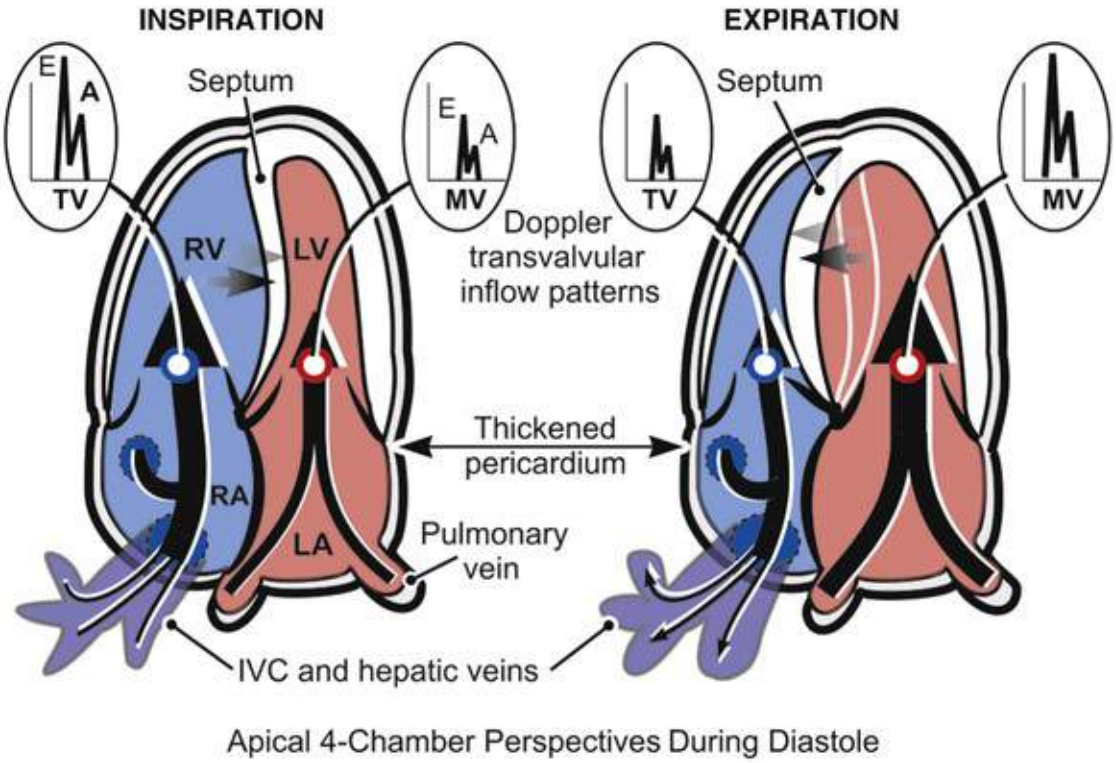

FIGURE 14.67 Schematic representing the echocardiographic manifestations of constriction that may be appreciated on the apical four-chamber view and PW Dopper. Mitral (*MV*) and tricuspid (*TV*) valve Doppler spectra are characterized by an increased E/A ratio and shortened deceleration time. With inspiration there is increased venous return to the right side of the heart, which can be accommodated within the rigid pericardium only by displacement of the interventricular septum to the left and reduced left-sided filling. On expiration, left-sided filling increases, the septum moves to the right, and there is flow reversal in the hepatic veins (**see Fig. 14.68**). *IVC,* Inferior vena cava; *LA,* left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. (Modified from Bulwer BE, Rivero JM, editors. Echocardiography Pocket Guide: The Transthoracic Examination. Burlington, Mass: Jones & Bartlett Learning; 2011, 2013, p 141. Reprinted with permission.)

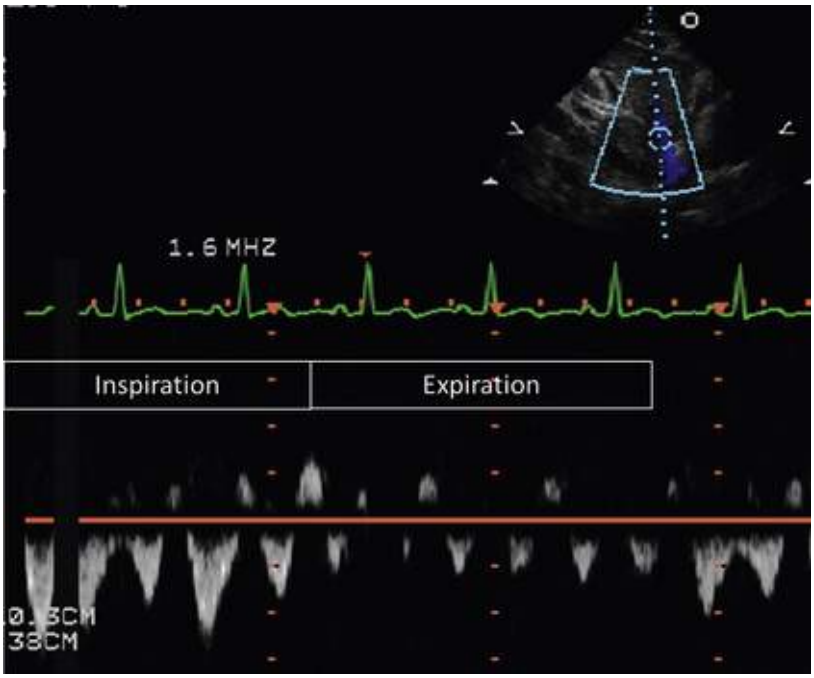

FIGURE 14.68 Hepatic venous flow recordings demonstrate expiratory diastolic flow reversal, seen in constriction.

In digital echocardiography laboratories where acquisitions are frequently limited to one to three beat

clips, it is essential that longer captures with respiratory gating be obtained to assess the impact of respiration. M-mode echocardiography in the parasternal window over multiple cycles is particularly useful for detection of leftward (posterior) motion of the septum on inspiration, the diastolic septal bounce, and pericardial thickening, as well as the flattened diastolic motion of the posterior wall.

Differentiation between conditions can be further complicated by coexisting pathologies in the patient. Fibrotic involvement extending from the pericardium into the myocardium may result in mixed constrictive-restrictive physiology. Echocardiographic reassessment after removal of the pericardial fluid causing tamponade may unmask underlying constriction (i.e., effusive-constrictive physiology while the effusion was present).

Malignant Involvement of the Pericardium

Malignant pericardial disease typically occurs on the basis of local spread or distal metastases, with lung and breast cancer being the most common primaries. Primary pericardial tumors are uncommon. The echocardiographic appearance may be that of pericardial effusion and/or solid tumor, which frequently invades locally into the myocardium (**Fig. 14.69**).

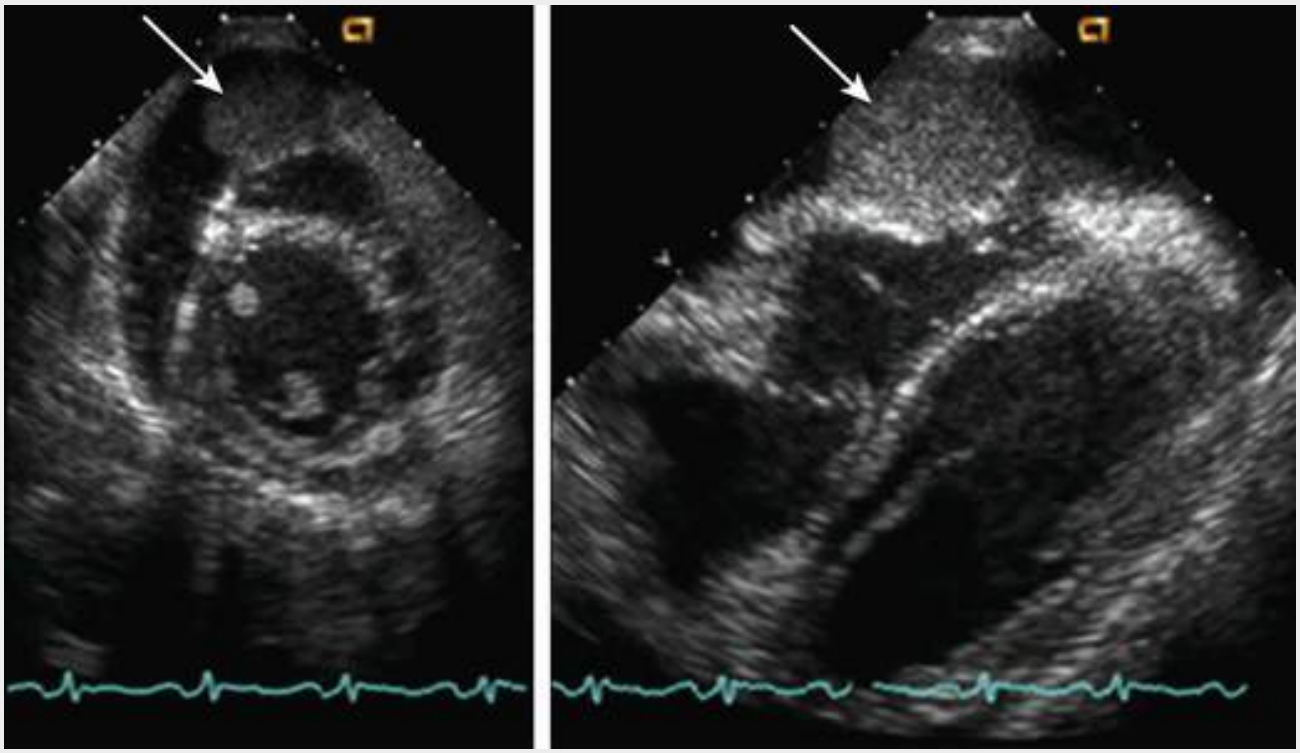

FIGURE 14.69 Subcostal echocardiograms showing a tumor metastasis *(arrows)* within the pericardial space and invading the right ventricular myocardium. The tumor is surrounded by pericardial effusion.

Other Pericardial Pathology

Congenital absence of the pericardium is a rare abnormality that usually involves the left pericardium and is associated with a leftward shift in the position of the heart, as well as exaggerated translation. The net result is an echocardiographic pattern that mimics RV volume overload. A *pericardial cyst* is a benign abnormality that is typically detected as an incidental finding of an echo-free accumulation adjacent to the heart.

Diseases of the Aorta

Transthoracic echocardiography is a first-line tool to assess the thoracic aorta for pathologic processes[17,72] (**see Chapter 63**). TTE can visualize the proximal aortic root and ascending aorta, aortic arch up to the isthmus (takeoff of the left subclavian artery), and limited portions of the descending thoracic and proximal abdominal aorta (**Fig. 14.70**). TEE can be used to more comprehensively examine the entire thoracic aorta (**Fig. 14.71**), with the exception of a small area of distal ascending aorta (because of shadowing from the air-filled trachea interposed between the esophagus and the heart). Therefore, for screening purposes or for serially monitoring a known aortic abnormality for stability, TTE may be sufficient. Higher degrees of suspicion for an acute aortic process or disease extending beyond the TTE windows require TEE evaluation (or alternatively, CT or magnetic resonance angiography [MRA]).

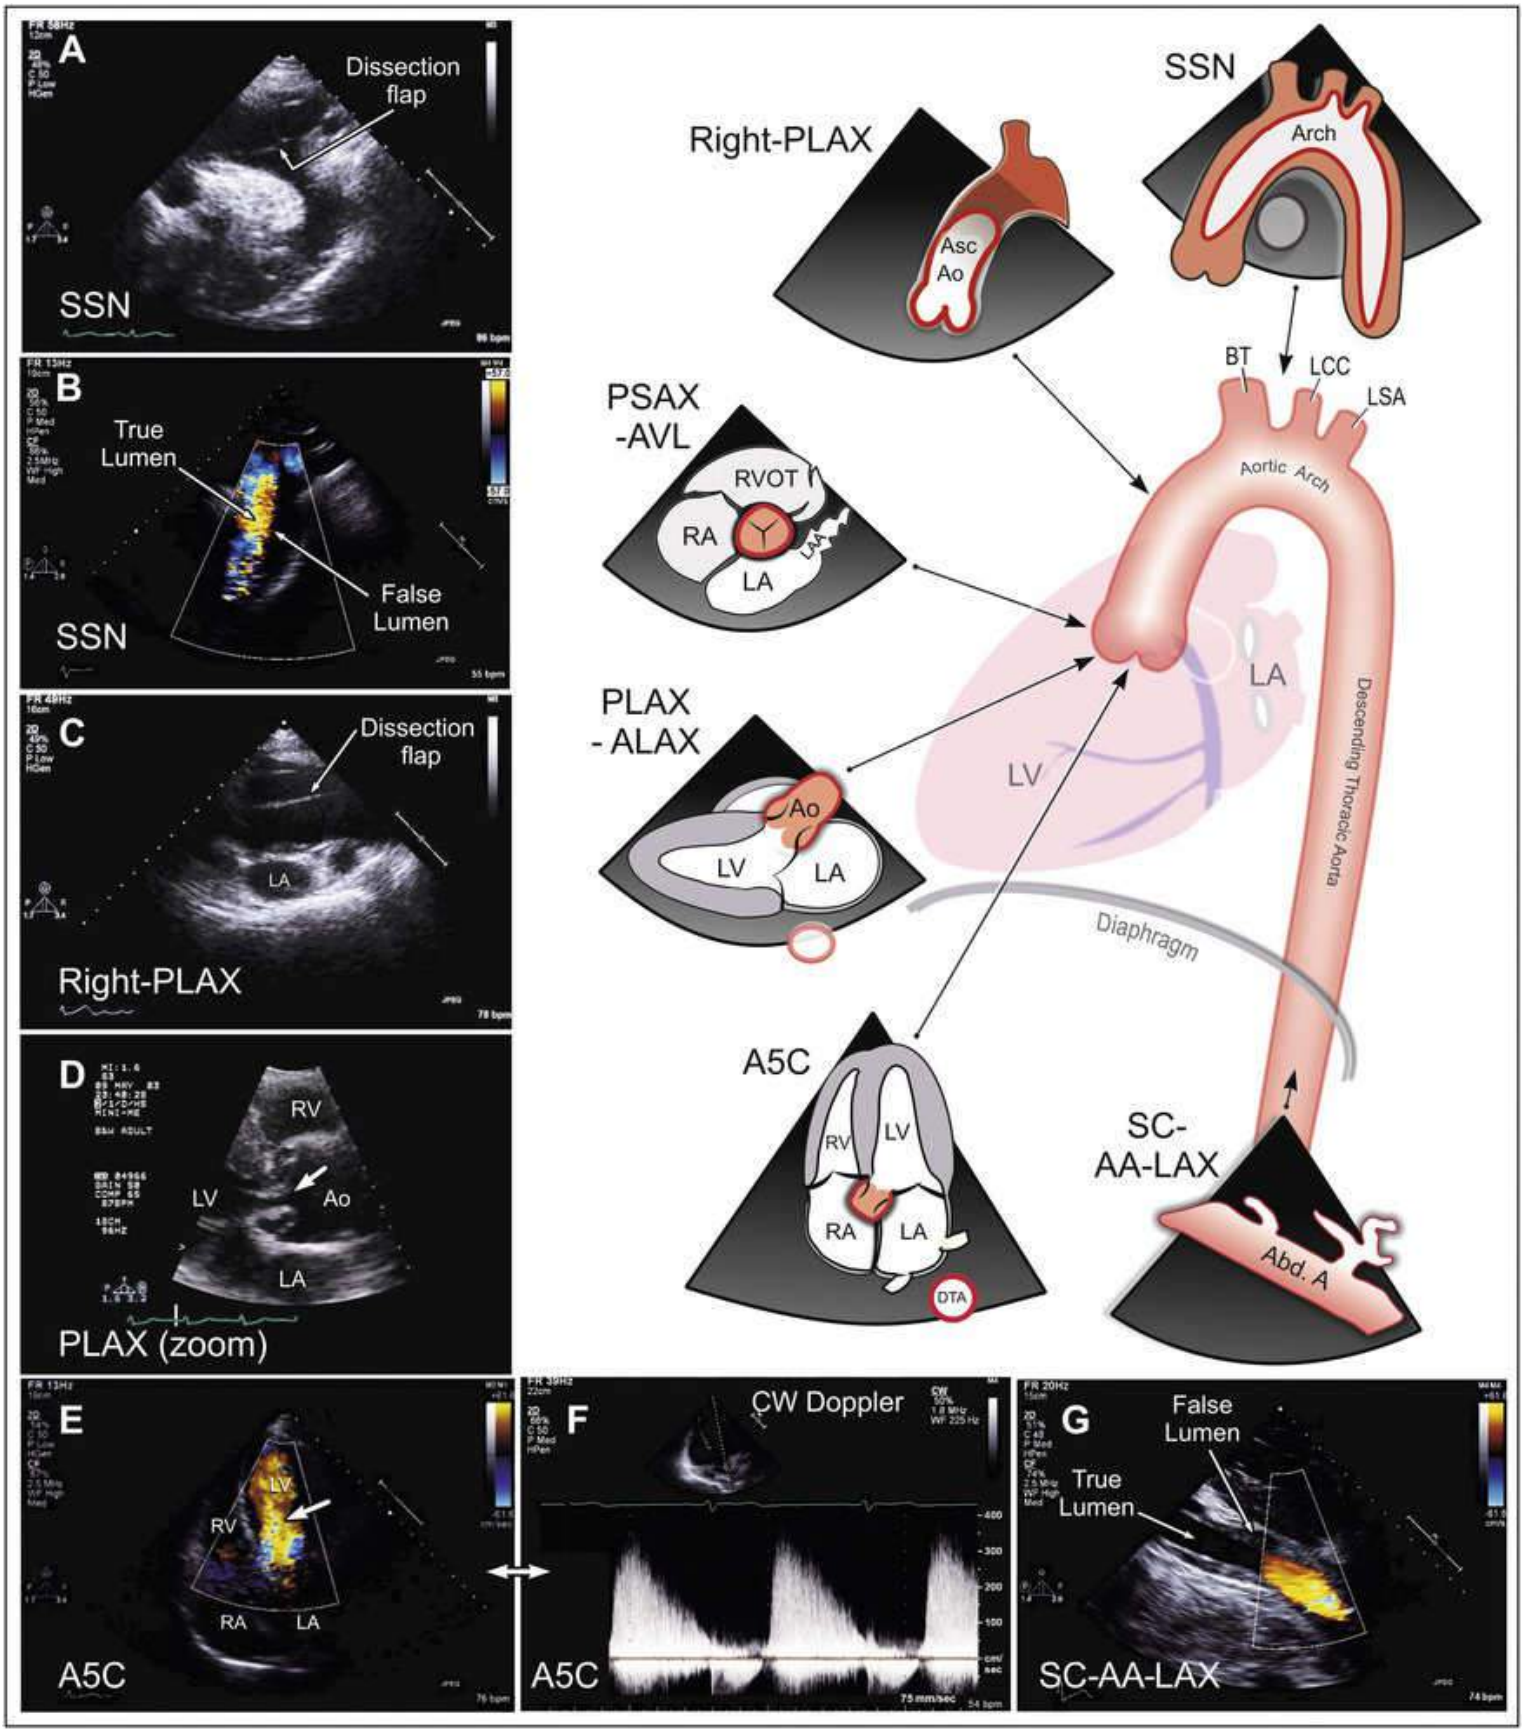

FIGURE 14.70 Transthoracic views of the aorta and examples of acute aortic pathologies from each window. The composite illustrates **(A, B)** suprasternal notch 2D and color Doppler views of a type A dissection flap that is seen extending into the brachiocephalic artery; **(C, D)** a type A dissection flap that originates at the level of the aortic sinuses, prolapses through the aortic valve, and also extends into the ascending aorta in the parasternal long-axis view (see Video 14.43); **(E, F)** color and spectral Doppler apical five-chamber views illustrating the resultant severe aortic insufficiency (see Video 14.44); and **(G)** an abdominal aortic type B dissection with a small central true lumen and chronic thrombus in the circumferential false lumen in the subcostal long-axis view. *ALAX,* Apical long axis; *PLAX,* parasternal long axis; *PSAX,* parasternal short axis; *SSN,* suprasternal notch; *SC,* subcostal; *Ao,* aorta; *AVL,* aortic valve level; *BT,* brachiocephalic trunk; *DTA,* descending thoracic aorta; *LCC,* left common carotid artery;

During the standard echocardiographic examination, the normal diameter of the aorta should be assessed at the aortic annulus, sinuses of Valsalva, sinotubular junction, and ascending aorta. The upper limit of normal varies with age, sex, and BSA (**Table 14.10 and eFig. 14.26**). More of the ascending aorta can be viewed by moving the transthoracic probe up one interspace, angling the probe more cephalad, or utilizing right parasternal windows.

TABLE 14.10

Normal Values for Aortic Size in Adults

Aortic Root	ABSOLUTE VALUES (cm)		INDEXED VALUES (cm/m^2)	
	Men	Women	Men	Women
Annulus	2.6 ±0.3	2.3 ±0.2	1.3 ±0.1	1.3 ±0.1
Sinuses of Valsalva	3.4 ±0.3	3.0 ±0.3	1.7 ±0.2	1.8 ±0.2
Sinotubular junction	2.9 ±0.3	2.6 ±0.3	1.5 ±0.2	1.5 ±0.2
Proximal ascending aorta	3.0 ±0.4	2.7 ±0.4	1.5 ±0.2	1.6 ±0.3

EFIGURE 14.26 Normal aortic root sizes. The 95% confidence intervals for aortic root diameter at sinuses of Valsalva on the basis of body surface area (BSA) in **A,** children and adolescents; **B,** adults age 20 to 39; and **C,** adults age 40 or older.

Focal Aortic Pathology

Atherosclerotic plaque can be visualized as irregular, heterogeneous, or echobright calcified foci adherent to the endothelial side of the lumen. These plaques often accumulate at the sinotubular junction and aortic arch. Plaque that is thicker than 5 mm or that has mobile or protruding elements appears to be at higher risk of being associated with stroke (**Fig. 14.72A**). *Ulcerated aortic plaque* is thought to be a potential precursor to intramural hematomas (see later). In patients with bicuspid valves, the descending aorta should always be evaluated carefully for signs of narrowing and blood flow acceleration at the isthmus to rule out *aortic coarctation*.

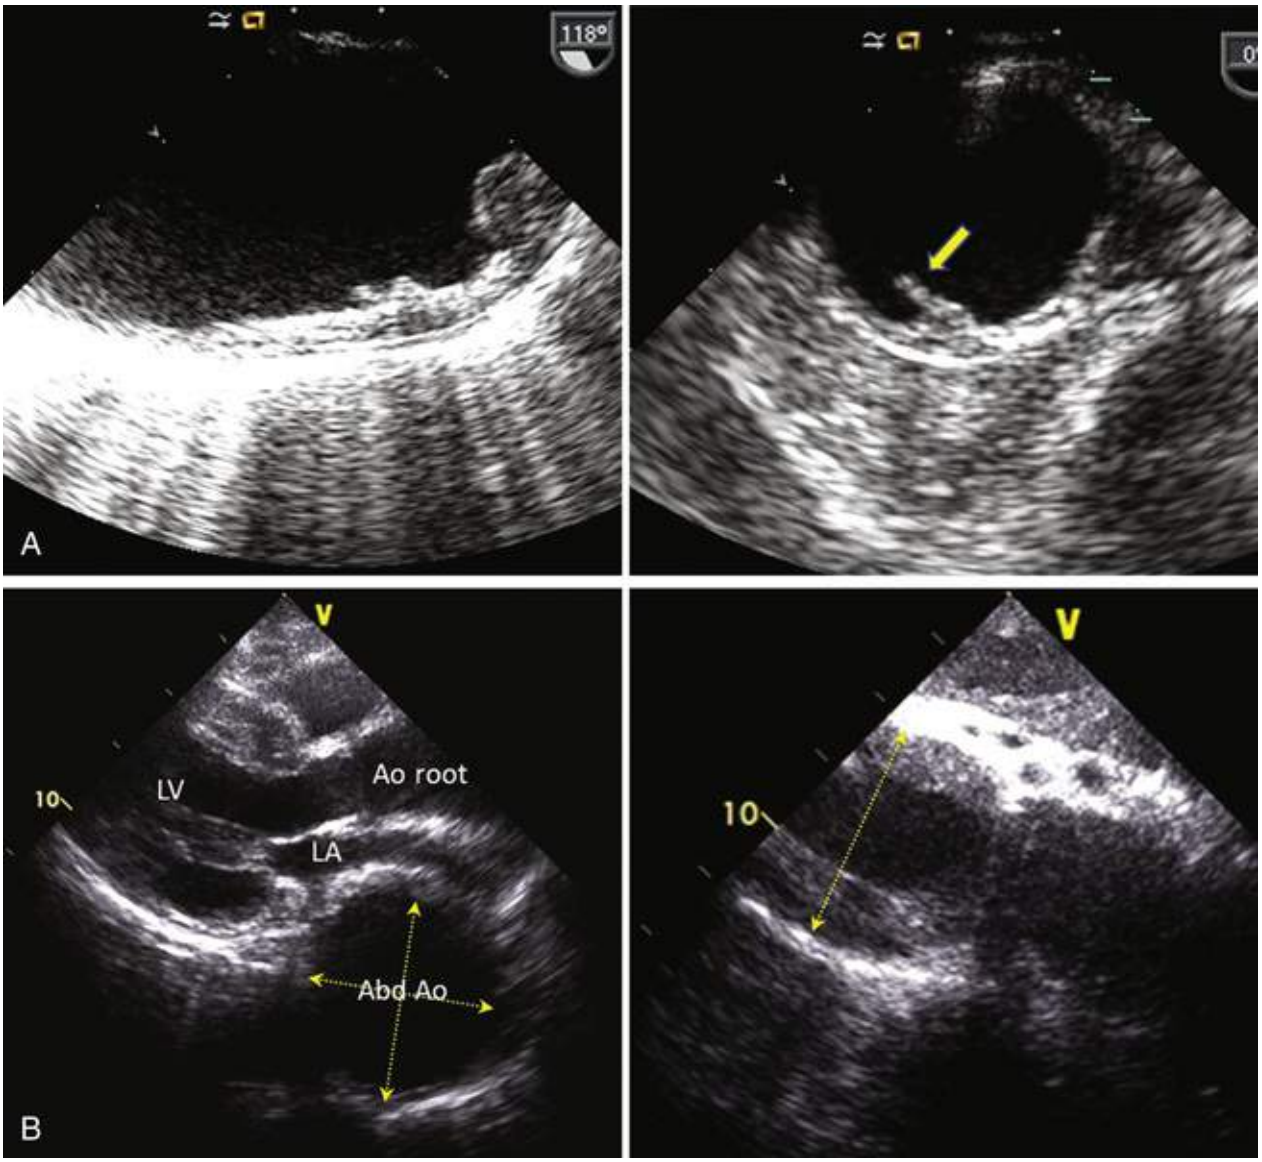

FIGURE 14.72 Aortic atheroma and aneurysm. **A,** TEE views of complex aortic atheroma in the ascending aorta. In the long-axis view **(left),** the atheroma is seen to be irregular and measures up to 1.0 cm in thickness. In the short-axis view **(right),** a protuberant finger-like atheroma is seen and is independently mobile. **B,** Transthoracic parasternal long-axis (**left**) and subcostal (**right**) views of a large 7-cm-diameter descending thoracoabdominal aortic aneurysm (*dotted arrows* spanning the diameter) compressing the posterior aspect of the left atrium (*LA*), within which diffuse circumferential thick mural thrombus is layered. *Ao,* Aortic; *LV,* left ventricle.

Aortic Emergencies

Aortic aneurysms, technically defined as vessel dilation greater than 50% above the normal diameter of the aorta, may occur anywhere along the course of the aorta (**Fig. 14.72B**), although they are more common in the abdominal location. Patients with connective tissue syndromes (e.g., Marfan, Loeys-Dietz, Ehlers-Danlos type IV) and patients with bicuspid aortic valves are thought to have defects in the elastic and smooth muscle composition of the aorta and thus appear to be prone to the development of ascending aneurysms (generally defined as ascending aortic diameter >3.6 cm). Marfan syndrome in particular often affects only the sinuses of Valsalva symmetrically, whereas diameters at the sinotubular junction and ascending aorta are relatively preserved. If the aneurysm involves the ascending aorta, sinuses, and the proximal root all the way to the annulus (termed *aortoannular ectasia*), the resulting incomplete cusp coaptation may cause aortic insufficiency and necessitate valve repair as well. Isolated *sinus of Valsalva aneurysms* are focal dilations that asymmetrically affect only one sinus (most often the right, as shown in

Fig. 14.73). They are usually discovered incidentally, and their cause is uncertain. Although not considered an acute aortic emergency, there have been case reports of rupture of these aneurysms into the right ventricle, right atrium, and other locations. In contrast to *ascending* aneurysms, most *descending* aortic aneurysms are associated with atherosclerosis. Whereas ascending aneurysms are typically fusiform, abdominal aneurysms may be more irregular, focal, and saccular in shape.

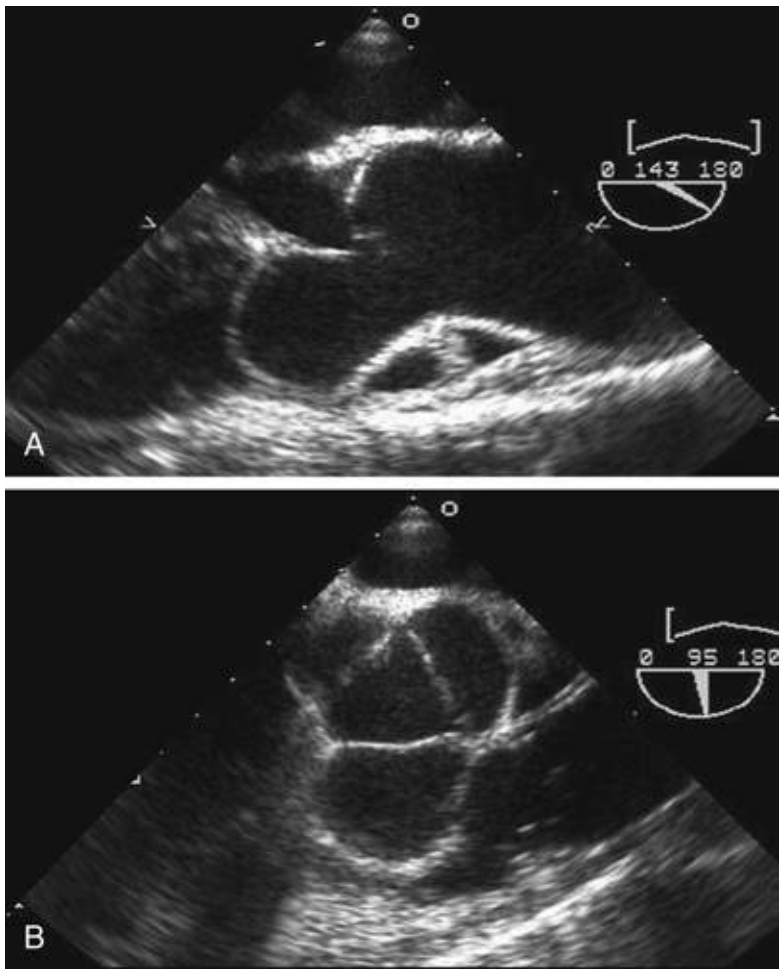

FIGURE 14.73 Sinus of Valsalva aneurysm. **A,** TEE long-axis view of a right sinus of Valsalva aneurysm (measuring 2.5 × 2.8 cm). **B,** TEE short-axis view of the trileaflet aortic valve in the open position showing the right sinus aneurysm in cross section. The patient had mild aortic insufficiency.

The most common emergency indication for echocardiography in patients with aortic diseases is to detect *aortic dissection*, a tear in the aortic intima that enables blood to force its way between the other layers of the vessel wall. Although it can arise de novo, aortic dissection and rupture are the most feared sequelae of aortic aneurysms and thus share the same causative associations and risk factors, including connective tissue disorders, aortic valve disease (personal or family history), hypertension, smoking, and atherosclerosis. **Figs. 14.70 and 14.71** show examples of aortic dissection and their location and appearance (Videos 14.43 and 14.44). Recent aortic manipulation, such as cardiac catheterization, cardiac surgical bypass, placement of intra-aortic balloon pumps, and intravascular stenting, is also considered a high-risk condition.[72] Serious morbidity from compromised blood flow to the coronary arteries, central nervous system, renal arteries, and other organs may occur, and if the dissection ruptures through all three layers, massive bleeding and death can rapidly ensue. Dissection tends to propagate in antegrade fashion (i.e., from the proximal toward the distal aorta), although retrograde extension may also occur all the way back to the sinuses, causing aortic insufficiency or occluding coronary artery ostia

(Video 14.45). The mortality rate is high, and surgical treatment has been shown to be the most effective therapy for patients with ascending (DeBakey types I and II or Stanford type A) dissections. *Blunt chest trauma,* in particular rapid-deceleration injuries such as in motor vehicle accidents, may cause tears at the ligamentum arteriosum (near the aortic isthmus, just distal to the left subclavian artery), which demarcates a hinge point between the relatively tethered descending thoracic aorta and the more mobile arch and ascending aorta. Tertiary syphilis, now a rare disease in the developed world, can cause *aortitis,* that is, inflammation of the aortic adventitia, weakening of the walls, and subsequent development of descending aortic aneurysms and dissections. Rarely, other systemic arteritides, such as giant cell arteritis, can also cause aneurysm formation in the ascending aorta.

TTE has somewhat limited sensitivity (70% to 80% for all locations with higher sensitivity in type A dissections) and specificity (63% to 93%) for aortic dissection because of limited views of the abdominal aorta. TEE has been shown to have a sensitivity reaching 99% and specificity of 89%, particularly with ascending dissections.[72] An aortic dissection flap on echocardiography appears as a linear or thin serpiginous tissue plane extending parallel (in the long-axis plane) (**Fig. 14.74A; see also Fig. 14.70A, C**) or semicircumferentially (in the short-axis plane) (**see Fig. 14.71I**) to the aortic walls. It represents the intima that has split from the other layers of the aorta. An acute, unthrombosed flap will undulate independently and usually bulge outward from the true lumen in pulsatile fashion during systole. These characteristics can be demonstrated by M-mode and can be used to distinguish true disease from reverberation artifact. If color Doppler is used to sweep along the flap, one may occasionally be able to identify the site of the primary tear as a communication between the false and true lumen (Video 14.46). The false lumen may be seen to contain more spontaneous echocardiographic contrast or even formed thrombus. By color and spectral Doppler, forward flow in systole can also help identify the true lumen (**Fig. 14.74B, E**). Complications arising from aortic dissection that may be directly imaged by ultrasound include (1) extension of the flap into the coronary arteries with loss of the diastolic-dominant coronary flow by spectral and color Doppler and wall motion abnormality signaling MI; (2) AR (**see Fig. 14.70E, F**); (3) extension of the flap into the carotid arteries (causing stroke) or the innominate or subclavian arteries (**see Fig. 14.70A**); (4) pericardial effusion, which is frequently frank hemopericardium; (5) pleural effusion, which is more common on the left than on the right side; and (6) periaortic hematoma, signifying a leak in the adventitia and impending complete rupture.

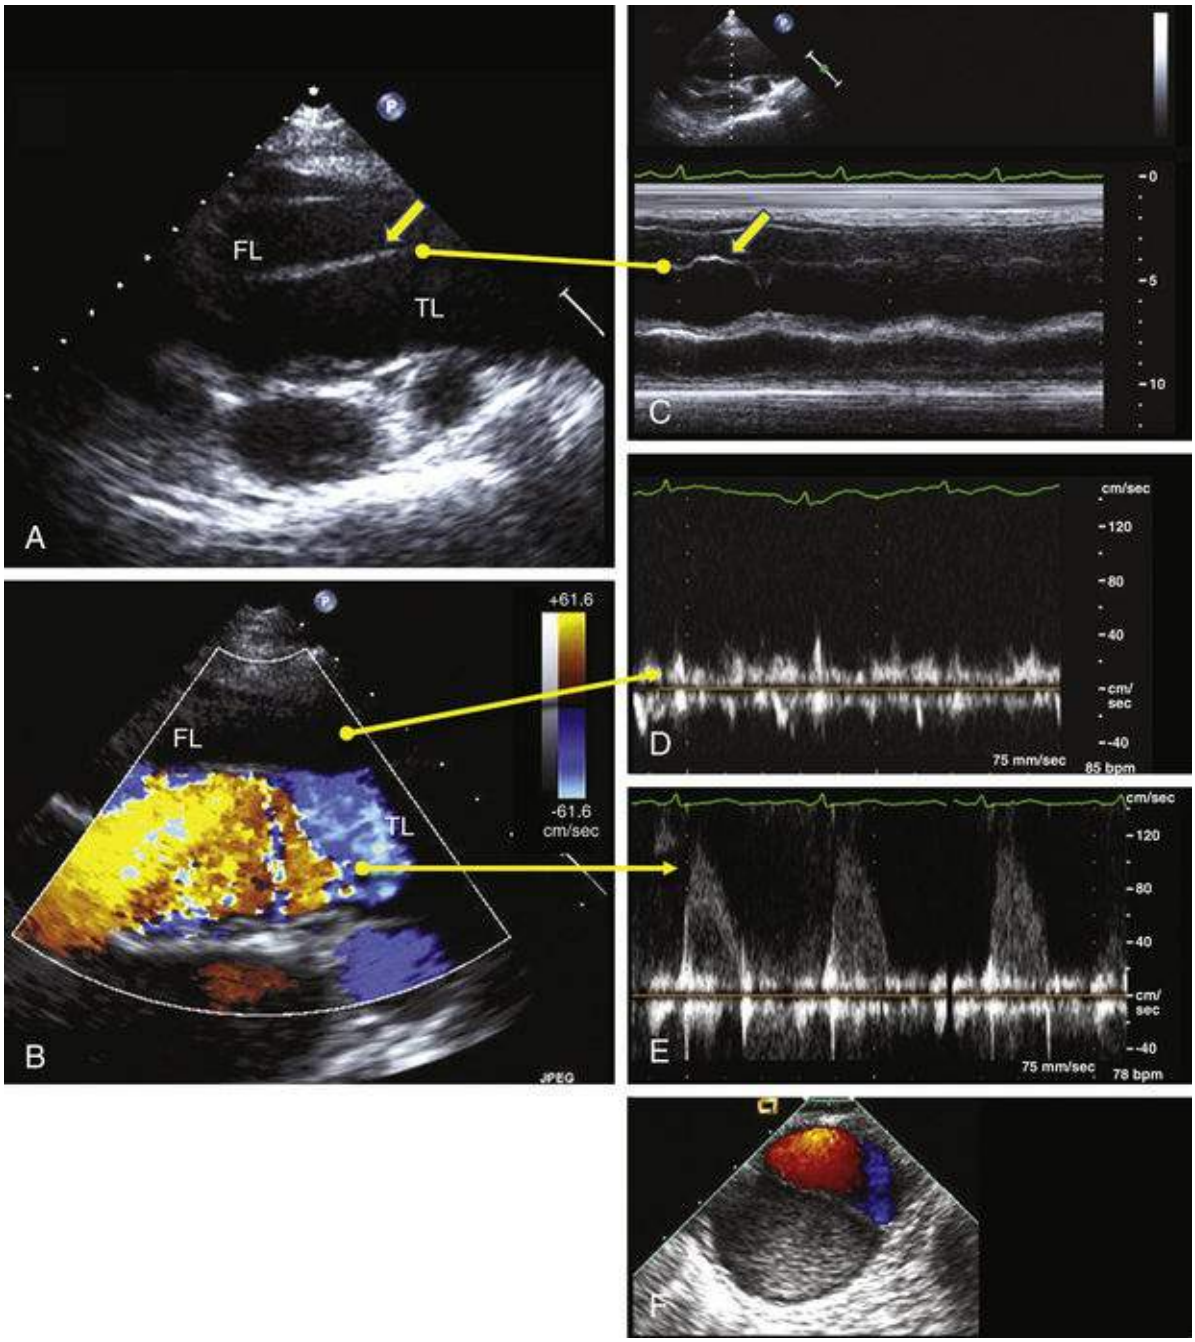

FIGURE 14.74 Aortic dissection demonstrating true and false lumens. **A,** TTE high parasternal long-axis view of a type A aortic dissection. The linear dissection flap is indicated by the *arrow. FL,* False lumen; *TL*, true lumen. **B,** TTE view at the same level with color flow Doppler illustrating brisk and turbulent color flow within the true lumen. **C,** M-mode illustrating systolic pulsation of the dissection flap *(arrow)* outward from the true aortic lumen. **D,** Low-velocity spectral Doppler flow without clear cyclic variation in the false lumen. **E,** Systolic forward high-velocity spectral Doppler flow in the true lumen. **F,** TEE short-axis view of the ascending aorta in a different type A dissection case demonstrating spontaneous echocardiographic contrast in the false (larger) lumen and brisk systolic flow in the true (smaller) lumen by color Doppler.

Other aortic emergencies are less common but equally life threatening. *Aortic transection* occurs as a result of severe deceleration injury and consists of complete shearing of the aorta at the isthmus, with the severed ends of the aorta floating freely within hematoma. This is so lethal that examples are rarely captured on TEE during emergency surgery or endovascular repair, although local containment of blood within the mediastinum can permit a very brief window of survival. A partial transection is shown in **Fig. 14.71F, G**. *Aortic intramural hematoma* is an accumulation of blood that remains contained within the aortic media; it accounts for approximately 5% to 20% of acute aortic syndromes (**see Fig. 14.71A, B**). On echocardiography, intramural hematoma appears as a smooth, homogeneously echogenic bulge within the medial layer of aortic wall. It is hypothesized to arise from rupture of a penetrating atherosclerotic

ulcer, spontaneous rupture of the vasa vasorum, or more frequently, blunt trauma. Intramural hematomas are distinguished from the typically focal, echobright, and irregular plaque in that they lie within the aortic wall and extend smoothly and longitudinally along the aorta. On cross-sectional views the hematoma appears as a crescentic or circular area of homogeneous thickening around the central aortic lumen. Unlike dissection, the intimal layer is still intact and is not mobilized, so there is no detectable intimal tear and no blood flow communication with the aortic lumen. If the intramural hematoma is relatively small, additional imaging with CT or MRA may be required to identify the hematoma definitively and distinguish it from the differential diagnoses of plaque or periaortic fat. Intramural hematomas can arise in either ascending or descending locations and may enlarge or progress to frank aortic dissection and may have similar mortality rates. Thus the principles of medical and surgical management are essentially the same as for typical aortic dissections.[72]

Pulmonary Embolism

Echocardiography can be extremely useful in the diagnosis and management of acute pulmonary embolism (**see Chapter 84**). Although not generally used as the primary diagnostic method for assessing pulmonary embolism, echocardiography provides information complementary to other diagnostic tests, has prognostic value, and may inform or monitor therapy (particularly if CT angiography is not feasible).[73] Echocardiography performed for other indications, including dyspnea, chest pain, and hypotension, also occasionally leads to the incidental discovery of pulmonary embolus. Thrombi that result in pulmonary embolism generally arise from the deep venous system in the legs; echocardiography can be used to directly visualize thrombus anywhere from the vena cava to the pulmonary arteries (**Fig. 14.75** and Video 14.47). Thrombi in the pulmonary arteries can generally be visualized to approximately just past the bifurcation with TTE; when found, they are associated with RV dysfunction and high early mortality. Although TEE can image slightly farther into the main pulmonary artery branches, it is rarely used as a primary diagnostic modality for pulmonary embolism. The pulmonary artery bifurcation should be carefully assessed from the short-axis views in patients with suspected pulmonary embolism, and it is not uncommon for so-called saddle emboli to become lodged at the bifurcation (**Fig. 14.75, right**). Putative thrombi need to be distinguished from other cardiac masses, including myxomas, fibroelastomas, and vegetations (see later, Cardiac Masses).

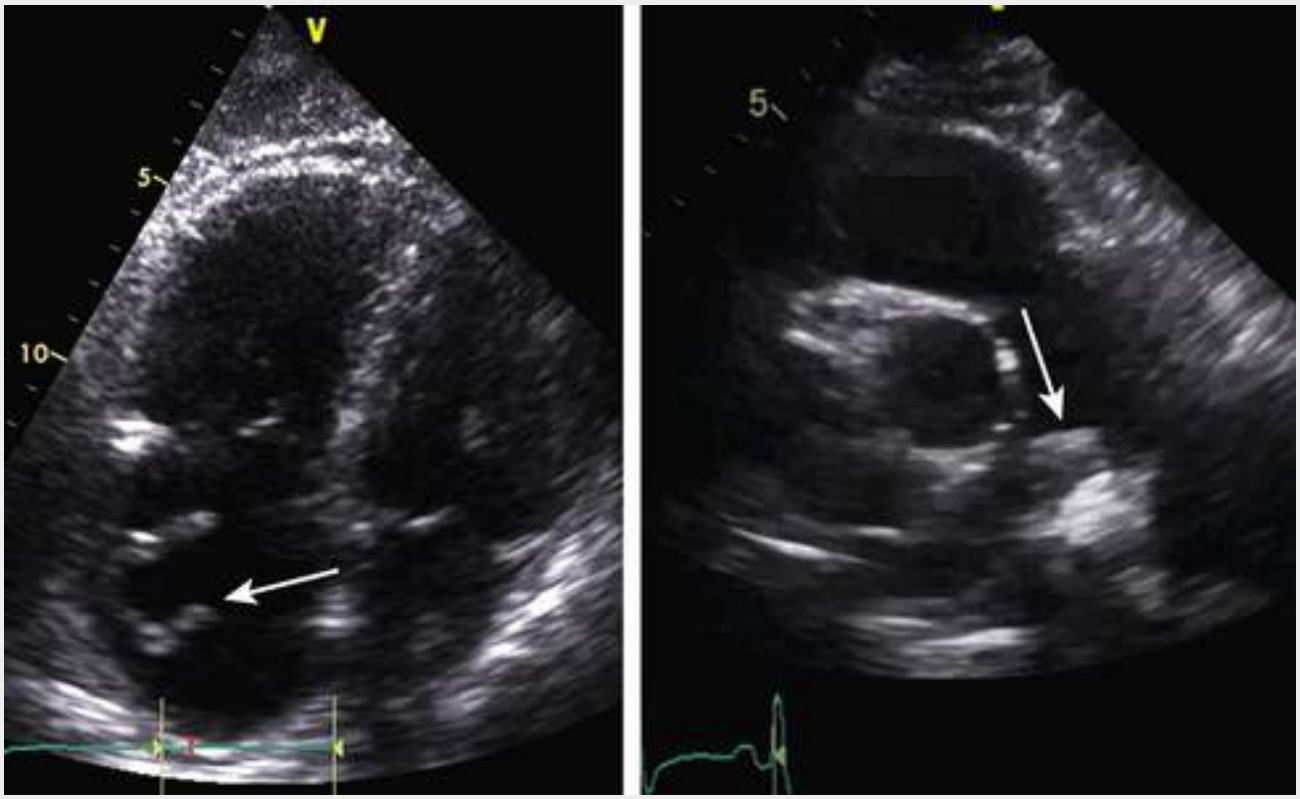

FIGURE 14.75 **Left,** Thromboembolus in the right atrium (*RA*). The *arrow* indicates a serpentine mass that is a thrombotic "cast" of a deep vein of the lower extremities that has embolized to the RA. *RV,* Right ventricle. (See Video 14.47.) Note the right-sided heart dilation and hypokinesis, clues indicating that a significant acute pulmonary embolus has also occurred. **Right**, Saddle embolus at the bifurcation of the pulmonary artery (*arrow*). (See Video 14.48.)

The characteristic echocardiographic findings in pulmonary embolism result in part from the unique physiology of the right ventricle. The normal right ventricle is generally accustomed to low pulmonary vascular resistance (PVR) and thus extremely low afterload, and RV systolic pressure normally is low. In acute pulmonary embolism, PVR rises substantially and abruptly, which results in RV dilation and, in severe cases, failure. Thus, RV dilation is the echocardiographic hallmark of pulmonary embolism. It is best visualized on the apical four-chamber view, where classic findings include RV diameter greater than LV diameter (ratio >1.0) and a small, underfilled, but normally functioning left ventricle. A distinctive regional wall motion abnormality has been recognized in acute pulmonary embolism in which the free RV midwall becomes dyskinetic, with relative sparing of the apex and base. This pattern, known as the *McConnell sign*, is highly specific for conditions in which PVR increases abruptly[74] (**Fig. 14.76** and Video 14.48). RV TAPSE may also be decreased in patients with acute pulmonary embolus. Both RV dilation and RV regional dysfunction will be less apparent in patients in whom PVR has been elevated for a longer period, resulting in RV hypertrophy. In these patients, pulmonary pressure will ultimately rise, and the right ventricle may not show evidence of dilation or dysfunction in acute pulmonary embolism. Thus the classic echocardiographic RV patterns are of lower sensitivity and have low negative predictive value in patients with longstanding pulmonary hypertension, such as those with chronic obstructive pulmonary disease (COPD) or chronic thromboembolic disease.

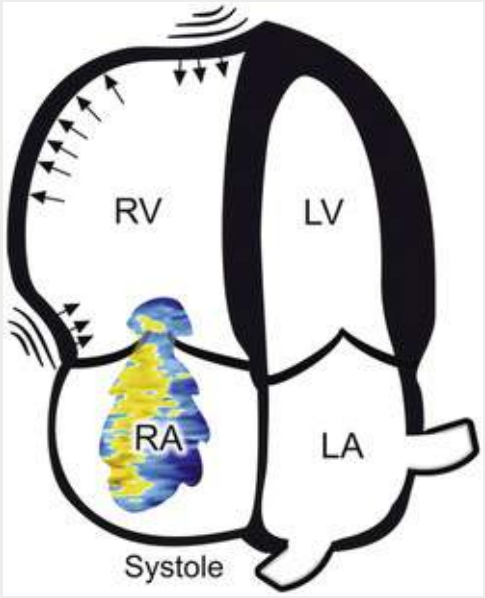

FIGURE 14.76 Regional right ventricular dysfunction (McConnell sign) in acute pulmonary embolism. The right ventricle (RV) is enlarged and right ventricular regional function is abnormal, with dyskinesis of the midwall region and relative sparing of the apex and base. Tricuspid regurgitation is usually present. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium.

In patients without a previous history of pulmonary hypertension, even in the setting of acute pulmonary embolus, the tricuspid regurgitant (TR) velocity will remain relatively normal, rarely exceeding 3 m/sec. Patients with preexisting pulmonary vascular disease, however, may have increased TR velocity consistent with elevated pulmonary systolic pressure. Assessment of RV dilation and dysfunction has now been incorporated into treatment algorithms and are useful particularly in intermediate-risk patients.[73] The presence of RV dilation or dysfunction in acute pulmonary embolism is an independent predictor of adverse outcomes and short-term mortality, even in hemodynamically stable patients. In terms of response to therapy for acute pulmonary embolism, improvement in RV function can be seen on echocardiography within several days of successful treatment (reperfusion by either embolectomy or thrombolysis) of pulmonary embolism.

Infective Endocarditis

Echocardiography is the first-line modality for the detection, evaluation, and management of endocarditis (**see Chapter 73**). American College of Cardiology/American Heart Association Class I indications for echocardiography apply to the following settings: (1) in patients with suspected endocarditis (with or without positive blood cultures) to detect valvular vegetations; (2) in patients with known infective endocarditis to evaluate for valve lesions such as regurgitation and to assess for complications such as abscess and intracardiac shunts; (3) to reevaluate patients with known endocarditis who have high-risk features such as a virulent organism, clinical deterioration, persistent or recurrent fever or bacteremia, and a new murmur; and (4) in symptomatic patients with nondiagnostic TTE or prosthetic valves, for which TEE is likely to have higher sensitivity for both vegetations and complications.[75]

Infective endocarditis is definitively diagnosed by culture or pathologic examination of a vegetation (in situ or embolized) or intracardiac abscess. However, many cases are diagnosed on clinical grounds by using the modified Duke criteria as a guideline. The first criterion is positive blood cultures consistent with infective endocarditis. The second major criterion is an echocardiogram demonstrating (1) a vegetation (**Fig. 14.77A, B**, and Video 14.49) (i.e., an oscillating intracardiac mass on a valve, in the path of a regurgitant jet, or on implanted material) in the absence of an alternative anatomic explanation,

(2) an abscess (**Fig. 14.77C** and Video 14.50), or (3) new partial dehiscence of a prosthetic valve[75] (**Fig. 14.77D**; see Video 14.38). The sensitivity of TTE ranges up to 63%, with a specificity close to 100%. The suboptimal sensitivity often results from physical imaging factors causing poor image quality and acoustic shadowing and also depends on the size of the vegetation. Because of its higher 2D resolution and different windows, TEE has much higher sensitivity (94% to 100%) and is especially advantageous in assessing prosthetic valves and diagnosing abscesses. Thus a reasonable diagnostic approach is to use TTE as the first-line screening tool; if this is nondiagnostic, one may turn to TEE if clinical suspicion for endocarditis is high, as in the patient with a prosthetic valve or predisposing condition, clinical features suspicious for a complicated endocarditis, or a potential indication for cardiac surgery.[76]

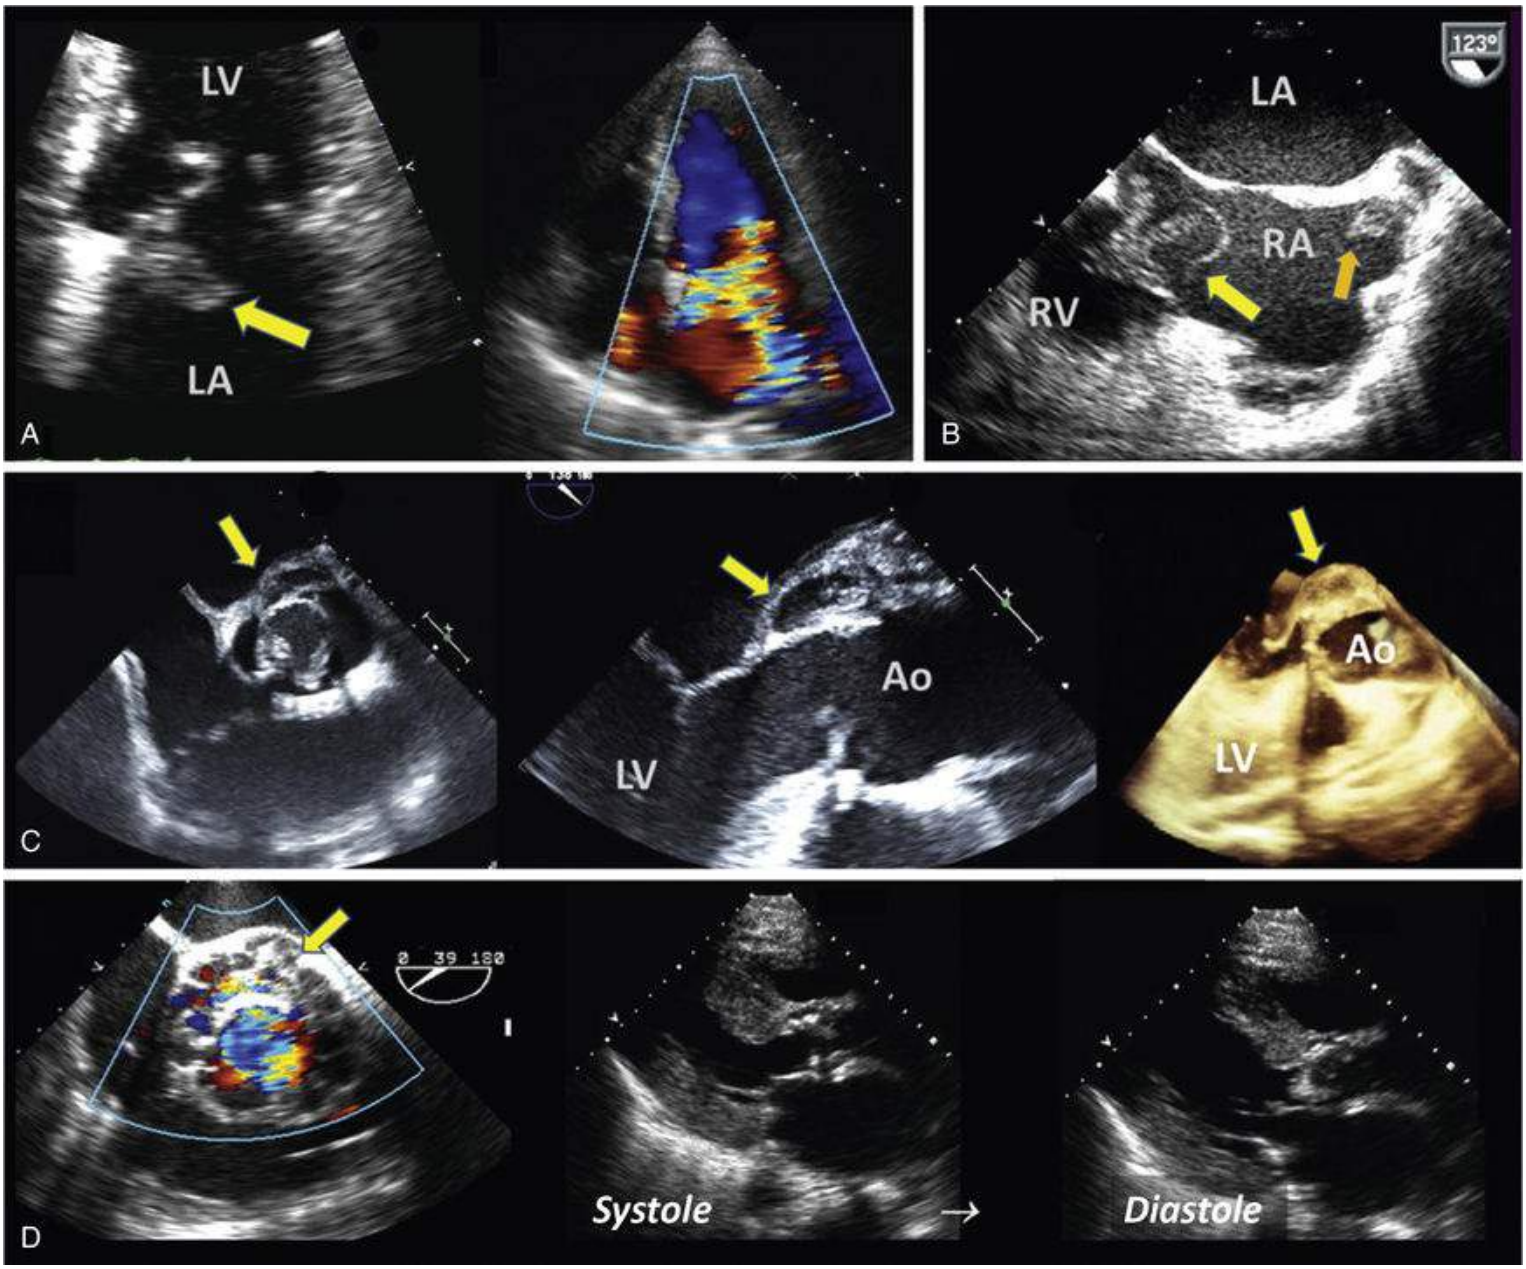

FIGURE 14.77 Echocardiography in endocarditis. **A,** Vegetation (*arrow*) on the left atrial aspect of a rheumatic mitral valve **(left panel)** with color Doppler demonstration of a second noncentral jet of MR at the base of the leaflet and vegetation indicative of leaflet perforation **(right panel).** (See corresponding Video 14.49.) **B,** Vegetation (*yellow arrow*) on the right atrial aspect of the tricuspid valve on a TEE long-axis view. An additional vegetation (*orange arrow*) in the superior vena cava associated with a previous indwelling catheter is noted, and the eustachian valve was also infected in this patient with a history of intravenous drug abuse. **C,** Paravalvular abscess (*arrow*) as indicated by the crescentic echolucent area with thickening from the 11- 1 o'clock position on short-axis **(left panel)** and long-axis **(middle panel)** TEE views anterior to the annulus of a bicuspid aortic valve (open in systole), also visualized on the 3D TEE view **(right panel).** (See Video 14.50.) **D,** Ringlike abscess around the annulus of a bioprosthetic aortic valve as seen on a short-axis TEE view **(left panel).** This causes dehiscence of the valve, as seen on long-axis TEE views **(middle and right panels),** in which it rocks forward in systole and prolapses into the LVOT in diastole. (See Video 14.38.) *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

Vegetations appear as discrete echogenic masses that are adherent to but distinct from the leaflet itself. A typical mitral vegetation is shown in **Fig. 14.77A**; see Video 14.49. Characteristics of vegetations that aid in distinguishing them from other masses include localization, texture, motion, shape, and associated abnormalities. Vegetations are typically located on the upstream, or low-pressure, side of the valve, in the path of any regurgitant bloodstream (i.e., the atrial aspect of atrioventricular valves and the ventricular aspect of semilunar valves); less often, they are attached to the periphery of septal defects, to chordae, or

to the mural endocardium. The *echodensity* of a vegetation is usually similar to that of myocardium, although advanced vegetations can be inhomogeneous, with findings indicative of liquefaction (which is echolucent) or calcification (which is echodense or bright). Independent *motion* of vegetations is frequently oscillating or erratic. Large vegetations can prolapse into the upstream chamber and create a "ball-and-chain" effect that causes leaflet flail and regurgitation. Vegetations vary tremendously in *shape* but often appear as compact multilobulated or pedunculated, amorphous, and friable agglomerations compared with tumor tissue or thrombus. The vegetation can extend some distance from the valve to which it is tethered and may occur in multiples on the same or different valves. *Associated abnormalities* such as regurgitation, abscesses, and intracardiac channels can accompany advanced endocarditis. There are no distinguishing characteristics that are organism specific, although staphylococcal infections (particularly methicillin-resistant *Staphylococcus aureus* and *S. lugdunensis*) tend to be more destructive and form abscesses, and fungal infections are often impressively large and dendritic in appearance.[77]

Vegetations devoid of microorganisms are the hallmark of *noninfectious endocarditis*, also called "nonbacterial thrombotic" or "nonbacterial marantic" endocarditis (**see Chapter 73**). The typical lesions are small (1 to 5 mm), verrucous, nondestructive nodules that adhere to the upstream side of the valve (typically mitral or aortic) along the line of closure and contain only cellular and fibrin elements. These aseptic lesions are seen in up to 43% of patients with systemic lupus erythematosus (SLE) and 29% of those with antiphospholipid syndrome (APS), in whom they can cause cerebral embolization. These also occur in patients with advanced neoplasms, sepsis, and prothrombotic tendencies in association with clinical features indistinguishable from those of typical infective endocarditis[78] (see later, Systemic Diseases and Echocardiography).

Of note, the presence of preexisting thickening and degenerative changes in leaflets can render the diagnosis challenging. On occasion, myxomatous leaflets, ruptured chordae, calcified structures, and fibrin strands can either mask or mimic a vegetation. Papillary fibroelastomas and thrombi can resemble valvular vegetations. In these circumstances, clinical correlation with other Duke diagnostic criteria is important. Comparison with previous echocardiograms should also be undertaken; a stable finding over years is unlikely to represent a vegetation. Use of TEE for higher-resolution images is often indicated, particularly if a cardiac device is involved[79] or a complication (e.g., embolization, valve destruction, abscess) is suspected.

Among patients with endocarditis, 66% to 75% have risk factors for infection, and echocardiography should be used to scrutinize the relevant structures at risk especially carefully. Patients with prosthetic valves, complex cyanotic congenital heart disease, surgical systemic-pulmonary shunts, bicuspid aortic valves, rheumatic heart disease, or mitral valve prolapse are at higher risk. Previous endocarditis and IV drug abuse are strong predisposing factors for tricuspid and pulmonic valve endocarditis. Other intracardiac structures that are prone to infection, usually at the time of placement or access, include defibrillator/pacemaker wires and chronic indwelling IV catheters, particularly when used for total parenteral nutrition or hemodialysis in immunocompromised patients. Echocardiographic characteristics associated with a poorer prognosis and embolization include vegetation size greater than 1.0 cm (which confers a 2.5-fold higher risk for embolization, especially if on the mitral valve), increasing size of the vegetation over time despite therapy, very mobile vegetation, and paravalvular abscess (more common with prosthetic valves and increasing mortality twofold).[79,80]

The natural history of vegetations after medical therapy is of interest because most will still be apparent on follow-up echocardiography in 1 to 2 months, even after successful medical treatment. Approximately half will become more echodense over time. These observations probably reflect the varied components of the vegetation, which include not only bacteria but also inflammatory cells,

fibroblasts, and extracellular matrix. Growth of a vegetation over time and increasing valvular regurgitation are poor prognostic signs. However, the mere persistence of vegetations in the absence of symptoms or positive blood cultures is not associated with increased clinical complications. Thus, treatment of endocarditis should not be guided by the echocardiographic morphology of the vegetation over time but by clinical response to therapy.

Role of Echocardiography in Surgery for Endocarditis

If left untreated, infective vegetations are destructive via pathways that are apparent on echocardiograms and ECGs and by clinical sequelae. If present, these vegetations are indications for surgery, particularly if recalcitrant to medical therapy. Indications include (1) embolism to the coronary arteries, brain, lungs, spleen, kidney, or extremities; (2) severe valvular regurgitation and heart failure secondary to leaflet malcoaptation, perforations, or flail; (3) abscess, which may invade the cardiac conduction system; (4) mycotic aneurysms of vessels and valves; (5) pseudoaneurysms or fistulas of the heart; and (6) suppurative or hemorrhagic pericarditis.

Typical paravalvular extension patterns can be detected on echocardiograms (and ECGs). On the *aortic valve*, involvement of the right cusp can lead to necrosis of the membranous interventricular septum, aneurysm of the right sinus of Valsalva, and valve dehiscence. Embolization into the RCA can also occur and cause MI. Involvement of the left cusp can affect the intervalvular fibrosa and extend to infect the base of the anterior mitral valve leaflet. There is also the potential to form an aortic-to-LVOT fistula, or paravalvular leak. Involvement of the noncoronary cusp can extend to the posterior interventricular septum, where the His conduction fibers are located, which can lead to the development of an intra- or infrahisian block (third-degree atrioventricular block) or bundle branch block.

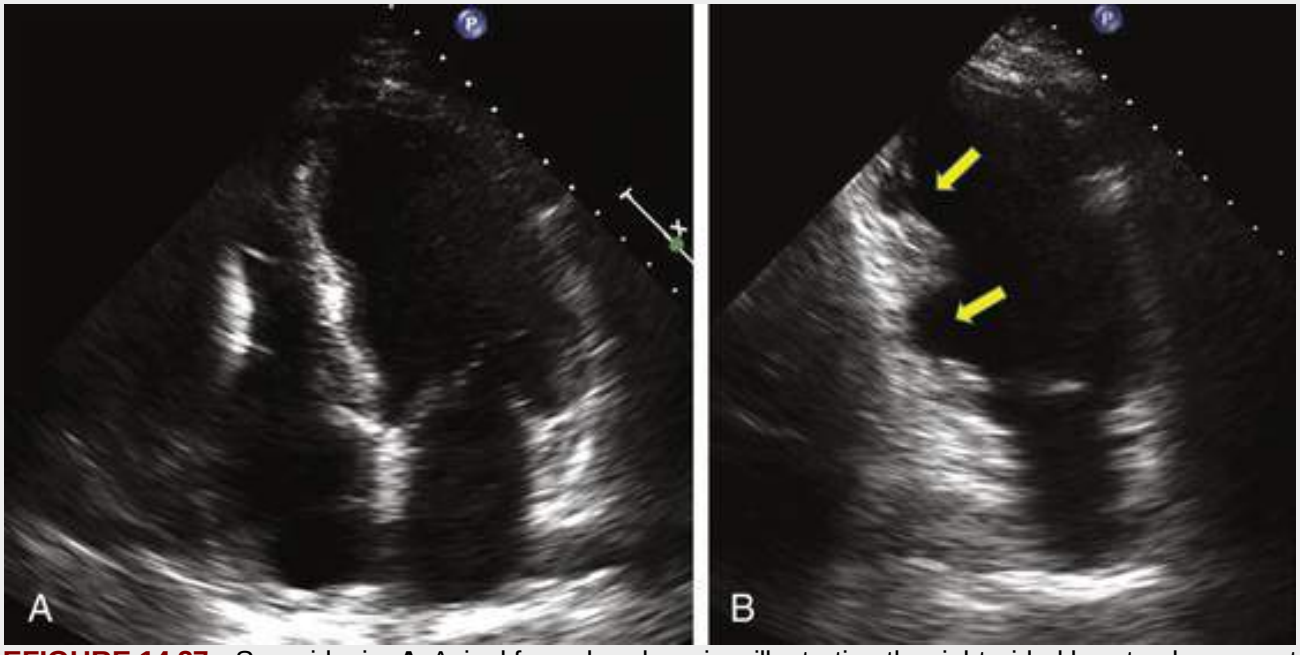
Severe infection of the *mitral valve* less frequently leads to conduction disturbances. Although first- or second-degree atrioventricular block can occur, supraventricular tachycardias are more common. *Tricuspid valve* infection can extend to involve the tricuspid annulus and eustachian valves (**Fig. 14.77B**), seed the pulmonic valve, and cause septic pulmonary emboli in 25% to 80% of cases.[79]

Systemic Diseases and Echocardiography

Aside from conditions that directly affect the heart itself, many systemic diseases with cardiac manifestations are detectable on echocardiography. Uncontrolled hypertension causes symmetrically increased wall thickness and LV hypertrophy in association with LA enlargement and diastolic dysfunction. Renal disease causes early calcification of the valves and potentially uremic pericardial effusions. Hypothyroidism can be associated with a myxedematous pericardial effusion. COPD can cause conspicuous right-sided heart enlargement, RV hypertrophy, elevated TR velocity, and a prominent pericardial fat pad secondary to corticosteroid treatment.

There are diseases that affect all tissue layers of the heart. Amyloidosis is notorious for causing restrictive cardiomyopathy (see earlier and **Fig. 14.31F**), but also frequently causes valvular thickening and pericardial effusions. Infiltration of amyloid into the atrial walls leads to poor atrial contractility and a high prevalence of atrial thrombi, even when sinus rhythm is still present.[47] Granulomatous diseases such as sarcoidosis can cause a focal myocarditis with granulomas (**eFig. 14.27**), which results in very localized areas of akinesis in a noncoronary distribution (see Video 14.14). Pericarditis, valvulitis, and coronary and aortic arteritis have also been reported with Wegener granulomatosis. Although

scleroderma is known to cause direct myocardial fibrosis histologically, on echocardiography this becomes apparent in only a minority of patients, usually late in the course of disease. Instead, the most common echocardiographic abnormalities in scleroderma are elevated RV systolic pressure, RV dilation, and pericardial effusion, as well as LA enlargement and diastolic dysfunction.



EFIGURE 14.27 Sarcoidosis. **A,** Apical four-chamber view illustrating the right-sided heart enlargement (containing a pacemaker wire) and the septal focal wall motion abnormalities in the left ventricle ("scalloping") typically seen in sarcoid heart disease. RV dilation is often secondary to pulmonary hypertension from sarcoid lung involvement. **B,** Apical two-chamber view illustrating very focal areas of thinning and akinesis (*arrows*) in the inferior LV wall because of sarcoid granulomas and/or myocardial scarring. (See corresponding Video 14.14.)

Other diseases that have echocardiographic manifestations include human immunodeficiency virus (HIV) infection (**see Chapter 82**), in which the most common abnormalities are dilated cardiomyopathy, pericardial effusion (seen in 12% to 25% of cases), but also HIV-related pulmonary hypertension and cardiac lymphomas. The prolonged duration of HIV infection and highly active antiretroviral therapy (HAART) regimens may contribute directly and indirectly (via lipodystrophic effects and chronic inflammation) to both cardiomyopathy and the excess risk of CAD in this population.[81]

Similarly, even when cancers spare the heart, the radiation and chemotherapy regimens used to attack the neoplasms can have cardiac effects (**see Chapter 81**). Ideally, the early detection of cardiomyopathy in patients who receive chemotherapy, particularly with anthracyclines (as well as tyrosine kinase inhibitors and immunomodulators), allows modification of the protocol before irreversible damage occurs. Screening for LVEF is the most widely used strategy, but a growing body of evidence indicates that a decrease in peak systolic GLS (>15% change from baseline) is a more sensitive and earlier predictor of cardiotoxicity. Currently, however, GLS is still greatly in need of standardization among vendors and researchers, and insufficient data exist to indicate if decrements in GLS during chemotherapy will predict chronic irreversible heart failure.[82] Aside from chemotherapy damage, survivors of Hodgkin disease also frequently have early thickening and stenosis of the aortic valves, as well as accelerated CAD from radiotherapy.

Several other conditions predispose to valvular abnormalities (see earlier, Valvular Heart Disease). Rheumatic carditis and its sequelae are well-known historical examples and are still a significant cause

of heart disease in developing nations (**see Chapter 74**). More than 50% of patients with carcinoid tumors have cardiac involvement in which plaquelike deposits build up on the right-sided heart valves (typically the ventricular aspect of the tricuspid valve and the arterial aspect of the pulmonic valve). This causes a characteristic retracted and fixed appearance of the tricuspid and pulmonary leaflets and a combination of valvular stenosis and regurgitation (**see Fig. 14.53**; see Video 14.35). Cardiac involvement confers a worse median survival time for carcinoid. The hematologic malignancies and any thrombophilic state (e.g., sepsis, disseminated intravascular coagulation, SLE, APS) can cause nonbacterial marantic endocarditis in which the sterile vegetations and fibrin strands undergo frequent cycles of growth and subsequent fragmentation and embolization, with associated valvulitis and leaflet destruction. The systemic vasculitides such as Takayasu arteritis and Behçet disease are notable causes of AR, particularly in younger patients.[83]

Pulmonary Hypertension

Echocardiography can assess for pulmonary hypertension and causative conditions. In the absence of known pulmonary disease, the presence of an enlarged right side of the heart with a normal-appearing left ventricle prompt a search for secondary causes of pulmonary hypertension (**Fig. 14.78**) (**see Chapter 85**). Causes that are detectable by echocardiography include intracardiac shunts with atrial septal defects (ASDs) (and most shunts above the tricuspid valve), MS, and occasionally pulmonary thromboembolism. Noncardiac causes include mixed connective tissue disease, systemic sclerosis, SLE, and sickle cell disease, in which pulmonary hypertension is an important cause of morbidity and mortality. In general, most of the indices of pulmonary artery systolic pressure and right-sided heart failure (e.g., interventricular septal flattening, TAPSE, FAC) have been shown to be predictors of mortality in patients with diverse causes of both primary and secondary pulmonary hypertension.[84]

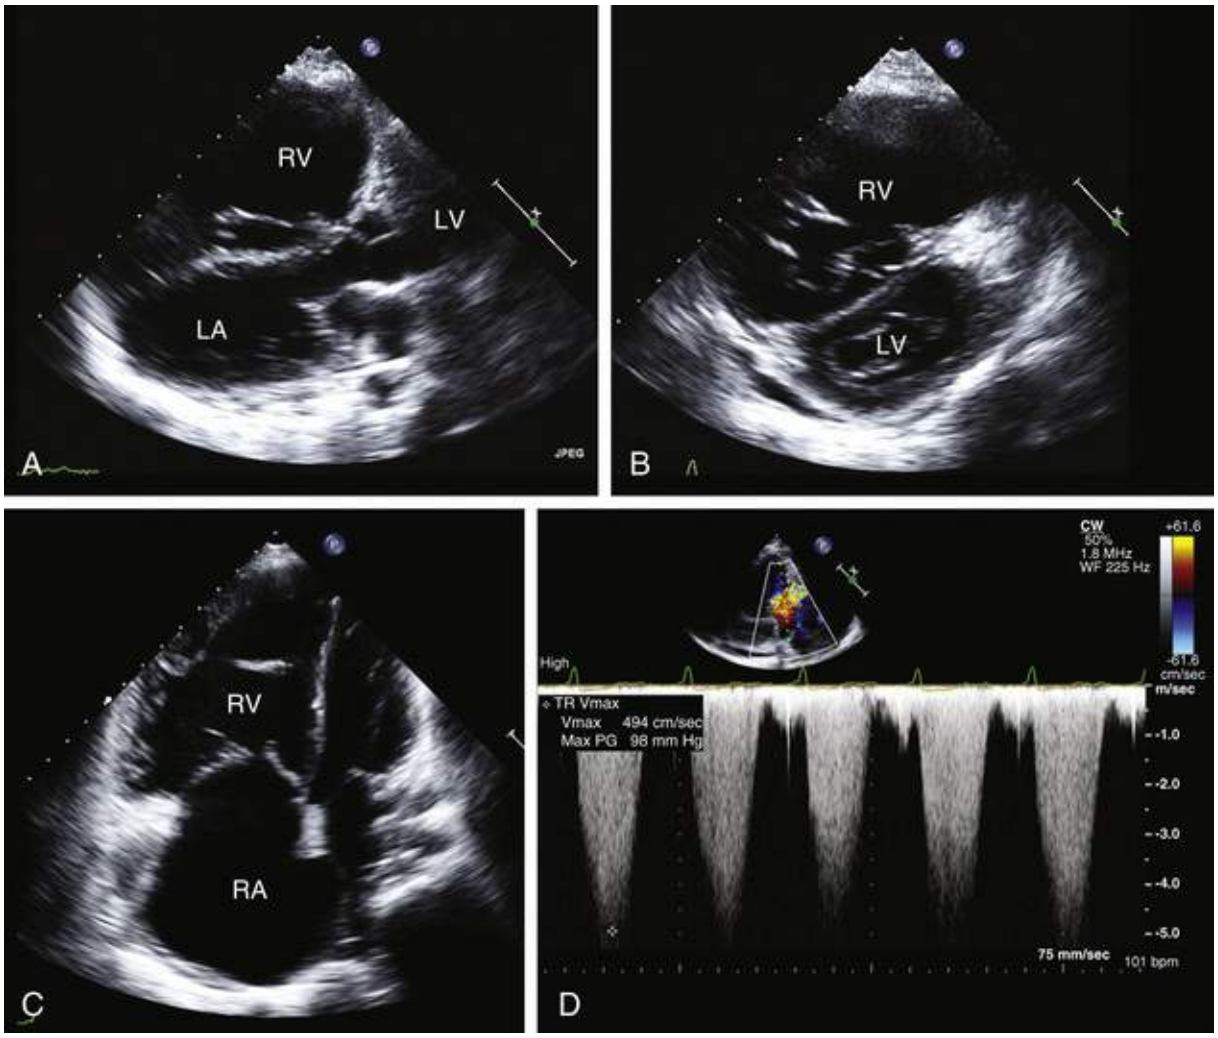


FIGURE 14.78 Pulmonary hypertension secondary to chronic thromboembolic disease. **A,** Parasternal long-axis view illustrating a small left ventricular cavity and enlarged right ventricular outflow tract. **B,** Parasternal short-axis view demonstrating the D-shaped left ventricular cavity caused by systolic and diastolic septal flattening, i.e., pancyclic elevated right ventricular pressure. **C,** Apical four-chamber view. Note the dilated right atrium and tricuspid annulus with incomplete closure of the tricuspid valve, as well as leftward distention of the interatrial septum. **D,** Severe tricuspid regurgitation (TR) with an elevated TR velocity corresponding to a calculated right ventricular systolic pressure of 98 mm Hg plus right atrial pressure. The upslope of the tricuspid regurgitant jet is slow, indicative of poor right ventricular contractility. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

Two-dimensional echocardiographic findings in patients with pulmonary hypertension include flattening of the interventricular septum (first in diastole and subsequently, as pressure rises further, in systole), dilation of the pulmonary artery, RV hypertrophy, RV dilation, and ultimately RV dysfunction. Typical Doppler findings include elevated TR velocity, enlargement of the right atrium, dilation of the IVC and hepatic veins, and loss of respirophasic size variation in the IVC.

Pulmonary artery pressure (PAP) can be assessed relatively accurately by using the Bernoulli equation to estimate the pressure gradient between the right ventricle and the right atrium. If TR is not present or the TR jet is acquired off-axis, this measurement will be impossible to make or will underestimate the severity of pulmonary hypertension. In addition to PAP assessment, PVR (in Woods units) can be measured noninvasively by using the validated formula:

$$\text{PVR} = 10(\text{TR peak velocity}/\text{VTI}_{\text{RVOT}}) + 0.16$$

where TR peak velocity is measured in m/sec and VTI_{RVOT} in cm. This approach may have utility in

distinguishing high PAP caused by increased pulmonary blood flow (as occurs in high-output states such as hyperthyroidism, anemia, and obesity) from that caused by elevated PVR.

Assessment of RV size and function is essential in pulmonary hypertension. RV FAC, TAPSE, RV Tei index, and tricuspid annular systolic velocity (S′) are typically used to assess RV function in patients with pulmonary hypertension (**see Table 14.6**). Myocardial strain imaging of the right ventricle may prove to be useful in patients with pulmonary hypertension, but the wide range in normative data limits its clinical application at present.[85]

There are several distinguishing features between the echocardiographic findings of pulmonary hypertension and acute pulmonary embolism. Acute pulmonary embolism is not usually associated with RV hypertrophy, elevation in PAP, or flattening of the interventricular septum in systole, unless the pulmonary embolism is chronic or longstanding thromboembolic disease has resulted in pulmonary hypertension. In addition, the regional RV dysfunction in acute pulmonary embolism usually spares the apex, whereas there is global RV hypokinesis in pulmonary hypertension.

Cardiac Masses

Cardiac tumors are relatively rare, ranging from an incidence of 1% to 2% in general autopsy series but up to 4% to 8% in cancer patient autopsies, so routine screening is not recommended. Among primary tumors of the heart, up to 90% or more are detected incidentally and three quarters are benign. It is the location of an intracardiac or extracardiac mass—in the context of the patient's age, clinical findings, and comorbidities—that is often the best indicator of the type of tumor; morphologic features of the mass play a secondary role in identification[86] (**Table 14.11**).

TABLE 14.11

Site-Specific Differential Diagnosis of Cardiac Tumors

SITE	ONCOLOGIC	ALSO CONSIDER NON-NEOPLASTIC MASSES	NORMAL OR VARIANT STRUCTURES
Left atrium	Myxoma Lipoma Bronchogenic carcinoma Sarcoma (involving the wall/pericardium) Hemangioma Paraganglioma	Thrombus Endocardial blood cyst	Lipomatous hypertrophy of interatrial septum External compression (by hernia, thoracic aorta, bezoar) Echocardiographic artifact: left upper pulmonary vein limbus (“Coumadin ridge”) Appendage pectinate muscles Atrial suture anastomosis after heart transplantation Inverted LA appendage (postoperative) Aberrant LA chorda
Right atrium	Myxoma Nephroblastoma, renal cell cancer Hepatocellular carcinoma Sarcoma (angiosarcoma) Paraganglioma Adrenal tumors	Thrombus (deep venous or in situ) or fibrin casts (of previous indwelling catheter/wire) Vegetation (on pacer/ICD wires) Lipomatous hypertrophy of interatrial septum	Eustachian valve Chiari network Crista terminalis Interatrial septal aneurysm Pectus excavatum
Left ventricle	Rhabdomyoma (often multiple) Fibroma Hamartomas Purkinje cell tumors (usually infants)	Thrombus Apical hypertrophic cardiomyopathy Subaortic membrane	Calcified or multilobed papillary muscles Redundant or severed mitral chordae Trabeculations, false tendons Focal upper septal hypertrophy Swirling from inhomogeneous intravenous echocardiographic contrast distribution
Right ventricle	Rhabdomyoma Fibroma	Thrombus	Redundant tricuspid chordae Tricuspid papillary muscle Moderator band
Valves/annuli	Papillary fibroelastoma Myxoma Hamartoma Lipomas	Lambl excrescences Focal or caseous mitral annular calcification Vegetation Marantic endocarditis Thrombus (especially on prosthetics) Pannus (especially on prosthetics) Abscess Blood cyst Rheumatoid nodule	Nodules of Arantius Myxomatous/degenerative changes Pannus; loose suture; bioglue or pledgets around prosthetic valves
Pericardium	Malignant involvement from lung, breast, lymphoma/leukemia, or gastrointestinal tract melanoma Mesothelioma Primary: spindle cell tumor, fibrous tumors, lipoma, liposarcoma, teratoma Paraganglioma	Pericardial or bronchogenic cyst Rheumatoid nodule Thrombus Hydatid cyst (*Echinococcus*)	Epicardial or mediastinal fat Pectus excavatum Atelectatic lung or fibrin in pleural/peritoneal spaces Vascular pseudoaneurysm Thymus (in infants)

ICD, Implantable cardioverter-defibrillator; *LA,* left atrial.

Modified from Wu J. Cardiac tumors and masses. In Stergiopoulos K, Brown DL, editors. Evidence-Based Cardiology Consult. New York: Springer Science + Business Media; 2014.

Nonetheless, the overall appearance of the mass (with respect to size, solid versus cystic, shape, degree of independent mobility, and fragility), its attachments, and the extent of myocardial, endocardial, or pericardial invasion can offer clues to its nature. Calcified or fibrotic areas appear echobright, whereas cystic degeneration causes echolucent foci on echocardiography. Obstruction to caval or valvular inflow will cause increases in peak spectral Doppler velocities, often with a mosaic color Doppler pattern signifying turbulent flow. Mitral stenosis and MR caused by an LA myxoma prolapsing across the mitral valve is a classic example (**Fig. 14.79** and Video 14.51). The echocardiographic appearance of this entity is so pathognomonic that usually no further workup is required before surgical resection. Similarly, papillary fibroelastomas occur so characteristically on the aortic and mitral valves and are so commonly seen as filamentous or amorphous growths that shimmer, undulate, and prolapse, that further assessment may not be required before surgery. However, the smaller lesions may be difficult to differentiate from highly mobile Lambl's excrescences (**Fig. 14.80** and Video 14.52).

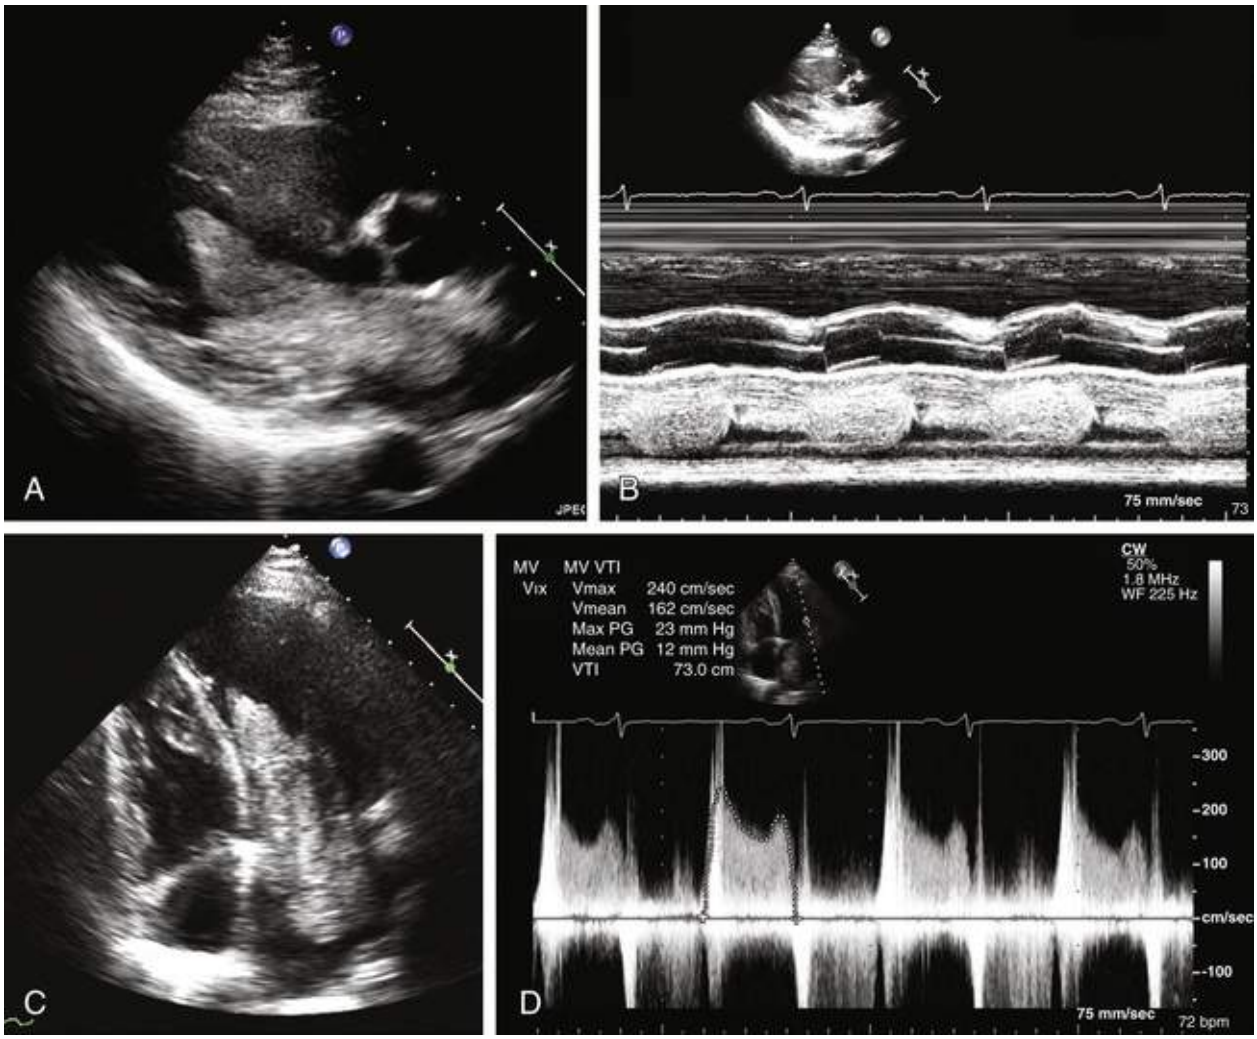

FIGURE 14.79 Left atrial myxoma. **A,** Parasternal long-axis view. **B,** M-mode view showing the mass prolapsing through the mitral valve into the left ventricle in diastole. **C,** Apical 4-chamber view. **D,** Transmitral gradients (mitral stenosis) as shown by CW Doppler, with peak and mean gradients of 23 and 12 mm Hg. (Modified from Wu J. Cardiac tumors and masses. In Stergiopoulos K, Brown DL, editors. Evidence-Based Cardiology Consult. New York: Springer Science + Business Media; 2014.)

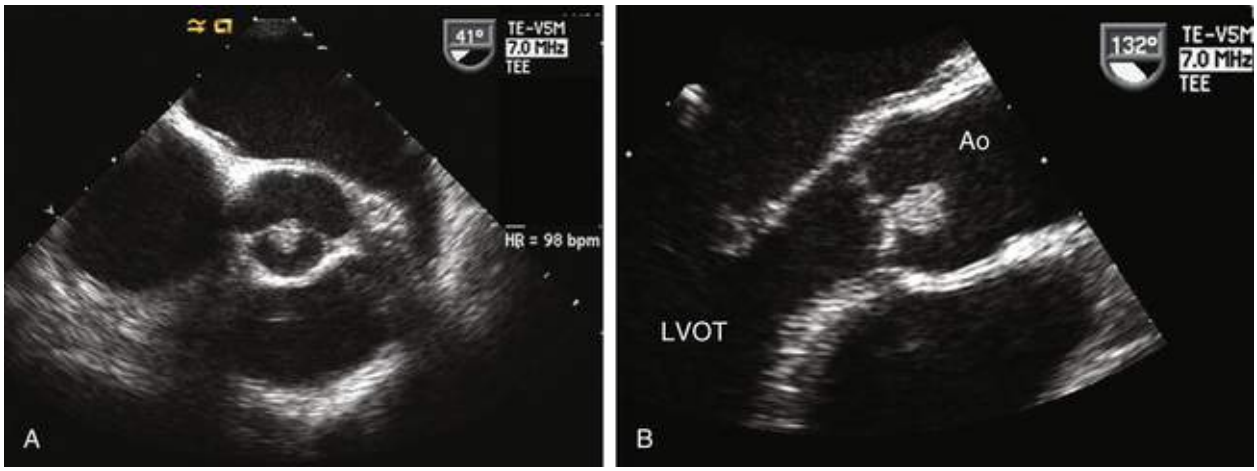

FIGURE 14.80 Papillary fibroelastoma on the aortic valve. **A,** TEE short-axis view showing the mass on the aortic aspect of the noncoronary cusp. **B,** TEE long-axis view. *Ao,* Aorta; *LVOT,* left ventricular outflow tact. In select patients, to refine the diagnostic possibilities, IV echocardiographic contrast material may be

used to determine whether a tumor hyperenhances. Hyperenhancement indicates that the mass is neovascularized and thus more likely to be malignant than a benign stromal tumor or thrombus.[23,24] One can also use 3D echocardiography to better illustrate the overall size, location, and attachments of intracavitary masses. Following diagnosis, echocardiography is a convenient way to monitor for recurrence, growth, or adverse sequelae after excision or treatment.

Common Primary Tumors

Myxoma accounts for more than 50% of primary cardiac tumors in adults, followed by papillary fibroelastomas and lipomas. Myxoma is a primary benign tumor believed to arise from mesenchymal (endocardial) cells. It typically arises in the left atrium (75% of cases, with the other 20% occurring in the right atrium and 5% in the ventricles) and is attached to the interatrial septum near the fossa ovalis by a stalklike pedicle. Attachments to the mitral valve have been described in a small percentage of cases. Grossly and on echocardiography, myxomas frequently appear as a gelatinous, compact mass, but there is a spectrum of morphologies. Smaller tumors tend to be more papillary or villous and are friable and thus prone to embolize. Larger myxomas have a smoother, globular, or grape cluster–like appearance and can grow large enough to fill the left atrium and cause both MS and a renowned tumor "plop" on auscultation as the mass prolapses into the left ventricle in diastole (**see Fig. 14.79** and Video 14.51). Approximately 7% of cases result from an autosomal dominant mutation and are part of the "Carney complex" syndrome, associated with skin lentiginosis and endocrine disorders.[87]

In adults, *papillary fibroelastomas* are the next most common cardiac benign tumors and the most common valvular tumor. Most (>80%) are found on left-sided (aortic or mitral) valves, although any valve may be affected, and 9% occur as multiple lesions. Pathologists usually classify fibroelastomas as an advanced or more florid form of *Lambl excrescences*, which are degenerative changes in the valves. Fibroelastomas tend to appear on either side of the aortic valve or on the atrial side of the mitral valve. Less frequently, they have also been known to arise on mitral chordae or papillary muscles. On echocardiography, papillary fibroelastomas appear round, oval, or irregular in shape and homogeneous in texture (**see Fig. 14.80** and Video 14.52). Almost half have a short stalk, which confers more mobility. Fibroelastomas are found most frequently in older adults as solitary lesions (<10% occur as multiple lesions), and shedding of the threadlike elements and associated clot accounts for their frequent manifestation as embolization (transient ischemic attack or stroke, angina, or sudden death).[86,87]

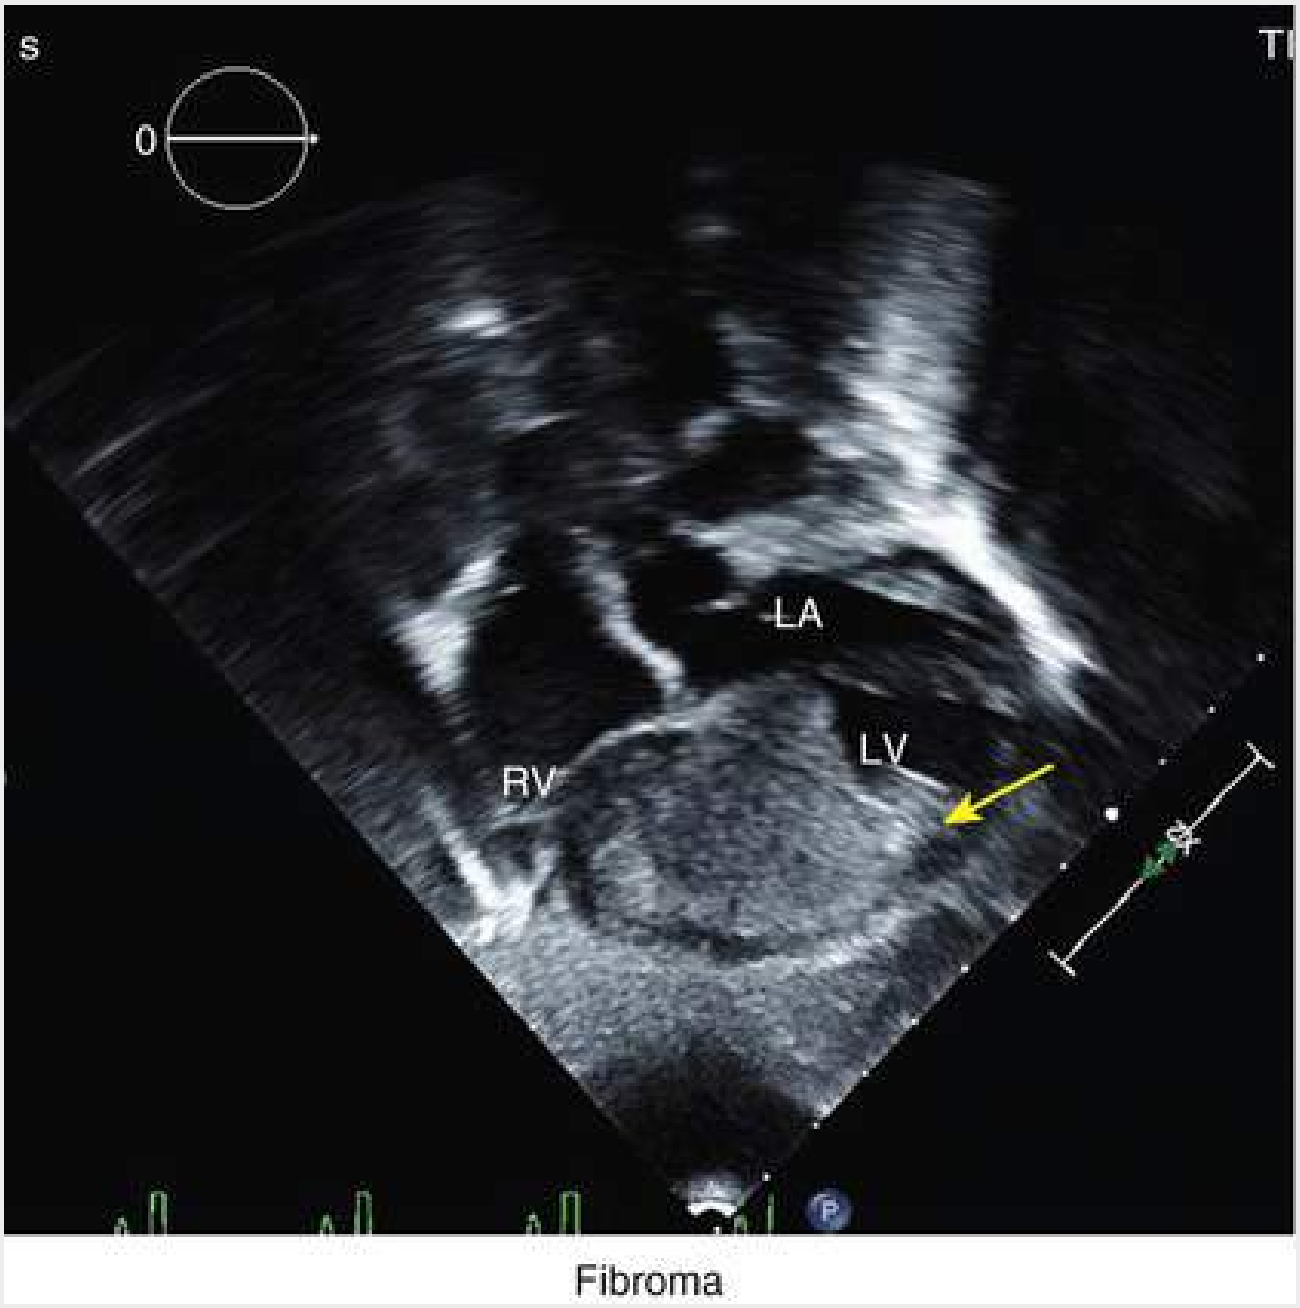
Lipomas are encapsulated collections of benign fat cells that tend to occur in subepicardial or subendocardial locations and may grow into the pericardial space. Although benign, usually discovered incidentally, and easily distinguished by CMR characteristics (**see Chapter 17**), these tumors tend to increase progressively and can cause mass effect, heart block, or tachyarrhythmias. On imaging, lipomas can be difficult to distinguish from *lipomatous hypertrophy of the interatrial septum*, which is a normal finding, particularly in elderly or obese patients (see later, Pseudoneoplasms). However, lipomatous hypertrophy is technically hyperplasia of epicardial adipocytes within the groove between the LA and RA walls and inferior pyramidal space, which spares the fossa ovalis and produces a characteristic dumbbell-shaped mass. Although lipomatous hypertrophy is unencapsulated and may reach an impressive thickness (1 to 2 cm or more), if the location is typical and no associated atrial arrhythmias or caval obstruction are present, no treatment is indicated.[88]

Pericardial cysts are benign fluid-filled tumors of the parietal pericardium and are thought to be a congenital abnormality.[89] They may be solitary or multilocular, and some have been documented to grow

to massive (>20 cm) size. They account for approximately 20% of benign primary cardiac masses (overall incidence of 1 in 10,000) and usually occur near the cardiophrenic borders (right more often than the left). This gives the appearance of cardiomegaly on chest radiographs and forms an encapsulated echolucent area on echocardiography. Of known cases, 75% are asymptomatic. If large, however, pericardial cysts may cause atypical chest pain, breathlessness, AF, persistent cough, or compressive problems such as RVOT obstruction. Rare cases of cardiac tamponade secondary to intrapericardial rupture and hemorrhage have been reported.

Rhabdomyomas are the most common primary cardiac neoplasm in children and are usually found during the first year of life. They tend to be solid intramyocardial lesions containing striated myocyte fibers, and 90% occur as multiple tumors. Although most patients are asymptomatic, larger tumors have been known to cause arrhythmias, LVOT obstruction, and heart failure. Half the cases are associated with tuberous sclerosis. Most regress spontaneously, and overall these tumors are rare in young adults.[86,87]

Fibromas are the second most common pediatric cardiac neoplasm. They arise in the ventricular myocardial layer, are five times more common in the left ventricle, and consist of solid tumors containing fibroblasts. These tumors often occur in the LV septum or free wall, where they can become quite large and develop calcific foci (**eFig. 14.28**). Unlike rhabdomyomas, fibromas do not spontaneously regress and may grow to a size that obliterates the heart chamber, interferes with valvular function, or causes arrhythmia and necessitates surgical resection.[88]



EFIGURE 14.28 Fibroma. Transthoracic pediatric echocardiogram five-chamber view showing a large (5-cm) fibroma (*arrow*) arising in the distal left ventricle and exerting mass effect on the right ventricle.

Secondary Tumors

Secondary cardiac tumors outnumber primary ones by 20 to 40 to 1. In principle, any malignant tumor may metastasize to the heart. The most common site of involvement is the pericardium, with invasion of the myocardium seen next in frequency.[86]

Pericardial involvement in cancers may arise from direct invasion of tumor from adjacent lung or mediastinum (e.g., mesothelioma, lymphoma), or there may be more diffuse involvement and effusive/constrictive changes. The most frequent sources of malignant pericardial disease are lung cancer, lymphoma/leukemia, and breast cancer because of their relatively high prevalence,[86] with some worldwide variability. Of all malignancies, *melanoma* has the highest predilection to metastasize to the heart and pericardium. Cardiac metastases from any source typically are small and multiple or cause effusion or diffuse thickening of the pericardium. However, bulky large solitary tumor lesions may also occur (**see Fig. 14.69**).

Secondary tumors may also invade the heart by direct extension[86]: renal cell carcinoma, Wilms tumor, uterine leiomyosarcoma, hepatomas, and adrenal tumors can be detected extending into the right atrium via the IVC on echocardiography. Bronchogenic carcinomas can invade the left atrium through the pulmonary veins. Lymphatic and hematogenous routes are also pathways to the heart. The location and mass effect of the metastases, rather than type of primary, tend to determine the patient's symptomatology.

Alternative Diagnoses

Pseudoneoplasms

With the abundance of cardiac imaging being performed by various modalities, it is inevitable that normal or slight variants of normal structures, degenerative or acquired lesions, and noncancerous masses may be detected. The onus is on the cardiologist or radiologist to distinguish between the following entities (listed in Table 14.11) and a true neoplasm.

Intracardiac Thrombus

Masses such as thrombi and vegetations have obvious clinical implications. On echocardiography, formed thrombi appear relatively homogeneous in echodensity and have a gel-like or deformable appearance (**Fig. 14.81B**). Old thrombi may have more echobright regions and a compact immobile or laminated appearance (**see Fig. 14.31A**). Clues that a mass is actually a thrombus include residence in areas of stasis (e.g., tip of LA appendage or within LV aneurysm), “wisps” of spontaneous echocardiographic contrast associated with the surface (**Fig. 14.81A** and Video 14.53), and associated predisposing cardiac conditions, including mitral stenosis, prosthetic valves, cardiomyopathy, aneurysms of any chamber, or AF (Video 14.54). Ropelike vacillating masses in the right side of the heart often represent thromboemboli from the deep venous system (**see Fig. 14.75, left**, and Video 14.47), in which case the IVC, as well as the pulmonary arteries, should be inspected for portions of the same clot. With anticoagulation, intracardiac thrombi frequently regress or remain stable.

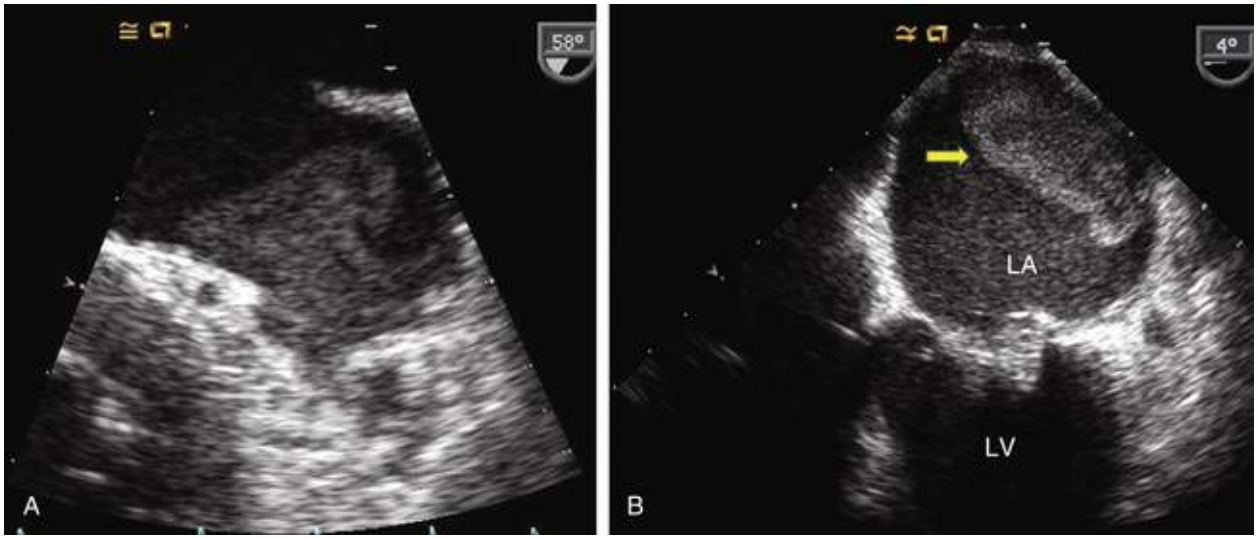


FIGURE 14.81 Spontaneous echocardiographic contrast and left atrial appendage thrombus. **A**, Zoomed TEE view of spontaneous echocardiographic contrast in the left atrial appendage in a patient with a bileaflet mechanical mitral prosthesis who was subtherapeutic with warfarin treatment. **B,** TEE view of organized thrombus (*arrow*) in the left atrial appendage in a patient following mitral annuloplasty. *LA,* Left atrium; *LV,* left ventricle. (See Videos 14.53 and 14.54.)

The presence of LV aneurysms or severe dilated cardiomyopathy should always prompt vigilance for thrombi. Conversely, it would be highly unusual for a thrombus to form in an area with normal wall motion. Use of a high-frequency (7 to 8 MHz) probe to focus on the cardiac apex, angling it at unconventional views and sweeping across the field as needed, can better define thrombus versus myocardium and trabeculations and will also decrease noise and reverberation artifact. Ultrasound contrast enhancement is often the key when endocardial border definition is poor.

With its higher resolution and proximity to the base of the heart, TEE plays a major role in ruling out intracardiac thrombi (or other sources of emboli, such as atheroma or vegetation) when no identifiable source is found after imaging the head and neck arteries and the heart by TTE. An embolic stroke or unusually high transvalvular gradients in a patient with a mechanical (or even bioprosthetic) valve should prompt referral for TEE, contingent on the assumption that the findings on TTE were nondiagnostic and that they would alter management. TEE is also frequently used to facilitate the decision to anticoagulate, cardiovert, or perform radiofrequency ablation of a tachyarrhythmia, particularly in high-risk patients (i.e., those with the predisposing cardiac conditions mentioned earlier or those found to be underanticoagulated before a planned procedure). TEE should be performed before percutaneous mitral valvuloplasty for rheumatic mitral stenosis to rule out LA thrombus (as well as to better define the mitral anatomy and degree of regurgitation) and thus avert potentially catastrophic embolic complications.[17-19,76]

Vegetations and Pannus.

Vegetations tend to arise on the upstream side of valves or at areas of flow turbulence. Valves with degenerative changes, prosthetic valves, and indwelling catheters or pacemaker/defibrillator wires are well-recognized nidi for infection. Thick, immobile, heaped-up irregular masses affixed to the annuli of older prosthetic valves may represent pannus (fibrovascular granulation tissue) (**see Fig. 14.59**). For both thrombi and vegetations, the larger and/or highly mobile masses that threaten the pulmonary, systemic, or cerebral circulation with embolization or cause severe valvular dysfunction may compel emergency surgical resection (see earlier, Infective Endocarditis).

Normal Variants and Artifacts.

Normal or mild variants of normal structures have also been mistaken for neoplasms on echocardiography. The most common errors are mistaking lipomatous hypertrophy, upper septal hypertrophy, a redundant mitral chorda or prominent/multilobed papillary muscle, interatrial septal aneurysm, or pericardial fat for a mass. Degenerative changes such as valvular calcification or external compression of chambers of the heart by adjacent structures (e.g., from esophageal hernia indenting posterior wall of left atrium) can give the appearance of a large mass when viewed in only one plane. Knowledge of the typical appearance of these abnormalities, use of echocardiographic contrast, and either careful tilting and sweeping of the transducer plane or use of 3D echocardiography to track the boundaries and attachments of these entities can reveal their true nature.

Adult Congenital Heart Disease

Echocardiography plays a critical role in the evaluation and management of both children and adults with congenital heart disease (**see Chapter 75**). Consequently, this section focuses on the role of echocardiography in diagnosing common shunts (ASDs and VSDs), as well as transposition of the great arteries and tetralogy of Fallot, complex lesions that may be seen by cardiologists caring for adults. The

use of echocardiography for the selection and implantation of ASD closure devices is also covered.

Atrial Septal Defect

ASDs account for approximately 10% of all congenital heart disease and 20% to 40% of congenital heart disease occurring in adulthood. The initial diagnosis of ASD is often made at echocardiography for nonspecific symptoms or for a heart murmur in an asymptomatic individual.

General Imaging Principles.

Fig. 14.82 provides the anatomic classification of ASDs. Although secundum defects are often isolated anomalies, ASDs of other types are frequently associated with other structural anomalies. Multiple ASDs may be encountered in the same patient. Secundum and primum ASDs can generally be diagnosed with 2D TTE, but TEE is typically required to detect sinus venosus and coronary sinus defects. On TTE, although parasternal and apical views are useful, the subcostal view is particularly important because it optimizes the Doppler detection of shunts and minimizes the chance that normal thinning of the fossa will be mistaken for a secundum defect. In the absence of significant pulmonary hypertension, ASD flow is typically left to right, reflecting normal intracardiac pressures. However, agitated saline injections may demonstrate the transient right-to-left shunts that can occur in patients with ASDs or show negative contrast enhancement ("ghosting") when the shunt flow from the left atrium meets the contrast-enhanced RA blood pool.

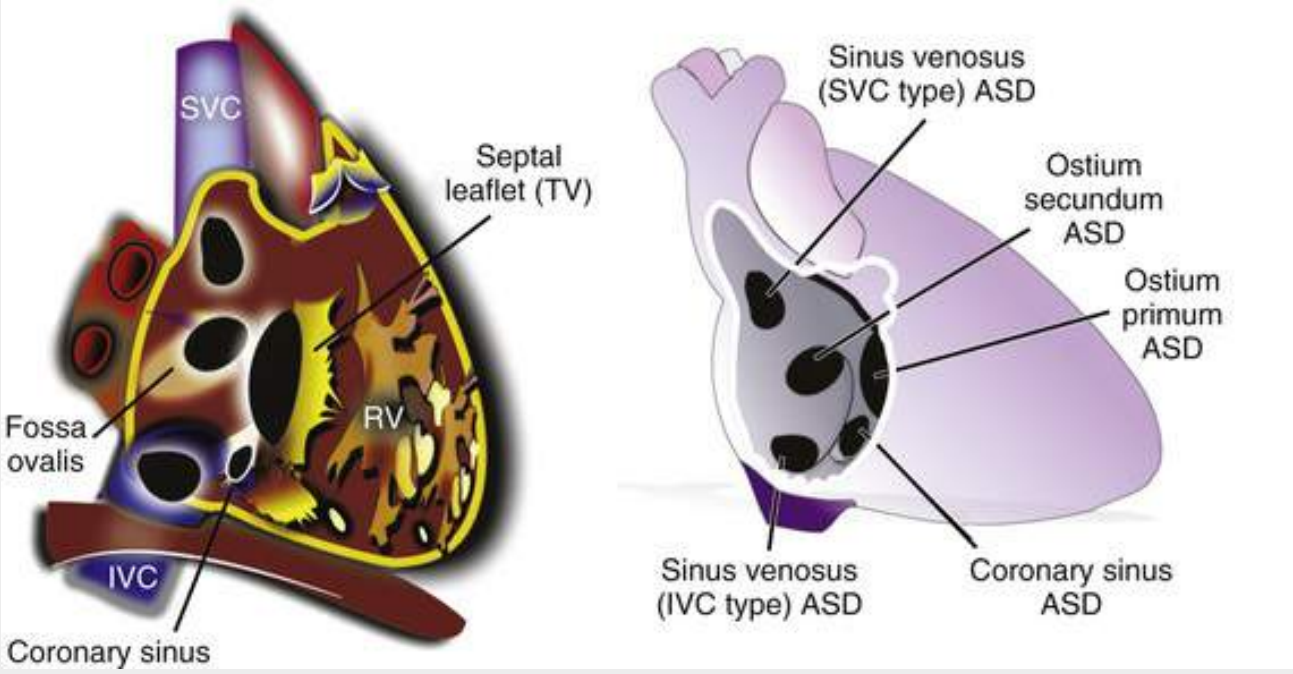

FIGURE 14.82 Classification of atrial septal defects (ASDs). *IVC, SVC,* Inferior, superior vena cava; *RV,* right ventricle; *TV,* tricuspid valve.

Regardless of location, hemodynamically significant ASDs will be associated with evidence of RV volume overload, characterized by RV enlargement and diastolic flattening of the interventricular septum. Pulmonary hypertension, which may complicate large defects, will result in flattening that persists through systole. This 2D appearance of RV volume overload and right-sided heart enlargement is

considered evidence of a hemodynamically significant shunt ($Q_p/Q_s \geq 1.5 : 1$). Q_p/Q_s, or the ratio of RV output (RV SV) to LV output (LV SV), may be calculated directly by applying the principles of the continuity equation:

$$Q_p/Q_s = (\pi[D_{RVOT}/2]^2 \times VTI_{RVOT})/[\pi(D_{LVOT}/2]^2 \times VTI_{LVOT})$$

where D indicates the diameter of the RVOT and LVOT, respectively (**Fig. 14.83**). Additionally, PVR can be calculated in Wood units (see earlier, Pulmonary Hypertension); normal PVR is 0.5 to 1.5 Wood units.[84]

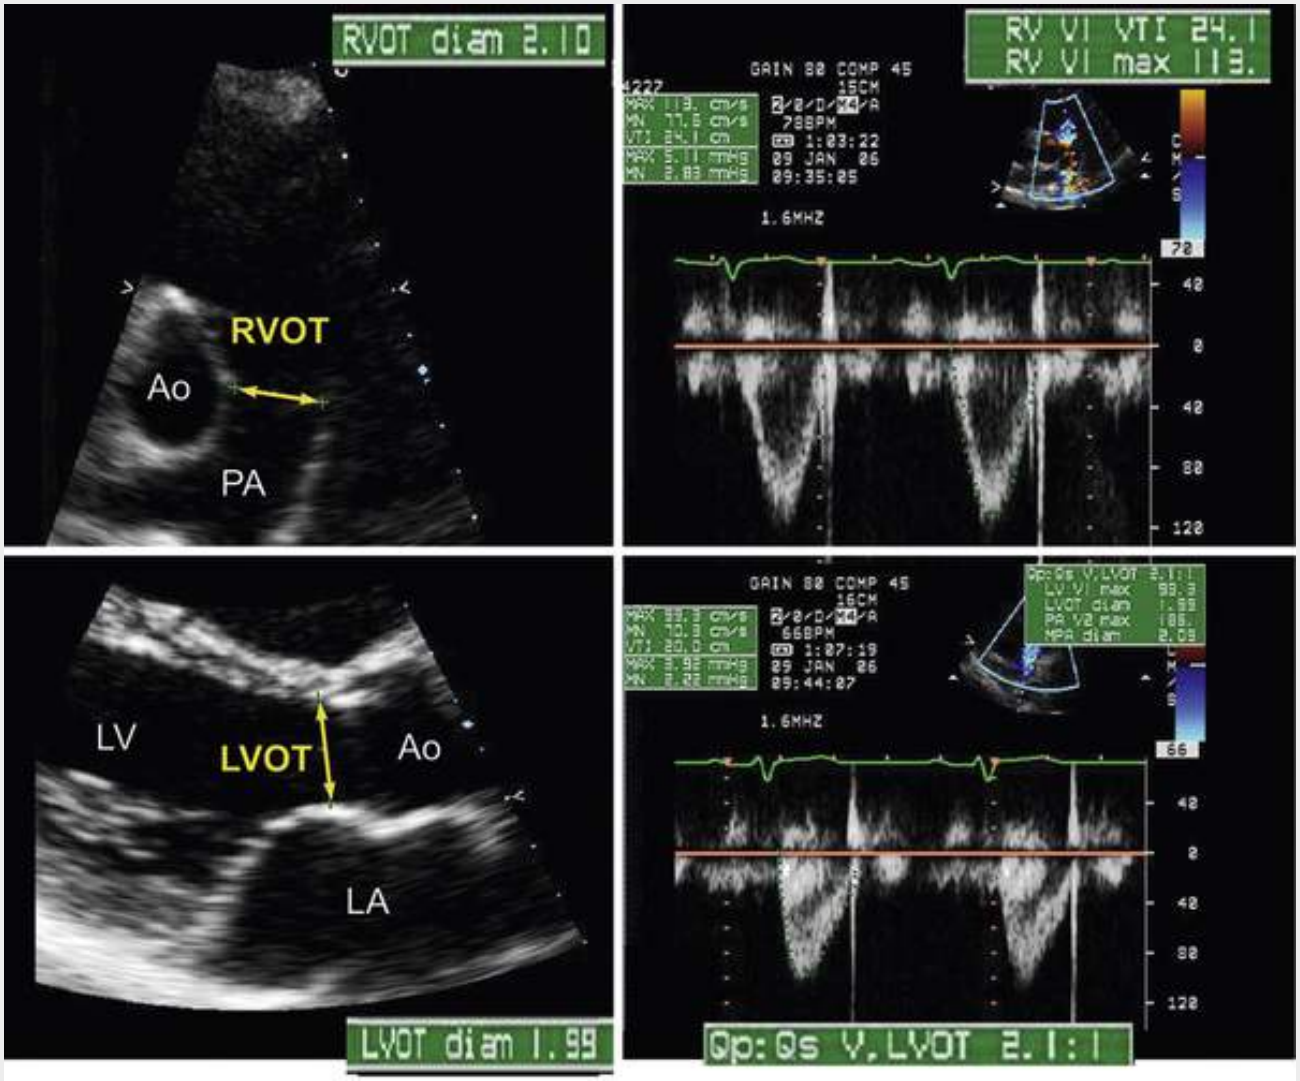

FIGURE 14.83 Q_p/Q_s calculation. For ASDs, Q_p is equivalent to RV stroke volume (SV), which equals $CSA_{RVOT} \times VTI_{RVOT}$, in which $CSA_{RVOT} = \pi(D/2)^2$. Q_s is equivalent to LV SV calculated as $CSA_{LVOT} \times VTI_{LVOT}$, where $CSA_{LVOT} = \pi(D/2)^2$. The **upper and lower panels** illustrate the derivation of RV and LV SV, respectively, from echo data. *Ao,* Aorta; *LA,* left atrium; *PA,* pulmonary artery.

If clinically appropriate, secundum ASDs may be potentially closed by transcatheter techniques. The other types of ASD require surgical closure.

Secundum Atrial Septal Defect

Secundum ASDs account for 75% of all ASDs and 30% to 40% of congenital disease seen in patients older than 40 (**see Chapter 75**). **Figs. 14.84 and 14.85** show the 2D TTE and TEE echocardiographic appearance of these defects. They are the only ASDs that are eligible for catheter-based closure. In planning transcatheter closure, TEE is used to (1) ensure that only one (or more) secundum ASD is present, and not other interatrial shunts that cannot be closed percutaneously, (2) precisely size the defect, and (3) ensure that there is enough adjacent tissue rim to anchor the device. 3D TEE is especially advantageous for displaying en face displays of the septum before and during implantation[90,91] (**eFig. 14.29**). Of the two devices currently approved by the U.S. Food and Drug Administration, the Amplatzer may be used for defects up to 35 mm, whereas the Helex device may be used only for defects up to 17 to 18 mm, although it may be placed successfully in patients with deficient anterior rims.

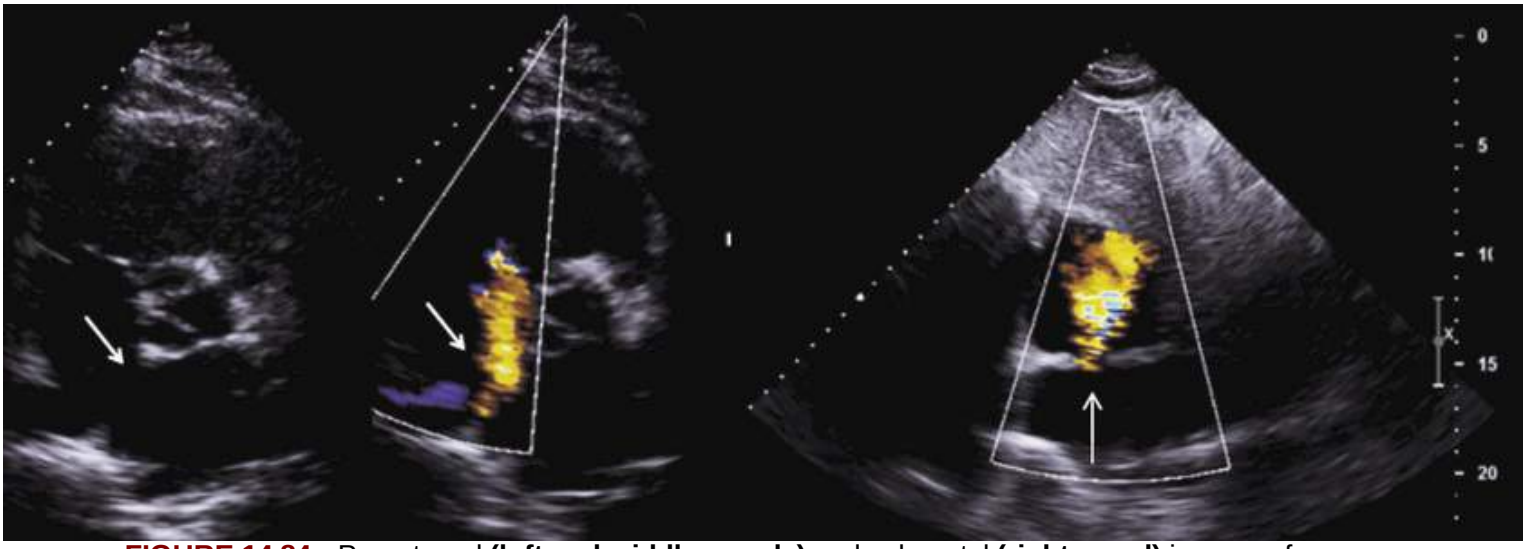

FIGURE 14.84 Parasternal **(left and middle panels)** and subcostal **(right panel)** images of a secundum ASD and its associated left-to-right shunt (*arrows*).

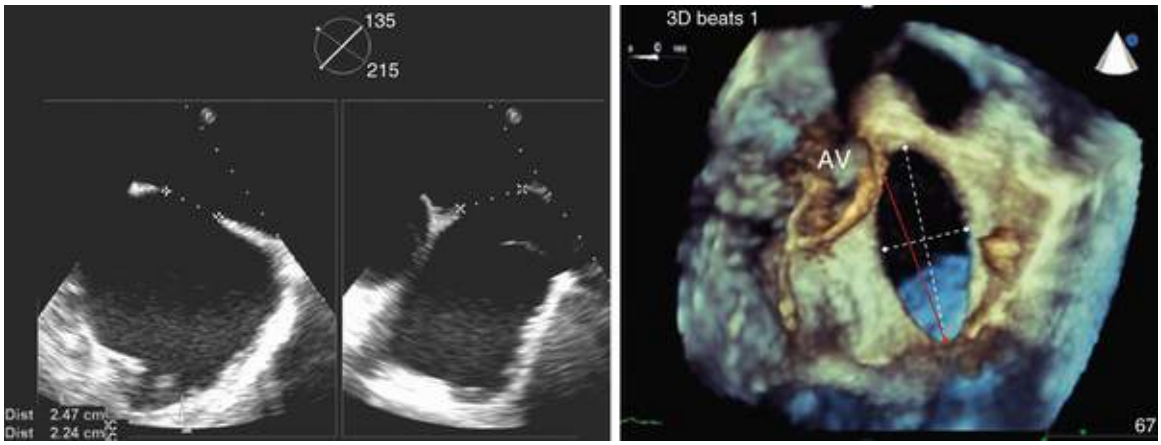

FIGURE 14.85 Biplane two- and three-dimensional TEE measurement of ASD dimensions. **Left**, Biplane 2D TEE measurement of ASD dimensions. The 0 to 45-degree midesophageal view can be used to measure the anterior (toward aorta) and posterior (toward pulmonary veins) rims, whereas the 90- to 120-degree view images the superior (toward SVC) and inferior (toward IVC) rims. **Right**, Large secundum ASD viewed by 3D TEE from the left atrial perspective. Note that the 2D TEE–measured diameter (*red line*) is typically smaller than that measured by 3D TEE (*white dotted lines*). Also note that there is a deficient anterior rim, i.e., no separation between the defect and the aortic valve (*AV*).

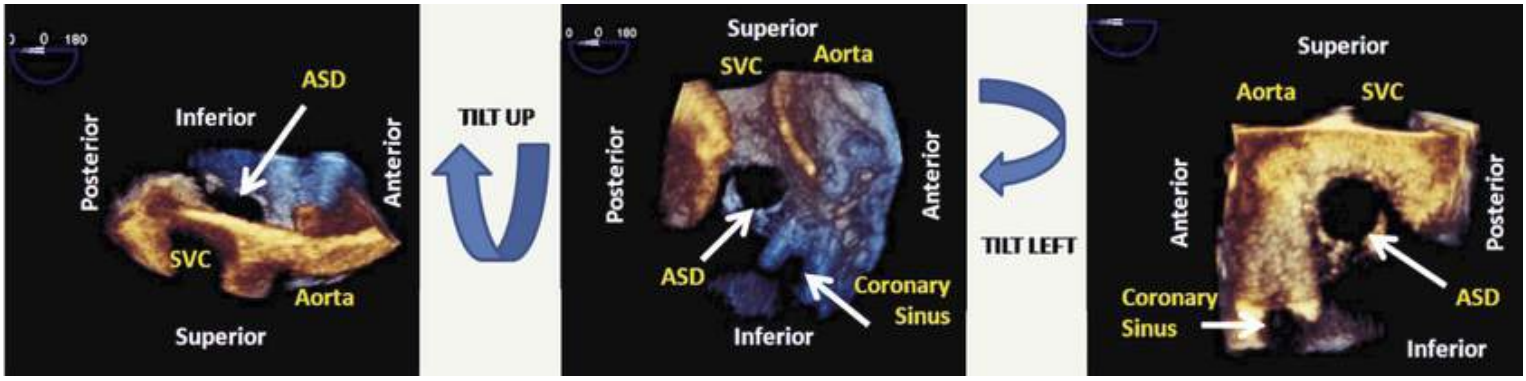

EFIGURE 14.29 Three-dimensional TEE imaging of atrial septal defects (ASDs). The TUPLE maneuver provides an easy method to image the right and left sides of the interatrial septum. The initial image is a zoomed 3D volume set acquired from a midesophageal zero-degree window. (From Saric M, Perk G, Purgess JR, Kronzon I. Imaging atrial septal defects by real-time three-dimensional transesophageal echocardiography: step-by-step approach. J. Am Soc Echocardiogr 2010;23:1128.)

With 2D TEE, orthogonal diameters are recorded during ventricular systole, and a screen for presence of fenestrations is performed. 3D echocardiography allows en face displays of the entire defect in relation to the surrounding landmarks; measurements can be performed online with less risk of undersizing the defect compared to standard 2D imaging (**Fig. 14.85**). Acceptable rim margins are at least 3 mm for the anterior rim and 5 mm for all other rims. Deficiency of the anterior rim is the most common[92,93] (**Fig. 14.85, right, and Fig. 14.86**).

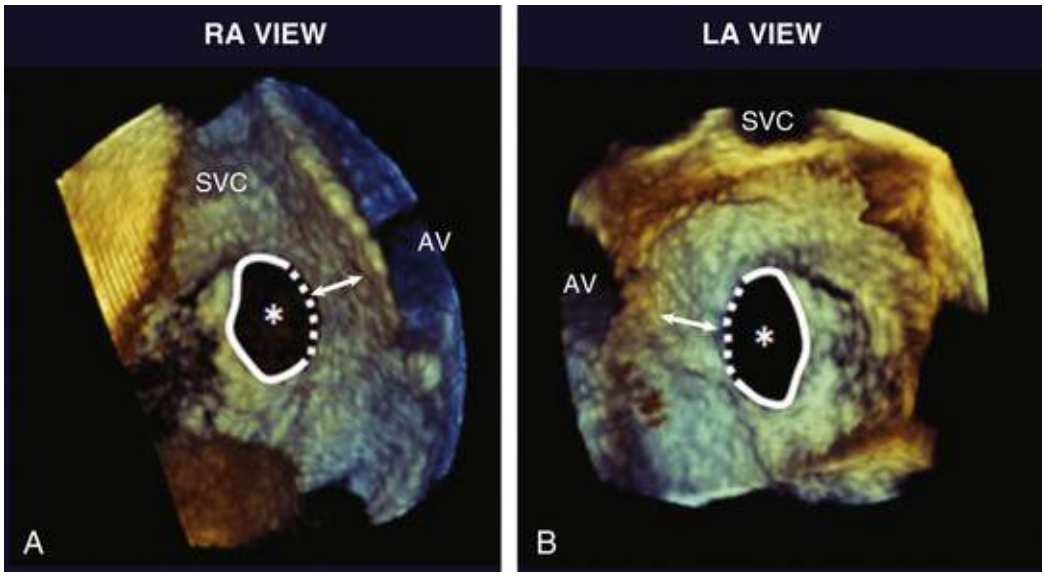

FIGURE 14.86 Assessment of ASD rims with 3D TEE in the **A,** right atrial (RA), and **B,** left atrial (LA), views. The anterior rim is represented as the distance between the *dotted line* and the aorta (*arrow*). *AV,* Aortic valve. (From Saric M et al. Imaging atrial septal defects by real-time three-dimensional transesophageal echocardiography: step-by-step approach. J Am Soc Echocardiogr 2010;23:1128.)

Device closure is guided by either TEE or intracardiac echocardiography (ICE). In sequential order, the key steps are placement of the guidewire across the defect (avoiding any smaller secondary fenestrations), balloon sizing of the defect, occluder placement followed by a tug to ensure optimal seating, assessment for residual shunt by color Doppler, and a survey for any complications such as pericardial effusion. Small residual shunts may be present immediately following deployment but often resolve after endothelialization of the device. **Fig. 14.87** illustrates the 2D and 3D TEE appearance of a successfully deployed Amplatzer device.

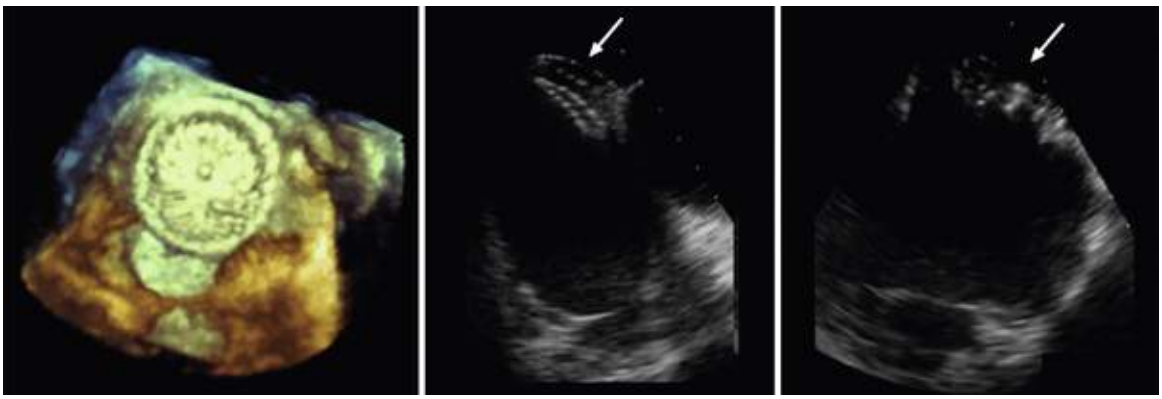

FIGURE 14.87 Postimplantation appearance of an Amplatzer ASD closure device. **Left panel,** 3D left atrial perspective. **Middle** and **right panels,** Orthogonal 2D TEE views. The *arrow* points to the left atrial disc.

A *patent foramen ovale* (PFO) is a related condition characterized by incomplete fusion of the septum primum and septum secundum following birth. It may be detected by saline contrast demonstration of a right-to-left interatrial shunt, typically with maneuvers that raise RA pressure (cough, Valsalva or Müller maneuver). PFO is a common condition that occurs in 20% to 35% of the normal population. It is also frequently associated with aneurysm of the interatrial septum. Echocardiography with saline contrast injection is often used to elucidate whether a PFO is present and could allow a paradoxical embolism to occur in patients without a clear source of left-sided embolic events. Video 14.55 shows both a PFO

and an interatrial septal aneurysm. Evaluation for a PFO is one reason for performing TTE and TEE in patients with transient ischemic attacks, embolic stroke, or other embolic events.[80]

Primum Atrial Septal Defect

Primum ASDs account for 15% to 20% of ASDs and occur as part of the spectrum of atrioventricular (AV) canal defects. They may occur as isolated defects (partial AV canal defect) or may be accompanied by inlet VSDs (complete AV canal defect). Partial AV canal defects typically have an associated cleft mitral valve. In complete AV canal defects there is a common single AV valve. AV canal defects are the most common congenital heart abnormality in Down syndrome. Primum defects can be seen on apical or subcostal views if posterior angulation is ensured to demonstrate the inlet portion of the ventricular septum (**Fig. 14.88**). These defects must be closed surgically.

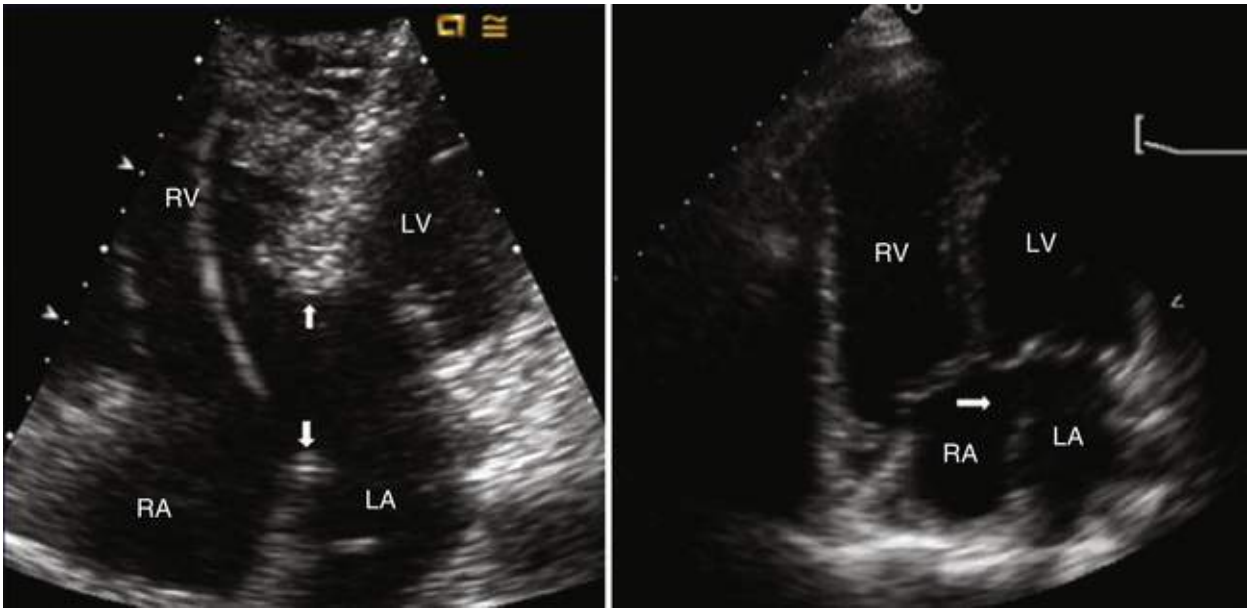

FIGURE 14.88 Apical four-chamber views showing complete **(left)** and partial **(right)** atrioventricular canal defects. In the **left panel,** *arrows* outline a large defect with atrial and ventricular components. In the **right panel** there is a primum ASD (*arrow*) with an intact ventricular septum. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

Sinus Venosus Atrial Septal Defect

Sinus venosus ASDs account for 2% to 10% of ASDs and occur in two locations. The SVC type creates a confluence among the left atrium, right atrium, and SVC as it enters the right atrium. It is frequently accompanied by partial anomalous drainage of the right upper pulmonary vein, which is created when this vein enters the confluence. Partial anomalous drainage contributes to the left-to-right shunt. IVC-type defects are less common and create a confluence among the left atrium, right atrium, and IVC as it enters the right atrium. They may be accompanied by partial anomalous drainage of the right lower pulmonary vein. These defects should be suspected in patients with markers of RV volume overload without apparent cause. Typically, TEE is required to make the diagnosis, although SVC-type defects may be demonstrated with subcostal TTE. **Fig. 14.89** shows the TEE appearance of a sinus venosus ASD with partial anomalous pulmonary venous drainage. Sinus venosus ASDs must be closed surgically.

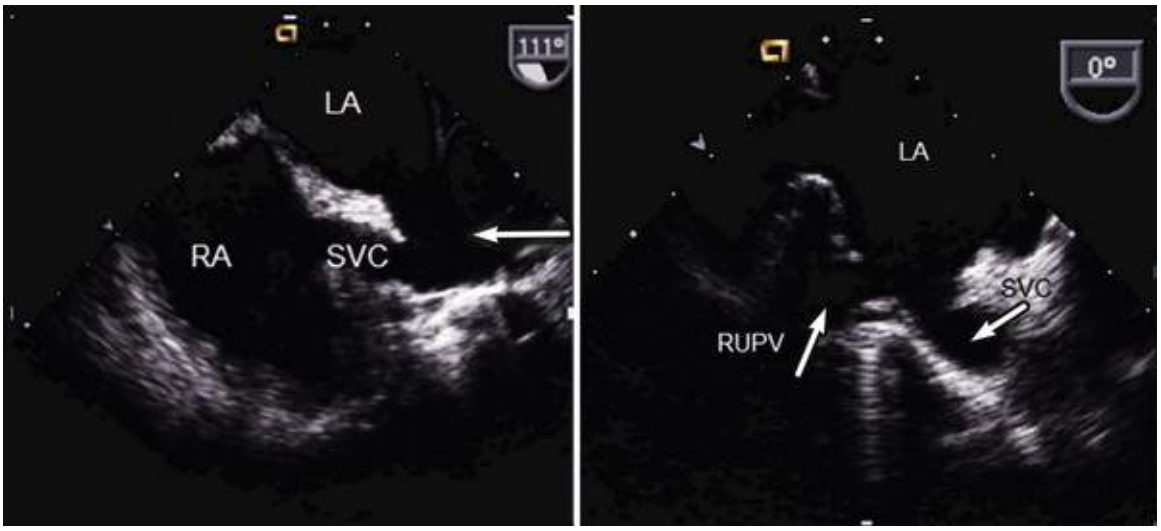

FIGURE 14.89 TEE images of a sinus venosus ASD (SVC type) with anomalous drainage of the right upper pulmonary vein (*RUPV*). A confluence is created between the superior vena cava (*SVC*), RUPV, and adjoining atria. *LA,* Left atrium; *RA,* right atrium.

Coronary Sinus Atrial Septal Defect

Coronary sinus ASDs are rare and may be associated with fenestrations or complete unroofing of the coronary sinus into the left atrium. They are frequently associated with a persistent left SVC, a more frequent finding (0.3% of the general population) and the most common cause of a dilated coronary sinus in general. The diagnosis is facilitated with TEE.

Ventricular Septal Defect

There are a number of classifications for VSDs. **Fig. 14.90** shows one anatomic classification, and **Fig. 14.91** outlines the division of the interventricular septum into its membranous, inlet, outlet, and trabecular portions along with the echocardiographic views that may be used to identify defects in each of these locations. VSDs vary in size and are considered to be small (restrictive) when less than half the size of the aortic root and when the LV-RV pressure gradient is greater than 64 mm Hg. Moderately restrictive VSDs are approximately half the size of the root, with gradients of approximately 36 mm Hg. With larger nonrestrictive defects, LV and RV systolic pressures are equalized. These latter defects are those that most often result in irreversible pulmonary vascular changes (Eisenmenger syndrome). Echocardiography may be used to size defects and LV-RV gradients. Shunting may be assessed by both color flow mapping and Q_p/Q_s calculated with the continuity equation. Although chamber size may be normal in the setting of small defects, LV and LA enlargement is expected in those that are hemodynamically significant.

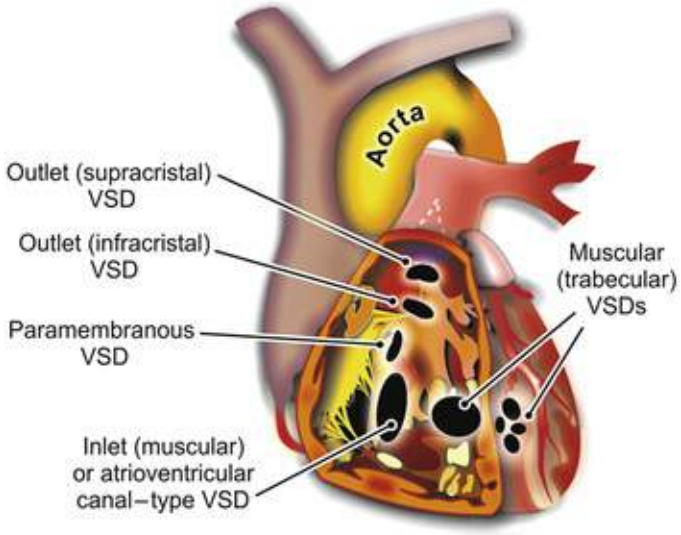

FIGURE 14.90 Anatomic classification system for ventricular septal defects (VSDs).

Membranous (Paramembranous) and Outlet Ventricular Septal Defects

Eighty percent of VSDs involve the membranous septum. They vary in size, but even small defects can

generally be detected on the parasternal long-axis view, as revealed by a high-velocity color Doppler jet. Membranous defects may be associated with wind-sock aneurysms that reflect varying degrees of spontaneous closure (**Fig. 14.92**). Even though the jets of membranous and outlet defects appear similar on the parasternal long-axis view, these defects may be distinguished from one another on short-axis views at the level of the great vessels. Membranous defects will be directed toward the septal leaflet of the tricuspid valve (10 to 11 o'clock position on the short-axis clock face), whereas outlet defects will be associated with jets that are directed toward the pulmonic valve (**Fig. 14.93**). Either defect may be accompanied by aortic cusp prolapse and consequent AR.

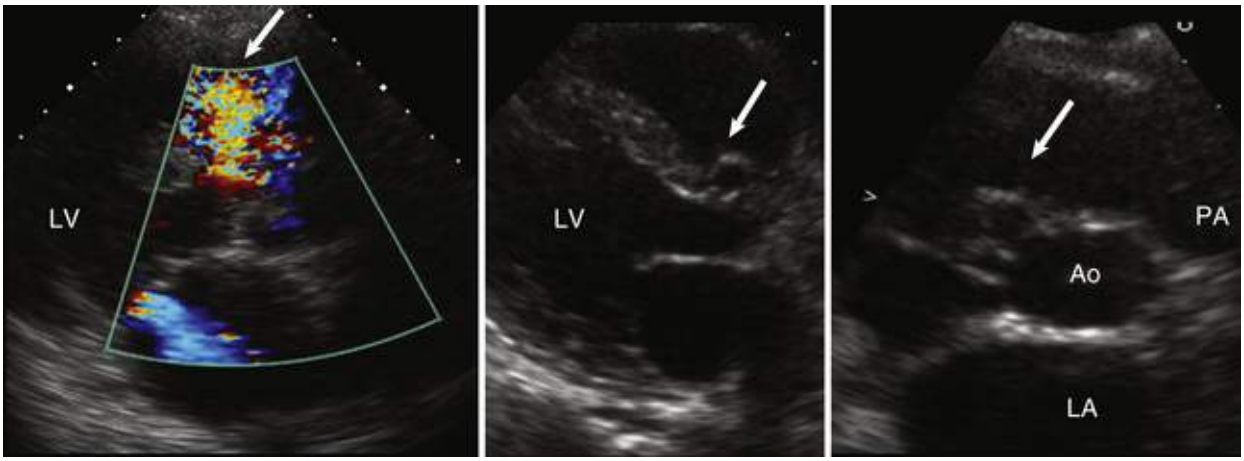

FIGURE 14.92 Parasternal views of a membranous VSD partially closed with a wind-sock aneurysm. **Left,** A systolic left-to-right jet is identified. **Middle,** With slight angulation, a wind-sock aneurysm representing partial spontaneous closure of the defect is identified. *LV,* Left ventricle. **Right,** In the short-axis view, the wind sock helps localize the VSD to the 11 o'clock position, as opposed to outlet defects, which are seen in the 12 to 2 o'clock position (compare with **Fig. 14.93**). *Ao,* Aorta; *LA,* left atrium; *PA,* pulmonary artery.

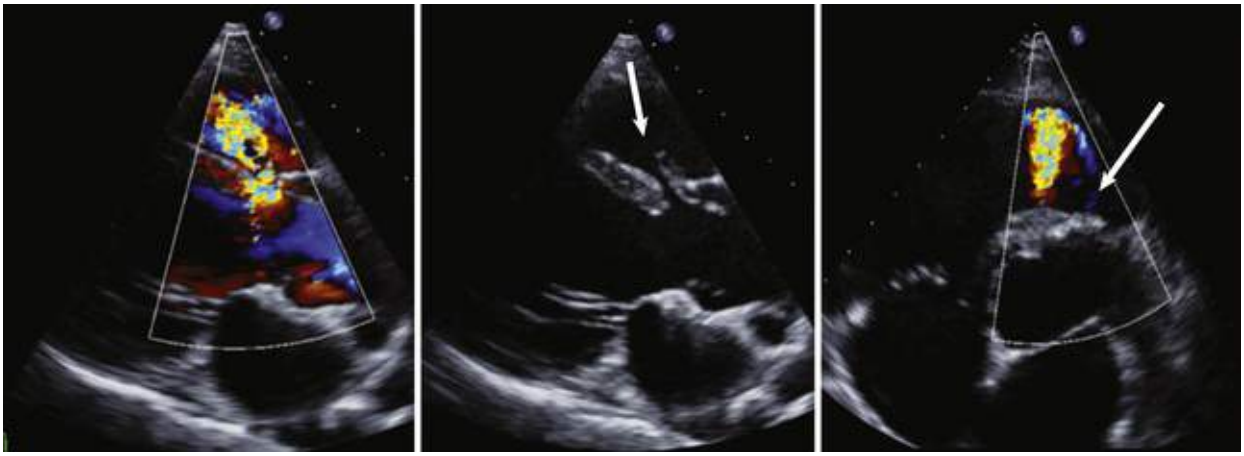

FIGURE 14.93 Parasternal images illustrating an outlet VSD. In the parasternal long-axis view **(left** and **middle panels)**, the VSD jet and the defect (*arrow*) may be indistinguishable from those of a membranous defect. However, in the short axis **(right panel)**, the jet is seen at the 12 o'clock position immediately next to the pulmonic valve (*arrow*). (Compare with **Fig. 14.92**.)

Inlet Ventricular Septal Defects

Inlet defects have been addressed in the preceding discussion of complete AV canal defects. Although

often easily detected (**see Fig. 14.88**, left panel), inlet VSDs may be partially closed by adjacent AV valve tissue. In such situations, nonstandard views and TEE may be required to detect the ventricular component of the AV canal defect.

Muscular Ventricular Septal Defects

Muscular defects vary considerably in size and location and may be multiple. When small and serpiginous, they may easily be missed with conventional echocardiographic views. Because these small defects are associated with loud murmurs with or without a thrill, a detailed evaluation using nonstandard views, such as sliding/tilting the transducer systematically down the barrel of the left ventricle with color Doppler sweeps, is warranted in any patient with these clinical manifestations (**Fig. 14.94**).

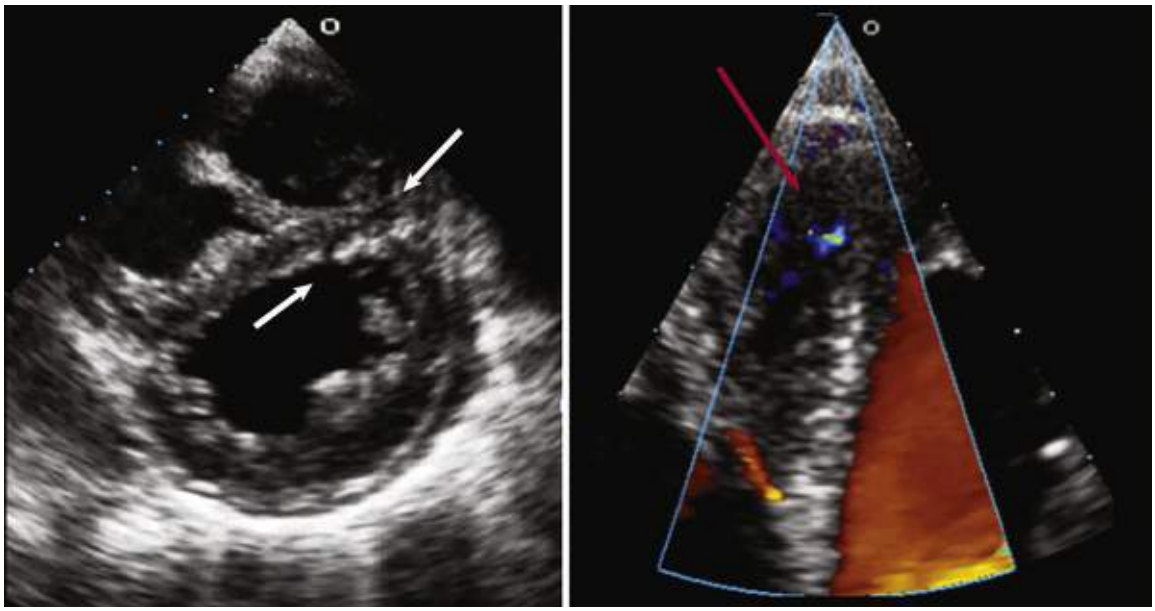

FIGURE 14.94 Parasternal short-axis **(left)** and off-axis apical **(right)** views demonstrating a serpiginous muscular VSD. The *white arrows* point to LV and RV entry points. The *red arrow* identifies a small left-to-right shunt.

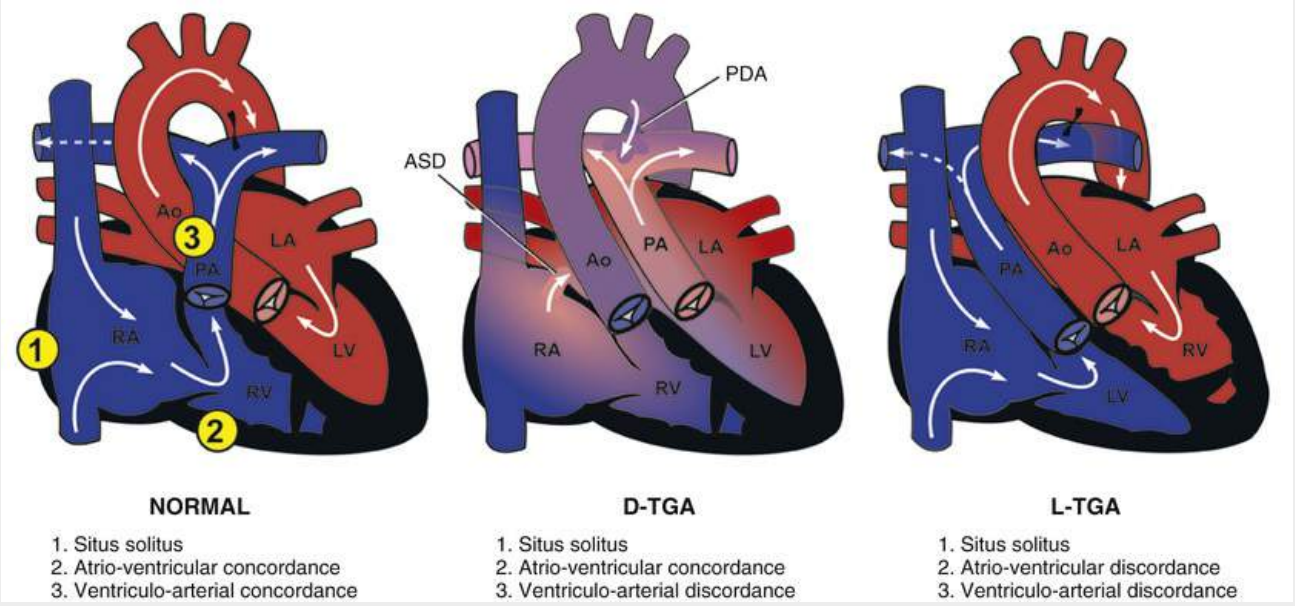
Transposition of the Great Arteries

Transposition of the great arteries (TGA) arises from failure of the aorticopulmonary septum to take its normal spiraling course (**see Chapter 75**). In dextro (D)–TGA the aorta lies anterior and to the right of the pulmonary artery and arises from the right ventricle, with the pulmonary artery arising from the left ventricle (**eFig. 14.30, middle panel**). D-TGA accounts for 5% to 7% of all congenital heart disease and, in the absence of shunting (VSD, ASD, patent ductus arteriosus) or surgery, D-TGA would be fatal. The most common associated anomalies are VSD (30% to 45%), pulmonary outflow tract obstruction (25%), and coarctation. Patients seen by cardiologists treating adults with congenital heart disease will have undergone corrective surgery consisting of either an atrial baffle/switch (Mustard or Senning) procedure in the past, or more recently an arterial switch procedure.[92]



EFIGURE 14.30 Schematic representation of blood flow through hearts with D-transposition of the great arteries (TGA) and L-TGA.

With baffle procedures the systemic venous baffle directs deoxygenated blood across the mitral valve into the left ventricle, from which it is ejected into the pulmonary artery. The pulmonary venous baffle directs oxygenated blood returning from the lungs to the tricuspid valve and into the right ventricle, from which it is pumped into the aorta. The end result is a "physiologic" circulation. Although short- and mid-term results are good, the right ventricle ultimately fails because of its inability to sustain its role as the systemic ventricle. Other complications detectable by echocardiography include baffle obstruction, baffle leaks, and pulmonary hypertension (the cause of which is incompletely understood).

The echocardiographic hallmark of transposition is parallel orientation of the great vessels, best appreciated on parasternal long-axis or apical views (**Fig. 14.95**). The diagnosis can be confirmed by demonstrating that the posterior great vessel (the pulmonary artery) bifurcates and the anterior aorta gives off arch vessels. In patients with D-TGA who have undergone atrial switch surgery, the baffles can be traced as they crisscross the atrium, with color flow mapping and spectral Doppler identifying areas of obstruction and baffle leak. The hypertrophied right ventricle has the rounded contour typically associated with the left ventricle, whereas the left ventricle is crescentic, a result of reversal of the normal septal curvature because of systemic RV pressures. RV systolic function may be reduced with accompanying functional TR.

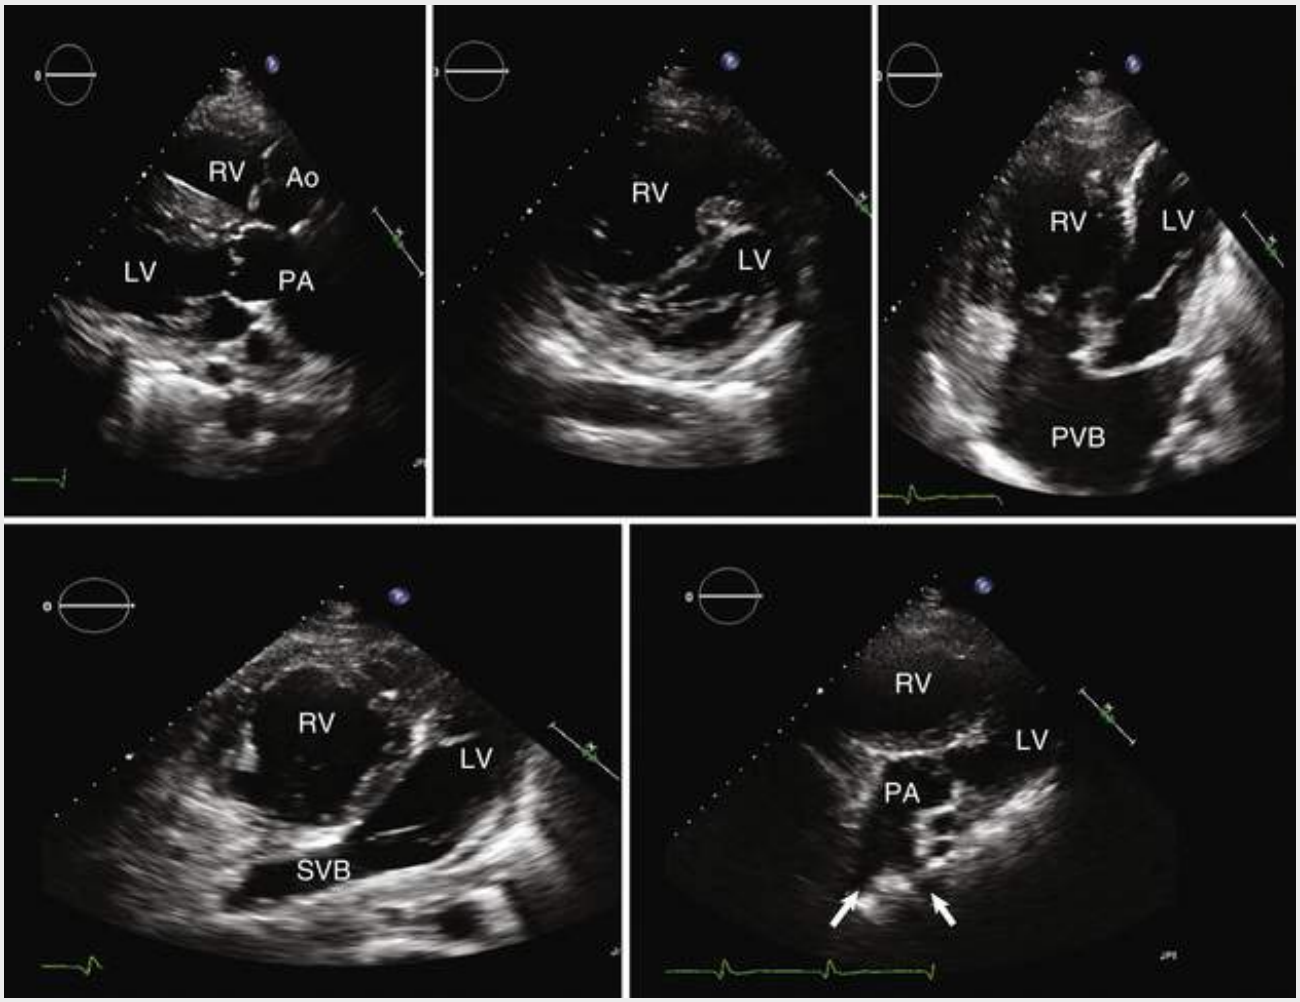


FIGURE 14.95 D-Transposition of the great arteries after Mustard baffle surgery. **Top left,** Parasternal long-axis view showing parallel orientation of the aorta (*Ao*) and pulmonary artery (*PA*). The aorta is anterior. **Top middle,** Parasternal short-axis view showing septal inversion reflecting the fact that the right ventricle (*RV*) is the systemic ventricle. **Top right,** Apical four-chamber view showing the pulmonary venous baffle (*PVB*), which directs pulmonary venous flow across the tricuspid valve into the RV. **Bottom left,** The four-chamber view has been angulated to demonstrate the systemic venous baffle (*SVB*), which directs systemic venous return across the mitral valve into the left ventricle (*LV*). Note the right ventricular hypertrophy and enlargement. **Bottom right,** The four-chamber view is angulated anteriorly to demonstrate the connection between the LV and PA. *Arrows* point to the PA bifurcation.

Levo (L)–TGA, also termed *congenitally corrected transposition*, is rare and accounts for less than 1% of all congenital heart disease. In L-TGA, transposition, with the aorta anterior and typically to the left of the pulmonary artery, is also accompanied by ventricular inversion. Thus, systemic venous blood returning to the right atrium drains into the morphologic left ventricle and is pumped into the pulmonary artery. Pulmonary venous blood returning to the left atrium crosses the tricuspid valve into the morphologic right ventricle, from which it is ejected into the aorta. Therefore the circulation is "normalized" (**eFig. 14.30, right panel**). Associated abnormalities are common and include VSD (70% of patients), pulmonary outflow tract obstruction that is typically subvalvular (40%), and abnormalities of the tricuspid (systemic AV) valve (90%). Patients, particularly those without associated anomalies, may remain undiagnosed until adulthood, but eventually the morphologic right ventricle will fail because it cannot meet the pressure demands of the systemic circulation.

Echocardiographic features of L-TGA again include parallel orientation of the great vessels as with all cases of transposition, but on apical views, ventricular inversion becomes apparent. Ventricular morphology may be determined by the structure of its AV valve and the pattern of trabeculation. The morphologic right ventricle is associated with a tricuspid AV valve, which is identified by the presence of three leaflets and leaflet insertion that is apical to that of the mitral valve. The morphologic right

ventricle is coarsely trabeculated with a moderator band, whereas the morphologic left ventricle is smooth walled and has two discrete papillary muscles. In assessing ventricular morphology by the four-chamber view, it is essential to maintain standard transducer orientation and avoid rotating the transducer so that an image is created in which the right and left ventricles occupy their expected positions. **Fig. 14.96** illustrates ventricular inversion in a patient with L-TGA. As with D-TGA, the morphologic right ventricle is hypertrophied with a round contour, and the morphologic left ventricle is crescentic. The septal curvature is reversed, consistent with the systemic pressure in the morphologic right ventricle.[92]

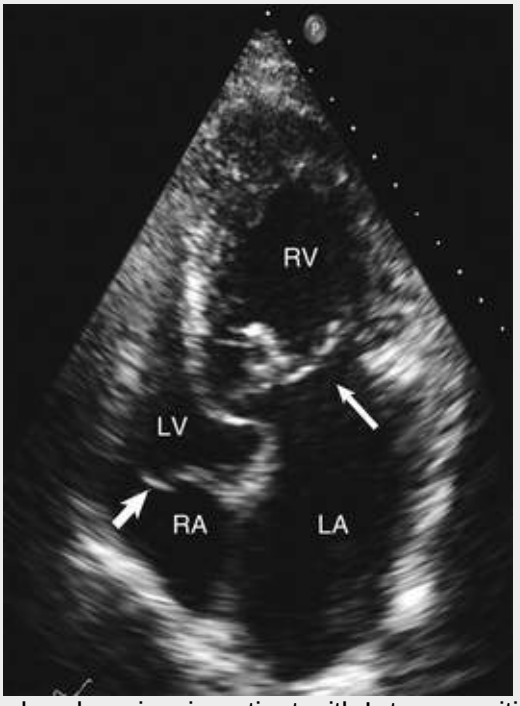

FIGURE 14.96 Apical four-chamber view in patient with L-transposition of the great arteries. The ventricles are inverted with the right ventricle (*RV*) to the right, identified on the basis of its heavy trabeculation and tricuspid atrioventricular valve (*thin arrow*). Although the insertion of the tricuspid valve is always apical to that of the mitral valve, in this case the offset is accentuated, consistent with the Ebstein anomaly. Unlike isolated Ebstein anomaly, that seen with L-TGA does not have a sail-like leaflet or adherence of the septal leaflet to the septum. The *thick arrow* points to the mitral valve. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium.

Tetralogy of Fallot

Tetralogy of Fallot is the most common form of cyanotic congenital heart disease and accounts for 10% of all congenital heart cases. The tetralogy of abnormalities consists of an overriding aorta, nonrestrictive subaortic VSD, RVOT obstruction (typically infundibular with variable valvular abnormalities), and secondary RV hypertrophy. Each of these features is readily identifiable with echocardiography (**Fig. 14.97**). *Pentalogy of Fallot* refers to the condition in which an ASD is also present.

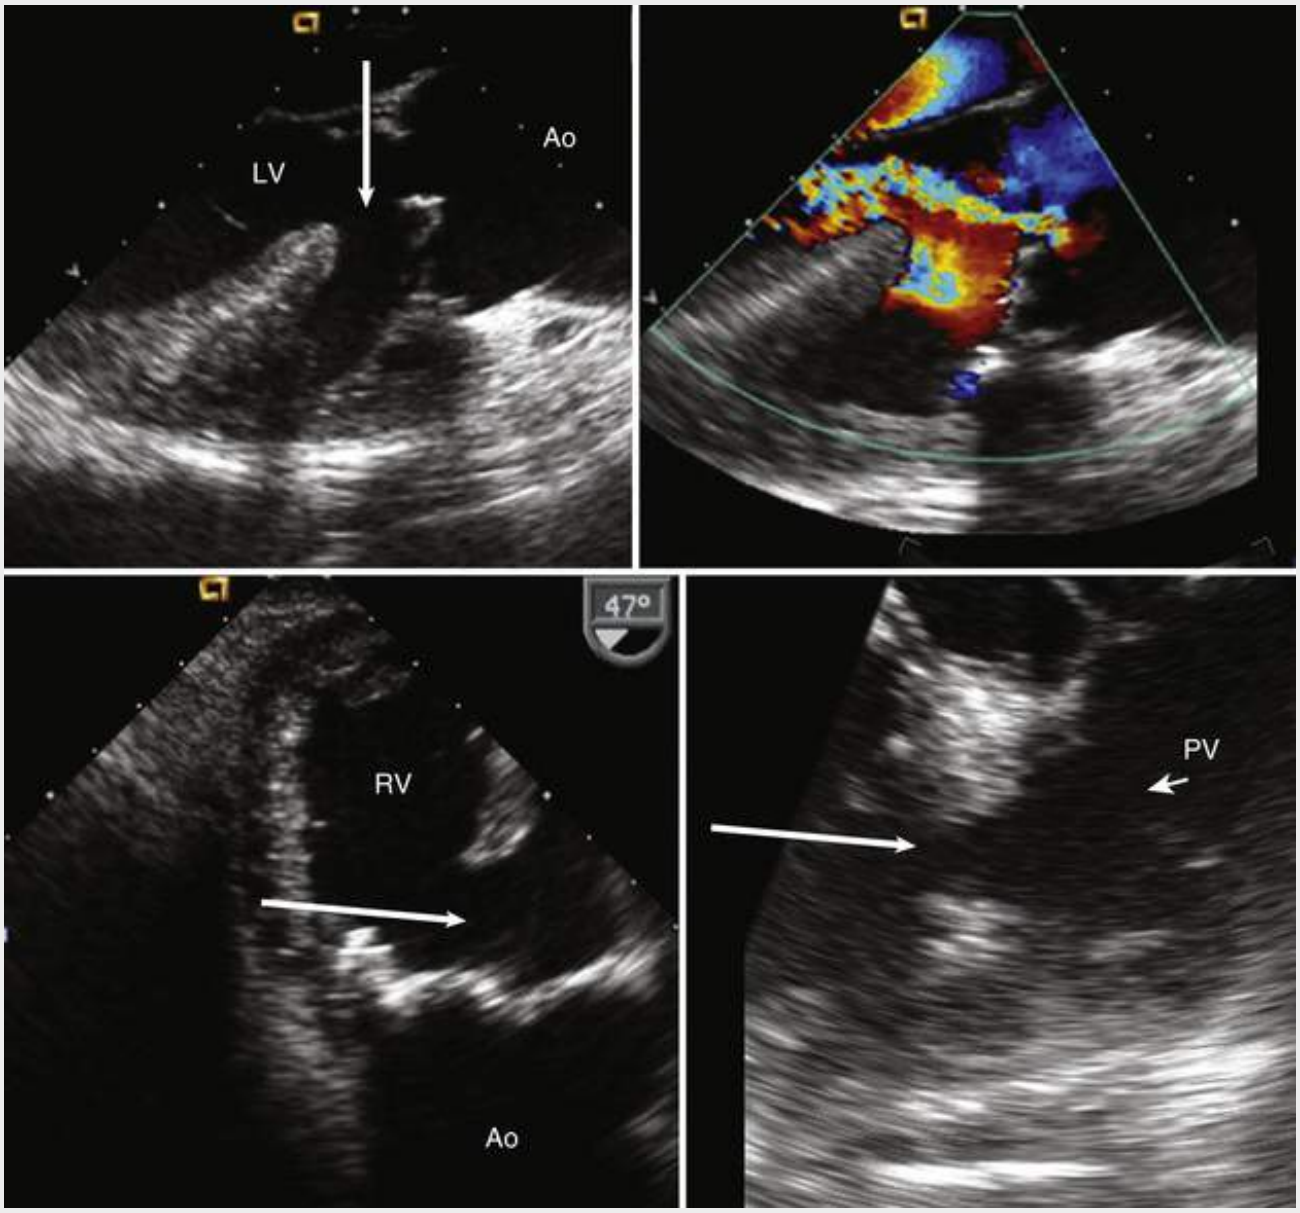

FIGURE 14.97 TEE images of a patient with tetralogy of Fallot. **Upper left,** Midesophageal image showing the aorta (*Ao*) overriding a large (nonrestrictive) VSD (*arrow*). **Upper right,** There is mild aortic regurgitation. **Lower left,** From a deep transgastric view, severe right ventricular hypertrophy is seen. The *arrow* points to the VSD. **Lower right,** In this midesophageal view, focal infundibular narrowing is seen (*arrow*). The pulmonic valve (*PV*) is not well seen but, in other views, was shown to be normal. *LV,* Left ventricle; *RV,* right ventricle.

Surgery for the tetralogy consists of patching the VSD and a tailored approach to relieving the RVOT obstruction. Pulmonic regurgitation, sometimes severe, is a frequent finding after surgery for tetralogy of Fallot and may drive the need for repeated surgery. Other problems to remain vigilant for in the years after surgery include residual infundibular (subvalvular) and supravalvular pulmonic stenosis, as well as aneurysmal degeneration of the patch used to open up the infundibulum and/or pulmonary artery.[93]

Cardiac Procedures and Future Directions

The role of TTE and TEE has been discussed in conventional surgical procedures, particularly in the setting of evaluation and treatment of CAD, cardiomyopathies, valvular disease, LVADs, and intracardiac shunts and congenital heart disease. The past decade has seen swift and remarkable advances in percutaneous interventions, which often require accurate preprocedural assessment and skilled intraprocedural echocardiography to guide effective deployment of devices. Knowledge of how these

newer and developing devices work and their potential failings is essential for complete follow-up echocardiographic evaluation. Transcatheter treatment of AS and MR is currently an attractive alternative for patients at high surgical risk (**see Chapter 72**). *Transcatheter pulmonary valve implantation* is now routine in pediatric centers experienced in congenital heart disease. In general, echocardiographic guidance is required for patient screening for appropriate anatomy, followed by proper device selection (type and size), placement, and deployment of most of the available percutaneous devices.

Transcatheter aortic valve implantation (TAVI) can be performed through transfemoral, LV apical, or transaortic approaches, using only TTE guidance and fluoroscopy/angiography. A preprocedural CT angiogram or TEE may be used to assess the aortic annular and root size. The coronary ostia need to be high enough—ideally 1.0 cm or more from the annulus—to avoid being occluded by the stented valve or displaced native leaflets. This latter measurement, as well as precise annular measurements, was inaccurate or virtually impossible without 3D TEE, and some platforms now allow precise detailed online measurements throughout the cardiac cycle (4D TEE) and volume reconstruction at bedside (**Fig. 14.98**). Intraprocedural TEE is used to ensure that the stented valve is properly seated across the aortic annulus and to assess for paravalvular leakage. Paravalvular aortic insufficiency is not uncommon (**see Fig. 14.61**); if the degree is significant, further reexpansion of the stented valve or even implantation of a second valve may be undertaken. Surveillance for wall motion abnormalities caused by coronary ostial inclusion and pericardial effusion should continue during and after balloon inflations.[94]

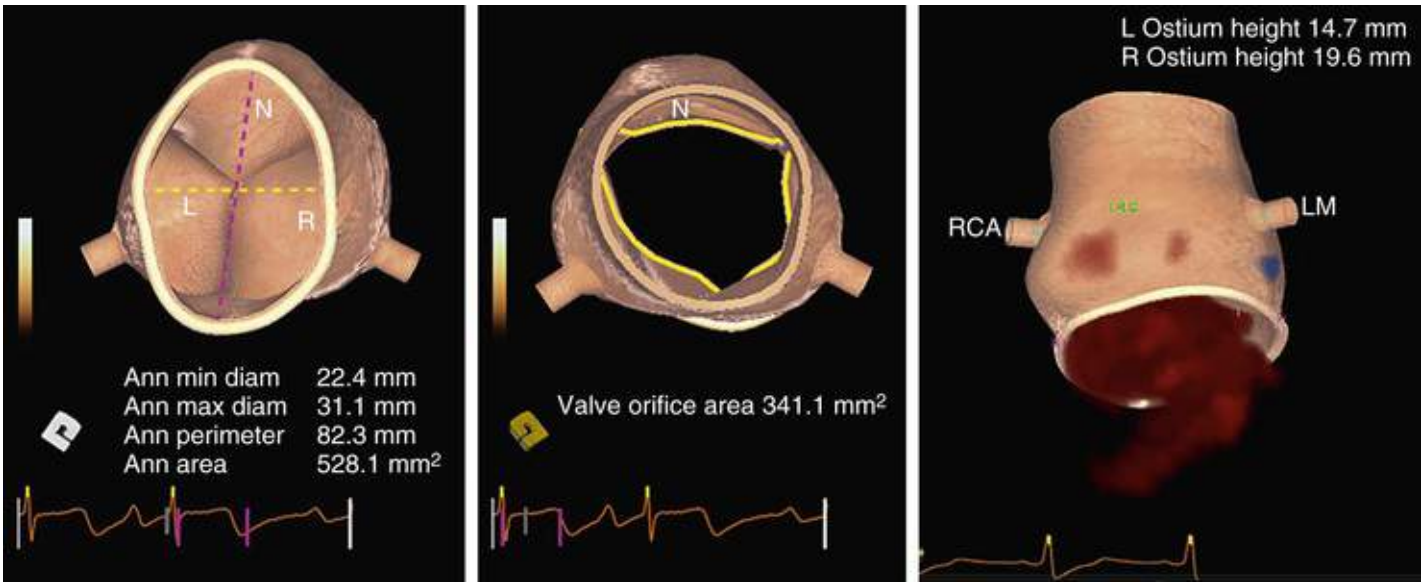

FIGURE 14.98 Three-dimensional TEE volume-rendered still frames of a normal aortic root. **Left,** The true orthogonal long and short axes of the annulus may be determined, as well as annular area. **Middle,** Valve orifice area and leaflet lengths. **Right,** Heights of the coronary ostia from the annulus (which is of particular importance in planning for TAVI).

Transcatheter mitral valvuloplasty devices for MR are now commercially available for degenerative MR and are undergoing clinical trials for functional MR. They are ideally implanted under TEE guidance, although use of TTE alone is feasible. Echo imaging is essential to select appropriate candidates for treatment, properly deliver the devices, and assess for the degree of reduction in MR. The MitraClip in particular requires both echocardiographer and interventionalist expertise to approach the mitral valve via transseptal puncture, then ensure that the device arms are being placed on the midscallops of the mitral valve perpendicular to the coaptation line, which ultimately creates the percutaneous equivalent of the Alfieri stitch (i.e., edge-to-edge repair). Previously, clip deployment was not feasible without good

transgastric views, but 3D technology has made the procedure easier and more accurate[94] (**Fig. 14.99** and Video 14.56).

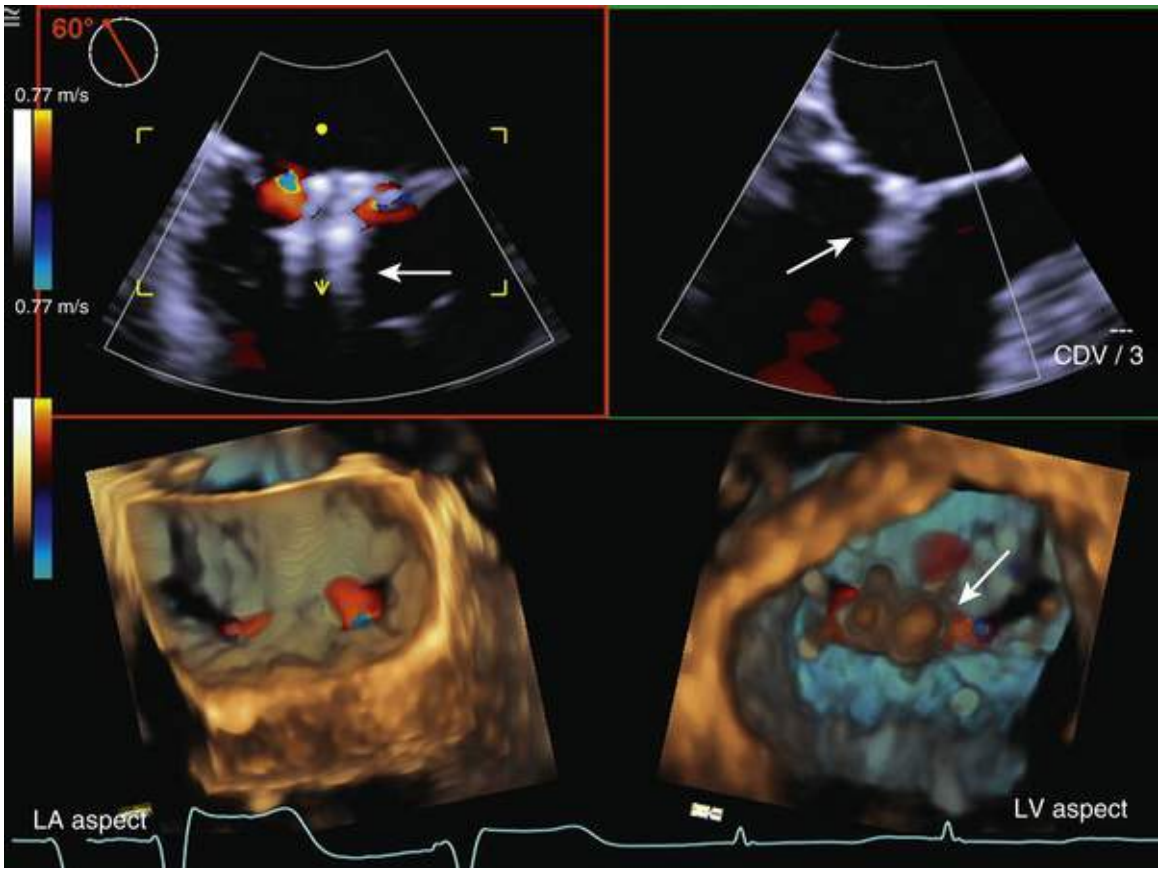

FIGURE 14.99 Three-dimensional TEE images in a patient following MitraClip placement, with trace residual mitral regurgitation (MR) seen in the now double-orifice valve. **Upper panels,** Apical 60-degree and 120-degree views of the device in early systole. **Lower panels,** The valve as viewed from the left atrial and left ventricular aspects. *White arrow,* MitraClip device. (See corresponding Video 14.56.)

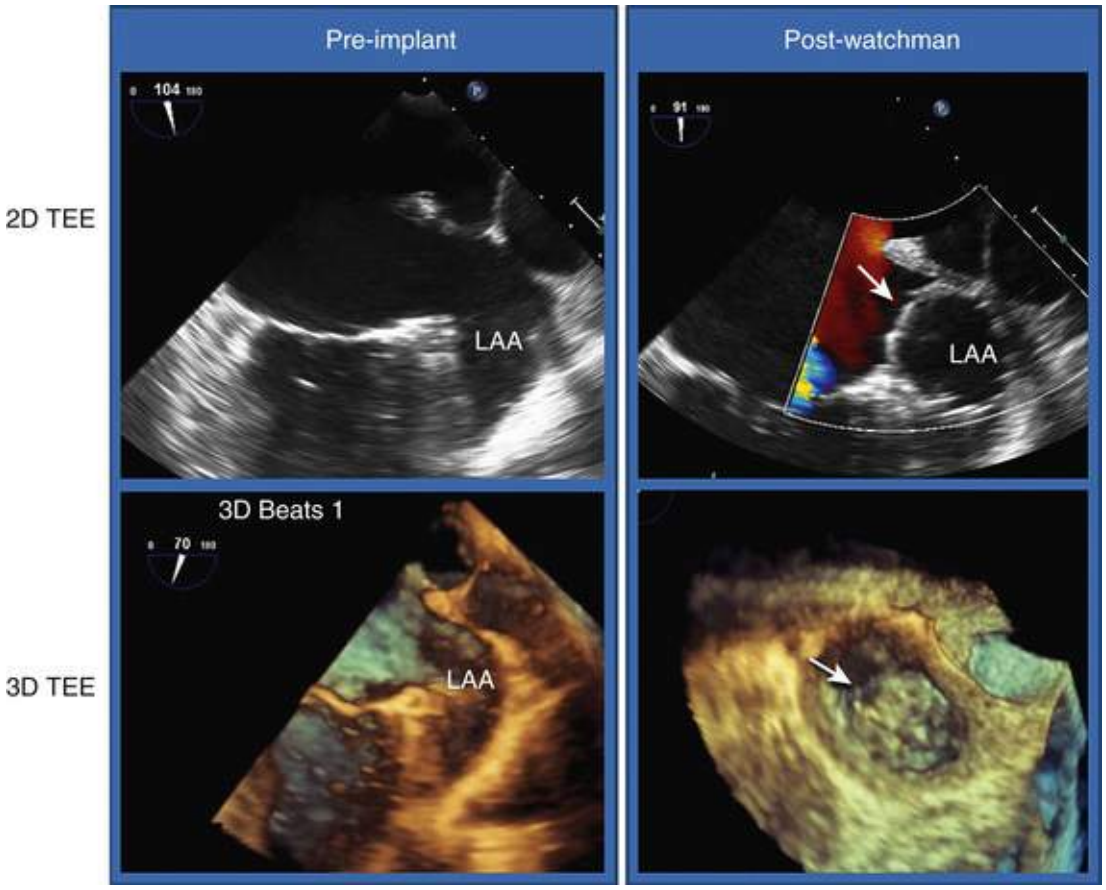
In the subspecialty of electrophysiology, occlusion of the LA appendage is possible with a variety of devices and is targeted toward patients at high risk for recurrent strokes (despite anticoagulation or unable to take anticoagulants) (**eFig. 14.31**). TEE is performed before the procedure primarily to size the LA appendage and ensure that it can receive an appropriately sized device, as well as to exclude appendage thrombus. For the Watchman device, the ostia of the appendage diameters are measured at several angles, and the appendage must be longer than its width.



EFIGURE 14.31 The Watchman device to occlude the left atrial appendage (LAA) for stroke prevention. **Left panels,** 2D and 3D TEE views of the LAA before implantation. Measurements of the LAA ostia taken at multiple angles for selection of the appropriate Watchman device. The appendage length must be longer than its width to accommodate device implantation. **Right panels,** Appendage occluder device (*arrow*) well seated at the neck of the appendage, with no residual flow around the device by color Doppler; **top panel,** 2D view; **bottom panel,** 3D en face view).

The increasing population of patients with structural and adult congenital heart disease has led to demand for continued innovation in structural interventions. Current interventions include stenting of the pulmonary arteries or veins, percutaneous treatment of complex lesions (coronary fistulas, other vascular malformations, and collaterals), angioplasty and stenting of surgical conduits and aortic coarctation, and a growing list of other minimally invasive interventions for conditions that were previously remediable only by open surgery. Occluder devices are now used also to treat paravalvular leaks in high-risk patients. TAVI is now being performed for failed bioprostheses (“valve-in-valve” procedures), severe AR, bicuspid or unicuspid valves, and other situations in which surgery is too risky or undesirable. It will be imperative to have continued follow-up within registries and intermediate- and long-term echocardiographic data analyzed, because these and other interventions move through experimental trials and ultimately filter into the clinical arena.

Handheld Echocardiography

The era of miniaturization has ushered in increasingly smaller and capable portable ultrasound machines, which were introduced commercially in 2004. Current laptop-size devices are a lightweight alternative to the traditional 400-lb full-size machines and have increased the availability and usefulness of cardiac ultrasound at the point of care. Laptop ultrasound has virtually all the capabilities of full-size machines, including the capability for tissue Doppler and strain imaging, stress and TEE studies, automatic quantification of LVEF, and more recently, 4D imaging. They can operate wirelessly. Many systems offer

the capability to perform vascular, abdominal, and obstetric ultrasound on the same machine and can accommodate a wide range of transducers, including pediatric.

Handheld ultrasound devices introduced this decade are small enough to fit in the physician's coat pocket. They may serve as an extension to the physical examination and are more likely to be readily available in an acute emergency for a focused examination. In the hands of experienced sonographers, the current devices offer harmonic 2D and color Doppler imaging with good image quality and accuracy compared with conventional machines.[95] None of the current handheld devices supports spectral Doppler and thus are limited in the quantification of valve stenosis. Recent developments include miniaturized disposable TEE probes, intended for continuous monitoring of cardiac preload in ICUs and during surgeries, as well as smartphone-based ultrasound systems in which a stand-alone transducer (3.5 to 5 mHz and higher) can be plugged into a smartphone or tablet that processes the data into images and can transfer the data wirelessly.

The lower cost and portability also render the technology more accessible for health care in underdeveloped regions. Along with these innovations, however, education and training are required for optimal use by noncardiologists.[95,96] With sufficient user experience and continual improvements in design and function, these instruments likely will become as familiar in clinical settings as the stethoscope. At present, although handheld devices can complement the physical examination, they do not supplant a complete formal echocardiographic study with a high-end machine and experienced sonographer.

Appropriate Use Criteria

Echocardiography

Scott D. Solomon and Robert O. Bonow

During the past three decades, there has been explosive growth in the use of cardiac imaging, particularly in the applications of echocardiography, Doppler echocardiography, and stress echocardiography. The American College of Cardiology/American Heart Association (ACC/AHA) guidelines for the use of echocardiography were last updated in 2003. Whether cardiac imaging and in particular echocardiography leads to enhanced quality of care and improved patient outcomes is unclear. It is difficult to tie an imaging test to patient outcomes because any impact of diagnostic testing on patient-related outcomes is ultimately tied to downstream management strategies that the diagnostic tests may or may not set in motion. In addition, no prospective randomized trials have been designed to demonstrate the efficacy of imaging in achieving optimal patient outcomes. Thus, no firm foundation on which to develop evidence-based guidelines is available.

Against this background, the ACC has moved from the development of practice guidelines in cardiovascular imaging to the development of appropriate use criteria (AUC). Partnering with a number of subspecialty societies, the ACC has spearheaded the delivery of AUC for imaging, which are designed to define the appropriate test for the appropriate indication in the appropriate patient. The process used for development of appropriateness criteria is only partially evidence based and is heavily weighted by expert consensus.

The AUC for echocardiography are based on a number of common clinical scenarios in which imaging is often used. These scenarios are then rated by a panel with a broad array of expertise (i.e., not just imaging experts) to evaluate the “appropriateness” of echocardiography in each situation in terms of the following definition: “An appropriate imaging study is one in which the expected incremental

information, combined with clinical judgment, exceeds the expected negative consequences by a sufficiently wide margin for a specific indication that the procedure is generally considered acceptable care and a reasonable approach for the indication." Rating scores are made on a scale of 1 to 9, in which a score of 9 indicates highly appropriate use of testing. Using an iterative modified Delphi exercise process with predefined rules, a final rating score is established for each indication and grouped as A, score of 7 to 9, indicating an *appropriate* test for the specific indication (the test *is* generally acceptable and *is* a reasonable approach for the indication); M, score of 4 to 6, indicating that the test *may* be generally appropriate for the indication); and R, score of 1 to 3, indicating that the test would *rarely* be appropriate for that indication.[1]

The AUC for echocardiography were first published in 2007, followed by AUC for stress echocardiography in 2008. The echocardiography AUC were updated in 2011.[2] These criteria are summarized in **Table 14G.1**. These AUC criteria were published before the updated terminology noted above[1] and use the previous methodology in which the term "inappropriate" (I) is used for ratings of 1 to 3 and ratings of 4 to 6 are termed "uncertain" (U) appropriateness. Ratings of 7 to 9 remain "appropriate" (A). The more recent AUC documents for multimodality imaging in patients with stable ischemic heart disease, heart failure, and chest pain[3-5] do conform to the updated terminology and provide criteria for the use of echocardiography in these conditions relative to the applications of the other imaging modalities (**see Chapter 18** Appropriate Use Criteria).

TABLE 14G.1

Echocardiography Appropriate Use: Transthoracic, Transesophageal, and Stress

TRANSESOPHAGEAL ECHOCARDIOGRAPHY FOR GENERAL EVALUATION OF CARDIAC STRUCTURE AND FUNCTION		
	Indication	Appropriateness Score* (1-9)
Suspected Cardiac Cause—General		
1.	Symptoms or conditions potentially related to a suspected cardiac cause, including but not limited to chest pain, shortness of breath, TIA, stroke, or peripheral embolic event	A (9)
2.	Previous testing that is concerning for heart disease or structural abnormality, including but not limited to chest radiography, baseline scout images for stress echocardiography, electrocardiography, or cardiac biomarkers	A (9)
Arrhythmias		
3.	Infrequent APCs or VPCs or palpitations without other evidence of heart disease	I (2)
4.	Frequent VPCs or exercise-induced VPCs	A (8)
5.	Sustained or nonsustained atrial fibrillation, SVT, or VT	A (9)
6.	Asymptomatic isolated sinus bradycardia	I (2)
Lightheadedness/Presyncope/Syncope		
7.	Clinical symptoms or signs consistent with a cardiac diagnosis known to cause lightheadedness/presyncope/syncope (including but not limited to aortic stenosis, hypertrophic cardiomyopathy, or heart failure)	A (9)
8.	Lightheadedness/presyncope/syncope when there is very low clinical suspicion for cardiovascular disease	I (3)
9.	Syncope when no other symptoms or signs of cardiovascular disease are present	A (7)
Evaluation of Ventricular Function		
10.	Initial evaluation of ventricular function (e.g., screening) with no symptoms or signs of cardiovascular disease	I (2)
11.	Routine reevaluation of ventricular function with known CAD and no change in clinical status or findings on cardiac examination	I (3)
12.	Evaluation of left ventricular function with previous ventricular function evaluation showing normal function (e.g., previous echocardiography, left ventriculography, CT, SPECT, CMR) in patients in whom there has been no change in clinical status or findings on cardiac examination	I (1)
Perioperative Evaluation		
13.	Routine perioperative evaluation of ventricular function with no symptoms or signs of cardiovascular disease	I (2)
14.	Routine perioperative evaluation of cardiac structure and function before noncardiac solid-organ transplantation	U (6)
Pulmonary Hypertension		
15.	Evaluation of suspected pulmonary hypertension, including evaluation of right ventricular function and estimated pulmonary artery pressure	A (9)
16.	Routine (<1 year) reevaluation of known pulmonary hypertension without change in clinical status or findings on cardiac examination	I (3)
17.	Routine (≥1 year) reevaluation of known pulmonary hypertension without change in clinical status or findings on cardiac examination	A (7)
18.	Reevaluation of known pulmonary hypertension if change in clinical status or findings on cardiac examination occurs or to guide therapy	A (9)
TRANSTHORACIC ECHOCARDIOGRAPHY FOR CARDIOVASCULAR EVALUATION IN AN ACUTE SETTING		
Hypotension or Hemodynamic Instability		
19.	Hypotension or hemodynamic instability of uncertain or suspected cardiac cause	A (9)
20.	Assessment/monitoring of volume status in a critically ill patient	U (5)
Myocardial Ischemia/Infarction		
21.	Acute chest pain with suspected myocardial infarction and nondiagnostic ECG when a resting echocardiogram can be performed during pain	A (9)
22.	Evaluation of a patient without chest pain but with other features of an ischemic equivalent or laboratory markers indicative of ongoing myocardial infarction	A (8)

23.	Suspected complication of myocardial ischemia/infarction, including but not limited to acute mitral regurgitation, ventricular septal defect, free wall rupture/tamponade, shock, right ventricular involvement, heart failure, or thrombus	A (9)
Evaluation of Ventricular Function After Acute Coronary Syndrome		
24.	Initial evaluation of ventricular function following ACS	A (9)
25.	Reevaluation of ventricular function following ACS during recovery phase when results will guide therapy	A (9)
Respiratory Failure		
26.	Respiratory failure or hypoxemia of uncertain cause	A (8)
27.	Respiratory failure or hypoxemia when a noncardiac cause of respiratory failure has been established	U (5)
Pulmonary Embolism		
28.	Suspected pulmonary embolism to establish the diagnosis	I (2)
29.	Known acute pulmonary embolism to guide therapy (e.g., thrombectomy and thrombolytics)	A (8)
30.	Routine reevaluation of previous pulmonary embolism with normal right ventricular function and pulmonary artery systolic pressure	I (1)
31.	Reevaluation of known pulmonary embolism after thrombolysis or thrombectomy for assessment of change in right ventricular function and/or pulmonary artery pressure	A (7)
Cardiac Trauma		
32.	Severe deceleration injury or chest trauma when valve injury, pericardial effusion, or cardiac injury is possible or suspected	A (9)
33.	Routine evaluation in the setting of mild chest trauma with no changes on the ECG or biomarker elevation	I (2)
TRANSTHORACIC ECHOCARDIOGRAPHY FOR EVALUATION OF VALVULAR FUNCTION		
Murmur or Click		
34.	Initial evaluation when there is a reasonable suspicion of valvular or structural heart disease	A (9)
35.	Initial evaluation when there is very low suspicion of valvular or structural heart disease	I (2)
36.	Reevaluation in a patient without valvular disease on a previous echocardiogram and no change in clinical status or findings on cardiac examination	I (1)
37.	Reevaluation of known valvular heart disease with a change in clinical status or findings on cardiac examination or to guide therapy	A (9)
Native Valvular Stenosis		
38.	Routine (<3 years) reevaluation of mild valvular stenosis without change in clinical status or findings on cardiac examination	I (3)
39.	Routine (≥3 years) reevaluation of mild valvular stenosis without change in clinical status or findings on cardiac examination	A (7)
40.	Routine (<1 year) reevaluation of moderate or severe valvular stenosis without change in clinical status or findings on cardiac examination	I (3)
41.	Routine (≥1 year) reevaluation of moderate or severe valvular stenosis without change in clinical status or findings on cardiac examination	A (8)
Native Valvular Regurgitation		
42.	Routine reevaluation of trace valvular regurgitation	I (1)
43.	Routine (<3 years) reevaluation of mild valvular regurgitation without change in clinical status or findings on cardiac examination	I (1)
44.	Routine (≥3 years) reevaluation of mild valvular regurgitation without change in clinical status or findings on cardiac examination	U (4)
45.	Routine (<1 year) reevaluation of moderate or severe valvular regurgitation without change in clinical status or findings on cardiac examination	U (6)
46.	Routine (≥1 year) reevaluation of moderate or severe valvular regurgitation without change in clinical status or findings on cardiac examination	A (8)
Prosthetic Valve		
47.	Initial postoperative evaluation of prosthetic valve for establishment of baseline	A (9)
48.	Routine (<3 years) reevaluation of prosthetic valve if no known or suspected valve dysfunction	I (3)
49.	Routine (≥3 years) reevaluation of prosthetic valve if no known or suspected valve dysfunction	A (7)
50.	Evaluation of prosthetic valve with suspected dysfunction or change in clinical status or findings on cardiac examination	A (9)
51.	Reevaluation of known prosthetic valve dysfunction when it would change management or guide therapy	A (9)
Infective Endocarditis (Native or Prosthetic Valves)		
52.	Initial evaluation of suspected infective endocarditis with positive blood cultures or a new murmur	A (9)
53.	Transient fever without evidence of bacteremia or a new murmur	I (2)
54.	Transient bacteremia with a pathogen not typically associated with infective endocarditis and/or documented nonendovascular source of infection	I (3)
55.	Reevaluation of infective endocarditis at high risk for progression or complication or with a change in clinical status or findings on cardiac examination	A (9)
56.	Routine reevaluation of uncomplicated infective endocarditis when no change in management is contemplated	I (2)
TRANSTHORACIC ECHOCARDIOGRAPHY FOR EVALUATION OF INTRACARDIAC AND EXTRACARDIAC STRUCTURES AND CHAMBERS		
57.	Suspected cardiac mass	A (9)
58.	Suspected cardiovascular source of embolus	A (9)
59.	Suspected pericardial conditions	A (9)
60.	Routine reevaluation of known small pericardial effusion with no change in clinical status	I (2)
61.	Reevaluation of known pericardial effusion to guide management or therapy	A (8)
62.	Guidance of percutaneous noncoronary cardiac procedures, including but not limited to pericardiocentesis, septal ablation, or right ventricular biopsy	A (9)
TRANSTHORACIC ECHOCARDIOGRAPHY FOR EVALUATION OF AORTIC DISEASE		
63.	Evaluation of the ascending aorta in the setting of a known or suspected connective tissue disease or genetic condition that predisposes to aortic aneurysm or dissection (e.g., Marfan syndrome)	A (9)
64.	Reevaluation of known ascending aortic dilation or history of aortic dissection to establish a baseline rate of expansion or when the rate of expansion is excessive	A (9)
65.	Reevaluation of known ascending aortic dilation or history of aortic dissection with a change in clinical status or findings on cardiac examination or when findings may alter management or therapy	A (9)
66.	Reevaluation of known ascending aortic dilation or history of aortic dissection without a change in clinical status or findings on cardiac examination when findings would not change management or therapy	I (3)
TRANSTHORACIC ECHOCARDIOGRAPHY FOR EVALUATION OF HYPERTENSION, HEART FAILURE, OR CARDIOMYOPATHY		
Hypertension		
67.	Initial evaluation of suspected hypertensive heart disease	A (8)
68.	Routine evaluation of systemic hypertension without suspected hypertensive heart disease	I (3)
69.	Reevaluation of known hypertensive heart disease without change in clinical status or findings on cardiac examination	U (4)
Heart Failure		
70.	Initial evaluation of known or suspected heart failure (systolic or diastolic) based on symptoms, signs, or abnormal test results	A (9)
71.	Reevaluation of known heart failure (systolic or diastolic) with change in clinical status or findings on cardiac examination and no clear precipitating change in medication or diet	A (8)
72.	Reevaluation of known heart failure (systolic or diastolic) with change in clinical status or findings on cardiac examination and a clear precipitating change in medication or diet	U (4)
73.	Reevaluation of known heart failure (systolic or diastolic) to guide therapy	A (9)
74.	Routine (<1 year) reevaluation of heart failure (systolic or diastolic) when there is no change in clinical status or findings on cardiac examination	I (2)
75.	Routine (≥1 year) reevaluation of heart failure (systolic or diastolic) when there is no change in clinical status or findings on cardiac examination	U (6)
Device Evaluation (Including Pacemaker, Implantable Cardioverter-Defibrillator, or Cardiac Resynchronization Therapy)		
76.	Initial evaluation or reevaluation after revascularization and/or optimal medical therapy to determine candidacy for device therapy and/or to determine	A (9)

	optimal choice of device	
77.	Initial evaluation for optimization of device for cardiac resynchronization therapy after implantation	U (6)
78.	Known implanted pacing device with symptoms possibly caused by device complication or suboptimal pacing device settings	A (8)
79.	Routine (<1 year) reevaluation of implanted device without change in clinical status or findings on cardiac examination	I (1)
80.	Routine (≥1 year) reevaluation of implanted device without change in clinical status or findings on cardiac examination	I (3)
Ventricular Assist Devices and Cardiac Transplantation		
81.	To determine candidacy for ventricular assist device	A (9)
82.	Optimization of ventricular assist device settings	A (7)
83.	Reevaluation of signs/symptoms suggestive of ventricular assist device–related complications	A (9)
84.	Monitoring for rejection in a cardiac transplant recipient	A (7)
85.	Cardiac structure and function evaluation in a potential heart donor	A (9)
Cardiomyopathies		
86.	Initial evaluation of known or suspected cardiomyopathy (e.g., restrictive, infiltrative, dilated, hypertrophic, or genetic cardiomyopathy)	A (9)
87.	Reevaluation of known cardiomyopathy with change in clinical status or findings on cardiac examination or to guide therapy	A (9)
88.	Routine (<1 year) reevaluation of known cardiomyopathy without change in clinical status or findings on cardiac examination	I (2)
89.	Routine (≥1 year) reevaluation of known cardiomyopathy without change in clinical status or findings on cardiac examination	U (5)
90.	Screening evaluation for structure and function in first-degree relatives of a patient with inherited cardiomyopathy	A (9)
91.	Baseline and serial reevaluations in patients undergoing therapy with cardiotoxic agents	A (9)
TRANSTHORACIC ECHOCARDIOGRAPHY FOR ADULT CONGENITAL HEART DISEASE		
92.	Initial evaluation of known or suspected adult congenital heart disease	A (9)
93.	Known adult congenital heart disease with change in clinical status or findings on cardiac examination	A (9)
94.	Reevaluation to guide therapy for known adult congenital heart disease	A (9)
95.	Routine (<2 years) reevaluation of adult congenital heart disease following complete repair: Without residual structural or hemodynamic abnormality Without change in clinical status or findings on cardiac examination	I (3)
96.	Routine (≥2 years) reevaluation of adult congenital heart disease following complete repair: Without residual structural or hemodynamic abnormality Without change in clinical status or findings on cardiac examination	U (6)
97.	Routine (<1 year) reevaluation of congenital heart disease following incomplete or palliative repair: With residual structural or hemodynamic abnormality Without change in clinical status or findings on cardiac examination	U (5)
98.	Routine (≥1 year) reevaluation of congenital heart disease following incomplete or palliative repair: With residual structural or hemodynamic abnormality Without change in clinical status findings on cardiac examination	A (8)
TRANSESOPHAGEAL ECHOCARDIOGRAPHY		
TEE as Initial or Supplemental Test—General Uses		
99.	Use of TEE when there is a high likelihood of a nondiagnostic TTE because of patient characteristics or inadequate visualization of relevant structures	A (8)
100.	Routine use of TEE when a diagnostic TTE is reasonably anticipated to resolve all diagnostic and management concerns	I (1)
101.	Reevaluation of previous TEE findings for interval change (e.g., resolution of thrombus after anticoagulation, resolution of vegetation after antibiotic therapy) when a change in therapy is anticipated	A (8)
102.	Reevaluation of previous TEE findings for interval change (e.g., resolution of thrombus after anticoagulation, resolution of vegetation after antibiotic therapy) when no change in therapy is anticipated	I (2)
103.	Guidance during percutaneous noncoronary cardiac interventions, including but not limited to closure device placement, radiofrequency ablation, and percutaneous valve procedures	A (9)
104.	Suspected acute aortic pathology, including but not limited to dissection/transection	A (9)
105.	Routine assessment of pulmonary veins in asymptomatic patient after pulmonary vein isolation	I (3)
TEE as Initial or Supplemental Test—Valvular Disease		
106.	Evaluation of valvular structure and function to assess suitability for and assist in planning of an intervention	A (9)
107.	To diagnose/manage infective endocarditis with a low pretest probability (e.g., transient fever, known alternative source of infection, or negative blood cultures/atypical pathogen for endocarditis)	I (3)
108.	To diagnose/manage infective endocarditis with a moderate or high pretest probability (e.g., staphylococcal bacteremia, fungemia, prosthetic heart valve, or intracardiac device)	A (9)
TEE as Initial or Supplemental Test—Embolic Event		
109.	Evaluation for cardiovascular source of embolus with no identified noncardiac source	A (7)
110.	Evaluation for cardiovascular source of embolus with a previously identified noncardiac source	U (5)
111.	Evaluation for cardiovascular source of embolus with a known cardiac source in which TEE would not change management	I (1)
TEE as Initial Test—Atrial Fibrillation/Flutter		
112.	Evaluation to facilitate clinical decision making with regard to anticoagulation, cardioversion, and/or radiofrequency ablation	A (9)
113.	Evaluation when a decision has been made to anticoagulate and not to perform cardioversion	I (2)
STRESS ECHOCARDIOGRAPHY FOR DETECTION OF CORONARY ARTERY/RISK ASSESSMENT: SYMPTOMATIC OR ISCHEMIC EQUIVALENT		
Evaluation of Ischemic Equivalent (Nonacute)		
114.	Low pretest probability of CAD ECG interpretable *and* able to exercise	I (3)
115.	Low pretest probability of CAD ECG uninterpretable *or* unable to exercise	A (7)
116.	Intermediate pretest probability of CAD ECG interpretable *and* able to exercise	A (7)
117.	Intermediate pretest probability of CAD ECG uninterpretable *or* unable to exercise	A (9)
118.	High pretest probability of CAD Regardless of ECG interpretability and ability to exercise	A (7)
Acute Chest Pain		
119.	Possible ACS ECG: no ischemic changes or uninterpretable ECG Low-risk TIMI score Negative troponin levels	A (7)
120.	Possible ACS ECG: no ischemic changes or uninterpretable ECG Low-risk TIMI score	A (7)

	Peak troponin: borderline, equivocal, minimally elevated	
121.	Possible ACS ECG: no ischemic changes or uninterpretable ECG High-risk TIMI score Negative troponin levels	A (7)
122.	Possible ACS ECG: no ischemic changes or uninterpretable ECG High-risk TIMI score Peak troponin: borderline, equivocal, minimally elevated	A (7)
123.	Definite ACS	I (1)
STRESS ECHOCARDIOGRAPHY FOR DETECTION OF CORONARY ARTERY DISEASE/RISK ASSESSMENT: ASYMPTOMATIC (WITHOUT ISCHEMIC EQUIVALENT)		
General Patient Populations		
124.	Low global CHD risk	U (1)
125.	Intermediate global CHD risk ECG interpretable	I (2)
126.	Intermediate global CHD risk ECG uninterpretable	U (5)
127.	High global CHD risk	U (5)
STRESS ECHOCARDIOGRAPHY FOR DETECTION OF CORONARY ARTERY DISEASE/RISK ASSESSMENT: ASYMPTOMATIC (WITHOUT ISCHEMIC EQUIVALENT) IN PATIENT POPULATIONS WITH DEFINED COMORBID CONDITIONS		
New-Onset or Newly Diagnosed Heart Failure or Left Ventricular Systolic Dysfunction		
128.	No previous CAD evaluation *and* no planned coronary angiography	A (7)
Arrhythmias		
129.	Sustained VT	A (7)
130.	Frequent PVCs, exercise-induced VT, or nonsustained VT	A (7)
131.	Infrequent PVCs	I (3)
132.	Atrial fibrillation or other SVT	U (6)
Syncope		
133.	Low global CHD risk	I (3)
134.	Intermediate or high global CHD risk	A (7)
Elevated Troponin		
135.	Troponin elevation without symptoms or additional evidence of ACS	A (7)
STRESS ECHOCARDIOGRAPHY FOLLOWING PREVIOUS TEST RESULTS		
Asymptomatic: Previous Evidence of Subclinical Disease		
136.	Coronary calcium Agatston score <100	I (2)
137.	Low to intermediate global CHD risk Coronary calcium Agatston score between 100 and 400	U (5)
138.	High global CHD risk Coronary calcium Agatston score between 100 and 400	U (6)
139.	Coronary calcium Agatston score >400	A (7)
140.	Abnormal carotid intimal medial thickness (≥0.9 mm and/or the presence of plaque encroaching into the arterial lumen)	U (5)
Coronary Angiography (Invasive or Noninvasive)		
141.	Coronary artery stenosis of unclear significance	A (8)
Asymptomatic *or* Stable Symptoms, Normal Findings on Previous Stress Imaging Study		
142.	Low global CHD risk Last stress imaging study <2 years ago	I (1)
143.	Low global CHD risk Last stress imaging study ≥2 years ago	I (2)
144.	Intermediate to high global CHD risk Last stress imaging study <2 years ago	I (2)
145.	Intermediate to high global CHD risk Last stress imaging study ≥2 years ago	U (4)
Asymptomatic *or* Stable Symptoms With Abnormal Findings on Coronary Angiography *or* Previous Stress Study, No Previous Revascularization		
146.	Known CAD on coronary angiography *or* previous abnormal findings on stress imaging study Last stress imaging study <2 years ago	I (3)
147.	Known CAD on coronary angiography *or* previous abnormal findings on stress imaging study Last stress imaging study ≥2 years ago	U (5)
Treadmill Electrocardiographic Stress Test		
148.	Low-risk treadmill score (e.g., Duke)	I (1)
149.	Intermediate-risk treadmill score (e.g., Duke)	A (7)
150.	High-risk treadmill score (e.g., Duke)	A (7)
New, Worsening, or Unresolved Symptoms		
151.	Abnormal findings on coronary angiography *or* abnormal findings on previous stress imaging study	A (7)
152.	Normal findings on coronary angiography *or* normal finding on previous stress imaging study	U (6)
Previous Noninvasive Evaluation		
153.	Equivocal, borderline, or discordant stress testing when obstructive CAD remains a concern	A (8)
STRESS ECHOCARDIOGRAPHY FOR RISK ASSESSMENT: PERIOPERATIVE EVALUATION FOR NONCARDIAC SURGERY WITHOUT ACTIVE CARDIAC CONDITIONS		
Low-Risk Surgery		
154.	Perioperative evaluation for risk assessment	I (1)
Intermediate-Risk Surgery		
155.	Moderate to good functional capacity (≥4 METs)	I (3)
156.	No clinical risk factors	I (2)
157.	≥1 clinical risk factor Poor or unknown functional capacity (<4 METs)	U (6)
158.	Asymptomatic <1 year after normal findings on catheterization, noninvasive test, or previous revascularization	I (1)
Vascular Surgery		
159.	Moderate to good functional capacity (≥4 METs)	I (3)

160.	No clinical risk factors	I (2)
161.	≥1 clinical risk factor Poor or unknown functional capacity (<4 METs)	A (7)
162.	Asymptomatic <1 year after normal findings on catheterization, noninvasive test, or previous revascularization	I (2)
STRESS ECHOCARDIOGRAPHY FOR RISK ASSESSMENT: WITHIN THREE MONTHS OF AN ACUTE CORONARY SYNDROME		
ST-Segment Elevation Myocardial Infarction		
163.	Primary PCI with complete revascularization No recurrent symptoms	I (2)
164.	Hemodynamically stable, no recurrent chest pain symptoms or signs of heart failure To evaluate for inducible ischemia No previous coronary angiography since the index event	A (7)
165.	Hemodynamically unstable, signs of cardiogenic shock, or mechanical complications	I (1)
Unstable Angina/Non–ST-Segment Elevation Myocardial Infarction		
166.	Hemodynamically stable, no recurrent chest pain symptoms or signs of heart failure To evaluate for inducible ischemia No previous coronary angiography since the index event	A (8)
ACS—Asymptomatic after Revascularization (PCI or CABG)		
167.	Before hospital discharge	I (1)
Cardiac Rehabilitation		
168.	Before initiation of cardiac rehabilitation (as a stand-alone indication)	I (3)
STRESS ECHOCARDIOGRAPHY FOR RISK ASSESSMENT: AFTER REVASCULARIZATION (PCI OR CABG)		
Symptomatic		
169.	Ischemic equivalent	A (8)
Asymptomatic		
170.	Incomplete revascularization Additional revascularization feasible	A (7)
171.	<5 years after CABG	I (2)
172.	≥5 years after CABG	U (6)
173.	<2 years after PCI	I (2)
174.	≥2 years after PCI	U (5)
Cardiac Rehabilitation		
175.	Before initiation of cardiac rehabilitation (as a stand-alone indication)	I (3)
STRESS ECHOCARDIOGRAPHY FOR ASSESSMENT OF VIABILITY/ISCHEMIA		
Ischemic Cardiomyopathy/Assessment of Viability		
176.	Known moderate or severe left ventricular dysfunction Patient eligible for revascularization Use of dobutamine only	A (8)
STRESS ECHOCARDIOGRAPHY FOR HEMODYNAMICS (INCLUDES DOPPLER DURING STRESS)		
Chronic Valvular Disease—Asymptomatic		
177.	Mild mitral stenosis	I (2)
178.	Moderate mitral stenosis	U (5)
179.	Severe mitral stenosis	A (7)
180.	Mild aortic stenosis	I (3)
181.	Moderate aortic stenosis	U (6)
182.	Severe aortic stenosis	U (5)
183.	Mild mitral regurgitation	I (2)
184.	Moderate mitral regurgitation	U (5)
185.	Severe mitral regurgitation Left ventricular size and function not meeting surgical criteria	A (7)
186.	Mild aortic regurgitation	I (2)
187.	Moderate aortic regurgitation	U (5)
188.	Severe aortic regurgitation Left ventricular size and function not meeting surgical criteria	A (7)
Chronic Valvular Disease—Symptomatic		
189.	Mild mitral stenosis	U (5)
190.	Moderate mitral stenosis	A (7)
191.	Severe mitral stenosis	I (3)
192.	Severe aortic stenosis	I (1)
193.	Evaluation of equivocal aortic stenosis Evidence of low cardiac output or left ventricular systolic dysfunction (“low-gradient aortic stenosis”) Use of dobutamine only	A (8)
194.	Mild mitral regurgitation	U (4)
195.	Moderate mitral regurgitation	A (7)
196.	Severe mitral regurgitation Severe left ventricular enlargement or systolic dysfunction	I (3)
Acute Valvular Disease		
197.	Acute moderate or severe mitral or aortic regurgitation	I (3)
Pulmonary Hypertension		
198.	Suspected pulmonary hypertension Normal or indeterminate findings on resting echocardiographic study	U (5)
199.	Routine evaluation of patients with known resting pulmonary hypertension	I (3)
200.	Reevaluation of patient with exercise-induced pulmonary hypertension to evaluate response to therapy	U (5)
CONTRAST USE IN TRANSTHORACIC/TRANSESOPHAGEAL ECHOCARDIOGRAPHY OR STRESS ECHOCARDIOGRAPHY		
201.	Routine use of contrast All left ventricular segments visualized on non–contrast-enhanced images	I (1)
202.	Selective use of contrast ≥2 contiguous left ventricular segments are *not* seen on non–contrast-enhanced images	A (8)

[*] *A,* Appropriate; *I,* inappropriate; *U,* uncertain.

ACS, Acute coronary syndrome; *APC,* atrial premature contraction; *CABG,* coronary artery bypass grafting; *CAD,* coronary artery disease; *CHD,* coronary heart disease; *ECG,* electrocardiogram; *METs,* metabolic equivalents; *MRI,* magnetic resonance imaging; *PCI,* percutaneous coronary intervention; *SVT,* supraventricular tachycardia; *TEE,* transesophageal echocardiography; *TTE,* transthoracic echocardiography; *TIA,* transient ischemic attack; *TIMI,* Thrombolysis in Myocardial Infarction; *UA,* unstable angina; *VPC,* ventricular premature contraction; *VT,* ventricular tachycardia.

The Chest Radiograph in Cardiovascular Disease

Cylen Javidan-Nejad, Sanjeev Bhalla

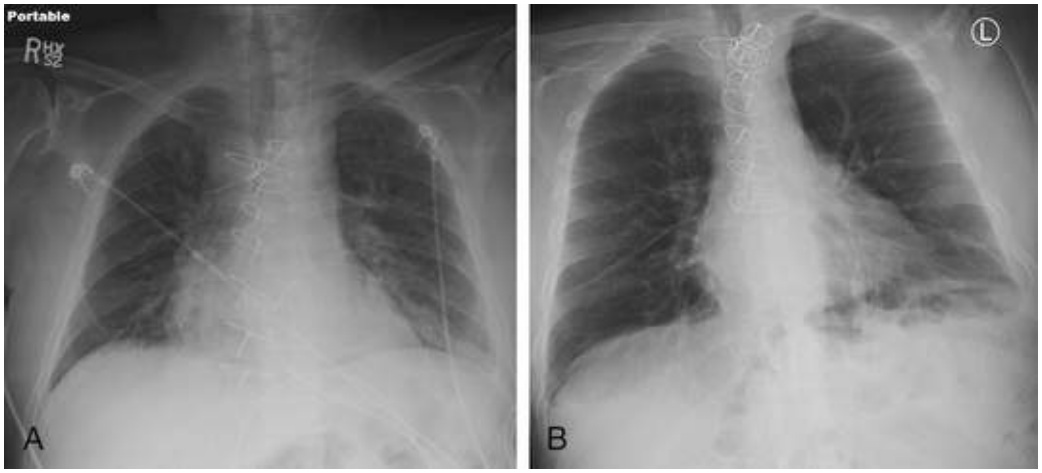
The chest radiograph, or chest x-ray film (CXR), is the most common imaging study. It is relatively inexpensive, readily available, and low in radiation dose, exposing the patient to less ionizing radiation than computed tomography (CT), conventional angiography, or cardiac scintigraphy (**see Chapters 16, 18, and 20**). The CXR is often first-line imaging for most medical conditions, including suspected cardiovascular disease.[1]

Overview

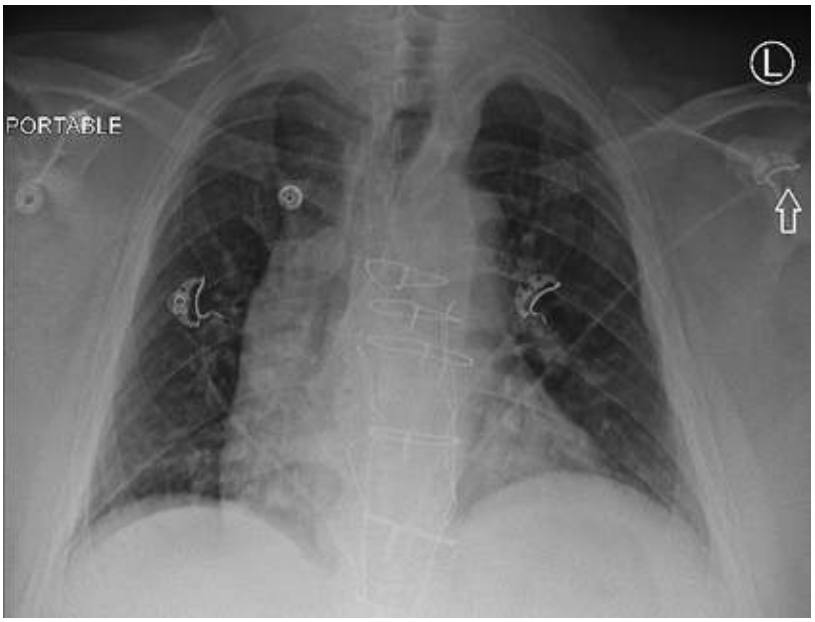
A standard CXR is acquired with the patient upright in deep inspiration and consists of posteroanterior (PA) and lateral views. The PA view is a frontal view acquired with the patient facing the image detector, with the x-ray tube directed to the center of the patient's upper back. The lateral view is acquired with the left side of the patient against the detector and the x-ray tube directed to the patient's right side. For both views, the x-ray tube is placed 6 feet (1.8 m) from the recording surface, which is the optimal distance to minimize image distortion and maximize spatial resolution, while exposing the patient to the least possible radiation dose. An anteroposterior (AP) view is also a frontal radiograph performed for patients who are unable to stand. It is typically used for portable bedside radiography. The AP view is obtained

with the patient facing the tube and lying on the detector plate.[2]

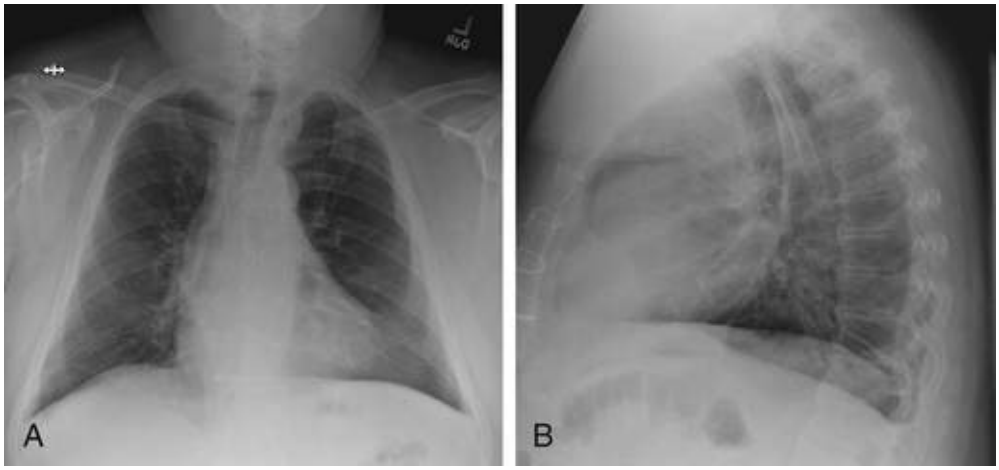
The positioning of the PA and lateral CXR is performed to minimize magnification of the heart and mediastinum by placing these structures as close as possible to the image recording surface. On a PA view the heart size and mediastinal vessels are smaller and more sharply defined than on an AP view (**eFig. 15.1**). This difference is caused by the divergence of the x-ray beam from the source, which magnifies structures located farther from the image detector. A useful analogy is to contrast the size of the shadow of your hand when you lift your hand away from the sidewalk. In this example the sun is the x-ray point source, and the sidewalk is the detector (**eFig. 15.2**). On a lateral view the right hemithorax is magnified relative to the left hemithorax. This feature may be helpful in determining if a small pleural effusion is right or left sided when visible only on the lateral view[3] (**eFig. 15.3**).



EFIGURE 15.1 Comparison of anteroposterior (AP) and posteroanterior (PA) views. **A,** Portable AP view shows an enlarged cardiac silhouette, indistinct hilar vasculature, and a widened mediastinum. **B,** PA view of the same patient obtained 5 hours later after removal of the central venous catheter shows the true normal size of the heart with no mediastinal widening.

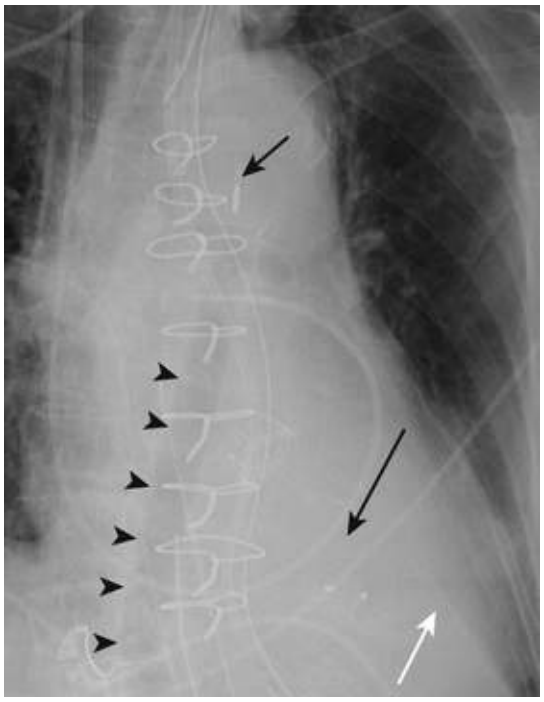


EFIGURE 15.2 Limitations of portable technique. Portable radiograph shows an apparent large right atrial contour and a mediastinal widening to the right of the spine. Comparison with a standard PA chest radiograph obtained the previous day (**see eFig. 15.3A**) would reveal that these apparent abnormalities were caused by the portable technique and patient rotation.



EFIGURE 15.3 Costophrenic angles (CPAs) on the lateral view. Standard PA **(A)** and lateral **(B)** radiographs of the same patient shown in **eFig. 15.2** were obtained the previous day and show no blunting of the right lateral CPA on the PA view, with blunting of the right posterior CPA on the lateral view. The posterior right CPA is located farther behind the spine than the posterior left CPA due to magnification of the right-sided structures, which are located farther from the image recording surface.

On a portable AP CXR, the heart appears relatively larger and the hilar vasculature crowded, a result of the study's recumbent nature and the inability to achieve full inspiration. Portable x-ray machines have lower tube output power, with resultant longer exposure times and increased cardiac and respiratory motion artifacts, as well as decreased resolution.[4] The most common application of portable radiographs is in evaluating the proper course and positioning of mechanical devices placed in a patient, such as endotracheal tubes, central venous catheters, gastric and feeding tubes, and cardiac devices such as pacemakers and implantable cardioverter-defibrillators (ICDs)[5] (**eFig. 15.4**).



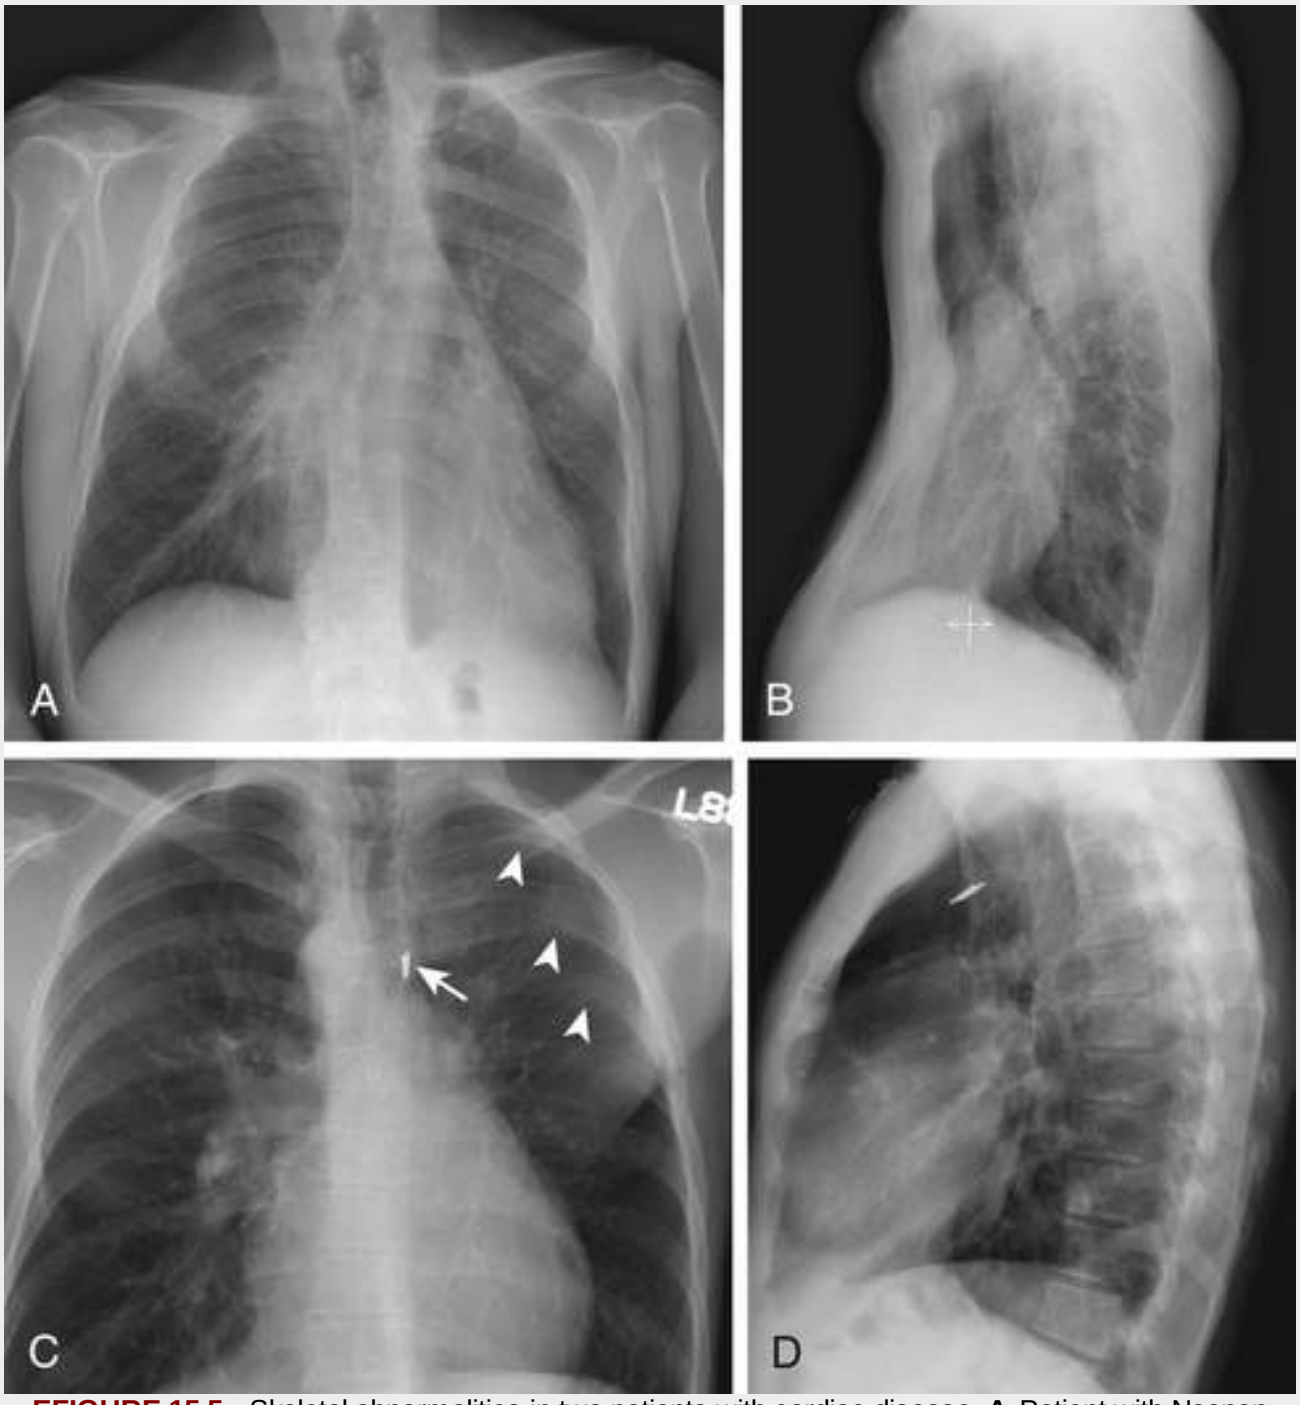
EFIGURE 15.4 Assessment of cardiac and intravascular devices. Coned-down view of portable chest radiograph of patient in intensive care unit shows an intra-aortic balloon device (IABP), with its metallic marker (*short black arrow*) projecting a few centimeters below the aortic arch, indicating that it is well positioned. The inflated balloon of the IABP creates a radiolucent column (*arrowheads*) over the descending aorta. A ventricular septal occluder device (*long arrow*) projects over the heart. The positions of other tubes and catheters are also depicted, such as the pulmonary arterial catheter with its tip in the right pulmonary artery. The left ventricle apex is obscured by a small, left pleural effusion (*white arrow*).

The Normal Chest Radiograph

A CXR can reveal abnormalities of anatomy and physiology by demonstrating an abnormal size or shape of the heart or of specific cardiac chambers; enlarged or diminished size of a normal mediastinal structure; unusual calcifications; and extracardiac findings in the lungs, chest wall, or abdominal organs. The first (and arguably the most difficult) step in the evaluation of a CXR is to distinguish normal findings and normal variants from pathology.

A systematic approach to evaluation of the CXR can begin by assessing the heart size. On a PA radiograph the cardiac/thoracic ratio is approximately 0.5 to 0.6. To calculate this ratio, the horizontal thoracic diameter is measured along the inner margins of the ribs at the level of the dome of the right hemidiaphragm, and the cardiac diameter is calculated as the sum of the most rightward and the most leftward diameters of the heart from the midline. In practice this is done qualitatively. Normally the heart projects over the spine, with about one quarter of its diameter projecting to the right of the midline and three quarters to the left of the midline. The cardiac apex is normally directed to the left, located adjacent to the diaphragm[6] (**see eFig. 15.4**).

Because the cardiac silhouette represents a summation of the heart and surrounding structures, the heart size can erroneously appear enlarged when abundant mediastinal fat and prominent pericardial fat pad or a large pericardial effusion are present.[7] When the lungs are hyperinflated (e.g., emphysema), the cardiac/thoracic ratio decreases, and the heart can seem abnormally small. A truly decreased heart size occurs when the patient is hypovolemic, as in Addison disease or chronic malnourishment (**eFig. 15.5**). Skeletal abnormalities such as pectus excavatum and scoliosis of the thoracic spine can alter the rotation of the heart and make it appear enlarged on a frontal radiograph.



EFIGURE 15.5 Skeletal abnormalities in two patients with cardiac disease. **A,** Patient with Noonan syndrome and spontaneously healed ventriculoseptal defect presents with scoliosis and severe pectus excavatum deformity. The very short distance between the sternum and the spine causes a leftward rotation and displacement of the heart into the left hemithorax defect **(A, B). C,** Patient with tetralogy of Fallot who had a Blalock-Taussig shunt in childhood presents with unilateral inferior rib notching (*arrowheads*). The left fourth and fifth ribs are fused due to lateral thoracotomy in early childhood. Surgical clips above the expected location of the main pulmonary artery (*white arrow*) is related to previous Blalock-Taussig shunt, which before definitive repair provided blood flow from the left subclavian artery to the left pulmonary artery **(C, D).** Note the right-sided aortic arch and the small, pediatric sternotomy wires.

The right heart border is created by the right atrium. The left heart border is formed by the left ventricle inferiorly and the left atrial (LA) appendage superiorly. The outline of the normal right ventricle is not visible on the frontal CXR because of its position anteriorly behind the sternum, with its outer edge located medial to the left ventricle (**Fig. 15.1A**).

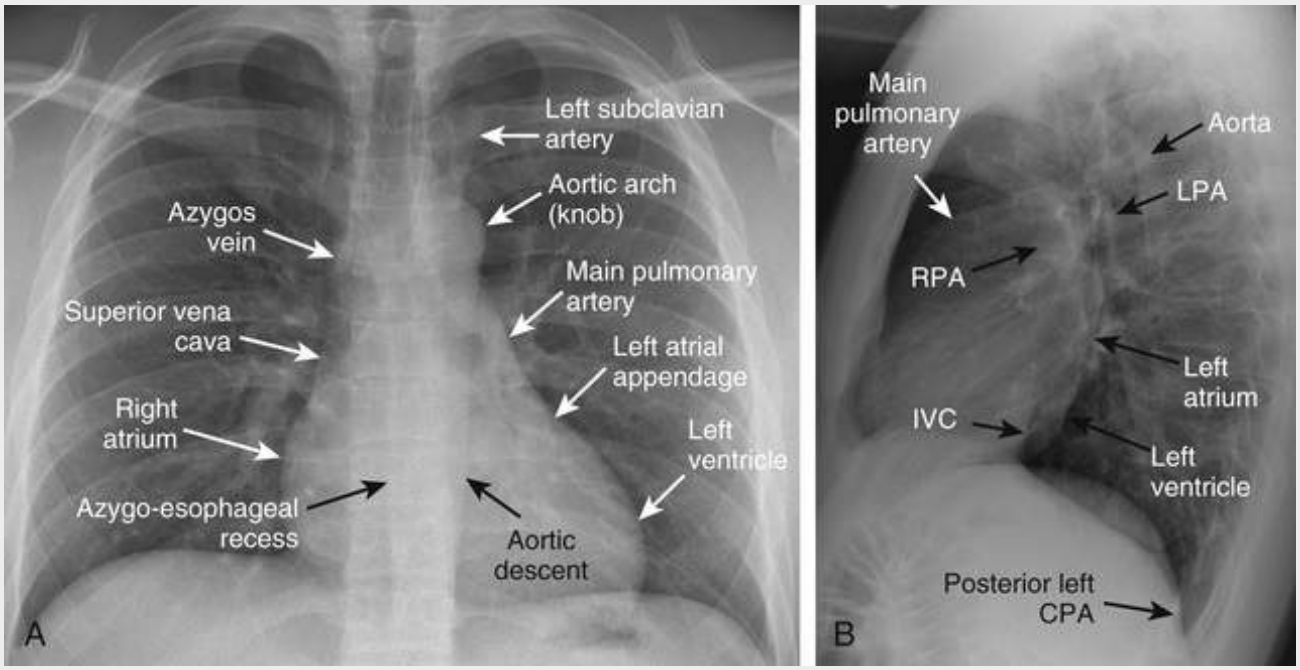


FIGURE 15.1 Normal standard two-view chest radiograph. PA **(A)** and lateral **(B)** views of the chest depict various normal cardiovascular structures. *CPA,* Costophrenic angle; *IVC,* inferior vena cava; *LPA,* left pulmonary artery; *RPA,* right pulmonary artery.

The right border of the mediastinum is created by the superior vena cava (SVC) at this level. The elliptical density projecting on the SVC, just above the right main bronchus, is the arch of the azygos vein as it travels anteroposteriorly from the spine to drain into the SVC. The normal azygos arch contour measures 1.0 cm in diameter and when enlarged can indicate increased systemic venous pressure from systemic fluid overload, right heart failure, or collateral flow through the azygos vein, as in congenital absence of the inferior vena cava (IVC).

The left border of the mediastinum above the heart is composed of two outward bulges, formed by the aortic arch (or aortic knob) superiorly and the main pulmonary artery (MPA) inferiorly. As a general guideline, the MPA and the aorta can be seen above the left main bronchus, whereas the LA appendage is seen just below. The left lateral wall of the descending aorta creates a vertical line projecting lateral to the spine superiorly and over the spine inferiorly as the aorta descends to the diaphragm. The right wall of the aorta is not visible because there is no interface between it and the right lung. Care should be taken not to confuse the azygoesophageal recess for the right aortic border (**Fig. 15.1A**).

On the lateral view the normal right ventricle should be flush with about one third of the lower sternum. Above that, the retrosternal space should be clear in a nonobese patient. The upper cardiac border mostly consists of the right ventricular outflow tract (RVOT), which normally has a relatively flat contour and is angled posteriorly. The posterior cardiac border consists of the left atrium superiorly and the left ventricle inferiorly. A linear vertical line extending from the right hemidiaphragm to project over the heart represents the posterior wall of the IVC.[8]

On the lateral view the vessels of the hila can be assessed. In the center of the hilum is an oval-shaped density composed of the right pulmonary artery (RPA) and right pulmonary veins, known as the “right hilar vascular confluence.” The left pulmonary artery (LPA) is located posterior to RPA and has an archlike configuration, parallel and inferior to the aortic arch. The right and left inferior pulmonary veins appear as branching, elongated densities posterior to the heart and inferior to the hila[9] (**Fig. 15.1B**).

On both PA and lateral views the ascending aorta is normally obscured by the MPA and both atria. The aorta normally increases in size with age, and the great arterial branches off the aortic arch become more tortuous, creating a widened superior mediastinum. Normally on an upright PA chest radiograph, the

vessels should not be visible in the outer third of the lungs, and the lower lung zone vessels should be larger in caliber than the upper vessels because of gravity. The right and left lungs should be symmetric in size and pulmonary vascular markings.[10]

Approach to Evaluation of a Chest Radiograph

A well-developed approach to the chest radiograph takes years to develop and is beyond the scope of this chapter. Each interpreter must develop a consistent approach that carefully looks at the bones, lungs (with attention for pleural abnormalities), vasculature, and heart.[11] Knowledge of the type of study (PA versus AP) will allow for a more accurate assessment of heart size and mediastinal contour.

Prior radiographs should be reviewed routinely because many abnormalities are put into appropriate perspective by determining whether they are new or old and the rate of change. For example, new enlargement of the aortic arch may be seen in the setting of aortic dissection, whereas chronic mediastinal widening is more likely to be related to a congenital variant such as a double aortic arch. The final step in image interpretation relies on the generation of a differential diagnosis based on the constellation of findings and an appropriate clinical history.[12]

Specific Cardiovascular Diseases

The specific cardiovascular diseases discussed next are grouped into four main categories to highlight the variety of cardiovascular conditions that may be seen on a CXR: diseases affecting (1) the heart size and morphology, (2) the coronary arteries, (3) the pericardium, and (4) the aorta.

Diseases Affecting Heart Size and Morphology

When the cardiac silhouette is enlarged, it is most often related to biventricular failure, with no definable individual chamber enlargement. In valvular disease and many types of congenital heart disease, however, individual chamber enlargement develops, identification of which is central to diagnosis. Acquired left heart disease can cause left ventricular (LV) or global cardiac enlargement when more than one cardiac chamber is enlarged. LV enlargement manifests as downward and leftward displacement of the LV apex on the frontal view and posterior displacement of the lower cardiac border on the lateral view (**Fig. 15.2**) (see Classic References, Higgins). Diseases that lead to LV enlargement are those associated with a volume-overload status, such as congestive heart failure, ischemic and nonischemic cardiomyopathies, and valvular regurgitation. True and false cardiac aneurysms and pericardial masses cause a focal convexity or masslike density along a cardiac border. Acquired heart diseases associated with normal LV size tend to be those diseases associated with a pressure-overload status, such as aortic stenosis or systemic arterial hypertension, or those associated with decreased myocardial compliance, such as hypertrophic or restrictive cardiomyopathies.

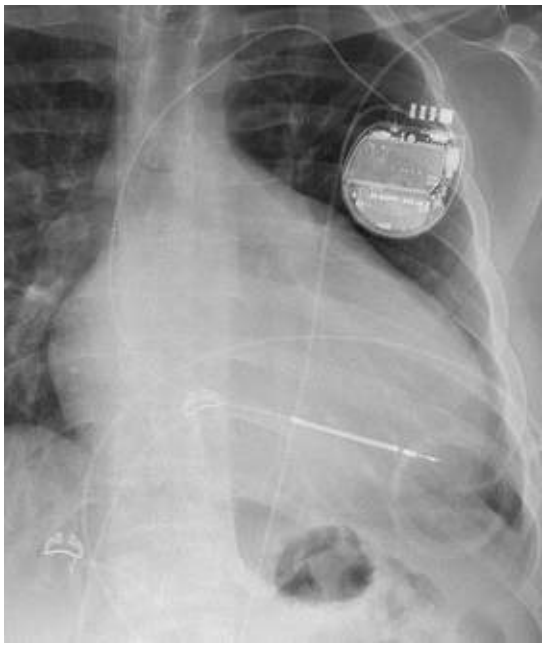

FIGURE 15.2 Left ventricle enlargement. Coned-down PA chest radiograph of 20-year-old man with severe nonischemic cardiomyopathy shows an extremely large left ventricle with the cardiac apex displaced toward the left. The patient also had pulmonary hypertension with an enlarged contour of the main pulmonary artery.

Left atrial enlargement (LAE) can be identified by a convex (versus normal concave) LA appendage contour. When LAE is present, the right border of the left atrium (seen as a retrocardiac curvilinear density) becomes laterally displaced and more convex, creating the *double density sign*. In LAE the distance from the midportion of this double density line to the middle of the left main bronchus exceeds 7 cm. Another finding of LAE is widening of the angle of the carina and upward deviation of the left main bronchus, caused by the mass effect of the left atrium on this bronchus. On the lateral view the upper aspect of the posterior cardiac contour becomes more convex when there is LAE (**Fig. 15.3**).

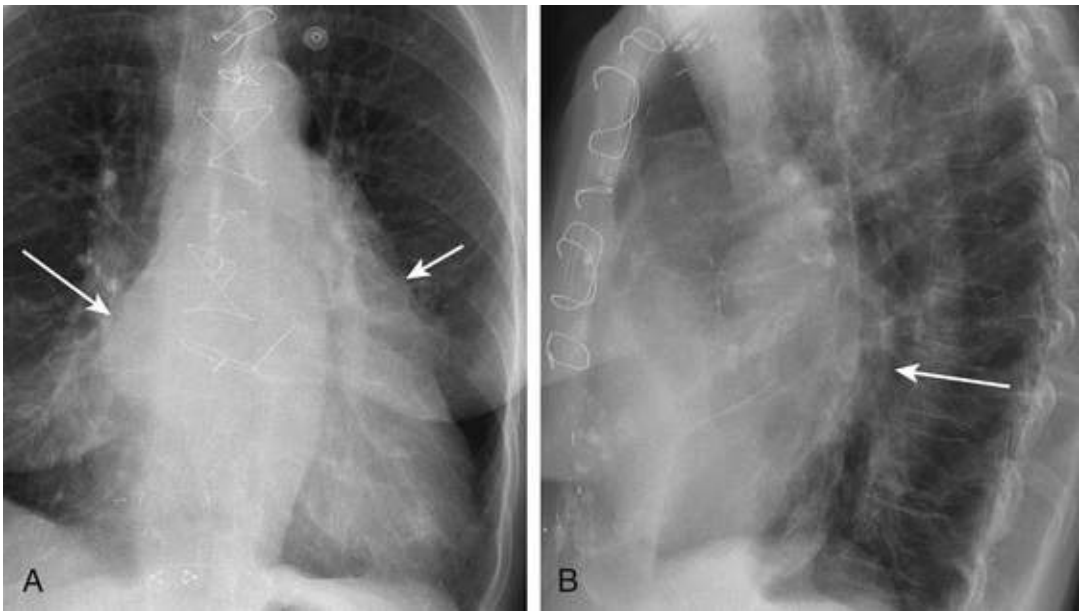

FIGURE 15.3 Left atrial enlargement (LAE). Coned-down PA **(A)** and lateral **(B)** chest radiographs in patient with mitral stenosis show findings of severe left atrial dilation. **A,** On the frontal view, a double density sign (*long arrow*) along the right cardiac border and a convexity along the upper left cardiac border (*short arrow*) reveal the LAE. **B,** Lateral view shows the posterior bulge of the left atrium (*arrow*).

When the right ventricle becomes enlarged, it pushes the left ventricle laterally, resulting in an enlarged appearance of the left heart. In certain situations, right ventricular (RV) enlargement will result in upturning of the cardiac apex. An enlarged RV outflow tract (RVOT) rarely results in a prominent upper cardiac border in the expected location of the LA appendage. The lateral chest radiograph is helpful in confirming RV enlargement by filling in of the lower aspect of the retrosternal space. RV hypertrophy can cause displacement of the entire posterior cardiac border toward the spine, simulating LV enlargement. The key to understanding this variant is to realize that, unlike in LV enlargement, the extension of the cardiac border posterior to the IVC is not increased (**Fig. 15.4**).

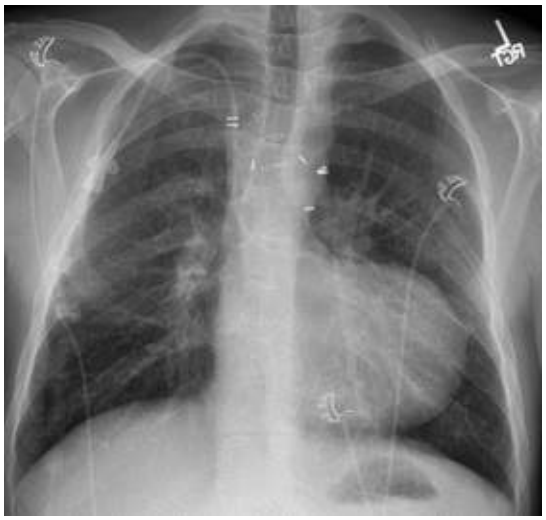

FIGURE 15.4 Boot-shaped heart in 30-year-old man with history of dextro-transposition of the great arteries (D-TGA) and hypoplastic left ventricle treated by total cavopulmonary connection. The PA radiograph reveals a boot-shaped heart caused by a greatly enlarged systemic right ventricle. The cardiac apex is directed upward. Note the mediastinum is very narrow, creating the "egg-on-string" appearance described in patients with D-TGA.

Right atrial enlargement (RAE) is almost always caused by tricuspid regurgitation, which also results in RV enlargement. Findings of RAE on the frontal view include increased convexity and elongation of the right cardiac border. RAE is difficult to identify on the lateral view.

Congestive Heart Failure

In congestive heart failure, both the left ventricle and the left atrium become enlarged because of the elevated LV end-diastolic volume (**see Chapters 21 and 23**). This enlargement may be exaggerated if the mitral annulus dilates and mitral regurgitation develops. As LA pressures increase, pulmonary venous hypertension (PVH) develops. Based on its severity, PVH can be divided into three grades: I or mild, II or moderate, and III or severe (see Classic References, Sharma). Each grade of PVH is associated with specific imaging findings (**Table 15.1**).

TABLE 15.1

Correlation of Pulmonary Venous Hypertension (PVH) with Mean Left Atrial (LA) Pressures and Imaging Findings on Chest Radiograph (CXR)

PVH Grade	MEAN LA PRESSURE (mm Hg)		Pulmonary Edema CXR Findings
	Acute Disease	Chronic Disease	
I	12-19	15-25	Mild pulmonary edema with vascular redistribution
II	20-25	25-30	Interstitial pulmonary edema with peribronchial cuffing and Kerley lines
III	>25	>30	Alveolar pulmonary edema with confluent air space opacities

The initial finding of PVH is redistribution of flow to the upper lung zones, resulting in equalization of the sizes of the vascular markings on an upright CXR. Over time the findings progress, with the upper lobe vessels larger than the lower lobe vessels. This phenomenon is known as *cephalization*, or pulmonary vascular redistribution (**Fig. 15.5A**).

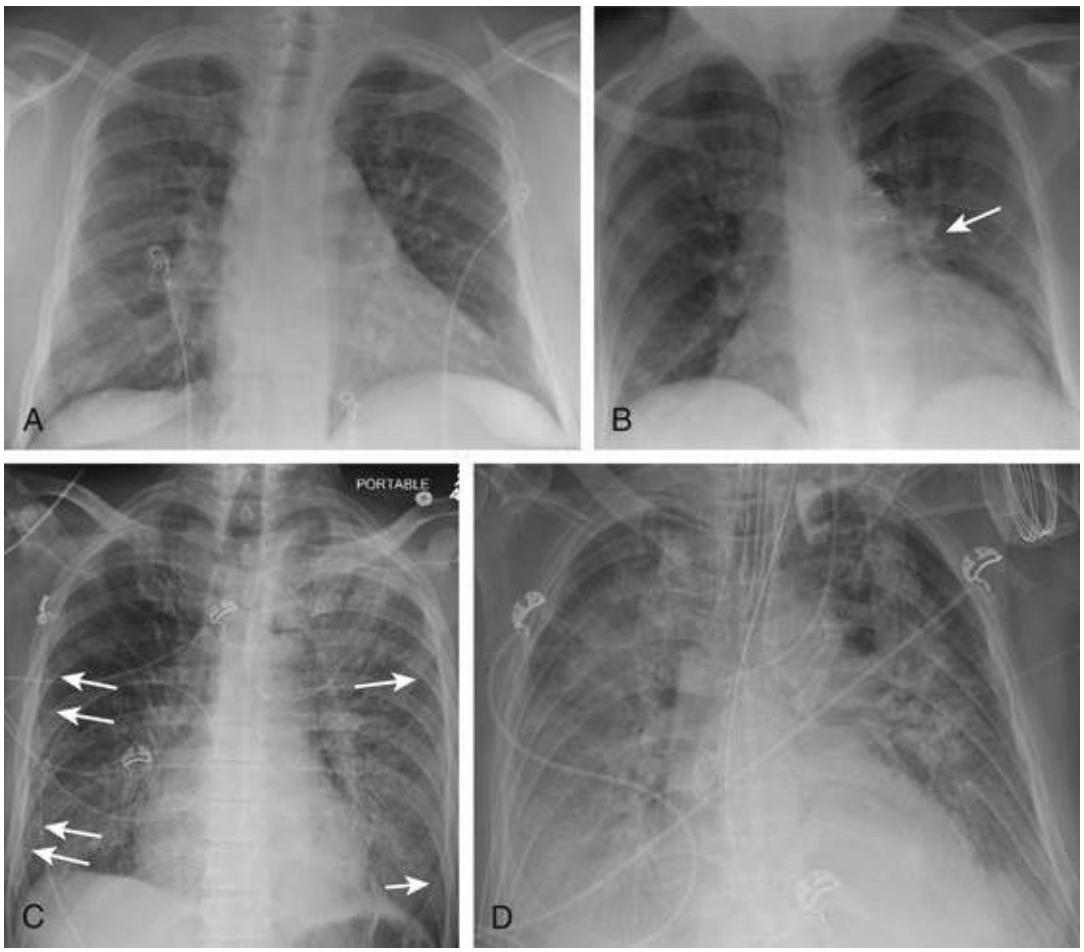

FIGURE 15.5 Pulmonary edema in four different patients with variable severity. **A,** Cephalization indicates pulmonary venous hypertension in which the upper lobe vessels are equal to or larger than the lower lobe vessels. At this point, pulmonary edema has not developed. **B,** With progression, mild pulmonary edema ensues; the vascular margins become indistinct, and peribronchial cuffing develops (*arrow*). Clothing clips project over the aorta and are external to this second patient. **C,** The third patient has left upper lobe pneumonia and suddenly developed worsening dyspnea. CXR shows moderate pulmonary edema with many interstitial lines, indicating fluid in the septa of the lung parenchyma (Kerley lines, *arrows*), superimposed on the left lobe pneumonia. **D,** The fourth patient has severe alveolar pulmonary edema that presents as bilateral air space opacities in both lungs on CXR. The bilateral pleural effusions are also caused by the congestive heart failure.

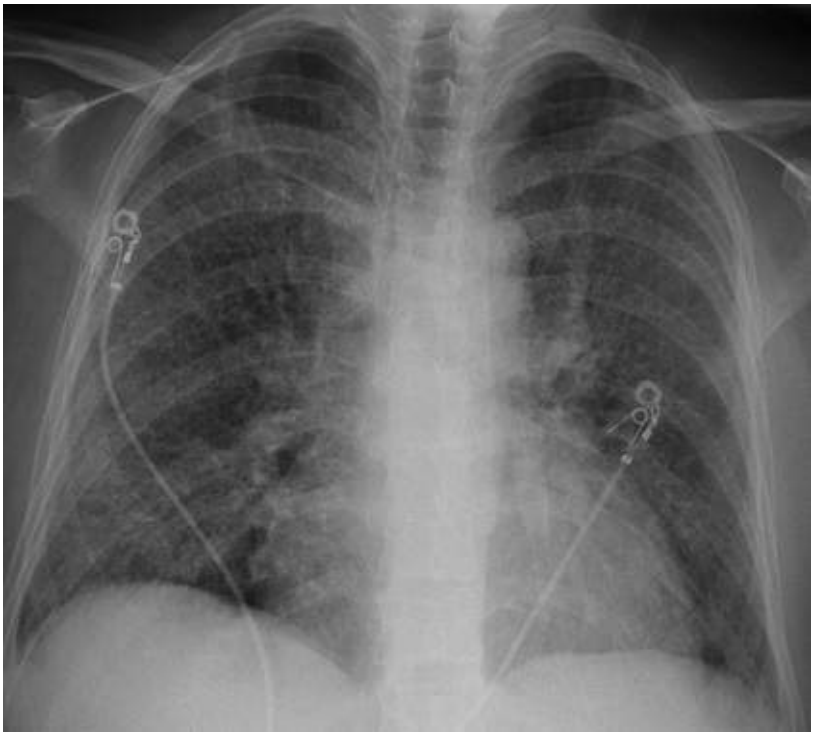
As the mean LA pressure increases, interstitial pulmonary edema develops from extravasation of fluid

into the lung interstitium surrounding the bronchovascular bundles and into the inter- and intralobular septa.[13] Such edema is manifest on a CXR with enlarged, poorly defined hilar vessels; thickening of the bronchial walls (peribronchial cuffing when viewed on end); fine central linear interstitial markings (Kerley A-lines), or peripherally appearing as parallel horizontal lines abutting the pleura (Kerley B-lines); and thickening of the fissural stripes, representing subpleural edema along the inner margin of the visceral pleura (**Fig. 15.5B**).

In severe pulmonary edema the fluid extends from the interstitium into the alveolar spaces, creating alveolar consolidations (or air space opacities), which tend to begin around the hila and progress in the middle and lower lung zones. Pleural effusions often develop in severe pulmonary edema (**Fig. 15.5C**). The distribution of findings is typically symmetric, creating a "bat wing" or "butterfly" appearance of the alveolar consolidations. If the patient has been lying on one side, the pulmonary edema tends to be more severe on that side because of the effect of gravity. Unilateral or focal pulmonary edema can result from central obstruction of a vein by a mass or surrounding mediastinal fibrosis or from a venous stricture, which can be a complication of LA ablation[14] (**see Chapter 38**).

It is important to distinguish cardiogenic from noncardiogenic pulmonary edema. Noncardiogenic pulmonary edema has many causes beyond heart failure, such as asphyxiation, drowning, intracranial hypertension, smoke and noxious fume inhalation, adult respiratory distress syndrome, and adverse reaction to certain drugs (e.g., diazepam, cocaine). In such patients the LA and pulmonary venous pressures are not significantly elevated, and heart size tends to be normal with no pleural effusions. The main cause of noncardiogenic pulmonary edema is diffuse alveolar damage with interruption of the alveolar-capillary membranes, leading to leakage of fluid into the alveolar spaces[15] (**eFig. 15.6**).



EFIGURE 15.6 Noncardiogenic pulmonary edema. Portable frontal chest radiograph of patient with multisubstance use demonstrates mixed interstitial and alveolar pulmonary edema. The heart size is normal. Echocardiography (not shown) demonstrated normal cardiac function.

Right heart failure is usually secondary to left heart failure. In such situations the azygos arch, SVC border, or IVC border can become enlarged, indicating systemic venous hypertension.[16]

Valvular Heart Disease

Knowing the location of cardiac valves is a key component of cardiac assessment on the CXR. To do this, on the lateral view an oblique line is drawn from the hilum to the cardiac apex. The expected location of the tricuspid valve is at the junction of the anterior and middle thirds of the line. The mitral valve is at the junction of the middle and posterior thirds, located just posterior to the line, and the aortic valve is located at that same location, but anterior to the line. On the frontal radiograph the tricuspid valve projects over the spine and has a vertical orientation. The mitral valve is located more cephalad and to the left of the spine[17] (**see Chapter 67**).

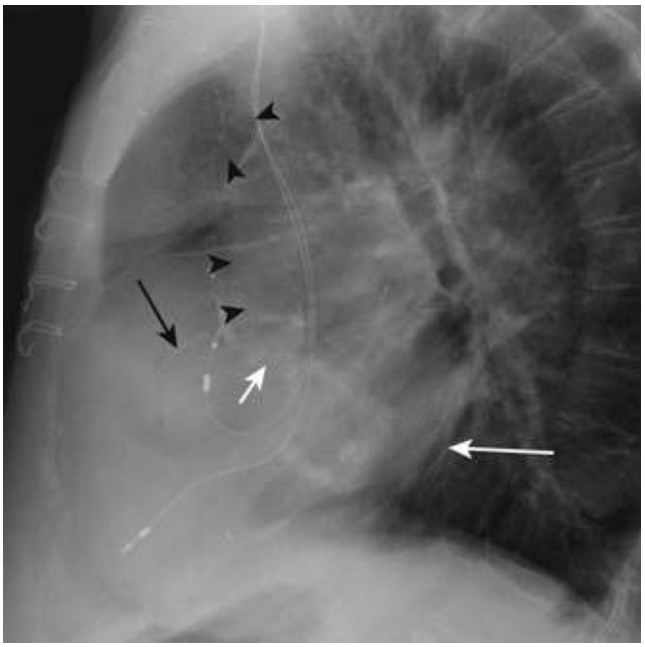
Valvular calcifications are only visible when very dense. Practically, only aortic valve and mitral annulus calcifications tend to be seen on CXRs. The lateral view is best for identifying calcifications of the valve leaflets and annulus. Manually adjusting the window setting of digital images can help reveal calcifications. In general, calcifications are best seen when oriented tangential to the x-ray beam.[18] **Table 15.2** provides the locations and appearance of various calcifications of the heart and vessels (**eFigs. 15.7 and 15.8**).

TABLE 15.2

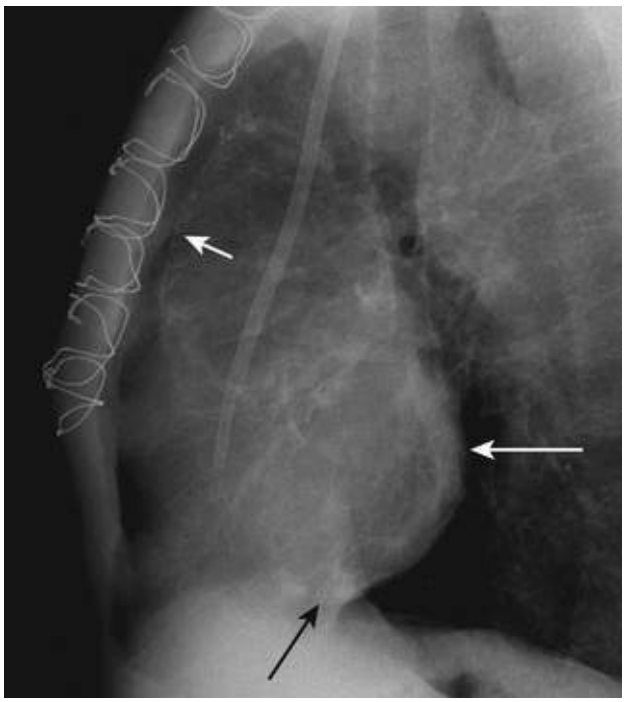
Cardiac Calcifications on a Chest Radiograph

LOCATION	EXAMPLE	LOCATION AND PATTERN OF CALCIFICATION
Myocardial wall	MI, left ventricular post-MI aneurysm	Apex or anterolateral walls of left ventricle
Left atrial wall	Longstanding mitral stenosis	Thin line roof of left atrium on lateral view
Pericardium	Calcific pericarditis	Most common in atrioventricular grooves and lateral to right atrial and right ventricular walls; not likely to involve the apex
Mitral annulus	Tumefactive calcification	Crescentic, reverse-C, or sometimes O-shaped coarse calcification
Mitral valve	Mitral stenosis	Lumplike mass in center of the expected location of mitral annulus
Aortic annulus and valve	Aortic stenosis	Irregular ring of dense calcification, which can also extend to the ring center when the leaflets are also calcified
Coronary artery	Atherosclerosis, aneurysms	Parallel lines (“train tracks”) when imaged along its length, and ring of calcification when imaged end on

MI, Myocardial infarction.



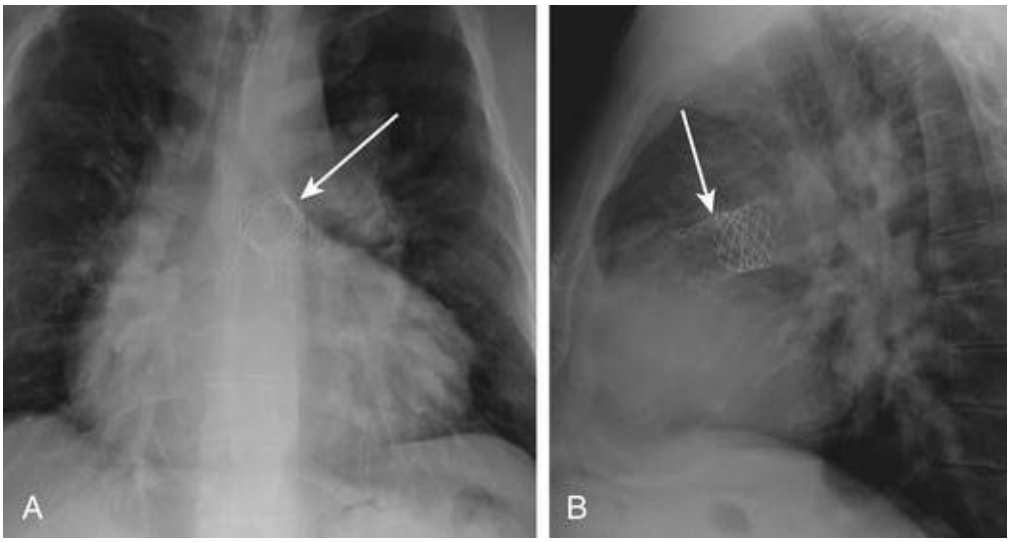
EFIGURE 15.7 Calcifications of the heart. Coned-down lateral chest radiograph of patient with known aortic stenosis shows nodular calcification in the expected location of the aortic valve (*short white arrow*), in addition to the reverse-C configuration of mitral annulus calcification (*long white arrow*). The *black arrowheads* depict atherosclerotic calcification of the anterior wall of the ascending aorta. A curvilinear calcific density crossing the aortic root and coursing anteriorly toward the apex (*black arrow*) represents calcification of the wall of the left anterior descending coronary artery.



EFIGURE 15.8 Calcifications of the heart. Coned-down lateral chest radiograph of patient with end-stage renal failure and heterotopic calcification of the myocardium. A dense, curvilinear, calcific density along the upper posterior cardiac border represents a densely calcified left atrial wall (*long white arrow*). This extends inferiorly also to involve the wall of the left ventricle (*black arrow*). Extensive atherosclerotic calcification of the ascending aorta is also present (*short white arrow*).

The aortic valve is located adjacent to the mitral valve, located slightly more anteriorly and superiorly, with a relatively more horizontal orientation. It projects over the spine on the frontal radiograph, making it difficult to visualize. The pulmonic valve is located superiorly above the expected location of the

RVOT, medial and caudal to the contour of the MPA (**eFig. 15.9**).



EFIGURE 15.9 Location of the right ventricular outflow tract. Frontal **(A)** and lateral **(B)** views of the chest show two Melody valves (*arrow*) placed in tandem in the pulmonary artery annulus and main pulmonary artery. This patient had a history of repaired tetralogy of Fallot and later developed moderately severe pulmonic regurgitation requiring placement of a Melody valve.

Diseases of the cardiac valves tend to cause specific cardiac chamber enlargement, instead of the global cardiomegaly typically seen with congestive heart failure. Stenotic valve diseases cause pressure overload of the chamber immediately proximal to the valve, leading to single-chamber enlargement. An example is mitral stenosis (MS), which causes marked LAE without LV dilation or hypertrophy (**see Chapter 69**). This is only true when complications of longstanding pressures have not yet developed, such as pulmonary hypertension from longstanding MS, in which the right ventricle also becomes enlarged. Moderate to severe regurgitation of a valve causes volume overload, which results in dilation of the cardiac chambers proximal and distal to the diseased valve.[18]

MS is responsible for the most severe enlargement of the LA on a chest radiograph, without significant LV enlargement. The left atrium can become so dilated that its lateral margin extends beyond the right atrial border. In such cases, on the frontal view the right cardiac border is created by the greatly enlarged let atrium. Chronic severe PVH combined with marked LAE can create the “Viking helmet” sign, with the enlarged vessels in the upper lobes representing the horns on the helmet (the heart) (**Fig. 15.6**). LA wall calcification is common in severe MS. This calcification appears linear and follows the expected contours of the left atrium, best seen on the lateral view [**see eFig. 15.7**]. Unlike MS, mitral regurgitation (MR) results in both LA and LV enlargement. The eccentric jet of regurgitation can be directed toward the ostium of the right superior pulmonary vein, leading to an asymmetric pulmonary edema in the right upper lobe[19] (**eFig. 15.10**).

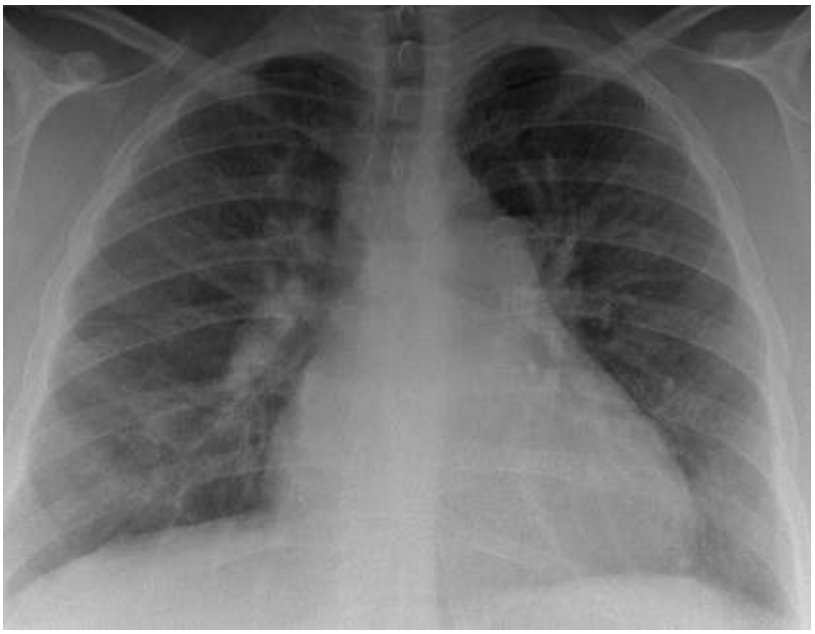


FIGURE 15.6 "Viking helmet" sign. PA radiograph of patient with known rheumatic heart disease and mitral stenosis shows cephalization of the upper lobe vessels, creating the Viking helmet sign. The left cardiac border is flattened because of left atrial enlargement, and the main pulmonary artery contour is enlarged from the ensuing pulmonary hypertension.

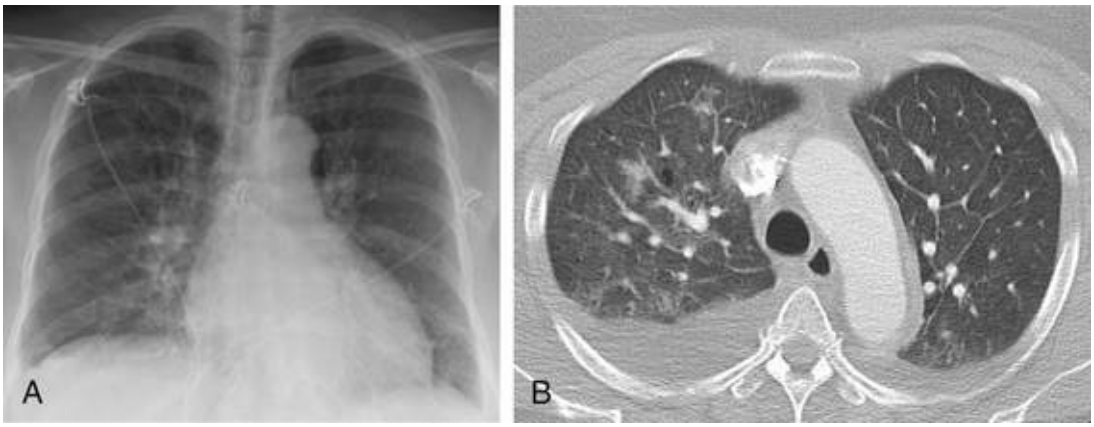
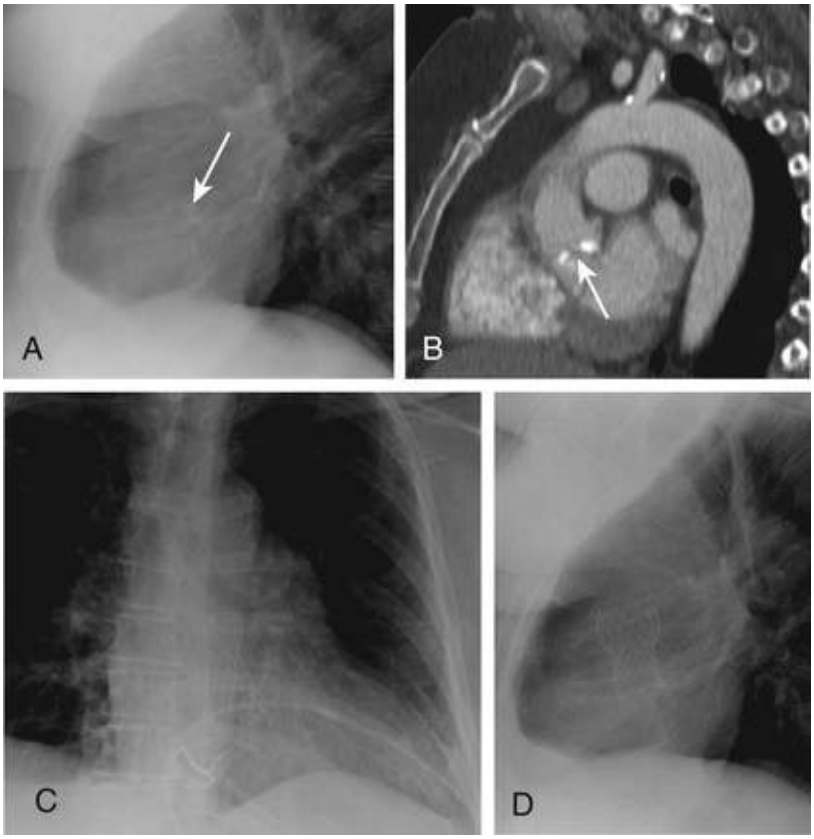


EFIGURE 15.10 Asymmetric pulmonary edema in 56-year-old woman with acute dyspnea was evaluated with CXR and CT to rule out pulmonary embolism. **A,** CXR showed mildly dilated, right upper lobe pulmonary vasculature, relative to that of the left upper lobe. **B,** CT image acquired 2 hours later revealed ground-glass opacities only involving the right upper lobe and representing early asymmetric pulmonary edema. There are also bilateral pleural effusions. Further laboratory workup excluded an infection and also revealed elevated troponin levels resulting from an acute myocardial infarction. Echocardiography showed mild to moderate mitral regurgitation and left ventricular ejection fraction of 30%.

Rarely, severe MR may present with fibrosis and areas of osseous metaplasia in the lungs from microhemorrhages secondary to elevated venous pressures. These tiny calcifications overlap calcified granulomas on CXR.[20]

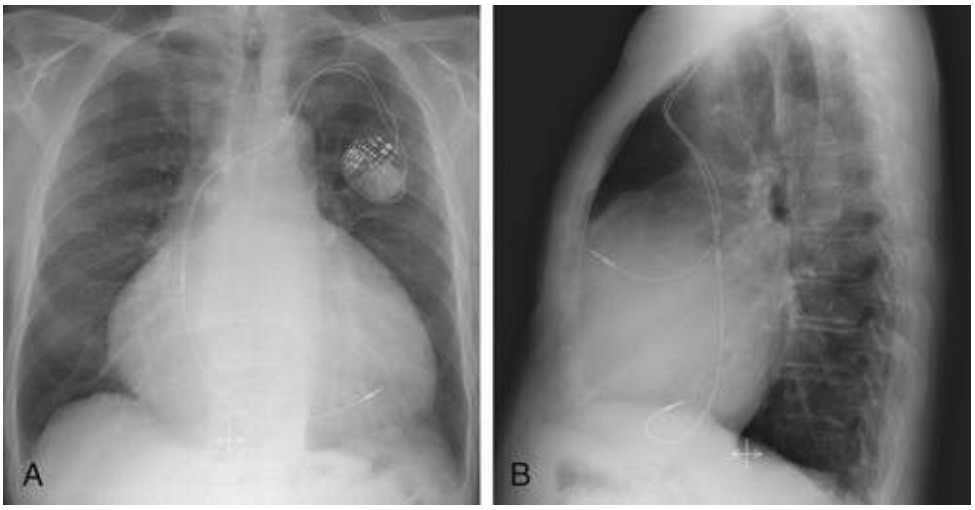
Chronic enlargement of the ascending aorta in the absence of systemic arterial hypertension, atherosclerotic aortic aneurysm, or type A aortic dissection should suggest aortic valve disease (**see Chapter 68**). If there is also LV dilation, aortic regurgitation should be the main consideration. However, if the LV size is normal, aortic stenosis (especially from a bicuspid aortic valve) should be suspected. Dilation of the ascending aorta on the PA view appears as an abnormal, smooth, convex contour superior to the expected location of the right atrium. On the lateral view the upper ascending aorta can be seen as

an upward convexity located posterior and slightly superior to the contour of the RVOT (**eFig. 15.11**). Severe calcification of the aortic valve leaflets in aortic stenosis is difficult to visualize on a chest radiograph and can sometimes be identified on the lateral view.[21]



EFIGURE 15.11 Aortic stenosis before and after repair. **A,** Lateral chest radiograph of elderly patient with severe aortic stenosis shows an irregular, ringlike calcification (*arrow*) in the expected location of the aortic valve. **B,** Corresponding CT image reconstructed in the sagittal plane across the valve shows densely calcified aortic valve leaflets (*arrow*), in keeping with patient history of stenosis. The location corresponds with the abnormality seen on the lateral chest radiograph. Coned-down images of the frontal **(C)** and lateral **(D)** chest radiographs obtained after transcatheter aortic valve replacement display the location of the valve replacement. Note that dark windowing of the images may be required to better visualize metallic hardware and calcifications.

Tricuspid valve stenosis (TS) is quite rare and only seen in congenital stenosis (**see Chapter 70**). Tricuspid regurgitation (TR) is much more common and may be seen in Ebstein anomaly (**Chapter 75**). In TS or TR the right atrium becomes extremely enlarged (**eFig. 15.12**). Acquired TS is seen with rheumatic heart disease and is frequently accompanied by valvular regurgitation caused by deformity of the leaflets. TR is most often encountered as a result of right heart failure secondary to left heart failure and from pulmonary hypertension. TR leads to both RA and RV enlargement on the CXR.[21,22]



EFIGURE 15.12 Right atrial and right ventricular enlargement in Ebstein anomaly. **A,** PA radiograph shows enlargement of the cardiac silhouette. The marked convexity of the right cardiac border is caused by the extremely dilated right atrium. The right ventricle is also much enlarged, as evidenced by the left lateral displacement of the right location of the tip of the ventricular lead of the cardiac pacemaker, which is located in the right ventricle. **B,** Lateral view reveals the long length of contact of the anterior cardiac border with the sternum, indicative of overall RV enlargement.

Pulmonic stenosis is most often a congenital anomaly and tends to manifest with RV enlargement accompanied by a very prominent MPA contour on the frontal view (**see Chapter 70**). The LPA also becomes enlarged, whereas the RPA size remains normal. The size of the RPA and LPA are best identified on the lateral chest radiograph[23] (**Fig. 15.7**).

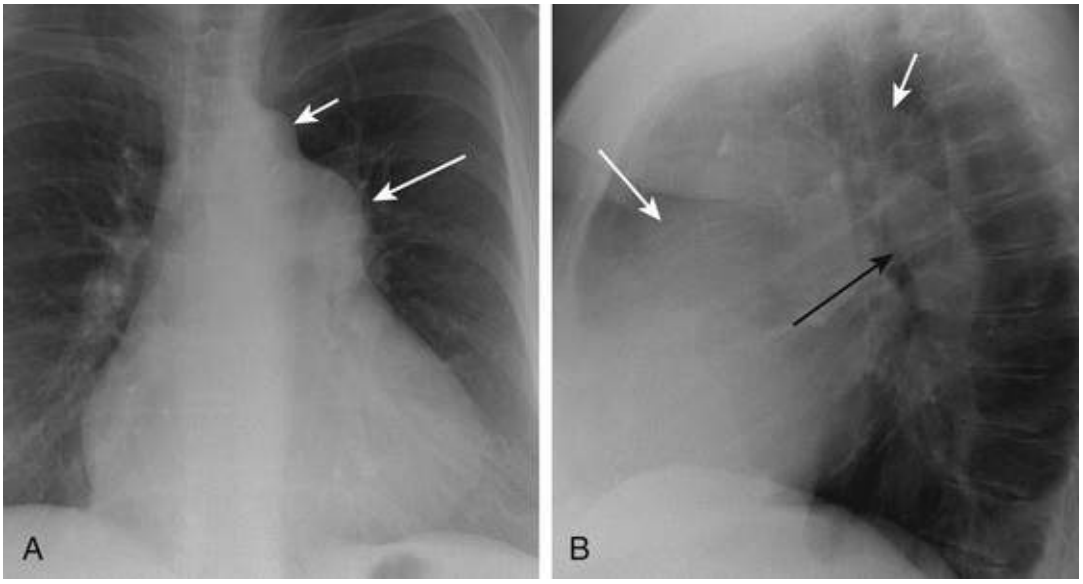


FIGURE 15.7 Congenital pulmonic stenosis. **A,** PA radiograph demonstrates marked enlargement of the main pulmonary artery (MPA) (*long white arrow*), such that it is larger the aorta (*short white arrow*). Note that the right pulmonary artery and its branches are normal sized, and the enlarged left pulmonary artery (LPA) is hidden behind the dilated MPA. **B,** On the lateral view the retrosternal space is filled by the enlarged right ventricle and the dilated MPA, which causes a masslike density with an upward convexity (*long white arrow*). Note dilated LPA (*long black arrow*) relative to the aorta (*short white arrow*).

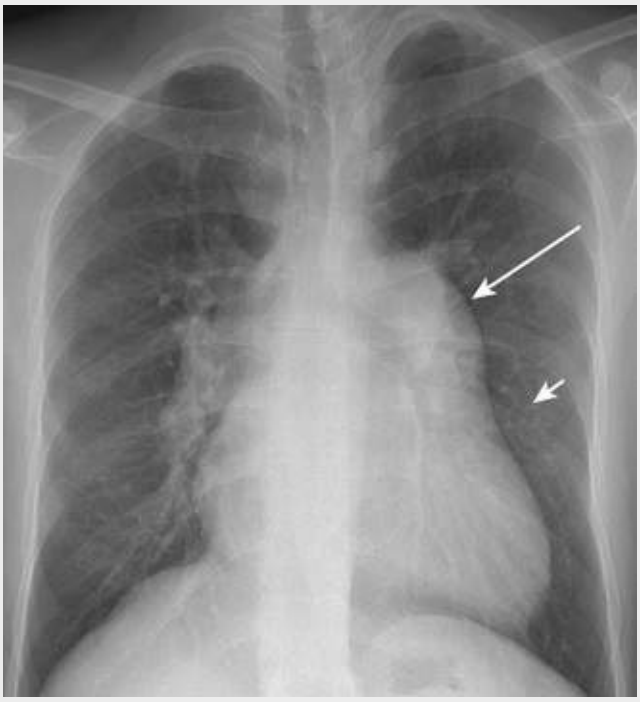
Pulmonary Hypertension

Pulmonary hypertension (PH) may result from intrinsic conditions involving the pulmonary arterial wall

or may occur in the setting of other conditions, such as chronic left heart disease, interstitial lung disease, or chronic pulmonary thromboembolism (**see Chapter 85**). Regardless of the cause, PH will manifest with RV, RA, and MPA enlargement. The degree of central RPA and LPA enlargement is directly proportional to the severity of the PH.

CXR and CT examination of these patients is usually performed to help identify the cause of the PH. Evidence of severe mitral or aortic valve disease or underlying lung disease can be detected on CXRs. "Pruning" of the pulmonary vasculature, whereby the enlarged pulmonary arteries abruptly taper so that the outer 2 cm of the lung appears devoid of vasculature, can be seen in many causes of severe PH, most notably idiopathic PH, Eisenmenger syndrome, and chronic thromboembolic disease[24] (**eFig. 15.13**).



EFIGURE 15.13 Eisenmenger syndrome (phenomenon). PA chest radiograph of an adult patient with untreated ventricular septal defect and pulmonary hypertension caused by development of Eisenmenger syndrome. Marked enlargement of the main pulmonary artery contour (*long arrow*) and overall enlargement of the heart result from an enlarged right ventricle and right atrium, in keeping with the severe pulmonary hypertension. Central pulmonary arteries in the hila are enlarged, with multiple smaller arterial branches peripheral to the hila indicating shunt vascularity (*short arrow*). The inferior vena cava contour is displaced posteriorly because of the right atrial dilation. Crosshairs placed during acquisition of the radiograph project over the diaphragm and to the right of (which means posterior to) the IVC.

Congenital Heart Diseases

In the clinical evaluation of patients with congenital heart disease (CHD), it is important to know if the patient is cyanotic (indicative of a right-to-left shunt) or acyanotic (**see Chapter 75**). On the CXR, the clinician must determine if there is an enlarged cardiac silhouette and whether the pulmonary vascularity is normal, disorganized, decreased, or increased.[25,26] The specific imaging findings of some of the more common CHDs are discussed here.

Atrial and ventricular septal defects (ASDs and VSDs), partial anomalous pulmonary venous connections (PAPVCs), and patent ductus arteriosus (PDA) are acyanotic CHDs associated with a left-to-right shunt. This shunting increases the size and sometimes tortuosity of the pulmonary arterial branches, creating the characteristic "shunt vascularity" on a CXR. Unlike the pruning seen with PH, shunt vascularity does not taper and results in vessels that can be seen all the way to the pleural surface.

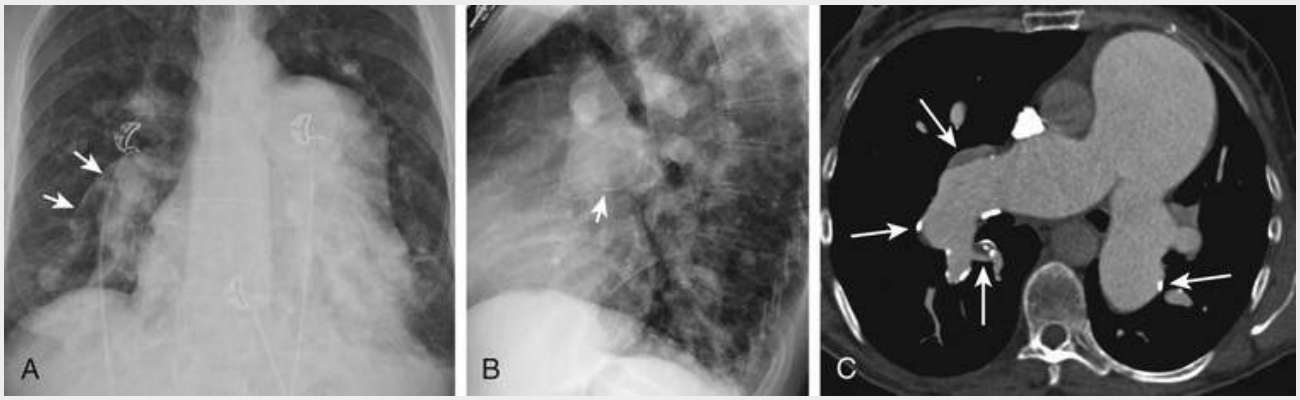
For this finding to become evident, a 2 : 1 shunt must exist (**eFig. 15.14**).

EFIGURE 15.14 Shunt vascularity. Preoperative AP chest radiograph of 4-month-old infant with ventricular septal defect. Dilated peripheral arterial branches extend to the pleura because of shunt vascularity. There is mild pulmonary edema. The left ventricle and left atrium are enlarged, resulting in an overall enlargement of the cardiac silhouette, displacement of the cardiac apex leftward and toward the diaphragm, and flattening of the upper left cardiac border. The internal and external portions of the nasogastric tube are noted.

In the setting of a shunt, the receiving cardiac chamber or vessel becomes enlarged. With an ASD, the right atrium, right ventricle, and MPA will be enlarged. VSDs tend to spare the right atrium to some degree but also result in LA dilation, unlike an ASD. In PAPVC a pulmonary vein drains into a systemic vessel (brachiocephalic vein, SVC, or IVC) leading to RA and RV enlargement. The aortic arch is not enlarged in ASDs, VSDs, or PAPVCs. Isolated PDA causes shunting from the proximal descending aorta into the MPA. This results in increased flow through the lungs and the left heart. Therefore, expected chest radiographic findings in addition to shunt vascularity are LA and LV enlargement. PDA is the only entity in this category where the aortic arch is enlarged.[27]

Longstanding shunting through the pulmonary arterial tree may eventually lead to pulmonary hypertension (Eisenmenger syndrome). Findings are similar to other causes of PH described earlier. One useful finding is calcification of the pulmonary arterial wall (similar to aortic atherosclerosis), which can be rarely seen when the shunting has been longstanding.[27,28] In fact, we have found that enlarged,

calcified pulmonary arteries on a CXR are almost secondary to a longstanding left-to-right shunt, usually an ASD (**eFig. 15.15**).



EFIGURE 15.15 Pulmonary arterial wall calcification caused by chronic shunting. Coned-down frontal **(A)** and lateral **(B)** chest radiographs of 45-year-old woman with newly discovered severe pulmonary hypertension resulting from a large untreated atrial septal defect. *Arrows* indicate the linear calcification of the right pulmonary artery wall. Note the greatly enlarged main pulmonary artery and the shunt vascularity in the lung parenchyma. **C,** Both calcified and noncalcified plaques along the walls of the very large pulmonary arteries (*arrows*) are well displayed by the contrast-enhanced CT image.

Tetralogy of Fallot is a cyanotic CHD in which the characteristic lesion of pulmonary or infundibular stenosis results in diminished pulmonary vascularity. The contour of the MPA may range from nearly normal to absent or very small. Even though the overall cardiac size is not enlarged, in tetralogy of Fallot the right ventricle is hypertrophied and dilated, pushing and rotating the heart into the left hemithorax. The right ventricle forms the cardiac apex, which is frequently directed upward, creating a boot-shaped heart (**see Fig. 15.4**). A right-sided aortic arch is present in up to 25% of patients, which appears as an absent left-sided aortic knob and an upper mediastinal outward bulge in the right paratracheal region.[29]

Coronary Artery Disease

Coronary artery abnormalities are best assessed by conventional angiography and contrast-enhanced CT angiography (**see Chapters 18 and 20**). In this section we discuss incidental coronary artery calcification, the role of a CXR after an acute myocardial infarction (MI), and the expected and unexpected radiographic findings after coronary artery bypass graft (CABG) surgery.

Atherosclerotic Calcification

Coronary artery calcifications are often discovered incidentally on a CXR. Cardiac motion blurs less dense calcification, while overlying soft tissues make the detection of subtle calcification impossible. Dual-energy subtraction chest radiography increases the sensitivity in detection of coronary artery calcification on CXR. This technique takes advantage of the differences between varying tissue attenuation of low- and high-energy photons, allowing for creation of calcium-only images.[30]

On the frontal CXR, the left main, left anterior descending (LAD), and left circumflex arteries and their proximal branches can be found at a site known as the “coronary artery calcification triangle.” This is best defined as a triangular area located in the left midheart immediately medial to the outer contour of the LA appendage, just below the level of the left main bronchus. This border forms the oblique side of the triangle. The other two sides are formed by the left border of the vertebral column and a horizontal line

drawn from the vertebral column to the left cardiac border, at approximately one-third the distance from the left bronchus to the diaphragm[31] (see Classic References, Souza). On the lateral radiograph, both the right coronary artery (RCA) and the LAD course anteriorly, curving downward toward the anterior margin of the heart (**see eFig. 15.7**). Generally, the RCA is anterior to the course of the LAD, which crosses the ascending aorta on the lateral projection.

Coronary artery *stents* can sometimes be mistaken for coronary artery calcifications. If the image is acquired with less motion blur, the clinician will be able to identify the higher metal attenuation of a stent relative to calcium and the parallel line of the stent (**Fig. 15.8**).

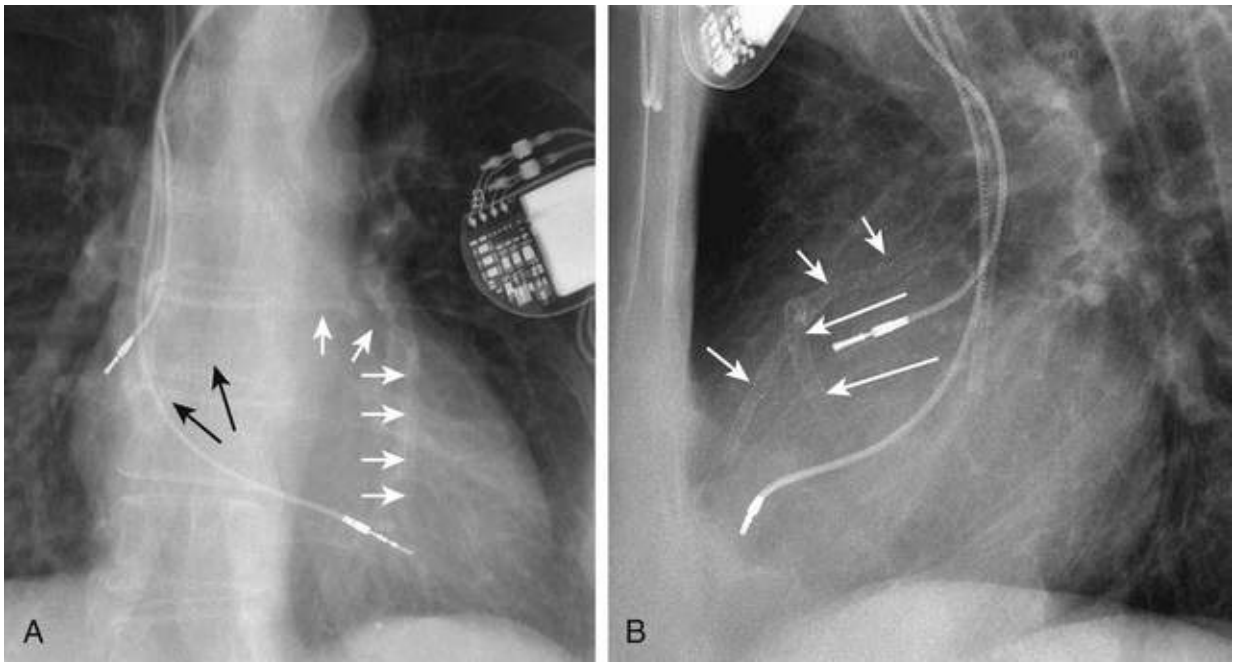


FIGURE 15.8 Coronary artery stents. Frontal **(A)** and lateral **(B)** views of the chest show coronary artery stents in a long length of the left anterior descending artery (LAD) (*short arrows*) and in the right coronary artery (RCA) (*long arrows*). On the frontal view the RCA is difficult to visualize because it projects over the spine. On the lateral view the courses of the LAD and RCA cross, such that the LAD extends more anteriorly toward the cardiac apex.

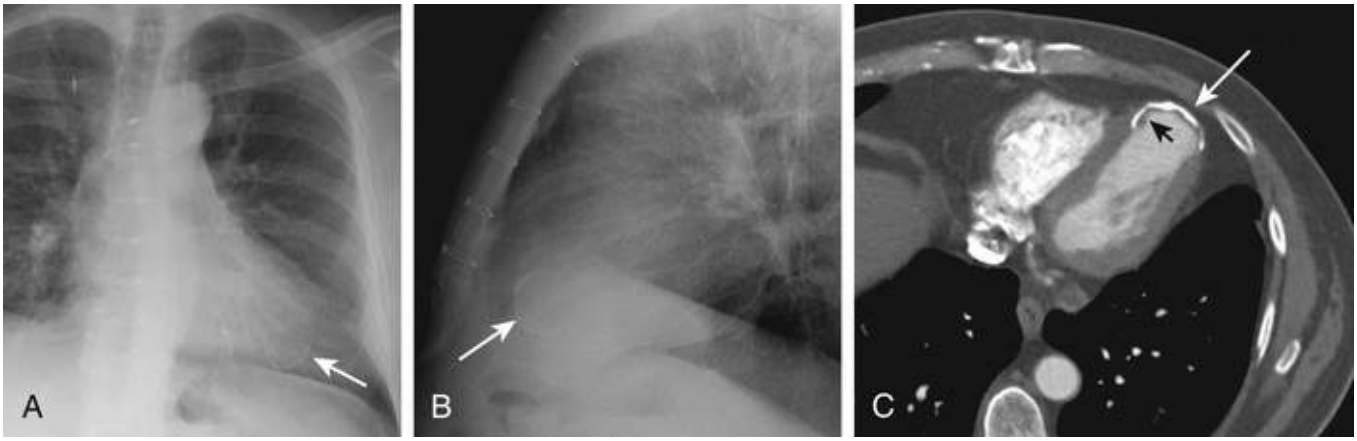
Coronary artery *aneurysms* tend to calcify and may be more easily appreciated on CXR than normal-sized calcified coronary arteries.[32] These coronary aneurysms are most often caused by atherosclerotic disease in Western countries and Kawasaki disease in the remainder of the world.

Acute Myocardial Infarction

Approximately half of patients presenting with an acute MI will have a normal CXR (see Classic References, Higgins).The abrupt dysfunction of the myocardium after an MI often leads to PVH and pulmonary edema. Unlike other causes of congestive heart failure, the heart size is usually normal, even with a large infarct. True and false aneurysms may develop after an MI. These may be recognized on CXR as a focal outpouching of the cardiac border on a chest radiograph, which may calcify. Other CXR findings include a double density sign at the expected locations of true and false LV aneurysms. True LV aneurysms are most often located at the LV apex and along the lateral wall and can present as a contour abnormality of the left cardiac border or a focal outpouching that could simulate a mass (**eFig. 15.16**). A false LV aneurysm is most frequently located along the inferolateral wall of the left ventricle and on the frontal view appears as a double density projecting over the heart, which would be more obvious on the

lateral view, where a saccular contour abnormality can be seen.[33]

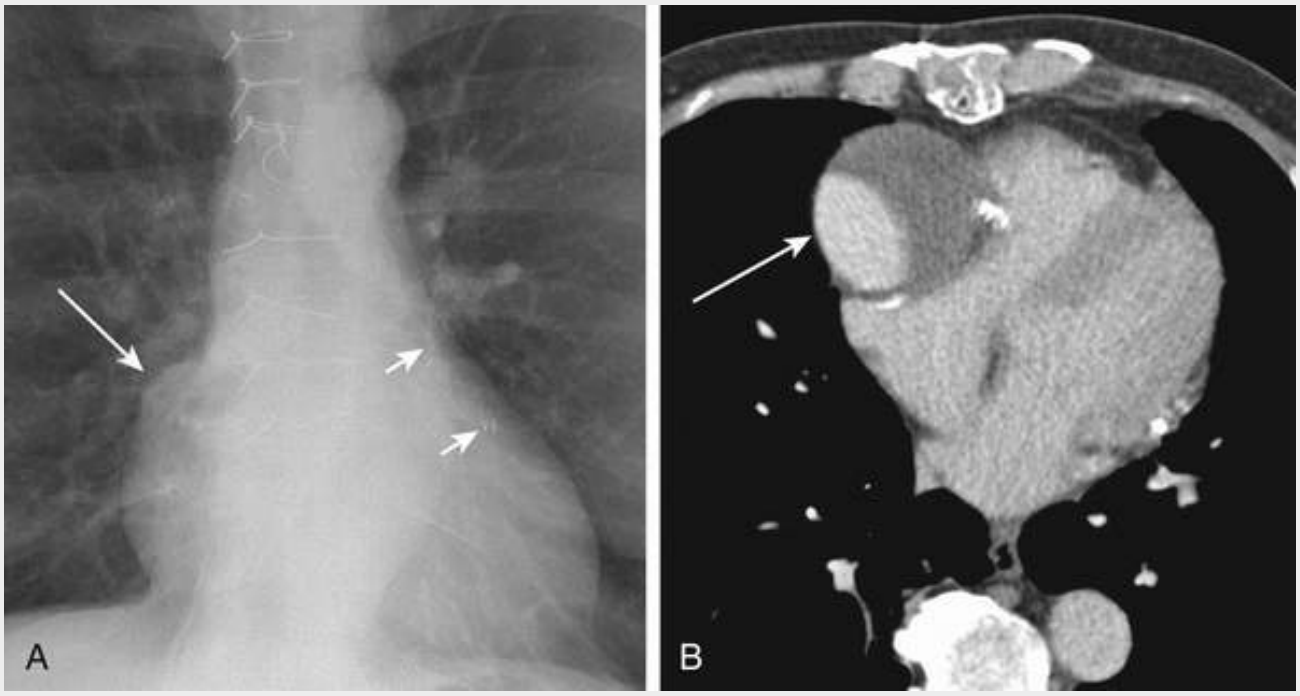


EFIGURE 15.16 True left ventricular aneurysm with myocardial calcification. Coned-down frontal **(A)** and lateral **(B)** chest radiographs demonstrate a curvilinear calcification in the region of the left ventricle (*arrows*). **C,** Coned-down contrast-enhanced axial CT image demonstrates the true aneurysm of the left ventricle apex (*arrow*) caused by a previous infarct. Its wall is calcified, with a thin margin of hypoattenuating thrombus along the luminal surface (*black arrow*).

Immediately after an acute MI, papillary muscle rupture can appear as sudden development of pulmonary edema as a result of MR (**see Chapter 58**). This edema is asymmetrically worse in the right upper lobe when the rupture is complete, similar to more chronic MR discussed previously. In the acute phase, cardiomegaly or LAE is not usually seen. Acute VSD has similar findings but is more often associated with mild cardiomegaly. If the patient survives these complications, the cardiomegaly could progress with development of both LA and LV enlargement.[34] Dressler syndrome most frequently occurs a few weeks to months after an MI and is caused by an autoimmune response to the antigens released by the dead myocytes. It presents as a late development of pericardial and pleural effusions.

Coronary Artery Bypass Grafts

The most common CABGs are saphenous vein grafts (SVGs) and internal mammary grafts. SVGs are anastomosed to the anterior wall of the ascending aorta above the level of the sinotubular junction of the aorta. A metallic ring or marker is usually placed, which helps identify the location of the ostium for future selective conventional coronary angiography. Shortly after CABG surgery, a pseudoaneurysm at the anastomosis site with the aorta can develop. Based on the size of the hematoma and pseudoaneurysm, this presents as a widened mediastinum on the frontal view and a masslike opacification in the retrosternal clear space on the lateral view. SVGs are more prone to intimal hyperplasia, wall calcification, and stenosis than their arterial counterparts and may develop true aneurysms anywhere along their course. These aneurysms tend to occur 10 to 20 years after bypass surgery. The calcification can be visible on chest radiography, and the aneurysms, which can be very large, may simulate a mass anywhere along the course of the SVG[35] (**eFig. 15.17**).



EFIGURE 15.17 Coronary artery bypass graft (CABG) aneurysm. **A,** Coned-down frontal view shows an abnormal budge along the upper margin of the cardiac border (*long arrow*) caused by an aneurysm of the saphenous vein CABG bypassing the right coronary artery. Surgical clips show the course of the left internal mammary artery CABG (*short arrows*) toward the left anterior descending coronary artery. **B,** Coned-down contrast-enhanced axial CT image demonstrates that this aneurysm (*arrow*) causes mass effect on the right atrium and right ventricle and contains an eccentric filling defect with a large amount of intraluminal thrombus.

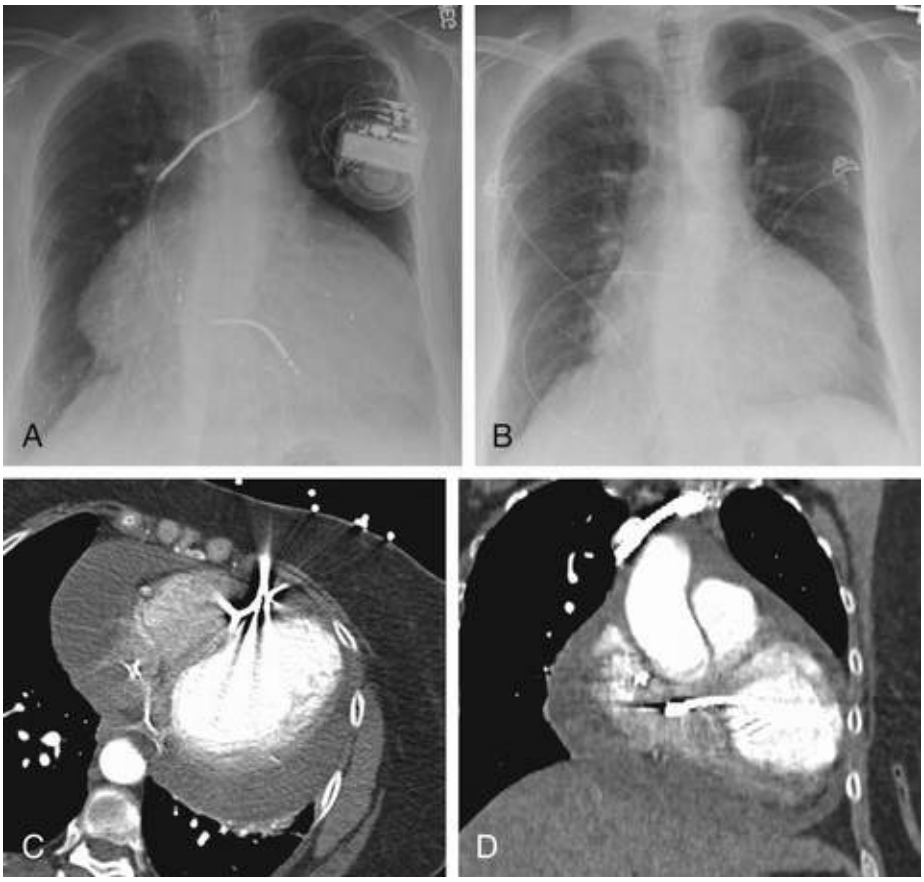
Internal mammary CABGs are more common on the left. Left internal mammary artery (LIMA) bypass grafts are anastomosed to the mid- to distal LAD or to a diagonal artery. The course of a LIMA graft can be followed on the frontal and lateral radiographs by the multiple metallic clips placed along its course. LIMA grafts have a vertical orientation on both PA and lateral views, coursing parallel to the mediastinum on the frontal view and posterior to the sternum on the lateral view. True aneurysms tend to be very unusual in LIMA grafts.

Pericardial Disease

Echocardiography is much more sensitive and specific in identifying pericardial disease than chest radiography (**see Chapters 14 and 83**).

Pericardial Effusion

The normal pericardium is composed of two layers, visceral and parietal, which form a thin sac containing 25 to 50 mL of fluid. With an increase in the amount of fluid, the overall size of the cardiac silhouette increases on CXR. This could be difficult to differentiate from global enlargement of the cardiac chambers, as seen with dilated cardiomyopathy. Any increase in the size of the cardiac silhouette (especially when acute) should suggest a pericardial effusion.[36] A large pericardial effusion may create a "water bottle" sign, where the right and lateral heart borders are straightened. Because the normal pericardial recesses become expanded by pleural fluid, this process may extend to the level of the aortic arch (**eFig. 15.18**).



EFIGURE 15.18 "Water bottle" sign of pericardial effusion. **A,** PA chest radiograph shows an extremely large cardiac silhouette, extending with the cardiac margins beginning higher than normal at the hilar level. **B,** Radiograph obtained 6 months earlier shows a more normal cardiac silhouette before the pericardial effusion developed. **C,** Contrast-enhanced CT axial image of the heart acquired at the time of the more recent radiograph shows a large pericardial effusion. **D,** On coronal reformatted image, the superior extent of the pericardial effusion into the pericardial recesses is displayed, creating the water bottle appearance.

On the lateral view a pericardial effusion may present as a vertical band of radiodensity (white or light gray) sandwiched by two radiolucent areas (dark gray). This is called the "fat pad" or "sandwich" sign and is visualized in the region of the cardiac apex close to the sternodiaphragmatic border. It is caused by separation of the epicardial and pericardial fat layers by the fluid in the pericardial sac (**Fig. 15.9**). Rarely a *variable density sign* can be seen, which appears as a band of greater lucency along the outer margin of the heart, parallel to the cardiac border. This sign is caused by decreased attenuation of the x-ray beam of the pericardial fluid compared with the more medial combination of pericardial fluid and myocardium (**eFig. 15.19**).

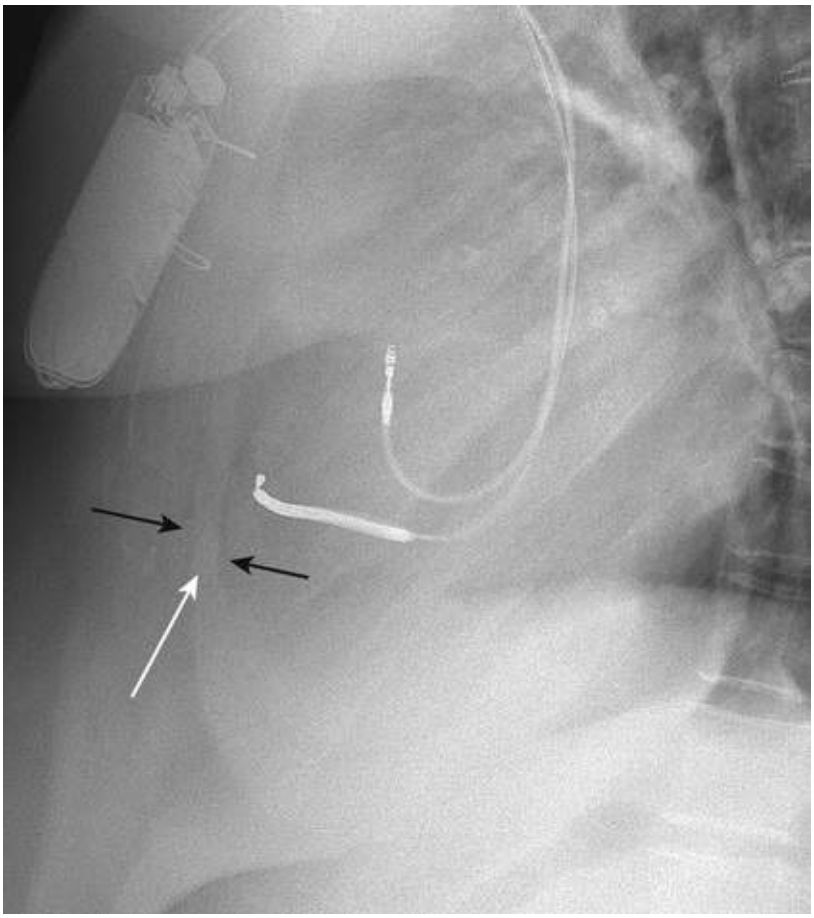


FIGURE 15.9 "Sandwich sign" of pericardial effusion. Coned-down lateral chest radiograph shows two dark bands of radiolucency (*black arrows*), separated by a band of radiodensity (*white arrow*), resulting from separation of the pericardial and epicardial fat pads by a moderate-sized pericardial effusion. The white band wraps around the inferior border of the heart, since the fluid tends to accumulate when standing.

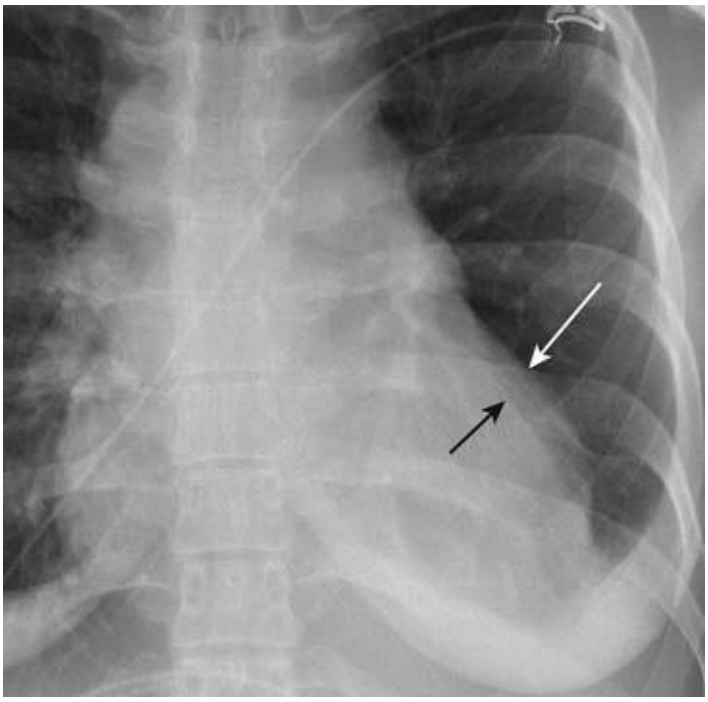
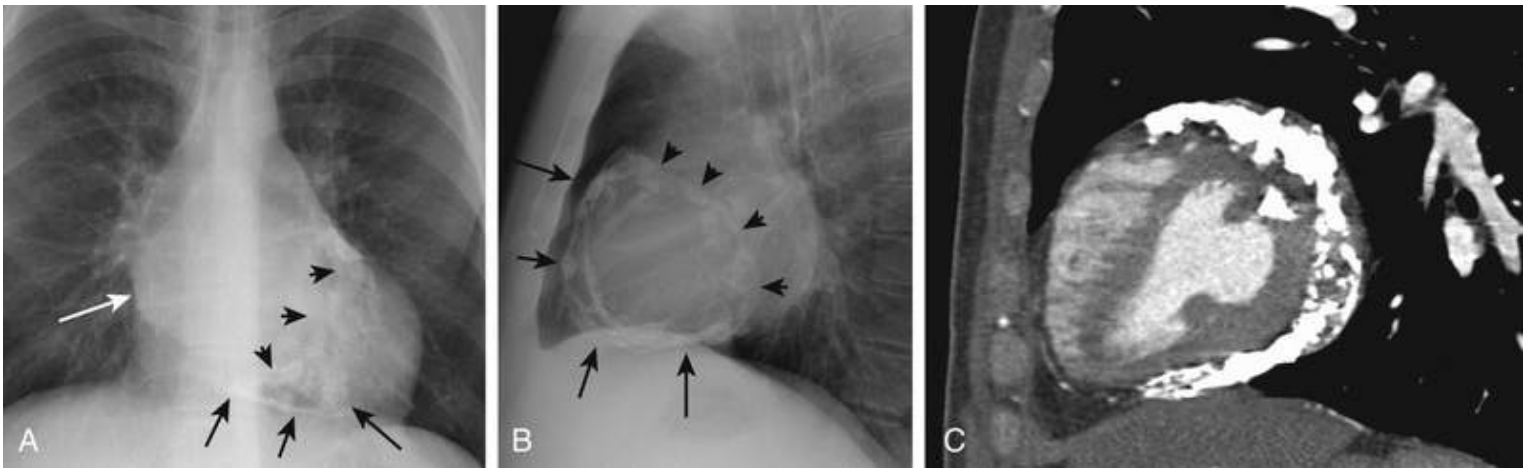


EFIGURE 15.19 Variable density sign of pericardial effusion. Coned-down PA radiograph shows a large cardiac silhouette caused by a known large pericardial effusion. There are two parallel lines along the left cardiac border; the medial line represents the margin of the myocardium (*black arrow*), and the lateral line represents the lateral margin of the visceral pericardium (*white arrow*). Note that patient also has a left pleural effusion.

Calcific Pericarditis

Calcific pericarditis may be associated with constrictive physiology. Pericardial calcification has a linear configuration and may be only visible on one view. It differs from LA calcification in that it is anteriorly located and often creates a ring along the expected location of the atrioventricular grooves.[37] **Table 15.2** compares various calcifications of the heart.

The most common site of pericardial calcification is along the atrioventricular (AV) groove and along the RV free wall. This pattern may impede diastolic relaxation of the right ventricle.[38] The overall heart size is normal on the CXR, even though on echocardiography, CT, and magnetic resonance imaging (MRI), dilation of the atria may be seen (**eFig. 15.20**). Other common sites of pericardial calcification and thickening include just anterior to the RVOT behind the sternum and along the LV free wall close to the left AV groove. In the latter situation, cephalization of the pulmonary vascularization and eventually edema and pleural effusions may be seen from increased left heart pressures.

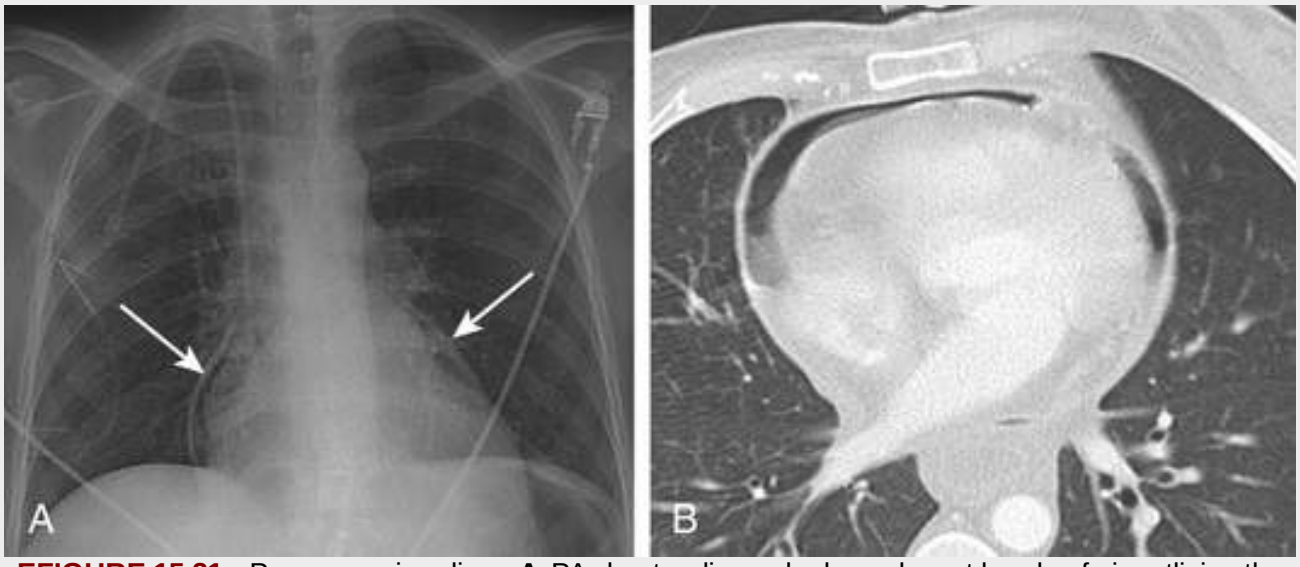


EFIGURE 15.20 Calcific pericarditis. **A,** Coned-down PA chest radiograph shows a nodular band of calcification (*black arrows*) projecting over the heart along the expected location of the left atrioventricular (AV) groove (*short black arrows*). There is also linear calcification along the inferior margin of the heart (*long black arrows*). Note the double density sign indicating left atrial dilation (*white arrow*). **B,** Lateral view shows a band of extensive calcification projecting over the heart, again in the AV groove (*black arrowheads*) and also around the apex and anterior and inferior walls of the right ventricle (*black arrows*). **C,** CT image depicts the extensive pericardial calcification.

Pneumopericardium

A pneumopericardium is most frequently seen after cardiac surgery or after placement of a surgical drain. It can rarely be caused by traumatic injury in which the pericardial space communicates with a pneumothorax. Other rare causes of pneumopericardium include infection and pericardial fistulas after esophageal dilation procedures or after ulceration of a hiatal hernia.

The CXR finding relies on the detection of gas along the cardiac border that does not extend above the aortic knob (where the pericardial recesses reflect). A pneumopericardium can accumulate along the anterior and inferior surface of the heart, appearing as a horizontal lucent (dark) line projecting over the lower heart close to diaphragm on the frontal radiograph[39] (**eFig. 15.21**).

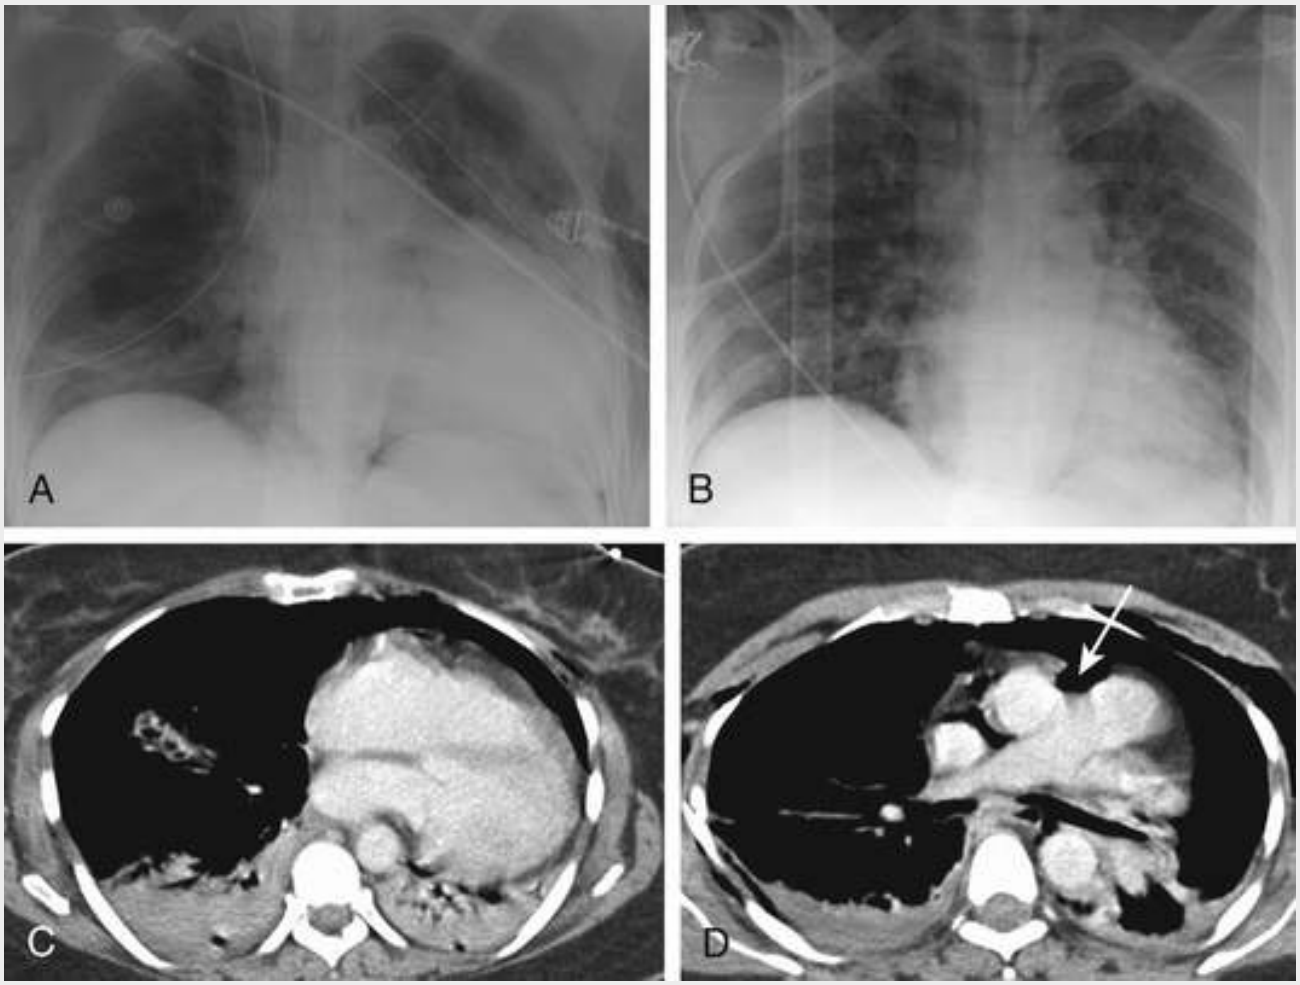


EFIGURE 15.21 Pneumopericardium. **A,** PA chest radiograph shows lucent bands of air outlining the right and left cardiac borders. A radiodense band outlining the pneumopericardium represents the thickening visceral pericardium (*arrows*). **B,** CT image obtained the same day demonstrates the small pneumopericardium, which developed after endoscopic balloon dilation of a distal esophageal stricture with a small fistula to the pericardium.

The pericardium is a true potential space, so gas within it tends to be uniformly lucent and moves with changes in patient positioning. These features are useful in distinguishing a pneumopericardium from a pneumomediastinum, which usually has thin strands of tissue from gas dissecting in the false space of the mediastinum and does not move with changes in positioning (e.g., lateral decubitus). When the gas extends above the aortic knob, it is also more typical of a pneumomediastinum than a pneumopericardium.

Congenital Absence of the Pericardium

Congenital absence of the pericardium is a rare condition that may involve absence of a portion of the pericardium, complete absence on one side, or bilateral absence. The ipsilateral medial pleura is usually also absent, resulting in direct communication between the pleural and pericardial spaces. Left complete absence is more common than right, and complete unilateral absence is more common than partial. Complete absence of the entire pericardium is rare. In absence of the entire left pericardium, the heart rotates into the left hemithorax and takes a somewhat tubular configuration. Another finding is separation of the aorta and MPA. This area is normally covered by the pericardium, which acts like a rubber band in keeping the two vessels together. In its absence the vessels separate, and lung insinuates into that space. Because of the rotation of the heart and separation of the aorta and the MPA, the frontal CXR will simulate a right anterior oblique projection despite the patient not being rotated (**eFig. 15.22**). In the era before widespread use of cardiac CT and MRI, diagnosis was confirmed by creating a small pneumothorax, which would extend around the heart through the absence. Another variant is absence of the diaphragmatic pericardium, in which the left lung could herniate under the rotated heart, creating a lucent band between the heart and the diaphragm.



EFIGURE 15.22 Partial absence of the pericardium. **A,** Portable AP chest radiograph of patient with multiple injuries from a motor vehicle accident shows leftward rotation of the heart (patient not rotated during imaging). **B,** AP radiograph obtained 4 hours earlier shows normal appearance of the heart, indicating that this is an acquired absence of the pericardium, with the heart herniating through the defect. CT images at the level of the ventricle **(C)** and the upper mediastinum **(D)** show marked leftward rotation of the heart, such that it drapes over the descending aorta **(C),** and no pericardium covering the space between the ascending aorta and the main pulmonary artery, allowing the lung to extend into that space (*arrow*).

Although partial absence of one side of the pericardium is not as common, it is potentially more dangerous. If a small portion of the heart, such as the atrial appendage, herniates through the defect, it may become strangulated. A change in the contour of the cardiac silhouette should raise concern for strangulation in a patient with known partial absence of the pericardium.[40]

Diseases of the Aorta

Aortic abnormalities of various causes have similar chest radiographic manifestations, making the clinical history and symptoms even more important in correctly diagnosing aortic conditions (**see Chapter 63**). In this section we discuss the specific radiographic findings of three groups: patients presenting after trauma, patients with acute chest pain because of an acute aorta syndrome, and patients with congenital aortic anomalies that may be discovered incidentally or from compressive symptoms.

Acute Traumatic Aortic Injury

Blunt acute traumatic aortic injury (ATAI) may result from rapid deceleration, as seen with motor vehicle crashes, falls, or direct crush injury. In these situations the aortic wall is disrupted, with development of a mediastinal hematoma of varying size. The injuries may range from a minimal intimal injury to complete

transection. The role of the CXR has continued to diminish in the multidetector CT era but is mainly to exclude a mediastinal hematoma in low-level trauma when the patient is asymptomatic (and able to verbalize the lack of symptoms). In the acute setting, radiographic findings are indicative of a mediastinal hematoma, which tends to be largest at the site of vascular wall injury. Most imaged aortic injuries occur at the level of the aortic isthmus (just distal to the left subclavian artery) because of the ligamentum arteriosum. Such injury presents with a mediastinum greater than 8 cm in width at the level of the top of the aortic arch (knob); an indistinct or enlarged contour of the aortic knob; an extra density extending from the left side of the mediastinum to the left lung apex (apical capping); rightward displacement of the trachea at the level of the third and fourth thoracic vertebral bodies; downward displacement of the left main bronchus to greater than 140 degrees from the trachea; and sometimes a left hemothorax (**Fig. 15.10**).

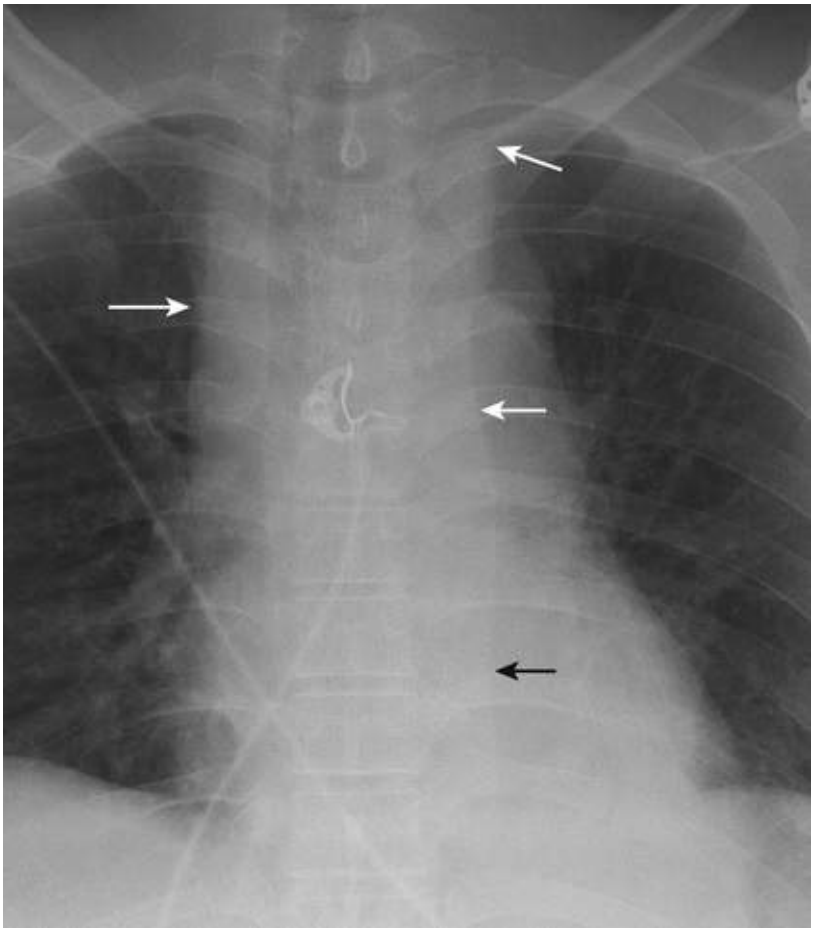


FIGURE 15.10 Mediastinal hematoma. Coned-down AP radiograph of young man who was a driver in a motor vehicle accident shows mediastinal widening (*arrows*) caused by acute traumatic aortic injury, which caused a large mediastinal hematoma. The displacement of the paravertebral line on the left extends to the left lung apex ("apical capping"). Note that the trachea is deviated to the right, and the left main bronchus is displaced inferiorly.

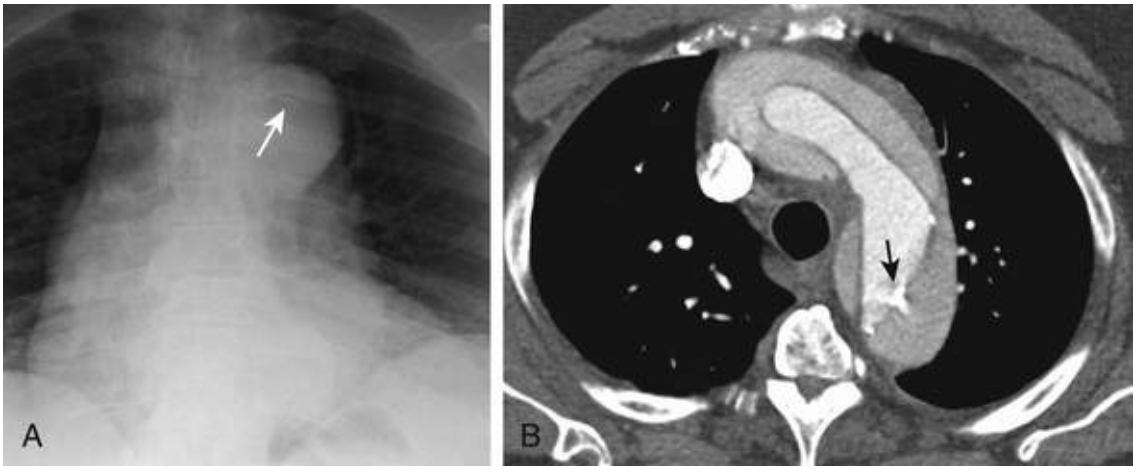
In the chronic setting where the ATAI has gone unrecognized and the mediastinal hematoma has resolved, an aortic *pseudoaneurysm* may be visible at the level of the isthmus. Although pseudoaneurysms can be subtle, they tend to have calcium along their undersurface; this allows them to be distinguished from atherosclerosis, which tends to be along the superior aspect of the aortic knob. If the ATAI results in traumatic injury to the great arterial branches of the aorta, there would be right-sided mediastinal widening, high-riding hematoma, and right apical capping.[41]

Aortic Aneurysm

Aneurysmal dilation of the aorta is most frequently caused by atherosclerotic disease but can also result from dissection, penetrating atherosclerotic ulcer, inheritable aortopathies (e.g., bicuspid aortopathy, Marfan disease), infectious aortitis, or vasculitis (e.g., Takayasu disease). The patient usually presents with acute chest pain when the aneurysm is unstable. Clearly, these patients will need full evaluation with cross-sectional imaging.

The radiographic findings include an enlarged contour or additional convexity along the expected course of the aorta in the mediastinum. On the frontal view, an aneurysmal ascending aorta presents as a widened right side of the mediastinum because of an additional convexity at the level of right cardiac border and just above it. On the lateral view, it appears as an additional convexity in the retrosternal space projecting over the MPA contour. Aneurysm of the aortic arch and descending aorta are easier to visualize on the PA and lateral views than aneurysm of the ascending aorta. A *saccular* aneurysm creates a masslike focal outpouching, whereas a *fusiform* aneurysm presents as alteration of a contour such as the aortic arch (knob). In situations where a mediastinal hematoma has developed, such as an acute aortic dissection or intramural hematoma, the imaging findings are similar to ATAI. An additional radiographic finding that can be seen with acute or chronic aortic dissection is the inward displacement of the calcified intima, which is most visible in the aortic arch when present[42] (**eFig. 15.23**).



EFIGURE 15.23 Displaced intimal calcification in aortic dissection. **A,** Frontal chest radiograph shows a curvilinear calcification (*arrow*) projecting over the aortic knob, located medial and parallel to the lateral contour of the aortic knob. **B,** Contrast enhanced CT obtained the same day shows an acute aortic dissection with a calcified intimal flap displaced medially toward the lumen (*arrow*).

Aortic Anomalies

Congenital anomalies of the aorta may present with stridor, dyspnea, and dysphagia, caused by compression of the trachea and esophagus. Many of these patients are asymptomatic and discovered incidentally. A *right-sided aortic arch* presents with an absent aortic contour on the left side of the mediastinum but with an abnormal contour on the right side. The trachea is deviated to the left by the right arch. This entity could be associated with tetralogy of Fallot, in which case a boot-shaped heart would also be present (**see Fig. 15.4**). A *double aortic arch* is a vascular ring in which the right arch is located more superiorly than the left arch.[43] The right arch is typically larger than the left (**Fig. 15.11**). *Aberrant right subclavian artery* (RSCA) is a common normal variant, in which the RSCA arises directly from the posterior aortic arch after the origin of the left subclavian artery. It ascends in the mediastinum after

passing between the spine and the esophagus. Aberrant RSCA is sometimes visible on a chest radiograph when there is a *diverticulum of Kommerell* at the origin of the aberrant RSCA. This diverticulum can become aneurysmal, in which case it appears as a poorly defined mass posterior to the trachea and superior to the aortic arch on the lateral view (**eFig. 15.24**).

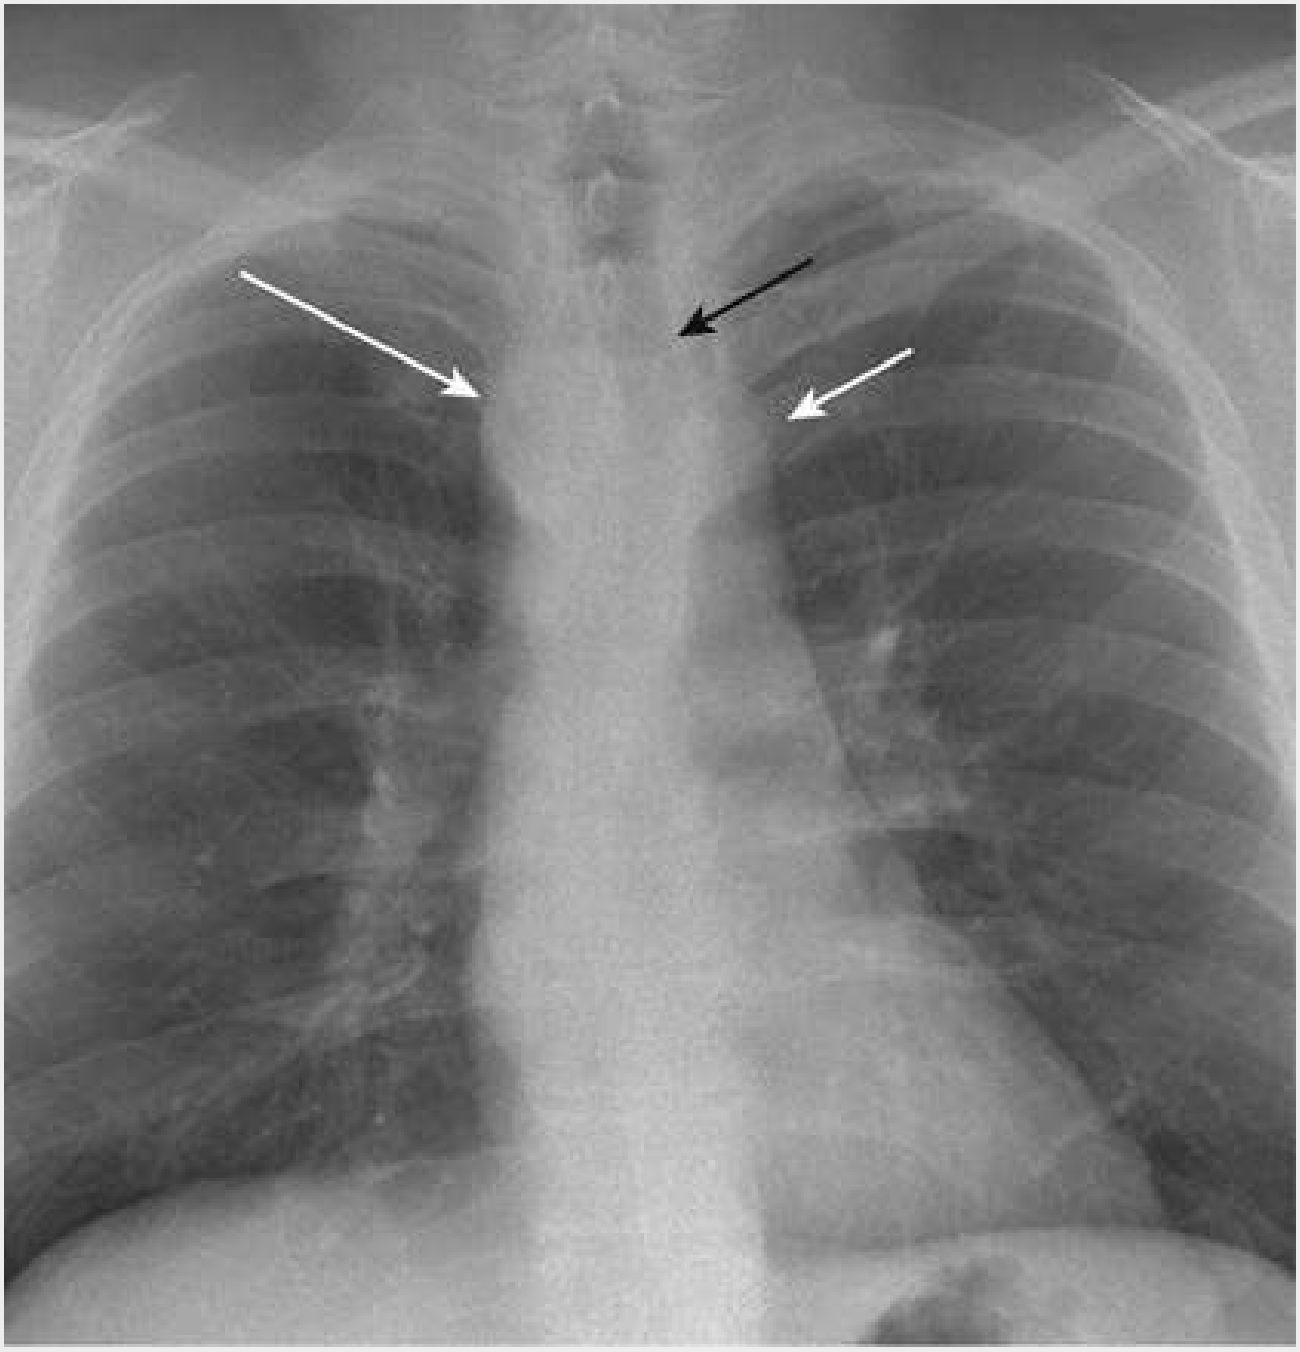


FIGURE 15.11 Double aortic arch. Coned-down PA chest radiograph shows right paratracheal budge representing the larger and higher right aortic arch (*long white arrow*), relative to the smaller and more inferiorly located left arch (*short white arrow*). Note that the trachea is deviated to the left by the right arch (*black arrow*).

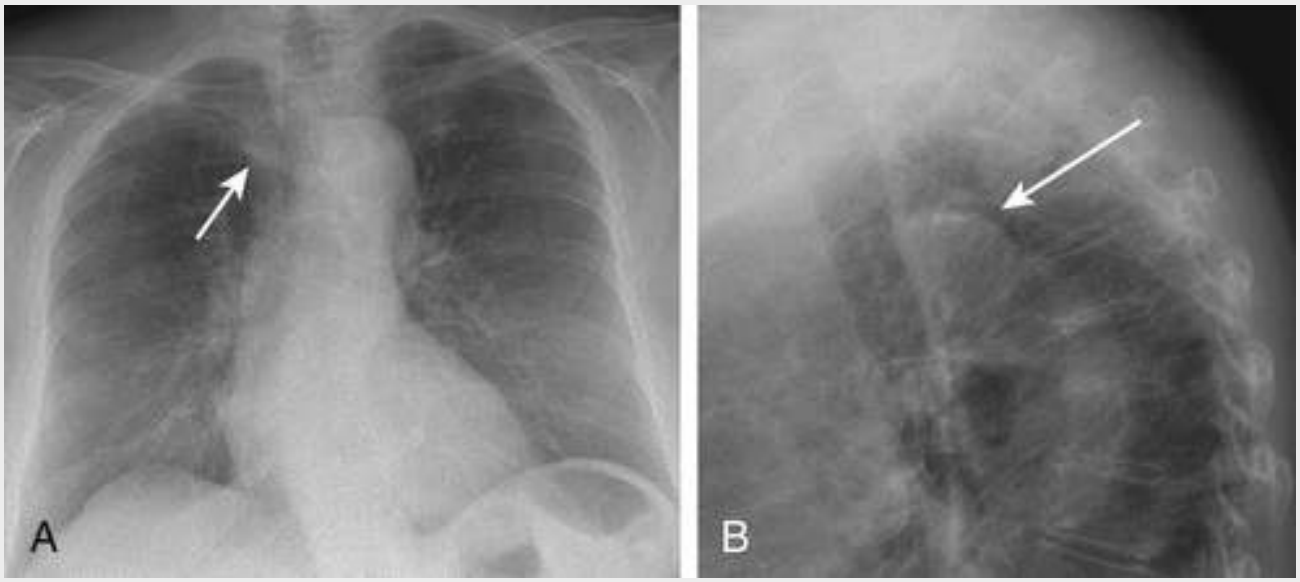
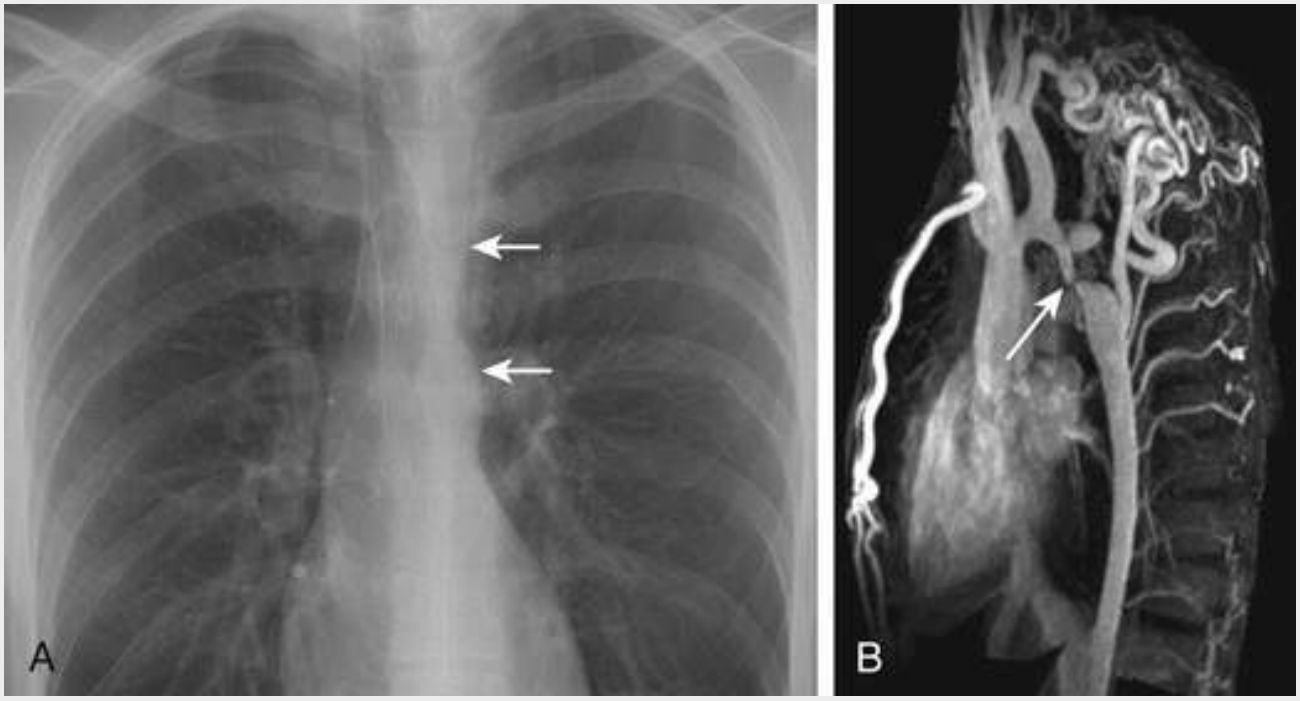


EFIGURE 15.24 Aberrant right subclavian artery with diverticulum of Kommerell. **A,** Frontal view shows a focal convexity along the right paratracheal region of the superior mediastinum (*arrow*). **B,** Lateral view shows retrotracheal density just above the aortic arch and posterior to the trachea (*arrow*). Both represent a prominent diverticulum of Kommerell.

An *aortic coarctation* may appear as an additional convexity immediately above the aortic knob on the frontal view, with possible bilateral rib notching along the undersurface of the ribs. The left mediastinal contour has been dubbed the "figure of 3 sign" (**eFig. 15.25**). When an aortic anomaly is suspected, a CT or MR angiogram of the aorta is indicated to evaluate further the full nature of the anomaly and the extent of collateral arterial flow when coarctation is present.



EFIGURE 15.25 Coarctation of the aorta. **A,** Coned-down frontal chest radiograph demonstrates inferior rib notching in patient with severe coarctation of the aorta (*arrows*). Note straightening of a mild outward curvature above the aortic knob caused by the left subclavian artery as it takes a relatively more vertical course above the coarctation site. This bulge with the aortic knob created the "figure of 3 sign" of coarctation. **B,** Thick, maximum intensity projection image of magnetic resonance angiography of the aorta shows the coarctation site at the aortic isthmus (*arrow*), with extensive intercostal and internal mammary arterial collaterals, which are dilated and tortuous.

Conclusion

The chest radiograph still maintains a role in initial evaluation of patients presenting with chest pain and shortness of breath and helps diagnose alternative causes for such symptoms, such as pneumonia or a pneumothorax. It continues to play a strong role in the evaluation of patients who have had cardiac devices and central venous catheters and cannulas placed in the hospital. The CXR also can delineate the physiologic status of the cardiovascular system. A careful evaluation of the CXR using a systematic approach in the context of the clinical presentation, while comparing to prior images, is essential to maximizing the potential of this ubiquitous imaging study.

Nuclear Cardiology

James E. Udelson, Vasken Dilsizian, Robert O. Bonow

The era of noninvasive radionuclide cardiac imaging in humans began in the early 1970s with the first reports of noninvasive evaluation of regional ventricular function at rest. Since that time, major advances have been achieved in the technical ability to image cardiac physiology and pathophysiology, including that of myocardial blood flow, myocardial metabolism, and ventricular function. Understanding how to apply the image information to the care of patients has also advanced, along with the effect of that information on clinical decision making. Ultimately, the role of information derived from any imaging procedure is to enhance the clinician's decision-making process for amelioration of symptoms and improvement of clinical outcomes.

Technical Aspects of Image Acquisition, Display, and Interpretation

Single-Photon Emission Computed Tomography of Perfusion and Function

The most common imaging procedure in nuclear cardiology is single-photon emission computed tomography (SPECT) *myocardial perfusion imaging* (MPI). After injection of the chosen radiotracer, the isotope is extracted from the blood by viable myocytes and retained within the myocyte for some time. Photons are emitted from the myocardium in proportion to the magnitude of tracer uptake, in turn related to perfusion. The standard camera used in nuclear cardiology studies, a gamma camera, captures the gamma ray photons and converts the information into digital data representing the magnitude of uptake and the location of the emission. The photoemissions collide along their flight path with a detector crystal. There, the gamma photons are absorbed and converted into visible light events (a *scintillation* event). Emitted gamma rays are selected for capture and quantitation by a collimator attached to the face of the camera detector system. Most often, parallel-hole collimators are used so that only photon emissions coursing perpendicular to the camera head and parallel to the collimation holes are accepted (**Fig. 16.1**). This arrangement allows appropriate localization of the source of the emitted gamma rays. Photomultiplier tubes, the final major component in the gamma camera, sense the light scintillation events and convert the events into an electrical signal to be further processed. The final result of SPECT imaging is the creation of multiple tomograms, or slices, of the organ of interest, composing a digital display representing radiotracer distribution throughout the organ.[1] With SPECT MPI, the display represents the distribution of perfusion throughout the myocardium.

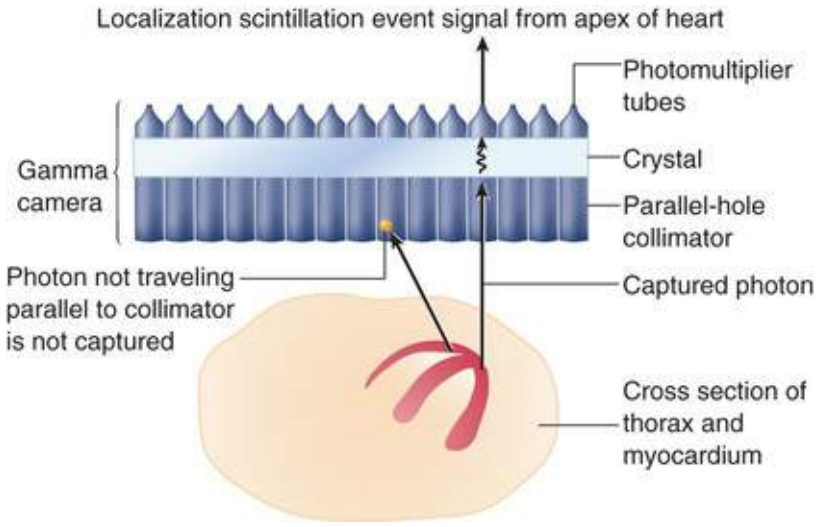

FIGURE 16.1 Capture of emitted photons by a gamma camera. Emissions are captured by a parallel-hole collimator, allowing photons to interact with a detector crystal, and are recorded as scintillation events. The event is localized on the basis of where the photon interacts with the crystal.

SPECT Image Acquisition

To construct the three-dimensional model of the heart from which tomograms are created, the myocardial perfusion data must be sampled from multiple angles over 180 or 360 degrees around the patient. Multiple images, each comprising 20 to 25 seconds of emission data, are collected. Each of the separate "projection" images constitutes a two-dimensional snapshot of myocardial perfusion from the angle at which the projection was acquired. Then the imaging information from each of the angles is back-projected onto an imaging matrix, creating a reconstruction of the organ of interest. Detailed reviews are available for more extensive information on the technical aspects of SPECT imaging and image reconstruction.[1]

SPECT Image Display

From the three-dimensional reconstruction of the heart, computer-processing techniques are used to identify the long axis of the left ventricle, and standardized tomographic images in three standard planes are derived. *Short-axis tomograms*, representing donutlike slices of the heart cut perpendicular to the long axis of the heart, are displayed beginning from the apex and moving toward the base. This tomographic orientation is similar to the short-axis view in two-dimensional echocardiography (**see Chapter 14**), although it is shifted counterclockwise (**Fig. 16.2A**). Tomographic slices cut parallel to the long axis of the heart and also parallel to the long axis of the body are termed *vertical long-axis tomograms* (**Fig. 16.2B**). Slices also cut parallel to the long axis of the heart but perpendicular to the vertical long-axis slices are known as *horizontal long-axis tomograms* (**Fig. 16.2C**). From all these tomographic planes, the entire three-dimensional myocardium is sampled and displayed, minimizing overlap of structures.

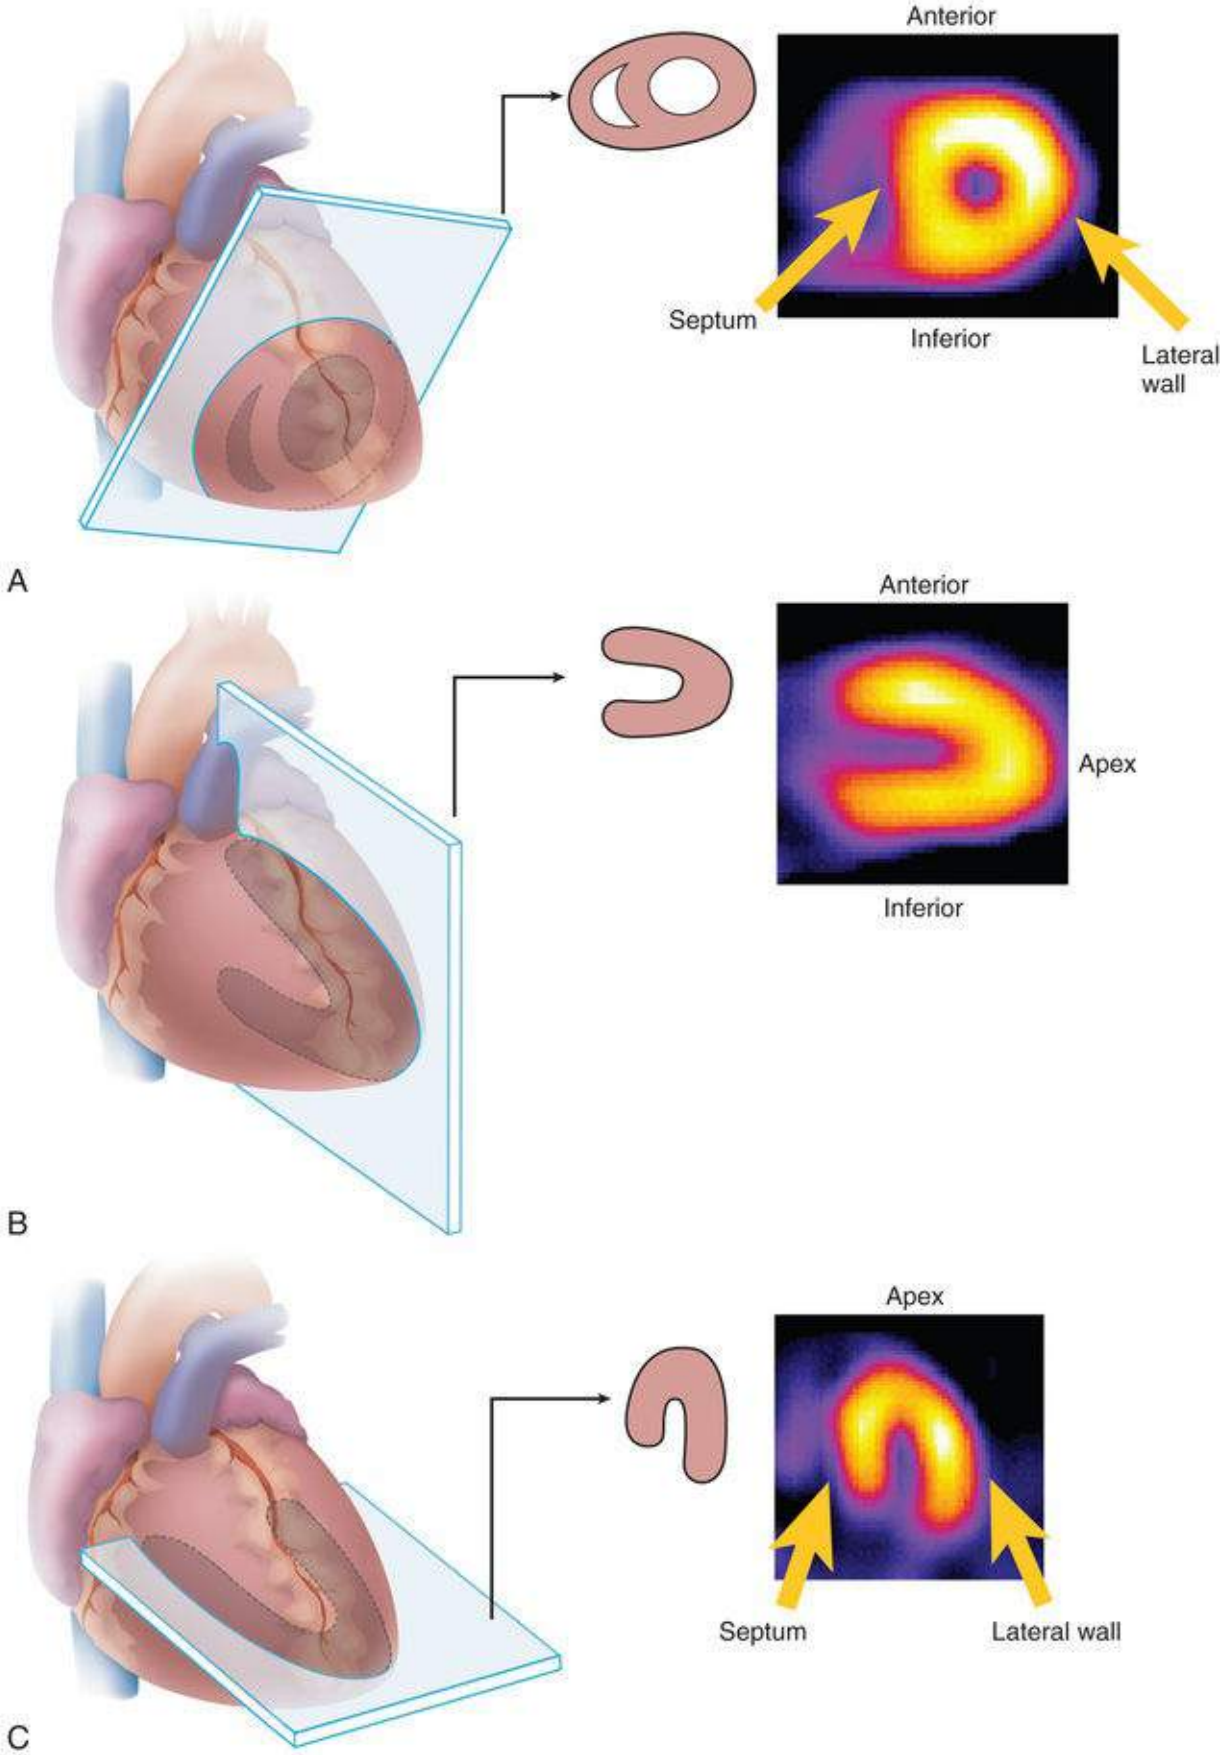

FIGURE 16.2 Standard SPECT imaging display. **A,** The short-axis images represent a portion of the anterior, lateral, inferior, and septal walls. **B,** Vertical long-axis images represent the anterior wall, apex, and inferior wall. **C,** Horizontal long-axis images represent the septum, apex, and lateral walls.

Basics of Quality Control.

The quality of SPECT MPI and the "accuracy" of the representation of regional myocardial perfusion depend on multiple quality control issues. Issues related to the patient and the organ being imaged include the stability of the tracer distribution in the organ of interest during the acquisition interval, the absence of motion of the patient or organ of interest or both during the acquisition, and the absence of overlying structures that would attenuate the photon emissions from one region relative to another region across the different projection images. Other quality control issues involve the camera and detector system, including the uniformity of photon detection efficiency across the camera face, as well as the stability of the camera across the entire orbit of acquisition.[2]

It is important in interpreting SPECT images to be aware of possible sources of image artifacts. Discrete motion of the patient, with consequent motion of the heart outside its original field, causes an abnormality in the final images that may be corrected with motion correction software. Imaging artifacts typically occur because of the effects of overlying structures that attenuate photon emissions. These artifacts include breast attenuation in women and attenuation of the inferobasal wall related to the diaphragm, usually seen in men. Strategies to overcome quality-specific problems such as attenuation are described subsequently.

High-Speed SPECT Imaging

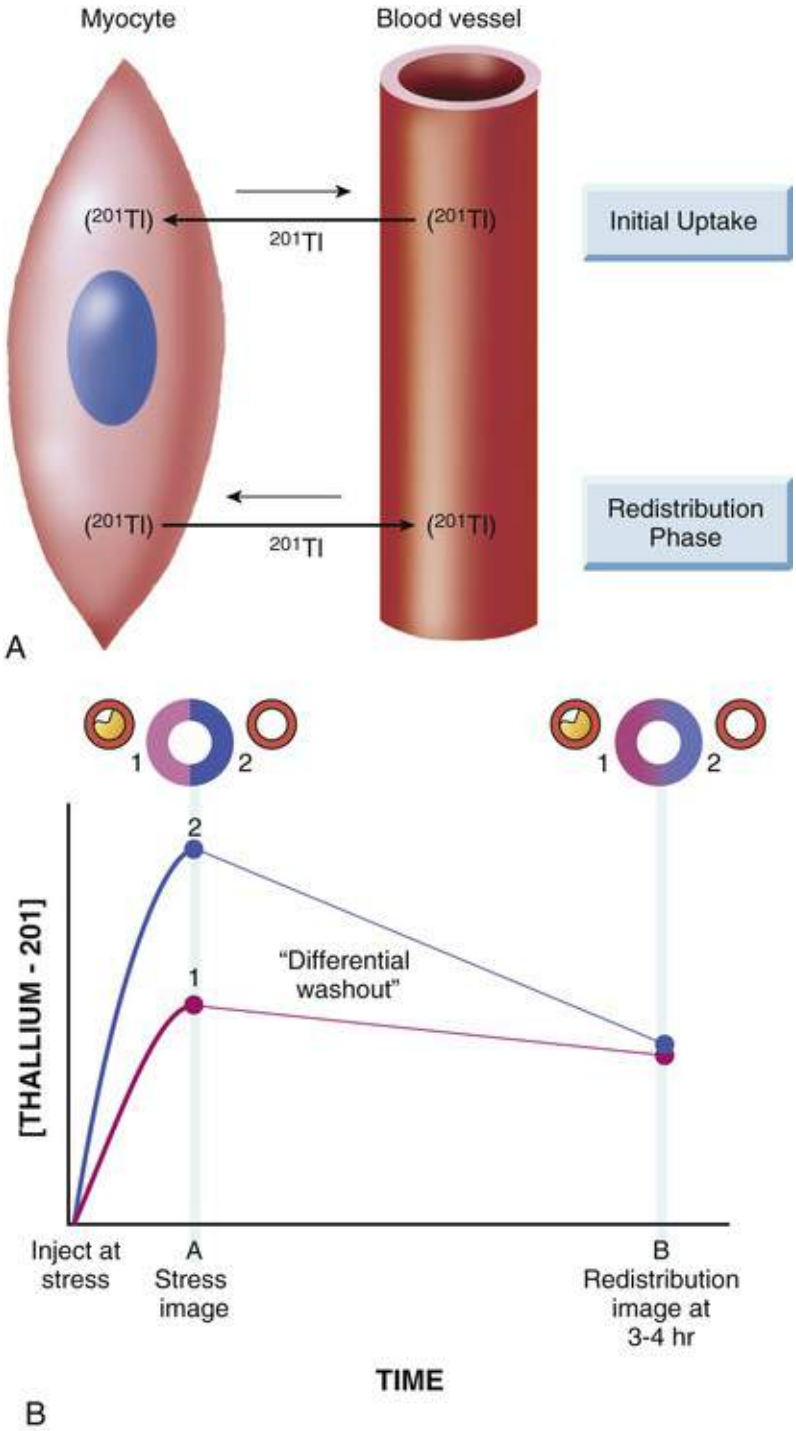
High-speed SPECT technology introduces an evolved design of SPECT in terms of both photon acquisition and reconstruction algorithms. Standard SPECT imaging with collimators using a parallel-hole design is inherently inefficient, because only a relatively small proportion of the camera and collimator surface area is used to capture photons emitted from the heart. Advances in camera and collimator technology have substantially increased the efficiency of count capture, by design features that allow much of the available detector area to image the cardiac field of view, increasing count sensitivity many-fold. One approach uses a series of small, pixilated, solid-state detector columns with cadmium zinc telluride or cesium iodide:thallium crystals, which provide considerably more information for each detected gamma ray. In addition, the design of the solid-state detector with wide-angle tungsten collimators combined with a novel image reconstruction algorithm provides true three-dimensional, patient-specific images localized to the heart.[3] Compared with the conventional SPECT cameras, the high-speed SPECT systems can provide up to an eightfold increase in count rates, thereby reducing imaging times significantly from 14 to 15 minutes with a conventional Anger gamma camera to 5 to 6 minutes with the newer solid-state cameras while achieving a twofold increase in spatial resolution.

In addition to advances in camera technology, software driving image reconstruction has also evolved. One technique, *resolution recovery,* improves spatial resolution while reducing noise in the images. Thus, studies acquired over a much shorter time, when reconstructed using these techniques, can yield images with the same signal-to-noise ratio as those using standard techniques and timing.[3] Reduced imaging times should translate to improved patient comfort and satisfaction, as well as less motion and fewer motion artifacts. An additional advantage of high-speed SPECT imaging is the potential for administration of lower doses of radiopharmaceuticals without sacrificing image resolution and quality, thereby reducing radiation dose to patients. The reduced imaging time in concert with reduced radiopharmaceutical doses may be cost-effective, with implications for future appropriateness of SPECT imaging.[3]

SPECT Perfusion Tracers and Protocols

Thallium-201

Thallium-201 (^{201}Tl) was introduced in the 1970s and propelled the clinical application of MPI as an adjunct to exercise treadmill testing. ^{201}Tl is a monovalent cation with biologic properties similar to those of potassium. Because potassium is the major intracellular cation in muscle and is virtually absent in scar tissue, ^{201}Tl is a well-suited radionuclide for differentiation of normal and ischemic myocardium from scarred myocardium.[4] Thallium-201 emits 80 keV of photon energy and has a physical half-life of 73 hours. The initial myocardial uptake early after intravenous injection of thallium is proportional to regional blood flow. First-pass extraction fraction (the proportion of tracer extracted from the blood as it passes through the myocardium) is high, in the range of 85%. It is transported across the myocyte cell membrane by the sodium/potassium ion (Na^+,K^+)–adenosine triphosphatase (ATPase) transport system and by facilitative diffusion. Peak myocardial concentration of thallium is achieved within 5 minutes of injection, with rapid clearance from the intravascular compartment. Although the initial uptake and distribution of thallium are primarily a function of blood flow, the subsequent redistribution of thallium, which begins within 10 to 15 minutes after injection, is unrelated to flow but is related to the rate of its clearance from myocardium, linked to the concentration gradient between myocyte levels and blood levels of thallium (**eFig. 16.1A**). Thallium clearance is more rapid from normal myocardium with high thallium activity than from myocardium with reduced thallium activity (ischemic myocardium), a process termed *differential washout* (**eFig. 16.1B**).



EFIGURE 16.1 Thallium-201 (^{201}Tl) redistribution. **A,** After initial uptake into the myocyte, an equilibrium is created between the intracellular and extracellular concentrations of thallium. After blood levels diminish during the redistribution phase, the equilibrium favors egress of thallium out of the myocyte. **B,** On the basis of that equilibrium, thallium concentration diminishes over time in zones of normal uptake while diminishing more slowly in zones with less initial thallium uptake, that is, those with diminished flow reserve or ischemia. In this example, segment 1 of the myocardial schematic is supplied by an artery with an 80% stenosis, and segment 2 is supplied by a normal artery. During peak stress, normal blood flow reserve is present in segment 2; blunted flow reserve, based on the presence of stenosis, is present in segment 1, and there is less initial thallium uptake into segment 1 (time point *A*). Thallium washout is more rapid from the territory with initially normal uptake and slower from the ischemic zone, creating the phenomenon of "differential washout." When redistribution imaging is done 3 to 4 hours later (time point *B*), thallium concentrations are equal in segments 1 and 2. Thus a reversible stress defect is seen in segment 1, based on the redistribution properties and differential washout. (Modified from Dilsizian V. SPECT and PET techniques. In Dilsizian V, Narula J, editors. Atlas of Nuclear Cardiology. Braunwald E, series editor. Philadelphia: Current Medicine; 2003, pp 19-46.)

Thallium studies can be divided into protocols in which ^{201}Tl is administered during stress and those in which it is given with the patient at rest.[4] After stress, the reversal of a thallium defect from the initial

peak stress to delayed 3- to 4-hour or 24-hour redistribution images is a marker of reversibly ischemic, viable myocardium. When thallium is injected in the resting state, the extent of thallium defect reversibility from the initial rest images to delayed redistribution images (at 3 to 4 hours) reflects viable myocardium with hypoperfusion at rest. When scarred myocardium is present, the initial rest or stress thallium defect persists over time; such deficits are termed *irreversible* or *fixed defects*. However, in some patients with coronary artery disease (CAD), the initial uptake of thallium during stress may be severely decreased, and tracer accumulation from the recirculating thallium in the blood during the redistribution phase may be slow or even absent because of rapid decline of thallium levels in the blood. The result is that some severely ischemic but viable regions may show no redistribution on either early (3- to 4-hour) or late (24-hour) imaging, even if viable myocardium is present. Viable myocardium in this situation can be revealed by raising blood levels of thallium by reinjection of a small dose (1 to 2 mCi) of thallium at rest. Thus, in some patients, thallium reinjection is necessary to identify viable myocardium when there are irreversible defects on stress-redistribution images.

Technetium 99m–Labeled Tracers

Technetium 99m (^{99m}Tc)–labeled myocardial perfusion tracers were introduced in the clinical arena in the 1990s.[4] ^{99m}Tc emits 140 keV of photon energy and has a physical half-life of 6 hours. Despite the excellent myocardial extraction and flow kinetic properties of ^{201}Tl, its energy spectrum of 80 keV is suboptimal for conventional gamma cameras (ideal photopeak in the 140-keV range). In addition, the long physical half-life of ^{201}Tl (73 hours) limits the amount of ^{201}Tl that may be administered to stay within acceptable radiation exposure parameters. Thus, ^{99m}Tc-labeled tracers improve on these two limitations of ^{201}Tl. Although three ^{99m}Tc-labeled tracers—sestamibi, teboroxime, and tetrofosmin—have received U.S. Food and Drug Administration (FDA) approval for detection of CAD, only sestamibi and tetrofosmin are available for clinical use at present.

Sestamibi and tetrofosmin are lipid-soluble cationic compounds with first-pass extraction fraction in the range of 60%. Myocardial uptake and clearance kinetics of both tracers are similar. They cross sarcolemmal and mitochondrial membranes of myocytes by passive distribution, driven by the transmembrane electrochemical gradient, and they are retained within the mitochondria.[4] Redistribution of these tracers is minimal compared with that for thallium. Consequently, myocardial perfusion studies with ^{99m}Tc-labeled tracers require two separate injections, one at peak stress and the second at rest.

Three basic protocols[5] with ^{99m}Tc-labeled tracers have been used: (1) a single-day study, in which myocardial blood flow is interrogated at rest and at peak stress, or in the reverse order, as long as the first injected dose is low (8 to 12 mCi) and the second injected dose is high (24 to 36 mCi); (2) a 2-day study (commonly performed in patients with large body habitus), in which higher doses of the tracer are injected (24 to 36 mCi) both at rest and at peak stress to optimize myocardial count rate; and (3) a dual-isotope technique, in which injection of ^{201}Tl at rest is followed by injection of a ^{99m}Tc tracer at peak stress. The last approach takes advantage of the favorable properties of each of the two tracers, including the high-quality gated SPECT images obtained with ^{99m}Tc and the potential to acquire redistribution images with ^{201}Tl (either at 4 hours before the stress study or at 24 hours after the ^{99m}Tc activity has decayed). **Table 16.1** compares the properties of the available isotopes for perfusion imaging.

TABLE 16.1

Properties of SPECT Tracers

TRACER	PHYSICAL HALF-LIFE	UPTAKE	MYOCARDIAL CLEARANCE	DIFFERENTIAL WASHOUT	MAXIMUM EXTRACTION
^{201}Tl	73 hours	Active	~50% at 6 hours	Yes	~0.70
^{99m}Tc-sestamibi	6 hours	Passive	Minimal	Minimal	0.39
^{99m}Tc-tetrofosmin	6 hours	Passive	Minimal	Minimal	0.24
^{99m}Tc-teboroxime	6 hours	Passive	~50% at 10 minutes	Yes	0.72

SPECT Image Interpretation and Reporting

SPECT myocardial perfusion images may be evaluated visually. The interpreter describes the perfusion pattern findings on stress and then visually interprets whether defects observed on the stress images are or are not reversible. Because the imaging data are digital, computer-aided quantitative analysis also may be used. Validated software programs for semiquantitative or fully automated quantitative analysis of SPECT myocardial perfusion images are now widely available.

General Principles of Interpretation and Reporting.

For any type of image interpretation, visual or quantitative, the key elements to be reported include the presence and location of perfusion defects and whether defects on stress images are reversible on the rest images (implying stress-induced ischemia) or whether stress perfusion defects are irreversible or fixed (often implying myocardial infarction) (**Fig. 16.3**). Moreover, substantial literature has documented that the extent and the severity of the perfusion abnormality are independently associated with clinical outcomes (risk of adverse events over time) and thus contribute importantly to the information on risk stratification to be conveyed to the ordering clinician.[6] The *extent* of perfusion abnormality refers to the amount of myocardium or vascular territory that is abnormal, and the *severity* refers to the magnitude of reduction in tracer uptake in abnormal zone relative to normal. **Figs. 16.4 to 16.6** provide examples of stress and rest SPECT myocardial perfusion abnormalities of varying extent and severity. These concepts imply that it is not sufficient to describe a stress perfusion imaging test as simply “abnormal.” Rather, a clinically relevant interpretation will include a description of the magnitude of abnormality as well as the extent of ischemia, extent of infarct, and localization to specific myocardial regions or vascular territories. The final report will incorporate all the clinical data, the stress testing result, and the imaging data to provide comprehensive information to the referring clinician, in a timely and clinically meaningful way. Guidelines for standardized reporting elements are available from professional societies.[7]

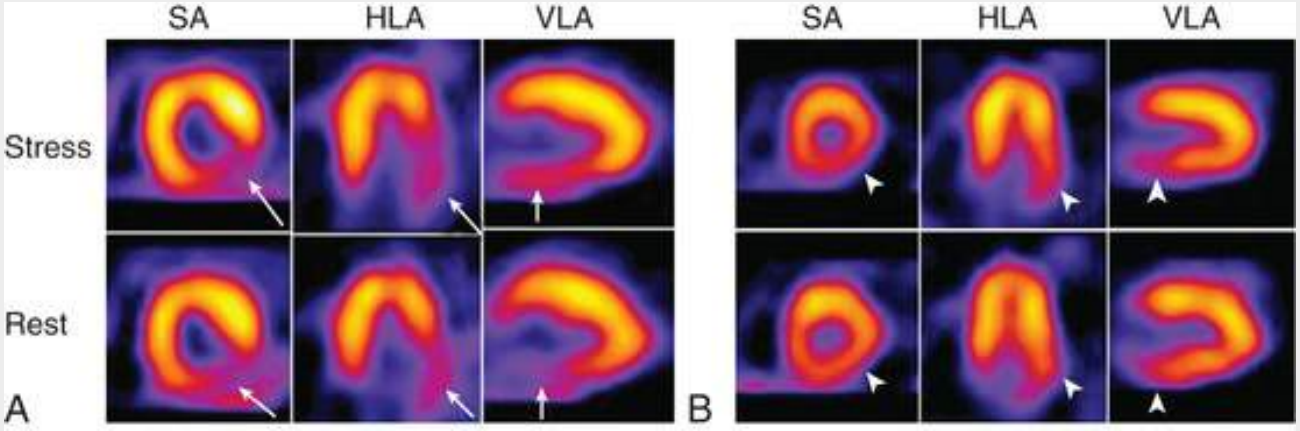


FIGURE 16.3 Examples of SPECT stress/rest perfusion imaging findings of infarct and ischemia. **A,** Fixed defect of the inferolateral wall (*arrows*), with similar reduction in tracer uptake in both stress and rest images in short-axis (SA), horizontal long-axis (HLA), and vertical long-axis (VLA) views, findings consistent with infarct. **B,** Reversible defect of the inferolateral wall (*arrowheads*), with relative reduction in tracer uptake in the inferolateral wall compared to the other walls in the stress images, with more homogeneous uptake in the rest images. These findings are consistent with blunted flow reserve in that area during stress, with normal perfusion at rest, identifying an area of stress-induced ischemia.

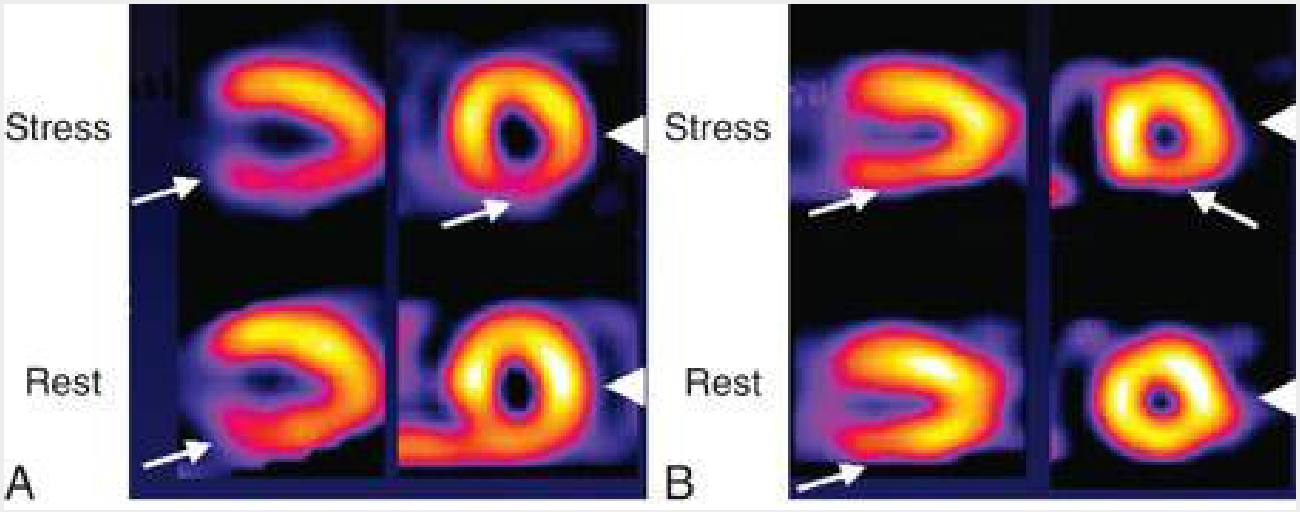

FIGURE 16.4 SPECT images of inferior wall abnormalities of differing extent and severity. **A,** Large, moderately severe, reversible inferior wall defect (*arrows*) reflecting a moderately severe flow reserve abnormality. **B,** Milder, reversible inferior wall defect (*arrows*) reflecting either a less severe stenosis or a severe stenosis with well-developed collaterals minimizing the defect severity. In both patients, a mild lateral wall reversible defect also is present (*arrowheads*). Note how the lateral wall brightens relative to the septum on the rest images compared with the stress images.

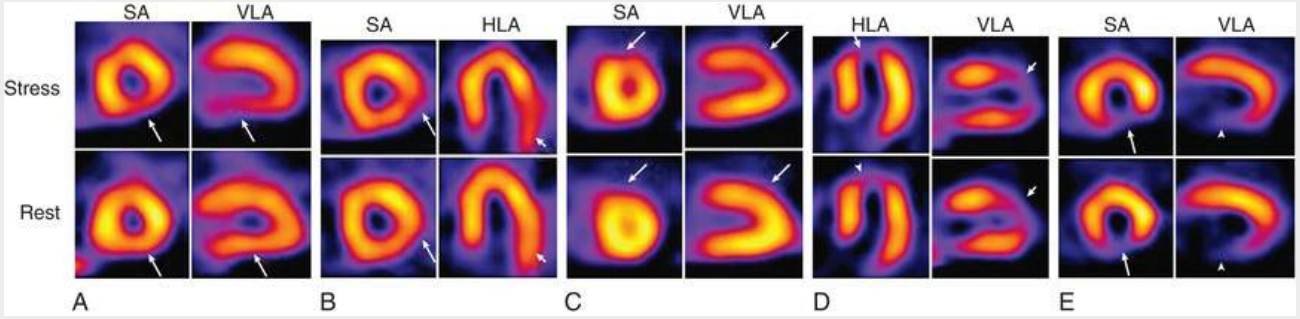

FIGURE 16.5 Examples of single vascular territory reversible defects. **A,** Reversible inferior wall defect (*arrows*) in short-axis (SA) and vertical long-axis (VLA) views, consistent with inducible ischemia in right coronary artery territory. **B,** Reversible lateral wall defect (*arrows*) in SA and horizontal long-axis (HLA) views (*arrows*), consistent with inducible ischemia in left circumflex coronary artery territory. **C,** Reversible anterior wall defect (*arrows*) in the SA and VLA views, consistent with inducible ischemia in left anterior descending (LAD) artery territory. **D,** Fixed perfusion pattern consistent with LAD artery territory infarct. There are fixed defects involving the apex in HLA view (*arrowheads*), and the anteroapical wall and apex in VLA view (*arrows*). **E,** Fixed perfusion defect pattern involving the inferior wall (*arrows*) in SA view and in VLA view (*arrowheads*), consistent with inferior infarct.

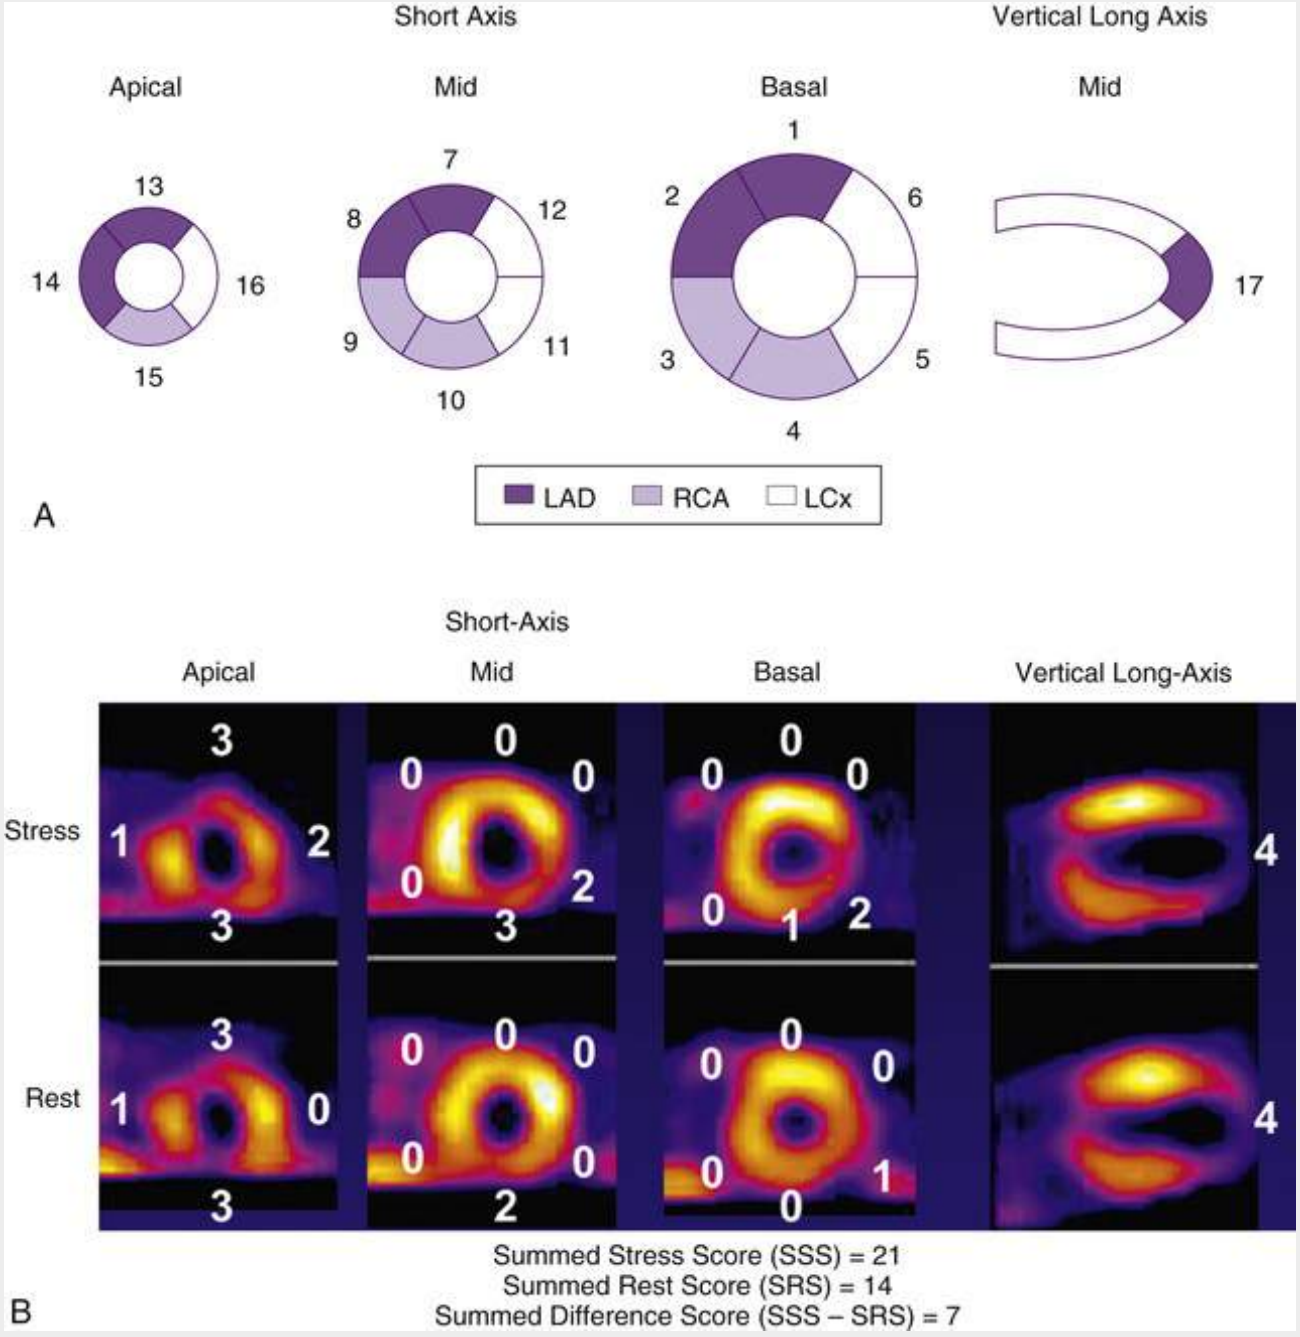
FIGURE 16.6 Examples of reversible defects in more than one vascular territory. **A,** Reversible lateral wall defect (*arrows*) in short-axis (SA) and horizontal long-axis (HLA) views, consistent with inducible ischemia in left circumflex (LCx) coronary artery territory, and a reversible inferior wall defect (*arrowheads*) in vertical long-axis (VLA) view, consistent with inducible ischemia in the right coronary artery (RCA) territory. **B,** Reversible anterior wall defect (*arrows*) in the SA and VLA views, consistent with inducible ischemia in the LAD artery territory, and a reversible lateral wall defect (*arrowheads*) in the SA and HLA views, consistent with inducible ischemia in LCx territory. **C,** Perfusion abnormalities in all three major vascular territories: reversible anterior wall defect (*arrows*) in SA and VLA views, consistent with inducible ischemia in LAD territory; reversible lateral wall defect (*arrowheads*) in SA and HLA views, consistent with inducible ischemia in LCx territory; and reversible inferior wall defect (*arrowheads*) in VLA view, consistent with inducible ischemia in RCA territory.

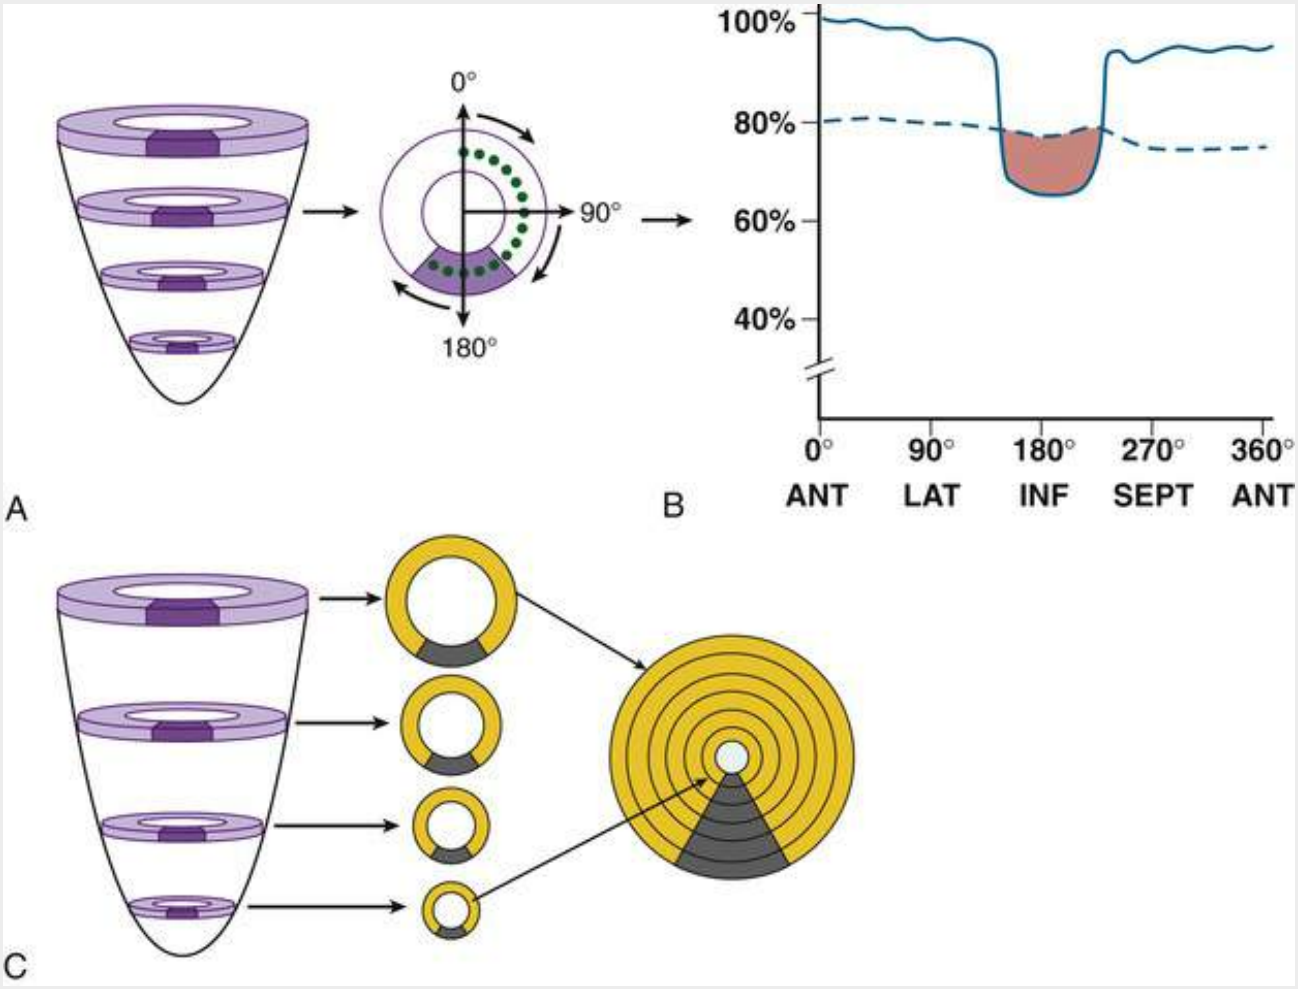
To minimize subjectivity in image interpretation, semiquantitative visual analysis or fully quantitative computer analysis may be applied to MPI data.[5] With semiquantitative visual analysis, a score is assigned to represent perfusion for each of multiple segments of the myocardium. A segmentation model has been standardized for this approach by dividing the myocardium into 17 segments[7] on the basis of three short-axis slices and a representative long-axis slice to depict the apex (**eFig. 16.2**). Perfusion is graded within each segment on a scale of 0 to 4, with 0 representing normal perfusion and 4 representing a very severe perfusion defect. Scores for all 17 segments are added to create a "summed" score. The sum of the segmental scores from the stress images, the *summed stress score* (SSS), represents the extent and severity of stress perfusion abnormality—the magnitude of perfusion defects related to both ischemia and infarction. The sum of the 17 segmental scores from the rest images, the *summed rest score* (SRS), represents the extent of infarction. The *summed difference score* (SDS) is derived by subtracting the SRS from the SSS and represents the extent and severity of stress-induced ischemia. The segmental scores can be assigned subjectively by the image interpreter or automatically by widely available software programs. As discussed later, a substantial literature has validated these summed scores, particularly the SSS, as predictors of natural history outcomes.



EFIGURE 16.2 **A,** Standard segmental myocardial display for semiquantitative visual analysis in a 16-segment model, with corresponding vascular territory schematic; *LAD,* left anterior descending artery; *LCx,* left circumflex coronary artery; *RCA,* right coronary artery. **B,** Segmental scoring of a patient whose stress and rest SPECT perfusion images show a severe apical fixed defect (in the vertical long axis), extending into the inferoapical and anteroapical walls (in the apical short axis), with evidence of reversible defects in the inferior and lateral walls (in the mid- and basal short axis). The summed stress score (SSS = 21) represents extensive perfusion abnormality at stress (reflecting ischemia and infarct); the summed rest score (SRS = 14) represents the extent of infarct; and the summed difference score (SDS = SSS − SRS = 7) represents the extent of ischemia.

Because SPECT MPI data are a digital representation of radiotracer distribution, the data can also be analyzed quantitatively. The most common technique involves creation of a circumferential profile of relative tracer activity around the tomogram of interest, such as a short-axis tomogram. With this technique, each short-axis tomogram is sampled at every 3 to 6 degrees for 360 degrees, along a ray extending from the center of the image (**eFig. 16.3**). The maximum counts at a picture element (pixel) along the ray, usually occurring in the midportion of the myocardium, are recorded for each angle. The data may be plotted to create a profile of the perfusion pattern of that tomogram relative to the most "normal" area of uptake, which is assigned a value of 100% uptake. Circumferential profiles for an

individual patient can be compared directly with a composite profile representing normal perfusion. The normal perfusion data are created from studies performed in normal individuals with a very low clinical probability of CAD or in those with known normal coronary arteries. A quantitative extent of abnormality can be derived for each tomogram of the individual patient (the total amount of myocardium that falls below the lower limit of normal) as well as a derivation of the severity of the perfusion abnormality (the depth of the patient's perfusion abnormality relative to the lower limit of normal).



EFIGURE 16.3 Quantitative analysis of SPECT imaging. **A,** Circumferential profile analysis of tracer uptake along rays emanating from the center of the short-axis tomogram. From this procedure, a circumferential profile of tracer uptake around the myocardium is developed for each short-axis tomogram. In this example, there is a perfusion defect in the inferior wall (*darker purple area*). **B,** The data are plotted relative to location around the myocardium (*x* axis) and "normalized" to the point of peak uptake, which is assigned a value of 100% (*y* axis). The patient's data (*solid line*) are compared with lower limits of normal (*dashed line*) derived from a group of participants without CAD of the same gender. From this comparison, the quantitative extent and severity of the perfusion abnormality can be derived (*red area*). *ANT,* Anterior; *INF,* inferior; *LAT,* lateral; *SEPT,* septal. **C,** Data from all the individual short-axis tomograms can be combined to create a bull's-eye polar plot, representing a two-dimensional compilation of all of the three-dimensional short-axis perfusion data. The extent of the inferior wall perfusion defect (*gray area* on individual profiles and polar plot) is seen on the two-dimensional map. (Images courtesy Ernest Garcia, PhD.)

Most contemporary computer systems and analysis programs create "bull's-eye" or polar maps representing perfusion of the entire three-dimensional myocardium in a two-dimensional plot (**Fig. 16.7; see eFig. 16.3**). Quantitative data may be derived on the extent of global perfusion abnormality, the abnormality within vascular territories, and the extent of reversible and fixed defects. These are often displayed as "blackout maps," in which any pixel values falling below a set number of standard

deviations below the normal limits is assigned the color black, and the extent of that abnormality is expressed as a percentage of the presumed vascular territory and as a percentage of the left ventricle (**Fig. 16.8**).

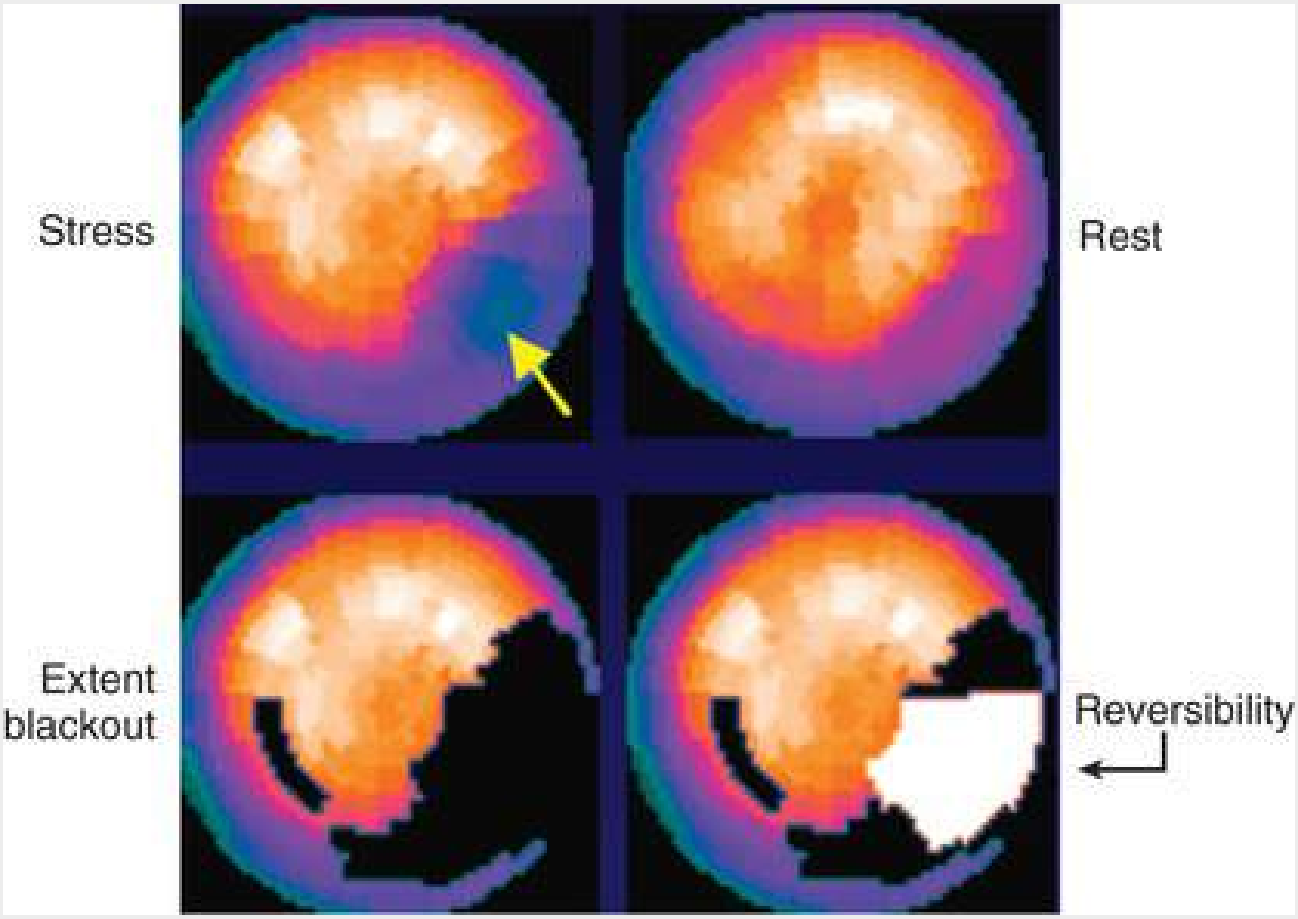


FIGURE 16.7 Example of bull's-eye polar plot for patient with reversible defect of inferolateral wall (*arrow* on stress bull's-eye plot, *upper left*). *Blackout area* (on extent blackout plot, *lower left*) represents the myocardium that falls below the lower limits of normal; in the reversibility plot (*lower right*); *white area* represents the extent of that abnormality that is reversible (ischemic) on rest imaging. (Images courtesy Ernest Garcia, PhD.)

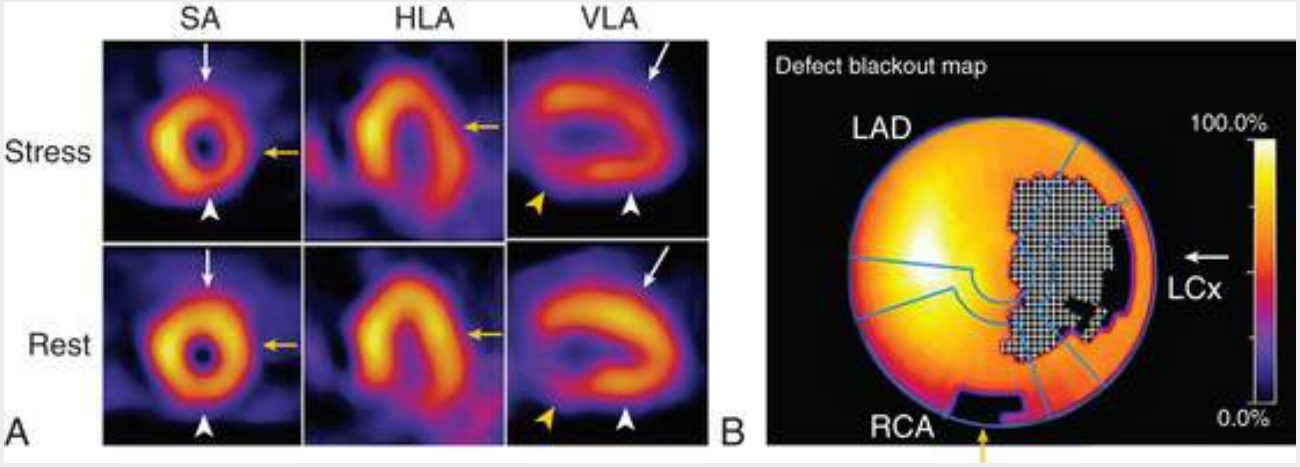

FIGURE 16.8 Examples of SPECT stress-rest perfusion imaging findings of extensive ischemia in all vascular territories and a small infarct. **A,** Reversible defects in the anterior wall and apex (*white arrows*), lateral wall (*yellow arrows*), and inferior wall (*white arrowheads*), consistent with inducible ischemia in all those territories. There is a small, fixed defect in the base of the inferior wall in the vertical long-axis (*VLA*) tomograms (*yellow arrowheads*), consistent with a small infarct. **B,** The polar map quantitation documents defects crossing into all vascular territories, with extensive reversibility (*white cross-hatched area, white arrow*), and a small irreversible area in the basal inferior wall (*blacked-out area, yellow arrow*). *SA,* Short-axis; *HLA,* horizontal long-axis view; *LAD,* left anterior descending artery; *LCx,* left circumflex artery; *RCA,* right coronary artery.

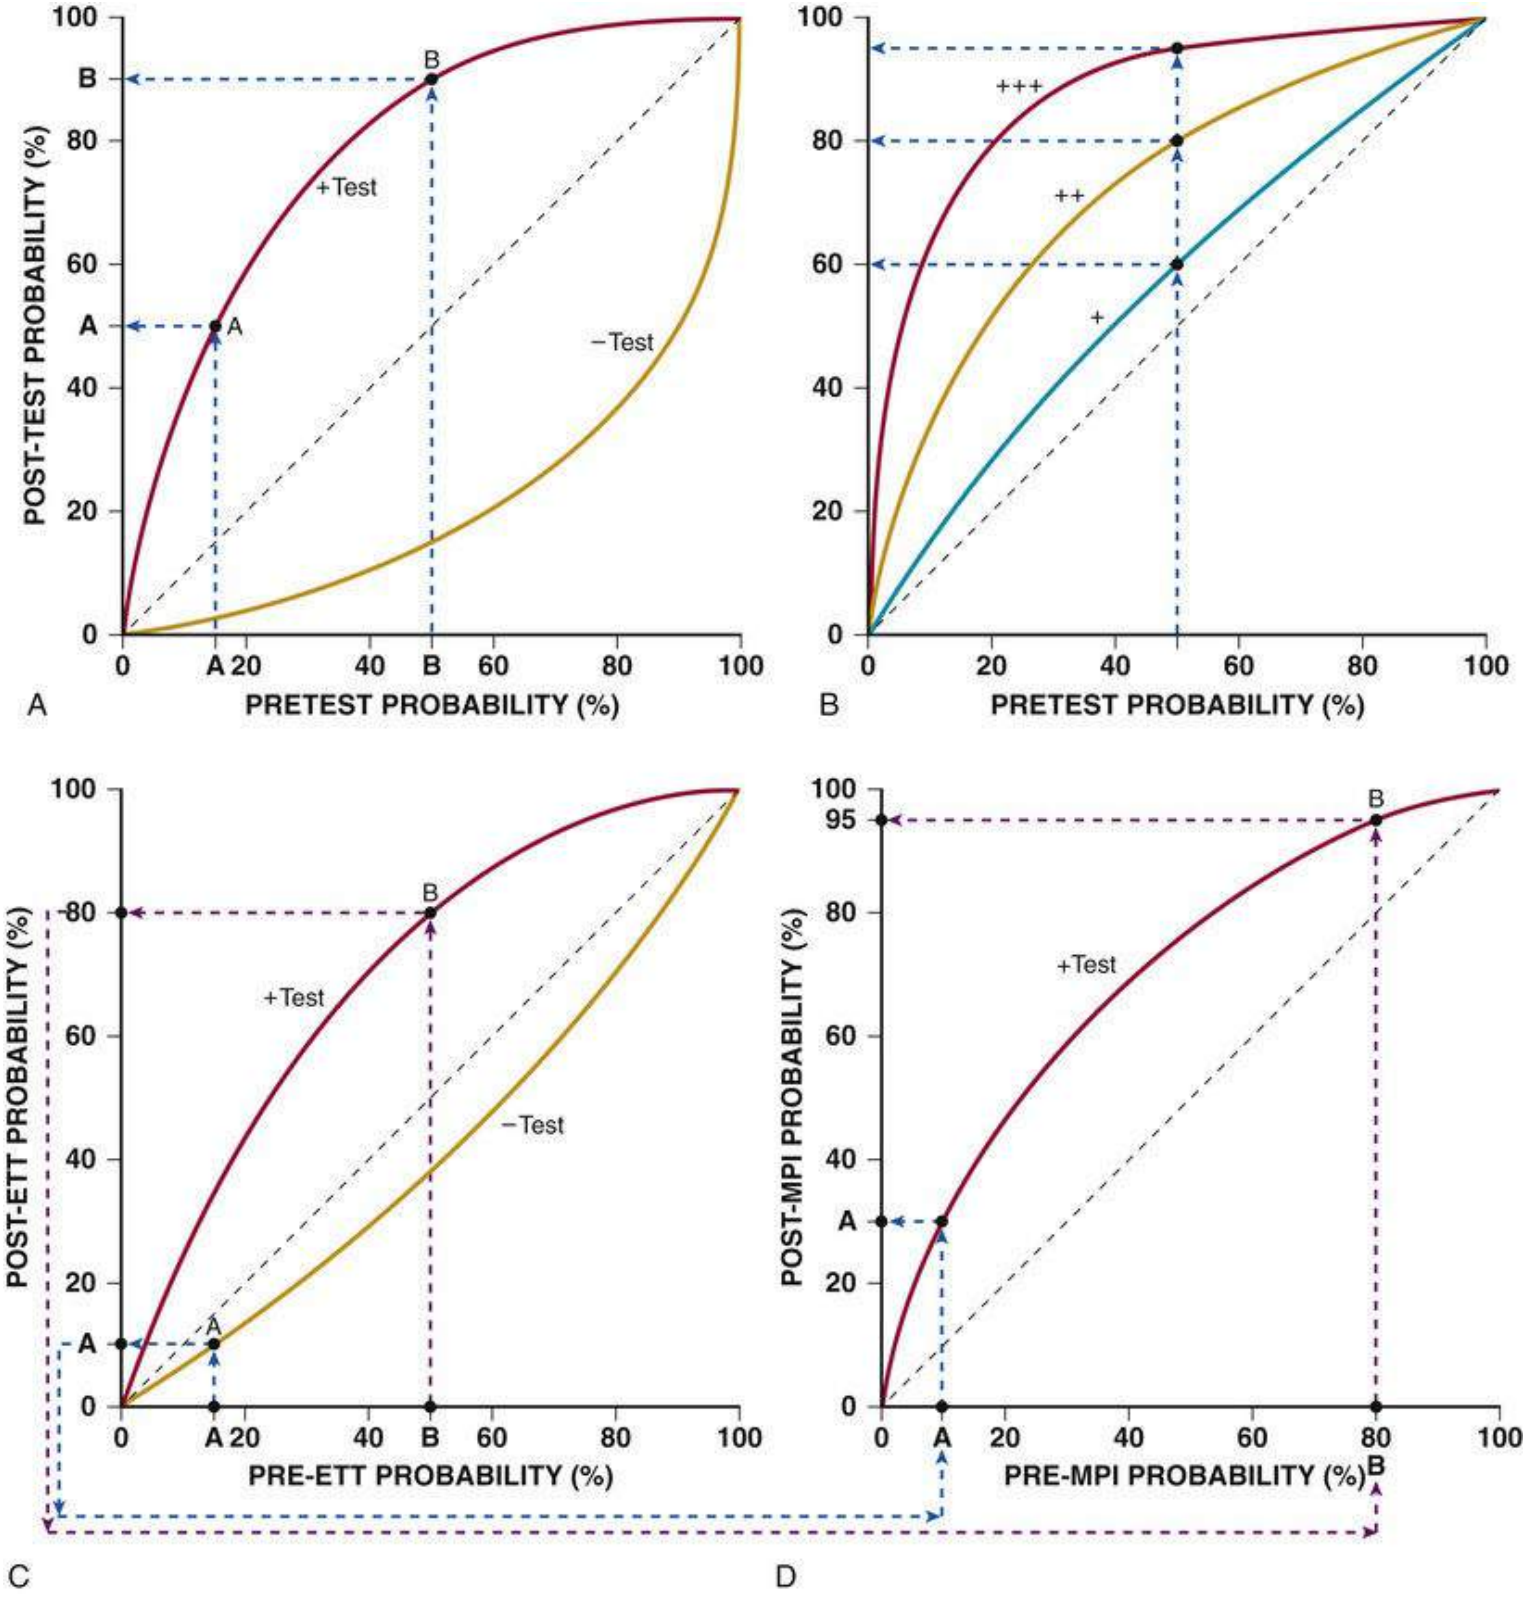
Reporting guidelines also outline the elements of a comprehensive reporting structure when semiquantitative and/or quantitative analysis are used.[7]

Incorporating Bayesian Principles Into Image Interpretation

Although it is possible to interpret MPI data in isolation and report only on what the images demonstrate, a more accepted interpretive methodologic principle is that the final interpretation should take into account the entirety of the data at hand. Therefore the image data build on the already-known clinical and stress test data, and the clinician should consider all this information when interpreting MPI data. An understanding of bayesian probability principles is useful in this regard. Bayes theorem posits that the post-test probability of disease (or risk of an event after a test) is influenced not only by the sensitivity and specificity of the test, but also by the pretest probability of disease (**see Chapter 13**). This principle is illustrated in **eFig. 16.4**. For a given positive test result, the post-test probability of disease may be distinctly lower in a patient with a very low pretest probability of disease compared with a different patient with a much higher pretest probability (**eFig. 16.4A**). In practice, MPI results are not simply positive or negative; rather, positive (i.e., abnormal) results can range from *borderline abnormal* (uncertainty whether the abnormality may be an artifact or a mild perfusion defect) to *strongly abnormal* (extensive and severe defects, highly likely to be real and unlikely to represent artifact). Thus the "test positive" curve in **eFig. 16.4A** can be thought of as a family of positivity curves, with distinct implications for post-test likelihood of disease (**eFig. 16.4B**).



EFIGURE 16.4 Influence of pretest probability on post-test interpretation and application of Bayes theorem. **A,** For patient with low pretest probability of disease (point *A* at 15% on *x* axis) with a positive test result, post-test probability of disease (point *A* at 50% on *y* axis) is lower than for a different patient with a higher pretest probability with the same positive test result (point *B* at 50% pretest probability on *x* axis, 90% post-test probability on *y* axis). In **B,** the "test positive" curve can be thought of as a family of curves influenced by how strongly positive the images can be. For a given pretest probability, the post-test probability becomes progressively higher as the image becomes more strongly abnormal. For a borderline abnormal study (+ curve), the post-test probability may be only slightly higher than the pretest value. For a strongly positive study (+++ curve), the post-test probability is very high no matter what the pretest probability. **C, D,** Sequential application of Bayes theorem. For a young patient with nonanginal chest pain, the pretest probability of coronary artery disease (CAD) is low (approximately 15%, point *A* on *x* axis in **C**). If the patient undergoes an exercise treadmill test (*ETT*) and exercises to a good workload with no symptoms and no electrocardiographic change, the post-ETT probability is even lower (10% on *y* axis in **C**). The post-ETT probability then becomes the pre-MPI probability, as seen in **D** (point *A* on *x* axis). A "positive" myocardial perfusion imaging (MPI) test result is still associated with a relative low post-test

probability of CAD (point *A* at 30% probability on *y* axis). If reported as positive, there is actually a greater chance that such a result represents a false-positive result (70%) as opposed to a true-positive result (30%). For an older patient with a history of chest pain (higher pretest probability, point *B* on *x* axis in **C**) in whom treadmill exercise reproduces those symptoms, with positive ECG changes, the post-ETT probability rises (point *B* on *y* axis in **C**), and that becomes the high pre-MPI probability (point *B* on *x* axis in **D**). Thus the same MPI results are much more likely to represent a true-positive finding (point *B* on *y* axis in **D**, 95%) and less likely to represent a false-positive study (5%).

The implication of incorporating these concepts for image interpretation can be illustrated by considering a mildly positive MPI study demonstrating a small, mild reversible inferobasal defect. Although this defect may represent a small area of inferior inducible ischemia, the image also may reflect diaphragm attenuation of the inferobasal wall predominantly affecting the stress image. The influence of the pretest probability data (i.e., pre-MPI) is illustrated in **eFig. 16.4C**. For a young patient with nonanginal chest pain, the pretest probability of CAD is low. If the patient undergoes an exercise treadmill test (ETT) as the stress portion of the MPI test and exercises to a good workload with no symptoms and no changes on the electrocardiogram (ECG), the post-ETT probability is even lower. The post-ETT probability then becomes the pre-MPI probability (**eFig. 16.4D**). A positive test result, especially a mildly positive result, is still associated with a relative low post-test probability of CAD. A result reported as positive is more likely to represent a false-positive than a true-positive finding. By contrast, for an older patient being evaluated for anginal chest pain in whom ETT reproduces those symptoms and who exhibits positive ECG changes, the pre-MPI probability is very high, so the same MPI results are much more likely to represent a true-positive than a false-positive finding (**eFig. 16.4C, D**). These examples illustrate how the clinical data may be incorporated into the MPI interpretation and also how bayesian probability principles may be incorporated sequentially so that the image reader conveys information to the referring clinician that reflects the post-test probability of disease (and risk), rather than simply reporting what the image data show in isolation.

Important Signs in SPECT Imaging Analysis Beyond Myocardial Perfusion

Other abnormal findings provide additional information beyond that indicated by the perfusion pattern alone, including lung uptake of tracer (particularly ^{201}Tl) and transient ischemic dilation of the left ventricle.

Lung Uptake

In some patients, substantial tracer uptake is apparent throughout the lung fields after stress that is not present at rest (**Fig. 16.9A**). Patients with lung uptake often have severe multivessel disease and exhibit elevation of pulmonary capillary wedge pressure and decreases in ejection fraction (EF) during exercise, all implying extensive myocardial ischemia.[4] It is likely that ischemia-induced elevation in left atrial and pulmonary pressures slows pulmonary transit of the tracer, allowing more time for extraction or transudation into the interstitial spaces of the lung, accounting for this imaging sign.

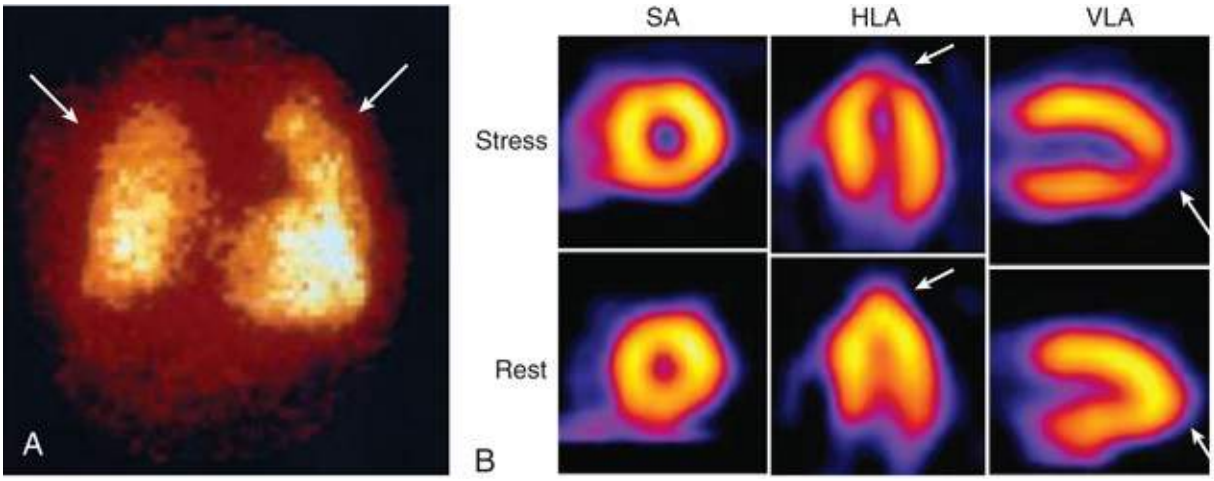


FIGURE 16.9 **A,** Increased lung uptake of ^{201}Tl (*arrows*) on planar imaging, viewed in the anterior projection. Lung uptake such as this pattern is associated with extensive CAD and an adverse prognosis. **B,** Apical reversible perfusion pattern consistent with ischemia (*arrows*) in the territory of the LAD artery. There is also transient ischemic dilation (TID), as the left ventricular cavity is larger (appears more dilated) in the stress images than in the rest images in all three tomographic views. The quantitative TID ratio was high at 1.49. Even though the perfusion pattern by itself suggests single-vessel LAD disease, the presence of TID makes the probability of multivessel disease more likely. *HLA,* Horizontal long-axis; *SA,* short-axis; *VLA,* vertical long-axis view.

Lung uptake of ^{201}Tl has been more extensively validated than lung uptake of the ^{99m}Tc tracers sestamibi and tetrofosmin. Splanchnic or background activity is minimal after thallium stress injection, allowing image acquisition earlier after stress. In addition, the redistribution properties of thallium mandate that imaging begin relatively early after stress, so lung uptake may be more apparent.

Transient Ischemic Dilation of the Left Ventricle

Transient ischemic dilation refers to an imaging pattern in which the left ventricle or left ventricular (LV) cavity appears larger on the stress images than on those obtained with the patient at rest[6] (**Fig. 16.9B**). For patients in whom the entire left ventricle appears larger during stress, the pathophysiology probably is related to extensive ischemia and prolonged postischemic systolic dysfunction, resulting in a dilated, dysfunctional left ventricle during the stress acquisition relative to the rest acquisition. In other patients the epicardial silhouette appears similar at stress and at rest, but with apparent dilation of the LV cavity. This pattern may represent diffuse subendocardial ischemia (relatively less tracer uptake in the subendocardium, creating the appearance of an enlarged LV cavity) and also is associated with severe and extensive CAD. Contemporary processing systems can automatically quantify transient ischemic dilation.

Both lung uptake and transient ischemic dilation provide clues to more extensive CAD than may have been suspected from the perfusion pattern alone. Both signs have been associated with angiographically extensive and severe CAD and with unfavorable long-term outcomes; accordingly, such changes are considered high-risk findings.

Common Normal Variations in SPECT Imaging.

Normal variations in perfusion images can be falsely interpreted as a defect. These perturbations from a completely homogeneous tracer pattern throughout the myocardium are related to structural variations of the myocardium as well as to technical factors associated with image acquisition.

One example is the “dropout” of the upper septum secondary to merging of the muscular septum with

the membranous septum (**Fig. 16.10A**). Apical thinning is another variation of normal that can be mistaken for a perfusion defect (**Fig. 16.10B**). The apex is anatomically thinner than other myocardial regions, creating this appearance. In normal SPECT images the lateral wall often may appear brighter than the contralateral septum (**Fig. 16.10C**). This difference is not caused by a disparity in lateral versus septal wall myocardial blood flow. Rather, during a SPECT acquisition, the camera is physically closer to the lateral myocardial wall (in proximity to the lateral chest wall) than to the septum through the course of the camera's orbit, so that the lateral wall emissions are subject to less soft tissue attenuation and the acquisition is associated with more efficient count capture from that region. A careful review of the data for a series of normal volunteers or patients with a low probability of CAD with one's own equipment is an important step in minimizing the influence of these normal variations on the sensitivity and specificity for detection of CAD.

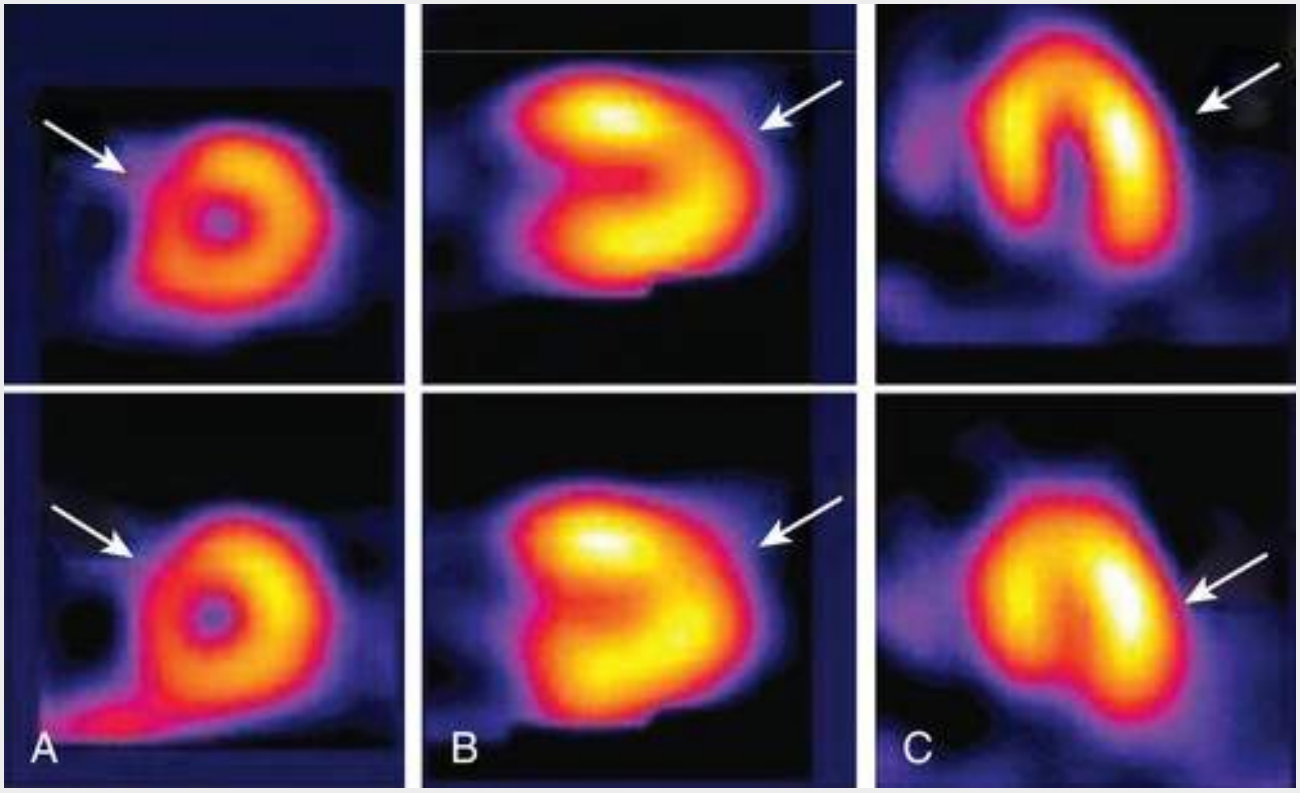

FIGURE 16.10 Normal variations in SPECT perfusion imaging. **A,** Normal "dropout" of the basal septum (*arrows*), which would be seen in the most basal short-axis tomograms. **B,** Normal apical thinning (*arrows*). **C,** The lateral wall often is slightly "hotter" than the septum, another normal variation.

Technical Artifacts Affecting Image Interpretation

Photon Attenuation.

This refers to undetected events in the heart caused by interaction of photons with the intervening soft tissue, breast, or diaphragm. Attenuation of photons can produce artifactual defects in both positron emission tomography (PET) and SPECT cardiac imaging that mimic true myocardial perfusion defects, thereby reducing specificity (i.e., increasing false-positive findings).

Breast Attenuation.

In patients with large or dense breasts, significant attenuation may create artifacts varying considerably in their appearance and location (**Fig. 16.11**). A review of the cine display of the raw projection images may reveal the presence of potential breast attenuation.[5] The availability of gender-matched quantitative databases has had a favorable although modest impact on this issue, because such databases generally

consist of individuals of average body and breast size.

FIGURE 16.11 Differential diagnosis of a mild fixed defect by incorporation of gated functional images. **A,** The summed images demonstrate a mild fixed anterior and anteroseptal defect in the short-axis (SA) and vertical long-axis (VLA) views (*arrows*). There was a suggestion of breast shadowing on review of the raw cine images (not shown). Thus this defect may represent either a nontransmural anterior infarct or an artifact consistent with breast attenuation. In such cases, the gated SPECT functional images are helpful in making this distinction. **B,** In the gated images, the same SA and VLA views are shown but frozen in end diastole and end systole. In both views, wall thickening from end diastole to end systole (*arrows*) appears normal. This appearance is most consistent with an attenuation artifact, because an infarct would be expected to result in abnormal wall thickening.

Several approaches to minimizing the impact of breast tissue have been taken to improve specificity (lowering the false-positive rate) in women. Most well validated is ECG-gated SPECT imaging with ^{99m}Tc-based agents (see later). The presence of preserved wall motion in the setting of a mildly to moderately severe fixed defect of the anterior or anterolateral wall suggests the absence of infarction and supports the interpretation of attenuation artifact (**Fig. 16.11**). Specificity for ruling out CAD in women has been improved significantly with this technique.[4]

Inferior Wall Attenuation.

Inferior wall attenuation artifacts are frequently encountered in SPECT imaging. This artifact may be caused by extracardiac structures, such as the diaphragm overlapping the inferior wall (**Fig. 16.12**). In addition, during a SPECT acquisition, the longer distance from the inferior wall to the camera means that photons must traverse a greater thickness of tissue before reaching the detectors, which may increase the degree of scatter and attenuation.

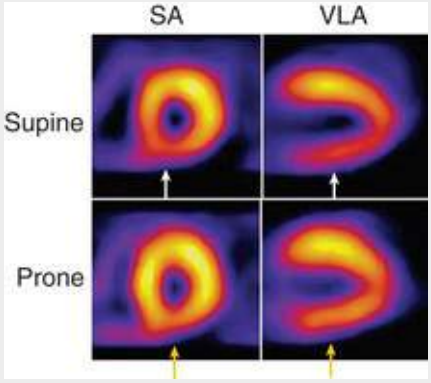

FIGURE 16.12 Example of the use of prone imaging to resolve diaphragm attenuation versus true defect. **Top row,** Standard supine images show an apparent inferior perfusion defect (*white arrow*). There was substantial diaphragm overlap of the inferior wall on the raw projection images (not shown), and the exercise stress test was very low risk, both suggesting that the defect was a false positive. **Bottom row,** The patient was reimaged in the prone position, which helps to create more separation between the diaphragm and the inferior wall. The prone images show normal perfusion of the inferior wall (*yellow arrows*), suggesting that the defect seen on the supine imaging was indeed a false positive. *SA,* Short-axis view; *VLA,* vertical long-axis view.

As with breast attenuation artifact detection, the demonstration of preserved wall thickening by gated SPECT imaging may be helpful in distinguishing attenuation artifact from infarct. The patient's positioning also may minimize the degree of attenuation. By imaging the patient in the prone position,[2,5] the inferior wall is shifted away from the diaphragm and is therefore less subject to attenuation (**Fig. 16.12**).

Artifacts Related to Extracardiac Tracer Uptake.

Tracer uptake in extracardiac structures can cause artifacts in SPECT images. When such a structure is near the heart, increased counts may reach the detector, falsely elevating the number of counts the system assigns to the nearby cardiac wall, so the cardiac region is displayed as falsely "hotter." A second possibility occurs when a nearby hot extracardiac structure causes a "ramp filter" or "negative lobe" artifact.[2] This artifact results from a hot extracardiac structure "stealing" counts from the heart during the calculation of the summed SPECT images. The adjacent myocardium appears falsely "cool." If substantial extracardiac uptake is noted, image acquisition can be repeated after waiting a longer time before imaging. Having the patient drink cold water may enhance clearance of tracer from visceral organs, particularly the bowel.

Attenuation Correction Methods

The 511-keV photons emitted by positron-emitting radiotracers in PET imaging are attenuated less per centimeter of soft tissue than are the lower-energy 80- to 140-keV photons typically emitted by SPECT radiotracers. In SPECT imaging, a single photon needs to travel from the heart to the camera; in PET imaging, two coincident photons (i.e., emitted simultaneously) need to travel across the entire body to reach their respective detectors (see later, Positron Emission Tomography). Although the total attenuation may actually be greater for PET than for SPECT, an important distinction in the case of PET is that the attenuation is the same along a projection line (the path the pair of photons traverse) independent of how deep in the body the annihilation took place. Thus, in PET, only the total attenuation through the whole body along a specific direction must be known. On the other hand, in SPECT, it is necessary to know the exact depth along a projection line where the radioactive decay took place in order to correct for attenuation. Therefore, attenuation correction for SPECT is theoretically more challenging. In recent years, several approaches to correct for attenuation in both PET and SPECT imaging have emerged, with the goal of "correcting" attenuation artifacts to minimize false-positive defects and to improve specificity.

PET Attenuation Correction.

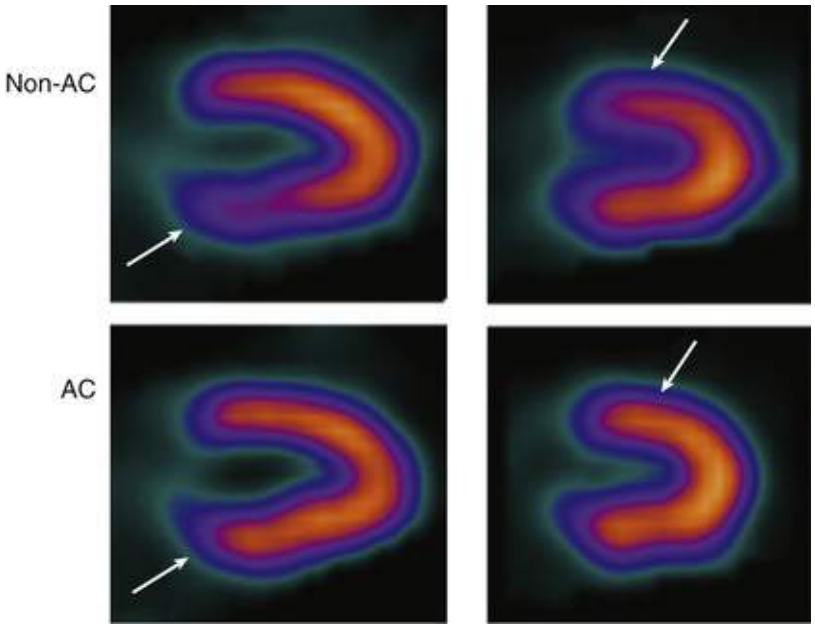
To measure the attenuation correction factor, a rod that rotates about the patient is filled with a relatively long-lived positron emitter, germanium-68, or a single-photon emitter, cesium-137. The rod is first made to rotate at a fixed speed in the gantry, and total coincident counts are measured without the patient (the blank scan) and repeated with the patient (the transmission scan). The ratio of coincident counts of blank scan and those of transmission scan yields the array of attenuation correction factors needed to correct each projection line. Once each projection line has been corrected for attenuation (and scatter), the emission data may be reconstructed into an attenuation-corrected emission image for clinical interpretation. As long as the patient does not move during the scanning procedure, cardiac PET images will be free from attenuation artifacts.

SPECT Attenuation Correction.

Approaches similar to PET attenuation correction have been attempted to correct attenuation artifacts in SPECT, but these methods have not been widely adopted because the problem of attenuation correction is fundamentally more challenging in SPECT than in PET. A number of commercially available SPECT gamma cameras have the ability to acquire transmission data and to perform attenuation correction. Several published studies suggest that incorporating attenuation correction into SPECT interpretation may increase the specificity of CAD diagnosis. However, the increased cost of SPECT attenuation correction systems and the additional time required to quality control, acquire, and process studies are factors that

have slowed the widespread deployment of this technology.

Despite these technical challenges, the application of attenuation correction in multicenter clinical trials, with different hardware and software approaches, has been shown to add to the diagnostic accuracy of stress myocardial perfusion SPECT, predominantly by improving specificity (**eFig. 16.5**). Guidelines suggest that incorporation of attenuation correction methodology into SPECT perfusion imaging studies is optional.[2] This recommendation presumes that, when it is performed, the attenuation correction methodology is applied by personnel highly knowledgeable about the technique and its stringent quality control.



EFIGURE 16.5 Impact of attenuation correction (*AC*). **Top row,** The non-AC images include examples of an inferior defect (*left column*) and an anterior defect (*right column*), which may represent diaphragmatic and breast attenuation, respectively, or may represent a true perfusion abnormality. **Bottom row,** With the application of AC, both images become normal in appearance, suggesting that the abnormalities in the non-AC images were highly likely to represent artifact. (Courtesy Ernest Garcia, PhD.)

Gated SPECT Imaging

An important advance in the use and application of SPECT MPI has been the incorporation of ECG-gated SPECT perfusion imaging for simultaneous assessment of LV function and perfusion. Before the use of gated SPECT, comprehensive information on both perfusion and function required separate testing modalities, such as SPECT MPI and separate radionuclide ventriculography (RVG) or echocardiography.

To assess parameters of cardiac function with echocardiography (**see Chapter 14**), LV endocardial borders are drawn over several beats to derive parameters such as ejection fraction (EF). With contrast left ventriculography, endocardial borders are drawn for either one beat or an average of several beats to calculate EF. In contrast, with MPI the number of counts recorded during any individual cardiac cycle is insufficient to create an interpretable image for assessment of ventricular function. This limitation is overcome with the use of a technique known as ECG *gating* (**Fig. 16.13**), in which an average cardiac cycle is created representing the average of several hundred beats acquired over 8 to 15 minutes.

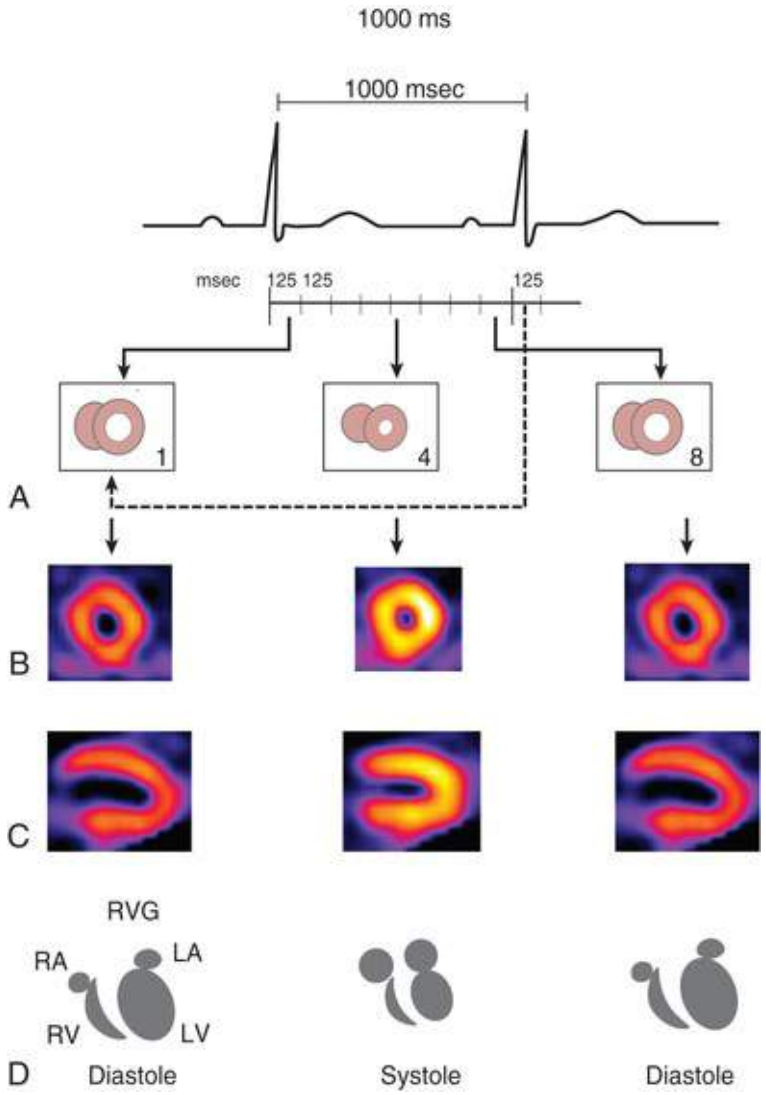


FIGURE 16.13 Basis for the technique of ECG gating. **A,** The scintigraphic acquisition data are collected in conjunction with the electrocardiogram. The R-R interval is divided into a prespecified number of "frames" (in this example, eight frames). At a heart rate of 60 beats/min (1000 msec/beat), each of the eight frames would comprise 125 milliseconds. For the first 125 milliseconds after the peak of the initial R wave, all imaging data are recorded in frame 1; the second 125 milliseconds are recorded in frame 2, and so on, until the peak of the next R wave is detected, and this is repeated for each beat in the acquisition. Frame 1 thus represents the end-diastolic events, and one of the frames in the middle of the acquisition (frame 4 in this example) represents end-systolic events. **B,** Examples of gated SPECT perfusion imaging. Short-axis images are seen at end diastole and at end systole. **C,** Similar timing with images displayed in the vertical long-axis orientation. Visually, wall thickening and brightening are seen across the course of systole. These events represent changes in regional and global function across the cardiac cycle. **D,** ECG-gated equilibrium radionuclide ventriculographic schematic images are shown at diastole and at end systole. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. (Modified from Germano G, Berman DS. Acquisition and processing for gated SPECT: Technical aspects. In Germano G, Berman DS, editors. Clinical Gated Cardiac SPECT. Armonk, NY: Futura; 1999, pp 93-114.)

During an ECG-gated image acquisition, the patient's ECG is monitored simultaneously. As the peak of an R wave is detected, the "gate" opens, and a set number of milliseconds of imaging information is stored in a "frame." For a typical gated SPECT acquisition, each R-R interval is divided into eight frames. For example, if the patient's heart rate at rest is 60 beats/min (1000 milliseconds per beat), an eight-frame acquisition across the cardiac cycle comprises 125 milliseconds per frame. After the first 125 milliseconds of imaging data have been recorded in frame 1, the gate closes and then instantly reopens, allowing the second 125 milliseconds of information to be recorded in frame 2 (**Fig. 16.13A**). This sequence continues through the prespecified number of frames throughout the cardiac cycle. When the R wave of the next beat is detected by the ECG-gated system, the sequence is repeated, and so on, for each

of the many beats that occurs throughout the image acquisition.

When several hundred beats have been recorded, an average cardiac cycle representing all the recorded beats can be reconstructed by redisplaying the frames sequentially in a cine or movie format.[8] The first few frames represent systolic events, and the latter frames represent diastolic events (**Fig. 16.13A**).

High-quality ECG-gated images require that the cardiac cycles that are included have reasonably homogeneous beat lengths. This usually is accomplished by *beat-length windowing*, whereby the computer acquisition system is programmed to accept beats of only certain cycle lengths into the acquisition. Typically, cycles with the beat length represented by the average heart rate of the patient (1000 msec in the preceding example), along with cycles fluctuating up to 10% to 15% around the average beat length, are allowed into the acquisition. Cardiac cycles with cycle lengths above or below that limit are rejected. For example, the short cardiac cycle from the R wave of a normal beat to the R wave of a premature ventricular complex (PVC) would not be allowed into the acquisition, nor would the long cycle representing the post-PVC pause. This makes physiologic sense; the short pre-PVC beat and the more prolonged post-PVC beat have distinctly different systolic and diastolic characteristics from those of the beats occurring during normal sinus rhythm.

Gated SPECT Interpretation of Regional Wall Motion.

Normal regional systolic function is depicted as brightening of the wall during systole[2,8] (**Fig. 16.13B**). The wall appears to thicken, with apparent endocardial excursion. Assessment of regional LV function by gated SPECT imaging is based on an effect known in imaging physics as the *partial volume effect*, sometimes referred to as the recovery coefficient effect. When objects being imaged fall below a certain thickness threshold, count (or photon) recovery from the object is related not only to the tracer concentration within that object but also to the thickness of the object.[8] For SPECT imaging, usually all myocardial wall thicknesses fall below that threshold. Although tracer concentration within the myocardium is constant during a gated SPECT image acquisition, the recovery of counts (and thus the brightness of the object being imaged) is related to wall thickness. Thus, during systolic wall thickening, it appears that the LV wall becomes brighter and thicker, even though the isotope concentration per gram of myocardial tissue is actually unchanged. This principle forms the basis for gated SPECT imaging.

Regional myocardial function usually is assessed visually, in a manner similar to the analysis performed in echocardiography. Regions that brighten normally have normal regional systolic performance, and those with diminished but apparent brightening are labeled *hypokinetic*. Regions with slight brightening are interpreted as *severely hypokinetic*, and regions with no apparent brightening as *akinetic* (**Fig. 16.14**). Regional function also can be analyzed by quantitative techniques and displayed in a polar map format, although visual analysis is performed most often.

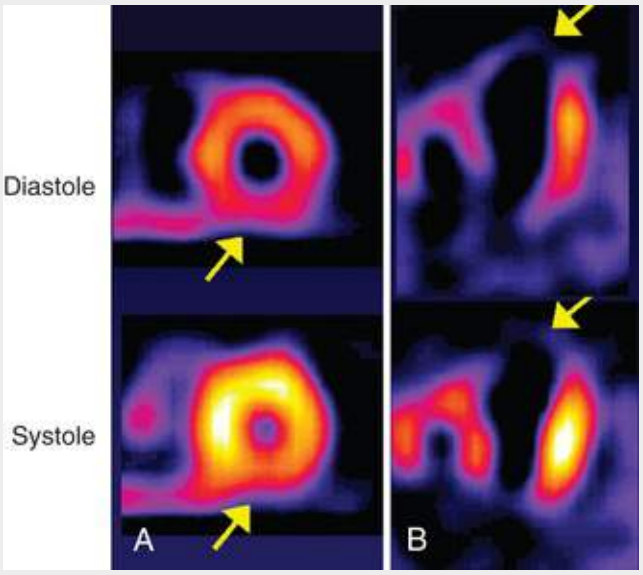

FIGURE 16.14 Examples of regional dysfunction detected by ECG-gated SPECT perfusion imaging. **A,** The severely hypokinetic inferior region appears to brighten less (*arrows*) than the other regions from diastole to systole. The lateral wall also brightens less than the normal septum and would therefore be interpreted as hypokinetic. **B,** The akinetic apex in the horizontal long axis (*arrows*) shows no apparent change from diastole to systole, in contrast to the normally thickening (brightening) lateral wall.

Gated SPECT Assessment of Global Left Ventricular Function.

All contemporary camera-computer systems have software capable of quantifying global LV function and computing the EF. These computer-based methodologies are fully automated and thus highly reproducible. The most common method involves automated interrogation of the apparent epicardial and endocardial borders of all the tomograms in all three orthogonal planes (**Fig. 16.15A**). These multiple two-dimensional contours are then reconstructed to create a surface-rendered three-dimensional display representing global LV function across the average cardiac cycle (**Fig. 16.15B**) that can be viewed from any direction by simple maneuvering of the computer display screen or cursor.[8] The three-dimensional display is accompanied by automated calculation of EF and LV volumes.

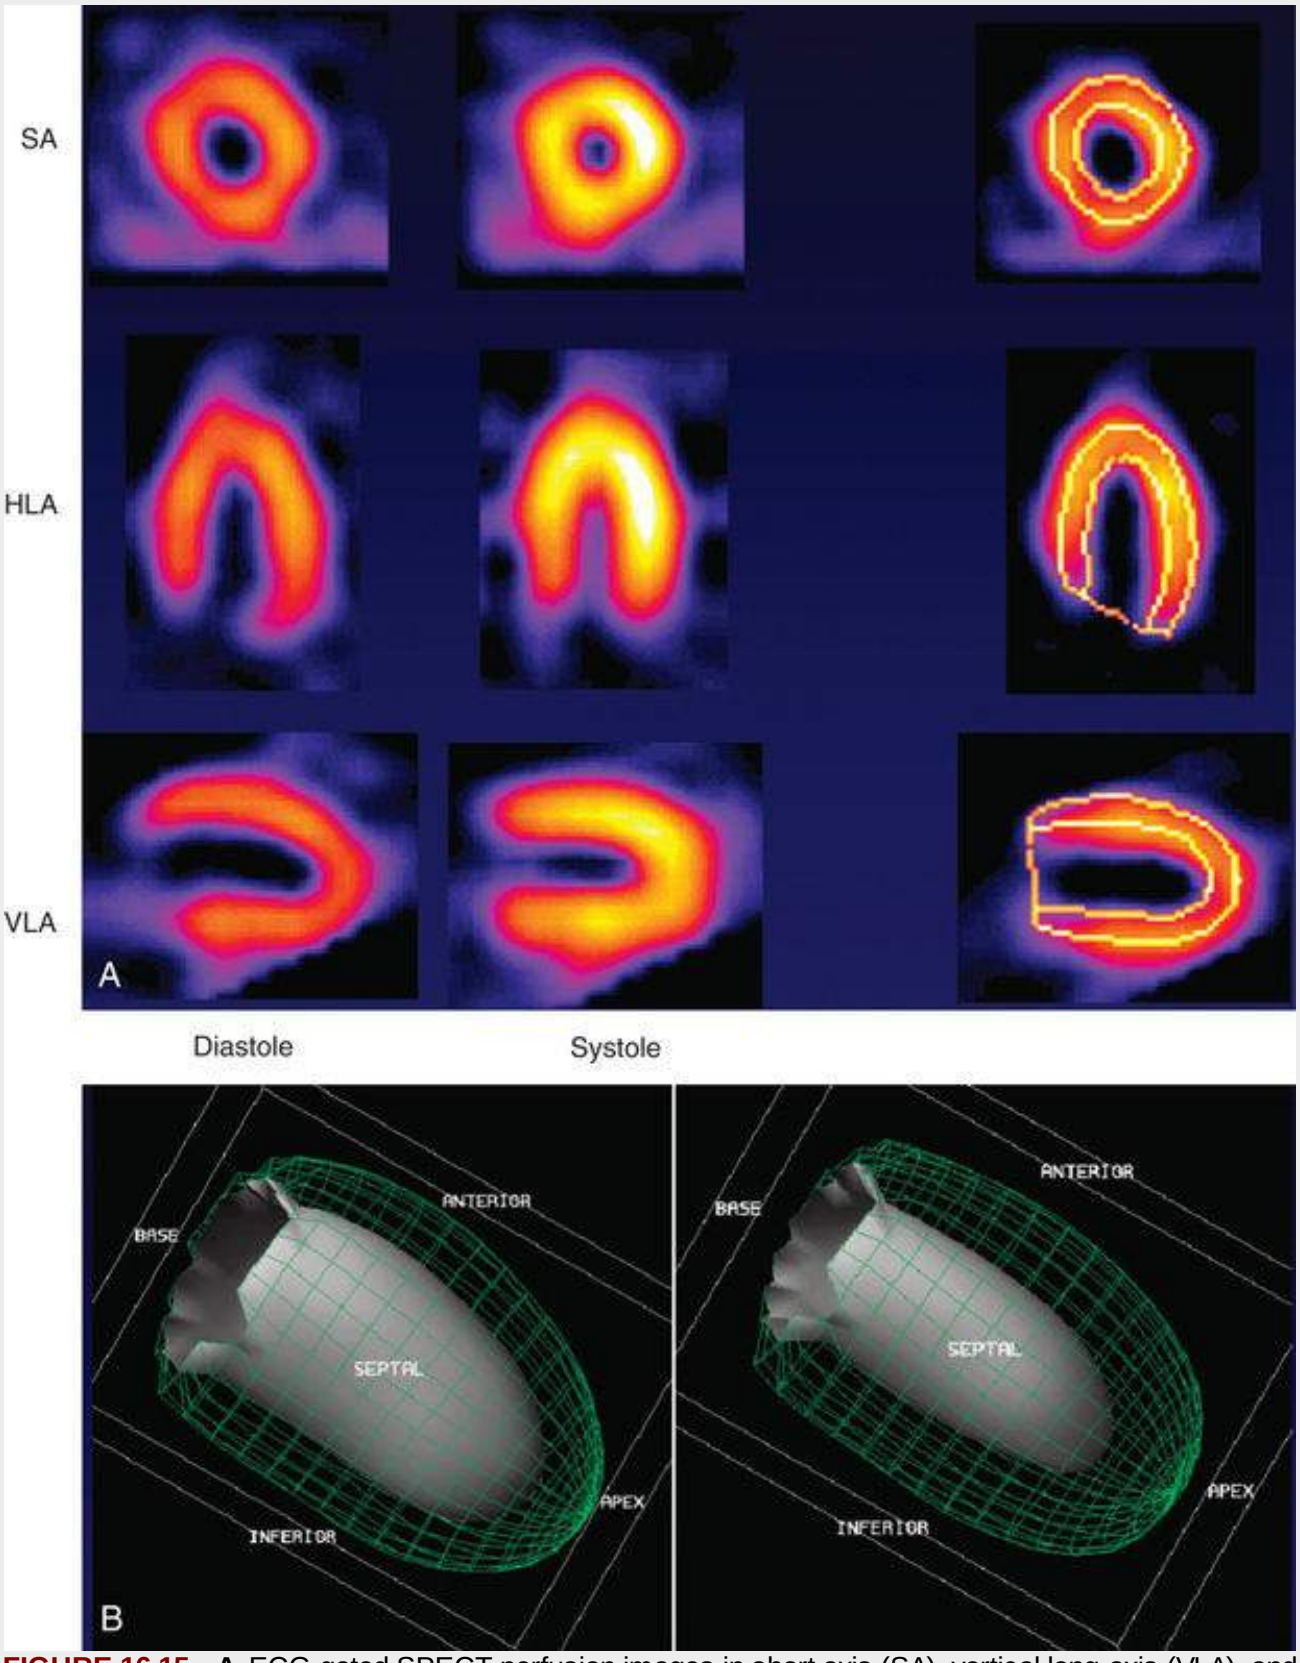

FIGURE 16.15 **A,** ECG-gated SPECT perfusion images in short axis (SA), vertical long-axis (VLA), and horizontal long-axis (HLA) views, shown frozen at end diastole (*left column*) and end systole (*middle column*). Endocardial and epicardial borders are shown on the diastolic frames as automatically assigned by the software analysis program (*right column*). **B,** From the contours that are created from all the two-dimensional tomograms, a three-dimensional surface-rendered image of the left ventricle can be created and displayed in multiple orientations, here frozen at end diastole (*left*) and end systole (*right*). The *green* "mesh" represents the epicardium, and the *gray* surface represents the endocardium. Ejection fraction (EF) is quantified from the volume change. During image interpretation, gated SPECT images are displayed in the cine format as an endless loop movie, rather than as the still frames depicted here.

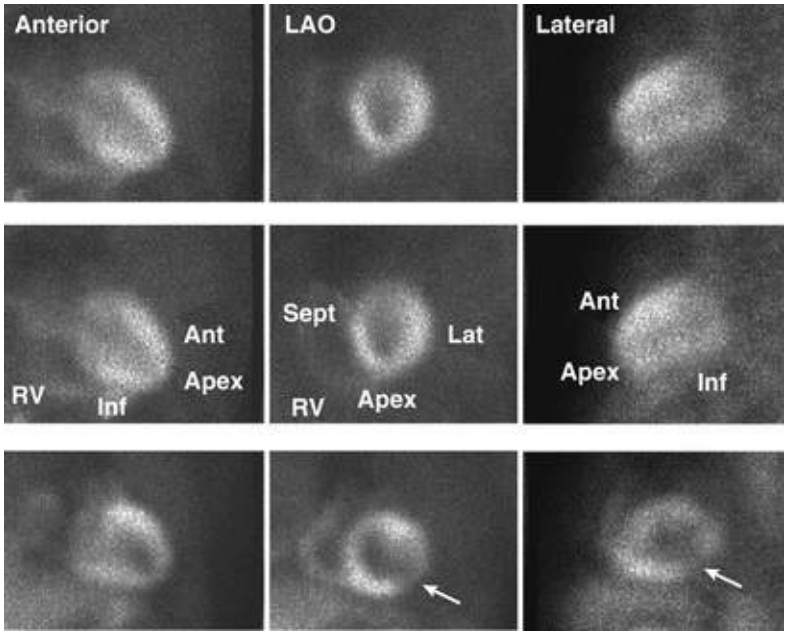
EF measurements from automated analysis of ECG-gated SPECT MPI have been extensively validated against those obtained using other quantitative techniques for assessing LV function, such as equilibrium

RVG, angiographic contrast left ventriculography, and cardiac magnetic resonance (CMR)[8] (**see Chapters 17 and 19**). Across a wide range of LV function, and even in the setting of severe perfusion defects, ECG-gated SPECT imaging provides robust, reproducible estimates of LVEF.

The incorporation of ECG-gated SPECT imaging into a SPECT acquisition is now routine in MPI and is recommended as standard by contemporary guidelines.[2,5] As discussed later, the addition of LV function data to the perfusion information provides incremental and independent prognostic information, in addition to its practical importance in management decisions. Gated SPECT imaging also has been an important advance in helping to differentiate attenuation artifacts from infarct, because regions with persistent low counts that show normal motion and thickening represent soft tissue artifacts rather than scar (**see Fig. 16.11**). Thus, gated SPECT has improved the specificity of perfusion imaging for ruling out CAD, particularly in women.[5]

Planar Myocardial Perfusion Imaging

Before the widespread application of tomographic (SPECT) perfusion imaging techniques, planar imaging was the standard acquisition and display methodology. In planar imaging, three separate two-dimensional images are obtained with the gamma camera after radiotracer injection and uptake into the myocardium.[2] The three standard views are an anterior, a left anterior oblique, and a more lateral view (**eFig. 16.6**).



EFIGURE 16.6 Examples of planar myocardial perfusion imaging (MPI). **Top row,** Normal stress planar perfusion study in the anterior, shallow left anterior oblique (*LAO*), and more lateral views. Tracer uptake is uniform throughout the myocardial walls. **Middle row,** The same normal planar stress perfusion images are shown, with the myocardial walls that are seen in each labeled view. The anterior wall (*Ant*), apex, and inferior (*Inf*) walls are seen in the anterior view, as well as right ventricle (*RV*). The septum (*Sept*), apex, and lateral walls (*Lat*) and the RV are seen in the shallow LAO view, and the anterior wall, apex, and inferior walls are seen in the lateral view. **Bottom row,** Abnormal planar study showing a lateral wall stress perfusion defect in the shallow LAO view (*arrow*), extending into the inferior wall in the lateral view (*arrow*). Rest images are not shown. (Courtesy Dr. Kim A. Williams.)

An advantage of planar imaging over SPECT imaging is its simplicity. Each of the three views can be acquired during 5 to 8 minutes with patients lying on a table with their arms by their sides. Planar imaging

is less affected by patient motion than is SPECT imaging. With planar imaging, extensive image processing is not required as with SPECT, so there are fewer sources of potential error and artifact. Because of its two-dimensional nature, however, planar imaging in each of the standard views generates substantial overlap of myocardial regions, with less differentiation of smaller and particularly milder perfusion abnormalities. The more standard orientation of SPECT imaging lends itself to easier understanding of the localization of perfusion abnormalities.

In contemporary practice, planar imaging may be used for patients who do not tolerate the position that must be maintained during a SPECT acquisition, those who have difficulty coping with presence of the larger SPECT camera so close to the body, or those with large body habitus that surpasses the weight and size limits of SPECT systems.[5]

Radionuclide Ventriculography or Angiography

Also known as radionuclide angiography or blood pool imaging, RVG may be performed using first-pass or by equilibrium-gated techniques.[8] The equilibrium technique often is referred to as *multiple gated acquisition* (MUGA) scanning. Although the two techniques each use specific tracers and data-recording methods, they provide similar results for global EF and chamber volumes. Both techniques provide a highly reproducible means to quantify global LV and right ventricular (RV) EF.

Equilibrium Radionuclide Angiography or Ventriculography (Gated Blood Pool Imaging)

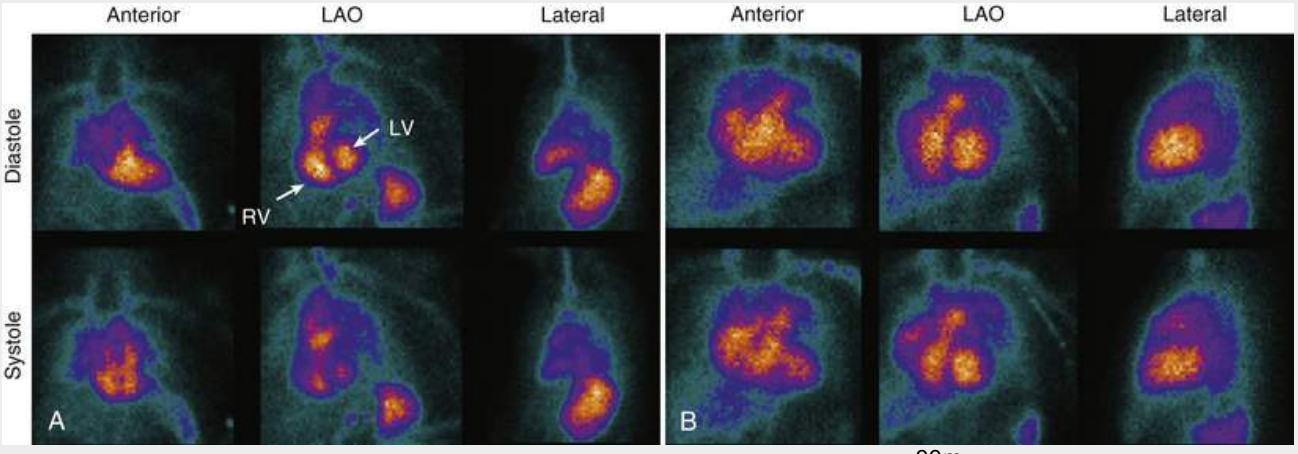
In equilibrium RVG studies, data are recorded in a computer system synchronized with the R wave of the patient's ECG, similar to ECG-gated SPECT (**see Fig. 16.13**). For labeling of the blood pool, ^{99m}Tc is bound to red blood cells (RBCs) or albumin. Image contrast usually is better with ^{99m}Tc-labeled RBCs, but ^{99m}Tc-labeled albumin is preferable in patients in whom RBC labeling may be difficult. Labeling of RBCs with ^{99m}Tc-pertechnetate requires a reducing agent, stannous pyrophosphate, which is administered 15 to 30 minutes before pertechnetate injection.

Image Acquisition.

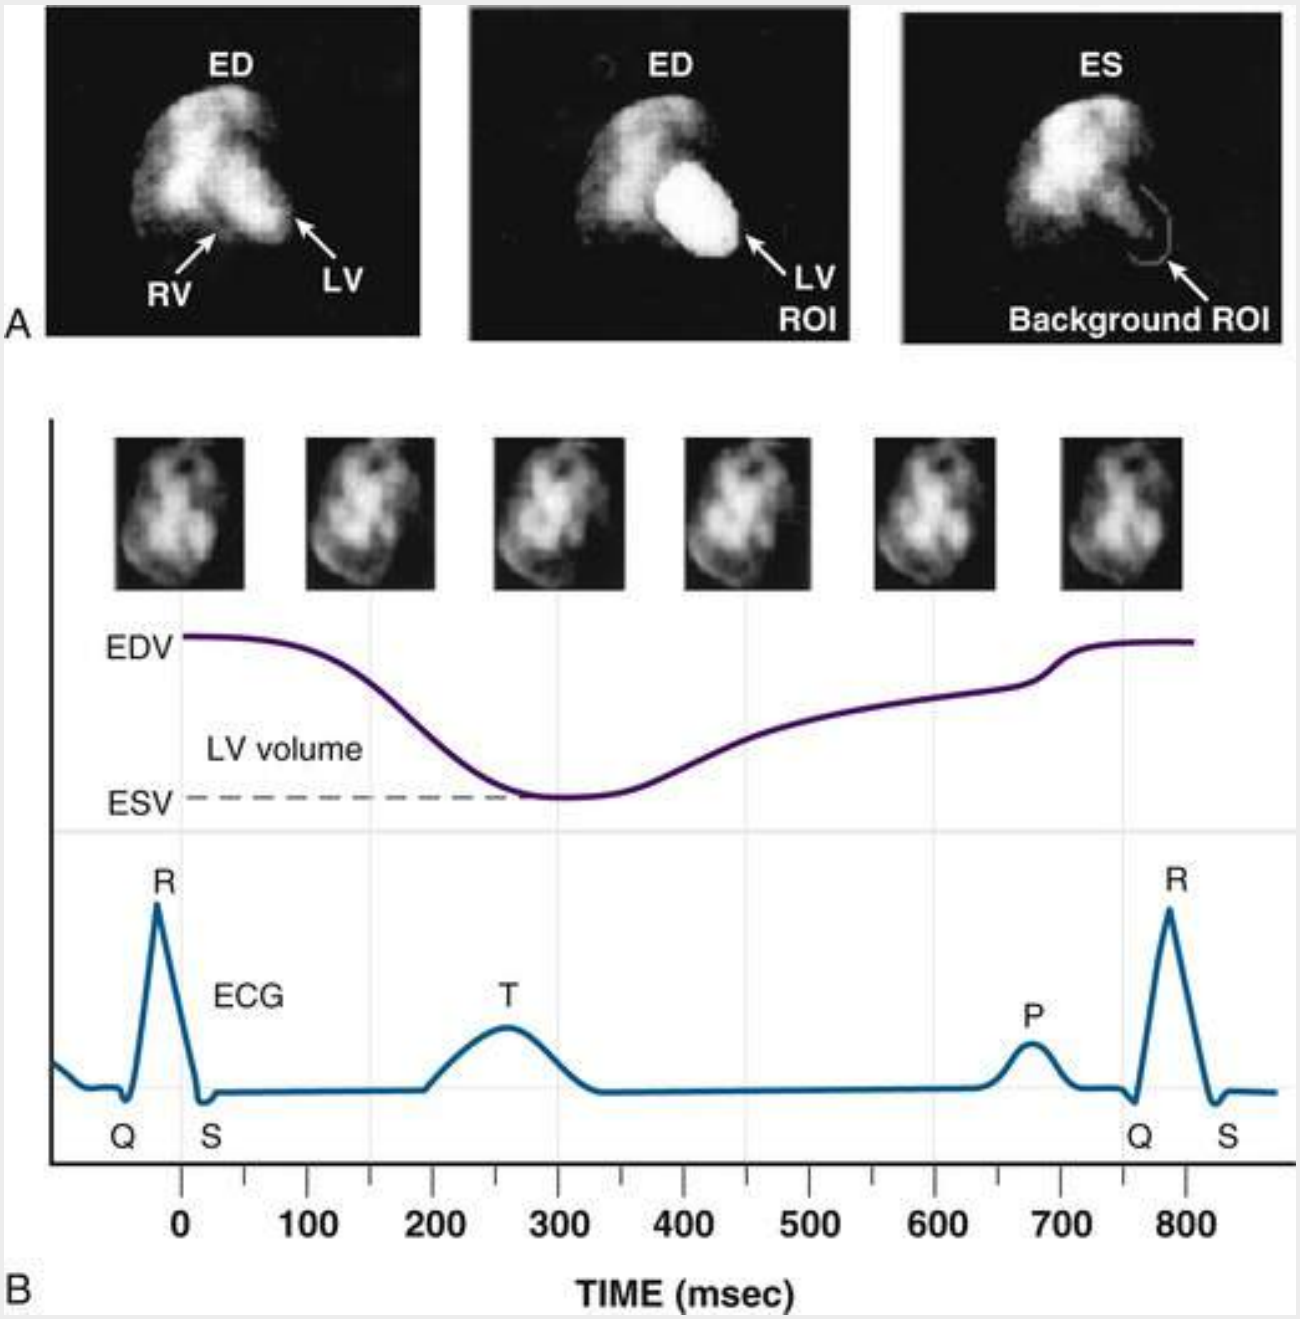
Although relatively few counts are recorded during a single ECG-gated cardiac cycle, the summation of counts from 800 to 1000 cardiac cycles produces an average cardiac cycle with high resolution. Images of the heart are usually acquired in three standard projections: anterior, “best septal” left anterior oblique (best separation of the left and right ventricles), and left lateral (or left posterior oblique). The minimum framing rate for a rest RVG study is 16 frames/cycle (approximately 50 msec/frame).[8] For quantitative assessment of diastolic indices and regional EF, the framing rate should be increased to 32 frames/cycle (approximately 25 msec/frame). For adequate counting statistics, images are acquired for a preset count of at least 250,000 per frame or count density of 300 counts per pixel, which corresponds to an acquisition time of 5 to 10 minutes per projection. For exercise studies, adequate counts can be obtained in the best septal view with a 2-minute acquisition using a high-sensitivity collimator. Arrhythmias such as multiple PVCs can adversely affect the study if these beats account for more than 10% of the total. In patients with atrial fibrillation, there may be considerable beat-to-beat variability, and the mean EF obtained during the period of acquisition may underestimate the actual LVEF.[8]

Image Display and Analysis.

Qualitative inspection of equilibrium studies as an endless cinematic loop of the cardiac cycle (**see Fig. 16.13D**) allows assessment of (1) size of heart chambers and great vessels; (2) regional wall motion; (3) global function (qualitative assessment) (**eFig. 16.7**); (4) ventricular wall thickness, pericardial effusion, pericardial fat pad, or paracardiac mass; and (5) extracardiac uptake, such as splenomegaly.
Quantification of systolic and diastolic indices and volumes is derived from the ventricular time-activity curve,[8] which is analogous to the angiographic time-volume curve (**eFig. 16.8**). In addition to the time-activity curve, functional images, such as amplitude and phase images, can be produced that have been useful in characterizing regional wall motion abnormalities and asynchrony.



EFIGURE 16.7 Equilibrium radionuclide ventriculography. The isotope (^{99m}Tc) is labeled to red blood cells, so the images represent the blood "pools" in the left ventricle (*LV*), the right ventricle (*RV*), the other cardiac chambers, and the great vessels as well as the spleen. Typically, three views are obtained, as shown. **A,** Normal LV function, with end-diastolic images in the *top row* and end-systolic images in the *bottom row.* LV and RV volumes diminish from diastole to systole. **B,** Images obtained in a patient with LV dysfunction. Significant LV and RV dilation is evident at both end diastole (*top*) and end systole (*bottom*), with severely diminished LV systolic function (i.e., much less volume change from end diastole to end systole compared with the study in **A**). *LAO,* Left anterior oblique.

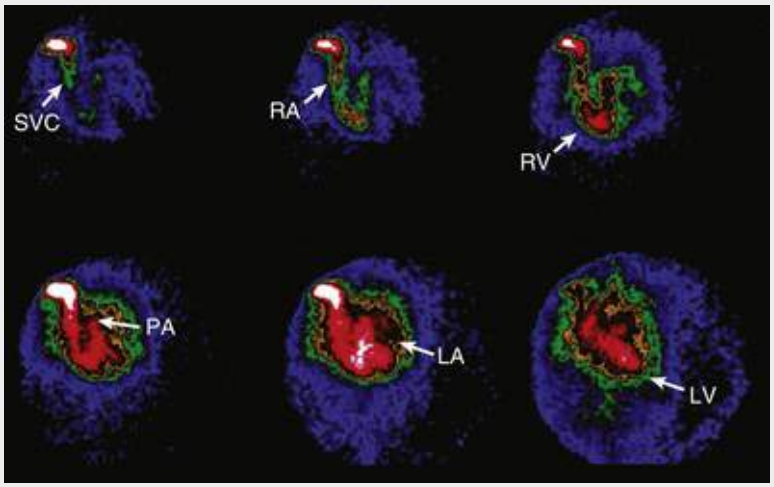


EFIGURE 16.8 Quantitative analysis of equilibrium electrocardiogram (ECG)-gated radionuclide ventriculography. **A,** Left anterior oblique view of the left ventricle (*LV*) and right ventricle (*RV*) is shown at end diastole (*ED*) **(left),** with a region of interest (*ROI*) identifying the LV contour at end diastole **(middle)** and a "background" ROI drawn at end systole (*ES*) **(right),** used to correct for count activity in front of and behind the LV. **B,** A time-activity curve illustrates the change in counts within the ROIs shown in **A** across a cardiac cycle. Because count activity is related to LV chamber volume, the time-activity curve represents the relative volume change of the LV chamber across a cardiac cycle, from end diastole to end systole and back to end diastole. *EDV,* End-diastolic volume; *ESV,* end-systolic volume. (From Green MV, Bacharach SL, Douglas MA, et al. The measurement of left ventricular function and the detection of wall motion abnormalities with high temporal resolution ECG-gated scintigraphic angiocardiography. IEEE Trans Nucl Sci 1976;23:1257.)

First-Pass Radionuclide Angiography or Ventriculography

In first-pass RVG studies, the bolus of radioactivity passes initially through the right chambers of the heart, then through the lungs, and finally through the left-sided chambers of the heart. Radiopharmaceuticals used for this purpose must produce adequate counts in a short time at an acceptably low radiation dose to the patient.[8]

Image Acquisition.
Images are acquired very rapidly as the tracer passes through the heart chambers. Separation of the right and left ventricles is achieved because of the temporal separation of the bolus. Image quality is related to the injection technique, which should be rapid (2 to 3 seconds) to achieve an uninterrupted bolus (**eFig. 16.9**). Images are acquired in the supine position after the rapid injection of 10 to 25 mCi of tracer (depending on type of camera/crystal) through an 18-gauge or larger intravenous catheter placed in the medial antecubital or external jugular vein. The shallow (20- to 30-degree) right anterior oblique projection is used, to optimize separation of the atria and great vessels from the ventricles and to view the ventricles parallel to their long axes. Although the right anterior oblique view maximizes overlap of the right and left ventricles, this is not a problem in most patients because the timing of tracer appearance reliably identifies each chamber sequentially. A 1-mCi tracer dose may be used to ensure proper positioning so that the right and left ventricles are in the field of view.



EFIGURE 16.9 First-pass radionuclide ventriculography. Individual frames from a first-pass acquisition, illustrating the path of the bolus isotope through the superior vena cava (*SVC*), right atrium (*RA*), right ventricle (*RV*), pulmonary outflow tract and lungs (pulmonary artery [*PA*]), left atrium (*LA*), and LV phase, from which the isotope bolus is then distributed systemically.

Image Analysis.
To identify the RV and LV phases, regions of interest are drawn around the right and left ventricles at end diastole.[8] Time-activity curves are generated, and cycles around and including the peak time-activity curve are used to calculate EFs. In general, two to five cardiac cycles are summed for the RV phase, and five to seven cycles are summed for the LV phase. From these data, quantitative analysis of LVEF and RVEF is performed.

Comparison of Equilibrium and First-Pass Techniques

Advantages of the first-pass technique are the high target-to-background ratio, more distinct temporal separation of the cardiac chambers, and rapidity of imaging. RVEF may be more readily assessed by the first-pass technique because of the more distinct separation of this structure from the other chambers with that technique. Advantages of equilibrium technique are the potential for repeated assessment of cardiac function during rapidly varying physiologic conditions, high count density, and acquisition of images in multiple projections. In contemporary practice, the equilibrium technique is performed much more

frequently.[2,5]

Positron Emission Tomography

Because of the quantitative capabilities of PET, measurement of myocardial perfusion and metabolism can be obtained with PET in absolute quantitative terms, a potential advantage compared with SPECT imaging. The radiotracers used in PET are labeled with positron-emitting isotopes that have chemical and physical properties identical to those of naturally occurring elements, such as carbon, oxygen, nitrogen, and fluorine. Incorporation of such elements allows interrogation of physiologically relevant processes in normal and diseased states.[4] Although most positron-emitting radiotracers are cyclotron produced with short half-lives, the development of generator-produced positron-emitting isotopes, such as rubidium-82 (^{82}Rb), makes it feasible for laboratories to perform cardiac PET studies without an on-site cyclotron.

Clinically available cardiac PET radiotracers fall within two broad categories: those that evaluate myocardial perfusion and those that evaluate myocardial metabolism (**Table 16.2**).[4] The perfusion tracers ^{82}Rb and ^{13}N-ammonia and the myocardial metabolic tracer 2-^{18}F-fluoro-2-deoxyglucose (FDG) have received FDA approval.

TABLE 16.2

Properties of Selected Positron Emission Tomography Tracers

TRACER	PRODUCED	HALF-LIFE	COMPOUND
Perfusion			
^{15}O	Cyclotron	2.1 minutes	H_2O
^{13}N	Cyclotron	10 minutes	NH_3
^{82}Rb	Generator	75 seconds	RbCl
Metabolism			
^{11}C	Cyclotron	20.4 minutes	Acetate, palmitate
^{18}F	Cyclotron	110 minutes	Deoxyglucose

Modified from Bergmann SR. Positron emission tomography of the heart. In Gerson MC, editor. Cardiac Nuclear Medicine. New York: McGraw-Hill; 1997, pp 267-300.

Image Acquisition.

PET employs camera systems designed to optimize the detection of positron-emitting radioisotopes. The process by which a positron-emitting radionuclide attempts to stabilize over time is termed *beta decay*, which occurs when the nucleus of an atom emits a positron, a positively charged beta particle (**Fig. 16.16**). After a high-energy positron is emitted from a nucleus, it travels a few millimeters in tissue and ultimately collides with an electron (a negatively charged beta particle). This collision results in complete annihilation of both the positron and the electron, with conversion to energy in the form of electromagnetic radiation composed of two high-energy gamma rays, each with 511-keV energy. The discharged gamma rays travel in perfectly opposite directions (180 degrees from each other). PET detectors can be programmed to register only events with temporal coincidence of photons that strike at directly opposing detectors. The outcome of such selective coincidence detection is an improvement in spatial and temporal resolution for PET over that achieved with SPECT imaging.[9] Unlike the procedure in SPECT, in which an extrinsic collimator is used to limit the direction at which photons enter the detector, the coincidence detection with PET provides “intrinsic” collimation and improves the sensitivity of the camera.

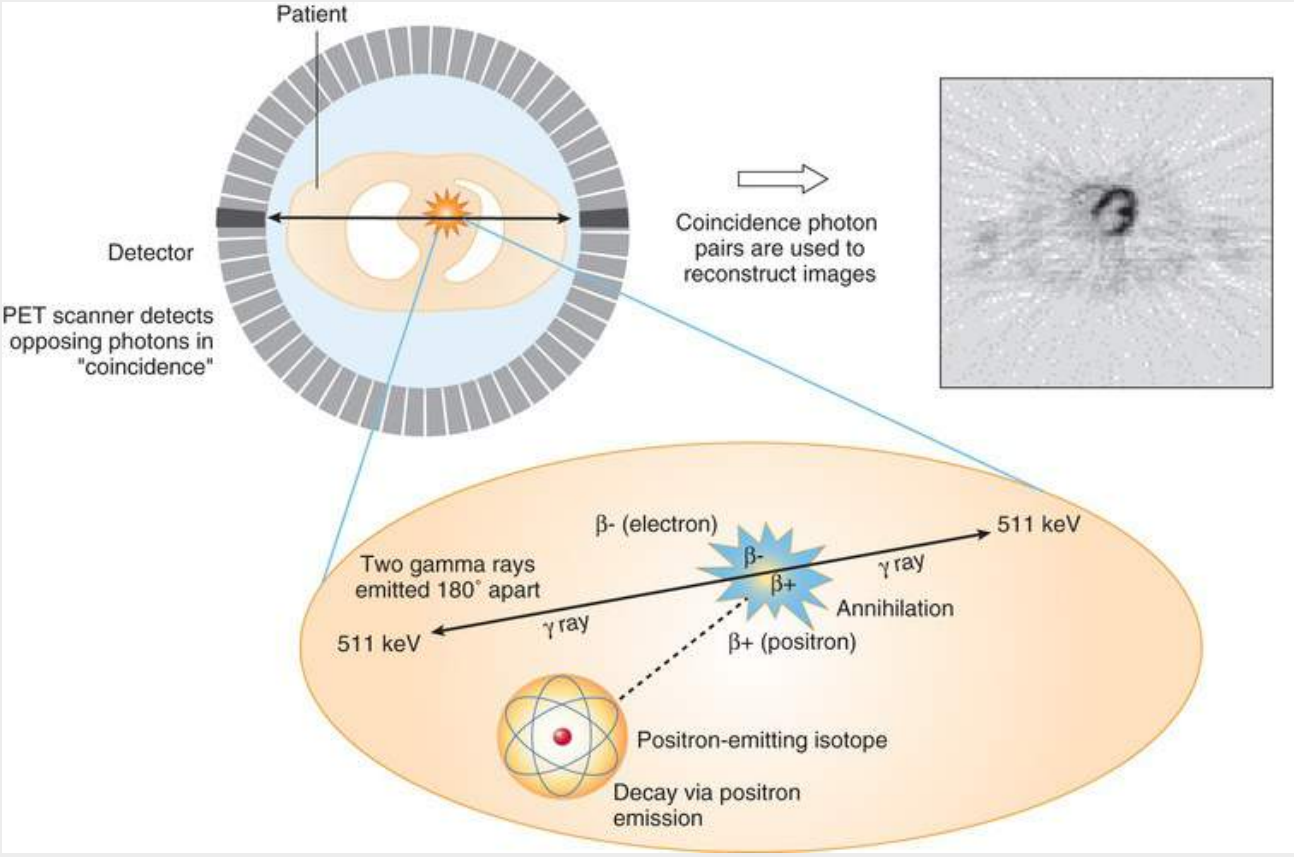


FIGURE 16.16 Schematic of positron and electron beta particle emission, with detection by a coincidence camera, as the basis of PET imaging.

In addition, an important distinction between PET and SPECT is in the ease of labeling primary substrates for energy metabolism and membrane receptor subtypes in the heart, allowing the interrogation of such physiologic pathways in vivo with PET. Moreover, dynamic-mode PET scanning permits potential analysis of the change in tracer content in a specific region of interest in the heart with time, allowing potential interrogation of the rate of change of a physiologic process.

Image Analysis.

Emission data are displayed as tomograms in the horizontal and vertical long-axis and short-axis views, as in SPECT display.[9] If the data are acquired in dynamic mode, with appropriate mathematical modeling, myocardial perfusion and metabolic data can be displayed in absolute terms: in milliliters per gram per minute for blood flow and moles per gram per minute for metabolism.

PET Perfusion Tracers

PET perfusion tracers can be divided into two types: (1) freely diffusible tracers, which accumulate and wash out from myocardial tissue as a function of blood flow, and (2) nondiffusible tracers, characterized by retention in myocardial tissue as a function of blood flow.[4,9] The rapid physiologic washout of the freely diffusible tracers, such as ^{15}O-water, makes it possible to repeat studies in rapid sequence. The images of the distribution of such tracers are usually not visually meaningful; mathematical modeling is done to arrive at flow values at each pixel. An advantage of freely diffusible tracers is that they do not depend on a metabolic trapping mechanism, which might change as a function of a changing metabolic environment.

The nondiffusible flow tracers are easier to image, because the tracer is retained in myocardium for a reasonable length of time. ^{82}Rb and ^{13}N-ammonia fall into this second category of flow tracers, the more microsphere-like flow tracers. ^{82}Rb is a cation, with biologic properties similar to those of potassium and

thallium, and uptake across the sarcolemmal membrane reflects active transport by the Na^+,K^+-ATPase pump. In experimental studies, its extraction fraction does not change significantly over a wide range of metabolic conditions. However, the very short half-life of 75 seconds for ^{82}Rb means that any trapped ^{82}Rb quickly disappears from the myocardium by physical decay. Despite its short half-life, ^{82}Rb is easily obtained, because it is generator produced, and it can be used clinically without the need for an on-site cyclotron.

^{13}N-ammonia is an extractable perfusion tracer, with a physical half-life of 10 minutes. Its transport across cell membranes may occur by passive diffusion or by the active Na^+-K^+ transport mechanism. Retention of ^{13}N-ammonia in the myocyte involves metabolic trapping. As with ^{82}Rb, myocardial uptake of ammonia reflects absolute blood flows up to 2 to 3 mL/g/min and plateaus at more hyperemic flows. The use of this tracer to assess myocardial blood flow has been extensively validated in both experimental and clinical studies.[9]

PET Perfusion Tracers: Research Directions.

^{18}F-labeled fluorobenzyl triphenyl phosphonium, originally developed for measurement of the mitochondrial membrane potential, has been introduced for MPI with PET.[10] The currently available PET myocardial perfusion tracers, ^{82}Rb-chloride and [^{13}N] ammonia, have short physical half-lives and require either an on-site cyclotron or generator, thereby limiting their widespread clinical application. The longer half-life of ^{18}F (110 minutes) allows the possibility of distribution as a single-dose unit on a daily basis, which may facilitate the clinical application of myocardial perfusion PET imaging. Moreover, the longer half-life of ^{18}F would allow assessment of perfusion during treadmill exercise, rather than with vasodilator stress alone, as is currently the case with ^{82}Rb PET.[10]

One such investigational agent, ^{18}F-flurpiridaz PET, has been studied in phase II and III clinical trials in comparison with ^{99m}Tc SPECT.[11] The high spatial resolution of PET imaging, along with high target-to-background ratios achieved with ^{18}F-flurpiridaz, allows the acquisition of very-high-quality electrocardiographic-gated PET images compared to SPECT, along with very good diagnostic accuracy in detection of significant CAD[10,11] (**Fig. 16.17**). In a human feasibility study where absolute quantitation of ^{18}F-flurpiridaz myocardial blood flow (MBF) was studied over a wide range of cardiac flow in the presence or absence of stress-inducible myocardial ischemia, there was a significant decrease in stress MBF in CAD territories, which allowed a clear distinction between vascular territories exhibiting stress-inducible myocardial ischemia and those with normal perfusion.[12] Further studies in larger numbers of patients will be needed to evaluate the clinical utility and diagnostic accuracy of ^{18}F-flurpiridaz absolute MBF, particularly in patients with multivessel CAD.

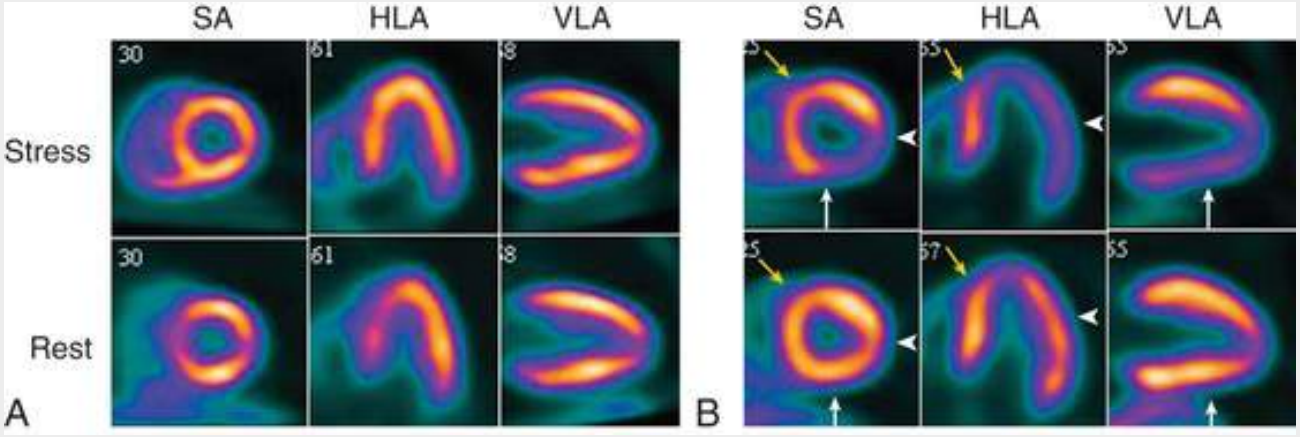

FIGURE 16.17 Representative examples of normal **(A)** and abnormal **(B)** ^{18}F-flurpiridaz PET myocardial perfusion images. **A,** Tomograms in the short-axis (SA), horizontal long-axis (HLA), and vertical long-axis (VLA) views of paired stress (*upper row*) and rest (*lower row*) images show normal distribution of the radiotracer in all myocardial regions. **B,** Paired stress and rest images show extensive reversible regional perfusion defects in all three coronary artery vascular territories: inferior wall reversible defect (*white arrows*), lateral wall reversible defect (*arrowheads*), and anteroseptal wall reversible defect (*yellow arrows*). (Modified from Dilsizian V, Taillefer R. Journey in evolution of nuclear cardiology: will there be another quantum leap with the F-18 labeled myocardial perfusion tracers? J Am Coll Cardiol Imaging 2012;5:1269-84.)

Clinical Application of PET Myocardial Perfusion Imaging

Advantages of PET perfusion imaging over SPECT include higher spatial resolution, improved attenuation and scatter correction, and potential for quantifying regional blood flow (**Fig. 16.18**). Although SPECT assessment of stress and rest myocardial perfusion has been firmly established as an important diagnostic and prognostic tool for the evaluation of myocardial ischemia and prior infarction, the interpretation of SPECT myocardial perfusion imaging studies has been primarily qualitative or semiquantitative in nature. The detrimental effects of soft tissue attenuation, which tends to degrade image quality, particularly in patients who are obese or have large body habitus, and increase interpretive errors, have long been recognized with SPECT. In concert with tracer-kinetic modeling and robust attenuation correction, PET permits the assessment of regional MBF of the left ventricle in absolute terms (mL/min/g tissue).[9,13] Quantitative absolute hyperemic MBF and flow reserve (representing the ratio of hyperemic and resting MBF)—derived from dynamic acquisition with measurements of resultant myocardial and blood pool time-activity curves—is a potentially powerful adjunct to PET perfusion imaging. As a result, a number of clinical studies with either ^{82}Rb or [^{13}N] ammonia PET have shown an improvement in either the sensitivity or specificity (as high as 95%) for detection of CAD compared with SPECT. However, the widespread use of PET myocardial perfusion studies in the clinical setting has been hampered by the requirement of an on-site cyclotron for [^{13}N] ammonia and the high cost of monthly generator replacement for ^{82}Rb. Moreover, the relatively short half-life of both ^{82}Rb and [^{13}N] ammonia limits the utility of PET perfusion studies to patients undergoing pharmacologic stress only. Because the exercise component of MPI studies has independent prognostic and diagnostic value, this represents an important limitation. On the other hand, the potential for quantifying MBF and blood flow reserve in absolute terms is highly desirable, with potential clinical applications. For example, patients with multivessel CAD may have uniform decrease in flow reserve, and the relative perfusion data from SPECT may fail to detect this “balanced” ischemia[13] (**Fig. 16.19**). At the other extreme, detection of mild abnormalities in MBF reserve with PET provides the potential for early identification of CAD characterized by endothelial dysfunction in asymptomatic patients with elevated cholesterol, smoking, hypertension, and insulin resistance.[14]

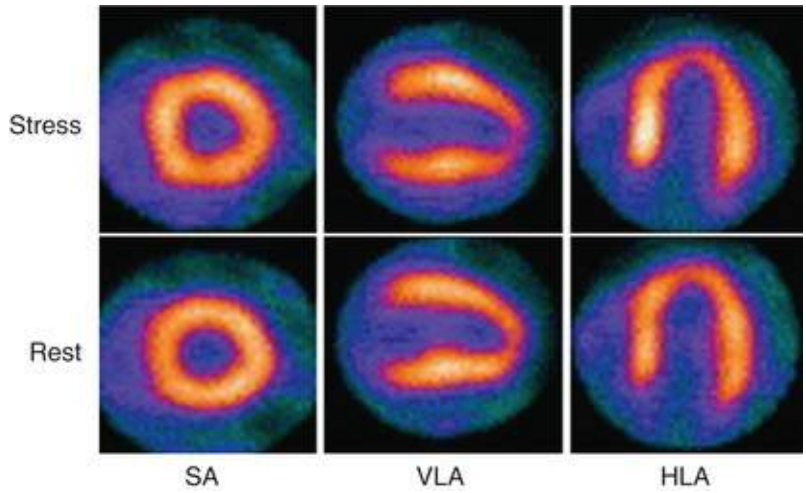

FIGURE 16.18 Example of high-quality stress **(top)** and rest **(bottom)** PET perfusion images, using ^{82}Rb as the perfusion tracer in the short axis (SA), vertical long axis (VLA), and horizontal long axis (HLA).

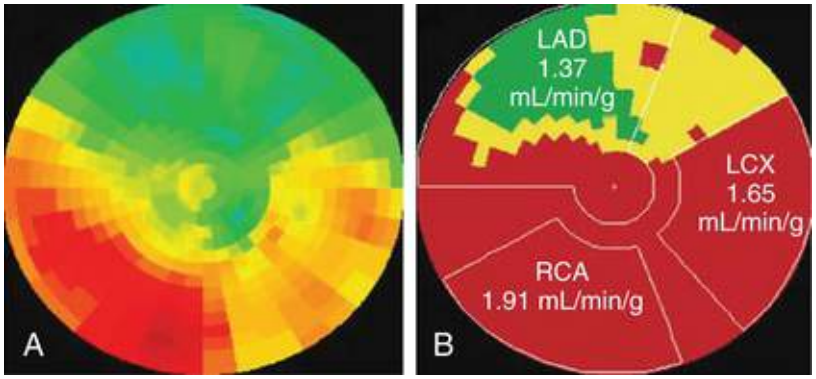

FIGURE 16.19 Polar maps of myocardial tracer uptake during adenosine vasodilation in patient with CAD. **A,** *Relative* distribution of tracer (as with SPECT studies) suggests single-vessel disease in left anterior descending artery (LAD) territory (*green* represents relatively reduced perfusion compared to the other territories). **B,** Quantitative assessment of adenosine-stimulated hyperemic myocardial blood flow reserve with ^{13}N-ammonia PET identifies abnormal flow reserve in all three vascular territories: LAD, left circumflex artery (LCX), and right coronary artery (RCA); normal hyperemic myocardial blood flow is approximately 3 mL/min/g. As such, the addition of the quantitative analysis of perfusion reserves suggests three-vessel disease instead of the single-vessel disease suggested by the standard analysis of relative distribution of flow. (Modified from Schindler TH, Schelbert HR. Quantitation of myocardial perfusion: absolute blood flow versus relative uptake. In Dilsizian V, Narula J, editors. Atlas of Nuclear Cardiology. 4th ed. New York: Springer; 2013, pp 145-194.)

Progress in PET Absolute Hyperemic Myocardial Blood Flow and Flow Reserve Assessment

An additional driver for cardiac PET comes from a potential paradigm shift in the evaluation and management of patients with CAD from an anatomic “gold standard” (coronary angiography) to a functional standard (fractional flow reserve).[15] PET absolute MBF provides a noninvasive alternative to invasive functional assessment of CAD, which may obviate the need for coronary angiography. Quantitative assessment of PET MBF in absolute terms is concurrent with the recent shift in the management of CAD.[16] Quantitative blood flow approaches offer an objective interpretation that is inherently more reproducible than visual analysis. Absolute quantification may aid in assessing the physiologic significance of known coronary artery stenosis, especially when of intermediate severity.

Moreover, noninvasive quantification of MBF extends the scope of conventional myocardial perfusion imaging from detection of end-stage, advanced, and flow-limiting epicardial CAD to balanced reduction of MBF in all three vascular territories, as well as early stages of atherosclerosis or microvascular dysfunction.[14] Adding quantification of hyperemic MBF and flow reserve to the visual interpretation of PET regional perfusion defects has been shown to improve the detection of CAD burden and accurately risk-stratify patients with varying clinical presentations.[17-19]

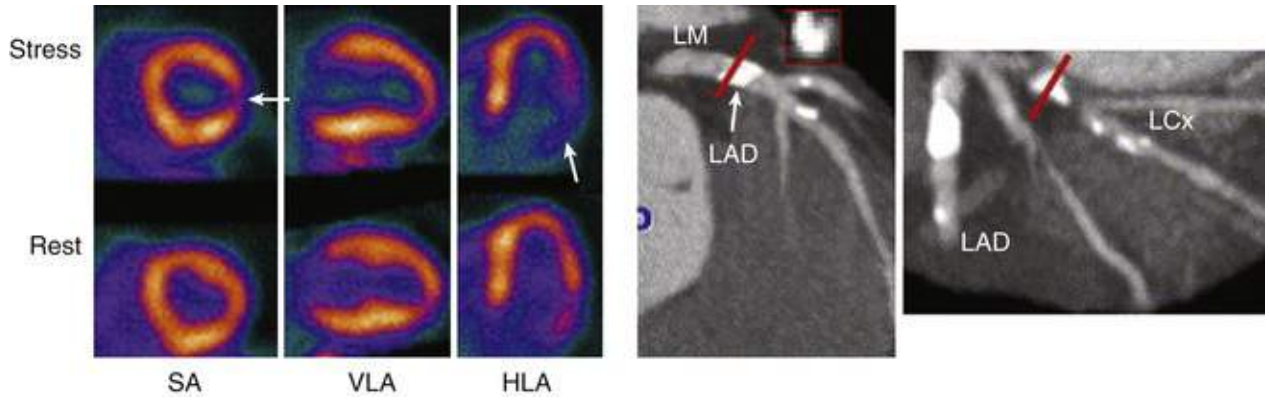
It is important to recognize, however, that myocardial flow reserve (MFR) ratio can be spuriously lowered by elevated resting blood flow in the denominator, as seen in patients with hypertension or high resting rate pressure product. Thus, it is important to interpret both hyperemic MBF and flow reserve in all patients. At present, quantitative absolute MBF measurements with PET appear most helpful in (1) patients without known prior history of cardiac disease who present with symptoms suspicious for myocardial ischemia, (2) patients with known CAD in whom more specific physiologic assessment is desired, (3) identification of an increased suspicion for multivessel CAD, (4) situations with a disparity between visual perfusion abnormalities and apparently normal coronary angiography to assess possible microvascular dysfunction, and (5) patients with heart transplant when vasculopathy may be present.[9]

PET Tracers of Myocardial Metabolism

PET is uniquely positioned to investigate alterations in myocardial metabolism and cellular physiology. Tracers for these applications are discussed in detail later (see Assessment of Myocardial Cellular Metabolism and Physiology).

Combined PET-CT and SPECT-CT Scanners

Scanners that combine PET or SPECT technology with radiographic computed tomography (CT) provide a tool for obtaining complementary anatomic and functional information in a single imaging session. CT angiography provides information on the presence and extent of luminal narrowing of epicardial coronary arteries with high sensitivity and specificity (**see Chapter 18**), whereas PET and SPECT provide information on the downstream functional consequences of anatomic lesions. Cardiac CT angiography is suited to determine whether an “obstructive” coronary artery stenosis is present, although the ability to accurately determine stenosis severity is limited with current-generation CT angiography systems. PET and SPECT, on the other hand, are more suited to determine if such a stenosis is physiologically significant regarding limitation of flow reserve. With the advent of hybrid PET-CT and SPECT-CT systems, such complementary information of anatomy and physiology can be realized immediately, at the same imaging session. The combination of these anatomic and functional modalities is particularly relevant in patients who have an intermediate finding on either SPECT-PET or CT angiography. The advantage afforded by the combined scanner is that the corresponding images are spatially aligned and can be acquired during a single imaging session (**eFig. 16.10**).



EFIGURE 16.10 Combined PET images of stress and rest perfusion **(left)** and cardiac CT angiography and calcium imaging **(right).** The PET images demonstrate a lateral wall reversible defect consistent with ischemia (*arrows* in short-axis [*SA*] and horizontal long-axis [*HLA*] images). *VLA,* Vertical long-axis view. However, the CT images demonstrate more extensive calcification and stenosis of the left main (*LM*), left anterior descending (*LAD*), and left circumflex (*LCx*) vessels. The combined information suggests that although the physiologic ischemia predominantly involves the lateral wall–LCx territory, more extensive CAD is present. *Red lines* represent planes for cross-sectional views of coronary arteries (not shown).

CT Attenuation Correction for PET

A subsidiary benefit of hybrid PET-CT and SPECT-CT imaging systems is in the potential to use the CT image to create the attenuation map for the MPI data.[9] This approach has allowed the replacement of germanium-68 or cesium-137 transmission scans with faster CT scans, reducing the overall duration of the PET procedure. One potential problem of using fast CT scans for attenuation correction, however, is the motion of the organs during respiration. The CT scanner "freezes" the heart, lungs, and liver at one point in the respiratory cycle, whereas the PET emission data are averaged over many respiratory cycles. Methods using respiratory gating to correct this problem are currently under investigation.

At present, the decision of whether a particular patient is a candidate for PET alone, CT angiography alone, or hybrid PET-CT depends on multiple factors. The age of the patient, underlying irregular heart rhythm, known coronary artery calcification or metallic implants, renal insufficiency, lung disease, or allergy to contrast medium will exclude a significant percentage of patients from being candidates for CT angiography. Because PET can be performed in a majority of these patients, and revascularization improves survival over medical therapy only in patients with a moderate to severe degree of inducible ischemia, most patients will not require simultaneous assessment of coronary artery anatomy and myocardial perfusion with hybrid PET-CT. The incremental radiation dose from performing two diagnostic studies also should be considered.

Patients with low-risk stress ECG or nuclear myocardial perfusion scans show no survival advantage from revascularization over medical therapy, regardless of the angiographic extent of coronary artery stenosis (**see Chapter 61**). On the other hand, among younger patients with strong family history or multiple risk factors for CAD, CT angiography may not only exclude significant coronary artery luminal narrowing but also detect early atherosclerosis by quantifying the extent of calcified plaques (**see Chapter 18**). The latter may have important implications for aggressive risk factor modification and medical therapy. Accordingly, hybrid PET-CT should be limited to only a small subset of patients in whom the knowledge of both coronary anatomy and physiology would be anticipated to have an impact on clinical management (e.g., anomalous coronary anatomy or myocardial bridging and chest pain).

All other applications, such as detection of endothelial dysfunction or microvascular disease and identification of soft plaques, remain experimental at this time, with limited clinical data to support widespread clinical application. In the future, with the potential development of new radiotracers that

target coronary artery plaque, hybrid PET-CT images that incorporate plaque anatomy with molecular imaging may provide valuable insights into differentiation of “vulnerable” from “nonvulnerable” plaque, which may be used to portend and potentially to prevent acute myocardial infarction.

Radiation Exposure Issues

Clinical decision making for the use of low-level ionizing radiation to obtain diagnostic nuclear cardiac studies must adhere to appropriate use criteria and encompass the broad range of the risk-benefit ratio, with the guiding principle to minimize exposure while obtaining the necessary high-quality diagnostic information. The prediction of risk of subsequent malignant transformation for an individual undergoing a medical diagnostic test or procedure employing ionizing radiation is a complex exercise with many uncertainties. Concerns about the late carcinogenic effects of exposure to low levels (<100 mSv) of ionizing radiation stem from extrapolation of exposure outcome data in survivors of atomic bomb explosions. Uncertainty remains, however, regarding the dose-response relationship in the lower range of exposure, adding complexity to assessment of the incremental risk to patients, as well as of tissue-specific reparative responses that also may be manifested at lower levels of exposure.[20] Nonetheless, exposure of the patient to ionizing radiation should be at the minimum dose consistent with obtaining a diagnostic examination. Each procedure is unique, and the methodology to achieve minimum exposure while maintaining diagnostic accuracy needs to be viewed in this light to ensure optimal patient care.

Myocardial Blood Flow, Myocardial Metabolism, and Ventricular Function

Assessment of Myocardial Blood Flow

Myocardial Blood Flow at Rest

The MBF at rest is tightly regulated to provide nutritive perfusion to viable, contractile myocytes (**see Chapter 57**). Although SPECT tracers to image MBF are commonly referred to as "perfusion tracers," they require viable myocyte cell membranes for uptake and retention.[4] Thus the uptake and retention of these tracers do reflect regional flow differences, but myocyte cell membrane integrity also is a prerequisite. Visualization of myocardial regions suggests the presence of working, viable cell membranes, but lack of visualization of myocardium does not necessarily indicate the absence of viable cells. Decreased regional myocardial tracer uptake at rest could reflect either lack of cell membrane integrity in an area of infarcted myocardium or reduced blood flow secondary to hibernating but viable myocardium. A severe reduction in tracer activity usually signifies infarction, but a more moderate reduction in regional activity of a blood flow tracer alone cannot always differentiate hibernating from partially scarred myocardium in patients with ischemic LV dysfunction. In these patients, techniques that assess intact cellular metabolic processes (e.g., FDG), the myocardial potassium space (e.g., ^{201}Tl redistribution), or the presence of some degree of uptake of the ^{99m}Tc tracers may be used as an adjunct to assessing viability of the myocardium.[4]

Imaging of Myocardial Infarction

In patients with previous myocardial infarction (MI), blood flow to the infarcted region is diminished, often severely, and few viable myocytes are present within the scarred territory.[4] Thus severely reduced uptake of a radionuclide perfusion tracer in a rest study is a good marker of presence, location, and extent of MI (**Fig. 16.20**).

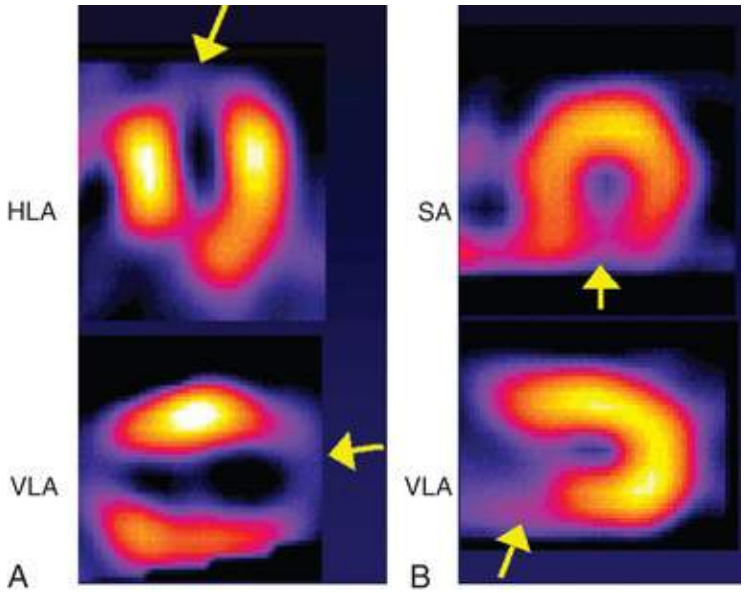


FIGURE 16.20 SPECT perfusion images demonstrating myocardial infarction in different locations. **A,** An apical infarction (*arrows*) in the horizontal long-axis (HLA) and vertical long-axis (VLA) views. **B,** An inferior infarction (*arrows*) in the short-axis (SA) and VLA views. In both studies, the severity of the defect suggests minimal myocyte viability within those territories.

Assessment of Infarct Size

Contemporary studies have used ^{99m}Tc-sestamibi to provide an assessment of infarct size.[21] Because clearance from the myocardium after initial uptake of this tracer is minimal, images acquired even hours after initial injection represent a "snapshot" of blood flow conditions and tracer uptake at the time of injection.

Infarct size as assessed by quantitative analysis of rest sestamibi uptake has been validated against many other measures of infarct size.[21] Moreover, a significant association between SPECT infarct size and death occurring during long-term follow-up has been demonstrated. Many clinical trials now use "final infarct size" as determined by sestamibi SPECT imaging as an early post-MI surrogate endpoint to assess new agents to reduce infarct size.

When a tracer such as sestamibi is injected during acute MI in the setting of an occluded infarct-related artery before reperfusion therapy, the resulting defect, even when imaged hours later after successful reperfusion, represents the "area at risk" of the occluded artery.[21] A second injection of sestamibi at rest with subsequent imaging can be done later during the post-MI course and represents final infarct size. The change in defect size between the initial image acquired in the acute stage and the later image represents the magnitude of salvaged myocardium from reperfusion. Therefore, SPECT imaging at rest in the early post-MI period can provide important information about final infarct size and infarct zone viability.

Assessment of Myocardial Perfusion During Stress

Coronary blood flow must respond rapidly to changing metabolic conditions and oxygen demand to meet the nutrient needs of myocytes being called on to contract more frequently and with more force. Oxygen extraction by the myocardium is nearly maximum at rest; thus any increase in oxygen demand can be met only through increasing coronary blood flow to deliver more oxygen per unit time (**see Chapter 57**). The major determinants of coronary blood flow include the perfusion pressure at the head of the system (principally aortic diastolic pressure) and the downstream resistance, residing predominantly in the coronary arteriolar bed. Because aortic diastolic pressure during exercise varies little from the value at

rest, the major mechanism responsible for increasing coronary blood flow during stress involves a reduction in coronary vascular resistance. During exercise stress, coronary blood flow can increase approximately two to three times above levels at rest. During pharmacologic stress to minimize coronary arteriolar resistance, using intravenous coronary arteriolar vasodilator agents such as dipyridamole, adenosine, or regadenoson (discussed later), coronary blood flow can increase up to four to five times above rest levels. The magnitude of blood flow increase secondary to any stress relative to flow values at rest is termed the *coronary blood flow reserve*.[22]

Perfusion Tracers and Coronary Blood Flow Reserve

The ideal perfusion tracer should track MBF across the entire physiologically relevant range achievable in animal models and in humans (**Fig. 16.21**). It should be extracted rapidly (from the blood into the myocyte), because the hemodynamic conditions during peak stress are not maintained for long periods. The ideal tracer also should be extracted as completely as possible out of the bloodstream, and it should be retained in myocardium for a sufficient period to be imaged. Moreover, perturbations in metabolic conditions, such as ischemia or common cardioactive drugs, should neither influence nor interfere with uptake so that the resulting regional tracer concentrations primarily reflect myocardial perfusion.[4]

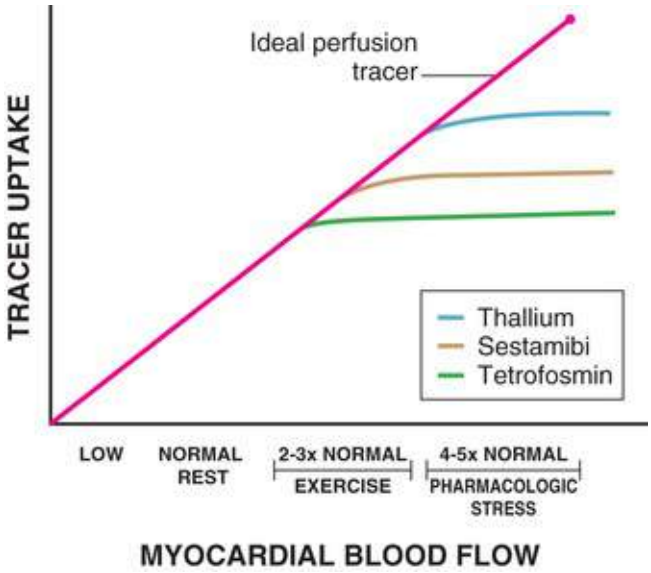

FIGURE 16.21 The relation between myocardial blood flow and perfusion tracer uptake. The ideal perfusion tracer would track myocardial blood flow across the entire range of physiologically relevant flows (*red line*). However, the available perfusion tracers "roll off" at higher levels of flow. The different tracers reach a plateau at different levels of myocardial blood flow, as demonstrated in this schematic example based on multiple studies in animal models.

Despite its excellent first-pass myocardial extraction (85%), the energy spectrum of ^{201}Tl is lower (69 to 80 keV) than optimum for current gamma cameras. The 140-keV energy spectrum of ^{99m}Tc perfusion tracers results in less scatter and soft tissue attenuation, with improved spatial resolution compared with thallium.[4] However, the first-pass myocardial extraction of both sestamibi and tetrofosmin is only in the 60% range with nonlinear extraction at high flows. Thus, none of the clinically available SPECT perfusion tracers has all the properties of an ideal perfusion tracer (**Fig. 16.21**). Nonetheless, regional differences in myocardial tracer uptake during exercise or pharmacologic stress have provided important diagnostic as well as prognostic information.[6]

The PET perfusion tracer ^{13}N-ammonia displays an extraction fraction exceeding 90%; ^{82}Rb has a

lower extraction fraction and reaches a plateau more rapidly at hyperemic range of flow. In the clinical setting, evaluation of regional MBF and flow reserve with ^{13}N-ammonia and ^{82}Rb has been validated for detection and localization of CAD.[9] As noted previously, most PET studies evaluating coronary flow reserve use pharmacologic rather than exercise stress.

Effect of a Coronary Stenosis on Coronary Blood Flow Reserve.

In animal models in which discrete coronary stenoses of varying degrees are induced, coronary blood flow at rest is maintained by autoregulatory dilation of the downstream arteriolar resistance vessels until a stenosis between 80% and 90% of vessel diameter is reached (**Fig. 16.22**). As stenosis severity increases further, the arteriolar vasodilatory capacity to maintain flow at rest is exhausted, at which point coronary blood flow at rest diminishes (**see Chapter 57**).

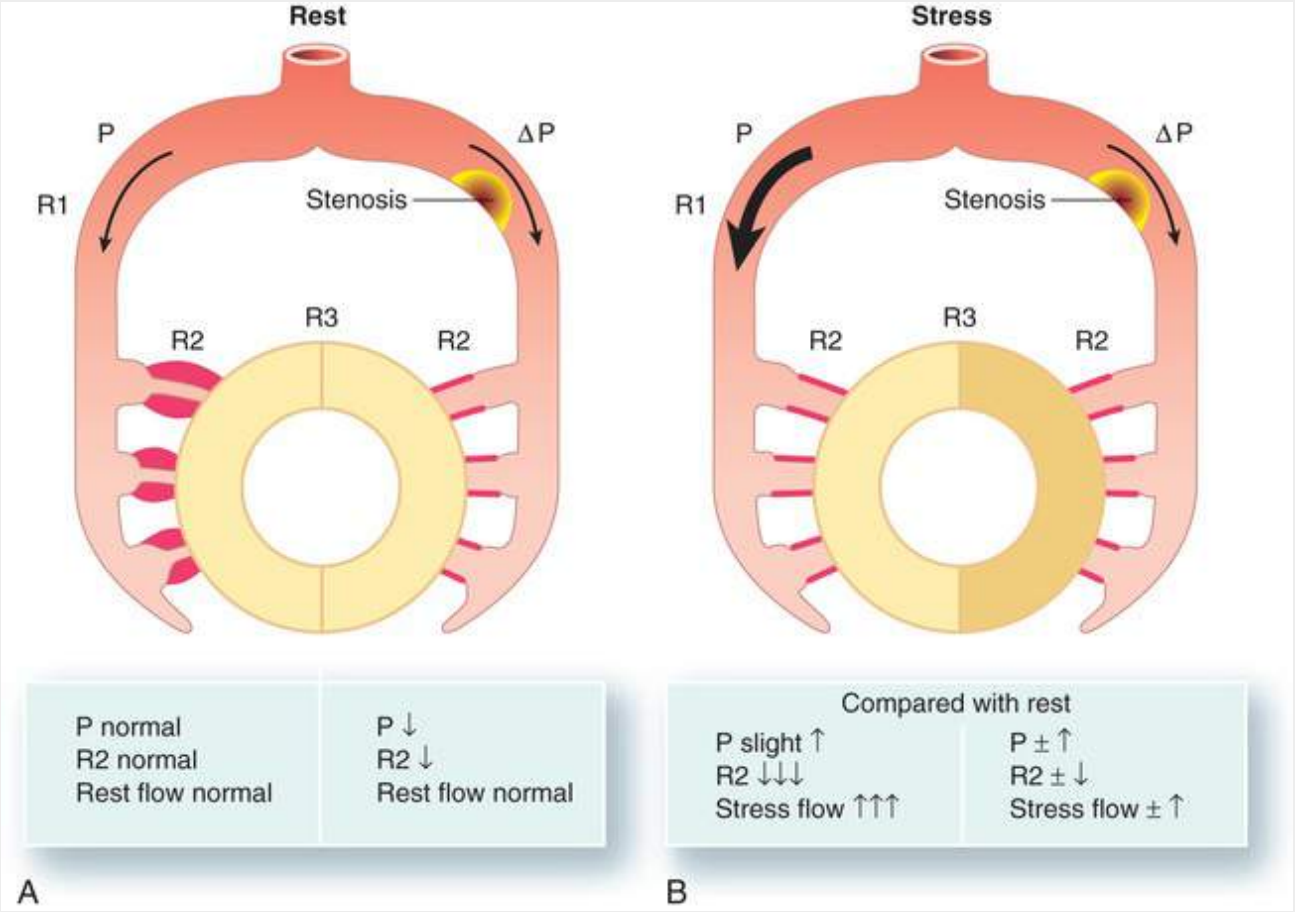

FIGURE 16.22 Effect of coronary resistance on coronary blood flow reserve. **A,** At rest, flow is driven by the pressure head (*P*) at the proximal end of the system. *R1* refers to resistance offered by the large epicardial conductance vessels. *R2* represents the coronary arteriolar resistance, which predominantly regulates coronary blood flow. *R3* represents the resistance provided by wall tension in the subendocardium. At rest in the normal vessel (*left vessel* on the drawing), some vasoconstrictor resistance is present. In the setting of an epicardial coronary stenosis (*right vessel*), blood flow at rest can be maintained, but at the expense of lowering of coronary resistance downstream (R2 decreased) by autoregulatory dilation of the arterioles. Thus, with lower resistance, flow at rest may be maintained despite the lower pressure head at the distal end of the stenosis. A perfusion tracer would show homogeneous uptake at rest. **B,** With demand stress or with administration of a coronary arteriolar vasodilator such as dipyridamole or adenosine, perfusion increases substantially in the area supplied by the normal epicardial artery (*left vessel* on the drawing) as resistance (R2) becomes minimal. However, blunted flow reserve is seen in the area supplied by the stenosis (*right vessel*), because most of the vasodilator reserve at the R2 level has been used to maintain flow at rest. Thus, heterogeneity of flow is established (based on presence of upstream stenosis) and can be imaged with a perfusion tracer as a defect in the territory supplied by the stenotic vessel.

By contrast, maximum coronary blood flow reserve begins to decrease when the upstream coronary stenosis reaches 50% diameter. Three levels of resistance influence coronary blood flow: that provided by the large-conductance epicardial vessels, designated R1; the coronary arteriolar resistance, R2; and the resistance in the subendocardium by wall tension from the ventricular chamber, R3 (**Fig. 16.22**). Under normal conditions, most of the resistance at rest is provided by R2, and most of the increase in coronary flow during heightened demand occurs through reduction of resistance at this level, potentially increasing flow as much as four times as demand increases. Normal epicardial vessels dilate slightly (R1 decreases slightly) in response to increased coronary flow as a consequence of normal endothelial cell function. Depending on the type of exercise performed, the R3 component may remain unchanged or may increase, with an increase in chamber radius and wall tension. Achieving maximal flow is predominantly dependent on the vasodilatory capacity of the downstream resistance vessels.[22] With a coronary stenosis, in which some vasodilatory reserve has been used to maintain flow at rest, less vasodilatory reserve is available to minimize resistance during stress. Thus, in a vessel with a moderate stenosis, coronary

blood flow reserve is blunted and detectable by a perfusion tracer (**Fig. 16.22**).

In contrast with animal models, human atherosclerotic CAD is more complex. Stenoses may not be discrete, the length and complexity of the stenosis may affect the coronary reserve, and impaired endothelial function plays a role (see Classic References, Gould). In patients with preserved endothelial function, the increased coronary flow during stress leads to coronary arterial and arteriolar vasodilation, contributing to maximal coronary flow reserve. Endothelial function often is abnormal, with early atherosclerosis or risk factors for atherosclerosis contributing to the blunting of coronary flow reserve. The development of collaterals to the distal perfusion bed of a myocardial territory with a severe upstream coronary stenosis also influences blood flow at rest and during stress.[22]

With SPECT imaging, relative regional differences of tracer uptake can be detected and quantified (**Fig. 16.23**), whereas with PET imaging, absolute regional coronary blood flow at rest and during stress (in milliliters per gram per minute) potentially can be quantified.[4,9]

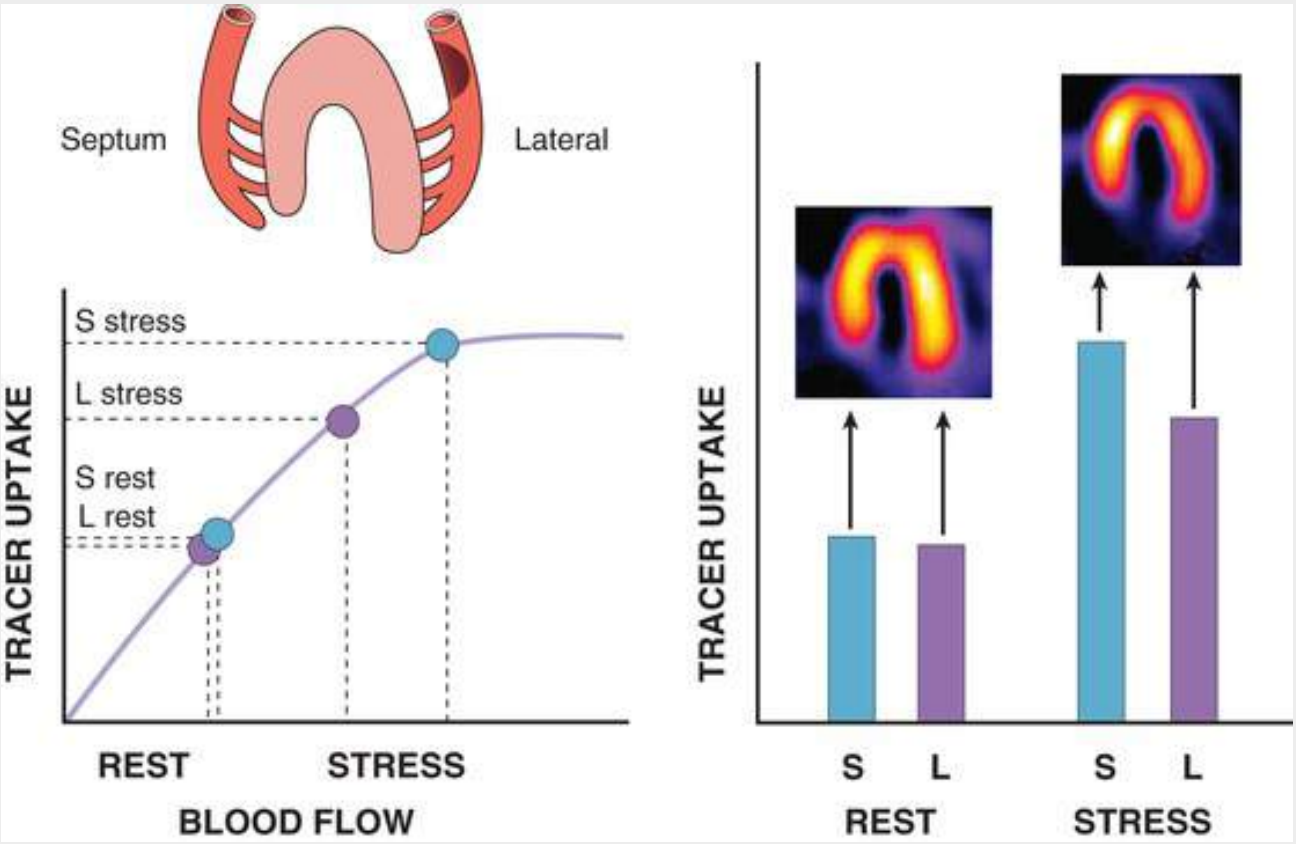

FIGURE 16.23 Graphs illustrating effect of coronary artery blood flow reserve abnormalities on perfusion tracer concentrations, with corresponding tomographic images. **Left,** Myocardial blood flow profiles at rest and stress of two myocardial regions, with region S (septum) supplied by a normal epicardial artery and region L (lateral wall) by an artery with significant epicardial coronary stenosis. Blood flow at stress is diminished in region L compared with S. **Right,** Perfusion tracer uptake profile is demonstrated with myocardial blood flow on the *y* axis. Tracer uptake is diminished in region L relative to S during stress. In the resulting perfusion images, a relative "defect" of tracer uptake is seen in the lateral wall compared with the septum, whereas both regions demonstrate similar tracer uptake at rest. The lateral wall thus demonstrates a reversible perfusion defect, reflecting the blunted coronary blood flow reserve and indirectly reflecting the presence of the coronary stenosis.

Detection of Stress-Induced Ischemia Versus Infarction

In standard practice, stress and rest myocardial perfusion images are compared to determine the presence,

extent, and severity of stress-induced perfusion defects and to determine whether such defects reflect regional myocardial ischemia or infarction.[2,5] Stress-induced perfusion abnormalities in regions that exhibit normal perfusion at rest are termed *reversible* perfusion defects, and such regions represent viable tissue with blunted coronary blood flow reserve (**Fig. 16.24A; see also Figs. 16.4 through 16.6 and 16.9B**). Strictly speaking, SPECT MPI demonstrates stress-induced reversible abnormalities in perfusion reserve, although these findings often are referred to as "ischemia." Regional myocardial tissue ischemia per se is not being demonstrated, although it is indeed often present, based on a mismatch between oxygen supply and demand. Perfusion abnormalities at stress that are *irreversible*, or fixed, as seen on rest images (unchanged from stress to rest), most often represent infarction, particularly if the defect is severe (**Fig. 16.24B; see also eFig. 16.2B**). When both viable myocardium and scarred myocardium are present, thallium redistribution or ^{99m}Tc tracer reversibility is incomplete, giving the appearance of partial reversibility on the delayed thallium or rest ^{99m}Tc images.

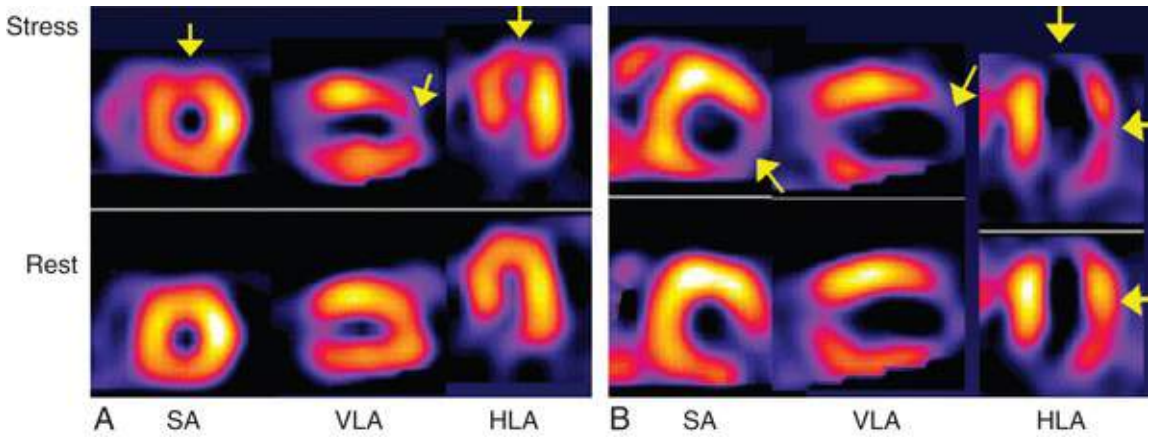

FIGURE 16.24 **A,** Example of SPECT anterior and apical reversible perfusion defects (*arrows*), representing inducible regional myocardial ischemia in short-axis (SA), vertical long-axis (VLA), and horizontal long-axis (HLA) views. **B,** Example of irreversible or fixed defects of inferolateral wall on SA images and of apex on VLA images (*arrows*), representing predominant myocardial infarction. On HLA image, evidence of a reversible lateral wall defect (*arrows*) representing lateral wall ischemia also is seen.

Exercise Stress to Induce Coronary Hyperemia

SPECT MPI frequently is performed with exercise stress to induce coronary hyperemia, particularly suitable for patients with exertional symptoms, because this provides the opportunity to link the symptoms induced during exercise to the location, extent, and severity of abnormal perfusion patterns.[5] Moreover, performing exercise stress in conjunction with MPI allows the opportunity to incorporate additional information on functional capacity, stress-induced electrocardiographic changes or arrhythmias, and use of heart rate reserve and heart rate recovery in the assessment of CAD probability or prognosis[23] (**see Chapter 13**).

Pharmacologic Stress to Induce Coronary Hyperemia

Exercise stress is the preferred modality to induce coronary hyperemia because it allows a correlation between exertional symptoms and the perfusion pattern and provides information on exercise duration, workload achieved, and presence and extent of ischemic electrocardiographic changes, all of which provide important diagnostic and prognostic information.[24] A substantial proportion of patients, however, are incapable of attaining a sufficient level of exercise. Patients with exertional symptoms may not

exercise adequately to reproduce these symptoms, and patients may not achieve more than 85% of the maximum predicted heart rate for age, considered the optimal level of exertion to achieve coronary hyperemic responses.[5,23] As the population ages and the prevalence of comorbid disease states such as peripheral vascular disease and diabetes increases, the proportion of patients referred for stress testing who are unable to achieve adequate levels of exercise will increase.

In such patients, pharmacologic stress testing can be used to induce coronary hyperemia. The most widely used agents for pharmacologic stress testing can be divided into those that act as coronary arteriolar vasodilators (adenosine, dipyridamole, and regadenoson) and adrenergic agents such as dobutamine.[5,24]

Mechanism of Coronary Arteriolar Vasodilator Pharmacologic Stress

Stimulation of adenosine A_{2a} receptors on the smooth muscle cells leads to enhanced production of adenylate cyclase, increased intracellular cyclic adenosine monophosphate (cAMP), and other effects that produce vasorelaxation. With maximal arteriolar vasodilation (maximal decrease in coronary resistance), coronary blood flow increases.

Adenosine is a powerful, endogenous molecule that acts as a regulator of blood flow in many organ beds, including the coronary circulation (**see Chapter 57**). It has many other effects mediated by different receptor subtypes. Adenosine A_1 receptors are present in the sinus node and atrioventricular (AV) node and mediate diminished heart rate and AV nodal conduction. Adenosine A_{2b} receptors are present in bronchioles and the peripheral vasculature, and stimulation may result in bronchial constriction and peripheral vasodilation.

Initial studies of adenosine demonstrated that a dose of 140 µg/kg/min induced maximal coronary hyperemia, with no further increase in maximum coronary blood flow at higher doses. After the onset of intravenous adenosine infusion, maximum coronary flow occurs at an average of 84 seconds, with a range of up to 125 seconds. Dipyridamole blocks the intracellular retransport of adenosine and inhibits adenosine deaminase, responsible for the intracellular breakdown of adenosine.[24] Thus, dipyridamole acts as an indirect coronary arteriolar vasodilator, increasing intracellular and interstitial concentrations of adenosine (**Fig. 16.25**). The newer agent regadenoson is similar to adenosine in that it directly interacts with the adenosine A_{2a} receptor.[24]

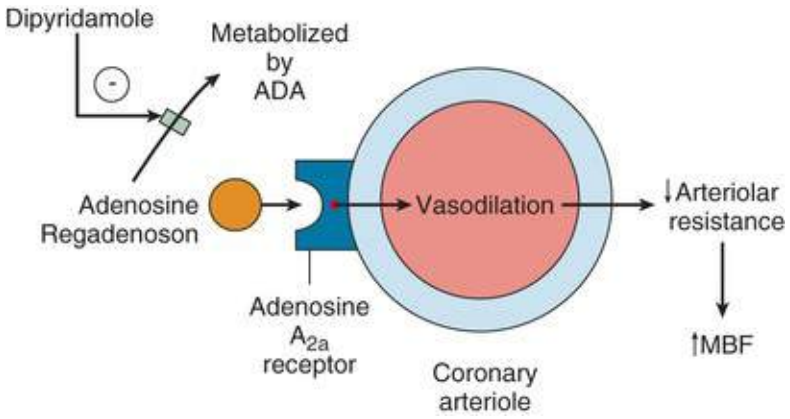

FIGURE 16.25 Schematic of the mechanism of action of dipyridamole, adenosine, and regadenoson. Exogenously administered adenosine acts directly on its receptor to result in coronary arteriolar vasodilation and a consequent increase in myocardial blood flow (MBF) as resistance is minimized. Regadenoson directly interacts with adenosine A_{2a} receptor. Adenosine A_{2a} receptor mediates coronary arteriolar vasodilation, which is the basis for pharmacologic stress testing. Dipyridamole blocks the intracellular retransport of adenosine and also inhibits adenosine deaminase (ADA), resulting in increased intracellular and interstitial concentrations of adenosine, which then interacts with its receptor.

Heterogeneity of Coronary Hyperemia with Pharmacologic Stress

With the administration of dipyridamole, adenosine, or regadenoson, the resistance vessels in the area subtended by a normal epicardial vessel dilate, diminishing coronary resistance and resulting in an increment in coronary blood flow four to five times above normal. Coronary resistance in a bed supplied by a stenotic epicardial vessel is diminished at rest (i.e., coronary vasodilator reserve has been used), and only minor or no further reductions can take place. Thus, MBF in that territory does not change or may even decrease slightly because of the peripheral vasodilation and drop in diastolic blood pressure characteristic of pharmacologic stress. The net result of these changes is heterogeneity in MBF, increased in the normal territory and relatively unchanged in the territory supplied by the stenotic epicardial vessel. Perfusion tracer administration in this setting demonstrates a defect in the area supplied by the stenotic vessel[24] (**see Fig. 16.22**).

During exercise stress, the increase in myocardial oxygen demand and limitation of oxygen supply create a supply-demand mismatch, often resulting in cellular ischemia. With pharmacologic stress, the perfusion defect may represent merely the heterogeneity in coronary flow reserve. “Demand” may change little during pharmacologic stress; there is often a reduction in blood pressure accompanied by a reflex but modest increase in heart rate, so that double product, reflecting oxygen demand, changes little during the vasodilator “stress.” Thus a supply-demand mismatch may not occur, and cellular ischemia may not be present, despite vasodilator-induced perfusion defects.[24]

Under certain conditions, true myocardial ischemia may indeed be present, related to development of a “coronary steal.” This phenomenon appears to occur when the myocardial perfusion bed supplied by a severe epicardial stenosis also is dependent on collateral vessels from remote coronary arteries. Blood flow through coronary collaterals depends on perfusion pressure, particularly if the collaterals are jeopardized (i.e., if the parent blood vessel is compromised by moderate coronary stenosis). In this setting, administration of a vasodilator stress agent diminishes the perfusion pressure supplying the collaterals, and collateral flow diminishes. Flow to the bed supplied by a severe epicardial stenosis may then decrease compared with flow at rest, and the diminished supply may create supply-demand mismatch and true myocardial ischemia, with ECG ST-segment depression.

Hemodynamic Effects of Vasodilator Pharmacologic Stress.

Administration of dipyridamole, adenosine, or regadenoson results in adenosine receptor–mediated systemic as well as coronary vasodilation, with an average reduction of 8 to 10 mm Hg in systolic and diastolic blood pressure, often accompanied by a reflex increase in heart rate.[24] The magnitude of the heart rate increase is variable, usually between 10 and 20 beats/min. A blunted heart rate response may be observed in patients who are taking beta blockers or in diabetic patients with underlying autonomic insufficiency.

Side Effects Associated With Vasodilator Pharmacologic Stress.

The side effects associated with pharmacologic vasodilator stress are the result of stimulation of the adenosine A_1, A_{2b}, and A_3 receptors and are common. After dipyridamole stress, approximately 50% of patients experience some side effect, and with adenosine more than 80% of patients experience untoward side effects, most commonly flushing, chest pain, or shortness of breath.[2,24] In the pivotal clinical trials of regadenoson, the prevalence of side effects was similar to that seen with adenosine, though a composite severity score was slightly lower.

As a result of adenosine's effect on the conduction system, AV block may develop during adenosine administration. Approximately 10% of patients manifest first-degree AV block, with 5% developing either second- or third-degree AV block. AV block is more common in patients who are studied while they are taking beta blockers or heart rate–lowering calcium channel blockers. Patients with baseline evidence of second- or third-degree AV block in the absence of a pacemaker should not receive adenosine. However, patients with first-degree AV block or left bundle branch block (LBBB) appear to tolerate adenosine infusion well, without an exacerbation of conduction abnormalities.[5,24]

Ischemic ST-segment depression is observed in 10% to 15% of patients undergoing pharmacologic vasodilator stress, probably representing the physiologic consequence of induction of a coronary steal and regional myocardial ischemia. Such patients often have extensive and severe perfusion defects on imaging and more often have collateralized multivessel disease on angiography.

Chest pain, even typical angina pectoris, frequently develops during pharmacologic vasodilator stress testing. Although it may reflect regional myocardial ischemia based on a coronary steal, chest pain also may occur in patients with no ischemic ECG changes and with normal perfusion studies because of involvement of adenosine A_1 receptors in the nociceptive pathway influencing the sensation of chest pain.[24] Thus, chest pain by itself is a nonspecific finding during vasodilator pharmacologic stress.

In early reports of dipyridamole testing, infrequent but severe episodes of bronchospasm occurred, possibly related to a nonspecific adenosine receptor–mediated mechanism. Thus, patients with a significant history of reactive airways disease should not undergo vasodilator stress testing.[5,24] Patients with chronic obstructive pulmonary disease (COPD) without a reactive airways component, however, generally tolerate the procedure well. Regadenoson has been studied in patients with mild to moderate asthma and in patients with moderate COPD. In a randomized trial the incidence of a greater than 15% decrement in forced expiratory volume in 1 second (FEV_1) from baseline was similar in regadenoson- and placebo-treated patients, although dyspnea was more common in the regadenoson patients.[25] No cases of severe bronchospasm occurred. These data suggest that regadenoson may be used in such patients, although with caution and after preparation to treat dyspnea.

Reversal of Effects of Vasodilator Pharmacologic Stress.

Methylxanthine compounds such as theophylline and caffeine act as competitive antagonists of adenosine at the receptor level, and infusion of intravenous (IV) aminophylline antagonizes the effects of the

vasodilator stress agents.[5] Because adenosine has a very short half-life (approximately 20 to 30 seconds), administration of aminophylline is rarely required during adenosine testing; simply stopping the infusion results in cessation of symptoms within 20 to 30 seconds. After IV dipyridamole or regadenoson, infusion of aminophylline at approximately 1 to 2 mg/kg over 30 seconds reverses side effects (as well as coronary vasodilator effects), usually within 1 to 2 minutes. Because the coronary vasodilator effects will be reversed as well, reversal of the vasodilator effect should be delayed until at least 1 to 2 minutes after radionuclide administration if it is clinically safe; otherwise, the true stress perfusion pattern may not be evident. In general, side effects from vasodilator pharmacologic stress, although common, may be tolerated for this time. However, with more severe side effects, such as severe shortness of breath or bronchospasm, or with more dramatic ST-segment abnormalities, more rapid reversal of the vasodilator effect is prudent. Because caffeine is a methylxanthine compound and antagonizes the effect of adenosine at its receptor, it is critical that patients be instructed to withhold caffeine, ideally for 24 hours before vasodilator pharmacologic stress testing.

In some patients, myocardial ischemia provoked during vasodilator stress testing triggers a cascade of events that maintains ischemia even after reversal of the vasodilator effect with aminophylline. The sensation of chest pain may drive a heightened sympathetic response, with an elevation of heart rate and blood pressure. In this setting, when aminophylline has been given to reverse the effects of the vasodilator, it is safe to administer sublingual nitroglycerin or other measures to relieve myocardial ischemia. It is not safe to give sublingual nitroglycerin before aminophylline to treat signs of myocardial ischemia. Because systemic vasodilation is present during vasodilator stress testing, administration of nitroglycerin before aminophylline may result in substantial systemic hypotension.

Protocols for Vasodilator Pharmacologic Stress Testing

Table 16.3 lists the accepted protocols for performing vasodilator pharmacologic stress testing.[5,24] Since the original descriptions of these protocols, iterations have been studied, with the goal of shortening the test procedure, minimizing side effects, or both, by shortening the duration of the adenosine infusion or adding low-level exercise.

TABLE 16.3
Pharmacologic Stress Protocols

AGENT	DOSE	DURATION	ISOTOPE INJECTION
Dipyridamole	142 μg/kg/min	4 minutes by hand infusion or pump	3 minutes after completion of infusion
Adenosine	140 μg/kg/min	6-minute infusion by pump	At 3 minutes into infusion
Regadenoson	0.4 mg (5 mL) rapid IV injection, followed by 5 mL saline flush	Bolus	10-20 seconds after the saline flush

Handgrip exercise may be used to raise peripheral blood pressure and thus coronary perfusion pressure. Reports are mixed on whether image quality is improved. This approach may be useful in patients with borderline low blood pressure before the test to avoid significant hypotension.

Low-level treadmill exercise has been increasingly applied in combination with vasodilator stress testing. Although no clear advantage in diagnostic performance has been shown, a reduction in side effects of pharmacologic stress testing has been consistently demonstrated, as well as a reduction in extracardiac tracer uptake with consequent improvement in image quality.

Differences Between Vasodilator and Exercise Stress

The perfusion images obtained by vasodilator pharmacologic stress are generally concordant with those

obtained with maximal exercise stress in the same patient, but with several important differences: Higher levels of coronary flow are achieved during vasodilator pharmacologic stress compared with exercise, possibly because of the increased resistance to flow with exercise caused by higher subendocardial pressures. Although theoretically this difference should result in increased sensitivity for detection of CAD with pharmacologic stress, such heightened sensitivity has not been clearly demonstrated. The failure to demonstrate increased sensitivity may result from the inability of the radionuclide tracers to reflect MBF adequately at the highest levels of flow[4] (**see Fig. 16.21**).

Vasodilator pharmacologic stress is less "physiologic" than exercise, and symptoms during testing (or lack thereof) cannot be as clearly linked to the perfusion pattern, as can be done with exercise stress. Optimal diagnostic performance of MPI during exercise often depends on the patient achieving a maximal level of stress, which does not always occur.

Anti-ischemic medications may significantly affect the results of MPI during exercise.[5] The extent and severity of myocardial perfusion defects also may be affected in an important way by background medication during pharmacologic stress. Antianginal medications should therefore be withheld if possible before the study.

Dobutamine Stress to Induce Coronary Hyperemia.

In some patients, vasodilator pharmacologic stress is contraindicated because of reactive bronchospastic airways disease or background methylxanthines. In such cases, IV dobutamine may be used to induce coronary hyperemia.[5] Dobutamine has a relatively rapid onset of action, with a half-life of approximately 2 minutes. This agent is given starting at a dose of 5 µg/kg/min and increased in a stepwise fashion by 5 µg/kg/min every 3 minutes, to a maximum dose of 40 µg/kg/min (**see Chapter 14**). Dobutamine is a broad adrenergic receptor agonist, at varying doses stimulating the $beta_1$, $beta_2$, and $alpha_1$ receptors. At relatively low doses, the predominant effect is an increase in contractility mediated through adrenergic receptors. As the dose is increased beyond 10 µg/kg/min, heart rate rises steadily, and the increase in oxygen demand stimulates an increase in MBF.

The hemodynamic response to dobutamine generally involves a modest increase in systolic blood pressure with a modest decrease in diastolic blood pressure through doses up to 20 µg/kg/min, with only small further changes after that point. Because the increase in MBF depends on the increase in oxygen demand, optimal sensitivity for MPI based on optimizing heterogeneity of flow depends on achieving an adequate heart rate response, often requiring a high dose of dobutamine.

The increment in MBF during maximal doses of dobutamine appears to be less than that achieved during vasodilator pharmacologic stress, so the degree of heterogeneity of coronary flow with a coronary stenosis also is less. Thus, vasodilator stress is the preferred pharmacologic modality for MPI in patients who cannot exercise adequately. Dobutamine stress is reserved for patients in whom vasodilator stress is contraindicated or cannot be performed because of background medications.[5,24]

Side effects of dobutamine are frequent and can be bothersome. The most common side effects include palpitations and chest pain, and arrhythmias including PVCs and nonsustained ventricular tachycardia may be encountered. Hypotension occurs in approximately 10% of patients, possibly as a result of myocardial mechanoreceptor stimulation during increased contractility with resulting withdrawal of peripheral constrictor tone. Hypotension during dobutamine stress does not have the same prognostic implications as exercise-induced hypotension. Because of the relatively short half-life, side effects generally resolve within a few minutes of stopping the infusion and can be aborted more quickly with IV

beta-adrenergic blockade.[5,24]

Assessment of Myocardial Cellular Metabolism and Physiology

Myocardial Ischemia and Viability

Programmed Cell Survival

Imbalance between oxygen supply and demand results in myocardial ischemia. If the imbalance is transient (i.e., triggered by exertion), it represents reversible ischemia. However, if supply-demand imbalance is prolonged, high-energy phosphates are depleted, and regional contractile function progressively deteriorates. If the supply-demand balance is sufficiently prolonged, cell membrane rupture with cell death follows.

The myocardium has several mechanisms of acute and chronic adaptation to a temporary or sustained reduction in coronary blood flow (**Fig. 16.26**), known as *stunning*, *hibernation*, and *ischemic preconditioning* (**see Chapter 57**). These responses to ischemia preserve sufficient energy to protect the structural and functional integrity of the cardiac myocyte. In contrast with programmed cell death, or *apoptosis*, the term *programmed cell survival* has been used to describe the commonality among myocardial stunning, hibernation, and ischemic preconditioning despite their distinct pathophysiology.[26]

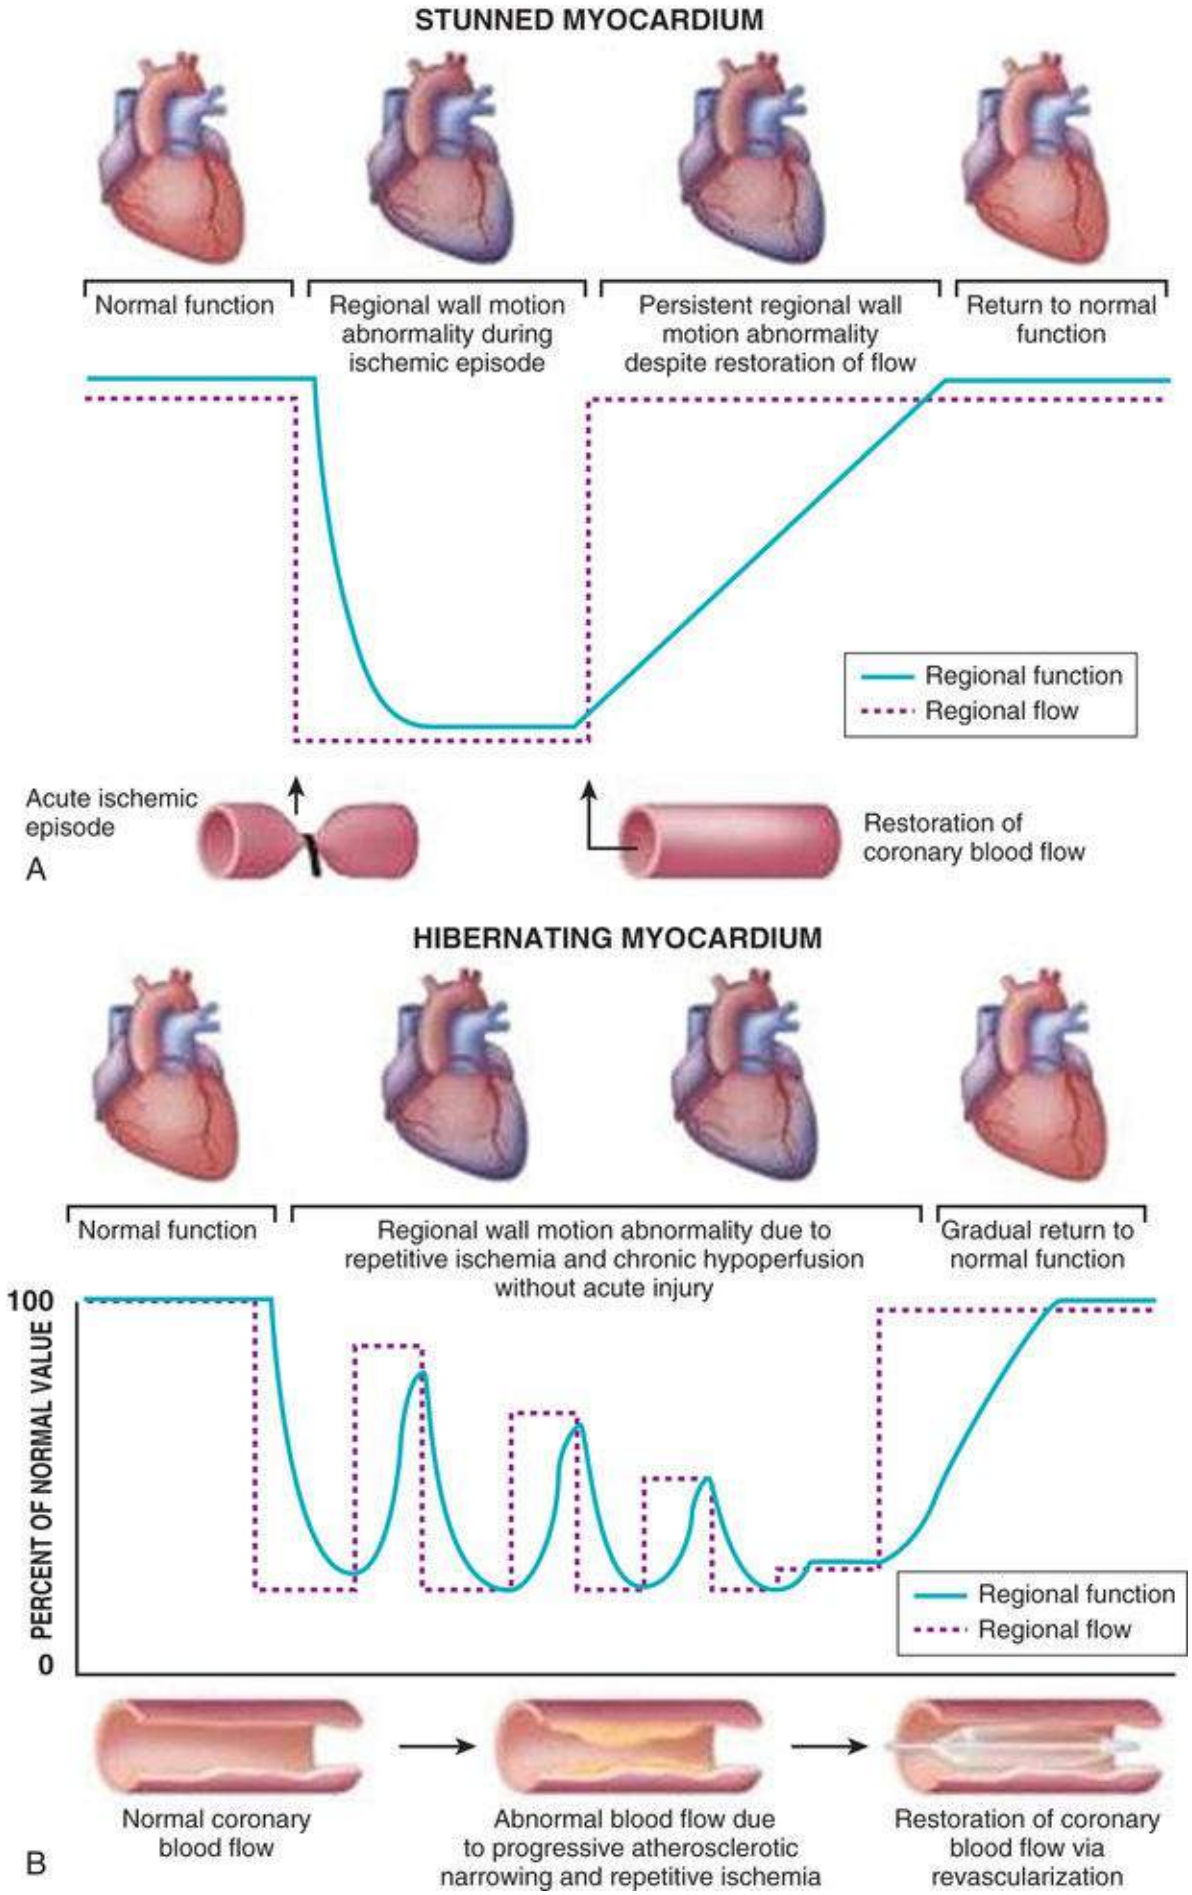

FIGURE 16.26 Pathophysiology of stunning **(A)** and hibernation **(B)**, representing different mechanisms of acute and chronic reversible left ventricular dysfunction. (Modified from Dilsizian V. Myocardial viability: Reversible left ventricular dysfunction. In Dilsizian V, Narula J, Braunwald E, editors. Atlas of Nuclear Cardiology. Philadelphia: Current Medicine; 2006.)

Stunned and Hibernating Myocardium

In stunned and hibernating myocardium, myocardial function is depressed at rest, but myocytes remain viable. Although LV dysfunction may be reversible in both stunning and hibernation, these states differ in the relationship between myocardial perfusion and function. *Stunned* myocardium is most often observed after a transient period of ischemia followed by reperfusion (depressed function at rest but preserved perfusion). The ischemic episodes can be single or multiple, brief or prolonged, but never severe enough to result in injury. This state is typically observed soon after coronary occlusion and reperfusion in the setting of acute MI. *Hibernating* myocardium refers to adaptive responses of the myocardium to repetitive episodes of ischemia resulting in myocardial hypoperfusion at rest[26] (depressed function and perfusion at rest). In clinical practice, it is likely that the adaptive responses of hibernation and stunning coexist.

Myocardial Viability

Requirements for cellular viability include (1) sufficient myocardial blood flow, (2) cell membrane integrity, and (3) preserved metabolic activity. MBF must be adequate to deliver substrate to the myocyte for metabolic processes and to remove the end products of metabolism. If MBF is severely reduced, metabolites accumulate, causing inhibition of the enzymes of the metabolic pathway, depletion of high-energy phosphates, cell membrane disruption, and cell death. Thus, with severe reduction in blood flow, perfusion tracers alone provide information about myocardial viability or absence of viability.[4] However, in regions in which the MBF reduction is less severe, perfusion information alone may be an insufficient signal to identify clinically relevant viability, and additional data, such as metabolic indices, may be important.

Because cell membrane integrity, another requisite for cell survival, is dependent on preserved intracellular metabolic activity to generate high-energy phosphates, tracers that reflect cation flux (e.g., ^{201}Tl), electrochemical gradients (sestamibi or tetrofosmin), or metabolic processes (FDG) provide insight into myocardial viability[4,26] (**Fig. 16.27**).

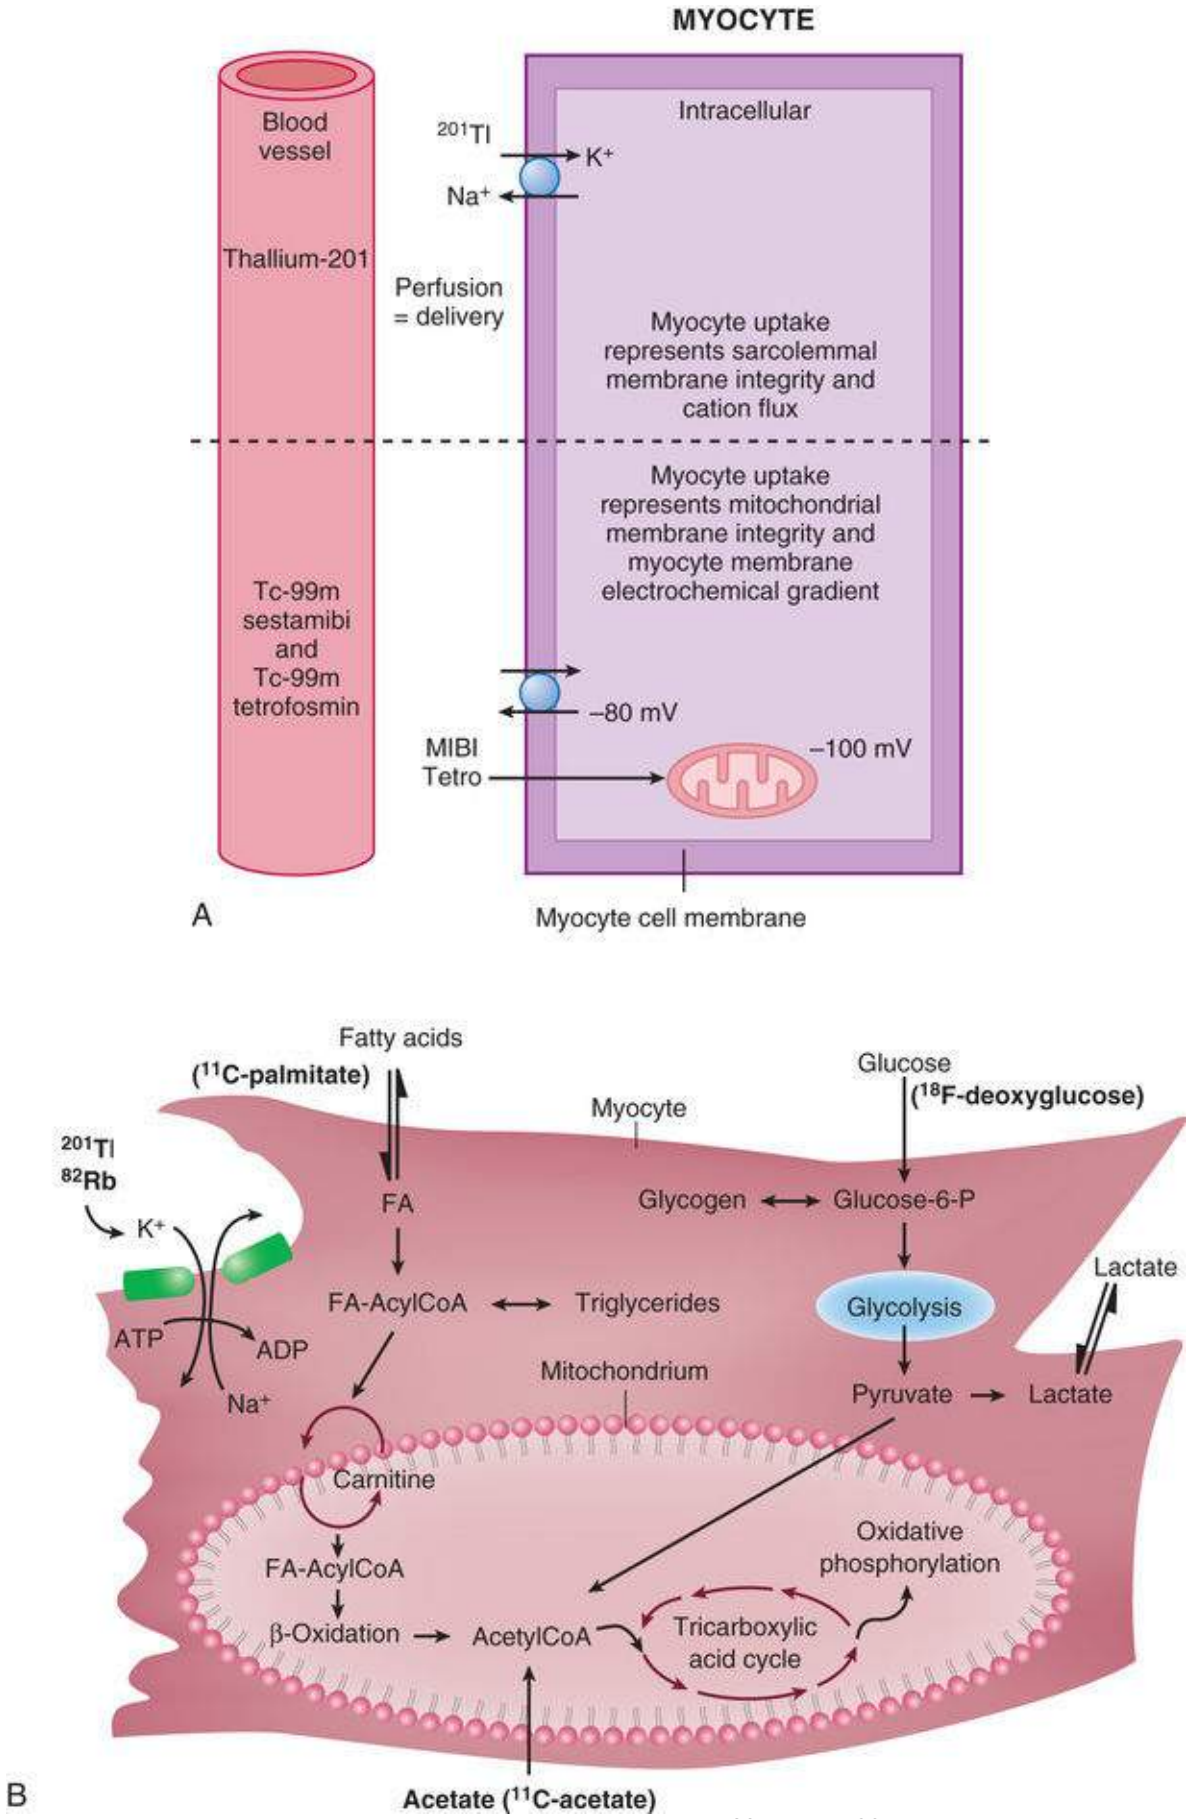

FIGURE 16.27 **A,** Mechanisms of uptake and retention of ^{201}Tl and ^{99m}Tc perfusion tracers. **B,** Mechanism of uptake and retention of PET agents tracing perfusion (^{82}Rb) and oxidative and anaerobic metabolism (^{11}C-acetate, ^{11}C-palmitate, and ^{18}F-deoxyglucose). *ADP,* Adenosine diphosphate; *ATP,* adenosine triphosphate; *CoA,* coenzyme A; *FA,* fatty acid; *Glucose-6-P,* glucose-6-phosphate. (Modified from Dilsizian V. SPECT and PET techniques. In Dilsizian V, Narula J, Braunwald E, editors. Atlas of Nuclear Cardiology. Philadelphia: Current Medicine; 2006.)

Major Myocardial Fuels and Energetics in Normal and Ischemic Myocardium

High-energy phosphates, such as adenosine triphosphate (ATP), provide the fuel that powers the myocyte contractile proteins (**see Chapter 22**). ATP is generated in the myocardium by two different but integrated metabolic processes: oxidative phosphorylation and glycolysis.[9,26] Fatty acids, glucose, and lactate are the major sources of energy in the heart, and depending on the arterial concentration of each and the physiologic condition, any one of these three can be the principal substrate (**Fig. 16.27B**). Increased uptake and use of one substrate will lead to a decreased contribution by the others.

In the fasting state, long-chain free fatty acids are the preferred source of energy in the heart, with glucose accounting for only 15% to 20% of the total energy supply. When the oxygen supply is normal, high levels of ATP and tissue citrate formed by breakdown of fatty acids suppress the oxidation of glucose. When the oxygen supply is decreased, ATP and citrate levels fall, and the rate of glycolysis is accelerated. Anaerobic glycolysis can be maintained only if lactate and hydrogen ion (the byproducts of glycolysis) are removed and do not accumulate. In the setting of severe hypoperfusion, these end products of the glycolytic pathway accumulate, causing inhibition of the glycolytic enzymes and depletion of high-energy phosphates, resulting in cell membrane disruption and cell death.[26] Thus, even to maintain anaerobic glycolysis, minimally sufficient blood flow is necessary.

Imaging of Alterations in Myocardial Metabolism

Imaging of Fatty Acid Metabolism.

Because fatty acids are the primary source of myocardial energy production in the fasting state, early PET studies focused on characterizing the kinetics of long-chain fatty acids, such as ^{11}C-palmitate.[4]

^{11}C-Palmitate.

Measurement by dynamic PET imaging allows determination of tracer inflow (by regional perfusion), peak accumulation, and release within a region of interest. Once in the cell, the tracer either enters the endogenous lipid pool or moves to the mitochondria, where rapid degradation by beta oxidation results in the generation of carbon dioxide. Depending on demand, approximately 80% of extracted ^{11}C-palmitate is activated for transport from the lipid pool into the mitochondria for breakdown by beta oxidation. Because of its complicated kinetic modeling and numerous confounding effects, ^{11}C-palmitate imaging has not gained wide clinical acceptance.

^{123}I-Bmipp.

Fatty acid imaging with radioiodine-labeled fatty acid analogues, such as iodine-123–labeled beta-methyliodopentadecanoic acid (BMIPP) with SPECT, is an investigational area for the assessment of ischemic memory.[4] After an ischemic episode, fatty acid metabolism may be suppressed for a prolonged period, and BMIPP imaging can demonstrate a regional metabolic defect even if perfusion has returned to normal. This metabolic signal of recent ischemia has been termed *ischemic memory* and theoretically may be clinically useful in patients who report to the emergency department (ED) with chest pain that resolved hours earlier. Although approved for clinical use in Japan, BMIPP has not yet received approval by the FDA.

Imaging of Glucose Metabolism.

Although fatty acids are the primary source of fuel in the fasting state, increased arterial glucose

concentration in the fed state results in an increase in insulin levels, stimulating glucose metabolism while inhibiting lipolysis. The result is a switch in myocardial metabolism from predominant use of fatty acids to glucose.

The principle of using a metabolic tracer that tracks glycolysis is based on the concept that glucose utilization may be preserved or increased relative to flow in hypoperfused but viable (hibernating) myocardium, termed *metabolism-perfusion mismatch*.[4,9,26] Myocardial glucose use is absent in scarred or fibrotic tissue, represented by metabolism-perfusion match (**Fig. 16.28**). Although the amount of energy produced by glycolysis may be adequate to maintain myocyte viability and to preserve the electrochemical gradient across the cell membrane, it may not be sufficient to sustain contractile function.[26]

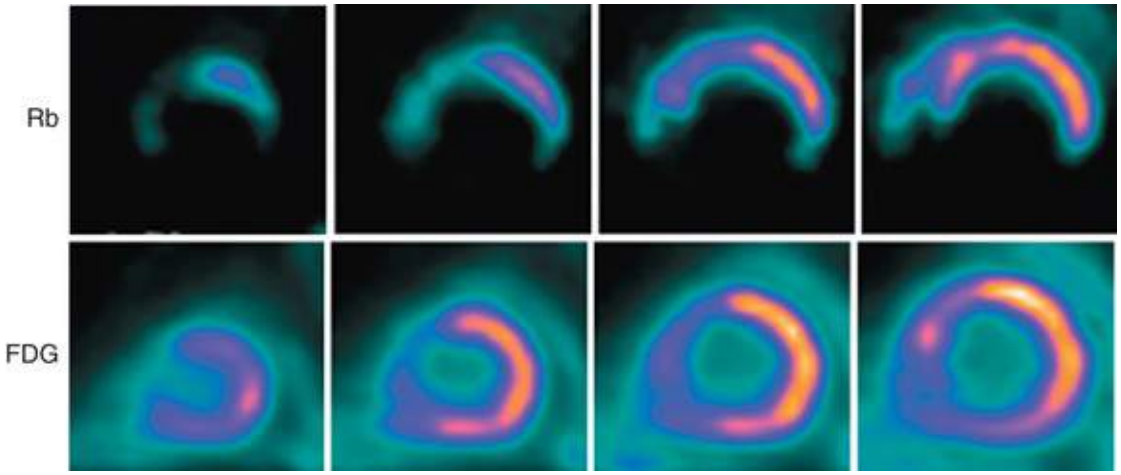

FIGURE 16.28 Assessment of viability by positron emission tomography (PET) imaging. **Top row,** Rubidium-82 (^{82}Rb) is used as a tracer of myocardial blood flow at rest in these short-axis images starting toward the apex (*left*) and moving toward the base of the heart (*right*). Myocardial perfusion is markedly decreased in the apical, inferior, inferolateral, and septal regions. **Bottom row**, ^{18}F-fluorodeoxyglucose (FDG) is used as a tracer of myocardial glucose metabolism. FDG uptake is enhanced relative to blood flow, demonstrating a pattern of perfusion-metabolism mismatch in most abnormally perfused myocardial regions, indicative of viable or hibernating myocardium. An exception is the anteroseptal region, which demonstrates a matched perfusion-metabolism pattern, indicative of nonviable or scarred myocardium. (From Taegtmeyer H, Dilsizian V. Imaging myocardial metabolism and ischemic memory. Nat Clin Pract Cardiovasc Med 2008;5[Suppl 2]:S42.)

2-^{18}F-Fluoro-2-Deoxyglucose.

FDG is a glucose analogue used to image myocardial glucose use with PET.[4,9,26] After injection of 5 to 10 mCi, FDG rapidly exchanges across the capillary and cellular membranes. It is phosphorylated by hexokinase to FDG-6-phosphate (**see Fig. 16.27B**) and not metabolized further or used in glycogen synthesis. Because its dephosphorylation rate is slow, FDG becomes trapped in the myocardium, permitting PET or SPECT imaging of regional glucose use. FDG uptake may be increased in dysfunctional but viable myocardium, and FDG uptake in asynergic myocardial regions with reduced blood flow at rest has become a scintigraphic marker of hibernation.

Diagnostic quality of FDG imaging is critically dependent on hormonal milieu and substrate availability. Most clinical FDG studies are performed after 50 to 75 g of glucose loading in the form of oral dextrose approximately 1 to 2 hours before the FDG injection, to increase glucose metabolism, to maximize FDG uptake, and to improve image quality.[4,9,26] Although 90% of FDG images are of diagnostic quality in nondiabetic patients, the quality of FDG images after glucose loading alone is less certain in

patients with clinical or subclinical diabetes, because the increase in plasma insulin levels may be attenuated, tissue lipolysis may not be inhibited, and free fatty acid levels may remain high. Standardization schemes to optimize FDG image quality in diabetic patients include (1) IV insulin injections after glucose loading, (2) hyperinsulinemic-euglycemic clamping, and (3) use of nicotinic acid derivative.[4,9]

Imaging of Oxidative Metabolism and Mitochondrial Function

^{11}C-Acetate.

All oxidative fuels are metabolized in the tricarboxylic acid cycle after conversion to acetyl coenzyme A (CoA). ^{11}C-acetate is avidly extracted by the myocardium and metabolized predominantly by conversion to ^{11}C-acetyl-CoA in the cytosol and by oxidation via the tricarboxylic acid cycle in the mitochondria to ^{11}C-carbon dioxide and water. Thus the rapid myocardial turnover and clearance of ^{11}C-acetate in the form of ^{11}C-carbon dioxide may reflect myocardial oxidative metabolism and provide insight into mitochondrial function.[4] Despite encouraging data in the literature, ^{11}C-acetate remains an investigational tracer.

Assessment of Left Ventricular Function

The EF as an index of global systolic LV performance is influenced by many factors, including the intrinsic state of contractility, preload, and afterload as well as neurohormonal and inotropic influences (**see Chapter 22**). Despite its load dependence, EF has proved to be clinically useful as a marker of LV performance. The radionuclide techniques used to image ventricular function, including RVG, gated SPECT, and gated PET imaging, have provided substantial insight into the physiology of LV function and the response to disease states (Videos 16.1 and 16.2).

Assessing the Left Ventricular Response to Exercise.

Equilibrium-gated RVG and first-pass RVG can evaluate ventricular performance during exercise. Most often, this is accomplished by imaging of the patient during bicycle exercise, supine or semisupine for equilibrium RVG and upright for first-pass RVG. EF measurements during exertion can then be compared with EF values at rest.[8]

The relative ease with which the EF response to exercise may be studied by RVG techniques led to many reports in the late 1970s and throughout the 1980s. However, evaluation of LV function during exercise by RVG has now been largely replaced by exercise echocardiography (**see Chapter 14**).

Evaluation of Left Ventricular Volumes.

With the RVG technique, the counts detected from the LV region of interest are proportional to LV volume. The proportional relation can be estimated from a blood sample of known volume, in which the quantitative relationship between counts and volume can be determined after correction for attenuation.[8]

The major advantage of the RVG technique for evaluation of ventricular volumes (and function) over contrast ventriculographic and echocardiographic methods is that the radionuclide techniques do not require assumptions about ventricular geometry. With use of RVG techniques, volumes are calculated from count rates over a region of interest (ROI) involving the left or right ventricle, or both, and are based on photon emissions from the ROI.[8] Thus the radionuclide techniques are not dependent on any assumption of ventricular geometry and are suitable for the study of ventricular volumes when ventricular geometry is abnormal.

LV volumes also may be calculated using gated SPECT perfusion imaging, and volumetric data have been validated against those obtained using other quantitative techniques.[5,8] At present, the accumulated experience with gated SPECT perfusion imaging for serial evaluation of LV volumes is less than that with equilibrium RVG volumetric techniques. Nonetheless, the ability to evaluate simultaneously LV function, perfusion, and volumes demonstrates the clinical versatility of gated SPECT MPI.

Serial Evaluation of Left Ventricular Function.

The quantitative nature of radionuclide analysis of ventricular function and the high reproducibility of the measurement make ECG-gated RVG or ECG-gated SPECT imaging well suited for serial follow-up evaluation of changes in LV systolic performance. Serial changes in LV function are clinically relevant in many clinical situations, such as in patients with heart failure,[27] those observed with valvular heart disease,[28] and those receiving cardiotoxic chemotherapy[29] (**see Chapters 25, 67, and 81**). Serial RVG studies demonstrating diminution in EF suggested that the early onset of myocardial dysfunction can herald the onset of a higher-risk clinical course directing clinical management decisions.

Disease Detection, Risk Stratification, and Clinical Decision Making

Stable Chest Pain Syndromes

Application of Radionuclide Imaging: Answering the Clinical Questions

For patients with stable symptoms of suspected CAD (**see Chapter 61**) who are referred for noninvasive testing, the two major goals of testing are to ascertain whether CAD is present or absent—the *diagnostic construct*—and to determine the longer-term prognosis or the risk for an adverse outcome over time—the *prognostic construct*. These goals of testing are linked to the two main treatment goals for patients with suspected or known CAD: (1) amelioration of symptoms in everyday life and (2) improvement in outcome.

Establishment of the presence or absence of CAD is an important goal of testing. The performance characteristics of radionuclide imaging for this purpose often are based on an angiographic definition of stenosis of 50% or greater, or 70% stenosis in an individual epicardial vessel. This definition of CAD is based in part on seminal studies in animal models showing that a 50% stenosis begins to blunt coronary flow reserve (**see Chapter 57**). Over time, however, a view has emerged that CAD is a more complex process than can be simply defined dichotomously by a 50% or even a 70% luminal stenosis. Throughout the progression of plaque growth, there is a risk of transformation from a stable plaque to an unstable plaque, with the potential for an acute coronary syndrome (ACS) that abruptly alters the natural history of the disease process[30] (**see Chapters 44 and 58**). Plaque encroachment of the lumen occurs later in the process but has a potentially important impact on the patient's everyday quality of life by causing symptoms related to exertional ischemia.

Patient-Related Outcomes as a “Gold Standard”

The evolution of preventive therapies such as 3-hydroxy-3-methylglutaryl-CoA reductase inhibitors (statins) to reduce cardiovascular risk has focused attention on the ability of global risk scores or noninvasive testing to assess risk of future events so that strategies to prevent future cardiac events can be instituted[31] (**see Chapter 45**). Thus, from the perspective of improving natural history, knowledge of

whether a stenosis greater than 50% is present in a patient with stable anginal symptoms becomes less important than knowledge of the patient's risk for a cardiovascular event (cardiac death or nonfatal MI). After initial investigations of the performance of radionuclide imaging to detect or to rule out CAD (sensitivity and specificity), the trajectory of the literature has been toward gaining more understanding of how noninvasive imaging results assess prognosis and stratify the risk of future cardiac events. This trend has occurred in parallel with similar directions in primary prevention efforts, such as the use of a Framingham risk score or the current "pooled cohort equation," leading to lifestyle and treatment interventions to lower that risk.[31] In much the same way, risk stratification and assessment of prognosis by noninvasive imaging will inform clinical management decisions geared toward reducing risk of MI and cardiac death and optimizing the selection of patients for revascularization and medical therapies.

Risk Stratification in Stable Chest Pain Syndromes

Definitions for Understanding the Literature.

For prognostic assessment, an important goal is to detect patients at risk for "hard" cardiac events. This definition includes nonfatal MI as well as cardiac death or all-cause mortality, irreversible events important to prevent.[32] "Soft" cardiac events include revascularization and hospital admission for management of ACS or heart failure. Such events occur more often than the hard cardiac events and thus contribute to a larger number of endpoints for data analysis. These events, however, are not as important in terms of natural history and may be driven by subjective changes in symptoms and, in the case of revascularization, by the results of the imaging tests themselves.

Risk categories as described in the American College of Cardiology/American Heart Association (ACC/AHA) stable angina guidelines are *low risk,* defined as a less than 1%/yr risk of hard cardiac events; *intermediate risk,* defined as a 1% to 3%/yr risk; and *high risk,* defined as a greater than 3%/yr risk.[32] These definitions are conceptually linked to implied treatment strategies. Patients with greater than 3%/yr risk would be most likely to benefit from a revascularization strategy, whereas those at low risk would be least likely to benefit from revascularization, in terms of natural history, and thus could be treated medically, with treatment directed against symptoms as well as risk factor modification.

Relation Between Extent of Perfusion Defect and Outcomes

Seminal studies in the 1980s demonstrated that the extent of perfusion abnormality by stress MPI has an important relationship with the subsequent likelihood of an adverse outcome (cardiac death or nonfatal MI). In patients presenting with chest pain and suspected CAD (without any previous known CAD-related history, such as MI or revascularization), the risk of cardiac death or MI increased as the number of reversible perfusion defects (i.e., the extent of inducible ischemia) increased. This concept has been confirmed many times by investigators worldwide. Moreover, this robust concept not only applies to exercise stress MPI but also extends across the spectrum of procedural variables in nuclear cardiology, including different stressors (vasodilator pharmacologic stress, dobutamine stress), isotopes (^{201}Tl and ^{99m}Tc agents), and imaging protocols.[5]

Fig. 16.29 provides an example of data on risk stratification implying therapeutic management strategies; in two older men with typical exertional angina, it would be predicted that the probability of CAD is high, according to established guidelines. What is not established from the clinical information, however, is the risk of cardiac events. This example demonstrates that patients presenting with similar

symptoms might be identified as having distinct natural history trajectories on the basis of perfusion imaging data, with distinct implications for subsequent management.

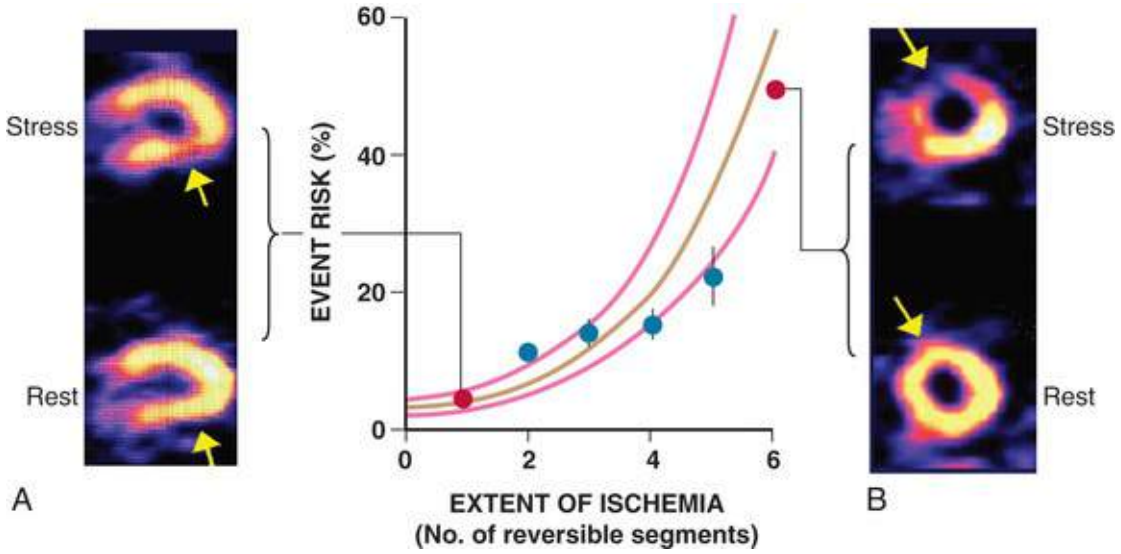

FIGURE 16.29 Prognostic implications of myocardial perfusion imaging (MPI). **Middle panel,** Cardiac event rate (risk of cardiac death or MI) during long-term follow-up plotted as a function of the extent of inducible ischemia (the number of reversible perfusion defects). An exponential relationship exists between the extent of ischemia and the risk of a cardiac event. The *brown line* represents modeling of data points; *magenta lines* represent confidence limits. **A, B,** SPECT perfusion images in two patients with stable anginal symptoms. **A,** Small area of inferoapical ischemia (*arrows*). When this extent of ischemia is plotted on the graph (line to *red circle* at *left* within graph), the patient is placed in a low-risk category. **B,** By contrast, the large, markedly affected area representing severe anterior and septal ischemia in a second case places the patient in a high-risk group (line to *red circle* at *right* within graph). (**A, B,** Modified from Ladenheim ML, Pollock BH, Rozanski A, et al. Extent and severity of myocardial hypoperfusion as predictors of prognosis in patients with suspected coronary artery disease. J Am Coll Cardiol 1986;7:464.)

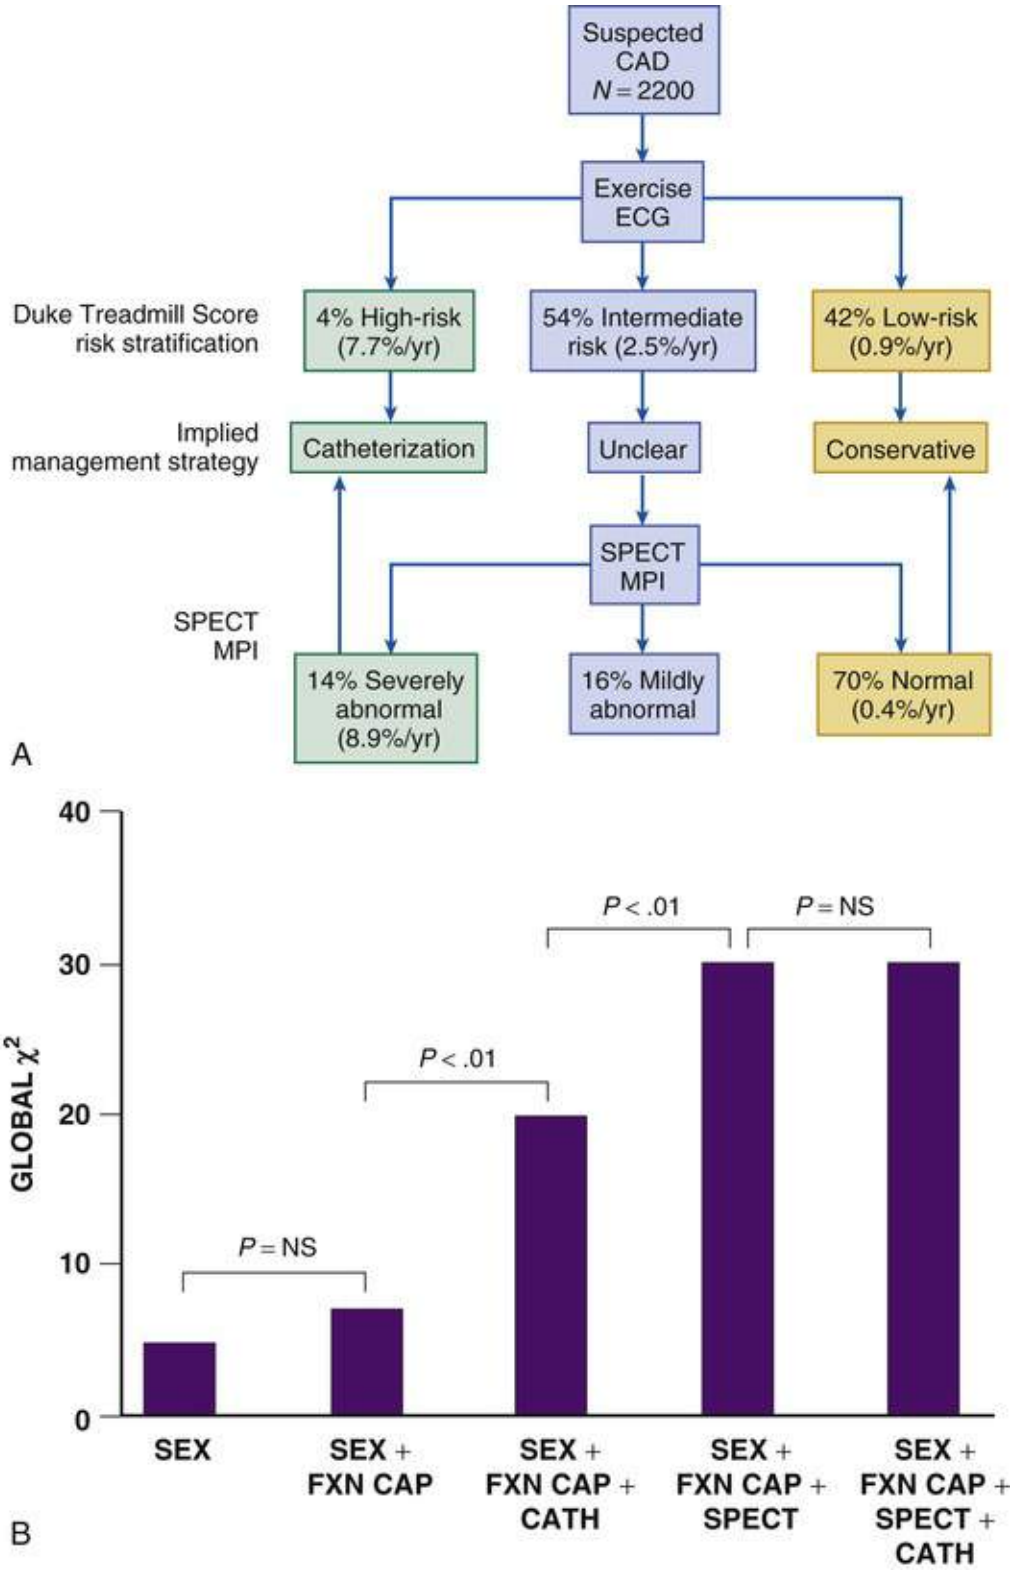
Incremental Value of Perfusion Imaging

The term *incremental value* implies that MPI data provide information on natural history risk and outcomes that are additive to (incremental to) information from more available or less expensive tests, such as clinical data and stress ECG findings.

Stress MPI data have been shown to have incremental prognostic value when added to prognostic stress ECG instruments such as the Duke treadmill score (DTS), a well-validated instrument incorporating symptoms, treadmill performance, and stress ECG findings to predict natural history outcomes (**see Chapter 13**). In a group of 2200 patients with suspected CAD referred for nuclear testing, the DTS was used to place patients in subgroups according to the risk of a hard event (**eFig. 16.11**). When information from stress MPI studies was incorporated, incremental value to predict outcome was demonstrated within each of the three DTS risk categories.



EFIGURE 16.11 Incremental value of SPECT perfusion imaging. **A,** Comparison with the Duke treadmill score (DTS). A large group of patients with suspected CAD initially were risk-stratified using the well-validated DTS. Figures in *parentheses* are the observed annual event rates. A majority of the population is classified as "intermediate risk" by DTS, and management strategy is not clear. High-risk patients may be managed aggressively, and low-risk patients may be managed conservatively. Among patients originally determined to be in the intermediate-risk category by the DTS, almost 70% demonstrated normal findings on SPECT perfusion study, associated with a very low event rate. After SPECT MPI, more patients are classified at the "extremes" of risk (low or high), for whom management is more clearly implied by the risk prediction. Thus the imaging data allowed further stratification and had incrementally better value compared with the DTS information. **B,** The incremental value of imaging data may be expressed as the incremental chi-square value, a statistical measure of the strength of the association of clinical, demographic, stress, or imaging factors to risk stratification. Among patients with known CAD who had undergone catheterization (*CATH*), clinical information is added on the *x* axis, with the global chi-square value associated with the information depicted on the *y* axis. The larger the chi-square value, the stronger the relation between the combination of factors on the *x* axis and the natural history outcome of cardiac

death or myocardial infarction. Even when anatomic information is available, the physiologic information provided by SPECT MPI adds significantly to risk prediction ability. *FXN CAP,* Functional capacity. (**A,** Modified from Hachamovitch R, Berman DS, Kiat H, et al. Exercise myocardial perfusion SPECT in patients without known coronary artery disease: incremental prognostic value and use in risk stratification. Circulation 1996;93:905; **B,** modified from Iskandrian AS, Chae SC, Heo J, et al. Independent and incremental prognostic value of exercise single-photon emission computed tomography (SPECT) thallium imaging in coronary artery disease. J Am Coll Cardiol 1993;22:665.)

The importance of this information in driving management decisions for patients can be illustrated by considering how clinicians would manage patients on the basis of certain amounts of information. With use of the DTS information alone, the management of low-risk patients probably would be conservative, and the management of high-risk patients would likely involve revascularization. The optimal management of intermediate-risk patients is unclear, but many probably would be referred for catheterization. In almost 70% of the patients in the intermediate DTS category, however, stress perfusion study findings were normal (**eFig. 16.11A**), associated with a very-low-risk natural history, implying that conservative management would be a safe and effective strategy.

Another method used to demonstrate the incremental value of MPI data over that of clinical, stress, and even angiographic data involves the creation of a multivariable model to measure the strength of association of individual factors with the natural history outcomes (Classic References, Beller). This often is illustrated by assessing the incremental chi-square value, measuring the strength of the association of the factor with subsequent cardiac death and nonfatal MI (**eFig. 16.11B**). Contemporary studies might also use analytic techniques such as net reclassification index to assess the value of an additional increment of information in classifying prognostic risk.[33]

Identification of Treatment Benefit After Risk Stratification

Although numerous studies intimate that the extent and severity of perfusion abnormality are related to subsequent natural history risk, few studies have documented reduction in that risk associated with a particular therapy. Current information suggests that more extensive ischemia determined by MPI identifies patients in whom revascularization may lead to an improvement in outcome. In a group of more than 10,000 patients with suspected CAD studied by stress MPI, the extent of ischemic myocardium predicted reduction in the risk of death with revascularization compared with medical therapy (**Fig. 16.30**), beginning at just over 10% of ischemic myocardium.[6] As the percentage of ischemic myocardium increased, the magnitude of benefit of revascularization increased as well. Thus, MPI data appear to predict the magnitude of a potential treatment benefit from revascularization, helping to guide management decisions. These observational data were developed using techniques to account and correct for differences in the populations treated with revascularization versus medical therapy, but such techniques cannot account for all possible differences between groups. The concept that revascularization may improve outcome in stable outpatients with extensive inducible ischemia is currently being prospectively tested in the randomized, controlled International Study of Comparative Health Effectiveness with Medical and Invasive Approaches (ISCHEMIA) trial.[34]

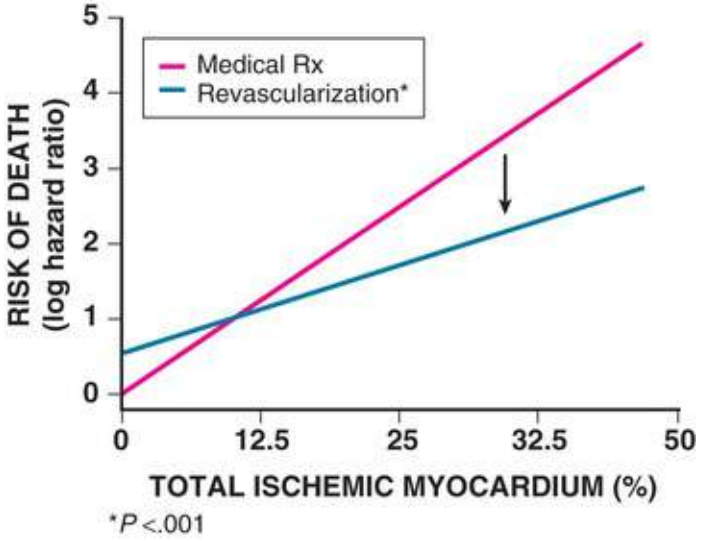


FIGURE 16.30 Predicting the magnitude of treatment benefit by revascularization. Risk of death is plotted as a function of the percentage of ischemic myocardium by SPECT perfusion imaging. The *lines* represent patients treated with medical therapy (Medical Rx) or revascularization. When the magnitude of ischemia exceeds approximately 12%, a potential survival benefit accrues to revascularization. (Modified from Hachamovitch R, Hayes SW, Friedman JD, et al. Comparison of the short-term survival benefit associated with revascularization compared with medical therapy in patients with no prior coronary artery disease undergoing stress myocardial perfusion single photon emission computed tomography. Circulation 2003;107:2900.)

Prognostic Value of Normal Myocardial Perfusion Imaging.

A consistent finding in studies assessing prognosis has been the benign outcome associated with a normal stress MPI study. As summarized in the American Society of Nuclear Cardiology (ASNC) imaging guidelines,[5] data on outcomes associated with normal findings on a stress SPECT MPI study involve almost 21,000 patients. In patients with a normal study result, the hard event rate (i.e., rate of cardiac death or nonfatal MI) occurring during an average follow-up period of 2 years is 0.7%/yr. This concept applies across a broad spectrum of isotopes, protocols, and stressors.[5] The prediction of low-risk outcome after a normal MPI study extends approximately 2 years after testing (i.e., the "warranty period").[6] Patients who at baseline represent higher-risk subsets (i.e., those with diabetes) are at slightly higher risk for an adverse outcome after normal results of a stress MPI study, consistent with Bayes theorem; that is, for a certain MPI finding, the post-test probability (outcome risk) is related in part to the pretest risk.

Even when angiographic CAD is present with a stable symptom complex, a normal stress MPI study result is associated with a low-risk outcome (approximately 0.9%/yr).[5] The mechanism for a normal MPI study result despite established CAD may involve preserved endothelial function, allowing appropriate flow-mediated vasodilation during stress, reducing the impact of an angiographic stenosis on downstream myocardial perfusion. If this is true, such preserved endothelial function may identify a decreased susceptibility to plaque fissuring or rupture and a greater likelihood of a stable clinical course. Another mechanism may involve the presence of robust collaterals, allowing normal stress perfusion in the setting of a stenosis, and protecting against infarction should the stenosis become completely occluded.

Detecting the Presence and Extent of CAD

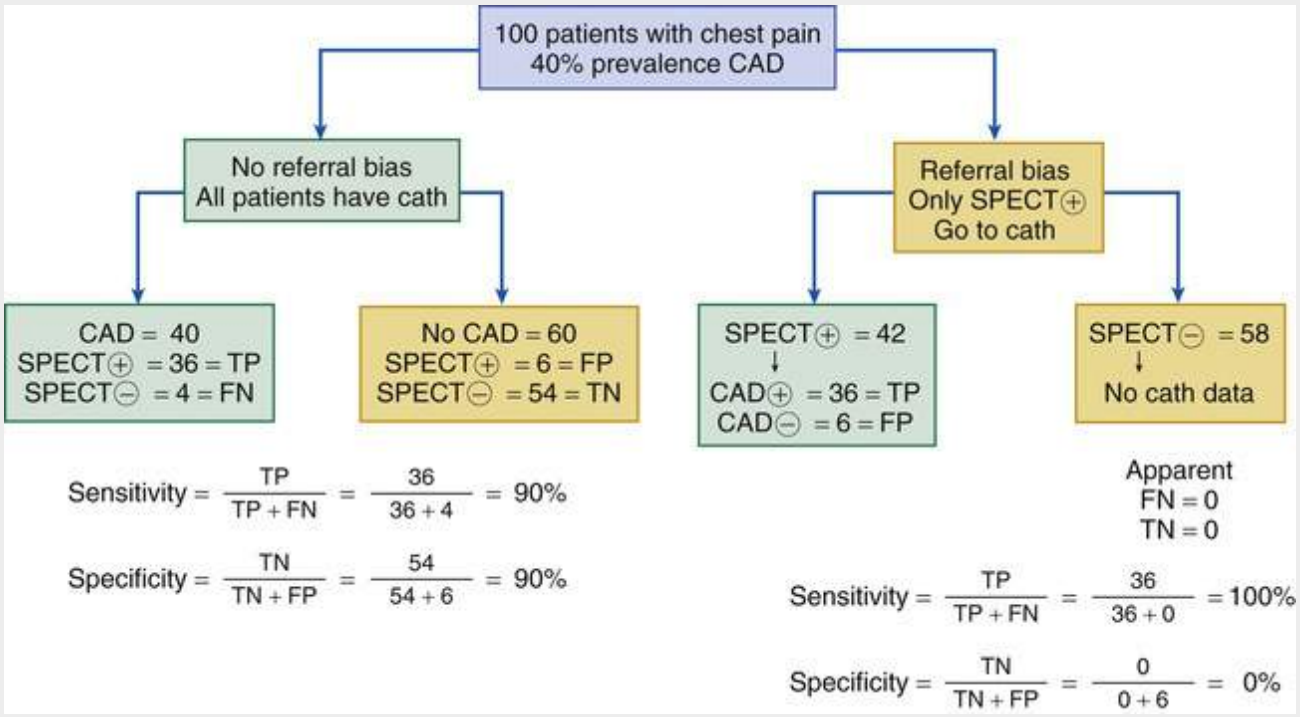
Noninvasive testing in patients with suspected CAD is typically performed to determine the presence or absence of angiographic CAD. In this paradigm, angiography is the gold standard to define the presence or absence of CAD, and performance of the noninvasive test is measured by its sensitivity (percentage of

true-positive test results among those with CAD, as defined by angiography) as well as by its specificity (percentage of true-negative test results among patients without CAD).[5] Published values of sensitivity to detect CAD and specificity to rule out CAD vary widely. An appreciation of the many methodologic or physiologic factors that may influence these performance characteristics is necessary for imaging data to be incorporated appropriately into clinical decision making.

Methodologic Influences on Sensitivity and Specificity

Referral Bias.

The apparent accuracy of any noninvasive test to detect CAD depends on the indications for coronary angiography. Accuracy of a new diagnostic test usually is determined initially in patients who are undergoing coronary angiography. As the test becomes implemented in routine diagnostic strategies, its results determine which patients are to be referred for coronary angiography (**eFig. 16.12**). For example, patients with abnormal MPI findings are more likely to undergo coronary angiography than those with normal MPI findings. This inherent selection process results in a phenomenon termed *post-test referral bias*, in which the specificity of a diagnostic test declines over time as it is accepted into clinical practice and plays a gatekeeper role in determining which patients undergo angiography.[5] In its extreme form, in which only patients with an abnormal test result are referred for angiography (as in **eFig. 16.12**), post-test referral bias drives the specificity to zero (all patients with normal coronary arteriograms have false-positive MPI results, and there are no true negatives). The same phenomenon artificially increases the sensitivity of the test and in its extreme drives the sensitivity to 100% (all patients with abnormalities on coronary arteriograms have true-positive findings on MPI, with no false negatives). This concept holds not only for MPI but also for any diagnostic test that might determine the indications for angiography.



EFIGURE 16.12 The effect of referral bias on specificity calculation. If the test being evaluated is used as the "gatekeeper" to coronary angiography, many patients in whom testing yields true negatives (i.e., those with a normal test result and no have CAD) will not undergo angiography, so their data will not be included in the specificity calculations (*right*). This has an effect of artificially reducing the apparent specificity of the noninvasive test in question. *FN,* False-negative; *FP,* false-positive; *TN,* true-negative; *TP,* true-positive value. (Modified from Rozanski A, Diamond GA, Berman D, et al. The declining specificity of exercise radionuclide ventriculography. N Engl J Med 1983;309:518.)

The concept of "normalcy rate" has been developed in an attempt to compensate for this referral bias. Normalcy is calculated in the same manner as for specificity but includes only the imaging test results of patients with a clinically low or very low pretest likelihood of having CAD, whether or not they are referred for cardiac catheterization. Normalcy rates tend to be higher than specificity.

Angiography as the Gold Standard.

In humans, coronary atherosclerosis is a complex disease most often involving the coronary arteries diffusely and not merely focally. Moreover, whether a given discrete stenotic lesion, imaged at rest during coronary angiography, results in a perfusion abnormality during stress is dependent on a number of factors besides the percentage degree of stenosis. These factors include the dilatory or constrictor response of the vessel during stress (mediated by endothelial function) and the presence or absence of collaterals. For example, a vessel with 70% stenosis but with preserved endothelial function and a well-developed collateral supply may not be associated with an abnormality on stress MPI. In a diagnostic construct, such a result would be categorized as a false-negative finding, reducing MPI sensitivity. However, the MPI data may be providing the correct physiologic information about the functional significance of the angiographic finding, demonstrating that collateral flow during exercise or normal endothelial function, or both, is associated with preserved coronary blood flow reserve despite the coronary stenosis. This example illustrates the limitation of using angiography as a gold standard in evaluation of a physiologic modality.

Many studies define CAD as 50% or greater stenosis, whereas others use a threshold of 70% or greater stenosis.[4,12] Use of ≥50% would decrease sensitivity (because some 50% to 70% stenoses are not hemodynamically significant) and increase specificity. By contrast, use of ≥70% would increase sensitivity (because more such stenoses are likely to be associated with a perfusion abnormality), but decrease specificity, because any positive scan result with 50% to 70% stenosis would be considered

false positive.

Physiologic Influences on Sensitivity and Specificity.

A number of disease processes involving the coronary vasculature or the myocardium may result in abnormalities in myocardial perfusion in the absence of a discrete coronary stenosis. In a diagnostic construct for CAD, such abnormalities would be labeled false positive, reducing specificity (i.e., the test result is positive in the absence of epicardial CAD). However, MPI may actually be providing correct information about perfusion physiology.

Left Bundle Branch Block.

Isolated reversible perfusion defects of the septum in patients with LBBB may be seen in the absence of stenosis of the left anterior descending (LAD) coronary artery.[5] This phenomenon may represent true heterogeneity of flow between the LAD and left circumflex arterial territories, related to delayed relaxation of the septum in LBBB leading to reduced coronary flow reserve in early diastole, or reduced oxygen demand as a result of late septal contraction, when wall stress is decreasing. Accordingly, the specificity and predictive value of a septal perfusion defect with LBBB are low. However, apical or anterior involvement in septal perfusion defects increases the specificity for CAD. Because a septal defect in LBBB most often is seen at high heart rates, pharmacologic stress improves specificity, and vasodilator stress is recommended in the setting of LBBB.[5]

Hypertrophic Cardiomyopathy.

The asymmetric septal hypertrophy in many patients with HCM can lead to the appearance of a greater amount of tracer uptake in the hypertrophied septum relative to the lateral wall, creating the impression of a mild lateral wall perfusion defect, especially when polar maps are employed (**see Chapter 78**). Many reports have demonstrated myocardial perfusion abnormalities in patients with HCM in the absence of epicardial CAD.[35] Such findings have important pathophysiologic relevance: patients with fixed perfusion defects are likely to have thinned akinetic walls on echocardiography and diminished EF (**Fig. 16.31**). Of asymptomatic patients with HCM, approximately 50% have inducible, reversible perfusion abnormalities in the absence of CAD, typically involving the septum. Thus, inducible perfusion defects in HCM that represent inducible myocardial ischemia, possibly related to microvascular abnormalities, have low specificity for CAD in patients with HCM. The blunted coronary flow reserve in patients with HCM is associated with a more unfavorable natural history.[35]

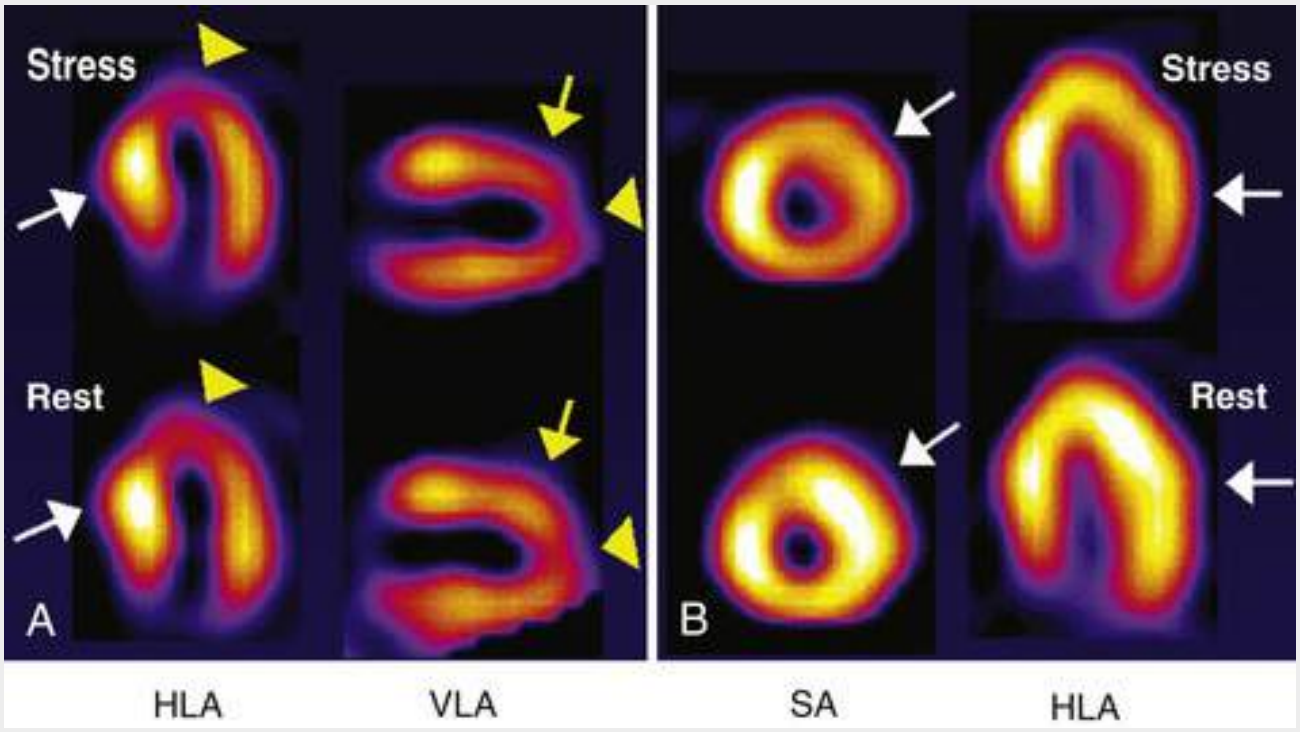


FIGURE 16.31 SPECT perfusion imaging in hypertrophic cardiomyopathy in young asymptomatic patients with normal coronary arteries. **A,** Fixed perfusion defect of the apex consistent with infarction, indicated by *yellow arrowheads* in the horizontal (HLA) and vertical (VLA) long-axis images, with a reversible defect of the anterior wall (*yellow arrows* in VLA images). The hypertrophied septum is evident (*white arrows* in HLA images). **B,** Extensive inducible silent ischemia in the anterior, lateral, and inferior walls (*white arrows*). Transient ischemic cavity dilation also is present, possibly related to subendocardial ischemia. (Based on data from O'Gara PT, Bonow RO, Maron BJ, et al. Myocardial perfusion abnormalities in patients with hypertrophic cardiomyopathy: assessment with thallium-201 emission computed tomography. Circulation 1987;76:1214; and Udelson JE, Bonow RO, O'Gara PT, et al. Verapamil prevents silent myocardial perfusion abnormalities during exercise in asymptomatic patients with hypertrophic cardiomyopathy. Circulation 1989;79:1052.)

Dilated Cardiomyopathy.

Abnormalities in myocardial perfusion are common in patients with DCM despite normal epicardial coronary arteries.[5] Several studies have demonstrated abnormal coronary flow reserve in these patients (**see Chapter 77**). An important diagnostic consideration in patients with LV systolic dysfunction involves distinguishing those whose cardiomyopathy may be primarily caused by CAD (many of whom have potentially reversible LV dysfunction) from those with idiopathic DCM. Although many patients with DCM may have perfusion abnormalities detected on MPI, the absence of perfusion abnormalities virtually excludes CAD as the cause of the cardiomyopathy[36] (**Fig. 16.32**). Extensive perfusion abnormalities in the setting of LV dysfunction are virtually always associated with CAD rather than with DCM, especially when the perfusion defects are segmental.

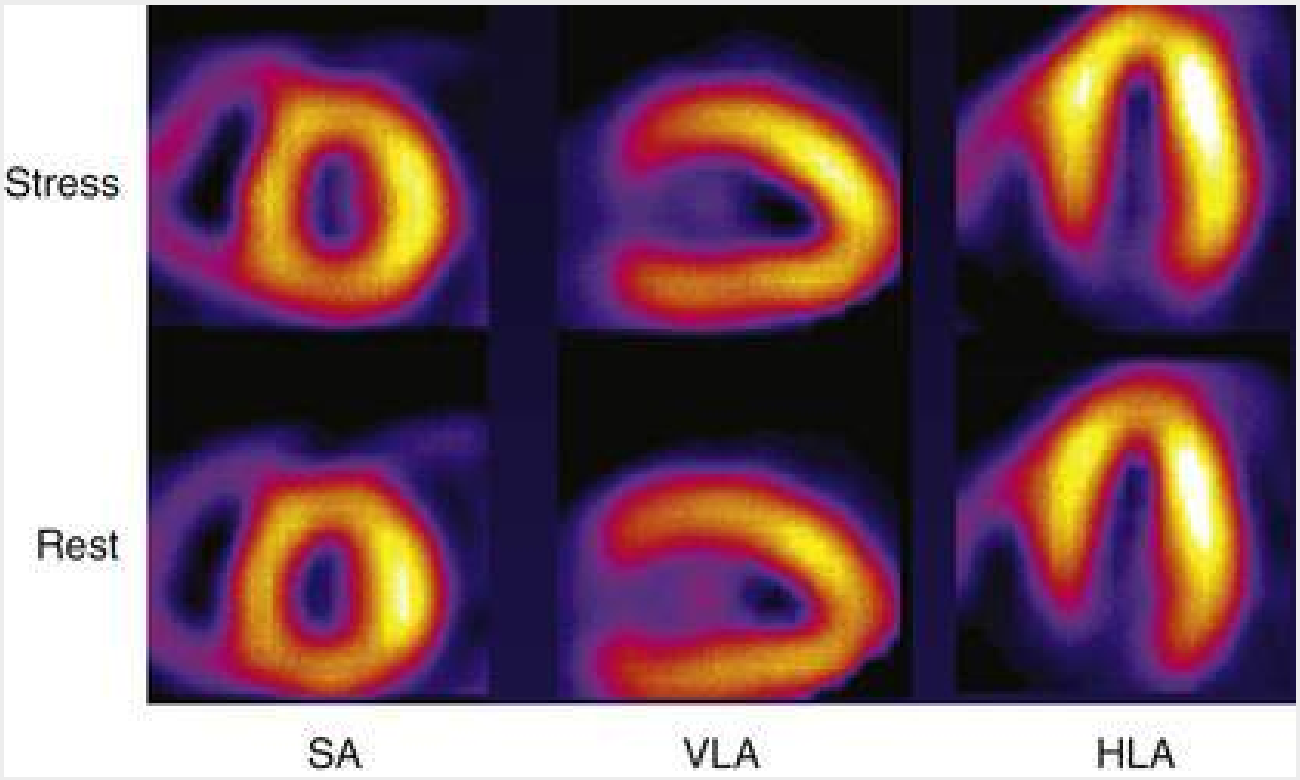

FIGURE 16.32 SPECT perfusion images obtained during stress and at rest in a patient with heart failure. The images depict a dilated left ventricle but with normal perfusion patterns, suggesting a low likelihood that CAD is the cause of heart failure. *HLA,* Horizontal long axis; *SA,* short axis; *VLA,* vertical long axis.

Endothelial Dysfunction.

Abnormalities in myocardial perfusion detected by SPECT MPI have been demonstrated in patients with coronary endothelial dysfunction, in the absence of "significant" epicardial vessel stenosis. That these perfusion findings represent true abnormalities in coronary flow reserve is supported by studies showing improvement in perfusion on follow-up MPI after treatment with medical therapies directed at improving endothelial function.[5] Further support for this concept comes from CMR studies demonstrating blunted subendocardial coronary flow reserve in patients with angina and normal coronary arteries[37] (**see Chapter 17**).

Sensitivity and Specificity of Myocardial Perfusion Imaging

ASNC imaging guidelines summarize sensitivity and specificity data from many studies involving patients undergoing exercise SPECT imaging.[5] Sensitivity to detect CAD was 87% (range, 71% to 97%) in this pooled analysis, and specificity to rule out CAD was 73% (range, 36% to 100%). Few if any of these studies incorporated ECG-gated SPECT imaging of regional function or attenuation correction, techniques that appear to enhance specificity. For example, in one study of women undergoing coronary angiography, specificity was improved from 76% to 96% when gated SPECT ^{99m}Tc-sestamibi imaging was used compared with nongated SPECT ^{201}Tl imaging.[5]

Influence of Perfusion Tracer on CAD Detection

Despite the expectation of improved diagnostic accuracy with use of ^{99m}Tc-based agents, on the basis of more favorable attributes as a radioisotope for gamma camera imaging compared with ^{201}Tl, studies comparing the widely used agents have not shown significant improvement in sensitivity or specificity. An exception is the improved specificity in women using ^{99m}Tc-sestamibi compared with ^{201}Tl. Thus the choice of radiotracer for MPI does not notably affect the discrimination between the presence and

absence of CAD. Studies often include participants who may not fully represent those most challenged by imaging. The ^{99m}Tc-based agents, with their greater photon energy, would be expected to offer improved performance in obese patients and those with large breasts, as well as allowing the option of higher-quality gated images.

Influence of Automated Quantitation of Myocardial Perfusion Images on CAD Detection

Both intra- and interobserver variability in the visual analysis of myocardial perfusion images may be significant. Several methods of quantitative analysis of MPI have been developed[1,5] to reduce the variability in reading by "objectifying" image analysis, comparing regional uptake values against a database of normal values. Automated quantitative analysis systems are incorporated into most SPECT camera computer equipment. Some of the most common are Emory Toolbox, Cedars QPS, and 4D-MSPECT[1] (**Fig. 16.33**). Although published data do not clearly demonstrate improved sensitivity or specificity of these programs over visual analysis for CAD detection, such data arise from expert centers, often where the quantitative software was developed, and the visual analysis data are derived from experienced readers in laboratories with excellent quality control. In practice, use of contemporary quantitative programs can improve image acquisition quality as well as interpretation. Some programs incorporate motion-sensing algorithms that interrogate the raw data and alert the technologist that motion correction may be needed.

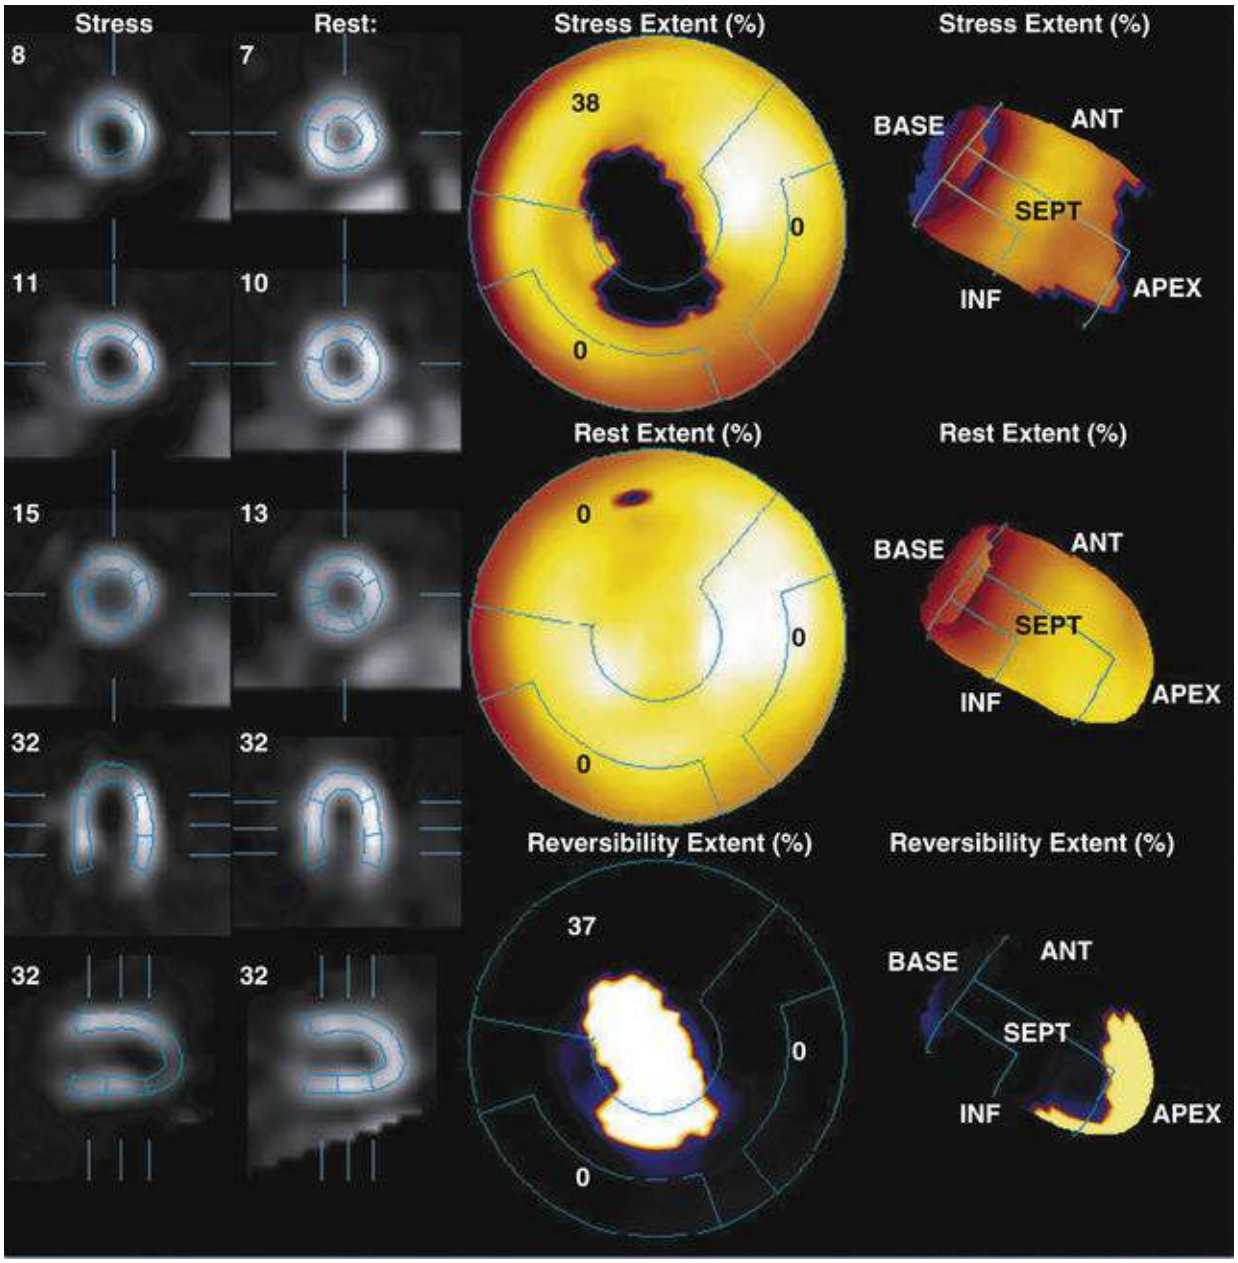

FIGURE 16.33 Automated quantitative analysis software display. Selected short- and long-axis tomograms from stress and rest studies (*two left columns*) are automatically segmented and scored. Bull's-eye plots are created (*third column*) representing the stress (*top*) and rest (*middle*) data and demonstrate a large apical reversible defect. The *bottom* bull's-eye plot displays the extent of ischemic myocardium (*white area*), which measures 23% of the total myocardium. The bull's-eye information also is displayed in a three-dimensional format (*right column*, *top*, *middle*, and *bottom*). Numbers on the bull's-eye maps represent the percentage of the vascular territory that is abnormal. *ANT,* Anterior; *INF,* inferior; *SEPT,* septal. (Images courtesy Guido Germano, PhD.)

Pharmacologic Stress Testing for Detecting CAD

Reports examining the sensitivity and specificity of vasodilator pharmacologic stress combined with MPI for the detection of CAD have achieved results similar to those reported with exercise stress. A pooled analysis involving 2465 catheterized patients in 17 studies[5] demonstrated sensitivity of 89% and specificity of 75%, similar to values from exercise SPECT MPI studies.

The more powerful hyperemic stress response achieved with vasodilator stress versus exercise might be expected to result in improved sensitivity to detect CAD, particularly more moderate stenoses. Such improvement has not been demonstrated, however, possibly because of the "roll-off" property of the common perfusion tracers, caused by diffusion limitation at hyperemic blood flow levels[4] (**see Fig.**

16.21). Thus the more favorable hyperemic stress achieved with pharmacologic stress is offset by the lack of linear tracer uptake in the areas with the highest flow.

The diagnostic ability of dobutamine stress imaging appears to be generally similar to that of other pharmacologic and exercise stress modalities for the detection of CAD.[5] However, because maximal coronary flow reserve is not achieved as often as with vasodilator pharmacologic stress, and side effects are substantial, dobutamine is recommended only when adenosine, dipyridamole, or regadenoson is contraindicated, such as in a patient with important reactive airways disease.

Effect of Submaximal Exercise Performance on CAD Detection

The sensitivity of MPI to detect CAD is optimized by achieving the highest possible level of oxygen demand to stimulate the greatest increment in coronary flow reserve. In exercise ECG testing, sensitivity to detect CAD falls significantly if greater than 85% of maximum predicted heart rate for age is not achieved[23] (**see Chapter 13**). Because perfusion heterogeneity usually develops at a lower degree of supply-demand mismatch than ECG changes, the sensitivity of MPI to detect CAD is maintained at somewhat lower workloads.[5] However, the extent and severity of reversible perfusion defects may be diminished at submaximal versus maximal workloads, which may affect the prognostic value of the test.

Thus the selection of a stress protocol can be summarized as follows. Exercise is the preferred stressor because it allows the optimal potential association of symptoms with perfusion abnormalities. The use of exercise also allows incorporation of validated stress test criteria such as the DTS, heart rate reserve, or heart rate recovery with the MPI data.[23] For patients who cannot exercise adequately, vasodilator stress with adenosine, dipyridamole, or regadenoson is the procedure of choice; dobutamine is used for patients with a contraindication to the vasodilators.[24] For patients who begin exercise but do not reach 85% of maximum predicted heart rate for age, or who do not reach an appropriate symptomatic endpoint, isotope injection at stress can be withheld, the exercise portion of the test terminated, and vasodilator stress performed to optimize diagnostic and risk stratification information.

Defining the Extent of CAD

In formulating a management strategy for patients, it is important to determine the *extent* of disease rather than only the presence or absence of disease. The term *extensive CAD* refers to angiographic patterns of CAD that have prognostic significance and suggest treatment benefit from revascularization, such as left main or severe three-vessel CAD involving the proximal LAD coronary artery.

Detecting Multivessel CAD

SPECT MPI is limited by the *relative* nature of the perfusion information: If all areas are hypoperfused in the presence of three-vessel CAD, the least hypoperfused area appears normal, and the true extent of CAD may be underestimated. However, incorporation of other findings, including regional functional abnormalities, can be used to estimate more correctly the probability of disease extent.

Wall motion abnormalities on poststress gated SPECT images may be of benefit in the detection of extensive CAD. Incorporating the finding of poststress wall motion abnormality on gated SPECT imaging with the degree of perfusion abnormality allows improved sensitivity for detection of proximal severe LAD stenoses or multivessel disease related to 90% or greater proximal stenoses.[5] Numerous reports suggest that nonperfusion signs such as lung uptake of ^{201}Tl after stress or transient ischemic dilation raise the probability of multivessel CAD for any given extent of perfusion abnormality.[5]

Another approach with increasing validation is measurement of myocardial flow reserve (MFR, the

ratio of stress to rest MBF) using PET technology. This can be done using available perfusion tracers such as ^{82}Rb. In a study of 120 patients undergoing stress ^{82}Rb perfusion imaging and coronary angiography, the MFR data were more powerful than the stress perfusion pattern at discriminating between the presence and absence of three-vessel CAD, and this measure was an independent predictor of the presence of three-vessel CAD.[38]

Findings unrelated to imaging also are useful in enhancing the diagnosis of left main or three-vessel CAD. The development of greater than 2 mm of ST-segment depression or hypotension on ECG treadmill testing increases the likelihood of left main or three-vessel CAD.[23]

Detection of CAD in Women

The detection of CAD by exercise ECG testing can be challenging in women[32] (**see Chapter 89**). The use of ^{201}Tl for detecting CAD in women is limited by potential artifacts associated with breast attenuation, resulting in false positives and reduced specificity. The use of ^{99m}Tc-labeled tracers should improve specificity because these agents are associated with slightly less tissue attenuation, as demonstrated in a study comparing ^{201}Tl SPECT with ^{99m}Tc-sestamibi–gated SPECT for the detection of angiographic CAD.[4] Incorporation of gated SPECT sestamibi imaging resulted in a specificity of 92%, versus 67% with ^{201}Tl (**see Fig. 16.11**).

Detection of CAD in Valvular Heart Disease

Several studies have evaluated the use of MPI in the assessment of concomitant CAD in patients with valvular heart disease; most involved patients with aortic stenosis. Sensitivity of MPI has ranged from 61% to 100%, with specificity of 64% to 77%.[5] Although it is potentially useful in select patients to assist in symptom evaluation, these performance characteristics are not sufficient to preclude the use of coronary angiography to define the presence of CAD in patients being considered for surgery (**see Chapters 67 to 69**).

Patients with Established Coronary Artery Disease

Several potential roles for SPECT MPI in patients with established CAD are recognized. Clinical questions may remain after angiography regarding the “physiologic significance” of stenotic lesions. The results of stress-rest SPECT MPI correlate generally with invasive measures of coronary flow reserve. Moreover, improvement of ischemia on SPECT imaging is a common finding after successful percutaneous coronary intervention (PCI), suggesting that SPECT MPI can identify the “culprit” ischemic lesion.[5]

Imaging After Coronary Artery Bypass Surgery.
In patients in whom recurrent symptoms develop after coronary artery bypass graft (CABG) surgery, SPECT MPI can accurately detect the presence and location of graft stenoses, even if the symptoms are atypical for ischemia. In symptomatic post-CABG patients, such information can guide the need for catheterization and intervention.

A number of studies have concordantly demonstrated the value of SPECT MPI in risk stratification of patients after CABG surgery, especially late, even in the absence of symptoms.[5] The extent of perfusion abnormality is related to the subsequent risk of cardiac death and nonfatal MI, and SPECT information

has incremental predictive value over clinical and stress data. Because the risk of cardiac events generally is low in the early years after CABG, routine stress MPI for detection of ischemia in an asymptomatic patient is considered a “rarely appropriate” indication for testing within 5 years after CABG by appropriate use criteria.[39]

Imaging After Percutaneous Coronary Intervention.

Exercise MPI is superior for detecting the presence and location of restenosis after PCI compared with exercise ECG, and current guidelines consider stress imaging in symptomatic patients after PCI as appropriate.[39] The extent of SPECT MPI abnormality in patients studied after PCI is associated with the subsequent risk of cardiac death or MI on long-term follow-up, even late after PCI, and this appears to hold true in patients even in the absence of symptoms. Thus, although routine assessment of asymptomatic patients after PCI with SPECT MPI is considered “rarely appropriate” within 2 years after PCI, or is considered “may be appropriate” more than after 2 years after PCI,[39] important information may be gleaned by imaging in symptomatic patients to guide decisions for reintervention.

Very early after PCI, SPECT MPI may demonstrate a mild reversible defect in the territory of the treated vessel (although less severe than before PCI).[5] This defect may be caused by delayed return of full coronary flow reserve after PCI, representing a true physiologic phenomenon.

Detection of Preclinical CAD and Risk Stratification in Asymptomatic Patients

Because sudden cardiac death is too often the first manifestation of CAD, interest in screening populations for CAD or for CAD risk is considerable. On the basis of Bayesian principles, the low prevalence of CAD in the general asymptomatic population results in low predictive value for a positive test result, although negative predictive value (NPV) is high. Current guidelines and appropriate use criteria do not recommend routine stress MPI in asymptomatic populations.[5,39]

A key question in considering testing such as SPECT MPI in asymptomatic populations is how the information will be used to manage or to reduce risk. Current guidelines suggest aggressive risk factor reduction therapy in those at high clinical risk for the development of vascular disease.[31] Whether further intensification of risk factor reduction in the patient with an abnormal imaging test, or diminished aggressiveness of risk factor reduction with a normal MPI study, results in improved outcomes is unproven and worthy of study.

Patients with diabetes are at significant risk for CAD development and cardiac events. An emerging body of literature suggests that a substantial proportion of asymptomatic diabetic patients have abnormal SPECT MPI studies, and that such patients may be at even higher risk for events over time. Studies suggest that results of SPECT MPI studies are abnormal in 20% to 40% of asymptomatic diabetic patients, often with evidence of inducible, silent ischemia.[40] SPECT MPI demonstrates substantial risk value in stratification in patients with diabetes, with risk being higher for any given perfusion abnormality than in nondiabetic patients. However, a randomized trial of screening asymptomatic diabetic patients with stress SPECT MPI showed no differences in outcomes during long-term follow-up between those who were screened and those not screened, with event rates low in both groups.[40] Thus, appropriate use criteria at present do not suggest the need for routine screening in asymptomatic diabetic patients with stress SPECT MPI.[39]

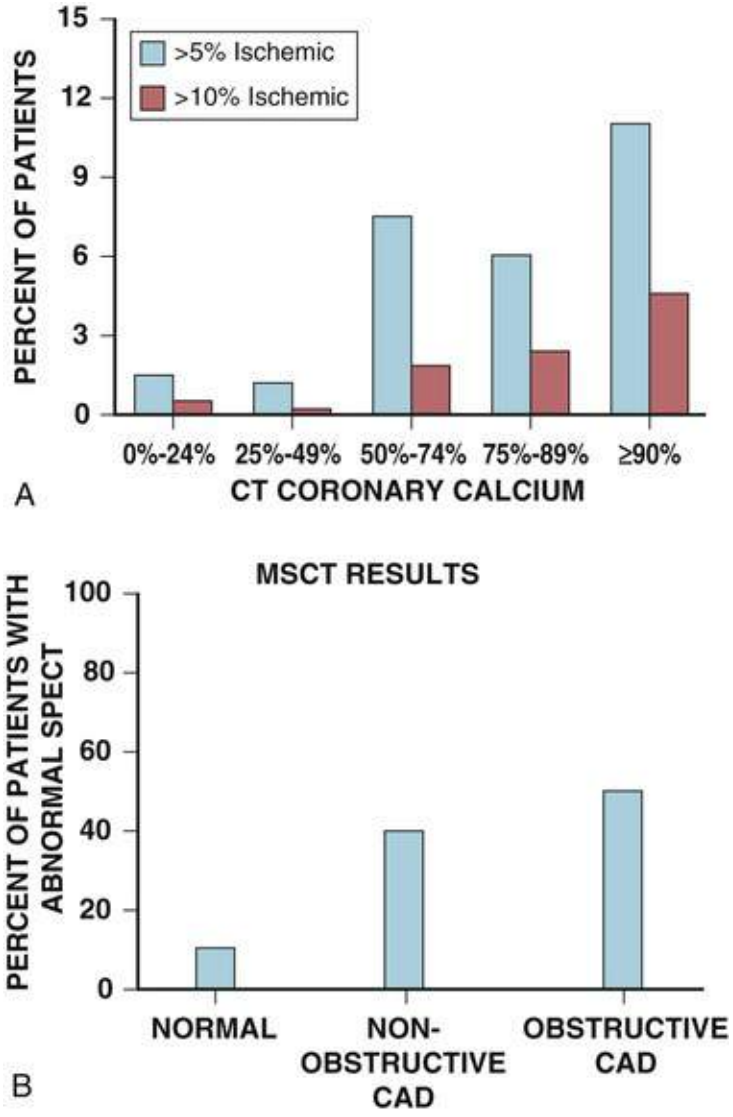
Myocardial Perfusion Imaging After CT Coronary Calcium Imaging or CT

Angiography

With the growing availability and use of noninvasive CT cardiac imaging (**see Chapter 18**), clinicians now often see patients with substantial coronary artery calcium (CAC), raising the possibility of multivessel CAD, or with apparent moderate or even severe stenoses seen on CT coronary angiography, raising questions about physiologic significance and risk stratification.

SPECT MPI and Coronary Calcium Imaging

Although extensive CAC and a high CAC score are indicative of atherosclerosis, studies to date have suggested that even extensive CAC is associated with important myocardial perfusion abnormalities in only a minority of patients. In one study of more than 1000 patients (approximately 50% of whom were asymptomatic),[41] only 10% of those with the highest CAC scores (Agatston score >400) had abnormal perfusion on stress SPECT MPI, and only 5% had "high-risk" SPECT MPI perfusion patterns warranting consideration of the potential benefit of revascularization (**eFig. 16.13**). Thus, although the extensive CAC on CT is well validated to represent subclinical atherosclerosis deserving of aggressive risk factor modification, it does not always indicate obstructive stenoses resulting in reduction in coronary flow reserve. On the basis of this concept, stress SPECT MPI is considered to be an appropriate test to determine the need for and potential benefit of catheterization and potential revascularization after CT demonstration of CAC, when baseline coronary heart disease risk is high and the Agatston score is greater than 100.[39] With lower baseline risk and lower Agatston scores, SPECT MPI is considered rarely appropriate.[39]



EFIGURE 16.13 **A,** In a study of 1195 patients without known CAD who underwent both SPECT perfusion imaging and assessment of coronary calcium by computed tomography (CT), the *x* axis categorizes patients by the age-corrected percentile of coronary calcium. Even when coronary calcium at a level greater than 90% for age is present, only 11% of patents had ischemia involving more than 5% of the left ventricle on SPECT, and only approximately 5% of such patients had ischemia involving more than 10% of the left ventricle. **B,** Prevalence of an abnormal SPECT perfusion study based on results of multislice CT (MSCT) angiography. Even when "obstructive" CAD (stenosis >50%) is confirmed by CT angiography, abnormal perfusion is present in only approximately 50% of patients. (**A,** Modified from Berman DS, Wong ND, Gransar H, et al. Relationship between stress-induced myocardial ischemia and atherosclerosis measured by coronary calcium tomography. J Am Coll Cardiol 2004;44:923; **B,** modified from Schuijf JD, Wijns W, Jukema JW, et al. Relationship between noninvasive coronary angiography with multi-slice computed tomography and myocardial perfusion imaging. J Am Coll Cardiol 2006;48:2508.)

Refining Risk Stratification by Incorporating Both CT Calcium Imaging and SPECT MPI.
Substantial literature now documents that patients with CAC, especially if extensive, are at higher risk for cardiac events over time compared with those with no CAC. However, many with extensive CAC exhibit normal stress perfusion on MPI, a finding that extensive data suggest is associated with low risk. How can these seemingly contradictory bodies of literature be reconciled? It is important to understand that "high risk" is a relative term; that is, patients with extensive CAC are at higher risk than those without CAC, but among those with extensive CAC, most will still not experience cardiac events. For example, in the Multi-Ethnic Study of Atherosclerosis (MESA), there was a clear gradient of risk as

CAC scores increased, but the absolute risk of events was low (approximately 1%/yr even among persons with high calcium scores)[42] (**see Chapter 18**). Therefore, combining data from CAC and SPECT MPI may provide a refinement of risk stratification. Conceptually, those patients with no CAC and normal SPECT MPI findings should have the lowest risk, and those patients with both evidence of CAC and abnormal findings on SPECT MPI the highest risk. Patients with either CAC or SPECT MPI abnormalities should have an intermediate risk. Thus, information from the two testing modalities may be complementary in refining the risk assessment of future coronary events, thereby curtailing the aggressiveness of primary prevention. Studies are ongoing in this regard.

SPECT MPI After CT.

With the growing availability and technical evolution of multidetector CT angiography, clinicians may now be faced with new questions about the physiologic significance of noninvasively detected coronary stenoses. Whereas CT angiography data demonstrate high sensitivity and moderate specificity to detect or to rule out obstructive stenoses, the spatial resolution is still not of a caliber such that accurate determination of the severity of an individual stenosis is consistently reliable or quantifiable, particularly in the intermediate range. Moreover, in a coronary segment that is heavily calcified, stenoses are particularly difficult to detect, to rule out, or to quantitate. SPECT MPI can assess the physiologic significance of a stenosis during stress and potentially link the perfusion abnormality to the patient's symptoms. This concept gives pause to moving directly to invasive angiography (and potential PCI) after CT angiography and suggests that assessment of the physiologic significance of CT angiography–defined stenoses may be important for clinical decision making. The development of noninvasive assessment of fractional flow reserve using fluid dynamic concepts and CT angiography is attempting to address this issue (**see Chapter 18**).

Selection of Initial Testing Strategy for Patients with Suspected CAD

CT angiography has evolved substantially, is a relatively rapid test to perform with modest radiation exposure using contemporary techniques, and has a very high NPV to rule out CAD. A fundamental question emerges as to whether it is optimal initially to evaluate a patent with symptoms suggestive of CAD with an anatomic strategy (CT angiography), to identify the presence/extent or absence of anatomic CAD, or with a functional stress test strategy, to identify the presence/extent or absence of stress-induced ischemia. This question was addressed by the Prospective Multicenter Imaging Study for Evaluation of Chest Pain (PROMISE) trial, in which over 10,000 patients with symptoms suggestive of CAD/ischemia were randomized to an initial assessment by either CT angiography or functional stress testing (ECG, MPI, or echocardiography) and followed for an outcome composite incorporating death from any cause, MI, hospitalization for unstable angina, and major complication of procedures or testing.[43] PROMISE was a “pragmatic effectiveness” trial, in that the results were provided to the referring clinician to inform clinical decisions (i.e., decision making was not driven by protocol). After an average of approximately 2 years of follow-up, there was essentially no difference in the primary endpoint outcome composite, suggesting that the initial assessment strategies were associated with similar outcomes. Some differences did emerge among the secondary outcomes. The CT angiography strategy was associated with fewer downstream catheterizations with normal coronary results, suggesting fewer false positives, leading to what would be an unnecessary catheterization compared to functional testing. However, CT angiography was also associated with substantially more downstream invasive catheterization procedures and almost twice as many revascularization procedures, with the previously noted absence of outcome difference.

The results of PROMISE do suggest that an anatomic strategy using CT angiography is an acceptable alternative to functional stress testing. In practice, choice of an initial testing strategy should be informed

not only by results of trials such as PROMISE, but also by local expertise and quality as well as by the appropriateness of any testing given the clinical scenario.

Acute Coronary Syndromes

Application of Radionuclide Imaging: Answering the Clinical Questions

For patients with suspected ACS, radionuclide imaging techniques can play a diagnostic role (is the clinical presentation caused by ischemia and CAD?) and can also provide prognostic information. Among patients who present with an ACS and ST-segment depression or elevation (**see Chapters 59 and 60**), the typical role of imaging is in the stabilized patient after angiography and PCI, to provide risk stratification information to drive management strategies aimed at improving natural history.

Suspected Acute Coronary Syndromes in Emergency Department

Many patients presenting to the ED with symptoms suggestive of ACS, but with nondiagnostic findings on initial ECG and biomarker assays, are admitted to an observation unit for serial biomarker studies and possible stress testing. ^{99m}Tc-based perfusion agents may be administered to a patient in the ED at rest, with images acquired 45 to 60 minutes later,[5] and because redistribution is minimal, images reflect MBF at injection. In this setting, NPV for ruling out MI is high in all observational series.[5] Patients with positive MPI have a higher risk of cardiac events during the index hospitalization as well as during follow-up (**Fig. 16.34**). Thus, rest SPECT MPI can provide information to assist triage decisions for or against hospital admission from the ED.

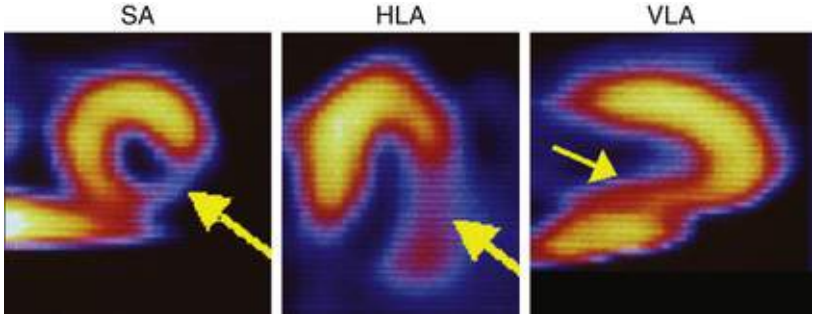


FIGURE 16.34 Example of rest SPECT images in a patient evaluated in the ED with chest pain and nondiagnostic initial electrocardiographic findings. A severe inferolateral resting perfusion defect (*arrow*, all images) suggests ischemia at rest or infarction in that territory. Subsequent emergent angiography demonstrated an occluded left circumflex artery. *HLA,* Horizontal long axis; *SA,* short axis; *VLA,* vertical long axis.

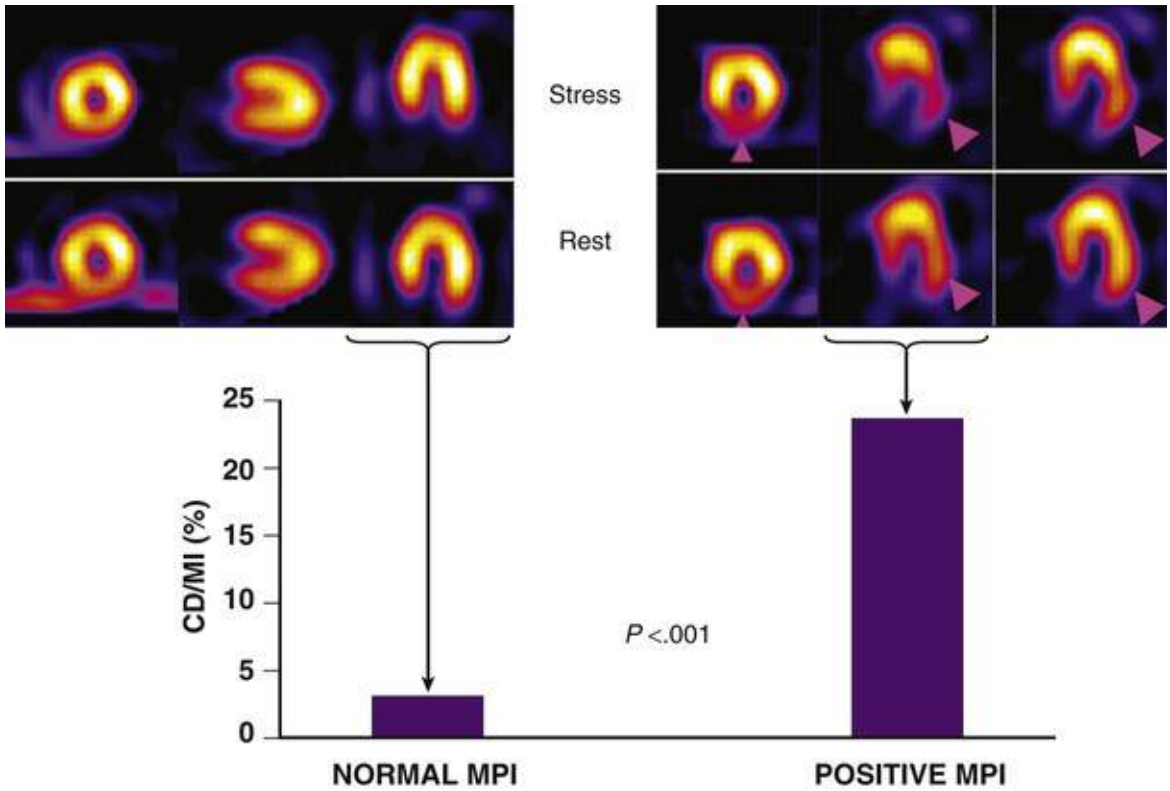
The Emergency Room Assessment of Sestamibi for Evaluation of Chest Pain (ERASE Chest Pain) trial in 2475 patients with symptoms suggestive of ACS randomly assigned them to receive an MPI strategy or usual ED care. A significant 20% relative reduction in unnecessary hospital admission was reported for patients ultimately found not to have ACS of those assigned to MPI (see Classic References, Udelson). The imaging data were among the most powerful factors associated with the decision to discharge the patient appropriately from the ED.

Thus, evidence from randomized controlled trials (RCTs) suggests that incorporation of SPECT MPI in ED evaluation of patients with suspected ACS but no definitive ECG changes can improve triage decisions. Rest MPI in these patients may be appropriate.[44]

Non–ST-Segment Elevation Myocardial Infarction and Unstable Angina

Guidelines recommend that patients with high-risk clinical characteristics in the setting of unstable angina undergo direct catheterization[30] (**see Chapter 60**). Contemporary clinical trials suggest that patients with positive biomarker assays or with a high-risk Thrombolysis in Myocardial Infarction (TIMI) score benefit in terms of outcome from an "invasive" strategy.[30] For patients with intermediate or low clinical risk (i.e., with "medically stabilized" unstable angina), stress MPI has been shown to have substantial risk stratification value and is considered an appropriate test.[44] Patients without ischemia or infarction, especially in the presence of preserved LV function, have a low-risk outcome, suggesting that such patients can be managed conservatively without catheterization, whereas patients with significant inducible ischemia are at high risk and thus are selected for intervention (**eFig. 16.14**).



EFIGURE 16.14 SPECT perfusion imaging in patients after medical stabilization of unstable angina. **Upper left,** Normal study findings, associated with a low risk of cardiac events during follow-up, suggesting that such a patient can be managed conservatively without catheterization but with aggressive secondary preventive strategies. The *bottom graph* is a summary of predictive values of SPECT imaging in the aftermath of unstable angina from multiple studies. Similar to the concepts in populations with stable chest pain, abnormal perfusion imaging after unstable angina is associated with a substantial increase in the risk of cardiac death or myocardial infarction (CD/MI) during follow-up. **Upper right,** Example of a high-risk stress-rest SPECT myocardial perfusion imaging (MPI) study result in the aftermath of unstable angina. Despite the stabilization of symptoms, extensive reversible perfusion abnormalities in the inferior and lateral walls suggest high risk of cardiac death or myocardial infarction, or both, during follow-up. This patient would therefore be managed more aggressively with catheterization and intervention. (Modified in part from Brown KA. Management of unstable angina: the role on noninvasive risk stratification. J Nucl Cardiol 1997;4:S164.)

Although the results of randomized clinical trials, such as Treat Angina with Aggrastat and Determine Cost of Therapy with an Invasive or Conservative Strategy (TACTICS)–TIMI 18, suggest slight superiority of an invasive approach in patients with unstable angina or non–ST-segment elevation MI (NSTEMI), subgroup analyses indicate that an important proportion of patients may be well managed by the conservative strategy of risk stratification by MPI, followed by more selective catheterization and

intervention. Moreover, a large randomized trial of patients with ACS and positive troponin T reported no difference in outcomes between an invasive strategy and a more selective invasive strategy in which patients were examined for ischemia before proceeding with catheterization while receiving contemporary aggressive medical therapy.[30] Therefore, patients without elevation of troponin or high TIMI risk score may be managed by a more conservative approach with risk stratification using imaging techniques.[30]

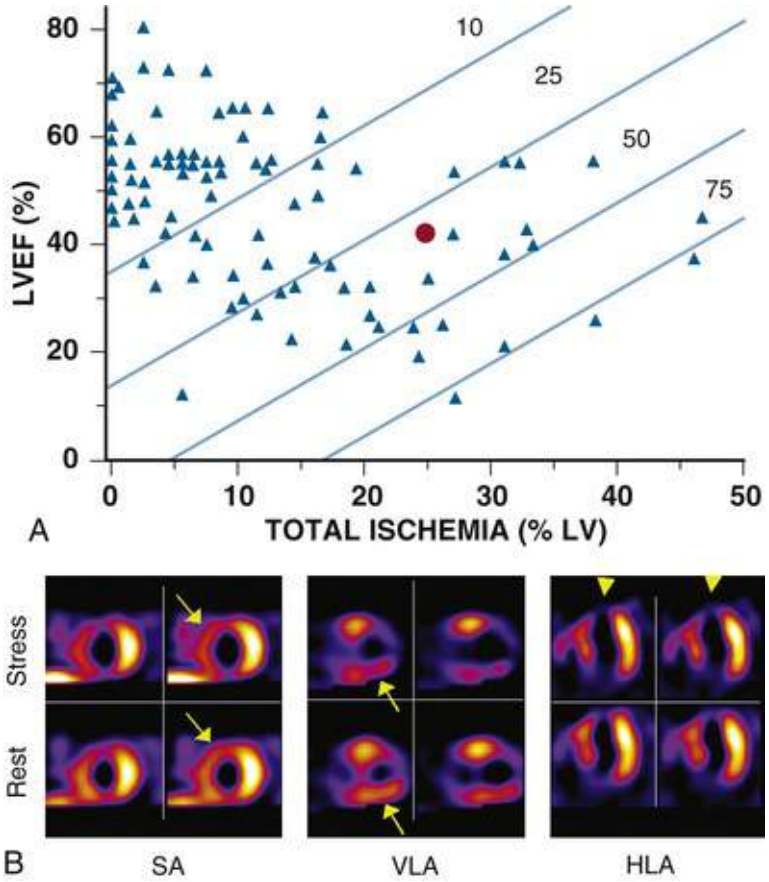
ST-Segment Elevation Myocardial Infarction

Clinical variables such as recurrent ischemia, heart failure, and nonacute arrhythmias during hospitalization for acute ST-segment elevation MI (STEMI) identify a subgroup of patients at high risk in whom catheterization and intervention are indicated, and who have not already undergone primary PCI as the initial approach for their STEMI[44] (**see Chapter 59**).

Assessment of Inducible Ischemia After Acute Myocardial Infarction

Three major determinants of risk after an acute MI are the residual LV function at rest, the extent of ischemic jeopardized myocardium, and the susceptibility to ventricular arrhythmias. Gated SPECT MPI can provide much of this information comprehensively and thus may be an important test in the stable patient after STEMI. Contemporary guidelines suggest that noninvasive assessment of the presence and extent of inducible ischemia is indicated (class I recommendation) for patients who have not already had coronary angiography and do not have other high-risk features that would drive a decision to perform angiography.[45]

Studies in the reperfusion era have reported generally similar results regarding the relation of stress-induced ischemia to post-MI outcomes. In a study of 134 consecutive patients tested within 14 days of an uncomplicated MI, the extent of ischemia on SPECT MPI was the only significant variable associated with a future cardiac event on Cox regression analysis (**eFig. 16.15**). The extent of SPECT ischemia remained strongly correlated with cardiac events in those who received thrombolytic therapy. The quantitated extent of ischemia on adenosine SPECT MPI also has been shown to be an important predictor of cardiac events in post-MI risk stratification. Post-MI patients with extensive inducible ischemia are at high risk for future cardiac events, and interventional management is likely to result in improved outcome.

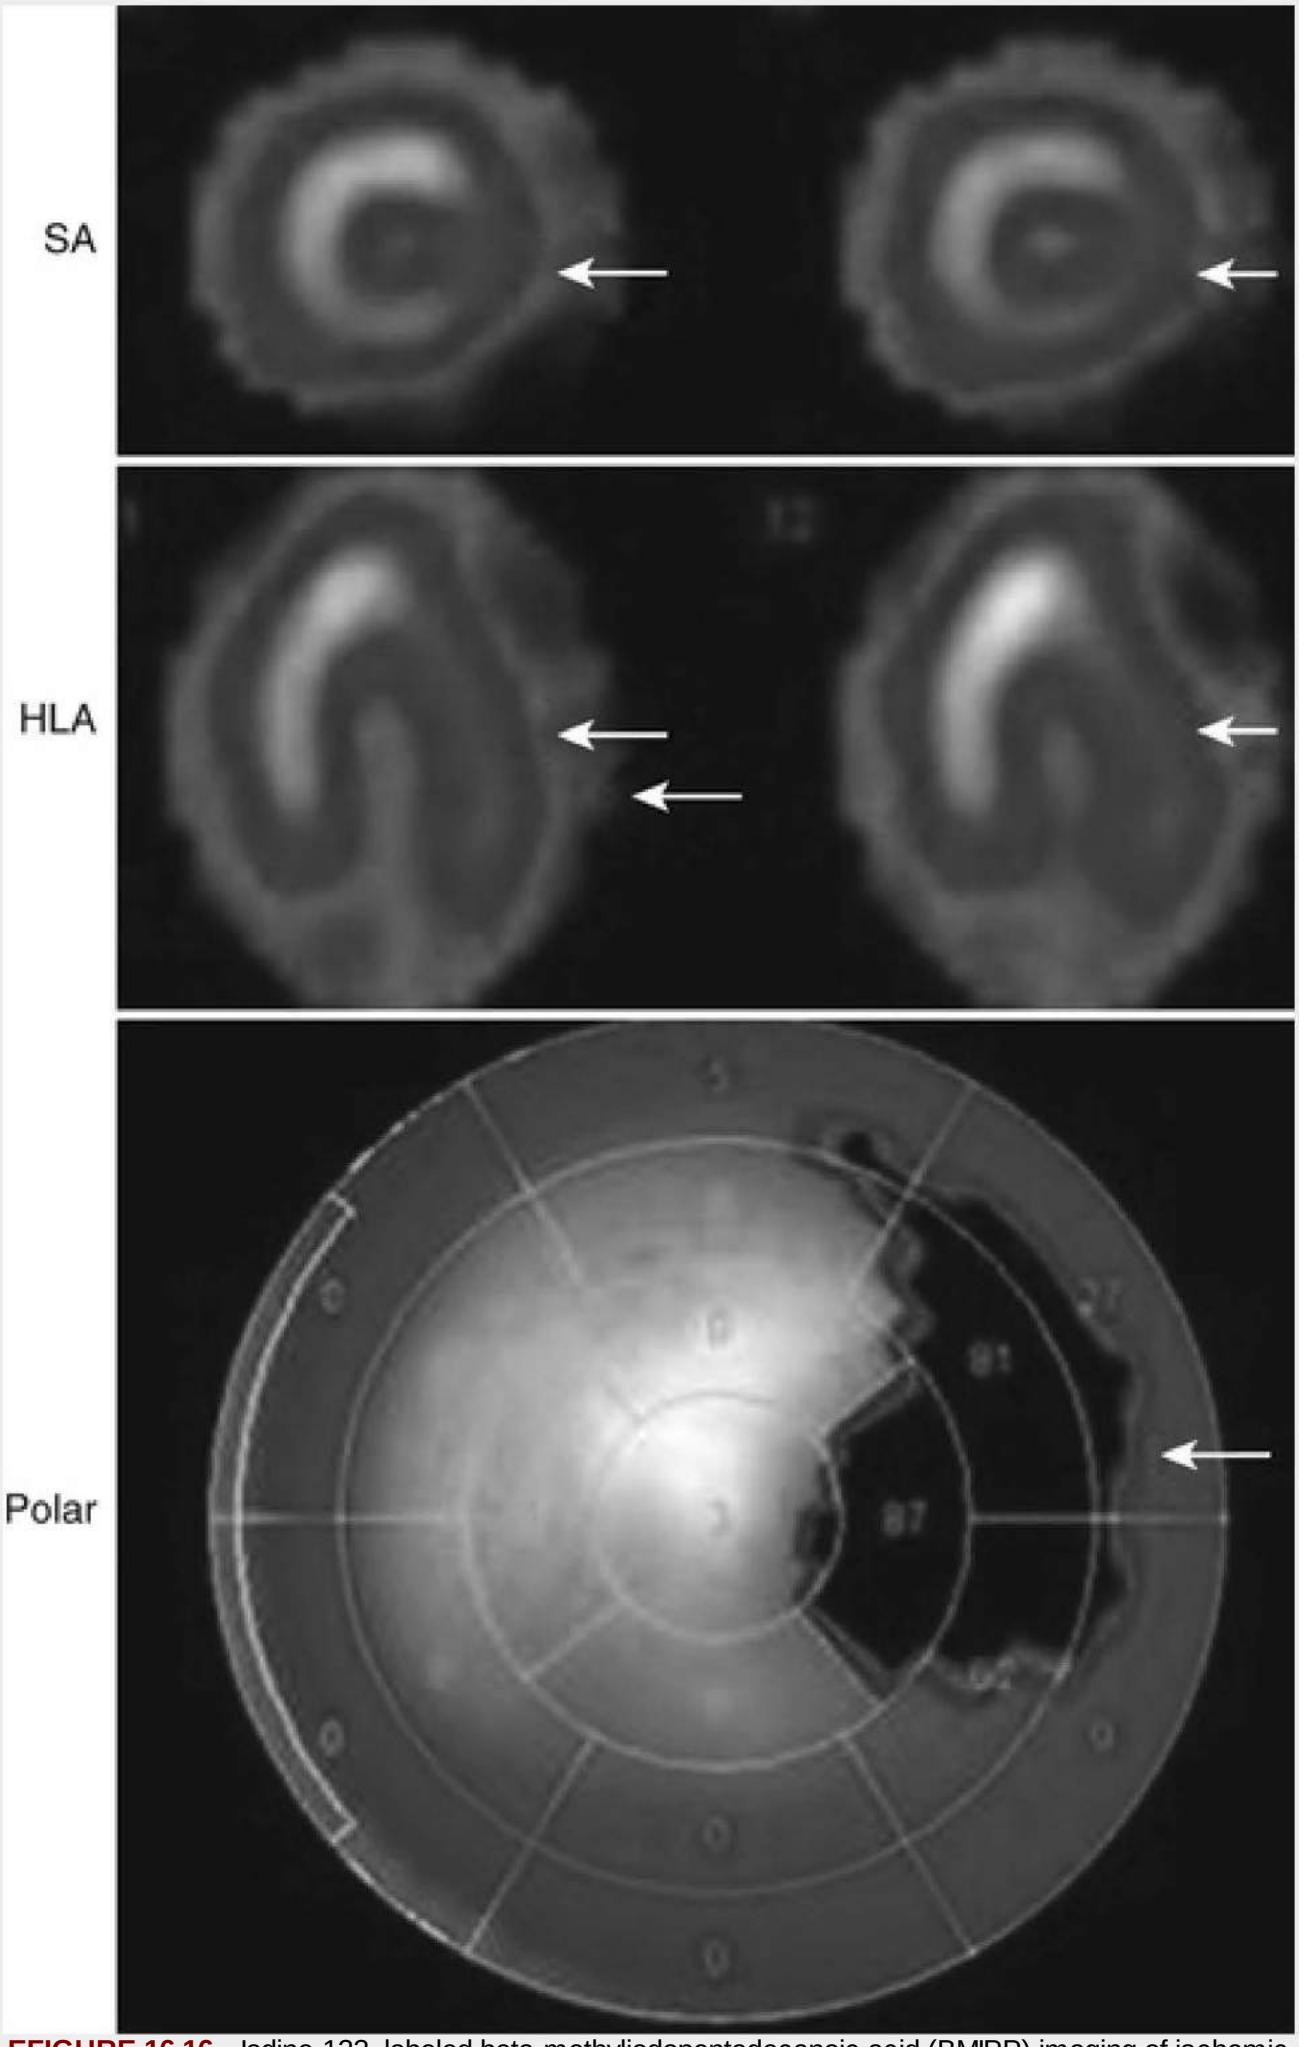


EFIGURE 16.15 **A,** Risk of cardiac event during long-term follow-up after myocardial infarction (MI) is predicted by the combination of infarct size (represented by LVEF) and the extent of reversible ischemia. As the extent of inducible ischemia increases (*x* axis) and the left ventricular ejection fraction (LVEF) decreases (*y* axis), the outcome risk increases. The *blue lines* represent isobars of 10%, 25%, 50%, and 75% risk of an adverse event during post-MI follow-up. (*Large red circle* refers to images in **B**.) **B,** SPECT images obtained in patient studied several days after acute ST-segment elevation MI and medical stabilization. Besides the fixed defect representing the infarct in the anterior wall and apex (*arrowheads*), extensive inducible ischemia is evident both within and remote from the infarct territory (septum and inferior walls, *arrows*), involving 25% of the ventricle. Gated SPECT EF was 38%. On the basis of the data in **A,** there is an approximately 25% risk of a post-MI adverse event (*large red circle* in **A**). *HLA,* Horizontal long axis; *SA,* short axis; *VLA,* vertical long axis. (Modified from Mahmarian JJ, Mahmarian AC, Marks GF, et al. Role of adenosine thallium-201 tomography for defining long term risk in patients after acute myocardial infarction. J Am Coll Cardiol 1995;25:1333.)

Radionuclide Imaging in Acute Coronary Syndromes: Research Directions

Imaging of Ischemic Memory.

A possible future approach to risk stratification in patients with suspected ACS involves the imaging of fatty acid metabolism. As noted earlier, after a regional ischemic insult, abnormalities in fatty acid metabolism may persist long after perfusion has returned to normal, a finding termed ischemic memory. Imaging of fatty acid metabolism may therefore allow assessment of recent ischemia. Uptake of the radiolabeled fatty acid analogue BMIPP has been imaged with SPECT 1 to 5 days after presentation in patients with suspected ACS. SPECT imaging of fatty acid metabolism in patients presenting to the ED with suspected ACS adds incremental value to initial clinical information for assessment of the presence or absence of an ACS[46] (**eFig. 16.16**). Future studies will determine whether such techniques can help guide management decisions.



EFIGURE 16.16 Iodine-123–labeled beta-methyliodopentadecanoic acid (BMIPP) imaging of ischemic

memory in a patient presenting to emergency department with a suspected acute coronary syndrome. **Top row,** Short-axis (SA) tomograms demonstrate a significant lateral wall defect (*arrows*), suggesting prolonged postischemic suppression of fatty acid metabolism, referred to as ischemic memory. **Middle row,** Horizontal long-axis (HLA) images also demonstrate the defect (*arrows*), as does the polar map **(bottom row).** Subsequent angiography demonstrated a severe stenosis of the left circumflex coronary artery. (Modified from Kontos MC, Dilsizian V, Weiland F, et al. Iodofiltic acid I 123 [BMIPP] fatty acid imaging improves initial diagnosis in emergency department patients with suspected acute coronary syndromes: a multicenter trial. J Am Coll Cardiol 2010;256:290.)

Imaging in Heart Failure

Is Coronary Artery Disease the Cause of Heart Failure?

Determination of whether LV dysfunction represents the consequences of CAD or is caused by one of the many other disorders of nonischemic etiology is a critical early step in the management of patients with heart failure (HF). Because CAD is the most common cause of HF in developed countries, noninvasive assessment of myocardial ischemia and viability would identify the subgroup of HF patients who have a potentially reversible degree of LV dysfunction and may benefit from revascularization. Therapeutic interventions that improve dysfunctional but viable myocardium may significantly affect global LVEF, LV remodeling, and survival. The identification of CAD in patients with HF also has implications in secondary prevention strategies, because recurrent MI is a common mechanism of death in HF patients.

Normal stress MPI in a patient with HF and LV dysfunction is highly predictive of the absence of CAD. Studies of MPI for detection of CAD in patients with LV dysfunction have shown high sensitivity but modest specificity[36] (**Fig. 16.35; see also Fig. 16.32**). The modest specificity of MPI to rule out CAD is explained in part by pathologic and CMR studies[47] demonstrating patchy or larger confluent territories of fibrosis or scarring (**see Chapter 17**), manifested as fixed defects on SPECT MPI, in patients with nonischemic cardiomyopathy.

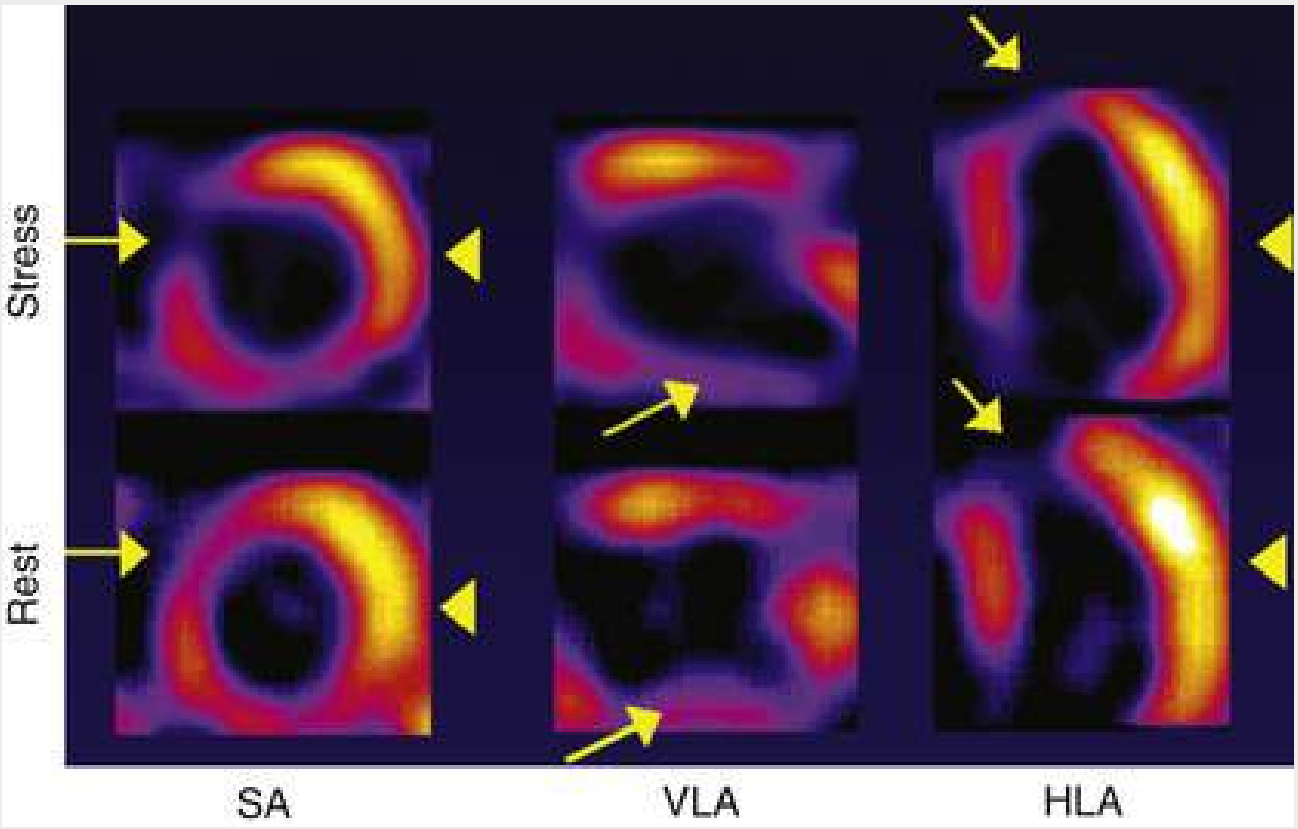


FIGURE 16.35 SPECT perfusion image demonstrating extensive severe fixed defects of the septum, apex, and inferior wall (*arrows*) suggestive of extensive previous myocardial infarction, as well as extensive inducible ischemia of the lateral wall (*arrowheads*). This set of findings strongly suggests that CAD is the cause of the heart failure syndrome observed in this patient. *HLA,* Horizontal long axis; *SA,* short axis; *VLA,* vertical long axis.

Although the presence of any perfusion abnormality is not specific for ruling out CAD, the pattern of perfusion abnormality may assist in the differentiation between CAD and nonischemic etiology of HF. More extensive or more severe perfusion defects, or both, are more likely to represent CAD and ischemic cardiomyopathy, whereas smaller and milder defects are more likely in patients with nonischemic cardiomyopathy.[36,47]

Assessment of Myocardial Viability and the Potential Benefit of Revascularization

A goal in assessing viability is to optimize selection of patients with HF whose symptoms and natural history may improve after revascularization. Data suggest that hibernation and stress-induced ischemia are common in patients with stable HF and LV dysfunction, even in the absence of angina.[47]

The potential for decreased HF symptoms after revascularization correlates with the magnitude of the PET mismatch pattern (i.e., enhanced FDG uptake relative to perfusion).[5] In a meta-analysis of outcome studies after viability imaging, patients with evidence of preserved myocardial viability[48] who underwent revascularization had a substantial reduction in the risk of cardiac death during long-term follow-up compared with those treated medically (**Fig. 16.36**). Revascularization conferred no advantage in patients without substantial myocardial viability. These data suggest that noninvasive imaging of viability and ischemia can potentially play a role in selecting patients for revascularization, with the expectation of ameliorating symptoms and improving natural history. However, this analysis was based on 24 retrospective studies in which there may have been inadequate adjustment for comorbidity and in which the medical management would not be considered adequate in terms of current guidelines recommendations. For example, few if any patients received beta blockers in these cohort studies. This

factor created the equipoise for the prospective STICH (Surgical Treatment of Ischemic Heart Disease) viability substudy, examining the influence of viability (determined by SPECT or dobutamine echocardiography) on outcomes associated with randomization to surgical or medical therapy.[49] In this study of more than 600 patients, viability status did not influence the intervention effect on outcome. This may result from better background medical therapies for patients with HF compared with those used in the older literature.

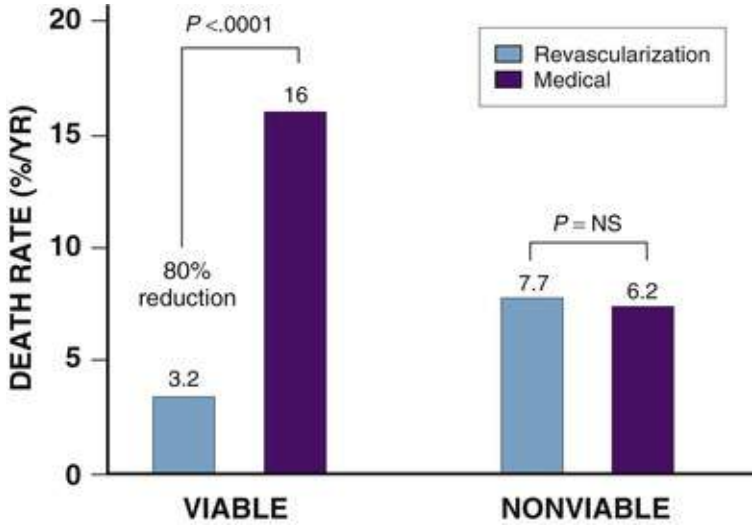

FIGURE 16.36 Data derived from a meta-analysis evaluating outcomes in patients with ischemic left ventricular dysfunction after viability testing. Among patients determined to have predominantly viable myocardium, treatment with medical therapy is associated with a 16% annual risk of cardiac death. Similar patients treated with revascularization have only a 3.2% annual risk of cardiac death, representing an 80% reduction in risk with revascularization. By contrast, patients with predominantly nonviable myocardium exhibit no difference in outcome whether they are treated with medical therapy or with revascularization. These data suggest that noninvasive interrogation of myocardial viability can identify treatment strategies associated with more favorable long-term outcomes. (Modified from Allman K, Shaw L, Hachamovitch R, Udelson JE. Myocardial viability testing and impact of revascularization on prognosis in patients with coronary artery disease and left ventricular dysfunction: a meta-analysis. J Am Coll Cardiol 2002;39:1151.)

On the basis of all these data, current HF guidelines consider revascularization as a class IIa indication (level of evidence B) to improve survival in patients with mild to moderate LV systolic dysfunction and significant multivessel CAD or proximal LAD stenosis when viable myocardium is present.[50]

Principles of Assessing Myocardial Viability by Radionuclide Techniques

The radionuclide tracers and techniques most often used to assess viability have been evaluated for their relation to preserved tissue viability by correlation of tracer uptake with histologically confirmed extent of tissue viability.[48] Quantitative analysis of tracer uptake correlates directly with the magnitude of preservation of tissue viability, and tracer uptake represents a continuous variable—that is, the magnitude of tracer uptake directly reflects the magnitude of preserved tissue viability. For a dysfunctional segment or territory, the probability of functional recovery after revascularization is related to the magnitude of tracer uptake, representing the degree of preserved myocardial viability (extent of hibernation or stunning) within that territory. A dysfunctional territory with normal or only mildly reduced tracer uptake thus has a high likelihood of improved function after revascularization. By contrast, a territory with a severe reduction in tracer uptake would represent predominant infarction, and the likelihood of improved function after revascularization would be low (**Figs. 16.37 and 16.38**). The magnitude of potential improvement of global LV function after revascularization is in turn determined by the extent of viable

dysfunctional myocardium.

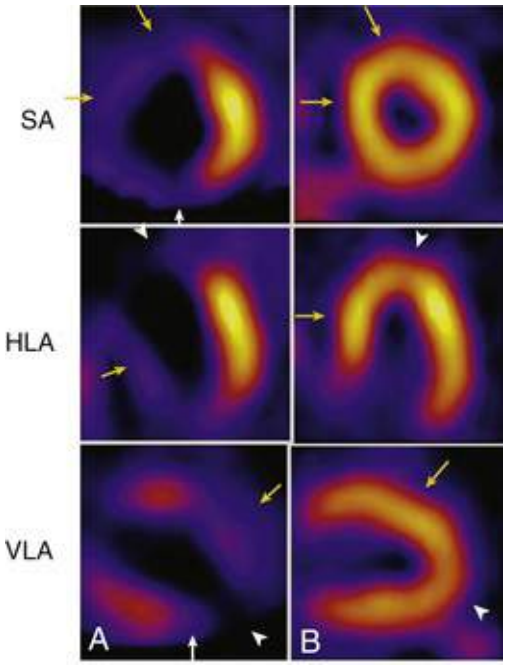

FIGURE 16.37 Resting SPECT perfusion imaging to assess myocardial viability. In column **A,** there are severe resting perfusion defects in the anterior wall and septum (*yellow arrows*), the apex (*arrowheads*), and the inferior wall (*white arrows*), all consistent with predominant infarct, in a patient with extensive CAD and severe LV dysfunction. It is not likely that revascularization would improve outcome or symptoms. In contrast, column **B** demonstrates images from a patient with an occluded proximal left anterior descending artery and severe hypokinesis of the subtended territories, with symptoms of heart failure and some angina. There is normal uptake throughout the anterior wall and septum (*yellow arrows*) as well as in the apex (*arrowheads*), consistent with completely retained viability. The images suggest that revascularization of the territory would be associated with improved regional function and likely improvement in symptoms. *HLA,* Horizontal long axis; *SA,* short axis, *VLA,* vertical long axis.

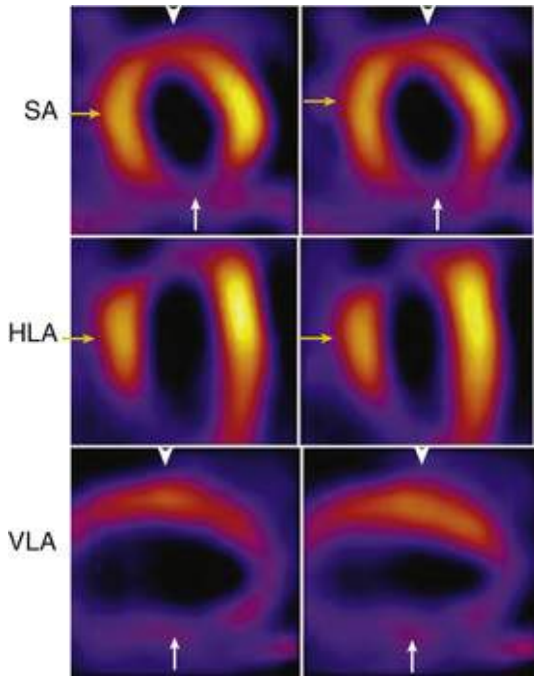

FIGURE 16.38 Resting ^{99m}Tc perfusion imaging to assess myocardial viability. Studies correlating tracer uptake with biopsy specimens have shown that the magnitude of uptake is related to the degree of retained myocyte viability within each territory. In this example, from a patient with multivessel CAD and significant LV dysfunction being considered for revascularization, different territories manifest distinct patterns of uptake and viability in these contiguous slices from the three orthogonal tomographic planes. There is a severe defect in the inferior wall (*white arrows*), consistent with predominant infarct. There is a moderately severe defect in the anterior wall (*white arrowheads*), in which there is clearly more uptake compared to the inferior wall. This would be consistent with an admixture of viable myocardium and infarct in that territory. There is only very mild reduction in tracer activity in the septum (*yellow arrows*), consistent with predominantly retained viability. Uptake in the lateral wall is normal, consistent with retained viability. *HLA,* Horizontal long axis; *SA,* short axis; *VLA,* vertical long axis.

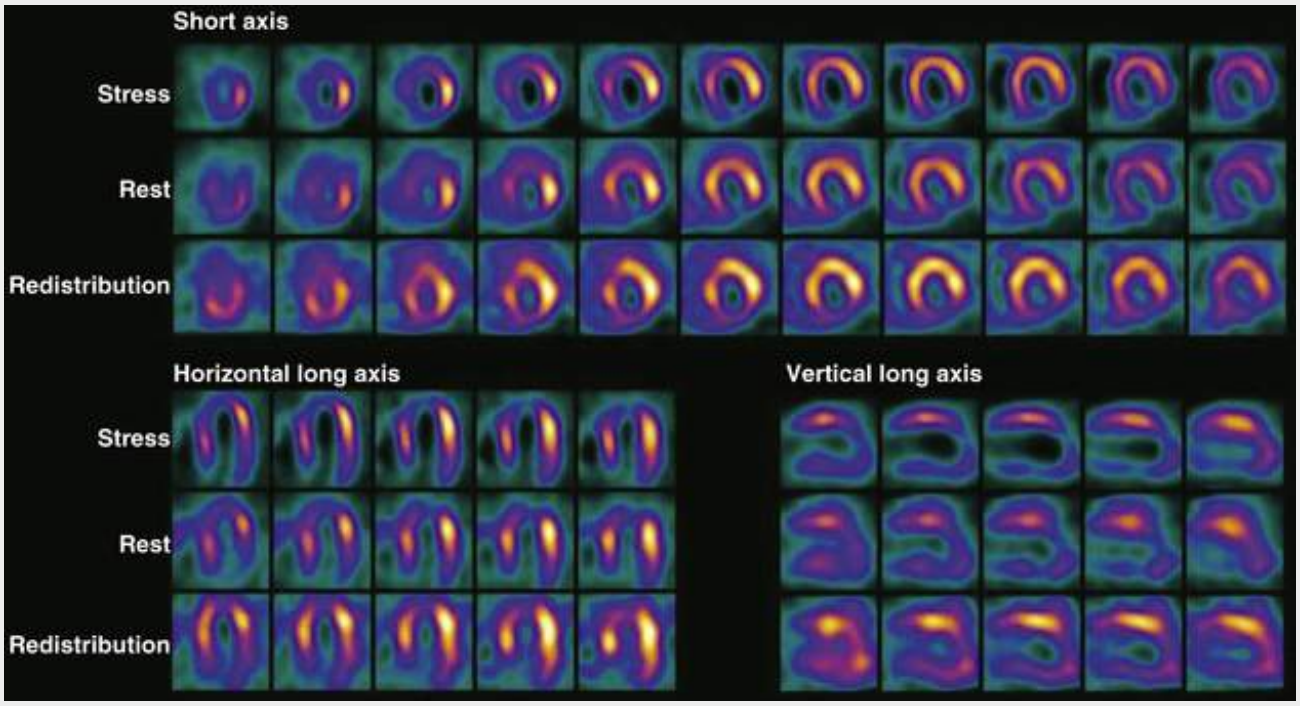
Imaging Protocols for Assessment of Myocardial Viability

Thallium-201.

The presence of ^{201}Tl after redistribution implies preserved myocyte cellular viability. Because the absence of ^{201}Tl uptake on the redistribution images is not a sufficient sign of the absence of regional viability, however, iterations of the standard ^{201}Tl protocol have been investigated[4] to optimize the assessment of regional viability (**eFig. 16.17**). After ^{201}Tl reinjection, approximately 50% of regions with fixed defects on stress-redistribution imaging show significant enhancement of ^{201}Tl uptake, predictive of improvement in regional LV function.[48] The presence of a severe ^{201}Tl defect after reinjection identifies areas with a very low probability of improvement in function.



EFIGURE 16.17 Rest-redistribution thallium imaging performed as part of a dual-isotope technetium-thallium stress imaging protocol in 55-year-old patient with severe heart failure and left ventricular dysfunction (ejection fraction 30%). The initial thallium images demonstrate several areas of reduced blood flow at rest involving the septum, anteroapical wall, and inferior wall. Thallium redistribution imaging 4 hours later demonstrates substantial redistribution of thallium in the septal, anteroapical, and inferior regions of the left ventricle, indicating myocardial viability, with only the basal portion of the inferolateral wall representing irreversibly damaged myocardium. After the thallium redistribution image acquisition, stress imaging with ^{99m}Tc-sestamibi demonstrates inducible ischemia in the septum and anterior wall. However, without the redistribution images, routine stress-rest imaging would have given misleading information about viability because of the apparently irreversible defects in the inferior and anteroapical walls. (From Holly TA, Bonow RO. Assessment of myocardial viability with thallium-201 and technetium-based agents. In Zaret BL, Beller GA, editors. Nuclear Cardiology: State of the Art and Future Directions. 4th ed. Philadelphia: Mosby; 2010, pp 594-607.)

Late redistribution imaging, 24 to 48 hours after the initial stress ^{201}Tl injection, allows more time for redistribution to occur and has good positive predictive value (PPV) for improvement in function. Even with late redistribution imaging, the NPV is suboptimal, because redistribution does not occur in some patients even after a prolonged period, and in addition, image quality may be poor.[4,5] In such patients, ^{201}Tl reinjection after late redistribution imaging may provide further insight into defect reversibility and thus viability.

With *rest-redistribution* ^{201}Tl imaging, images are obtained 15 to 20 minutes after tracer injection at rest, reflecting regional blood flow at rest, and images obtained 3 to 4 hours after redistribution reflect myocyte viability. The finding of a reversible resting defect may identify areas of myocardial hibernation (**eFig. 16.17**). This finding appears to be an insensitive but specific sign of potential improvement in regional function.[4,51]

^{99m}Tc Sestamibi and Tetrofosmin.

The performance of the ^{99m}Tc agents in predicting improvement in regional function after revascularization is similar to that of ^{201}Tl.[5] The key finding to evaluate is the magnitude of tracer uptake in a dysfunctional region. *Normal* uptake is consistent with preserved viability; only *mild* reduction in uptake is consistent with predominantly preserved viability; *moderate* reduction in uptake is consistent with an admixture of viable and infarcted tissue; and a *severe* defect is consistent with predominant infarct. Administration of nitrates to improve blood flow at rest before injection of sestamibi appears to improve slightly the ability of these tracers to detect myocardial viability.[4,51]

PET Blood Flow–Metabolism Mismatch.

The extent of the PET mismatch pattern (enhanced FDG uptake relative to blood flow; **see Fig. 16.28**) correlates with improvement in LV function after revascularization as well as with the clinical course, magnitude of improvement in HF symptoms, and survival after revascularization.[51] Patients with HF and an extensive PET match pattern (diminished blood flow and severe reduction in FDG uptake), representing predominant infarction, are unlikely to benefit clinically from revascularization.

Comparison of Imaging Techniques for Viability Assessment.

On the basis of a meta-analysis evaluating the ability of the various radionuclide techniques to predict improvements in regional function and EF, all the radionuclide techniques (as well as low-dose dobutamine echocardiography; **see Chapter 14**) perform in a relatively similar manner regarding PPV and NPV for improvements in regional function.[48] SPECT techniques appear to be slightly more sensitive, dobutamine echocardiography appears to be slightly more specific, and PET techniques appear to have better accuracy. A randomized trial of patients with moderate LV dysfunction being considered for revascularization randomly allocated to have viability information supplied by either PET imaging or SPECT stress-rest sestamibi imaging found no difference in outcomes during long-term follow-up.[48]

All these data suggest that differences between the imaging approaches to assess viability are small, and that choice of modality should be driven by the available expertise and experience. For patients with more severe LV dysfunction, in whom thinner myocardial walls are often present, an advantage of PET and CMR is their better spatial resolution for imaging thinner objects.

Selection of Patients with Heart Failure for Viability Assessment

Guidelines recommend that patients with HF and active angina benefit from revascularization and thus should be referred directly for angiography.[50] In some situations, subsequent noninvasive definition of regional viability and ischemia may be important to plan the revascularization strategy when the anatomy is known.

For patients with HF and no angina, studies suggest that ischemia and viability may be present in a significant proportion of such patients[51] who have potential benefit from revascularization. For most such patients with HF, a search for underlying ischemia and viability would be an appropriate clinical strategy at some point in their evaluation.[47] The imaging data can be used in decision making to help balance the risks and benefits of revascularization in a patient with HF and LV dysfunction by supplying information on potential benefit of a revascularization strategy.

Assessment of Left Ventricular Function in Heart Failure

For patients with the clinical syndrome of HF, the distinction between those with preserved and those with impaired systolic function has important clinical relevance. Clinical trials evaluating the use of such therapeutic agents as angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers, and beta blockers have focused on the subpopulation of HF patients with impaired systolic function[50] (**see Chapter 25**). Thus accurate determination of LV function in a patient with HF defines the evidence-based therapeutic approach that should be undertaken.

On the basis of the quantitative and reproducible nature of the EF results, equilibrium RVG techniques have been used in large clinical trials to identify systolic dysfunction.[5,51] In contemporary practice, ECG-gated SPECT is often used for determination of systolic function. The simultaneous assessment of LV systolic function as well as stress and rest perfusion by gated SPECT MPI can provide a range of information relevant to the care and clinical decision making for patients with HF, including the state of

LV function, the probability of CAD as the cause of HF, and the presence and extent of viability and ischemia.

Imaging in Inflammatory and Infiltrative Cardiomyopathies

Myocarditis
