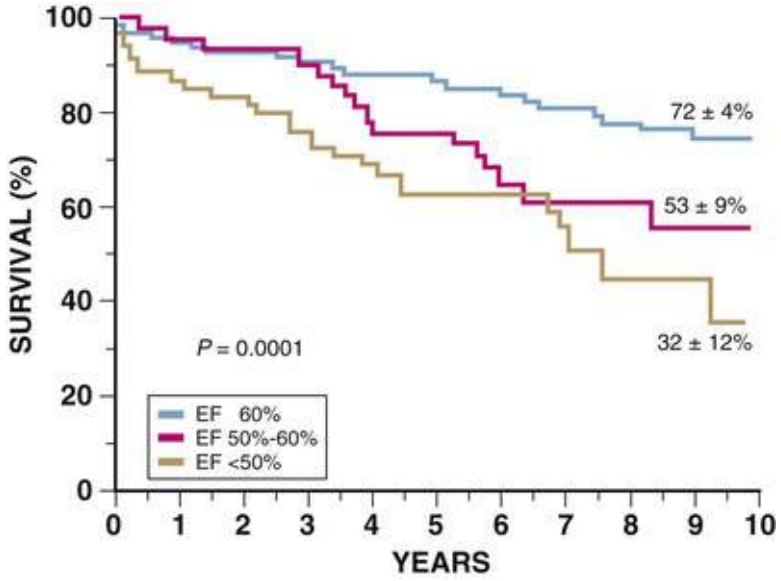
In most patients with severe primary MR, compensation is maintained for years, but in some patients the prolonged hemodynamic overload ultimately leads to myocardial decompensation.[61] ESV, preload, and afterload all increase, whereas EF and stroke volume decline. In such patients, there is evidence of neurohormonal activation and elevation of circulating proinflammatory cytokines. Plasma natriuretic peptide (NP) levels also increase in response to the volume load[64]—more in patients with symptomatic decompensation.

Coronary flow rates may be increased in patients with severe MR, but the increases in myocardial oxygen consumption (MVO_2) are relatively modest compared with patients with AS and AR, because myocardial fiber shortening, which is elevated in patients with MR, is not one of the principal determinants of MVO_2 (**see Chapter 22**). One of these determinants, mean LV wall tension, may actually be reduced in patients with MR, whereas the other two, contractility and heart rate, may be minimally affected. Thus, patients with MR have a low incidence of clinical manifestations of myocardial ischemia, compared with the much higher incidence in those with AS and AR, conditions in which MVO_2 is greatly augmented.

Assessment of Myocardial Contractility

Because the ejection phase indices of myocardial contractility are inversely correlated with afterload, patients with early MR (with reduced LV afterload) often exhibit elevations in ejection phase indices of myocardial contractility, such as EF, fractional fiber shortening, and velocity of circumferential fiber shortening (VCF).[63] Many patients ultimately develop symptoms because of elevated LA and pulmonary venous pressures related to the regurgitant volume and with no change in these ejection phase indices, which remain elevated. In other patients, however, major symptoms reflect serious contractile dysfunction, at which time EF, fractional shortening, and mean VCF have declined to low-normal or below-normal levels (**see Fig. 69.12**). As MR persists, the reduction in afterload, which increases myocardial fiber shortening and the aforementioned ejection phase indices, is opposed by the impairment of myocardial function characteristic of severe chronic diastolic overload. However, even in patients with overt HF secondary to MR, the EF and fractional shortening may be only modestly reduced. Therefore, values in the low-normal range for the ejection phase indices of myocardial performance in patients with chronic MR may actually reflect impaired myocardial function, whereas moderately reduced values (e.g., EF, 40% to 50%) generally signify severe, often irreversible, impairment of contractility, identifying patients who may do poorly after surgical correction of the MR (**eFig. 69.4**). In such patients, parameters of longitudinal shortening, such as global longitudinal strain (GLS), may better predict postoperative LV dysfunction than EF.[62] An EF of less than 35% in patients with chronic severe organic MR usually represents advanced myocardial dysfunction; such patients are high operative risks and may not experience satisfactory improvement after MVR.



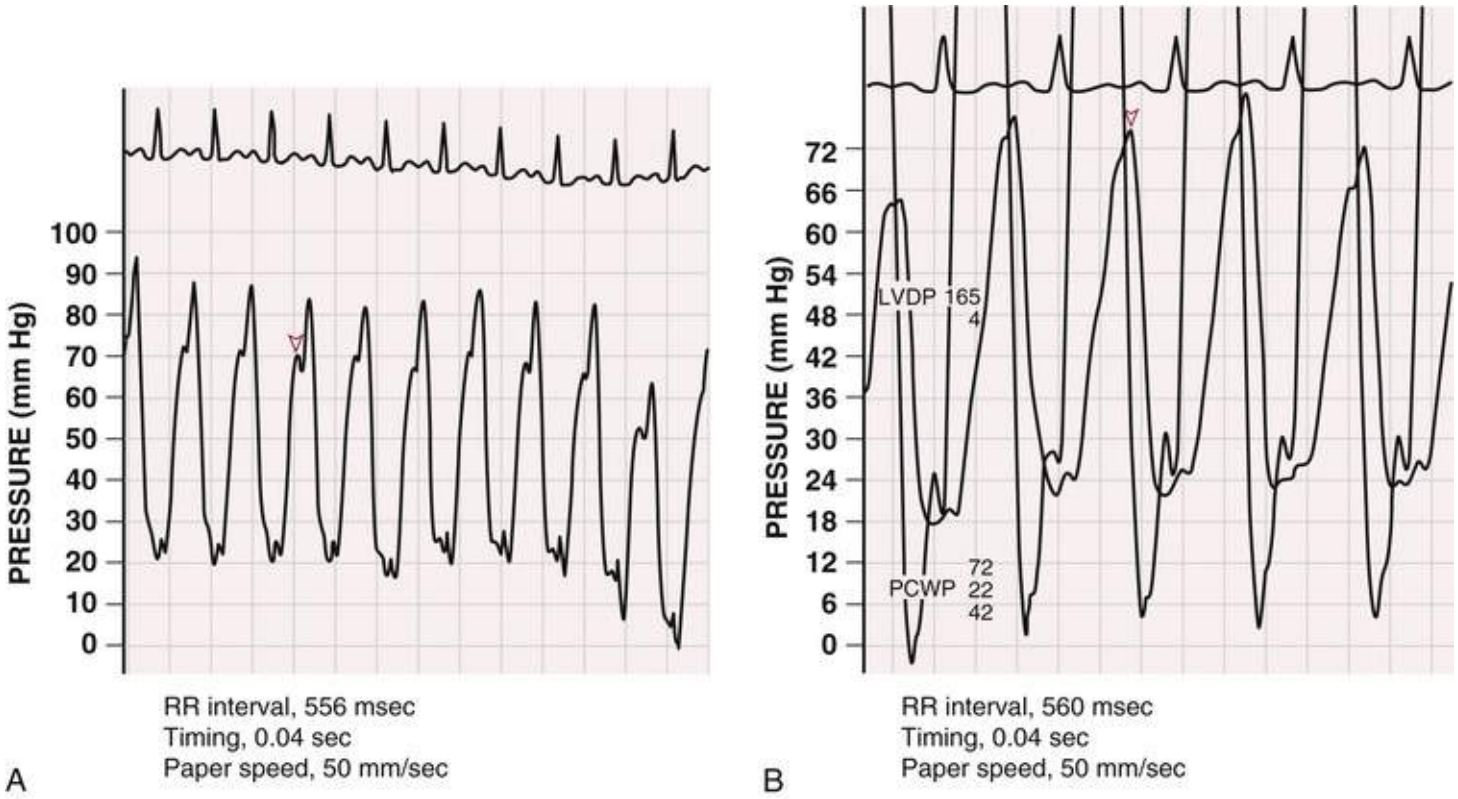
EFIGURE 69.4 Late survival of patients after surgical correction of mitral regurgitation. Patients are subdivided on the basis of the preoperative echocardiographic ejection fraction (EF). (From Enriquez-Sarano M, Tajik AJ, Schaff HV, et al. Echocardiographic prediction of survival after surgical correction of organic mitral regurgitation. Circulation 1994;90:833-7.)

End-Systolic Volume.

Preoperative myocardial contractility is an important determinant of the risk of operative death, cardiac failure perioperatively, and postoperative level of LV function. It is not surprising, therefore, that the end-systolic pressure-volume (or stress-dimension) relationship has emerged as a useful index for evaluating LV function in patients with MR. The simple measurement of end-systolic volume or diameter has been found to be a useful predictor of function and survival after mitral valve surgery.[61,65] A preoperative LV end-systolic diameter that exceeds 40 mm identifies a patient with a high likelihood of impaired LV systolic function after surgery.[21] GLS magnitude (**see Chapter 14**) less than 19.3% (a normal value in the absence of severe MR) has been shown to be more strongly predictive for postoperative LV dysfunction than traditional parameters such as EF and end-systolic diameter.[62]

Hemodynamics.

Effective (forward) cardiac output and EF are usually depressed in symptomatic patients with severe MR, whereas total LV output (the sum of forward and regurgitant flow) usually is elevated until late in the patient's course. The cardiac output achieved during exercise, not the regurgitant volume, is the principal determinant of functional capacity. The atrial contraction *a* wave in the LA pressure pulse usually is not as prominent in MR as in MS, but the *v* wave is characteristically much taller (**see Chapter 19**) because it is inscribed during ventricular systole, when the left atrium is being filled with blood from the pulmonary veins and from the left ventricle. Occasionally, backward transmission of the tall *v* wave into the pulmonary arterial bed may result in an early diastolic pulmonary arterial *v* wave (**eFig. 69.5**). In patients with isolated MR, the *y* descent in the PCWP pulse is particularly rapid because the distended left atrium empties rapidly during early diastole. However, in patients with combined MS and MR, the *y* descent is gradual. Although a left AV pressure gradient persisting throughout diastole signifies the presence of significant associated MS, a brief early diastolic gradient may occur in patients with isolated severe MR as a result of the rapid flow of blood across a normal-sized mitral orifice early in diastole, often accompanied by an early diastolic murmur at the apex.



EFIGURE 69.5 Hemodynamic tracings in a 45-year-old woman with acute mitral regurgitation from bacterial endocarditis. **A,** Pulmonary artery pressure. **B,** Simultaneous left ventricular diastolic pressure (LVDP) and pulmonary capillary wedge pressure (PCWP). The PCWP tracing demonstrates a markedly elevated *v* wave (*arrowhead*, **B**) that transmits to the pulmonary artery pressure (*arrowhead*, **A**). (Modified from Wisse B, Sniderman AD. Severe mitral regurgitation. N Engl J Med 2000;343:1386.)

Left Atrial Compliance.

The compliance of the left atrium (and pulmonary venous bed) is an important determinant of the hemodynamic and clinical picture in patients with severe MR. Three major subgroups of patients with severe MR based on LA compliance have been identified and are characterized next. These also usually correlate with the chronicity of severe regurgitation.

When severe MR develops acutely (e.g., with rupture of chordae tendineae, infarction of a papillary muscle head, leaflet disruption from trauma or endocarditis), the left atrium is initially normal in size and compliance. The pressure-volume relationship of the relaxed atrium is curvilinear, and the sudden volume load from the MR forces it to operate on a steeper portion of this curve, with an exaggerated rise in pressure (*v* wave) for a given regurgitant volume. This marked elevation of mean LA pressure leads to pulmonary congestion as a prominent symptom. Sinus rhythm usually is present, at least initially. Over time, the left atrium dilates, and its wall becomes hypertrophied to maintain contractile function. Chamber dilation shifts the pressure-volume curve to the right, increasing compliance at a given volume, whereas hypertrophy has the opposite effect, shifting the curve upward. The balance of these two remodeling processes will determine the overall impact on mean LA pressure and the *v* wave. As severe MR becomes chronic, dilation predominates, and the *v* wave may fall with an increase in operating compliance. If symptoms are tolerated (or nonexistent), this stage may last years, with progressive LA enlargement, which increases the risk of AF. At the extremes, patients may present with massive atrial enlargement and greatly increased compliance, with relatively modest LA pressure elevation. AF is likely, and the atrial wall may largely be replaced by fibrous tissue.

Clinical Presentation

The clinical stages of primary chronic degenerative MR demonstrate the progressive nature of the disease (**Table 69.3**).

TABLE 69.3

Stages of Chronic Primary Mitral Regurgitation (MR)

STAGE	DEFINITION	VALVE ANATOMY	VALVE HEMODYNAMICS*	HEMODYNAMIC CONSEQUENCES	SYMPTOMS
A	**At risk for MR**	Mild MVP with normal coaptation Mild valve thickening and leaflet restriction	No MR jet or small central jet area <20% LA on Doppler Small vena contracta <0.3 cm	None	None
B	**Progressive MR**	Severe MVP with normal coaptation Rheumatic valve changes with leaflet restriction and loss of central coaptation Previous IE	Central jet MR 20-40% LA or late systolic eccentric jet MR Vena contracta <0.7 cm RVol <60 mL RF <50% ERO <0.40 cm^2 Angiographic grade 1-2+	Mild LA enlargement No LV enlargement Normal pulmonary pressure	None
C	**Asymptomatic severe MR**	Severe MVP with loss of coaptation or flail leaflet Rheumatic valve changes with leaflet restriction and loss of central coaptation Previous IE Thickening of leaflets with radiation heart disease	Central jet MR >40% LA or holosystolic eccentric jet MR Vena contracta ≥0.7 cm RVol ≥60 mL RF ≥50% ERO ≥0.40 cm^2 Angiographic grade 3-4+	Moderate or severe LA enlargement LV enlargement Pulmonary hypertension may be present at rest or with exercise. *C1*: LVEF >60% and LVESD <40 mm *C2*: LVEF ≤60% and LVESD ≥40 mm	None
D	**Symptomatic severe MR**	Severe MVP with loss of coaptation or flail leaflet Rheumatic valve changes with leaflet restriction and loss of central coaptation Previous IE Thickening of leaflets with radiation heart disease	Central jet MR >40% LA or holosystolic eccentric jet MR Vena contracta ≥0.7 cm RVol ≥60 mL RF ≥50% ERO ≥0.40 cm^2 Angiographic grade 3-4+	Moderate or severe LA enlargement LV enlargement Pulmonary hypertension present	Decreased exercise tolerance Exertional dyspnea

*Several valve hemodynamic criteria are provided for assessment of MR severity, but not all criteria for each category will be present in each patient. Classification of MR severity as mild, moderate, or severe depends on data quality and integration of these parameters in conjunction with other clinical evidence.

From Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACCF guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2014;63:e57-185.

Symptoms

The nature and severity of symptoms in patients with chronic MR are functions of a combination of interrelated factors, including the severity of MR; rate of its progression; level of LA, pulmonary venous, and pulmonary arterial pressures; presence of episodic or chronic atrial tachyarrhythmias; and presence of associated valvular, myocardial, or coronary artery disease. In addition, there may be symptoms related to the underlying pathogenic cause of the MR (e.g., endocarditis, SLE, Marfan syndrome). Many patients with severe MR remain completely asymptomatic, although close questioning of the patient or family may reveal subtle reductions in functional capacity. Symptoms may occur with preserved LV contractile function in patients with chronic MR who have severely elevated pulmonary venous pressures or AF. In other patients, symptoms herald LV decompensation. In patients with rheumatic MR, the time between the initial attack of rheumatic fever and development of symptoms tends to be longer than in those with MS, often more than two decades. Hemoptysis and systemic embolization are less common in patients with isolated or predominant MR than in those with MS. The development of AF affects the course adversely but perhaps not as dramatically as in MS. Conversely, chronic weakness and fatigue secondary to a low cardiac output are more prominent features in MR.

In patients with severe chronic MR who have a greatly enlarged left atrium and relatively mild LA hypertension (patients with increased LA compliance), PVR does not usually rise markedly. Instead, the major symptoms, fatigue and exhaustion, are related to the depressed cardiac output. Right-sided HF, characterized by congestive hepatomegaly, edema, and ascites, may be prominent in patients with acute MR, elevated PVR, and pulmonary hypertension. Angina pectoris is rare unless CAD coexists.

The vast majority of patients with myxomatous degeneration and MVP are asymptomatic and remain so throughout life. Although early studies called attention to a MVP syndrome, with a characteristic systolic nonejection click and various nonspecific symptoms, such as fatigability, palpitations, postural orthostasis, and anxiety and other neuropsychiatric symptoms, as well as symptoms of autonomic dysfunction, these associations have not been confirmed in carefully controlled studies.[66] How and even whether these symptoms are related to the presence of MVP is not clear. Patients may complain of syncope, presyncope, palpitations, chest discomfort, and when MR is severe, symptoms of exertional dyspnea and diminished cardiac reserve. Chest discomfort may be typical of angina pectoris but is more often atypical in that it is prolonged, not clearly related to exertion, and punctuated by brief attacks of severe stabbing pain at the apex. The discomfort may be secondary to abnormal tension on papillary muscles. In patients with MVP and severe MR, the symptoms of the latter (fatigue, dyspnea, and exercise limitation) typically predominate. Patients with MVP also may develop symptomatic arrhythmias (see later).

Physical Examination

Palpation of the arterial pulse is helpful in differentiating aortic stenosis (AS) from MR, both of which may produce a prominent systolic murmur at the base of the heart and apex (**see Chapter 10**). The carotid arterial upstroke is sharp in severe MR and delayed in AS; the volume of the pulse may be normal or reduced in the presence of HF. The cardiac impulse, as with the arterial pulse, is brisk and hyperdynamic. It is displaced to the left, and a prominent LV filling wave is frequently palpable in thin patients.

Auscultation.

When chronic severe MR is caused by defective valve leaflets, S_1, produced by mitral valve closure, is usually diminished. Wide splitting of S_2 is common and results from the shortening of LV ejection and an earlier A_2 because of reduced resistance to LV ejection. In patients with severe pulmonary hypertension, P_2 is louder than A_2. The abnormal increase in the flow rate across the mitral orifice during the rapid filling phase is often associated with a third heart sound (S_3), which should not be interpreted as a feature of HF in these patients, and this may be accompanied by a brief diastolic rumble.

The systolic murmur is the most prominent physical finding; it must be differentiated from the systolic murmur of AS, tricuspid regurgitation (TR), and ventricular septal defect (VSD). In most patients with severe MR, the systolic murmur commences immediately after the soft S_1 and continues beyond and may obscure the A_2 because of the persisting LV-LA pressure difference after aortic valve closure. The holosystolic murmur of chronic MR is usually constant in intensity, blowing, high-pitched, and loudest at the apex, with frequent radiation to the left axilla and left infrascapular area, particularly with posteriorly directed jets. Radiation toward the sternum or aortic area, however, may occur with abnormalities of the posterior leaflet and is particularly common in patients with MVP and flail involving this leaflet. The murmur shows little change, even in the presence of large beat-to-beat variations of LV stroke volume, as in AF. This finding contrasts with that in most midsystolic (ejection) murmurs, such as in AS, which vary greatly in intensity with stroke volume and therefore with the duration of diastole. Little correlation has

been found between the intensity of the systolic murmur and severity of MR. In patients with severe MR caused by LV dilation, acute MI, or paraprosthetic valvular regurgitation, or in those who have marked emphysema, obesity, chest deformity, or a prosthetic heart valve, the systolic murmur may be barely audible or even absent, a condition referred to as “silent” MR.

The murmur of MR may be holosystolic, late systolic, or early systolic. When the murmur is confined to late systole, the regurgitation usually is secondary to MVP and may follow one or more midsystolic clicks and typically is not severe. Such late systolic MR is often associated with a normal S_1 because initial closure of the mitral valve cusps may be unimpaired. Occasionally, a late systolic murmur of papillary muscle dysfunction may be noted, becoming louder or holosystolic during acute myocardial ischemia, and may disappear when ischemia is relieved. A midsystolic click preceding a mid- to late systolic murmur, and the response of that murmur to a number of maneuvers, helps establish the diagnosis of MVP (discussed later). Early systolic murmurs are typical of acute MR. When the LA *v* wave is greatly elevated in acute MR, the murmur may diminish or disappear in late systole as the reverse pressure gradient declines. As noted, a short, low-pitched diastolic murmur following S_3 may be audible in patients with severe MR, even without accompanying MS.

Dynamic Auscultation.

Auscultation during positional changes or the Valsalva maneuver can be quite helpful in characterizing the MR murmur. When MR is holosystolic, it typically varies little during respiration. However, sudden standing usually diminishes the murmur, whereas squatting augments it. The late systolic murmur of MVP behaves in the opposite direction, decreasing in duration with squatting and increasing in duration with standing. Similarly, with the Valsalva maneuver, MVP clicks may occur earlier in systole with lengthening of the murmur. Holosystolic MR murmur is often softer during the strain of the Valsalva maneuver and shows a left-sided response (i.e., a transient overshoot that occurs six to eight beats after release of the strain). The murmur of MR usually is intensified by isometric exercise, differentiating it from the systolic murmurs of valvular AS and obstructive HCM, both of which are reduced by this intervention. The murmur of MR caused by LV dilation decreases in intensity and duration after effective therapy with cardiac glycosides, diuretics, rest, and particularly vasodilators.

Diagnosis and Evaluation

Differential Diagnosis

The holosystolic murmur of MR resembles that produced by a VSD, but the latter is usually loudest at the sternal border and is often accompanied by a thrill in the parasternal area. The murmur of MR may also be confused with that of TR, but the latter is usually lower in pitch and is heard best along the left sternal border, with augmentation during inspiration and a prominent *v* wave and *y* descent in the JVP.

When the chordae tendineae to the posterior leaflet of the mitral valve rupture, the regurgitant jet is often directed anteriorly, so that it impinges on the atrial septum adjacent to the aortic root and causes a prominent systolic murmur at the base of the heart, which can be confused with that of AS. On the other hand, when the chordae tendineae to the anterior leaflet rupture, the jet usually is directed to the posterior wall of the left atrium, and the murmur radiates to the axilla and may be transmitted to the spine or even the top of the head.

Patients with rheumatic disease of the mitral valve exhibit a spectrum of abnormalities, ranging from pure MS to pure MR. The presence of a S_3, a rapid LV filling wave and prominent LV impulse on

palpation, and a soft S_1 all favor predominant MR. By contrast, an accentuated S_1, a prominent OS with a short A_2-OS interval, and a soft, short systolic murmur all indicate predominant MS. Elucidation of the predominant valvular lesion may be complicated by the presence of a holosystolic murmur of TR in patients with pure MS and pulmonary hypertension; this murmur may sometimes be heard at the apex when the right ventricle is greatly enlarged and may therefore be mistaken for the murmur of MR.

Echocardiography

Echocardiography plays a central role in the diagnosis of MR, in determining its cause and potential for repair, and in quantifying its severity (**see Chapter 14**). In patients with severe MR, echocardiographic imaging shows enlargement of the left atrium and left ventricle, with increased systolic motion of both chambers. The underlying cause of the regurgitation, such as rupture of chordae tendineae, in MVP (**eFig. 69.6** and Video 69.10; **see Fig. 14.40**), rheumatic mitral disease, a flail leaflet (**eFig. 69.7** and Videos 69.11 and 69.12), vegetations (**see Chapter 73**), and regional or global LV dilation with leaflet tethering (**eFig. 69.8** and Video 69.13) can often be determined on transthoracic echocardiography (TTE). It also may show calcification of the mitral annulus as a band of dense echoes between the mitral apparatus and posterior wall of the heart. This technique also is useful for estimating the hemodynamic effects of MR on the left atrium and left ventricle; in patients with LV dysfunction, EDV and ESV are increased, and EF and shortening rate may decline.[12,65,67-69]

EFIGURE 69.8 Functional mitral regurgitation. **A,** Apical long-axis view showing a large posterior myocardial infarction, which is tethering the posterior leaflet preventing the anterior leaflet from closing. **B,** This causes a posteriorly directed jet of mitral regurgitation. *AML,* anterior mitral leaflet; *PML,* posterior mitral leaflet; arrow indicates tenting of the AML caused by tethering of the secondary chordae.

Doppler echocardiography in MR characteristically reveals a high-velocity jet in the left atrium during systole.[67] The severity of the regurgitation is reflected in the width of the jet across the valve and the size of the left atrium. Qualitative assessment using color flow Doppler imaging or pulsed techniques correlates reasonably well with quantitative methods in estimating the severity of MR. However, color flow jet areas are significantly influenced by the driving pressure (LV-LA gradient), jet eccentricity, and a host of instrument factors, such as transmit power and frequency, receiver gain, Nyquist limit, and wall filter (Videos 69.14 and 69.15), thereby limiting the accuracy of this approach. Importantly, however, the jet morphology can give important clues as to the mechanism of the MR. In organic MR the jet generally goes away from the most significant anatomic lesion, so posterior prolapse or flail typically produces an anterior jet, and vice versa. This rule breaks down in functional MR, where the typical cause is the anterior leaflet overriding a tethered posterior leaflet and producing a posteriorly directed jet.

Quantitative methods to measure regurgitant fraction, regurgitant volume, and regurgitant orifice area have greater accuracy when done carefully[70] (**Fig. 69.13**; **see also Figs. 14.42 and 14.43**), and these methods are strongly recommended (**see Table 69.3**).[12,21,71]

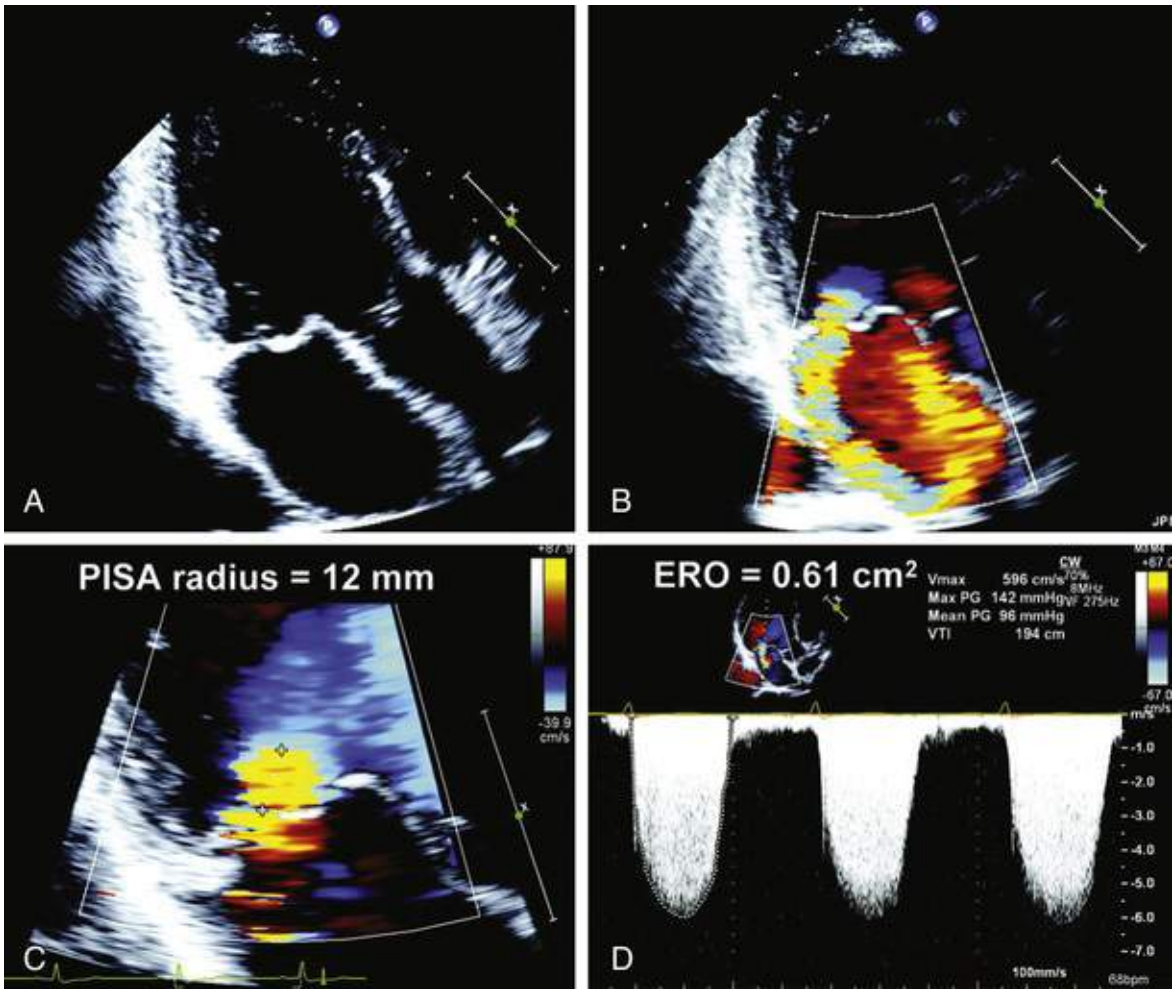

FIGURE 69.13 Severe mitral regurgitation caused by prolapse of the mitral valve with quantitative determination of effective regurgitant orifice area (ERO) on echocardiography. **A, B,** Severe prolapse of the mitral valve with severe MR. **C, D,** ERO was calculated with the proximal isovelocity surface area (PISA) radius and peak velocity of the MR jet. (From Kang DH, Kim JH, Rim JH, et al. Comparison of early surgery versus conventional treatment in asymptomatic severe mitral regurgitation. Circulation 2009;119:797-804.)

Regurgitant volume (RVol) is theoretically simple concept but challenging in practice. In principle, stroke volume is measured in two locations, one that includes the MR (forward flow across mitral annulus or total LV stroke volume) and one that does not (forward flow though LV outflow tract [if no AR] or right-sided stroke volume). Unfortunately, each of these stroke volumes requires multiple measurements, with any error propagating throughout the calculation, compounded at the end by needing to subtract one large number from another. The vena contracta, defined as the narrowest cross-sectional area of the regurgitant jet as mapped by color flow Doppler echocardiography, also predicts the severity of MR (**see Fig. 69.13**) but may suffer from "color blooming" artifact and limitation of lateral resolution.

The *proximal isovelocity surface area* (PISA) method may be the most practical quantitative method for daily use (**see Chapter 14**). It exploits the predictable flow acceleration leading into the mitral valve, which forms roughly hemispheric isovelocity shells that can be highlighted by shifting the aliasing velocity of the color display and identified where the color changes from blue to red (**see Fig. 14.42**). If the radial distance is r from the vena contracta to the contour with velocity v, the flow rate Q will be given by:

$$Q = 2\pi r^2 v$$

from which the *effective regurgitant orifice area* (EROA) can be obtained by dividing Q by the

maximal velocity through the orifice obtained by continuous-wave (CW) Doppler (Vmax). A simplification that works in the majority of cases assumes approximately 100 mm Hg of driving pressure across the regurgitant orifice (with Bernoulli equation, leading to a 5-m/sec Vmax). If the aliasing velocity is set to (approximately) 40 cm/sec, the calculation simplifies to EROA = $r^2/2$. An approximation to RVol can be obtained by multiplying EROA by the velocity time integral (VTI) of the regurgitant CW signal. **Fig. 69.14** shows how this simplified approach can be done in practice.

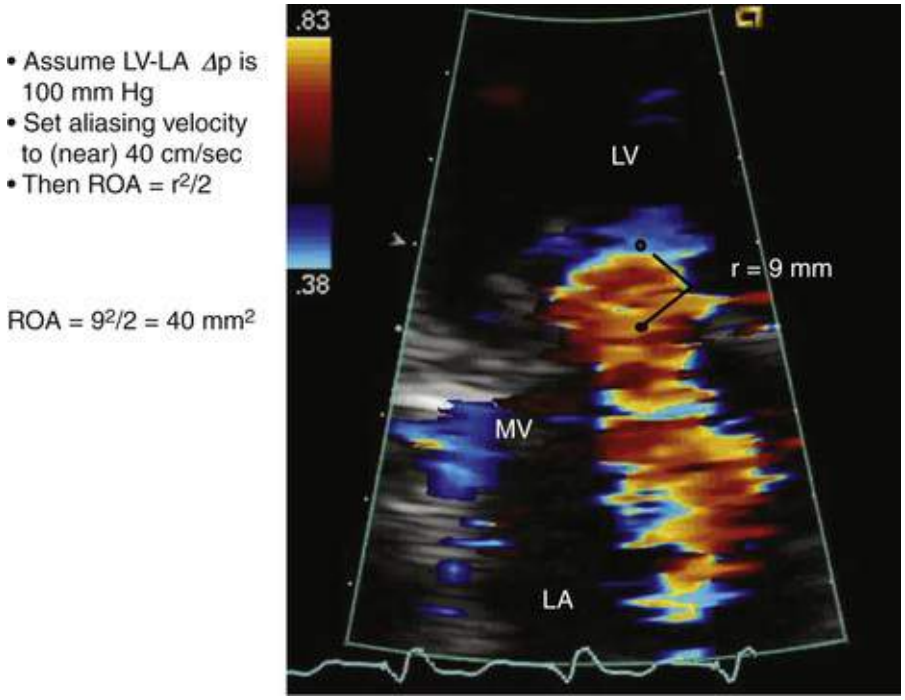

FIGURE 69.14 Simplified approach to estimating the regurgitant orifice area (ROA) using the proximal convergence method. The method assumes that the pressure difference is approximately 100 mm Hg between the left ventricle (LV) and the left atrium (LA) in systole (producing a 5-m/sec regurgitant jet velocity) and sets the color aliasing velocity to approximately 40 cm/sec. Then, by measuring the radius *r* from the *red-blue area* to the orifice (aided by switching the color off and on), the effective ROA (EROA) is given simply by $r^2/2$. This was validated against the complete formula in Pu M, Prior DL, Fan X, et al. Calculation of mitral regurgitant orifice area with use of a simplified proximal convergence method: initial clinical application. J Am Soc Echocardiogr 2001;14:180-5.

The most important caveat with the PISA equation involves nonholosystolic jets. **Fig. 69.15** shows a large proximal convergence zone with an EROA of 0.6 cm^2, but the CW Doppler demonstrates that this is a case of MVP where the regurgitation does not begin until the latter half of systole, so the regurgitation is much less severe than a single frame showing the largest jet, vena contracta, or convergence zone would imply (Video 69.16). When calculating RVol, one should multiply EROA by the VTI from the dense part of the CW signal, not including the faint, early systolic portion when regurgitation is mild. Nonholosystolic jets are quite common in MVP (without flail) and in functional MR where the MR is most prominent during early systole and isovolumic relaxation, with relatively little in midsystole when the mitral valve is firmly closed by LV pressure. Additional pitfalls of the PISA method include slight flow underestimation (on the order of v/v_{max}) as contours flatten out approaching the orifice; some overestimation as convergence zones are distorted by surrounding walls (a problem generally confined to already-severe MR); and further underestimation when the regurgitant orifice is elongated, as is common in functional MR.

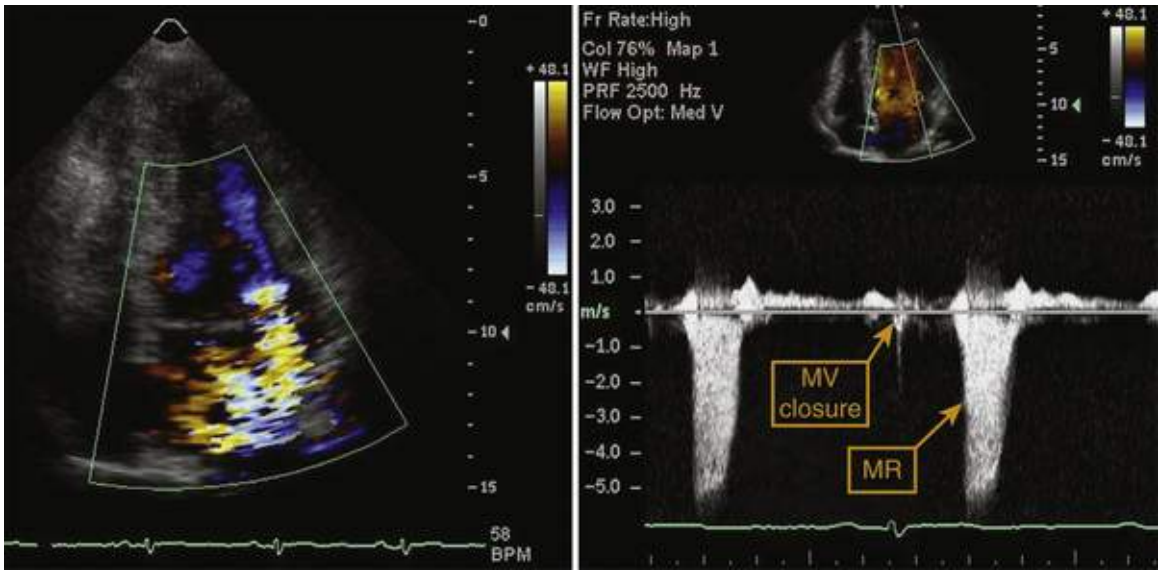

FIGURE 69.15 Limitation of the proximal isovelocity surface area (PISA) method when mitral regurgitation (MR) is not holosystolic. Although there is a large proximal convergence zone with an effective regurgitant orifice area (EROA) of 0.6 cm^2 **(left panel),** the continuous-wave Doppler (CWD) pattern **(right panel)** demonstrates that the regurgitation does not begin until the latter half of systole, which is very common in mitral valve (MV) prolapse. Thus the regurgitation is much less severe than a single frame showing the largest jet, vena contracta, or convergence zone would imply. When calculating regurgitant volume, one should multiply EROA by the velocity time integral (VTI) from the dense part of the CWD signal, not including the faint, early systolic portion when MR is mild.

Supportive evidence for MR severity can be found in pulmonary venous flow, where a normal-pattern systolic (S) wave greater than diastolic (D) wave generally indicates mild MR, and frank systolic reversal indicates severe MR, but the common "blunted" pattern (S < D) may be seen in all degrees of MR. A transmitral E wave greater than 1.2 m/sec is supportive of severe MR, whereas a pattern with E < A virtually excludes severe MR. Doppler echocardiography also is an important tool to estimate the systolic PAP and to determine the presence and severity of associated aortic regurgitation (AR) or TR.

In interrogating the mitral valve, it is important to localize the origin and direction of the regurgitant jet. The parasternal and apical long-axis views identify pathology of the posterior versus anterior leaflet and jet direction, whereas the often-neglected parasternal short-axis and apical two-chamber views can show where along the commissural closure line the dominant jet originates (**Fig. 69.16**).

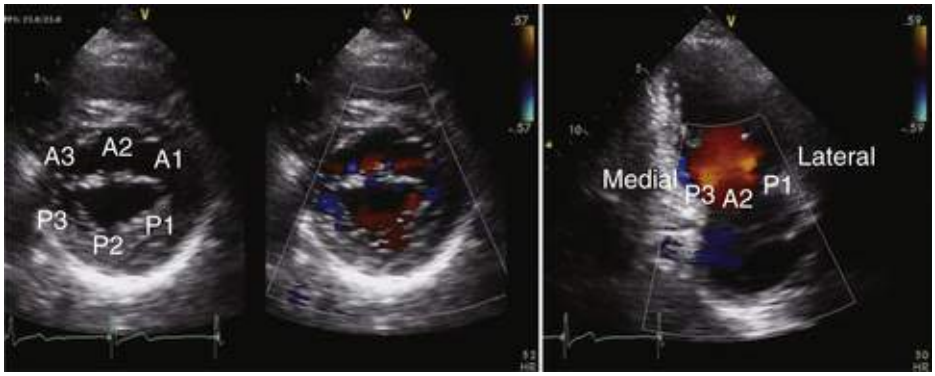

FIGURE 69.16 When examining the mitral valve echocardiographically, it is crucial to obtain anatomically oriented images that localize the origin of the regurgitant jet, particularly along the medial-lateral extent of the commissural closure line. The parasternal short-axis view **(left)** and apical two-chamber view **(right)** both allow this delineation. Localizing the proximal convergence zone in these views can be particularly helpful in assessing the mechanism.

Three-dimensional echocardiography is assuming a more central role in MR assessment, with LV

volumes routinely available, and surface rendering of the valve directly demonstrating the pathology. Multiplane imaging allows structured interrogation of the valve for optimally localizing the pathology.

TEE may be needed in addition to TTE for assessment of the detailed anatomy of the regurgitant mitral valve (**see Figs. 14.35 and 14.40** and Video 69.17) and the severity of MR in some patients. TEE is useful when the TTE images are suboptimal and also in determining whether mitral valve repair or clipping is feasible or whether MVR is necessary. Three-dimensional imaging and three-dimensional color Doppler[2,52,72] help elucidate the mechanism of MR (Video 69.18). **Fig. 69.17** shows how multiplane imaging can explore the full medial-lateral extent of the valve to localize jet origin.

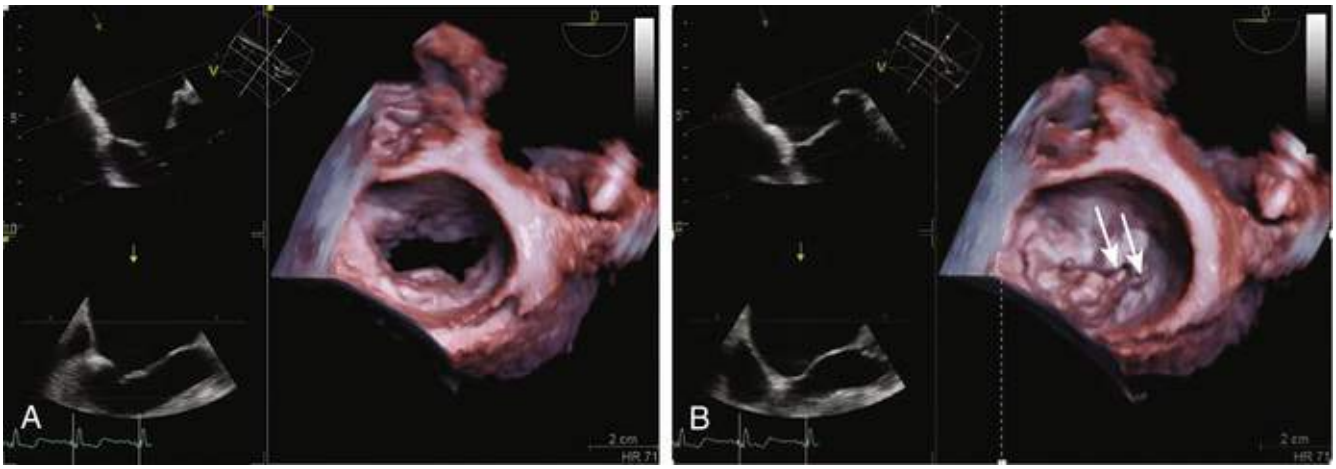

FIGURE 69.17 Three-dimensional echocardiography now allows direct visualization of the pathology, here demonstrating ruptured chordae to P_2 and P_3 (*arrows*). **A,** Ventricular diastole; **B,** systole.

Exercise echocardiography can be extremely helpful in determining severity of MR and hemodynamic abnormalities (e.g., pulmonary hypertension) during exercise.[73-75] This is a useful objective means to evaluate symptoms in patients who appear to have only mild MR at rest and, alternatively, to determine functional status and dynamic changes in hemodynamics in patients who otherwise appear stable and asymptomatic. Particularly helpful is an observation that late systolic MR becomes more holosystolic with exercise, particularly if PAP rises significantly. When ordering a treadmill exercise echocardiogram, the physician should provide guidance to the sonographer as to the priority for the various datasets to be obtained after exercise, because it is often impossible to obtain diagnostic mitral and tricuspid imaging as well as wall motion assessment while heart rate is still optimally high. If the focus is on the mitral valve, rapid acquisition of mitral color flow and CW Doppler and tricuspid CW Doppler images will usually be a priority. If the exercise is on a supine bicycle, comprehensive imaging can be obtained of all relevant parameters. Dobutamine echocardiography has little role in assessing organic MR but may be useful for ischemia or viability assessment in functional MR.

Other Diagnostic Evaluation Modalities

Electrocardiography.

The principal ECG findings are LA enlargement and AF. ECG evidence of LV enlargement occurs in approximately one third of patients with severe MR. Approximately 15% of patients exhibit ECG evidence of RV hypertrophy, a change that reflects the presence of pulmonary hypertension of sufficient severity to counterbalance the hypertrophied left ventricle of MR.

Radiography.

Cardiomegaly with LV enlargement, and particularly with LA enlargement, is a common finding in patients with chronic severe MR. Although the left atrium may be severely enlarged, little correlation has been found between LA size and pressure. Interstitial edema with Kerley B lines frequently is seen in patients with acute MR or with progressive LV failure.

In patients with combined MS and MR, overall cardiac enlargement and particularly LA dilation are prominent findings. Predominant MS is suggested by relatively mild cardiomegaly (principally straightening of the left cardiac border) and significant changes in the lung fields, whereas predominant MR is more likely when the heart is greatly enlarged and the changes in the lungs are relatively inconspicuous. Calcification of the mitral annulus, an important cause of MR in older adults, is most prominent in the posterior third of the cardiac silhouette. The lesion is best visualized on chest films exposed in the lateral or right anterior oblique projections (**see eFig. 15.7**), in which it appears as a dense, coarse, C-shaped opacity.

Cardiac Magnetic Resonance Imaging.

CMR provides accurate measurements of regurgitant flow that correlates well with quantitative Doppler imaging.[76] It also is the most accurate noninvasive technique for measuring LV EDV, ESV, and mass,[77] and has recently been included in guidelines for imaging in valvular regurgitation.[12] Although detailed visualization of mitral valve structure and function is obtained more reliably with echocardiography, particularly TEE, CMR offers a promising approach for more accurate assessment of regurgitant severity and its impact on chamber size.[78,79]

Cardiac Computed Tomography.

Cardiac CT imaging can provide useful structural information about the regurgitant mitral valve,[80-83] with particular value in sizing the mitral annulus and quantifying the degree of annular calcification.[84] CT appears to be particularly useful in planning for percutaneous MVR[85] and has been used in conjunction with three-dimensional printing to ensure an adequate fit of the proposed valve within the mitral apparatus.[86,87] Some have proposed CT imaging for quantification of the actual regurgitant severity, specifically the planimetered size of the EROA, but this will likely remain adjunctive given the availability of echocardiography and CMR.[88]

Left Ventricular Angiography.

Again, given the availability of echocardiography and CMR, there is little reason to perform left ventriculography to characterize MR. The prompt appearance of contrast material in the left atrium after its injection into the left ventricle indicates the presence of MR. The injection should be rapid enough to permit LV opacification but slow enough to avoid the development of premature ventricular contractions (PVCs), which can induce spurious regurgitation. The RVol can be determined from the difference between the total LV stroke volume, estimated by angiocardiography, and the simultaneous measurement of the effective forward stroke volume by the Fick method. In patients with severe MR, the RVol may approach or even exceed the effective forward stroke volume. Qualitative but clinically useful estimates of the severity of MR may be made by cineangiographic observation of the degree of opacification of the left atrium and pulmonary veins after the injection of contrast material into the left ventricle.

Disease Course

The natural history of chronic primary MR is highly variable and depends on a combination of the volume of regurgitation, state of the myocardium, and cause of the underlying disorder. Asymptomatic patients with mild primary MR usually remain in a stable state for many years. Severe MR develops in only a

small percentage of these patients, usually because of intervening infective endocarditis or rupture of the chordae tendineae. In patients with mild MR related to MVP, the rate of progression in severity of MR is highly variable; in most cases, progression is gradual unless a ruptured chorda causing flail leaflet supervenes. Regurgitation tends to progress more rapidly in patients with connective tissue diseases, such as Marfan syndrome, than in those with chronic MR of rheumatic or myxomatous origin. In asymptomatic patients with severe MR, the rate of progression to symptoms, LV dysfunction, pulmonary hypertension, or AF is 30% to 40% at 5 years[89] (**Fig. 69.18**). Acute rheumatic fever is a frequent cause of isolated severe MR among adolescents in developing nations, and these patients often have a rapidly progressive course.

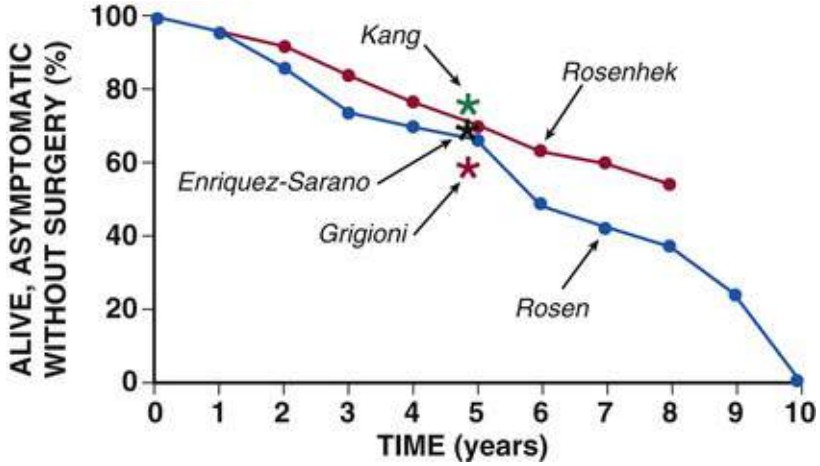

FIGURE 69.18 Five series examining the natural history of primary degenerative mitral regurgitation in patients who initially were asymptomatic with normal left ventricular systolic function. (From Bonow RO. Chronic mitral regurgitation and aortic regurgitation: have indications for surgery changed? J Am Coll Cardiol 2013;61:693-701. Data modified from Rosen SF et al. Natural history of the asymptomatic patient with severe mitral regurgitation secondary to mitral valve prolapse and normal right and left ventricular performance. Am J Cardiol 1994;74:374-80; Enriquez-Sarano M et al. Quantitative determinants of the outcome of asymptomatic mitral regurgitation. N Engl J Med 2005;352:875-83; Rosenhek R et al. Outcomes in mitral regurgitation due to flail leaflets: a multicenter European study. J Am Coll Cardiol Imaging 2008;1:133-41; and Kang DH et al. Comparison of early surgery versus conventional treatment in asymptomatic severe mitral regurgitation. Circulation 2009;119:797-804.)

AF is a common arrhythmia in patients with chronic MR, associated with age and LA dilation, and its onset is a marker for disease progression. Patients with AF have an adverse outcome compared with patients who remain in sinus rhythm,[61] and development of AF is considered an indication for operative intervention, especially in patients who are candidates for mitral valve repair.[21]

Because the natural history of severe MR has been altered greatly by surgical intervention, it is difficult now to predict the clinical course in patients who receive medical therapy alone. However, a 5-year survival of only 30% was reported in patients who were candidates for operation, presumably because of symptoms, but who declined surgery (**see eFig. 69.2**). Among patients with severe MR resulting from flail leaflets, the annual mortality rate without surgery is as high as 3%,[90,91] and at 20 years, 60% will have died (**Fig. 69.19**). The mortality is particularly high in those with LV systolic dysfunction, defined as LVEF of 60% or less[91] (**see eFig. 69.9**).

Long-term mortality associated with left ventricular dysfunction in mitral regurgitation due to flail leaflets: a multicenter analysis. Circ Cardiovasc Imaging 2014;7:363.)

Whether patients with severe MR who are asymptomatic and have normal LV function are at risk of death is a subject of debate.[61,89,92,93] In a study of 286 asymptomatic patients with severe MR and normal LV function followed without surgery, the annual mortality was less than 1% (5% mortality at 7 years). However, in 127 propensity score-matched patients in that study, the estimated actuarial 7-year survival was 99% ±1% in those treated with early surgery, compared with only 85% ±4% for those treated according to current guidelines for watchful waiting. Another study of patients with flail leaflets, noted earlier,[91] reported similar annual mortality rates of less than 1% in those with preserved LV systolic function (mortality <6% at 8 years; **see eFig. 69.9A**).

Mortality arguments aside, however, all studies uniformly indicate that among asymptomatic patients

with initially normal LVEF, severe MR is associated with a high likelihood of requiring surgery over the next 6 to 10 years because of HF symptoms, LV dysfunction, or AF (**see Fig. 69.18**). Moreover, long-term survival after successful surgical repair of primary degenerative MR is reduced in patients with even mild preoperative symptoms or LV dysfunction compared with those who undergo surgery when asymptomatic[94] (**Fig. 69.20**). These considerations have prompted recommendations for earlier surgery in patients who are candidates for repair,[21,37,61,89,92,95] especially in the setting of flail leaflets. Care should always be taken that the regurgitation is indeed severe. A common confounder is MR in MVP confined to late systole, which may look severe on an individual frame, but is actually mild or moderate on volumetric quantitation. These patients have been shown to have a better long-term prognosis than those with holosystolic MR.[96]

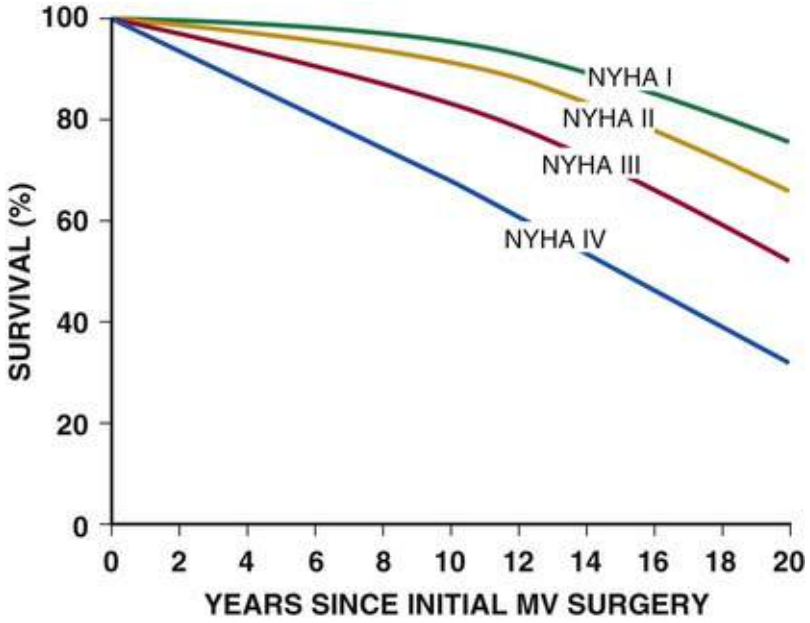

FIGURE 69.20 Long-term survival after mitral valve (MV) repair based on preoperative New York Heart Association (NYHA) functional status in 840 patients with primary degenerative mitral regurgitation. The median follow-up was 10.4 years. (From David TE, Armstrong S, McCrindle BW, Manlhiot C. Late outcomes of mitral valve repair for mitral regurgitation due to degenerative disease. Circulation 2013;127:1485-92.)

Medical Treatment of Primary Mitral Regurgitation

The role of pharmacologic therapy for MR remains another subject of uncertainty and debate. Although afterload reduction therapy undoubtedly is indicated and may be lifesaving in patients with acute MR and secondary forms of chronic MR (see later), the indications for such therapy in patients with chronic primary valvular MR are much less clear. Because afterload is not excessive in most patients with chronic MR, in whom systolic shortening is facilitated by the reduced systolic wall stress, systemic vasodilator therapy to reduce afterload further may not provide additional benefit. Acute administration of nitroprusside, nifedipine, and angiotensin-converting enzyme (ACE) inhibitors to severely symptomatic patients has been demonstrated to alter hemodynamics favorably in some studies, but these effects may not pertain to asymptomatic patients with preserved systolic function. Several small studies of chronic therapy with ACE inhibitors, ranging in duration from 4 weeks to 6 months, have failed to provide evidence of hemodynamic benefit, and no long-term studies or randomized trials have been done to make definitive recommendations. At present, convincing data are lacking that vasodilator therapy affects LV volumes or systolic function favorably in the absence of symptoms or hypertension, and current guidelines

do not recommend the use of these agents for chronic therapy of primary degenerative MR.[21,25]

On the basis of animal models of MR and evidence in patients with chronic MR of neuroendocrine activation and increased sympathetic activity, data from retrospective studies and a small prospective trial indicate that beta blockers may delay the progression of LV dysfunction and improve patient outcomes.[97,98] However, in the absence of definitive clinical trials, such therapy is not currently recommended. An exception would be patients with severe chronic MR, with symptoms or LV dysfunction (or both) who are not candidates for surgical or transcatheter treatment because of age or other comorbid conditions or contributing factors. These patients should receive standard, aggressive management for HF with ACE inhibitors and beta blockers (**see Chapter 25**). Routine antibiotic prophylaxis to prevent infective endocarditis is no longer recommended for patients with MR (**see Chapter 73**). All patients with AF, paroxysmal or chronic, should receive chronic anticoagulation, and appropriate measures should be taken to control the ventricular response rate and restore sinus rhythm, if possible.

Surgical Treatment of Primary Mitral Regurgitation

Surgical treatment should be considered for patients with functional disability and for patients with no symptoms or only mild symptoms but with progressively deteriorating LV function or progressively increasing LV dimensions, as documented by noninvasive studies.[21,25,61,89] In patients considered for surgery, two-dimensional TTE or TEE with Doppler evaluation and color flow Doppler imaging provide detailed assessment of mitral valve structure and function.[65] Left-heart catheterization and coronary arteriography are indicated principally to determine the presence and extent of CAD. In selected cases, right-heart catheterization and left ventriculography may be helpful resolving discrepancies between echocardiographic findings and the clinical picture, as well as detecting and assessing the severity of other associated valvular lesions.

Without surgical treatment, the prognosis for patients with MR and HF is poor (**see eFig. 69.2**), so mitral valve repair or replacement is indicated for symptomatic patients. When operative treatment is being considered, the chronic and often slowly but relentlessly progressive nature of MR must be weighed against the immediate risks and long-term uncertainties attendant on surgery, especially if MVR is required. Surgical mortality depends on the patient's clinical and hemodynamic status, particularly LV function; age[99,100] (**see Chapter 88**); presence of comorbid conditions such as renal, hepatic, or pulmonary disease;[101] and the skill and experience of the surgical team.[37,102] The decision to replace or to repair the valve is of critical importance, and mitral valve repair is strongly recommended whenever possible (**Fig. 69.21**). Replacement involves the operative risk, as well as the risks of thromboembolism and anticoagulation in patients receiving mechanical prostheses, of late structural valve deterioration in patients receiving bioprostheses, and of late mortality, especially in patients with associated CAD who require CABG. Mitral repair is more likely to occur in a surgical center doing more than 20 MR procedures per year, emphasizing the critical importance of surgical experience and expertise.[103] Surgical mortality in patients requiring MVR does not depend significantly on which of the currently used tissue or mechanical valve prostheses is selected.

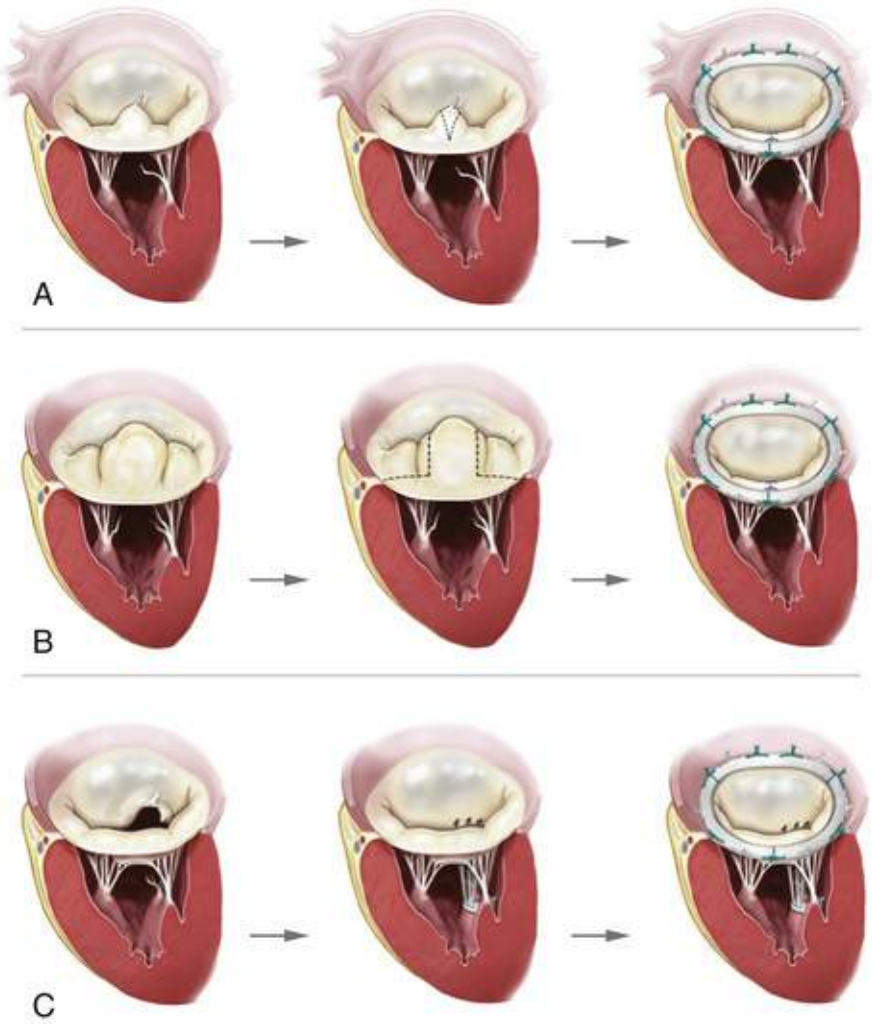

FIGURE 69.21 Most frequently applied surgical approaches currently used for repair of posterior leaflet prolapse. **A,** Triangular resection; **B,** quadrangular resection and sliding leaflet plasty; **C,** neochordoplasty with polytetrafluoroethylene sutures. *Dashed lines* represent the area of leaflet to be excised. (From Castillo JG, Adams DH. Mitral valve repair and replacement. In Otto CM, Bonow RO, editors. Valvular Heart Disease: ACompanion to Braunwald's Heart Disease. Philadelphia: Saunders; 2013, pp 327-340.)

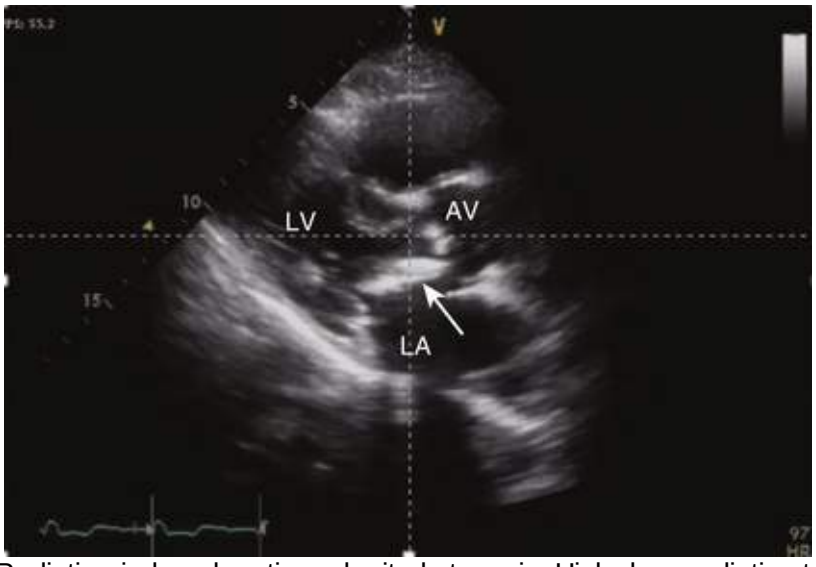
Repair of primary degenerative MR most often is successful in (1) children and adolescents with pliable valves, (2) adults with MR secondary to MVP, (3) cases with annular dilation, (4) cases with chordal rupture, and (5) cases with perforation of a mitral leaflet caused by infective endocarditis. These clinical categories represent the vast majority of patients with MR in the United States and other developed countries. These procedures are less likely to be successful in older patients with the rigid, calcified, deformed valves of rheumatic or radiation heart disease (**eFig. 69.10** and Video 69.19) or in those with severe subvalvular chordal thickening and major loss of leaflet substance, many of whom require MVR. The presence of severe mitral annular calcification poses a challenge to both repair and replacement strategies.[104] However, younger patients who have severe rheumatic MR in the absence of active carditis may undergo successful repair.[37,102] This consideration is particularly important in developing countries.



EFIGURE 69.10 Radiation-induced aortic and mitral stenosis. High-dose radiation to the chest induces severe fibrosis and calcification of the aortic and mitral valves. A characteristic finding is heavy calcification along the aorto-mitral curtain (*arrow*). *LV,* left ventricle; *LA,* left atrium; *AV,* aortic valve.

Mitral valve repair for degenerative MR consists of reconstruction of the valve, which usually is accompanied by a mitral annuloplasty using a rigid or flexible prosthetic ring (**see Fig. 69.21**).[105] Prolapsed valves causing severe MR usually are treated with resection of the prolapsing segment(s) with plication and reinforcement of the annulus. Replacing, reimplanting, elongating, or shortening of the chordae tendineae, splitting the papillary muscles, and repairing the subvalvular apparatus have been successful in select patients with pure or predominant MR in whom subvalvular pathology contributes to the MR.[37,105] Repair of anterior and posterior prolapsing leaflets has been successful in experienced centers, although results are less successful than where pathology is confined to one leaflet. Deep clefts are sometimes found between scallops, which can simply be closed. Intraoperative TEE with Doppler is critical for assessing the adequacy of mitral valve repair.[106] In the minority of patients with persistent significant MR in whom the operative results are unsatisfactory, the problem usually can be corrected immediately or, if necessary, the valve can be replaced. LV outflow tract obstruction caused by systolic anterior motion of the mitral valve occurs in 5% to 10% of patients after mitral valve repair for degenerative MR.[39] The causes are multifactorial but may include excess valvular tissue with severe leaflet redundancy and/or an interventricular septum bulging into a small, hyperdynamic left ventricle. These complications also may be recognized intraoperatively on TEE, guiding treatment with volume loading and beta blockers, which often is helpful. The obstruction usually disappears with time; if it does not, a second pump run and repeat repair or MVR may be necessary. Recognizing the risk for outflow tract obstruction in the preoperative TEE allows prophylactic surgical strategies: a sliding annuloplasty for excessive posterior leaflet length (detachment of the leaflet and reattachment to shorten it); reefing to pull back the free margin of an excessively long anterior leaflet; and myomectomy for an upper septal bulge.[107]

Preoperative AF is an independent predictor of reduced long-term survival after mitral valve surgery for chronic MR. The persistence of AF postoperatively requires long-term anticoagulation, thereby partially nullifying the advantages of mitral valve repair. In patients who have developed AF, whether chronic or paroxysmal, outcomes are improved if a maze procedure is performed at the time of mitral valve repair or replacement,[61,108] with reduced risk of postoperative stroke. The decision to perform a maze procedure should be based on surgical expertise as well as patient age and comorbid conditions, because this procedure may add to the length and complexity of the operation. The technique consists of electrically isolating portions of the atria from each other and the pulmonary veins using either suture

lines (“cut and sew”), radiofrequency energy, or cryotherapy.[109,110]

Mitral Valve Repair Versus Replacement.

Although mitral valve replacement (MVR) has been used successfully in treating MR for almost six decades, some dissatisfaction with the results of this operation has been reported. First, LV function often deteriorates after MVR, contributing to early and late mortality and late disability. The increase in afterload consequent to abolishing the low impedance leak was first believed to be responsible, but now it is clear that the loss of annular-chordal-papillary muscle continuity (**see Fig. 69.7**) interferes with LV geometry, volume, and function in patients who have undergone MVR. This limitation does not occur after mitral valve repair. Animal experiments have shown convincingly that the normal function of the mitral valve apparatus primes the left ventricle for normal contraction that is prevented when surgery causes discontinuity of this apparatus. Animal experiments and human trials indicate that preservation of the papillary muscle and its chordal attachments to the mitral annulus is beneficial to postoperative LV function after mitral valve reconstruction and replacement. Thus, preservation of these tissues, whenever possible, is now considered a critical feature of MVR.[39,105,109,110]

A second disadvantage of MVR is inherent problems with the prosthesis itself, including the risks of thromboembolism or hemorrhage associated with mechanical prostheses, late structural deterioration of bioprostheses, and infective endocarditis with all prostheses. Outcomes after mitral valve repair are more favorable than those with MVR in comparative studies,[100] although this benefit has never been subjected to a prospective randomized trial in organic MR (see later for a randomized trial in functional MR). For these reasons, increasing efforts are being made to repair the mitral valve whenever possible in patients with isolated or predominant MR.[39,89,102,105,111,112]

With growing experience in mitral valve repair for degenerative causes of MR, including MVP and rupture of chordae tendineae, the number of patients having valve reconstruction is increasing each year. In many centers in the United States, more than two thirds of all patients requiring operation for pure or predominant MR now undergo mitral valve repair. This percentage has steadily increased, and currently 69% of patients in the STS database undergoing surgery for isolated primary MR undergo mitral valve repair.[103] However, many patients who are candidates for repair continue to undergo MVR, and most mitral valve operations in the United States continue to be performed by low-volume surgeons, in whom the likelihood of performing a successful mitral valve repair is lower than that of higher-volume valve surgeons.[113] Mitral valve repair is a technically more demanding procedure than MVR, with a distinct learning curve for the surgeon. In addition, MR recurs after mitral valve repair in a subset of patients with degenerative valve disease that is predicted in part by the presence of residual MR immediately after repair.[114,115] Thus there is growing emphasis on referral of patients requiring surgery for pure MR to centers of excellence in performing mitral valve repair.[21,25,39,89,116]

Minimally invasive surgical techniques using a small, low, asymmetric sternotomy or anterior thoracotomy and percutaneous CPB[117] have been found to be less traumatic and can be used for mitral valve repair and replacement. This approach has been reported to reduce cost, improve cosmetic results, and shorten the recovery time. However, it also is demanding technically and is successfully performed by only a minority of cardiac surgeons. Recent advances in robotic surgery have allowed this approach to be used for a wide range of mitral valve procedures, but the learning curve is also quite steep and technically demanding.[118]

Percutaneous Mitral Valve Repair.

In 2013 the U.S. Food and Drug Administration (FDA) approved the MitraClip system for percutaneous mitral valve repair in patients with organic MR and a prohibitive risk for open heart surgery (predicted mortality >8%). It was subsequently given a class IIb indication in the 2014 valve guideline and has now been used in more than 30,000 patients (**see Chapter 72**).

Surgical Results

Operative mortality rates of 1% to 9% are now common in many centers for patients with pure or predominant MR (NYHA Class II or III) who undergo elective isolated mitral valve repair or replacement. The overall mortality rate was 3.0% in the STS database of 77,836 patients undergoing isolated mitral valve surgery between 2002 and 2010,[119] with a significant increase in the percentage of patients undergoing mitral valve repair from 54.8% (2002–2006) to 61.8% (2007–2010). Mortality was significantly lower in the repair than replacement patients (1.4% vs 5.4% in 2007-10). Patients undergoing mitral valve repair are younger and less symptomatic and have considerably fewer comorbid conditions than those undergoing MVR, and these factors contribute to the observed differences in operative mortality. It also is not possible in the STS database to differentiate patients undergoing surgery for primary forms of MR from those with LV dysfunction and secondary MR. Among the 22,786 patients undergoing mitral valve repair in 2007 to 2010 with a STS predicted risk of mortality (PROM) score of 0 to 4%, the operative mortality was 0.9%.

The combination of mitral valve surgery with CABG was associated with an mortality rate of 6.2% between 2011 and 2014,[120] and even higher (up to 25%) in patients with severe LV dysfunction, especially when pulmonary or renal function is impaired, or when the operation must be carried out on an emergency basis. A strong gradient was found between surgical centers of the highest (three-star) rating, with 2.6% risk-adjusted mortality to 11.1% in one-star centers. Age per se is no barrier to successful surgery; mitral valve repair or replacement can be performed in patients older than 75 years if their general health status is adequate,[99,100,121] although surgery in these patients carries higher risk than in younger patients (**see Chapter 88**). Medicare data covering 2000 through 2009 indicate an operative mortality of 3.9% for patients older than 65 undergoing mitral valve repair and 8.9% for those undergoing MVR.[122] The 1-, 5-, and 10-year survival rates were 90.9%, 77.1%, and 53.6%, respectively, in patients undergoing mitral valve repair and 82.6%, 64.7%, and 37.2%, respectively, in those undergoing MVR. As in the STS database, Medicare patients undergoing mitral valve repair were younger and had fewer comorbid conditions than those undergoing MVR. These favorable outcomes of elderly patients undergoing mitral valve surgery, especially repair, support the earlier identification and surgical referral in this age-group.

Surgical treatment substantially improves survival in patients with symptomatic MR. Preoperative factors, such as age younger than 60 years, NYHA Class I or II, cardiac index exceeding 2.0 liters/min/m^2, LV end-diastolic pressure less than 12 mm Hg, and a normal EF (which should be >60% in patients with severe primary MR) and ESV, all correlate with excellent immediate and long-term survival rates. Both preoperative LVEF (**see eFigs. 69.4 and 69.9**) and end-systolic diameter are important predictors of short- and long-term outcomes.[61] Excellent outcome is anticipated in patients with end-systolic diameter less than 40 mm and EF of 60% or more. Intermediate outcomes are observed in patients with end-systolic diameter of 40 to 50 mm and EF of 50% to 60%. Poor outcomes are associated with values beyond these limits. With improved echocardiographic and magnetic resonance technology, including three-dimensional imaging, it is now possible to have more accurate ventricular volumes to guide timing of surgery, as detailed in a recent guideline,[12] although long-term data are limited. A recent magnetic resonance study showed a greater likelihood for progressing to a need for surgery among those with

LVEDV index greater than 100 mL/m^2, RVol greater than 55 mL, and regurgitant fraction of 40%. One parameter that will probably gain increasing importance in guiding timing of intervention is global longitudinal strain. In a study of 233 patients undergoing mitral valve repair for organic MR, GLS was the best predictor of a postoperative LV dysfunction, with values closer to zero than −19.9% predicting LVEF less than 50% at 1 year after surgery, with sensitivity and specificity of 90% and 79%, respectively.[62]

A large proportion of operative survivors exhibit improved clinical status, quality of life, and exercise tolerance after mitral valve repair or replacement.[112] Severe pulmonary hypertension is reduced, LVEDV and LV mass decrease, and coronary flow reserve increases. Depressed contractile function improves, especially if the papillary muscles and chordal attachment to the annulus remain intact. However, patients with MR who have marked LV dysfunction preoperatively sometimes remain symptomatic, with depressed LV function, despite a technically satisfactory surgical procedure. Progressive LV dysfunction and death from HF may occur, presumably because LV dysfunction may be advanced and largely irreversible by the time patients with pure MR develop serious symptoms. Thus, every effort should be made to operate on patients before they develop serious symptoms, and even asymptomatic patients with severe MR may be considered for surgery in an experienced center if there is a high likelihood (>95%) that the valve can be repaired successfully without residual MR.[21,25,61,89,95,123]

Even though surgical results are suboptimal in patients with MR who have developed severe symptoms or marked LV dysfunction,[61,90] an operation is still indicated for most of these patients because conservative therapy has little to offer. Postoperative survival rates are lower in patients in AF than in those in sinus rhythm.[21,61] As with patients with MS, the arrhythmia by itself does not unfavorably influence outcome but is a marker for older age and other clinical and hemodynamic features associated with less optimal results.

Indications for Surgery

The proposed management strategy for patients with chronic severe primary MR from the 2014 valve guideline[21] was modified slightly by the 2017 focused update[124] (**Fig. 69.22**). The threshold for surgical treatment of primary MR is decreasing because of a reduction in operative mortality, improvement in mitral valve repair procedures, long-term results indicating durability of repair in experienced centers, and the recognition of the poor long-term results in many patients when severe primary MR is corrected only after a long history of symptoms, impaired LV function, AF, or pulmonary hypertension. A detailed echocardiographic examination should be done to assess the likelihood that mitral valve repair, rather than replacement, is possible, and the difference in outcomes between these procedures should be weighed in deciding whether or not to proceed.

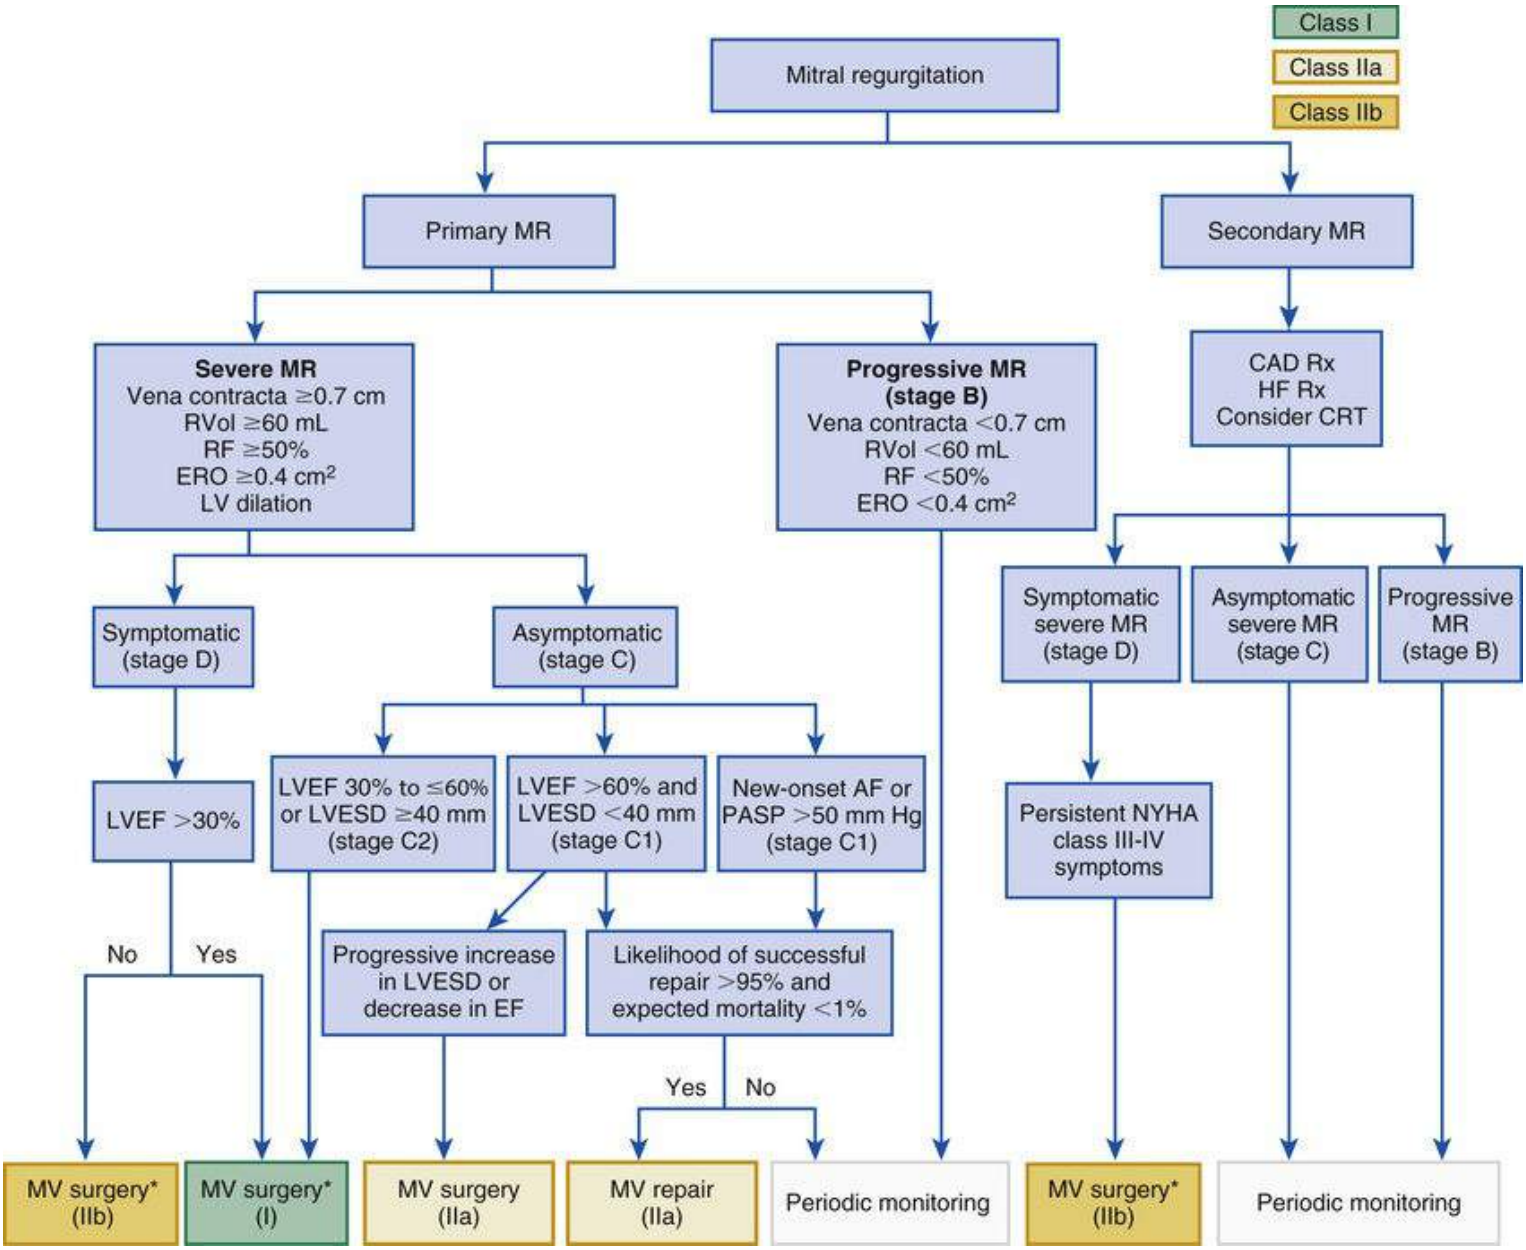


FIGURE 69.22 Updated 2017 indications for mitral valve (MV) surgery for chronic severe mitral regurgitation (MR). *Mitral valve repair preferred over mitral valve replacement when possible. AF, Atrial fibrillation; CAD, coronary artery disease; CRT, cardiac resynchronization therapy; ERO, effective regurgitant orifice; HF, heart failure; LVEF, left ventricular ejection fraction; LVESD, left ventricular end-systolic dimension; PASP, pulmonary artery systolic pressure; RF, regurgitant fraction; RVol, regurgitant volume; Rx, therapy. (From Nishimura RA, Otto CM, Bonow RO, et al. 2017 AHA/ACC focused update of the 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. Circulation 2017;135:e1159-95.)

Asymptomatic Patients.

Asymptomatic patients (NYHA Class I) should be considered for mitral valve repair if they have LV systolic dysfunction (EF ≤60% and/or LV end-systolic diameter of 40 mm).[21] It also is reasonable to consider mitral valve repair in asymptomatic patients when AF or pulmonary hypertension is present. Critical in such patients is certainty that the MR is truly severe. Special caution should be exercised in patients with MVP and late systolic MR (**see Fig. 69.15**), since instantaneous parameters of MR magnitude (jet area, ERO by proximal convergence) may appear severe, while the brief duration of the regurgitation makes volumetric magnitude only moderate. Exercise echocardiography may be helpful risk-stratifying such patients.[96]

A number of centers are moving toward a more aggressive surgical approach in which mitral valve

repair is recommended to all patients with severe MR, independent of symptoms or LV function.[39,61,89,123] This approach is supported by data indicating that patients who undergo mitral valve repair while asymptomatic have significantly greater long-term survival rates than patients with even mild (NYHA Class II) preoperative symptoms (**see Fig. 69.20**).[94] In addition, patients with severe MR related to flail leaflets have greater long-term survival if they undergo prompt surgery rather than waiting for development of more severe symptoms or more severe hemodynamic compromise (**see Fig. 69.19**).[90] However, this recommendation for mitral valve repair in asymptomatic patients should be considered only for those with truly severe MR[12] (**see Table 69.3**) who are referred to centers where the surgical experience indicates a high degree of certainty of successful mitral valve repair.[39,105] Unfortunately, successful mitral valve repair cannot be guaranteed, and even in the best of circumstances, some young asymptomatic patients may be subjected to the risks of prosthetic valves prematurely and unnecessarily with this approach.

When mitral valve repair is not recommended, asymptomatic patients with normal LV function should be followed clinically and by echocardiography every 6 to 12 months with vigilance for any decline in functional capacity. A careful history or an exercise test often reveals that these patients are not truly asymptomatic.

If mitral valve replacement is likely to be necessary, a higher threshold for clinical and hemodynamic impairment should be used than if mitral valve repair is contemplated, and there are few indications for MVR in truly asymptomatic patients other than LV systolic dysfunction (**see Fig. 69.22**). Because of the higher operative mortality, older patients (>75 years) should generally undergo surgery only if they are symptomatic. In the setting of excessive operative risk, percutaneous intervention in primary MR with mitral clipping can be considered.

Symptomatic Patients.

Patients with severe primary MR and moderate or severe symptoms (NYHA Class II, III, and IV) should generally be considered for surgery. One exception is that of patients in whom the LVEF is less than 30% and echocardiography suggests that MVR will be required and that the subvalvular apparatus cannot be preserved. Because of the high risk of operation and the poor long-term results in these patients, medical therapy may be advised, but the outcome is poor in any event. However, when mitral valve repair appears possible, even patients with serious LV dysfunction may be considered for operation (**see Fig. 69.22**).[125]

Transcatheter Mitral Valve Repair

There is growing interest in the development of percutaneous approaches to mitral valve repair using either the edge-to-edge technique or the coronary sinus approach for percutaneous mitral annuloplasty[126] (**see Chapter 72**). The edge-to-edge method has generated the greatest clinical experience, mirroring the concept of the surgical Alfieri method for repair of MR by stitching the two mitral leaflets to create a double mitral orifice.[127] The transcatheter MitraClip device (Abbot Vascular) has received regulatory approval in both Europe and the United States. This device is delivered through an atrial transseptal approach and joins the tips of the anterior and posterior mitral leaflets, reducing and in some cases eliminating the MR (**see Fig. 72.8**). Data from clinical registries and a prospective clinical trial demonstrate successful implantation of the device in most patients in experienced centers,[128,129] although a second clip is needed in many patients to achieve effective reduction in MR. The reduction in MR is associated with favorable LV remodeling and amelioration of symptoms, both immediately and up to 4 years, with clinical results equivalent to those achieved surgically,[130,131] with worse results noted in those

with complex valve pathology.[132] Longer-term outcomes are not yet available. In view of the excellent and durable results with surgical repair of primary MR, including that in elderly patients, the MitraClip has been FDA approved only for those patients considered at prohibitive surgical risk because of extensive medical comorbidity. Data in this particular subset of patients treated with the edge-to-edge device have shown effectiveness in functional improvement and symptom relief.[133] Of note, whereas the MitraClip is approved in Europe for both primary and secondary MR, the FDA has only approved it for primary MR in the United States.

Chronic Secondary Mitral Regurgitation

Secondary MR stemming from LV dilation and systolic dysfunction (Video 69.20), often with concomitant mitral annular dilation, is a common consequence of ischemic and nonischemic cardiomyopathies[55] (**see Chapters 61 and 77**). **Table 69.4** outlines the clinical stages of secondary MR, updated to reflect the 2017 valve guideline,[124] which reestablished a single scale of severity for MR regardless of etiology, also reflected in the updated American Society of Echocardiography guideline for grading valve regurgitation.[12] Numerous studies have shown that secondary MR identifies patients with HF at higher risk for hemodynamic deterioration and death than those without MR (**see Chapter 23**). Even mild degrees of MR that would be well tolerated for decades in patients with primary MR stemming from MVP are associated with increased mortality over 3 to 5 years.[59,60] Because the mechanism of ischemic and nonischemic (or functional) MR is related to the magnitude of LV remodeling, patients with MR generally have lower EF and higher ESV than those without MR, and MR of greater severity is associated with more severe LV dysfunction and remodeling. Thus, MR is a marker of significant regional or global LV dysfunction. What is less clear is whether secondary MR, once established, contributes to progression of LV dysfunction and plays a causative role in the observed worse outcomes or is more a marker for poor outcome even if the MR was not present. Thus, whether secondary MR should be a target for surgical or device intervention remains uncertain.

TABLE 69.4

Stages of Chronic Secondary Mitral Regurgitation (MR)

STAGE	DEFINITION	VALVE ANATOMY	VALVE HEMODYNAMICS*	ASSOCIATED CLINICAL FINDINGS	SYMPTOMS
A	**At risk of MR**	Normal valve leaflets, chords, and annulus in a patient with coronary disease or cardiomyopathy	No MR jet or small central jet area <20% LA on Doppler Small vena contracta <0.30 cm	Normal or mildly dilated LV size with fixed (infarction) or inducible (ischemia) regional wall motion abnormalities Primary myocardial disease with LV dilation and systolic dysfunction	Symptoms caused by coronary ischemia or HF may be present that respond to revascularization and appropriate medical therapy.
B	**Progressive MR**	Regional wall motion abnormalities with mild tethering of mitral leaflet Annular dilation with mild loss of central coaptation of the mitral leaflets	ERO† <0.40 cm^2 RVol <60 mL RF <50%	Regional wall motion abnormalities with reduced LV systolic function LV dilation and systolic dysfunction caused by primary myocardial disease	Symptoms caused by coronary ischemia or HF may be present that respond to revascularization and appropriate medical therapy.
C	**Asymptomatic severe MR**	Regional wall motion abnormalities and/or LV dilation with severe tethering of mitral leaflet Annular dilation with severe loss of central coaptation of the mitral leaflets	ERO† ≥0.40 cm^2 RVol ≥60 mL RF ≥50%	Regional wall motion abnormalities with reduced LV systolic function LV dilation and systolic dysfunction caused by primary myocardial disease	Symptoms caused by coronary ischemia or HF may be present that respond to revascularization and appropriate medical therapy.
D	**Symptomatic severe MR**	Regional wall motion abnormalities and/or LV dilation with severe tethering of mitral leaflet Annular dilation with severe loss of central coaptation of mitral leaflets	ERO† ≥0.40 cm^2 RVol ≥60 mL RF ≥50%	Regional wall motion abnormalities with reduced LV systolic function LV dilation and systolic dysfunction caused by primary myocardial disease	HF symptoms caused by MR persist even after revascularization and optimization of medical therapy. Decreased exercise tolerance Exertional dyspnea

*Several valve hemodynamic criteria are provided for assessment of MR severity, but not all criteria for each category will be present in each patient. Categorization of MR severity as mild, moderate, or severe depends on data quality and integration of these parameters in conjunction with other clinical evidence.

†The measurement of the proximal isovelocity surface area (PISA) by two-dimensional transthoracic echocardiography (TTE) in patients with secondary MR underestimates the true ERO because of the crescentic shape of the proximal convergence.

ERO, Effective regurgitant orifice; *HF,* heart failure; *LA,* left atrium; *LV,* left ventricular; *RF,* regurgitant fraction; *RVol,* regurgitant volume.

From Nishimura RA, Otto CM, Bonow RO, et al. 2017 AHA/ACC focused update of the 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. Circulation 2017;135:e1159-95.

Clinical Presentation

Symptoms

Patients with secondary MR related to LV dysfunction often present with HF symptoms, but many are asymptomatic (at least with regard to the MR), with MR detected incidentally on physical examination or echocardiography. AF is common.

Physical Examination

An apical S_3 is a common finding. As noted previously, the systolic murmur of secondary MR related to LV dilation may be soft and barely audible, particularly in patients with nonholosystolic MR that becomes minimal in midsystole. Thus the physical examination can be misleading regarding the presence and severity of secondary MR. The murmur of papillary muscle dysfunction may occur in late systole and is highly variable, often accentuated or holosystolic during acute myocardial ischemia and absent when ischemia is relieved.

Diagnosis and Evaluation

Echocardiography

Echocardiography is important in identifying the degree of LV dilation and systolic dysfunction, the presence and severity of MR (Video 69.21), and mechanisms responsible for secondary MR[2,55,134] (**see Chapter 14**). MR develops as a result of annular dilation and tethering of the mitral leaflets from geometric displacement or traction of the papillary muscles, and this tethering results in restricted leaflet closure with incomplete coaptation during systole (**see Figs. 14.31B and 14.41**). Most often the posterior leaflet is more severely restricted in closure, allowing the anterior leaflet to override it, producing a posteriorly directed jet of MR that may arise broadly along the commissural closure line. Because the magnitude of MR can vary so widely with loading conditions and ischemia, evaluation with exercise echocardiography can be informative.[54]

Cardiac Magnetic Resonance Imaging

CMR is useful in assessing severity of LV remodeling and contractile dysfunction, as well as the pattern of myocardial fibrosis as it relates to regional dysfunction and papillary muscle dysfunction.[12,135]

Medical Management of Secondary Mitral Regurgitation.

Patients with secondary MR stemming from LV dilation and dysfunction should undergo aggressive evidence-based medical management for LV systolic dysfunction (**see Chapter 25**). Beneficial reverse remodeling with medical therapy, especially with beta blockers, will reduce the severity of MR in many patients.

Resynchronization Therapy.

In patients with a dilated or ischemic cardiomyopathy and secondary MR, successful reverse remodeling with resynchronization therapy by biventricular chamber pacing (**see Chapters 25 and 26**) significantly reduces MR severity.[136,137] The mechanism of this effect probably is similar to that achieved in some patients with medical management, namely, LV remodeling with a reduction in ventricular size and associated improvement in alignment of the papillary muscles. This leads to improved leaflet coaptation and decreased regurgitant flow across the mitral valve.

Surgical Treatment of Secondary Mitral Regurgitation

Ischemic MR secondary to regional LV dysfunction with annular dilation may be treated by annuloplasty[138] (**see Chapter 28**), with rings designed to reduce the annular dilation and restore annular shape (**Fig. 69.23**). Annuloplasty also is successful in many patients with significant functional MR resulting from DCM. In select patients, mitral valve surgery improves symptomatic status.[139,140] Episodic MR caused by transient ischemia often is eliminated by coronary revascularization, whereas moderate to severe chronic MR secondary to ischemic heart disease usually requires mitral valve repair or replacement.[39,55] In patients undergoing CABG, some investigators recommend that concomitant mitral valve repair be considered for even mild MR. Several randomized trials have provided conflicting data on this subject. In the POINT study, a prospective trial of CABG versus CABG plus mitral valve repair in 102 patients with ischemic MR, those receiving mitral valve repair showed greater symptomatic improvement and higher LVEF and lower LV dimensions and PAP compared with those receiving CABG

alone, but no difference in survival between the two groups was demonstrated.[55,141] Subsequently, the RIME trial of CABG versus CABG plus mitral valve repair in 73 patients with ischemic MR of moderate severity reported higher peak oxygen consumption, lower LVESV index, and lower B-type natriuretic peptide (BNP) levels in patients receiving mitral valve repair, but once more, survival did not differ between the two groups.[142] Countering these small studies is the Cardiothoracic Surgical Trials Network (CTSN) trial of 301 patients with moderate MR (defined as ROA of 0.2 to 0.4 cm^2) all requiring CABG and randomized to mitral valve repair (with annuloplasty) versus CABG alone. Although significantly more patients had moderate or greater MR at 12 months in the no-repair group (31.0% versus 11.2%; $P < 0.001$), for the prespecified primary endpoint of postoperative ESV, there was no difference, nor was there any difference in mortality or major adverse cardiac events.[143] Similar results have been reported at follow-up to 2 years (**Fig. 69.24**).[144]

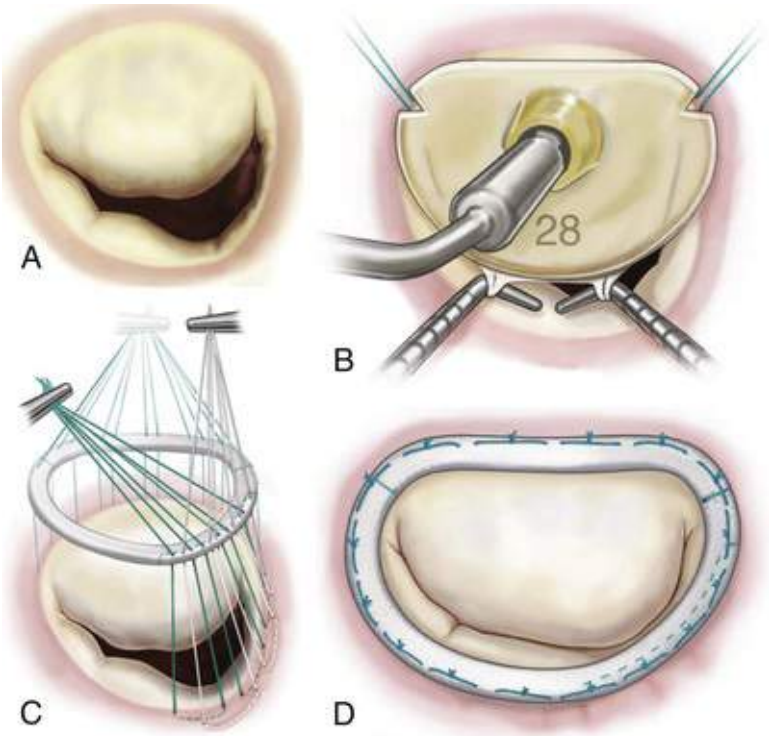

FIGURE 69.23 Surgical approach to ischemic mitral regurgitation. **A,** Typical findings with leaflet restriction predominantly in the P_2-P_3 region resulting in malcoaptation of the mitral leaflets. **B,** Sizing the annulus with a Carpentier-Edwards sizer is based primarily on the surface area and height of the anterior leaflet. **C,** Suturing the annuloplasty ring. **D,** After placement of a full remodeling annuloplasty ring, surface of coaptation is restored. (Modified from Carpentier A, Adams DH, Filsoufi F, editors. Carpentier's Reconstructive Valve Surgery. Philadelphia: Saunders; 2010.)

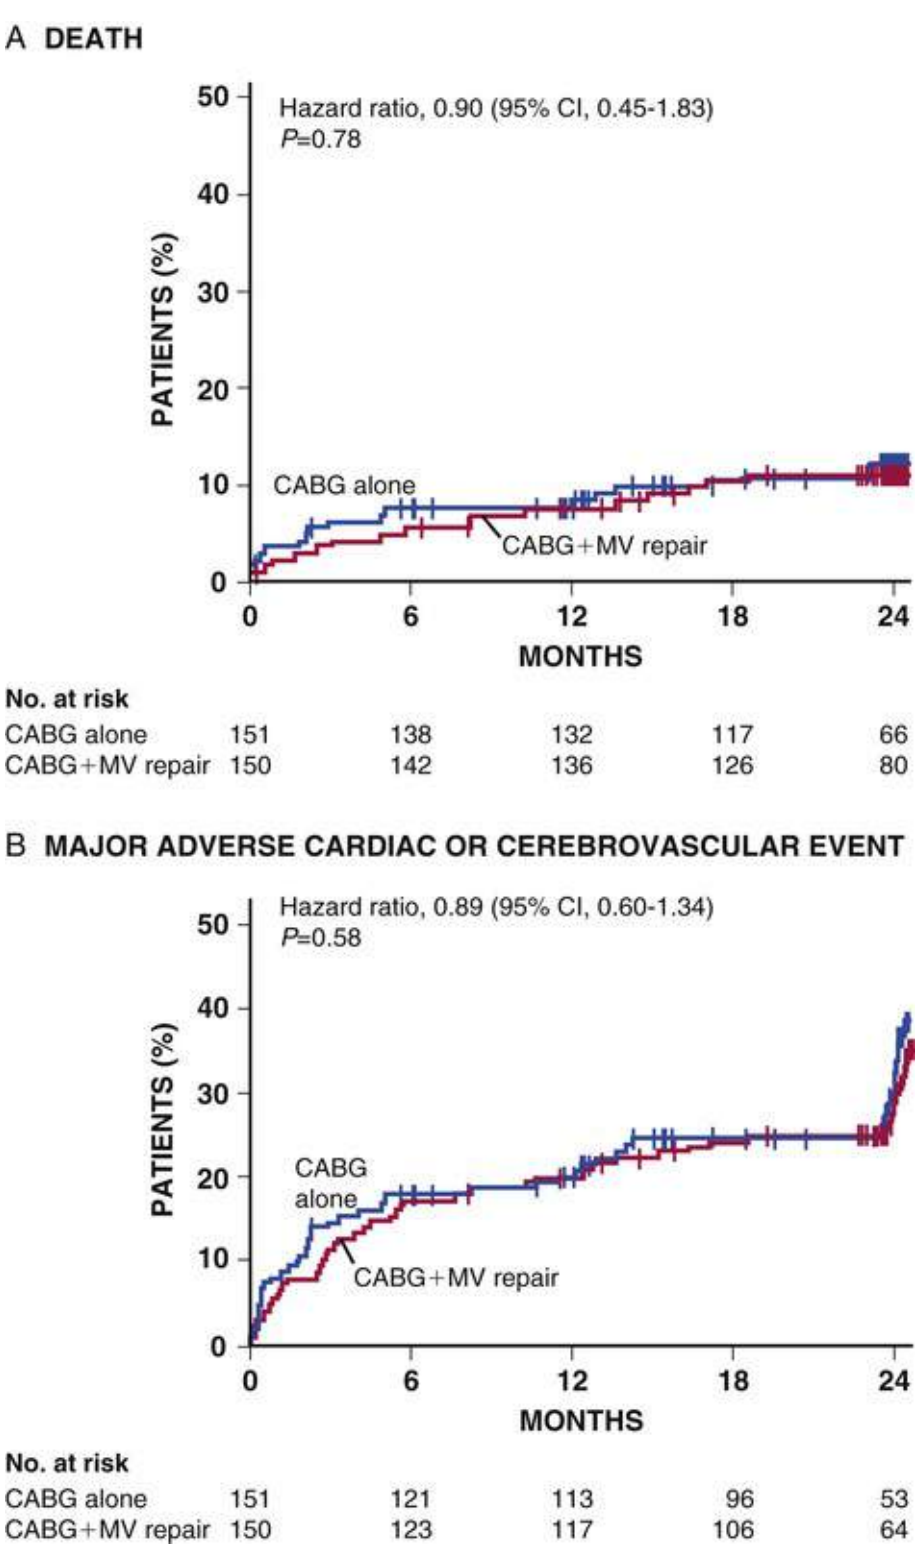

FIGURE 69.24 Two-year outcomes of patients with moderate mitral regurgitation undergoing coronary artery bypass surgery (CABG) who were randomized to CABG alone versus CABG plus mitral valve (MV) repair. **A,** Death. **B,** Composite endpoint of major adverse cardiac or cerebrovascular events. (From Michler RE, Smith PK, Parides MK, et al. Two-year outcomes of surgical treatment of moderate ischemic mitral regurgitation. N Engl J Med 2016;374:1932-41.)

These trials illustrate that in patients with functional MR, the primary problem is disease of the LV myocardium, and prognosis is strongly influenced by the degree of LV dysfunction and residual ischemia. Mitral valve repair or replacement in these latter patients has a less beneficial effect on long-term outcome, particularly in those with ischemic MR, than in patients with degenerative MR. Thus the indications for mitral valve surgery are less clear for secondary MR than for primary MR, exemplified by there being no class I or IIa indications for isolated surgery in secondary MR (**see Fig. 69.22**). Moreover, unlike repair of primary MR caused by myxomatous disease or fibroelastic deficiency, in which an

experienced surgeon can produce results that are durable for decades, mitral valve repair of secondary MR is often not durable because of progression of the underlying LV myocardial disease.[145] This has fueled suggestions that mitral valve replacement might provide a more durable surgical solution to secondary MR with reduced recurrence rates.[146] This was addressed in a retrospective, propensity-matched study of MVR versus mitral valve repair in 1006 patients with ischemic MR.[147] Survival did not differ between the two groups, but patients undergoing mitral valve repair had a significantly greater likelihood of requiring reoperation. These results were further confirmed in a CTSN prospective randomized clinical trial of mitral valve repair versus replacement in 251 patients with severe ischemic MR,[148] which demonstrated that MVR achieved equivalent degrees of reduction in LV volume with replacement and repair, with less recurrent MR during the follow-up period, now confirmed to 2 years[149] (**Fig. 69.25**). This equipoise was driven largely by the 32.6% of repair patients who had recurrent moderate or greater MR at 1 year (rising to 58.8% at 2 years). Among the patients with recurrent MR, LV end-systolic volume index was significantly larger than in those without recurrence (62.6 ±26.9 and 42.7 ±26.4 mL, respectively; $P < 0.001$). These data have informed predictive models to identify patients most likely to fail a mitral valve repair,[150] including those with larger EROA, outward tethering of the valve, and those with inferobasal aneurysms. In multivariate analysis, the ratio of LV end-systolic diameter to the annuloplasty ring diameter was most predictive of recurrent MR.[151] Such patients appear to be better served by a chordal-sparing MVR.

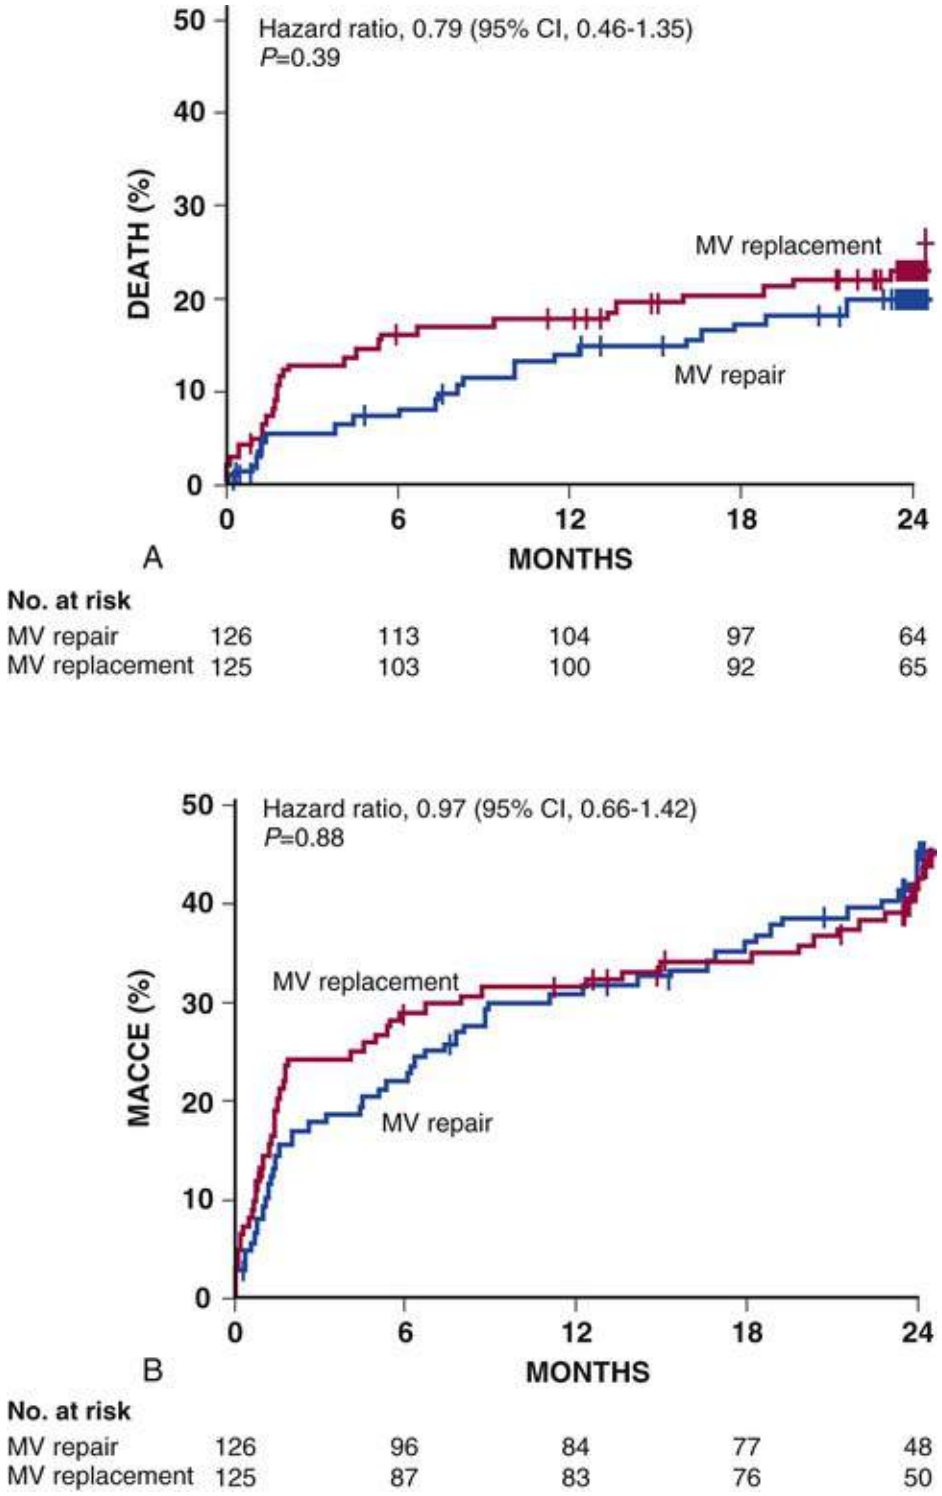

FIGURE 69.25 Postoperative outcomes of patients with ischemic mitral regurgitation randomly assigned to mitral valve (MV) repair versus replacement. **A,** Mortality. **B,** Composite endpoint of death, stroke, repeat MV surgery, hospitalization for heart failure, and increase in NYHA functional class by 1 or more; MACCE, major adverse cardiac or cerebrovascular events. (From Goldstein D, Moskowitz AJ, Gelijns AC, et al. Two-year outcomes of surgical treatment of severe ischemic mitral regurgitation. N Engl J Med 2016;374:344-53.)

Transcatheter Treatment of Secondary Mitral Regurgitation.

Considering the high mortality and morbidity associated with secondary MR in the setting of LV dysfunction, whether medically or surgically treated, and evidence of symptomatic improvement among some patients after surgical mitral valve repair or replacement, a less invasive intervention to reduce or eliminate MR is appealing. In Europe, where the MitraClip is an approved device for all MR etiologies,

approximately two thirds of device implantations are in patients with secondary MR,[152] with registry data indicating substantial reduction in MR severity and improved symptom status,[129] with similar results in patients with functional MR from ischemic and nonischemic etiologies[153] (**see Chapter 72**). One European study reported improved symptoms and beneficial reverse LV remodeling after MitraClip implantation in patients with severe MR and HF who had not responded to previous beta blockade and resynchronization therapy.[154] The MitraClip is not yet approved in the United States for secondary forms of MR, pending results of ongoing prospective clinical trials in this condition.

Acute Mitral Regurgitation

The causes of acute MR are diverse and represent acute manifestations of disease processes that may, under other circumstances, cause chronic MR (**see eTable 69.1**). Especially important causes of acute MR are spontaneous rupture of chordae tendineae, infective endocarditis with disruption of valve leaflets or chordal rupture, ischemic dysfunction or rupture of a papillary muscle, and malfunction of a prosthetic valve.

Clinical Presentation

Acute severe MR causes a marked reduction in forward stroke volume, a slight reduction in ESV, and an increase in EDV. One major hemodynamic difference between acute and chronic MR derives from the differences in LA compliance. Patients who develop acute severe MR usually have a normal-sized left atrium, with normal or reduced LA compliance. The LA pressure rises abruptly, which often leads to pulmonary edema, marked elevation of PVR, and right-sided HF.

Because the *v* wave is markedly elevated in patients with acute severe MR, the reverse pressure gradient between the left ventricle and left atrium declines at the end of systole, and the murmur may be decrescendo rather than holosystolic, ending well before A_2. It usually is lower-pitched and softer than the murmur of chronic MR. A left-sided S_4 frequently is found. Pulmonary hypertension, which is common in patients with acute MR, may increase the intensity of P_2, and the murmurs of pulmonic regurgitation and TR also may develop, along with a right-sided S_4. In patients with severe, acute MR, a *v* wave (late systolic pressure rise) in the PAP pulse (**see eFig. 69.5**) may rarely cause premature closure of the pulmonic valve, an early P_2, and paradoxical splitting of S_2. Acute MR, even if severe, often does not increase overall cardiac size, as seen on the chest radiograph, and may produce only mild LA enlargement despite marked elevation of LA pressure. In addition, the echocardiogram may show little initial increase in the LV or LA internal diameter, but increased LV systolic motion is prominent. Characteristic features on Doppler echocardiography are the severe jet of MR (**see Fig. 14.30**) and elevation of the systolic PAP. Similar to the physical examination, the high atrial *v* wave can lead to early cessation of MR and a triangular-shaped CW Doppler profile instead of the usual parabolic shape. Careful interrogation of the valve by both TTE and TEE is essential to identify the mechanism and underlying etiology of the acute valve dysfunction.

In severe MR secondary to acute MI, pulmonary edema, hypotension, and frank cardiogenic shock may develop. It is essential to determine the cause of the MR, which may be a ruptured papillary muscle (**see Fig. 14.30**), annular dilation from severe LV dilation, or papillary muscle displacement with leaflet tethering.[155]

Medical Management of Acute Mitral Regurgitation

Afterload reduction is particularly important in treating patients with acute MR. IV nitroprusside may be lifesaving in patients with acute MR caused by rupture of the head of a papillary muscle complicating an acute MI. It may permit stabilization of clinical status, thereby allowing coronary arteriography and surgery to be performed with the patient in optimal condition. In patients with acute MR who are hypotensive, an inotropic agent such as dobutamine should be administered with the nitroprusside. Intra-aortic balloon counterpulsation may be necessary to stabilize the patient while preparations for surgery are made.

Surgical Treatment of Acute Mitral Regurgitation

Emergency surgical treatment may be required for patients with acute LV failure caused by acute severe MR. Emergency surgery is associated with higher mortality rates than for elective surgery for chronic MR.[119] However, unless patients with acute severe MR and HF are treated aggressively, a fatal outcome is almost certain.

Acute papillary muscle rupture requires emergency surgery with mitral valve repair or replacement. In patients with papillary muscle dysfunction, initial treatment should consist of hemodynamic stabilization, usually with the aid of an intra-aortic balloon pump, and surgery should be considered for those patients who do not experience improvement with aggressive medical therapy. If patients with MR can be stabilized by medical treatment, it is preferable to defer operation until 4 to 6 weeks after the infarction, if possible. Vasodilator treatment may be useful during this period. However, medical management should not be prolonged if multisystem (renal and/or pulmonary) failure develops.

Surgical mortality rates also are higher in patients with acute MR and refractory HF (NYHA Class IV), those with prosthetic valve dysfunction, and those with active infective endocarditis (of a native or prosthetic valve). Despite the higher surgical risks, the efficacy of early operation has been established in patients with infective endocarditis complicated by medically uncontrollable congestive heart failure and recurrent emboli (**see Chapter 73**).

Percutaneous Treatment of Acute Mitral Regurgitation

Experience is limited with percutaneous approaches to acute MR, although early reports support the selective use of the MitraClip in postinfarct MR[156] and even endocarditis, once the infection has been cleared.[157]

Tricuspid, Pulmonic, and Multivalvular Disease

Patricia A. Pellikka

Tricuspid Stenosis

Causes and Pathology

Tricuspid stenosis (TS) is almost always rheumatic in origin, although rheumatic valve disease more frequently affects left-sided valves.[1] Other causes of obstruction to right atrial (RA) emptying are unusual and include congenital tricuspid atresia (**see Chapter 75**); RA tumors, which may produce a clinical picture suggesting rapidly progressive TS (**Chapter 95**); and device leads, which more often are associated with tricuspid regurgitation (TR), but can become looped and fused to the tricuspid valve apparatus and, particularly if multiple, cause obstruction. The carcinoid syndrome (**see Chapter 77**) and use of ergot-related drugs more frequently produce TR, which if severe contributes to a gradient across the tricuspid valve[2] (Video 70.1C). Dysfunction, including thrombosis, of a tricuspid mechanical or bioprosthetic valve can result in stenosis. Rarely, obstruction to right ventricular (RV) inflow can be caused by endomyocardial fibrosis, tricuspid valve vegetations, or extracardiac tumors.

Most patients with rheumatic tricuspid valve disease have TR or a combination of TS and TR. Isolated rheumatic tricuspid valve disease is uncommon, and this lesion generally accompanies mitral valve disease, which dominates the presentation (**see Chapter 69**). In many patients with TS, the aortic valve also is involved (i.e., trivalvular stenosis is present). TS is found at autopsy in approximately 15% of patients with rheumatic heart disease but is of clinical significance in only approximately 5%. Organic tricuspid valve disease is more common in India, Pakistan, and other developing nations near the equator than in North America or Western Europe. The anatomic changes of rheumatic TS resemble those of mitral stenosis (MS), with fusion and shortening of the chordae tendineae and fusion of the leaflets at their edges, producing a diaphragm with a fixed central aperture. However, valvular calcification is rare. As with MS, TS is more common in women. The right atrium often is greatly dilated in TS, and its walls are thickened. There may be evidence of severe passive congestion, with enlargement of the liver and spleen.

Pathophysiology

A diastolic pressure gradient between the right atrium and ventricle—the hemodynamic expression of TS—is augmented when the transvalvular blood flow increases during inspiration or exercise. A relatively modest diastolic pressure gradient (i.e., a mean gradient of only 5 mm Hg) usually is sufficient to elevate the mean RA pressure to levels that result in systemic venous congestion and, unless sodium intake has been restricted or diuretics have been given, is associated ultimately with jugular venous distention (JVD), ascites, and edema.

In patients with sinus rhythm, the RA *a* wave may be very tall. Resting cardiac output usually is markedly reduced and fails to rise during exercise. This accounts for the normal or only slightly elevated left atrial (LA), pulmonary artery, and RV systolic pressures, despite the presence of accompanying mitral valvular disease.

A mean diastolic pressure gradient across the tricuspid valve as low as 2 mm Hg, and the typical echocardiographic appearance of leaflet restriction or “doming” is sufficient to establish the diagnosis of TS. Exercise, deep inspiration, and the rapid infusion of fluids or administration of atropine may greatly enhance a borderline pressure gradient in a patient with TS. The diagnosis is generally made with transthoracic echocardiography (TTE); occasionally, transesophageal echocardiography (TEE) or other imaging is necessary. Rarely is invasive assessment necessary.

Clinical Presentation and Diagnosis

Symptoms.

The low cardiac output characteristic of TS causes fatigue, and patients often experience discomfort caused by hepatomegaly, ascites, and anasarca (**Table 70.1**). The severity of these symptoms, which are secondary to an elevated systemic venous pressure, is out of proportion to the degree of dyspnea. Some patients complain of a fluttering discomfort in the neck, caused by giant *a* waves in the jugular venous pulse (JVP). Occasionally, the symptoms of MS (severe dyspnea, orthopnea, and paroxysmal nocturnal dyspnea) may be masked in the presence of severe TS because the latter prevents surges of blood into the pulmonary circulation behind the stenotic mitral valve. The absence of symptoms of pulmonary congestion in a patient with obvious MS should suggest the possibility of TS.

TABLE 70.1

Clinical and Laboratory Features of Rheumatic Tricuspid Stenosis

History
Progressive fatigue, edema, anorexia
Minimal orthopnea, paroxysmal nocturnal dyspnea
Rheumatic fever in two thirds of patients
Female preponderance
Pulmonary edema and hemoptysis rare
Physical Findings
Signs of multivalvular involvement
Diastolic rumble at lower left sternal border, increasing in intensity with inspiration
Often confused with mitral stenosis
Peripheral cyanosis
Neck vein distention, with prominent *a* waves and slow *y* descent
Absent right ventricular lift
Associated murmurs of mitral and aortic valve disease
Hepatic pulsation
Ascites, peripheral edema
Imaging Findings
Electrocardiogram: Tall right atrial P waves and no right ventricular hypertrophy
Chest radiograph: Dilated right atrium without enlarged pulmonary artery segment
Echocardiogram: Diastolic doming of tricuspid valve leaflets, thickening of valve, diastolic pressure gradient across tricuspid valve, right atrial enlargement

Modified from Ockene IS. Tricuspid valve disease. In Dalon JE, Alpert JS, editors. Valvular Heart Disease. 2nd ed. Boston: Little Brown; 1987, pp 356, 390.

Physical Examination.

Because MS occurs frequently in patients with TS and the two valvular lesions have similar physical findings, and because the physical findings in TS are subtle, echocardiography is essential for the diagnosis of TS. The physical findings of TS may be attributed to MS, which is more common and associated with a louder murmur. Therefore a high index of clinical suspicion is required to detect TS. In the presence of sinus rhythm, the *a* wave in the JVP is tall, and a presystolic hepatic pulsation often is palpable. The *y* descent is slow and barely appreciable. The lung fields are clear, and despite engorged neck veins and the presence of ascites and anasarca, the patient may be comfortable while lying flat. Thus the diagnosis of TS may be suspected from inspection of the JVP in a patient with MS but without clinical evidence of pulmonary hypertension. This suspicion is strengthened when a diastolic thrill is palpable at the lower left sternal border, particularly if the thrill appears or becomes more prominent during inspiration.

The auscultatory findings of the accompanying MS usually are prominent and often overshadow the more subtle signs of TS. A tricuspid opening snap (OS) may be audible but often is difficult to distinguish from a mitral OS. However, the tricuspid OS usually follows the mitral OS and is localized to the lower left sternal border, whereas the mitral OS usually is most prominent at the apex and radiates more

widely. The diastolic murmur of TS is also usually heard best along the lower left parasternal border in the fourth intercostal space and usually is softer, higher-pitched, and shorter in duration than the murmur of MS. The presystolic component of the TS murmur has a scratchy quality and a crescendo-decrescendo configuration that diminishes before the first heart sound (S_1). The diastolic murmur and OS of TS both are augmented by maneuvers that increase transtricuspid valve flow, including inspiration, the Müller maneuver (forced inspiration against a closed glottis), assumption of the right lateral decubitus position, leg raising, inhalation of amyl nitrite, squatting, and isotonic exercise. The murmur and OS are reduced during expiration or the strain of the Valsalva maneuver and return to control levels immediately (i.e., within two or three beats) after Valsalva release.

Electrocardiography.

In the absence of atrial fibrillation (AF) in a patient with valvular heart disease, TS is suggested by the presence of electrocardiographic evidence of RA enlargement (**see Chapter 12**). The P wave amplitude in leads II and V_1 exceeds 0.25 mV. Because most patients with TS have mitral valve disease, the electrocardiographic signs of biatrial enlargement are often seen. The amplitude of the QRS complex in lead V_1 may be reduced by the dilated right atrium.

Radiography.

The key radiologic finding is marked cardiomegaly with conspicuous enlargement of the right atrium (i.e., prominence of the right heart border), which extends into a dilated superior vena cava and azygos vein, but without conspicuous dilation of the pulmonary artery. The vascular changes in the lungs characteristic of mitral valvular disease may be masked, with little or no interstitial edema or vascular redistribution, but LA enlargement may be present.

The stenotic tricuspid valve can also be visualized with cardiac magnetic resonance imaging (CMR) or computed tomography (CT) and RA and RV volumes quantified.

Echocardiography

The tricuspid valve should be carefully inspected at echocardiography in any patient with known or suspected rheumatic heart disease or other valve disease known to affect multiple valves. The echocardiographic changes (**see Chapter 14**) of the tricuspid valve in rheumatic TS resemble those observed in the mitral valve in rheumatic MS.[3] Two-dimensional echocardiography characteristically shows diastolic doming of the leaflets (**see Fig. 14.51**), thickening and restricted motion of the other leaflets, reduced separation of the tips of the leaflets, and a reduction in diameter of the tricuspid orifice. The presence of commissural fusion and the anatomy of the valve and subvalvular apparatus should also be assessed, because these features may impact therapy. TEE allows added delineation of the details of valve structure (see Video 70.2, which shows thickening and stenosis of the tricuspid valve and associated thrombus on the lateral aspect of the right atrium), and Doppler echocardiography can be helpful in assessing severity of TS when two-dimensional images are suboptimal. In TS, Doppler echocardiography shows a prolonged slope of antegrade flow and compares well with cardiac catheterization in the quantification of TS and assessment of associated TR. Doppler evaluation of TS has largely replaced the need for catheterization to assess severity. Severe TS is characterized by a valve area of 1 cm^2 or less, as assessed by the continuity equation. The pressure half-time is generally greater than 190 milliseconds, and the right atrium and inferior vena cava are dilated. The mean pressure gradient across the tricuspid valve varies with heart rate, but a mean gradient of 5 mm Hg or greater is consistent with significant TS.[4] Additional assessment of valve morphology may be provided by three-dimensional echocardiography, which allows en face views of the tricuspid valve and simultaneous views of all three

leaflets.[3]

Cardiac Catheterization

Invasive hemodynamic assessment of TS is rarely needed but is appropriate in the symptomatic patient in whom the physical findings and noninvasive data are discordant. It may occasionally be undertaken in patients undergoing invasive hemodynamic assessment for another indication. RA and RV pressures can be recorded simultaneously, using two catheters or a single catheter with a double lumen, with one lumen opening on either side of the tricuspid valve.

Management

Although the fundamental approach to the management of severe TS is surgical treatment, intensive sodium restriction and diuretic therapy may diminish symptoms secondary to accumulation of excess salt and water. If AF is present, ventricular rate control is needed to improve diastolic filling. A preparatory period of diuresis may diminish hepatic congestion, thereby improving hepatic function sufficiently to diminish the risks of subsequent operation.

Most patients with TS have coexisting valvular disease that requires surgery. Surgical treatment of TS should be done at mitral valve repair or replacement in TS patients with mean diastolic pressure gradient exceeding 5 mm Hg and tricuspid orifice less than approximately 2.0 cm^2. The final decision concerning surgical treatment is sometimes made at the operating table.

Because TS almost always is accompanied by some TR, simple finger fracture valvotomy may not result in significant hemodynamic improvement, and may merely substitute severe TR for TS. However, open valvotomy or commissurotomy in which the stenotic tricuspid valve is converted into a functionally bicuspid valve may result in improvement, but annuloplasty may also be necessary if annular dilation is present.[5] The commissures between the anterior and septal leaflets and between the posterior and septal leaflets are opened. It is not advisable to open the commissure between the anterior and posterior leaflets because of the concern of producing severe TR. If open valvotomy does not restore reasonably normal valve function, the tricuspid valve may have to be replaced. A large bioprosthesis is preferred to a mechanical prosthesis in the tricuspid position because of the high risk of thrombosis of the latter and the longer durability of bioprostheses in the tricuspid than in the mitral or aortic positions. Tricuspid balloon valvuloplasty is feasible, but has limited efficacy and may result in significant TR. It may be considered in the rare patient without TR, but because of lack of long-term outcome data, surgical therapy is preferred.

Tricuspid Regurgitation

Causes and Pathology

A trivial to mild amount of TR is frequently seen with echocardiography in patients with a normal right heart and structurally normal tricuspid valve. This is of no consequence and, under normal conditions, does not increase in severity. However, various conditions can lead to greater degrees of TR. The most common cause of TR is *not* intrinsic involvement of the valve itself (i.e., primary TR) but rather dilation of the right ventricle and of the tricuspid annulus causing secondary (functional) TR[6-8] (**Table 70.2**; **see also Fig. 14.52**). Right-sided heart dilation may result from volume overload as seen with left-to-right shunts in atrial septal defects (ASDs) or anomalous pulmonary venous connections. Dilation may be a

complication of RV failure of any cause. It is observed in patients with RV hypertension secondary to any form of cardiac or pulmonary vascular disease. Thus, secondary TR may be seen in mitral valve disease,[8,9] acute or chronic pulmonary thromboembolic disease, or chronic obstructive lung disease. In general, RV systolic pressure greater than 55 mm Hg will cause functional TR. TR can also result from RV infarction, congenital heart disease (e.g., pulmonic stenosis and pulmonary hypertension secondary to Eisenmenger syndrome; **see Chapter 75**), primary pulmonary hypertension (**Chapter 85**), and cor pulmonale. In infants, TR may complicate RV failure secondary to neonatal pulmonary diseases and pulmonary hypertension with persistence of the fetal pulmonary circulation. In all these cases, TR reflects the presence of, and in turn aggravates, severe RV failure. Functional TR may diminish or disappear as the right ventricle decreases in size with the treatment of heart failure. TR can also result from dilation of the annulus in Marfan syndrome, in which RV dilation secondary to pulmonary hypertension is not present.

Modified from Waller BF. Rheumatic and nonrheumatic conditions producing valvular heart disease. In Frankl WS, Brest AN, editors. Cardiovascular Clinics. Valvular Heart Disease: Comprehensive Evaluation and Management. Philadelphia: FA Davis; 1989, pp 35, 95.

A variety of disease processes can affect the tricuspid valve apparatus directly and lead to regurgitation (primary TR).[1,10] Organic TR may occur on a congenital basis (**see Chapter 75**), as part of Ebstein anomaly, defects involving the atrioventricular canal, when the tricuspid valve is involved in the formation of an aneurysm of the ventricular septum, or in corrected transposition of the great arteries, or it may occur as an isolated congenital lesion. Rheumatic fever may involve the tricuspid valve directly. When this occurs, it usually causes scarring of the valve leaflets and chordae tendineae, leading to limited leaflet mobility and either isolated TR or a combination of TR and TS. Rheumatic involvement of the mitral, and often the aortic, valve coexists.

TR may result from prolapse of the tricuspid valve caused by myxomatous changes in the valve and chordae tendineae; mitral valve prolapse (MVP) is usually present in these patients as well. Tricuspid valve prolapse has been estimated to occur in 20% of all patients with MVP, but compared to MVP,

diagnostic criteria are less well defined. Tricuspid valve prolapse also may be associated with ASD.

Distortion of the tricuspid leaflets by transvenous pacemaker and defibrillator leads is an increasingly common cause of clinically significant TR.[11] Injury to the tricuspid valve or subvalvular apparatus may complicate endomyocardial biopsy.

TR or the combination of TR and TS is an important feature of the *carcinoid syndrome* (**Fig. 70.1; see also Fig. 14.53**), which leads to focal or diffuse deposits of fibrous tissue on the endocardium of the valvular cusps and cardiac chambers, as well as on the intima of the great veins and coronary sinus. The white, fibrous carcinoid plaques are most extensive on the right side of the heart, where they usually are deposited on the ventricular surfaces of the tricuspid valve and cause the cusps to adhere to the underlying RV wall, thereby producing TR. A similar process may affect the tricuspid valve in patients who have used drugs that increase serotonin levels or simulate its effect on serotonin receptors (see Video 70.1). These include the anorectic drugs fenfluramine and phentermine, ergot derivatives used for treating migraine headaches (ergotamine, methysergide) or Parkinson disease (pergolide, cabergoline), or the synthetic stimulant and hallucinogen 3,4-methylenedioxymethamphetamine (MDMA, “Ecstasy”).

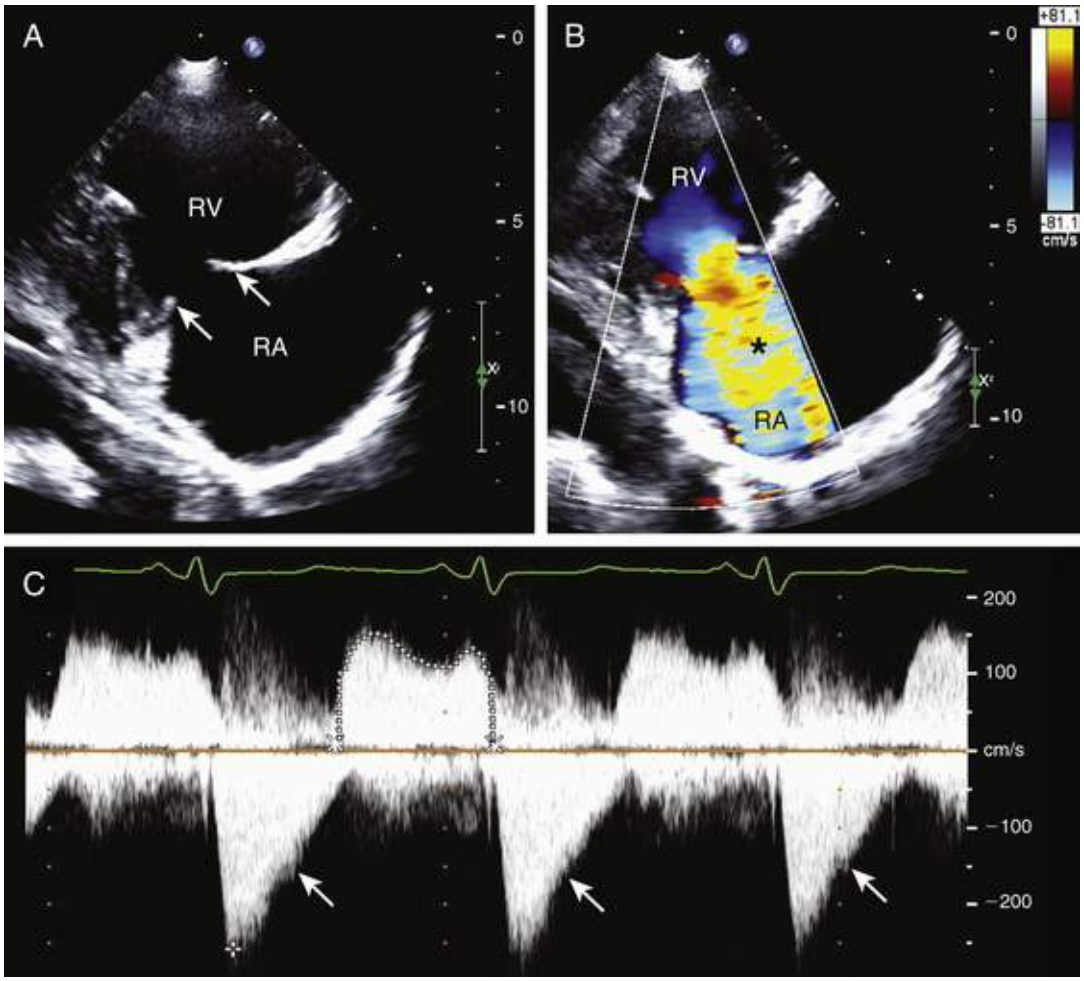

FIGURE 70.1 Transthoracic echocardiographic images of the tricuspid valve in a patient with carcinoid valvular heart disease. **A,** Two-dimensional parasternal long-axis image of the tricuspid valve inflow view in midsystole demonstrates a marked thickening and retraction of the tricuspid valve leaflets (*arrow*), resulting in failure of leaflet closure. **B,** Color Doppler imaging of the tricuspid valve in the parasternal long-axis tricuspid valve inflow view in midsystole demonstrates a broad regurgitant jet that occupies the entire right atrium, consistent with severe tricuspid valve regurgitation (*). *RA,* Right atrium; *RV,* right ventricle. **C,** Continuous-wave Doppler imaging across the tricuspid valve demonstrates a dense, systolic, dagger-shaped tricuspid regurgitant jet consistent with severe TR (*arrow*). Less severe forms of TR are typically associated with parabolic-shaped regurgitant jets. (From Luis SA, Pellikka PA. Carcinoid heart disease: diagnosis and management. Best Pract Res Clin Endocrinol Metab 2016;30:149.)

Other causes of TR include penetrating and nonpenetrating trauma,[12] dilated cardiomyopathy, and infective endocarditis (IE), particularly staphylococcal endocarditis in intravenous (IV) drug users. Endomyocardial fibrosis with shortening of the tricuspid leaflets and chordae tendineae is an important cause of TR in tropical Africa. Less common causes of TR include cardiac tumors (particularly RA myxoma), endomyocardial fibrosis, methysergide-induced valvular disease, and systemic lupus erythematosus involving the tricuspid valve.

Clinical Presentation and Diagnosis

The clinical stages of TR are outlined in **Table 70.3**.[13]

TABLE 70.3

Stages of Tricuspid Regurgitation (TR)

STAGE	DEFINITION	VALVE ANATOMY	VALVE HEMODYNAMICS*	HEMODYNAMIC CONSEQUENCES	SYMPTOMS
A	**At risk of TR**	*Primary:* Mild rheumatic change Mild prolapse Other (e.g., IE with vegetation, early carcinoid deposition, radiation) *Intra-annular:* RV pacemaker or ICD lead Postcardiac transplantation (biopsy related) *Functional:* Normal Early annular dilation	No or trace TR	None	None or in relation to other left heart or pulmonary/pulmonary vascular disease
B	**Progressive TR**	*Primary:* Progressive leaflet deterioration/destruction Moderate to severe prolapse, limited chordal rupture *Functional:* Early annular dilation Moderate leaflet tethering	*Mild TR:* Central jet area <5 cm^2 Vena contracta width not defined CW jet density and contour: soft and parabolic Hepatic vein flow: systolic dominance *Moderate TR:* Central jet area 5-10 cm^2 Vena contracta width not defined, but <0.70 cm CW jet density and contour: dense, variable contour Hepatic vein flow: systolic blunting	*Mild TR:* RV/RA/IVC size normal *Moderate TR:* No RV enlargement No or mild RA enlargement No or mild IVC enlargement with normal respirophasic variation Normal RA pressure	None or in relation to other left heart or pulmonary/pulmonary vascular disease
C	**Asymptomatic, severe TR**	*Primary:* Flail or grossly distorted leaflets *Functional:* Severe annular dilation (>40 mm or 21 mm/m^2) Marked leaflet tethering	*Severe TR:* Central jet area >10 cm^2 Vena contracta width >0.7 cm CW jet density and contour: dense, triangular with early peak Hepatic vein flow: systolic reversal	RV/RA/IVC dilated with decreased IVC respirophasic variation Elevated RA pressure with "*c-v*" wave Diastolic interventricular septal flattening may be present.	None, or in relation to other left-heart or pulmonary/pulmonary vascular disease
D	**Symptomatic, severe TR**	Same as for stage C	Same as for stage C	Same as for stage C Right ventricular systolic function eventually reduced	Fatigue, palpitations, dyspnea, abdominal bloating, anorexia, edema

*Several valve hemodynamic criteria are provided for assessment of TR severity, but not all criteria for each category will necessarily be present in every patient. Classification of TR severity as mild, moderate, or severe also depends on image quality an integration of these parameters with clinical findings.

CW, Continuous-wave; *ICD,* implantable cardioverter-defibrillator; *IE,* infective endocarditis; *IVC,* inferior vena cava; *RA,* right atrium; *RV,* right ventricle.

From Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACCF guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2014;63:e57.

Symptoms.

In the absence of pulmonary hypertension or RV failure, TR generally is well tolerated. When pulmonary hypertension and TR coexist, cardiac output declines and the manifestations of right-sided heart failure become intensified. Thus the symptoms of TR result from a reduced cardiac output and from ascites, painful congestive hepatomegaly, and massive edema. Occasionally, patients exhibit throbbing pulsations in the neck, which intensify on effort and are caused by JVD, and systolic pulsations of the eyeballs also have been described. In the many patients with TR who have mitral valve disease, the symptoms of the

latter usually predominate. Symptoms of pulmonary congestion may abate as TR develops but are replaced by weakness, fatigue, and other manifestations of a depressed cardiac output.

Physical Examination.

In patients with severe TR, evidence of weight loss and cachexia, cyanosis, and jaundice are often present on inspection. AF is common. JVD also is evident, the normal *x* and *x*′ descents disappear, and a prominent systolic wave—a *c*-*v* wave (or *s* wave)—is apparent. The descent of this wave, the *y* descent, is sharp and becomes the most prominent feature of the venous pulse, except with coexisting TS, in which case it is slowed. A venous systolic thrill and murmur in the neck may be present in patients with severe TR. The RV impulse is hyperdynamic and thrusting in quality. Systolic pulsations of an enlarged tender liver are frequently present initially. However, in patients with chronic TR and congestive cirrhosis, the liver may become firm and nontender. Ascites and edema are common.

With auscultation, the murmur of mild TR may be very subtle and of short duration. When TR occurs in the absence of pulmonary hypertension (e.g., in IE or after trauma), the murmur usually is of low intensity and limited to the first half of systole. With greater degrees of TR, auscultation usually reveals a S_3 originating from the right ventricle, which is accentuated by inspiration. When TR is associated with and secondary to pulmonary hypertension, P_2 is accentuated as well, and the systolic murmur usually is high-pitched, pansystolic, and loudest in the fourth intercostal space in the parasternal region (but occasionally is loudest in the subxiphoid area). When the right ventricle is greatly dilated and occupies the anterior surface of the heart, the murmur may be prominent at the apex and difficult to distinguish from that produced by mitral regurgitation (MR).

The response of the systolic murmur to respiration and other maneuvers is of considerable aid in establishing the diagnosis of TR. The murmur characteristically is augmented during inspiration (Carvallo sign), with inspiration associated with an increase in RV size and tricuspid valve annulus dimension, as well as an increase in regurgitant orifice area.[14] However, when the failing ventricle can no longer increase its stroke volume with the patient in the recumbent or sitting position, the inspiratory augmentation may be elicited by standing. The murmur also increases during the Müller maneuver (see earlier), exercise, leg raising, and hepatic compression. It demonstrates an immediate overshoot after release of the Valsalva strain but is reduced in intensity and duration in the standing position and during the strain of the Valsalva maneuver. Increased atrioventricular flow across the tricuspid orifice in diastole may cause a short, early diastolic flow rumble in the left parasternal region following the third heart sound (S_3). Tricuspid valve prolapse, as with MVP, causes nonejection systolic clicks and late systolic murmurs. In tricuspid valve prolapse, however, these findings are more prominent at the lower left sternal border. With inspiration, the clicks occur later, and the murmurs intensify and become shorter in duration.

Electrocardiography.

Changes on the electrocardiogram (ECG) usually are nonspecific and characteristic of the lesion causing TR. Incomplete right bundle branch block, Q waves in lead V_1, and AF are often found.

Radiography.

In patients with functional TR, marked cardiomegaly usually is evident, and the right atrium is prominent. Evidence of elevated RA pressure may include distention of the azygos vein and the presence of a pleural effusion. Ascites with upward displacement of the diaphragm may be present. Systolic RA pulsations may be present on fluoroscopy.

Echocardiography

The goal of echocardiography is to estimate the severity of TR and assess pulmonary artery pressure (PAP) and RV function[6,15] (**see Chapter 14**). In patients with TR secondary to dilation of the tricuspid annulus, the right atrium, right ventricle, and tricuspid annulus all usually are greatly dilated on echocardiography.[15-17] There is evidence of RV diastolic overload with paradoxical motion of the ventricular septum similar to that observed in ASD. Exaggerated motion and delayed closure of the tricuspid valve are evident in patients with Ebstein anomaly. Prolapse of the tricuspid valve caused by myxomatous degeneration may be evident on echocardiography. Echocardiographic indications of tricuspid valve abnormalities, especially TR by Doppler examination, can be detected in the vast majority of patients with carcinoid heart disease (**see Fig. 70.1**). A similar appearance of the tricuspid valve may be seen in patients who have used drugs that increase serotonin levels or simulate its effect on serotonin receptors (see Video 70.1). In patients with TR caused by endocarditis, echocardiography may reveal vegetations on the valve or a flail valve. TEE enhances detection of TR. Doppler echocardiography is a sensitive technique for visualizing the TR jet. The magnitude of TR can be quantified using techniques similar to those used to evaluate MR.[14,17,18]

Cardiac Magnetic Resonance Imaging

CMR is useful for determining the three-dimensional geometric relationships between the right ventricle and the tricuspid annulus and leaflets in patients with functional TR.[19,20]

Hemodynamic Findings

The RA and RV end-diastolic pressures often are elevated in TR, whether the condition is caused by organic disease of the tricuspid valve or is secondary to RV systolic overload. The RA pressure tracing usually reveals absence of the *x* descent and a prominent *v* or *c-v* wave (ventricularization of the atrial pressure). Absence of these findings essentially excludes moderate or severe TR. As the severity of TR increases, the contour of the RA pressure pulse increasingly resembles that of the RV pressure pulse. A rise or no change in RA pressure on deep inspiration, rather than the usual fall, is a characteristic finding.[21] Determination of the pulmonary artery (or RV) systolic pressure may be helpful in deciding whether the TR is primary or secondary to RV dilation. A pulmonary artery or RV systolic pressure less than 40 mm Hg favors a primary cause, whereas a pressure greater than 55 mm Hg suggests that TR is secondary.

Management

TR in the absence of pulmonary hypertension usually is initially well tolerated and may not require surgical treatment. However, if TR is severe and sustained, eventually right-sided heart failure will ensue; thus appropriate consideration of and timing for surgery are indicated (**see Chapter 72**, Guidelines). Functional TR in the setting of pulmonary hypertension is associated with heart failure and poor survival[22,23] (**see Chapter 85**).

Surgical treatment of acquired TR secondary to annular dilation was greatly improved with the development of annuloplasty techniques, with or without an annuloplasty ring.[5,24] Repair rates have increased, especially over the past decade, and tricuspid valve surgery, usually concomitant with another cardiac operation, is the third most frequently performed valve surgery in North America.[8] Tricuspid valve repair accounts for 73% of tricuspid valve operations. For tricuspid valve replacement (TVR),

bioprostheses are increasingly being used and now account for 46% of TVRs.[25] At mitral valve surgery in patients with TR secondary to pulmonary hypertension, the severity of the TR should be assessed. It should be determined whether the TR is secondary to pulmonary hypertension, in which case the valve is normal, or whether it is secondary to other disease processes. Patients with mild TR without annular dilation usually do not require surgical treatment; pulmonary vascular pressures decline after successful mitral valve surgery, and the mild TR tends to disappear. However, even mild TR should be repaired if there is dilation of the tricuspid annulus, because the TR is likely to progress in severity if left untreated.[26]

Excellent results have been reported in patients with mild to moderate TR with the use of suture annuloplasty of the posterior (unsupported) portion of the annulus. Patients with severe TR require ring annuloplasty.[24,27] Surgical mortality rates in the Society of Thoracic Surgeons (STS) National Database decreased from 10.6% in 2000 to 8.2% in 2010 despite increased patient comorbidity.[8] Concomitant surgical procedures, renal and hepatic dysfunction, and preoperative symptomatic status are the principal determinants of surgical risk.[8,19,28] Reoperation is associated with in-hospital mortality of 13.9% but improvement in functional class in survivors.[29] Residual TR after tricuspid annuloplasty is determined principally by the degree of preoperative tricuspid leaflet tethering.[27,30] If these procedures do not provide a good functional result at the operating table, as assessed by TEE, TVR using a large bioprosthesis may be required. Transcatheter approaches to tricuspid valve repair and replacement using various methods and devices are feasible and currently being studied in clinical trials[31,32] (**see Chapter 72**).

When organic disease of the tricuspid valve (Ebstein anomaly or carcinoid heart disease) causes TR severe enough to require surgery, TVR usually is needed. The risk of thrombosis of mechanical prostheses is greater in the tricuspid than in the mitral or the aortic position, presumably because pressure and flow rates are lower in the right side of the heart. For this reason, a bioprosthesis is the valve of choice for the tricuspid position in adults. Graft durability of more than 10 years has been established. Postoperative vitamin K antagonist therapy is recommended after bioprosthetic TVR in patients with carcinoid heart disease because of a potential for thrombosis.[33]

In treating the difficult problem of tricuspid endocarditis in IV drug users (**see Chapter 73**), total excision of the tricuspid valve without immediate replacement generally can be tolerated by these patients, who usually do not have associated pulmonary hypertension. However, management decisions should be made by a heart valve team, including cardiology, cardiac surgery, and infectious disease specialists. Diseased valvular tissue should be excised to eradicate the endocarditis, and antibiotic treatment can then be continued. RV dysfunction will eventually occur if the resultant severe TR is untreated. A bioprosthetic valve may therefore be inserted several months after valve excision and control of the infection.

Pulmonic Stenosis

Causes and Pathology

Congenital pulmonic stenosis (PS) is the most common etiologic type of PS (**see Chapter 75**), with an estimated worldwide birth prevalence of 0.5 per 1000 live births, and a higher prevalence in Asia.[34] Noonan syndrome is associated with PS, and PS may be seen with tetralogy of Fallot, Williams syndrome, and with other congenital heart defects. The pulmonic valve may be bicuspid, unicommissural, acommissural, or dysplastic. Rheumatic inflammation of the pulmonic valve is very uncommon, usually is associated with involvement of other valves, and rarely leads to serious deformity. Carcinoid heart disease often involves the pulmonic valve, and plaques, similar to those involving the tricuspid valve, are

often present in the outflow tract of the right ventricle of patients with malignant carcinoid. The plaques result in constriction of the pulmonic valve annulus, retraction, thickening and fusion of the valve cusps, and a combination of PS and pulmonic regurgitation (PR) (**Fig. 70.2**).[35] Another cause of PS is extrinsic compression by cardiac tumors or by aneurysm of the sinus of Valsalva.

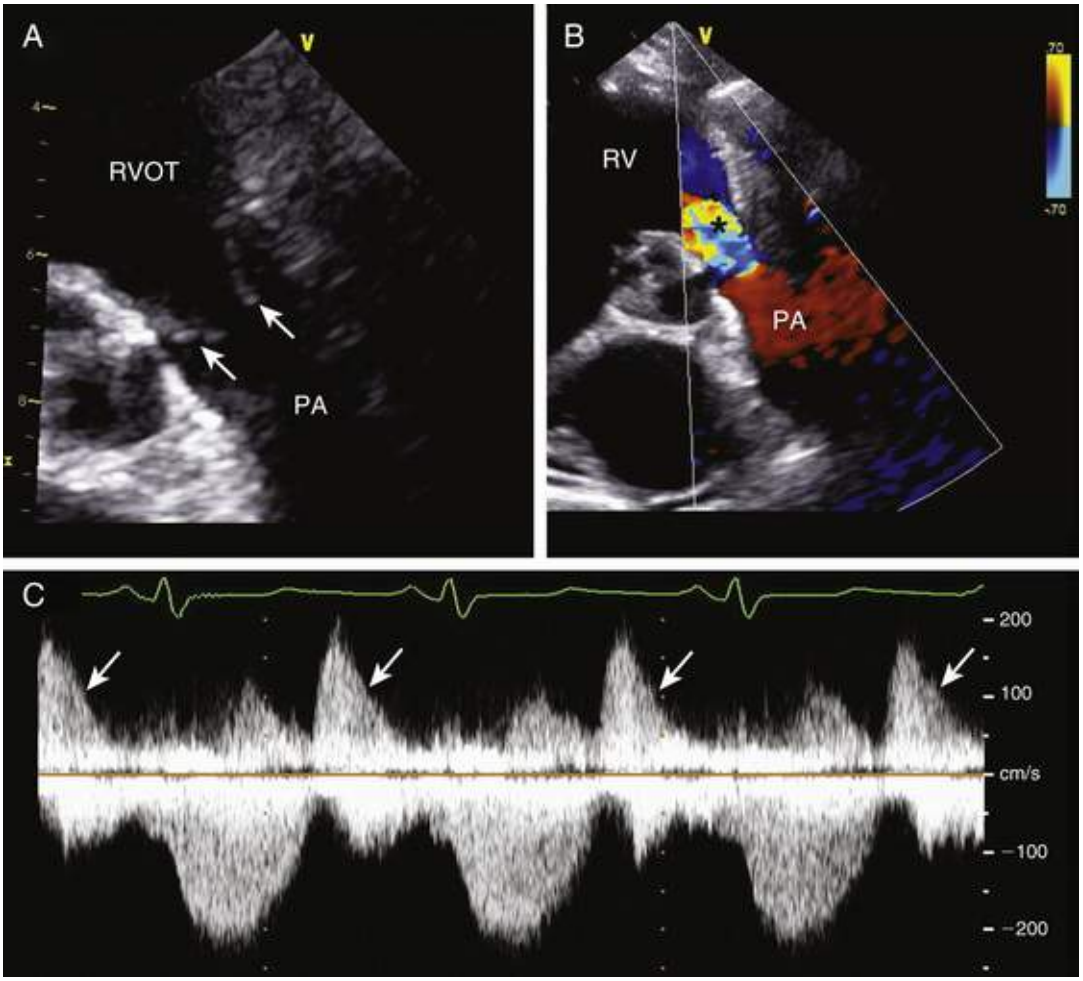

FIGURE 70.2 Transthoracic echocardiography images of the pulmonic valve in a patient with carcinoid heart disease. **A,** Zoomed two-dimensional parasternal short-axis image at the level of the aortic valve shows the pulmonic valve in long axis in mid-diastole, demonstrating a marked thickening with retraction of the pulmonic valve leaflets (*arrow*) and resulting in failure of leaflet closure. **B,** Color Doppler imaging of the pulmonic valve in the same view shows a broad regurgitant jet occupying the entire width of the right ventricular outflow tract (*RVOT*), consistent with severe pulmonic valve regurgitation (*). *RV,* Right ventricle; *PA,* pulmonary artery. **C,** Continuous-wave Doppler imaging across the pulmonic valve demonstrates a dense, diastolic, pulmonary regurgitant jet that returns to baseline before the end of diastole, consistent with severe PR (*arrow*). (From Luis SA, Pellikka PA. Carcinoid heart disease: diagnosis and management. Best Pract Res Clin Endocrinol Metab 2016;30:149.)

Clinical Presentation

Not until PS is severe do symptoms develop, including fatigue, dyspnea, exertional presyncope or syncope, and eventually, right-sided heart failure. The systolic ejection murmur of PS is heard at the left base and increases with inspiration. With increasing severity of PS, the ejection click moves closer to S_1; the click disappears in severe PS. With severe PS, the JVP shows a prominent *a* wave, and a RV lift becomes palpable.

Management

Management of congenital PS focuses on balloon dilation when PS is severe or the patient is symptomatic. For the mixed PS and PR of carcinoid involvement of the pulmonic valve, patch annuloplasty at pulmonic valve replacement (PVR) is frequently advisable.[33] Transcatheter PVR is increasingly being used for PS, atresia, or PR[36] (**see Chapter 72**). Long-term outcome after surgical treatment of PS is excellent.[37]

Pulmonic Regurgitation

Causes and Pathology

Pulmonic regurgitation can result from dilation of the valve ring secondary to pulmonary hypertension (of any cause) or from dilation of the pulmonary artery. IE can involve the pulmonic valve, resulting in valve regurgitation. As more patients with congenital heart disease survive to adulthood (**see Chapter 75**), there is an increasing population of young adults with residual PR after surgical treatment of tetralogy of Fallot (**Fig. 70.3**) or surgical or transcatheter treatment of congenital PS (**see Fig. 14.54**). PR also may result from various lesions that directly affect the pulmonic valve. These include congenital malformations, such as absent, malformed, fenestrated, or supernumerary leaflets. These anomalies may occur as isolated lesions but more often are associated with other congenital anomalies, particularly tetralogy of Fallot, ventricular septal defect (VSD), and valvular PS. Less common causes include trauma; carcinoid syndrome, in which leaflet thickening and retraction result in mixed stenosis and regurgitation (**see Fig. 70.2**); rheumatic involvement; injury produced by a pulmonary artery flow–directed catheter; syphilis; and chest trauma.

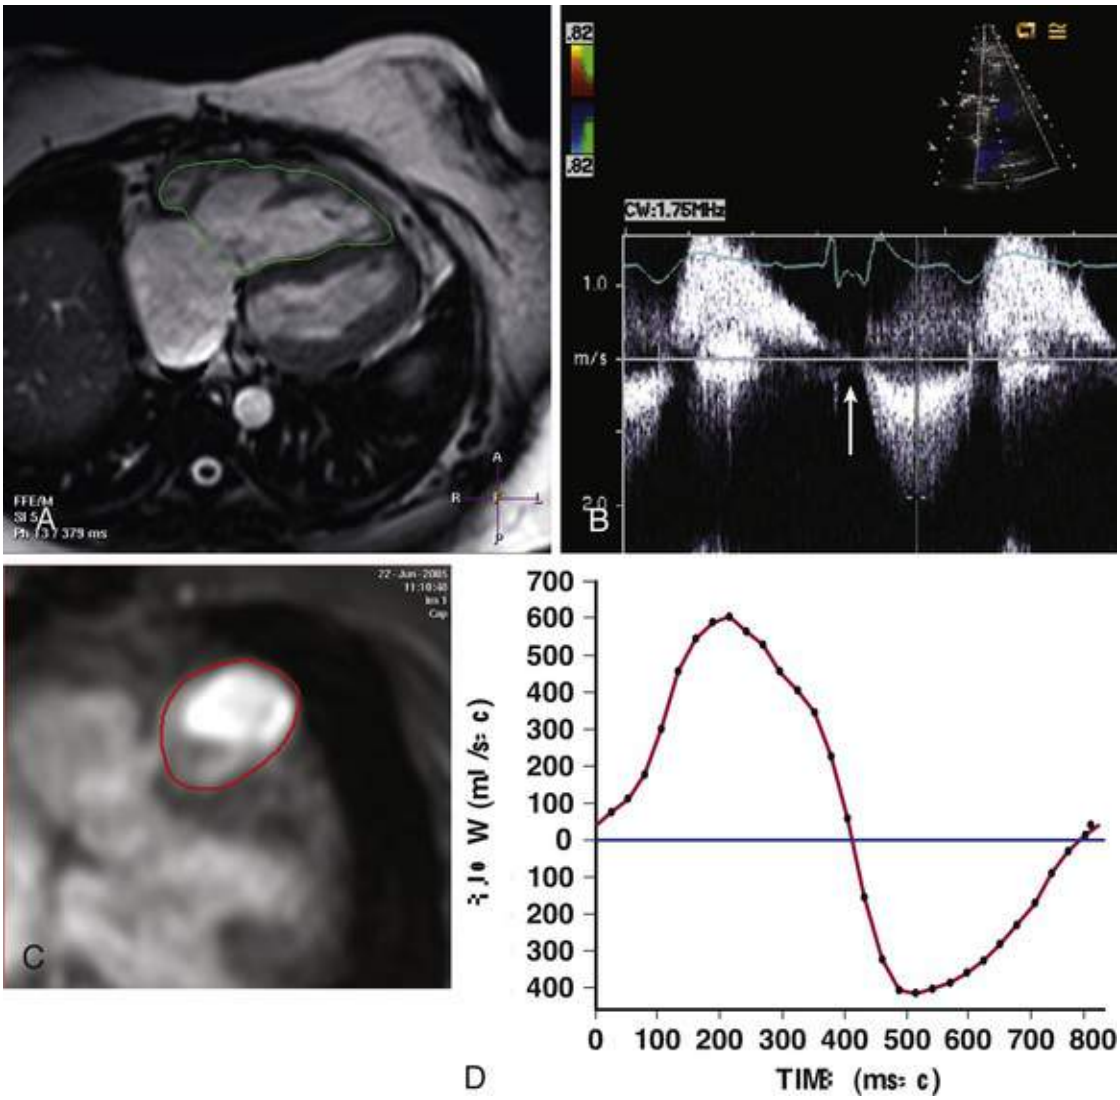

FIGURE 70.3 Cardiac magnetic resonance imaging (CMR) and Doppler echocardiographic evaluation in a 40-year-old woman who underwent repair of tetralogy of Fallot as a child. She was asymptomatic, but significant right ventricular (RV) enlargement was seen on echocardiography. **A,** RV dilation (*green circled area*) is confirmed in the CMR images, with a calculated RV end-diastolic volume of 444 mL. **B,** Doppler tracing shows a dense signal in diastole with a steep deceleration slope that reaches the baseline before the end of diastole (*arrow*). **C,** Interrogation of pulmonary artery flow in the CMR phase-velocity images is performed by drawing a region of interest (*red*) around the pulmonary artery. **D,** Graph of the pulmonary artery flow within the region of interest indicated in **C** demonstrates both antegrade and retrograde flow. The total RV stroke volume was 245 mL, with antegrade flow of 98 mL, yielding a regurgitant fraction of 67%.

Clinical Presentation

As in TR, isolated PR causes RV volume overload and may be tolerated for many years without difficulty unless it complicates, or is complicated by, pulmonary hypertension. In this case, PR usually is accompanied by and aggravates RV failure. Patients with PR caused by IE who develop septic pulmonary emboli and pulmonary hypertension often exhibit severe RV failure. In most patients, the clinical manifestations of the primary disease are severe and usually overshadow the PR.

Physical Examination.

The right ventricle is hyperdynamic and produces palpable systolic pulsations in the left parasternal area, and an enlarged pulmonary artery often produces systolic pulsations in the second left intercostal space.

Sometimes systolic and diastolic thrills are felt in the same area. A tap reflecting pulmonic valve closure usually is easily palpable in the second intercostal space in patients with pulmonary hypertension and secondary PR.

Auscultation.

P_2 is not audible in patients with congenital absence of the pulmonic valve; however, this sound is accentuated in patients with PR secondary to pulmonary hypertension. Wide splitting of S_2 caused by prolongation of RV ejection accompanying the augmented RV stroke volume may be noted. A nonvalvular systolic ejection click generated by the sudden expansion of the pulmonary artery by the augmented RV stroke volume frequently initiates a midsystolic ejection murmur, most prominent in the second left intercostal space. An S_3 and S_4 originating from the right ventricle often are audible, most readily in the fourth intercostal space at the left parasternal area, and are augmented by inspiration.

In the absence of pulmonary hypertension, the diastolic murmur of PR is low-pitched and usually is heard best at the third and fourth left intercostal spaces adjacent to the sternum. The regurgitant murmur reflects the diastolic pressure gradient between the pulmonary artery and the right ventricle; because these pressures are usually lower than left-sided pressures, the murmur of PR is less likely to be heard than that of a similar grade of aortic regurgitation (AR). The PR murmur commences when pressures in the pulmonary artery and right ventricle diverge, approximately 0.04 second after P_2. The murmur becomes louder during inspiration.

When systolic PAP exceeds approximately 55 mm Hg, dilation of the pulmonic annulus results in a high-velocity regurgitant jet, causing the audible murmur of PR, or Graham Steell murmur. This murmur is high-pitched, blowing, and decrescendo, beginning immediately after P_2, and is most prominent in the left parasternal region in the second to fourth intercostal spaces. Thus, although it resembles the murmur of AR, it usually is accompanied by severe pulmonary hypertension—that is, an accentuated P_2 or fused S_2, an ejection sound, and a systolic murmur of TR—and not by a widened arterial pulse pressure. Sometimes, a low-frequency presystolic murmur is present, originating from increased diastolic flow across the tricuspid valve.

The murmur of PR secondary to pulmonary hypertension usually increases in intensity with inspiration, is diminished during the Valsalva strain, and returns to baseline intensity almost immediately after release of the Valsalva strain. This PR murmur resembles and may be confused with the diastolic blowing murmur of AR. However, a diastolic blowing murmur along the left sternal border in patients with rheumatic heart disease and pulmonary hypertension (even in the absence of peripheral signs of AR) usually is caused by AR rather than PR.

Electrocardiography.

In the absence of pulmonary hypertension, PR often results in an ECG that reflects RV diastolic overload—an rSr (or rsR) configuration in the right precordial leads. PR secondary to pulmonary hypertension is usually associated with electrocardiographic evidence of RV hypertrophy.

Radiography.

Both the pulmonary artery and right ventricle are usually enlarged, but these signs are nonspecific. Fluoroscopy may demonstrate pronounced pulsation of the main pulmonary artery.

Cardiac Magnetic Resonance Imaging.

CMR may be used to assess pulmonic valve anatomy, recognize any obstruction above or below the valve, measure pulmonary artery dilation, and quantify PR severity (**see Fig. 70.3**). CMR also is useful in evaluating RV dilation and systolic function.[38]

Echocardiography

A trivial or mild degree of PR can be detected by Doppler echocardiography in most normal patients. With more severe degrees, two-dimensional echocardiography shows RV dilation and, in patients with pulmonary hypertension, RV hypertrophy as well. RV function can be evaluated. Abnormal motion of the septum characteristic of volume overload of the right ventricle in diastole and septal flutter may be evident. The motion of the pulmonic valve may point to the cause of the PR. Absence of *a* waves and systolic notching of the posterior leaflet suggest pulmonary hypertension; large *a* waves indicate PS. Doppler echocardiography is extremely accurate in detecting PR and in helping estimate its severity (**see Figs. 70.2 and 70.3; see also Fig. 14.54**). Severe PR is associated with a reduced pressure half-time, indicating rapid equalization of pressure in the right ventricle and pulmonary artery. Additionally, the density of the Doppler profile of the jet is increased, and reversal of flow in the pulmonary artery by color flow imaging can be detected a distance from the valve. Abnormal Doppler signals in the RV outflow tract, with velocity sustained throughout diastole, are generally observed in patients in whom PR is caused by dilation of the valve ring secondary to pulmonary hypertension. When the velocity falls during diastole, PAP is usually normal, and the regurgitation is caused by an abnormality of the valve itself.

Management

Except in patients with previous surgery for tetralogy of Fallot or similar RV outflow obstruction or for carcinoid heart disease, PR alone is seldom severe enough to require specific treatment. Treatment of the primary condition, such as IE, or the lesion responsible for the pulmonary hypertension, such as surgery for mitral valvular disease, often ameliorates the PR. The timing of surgery for severe PR is based on the degree of RV dilation and evidence of systolic dysfunction.[13,39] In these patients, PVR may be carried out, preferably with a pulmonary allograft. There is growing experience with catheter-based approaches to PVR in native pulmonic valve disease and in PR after surgical correction of congenital heart defects[36] (**see Chapter 72**).

Multivalvular Disease

Various clinical and hemodynamic syndromes can be produced by different combinations of valvular abnormalities. Multivalvular involvement has diverse causes (**Table 70.4**). It frequently is caused by rheumatic fever but is also seen with congenital heart disease, carcinoid heart disease, radiation heart disease, and connective tissue disorders. Myxomatous MR and MVP may be associated with tricuspid valve prolapse and TR, or with pulmonary hypertension, tricuspid annulus dilation, and TR. Marfan syndrome and other connective tissue disorders may cause multivalve prolapse and dilation, resulting in multivalvular regurgitation. Degenerative calcification of the aortic valve may be associated with degenerative mitral annular calcification, resulting in concomitant aortic stenosis (AS) and MR. Different pathologic conditions may affect two valves in the same patient (e.g., IE on the aortic valve causing AR and ischemia causing MR).

TABLE 70.4
Causes of Multivalvular Heart Disease

Acquired
Systemic diseases
Infective endocarditis
Carcinoid heart disease
Systemic lupus erythematosus
Cardiac diseases
Infective endocarditis
Rheumatic heart disease
Degenerative
Calcific diseases, increased with age, prior radiation, chronic kidney disease
Iatrogenic
Adverse drug effects: ergot-related antagonists
Radiation therapy
Functional (annulus dilatation), caused by:
Ischemic heart disease
Hypertensive heart disease
Chronic arrhythmia
Pulmonary hypertension
Cardiomyopathy
Congenital
Connective tissue disorders
Marfan syndrome
Ehlers-Danlos syndrome
Other
Trisomy 18, 13, and 15
Shone syndrome
Ochronosis
Mixed
Multiple conditions may contribute to valve dysfunction, such as:
Degenerative diseases may lead to associated functional disease.
Congenital heart disease may predispose to infective endocarditis or degenerative disease.

In patients with multivalvular disease, the clinical manifestations depend on the relative severity of each of the lesions. When the valvular abnormalities are of approximately equal severity, clinical manifestations produced by the more proximal (upstream) of the two valvular lesions (i.e., the mitral valve in patients with combined mitral and aortic valvular disease and the tricuspid valve in patients with combined tricuspid and mitral valvular disease) are generally more prominent than those produced by the distal lesion. Thus the proximal lesion tends to mask the distal lesion.

It is important to recognize multivalvular involvement preoperatively because failure to correct all significant valvular disease at the time of operation increases mortality. Specific guideline recommendations exist for concomitant valve surgery in patients undergoing surgery on another valve.[13,40] In patients with multivalvular disease, the relative severity of each lesion may be difficult to estimate by clinical examination because one lesion may mask the manifestations of the other. Therefore, patients with suspected multivalvular involvement being considered for surgical treatment should undergo careful clinical evaluation and full Doppler echocardiographic evaluation. Stress echocardiography is well suited for the assessment of multivalvular disease and may be especially useful when the patient's symptoms are disproportionate to the resting hemodynamics. Mixed stenotic and regurgitant lesions can be assessed with a combination of two- and three-dimensional imaging, including planimetry of stenotic orifices, color flow imaging, and Doppler. Multiple valves can be systematically assessed during exercise;[41] this is particularly helpful in assessing the patient with exertional symptoms, especially when these seem disproportionate to findings on imaging at rest. Right and left cardiac catheterization may occasionally be necessary. If there is any question concerning the presence of significant AS in patients undergoing mitral valve surgery, the aortic valve should be inspected, because overlooking this condition can lead to a high perioperative mortality. Similarly, it is useful to palpate the tricuspid valve at mitral valve surgery. Intraoperative TEE is also important for assessing the impact of repair of one valve lesion on another.

Mitral Stenosis and Aortic Valve Disease

Aortic valve involvement is present in approximately one third of patients with rheumatic MS. Rheumatic aortic valve disease may result in primary regurgitation, stenosis, or mixed stenosis and regurgitation. AR is evident on physical examination in approximately two thirds of patients with severe MS, but is severe in only approximately 10%. Since a proximal lesion may mask signs of a distal lesion on physical examination, significant AR may be missed in patients with severe MS because the widened pulse pressure may be absent. An accentuated S_1 and an OS in a patient with AR should suggest mitral valvular disease. AS is evident on physical examination based on the typical murmur, even when MS is present; however, cardiac output tends to be reduced more than in patients with isolated AS. On physical examination, an S_4 (which is common in patients with pure AS) usually is not present. The midsystolic murmur characteristic of AS may be reduced in intensity and duration because the stroke volume is reduced by the MS.

Echocardiography is of decisive value in the evaluation of patients with rheumatic disease and allows accurate diagnosis of the presence and severity of multivalve involvement, taking into consideration the altered flow conditions with serial lesions. For example, the gradient across the stenotic aortic valve may be relatively low when MS is present because of a low cardiac output; valve area calculations are especially helpful in this setting.

Because double-valve replacement is associated with increased short- and long-term risks, balloon mitral valvuloplasty (BMV) can be the first procedure if MS is the predominant lesion, with subsequent aortic valve replacement (AVR) when needed. If percutaneous BMV is not an option or concurrent AVR is needed, surgical valvotomy may be considered as an option.

It is vital to recognize the presence of hemodynamically significant aortic valvular disease (i.e., AS, AR) preoperatively in patients who are to undergo BMV. This procedure may be hazardous because it can impose a sudden hemodynamic load on the left ventricle that had previously been protected by the MS and may lead to acute pulmonary edema.

Aortic Stenosis and Mitral Regurgitation

AS is often accompanied by MR caused by MVP, annular calcification, rheumatic disease, or functional MR. The increased LV pressure secondary to LV outflow obstruction may augment the volume of MR flow, whereas the presence of MR may diminish the ventricular preload necessary for maintenance of the LV stroke volume in patients with AS. The result is a reduced forward cardiac output and marked LA and pulmonary venous hypertension. Significant MR is one explanation for low-output AS[42] (**see Chapter 68**). The development of AF (caused by LA enlargement) has an adverse hemodynamic effect in the presence of AS. Physical findings may be confusing because it may be difficult to recognize two distinct systolic murmurs. However, on echocardiography, the cause and severity of AS and MR can be accurately diagnosed. In most patients, MR is mild to moderate, and it is appropriate to treat AS alone. When MR is severe or there is significant structural mitral valve disease, concurrent mitral repair (whenever possible) or valve replacement at the time of AVR should be considered.

Aortic and Mitral Regurgitation

The relatively infrequent combination of AR and MR may be caused by rheumatic heart disease, prolapse of both the aortic and the mitral valves secondary to myxomatous degeneration, or dilation of both annuli in patients with connective tissue disorders. The clinical features of AR usually predominate, and it is sometimes difficult to determine whether the MR is caused by organic involvement of this valve or by

dilation of the mitral valve ring secondary to LV enlargement. When both valvular leaks are severe, this combination of lesions is poorly tolerated. The normal mitral valve ordinarily serves as a backup to the aortic valve, and premature (diastolic) closure of the mitral valve limits the volume of reflux that occurs in patients with acute AR. With severe combined regurgitant lesions, regardless of the cause of the mitral lesion, blood may reflux from the aorta through both chambers of the left side of the heart into the pulmonary veins. Physical and laboratory examinations usually show evidence of both lesions. An S_3 and a brisk arterial pulse frequently are present. The relative severity of each lesion can be assessed best by Doppler echocardiography, especially using proximal isovelocity surface area (PISA) or vena contracta methods, three-dimensional imaging, or contrast angiography. This combination of lesions leads to severe LV dilation. MR that occurs in patients with AR secondary to LV dilation often regresses after AVR alone. If severe, the MR may be corrected by annuloplasty at AVR. An intrinsically normal mitral valve that is regurgitant because of a dilated annulus should not be replaced.

Surgical Treatment of Multivalvular Disease

Replacement or repair of multiple valves presently comprises 12% of valve procedures and usually is associated with a higher risk and poorer survival than replacement of either of the valves alone.[43] The operative risk of double-valve replacement is approximately 70% higher than for single-valve replacement. The STS National Database Committee has reported an overall operative mortality rate of 9.6% for multivalve (usually double-valve) replacement in 3840 patients, compared with 3.2% and 5.7% for isolated AVR and mitral valve replacement, respectively.[44,45] The long-term survival depends strongly on the preoperative functional status. Patients operated on for combined AR and MR have poorer outcomes than patients undergoing double-valve replacement for any of the other combinations of lesions, presumably because both AR and MR may produce irreversible LV damage. Mitral valve repair or, in the case of MS, BMV performed in combination with AVR may be preferable to double-valve replacement and should be considered. Moreover, it should be expected that most patients will experience some decrease in functional MR severity after AVR. In the setting of planned AVR, management of coexistent MR should take into consideration the severity of MR, its mechanism, operative risks and comorbidities.[46] Risk factors that reduce long-term survival after double-valve replacement include advanced age, less favorable functional status, decreased LV ejection fraction, greater LV enlargement, and accompanying ischemic heart disease requiring coronary artery bypass grafting.[45,47]

In view of the higher risks, a higher threshold is required for multivalvular versus single-valve surgery. Thus patients generally are advised not to undergo multivalvular surgery until they reach late New York Heart Association (NYHA) Class II or III, unless they exhibit evidence of declining LV function. Despite a detailed noninvasive and invasive workup, the decision to treat more than one valve often is made on the basis of findings on palpation or direct inspection at the operating table, or the findings on intraoperative TEE.

Prosthetic Heart Valves

Philippe Pibarot, Patrick T. O'gara

The past six decades have witnessed significant advancements in patient survival and functional outcomes following heart valve replacement surgery.[1] Continued refinements in prosthetic valve design and

performance, operative techniques, myocardial preservation, systemic perfusion, cerebral protection, and anesthetic management have enabled the application of surgical and transcatheter valve therapy to an increasingly wider spectrum of patients. Minimally invasive surgical approaches and the aggressive use of primary valve repair when anatomically appropriate are now routine practice in the vast majority of high-volume centers. Heart valve teams have been formed to provide multidisciplinary assessment and treatment of complex patients, including with the use of transcatheter heart valve replacement or repair when appropriate[2] (**see Chapter 72**). More than 43,000 aortic or mitral valve replacement operations (with or without coronary artery bypass) were reported to the Society of Thoracic Surgeons (STS) National Adult Cardiac Database in 2015.[3] Familiarity with the specific hemodynamic attributes, durability, thrombogenicity, and inherent limitations of currently available heart valve substitutes, as well as their potential for long-term complications, is critical to appropriate clinical decision making for patients in whom repair is not appropriate or feasible. The choice of valve prosthesis is inherently a trade-off between durability and risk of thromboembolism, with the associated hazards and lifestyle limitations of anticoagulation. The ideal heart valve substitute remains an elusive goal.

Types of Prosthetic Heart Valves

Mechanical Valves

The three basic types of mechanical prosthetic valves are bileaflet, tilting disc, and caged ball (**Fig. 71.1**; **see also Fig. 14.55**). The St. Jude bileaflet valve was first used in 1977 and is the most frequently implanted mechanical prosthesis worldwide. It consists of two pyrolytic semicircular “leaflets” or discs with a slitlike central orifice between the two leaflets and two larger semicircular orifices laterally. The opening angle of the leaflets relative to the annulus plane ranges from 75 to 90 degrees. The CarboMedics valve is a variation of the St. Jude prosthesis that can be rotated to prevent limitation of leaflet excursion by subvalvular tissue. For a given valve annulus size, effective orifice area (EOA) is generally larger and transprosthetic pressure gradient lower for the bileaflet mechanical valves compared to the tilting disc valves. Because the central orifice is smaller than the lateral orifices in bileaflet valves, the blood flow velocity may be locally higher within the inflow aspect of the central orifice; this phenomenon may lead to overestimation of gradient and underestimation of EOA by transthoracic echocardiography (TTE)[4,5] (**see Chapter 14**). Bileaflet valves typically have a small amount of normal regurgitation (“washing jet”), designed in part to decrease the risk of thrombus formation. A small, central jet and two converging jets emanating from the hinge points of the discs can be visualized on color Doppler flow imaging.

Latib A, Naganuma T, Abdel-Wahab M, et al. Treatment and clinical outcomes of transcatheter heart valve thrombosis. Circ Cardiovasc Interv 2015;8:1-8; **N,** courtesy Gosta Petterson, Cleveland Clinic.)

Tilting disc or monoleaflet valves use a single, circular disc that rotates within a rigid annulus to occlude or open the valve orifice. The disc is secured by lateral or central metal struts. The opening angle of the disc relative to the valve annulus ranges from 60 to 80 degrees, resulting in two orifices of different size. The nonperpendicular opening angle of the valve occluder tends to slightly increase the resistance to blood flow, particularly in the major orifices. Tilting disc valves also have a small amount of

regurgitation, arising from small gaps at the perimeter of the valve.

The bulky Starr-Edwards ball-in-cage valve, the oldest commercially available prosthetic heart valve first used in 1965, is now very rarely implanted. The ball-cage valve is more thrombogenic and has less favorable hemodynamic performance characteristics than either bileaflet or tilting disc valves.

Currently available mechanical valves have excellent, long-term durability, with up to 45 years for the Starr-Edwards valve and more than 30 years for the St. Jude valve. Structural deterioration, exemplified by some older-generation Björk-Shiley (strut fracture with disc embolization) and Starr-Edwards (ball variance) prostheses, is now extremely rare. Ten-year freedom from valve-related death exceeds 90% for both St. Jude and CarboMedics bileaflet valves. All patients with mechanical valves require lifelong anticoagulation with a vitamin K antagonist (VKA). Long-term issues associated with mechanical valves include infective endocarditis, paravalvular regurgitation (PVR), hemolytic anemia, thromboembolism/valve thrombosis, pannus ingrowth, and hemorrhagic complications related to anticoagulation.

Tissue Valves

Tissue or biologic valves include stented and stentless bioprostheses (porcine, bovine), homografts (or allografts) from human cadaveric sources, and autografts of pericardial or pulmonic valve origin (**see Fig. 71.1**; **see also Fig. 14.57**). Tissue valves provide an alternative, less thrombogenic heart valve substitute that does not require long-term anticoagulation in the absence of additional risk factors for thromboembolism.

Stented Bioprosthetic Valves

The traditional design of a heterograft valve consists of three biologic leaflets made from the porcine aortic valve or bovine pericardium treated with glutaraldehyde to reduce its antigenicity. The leaflets are mounted on a metal or polymeric stented ring; they open to a circular orifice in systole, resembling the anatomy of the native aortic valve (**see Fig. 71.1**). The vast majority of bioprosthetic valves are treated with anticalcifying agents or processes. The newer generations of bovine pericardial valves (Carpentier-Edwards Magna or St. Jude Trifecta) offer improved hemodynamic performance compared with earlier-generation bioprostheses. A small degree of regurgitation can be detected by color Doppler flow imaging in 10% of normally functioning bioprostheses. One limitation of earlier generations of bioprosthetic valves was their limited durability due to *structural valve deterioration* (SVD), typically beginning within 5 to 7 years after implantation, but varying by position and age at implant, with tissue changes characterized by calcification, fibrosis, tears, and perforations. SVD occurs earlier for mitral than for aortic bioprosthetic valves, perhaps because of exposure of the mitral prosthesis to relatively higher left ventricular (LV) closing pressures. The process of SVD is accelerated in younger patients, in those with disordered calcium metabolism (end-stage renal disease), and possibly in pregnant women, independent of younger age. With newer-generation bioprosthetic pericardial valves, the durability is excellent, with SVD rates of 2% to 10% at 10 years, 10% to 20% at 15 years, and 40% at 20 years.[6,7]

Stentless Bioprosthetic Valves

The rigid sewing ring and stent-based construction of certain bioprostheses allow for easier implantation and maintenance of the three-dimensional relationships of the leaflets. However, these features also contribute to impaired hemodynamic performance. Stentless porcine valves were developed in part to

address these issues (**see Fig. 71.1**). Their use has been restricted to the aortic position. Implantation is technically more challenging, whether deployed in a subcoronary position or as part of a miniroot, and thus these valves are preferred by only a minority of surgeons. Early postoperative mean gradients can be less than 15 mm Hg, with further improvement in valve performance over time from aortic root remodeling, lower peak exercise transvalvular gradients, and more rapid reduction in LV mass.[8] Sutureless bioprosthetic valves have also been developed to decrease the complexity and duration of implantation of bioprosthetic valves (**see Fig. 71.1**).

Homografts

Aortic valve homografts are harvested from human cadavers within 24 hours of death and are treated with antibiotics and cryopreserved at −196°C. They are now usually implanted in the form of a total root replacement with reimplantation of the coronary arteries. Homograft valves appear resistant to infection and are preferred by some surgeons for management of aortic valve and root endocarditis in the active phase. Neither immunosuppression nor routine anticoagulation is required. Despite earlier expectations, long-term durability beyond 10 years is not superior to that for current-generation pericardial valves,[9] and reoperation may be technically more challenging.

Autografts

In the Ross procedure the patient's own pulmonic valve or autograft is harvested as a small tissue block containing the pulmonic valve, annulus, and proximal pulmonary artery and is inserted in the aortic position, usually as a complete root replacement with reimplantation of the coronary arteries.[9] The pulmonic valve and right ventricular outflow tract are then replaced with either an aortic or pulmonic homograft. Thus the procedure requires two separate valve operations, a longer time on cardiopulmonary bypass, and a steep learning curve. With appropriate selection of young patients by expert surgeons at experienced centers of excellence, operative mortality rates are less than 1% and 20-year survival rates as high as 95%, similar to the general population.[10] Advantages of the autograft include the ability to increase in size during childhood growth, excellent hemodynamic performance characteristics, lack of thrombogenicity, and resistance to infection. The hemodynamic performance characteristics of the pulmonary autograft are similar to those of a normal, native aortic valve. The procedure is usually reserved for children and young adults, but should be avoided in patients with dilated aortic roots, given the unacceptably high incidence of accelerated degeneration, pulmonary autograft dilation, and significant regurgitation.

Transcatheter Bioprosthetic Valves

Transcatheter aortic valve replacement (TAVR) is a valuable alternative to surgical aortic valve replacement in patients with symptomatic severe aortic stenosis (AS) considered to be at extreme, high, or intermediate surgical risk (**see Chapter 72**). Two main types of transcatheter aortic valves are currently used: balloon-expandable valves and self-expanding valves (**see Fig. 71.1**).

The Edwards SAPIEN XT and SAPIEN 3 balloon-expandable valves consist of a three-leaflet pericardial bovine valve mounted in a cobalt chromium frame. These valves are available in 20, 23, 26 and 29 mm sizes. Common access routes for TAVR are transfemoral, transapical, and transaortic. Approximately 75% to 80% of TAVR procedures are now performed by a transfemoral approach. As catheter sheath sizes decrease (now 14F or 16F for most valves), the balance is anticipated to shift even more toward the transfemoral approach. The transfemoral approach is associated with lower mortality

and quicker recovery compared to alternative access approaches.

The CoreValve balloon-expandable valve consists of three leaflets of porcine pericardium seated relatively higher in a nitinol frame to provide true supra-annular placement and is available in 26, 29, and 31 mm sizes. The CoreValve is most frequently implanted using the transfemoral approach.

For a given aortic annulus size, transcatheter valves have larger EOAs and lower gradients compared to surgical bioprosthetic valves.[11] PVR, however, occurs much more often following TAVR (**see Fig. 14.61**) and has adverse long-term consequences.[12] Mild regurgitation occurs in 25% to 60% of patients and moderate or severe regurgitation in 3% to 20%.[13,14] Moderate or severe PVR is associated with a 2.0- to 2.5-fold increase in mortality.[13] The most recent transcatheter balloon-expandable valve (SAPIEN 3) was designed with a skirt to reduce PVR. The rate of moderate or severe regurgitation has dropped to less than 3% with its use.[15] Some studies suggest that self-expanding valves have slightly larger EOAs and lower gradients but somewhat higher rates of PVR than balloon-expandable valves.[16]

Comparison of Mechanical and Tissue Valves

Obvious differences between valve types relate to durability (i.e., indefinite for mechanical versus limited for tissue valves) and need for anticoagulation (i.e., obligatory for mechanical versus none for tissue valves absent other risk factors for thromboembolism). Short- to intermediate-term hemodynamic performance characteristics with low-profile mechanical prostheses (e.g., St. Jude) are comparable to those with stented tissue valves of similar size. There are no important differences in rates of *prosthetic valve endocarditis* (PVE) (**see Chapter 73**), although some series have suggested a higher incidence of early (<1 year) infection with mechanical valves versus bioprostheses.[17] In the U.S. Veterans Affairs randomized trial conducted between 1977 and 1982, patients undergoing aortic valve replacement (AVR) had a better 15-year survival with a mechanical valve than with a bioprosthetic valve, whereas there was no difference in survival with mechanical versus biologic mitral valve replacement (MVR) (see Classic Reference, Hammermeister). With AVR, the increased mortality among patients allocated a bioprosthesis was driven largely by the higher rate of SVD. There was an increased risk of bleeding with mechanical valve replacement, but no significant differences were observed for other valve-related complications such as thromboembolism or PVE. A more recent, smaller randomized trial of patients 55 to 70 years of age with aortic valve disease also showed no difference in late survival between newer-generation mechanical and bioprosthetic valves, with higher rates of SVD and reoperation in patients with bioprostheses but no other differences in secondary endpoints.[18] In an analysis of more than 39,000 AVR patients age 65 to 80 years reported to the STS Adult Cardiac Surgery Database and linked to Medicare, patients receiving a bioprosthesis had a similar adjusted risk for death, higher risks for reoperation and endocarditis, and lower risks for stroke and bleeding, compared with patients receiving a mechanical valve.[19] Two propensity-matched analyses from New York's Statewide Planning and Research Cooperative System (SPARCS) reported no survival differences for patients 50 to 69 years of age undergoing mechanical versus bioprosthetic, AVR or MVR.[20,21] Rates of stroke and bleeding were higher, whereas rates of reoperation were lower, among mechanical valve recipients. A survival advantage among patients in this age-group who underwent mechanical rather than bioprosthetic valve replacement, however, was reported from the Swedish system for the Enhancement and Development of Evidence-Based Care in Heart Disease Evaluated According to Recommended Therapies (SWEDEHEART) registry.[22] Stroke risk was similar between the groups, although bleeding rates were higher and the need for reoperation was lower after mechanical valve replacement.

Comparison of Surgical and Transcatheter Valves

TAVR is well established for the treatment of high-risk and inoperable patients with symptomatic severe AS[2,12,23] (**see Chapter 72**). Furthermore, recent trials have shown that TAVR is equivalent or superior to surgical AVR in patients at intermediate surgical risk.[15,24,25] In these trials, TAVR with transfemoral access resulted in a lower incidence of death or stroke, whereas with transthoracic access, outcomes were similar for surgical and transcatheter valve replacement. TAVR also resulted in larger EOAs and lower rates of acute kidney injury, severe bleeding, and new-onset atrial fibrillation than did surgical AVR. Surgical AVR resulted in fewer major vascular complications and less paravalvular aortic regurgitation.

Choice of Valve Replacement Procedure and Prosthesis

Once the indication for valve replacement is established, the next step is to select the type of procedure (repair versus replacement) and the type of prosthetic valve should replacement be necessary.[2] The 2014 American Heart Association and American College of Cardiology (AHA/ACC) guidelines for the management of patients with valvular heart disease advocate shared (patient-cardiologist–cardiac surgeon) decision making on the choice of intervention (repair or replacement, transcatheter or surgical) as well as the type of prosthetic valve (mechanical valve or bioprosthesis).[2,26] This choice is based on consideration of several factors, including valve durability, expected hemodynamics for a specific valve type and size, surgical or interventional risk, the potential need for long-term anticoagulation, and patient preferences.

Choice of Procedure

In patients with severe AS having an indication for AVR (**see Chapter 68**), the choice between surgical AVR versus TAVR is based on the predicted surgical risk, which is assessed by combining the STS-PROM estimate (http://riskcalc.sts.org/stswebriskcalc/), patient frailty, major organ system dysfunction, and procedure-specific impediments.[2] TAVR is recommended in patients who meet an indication for AVR for severe AS and who have a prohibitive surgical risk and a predicted post-AVR survival longer than 1 year. Surgical AVR or TAVR is recommended for patients with high surgical risk, depending on patient-specific procedural risks and preferences. TAVR is a reasonable alternative to surgical AVR for intermediate-risk patients, whereas surgical AVR is recommended for patients with low surgical risk.[26]

In patients with chronic severe primary mitral regurgitation (MR) who meet an indication for mitral valve surgery (**see Chapter 69**), mitral valve repair is recommended over MVR when a successful and durable repair can be accomplished.[2] In patients with chronic secondary MR, MVR may actually be superior to mitral valve repair because it is associated with lower rates of recurrent MR.[27]

Tricuspid valve annuloplasty repair is frequently performed at left-sided valve surgery when tricuspid regurgitation (TR) is severe or when there is significant tricuspid annular dilation (>40 mm) despite only mild or moderate degrees of TR[2] (**see Chapter 70**). Tricuspid valve replacement is undertaken for severe disease that cannot be repaired, such as with advanced rheumatic disease, carcinoid, or destructive endocarditis.

Surgical or transcatheter pulmonic valve replacement in the adult is rare.

Choice of Prosthetic Valve

A bioprosthesis is recommended in patients of any age in whom anticoagulant therapy is contraindicated, cannot be managed appropriately, or is not desired.[2,26] A mechanical prosthesis is reasonable for AVR or MVR in patients younger than 50 who do not have a contraindication to anticoagulation, whereas a bioprosthesis is reasonable in patients older than 70 years.[26] Either a bioprosthetic or a mechanical valve is reasonable in patients between 50 and 70 years old. A bioprosthesis is reasonable for young women contemplating pregnancy to avoid the hazards of anticoagulation in this setting.

Medical Management and Surveillance After Valve Replacement

Antithrombotic Therapy

General Principles

Table 71.1 presents the antithrombotic regimen that is recommended in the 2014 AHA/ACC guideline for the different types of procedures and prosthetic valves.[2] All patients with mechanical heart valves require lifelong anticoagulation with a VKA, the intensity of which varies as a function of valve type or thrombogenicity, valve position and number, and the presence of additional risk factors for thromboembolism, such as atrial fibrillation, LV systolic dysfunction, a history of thromboembolism, and hypercoagulable state. Anticoagulant therapy with oral direct thrombin inhibitors or anti-Xa agents should not be used in patients with mechanical prostheses[2] (**see Chapter 93**). Although there is no clear consensus, a VKA may be used even in the absence of risk factors for thromboembolism for the first 3 to 6 months after bioprosthetic AVR or MVR.[26] Longer-term treatment of low-risk bioprosthetic AVR and MVR patients consists of low-dose aspirin, although there are no data to support this practice.

TABLE 71.1

Antithrombotic Therapy in Patients with Prosthetic Valves

PROSTHETIC VALVE	VKA (TARGET INR)	ASPIRIN (75-100 mg)	CLOPIDOGREL (75 mg)	CLASS
Mechanical Valves				
AVR: Bileaflet or current-generation single–tilting disc valves and no risk factors for thromboembolism*	Yes (INR: 2.5)	Yes	No	I
AVR: Older-generation valves† and/or any risk factor for thromboembolism*	Yes (INR: 3.0)	Yes	No	I
MVR: Mechanical valves	Yes (INR: 3.0)	Yes	No	I
AVR: On-X valve and no risk factors for thromboembolism	Yes (INR: 1.5-2.0)	Yes	No	IIb
Bioprosthetic Valves				
AVR or MVR: first 3 to 6 months	Yes (INR 2.5)	Yes	No	IIa
AVR or MVR: after first 3 to 6 months	No	Yes	No	I
Transcatheter Aortic Valves				
First 3 months	Yes	Yes	Yes	IIb
First 3-6 months	No	Yes	Yes	IIb
After first 6 months	No	Yes	No	IIb

*Risk factors for thromboembolism: atrial fibrillation, left ventricular (LV) dysfunction (LV ejection fraction ≤35%), left atrial (LA) dilation (LA diameter ≥50 mm), previous thromboembolism, and hypercoagulable condition.

†Ball-in-cage valves, older generation of single–tilting disc valves.

AVR, Aortic valve replacement; *MVR*, mitral valve replacement; *INR*, international normalized ratio; *VKA*, vitamin K antagonist.

From Nishimura RA, Otto CM, Bonow RO et al. 2017 AHA/ACC focused update of the 2014 AHA/ACC guideline on the management of patients with valvular heart disease. J Am Coll Cardiol 2017;70:252-89.

Interruption of Antithrombotic Therapy

In the planned interruption of VKA therapy for noncardiac surgery, the following must be taken into account: the nature of the procedure; the magnitude of risk of thromboembolism based on valve type, position, and number; underlying patient risk factors; and the competing risk of periprocedural hemorrhage.[2] Low-risk patients with low-profile bileaflet or tilting disc valves in the aortic position can usually stop VKA therapy 3 to 5 days before noncardiac surgery and then resume it postoperatively as soon as considered safe, without the need for a heparin "bridge." In all other patients, either low-molecular-weight heparin (LMWH) or intravenous unfractionated heparin (UFH) should be given both before and after surgery, as directed by the surgeon. The use of LMWH avoids the need for preoperative hospitalization. Randomized trial data are sparse and institutional/operator variability is great regarding the use of bridging strategies for noncardiac surgery in such patients.

Pregnancy

Pregnant patients with prosthetic valves should be followed carefully because of the increased hemodynamic burden that can cause or worsen heart failure if there is prosthetic valve dysfunction or if the hypercoagulable state related to pregnancy increases the risk of valve thrombosis (**see Chapter 90**). All antithrombotic regimens carry an increased risk to the fetus, an increased risk of miscarriage, and hemorrhagic complications for the mother. Therefore, patients require appropriate counseling, close monitoring, and adjustment of anticoagulation therapy. In pregnant patients with mechanical valves, warfarin is reasonable (class IIa) in the first trimester if the dose is 5 mg/day or less and is recommended (class I) to achieve a therapeutic international normalized ratio (INR) target in the second and third

trimesters. Discontinuation of warfarin with initiation of intravenous UFH is recommended before planned vaginal delivery in pregnant patients with a mechanical valve.

Infective Endocarditis Prophylaxis

Patients with prosthetic valves are at increased risk for infective endocarditis because of the foreign valve surface and sewing ring. Antibiotic prophylaxis is only indicated (class IIa) for patients with prosthetic valves who undergo dental procedures that involve manipulation of gingival tissue, the periapical region of teeth, or perforation of the oral mucosa (**see Chapter 73**) Prophylaxis is no longer recommended for nondental procedures such as transesophageal echocardiography (TEE), esophagogastroduodenoscopy, colonoscopy, or cystoscopy (unless there is active infection in these areas).[17,26]

Clinical Assessment

Postoperative visits should begin approximately 3 to 4 weeks after valve implantation. The first visit is focused on ensuring a smooth transition from hospital/rehabilitation facility to home, reconciling medications, and assessing neurocognitive function, wound healing, volume status, heart rhythm, and the auscultatory characteristics of prosthetic valve function. The history at subsequent visits is tailored to detect symptoms suggestive of heart failure or reduced functional capacity, arrhythmia, thromboembolism, or infection. Adherence to the recommended schedule of INR determinations and the relative time spent in the therapeutic range should be assessed in all anticoagulated patients. Problems with bleeding should be identified. A focused cardiovascular examination is repeated at each visit. Instructions regarding antibiotic prophylaxis are repeated. After the 6-month mark, follow-up visits can be conducted annually unless interim problems arise.

A chest radiograph is obtained by the surgeon at the first visit to assess for residual pleural fluid, pneumothorax, lung aeration, and heart size. An electrocardiogram (ECG) is routinely obtained and should be reviewed for rhythm, conduction, and dynamic repolarization changes. Postoperative baseline values for hemoglobin, hematocrit, lactate dehydrogenase (LDH), and bilirubin should be established for patients with mechanical heart valves, allowing future comparisons should hemolysis be suspected. It is less useful to follow the serum haptoglobin. Other laboratory studies are performed as clinically relevant.

Doppler Echocardiography.
An initial TTE examination performed 6 weeks to 3 months after prosthetic valve implantation is recommended to assess the results of surgery and serve as a baseline for comparison should complications or deterioration occur later. Repeat TTE as well as TEE is recommended if there is a change in clinical symptoms or signs suggesting valve dysfunction. In patients with a bioprosthetic valve, routine annual TTE follow-up is recommended after year 5 by the American Society of Echocardiography (ASE),[4] but not until year 10 in the 2014 AHA/ACC guideline.[2] Recent studies estimate that 25% to 30% of patients with a bioprosthesis implanted for less than 10 years in the aortic position have some degree of valve degeneration or dysfunction.[7] In patients with mechanical valves, routine annual echocardiography is not indicated in the absence of a change in clinical status.[2]

A complete echocardiogram includes two-dimensional imaging of the prosthetic valve, evaluation of the valve leaflet/occluder morphology and mobility, measurement of the transprosthetic velocity and

gradients, valve EOA, Doppler velocity index, estimation of degree of regurgitation, evaluation of LV size and systolic function, and calculation of systolic pulmonary artery pressure[4,5] (**see Chapter 14**). PVR is more common following TAVR than surgical AVR, and measurement of valve EOA is more challenging in transcatheter valves than in surgical valves because of the valve stent in the LV outflow tract.[26,28] Given that transcatheter valves are relatively new devices, more frequent follow-up is recommended, with specific recommendations provided by ASE and the Valve Academic Research Consortium (VARC) for Doppler-echocardiographic evaluation of these new valves.[28]

Evaluation and Treatment of Prosthetic Valve Dysfunction and Complications

The suspicion of prosthetic valve dysfunction may be the appearance of a new murmur or symptom in a patient with a prosthetic valve or the incidental finding of abnormally high flow velocities and gradients detected during a routine echocardiography. Doppler-echocardiography is the method of choice to evaluate prosthetic valve function, identify and quantitate prosthetic valve stenosis or regurgitation, and identify patient-prosthesis mismatch[4,5] (**Figs. 71.2 and 71.3**). Cinefluoroscopy and multidetector computed tomography (MDCT) (**see Chapter 18**) may also be very helpful to evaluate leaflet mobility in mechanical and bioprosthetic valves, respectively.[5] Prosthetic valve stenosis may be caused by thrombus formation, pannus ingrowth (or a combination of both), leaflet calcification in the case of bioprosthetic valves, and vegetations related to PVE. Prosthetic valve regurgitation may be caused by thrombus formation (mechanical valves), leaflet tear (bioprostheses), vegetations, or PVR.

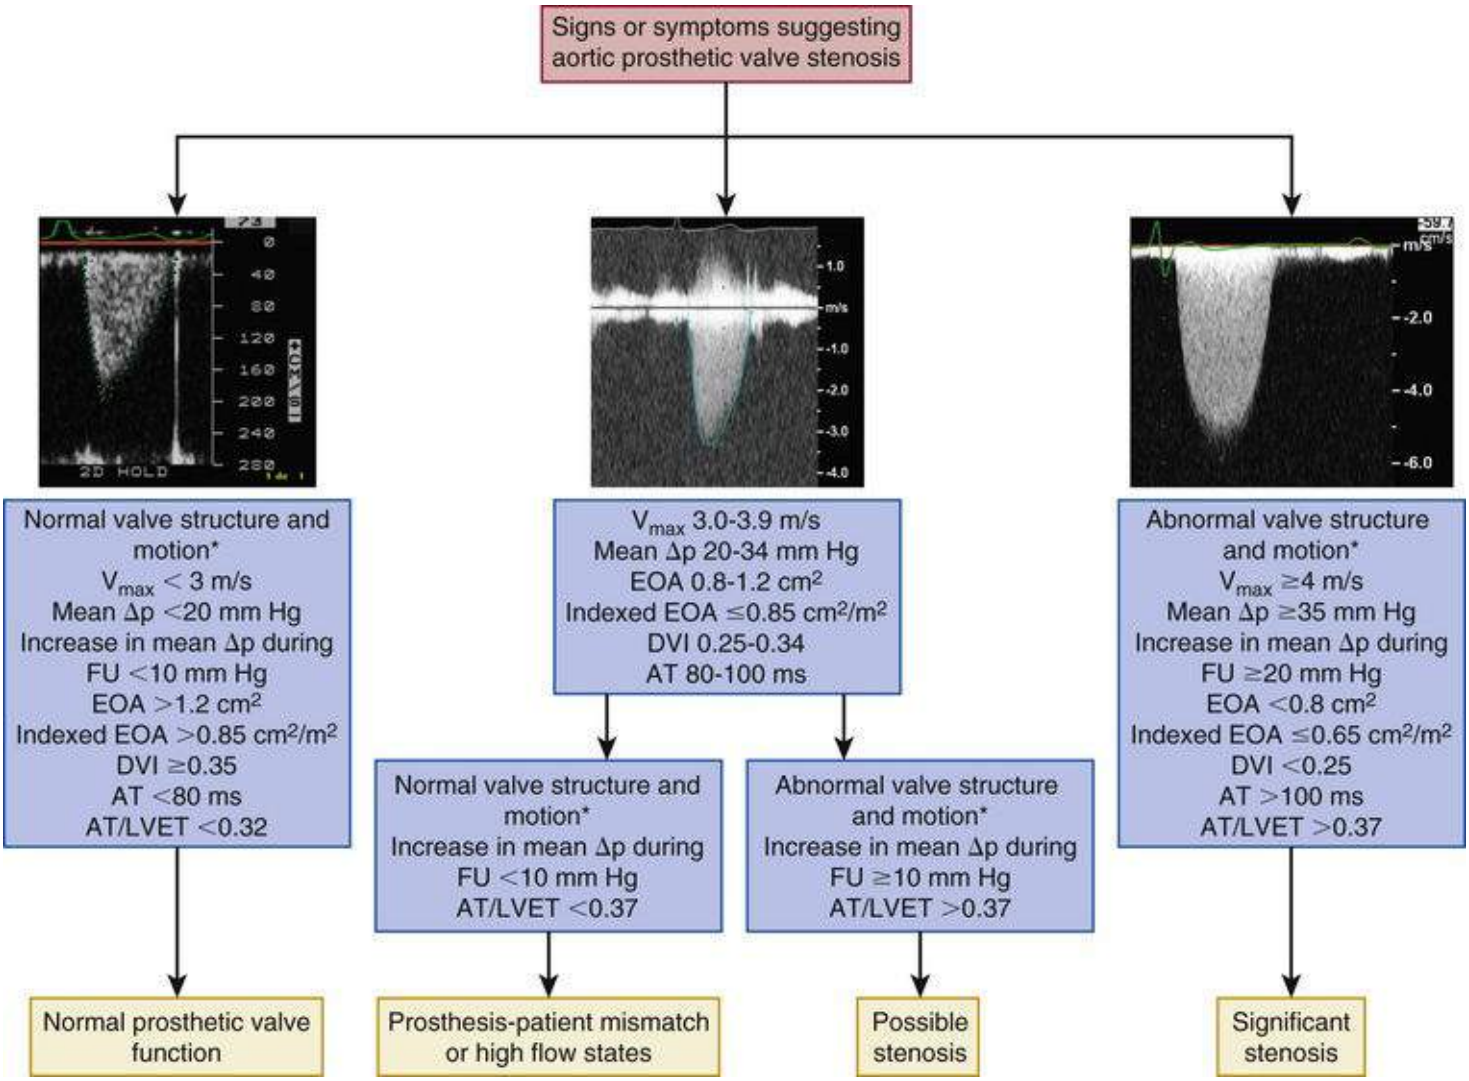

FIGURE 71.2 Evaluation of aortic prosthetic valve stenosis begins with standard measures of stenosis severity, including maximal velocity (V_{max}), mean pressure gradient (Δp), effective orifice area (EOA), and Doppler velocity index (DVI), the ratio of left ventricular (LV) outflow tract to aortic velocity. Normal values for each valve type and size should be referenced, but simple thresholds of 3 and 4 meters per second (m/s) for V_{max} and 20 and 35 mm Hg for mean Δp are a quick first step. For patients with intermediate measures of stenosis severity, the assessment of valve structure and motion and of the changes in Δp, EOA, and DVI during follow-up (FU) can be helpful to differentiate normal prosthetic valve function from concomitant prosthesis-patient mismatch or high flow states versus prosthetic valve stenosis. The shape of the velocity curve may also be helpful, with a triangular shape (short acceleration time [AT, i.e., time to peak velocity; ms, milliseconds] relative to LV ejection time [LVET]), suggesting normal valve function and a rounded waveform (increased AT/LVET ratio) suggesting significant stenosis. *Additional imaging, including transesophageal echocardiography, cinefluoroscopy, or computed tomography, may be needed to assess valve leaflet structure and motion.

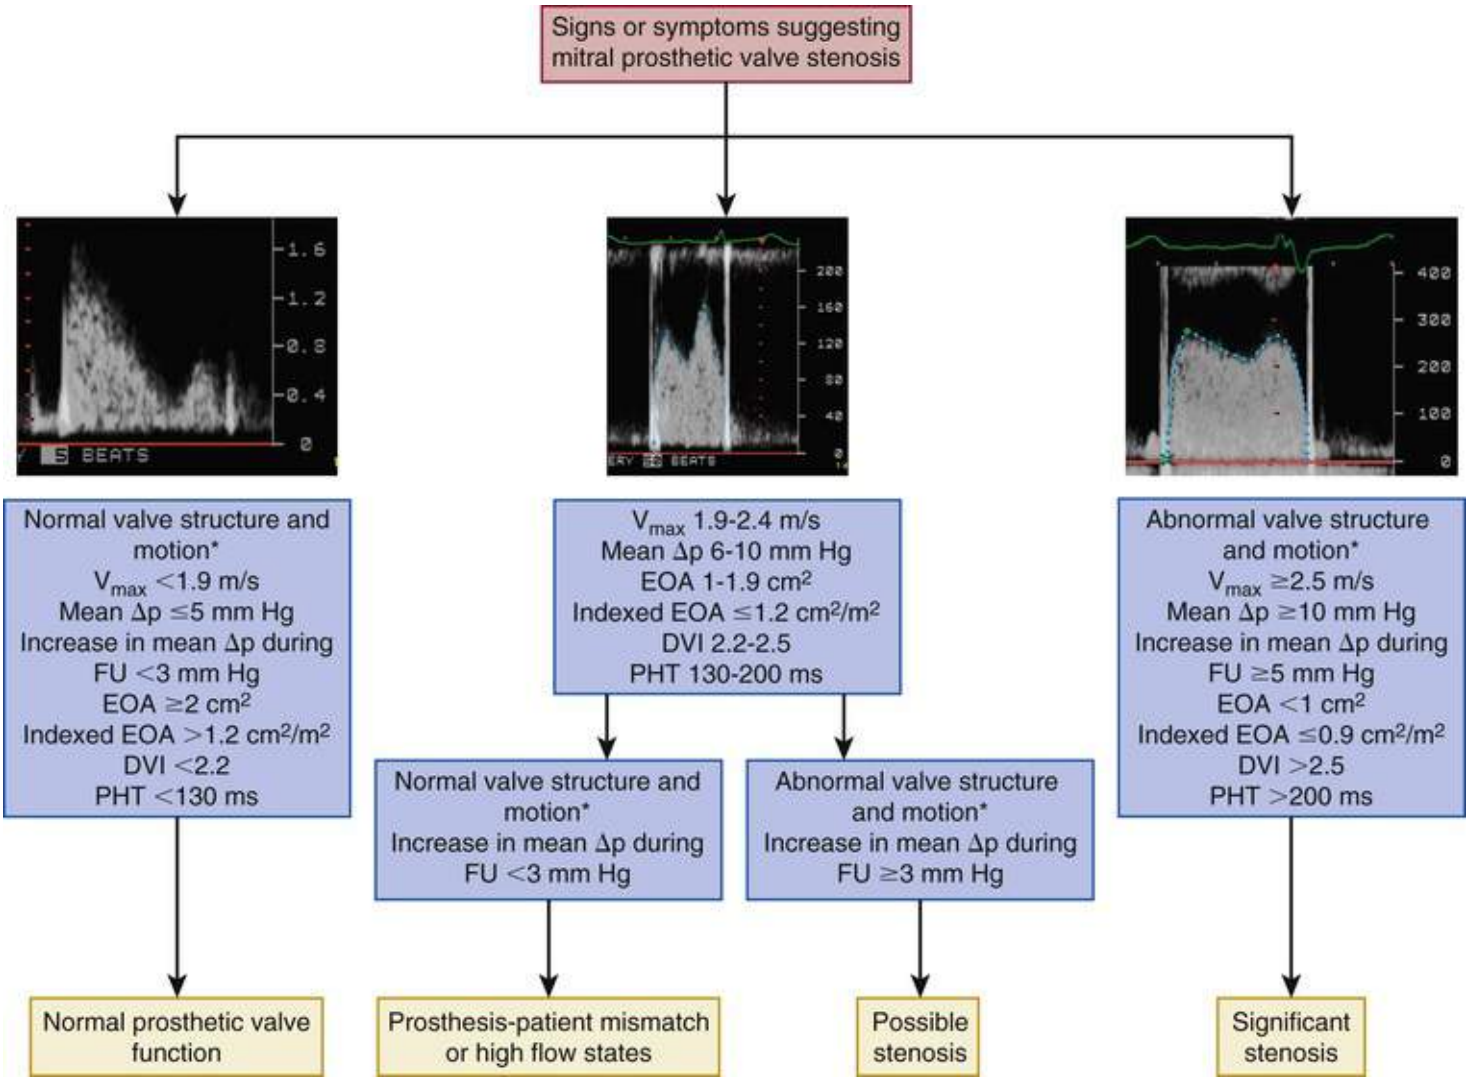

FIGURE 71.3 Evaluation of mitral prosthetic valve stenosis starts with standard measures of stenosis severity, including maximal velocity (V_{max}; m/s, meters per second), mean pressure gradient (mean Δp), effective orifice area (EOA), and pressure half-time (PHT; ms, milliseconds); FU, follow-up. Doppler velocity index (DVI) is the ratio of mitral to left ventricular (LV) outflow tract velocity, and therefore a value greater than 2.2 is abnormal. Normal values for each valve type and size should be referenced, but the thresholds shown are a quick first step. In patients with intermediate measures of stenosis severity, the differential diagnosis includes significant stenosis, prosthesis-patient mismatch, and a high flow state. *Additional imaging, including transesophageal echocardiography, cinefluoroscopy, or computed tomography, may be needed to assess valve leaflet structure and motion.

Prosthesis-Patient Mismatch

Patient-prosthesis mismatch (PPM) occurs when the size of a normally functioning prosthetic valve is too small in relation to the patient's body size, and thus to the patient's cardiac output requirements, resulting in abnormally high postoperative gradients. PPM is defined as an indexed EOA less than 0.85 cm^2 (severe, <0.65 cm^2) for aortic prosthetic valves and less than 1.2 cm^2 (severe, <0.9 cm^2) for mitral prosthetic valves. The prevalence of moderate PPM ranges from 20% to 70% and severe PPM from 2% to 10% after AVR or MVR.[29] Patients with aortic PPM have worse functional class and exercise capacity, reduced regression of LV hypertrophy, more adverse cardiac events, and increased risk of both perioperative and late mortality after AVR compared with patients who do not have PPM.[29] Patients with mitral PPM have persisting pulmonary hypertension and increased incidence of heart failure and death. A greater clinical impact of aortic PPM is also observed in specific groups of patients such as those with preexisting LV dysfunction or severe LV hypertrophy, and/or concomitant MR, as well as in those younger

than 65 to 70 years. PPM is less common with TAVR compared to surgical AVR, particularly in the subset of patients with a small aortic annulus.[11,30] **Figs. 71.2 and 71.3** provide algorithms for differentiating between normal prosthetic valve function, PPM, and intrinsic valve dysfunction caused by SVD, thrombus, or pannus.

Structural Valve Deterioration

Mechanical prostheses have an excellent durability, and SVD is extremely rare with contemporary valves, although mechanical failure (e.g., strut fracture, leaflet escape, occluder dysfunction caused by lipid adsorption) occurred with some models in the past. On the other hand, SVD from leaflet calcification or collagen fiber disruption is the major cause of bioprosthetic valve failure. SVD may lead to leaflet stiffening and progressive stenosis or leaflet tear with ensuing transvalvular regurgitation (**Fig. 71.4**; **see also Fig. 14.60**). Although SVD of bioprostheses has long been considered a purely passive degenerative process, more recent studies suggest that active and potentially modifiable processes may be involved, including lipid infiltration, inflammation, immune rejection, and active mineralization. Transcatheter valve-in-valve implantation offers a valuable alternative to surgery for patients with failed bioprosthetic valves who are at high or extreme surgical risk for reoperation[26,31] (**see Chapter 72**).

Paravalvular Regurgitation

Paravalvular regurgitation (PVR) occurs external to the prosthetic valve at the interface between the sewing ring and the native valve annulus (**Fig. 71.4**). It can occur as a result of inadequate technique, suture dehiscence, compromised native tissue integrity (dense calcification, extensive myxomatous degeneration), infection, or chronic abrasion of the sewing ring against a calcified or rigid annulus. The magnitude of the regurgitant volume will depend on the size of the orifice. A small, hemodynamically inconsequential paravalvular leak is usually discovered incidentally during routine TTE with color

Doppler flow imaging, with no change in management indicated. However, small paravalvular leaks may be associated with significant intravascular hemolysis and anemia as red blood cells are forced through a narrow orifice at high velocity. Despite a high clinical index of suspicion in this circumstance, a new, regurgitant murmur may not be audible. TEE may be necessary to differentiate PVR from transvalvular regurgitation and to visualize the defect appropriately, especially with mitral prostheses. Larger paravalvular leaks may result in significant volume overload and heart failure, to an extent that reoperation might be indicated. Significant PVR may develop during the late postoperative period and is often the result of endocarditis. Experience with transcatheter closure devices in patients with clinically important PVR has increased, but results to date have been mixed.[32] Management can prove challenging, and a conservative approach with medical therapy is often chosen, in part related to the risks associated with reoperation in some patients.

PVR occurs more frequently after transcatheter than surgical AVR; its incidence is significantly lower with newer-generation TAVR prostheses. Because PVR jets after transcatheter AVR are often multiple, irregular, and eccentric, the imaging and grading of PVR can be challenging (**Fig. 71.4**; **see also Fig. 14.61**). A multiwindow, multiparametric, integrative approach is essential to assess the severity of PVR by Doppler echocardiography.[14,28] Other imaging modalities, such as cineangiography, cardiac CT, and cardiac magnetic resonance imaging (**see Chapters 17 and 18**), as well as serum biomarkers, may also be useful to complement or corroborate the findings on echocardiography.[5,14,33] Corrective procedures such as repeat balloon dilation, valve-in-valve implantation, and transcatheter leak closure may be considered depending on the severity of PVR and the risk of procedural complications.[14]

Thromboembolism and Bleeding

Thromboemboli are a major source of morbidity in patients with prosthetic heart valves. The incidence of clinically recognizable events ranges from 0.6% to 2.3% per patient-year,[2] an estimate that does not account for any subclinical episodes that might be detected with sensitive imaging techniques.[34] Thromboembolic incidence rates are similar for non-anticoagulated patients with bioprostheses and appropriately anticoagulated patients with mechanical valves. Risk factors for thromboembolism include the inherent thrombogenicity of the prosthesis, valve position (mitral > aortic), valve number, time spent out of the therapeutic range of anticoagulation, a history of thromboembolism, hypercoagulable state, atrial fibrillation, left atrial enlargement, and LV systolic dysfunction. The risk of bleeding, estimated at 1% per patient-year, increases with age and the intensity of anticoagulation. In patients with uncontrollable bleeding who require reversal of anticoagulation, administration of fresh-frozen plasma or prothrombin-complex concentrate is reasonable.

Management of a thromboembolic event in patients with mechanical valves generally proceeds as follows[2]:

- For patients whose INR is subtherapeutic, the dose of the VKA is advanced to achieve the intended INR range.
- For patients whose INR is in the therapeutic range, the dose of the VKA is advanced to achieve a higher INR range, *and/or* low-dose aspirin is provided if not already used.
- The patient and family are informed about the increased risks of

bleeding.
- The potential for drug interactions is reviewed.

Reoperation to implant a less thrombogenic valve is rarely undertaken for patients with recurrent thromboemboli despite aggressive antithrombotic therapy.

Prosthetic Valve Thrombosis

The incidence of mechanical valve thrombosis is estimated at 0.3% to 1.3% per patient-year in developed countries, but as high as 6% per patient-year in developing countries.[2] Thrombosis of a mechanical heart valve can have devastating consequences (**see Figs. 71.1 and 71.4**). Bioprosthetic (surgical or transcatheter) valve thrombosis is less common, with a reported incidence of 0.03% to 0.5% per patient-year.[35] However, recent studies suggest that subclinical thrombosis may occur in 5% to 15% of patients within the first 2 years after TAVR.[36-38]

Clinical suspicion of prosthetic valve thrombosis should be raised by symptoms of heart failure, thromboembolism, or low cardiac output, coupled with a decrease in the intensity of the valve closure sounds (mechanical valves), new and pathologic murmurs, or documentation of inadequate anticoagulation. Thrombosis is more common in the mitral and tricuspid positions than in the aortic position. Although differentiation from pannus formation can be difficult, the clinical context usually allows accurate diagnosis. Evaluation with TTE/TEE can help guide management decisions[4,5] (**see Fig. 14.59**). In patients with mechanical valves, confirmation of abnormal leaflet or disc excursion in the presence of an occluding thrombus can also be obtained with cinefluoroscopy.[5] MDCT can be useful to identify leaflet thickening and reduced mobility after valve replacement with a bioprosthesis[36] (**see Fig. 71.4**).

Emergency surgery is reasonable for patients with left-sided prosthetic valve thrombosis and shock or New York Heart Association (NYHA) Functional Class III or IV symptoms and for patients with a large thrombus burden (≥0.8 cm^2 on TEE).[2] Fibrinolytic therapy is reasonable for patients with recent-onset (<2 weeks) NYHA Class I or II symptoms and small thrombus burden (<0.8 cm^2) and for sicker patients with larger thrombi when surgery is either not available or inadvisable. Fibrinolytic therapy is generally recommended for patients with right-sided prosthetic valve thrombosis.[2] Some patients with no or minimal symptoms and small thrombi can often be managed with intravenous UFH alone and then converted to fibrinolytic therapy if unsuccessful. An encouraging report of the efficacy of low-dose, slow-infusion tissue plasminogen activator in pregnant women with prosthetic valve thrombosis should prompt investigation of this approach in other patient subsets.[39] Any course of fibrinolytic therapy is followed at the appropriate interval by a continuous infusion of UFH during the transition to VKA therapy targeted to a higher INR, with or without low-dose aspirin. Serial TTE studies are useful to assess the response to treatment. In patients with suspected or confirmed bioprosthetic valve thrombosis who are hemodynamically stable and have no contraindications to anticoagulation, initial treatment with a VKA is reasonable.[26,35,36,38]

Infective Endocarditis

Prosthetic valve endocarditis is the most severe form of infective endocarditis (IE) and occurs in 1% to 6% of patients with valve prostheses, accounting for 10% to 30% of all IE cases[17] (**see Chapter 73**).

PVE is an extremely serious condition with high mortality (30% to 50%). The diagnosis, based on the Modified Duke Criteria, relies predominantly on the combination of positive blood cultures and echocardiographic evidence of prosthetic valve infection, including vegetations, paravalvular abscess, or a new PVR.[17] TEE is essential in patients with prosthetic valves because of its greater sensitivity in detecting these abnormalities. Recent studies suggest that increased uptake of ^{18}F-fluorodeoxyglucose measured by positron emission tomography combined with computed tomography (PET-CT) may improve the early diagnosis of PVE[40] (**see Fig. 16.47**). Despite prompt and appropriate antibiotic treatment, many patients with PVE will eventually require surgery. Medical treatment alone is more likely to succeed in late PVE (>6 months after surgery) and in nonstaphylococcal infections. Surgery should be considered in patients with heart failure; failure of antibiotic treatment; hemodynamically significant prosthetic valve regurgitation, especially if associated with deterioration of LV function; large vegetations (>10 mm); persistently positive blood cultures on therapy; recurrent emboli with persistent vegetations; and intracardiac fistula formation[2] (**see Fig. 73.4**). PVE after TAVR occurs predominantly within the first year after the procedure; its incidence is low (1%/patient-year), but in-hospital (approximately 35%) and 2-year (67%) mortality rates are high,[41] likely reflective of patient age and comorbidities.

Hemolytic Anemia

The development of a nonimmune hemolytic anemia after valve replacement or repair is usually attributable to PVR with intravascular red blood cell destruction. Diagnosis is based on a high index of suspicion, coupled with laboratory evidence of hemolysis, including the characteristic changes in red blood cell morphology (schistocytes), elevated indirect bilirubin and LDH, a high reticulocyte count, and depressed serum haptoglobin. Reoperative surgery or catheter closure of the defect is indicated when heart failure, a persistent transfusion requirement, or poor quality of life intervenes. Empiric medical measures include iron and folic acid replacement therapy and beta-adrenoreceptor blockers. It is important to exclude PVE as a cause.

Transcatheter Therapies for Valvular Heart Disease

Howard C. Herrmann, Michael J. Mack

The impetus for the development of transcatheter therapies for valvular heart disease (VHD) arises from two major factors. First, a transcatheter therapy can avoid the risks associated with more invasive surgical approaches, particularly those associated with cardiopulmonary bypass and median sternotomy, while preserving or enhancing outcomes. Second, the patient wants to avoid the invasiveness and prolonged recovery associated with major surgery. However, these factors must always be balanced with the efficacy of the transcatheter approach. In this regard, the patient will always prefer a transcatheter approach that is less invasive, provides a faster patient recovery, and has similar efficacy to a more invasive surgical approach. However, a less efficacious approach, even if safer and associated with faster recovery, will require more complex decision making that takes into account the patient's age, comorbidities, and goals of care.

Historically, the first and quite successful transcatheter therapy for VHD was balloon valvuloplasty for congenital pulmonic stenosis, developed by Dr. Jean Kan in 1982. That led to a decade of extension of balloon therapies to the treatment of mitral stenosis (MS) and aortic stenosis (AS) and opened the door to other transcatheter therapies for regurgitation lesions, such as MitraClip (Abbott Vascular, Santa Clara, California) repair for mitral regurgitation (MR). More recently, the success of transcatheter aortic valve replacement (TAVR) with both balloon-expandable and self-expanding prostheses for severe, symptomatic AS has ushered in an entire medical specialty focused on transcatheter therapy of VHD. This chapter addresses the indications, techniques, clinical, and investigational therapies available for AS, MS, MR, and tricuspid regurgitation (TR).

Aortic Stenosis (See Chapter 68)

Paul Dudley White stated in 1931 that “there is no treatment for aortic valve disease.” In 1952, however, Hufnagel implanted a “ball and cage” prosthesis in the descending aorta for the treatment of aortic regurgitation (AR). The subsequent pioneering work of Harken, Braunwald, and Starr led to the treatment of patients with severe AS with surgical aortic valve replacement (SAVR) using a mechanical valve in 1960 (see Classic References, Harken). Currently, a wide variety of mechanical and bioprosthetic valves are used for the treatment of AS, with more than 90% of SAVRs performed with tissue valves (**see Chapter 71**).

Balloon Aortic Valvuloplasty

Transcatheter treatment of AS began in 1985 with balloon aortic valvuloplasty (BAV) by Cribier (see Classic References). Early feasibility and safety were accomplished with a modicum of success and modest improvement in valve area and clinical symptomatic relief. Although extensively employed for a number of years, BAV was largely abandoned because of the minimal duration of benefit, with symptomatic relief for only months, and restenosis rates of more than 80% at 1 year and no prolongation of patient survival (see Classic References, NHLBI).

However, there currently remains a role for BAV primarily as “bridge” therapy. Although there is occasionally a role for palliation in the elderly or premorbid patient, BAV is most frequently used for clinical decision making in two situations.[1,2] First, as a diagnostic tool, BAV can help clarify the cause of symptoms, such as chronic obstructive lung disease or heart failure as the cause of dyspnea in a patient with AS. In this setting, both the risks of BAV and the modest improvement in valve area must be factored into the expected benefit. Second, in addition to its role as a “bridge to decision,” BAV also has a limited role as a “bridge to therapy.” In patients with recent acute decompensated heart failure, acute renal failure, or decompensated left ventricular (LV) function, treatment with BAV as temporizing therapy can allow end-organ and cardiac recovery.

Transcatheter Aortic Valve Replacement

The idea of implanting a prosthetic valve to prevent restenosis after balloon valvuloplasty is credited to Henning Andersen, a Danish cardiologist who fashioned a stent from stainless steel surgical wires and mounted a bioprosthetic valve inside the stent. His initial animal experiments demonstrating feasibility were presented at the European Society of Cardiology in 1992 (see Classic References, Andersen). The ensuing decade led to improvements in valve and stent design along with development of a delivery system, culminating in the first successful human implantation by Cribier in 2002 (see Classic References). Although additional implants were performed over the next few years, efforts to expand to other centers and broaden experience were plagued by difficulties in safely reproducing Cribier's original antegrade transseptal delivery. The development of the *retrograde transfemoral* arterial route by Webb and colleagues[3] and the *antegrade transapical* approach by Walther and associates[4] allowed expansion of the procedure to other operators and centers. Progress was facilitated by the development of smaller-caliber and steerable delivery systems.

Two main types of stent design are used for TAVR: balloon-expandable and self-expanding (**Fig. 72.1**). One of each type is approved by the U.S. Food and Drug Administration (FDA) for use in the United

States. The Edwards Sapien Valve (Edwards Lifesciences, Irvine, California) is a cobalt chromium balloon-expandable valve with the valve leaflets made of treated bovine pericardium. The original Sapien THV valve was replaced by the second-generation Sapien XT valve and now the third-generation Sapien 3 valve. Most other TAVR valve designs are self-expanding nitinol valves. CoreValve (Medtronic, Minneapolis, Minnesota) is the most common self-expanding valve, now in its third generation as the Evolut-PRO valve. Both these valves are FDA approved for commercial use in the United States, with more than 75,000 commercial implants by late 2016.[5] Numerous other valves have received commercial approval for use in Europe and are in investigational device exemption (IDE) trials in the United States.

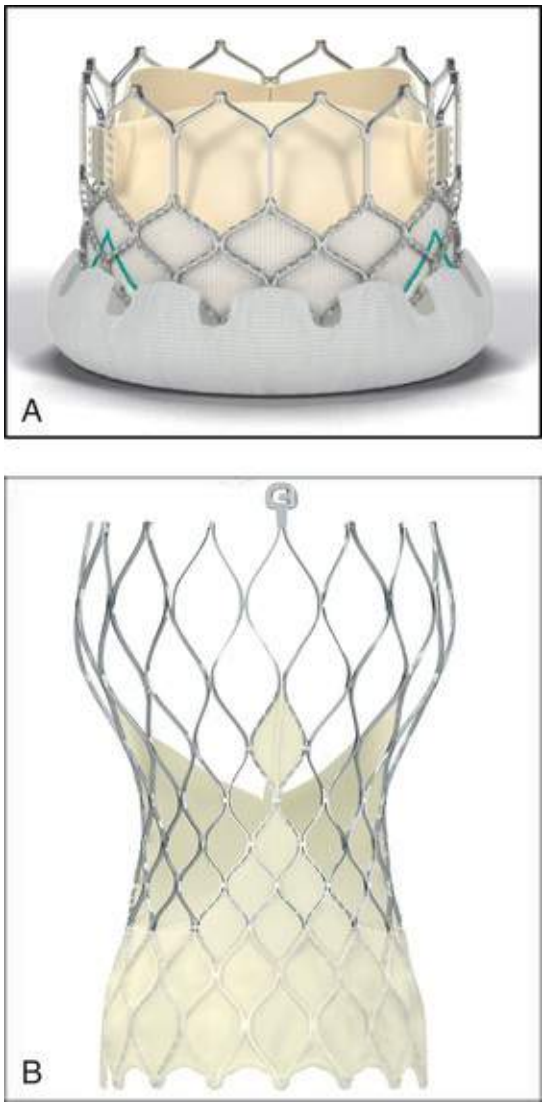

FIGURE 72.1 Transcatheter aortic valves currently approved for use in the United States. **A,** Sapien 3 balloon-expandable valve. **B,** Third-generation CoreValve (Evolut-PRO) self-expanding valve.

Currently, 85% to 90% of all TAVR valves are implanted by a transfemoral approach.[5] For patients in whom a transfemoral approach is not feasible, a number of other "alternative access" routes are used. The original transapical delivery is now seldom used for TAVR, as is the direct transaortic route, which is performed by an upper partial sternotomy or limited right anterior thoracotomy. The more preferred alternative access approach currently is a *subclavian* approach, usually the left, which can be facilitated by a side graft sewn onto the artery. Other innovative alternative access approaches include transcarotid, transcaval, and transmediastinal.

Evidence Base

A robust evidence base has compared TAVR to the standard of care for AS (**Table 72.1**). The series of PARTNER trials began with PARTNER 1B, which demonstrated superiority of TAVR to medical therapy in inoperable patients, with an absolute survival advantage of 23% at 5 years.[6] The PARTNER 1Al and CoreValve trials randomized high–surgical risk patients between TAVR and SAVR.[7,8] Both trials were noninferiority trials and showed either no difference or improved survival with TAVR at 1 year. Patients in PARTNER 1A have been followed to 5 years with no survival difference seen.[9]

TABLE 72.1

Randomized Trials of Transcatheter Aortic Valve Replacement

RISK	TRIAL	TAVR (*n*)	COMPARATOR (*n*)	OUTCOME
Inoperable	PARTNER 1B	179	Medical (179)	TAVR superior to medical
High risk	PARTNER 1A	348	SAVR (351)	TAVR = SAVR
	CoreValve	394	SAVR (401)	TAVR superior to SAVR
Intermediate risk	PARTNER 2A	1011	SAVR (1021)	TAVR = SAVR
	SURTAVI	864	SAVR (796)	TAVR = SAVR
Low risk*	PARTNER 3	TAVR vs. SAVR, total enrollment = 1228		
	CoreValve Evolut-R	TAVR vs. SAVR, total enrollment = 1200		

*The low-risk trials are ongoing.

Two multicenter randomized trials have compared TAVR to SAVR in symptomatic patients at intermediate surgical risk. The PARTNER 2A trial[10] randomized 2036 patients to the balloon-expandable Sapien valve versus SAVR, and the SURTAVI trial[11] randomized 1746 patients to a self-expanding TAVR (84% CoreValve, 16% Evolut-R) versus SAVR. The results of both trials demonstrated noninferiority of TAVR to SAVR for the composite endpoint of death and stroke at 2 years.

The mortality rate of TAVR has consistently improved over the past decade. More centers are gaining experience and surmounting a learning curve. Improvements in delivery systems, with smaller-caliber devices, allow a higher percentage of patients to be candidates for treatment with a transfemoral approach. Better patient selection is also a major contributor to improved outcomes. Clinical experience has defined the patient group with severe AS who have excessive frailty, comorbidities, and disability and are thus unlikely to improve after the procedure (“cohort C patients”). In a large registry of symptomatic, intermediate-risk patients who underwent TAVR using the balloon-expandable Sapien 3 system, survival was markedly superior to the surgical arm of PARTNER 2A.[12] (Importantly, PARTNER 2A was not a prospective randomized trial but used historic surgical controls.) Trials comparing TAVR to SAVR in low-risk patients are currently underway.

Complications.

The complications associated with TAVR have been somewhat addressed by improvements in devices, delivery, technique, and patient selection. These complications include stroke, paravalvular leak, need for a new, permanent pacemaker, and valve thrombosis.

An early concern of TAVR was an increased risk of stroke associated with the procedure. The incidence of clinically evident stroke both in randomized trials when examined by a neurologist and in clinical commercial registries ranges from 2% to 9%.[13] However, the use of sophisticated neuroimaging with diffusion-weighted (DW) magnetic resonance imaging (MRI) demonstrates the presence of embolic lesions in the brain in 68% to 100% of patients undergoing TAVR[9] (**Fig. 72.2**). This has led to the

development of cerebral protection devices that either capture or deflect emboli during the procedure. Results to date have been mixed; some studies have shown a decrease in both number and volume of lesions detected by DW MRI, but a recent major randomized trial of cerebral protection failed to meet its primary endpoint.[14] Nonetheless, this device (Sentinal, Claret Medical, Santa Rosa, California) recently received FDA approval. What remains unclear is the clinical relevance and significance of these radiographic lesions. Evidence in other clinical situations suggests that these findings are associated with long-term neurocognitive decline.

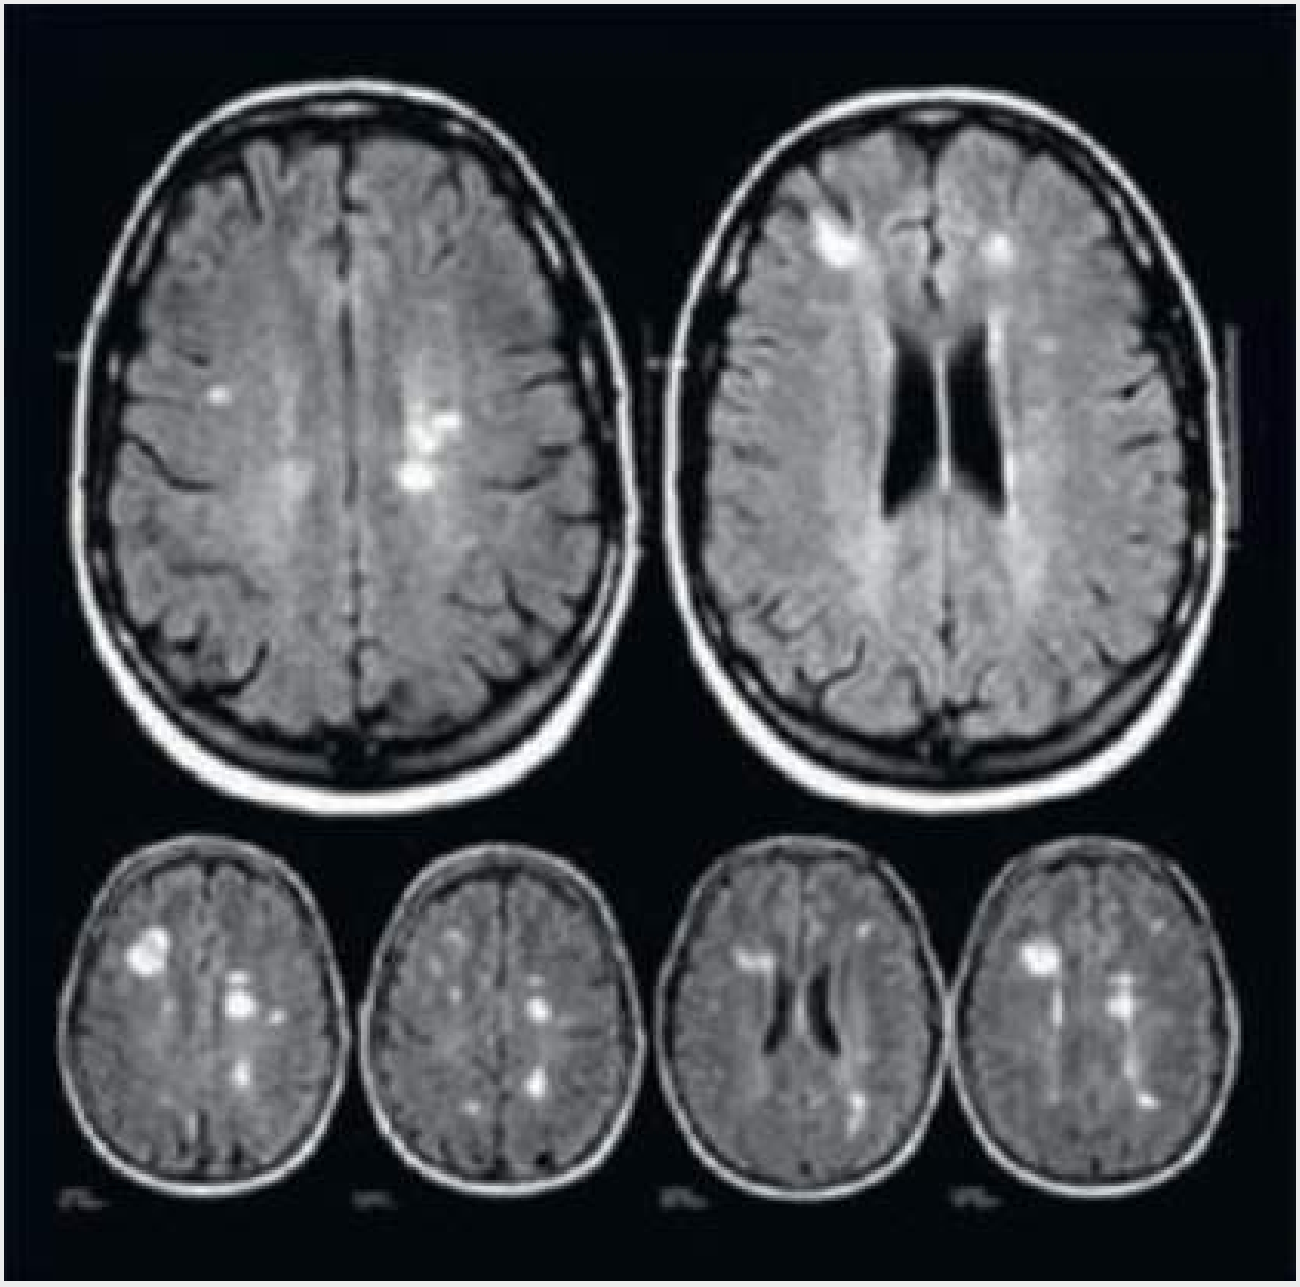

FIGURE 72.2 Typical findings on diffusion-weighted MRI after transcatheter aortic valve replacement (TAVR) showing multiple embolic lesions.

The incidence of moderate to severe paravalvular leak was significantly problematic in the initial trials of TAVR. However, improvements in valve design and increased availability of additional valve sizes, as well as the routine use of three-dimensional (3D) computed tomography (CT) reconstruction for preprocedural planning (**see Chapter 18**), allowing a more accurate selection of appropriate valve size (**Fig. 72.3; see also Fig. 18.15**), have decreased the incidence of moderate to severe paravalvular leak to

the range of 3% to 6% in current experience, although mild paravalvular regurgitation occurs in up to one third of patients.[15,16]

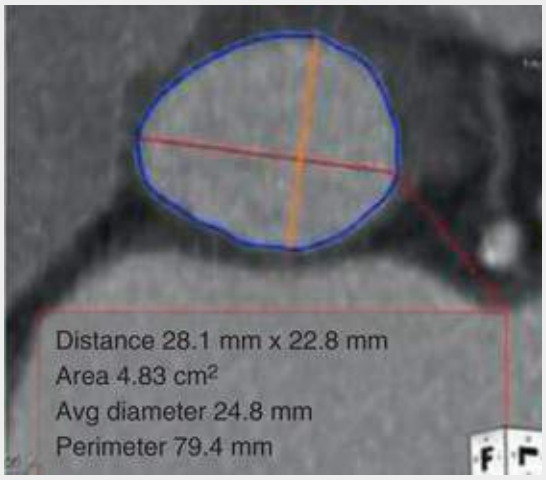

FIGURE 72.3 Three-dimensional reconstruction of a multislice CT scan for annular sizing for TAVR.

The requirement for a new, permanent pacemaker in many patients continues to be an issue with TAVR. The incidence ranges from approximately 10% to 30%, with most current studies closer to the lower end of this range.[17-19] Patients with preexisting conduction system abnormalities are particularly prone to develop increased conduction system block after TAVR and thus require a new, permanent pacemaker. This requirement may gain increasing importance as TAVR becomes more frequently employed in younger patients with a longer life expectancy. On the other hand, younger patients are less likely to have preexisting conduction system disease and therefore may be less likely to require a new pacemaker. Avoidance of valve oversizing and overinflation during deployment as well as slightly higher valve placement all may be beneficial in reducing the need for a new pacemaker.

Another concern associated with TAVR is valve leaflet thickening and thrombosis. This issue was initially discovered by using sophisticated imaging with four-dimensional reconstruction of multislice CT (4D CT) scans during research trials and registries.[20] The subsequent expanded use of these imaging modalities in surveillance studies revealed an incidence of approximately 7% to 10%.[21] Numerous studies have also shown resolution of these imaging abnormalities with anticoagulation, indicating valve thrombosis as the etiology[22] (**Fig. 72.4**). Current recommendations include the use of CT for detection whenever a clinical situation arises suggesting leaflet thrombosis, including an increase in mean transvalvular gradient, new or persistent heart failure, or stroke occurring beyond the periprocedural period.

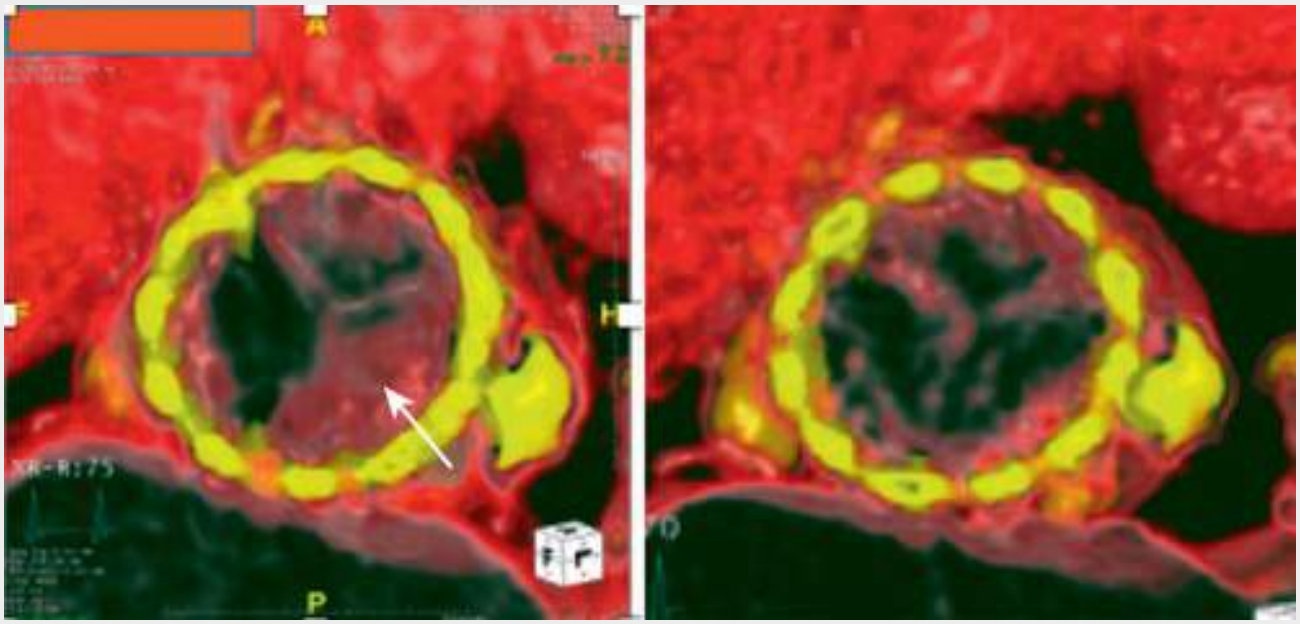

FIGURE 72.4 Four-dimensional CT scan demonstrating thrombus (*arrow*) on TAVR valve **(left)** with resolution after 30 days of warfarin therapy **(right).**

Valve Durability.

The question of valve durability remains unanswered with TAVR. Randomized studies to 5 years and single-center experience up to 10 years have not yet shown a major reason for concern regarding durability.[9,23] However, all the studies are subject to survivorship bias, and with small numbers of patients alive at 5 years or longer after the procedure, the ultimate issue of durability with surgical valves remains undetermined.

Imaging

Sophisticated imaging techniques are crucial to the success of a TAVR program. The use of high-quality transthoracic echocardiography (TTE) for initial determination of the diagnosis and severity of AS is mandatory (**see Chapter 14**), and the use of multislice CT scanning is critical for preprocedural planning (**Chapter 18**). Determination of annular size, height of coronary arteries, and presence of ascending aortic and LV outflow tract calcification are all critical to procedural success (**Fig. 72.5**). The use of transesophageal echocardiography (TEE) for diagnosis may be helpful when determining whether bicuspid valve disease is present and when chronic kidney disease precludes CT imaging. The use of TTE for patient follow-up and the "for cause" use of 4D CT or TEE have become routine practice.

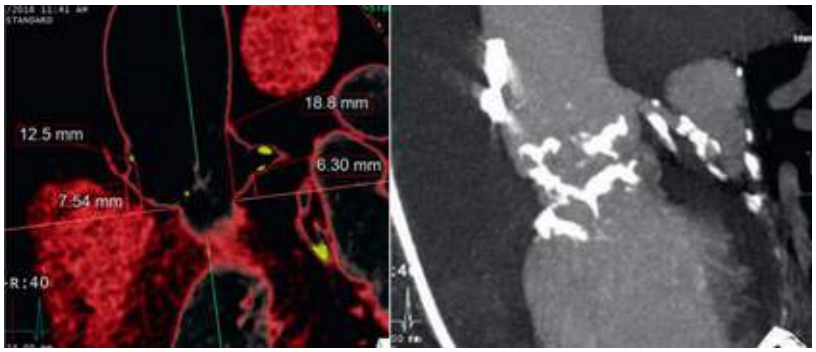

FIGURE 72.5 Three-dimensional CT scans. **Left,** Coronary height relative to the aortic annulus. **Right,** Calcification of the aortic root, annulus, and left ventricular outflow tract.

Heart Team Approach

The use of the multidisciplinary heart team has been an important part of the introduction of TAVR into clinical practice[24] (**see Chapter 67**). The members of the heart team include interventional cardiologists, cardiac surgeons, imaging specialists, anesthesiologists, midlevel providers, research coordinators, fellows-in-training, and geriatricians. Recent concerns are that the heart team is logistically unwieldly and has somewhat outlived its usefulness because patient decision making has become more straightforward.[25] However, as the role of TAVR becomes greater in intermediate-risk and possibly low-risk patients with AS, and transcatheter therapies are applied to other valvular lesions, the role of the heart team in patient-centered decision making will be even more important.

Minimalist Techniques

TAVR procedures are now usually performed percutaneously through a transfemoral approach, obviating the need for general anesthesia. The "minimalist approach," in which the procedures is performed under local anesthesia with mild to moderate sedation and without the routine use of intraprocedural TEE, has resulted in less resource utilization without jeopardizing outcomes.[26] Currently, this approach is used in approximately 15% to 20% of TAVR procedures in the United States, with as high as 90% in some centers.[5]

Future Perspectives.

The future bodes well for TAVR procedures. Currently, two randomized trials are ongoing in low–surgical risk patients between TAVR and SAVR. The two trials also include a subgroup of patients undergoing surveillance 4D CT scans for valve thrombosis to determine the true incidence, predisposing factors, and clinical relevance of the imaging abnormalities previously noted. Other ongoing registry studies include the role of TAVR in bicuspid aortic valves, and aortic and mitral "valve-in-valve" placement in degenerated bioprosthetic surgical valves (**see Chapter 71**). Both FDA-approved devices have received indications for high-risk patients with structurally degenerated aortic bioprostheses. Later-generation TAVR valves in completed or ongoing studies are likely to be introduced into clinical practice in the near future.

The role of adjunctive therapy remains in question. Although the use of dual-antiplatelet therapy has become routine, no strong evidence base supports DAPT. Clinical trials of the novel oral anticoagulants rivaroxaban and apixaban, alone and in combination with antiplatelet regimens, are ongoing. Cost-effectiveness of TAVR also remains an open question. The high cost of the device, approximately $32,000, has raised questions about the ultimate cost-effectiveness of the procedure. However, some evidence shows that the decreased utilization of resources, including a shorter hospital stay, now 1 to 2 days in major programs, offsets the higher device costs.[27]

Mitral Stenosis (See Chapter 69)

In the patient with severe and symptomatic MS, TTE is key to diagnose and confirm the functional severity of the stenosis (**see Chapter 14**).

Mitral Balloon Valvuloplasty

Determining the morphology of the mitral valve and subvalvular apparatus is important in preprocedural planning for mitral balloon valvuloplasty (MBV). The suitability of a valve for MBV can be determined using a morphologic score; the most widely used is the system of Wilkins (see Classic References), which assigns a score of 1 to 4 for leaflet mobility, valve thickening, calcification, and subvalvular thickening (**see Table 14.9**). The severity of concomitant MR is also a key determining factor for MBV, both as it relates to the final result, which may increase up to 1 grade, and to confirm that the patient's symptoms are indeed caused by valvular obstruction and not concomitant regurgitation. In the latter case, mitral valve replacement may be a better option for symptomatic relief. TEE is a final step to assess further the severity of MR and valve morphology and to ensure the absence of left atrial (LA) thrombus before MBV.

Indications

MBV is indicated in symptomatic MS patients who have at least moderate to severe MS, favorable valve morphology, the absence of LA thrombus, and less than moderate to severe MR. In patients with rheumatic MS and calcified nonpliable valves who are at high-risk or unsuitable for open surgery, MBV may be a reasonable alternative to provide palliative symptomatic relief. MBV may also be considered in asymptomatic patients with moderate to severe MS and new-onset atrial fibrillation after excluding LA thrombus (class IIb). In patients with symptoms and mild MS (mitral valve area [MVA] >1.5 cm^2), MBV can be considered if there is evidence of significant MS with exercise testing (class IIb).[28] The mechanism of benefit is separation of the fused commissures, which relieves the physical obstruction, thereby reducing the gradient and increasing MVA.

Procedure.

The transvenous antegrade transseptal route is typically used to gain access to the left atrium to perform MBV. Inoue first used a self-positioning latex balloon wrapped with a nylon mesh to allow phased balloon expansion in 1982 and described the technique in 1984 (see Classic References). The double-balloon technique involves two peripheral arterial balloons tracked over separate guidewires placed in the left ventricle and simultaneously inflated.

The double-balloon technique was the first one used in the United States. Following transseptal catheterization and therapeutic anticoagulation, a balloon-tipped end-hole catheter is used to traverse the mitral valve via the transseptal puncture site. This catheter is navigated to the apex of the left ventricle, and once positioned, a 260-cm guidewire is placed in the LV apex or looped across the aortic valve into the descending aorta. A second guidewire is placed using a similar technique or by using a dual-lumen catheter. Two 18- or 20-mm dilation balloons are tracked and positioned on the wires and inflated simultaneously to dilate the valve.

The Inoue technique has mostly replaced the double-balloon technique, in part because there is no risk of LV perforation with the Inoue balloon (**Fig. 72.6**). The initial size of the Inoue balloon is based on

patient's height. Once inserted over a guidewire into the left atrium, it can be steered across the mitral valve orifice with an internal stylet and then sequentially inflated multiple times over a 4-mm diameter range, with both hemodynamic and echocardiographic results assessed, to achieve the maximal dilation with the least increase in grade of MR. As such, it is important to evaluate carefully for severe commissural calcium preprocedurally. Calcium does not split with balloon inflation but does increase the potential for tearing the leaflets creating MR.

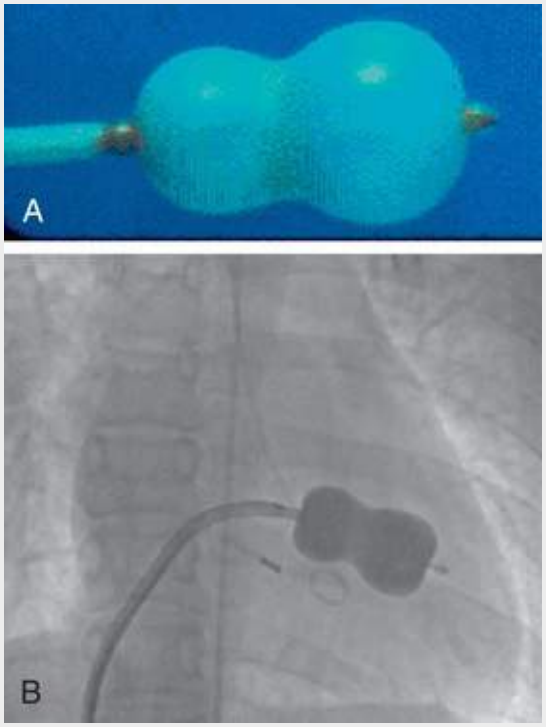

FIGURE 72.6 **A,** Inoue mitral balloon valvuloplasty catheter and three-stage balloon. **B,** Partially inflated Inoue balloon positioned across the mitral valve.

A reduction in mean mitral valve gradient by 50% or an increase in MVA greater than 1.5 cm^2 is considered a successful result and can be achieved in more than 80% of appropriately selected patients. An increase in MR by more than 1 grade after balloon inflation should signal an end to the procedure despite a residual gradient. Event-free survival after MBV is influenced by valve morphology. In a large study of 879 North American patients with a mean follow-up of 4.2 ±3.7 years, there was a greater immediate increase in MVA after MBV and improved long-term survival (82% versus 57%; $P < 0.0001$) in patients with a Wilkins score of 8 or less (**Fig. 72.7**). Patients with higher echocardiographic scores have more events in the long term, including need for repeat MBV, need for mitral valve surgery, and death (**Fig. 72.7B**). In multivariate analysis, age, post-MBV MR grade of 3+ or higher, prior surgical commissurotomy, New York Heart Association (NYHA) Class IV symptoms, and elevated post-MBV pulmonary artery systolic pressure were all independently associated with worse outcome at follow-up.

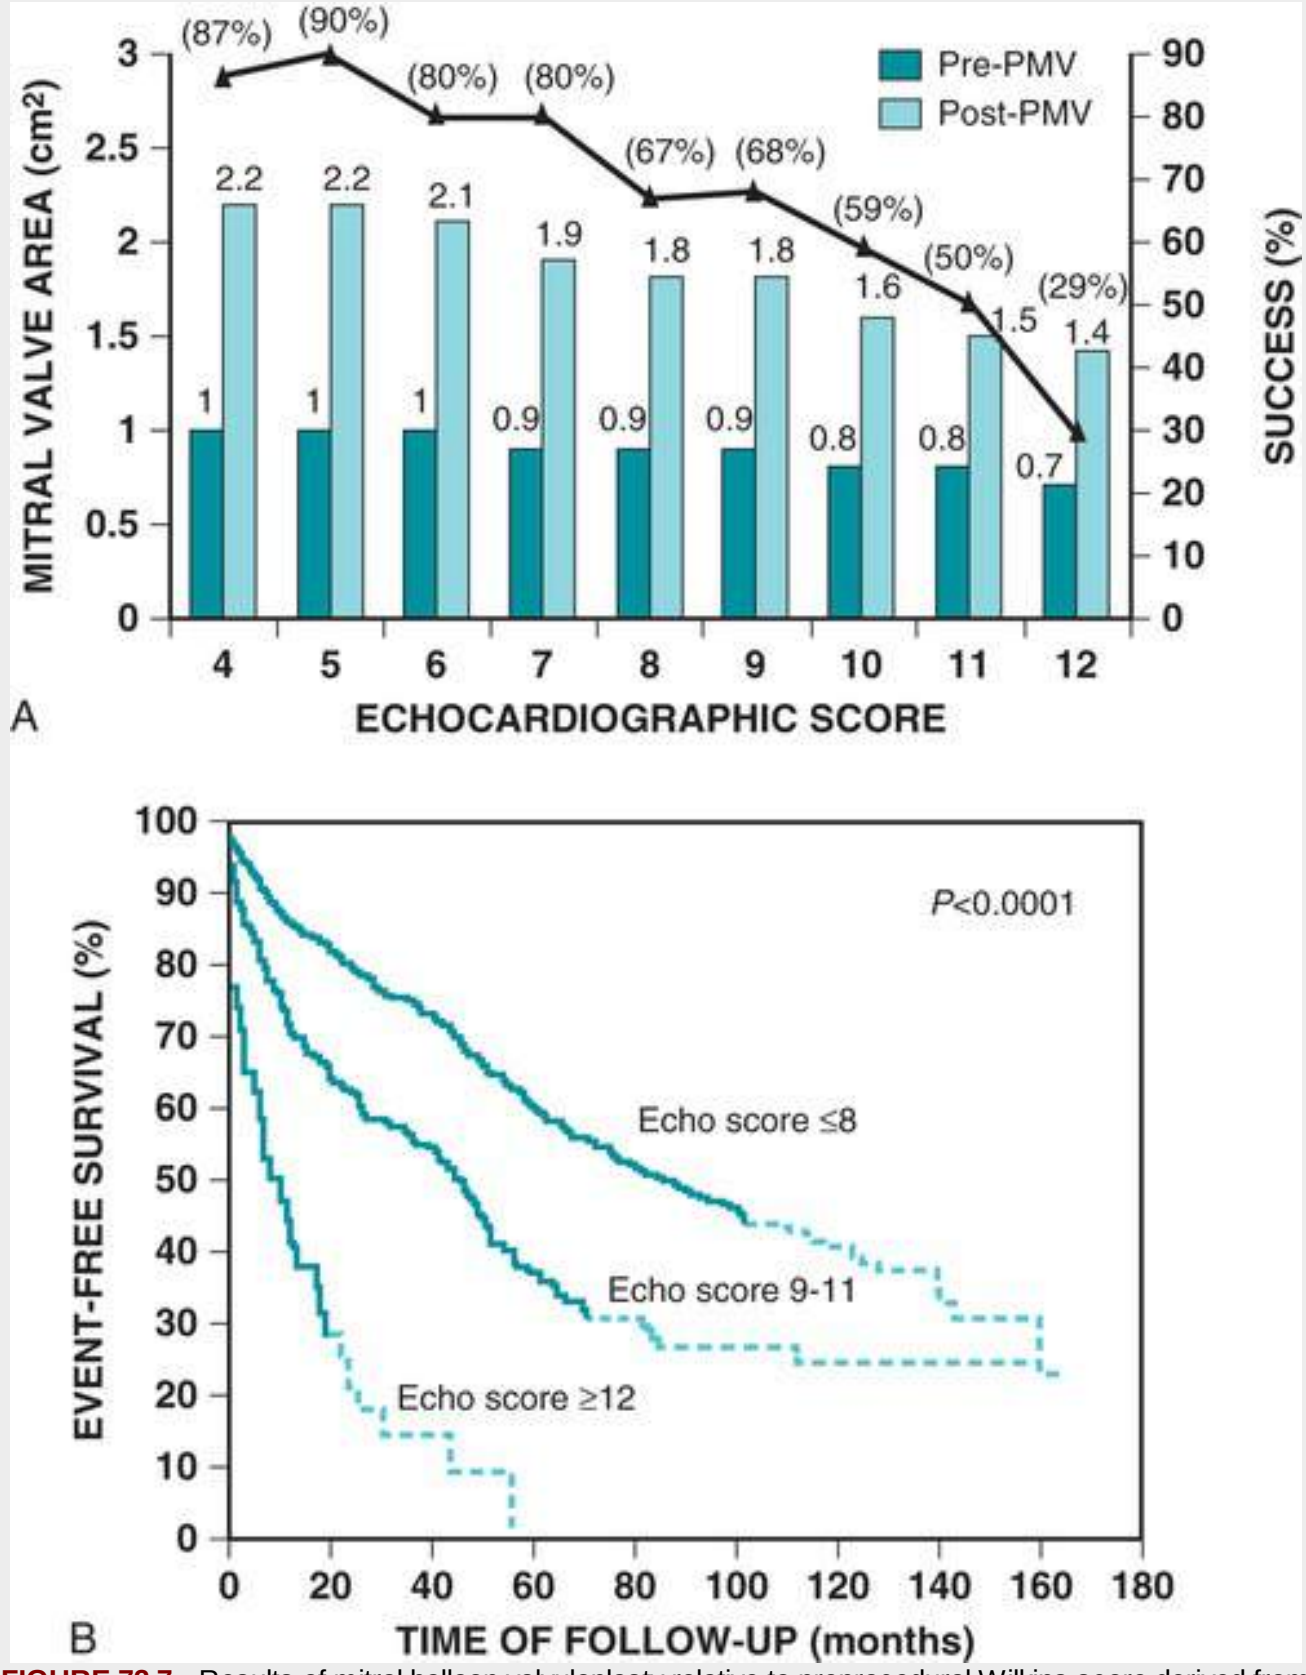

FIGURE 72.7 Results of mitral balloon valvuloplasty relative to preprocedural Wilkins score derived from echocardiography. **A,** *Bars* indicate mitral valve area before and after percutaneous mitral valvuloplasty (PMV) as a function of the echocardiographic score, and the connected *triangles* indicate procedural success rate. **B,** Association between echocardiographic score and postprocedural event-free survival. (From Palacios IF, Sanchez PL, Harrell LC, et al. Which patients benefit from percutaneous mitral valvuloplasty? Prevalvuloplasty and postvalvuloplasty variables that predict long-term outcome. Circulation 2002;105:1465-71. Copyright 2002 American Heart Association Inc.)

The most common complication from MBV, severe MR, occurs in 2% to 10% of patients, with no significant difference between the Inoue and double-balloon techniques. Overall procedural mortality is approximately 1%. Other, less common procedural complications include pericardial tamponade,

embolic events, vascular complications, arrhythmias, bleeding, stroke, myocardial infarction, residual atrial septal defect, and LV perforation.

Echocardiography is essential for many aspects of MBV, including the transseptal puncture and assessment of postprocedural results and complications (**see Chapter 14**). TEE is considered the gold standard, and 3D TEE has been shown to be superior to TTE in reducing fluoroscopy time and the interval from first transseptal puncture to first balloon inflation.[29] Intracardiac echocardiography can also be used, with the advantage of avoiding the endotracheal intubation and general anesthesia usually required for TEE.

Mitral Regurgitation

Unlike MS, which is primarily caused by rheumatic fever, MR is a more diverse disease that results from dysfunction of any of the portions of the complex mitral valve apparatus, including the leaflets, chords, annulus, and left ventricle. As discussed in **Chapter 69**, MR is often further classified into *primary* (organic or degenerative) disease, which affects the leaflets (e.g., fibromuscular dysplasia, mitral valve prolapse, rheumatic disease), and *secondary* (ischemic or functional) disease, which spares the leaflets (e.g., diseases of atrium and ventricle, including ischemic dysfunction and dilated cardiomyopathy). Patients with severe MR have decreased survival, whether symptomatic or not, and surgery is often recommended.[30] In asymptomatic patients with primary MR and preserved LV function, a "watchful waiting" or "active surveillance" approach can be considered until the development of symptoms, LV dysfunction, pulmonary hypertension, or atrial fibrillation,[31] and current guidelines recommend surgery in patients who have reached these endpoints.[28] Surgery may also be considered for asymptomatic patients with normal LV function in whom there is a high likelihood of successful mitral valve repair.[28]

Rationale for Transcatheter Therapy

Surgery improves survival in observational studies but is associated with mortality rates of 1% to 5% and additional morbidity rates of 10% to 20%, including stroke, reoperation, renal failure, and prolonged ventilation.[32] The risks of surgery are particularly high in patients who are elderly or have LV dysfunction and secondary MR. In one study of more than 30,000 patients undergoing mitral valve replacement, mortality increased from 4.1% in those younger than 50 years to 17.0% in octogenarians,[33] although these outcomes improved in a more recent report.[34] The risks and morbidity of surgery coupled with patient preference have stimulated attempts to develop less invasive solutions.

When considering percutaneous or transcatheter approaches for mitral repair, it is useful to classify them according to the major structural abnormality that they address.[35] Unlike the extensive toolbox available to the mitral surgeon, transcatheter approaches are much more limited and often able to address only a single major element of the dysfunctional valve that contributes to MR.[36]

Table 72.2 lists some of the devices, their manufacturers, and current state of development.

TABLE 72.2

Devices for Transcatheter Mitral Valve Repair and Replacement

TYPE/INDICATION	BRAND NAME	MANUFACTURER	STATUS
Leaflet/chordal	MitraClip	Abbott Vascular, Abbott Park, Ill	CE Mark FDA approved
	NeoChord DS1000 System	NeoChord, Eden Prairie, Minn	CE Mark U.S. IDE trial
	Harpoon NeoChord	Edwards LifeSciences, Irvine, Calif	Phase 1 (OUS)
	Mitra-Spacer	Cardiosolutions, West Bridgewater, Mass	Phase 1 (OUS)
	MitraFlex	TransCardiac Therapeutics, Atlanta, Ga	Preclinical
	Middle Peak Medical	Middle Peak Medical, Palo Alto, Calif	Phase 1 (OUS)
Indirect annuloplasty	CARILLON XE2 Mitral Contour System	Cardiac Dimensions, Kirkland, Wis	CE Mark
	Kardium MR	Kardium, Richmond, British Columbia, Canada	Preclinical
	Cerclage annuloplasty	National Heart, Lung and Blood Institute, Bethesda, Md	Phase 1 (OUS)
Direct or left ventricular annuloplasty	Mitralign Percutaneous Annuloplasty System	Mitralign, Tewksbury, Mass	CE Mark
	GDS Accucinch System	Guided Delivery Systems, Santa Clara, Calif	Phase 1 (OUS)
	Boa RF Catheter	QuantumCor, Laguna Niguel, Calif	Preclinical
	Cardioband	Valtech Cardio, Or Yehuda, Israel	CE Mark
	Millipede System	Millipede, Santa Rosa, Calif	Phase 1 (OUS)
	Arto System	MVRx, Belmont, Calif	Phase 1 (OUS)
Hybrid surgical	Adjustable Annuloplasty Ring	Mitral Solutions, Fort Lauderdale, Fla	Phase 1 (OUS)
	enCor ring	MiCardia Corporation, Irvine, Calif	CE Mark Phase 1
Left ventricular remodeling	The Basal Annuloplasty of the Cardia Externally (BACE)	Mardil Medical, Minneapolis, Minnesota	Phase 1 (OUS)
	Tendyne Repair	Tendyne Holdings, Baltimore, Md	Preclinical
	MitraSpacer	Cardiosolutions, Stoughton, Mass	Phase 1 (OUS)
Replacement	CardiAQ-Edwards	Edwards Lifesciences, Irvine, Calif	Phase 1 (OUS) U.S. EFS
	Tendyne	Abbott Vascular, Chicago	Phase 1 (OUS) U.S. EFS
	Tiara	Neovasc, Richmond, British Columbia, Canada	Phase 1 (OUS) U.S. EFS
	Intrepid (Twelve)	Medtronic, Minneapolis, Minn	Phase 1 (OUS) U.S. EFS
	Caisson	Caisson Interventional, Maple Grove, Minn	U.S. EFS

Leaflet Repair with MitraClip Device

MitraClip (Abbott Vascular) was the first transcatheter mitral valve repair technology to receive CE (Conformité Européenne) Mark approval (European Union) and has now also received limited FDA approval for patients with primary (degenerative) MR and prohibitive surgical risk (**Fig. 72.8**). This system replicates the Alfieri stitch operation, in which the middle scallops of the posterior and anterior leaflets (P2 and A2, respectively) are sutured together to create a double-orifice mitral valve. The operation, although usually performed with adjunctive ring annuloplasty, has proved effective and durable in a wide variety of pathologies as well as in select patients without annuloplasty.[37]

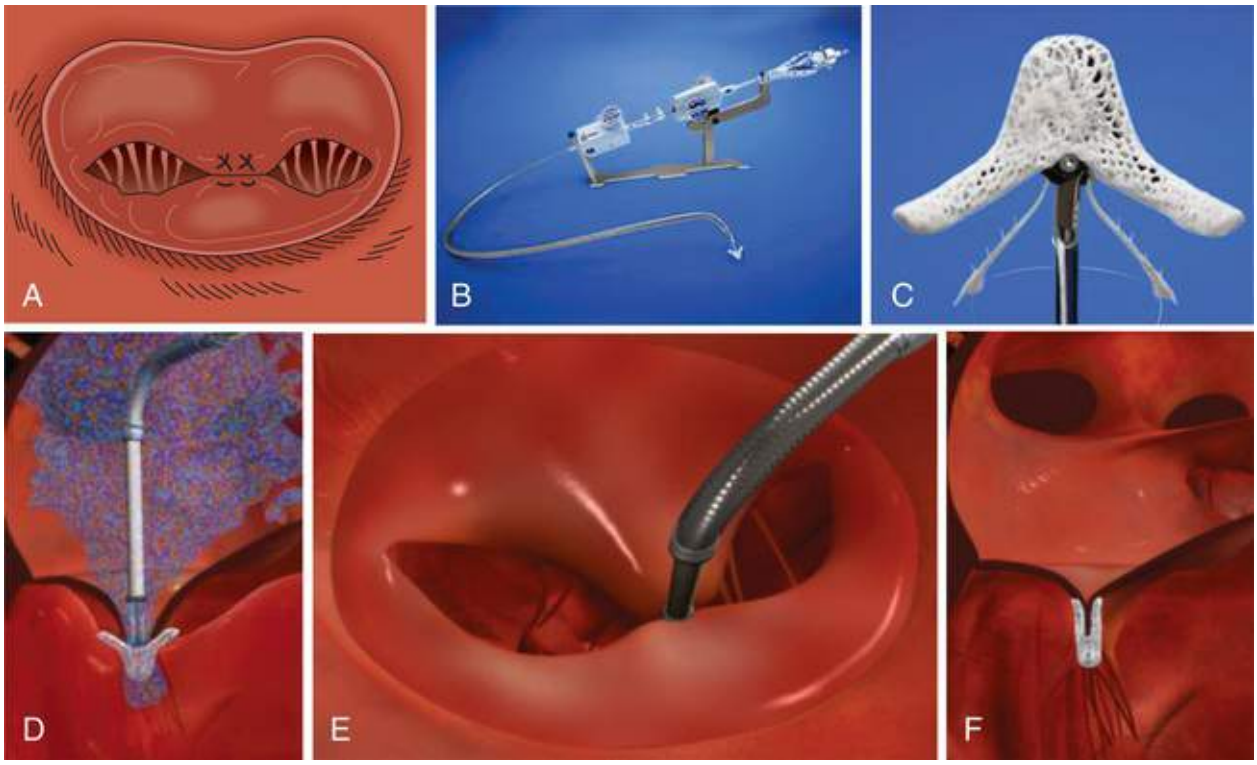

FIGURE 72.8 MitraClip leaflet coaptation system (Abbott Vascular) creates a bridge between the P2 and A2 segments of the mitral valve similar to the Alfieri stitch operation **(A)** utilizing a clip delivery system **(B)** and the MitraClip NT **(C)**. **D,** Side view, and **E,** left atrial view, of the clip delivery system as it is advanced through the mitral valve in the open position prior to grasping of the leaflets. **F,** The final result is illustrated after the clip has been released and the delivery system removed. (Courtesy Abbott Vascular, Inc.)

Trials with MitraClip have confirmed its feasibility (e.g., Endovascular Valve Edge-to-Edge Repair Study [EVEREST] I), and its safety and efficacy were compared with those of surgical repair in a randomized trial (EVEREST II).[38] The procedure is performed with standard catheterization techniques using a transseptal approach from the right femoral vein.[39] The clip delivery system is introduced through a 24F sheath into the left atrium, where it can be guided by TEE using a series of turning knobs through the mitral valve into the left ventricle. A properly aligned and oriented clip can grasp the P2 and A2 segments of the leaflets from the ventricular side to create leaflet apposition. Once leaflet insertion is confirmed by echocardiography, the clip can be released. If a suboptimal grasp occurs, the leaflet can be released, allowing repositioning before a second grasp attempt. Additionally, a second or more clips can be placed as needed for optimal MR reduction.

In the randomized EVEREST II trial, 184 patients received MitraClip therapy and 95 underwent surgical repair or replacement.[40] These patients were almost a decade older (mean age, 67 years) than in usual surgical series and had more comorbidities. Major adverse events at 30 days were significantly less frequent with MitraClip therapy (9.6% versus 57% with surgery; $P < 0.0001$), although much of the difference could be attributed to the greater need for blood transfusions with surgery. The freedom from the combined outcome of death, mitral valve surgery, and MR severity greater than 2+ at 12 months was higher with surgery (73%) than with MitraClip therapy (55%; $P = 0.0007$). In patients with acute MitraClip therapy success, the result appears durable, with a very low rate of later mitral valve surgery.[41]

Subsequent analyses of this study and additional registries have demonstrated persistent reductions in MR grade, improvement in NYHA functional class, and reduction in LV dimensions with MitraClip therapy.[41] Other studies have shown a lack of MS, no effect of initial rhythm on results, and importantly, greater benefit than with surgery for higher-risk patients[42] (**Fig. 72.9**).

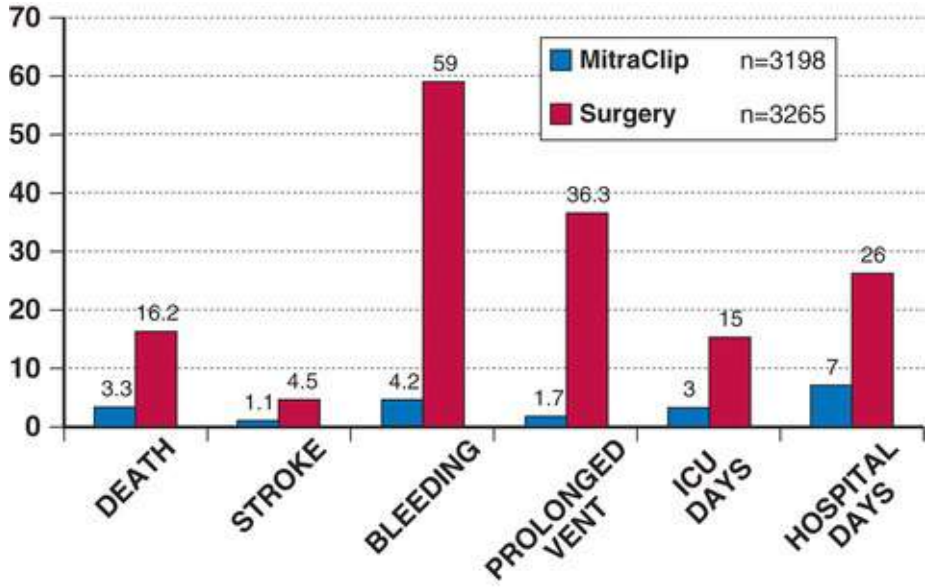

FIGURE 72.9 Meta-analysis of outcomes of the MitraClip compared to mitral valve surgery in high-risk patients. ICU, Intensive care unit; Vent, ventilation. (From Philip F, Athappan G, Tuzcu EM, et al. MitraClip for severe symptomatic mitral regurgitation in patients at high surgical risk. Catheter Cardiovasc Interv 2014;84:581-90.)

Although the EVEREST II trial failed to demonstrate efficacy equivalent to that of surgery for a diverse group of patients with varied risk and etiology, the EVEREST High-Risk Registry and prohibitive-risk patient subset, combined with the experience outside the United States, indicate a more appropriate role in high-risk patients and those with secondary functional and ischemic MR. In addition to improved symptoms, a 50% to 70% reduction in hospitalization for heart failure in the year after versus the year before MitraClip implantation has been observed, prompting a randomized trial, COAPT (Clinical Outcomes Assessment of the MitraClip Percutaneous Therapy for High Surgical Risk Patients), to compare the device with medical therapy in patients with secondary MR.[42] Several other devices, designed to provide leaflet repair, including NeoChord, Mitra-Spacer, and MitraFlex, are in preclinical or phase 1 evaluation (**see Table 72.2**).

Indirect Annuloplasty

The venous anatomy of the heart is of particular interest for treating MR because of the ease of access (from the right internal jugular vein) and the location of the great cardiac vein in proximity to the posterior mitral annulus. Some of the first attempts to treat MR without surgery did so by mimicking surgical ring annuloplasty through placement of devices in the coronary sinus, so-called indirect or percutaneous coronary sinus annuloplasty. The goal of this approach is to remodel the posterior annulus, cinching the great cardiac vein or pushing on the posterior annulus from the vein to improve leaflet coaptation.

The CARILLON XE2 Mitral Contour System (Cardiac Dimensions) has CE Mark and uses anchors placed in the coronary sinus that are pulled toward each other with a cinching device to reduce the mitral annular dimension by traction (**Fig. 72.10**). Early evaluation in the Amadeus study demonstrated feasibility, with implantation in 30 of 48 patients and modest improvement in quantitative measures of MR with a small risk of coronary compromise (15%) and death (one patient). More recently, a redesigned device was tested in the TITAN (Transcatheter Implantation of Carillon Mitral Annuloplasty Device) trial.[43] Of 65 patients with secondary MR (62% ischemic), the device was implanted successfully in 36 patients, with a mean age of 62 years, mean ejection fraction (EF) of 29%,

predominantly NYHA Functional Class III symptoms, and 2+ (30%), 3+ (55%), or 4+ (15%) grade MR. Quantitative measures of MR were better at 6 and 12 months than in 17 patients who did not receive implants.

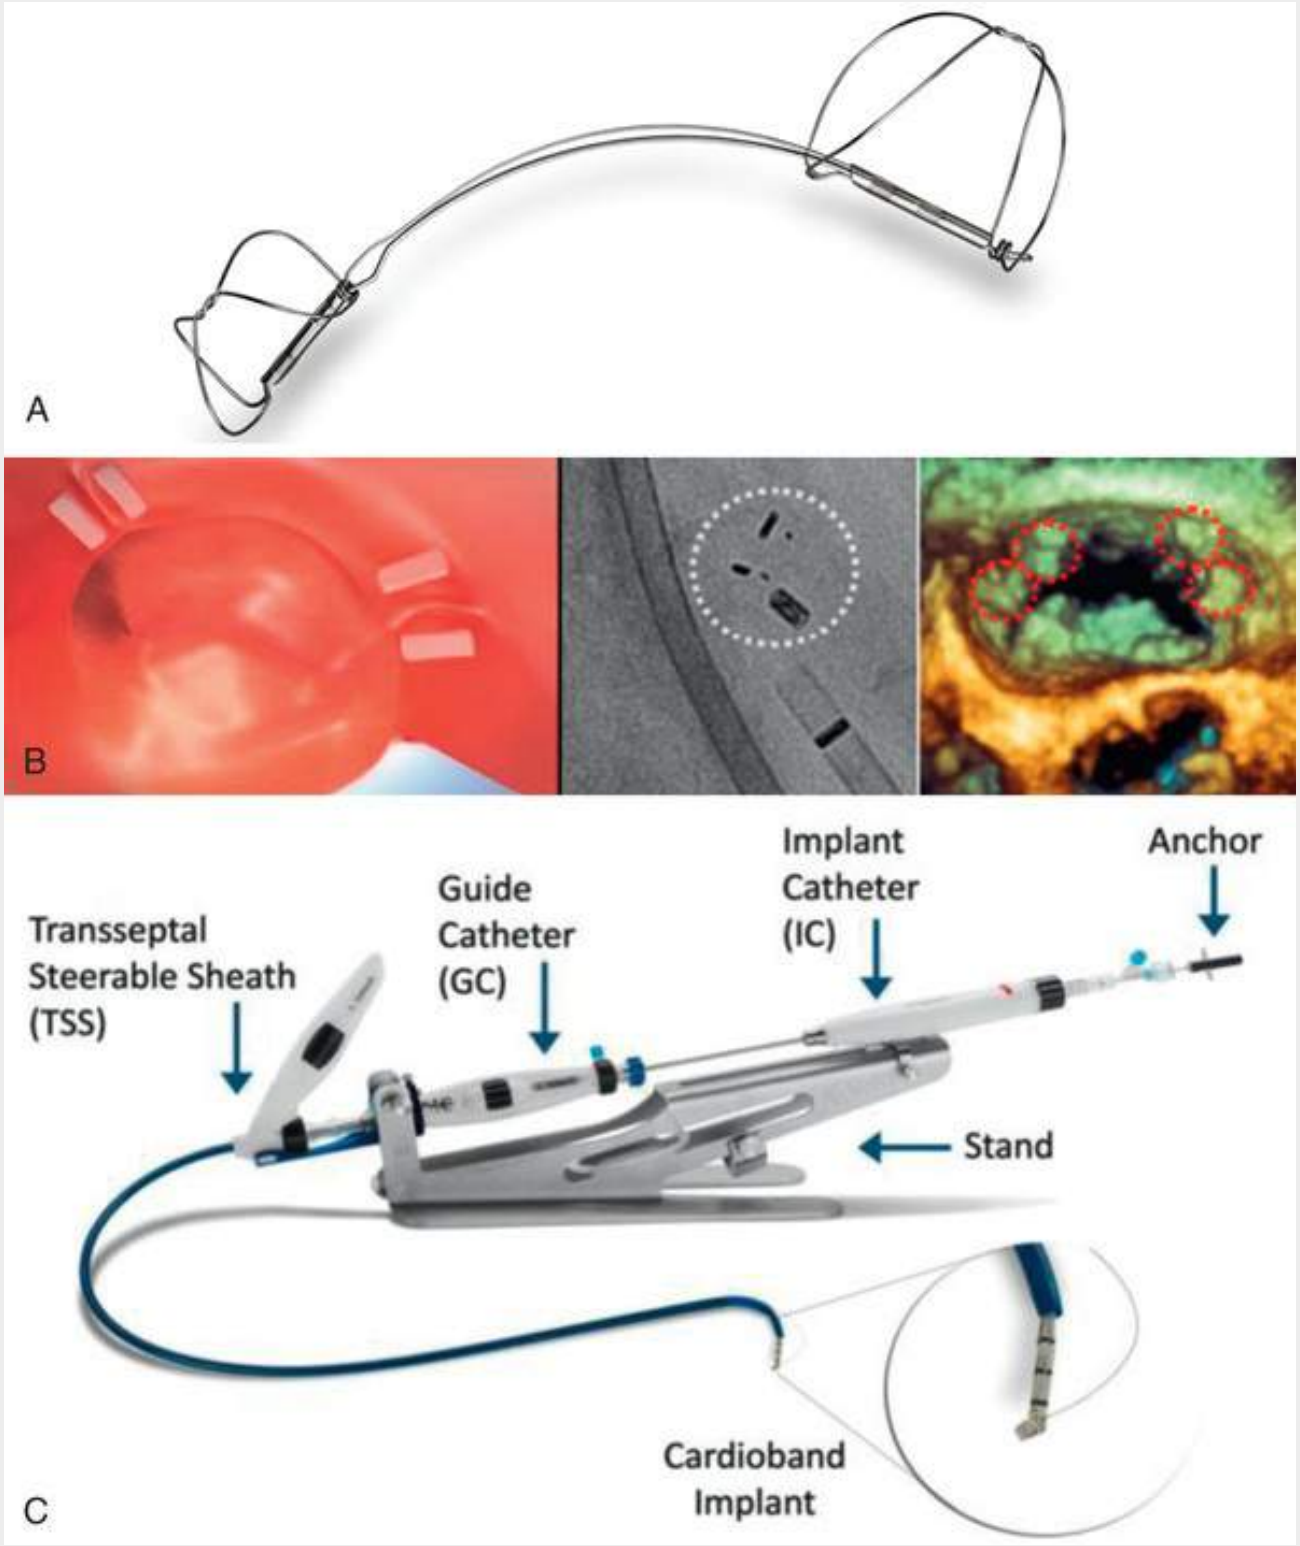

FIGURE 72.10 Evolving devices for mitral valve repair. **A,** Carillon XE2 Mitral Contour System (Cardiac Dimensions) **B,** Mitralign Percutaneous Annuloplasty System (Mitralign, Tewksbury, Mass). **C,** Cardioband annuloplasty system (Valtech Cardio, Or Yehuda, Israel). (From Nickenig G, Schueler R, Dager A, et al. Treatment of functional mitral valve regurgitation with a percutaneous annuloplasty system. J Am Coll Cardiol 2016;67:2927-2936.)

In general, indirect annuloplasty devices may be able to provide modest MR reduction in select patients, but likely less than that achievable surgically with a complete ring placed directly on the

annulus. The limited efficacy is related to the location of the coronary sinus relative to the annulus (up to 10 mm more cranial), great individual anatomic variability, and limited benefit of partial annular remodeling. Whether this level of efficacy will result in sufficient symptomatic improvement and LV remodeling to justify the procedure requires further study. Some “super-responders” may be identified on the basis of anatomic considerations before the procedure. The risks of this approach must also be considered. In addition to the risk for damage to the cardiac venous system, devices in this location can compress the left circumflex or diagonal coronary arteries, which traverse between the coronary sinus and the mitral annulus in most patients.[43]

In this regard, one novel indirect approach to reduce the septal-lateral dimension that deserves further consideration is the *cerclage annuloplasty* technique, which recently entered clinical evaluation. This approach attempts to create a more complete circumferential annuloplasty by placing a suture from the coronary sinus through a septal perforator vein into the right atrium or ventricle, where it is snared and tensioned with the proximal end from the right atrium to create a closed pursestring suture.[44] The procedure is guided by cardiac MRI and also uses a novel rigid protection device to avoid coronary compression.

Direct Annuloplasty and Left Ventricular Remodeling Techniques

Several devices have been developed to remodel more directly the mitral annulus, in part because of the limitations of indirect coronary sinus annuloplasty described earlier (**see Table 72.2**). The Mitralign Percutaneous Annuloplasty System (Mitralign) was originally based on the surgical techniques of Paneth's posterior suture plication. In this procedure a transaortic catheter is advanced to the left ventricle and used to deliver pledgeted anchors through the posterior annulus that can be pulled together to shorten (plicate) the annulus up to 17 mm (with two implants) (**Fig. 72.10B**). In 50 of 71 patients successfully treated in a phase 1 trial, septal-lateral dimension was reduced about 2 mm, MR grade at 6 months was reduced by a mean of 1.3 grades in 50% of patients, and modest symptomatic improvement was observed.[45] A CE Mark trial is underway. The Accucinch (Guided Delivery Systems) device utilizes a catheter approach to place up to 12 anchors along the ventricular surface of the posterior mitral annulus. A cable running through the anchors is tensioned to create posterior annular plication. In a later development the anchors are placed in the ventricular myocardium just below the valve plane (percutaneous ventriculoplasty).

More recently, the Cardioband annuloplasty system (Valtech Cardio, Or Yehuda, Israel) received CE Mark. This is an adjustable, catheter-delivered, sutureless device that is inserted transseptally and directly anchored on the atrial side of the annulus with subsequent adjustment (**Fig. 72.10C**). In a phase 1 European study, 31 high-risk patients with severe secondary MR received treatment.[46] Mean septal-lateral dimension was reduced from 37 to 29 mm, with initial reduction in MR grade to “trace” or “mild” in 93% of patients and to moderate MR or less at 30 days in 88%.[46]

The basis for devices to treat MR by affecting the shape of the left ventricle arises from the pathophysiology of secondary ischemic or functional MR (**see Chapter 69**). Changes in the inferior and lateral left ventricle from infarction can lead to tethering or tenting of the posterior leaflet, allowing anterior leaflet override as the mechanism of MR. Similarly, failure of leaflet coaptation from global LV enlargement causing annular distention is the major mechanism for MR in dilated cardiomyopathy.[42] Although ring annuloplasty can often ameliorate MR caused by LV distortion, procedures that also address the underlying LV pathology may be more beneficial. The Basal Annuloplasty of the Cardia Externally (BACE) device (Mardil) is a surgically implanted external tension band placed around the heart externally to treat ischemic MR at the time of coronary artery bypass graft (CABG) surgery. In a

preliminary report of 11 patients treated in India, MR grade was reduced acutely from grade 3.3 to 0.6. Preclinical work with a transcatheter approach to approximate the papillary muscles is also in development (Tendyne Repair).

Transcatheter Mitral Valve Replacement

The rationale for transcatheter mitral valve replacement (TMVR) is based on several lessons learned from surgical valve replacement[47] and results thus far with transcatheter mitral valve repair. With the current state of technologic development and clinical experience, transcatheter repairs do not appear to reduce MR to the same extent as surgical repairs. Moreover, in patients with secondary ischemic MR, mitral valve replacement (MVR) appears to provide more complete and durable elimination of MR than valve repair. In a surgical trial of 251 patients with severe ischemic MR randomized to mitral repair versus chordal-sparing MVR,[48] recurrent moderate or severe MR was higher at 12 months in the repair group (32.6%) than the replacement group (2.3%).

Early experience with valve-in-valve treatment using TAVR devices in previously implanted degenerating surgical mitral bioprostheses and annuloplasty rings has confirmed the feasibility of this approach. Balloon-expandable TAVR prostheses were initially implanted in degenerating bioprostheses and surgical annuloplasty rings via a transapical approach.[49] Subsequently, the feasibility of transseptal delivery and transatrial delivery has been demonstrated. Complications, including valve embolization, bleeding, and death, have been reported, but the early results have generally been favorable, with excellent reduction in MR grade and low residual transmitral gradients, resulting in the Sapien 3 device receiving FDA approval for this indication.[5]

Despite these initial demonstrations of the feasibility of transcatheter mitral valve-in-valve implantation, de novo placement of such devices in native valves, even those with mitral annular calcification, has proved more challenging.[50] Compared to TAVR, mitral devices need to be larger, and fixation to the diseased mitral apparatus is hampered by the greater valve complexity, lack of calcium, potential need for orientation, and noncircular annular shape.

Most current designs use a stent-based bioprosthesis that is self-expanding, anchors to attach to the annulus and/or leaflets, and a sealing skirt. Because the size of the mitral annulus requires a large prosthesis, initial experience has been with transapical delivery systems, although early experience with several transseptal and transatrial delivery approaches is underway. Novel devices that use a two-stage deployment with separate anchoring and valve portions are also being tested.

At least five TMVR devices have entered early feasibility investigation clinically in the United States (**Fig. 72.11; see also Table 72.2**), and more than 30 are in early development. The initial experience with TMVR has been challenging, in part from inclusion of compassionately treated patients with multiple comorbidities and predominantly treated with a relatively invasive transapical approach. Current trials are therefore targeting high-risk, but not inoperable, patients with both primary and secondary MR. Phase 2 study investigators will address that most patients with secondary MR do not have high short-term mortality and therefore are frequently medically managed. Overcoming procedural complications of TMVR will be essential to realize the symptomatic benefits compared to medical care. Patient comorbidities, cardiac and noncardiac, could hamper and confound comparative evaluations.

FIGURE 72.11 Transcatheter mitral valve replacement devices in early U.S. feasibility evaluation. *Top row,* CardiAQ-Edwards Transcatheter Mitral Valve (Edwards Lifesciences, Irvine, Calif) and Tendyne (Courtesy Abbott). *Bottom row,* Intrepid (Medtronic, Minneapolis), Tiara (Neovasc, Richmond, BC, Canada), and Caisson (Caisson Interventional, Maple Grove, Minn).

In the largest study of such a device to date, Muller and colleagues[51] treated 30 patients at high risk for surgery with a transcatheter transapical self-expanding nitinol prosthesis supporting a trileaflet porcine pericardial valve (Tendyne Mitral Valve System, Abbott Vascular, Roseville, Minnesota). The device was successfully implanted in 28 patients (93%) and was retrieved without complications in the other two patients. Grade 0 MR was reported in all but one patient. There were no device embolizations, strokes, or LV outflow tract obstruction. At 30 days, one patient died from pneumonia, and only one patient had mild MR. Overall freedom from major adverse events was 83%, and there was significant improvement in NYHA class, walk time, and quality of life.

It is hoped that improvements in devices, operator and procedural experience, and patient selection will lead to better outcomes. The potential advantages of this approach include the avoidance of both the surgical incision and the effects of cardiopulmonary bypass. Such devices could be fully sparing of the subvalvular apparatus and provide MR reduction that is equivalent to that achieved with surgical valve replacement. However, the early high mortality, although in very-high-risk patients receiving the device as a compassionate approach, has tempered some of the early enthusiasm for TMVR.[52]

In this regard, it is useful to emphasize that TMVR is not a “mitral TAVR.”[52,53] The mitral valve is more complex than the aortic valve, and MR has a vast array of etiologies. Unlike AS, MR is not as often a disease of elderly persons, and repair (not replacement) is the preferred surgical therapy, especially for patients with primary MR. Replacement may have less favorable effects on normal vortex flow and LV remodeling than successful repair.[54] Transcatheter prostheses in the mitral position will likely have lower durability, more risks associated with paravalvular leak,[55] and a greater risk of embolization, LV outflow tract obstruction, and thrombosis. Finally, the more frequent association with TR, which may need to be addressed, and the lower short-term mortality will be impediments to the design of rigorous clinical trials.[52,53]

Tricuspid Regurgitation

Moderate or severe TR affects approximately 1.6 million U.S. patients, but less than 1% undergo surgery.[56] Current guidelines recommend concomitant tricuspid repair or replacement during left-sided heart surgery for severe TR and for nonsevere TR with annular dilation.[28] A number of transcatheter devices to treat TR are under development, some of which are in early clinical feasibility evaluation.[57] Several are based on prior transcatheter mitral approaches (MitraClip, Mitralign), while others use more novel approaches. The TriCinch device places a corkscrew annular anchor tensioned to a stent in the inferior vena cava. The FORMA device fills the orifice with a balloon to reduce the effective regurgitant orifice area. Several companies are developing analogs of ring annuloplasty placed directly on the valve (Millipede) or implanted externally via the pericardial space (Triapta). Additionally, caval valve implants with current TAVR devices and novel devices specifically designed for this purpose (Tric Valve) are under evaluation.

Conclusion

Transcatheter therapy of valvular heart disease is an exciting area of cardiovascular medicine. The initial success of balloon valvuloplasty for stenotic lesions leading to the more recent growth of TAVR has revolutionized the modern approach to aortic stenosis. The complexity of the mitral valve apparatus and the myriad causes of mitral regurgitation have slowed the development of transcatheter mitral valve repair and replacement. Fueled by the ever-growing prevalence of heart failure in the aging U.S. population[58]—most of these older patients with heart failure have significant MR—and aided by the ingenuity of physicians and engineers, we can anticipate that transcatheter mitral and tricuspid valve therapies will soon become an available option for many patients in the near future.

Guidelines

Management of Valvular Heart Disease

Robert O. Bonow and Catherine M. Otto

The American College of Cardiology and the American Heart Association (ACC/AHA) first published guidelines for the management of patients with valvular heart disease (VHD) in 1998. These were revised in 2006, updated in 2008, and then completely revised in 2014.[1] The guidelines were updated once more in 2017.[2] Some materials from the 2014 guidelines and the 2017 update are presented in this chapter and **Chapters 68 to 71**. In addition to the guidelines, recommendations for the evaluation and management of VHD are included in appropriate use criteria (AUC) for echocardiography from the ACC and other organizations,[3] as well as ACC recommendations for assessment of athletes with cardiovascular abnormalities.[4] ACC and partner organizations have also published AUC criteria for management of patients with aortic stenosis.[5] The 2014 ACC/AHA guidelines and the 2017 update are summarized in this chapter. The European Society of Cardiology and European Association for Cardio-Thoracic Surgery have also published guidelines for management of patients with VHD.[6] There are slight differences between the U.S. and European guidelines, but most recommendations are concordant.

As with other ACC/AHA guidelines, these recommendations use the standard ACC/AHA classification system for indications:

Class I: Conditions for which there is evidence and/or general agreement that the test is useful and effective

Class II: Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness or efficacy of performing the test

Class IIa: Weight of evidence or opinion in favor of usefulness or efficacy

Class IIb: Usefulness or efficacy less well established by evidence or opinion

Class III: Conditions for which there is evidence and/or general agreement that the test is not useful or effective and in some cases may be harmful (specifying “no benefit” or “harmful”)

Three levels are used to rate the evidence on which recommendations have been based:

Level A recommendations are derived from data from multiple randomized clinical trials.

Level B recommendations are derived from moderate-quality evidence from one or more randomized trials or meta-analyses (B-R) or nonrandomized, observational, or registry studies (B-NR).

Level C recommendations are based on nonrandomized observational studies with limitations of design (C-LD) or the consensus opinion of experts (C-EO).

The ACC/AHA guidelines define stages of progression of VHD to include patients at risk, asymptomatic patients with established mild to severe VHD, and symptomatic patients with VHD (**Table 72G.1; see also Tables 68.2, 68.5, 69.1, 69.3, 69.4, and 70.3**). The guidelines further emphasize that the clinical assessment should be based on the patient's symptomatic status and findings from the physical examination. Cardiac auscultation remains the most widely used method of screening for VHD. The chest radiograph and electrocardiogram (ECG), if normal, can often provide reassurance that a murmur is clinically insignificant. Echocardiography should be considered after assessment of these more routine data, and echocardiography is determined to be inappropriate for the evaluation of murmurs that experienced observers consider innocent or functional. In contrast, echocardiography is considered appropriate even in asymptomatic patients with murmurs suggesting significant valvular disease or with other signs or symptoms of cardiovascular disease (**Table 72G.2**), and there is emphasis on the use of Doppler echocardiography to quantify the severity of valvular stenosis and regurgitation. The recommended frequency of echocardiography in asymptomatic patients is shown in **Table 67.2**. In some cases, cardiac magnetic resonance imaging (CMR), cardiac catheterization and angiography, and exercise stress testing (**see Table 67.3**) are appropriate. For patients with severe aortic stenosis and low cardiac output (low-flow, low-gradient aortic stenosis), dobutamine stress echocardiography may be a reasonable tool for evaluation.

TABLE 72G.1

Stages of Progression of Valvular Heart Disease (VHD)[1]

STAGE	DEFINITION	DESCRIPTION
A	At risk	Patients with risk factors for the development of VHD
B	Progressive	Patients with progressive VHD (mild to moderate severity and asymptomatic)
C	Asymptomatic severe	Asymptomatic patients who have reached the criteria for severe VHD
		C1: Asymptomatic patients with severe VHD in whom the left or right ventricle remains compensated
		C2: Asymptomatic patients who have severe VHD, with decompensation of the left or right ventricle
D	Symptomatic severe	Patients who have developed symptoms as a result of VHD

TABLE 72G.2

ACC/AHA Guidelines for Diagnostic Testing in Patients with Valvular Heart Disease[1]

CLASS	INDICATION	LOE
General Indications for Valvular Heart Disease (VHD)		
I	TTE in the initial evaluation of patients with known or suspected VHD to confirm the diagnosis, establish etiology, determine severity, assess hemodynamic consequences, determine prognosis, and evaluate for timing of intervention.	B
	TTE in patients with known VHD with any change in symptoms or physical examination findings.	C
	Periodic monitoring with TTE in asymptomatic patients with known VHD at intervals depending on valve lesion, severity, ventricular size, and ventricular function.	C
	Cardiac catheterization for hemodynamic assessment in symptomatic patients with VHD when noninvasive tests are inconclusive or when there is a discrepancy between the findings on noninvasive testing and physical examination regarding severity of the valve lesion.	C
	Coronary angiography before valve intervention in patients with VHD with symptoms of angina, objective evidence of ischemia, decreased LVEF, history of CAD, or CAD risk factors (including men age >40 years and postmenopausal women).	C
IIa	Exercise testing is reasonable in selected patients with asymptomatic severe VHD to (1) confirm the absence of symptoms, (2) assess the hemodynamic response to exercise, or (3) determine prognosis (note class I recommendation for MS).	B
Indications for Specific Valve Diseases		
I	TTE in patients with dilated aortic sinuses or ascending aorta or with a BAV (stages A and B) to evaluate the presence and severity of AR.	B
	TEE in patients with MS considered for percutaneous mitral balloon commissurotomy to assess the presence or absence of left atrial thrombus and to further evaluate the severity of MR.	B
	TEE for evaluation of patients with chronic primary MR (stages B to D) in whom noninvasive imaging provides nondiagnostic information regarding severity of MR, mechanism of MR, and/or status of LV function.	C
	Intraoperative TEE to establish the anatomic basis for chronic primary MR (stages C and D) and to guide repair.	B
	CMR in patients with moderate or severe VHD (stages B, C, and D) and suboptimal TTE images for the assessment of LV systolic function, systolic and diastolic volumes, and assessment of VHD severity.	B
	MRA or CTA in patients with BAV when morphology of the aortic sinuses, sinotubular junction, or ascending aorta cannot be assessed accurately or fully by TTE.	C
	Serial TTE, MRA, or CTA to evaluate the size and morphology of the aortic sinuses and ascending aorta in patients with BAV and an aortic diameter greater than 4.0 cm, with the examination interval determined by the degree and rate of progression of aortic dilation and by family history. In patients with aortic diameter greater than 4.5 cm, this evaluation should be performed on an annual basis.	C
	Exercise testing with Doppler or invasive hemodynamic assessment in patients with MS to evaluate the response of the mean mitral gradient and pulmonary artery pressure when there is a discrepancy between resting Doppler echocardiographic findings and clinical symptoms or signs.	C
	Noninvasive imaging (stress nuclear/positron emission tomography, CMR, or stress TTE), coronary CTA, or cardiac catheterization, including coronary arteriography, is useful to establish etiology of chronic secondary MR (stages B to D) and/or assess myocardial viability, which in turn may influence management of functional MR.	C
IIa	Low-dose dobutamine stress testing using echocardiographic or invasive hemodynamic measurements is reasonable in patients with stage D2 AS with all the following: Calcified aortic valve with reduced systolic opening LVEF less than 50% Calculated valve area of 1.0 cm^2 or less Aortic velocity less than 4 m/sec or mean pressure gradient less than 40 mm Hg	B
III	Exercise testing should not be performed in symptomatic patients with AS when the aortic velocity is 4 m/sec or greater or the mean pressure gradient is 40 mm Hg or greater (stage D).	B

LOE, Level of evidence; *AR,* aortic regurgitation; *AS,* aortic stenosis; *BAV,* bicuspid aortic valve; *CAD,* coronary artery disease; *CMR,* cardiac magnetic resonance imaging; *CTA,* computed tomographic angiography; *LVEF,* left ventricular ejection fraction; *MR,* mitral regurgitation; *MRA,* magnetic resonance angiography; *MS,* mitral stenosis; *TEE,* transesophageal echocardiography; *TTE,* transthoracic echocardiography.

Aortic Stenosis (see Chapter 68)

The guidelines include limited indications for medical therapy for aortic stenosis (AS) other than control of blood pressure (**Table 72G.3**).

TABLE 72G.3

ACC/AHA Guidelines for Medical Management of Valvular Heart Disease[1]

DISEASE	CLASS	INDICATION	LOE
Aortic stenosis (AS)	I	Hypertension in patients at risk for development of AS (stage A) and in patients with asymptomatic AS (stages B and C) should be treated according to standard GDMT, started at a low dose and gradually titrated upward as needed with frequent clinical monitoring.	B
	IIb	Vasodilator therapy may be reasonable if used with invasive hemodynamic monitoring in the acute management of patients with severe decompensated AS (stage D) with NYHA Class IV HF symptoms.	C
	III	Statin therapy is not indicated for prevention of hemodynamic progression of AS in patients with mild to moderate calcific valve disease (stages B to D).	A
Aortic regurgitation (AR)	I	Treatment of hypertension (systolic BP >140 mm Hg) is recommended in patients with chronic AR (stages B and C), preferably with dihydropyridine calcium channel blockers or ACE inhibitors/ARBs.	B
	IIa	Medical therapy with ACE inhibitors/ARBs and beta blockers is reasonable in patients with severe AR who have symptoms and/or LV dysfunction (stages C2 and D) when surgery is not performed because of comorbidities.	B
Mitral stenosis (MS)	I	Anticoagulation (vitamin K antagonist or heparin) is indicated in patients with (1) MS and AF (paroxysmal, persistent, or permanent), (2) MS and prior embolic event, or (3) MS and left atrial thrombus.	B
	IIa	Heart rate control can be beneficial in patients with MS and AF and fast ventricular response.	C
	IIb	Heart rate control may be considered for patients with MS in normal sinus rhythm and symptoms associated with exercise.	B
Mitral regurgitation (MR)	I	Patients with chronic secondary MR (stages B to D) and HF with reduced LVEF should receive standard GDMT therapy for HF, including ACE inhibitors, ARBs, beta blockers, and/or aldosterone antagonists as indicated.	A
		Cardiac resynchronization therapy with biventricular pacing is recommended for symptomatic patients with chronic severe secondary MR (stages B to D) who meet the indications for device therapy.	A
	IIa	Medical therapy for systolic dysfunction is reasonable in symptomatic patients with chronic primary MR (stage D) and LVEF less than 60% in whom surgery is not contemplated.	B
	III	Vasodilator therapy is not indicated for normotensive asymptomatic patients with chronic primary MR (stages B and C1) and normal systolic LV function.	B
Tricuspid regurgitation (TR)	IIa	Diuretics can be useful for patients with severe TR and signs of right-sided HF (stage D).	C
	IIb	Medical therapies to reduce elevated pulmonary artery pressures and/or pulmonary vascular resistance might be considered in patients with severe functional TR (stages C and D).	C

LOE, Level of evidence; *ACE,* angiotensin-converting enzyme; *AF,* atrial fibrillation; *ARBs,* angiotensin receptor blockers; *AS,* aortic stenosis; *GDMT,* guideline-directed medical therapy; *HF,* heart failure; *LVEF,* left ventricular ejection fraction.

Aortic Valve Replacement

Surgery is recommended for patients with severe AS who have symptoms or left ventricular (LV) systolic dysfunction or are undergoing other forms of cardiac surgery (**Table 72G.4**). The ACC/AHA guidelines are generally supportive (class IIa) of aortic valve replacement (AVR) for asymptomatic patients with very severe AS (peak aortic valve velocity >5 m/sec) and those with moderate AS who are undergoing other forms of cardiac surgery. A class IIa recommendation is also given for patients with symptomatic low-flow, low-gradient AS with either normal or depressed LV systolic function, while stressing the care required to be certain that the AS is severe and is likely the cause of the symptoms. The 2017 guidelines update[2] provides the updated recommendations for selection of surgical AVR versus transcatheter AVR or aortic balloon valvotomy (**Table 72G.5**)

TABLE 72G.4

ACC/AHA Guidelines for Aortic Valve Replacement (AVR) for Aortic Stenosis (AS)[1]

CLASS	INDICATION	LOE
I	AVR with severe high-gradient AS who have symptoms by history or on exercise testing (stage D1).	B
	AVR for asymptomatic patients with severe AS (stage C2) and LVEF less than 50%.	B
	AVR for patients with severe AS (stage C or D) when undergoing other cardiac surgery.	B
IIa	AVR is reasonable for asymptomatic patients with very severe AS (stage C1, aortic velocity ≥5 m/sec) and low surgical risk.	B
	AVR is reasonable in asymptomatic patients (stage C1) with severe AS and decreased exercise tolerance or an exercise fall in blood pressure.	B
	AVR is reasonable in symptomatic patients with low-flow/low-gradient severe AS with reduced LVEF (stage D2) with a low-dose dobutamine stress study that shows an aortic velocity of 4 m/sec or more (or mean pressure gradient ≥40 mm Hg) with a valve area of 1.0 cm^2 or less at any dobutamine dose.	B
	AVR is reasonable in symptomatic patients with low-flow, low-gradient severe AS (stage D3) who are normotensive and have LVEF of 50% or greater, if clinical, hemodynamic, and anatomic data support valve obstruction as the most likely cause of symptoms.	C
	AVR is reasonable for patients with moderate AS (stage B) (aortic velocity, 3.0 to 3.9 m/sec) who are undergoing other cardiac surgery.	C
IIb	AVR may be considered for asymptomatic patients with severe AS (stage C1) and rapid disease progression and low surgical risk.	C

LOE, Level of evidence; *LVEF,* left ventricular ejection fraction.

TABLE 72G.5

Updated ACC/AHA Guidelines for Choice of Surgical Versus Transcatheter Treatment of Aortic Stenosis (AS)[2]

CLASS	INDICATION	LOE
I	For patients in whom TAVR or high-risk surgical AVR is being considered, members of a heart valve team should collaborate to provide optimal patient care.	C
	Surgical AVR in symptomatic and asymptomatic patients with severe AS who meet an indication for AVR (listed in Table 72G.4) when surgical risk is low or intermediate. (*Modified 2017*)	B
	TAVR in patients who meet an indication for AVR for AS who have a prohibitive surgical risk and a predicted post-TAVR survival >12 months. (*Modified 2017*)	A
	TAVR or surgical AVR in patients with severe AS who meet an indication for AVR and who have high surgical risk. (*Modified 2017*)	A
IIa	TAVR is a reasonable alternative to surgical AVR for symptomatic patients with severe AS and an intermediate surgical risk. (*New 2017*)	B
IIb	Percutaneous aortic balloon dilation may be considered as a bridge to surgical or transcatheter AVR in severely symptomatic patients with severe AS.	C
III	TAVR is not recommended in patients in whom the existing comorbidities would preclude the expected benefit from correction of AS.	B

LOE, Level of evidence; *AVR,* aortic valve replacement; *TAVR,* transcatheter AVR.

Chronic Aortic Regurgitation

The ACC/AHA guidelines consider vasodilator therapy appropriate for patients with hypertension, with weak endorsement for those with severe aortic regurgitation (AR), normal LV function, and evidence of LV dilation (**see Table 72G.3**). However, there is no endorsement for long-term vasodilator therapy in normotensive patients with normal LV function and mild AR. Vasodilator therapy is not an alternative to surgery for patients who are appropriate candidates for valve replacement, including those with asymptomatic LV dysfunction, but might be considered in those who have prohibitively high risks for surgery because of medical comorbidities.

Aortic Valve Replacement

The 2014 ACC/AHA guidelines recommend AVR for patients with severe AR and symptoms (**Table 72G.6**), as well as asymptomatic patients with LV systolic dysfunction (ejection fraction [EF] <50%) or those undergoing other forms of cardiac surgery. The guidelines were not supportive of surgery solely because of a decline in EF during exercise. Class IIa indications include patients with severe AR and normal LV function who have severe LV dilation (LV end-systolic dimension >50 mm) and those with moderate AR undergoing other forms of cardiac surgery. A class IIb recommendation includes those patients with severe AR, normal LV systolic function, and LV end-diastolic dimension greater than 65 mm, particularly if there is evidence of progressive LV dilation.

TABLE 72G.6

ACC/AHA Guidelines for Aortic Valve Replacement (AVR) for Chronic Aortic Regurgitation (AR)[1]

CLASS	INDICATION	LOE
I	AVR for symptomatic patients with severe AR regardless of LV systolic function (stage D).	B
	AVR for asymptomatic patients with chronic severe AR and LV systolic dysfunction (LVEF <50%) (stage C2).	B
	AVR for patients with severe AR (stage C or D) while undergoing cardiac surgery for other indications.	C
IIa	AVR is reasonable for asymptomatic patients with severe AR with normal LV systolic function (LVEF ≥50%), but severe LV dilation (stage C2, LVESD >50 mm).	B
	AVR is reasonable in patients with moderate AR (stage B) who are undergoing other cardiac surgery.	C
IIb	AVR may be considered for asymptomatic patients with severe AR and normal LV systolic function (stage C1, LVEF ≥50%) but severe LV dilation (LVEDD >65 mm) if surgical risk is low.*	C

*Particularly in the setting of progressive LV enlargement.

LOE, Level of evidence; *LV,* left ventricular; *LVEDD,* LV end-diastolic dimension; *LVEF,* LV ejection fraction; *LVESD,* LV end-systolic dimension.

Bicuspid Aortic Valve With Dilated Ascending Aorta

In patients with bicuspid aortic valve (BAV), CMR or computed tomography (CT) should be used when echocardiography cannot adequately assess the aortic sinuses or ascending aorta, or to quantify the severity of dilation and involvement of the ascending aorta further (**see Table 72G.2**). Recommendations for surgical repair or replacement were updated in 2016.[7] Surgery is indicated if the diameter of the aortic root or ascending aorta is greater than 5.5 cm (or smaller in patients of small stature), is greater than 5.0 cm in patients with risk factors for dissection (family history of aortic dissection or aortic growth rate of 0.5 cm/year or more), or if the patient is at low surgical risk and the surgery is performed by an experienced aortic surgical team in a center with established expertise in these procedures (**Table 72G.7**). Aortic surgery is also reasonable in patients with a BAV undergoing aortic valve surgery because of severe AS or AR (**see Tables 72G.4 and 72G.6**) if the diameter of the ascending aorta is greater than 4.5 cm.

TABLE 72G.7

Updated ACC/AHA Guidelines for Aortic Surgery in Patients with Bicuspid Aortic Valve (BAV)[7]

CLASS	INDICATION	LOE
I	Surgery to repair the aortic sinuses or replace the ascending aorta in patients with BAV if the diameter of the aortic sinuses or ascending aorta is greater than 5.5 cm.	B
IIa	Operative intervention to repair the aortic sinuses or replace the ascending aorta is reasonable in patients with BAV if the diameter of the aortic sinuses or ascending aorta is greater than 5.0 cm and a risk factor for dissection is present (family history of aortic dissection or if the rate of increase in diameter is ≥0.5 cm/year) or if the patient is at low surgical risk and surgery is performed by an experienced aortic surgical team in a center with established expertise in these procedures. (*Modified 2017*)	B
	Replacement of the ascending aorta is reasonable in patients with a BAV undergoing aortic valve surgery because of severe AS or AR (see Tables 72G.4 and 72G.6) if the diameter of the ascending aorta is greater than 4.5 cm.	C

LOE, Level of evidence; *AR,* aortic regurgitation; *AS,* aortic stenosis.

Mitral Stenosis (see Chapter 69)

Patients with more than mild mitral stenosis (MS) should be counseled to avoid unusual physical stresses. Anticoagulation is recommended for patients with MS if they have a history of atrial fibrillation, prior embolic event, or left atrial (LA) thrombus (**see Table 72G.3; see also eTable 67.1**). The guidelines are

not strongly supportive of anticoagulation on the basis of LA size alone.

Percutaneous Mitral Balloon Valvotomy

In centers with skilled operators, the guidelines recommend percutaneous mitral balloon commissurotomy (PMBC) as the initial procedure of choice for symptomatic patients with moderate or severe MS and favorable valve morphology and for asymptomatic patients with pulmonary hypertension (**Table 72G.8**). PMBC is not indicated for patients with mild MS, LA thrombus, or moderate to severe mitral regurgitation (MR).

TABLE 72G.8

ACC/AHA Guidelines for Intervention for Mitral Stenosis (MS)[1]

CLASS	INDICATION	LOE
I	PMBC for symptomatic patients with severe MS (MVA ≤1.5 cm^2, stage D) and favorable valve morphology in the absence of contraindications.	A
	Mitral valve surgery in severely symptomatic patients (NYHA Class III/IV) with severe MS (MVA ≤1.5 cm^2, stage D) who are not high risk for surgery and who are not candidates for or failed previous PMBC.	B
	Concomitant mitral valve surgery for patients with severe MS (MVA ≤1.5 cm^2, stages C or D) undergoing other cardiac surgery.	C
IIa	PMBC is reasonable for asymptomatic patients with very severe MS (MVA ≤1 cm^2, stage C) and favorable valve morphology in the absence of contraindications.	C
	Mitral valve surgery is reasonable for severely symptomatic patients (NYHA Class III/IV) with severe MS (MVA ≤1.5 cm^2, stage D) provided there are other operative indications.	C
IIb	PMBC may be considered for asymptomatic patients with severe MS (MVA ≤1.5 cm^2, stage C) and favorable valve morphology who have new onset of AF in the absence of contraindications.	C
	PMBC may be considered for symptomatic patients with MVA greater than 1.5 cm^2 if there is evidence of hemodynamically significant MS during exercise.	C
	PMBC may be considered for severely symptomatic patients (NYHA Class III/IV) with severe MS (MVA ≤1.5 cm^2, stage D) who have suboptimal valve anatomy and are not candidates for surgery or at high risk for surgery.	C
	Concomitant mitral valve surgery may be considered for patients with moderate MS (MVA, 1.6 to 2.0 cm^2) undergoing other cardiac surgery.	C
	Mitral valve surgery and excision of the left atrial appendage may be considered for patients with severe MS (MVA ≤1.5 cm^2, stages C and D) who have had recurrent embolic events while receiving adequate anticoagulation.	C

LOE, Level of evidence; *MVA,* mitral valve area; *NYHA,* New York Heart Association; *PMBC,* percutaneous mitral balloon commissurotomy.

Surgical Options

When possible, mitral valve repair is indicated for patients with symptomatic, moderate or severe MS when PMBC is not possible. Mitral valve repair may be considered for asymptomatic patients who experience recurrent embolic events despite adequate anticoagulation (class IIb). Mitral valve replacement (MVR) is an option when repair is not feasible.

Chronic Primary Mitral Regurgitation

In patients with chronic primary MR, transesophageal echocardiography (TEE) is considered most appropriate for intraoperative guidance and when transthoracic studies are inadequate (**see Table 72G.2**).

Surgery and Transcatheter Intervention

The ACC/AHA guidelines consider mitral valve repair to be the operation of choice for patients with suitable valves when performed by an experienced operator (**Table 72G.9**). Class I recommendations for repair are preferred to MVR in patients with primary MR limited to the posterior mitral leaflet and in patients with primary MR involving the anterior leaflet or both leaflets, when a successful and durable repair can be accomplished.

TABLE 72G.9

Updated ACC/AHA Guidelines for Intervention for Chronic Primary Mitral Regurgitation (MR)[2]

CLASS	INDICATION	LOE
I	MV surgery for symptomatic patients with severe primary MR (stage D) and LVEF greater than 30%.	B
	MV surgery for asymptomatic patients with severe primary MR and LV dysfunction (LVEF 30% to 60% and/or LVESD ≥40 mm, stage C2).	B
	MV repair in preference to MVR when surgical treatment for patients with severe primary MR limited to the posterior leaflet.	B
	MV repair in preference to MVR when surgical treatment for patients with severe primary MR involving the anterior leaflet or both leaflets when a successful and durable repair can be accomplished.	B
	Concomitant MV repair or replacement in patients with severe primary MR undergoing cardiac surgery for other indications.	B
IIa	MV repair is reasonable in asymptomatic patients with severe primary MR (stage C1) with preserved LV function (LVEF >60% and LVESD <40 mm) in whom the likelihood of a successful and durable repair without residual MR is greater than 95% with an expected mortality less than 1% when performed at a Heart Valve Center of Excellence.	B
	MV surgery is reasonable for asymptomatic patients with severe primary MR and preserved LV function (LVEF >60% and LVESD <40 mm) with a progressive increase in LV size or decrease in LVEF on serial imaging studies. (*New 2017*)	C
	MV repair is reasonable for asymptomatic patients with severe nonrheumatic primary MR (stage C1) and preserved LV function in whom there is a high likelihood of a successful and durable repair with (1) new onset of AF or (2) resting pulmonary hypertension (PA systolic pressure >50 mm Hg).	B
	Concomitant MV repair is reasonable in patients with moderate primary MR (stage B) undergoing cardiac surgery for other indications.	C
IIb	MV surgery may be considered in symptomatic patients with severe primary MR and LVEF of 30% or less (stage D).	C
	Transcatheter MV repair may be considered for severely symptomatic patients (NYHA Class III/IV) with severe primary MR (stage D) who have a reasonable life expectancy, but a prohibitive surgical risk because of severe comorbidities.	B
III	MVR should not be performed for the treatment of isolated severe primary MR limited to less than one half of the posterior leaflet unless MV repair has been attempted and was unsuccessful.	B

LOE, Level of evidence; *AF,* atrial fibrillation; *LV,* left ventricular; *LVEF,* LV ejection fraction; *LVESD,* LV end-systolic dimension; *MV,* mitral valve; *MVR,* mitral valve replacement; *NYHA,* New York Heart Association; *PA,* pulmonary artery.

Surgery is recommended for patients with chronic severe primary MR with symptoms independent of LV function and in asymptomatic patients when there is evidence of LV dysfunction (EF 30% to 60% and/or end-systolic dimension >40 mm). The guidelines also support mitral valve repair in asymptomatic patients with severe primary MR and normal LV function, with the recommendation that it is reasonable (class IIa) to perform surgery in such patients in the setting of an experienced Heart Valve Center of Excellence in which the likelihood of successful repair without residual MR is greater than 95% and with an anticipated operative mortality less than 1%. Surgery is also reasonable (class IIa) in patients with new-onset atrial fibrillation or pulmonary hypertension (pulmonary artery systolic pressure >50 mm Hg at rest).

Transcatheter mitral valve repair may be considered for severely symptomatic patients with severe primary MR (stage D) who have a reasonable life expectancy, but a prohibitive surgical risk because of severe comorbidities.

Chronic Secondary Mitral Regurgitation

Management of patients with chronic secondary forms of MR is focused primarily on treatment of the underlying LV dysfunction with medical and device therapies (**see Table 72G.3**). Indications for surgical intervention are less certain (**Table 72G.10**), but it is reasonable (class IIa) to perform mitral valve repair or MVR for patients with chronic severe secondary MR (stages C and D) who are undergoing coronary artery bypass grafting (CABG) or AVR. Mitral valve repair or replacement may be considered (class IIb) in patients with severe secondary MR and heart failure symptoms who have not responded to guideline-directed medical therapy (GDMT) for heart failure, including cardiac resynchronization therapy in appropriate patients. Updated guideline recommendations for secondary MR[2] incorporate results of randomized clinical trials that it is reasonable to choose chordal-sparing MVR over downsized annuloplasty repair if operation is considered for severely symptomatic patients. Moreover, the usefulness of mitral valve repair is uncertain in patients with chronic, moderate, ischemic MR undergoing CABG. Transcatheter mitral valve repair is not yet approved in the United States for secondary ischemic

or functional MR.

TABLE 72G.10

Updated ACC/AHA Guidelines for Intervention for Chronic Secondary Mitral Regurgitation (MR)[2]

CLASS	INDICATION	LOE
IIa	MV surgery is reasonable for patients with chronic severe secondary MR (stages C and D) who are undergoing CABG or AVR.	C
	It is reasonable to choose chordal-sparing MVR over downsized annuloplasty repair if operation is considered for severely symptomatic patients (NYHA Class III/IV) with chronic severe ischemic MR (stage D) and persistent symptoms despite GDMT for heart failure. (*New 2017*)	B
IIb	MV surgery may be considered for severely symptomatic patients (NYHA class III-IV) with chronic severe secondary MR (stage D).	B
	In patients with chronic, moderate, or ischemic MR (stage B) undergoing CABG, the usefulness of mitral valve repair is uncertain. (*Modified 2017*)	B

LOE, Level of evidence; *AVR,* aortic valve replacement; *CABG,* coronary artery bypass graft surgery; *GDMT,* guideline-directed medical therapy; *MV,* mitral valve; *NYHA,* New York Heart Association.

Tricuspid Valve Disease (see Chapter 70)

Tricuspid valve repair is appropriate for correcting severe tricuspid regurgitation (TR) in patients with mitral valve disease requiring valve repair or replacement (**Table 72G.11**). Tricuspid valve replacement or annuloplasty is considered reasonable for patients with symptomatic severe primary TR unresponsive to medical therapy, which consists primarily of diuretics. Annuloplasty may be considered for patients with mild to moderate TR who are undergoing surgery for mitral valve disease if they have pulmonary hypertension or dilation of the tricuspid annulus.

TABLE 72G.11

ACC/AHA Guidelines for Intervention for Tricuspid Valve Disease[1]

CLASS	INDICATION	LOE
I	Tricuspid valve surgery is recommended for patients with severe TR (stages C and D) undergoing left-sided valve surgery.	C
	Tricuspid valve surgery is recommended for patients with severe TS at operation for left-sided valve disease.	C
	Tricuspid valve surgery is recommended for patients with isolated, symptomatic severe TS.	C
IIa	Tricuspid valve repair can be beneficial for patients with mild, moderate, or greater functional TR (stage B) at left-sided valve surgery with either tricuspid annular dilation or prior evidence of right-sided heart failure.	B
	Tricuspid valve surgery can be beneficial for patients with symptoms due to severe primary TR that are unresponsive to medical therapy (stage D).	C
IIb	Tricuspid valve repair may be considered for patients with moderate functional TR (stage B) and pulmonary artery hypertension at left-sided valve surgery.	C
	Tricuspid valve surgery may be considered for asymptomatic or minimally symptomatic patients with severe primary TR (stage C) and progressive degrees of moderate or greater RV dilation and/or systolic dysfunction.	C
	Reoperation for isolated tricuspid valve repair or replacement may be considered for persistent symptoms caused by severe TR (stage D) in patients who have undergone previous left-sided valve surgery and who do not have severe pulmonary hypertension or significant RV systolic dysfunction.	C
	Percutaneous balloon tricuspid commissurotomy might be considered in patients with isolated, symptomatic severe TS without accompanying TR.	C

LOE, Level of evidence; *RV,* right ventricular; *TR,* tricuspid regurgitation; *TS,* tricuspid stenosis.

Prosthetic Heart Valves (see Chapter 71)

Choices in Valve Surgery

Numerous options are available for the surgical management of VHD. The ACC/AHA guidelines generally favor mitral valve repair over replacement. The standard surgical approach usually entails a median sternotomy with cardiopulmonary bypass. However, numerous alternatives are gaining acceptance. These include minimally invasive approaches to valve repair such as ministernotomy, small right thoracotomy, and robotic surgery. Transcatheter AVR (TAVR) and percutaneous approaches to mitral valve repair are approved procedures in the United States and Europe.

When replacement is necessary, several variables influence the selection of a bioprosthetic versus a mechanical valve (**Table 72G.12**). Patient preference plays an important role in determining the choice of a prosthetic valve. The class I recommendations are important considerations. First, choice of valve intervention and prosthetic valve type should be a shared decision process that hinges importantly on the desires of the patient. Second, a bioprosthesis is recommended in patients of any age for whom anticoagulant therapy is contraindicated, cannot be managed appropriately, or is not desired. In the 2017 guidelines update,[2] bioprosthetic valves are considered reasonable (class IIa) for patients 70 years and older, and a mechanical prosthesis is reasonable for AVR or MVR in patients younger than 50 who do not have a contraindication to anticoagulation. For patients age 50 to 70, it is reasonable to individualize the choice of mechanical or bioprosthetic valve prosthesis on the basis of individual patient factors and preferences, after full discussion of the trade-offs involved.

TABLE 72G.12

Updated ACC/AHA Guidelines for Selection of Prosthetic Heart Valves[2]

CLASS	INDICATION	LOE
I	Choice of valve intervention and prosthetic valve type should be a shared decision process with patient.	C
	A bioprosthesis is recommended in patients of any age for whom anticoagulant therapy is contraindicated, cannot be managed appropriately, or is not desired.	C
IIa	A mechanical prosthesis is reasonable for AVR or MVR in patients younger than 50 who do not have a contraindication to anticoagulation. (*Modified 2017*)	B
	A bioprosthesis is reasonable in patients older than 70.	B
	For patients age 50 to 70, it is reasonable to individualize the choice of either a mechanical or a bioprosthetic valve prosthesis on the basis of individual patient factors and preferences, after full discussion of the trade-offs involved. (*Modified 2017*)	B
IIb	Replacement of the aortic valve by a pulmonary autograft (the Ross procedure), when performed by an experienced surgeon, may be considered in young patients when anticoagulation with a VKA is contraindicated or undesirable.	C

LOE, Level of evidence; *AVR,* aortic valve replacement; *MVR,* mitral valve replacement; *VKA,* vitamin K antagonist.

Imaging Prosthetic Heart Valves

Table 72G.13 provides recommendations for imaging in patients with prosthetic heart valves.

TABLE 72G.13

ACC/AHA Guidelines for Imaging of Prosthetic Heart Valves[1]

CLASS	INDICATION	LOE
I	An initial TTE study in patients after prosthetic valve implantation for evaluation of valve hemodynamics.	B
	Repeat TTE in patients with prosthetic heart valves if there is a change in clinical symptoms or signs suggesting valve dysfunction.	C
	TEE is recommended when clinical symptoms or signs suggest prosthetic valve dysfunction.	C
IIa	Annual TTE is reasonable in patients with a bioprosthetic valve after the first 10 years, even in the absence of a change in clinical status.	C

LOE, Level of evidence; *TEE,* transesophageal echocardiography; *TTE,* transthoracic echocardiography.

Anticoagulation Therapy

The ACC/AHA guidelines recommend warfarin therapy for patients with mechanical valves (**Table 72G.14**). For patients with aortic valve prostheses, those with bileaflet mechanical valves and Medtronic-Hall valves should maintain an international normalized ratio (INR) between 2 and 3, whereas those with Starr-Edwards valves or mechanical disc valves should maintain INR between 2.5 and 3.5. The same target is indicated after MVR with a mechanical valve. In the 2017 guidelines update,[2] INR of 1.5 to 2.0 is considered a reasonable target in patients with mechanical On-X AVR and no thromboembolic risk factors. For bioprostheses, short-term anticoagulation with warfarin (INR, 2.5) is reasonable for AVR and MVR (3 to 6 months after surgery) and TAVR (3 months after implantation) in

patients at low risk of bleeding. Low-dose aspirin (75 to 100 mg/day) is recommended in addition to warfarin (class I) for all patients with mechanical heart valves and is reasonable (class IIa) in those with biologic valves. Clopidogrel may be considered for those who cannot take aspirin.

TABLE 72G.14

Updated ACC/AHA Guidelines for Antithrombotic Therapies for Prosthetic Heart Valves[2]

CLASS	INDICATION	LOE
I	Anticoagulation with a VKA and INR monitoring in patients with a mechanical prosthetic valve.	A
	Anticoagulation with a VKA to achieve an INR of 2.5 in patients with a mechanical AVR (bileaflet or current-generation single tilting disc) and no risk factors for thromboembolism.	B
	Anticoagulation with a VKA to achieve an INR of 3.0 in patients with a mechanical AVR and additional risk factors for thromboembolic events (AF, previous thromboembolism, LV dysfunction, or hypercoagulable conditions) or an older-generation mechanical AVR (e.g., ball-in-cage).	B
	Anticoagulation with a VKA to achieve an INR of 3.0 in patients with a mechanical MVR.	B
	Aspirin, 75 to 100 mg daily, in addition to anticoagulation with a VKA in patients with mechanical valve prosthesis.	A
IIa	Aspirin, 75 to 100 mg daily, is reasonable in all patients with a bioprosthetic aortic or mitral valve.	B
	Anticoagulation with a VKA to achieve a target INR of 2.5 is reasonable for the first 3 months and for as long as 6 months after bioprosthetic MVR or AVR in patients at low risk of bleeding. (*Modified 2017*)	B
IIb	A lower target INR of 1.5 to 2.0 may be reasonable in patients with mechanical On-X AVR and no thromboembolic risk factors. (*New 2017*)	B
	Anticoagulation with a VKA with a goal INR of 2.5 may be reasonable for the first 3 months after TAVR in patients at low risk of bleeding. (*New 2017*)	B
	Clopidogrel, 75 mg daily, may be reasonable for the first 6 months after a TAVR, in addition to lifelong aspirin, 75 to 100 mg daily.	C
III	Anticoagulant therapy with oral direct thrombin inhibitors or anti-Xa agents should not be used in patients with mechanical valve prostheses.	B

LOE, Level of evidence; *AF,* atrial fibrillation; *AVR,* aortic valve replacement; *INR,* international normalized ratio; *MVR,* mitral valve replacement; *TAVR,* transcatheter AVR; *VKA,* vitamin K antagonist.

Bridging Therapy

Antithrombotic medications must sometimes be interrupted in patients with mechanical valve prostheses for noncardiac surgery, invasive procedures, or dental care. In patients at low risk of thrombosis, warfarin should be stopped 48 to 72 hours before the procedure and started no more than 24 hours after the procedure (**Table 72G.15**). The ACC/AHA guidelines indicate that the use of heparin is usually unnecessary for patients at low risk of thrombosis, defined as those with a bileaflet mechanical aortic valve prosthesis with no risk factors. In the 2017 guidelines update,[2] bridging anticoagulation during the interval when INR is subtherapeutic preoperatively is reasonable on an individualized basis, with the risks of bleeding weighed against the benefits of thromboembolism prevention, for patients who are undergoing invasive or surgical procedures with a (1) mechanical AVR and any thromboembolic risk factor, (2) older-generation mechanical AVR, or (3) mechanical MVR. The recommended bridging therapy is intravenous unfractionated heparin or subcutaneous doses of low-molecular weight heparin.

TABLE 72G.15

Updated ACC/AHA Guidelines for Bridging Antithrombotic Therapies for Mechanical Heart Valves[2]

CLASS	INDICATION	LOE
I	Continuation of VKA anticoagulation with a therapeutic INR is recommended in patients with mechanical heart valves undergoing minor procedures (e.g., dental extractions, cataract removal) where bleeding is easily controlled.	C
	Temporary interruption of VKA anticoagulation, without bridging agents while INR is subtherapeutic is recommended in patients with a bileaflet mechanical AVR and no other risk factors for thrombosis who are undergoing invasive or surgical procedures.	C
IIa	Bridging anticoagulation therapy during the interval when INR is subtherapeutic preoperatively is reasonable on an individualized basis, with the risks of bleeding weighed against the benefits of thromboembolism prevention, for patients who are undergoing invasive or surgical procedures with a (1) mechanical AVR and any thromboembolic risk factor, (2) older-generation mechanical AVR, or (3) mechanical MVR. (*Modified 2017*)	C
	Administration of fresh-frozen plasma or prothrombin-complex concentrate is reasonable in patients with mechanical valves receiving VKA therapy who require emergency noncardiac surgery or invasive procedures.	C

LOE, Level of evidence; *AVR,* aortic valve replacement; *INR,* international normalized ratio; *MVR,* mitral valve replacement; *VKA,* vitamin K antagonist.

Prosthetic Valve Thrombosis

Emergency surgery is most reasonable for patients with a thrombosed left-sided prosthetic valve and moderate to severe symptoms (NYHA Class III or IV) or a large clot burden. Fibrinolytic therapy may be considered for patients with less severe symptoms, smaller clot burdens, or when surgery is high risk or unavailable (**Table 72G.16**).

TABLE 72G.16

Updated ACC/AHA Guidelines for Management of Prosthetic Valve Thrombosis[2]

CLASS	INDICATION	LOE
Diagnosis and Follow-Up		
I	Urgent evaluation with multimodality imaging is indicated in patients with suspected mechanical prosthetic valve thrombosis to assess valvular function, leaflet motion, and the presence and extent of thrombus. (*Modified 2017*)	B
Medical Therapy		
I	Fibrinolytic therapy is reasonable for patients with a thrombosed left-sided prosthetic heart valve, recent onset (<14 days) of NYHA Class I or II symptoms, and a small thrombus (<0.8 cm^2).	B
IIa	Fibrinolytic therapy is reasonable for thrombosed right-sided prosthetic heart valves.	B
Indications for Intervention		
I	Urgent initial treatment with either slow-infusion low-dose fibrinolytic therapy or emergency surgery is recommended for patients with a thrombosed left-sided mechanical prosthetic heart valve presenting with symptoms of valve obstruction. (*Modified 2017*)	B

LOE, Level of evidence; *NYHA,* New York Heart Association.

Prosthetic Valve Stenosis and Regurgitation

The 2017 guidelines update[2] includes recommendations for transcatheter valve-in-valve treatment of severe bioprosthetic AS or AR in patients judged by the heart team to be at high or prohibitive risk for surgical therapy, in whom improvement in hemodynamics is anticipated (**Table 72G.17**).

Table 72G.17

Updated ACC/AHA Guidelines for Management of Prosthetic Valve Stenosis and Regurgitation[2]

CLASS	INDICATION	LOE
Prosthetic Valve Stenosis		
I	Repeat valve replacement is indicated for severe symptomatic prosthetic valve stenosis.	C
IIa	In patients with suspected or confirmed bioprosthetic valve thrombosis who are hemodynamically stable and have no contraindications to anticoagulation, initial treatment with a VKA is reasonable. (*New 2017*)	C
	For severely symptomatic patients with bioprosthetic AS judged by the heart team to be at high or prohibitive risk of reoperation, and in whom improvement in hemodynamics is anticipated, a transcatheter valve-in-valve procedure is reasonable. (*New 2017*)	B
Prosthetic Valve Regurgitation		
I	Surgery is recommended for operable patients with mechanical heart valves who have intractable hemolysis or HF caused by severe prosthetic or paraprosthetic regurgitation.	B
IIa	Surgery is reasonable for asymptomatic patients with severe bioprosthetic regurgitation if operative risk is acceptable. (*Modified 2017*)	C
	Percutaneous repair of paravalvular regurgitation is reasonable in patients with prosthetic heart valves and intractable hemolysis or NYHA Class III/IV HF who are at high risk for surgery and have anatomic features suitable for catheter-based therapy when performed in centers with procedural expertise.	B
	For severely symptomatic patients with bioprosthetic AR judged by the heart team to be at high or prohibitive risk for surgical therapy, in whom improvement in hemodynamics is anticipated, a transcatheter valve-in-valve procedure is reasonable. (*New 2017*)	B

LOE, Level of evidence; *AR,* aortic regurgitation; *AS,* aortic stenosis; *HF,* heart failure; *NYHA,* New York Heart Association; *VKA,* vitamin K antagonist.

Valvular Heart Disease in Pregnancy

Native Valve Disorders

Table 72G.18 provides the management considerations for patients with VHD who want to become pregnant or who have become pregnant.

TABLE 72G.18

ACC/AHA Guidelines for Management of Valvular Heart Disease (VHD) in Pregnancy[1]

CLASS	INDICATION	LOE
General Considerations		
I	All patients with suspected VHD should undergo a clinical evaluation and TTE before pregnancy.	C
	All patients with severe VHD (stages C and D) should undergo prepregnancy counseling by a cardiologist with expertise in managing patients with VHD during pregnancy.	C
	All patients referred for a valve operation prior to pregnancy should receive prepregnancy counseling by a cardiologist with expertise in managing patients with VHD during pregnancy regarding the risks and benefits of all options for operative interventions, including mechanical prosthesis, bioprosthesis, and valve repair.	C
	Pregnant patients with severe VHD (stages C and D) should be followed in a tertiary care center with a dedicated heart valve team of cardiologists, surgeons, anesthesiologists, and obstetricians with expertise in the management of high-risk cardiac patients during pregnancy.	C
	Exercise testing is reasonable in asymptomatic patients with severe VHD prior to pregnancy.	C
III	ACE inhibitors and ARBs should *not* be given to pregnant patients with valve disease.	B
	Valve operation should *not* be performed in pregnant patients with valve stenosis in the absence of severe symptoms.	C
Indications for Medical Therapy for Native Valve Stenosis		
IIa	Anticoagulation should be given to pregnant patients with MS and AF unless contraindicated	C
	Use of beta blockers as required for rate control is reasonable for pregnant patients with MS in the absence of contraindication, if tolerated.	C
IIb	Use of diuretics may be reasonable for pregnant patients with MS and heart failure symptoms (stage D).	C
Interventions for Native Valve Stenosis		
I	Valve intervention for symptomatic patients prior to pregnancy with severe AS (aortic velocity ≥4 m/sec or mean pressure gradient ≥40 mm Hg, stage D).	C
	Valve intervention for symptomatic patients prior to pregnancy with severe MS (mitral valve area ≤1.5 cm^2, stage D).	C
	PMBC for asymptomatic patients prior to pregnancy with severe MS (mitral valve area ≤1.5 cm^2, stage C) who have valve morphology favorable for PMBC.	C
IIa	Valve intervention is reasonable for asymptomatic patients prior to pregnancy with severe AS (aortic velocity ≥4 m/sec or mean pressure gradient ≥40 mm Hg, stage C).	C
	PMBC is reasonable for pregnant patients with severe MS (mitral valve area ≤1.5 cm^2, stage D) with valve morphology favorable for PMBC who remain symptomatic with NYHA Class III or IV symptoms despite medical therapy.	B
	Valve intervention is reasonable for pregnant patients with severe MS (mitral valve area ≤1.5 cm^2, stage D) and valve morphology not favorable for PMBC only if there are refractory NYHA Class IV symptoms.	C
	Valve intervention is reasonable for pregnant patients with severe AS (mean pressure gradient ≥40 mm Hg, stage D) only if there is hemodynamic deterioration or NYHA Class III or IV symptoms.	B
III	Valve operation should *not* be performed in pregnant patients with valve stenosis in the absence of severe symptoms.	C
Interventions for Native Valve Regurgitation		
I	Valve repair or replacement is recommended prior to pregnancy for symptomatic women with severe valve regurgitation (stage D).	C
IIa	Valve operation for pregnant patients with severe valve regurgitation is reasonable only if there are refractory NYHA Class IV symptoms (stage D).	C
IIb	Valve repair prior to pregnancy may be considered in the asymptomatic patient with severe MR (stage C) and a valve suitable for valve repair, but only after detailed discussion with the patient regarding the risks and benefits of the operation and its outcome on future pregnancies.	C

LOE, Level of evidence; *ACE,* angiotensin converting enzyme; *AF,* atrial fibrillation; *ARBs,* angiotensin receptor blockers; *AS,* aortic stenosis; *MR,* mitral regurgitation; *MS,* mitral stenosis; *NYHA,* New York Heart Association; *PMBC,* percutaneous mitral balloon commissurotomy; *TTE,* transthoracic echocardiography.

Prosthetic Heart Valves

Table 72G.19 outlines the management of patients with prosthetic heart valves during pregnancy, including management of anticoagulation in patients with mechanical heart valves.

TABLE 72G.19

ACC/AHA Guidelines for Management of Prosthetic Heart Valves in Pregnancy[1]

CLASS	INDICATION	LOE
Indications for Evaluation		
I	All patients with a prosthetic valve should undergo a clinical evaluation and baseline TTE prior to pregnancy.	C
	All patients with a prosthetic valve should undergo prepregnancy counseling by a cardiologist with expertise in managing patients with VHD during pregnancy.	C
	TTE should be performed in all pregnant patients with a prosthetic valve if not previously done prior to pregnancy.	C
	Repeat TTE should be performed in all pregnant patients with a prosthetic valve who develop symptoms.	C
	TEE should be performed in all pregnant patients with a mechanical prosthetic valve who have prosthetic valve obstruction or experience an embolic event.	
	Pregnant patients with a mechanical prosthesis should be followed in a tertiary care center with a dedicated Heart Valve Team of cardiologists, surgeons, anesthesiologists, and obstetricians with expertise in the management of high-risk cardiac patients.	C
Indications for Antithrombotic Therapy		
I	Therapeutic anticoagulation with frequent monitoring is recommended for all pregnant patients with a mechanical prosthesis.	B
	Warfarin is recommended in pregnant patients with a mechanical prosthesis to achieve a therapeutic INR in the second and third trimester.	B
	Discontinuation of warfarin with initiation of intravenous UFH (with APTT >2 times control) is recommended before planned vaginal delivery in pregnant patients with a mechanical prosthesis.	C
	Low-dose aspirin, 75 to 100 mg daily, is recommended for pregnant patients in the second and third trimesters with a mechanical valve or a bioprosthesis.	C
IIa	Continuation of warfarin during the first trimester is reasonable for pregnant patients with a mechanical prosthesis if the dose of warfarin to achieve a therapeutic INR is 5 mg or less daily, after full discussion with the patient regarding risks and benefits.	B
	Dose-adjusted LMWH at least twice daily (with target anti-Xa level of 0.8 to 1.2 U/mL, 4 to 6 hours after dose) during the first trimester is reasonable for pregnant patients with a mechanical prosthesis if the dose of warfarin is greater than 5 mg/day to achieve a therapeutic INR.	B
	Dose-adjusted continuous intravenous UFH (with APTT at least 2 times control) during the first trimester is reasonable for pregnant patients with a mechanical prosthesis if the dose of warfarin is greater than 5 mg per day to achieve a therapeutic INR.	B
IIb	Dose-adjusted LMWH at least twice daily (with target anti- Xa level of 0.8 to 1.2 U/mL, 4 to 6 hours after dose) during the first trimester may be reasonable for pregnant patients with a mechanical prosthesis if the dose of warfarin is 5 mg or less daily to achieve a therapeutic INR.	B
	Dose-adjusted continuous infusion of UFH (with APTT at least 2 times control) during the first trimester may be reasonable for pregnant patients with a mechanical prosthesis if the dose of warfarin is 5 mg or less daily to achieve a therapeutic INR.	B
III	LMWH should *not* be administered to pregnant patients with mechanical prostheses unless anti-Xa levels are monitored 4 to 6 hours after administration.	B

LOE, Level of evidence; *APTT,* activated partial thromboplastin time; *INR,* international normalized ratio; *LMWH,* low-molecular-weight heparin; *TEE,* transesophageal echocardiography; *TTE,* transthoracic echocardiography; *UFH,* unfractionated heparin.

Cardiovascular Infections

Larry M. Baddour, William K. Freeman, Rakesh M. Suri, Walter R. Wilson

Historically, the focus of cardiovascular infections has been on infective endocarditis (IE) as the primary syndrome. In this chapter, infections that involve cardiovascular devices, including permanent pacemakers, implantable cardioverter-defibrillators, coronary stents, and ventricular assist devices, also are addressed, because infection is a frequent complication with some devices, often necessitating their removal. Moreover, the indications for devices continue to expand, involving an increasing number of patients, particularly among aging populations in many developed countries. These devices may be lifesaving and improve quality of life, but device removal generally is required for infection cure, and removal procedures are associated with notable morbidity and mortality. Certain aspects of antimicrobial therapy also are unique, because IE often is caused by multidrug-resistant organisms acquired in the health care setting. Consequently, fewer drugs are available for treating these infections, with an increased likelihood of drug-related toxicities. In addition, longer durations of therapy may be needed, which can increase the rate of drug-induced adverse events.

Infective Endocarditis

Before the pandemic of human immunodeficiency virus (HIV) infection, IE was the syndrome for which the expertise of infectious diseases physicians was almost universally requested. IE has the proclivity to cause complications both at the cardiac valve site and at extracardiac locations that can predispose affected patients to serious morbidity and mortality. Management of IE therefore requires a team approach, which generally includes specialists in infectious diseases, cardiovascular medicine, and cardiovascular surgery with particular expertise in IE. Thus, every patient with IE should be managed in the inpatient setting of a medical center with experienced medical and surgical specialists to provide care, which often includes emergent diagnostic and surgical interventions.

Epidemiology

The global burden of disease from IE is largely unknown. Much of the world's population lives in developing countries, where many people do not have routine access to advanced medical care, and usually no local or national infrastructure exists for disease reporting (**see Chapter 1**). Thus the clinical characterization of IE is biased, shaped by the collective experiences at large teaching facilities in countries where patient access is available and disease reporting is done. However, even in many developed countries, including the United States, IE is not included among the diagnoses requiring mandatory reporting to public health agencies that would define a statewide or national disease incidence or burden.

IE is a heterogeneous syndrome that is heavily influenced by the epidemiology of the infection. For example, in developing countries where rheumatic fever is still endemic, younger adults with longstanding rheumatic heart disease frequently present with a subacute clinical course spanning several weeks that involves left-sided native valve infection caused by viridans group streptococci. By contrast, in large, teaching, tertiary care centers in developed countries, patients with previous health care exposure frequently present with an acute illness that can be measured in days and is caused by *Staphylococcus aureus*, with numerous anatomic sites of metastatic foci of infection and worse

outcomes.

The incidence of IE is influenced by multiple host factors that modify the risk of infection. Such factors include the underlying anatomic (usually valvular) cardiac conditions that result in turbulent blood flow and endothelial cell disruption (see later, Pathogenesis). In addition, aging of the population in developed countries has resulted in more patients with myxomatous degeneration of the mitral valve, with subsequent prolapse and insufficiency (**see Chapter 69**). At the same time, a dramatic fall in the incidence of rheumatic fever has reduced the overall risk of IE in younger persons. Advances in medicine also alter the incidence of IE. For example, reduced use of tunneled catheters and increasing use of arteriovenous fistulas for chronic hemodialysis will reduce the risk of bloodstream infection. Improvement in oral health in developed countries also may affect the incidence of IE, but this remains to be determined.

Population-based studies[1,2] have been used to estimate both the incidence of IE and its clinical characterization, but complete case ascertainment is difficult to secure. For example, in the United States, patients may receive medical care in locations that are not in their place of residence. Thus, large medical centers that have unique expertise in endocarditis management may be unable to obtain complete case ascertainment in a population because of changing referral patterns or second-party coverage. Data generated from a population-based investigation will have limited applicability (generalizability) if the cohort under study is not representative of other populations in demographic or clinical features.

Incidence studies of IE are limited in number and in geographic coverage of populations.[1,2] The incidence reported among surveys from Western Europe and Olmsted County, Minnesota, has been stable for many years, at fewer than 10 cases per 100,000 person-years, with the exception of one analysis[3] from northwestern Italy that demonstrated a small but statistically significant increase in incidence. Historically, a sex predilection has been noted, with males more often affected by IE. This results in part from a major contribution of injection drug use (IDU), which more frequently is reported among men, but even in cohorts with IE and a low frequency of reported IDU, males still predominate. This male predominance may be fading, as reported in a recent analysis[2] in which the female incidence had increased, with a high level of health care exposure cited as a predisposing condition for the development of IE. Thus, access to health care can influence the epidemiology of IE.

Health care exposure, including both nosocomial and non-nosocomial exposure, has been recognized only recently[2,4] as a major contributor to the development of IE. Not only do indwelling central venous catheters and hemodialysis predispose to bloodstream infection, but infection with antimicrobial resistant pathogens is more likely to occur as a consequence of health care–related exposure. The virulence of some of these pathogens, in particular methicillin-resistant *S. aureus* (MRSA), is notable and is associated with increased mortality in patients with IE.

Injection drug users are a unique group at increased risk for IE. Thus the modified Duke criteria (see Classic References, Li) include IDU as a “minor” criterion to satisfy a case definition of IE. These patients, who tend to be young, male, and otherwise healthy, account for a large proportion of IE cases in inner-city medical centers in developed countries.[5] Their contact with the health care system often is limited to short stays in an emergency department (ED). Some patients, however, harbor chronic bloodborne viral infections, including those caused by hepatitis viruses and HIV, often unrecognized until the affected person presents with manifestations of IE and undergoes subsequent screening for viral infections not directly related to heart valve infection. The predominant pathogen involving IDU patients with IE is *S. aureus*; less common is a panoply of other organisms, including aerobic gram-negative bacilli and anaerobic and aerobic oral flora, with polymicrobial infections also seen in a minority of patients. Patients tend to delay seeking medical care and present with systemic complications of

infection. Because the right side of the heart, especially the tricuspid valve associated with heroin use,[5] usually is involved, patients often present with pulmonary complications, including septic pulmonary emboli, empyema, and lung abscesses. In a minority of patients, bilateral IE develops, with complications involving both the pulmonary and systemic circulations. Although outcomes of IDU patients with right-sided IE generally are good, these patients are well recognized to be at risk for recurrent bouts of IE, particularly if they continue injecting illicit drugs and if prosthetic valve placement was required to treat the previous valve infection.

Microbiology

Any of a vast array of bacteria and fungi can cause IE,[6] as is evident in novel case reports and literature reviews of IE caused by unusual organisms. Although changes in the prevalence of pathogens causing IE have emerged in recent years because of critical changes in the epidemiology of IE in developed countries,[2,7] the overall distribution of infecting organisms has remained the same, with gram-positive cocci being predominant. These include streptococcal, staphylococcal, and enterococcal species. Important virulence factors unique to each genus group appear to be operative in infection pathogenesis (see later). It is therefore not surprising that the modified Duke criteria (see Classic References, Li) listed only these three groups of pathogens as "typical microorganisms" in the designation of the major criterion of "blood culture positive" for IE.

Streptococcal Species

Among streptococci, the viridans group streptococci (VGS) are the predominant organisms that cause IE. A "subacute" presentation is typical, with symptoms of infection present for weeks to a few months, with low-grade fever, night sweats, and fatigue being common. These organisms normally are found in the mouth of humans and tend to cause indolent infections. Sustained bacteremia due to this group of bacteria should prompt a consideration of the diagnosis of IE, as few other infection syndromes cause sustained bloodstream infection. The viridians group includes several evolving species of streptococci and currently includes *sanguis, oralis* (*mitis*), *salivarius, mutans, intermedius, anginosus,* and *constellatus*. The latter three species have been referred to the *Streptococcus anginosus or S. milleri* group and are unique in that they have a proclivity to produce abscess formation and metastatic infection foci, both within the heart and in extracardiac locations in patients with IE.

The VGS also include species of *Gemella, Abiotrophia*, and *Granulicatella*. For *Gemella,* one species designated as *morbillorum* was previously listed in the *Streptococcus* genus. These organisms can cause IE and exhibit metabolic characteristics similar to those of the "nutritionally variant streptococci," which have now been reassigned to the *Abiotrophia* and *Granulicatella* genera. The recommended medical therapy for infections caused by these unique organisms is discussed later (see Antimicrobial Therapy).

The VGS constitute the predominant cause of native valve infection acquired in the community setting, in both developing and developed nations. A common substrate for infection from these organisms has been rheumatic valvular disease, but as mentioned, the incidence of acute rheumatic fever has fallen dramatically in developed countries.

Similar to other bacteria, VGS have developed resistance to some antibiotics. Fortunately, resistance to penicillin is seen in a minority of IE isolates. Resistance is not based on beta-lactamase production, and the definitions used[6] to characterize strains as being "penicillin resistant" are not the same as the break points recommended by the Clinical and Laboratory Standards Institute (CLSI). This distinction can be confusing for some clinicians, because selection of antibiotic therapy is based on in vitro susceptibility

results.

Unlike VGS, beta-hemolytic streptococci typically cause an acute presentation of IE. Injection drug users and elderly persons are two at-risk groups. Complications are common and often involve valve destruction and distant sites, frequently musculoskeletal, of infection. The prevalence of beta-hemolytic streptococci among cases of IE is less than 10%. Beta-hemolytic streptococci have remained uniquely susceptible to penicillin, with extremely rare exception. Nevertheless, it is prudent to obtain susceptibility testing on all isolates. Surgery is often required for management of severe valvular and perivalvular involvement.

Streptococcus gallolyticus (formerly known as *S. bovis*) deserves particular attention. The organism usually is found in the gastrointestinal (GI) tract, and when recovered from blood culture, whether related to IE or not, an examination for an underlying GI lesion, including colon cancer, should be performed. Although it currently is the cause of less than 10% of cases of IE, the expectation is that it will become more prominent in aging populations and those with increasing restrictions on cancer prevention screening.

Historically, IE from *Streptococcus pneumoniae* has received considerable attention. Although it continues to be a common cause of community-acquired bloodstream infection that often is related to pneumonia, it is a rare cause of IE today. When *S. pneumoniae* does cause IE, the clinical presentation usually is that of an acute syndrome associated with valve destruction. It can be associated with meningitis as well as other intracranial complications. Invasive isolates of pneumococci tend to be penicillin susceptible, but susceptibility testing is required to confirm this impression. As with IE from beta-hemolytic streptococci, surgery often is required to address valve-related complications.

Staphylococcal Species

The staphylococci are the second group of gram-positive cocci that are well recognized as causes of IE. *S. aureus* is a common cause of both native and prosthetic valve endocarditis.[6,7] The presentation in cases caused by *S. aureus* is acute in onset and associated with considerable systemic toxicity. In cases of left-sided heart infection, morbidity and mortality rates are high, despite appropriate therapy, including surgical intervention. Right-sided heart infection, predominantly of the tricuspid valve in injection drug users, has a much higher cure rate than that for left-sided heart infection, and mortality rates are low, unless bilateral infection is present. Unfortunately, the rate of IE from *S. aureus* is increasing, in part because of an increased exposure to health care. In addition, resistance to oxacillin and other antibiotics also has increased, which has made treatment more difficult.

Although coagulase-negative staphylococci are recognized as frequent pathogens of prosthetic valve infection, they also can cause native valve infection in a minority of IE cases. Although these infections usually are subacute in presentation, the morbidity and mortality associated with IE caused by coagulase-negative staphylococci are considerable. Of the more than 30 species of coagulase-negative staphylococci, two deserve special attention. *Staphylococcus epidermidis* is the most commonly identified species to cause bacteremia and IE. *Staphylococcus lugdunensis* is another species that causes both native and prosthetic valve endocarditis and tends to be more virulent than the other species of coagulase-negative staphylococci. Because this group of organisms is the most common cause of contaminated blood cultures, a delay in diagnosis can result from misinterpretation of blood culture results. Multiple sets of blood culture specimens should therefore be collected to better distinguish contamination from bloodstream infection. Except for *S. lugdunensis*, many strains of which remain penicillin susceptible, coagulase-negative staphylococci are more drug resistant than *S. aureus*; accordingly, fewer treatment options are available.

Enterococcal Species

Age is strongly associated with the development of IE caused by enterococcal species, with the prevalence of these organisms in IE cases doubling among elderly persons compared with young adults. A majority of infections are caused by *Enterococcus faecalis* and are associated with genitourinary (GU) tract abnormalities. In the past, enterococcal IE was community acquired, and enterococci were well recognized as part of the normal gut flora in humans. More recently, enterococcal species associated with health care exposure and central venous catheter use have contributed to infection predisposition. With this group of organisms, a subacute IE presentation is typical, and antibiotic therapy requires penicillin or ampicillin combined with an aminoglycoside, usually gentamicin. Multidrug-resistant enterococcal species, in particular *Enterococcus faecium*, can cause IE that is difficult to cure; this includes infection caused by vancomycin-resistant strains collectively termed *vancomycin-resistant enterococci* (VRE).

HACEK Organisms

The HACEK organisms are fastidious gram-negative bacilli comprising *Haemophilus* species (other than *H. influenzae*); *Aggregatibacter actinomycetemcomitans* (formerly *Actinobacillus actinomycetemcomitans*) and *Aggregatibacter aphrophilus* (formerly *Haemophilus aphrophilus*); *Cardiobacterium hominis*; *Eikenella corrodens*; and *Kingella kingae* and *K. denitrificans*. They colonize in the oropharynx and upper respiratory tract, causing subacute IE presentation that is community acquired. Most of the organisms in blood cultures may require several days of incubation. Because of the indolent clinical course, diagnosis often is delayed, with the formation of large vegetations observed at echocardiography. As a result, embolism to the brain or other systemic sites occurs frequently.

Aerobic Gram-Negative Bacilli

In view of their universal causation of bloodstream infection, it is noteworthy that IE caused by aerobic gram-negative bacilli is rare. This observation attests to the unique virulence factors that characterize gram-positive cocci in IE pathogenesis and are not found in gram-negative bacilli. This group includes *Escherichia coli*, *Klebsiella* spp., *Enterobacter* spp., *Pseudomonas* spp., and others. In cases of IE caused by these organisms, presentations generally have been acute and sometimes associated with systemic toxicity, including sepsis and its complications. IE can be either community or health care associated. Outcomes of IE caused by aerobic gram-negative bacilli are characterized by increased morbidity and mortality rates.

Fungi

Fungi are extremely rare causes of IE. Identification of these organisms often is difficult because some do not grow in routine blood culture media. Even when selected culture media are used, fungal isolation may not be achieved. Thus, fungi can cause either blood culture–positive or culture-negative IE.

The bulk of these infections are caused by *Candida* spp., although a broad array of fungi may cause IE. These infections usually are health care associated and involve prosthetic valves, often arising as a result of a central venous catheter infection. An indwelling right-heart catheter, such as a flotation catheter, can denude a valve and nonvalvular endothelial surface, predisposing the patient to fungal (or bacterial) right-sided IE. In addition, IDU is a well-recognized risk factor for fungal IE.

Clinical presentations range in severity from acute to subacute. Complications are frequent, and surgical intervention is recommended as a routine intervention, particularly with infections caused by molds such as *Aspergillus* spp. Because relapsing IE is a concern and can be delayed in onset, many

clinicians advocate the use of lifelong oral antifungal suppressive therapy, usually with an azole, after initial parenteral therapy is completed.

Culture-Negative Endocarditis

For a majority of cases that are designated as blood culture–negative endocarditis, the pathogen is not recovered from blood cultures, because the patient's recent exposure to an antimicrobial had suppressive or killing activity against the pathogen. In addition, with some uncommon causes of culture-negative endocarditis, the pathogen either will not grow in routine blood culture media or grows slowly in the media and is not detected in the time used for blood cultures. In the former scenario, nothing can be done. In the latter, blood cultures can be held for an extended period, at least 14 days, to determine if an isolate is recovered. Other techniques, such as special culture methods or serologic studies, also are used to isolate or identify infection. Organisms that should be included in this category include fungi, *Coxiella burnetii*, *Bartonella* spp., *Brucella* spp., *Tropheryma whippelii*, and *Legionella* spp.

Pathogenesis

Investigations that examine pathogenic mechanisms will likely lead to the development of future novel therapies, many of them unrelated to the traditional activities of antimicrobial agents that will be used in the management and prevention of IE.

Two overarching aspects of endocarditis pathogenesis have been identified.[6] Already noted is a primary predilection for development of IE from an underlying valvular or nonvalvular cardiac structural abnormality that results in blood flow turbulence, endothelial disruption, and platelet and fibrin deposition. This lesion, termed *nonbacterial thrombotic endocarditis* (NBTE), serves as a nidus for subsequent adhesion by bacteria or fungi in the bloodstream. This pathway is thought to account for a majority of cases of IE, most often related to left-sided valvular stenosis or regurgitation. This picture of pathogenesis is mirrored, in many ways, by the animal model of endocarditis that has been used for decades to examine the pathogenesis, treatment, and prevention of IE. The microbiologic and histopathologic findings in infected animals reflect those seen in humans. A second factor is that infection may involve normal valves. Some reservations regarding this pathway of infection seem appropriate, because it is impossible to know if a valve is completely normal, including its endothelial surface, before onset of valve infection. In addition, animals do not develop experimental endocarditis after an intravascular challenge with a relatively large inoculum of virulent organisms, in particular *S. aureus*, in the absence of a previous disruption of the cardiac endothelial surface. Nevertheless, in vitro endothelial cell cultures studies have demonstrated uptake of organisms by endothelial cells.

The predominance of gram-positive cocci as causing IE deserves additional comment. Advances in molecular biologic techniques have resulted in the ability to define virulence factors that are unique to these organisms (see Classic References, Moreillon). Infectivity studies that have compared “wild-type” parent strains to molecularly “engineered” strains using an experimental IE model have been of critical importance in defining virulence factors among strains of staphylococci, streptococci, and enterococci. Some of these factors serve as “adhesins” and are largely responsible for initial bacterial attachment to an NBTE nidus or to endothelial cells. They also are responsible for the attachment to medical devices, including prosthetic valves and cardiovascular implantable electronic device (CIED) leads. In this regard, biofilm formation occurs with some of these organisms and is important in both native tissue and prosthetic valve infections, in the context of factors responsible for the propagation of IE after initial

bacterial attachment.

The findings from these investigations are expected to affect future treatment and prevention of IE. Novel vaccines containing bacterial proteins that function as adhesins and are good immunogens are being examined, for example, and already have proved to be efficacious in the prevention of experimental IE. In this case, the protein (FimA) is expressed by several VGS species in the pathogenesis of IE. In addition, it is conceivable that work focusing on treatment and prevention of dental caries by VGS could have some role in the management and prevention of IE.

Clinical Presentation

Predisposing Cardiac Conditions

Predisposing conditions to IE have evolved over the decades since early clinical series were reported. More recently, the International Collaboration on Endocarditis–Prospective Cohort Study (ICE-PCS)[7] has detailed the clinical presentation in 2781 patients with definite IE. Native valve IE was predominant (72%), followed by prosthetic valve endocarditis (21%) and pacemaker or implantable cardioverter-defibrillator (ICD) IE (7%). Consistent with numerous earlier series, this international cohort study found that IE manifests with definite vegetations most frequently in the mitral valve position (41%), followed by the aortic valve position (38%), whereas the tricuspid (12%) and pulmonary (1%) valves were much less frequently involved.[7]

Preexisting valvular regurgitant lesions are much more prone to infection than stenotic lesions. It has been suggested that the incidence of IE is directly related to the impact of pressure on the closed valve, with shear stress disruption of the valvular endothelium in the vicinity of the egressing regurgitant jet. In the presence of the Venturi effect, circulating organisms are deposited within the high-velocity, lowered-pressure eddy zones of the regurgitant orifice of the receiving chamber, leading to the typical localization of vegetations on the upstream aspect of the infected valve.

Mitral regurgitation associated with degenerative mitral valve prolapse (MVP), particularly with advanced myxomatous leaflet thickening, is the most common predisposing condition for IE and is far more common than rheumatic mitral valve disease.[7] A recent population-based study demonstrated that an increased incidence of IE in patients with MVP was associated with either preexisting mitral regurgitation of at least moderate severity, or flail mitral leaflet.[8] Functional mitral regurgitation, associated with left ventricular (LV) remodeling causing malcoaptation of intrinsically normal mitral leaflets in a low-pressure, low-cardiac-output state (**see Chapter 69**), is quite uncommonly complicated by IE. The second most common native valve lesion predisposing to IE is aortic regurgitation. The risk of IE in patients with bicuspid aortic valve (BAV) is low (**see Chapter 68**), with an incidence of approximately 2% during follow-up periods ranging from 9 to 20 years.[9,10] BAV, however, is relatively common (16% to 43%) in case series of confirmed aortic valve IE,[11,12] is associated with a high incidence of periannular complications of IE (50% to 64%), and is a strong independent predictor of perivalvular extension of infection.[11] In patients older than 65 years of age, nonrheumatic aortic stenosis is seen as the aortic valve lesion in IE at a rate almost three times that of younger patients (28% and 10%, respectively).[13] Structurally normal valves may also be affected in IE, with risk associations of advanced age, renal failure requiring hemodialysis, and infection caused by *S. aureus* or enterococci.[14]

Congenital heart disease (**see Chapter 75**), other than BAV disease, is a predisposing condition to IE in approximately 5% to 12% of cases.[1,7,15] Unrepaired ventricular septal defects are the most frequent congenital heart disease lesions associated with IE, followed by ventricular outflow tract obstructive lesions, such as with tetralogy of Fallot.[16] Any highly turbulent shunt lesion can predispose affected

patients to IE, as can the presence of prosthetic material employed for palliative shunts, conduits, or shunt closures, particularly if a residual shunt is present after surgical intervention. Low-velocity, low-turbulence shunt lesions, such as secundum atrial septal defect, are much less prone to endocardial disruption and are associated with a very low incidence of IE.[16]

Additional conditions contribute to the anatomic cardiac lesions in the predisposition to risk of IE. These include a history of previous IE, the presence of chronic intravenous (IV) access, IV drug abuse, and indwelling endocavitary devices. Predisposing general medical conditions include diabetes mellitus, underlying malignancy, renal failure requiring hemodialysis, and chronic immunosuppressive therapy.[7,15] A history of an invasive or dental procedure can be identified in approximately 25% of patients within 60 days of clinical presentation with IE.[7] A history of cardiac disease may be present in approximately 50% to 65% of patients.[17] Superimposed and of mounting concern is the increasing frequency of health care–associated IE. In a report from the ICE-PCS investigators,[18] 19% of the cases in a study cohort of 1622 patients with IE were considered to be nosocomial (defined as related to hospitalization for more than 2 days before presentation with IE). An additional 16% of cases were related to non-nosocomial health care (e.g., outpatient hemodialysis, IV chemotherapy, wound care, or residence in a long-term care facility) received within 30 days of onset of symptoms of IE.

A recent study demonstrated that a portal of pathogen entry responsible for IE could be identified in almost 75% of patients if a systematic search was pursued.[19] In this study, the most common entry site was cutaneous (40%), associated with health care delivery, such as vascular access or a surgical site, or sites used for intravenous drug abuse. The second most common (29%) portal of entry was oral/dental, with an active infection implicated much more frequently than a prior dental procedure. Thirdly, a GI source was detected in 23% of patients, in the majority with colonic neoplasm, or less commonly, ulcerative or inflammatory disease. Far less (<5%) frequently, a GU, otorhinolaryngologic, or respiratory portal of entry was detected.[19]

Symptoms

The presentation of IE encompasses a broad spectrum of symptoms and is influenced by multiple contributing factors. These factors would include (1) the virulence of the infecting organism and persistence of bacteremia, (2) extent of local tissue destruction of the involved valve(s) and hemodynamic sequelae, (3) perivalvular extension of infection, (4) septic embolization to any organ in the systemic arterial circulation or to the lungs, as in the case of right-sided IE, and (5) the consequences of circulating immune complexes and systemic immunopathologic factors.

The diverse potential symptoms associated with IE are listed in **Table 73.1**. The frequency of symptoms has been approximated from numerous clinical series in both the older and more contemporary literature. Fever (>38°C) is the most common presenting symptom in up to 95% of patients, but may be absent in up to 20% of cases, particularly in elderly persons,[13] the immunocompromised, patients treated with previous empiric antibiotic therapy, or patients with CIED infections.[20,21] Fever defervescence usually occurs within 5 to 7 days of appropriate antibiotic therapy. Persistence of fever may indicate progressive infection with perivalvular extension such as abscess, septic embolization, an extracardiac site of infection (native or prosthetic), infected indwelling catheters or devices, inadequate antibiotic treatment of a resistant organism, or even an adverse reaction to the antibiotic therapy itself.

TABLE 73.1

Symptoms in Infective Endocarditis

SYMPTOM	PATIENTS AFFECTED (%)
Fever	80-95
Chills	40-70
Weakness	40-50
Malaise	20-40
Sweats	20-40
Anorexia	20-40
Headache	20-40
Dyspnea	20-40
Cough	20-30
Weight loss	20-30
Myalgia/arthralgia	10-30
Stroke	10-20
Confusion/delirium	10-20
Nausea/vomiting	10-20
Edema	5-15
Chest pain	5-15
Abdominal pain	5-15
Hemoptysis	5-10
Back pain	5-10

Other nonspecific constitutional symptoms of infection, such as chills, sweats, cough, headache, malaise, nausea, myalgias, and arthralgias, are less common accompanying symptoms and may be noted in approximately 20% to 40% of patients. In more protracted subacute cases of IE, symptoms and signs such as anorexia, weight loss, weakness, arthralgias, and abdominal pain may also occur in 5% to 30% of patients, misleading the clinician to pursue incorrect diagnoses such as malignancy, connective tissue disease, or other chronic infection or systemic inflammatory disorders.

Symptoms of dyspnea are important to recognize because they may indicate a severe hemodynamic lesion, usually left-sided valvular regurgitation. Associated symptoms of orthopnea and paroxysmal nocturnal dyspnea herald the onset of heart failure (HF). Early recognition of HF symptoms is imperative because it is the most common complication of IE, has the greatest impact on prognosis, is the most frequent indication for surgical intervention, and is the most important predictor of poor outcome with surgical therapy for IE.[22] HF complicates the course of approximately 30% to 50% of patients with IE,[7,15,23,24] and even with early surgical intervention, still doubles in-hospital mortality to almost 25%.[24]

A variety of chest pain syndromes can accompany IE. Pleuritic chest pain may result from septic pulmonary embolization and infarction complicating tricuspid IE. Much less common is angina pectoris related to embolization of vegetation fragments into the coronary circulation, which complicates IE in approximately 1% of the cases. Musculoskeletal chest symptoms related to systemic infection or superimposed infectious pneumonitis also would be in the differential diagnosis.

Physical Examination

Potential findings on physical examination are delineated in **Table 73.2**. These data are approximated from both older and more recently reported clinical series.[7,15,18,22-24] A definite murmur is audible in at least 80% of patients on presentation, particularly with left-sided IE. In the large ICE-PCS collaboration, the murmur was new in almost 50% of the patients.[7] The same cohort study found that worsening of a preexisting murmur occurred in 20% of cases. The presence of a new heart murmur also is noted more frequently in patients with IE complicated by HF,[22] and an S_3 gallop and pulmonary rales would further substantiate this diagnosis. Murmurs are detected in less than half of patients with IE complicating an implanted cardiac device[20] and are infrequently heard in patients with right-sided IE. Heart murmurs associated with acute IE complicated by extensive left-sided valvular destruction with acute, severe

regurgitation may also be deceptively unimpressive because of the nature of the decompensated hemodynamics in these unstable patients. Precipitous HF, pulmonary edema, and cardiogenic shock are most often associated with severe acute aortic regurgitation associated with IE, less so by severe acute mitral regurgitation. Severe tricuspid regurgitation, even as an acute complication of IE, is much better tolerated.

TABLE 73.2

Physical Findings in Infective Endocarditis

FINDING	PATIENTS AFFECTED (%)
Fever	80-90
Heart murmur	75-85
New murmur	10-50
Changing murmur	5-20
Central neurologic abnormality	20-40
Splenomegaly	10-40
Petechiae/conjunctival hemorrhage	10-40
Splinter hemorrhages	5-15
Janeway lesions	5-10
Osler nodes	3-10
Retinal lesion or Roth spot	2-10

A central neurologic abnormality usually is identified, and focal deficits consistent with stroke may be detected in 10% to 20% of patients[7,22] (**see Chapter 65**). In subacute, indolent IE, an acute stroke typically is the event that prompts the patient to seek medical attention. Most frequently, the stroke is cardioembolic in nature but may infrequently result from complications of intracranial cerebrovascular mycotic aneurysm, such as hemorrhagic rupture. Seizures, visual deficits, cranial nerve deficits, subarachnoid hemorrhage, and toxic encephalopathy are other potential neurologic complications of IE. The development of neurologic deterioration during the course of IE is associated with significantly increased mortality.

Abdominal examination may elicit nonspecific findings of tenderness and discomfort, particularly in the left upper quadrant, suggestive of splenic embolization and infarction, particularly if complicated by splenic abscess. The spleen is a common site of septic embolization. This most often is not identified by localized symptoms or findings but is discovered incidentally on computed tomography (CT) or using other imaging techniques. Splenomegaly usually is associated with a more protracted course of subacute IE and generally is reported in approximately 10% of patients in more recent clinical series in which the diagnosis is established earlier in the course of the disease.[7,15,18]

As a result of advances leading to earlier diagnosis and therapy, the classic peripheral manifestations of IE are now infrequently observed. Petechiae are the most common, occurring on the conjunctivae, oral mucosa, or extremities. Janeway lesions are painless hemorrhagic macules with a predilection for the soles or palms and are sequelae of peripheral septic embolization, most often associated with staphylococcal IE. Splinter subungual hemorrhages also are painless, dark-red linear lesions in the proximal nailbed and may coalesce. Brown distal splinter lesions at the tips of the nails are quite common in patients who perform manual labor and are caused by trauma, not infection. *Osler nodes* are painful, erythematous, nodular lesions usually located in the pads of the fingers and toes and are the result of immune complex deposition and focal vasculitis. *Roth spots* are retinal hemorrhages with a pale center of coagulated fibrin and also are related to immune complex–mediated vasculitis secondary to IE. An immune complex–mediated diffuse glomerulonephritis rarely may be associated with these findings. Both Osler nodes and Roth spots can be observed with other disorders, such as systemic lupus erythematosus (SLE), leukemia, and nonbacterial endocarditis. Aside from petechiae and conjunctival

hemorrhage, these peripheral findings were detected in less than 10% of patients in the recent ICE-PCS cohort.[7] A recent multicenter prospective cohort study of 1804 patients with IE confirmed similar results as pertains to the spectrum of clinical presentations and physical examination findings.[25]

Diagnosis

The protean clinical presentations and manifestations of IE encompass a broad differential diagnosis in the patient presenting with fever without a readily apparent cause. Other primary cardiac diagnoses that may potentially mimic IE include acute rheumatic fever, left atrial myxoma, antiphospholipid antibody syndrome, and nonbacterial thrombotic or marantic endocarditis. A number of connective tissue disorders, including SLE, reactive arthritis, polymyalgia rheumatica, and vasculitides, may be additional diagnostic considerations in select patients, as well as many other serious syndromes of infectious disease. The index of clinical suspicion for IE incrementally increases in the presence of predisposing cardiac conditions, new or changing murmurs, bloodstream infection, clinical evidence of embolic phenomena, and evolving HF or certain other hemodynamic abnormalities.

In 1994, Durack and associates proposed diagnostic criteria, subsequently known as the Duke criteria, to establish the diagnosis of definite or possible IE, and also to reject the diagnosis of IE. These criteria incorporated direct histopathologic evidence of IE or major clinical criteria, namely, blood culture positivity and evidence of endocardial involvement, supplemented by minor clinical criteria, for the definite diagnosis of IE. Thereafter, multiple clinical series using the Duke criteria for the diagnosis of IE reported the sensitivity to be in the range of 80%, with both specificity and negative predictive value (NPV) exceeding 90%.[6,22] Recognizing the increasing impact of *S. aureus* IE, the potential for IE associated with Q fever *Coxiella burnetii* infection, and the evolving role of transesophageal echocardiography (TEE) in the diagnosis of IE, Li and colleagues (see Classic References) proposed the modified Duke criteria (**Table 73.3**). *Major clinical criteria* include (1) blood culture positivity for bacteria typically associated with IE, or persistently positive cultures for organisms uncommonly associated with IE, or a blood culture or serology clearly positive for *C. burnetii* and (2) evidence of endocardial involvement by echocardiographic imaging demonstrating vegetation, significantly new valvular regurgitation, dehiscence of a prosthetic valve, or findings consistent with perivalvular extension of infection, such as abscess. *Minor clinical criteria* include (1) predisposing cardiac conditions or IV drug use; (2) persistent fever with temperatures greater than 38°C without an alternative explanation; (3) vascular phenomena such as systemic or pulmonary embolism, mycotic aneurysm, or intracranial or cutaneous hemorrhagic lesions; (4) immunologic phenomena such as Osler nodes, Roth spots, or glomerulonephritis; and (5) positive blood culture status not meeting major criteria or serologic evidence of active infection with an organism that could be associated with IE. By this diagnostic classification, a *definite* clinical diagnosis of IE is established in the presence of (a) two major criteria or (b) one major and three minor criteria, or (c) five minor criteria. A *possible* clinical diagnosis of IE is appropriate in the presence of (a) one major and one minor criterion or (b) three minor criteria. The diagnosis of IE is *rejected* if clinical evaluation (a) does not meet criteria for possible IE or (b) reveals complete resolution of a suspected IE syndrome or absence of anatomic evidence for IE on a course of antibiotic therapy for 4 days or less, or if (c) an alternative diagnosis explaining the initial presentation is confirmed.

TABLE 73.3

Definition of Infective Endocarditis (IE): Modified Duke Criteria

Definite Infective Endocarditis
Pathologic Criteria
• Microorganisms demonstrated by results of cultures or histologic examination of a vegetation, a vegetation that has embolized, or an intracardiac abscess specimen; *or* • Pathologic lesions; vegetation, or intracardiac abscess confirmed by results of histologic examination showing active endocarditis
Clinical Criteria
• 2 major criteria, *or* • 1 major criterion and 3 minor criteria, *or* • 5 minor criteria
Possible Infective Endocarditis
• 1 major criterion and 1 minor criterion, *or* • 3 minor criteria
Rejected Diagnosis of Infective Endocarditis
• Firm alternate diagnosis explaining evidence of suspected IE, *or* • Resolution of IE syndrome with antibiotic therapy for ≤4 days, *or* • No evidence of IE at surgery or autopsy, on antibiotic therapy for ≤4 days, *or* • Does not meet criteria for possible IE
Definition of Terms Used in the Modified Duke Criteria for Diagnosis of Infective Endocarditis
Major Criteria
• Blood culture findings positive for IE Typical microorganisms consistent with IE from two separate blood cultures: • Viridans streptococci, *Streptococcus gallolyticus* (formerly known as *S. bovis*), *Staphylococcus aureus*, HACEK group, *or* • Community-acquired enterococci, in the absence of a primary focus, *or* Microorganisms consistent with IE from persistently positive blood culture findings, defined as: • ≥2 positive culture findings of blood samples drawn >12 hours apart, *or* • 3 or most of ≥4 separate culture findings of blood (with first and last sample drawn ≥1 hour apart) • Single positive blood culture for *Coxiella burnetii* or anti–phase I IgG titer ≥1 : 800 • Evidence of endocardial involvement Echocardiographic findings positive for IE (TEE recommended in patients with prosthetic valves, rated at least possible IE by clinical criteria or complicated IE [paravalvular abscess]; TTE as first test in other patients), defined as follows: • Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation, *or* • Abscess, *or* • New partial dehiscence of prosthetic valve New valvular regurgitation; worsening or changing of preexisting murmur not sufficient
Minor Criteria
• Predisposition, predisposing heart condition, or intravenous drug use • Fever—temperature >38°C • Vascular phenomena, major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway lesions • Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, and rheumatoid factor • Microbiologic evidence: positive blood culture finding but does not meet a major criterion as noted above (excludes single positive culture findings for coagulase-negative staphylococci and organisms that do not cause endocarditis) or serologic evidence of active infection with organism consistent with IE

TEE, Transesophageal echocardiography; *TTE,* transthoracic echocardiography.

Modified from Li JS, Sexton DJ, Mick N, et al. Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis. Clin Infect Dis 2000;30:633.

Since their publication in 2000, the modified Duke criteria have been validated in subsequent investigations of diagnostic accuracy (confirmed to be high) and also clinical and epidemiologic utility and have been endorsed by guideline documents pertinent to the evaluation and management of the patient with IE.[6,22] In view of the vast heterogeneity of the clinical presentations of IE, the modified Duke criteria must always be used in combination with circumspect clinical judgment.

Basic Laboratory Testing

Microbiology

The microbiology and epidemiology of the pathogens associated with IE are detailed earlier in this chapter. As determined from data summarized from contemporary cohort series,[7,18,26-29] the organisms identified in patients with IE in a variety of clinical settings are listed in **Table 73.4**. In community-acquired IE, viridans group streptococci remain the most frequently isolated organism, followed closely by *S. aureus*, which is the predominant organism implicated in health care–associated IE, accounting for more than 40% of cases both in and out of the hospital environment. A defined portal of entry, such as an

intravascular catheter or tissue disruption from a recent surgical or dental procedure, can be implicated in 25% to 67% of such cases.[15,18,26] MRSA IE is much more common in health care–associated than in community-acquired IE (47% versus 12%, respectively).[18] In IE associated with IV drug abuse, *S. aureus* accounts for almost 70% of cases.[7]

TABLE 73.4
Microbiology of Infective Endocarditis (IE)

ORGANISM	NATIVE VALVE				PROSTHETIC VALVE	
	Health Care–Associated IE (%)					
	Community-Acquired IE (%) (*n* = 1201)[19,26]	Nosocomial (*n* = 370)[18,26]	Nonnosocomial (*n* = 254)[18]	Intravenous Drug Users with IE (%) (*n* = 237)[7]	Early IE (%) (*n* = 140)[27-29]	Late IE (%) (*n* = 390)[27,29]
Staphylococcus aureus	21	45	42	68	34	19
Coagulase-negative staphylococci	6	12	15	3	28	20
Enterococcus species	10	14	16	5	10	13
Viridans group streptococci	26	10	6	10	1	11
*Streptococcus gallolyticus**	10	3	3	1	1	7
HACEK	3	0	0	0	0	2
Fungi	0	2	2	1	6	3
Other	13	7	10	7	6	15
Negative blood culture	11	7	6	5	14	10

*Formerly *Streptococcus bovis.*

HACEK, *Haemophilus* spp., other than *H. influenzae*; *Aggregatibacter actinomycetemcomitans* [formerly *Actinobacillus actinomycetemcomitans*], *Aggregatibacter aphrophilus* [formerly *Haemophilus aphrophilus*]; *Cardiobacterium hominis*; *Eikenella corrodens*; *Kingella kingae* and *K. denitrificans.*

In patients with prosthetic valves (**see Chapter 71**), early prosthetic valve endocarditis has been defined as occurring as early as 60 days or less[27] up to 1 year[22,28,29] after surgery. *S. aureus* also is the leading pathogen in early prosthetic valve endocarditis (PVE), accounting for approximately 35% of cases, of which approximately one fourth are MRSA,[27] followed closely by coagulase-negative staphylococci. Streptococcal early PVE is unusual. Late PVE is caused less often by staphylococci, which nevertheless are still the most common infecting organism, and a higher occurrence of infections with both VGS and *Streptococcus gallolyticus* (formerly *S. bovis*) has been documented. As with community-acquired native valve IE, enterococcal infections account for approximately 10% of cases of both early and late PVE.

Negative blood culture results are observed in approximately 5% to 15% of the cases for both native and prosthetic valve IE. The most common cause for this discrepancy is the administration of antibiotic therapy before blood culture samples are drawn, as noted previously, and often such antibiotic therapy is directed empirically toward poorly defined symptoms of infection well before IE is considered. In the large ICE-PCS, 62% of patients with culture-negative IE had received antibiotic therapy within 7 days of obtaining the initial blood culture.[7] Other reasons for blood culture negativity would include IE caused by fastidious organisms or unusual pathogens such as *Bartonella* or *Legionella* spp., *C. burnetii*, or fungi. Rapid detection of pathogens associated with IE by polymerase chain reaction (PCR) techniques may become a reliable alternative to standard blood culture techniques in such cases.[30]

Other Blood Testing

The complete blood count often is abnormal in IE. In patients with subacute IE, a normochromic normocytic anemia of variable severity is detected in a majority of patients, often with low serum iron and total iron-binding capacity. Even with the systemic infection of IE, a leukocytosis with a left differential shift may be detected in only 50% to 60% of patients[23] and is more common with acute than with subacute IE. Leukopenia also may infrequently occur with subacute IE and usually is associated with splenomegaly. Thrombocytopenia may occur in approximately 10% of patients and has been found to be a predictor of early adverse outcome in IE. Sy and colleagues[31] reported a hazard ratio (HR) of approximately 1.13 for each 20×10^9/L decrement in the platelet count as a multivariate predictor of mortality from days 1 to 15 after presentation with IE.[31]

The erythrocyte sedimentation rate (ESR) usually is elevated in patients with IE, and in ICE-PCS, was elevated in 61% of patients. This large cohort study found that an elevated ESR was independently associated with a decreased risk of in-hospital death, presumably because of an association with subacute IE with a more indolent course.[7] The same study found that the C-reactive protein (CRP) also was elevated in approximately 60% of patients, whereas the rheumatoid factor concentration was abnormal in 5%[7]—the latter usually a feature of protracted subacute IE, not acute IE. Inclusion of ESR and CRP in the minor modified Duke criteria for the diagnosis of IE has been proposed, but is not endorsed by current guideline recommedations.[6]

Procalcitonin (PCT) is another protein that rises in response to a proinflammatory stimulus, particularly with severe bacterial infection. A meta-analysis of six studies, including 1006 patients with suspected IE, found PCT to be only 64% sensitive and 73% specific for the diagnosis of IE, and was less accurate than CRP.[32] PCT and other bacteremia-activated markers, such as cellular and vascular adhesion molecules, are currently not recommended as routine biomarkers for the diagnosis of IE.[33]

A new elevation in serum creatinine occurs in 10% to 30% of patients with IE[22] and may be related to multifactorial reasons including renal hypoperfusion from severe sepsis or HF, embolic renal infarction, immune complex–mediated glomerulonephritis, and toxicity from either antibiotic therapy or contrast agents used for imaging. Renal dysfunction developing within the first 8 days of presentation is independently predictive of early IE mortality, with HR of 1.13 per incremental increase in serum creatinine of 0.23 mg/dL,[31] and persistent serum creatinine elevation to greater than 2 mg/dL is predictive of 2-year mortality.[25] Urinalysis usually demonstrates hematuria and proteinuria. In cases of immune complex glomerulonephritis, red blood cell casts are evident, associated with depressed serum complement levels.

Limited studies conducted with small numbers of patients have assessed the prognostic value of cardiac biomarkers in IE. The cardiac troponins may be elevated from ventricular wall stress in HF, myocardial injury with myocardial abscess or embolic infarction, or septicemia alone. An increase in troponin I level to greater than 0.4 ng/mL significantly increases the risk of in-hospital mortality and need for early valve replacement.[34] A subset analysis of ICE-PCS demonstrated that in patients with IE, a troponin T level of 0.08 ng/mL or higher was associated with increased risk of cardiac abscess, central nervous system (CNS) events, and death IE (see Classic References, Stancoven). An elevation of the B-type natriuretic peptide (BNP) level to 400 pg/mL or higher also has been associated with a fourfold risk of the same three complications of IE, even with exclusion of patients with LV dysfunction or severe left-sided valve regurgitation.[35] In another study, elevation of the NT-proBNP level to 1500 pg/mL or higher at hospital admission was an independent predictor of need for surgical intervention or death within 30 days.[36]

Electrocardiogram

The 12-lead electrocardiogram (ECG) usually demonstrates nonspecific findings in patients with uncomplicated IE. Because of the close proximity of the atrioventricular node and proximal intraventricular conduction system to the aortic valve and root, perivalvular extension of infection from this location is the most common cause of new atrioventricular block (AVB) of any degree or bundle branch block (BBB). With perivalvular extension of infection, the incidence of AVB ranges from 10% to 20%, whereas new BBB occurs in approximately 3%.[18,28] The occurrence of a new conduction abnormality also is a multivariate risk predictor for death associated with IE.[18] More uncommonly, perivalvular extension complicating aortic valve IE may compromise proximal coronary artery patency, or emboli from aortic valve vegetations may cause damage, resulting in ischemic ECG changes or even ST-segment elevation acute coronary syndromes.[22] Other atrial and ventricular arrhythmias may potentially complicate structural or hemodynamic complications of IE. In a recent investigation that included 507 patients with left-sided native valve IE, new-onset atrial fibrillation was independently associated with HF and in-hospital mortality.[37]

Imaging

Imaging for Diagnosis of Infective Endocarditis

With use of the modified Duke criteria, a major clinical criterion for the diagnosis of IE is the demonstration of endocardial involvement with vegetations, perivalvular extension of infection, or evidence of disruption of the integrity of either native or prosthetic valves (**see Table 73.3**). Over the past several decades, echocardiography has been established as the imaging modality of choice for this purpose (**see Chapter 14**). Using early-generation imaging systems, initial studies reported the sensitivity of transthoracic echocardiography (TTE) to be in the range of 40% to 60% for the detection of native valvular vegetations, and substantially less for prosthetic valve vegetations.[38] With evolving advances in harmonic imaging and numerous other techniques to improve spatial image resolution, the sensitivity of current TTE imaging techniques for detection of native valve IE recently has been shown to be 82% and as high as 89% if high-quality TTE images are available (**Fig. 73.1; see also Fig. 14.77A**).[39] The specificity for TTE in the diagnosis of IE has been reported to be in the range of 70% to 90%.[24,38-40]

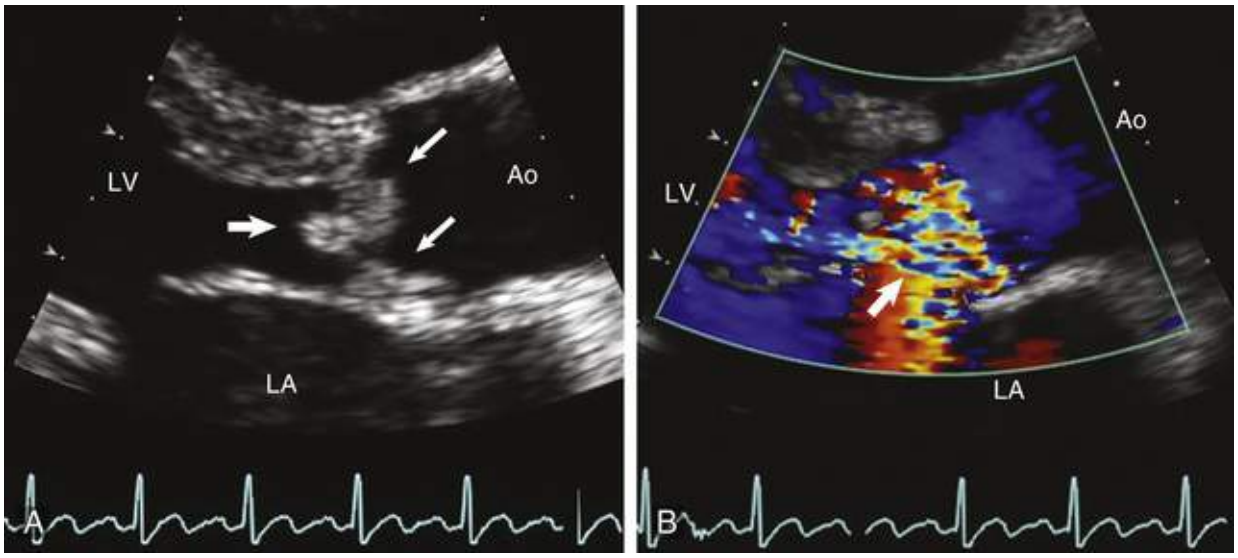

FIGURE 73.1 Infective endocarditis of the native aortic valve. **A,** Transthoracic echocardiography shows vegetations (*small arrows*) attached to the left ventricular aspects of the valve cusps and prolapsing into the left ventricular outflow tract (*large arrow*) during diastole. **B,** Severe aortic regurgitation (*arrow*) is shown by color Doppler. *Ao,* Ascending aorta; *LA,* left atrium; *LV,* left ventricle.

TEE circumvents multiple potential impediments to TTE imaging, such as body habitus, pulmonary disease, and other sources of acoustic interference between the chest wall and heart. Owing to much closer proximity of the transducer to the heart, TEE is performed with higher-frequency imaging, greatly enhancing spatial resolution (**Fig. 73.2; see also Fig. 14.77B**). With numerous imaging projections available, multiplane two-dimensional and three-dimensional TEE can characterize vegetations with a resolution size of approaching 2 to 3 mm, with sensitivity in the range of 90% to 100% and specificity exceeding 90%.[38-41] PVE, characterized by a lower incidence of valvular vegetations (60 to 70%) and higher incidence of periannular infection and associated complications (30 to 50%), is difficult to detect with TTE, generally with a sensitivity of less than 50%.[22] Valvular vegetations have been more frequently identified with IE involving transcatheter-implanted aortic bioprostheses (**see Chapter 72**), with perivalvular complications less common than for surgically implanted prostheses.[42,43] With sensitivity reported in the range of 80% to 95% and specificity greater than 90%,[24,44] TEE clearly is the imaging procedure of choice for the evaluation of suspected PVE (**Figs. 73.3 and 73.4**).

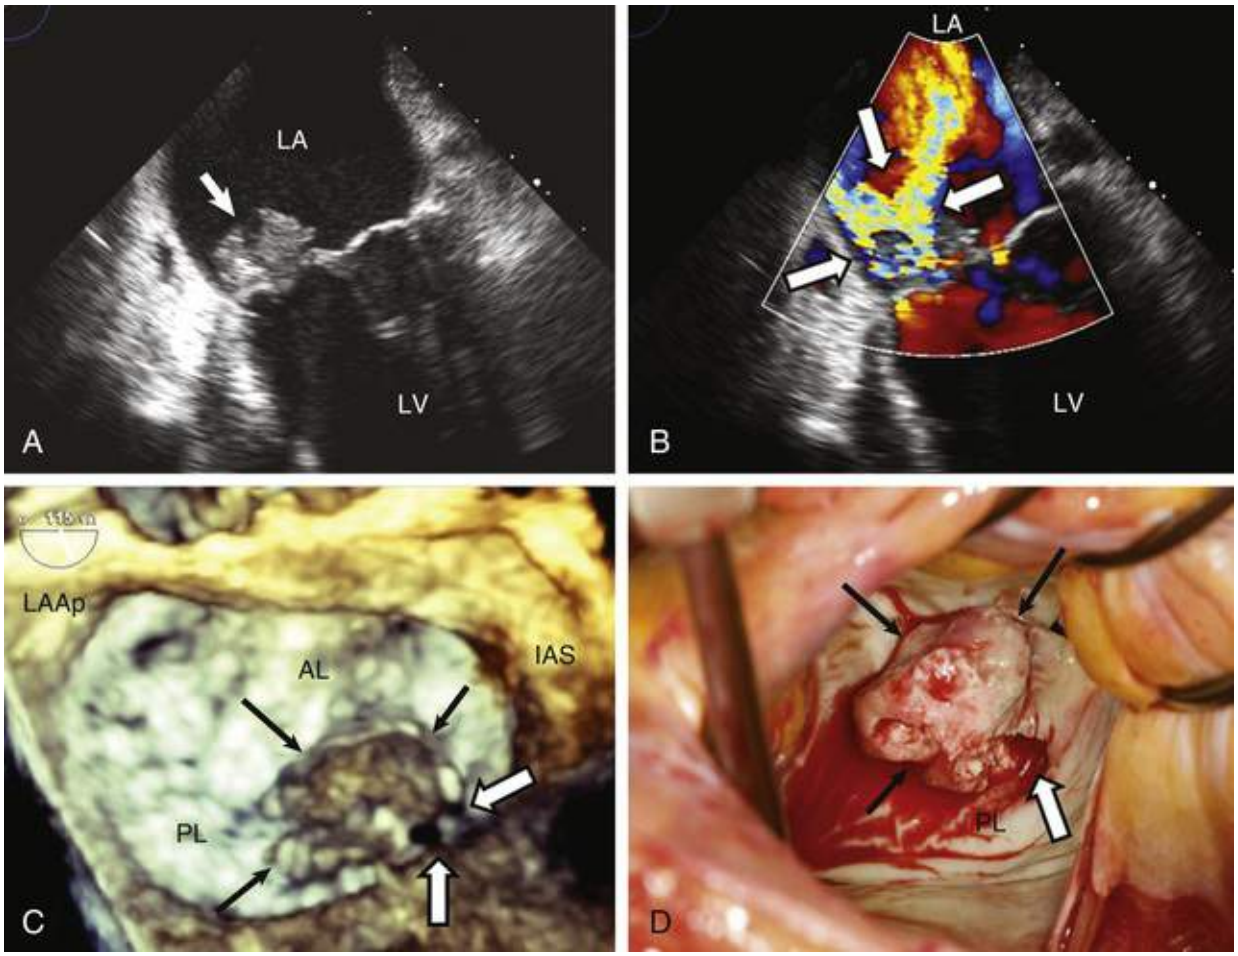

FIGURE 73.2 Infective endocarditis involving the mitral valve. **A,** Transesophageal echocardiography (TEE) image shows a large vegetation (*arrow*) attached to the atrial aspect of the posterior leaflet. **B,** Color Doppler image demonstrates a complex jet of mitral regurgitation (*arrows*) coursing through the body of the posterior mitral leaflet and vegetative mass, consistent with leaflet perforation. **C,** Three-dimensional TEE image of the mitral valve, as viewed from the left atrium (*LA*). Large vegetations (*black arrows*) are attached to the medial aspect of the posterior leaflet (*PL*), with perforation (*white arrows*) at the margin of the posteromedial commissure. **D,** Intraoperative visualization of the mitral valve as viewed from the left atriotomy. The large vegetative mass (*black arrows*) is attached to the posterior leaflet, and the posteromedial perforation (*white arrow*) is confirmed. *AL,* Anterior leaflet; *IAS,* interatrial septum; *LAAp,* left atrial appendage; *LV,* left ventricle.

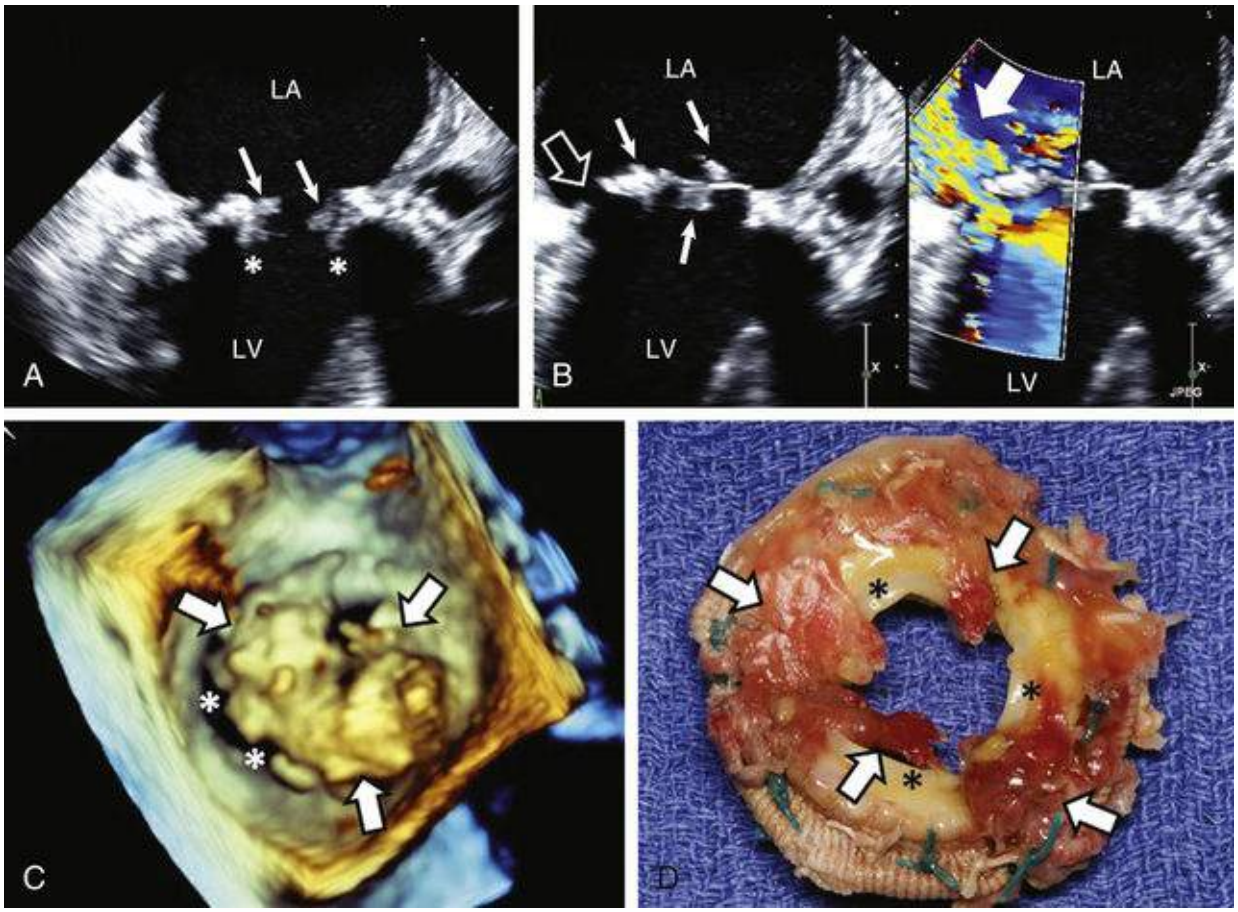

FIGURE 73.3 Infective endocarditis of a mitral bioprosthesis. **A,** On transesophageal echocardiography (TEE), multiple vegetations (*arrows*) can be seen within the inflow orifice of the bioprosthesis (*) during diastole. **B, Left,** During systole, a zone of inferolateral periannular prosthetic dehiscence (*large open arrow*) is evident with rocking motion of the prosthesis. Vegetations are present on the closed bioprosthetic leaflets and prosthetic annulus (*small arrows*). **Right,** Color Doppler image shows severe, eccentric periprosthetic mitral regurgitation (*large white arrow*) emanating from the zone of periannular dehiscence. *LA,* Left atrium; *LV,* Left ventricle. **C,** Three-dimensional TEE view from the left atrium shows an extensive mass of vegetations encompassing the periannular margins (*arrows*), which was not fully appreciated by two-dimensional imaging. A large crescentic zone of periannular dehiscence (*) is well visualized. **D,** The surgically excised mitral bioprosthesis shows extensive vegetations (*arrows*) attached to the atrial aspects of the prosthesis. Pannus ingrowth (*) into the prosthetic orifice also is present.

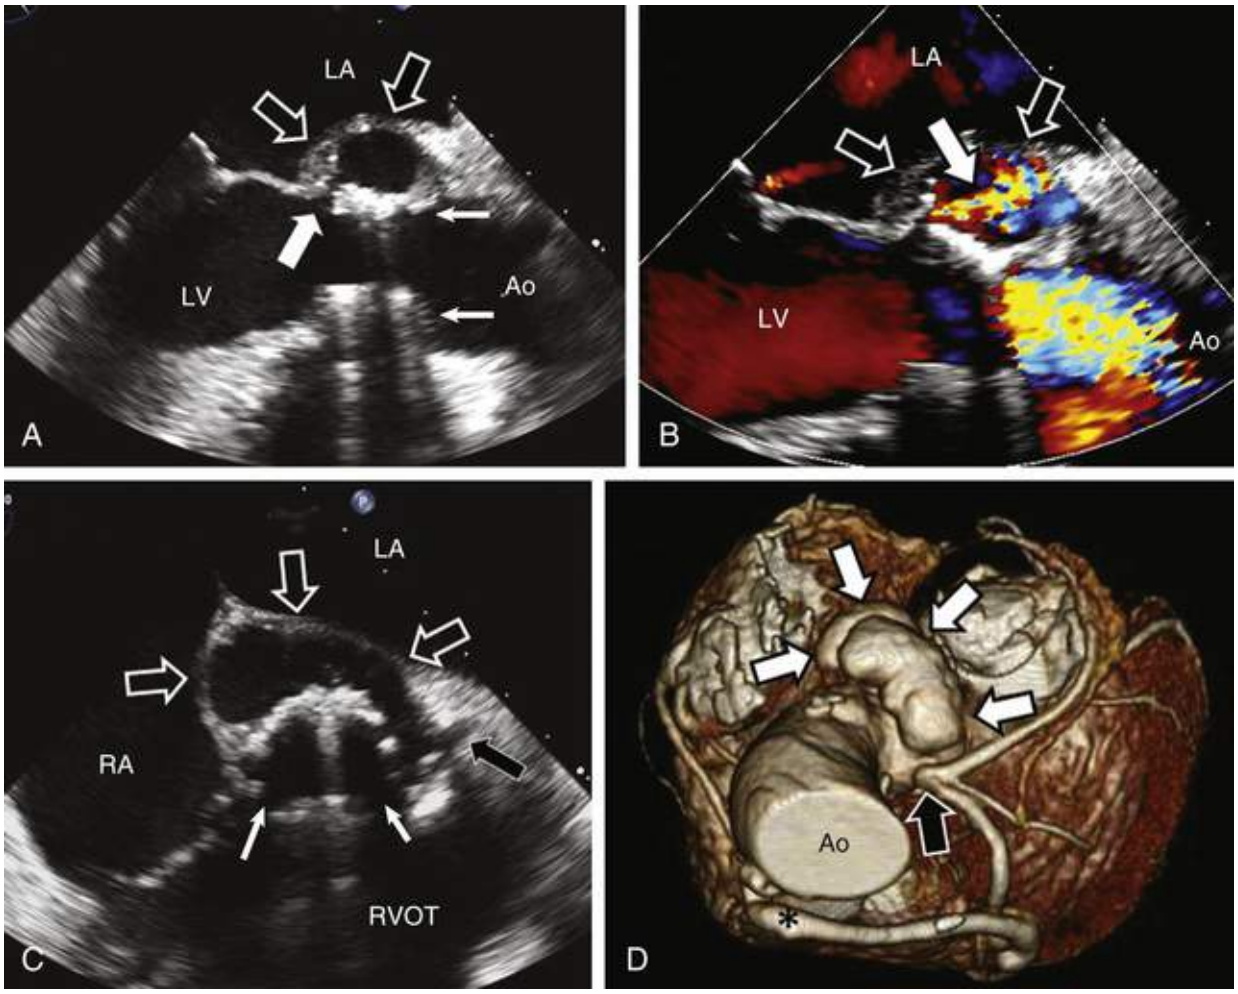

FIGURE 73.4 Periannular extension of infection complicating mechanical aortic prosthetic valve endocarditis. **A,** Transesophageal echocardiography (TEE) image shows a large, mycotic false aneurysm (*open arrows*) within the mitral-aortic intervalvular fibrosa adjacent to the prosthesis (*small arrows*). Communication with the left ventricular outflow tract is evident (*large white arrow*). **B,** Color Doppler image demonstrates flow communication (*arrow*) into the mycotic false aneurysm (*open arrows*) during systole, at which time the larger, color flow signal exits the aortic prosthesis into the ascending aorta (*Ao*). **C,** Short-axis TEE imaging of the mechanical aortic prosthesis (*small arrows*) indicates that the large mycotic false aneurysm (*large open arrows*) extends posteriorly adjacent to the left atrium (*LA*), bulges toward the right atrium (*RA*), and extends to the left main coronary artery (*black arrow*). **D,** Computed tomography with three-dimensional reconstruction, viewed from above and tilted anteriorly to show the posterior aortic root, shows the large posterolateral mycotic false aneurysm (*white arrows*) extending from the aortic root and encroaching upon the left main coronary artery (*black arrow*). A saphenous vein bypass graft (*) to the left anterior descending coronary artery also is seen. *LV,* Left ventricle; *RVOT,* right ventricular outflow tract.

In general, TTE is more readily available, and TTE may be more helpful in suspected cases of tricuspid valve endocarditis and in quantitating hemodynamic function manifested by valvular regurgitation, ventricular dysfunction, and elevated left and right ventricular filling pressures and pulmonary artery pressure. Because TTE and TEE provide complementary information, the most recent AHA guidelines[6] recommend both TTE and TEE be obtained in cases of suspected IE (**Fig. 73.5**). Variably mobile echodensities may be observed with echocardiography, particularly TEE. A differential diagnosis would include degenerative changes in a native valve, such as Lambl excrescences, endocardial fenestrations, ruptured or retracted chordae, and even acoustic artifacts reflected by calcified tissue. Valvular thickening, myxomatous changes, and sclerotic lesions move in concert with leaflet or cusp motion, without independent mobility of a vegetation, but may be difficult to discern from sessile vegetations. Filamentous valvular strands may be seen on both native and prosthetic valves. Thrombus associated with prosthetic valves may or may not be infected. Valvular neoplasms, such as papillary

fibroelastoma or rarely myxomas, also are included in the differential. Vegetations of IE typically are located on the upstream, lower-pressure side of the regurgitant valve, have soft tissue echocardiographic density (particularly early in the course of infection) and often are multiple and lobulated, with motion independent of the valve structure. Hyperrefractile, discretely nodular, or filamentous echodensities located on the downstream side of the valve are much less likely to represent vegetations associated with IE.

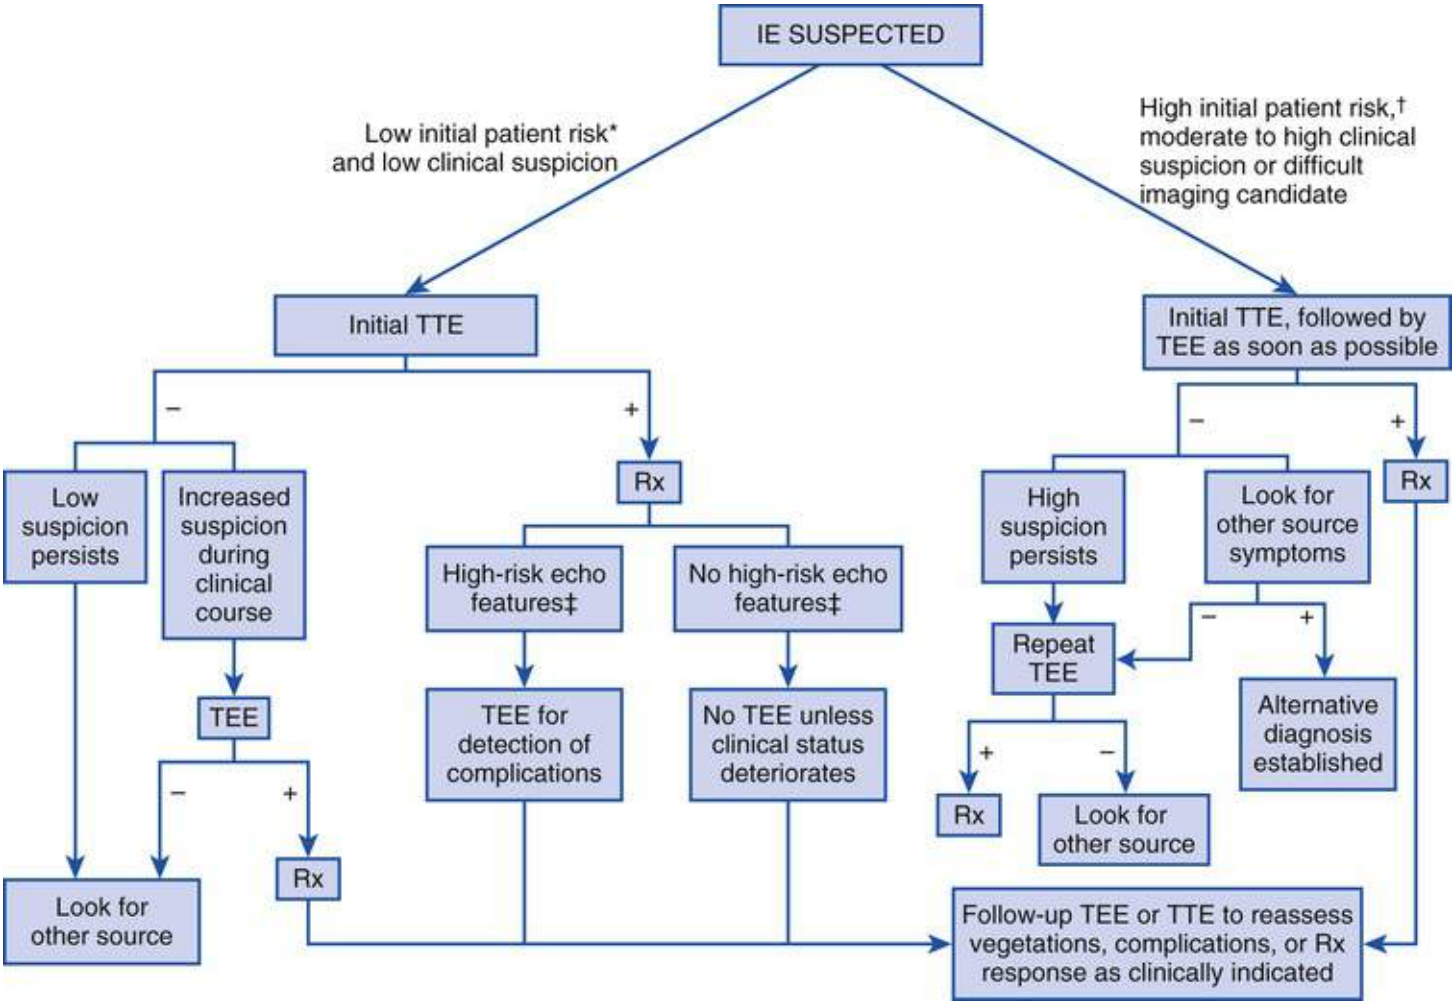

FIGURE 73.5 An approach to the diagnostic use of echocardiography (echo). Rx, Prescription; TEE, transesophageal echocardiography; TTE, transthoracic echocardiography. *For example, a patient with fever and a previously known heart murmur and no other stigmata of infective endocarditis (IE). †High initial patient risks include prosthetic heart valves, many congenital heart diseases, previous endocarditis, new murmur, heart failure, or other stigmata of endocarditis. ‡High-risk echocardiographic features include large or mobile vegetations, valvular insufficiency, suggestion of perivalvular extension, or secondary ventricular dysfunction (see text). (Modified from Baddour LM et al. Infective endocarditis in adults: diagnosis, antimicrobial therapy, and management of complications. Ascientific statement for healthcare professionals from the American Heart Association. Circulation 2015;132:1435; and Habib G et al. 2015 ESC guidelines for the management of infective endocarditis. The Task Force for the Management of Infective Endocarditis of the European Society of Cardiology. Eur Heart J 2015;36:3075.)

In addition to confirming the diagnosis of IE, echocardiography provides important information regarding complications of IE that indicate the potential need for surgery (**Table 73.5**).

TABLE 73.5

Echocardiographic Features That Suggest Potential Need for Surgical Intervention

Vegetation
Persistent vegetation after systemic embolization
Anterior mitral valve leaflet vegetation, particularly if it is highly mobile with size >10 mm*
One or more embolic events during the first 2 weeks of antimicrobial therapy*
Increase in vegetation size despite appropriate antimicrobial therapy*†
Valvular Dysfunction
Acute aortic or mitral insufficiency with signs of ventricular failure†
Heart failure unresponsive to medical therapy†
Valve perforation or rupture†
Perivalvular Extension
Valvular dehiscence, rupture, or fistula†
New heart block†‡
Large abscess or extension of abscess despite appropriate antimicrobial therapy†

*Surgery may be required because of risk of embolization.

†Surgery may be required because of heart failure or failure of medical therapy.

‡Echocardiography should not be the primary modality used to detect or monitor heart block.

See text for more complete discussion of indications for surgery based on vegetation characterizations.

Imaging for Delineation of Complications of Endocarditis

Local Valvular Destruction.

Caused most frequently by left-sided valvular regurgitant lesions, heart failure may complicate the course of approximately 30% to 40% of patients with IE, is three times more common in native than in prosthetic valve IE, and is the primary indication for early surgery in at least 50% to 60% of these patients.[22,24,40,45] New York Heart Association (NYHA) Functional Class III or IV HF complicating IE has the greatest impact on both medical and surgical prognosis, with reported in-hospital mortality rates in the range of 55% and 25%, respectively, in ICE-PCS.[45] HF most frequently is associated with aortic valve IE (30%), followed by mitral valve (20%) and tricuspid valve (<10%).[6]

New, moderate to severe valvular regurgitation may be detected by TEE in up to 70% of patients presenting with IE.[15] On imaging with TTE, and particularly with TEE, mechanisms contributing to valvular regurgitation include perforation, prolapse, and flail of the involved cusp or leaflet. Native valve perforations develop in 10% to 30% of patients with IE.[11,15,23,46] Even with TEE, which is much more sensitive than TTE (90% versus 45%), perforations can be difficult to visualize using two-dimensional imaging alone. Three-dimensional TEE imaging can significantly enhance detection of valvular perforations complicating IE (**see Fig. 73.2**).[41] Color Doppler imaging can readily identify a perforation, with color flow convergence entraining into the perforation from the exiting chamber and a regurgitant jet traversing through the body of a cusp or leaflet. Saccular mycotic aneurysms, most often present on the atrial aspect of the mitral valve, may rupture, leaving a large defect in the leaflet. Extensive vegetations may also impede valvular coaptation, leading to regurgitation, or rarely may cause stenosis.

Infectious destruction of left-sided native valvular cusp or leaflet integrity and disruption of the valvular support apparatus can lead to acute severe valvular regurgitation complicated by precipitous HF, pulmonary edema, and hemodynamic instability (**see Chapters 68 and 69**). In addition to identifying the mechanism(s) of regurgitation, echocardiographic imaging typically demonstrates normal LV size and ejection fraction (EF). In acute severe aortic regurgitation, Doppler assessment will demonstrate evidence of rapid elevation of LV diastolic filling pressures with very short aortic regurgitant pressure half-times and a restrictive pattern of mitral inflow. Such hemodynamics are associated with premature

closure of the mitral valve before the onset of systole. In acute severe mitral regurgitation, truncation of the usual parabolic continuous-wave Doppler regurgitant signal indicates late-systolic LV and left atrial (LA) pressure equilibration, consistent with a giant *v* wave noted on LA catheterization. Quantitative Doppler methods are quite useful to confirm the presence of acute severe regurgitation, because qualitative color flow jets may be complex, eccentric, or rapidly dissipating because of the loss of transvalvular pressure gradients.

Perivalvular Extension of Infection.

Perivalvular extension in IE includes the complications of periannular or intramyocardial abscess, mycotic false aneurysm, and fistula. The incidence of perivalvular extension ranges from 10% to almost 30% in native valve IE and at least 30% to 55% in PVE[15,27] (**see Figs. 73.3 and 73.4**). IE involving a transcatheter-implanted aortic bioprosthesis has been reported to have a lower incidence of complications from perivalvular extension of infection, such as abscess (15%), aortic mycotic pseudoaneurysm (4%), or aortoatrial fistula (4%).[42] Earlier series have reported the incidence of perivalvular extension of infection to approach 100% for aortic PVE.[6,22] Independent predictors of perivalvular extension are PVE, aortic valve involvement, and staphylococcal infection (from both coagulase-negative strains and *S. aureus*).[6,22] Periannular abscess has been reported in up to 50% of patients with native bicuspid aortic valve IE (**see Fig. 14.77C**), versus 20% in those with a tricuspid aortic valve.[11] Persistent fever, ongoing bacteremia despite appropriate antibiotic therapy, chest pain, a new heart murmur, recurrent embolism, or HF all should alert the clinician to the possible presence of perivalvular extension. After HF, perivalvular extension of infection is the second most common indication for early surgical intervention for IE, and although surgery clearly confers an early survival benefit,[46] perivalvular extension remains an independent predictor of increased in-hospital and 1-year mortality.[7,22,23,45] In left-sided native valve *S. aureus* IE, the echocardiographic findings of perivalvular extension of infection, such as intracardiac abscess, and LVEF less than 40% have been strong independent predictors of in-hospital early mortality.[47]

It is recognized that the sensitivity of TTE for the diagnosis of perivalvular extension is at best 50%, and even less in PVE. TEE has a reported sensitivity of 80% to 90%, specificities of greater than 90%, with positive predictive value (PPV) and NPV of 85% to 90% for diagnosis of perivalvular extension.[6,40] Although TEE is quite sensitive for the diagnosis of aortic perivalvular extension, mitral annular calcification may obscure small regions of mitral perivalvular extension, particularly in the posterior aspects of the annulus.[48] On echocardiographic imaging, early perivalvular abscess usually appears as a nonhomogeneous, soft tissue, echodense thickening that distorts the margins of normal periannular anatomy.

With IE in the aortic valve position, a high predilection for perivalvular extension of infection to involve the *mitral-aortic intervalvular fibrosa* (MAIF) has been recognized. The MAIF is the fibrous zone of continuity between the noncoronary cusp of the aortic valve and insertion of the anterior mitral valve leaflet. Being one of the least vascular structures of the heart, the MAIF is more susceptible to infection and mycotic false aneurysm formation. On echocardiographic imaging of these false aneurysms, systolic expansion of an echolucent cavity can be appreciated within the infected MAIF (**see Fig. 73.4**), with color Doppler flow communication usually evident from the subvalvular LV outflow tract. Potential complications of MAIF mycotic false aneurysms include fistulous communications into the left atrium or aorta, extension around the aortic root, compression of the proximal left coronary arteries with resultant myocardial ischemia, systemic embolization, and rupture into the pericardial space.[49] Fistulas from aortic perivalvular extension of infection may track into any cardiac chamber and are best identified with TEE

color flow Doppler techniques. Mitral valve IE complicated by perivalvular extension is less common, with much lower frequency of structural and conduction system sequelae. Prosthetic valve dehiscence is another manifestation of perivalvular extension of infection and usually is seen without impressive vegetations on the prosthesis itself (**see Fig. 73.3**). Imaging by TEE demonstrates crescentic defect adjacent to the sewing ring, variable rocking of the prosthesis, and periprosthetic regurgitation.

Cardiac 64-slice CT has been shown to be an accurate alternative imaging procedure for the evaluation of IE and perivalvular extension of infection (**see Chapter 18**). In a small group of patients with suspected IE, cardiac CT was 96% sensitive for the detection of valvular vegetations, identical in this respect to multiplanar TEE, compared with surgery.[50] Both imaging techniques had specificity and PPV/NPV exceeding 95%. Excellent correlation was found between cardiac CT and TEE in the determination of vegetation size and mobility; however, TEE was superior for the detection of small vegetations (≤4 mm) and valvular perforations. The sensitivity of cardiac CT for the detection of perivalvular extension of infection confirmed at surgery was 100%, versus 89% for TEE, and CT provided additional information regarding the extent of perivalvular extension not detected by TEE.[50] Similar findings have been reported in a series of patients with aortic prosthetic valve endocarditis, with good accuracy of 64-slice cardiac CT in the detection of early perivalvular extension of infection (**see Fig. 73.4**), periannular abscess, false aneurysm, and prosthetic valve dehiscence compared with TEE and surgery.[51]

Recently, positron emission tomography (PET)/CT imaging with fluorine 18–fluorodeoxyglucose (^{18}F-FDG) has incrementally improved the diagnostic accuracy in evaluation of suspected PVE, particularly CIED IE, increasing the sensitivity from approximately 60% to 70% with the modified Duke criteria with TEE imaging alone to 87% to 97% with the addition of ^{18}F-FDG PET/CT[52,53] (**see Fig. 16.47**). This resulted primarily from enhanced identification of infection in the tissue spaces adjacent to the prosthetic valve or implanted device, and less from the identification of sites of secondary infection. This imaging technique has been proposed as an additional major Duke criterion for the diagnosis of prosthetic device IE,[52] but because of the current lack of large studies, routine use of ^{18}F-FDG PET/CT has not been endorsed by guideline-writing committees to date.[6,22] Moreover, ^{18}F-FDG PET/CT has not been shown to be of incremental value in the diagnosis of native valve IE.[54]

Embolism.

Embolic events are common early in the course of IE, particularly before the institution of appropriate antibiotic therapy. Over the past two decades, numerous studies have reported an overall incidence of embolic events ranging from 20% to 50%.[6,22] In more recent clinical series, the reported incidence of acute stroke complicating IE ranged from 10% to 23%,[7,13,15,18,23] with rates of 15% to 25% reported for other embolic events not causing stroke.[7,11,13] Both stroke and other embolic events complicating IE occur more frequently in patients younger than 65 years[13] and are adverse predictors of outcome and survival in IE.[6,22] In a multicenter study using admission-screening CT imaging in 384 patients presenting with IE, 26% had one site of embolism, and another 9% had multiple sites of embolism in the following distribution: CNS (38%), spleen (30%), renal (13%), lung (10%), peripheral artery (6%), mesenteric (2%), and coronary (1%). The embolic event was clinically silent in 15% of all patients. The incidence of cerebral embolic events probably is significantly underestimated by clinical assessment. In a study of 130 patients with definite or possible IE by the modified Duke criteria, cerebral magnetic resonance imaging (MRI) found acute ischemic lesions in 52% of patients, whereas only 12% had acute neurologic symptoms.[55] In this study, MRI also demonstrated cerebral microhemorrhages in 57%, other hemorrhagic lesions in 8%, asymptomatic mycotic aneurysms in 8%, and abscesses in 6%. Screening cerebral MRI led

to significant modification of the diagnosis or treatment plan in 28% of the entire study group.[55]

Peripheral embolization with or without metastatic infection also may be detected with PET/CT, and clinically unsuspected lesions of this nature were observed in 28% of patients in one small series.[56] Imaging with PET/CT also is useful in the detection of perivalvular extension of infection, particularly of the aortic root, and for identification of CIED infections.

Numerous studies have examined the ability of echocardiographic characterization of vegetations to predict risk of embolic events in IE. More recent analyses have consistently shown that vegetations more than 10 mm in greatest dimension are independent predictors of embolism, with considerably higher risk with dimensions above 15 mm.[6,40,57-59] Before initiation of appropriate antibiotic therapy, such large vegetations are associated with a greater than 40% risk of a clinically evident or silent embolic event. Pedunculated and highly mobile vegetations also are independently associated with embolic risk.[40] Both vegetation length of more than 10 mm and severe vegetation mobility are multivariate predictors of embolism, even after initiation of antibiotic therapy. Mitral valve vegetations, particularly on the anterior leaflet in native valve IE, are more likely to embolize than those in the aortic position; the embolic risk generally is equivalent in native and in prosthetic valve IE.[6,40,60]

The infecting organism also has an impact on embolic risk. *Staphylococcus aureus* IE has been consistently implicated as an independent risk predictor for embolism; IE from *Streptococcus gallolyticus* and VGS is less implicated.[60] The presence of intracardiac perivalvular abscess is another independent risk for stroke associated with IE.[51]

Prediction of symptomatic embolism in IE has been proposed with the derivation and validation of a risk calculator employing the variables of age, diabetes mellitus, atrial fibrillation, embolism before initiation of antibiotic therapy, vegetation length, and the presence of *S. aureus* infection. This calculator, known as the Embolic Risk French Calculator, is available online. Employing this calculator, a 70-year-old patient with *S. aureus* IE, having all clinical risk variables present and vegetation size greater than 10 mm in length, would have an estimated 7-day embolic risk of 23%. The same-age patient with *S. aureus* IE but no clinical risk variables and vegetation size less than 10 mm would have an estimated 2% 7-day embolic risk.[61]

Over the past several decades, multiple clinical series have shown that the risk of embolism decreases dramatically, generally to less than 10% to 15%, within 1 week after initiation of appropriate antibiotic therapy.[6,22] The occurrence of stroke has been shown to fall to 3% after the first week of antibiotic therapy, with the overall incidence decreasing from 4.82 to 1.71 per 1000 patient-days during the second week of therapy.[60] With this documented response to antibiotic therapy, preemptive surgical intervention for potentially high-embolic-risk vegetations has not been previously advised unless there are recurrent embolic events despite ongoing appropriate antibiotic therapy.[6,22] This position has been challenged by a small study of patients with left-sided vegetations greater than 10 mm in diameter randomized to conventional management versus early surgery (within 48 hours).[62] On admission, almost 30% of each group had evidence of cerebral emboli and had no other indications for urgent surgical intervention. In patients randomized to conventional therapy, recurrent cerebral embolic events occurred in 13%, with an overall embolic event rate of 21% at 6 weeks, compared to a 0% over the same period for the early surgical patients; the in-hospital mortality was 3% for both groups.[62]

Recurrent embolic events or progressive increase in vegetation size despite appropriate antibiotic therapy, especially in the presence of significant perivalvular extension of infection or HF, would constitute clear indications for early surgical intervention.[6,22]

Thus far, no randomized controlled trials (RCTs) support the initiation of either antiplatelet or anticoagulant therapy to decrease embolic risk in IE. A retrospective analysis has suggested a lower

occurrence of embolic events in patients who continue to receive antiplatelet therapy taken before the onset of IE.[63] In a larger prospective cohort analysis, established antiplatelet therapy did not reduce the incidence of cerebrovascular complications associated with IE, but also did not increase the occurrence of hemorrhagic complications.[64] The investigators for the larger analysis reported that previously prescribed warfarin therapy, continued through the clinical course of left-sided native valve IE, was associated with a lower incidence of stroke, transient ischemic attack (TIA), and cerebral infections compared with those not receiving warfarin therapy (6% versus 26%, respectively), with the incidence of hemorrhagic complications being 2% in both groups.[65]

Approach to Echocardiographic Imaging.

Clinical risk assessment of the patient with suspected IE is the first step in deciding which echocardiographic imaging modality to use for evaluation (**Fig. 73.5** and **Table 73.6**). Patients with undifferentiated febrile syndromes, a chronic unchanged murmur, no physical examination findings suggestive of IE, and no high-risk cardiac anatomy (e.g., prosthetic valves or complex congenital heart disease [CHD]) are characterized as being at initially low patient risk with a lower pretest likelihood of IE. High initial patient risk characteristics that present a high pretest probability of IE and likelihood of adverse outcome include clinical findings of a significant new heart murmur, peripheral stigmata of IE, new HF, *S. aureus* bacteremia, and high-risk cardiac anatomy, including the presence of a prosthetic valve or complex CHD.[2,6] Independent risk factors for IE (established in 10% to 15% of cases) in the presence of *S. aureus* bacteremia include community-acquired status, IV drug abuse, significant preexisting native valve disease, intracardiac prosthesis or CIED, prolonged (>72 hours) bacteremia, secondary foci of infection, and embolic event.[66-68]

TABLE 73.6

Use of Echocardiography During Diagnosis and Treatment of Infective Endocarditis (IE)

Early
Echocardiography as soon as possible (<12 hours after initial evaluation) TEE preferred; obtain TTE views of any abnormal findings for later comparison TTE if TEE is not immediately available TTE may be sufficient in small children
Repeat Echocardiography
TEE after positive TTE as soon as possible in patients at high risk for complications TEE 7-10 days after initial TEE if suspicion exists without diagnosis of IE or with worrisome clinical course during early treatment of IE
Intraoperative
Prepump
Identification of vegetations, mechanism of regurgitation, abscesses, fistulas, and pseudoaneurysms
Postpump
Confirmation of successful repair of abnormal findings
Assessment of Residual Valve Dysfunction
Elevated afterload if necessary to avoid underestimating valve insufficiency or presence of residual abnormal flow
Completion of Therapy
Establish new baseline for valve function and morphology and ventricular size and function TTE usually adequate; TEE or review of intraoperative TEE may be needed for complex anatomy to establish new baseline

TEE, Transesophageal echocardiography; *TTE,* transthoracic echocardiography.

As shown in **Fig. 73.5**, patients at low initial risk should undergo TTE. In the absence of significant preexisting native valve disease or any prosthetic or implanted devices, adequate- or better-quality images detecting no vegetations exclude the diagnosis of IE, with NPV of 97% and sensitivity exceeding 90%.[69] With preexisting valve disease, the sensitivity approaches 60%, but with a similar NPV if TTE image quality is adequate.[70] Even with *S. aureus* bacteremia, initial TTE imaging is reasonable in the

absence of the previous risk factors.[6,66-68] If TTE images are limited or inadequate, TEE should be pursued. If TTE detects high-risk findings such as large (>10 mm in diameter) or highly mobile vegetations, suggests the presence of perivalvular extension of infection, or identifies new grade III to IV valvular regurgitation or new LV dysfunction, TEE should be promptly performed for further evaluation. Patients at high risk (e.g., new-onset HF, significant new murmur, clinical stigmata of IE, prior IE, prosthetic heart valves/devices, complex CHD, *S. aureus* bacteremia) should undergo initial imaging with TEE (**Fig. 73.5**), with supplemental TTE for complete semiquantitation of valvular regurgitation and delineation of left- and right-sided hemodynamics and ventricular function. If TEE is not immediately possible or available, TTE should be pursued first to avoid delay in imaging evaluation and diagnosis.

Provided that initial TTE images are of diagnostic quality and are negative for IE, if a low clinical suspicion for IE persists, other diagnoses should be pursued (**Fig. 73.5**). With increased clinical suspicion for IE throughout the patient's clinical course, an initially negative TTE should be followed up with TEE. If the initial TTE is positive for IE but high-risk findings as noted previously are lacking, TEE should not be mandatory, unless the patient is clinically unresponsive to antibiotic therapy or deteriorates during the clinical course. Any high-risk finding on TTE would warrant further evaluation with TEE.

As outlined in **Fig. 73.5**, if the initial TEE is negative for IE and there is diminishing clinical suspicion of IE, other diagnoses should be evaluated. If IE remains high in the differential diagnosis, repeat TEE should be performed in 3 to 5 days, recognizing that NPV of two sequential TEE studies is 98%.[6] After an initial TEE is positive for IE, it should be repeated throughout the patient's course as clinically indicated, to assess response to antibiotic therapy or evaluate clinical or hemodynamic deterioration.

At the completion of antibiotic therapy, repeat echocardiography is indicated to establish a new post-treatment baseline study of valvular morphology, residual vegetations, valvular regurgitation, and other hemodynamic factors and to assess ventricular function (**Table 73.6**). Provided that images are of diagnostic quality, TTE should be adequate for this purpose. With complex anatomy, or if prosthetic valve function remains in question, TEE usually is indicated.

Antimicrobial Therapy

Not only is it important to diagnose IE, but it also is critical that an etiologic diagnosis be obtained to ensure that optimal antimicrobial therapy is provided for attempted cure.[6,71] Because of the rarity of presentation, diagnosis of IE often eludes nonspecialists, which results in the administration of empiric therapy for a variety of more common febrile illnesses. This empiricism can greatly reduce the sensitivity of subsequent blood cultures when the IE diagnosis is eventually considered. Thus, initial empiricism results in a blood culture–negative presentation, which prompts administration of empiric antimicrobial therapy for IE. This scenario is a bane of infectious diseases specialists, who have traditionally cared for patients with IE. The antimicrobial regimen selected for therapy on the basis of the culture-negative state may not be curative. Moreover, the empiric regimen may include drugs, in particular aminoglycosides, that pose toxicity risks that might have been avoided had a pathogen been identified. Ultimately, this could result in a worst-case scenario in which a microbiologic cure is not achieved and irreversible toxicity occurs.

Some of the regimens employed in the treatment of IE are based on clinical trials with small numbers (dozens) of patients. Many of the regimens, however, are based on consensus opinion that is outlined in guidelines promulgated by societies or associations worldwide. Not surprisingly, these guidelines differ in their recommendations, which can be confusing for the practicing clinician.

Several tenets of medical management are important in defining an optimal antimicrobial regimen in

each case of IE. First, consultation with a physician who is experienced in the care of patients with IE is mandatory; this usually involves a specialist trained in infectious diseases. Second, selection and dosing of antimicrobial therapy are based on both pharmacokinetic and pharmacodynamic characteristics of specific drugs and in vitro susceptibility testing results of an isolated pathogen in blood or tissue specimen culture-positive cases. Third, antimicrobial treatment needs to be prolonged (over weeks), high dose, parenteral, and “cidal” in its activity against a patient's isolate. These aspects of medical therapy are necessary primarily because organisms in infected vegetations downregulate their metabolism once a relatively high concentration of organisms accumulate in vegetation tissue, which is an avascular structure.

Streptococci

Viridans Group Streptococci and *Streptococcus Gallolyticus*

Treatment regimens vary, depending on type of valve (native or prosthetic) and whether the streptococcal isolate is penicillin susceptible or not.[6] Regarding the latter issue, the definition of susceptibility to penicillin, as addressed previously, is based on minimum inhibitory concentrations (MICs) that are specific to treatment of the syndrome of IE; *highly penicillin-susceptible* status is defined as that of an isolate with an MIC of 0.12 µg/mL to penicillin. Therapy with either aqueous crystalline penicillin G sodium or ceftriaxone sodium should be microbiologically curative in 98% or more of patients with native valve IE who complete 4 weeks of treatment (**Table 73.7**). Because of the ease of administration of one dose per day of ceftriaxone parenterally, the bulk of therapy is with this agent rather than with intravenously administered aqueous crystalline penicillin G, which requires four to six doses per day. The once-a-day dosing of ceftriaxone sodium has been pivotal in some cases in allowing patients to avoid nursing home placement for multiple doses of antibiotic administration on a daily basis. In these patients the administration of one dose of ceftriaxone sodium each day has been done in a variety of outpatient venues that routinely administer parenteral medications.

TABLE 73.7

Therapy of Native Valve Endocarditis Caused by Highly Penicillin-Susceptible Viridans Group Streptococci and *Streptococcus gallolyticus*

REGIMEN	DOSE* AND ROUTE	DURATION (wk)	STRENGTH OF RECOMMENDATION	COMMENTS
Aqueous crystalline penicillin G sodium	12-18 million U/24 hr IV either continuously or in 4 or 6 equally divided doses	4	Class IIa, LOE: B	Preferred in most patients >65 yr or patients with impairment of eighth cranial nerve function or renal function Ampicillin, 2 g IV every 4 hr, is reasonable alternative to penicillin if a penicillin shortage exists.
or				
Ceftriaxone sodium	2 g/24 hr IV/IM in 1 dose	4	Class IIa, LOE: B	
Aqueous crystalline penicillin G sodium	12-18 million U/24 hr IV either continuously or in 6 equally divided doses	2	Class IIa, LOE: B	Two-week regimen not intended for patients with known cardiac or extracardiac abscess or for those with creatinine clearance of <20 mL/min, impaired eighth cranial nerve function, or *Abiotrophia*, *Granulicatella*, or *Gemella* spp. infection; gentamicin dose should be adjusted to achieve peak serum concentration of 3-4 µg/mL and trough serum concentration of <1 µg/mL when 3 divided doses are used; there are no optimal drug concentrations for single daily dosing.†
or				
Ceftriaxone sodium	2 g/24 hr IV or IM in 1 dose	2	Class IIa, LOE: B	
plus				
Gentamicin sulfate‡	3 mg/kg/24 hr IV or IM in 1 dose	2		
Vancomycin hydrochloride§	30 mg/kg/24 hr IV in 2 equally divided doses	4	Class IIa, LOE: B	Vancomycin therapy is reasonable only for patients unable to tolerate penicillin or ceftriaxone; vancomycin dose should be adjusted to a trough concentration range of 10-15 µg/mL.

*Doses recommended are for patients with normal renal function.

†Data for once-daily dosing of aminoglycosides for children exist, but no data for treatment of infective endocarditis (IE) exist.

‡Other potentially nephrotoxic drugs (e.g., nonsteroidal anti-inflammatory drugs) should be used with caution in patients receiving gentamicin therapy. Although it is preferred that gentamicin (3 mg/kg) be given as a single daily dose to adult patients with endocarditis caused by viridans group streptococci, as a second option, gentamicin can be administered daily in 3 equally divided doses.

§Vancomycin dosages should be infused during the course of at least 1 hour to reduce the risk of histamine-release "red man" syndrome.

Minimum inhibitory concentration (MIC) is ≤0.12 µg/mL. The subdivisions differ from Clinical and Laboratory Standards Institute–recommended break points that are used to define penicillin susceptibility.

IM, Intramuscularly; *IV,* intravenously; *LOE,* level of evidence.

From Baddour LM, Wilson WR, Bayer AS, et al. Infective endocarditis in adults: diagnosis, antimicrobial therapy, and management of complications. A scientific statement for healthcare professionals from the American Heart Association. Circulation 2015;132:1435-86.

Vancomycin is recommended in patients who cannot tolerate penicillin or cephalosporin therapy because of a history of immunoglobulin E (IgE)–mediated allergic reactions (**Table 73.7**). Before the preferred therapies of aqueous crystalline penicillin G or ceftriaxone are abandoned, consultation with an allergy specialist should be obtained, which may include skin testing to confirm that beta-lactam regimens are not a treatment option. Vancomycin should be administered intravenously for 4 weeks with serial, usually weekly monitoring of serum trough levels, if the dose is stable and the renal status is not changing. The desired serum trough level is 10 to 15 µg/mL; serum peak vancomycin levels are not required for treatment.

For selected patients, a 2-week treatment regimen can be used, but this should be based on input from an infectious diseases specialist. The combination regimen includes either aqueous crystalline penicillin G sodium or ceftriaxone sodium plus gentamicin sulfate (**Table 73.7**). The 2-week regimen should be limited to cases of uncomplicated native valve IE caused by VGS or *S. gallolyticus* strains that are highly susceptible to penicillin. The regimen would not be appropriate in patients with underlying renal or eighth

cranial nerve dysfunction. If the ceftriaxone-containing regimen is used, the single daily dose of the drug should be administered immediately before or after gentamicin dosing. No recommended guidelines for monitoring serum gentamicin concentrations are currently available.

Penicillin resistance is divided into two categories for VGS and *S. gallolyticus* infection in patients with native valve IE. In one group, relative resistance to penicillin is defined as a penicillin MIC greater than 0.12 µg/mL, to 0.5 µg/mL or less. In this group, 4 weeks of therapy is recommended with either aqueous crystalline penicillin G or ceftriaxone plus gentamicin once daily for the first 2 weeks of treatment (**Table 73.8**). Vancomycin can be used in patients who are not candidates for beta-lactam therapy. In the other group, penicillin resistance is defined as a penicillin MIC above 0.5 µg/mL. Fortunately, native valve IE due to these penicillin-resistant strains is rarely seen. In patients with these infections, a more aggressive course of therapy is recommended and is the same regimen as that used in the treatment of native valve IE caused by penicillin- and aminoglycoside-susceptible enterococci (**see Table 73.7**). Monotherapy with vancomycin should be administered in patients who are not candidates for the combination regimen.

TABLE 73.8

Therapy of Native Valve Endocarditis Caused by Strains of Viridans Group Streptococci (VGS) and *Streptococcus gallolyticus* Relatively Resistant to Penicillin

REGIMEN	DOSE* AND ROUTE	DURATION (WK)	STRENGTH OF RECOMMENDATION	COMMENTS
Aqueous crystalline penicillin G sodium	24 million U/24 hr IV either continuously or in 4–6 equally divided doses	4	Class IIa, LOE: B	It is reasonable to treat patients with IE caused penicillin-resistant (MIC ≥0.5 µg/mL) VGS strains with a combination of ampicillin or penicillin plus gentamicin as done for enterococcal IE with infectious diseases consultation. (Class IIa, LOE: C) Ampicillin, 2 g IV every 4 hr, is a reasonable alternative to penicillin if a penicillin shortage exists.
plus				
Gentamicin sulfate†	3 mg/kg/24 hr IV or IM in 1 dose	2		Ceftriaxone may be a reasonable alternative treatment option for VGS isolates that are susceptible to ceftriaxone. (Class IIb, LOE: C)
Vancomycin hydrochloride‡	30 mg/kg/24 hr IV in 2 equally divided doses	4	Class IIa, LOE: C	Vancomycin therapy is reasonable only for patients unable to tolerate penicillin or ceftriaxone therapy.

*Doses recommended are for patients with normal renal function.

†**See Table 73.7** for appropriate dose of gentamicin. Although it is preferred that gentamicin (3 mg/kg) be given as a single daily dose to adult patients with endocarditis caused by VGS, as a second option, gentamicin can be administered daily in 3 equally divided doses.

‡**See Table 73.7** for appropriate dosage of vancomycin.

Minimum inhibitory concentration (MIC) is >0.12 to <0.5 µg/mL for penicillin. The subdivisions differ from Clinical and Laboratory Standards Institute–recommended break points that are used to define penicillin susceptibility.

IE, Infective endocarditis; *IM,* intramuscularly; *IV,* intravenously *LOE,* level of evidence.

From Baddour LM, Wilson WR, Bayer AS, et al. Infective endocarditis in adults: diagnosis, antimicrobial therapy, and management of complications. A scientific statement for healthcare professionals from the American Heart Association. Circulation 2015;132:1435-86.

Patients who have IE involving a prosthetic valve or prosthetic material (e.g., annuloplasty ring) due to VGS or *S. gallolyticus* should receive 6 weeks of antibiotic therapy (**Table 73.9**). In those infected with strains that are highly susceptible to penicillin (MIC <0.12 µg/mL), the addition of gentamicin for the first 2 weeks of either penicillin or ceftriaxone therapy is optional. In patients infected with streptococci that harbor any level of resistance to penicillin (MIC >0.12 µg/mL), combination therapy for 6 weeks is recommended. In patients who do not tolerate beta-lactam therapy, vancomycin as monotherapy should be administered for 6 weeks.

TABLE 73.9

Therapy for Endocarditis of Prosthetic Valves or Other Prosthetic Material Caused by Viridans Group Streptococci (VGS) and *Streptococcus gallolyticus*

REGIMEN	DOSE* AND ROUTE	DURATION (WK)	STRENGTH OF RECOMMENDATION	COMMENTS
Penicillin-Susceptible Strain (≤0.12 μg/mL)				
Aqueous crystalline penicillin G sodium	24 million U/24 hr IV either continuously or in 4-6 equally divided doses	6	Class IIa, LOE: B	Penicillin or ceftriaxone together with gentamicin has not demonstrated superior cure rates compared with monotherapy with penicillin or ceftriaxone for patients with highly susceptible strain. Ampicillin, 2 g IV every 4 hr, is reasonable alternative to penicillin if a penicillin shortage exists.
or				
Ceftriaxone	2 g/24 hr IV or IM in 1 dose	6	Class IIa, LOE: B	
with or without				
Gentamicin sulfate†	3 mg/kg/24 hr IV or IM in 1 dose	2		Gentamicin therapy should not be administered to patients with creatinine clearance <30 mL/min.
Vancomycin hydrochloride‡	30 mg/kg/24 hr IV in 2 equally divided doses	6	Class IIa, LOE: B	Vancomycin is reasonable only for patients unable to tolerate penicillin or ceftriaxone.
Penicillin Relatively or Fully Resistant Strain (MIC >0.12 μg/mL)				
Aqueous crystalline penicillin sodium	24 million U/24 hr IV either continuously or in 4-6 equally divided doses	6	Class IIa, LOE: B	Ampicillin, 2 g IV every 4 hr, is a reasonable alternative to penicillin if a penicillin shortage exists.
or				
Ceftriaxone	2 g/24 hr IV/IM in 1 dose	6	Class IIa, LOE: B	
plus				
Gentamicin sulfate	3 mg/kg per 24 hr IV/IM in 1 dose	6		
Vancomycin hydrochloride	30 mg/kg/24 hr IV in 2 equally divided doses	6	Class IIa, LOE: B	Vancomycin is reasonable only for patients unable to tolerate penicillin or ceftriaxone.

*Doses recommended are for patients with normal renal function.

†**See Table 73.7** for appropriate dose of gentamicin. Although it is preferred that gentamicin (3 mg/kg) be given as a single daily dose to adult patients with endocarditis resulting from VGS, as a second option, gentamicin can be administered daily in 3 equally divided doses.

‡See text and **Table 73.7** for appropriate dose of vancomycin.

IM, Intramuscularly; *IV,* intravenously; *LOE,* level of evidence.

From Baddour LM, Wilson WR, Bayer AS, et al. Infective endocarditis in adults: diagnosis, antimicrobial therapy, and management of complications. A scientific statement for healthcare professionals from the American Heart Association. Circulation 2015;132:1435-86.

Bacteria Formerly Known as “Nutritionally Variant Streptococci”

Because of their previous designation as “nutritionally variant streptococci,” a discussion of organisms now included in nonstreptococcal categories is warranted, although the prevalence of these organisms causing IE is low. *Abiotrophia defectiva* and *Granulicatella* spp. and *Gemella* spp. have unusual metabolic characteristics that can result in diminished activity of cell wall–active antibiotics to kill these organisms and thus decreased cure rates. Moreover, because of this characteristic, the ability to perform in vitro susceptibility testing is adversely affected, with potentially unreliable results. Thus a regimen recommended for treatment of native valve IE is advocated (**see Table 73.7**).

Beta-Hemolytic Streptococci

Unlike IE caused by VGS and *S. gallolyticus*, IE caused by beta-hemolytic streptococci typically is characterized by an acute onset with rapid valve destruction and other complications that often require cardiovascular surgical intervention. Consultation with a specialist in infectious diseases and cardiology is recommended. Because IE is infrequently caused by these organisms, prospective clinical trial data for therapeutic decisions are lacking. Nevertheless, recommended therapy for IE caused by *Streptococcus*

pyogenes (group A) includes either aqueous crystalline penicillin G or ceftriaxone or cefazolin, and treatment is for at least 4 weeks. For the other types (groups B, C, F, and G) of beta-hemolytic streptococcal infections, gentamicin is advocated by some clinicians for the first 2 weeks of treatment.

Staphylococci

As noted previously, staphylococci have become more prominent as agents of IE in developed countries. In addition, antibiotic resistance has dramatically increased over the years, and for many patients, therapeutic choices are limited, although use of these agents has been largely unexamined in prospective clinical trials.

Infections caused by oxacillin-susceptible staphylococci can be treated with either nafcillin or oxacillin that is administered intravenously over 6 weeks for left-sided native valve IE or complicated right-sided IE (**Table 73.10**). Although previously included as an optional agent to be given over the first 3 to 5 days of therapy,[6] gentamicin is no longer advocated because of nephrotoxicity risk.[72] In the infrequent event that an isolate is penicillin susceptible (MIC ≤0.1 µg/mL with negative result on screening for beta-lactamase production), aqueous crystalline penicillin G can be given. Cefazolin is an option for patients with left-sided infection who are intolerant of penicillins but have not had an IgE-mediated allergic reaction to penicillins.

TABLE 73.10

Therapy for Endocarditis Caused by Staphylococci in the Absence of Prosthetic Materials

REGIMEN	DOSE* AND ROUTE	DURATION (wk)	STRENGTH OF RECOMMENDATION	COMMENTS
Oxacillin-Susceptible Strains				
Nafcillin or oxacillin	12 g/24 hr IV in 4-6 equally divided doses	6	Class I, LOE: C	For complicated right-sided IE and for left-sided IE. For uncomplicated right-sided IE, 2 wk (see text).
For penicillin-allergic (nonanaphylactoid-type) patients:				Consider skin testing for oxacillin-susceptible staphylococci and questionable history of immediate-type hypersensitivity to penicillin.
Cefazolin	6 g/24 hr IV in 3 equally divided doses	6	Class I, LOE: B	Cephalosporins should be avoided in patients with anaphylactoid-type hypersensitivity to β-lactams; vancomycin should be used in these cases.
Oxacillin-Resistant Strains				
Vancomycin†	30 mg/kg/24 hr IV in 2 equally divided doses	6	Class I, LOE: C	Adjust vancomycin dose to achieve trough concentration of 10-20 µg/mL (see text for vancomycin alternatives).
Daptomycin	≥8 mg/kg/dose	6	Class IIb, LOE: B	Await additional study data to define optimal dosing.

*Doses recommended are for patients with normal renal function.

†For specific dosing adjustment and issues concerning vancomycin, **see Table 73.7** footnotes.

IE, Infective endocarditis; *IV,* intravenously; *LOE,* level of evidence.

From Baddour LM, Wilson WR, Bayer AS, et al. Infective endocarditis in adults: diagnosis, antimicrobial therapy, and management of complications. A scientific statement for healthcare professionals from the American Heart Association. Circulation 2015;132:1435-86.

For uncomplicated right-sided native valve IE caused by oxacillin-susceptible staphylococci, 2 weeks of antibiotic therapy with nafcillin or oxacillin is an option. For patients who are intolerant of beta-lactam therapy, vancomycin can be used, but many favor a longer treatment. Daptomycin, 6 mg/kg/day intravenously, is another treatment option in patients intolerant of beta-lactam therapy.

Defining an optimal treatment regimen for native valve IE, including left- and right-sided infection, caused by oxacillin-resistant staphylococci is a more difficult task. Currently, IV vancomycin is recommended, but cure rates are less than desired. Daptomycin and ceftaroline are treatment options in patients intolerant of or nonresponsive to vancomycin, but prospective trial data including large cohorts

are lacking.

Therapy for PVE caused by staphylococci involves more complex regimens because of the difficulty in curing infections involving prosthetic valve material. For oxacillin-susceptible strains, nafcillin or oxacillin is given for at least 6 weeks in combination with rifampin, which can be administered either intravenously or orally (**Table 73.11**). Cefazolin can be used if the patient is intolerant of penicillins and has not had an IgE-mediated allergic reaction. Gentamicin is recommended for the initial 2 weeks of treatment as well. In patients intolerant of gentamicin, or if the infecting isolate is resistant to gentamicin and other aminoglycosides, levofloxacin can be given, provided that the isolate is susceptible to this agent. For PVE caused by oxacillin-resistant strains, IV vancomycin should be given in combination with rifampin for at least 2 weeks and gentamicin for 2 weeks.

TABLE 73.11

Therapy for Endocarditis of Prosthetic Valves or Other Prosthetic Material Caused by Staphylococci

REGIMEN	DOSE* AND ROUTE	DURATION (WK)	STRENGTH OF RECOMMENDATION	COMMENTS
Oxacillin-Susceptible Strains				
Nafcillin or oxacillin	12 g/24 hr IV in 6 equally divided doses	≥6	Class I, LOE: B	Vancomycin should be used in patients with immediate-type hypersensitivity reactions to β-lactam antibiotics (**see Table 73.7** for dosing guidelines). Cefazolin may be substituted for nafcillin or oxacillin in patients with non–immediate-type hypersensitivity reactions to penicillins.
plus				
Rifampin	900 mg/24 hr IV or orally in 3 equally divided doses	≥6		
plus				
Gentamicin†	3 mg/kg/24 hr IV or IM in 2 or 3 equally divided doses	2		
Oxacillin-Resistant Strains				
Vancomycin	30 mg/kg/24 hr in 2 equally divided doses	≥6	Class I, LOE: B	Adjust vancomycin to a trough concentration of 10-20 μg/mL.
plus				
Rifampin	900 mg/24 hr IV/PO in 3 equally divided doses	≥6		
plus				
Gentamicin	3 mg/kg/24 hr IV/IM in 2 or 3 equally divided doses	2		See text for gentamicin alternatives.

*Doses recommended are for patients with normal renal function.

†Gentamicin should be administered in close proximity to vancomycin, nafcillin, or oxacillin dosing. **See Table 73.7** for appropriate dose of gentamicin.

IM, Intramuscularly; *IV,* intravenously; *LOE,* level of evidence.

Enterococci.

Enterococci are common causative organisms in IE, particularly in the elderly population, and treatment requires both penicillin or ampicillin and an aminoglycoside (usually gentamicin) for attempted cure of infection. Because of the recommended 4 to 6 weeks of therapy, it often is difficult to complete the aminoglycoside-containing regimen in these older patients without the development of nephrotoxicity and/or ototoxicity. These adverse events are a greater concern in patients who are not candidates for penicillin therapy, usually because of previous allergic reaction, in whom vancomycin is combined with an aminoglycoside.

For native valve IE caused by strains that are susceptible to both penicillin and gentamicin, 4 weeks of antibiotic treatment is recommended in patients with symptoms for 3 months or less; 6 weeks is recommended for symptoms of IE longer than 3 months or for PVE (**eTable 73.1**). If an isolate is gentamicin resistant and streptomycin susceptible, streptomycin should be given with either ampicillin or penicillin (**eTable 73.2**). When the isolate is resistant to all aminoglycosides or the patient is unable to tolerate an aminoglycoside-containing regimen, a combination of "high-dose" ceftriaxone (4 g daily in two divided doses) with ampicillin has been successfully used,[73,74] but no head-to-head trials have been conducted to determine if the double–beta-lactam regimen is comparable in efficacy to the aminoglycoside-containing regimen. Nevertheless, historical data suggest comparable outcomes with the two regimens; thus double–beta-lactam therapy for IE caused by *Enterococcus faecalis* is a treatment option.[6,22] The beta-lactam combination should be administered for 6 weeks.

ETABLE 73.1

Therapy for Endocarditis Involving a Native or Prosthetic Valve or Other Prosthetic Material Resulting From *Enterococcus* Spp. Caused by Strains Susceptible to Penicillin and Gentamicin in Patients Who Can Tolerate β-Lactam Therapy*

REGIMEN	DOSE† AND ROUTE	DURATION (wk)	STRENGTH OF RECOMMENDATION	COMMENTS
Either				
Ampicillin sodium	2 g IV every 4 hr	4–6	Class IIa, LOE: B	Native valve: 4-wk therapy recommended for patients with symptoms of illness <3 mo; 6-wk therapy recommended for native valve symptoms >3 mo and for patients with prosthetic valve or prosthetic material. Recommended for patients with creatinine clearance >50 mL/min.
or				
Aqueous penicillin G sodium	18-30 million U/24 hr IV either continuously or in 6 equally divided doses	4–6	Class IIa, LOE: B	
plus				
Gentamicin sulfate‡	3 mg/kg ideal body weight in 2-3 equally divided doses	4–6		
or				
Double β-lactam:			Class IIa, LOE: B	Recommended for patients with initial creatinine clearance <50 mL/min or who develop creatinine clearance <50 mL/min during therapy with gentamicin-containing regimen.
Ampicillin	2 g IV every 4 hr	6		
plus				
Ceftriaxone	2 g IV every 12 hr	6		

*For patients unable to tolerate a β-lactam, **see eTable 73.3**.

†Doses recommended are for patients with normal renal and hepatic function.

‡Dose of gentamicin should be adjusted to achieve a peak serum concentration of 3 to 4 µg/mL and a trough concentration of <1 µg/mL.

IV, Intravenously; LOE, level of evidence.

ETABLE 73.2

Therapy for Endocarditis Involving a Native or Prosthetic Valve or Other Prosthetic Material Resulting from *Enterococcus* spp. Caused by a Strain Susceptible to Penicillin and Resistant to Aminoglycosides or a Streptomycin-Susceptible Gentamicin-Resistant Strain in Patients Able to Tolerate β-Lactam Therapy*

REGIMEN	DOSE† AND ROUTE	DURATION (wk)	STRENGTH OF RECOMMENDATION	COMMENTS
Double β-lactam:				Double β-lactam is reasonable for patients with normal or impaired renal function abnormal cranial nerve VIII function or if the laboratory is unable to provide rapid results of streptomycin serum concentration; native valve infection with symptoms of infection <3-mo duration may be treated for 4 wk with the streptomycin-containing regimen. PVE, NVE with symptoms >3 mo, or treatment with a double β-lactam regimen requires a minimum of 6 wk of therapy.
Ampicillin	2 g IV every 4 hr	6	Class IIa, LOE: B	
plus				
Ceftriaxone	2 g IV every 12 hr			
Alternative for Streptomycin-Susceptible Gentamicin-Resistant Strain				
Either				
Ampicillin sodium	2 g IV every 4 hr	4-6	Class IIa, LOE: B	Use is reasonable only for patients with availability of rapid streptomycin serum concentrations. Patients with creatinine clearance <50 mL/min or who develop creatinine clearance <50 mL/min during treatment should be treated with double–β-lactam regimen. Patients with abnormal cranial nerve VIII function should be treated with double–β-lactam regimen.
or				
Aqueous penicillin G sodium	18-30 million U/24 hr IV either continuously or in 6 equally divided doses			
plus				
Streptomycin sulfate‡	15 mg/kg ideal body weight per 24 hr IV or IM in 2 equally divided doses			

*For patients unable to tolerate a β-lactam, **see eTable 73.3**.

†Doses recommended for patients with normal renal and hepatic function.

‡Streptomycin dose should be adjusted to obtain a serum peak concentration of 20 to 35 µg/mL and a trough concentration of <10 µg/mL.

IM, Intramuscularly; *IV,* intravenously; *NVE,* native valve infective endocarditis; *PVE,* prosthetic valve infective endocarditis.

From Baddour LM, Wilson WR, Bayer AS, et al. Infective endocarditis in adults: diagnosis, antimicrobial therapy, and management of complications. A scientific statement for healthcare professionals from the American Heart Association. Circulation 2015;132:1435-86.

Some enterococcal isolates are penicillin resistant; most do not produce beta-lactamase as the mechanism of penicillin resistance and should be treated with a combination of vancomycin plus gentamicin. For the extremely rare isolate that produces beta-lactamase, ampicillin-sulbactam can be used with gentamicin (**eTable 73.3**). For enterococcal strains resistant to vancomycin (VRE) and penicillin, optimal treatment regimens are undefined, and therapy should be defined by a consulting infectious diseases expert. Often, daptomycin or linezolid is selected for use with other agents, depending on additional susceptibility results, which may require sending an isolate to a reference laboratory.

ETABLE 73.3

Vancomycin-Containing Regimens for Vancomycin- and Aminoglycoside-Susceptible Penicillin-Resistant *Enterococcus* Spp. for Native or Prosthetic Valve (or Other Prosthetic Material) Infective Endocarditis (IE) in Patients Unable to Tolerate β-Lactam

REGIMEN	DOSE* AND ROUTE	DURATION (wk)	STRENGTH OF RECOMMENDATION	COMMENTS
Unable to Tolerate β-Lactams				
Vancomycin†	30 mg/kg/24 hr IV in 2 equally divided doses	6	Class IIa, LOE: B	
plus				
Gentamicin‡	3 mg/kg/24 hr IV or IM in 3 equally divided doses	6		
Penicillin Resistance; Intrinsic or β-Lactamase Producer				
Vancomycin	30 mg/kg/24 hr IV in 2 equally divided doses	6	Class IIa, LOE: C	For β-lactamase–producing strain, if able to tolerate a β-lactam antibiotic, ampicillin-sulbactam§ plus aminoglycoside therapy may be used.
plus				
Gentamicin‡	3 mg/kg/24 hr IV or IM in 3 equally divided doses	6		

*Doses recommended are for adults with normal renal function.

†Dose of vancomycin should be adjusted to obtain a serum trough concentration of 10 to 20 µg/mL.

‡Dose of gentamicin should be adjusted to obtain serum peak and trough concentrations of 3 to 4 and <1 µg/mL, respectively.

§Ampicillin-sulbactam dosing is 3 g/6 hr IV.

IM, intramuscular; and IV, intravenous.

HACEK Organisms.

The primary choice of therapy for IE caused by the HACEK group of organisms is ceftriaxone, given for 4 weeks for native valve infection and 6 weeks for PVE (**eTable 73.4**). Cefotaxime and ampicillin-sulbactam are acceptable alternative therapeutic agents, but their use has been limited because of the ease of dosing (once daily) with ceftriaxone, which is not shared by these other two treatment options. Fluoroquinolones should be efficacious as second-line agents, but clinical experience is limited.

ETABLE 73.4

Therapy for Endocarditis Involving a Native or Prosthetic Valve or Other Prosthetic Material Caused by HACEK Microorganisms

REGIMEN	DOSE AND ROUTE	DURATION (wk)	STRENGTH OF RECOMMENDATION	COMMENTS
Ceftriaxone sodium*	2 g/24 hr IV or IM in 1 dose	4, NVE 6, PVE	Class IIa, LOE: B	Preferred therapy: cefotaxime or another third- or fourth-generation cephalosporin may be substituted.
or				
Ampicillin sodium	2 g IV every 4 hr		Class IIa, LOE: B	Ampicillin sodium may be an option if the growth of the isolate is sufficient to permit in vitro susceptibility results.
or				
Ciprofloxacin†	1000 mg/24 hr orally or 800 mg/24 hr IV in 2 equally divided doses		Class IIb, LOE: C	Fluoroquinolone therapy‡ may be considered for patients unable to tolerate cephalosporin and ampicillin therapy; levofloxacin or moxifloxacin may be substituted; fluoroquinolones generally are not recommended for patients <18 yr old. Treatment for 6 wk is reasonable in patients with PVE. (Class IIa, LOE: C)

*Patients should be informed that intramuscular injection of ceftriaxone is painful.

†Dose recommended for patients with normal renal function.

‡Fluoroquinolones are highly active in vitro against HACEK microorganisms. Published data on the use of fluoroquinolones for endocarditis caused by HACEK are minimal.

HACEK, *Haemophilus* spp., *Aggregatibacter* spp., *Cardiobacterium hominis, Eikenella corrodens, Kingella* spp.; *IM,* intramuscularly; *IV,* intravenously; *NVE,* native valve infective endocarditis; *PVE,* prosthetic valve infective endocarditis.

Aerobic Gram-Negative Bacilli and Fungi.

Although they rarely cause IE, coverage of both aerobic gram-negative bacilli and fungi is included here because many experts recommend a combined medical and surgical approach to management of IE caused by these pathogens.[6] Infectious diseases, cardiology, and cardiovascular surgery consultations should be sought in these cases. A lack of clinical trial data, reflecting in part the rarity of these syndromes, makes defining an optimal treatment regimen difficult.

Nevertheless, for IE caused by aerobic gram-negative bacilli, a combination of beta-lactam with an aminoglycoside is recommended, and the selection of these agents should be based on in vitro susceptibility testing results. A fluoroquinolone that is active against the isolated pathogen can be used instead of an aminoglycoside if the infecting isolate is aminoglycoside resistant or if the patient is intolerant of aminoglycosides.

Fungal IE primarily involves prosthetic valves and is characterized by poor outcomes. In some cases the infecting organism does not grow in routine blood cultures, and the infection can manifest as culture-negative endocarditis (discussed next). As noted previously, a majority of cases are caused by *Candida* spp., and many of the infections are health care associated. Because clinical trial data do not exist, defining an optimal treatment regimen is difficult, and drug therapy, which usually includes an amphotericin B–containing product, is associated with both infusion-related (rigors, fever, back pain, hypotension, bronchospasm, tachyarrhythmias) and delayed (nephrotoxicity, anemia, cation-wasting) adverse events that can be severe and limit use of these agents.[6] Moreover, relapse rates are high, even if valve surgery is done. The echinocandins (caspofungin, micafungin, and anidulafungin) have been useful in some patients who cannot tolerate an amphotericin B–containing regimen. Thus, many experts advocate the use of long-term oral suppressive therapy once initial “induction” therapy is completed and an active oral agent is identified. Azole agents, including fluconazole and voriconazole, have been used most often. Unfortunately, none of the echinocandins is available for oral use. The complexity of

antifungal selection warrants consultation with an expert in infectious diseases.

Culture-Negative Endocarditis.

Empiricism begets empiricism. In most cases, when no pathogen is isolated in blood cultures or in other specimens (embolism, valve tissue), empiric antimicrobial therapy is started before specimen collection. Therefore, selecting an optimal treatment regimen for these patients is difficult. Certainly, epidemiologic features of each case should be evaluated to assist in defining a treatment regimen (**Table 73.12**). In addition, the course of illness associated with the endocarditis presentation may offer clues to the cause of the infection and to the specific antibiotics already administered that might have accounted for negative specimen (usually blood) cultures. In addition, an evaluation of blood and tissue should be done to determine if rare causes of endocarditis could account for a culture-negative presentation, particularly in patients who did not receive recent antimicrobial therapy. An evaluation of these rare causes of culture-negative endocarditis is outlined earlier.

TABLE 73.12

Epidemiologic Clues in Etiologic Diagnosis of Culture-Negative Endocarditis

EPIDEMIOLOGIC FEATURE	COMMON MICROORGANISM
Injection drug use (IDU)	*Staphylococcus aureus*, including community-acquired oxacillin-resistant strains Coagulase-negative staphylococci β-Hemolytic streptococci Fungi Aerobic gram-negative bacilli, including *Pseudomonas aeruginosa* Polymicrobial
Indwelling cardiovascular medical devices	*S. aureus* Coagulase-negative staphylococci Fungi Aerobic gram-negative bacilli *Corynebacterium* spp.
Genitourinary disorders, infection, and manipulation, including pregnancy, delivery, and abortion	*Enterococcus* spp. Group B streptococci (*S agalactiae*) *Listeria monocytogenes* Aerobic gram-negative bacilli *Neisseria gonorrhoeae*
Chronic skin disorders, including recurrent infections	*S. aureus* β-Hemolytic streptococci *S. aureus* β-Hemolytic streptococci
Poor dental health, dental procedures	Viridans group streptococci (VGS) Nutritionally variant streptococci *Abiotrophia defectiva* *Granulicatella* spp. *Gemella* spp. HACEK organisms
Alcoholism, cirrhosis	*Bartonella* spp. *Aeromonas* spp. *Listeria* spp. *Streptococcus pneumoniae* β-Hemolytic streptococci
Burns	*S. aureus* Aerobic gram-negative bacilli, including *P. aeruginosa* Fungi
Diabetes mellitus	*S. aureus* β-Hemolytic streptococci *S. pneumoniae*
Early (≤1 yr) prosthetic valve placement	Coagulase-negative staphylococci *S. aureus* Aerobic gram-negative bacilli Fungi *Corynebacterium* spp. *Legionella* spp.
Late (>1 yr) prosthetic valve placement	Coagulase-negative staphylococci *S. aureus* Viridans group streptococci *Enterococcus* spp. Fungi *Corynebacterium* spp.
Dog or cat exposure	*Bartonella* spp. *Pasteurella* spp.

	Capnocytophaga spp.
Contact with contaminated milk or infected farm animals	*Brucella* spp. *Coxiella burnetii* *Erysipelothrix* spp.
Homeless, body lice	*Bartonella* spp.
HIV/AIDS	*Salmonella* spp. *S. pneumoniae* *S. aureus*
Pneumonia, meningitis	*S. pneumoniae*
Solid-organ transplantation	*S. aureus* *Aspergillus fumigatus* *Enterococcus* spp. *Candida* spp.
Gastrointestinal lesions	*Streptococcus gallolyticus (bovis)* *Enterococcus* spp. *Clostridium septicum*

HACEK, *Haemophilus* spp., *Aggregatibacter* spp., *Cardiobacterium hominis, Eikenella corrodens,* and *Kingella* spp; HIV/AIDS, human immunodeficiency virus infection and acquired immunodeficiency syndrome.

From Baddour LM, Wilson WR, Bayer AS, et al. Infective endocarditis in adults: diagnosis, antimicrobial therapy, and management of complications. A scientific statement for healthcare professionals from the American Heart Association. Circulation 2015;132:1435-86.

Based on epidemiologic features and the most likely cadre of pathogens, a strategy for selection of antimicrobial therapy can be devised with input from an infectious diseases physician who has expertise in IE management. Considerations include the type of valve—native or prosthetic—and, with prosthetic valves, time since implantation of the valve. These regimens are necessarily broad to cover the most likely pathogens, which include the streptococci, staphylococci, enterococci, and HACEK organisms. Certain epidemiologic features may dictate broader coverage. The most troubling aspects of this approach are that the selected empiric therapy may not be adequate for a specific pathogen, and antimicrobials that would not be administered if the pathogen were identified will be given, with the potential for development of toxicity that may not be fully reversible.

Indications for and Timing of Surgery

The frequency with which surgery is used in the treatment of IE increased on average by 7% per decade between 1969 and 2000, with an attendant decrease in early mortality. In the current era, surgery is the mainstay of therapy for complicated IE. Current practice guidelines (largely based on observational series and expert opinion) advise that surgery should be considered in the presence of (1) heart failure, (2) features suggestive of a high risk of embolism, and (3) uncontrolled infection[22,75] (see **Tables 73G.3** and **73G.4**). A review by Bannay and colleagues[76] demonstrated that early surgery led to significant improvements in survival after treatment for left-sided IE (adjusted HR for mortality, 0.55; 95% CI 0.35 to 0.87; $P = 0.01$). This benefit was further confirmed by a large, prospective, multinational study of the effect of early surgery on in-hospital mortality, accounting for treatment selection, survivorship, and hidden biases.[46] The investigators found that early surgery plus antimicrobial therapy (compared with medical management alone) was associated with a significant reduction in mortality in the overall cohort (12.1% versus 20.7%), as well as after propensity-based matching and adjustment for survivor bias (absolute risk reduction [ARR], −5.9%; $P < 0.001$). The results of these and other studies have led to management algorithms recommending the early consideration of surgical intervention after recognition of native valve IE.

Heart failure is the most frequently encountered reason for consideration of urgent surgical treatment. HF may be caused by severe regurgitation (aortic or mitral), intracardiac fistulas, or less often, vegetation-related valve obstruction. Emergent surgery for HF unresponsive to medical management is crucial, and swift intervention also is recommended, even if temporary stabilization of the patient can be

achieved. Delayed surgery may be considered in the absence of HF after healing of acute endocarditic lesions, which in some circumstances may increase the likelihood of native valve repair.

Uncontrolled infection, the next most likely reason for surgical intervention, can be characterized broadly by increasing vegetation size, abscess formation, false aneurysms, or the creation of fistulas. Persistent fever frequently is associated with these anatomic findings. Early surgery is indicated in the setting of uncontrolled infection associated with persistent fever and positive blood cultures despite an appropriate antibiotic regimen, but surgery ideally should be delayed until after exclusion of extracardiac sources of infection. Perivalvular extension of infection is more common in aortic valve IE (10% to 40% in native valve IE and 56% to 100% in PVE). Some clinicians have noted that perivalvular abscesses most frequently occur in the posterior or lateral portions of the mitral annulus, whereas in aortic IE, extension can occur through the intervalvular fibrosa. The predictors of intervalvular fibrosa invasion include presence of a prosthetic valve (**see Fig. 73.4**), aortic location, and infection with coagulase-negative staphylococci. Pseudoaneurysms and fistula formation occur on average in 1.6% of cases and are more frequently related to *S. aureus* infection (46%). Other, less frequent manifestations of extension include ventricular septal defect, third-degree atrioventricular block (AVB), and acute coronary syndrome. Urgent surgery generally is recommended to treat perivalvular extension of infection (except in rare circumstances) and in cases of IE due to fungi, multidrug-resistant organisms, and gram-negative bacteria. In general, perivalvular extension or infection with aggressive microorganisms warrants early surgery in the absence of severe comorbid disease that would otherwise be prognosis-limiting.

IE-related embolism is common (20% to 50% of cases) and can be fatal. Occult embolism may occur in approximately 20% of patients. A 2007 report indicated that the risk of embolism was highest in the first week after initiation of antibiotic therapy (4.8/1000 patient-days) and decreases thereafter (1.7/1000 patient-days).[60] Some experts therefore suggest that the greatest benefit to patient survival is the prevention of systemic embolization, which can best be realized during the first week of antibiotic therapy.

The exact timing of surgical intervention for embolism prevention should be based on the presence or absence of previous embolic events, other complications of IE, size and mobility of the vegetation, likelihood of conservative surgery (valve repair), and duration of antibiotic therapy.[77] Ultimately, extrapolation of surgical benefits also must consider factors of patient viability, comorbid conditions, potential consequences of conservative management, and patient preferences.

Surgery generally is recommended in the presence of large, mobile vegetations (>10 mm),[57] particularly after an embolic event occurring during treatment with appropriate antibiotics. Even if embolization has not occurred, the presence of HF, severe valvular dysfunction, persistent infection despite appropriate antibiotic therapy, or abscess plus a large vegetation (>10 mm) constitutes an indication for earlier surgery. Only one small, randomized trial has evaluated the role of valve surgery in IE management.[62] Patients underwent valve surgery within 48 hours of randomization. There were several exclusion criteria for enrollment, and patients had to have left-sided IE, severe valvular regurgitation without HF, and vegetations larger than 10 mm to be included in the study. Valve surgery patients had fewer embolic events in follow-up, but other outcome measures, including mortality and infection relapse rates, did not differ between the two groups (each with <40 patients).

Considerable debate surrounds the performance of surgical intervention with a history of recent neurologic embolization. Iung and coauthors[78] systematically performed cerebral and abdominal MRI in early IE and found neurologic lesions in 82% of cases (ischemic lesions in 25, microbleeds in 32, and silent aneurysms in 6), and abdominal lesions in 20 patients (34%). Of importance, these findings led to modifications of classification and/or therapy in 28% of patients. Rossi and colleagues[79] detailed a best-

evidence summary of whether there is an ideal time for surgery in IE with cerebrovascular complications, including intracranial hemorrhage (ICH), ruptured mycotic aneurysm, TIA, meningitis, encephalopathy, and brain abscess. The investigators recommended 1 to 2 weeks of antibiotic treatment before cardiac surgery is indicated. However, earlier surgery is indicated in HF (class I, level of evidence [LOE]: B) and uncontrolled infection (class I, LOE: B) and for prevention of embolic events (class I, LOE: B/C). After stroke, surgery should not be delayed in the absence of coma and once cerebral hemorrhage has been excluded by cranial CT (class IIa LOE: B). After a TIA or a silent cerebral embolism, surgery is recommended without delay (class I, LOE: B). After diagnosis of ICH, surgery should ideally be postponed for at least 1 month (class I, LOE: C). In the case of surgery for PVE, the general principles outlined for native valve IE should be followed. Every patient should have a repeated head CT scan immediately before the operation to rule out preoperative hemorrhagic transformation of a brain infarction. Presence of a hematoma warrants neurosurgical consultation and consideration of cerebral angiography to rule out a mycotic aneurysm.

Medical therapy in the setting of right-sided native valve IE is the mainstay of treatment, and surgical intervention most often can be deferred in the absence of (1) diuretic-resistant right-sided HF associated with severe tricuspid regurgitation, (2) fastidious organisms resistant to antimicrobial treatment (i.e., fungemia or persistent bacteremia for >7 days), or (3) vegetations larger than 20 mm in diameter associated with multiple pulmonary emboli and possible right-sided HF.

Surgical Intervention

Before surgical intervention, several considerations in addition to the confirmation of appropriate antibiotic therapy are important. First, coronary artery assessment using either cardiac catheterization or CT angiography is recommended, to ascertain whether concomitant coronary revascularization is necessary. Before the performance of cardiac surgery, identification of primary or secondary extracardiac sites of infection should be undertaken, and extirpation should be performed if practically possible.

The primary principles guiding surgical management of IE are (1) excision of infected material along with sterilization of remaining tissue and instruments, followed by (2) reconstruction of cardiac or valve structures to permit normal heart function. Valve repair almost always is a favored option in the treatment of valvular IE.[80] If the extent of débridement necessary to eradicate infection precludes valve reconstruction, prosthetic valve replacement may be necessary.

The specific techniques used are tailored to the anatomy encountered at operation. Perforations in a valve cusp or leaflet are reconstructed using pericardial patch or other matrix substances. In general, the use of prosthetic material should be minimized; however, in settings where valve replacement is required, consensus documents do not routinely recommend one particular valve substitute over another (i.e., mechanical versus biologic).[75]

Reports suggest that mitral valve IE can be repaired in up to 80% of patients, particularly by experienced teams at referral centers.[81] A combination of traditional valvuloplasty techniques is utilized,[82] and results are assessed by intraoperative TEE. Although theoretically appealing, mitral valve homografts and pulmonary autografts have failed to gain widespread acceptance.

In the setting of acute IE, mechanical or biologic (xenograft) aortic valve replacement may be required, with few early demonstrated differences between device types.[83,84] Homografts or stentless root xenograft conduits are selectively used to reconstruct severely affected aortic sinuses, repair abscess-related destruction, or correct aortoventricular discontinuity.[85]

Postsurgical outcomes depend on the etiologic microorganism, the extent of tissue destruction, the presence of systolic or diastolic HF, and comorbid conditions. Early operative mortality ranges between

5% and 15%.[86] A 2008 report suggested that surgery within the first week of antibiotic therapy is associated with in-hospital mortality rate of 15%, and the main predictor was periannular extension of disease; risk of recurrent IE was 12%.[87] With isolated infection of leaflets or cusps (particularly in the subacute/chronic phase), early mortality is lower and approaches that seen in normal valve repair and replacement surgery.

Postoperative complications in this high-risk patient population typically include profound intraoperative coagulopathy necessitating mediastinal reexploration, acute renal failure, stroke, low cardiac output, pneumonia, and AVB necessitating pacemaker implantation.[80,86,88]

Outpatient Management and Follow-Up Evaluation

Antimicrobial treatment of IE is done in the outpatient setting once microbiologic control of infection is obtained, and after surgical or other interventions, if required, are completed and clinical recovery is observed.[6] Parenteral therapy is delivered in a variety of settings, related in part to the individual patient's health care coverage; often, therapy is done in a patient's home by a family member who has received instruction regarding (usually) IV infusions. Serial laboratory monitoring for evidence of drug-related toxicity and serum concentrations of drugs, when applicable, is mandatory and can be accomplished in a variety of settings, including home health agencies, primary care offices, and infectious diseases clinics. Monitoring also includes serial visits with an experienced clinician to assess clinical status and evidence of drug tolerance and complications related to an indwelling venous catheter. As outlined earlier, beta-lactam antibiotics frequently are used in the treatment of IE caused by a variety of bacterial infections. These agents are well recognized to have various adverse effects, including diarrhea, which may or may not be caused by *Clostridium difficile* infection, as well as rash, fever, neutropenia, and less often, hepatobiliary or renal toxicities.

Once parenteral antimicrobial therapy is completed (**Table 73.13**), the indwelling venous catheter should be removed, because it can be a nidus of subsequent infection or of other, noninfectious complications, unless there is another need for the device. At completion of therapy, an echocardiogram should be obtained to serve as a baseline (**see Table 73.6**), because patients who have had an initial bout of IE, regardless of whether or not the valve was replaced, are at high risk for subsequent IE relapse or recurrence. Consultation with a cardiologist should determine whether TTE versus TEE is preferred. Daily dental hygiene and dental visits should be done to promote dental health.

TABLE 73.13

Patient Care During and After Completion of Antimicrobial Treatment

Initiation Before or at Completion of Therapy
Echocardiography to establish new baseline
Drug rehabilitation referral for patients who use illicit injection drugs
Education on the signs of endocarditis and need for antibiotic prophylaxis for certain dental/surgical/invasive procedures
Thorough dental evaluation and treatment if not performed earlier in evaluation
Prompt removal of intravenous catheter at completion of antimicrobial therapy
Short-Term Follow-Up
At least 3 sets of blood cultures from separate sites for any febrile illness and before initiation of antibiotic therapy
Physical examination for evidence of heart failure
Evaluation for toxicity resulting from current/previous antimicrobial therapy
Long-Term Follow-Up
At least 3 sets of blood cultures from separate sites for any febrile illness and before initiation of antibiotic therapy
Evaluation of valvular and ventricular function (echocardiography)
Scrupulous oral hygiene and frequent dental professional office visits

From Baddour LM, Wilson WR, Bayer AS, et al. Infective endocarditis in adults: diagnosis, antimicrobial therapy, and management of complications. A scientific statement for healthcare professionals from the American Heart Association. Circulation 2015;132:1435-86.

Patients and their family members should be educated about aspects of IE,[6] in particular the importance of obtaining three sets of blood culture specimens if the patient develops fever any time in the future before taking any antibiotic. The critical aspect of securing multiple sets of blood cultures before initiating antibiotic therapy cannot be overemphasized. If a bloodstream infection is confirmed as the cause of the fever, an evaluation for relapsing or recurrent IE is necessary, which generally will include TEE in the evaluation for a source of the infection, in addition to initiating treatment for infection.

Cardiovascular Implantable Electronic Device Infections

The number of patients with CIEDs has dramatically increased over the past two decades, and this trend will continue as the indications for their use expand (**see Chapters 27 and 41**) and the population continues to age. With this expansion of CIED placement, a concomitant increase in infections of these devices has been documented.[89-91] The accompanying morbidity, mortality, and financial burden from CIED infection have been substantial.

Epidemiology

Several database surveys suggest that the rate of CIED infection has increased more than the rate of device implantation.[91-93] Factors associated with increased CIED infection risk include device placement in older patients and those with more comorbidities (particularly renal failure), more leads placed per patient, increased need for device revision or replacement, and complications at the pocket site after device placement or revision, particularly hematoma formation and delayed or poor wound healing. Factors that reduce the likelihood of device infection include the administration of surgical site prophylaxis at the time of device placement or revision and a higher volume of devices implanted by the physician performing the procedure.

Clinical Syndromes

The most common presentation of CIED infections is that of erosion and/or inflammatory changes at the

shoulder generator pocket site, with or without systemic manifestations of infection.[92] For others, systemic manifestations of infection prompt clinical evaluation with or without local findings of infection at the pocket site. Pulmonary manifestations can develop, including pleuritic pain, lung infiltrates, and lung abscess. In addition, cardiac and peripheral stigmata of IE occur in patients with CIED infection, and there may be associated valve infection.

Microbiology

Staphylococcal species predominate as causes of CIED infection, accounting for 60% to 80% of infections in most series.[89-93] Both *S. aureus* and coagulase-negative staphylococci are common pathogens and often are oxacillin resistant. Other gram-positive cocci, including streptococcal and enterococcal species, can cause CIED infection. Aerobic gram-negative bacilli and fungi are identified as pathogens in only a small minority of cases. Rarely, nontuberculous mycobacteria have been identified as causes of CIED infection.

Pathogenesis

Device infection pathogenesis involves the interactions of device, pathogen, and host.[93] Regarding the host, risk factors associated with infection have been outlined previously. For both the device and the pathogen, certain characteristics may not be unique to CIED infection but are considered operative in all types of device infections. Important among the pathogen-related mechanisms is biofilm formation. Bacteria and yeasts can attach and accumulate on the surface of a device, with eventual formation of a layer of organisms and amorphous material that harbors living organisms, able in this setting to evade normal host immune response and antimicrobial therapy. In addition to the mechanical barrier of the biofilm, organisms that accumulate in biofilms in this setting may alter their metabolic activities, protecting them from the static and cidal effects of certain antimicrobials.

On the basis of the proven efficacy of surgical site prophylaxis at CIED implantation, most CIED infections are believed to result from bacterial or fungal contamination of the device at placement. A less frequent mode of device contamination is lead infection occurring as a complication of bloodstream infection from an ectopic nidus such as an infected intravascular catheter.

Ongoing investigations are examining the surface components and physical and chemical aspects of a device and how those features interact with a pathogen's cell surface structures to either enhance or inhibit initial organism adherence to the device. Elucidation of mechanisms of initial pathogen adherence could lead to the development of devices that are more resistant to infection. Moreover, adjunctive therapies that could be administered at device placement or as vaccines before device placement may become available in the future to further reduce infection risks.

Diagnosis

The diagnosis of CIED infection is straightforward in cases where percutaneous device erosion has occurred or purulent drainage is present at a pocket site. Erythema, swelling, and pain at the pocket site also indicate infection. Distinguishing local findings due to early postoperative healing versus those due to infection can sometimes be challenging and may require serial patient examinations to determine the etiology of the local manifestations.

Blood cultures should be obtained in all cases of CIED infection, including those with clinical

manifestations limited to the pocket site. The possibility of CIED infection should be considered in all patients with bloodstream infection. In patients with positive blood cultures, TEE should be performed. The sensitivity of TEE in detecting lead- and valve-related infection is superior to that of TTE.[89,90] A documented limitation of TEE, however, is that lead infection can occur with no abnormalities detected on the TEE image. Moreover, TEE identifies clots on leads in 5% to 10% of patients who have no infection.

Ultimately, intraoperative findings and Gram staining and culture of deep pocket tissue and device samples obtained at complete device removal are useful in confirming CIED infection.

Management

A primary tenet of management of CIED infection includes complete device removal, if infection cure is the goal.[90,94] Despite the well-recognized risks of lead extraction,[94,95] it is essential to reduce the likelihood of relapsing infection. A management algorithm has been developed to assist in the care of patients with CIED infections (**Figs. 73.6** and **73.7**). Duration of antimicrobial therapy is based on the clinical syndrome of CIED infection and the identified pathogen. The recommended duration of antimicrobial therapy for the different infection syndromes is not evidence based. Moreover, no evidence-based data are available to indicate the preferred route of therapy. In cases with complications such as valvular IE, duration of therapy can extend for 6 weeks or longer.

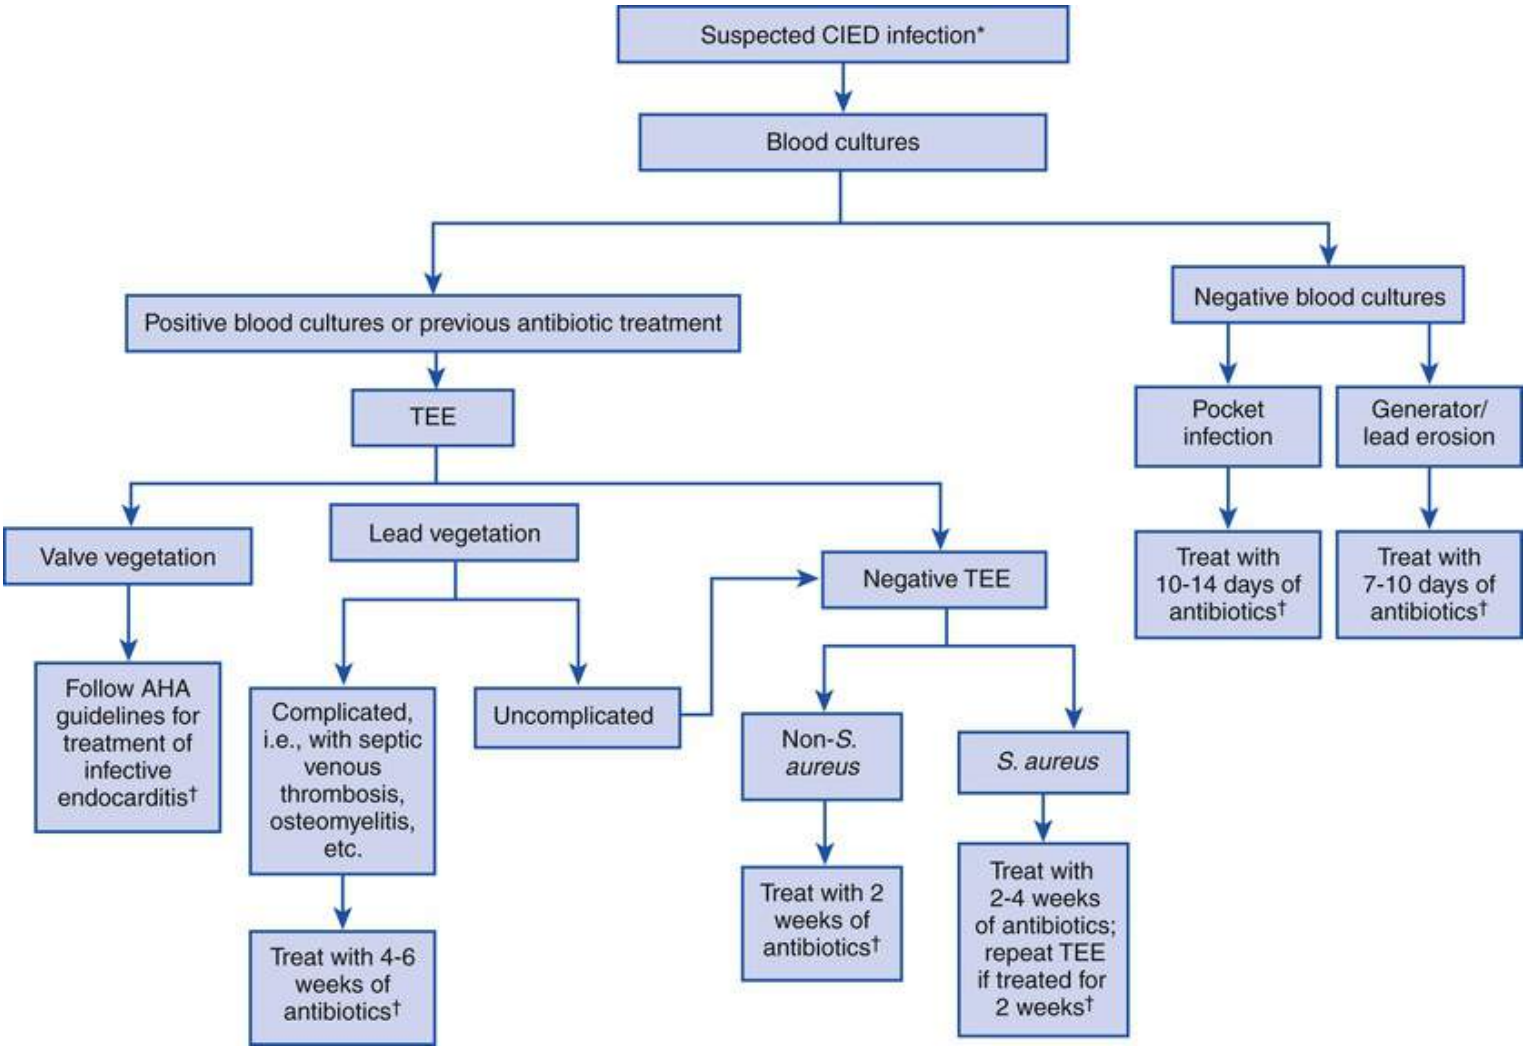

FIGURE 73.6 Approach to management of adults with cardiovascular implantable electronic device (CIED) infection. *A history, physical examination, chest radiograph, electrocardiogram, and echocardiographic device interrogation are standard baseline procedures before CIED removal. †Duration of antibiotics should be counted from the day of device explantation. Treatment can be extended to 4 or more weeks in the setting of metastatic septic complications (i.e., osteomyelitis, organ or deep abscess) or sustained bloodstream infection despite CIED removal. AHA, American Heart Association; TEE, transesophageal echocardiography. (Modified from Sohail MR, Uslan DZ, Khan AH, et al. Management and outcome of permanent pacemaker and implantable cardioverter-defibrillator infections. J Am Coll Cardiol 2007;49:1851.)

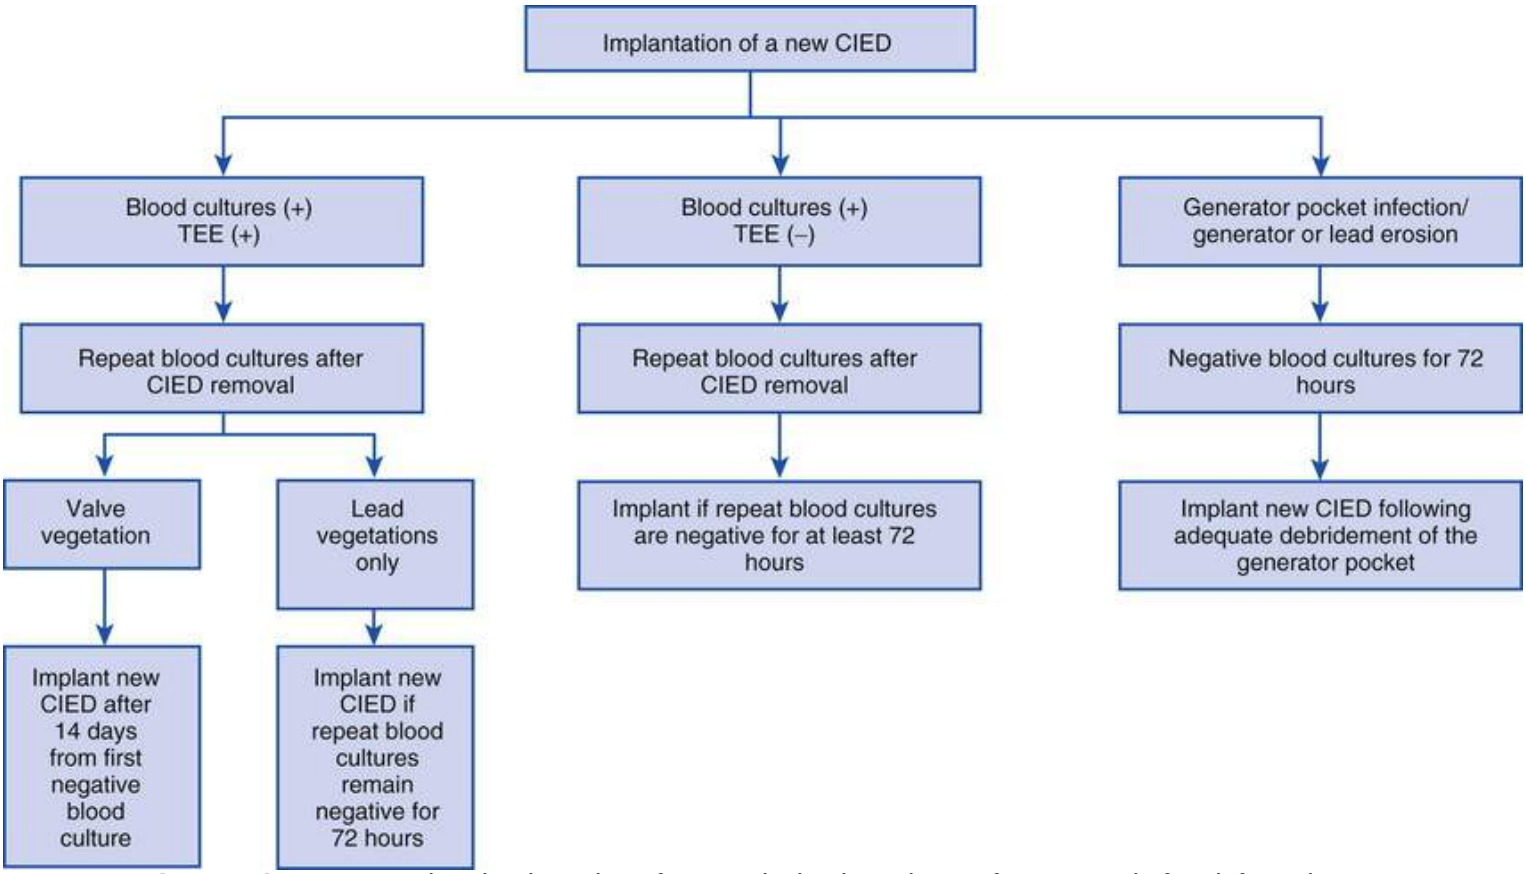

FIGURE 73.7 Approach to implantation of a new device in patients after removal of an infected cardiovascular implantable electronic device (CIED). TEE, Transesophageal echocardiography. (Modified from Sohail MR, Uslan DZ, Khan AH, et al. Management and outcome of permanent pacemaker and implantable cardioverter-defibrillator infections. J Am Coll Cardiol 49:1851, 2007.)

The optimal timing of new device placement is undefined. Each patient should undergo individualized assessment to determine the need for a new device. Some experts have advocated that a new device can be implanted 72 hours after removal of the infected device, provided that blood cultures are negative, no valvular IE is present, and control of infection at the pocket site is secured.[90,92]

Management of patients with bloodstream infection as the *sole* manifestation of an infection is more difficult.[90] In such patients a thorough evaluation, including TEE, identifies no nidus responsible for bloodstream infection. The obvious concern is that either the CIED is infected and serves as a source of bloodstream infection, or the bloodstream infection could secondarily infect the CIED. Decisions regarding device removal are complex. If the device is not removed, relapsing bloodstream infection is inevitable once antimicrobial therapy is completed, if the device is the source of bloodstream infection. Conversely, if the CIED is removed but was not infected, the patient was exposed to the risk and complications of device removal without benefit, as well as incurring considerable expense for the procedure.

Prophylaxis

Prospective, placebo-controlled, clinical trials and case-control and meta-analysis studies[96] consistently indicate that the preoperative administration of an antistaphylococcal antibiotic, usually cefazolin, given intravenously 30 to 60 minutes before device placement or revision, is effective in reducing the risk of CIED infection. If vancomycin is deemed a more appropriate choice, the IV administration should begin 2 hours before the procedure. Subsequent postoperative dosing is not recommended with either cefazolin or vancomycin.

Antimicrobial prophylaxis is not recommended for patients with CIEDs who undergo invasive procedures, such as dental, GI, or GU procedures, because evidence-based data indicating that such procedures carry a risk of CIED infection are lacking. The predominance of staphylococci as the agents of CIED infection suggests that these invasive procedures probably are not responsible for device infection, and "secondary" prophylaxis is not warranted.

Left Ventricular Assist Device Infections

Major advances in the technologic aspects of LV assist devices (LVADs) have been pivotal in impacting patient survival,[97,98] and the demand for these devices continues to grow in the United States (**see Chapter 29**). Not surprisingly, device infection occurs in patients with LVADs and will continue to be a major complication of LVAD use as long as it remains a percutaneous device. The most dramatic change in infection risk among cardiac devices may be that associated with LVADs. Infection risks have fallen, largely because of improvements in device design, including reduction in size.

Characterizing the incidence, epidemiology, and risk factors associated with LVAD infections is difficult because of the striking design changes in these devices since their inception.[97,98] The first-generation, pulsatile-flow, volume-displacement devices, including Novacor, Heartmate XVE, and other Thoratec devices, have been associated with higher rates of infection than the more recently reported rates with the second-generation, continuous-flow devices, including Heartmate II, VentrAssist, and MicroMed DeBakey.

Three categories of LVAD infections have been identified based on the portion of the device that is infected. These designations are somewhat arbitrary, however, because infection can involve more than one portion of an LVAD. The most common presentation is that of driveline infection. Erythema and drainage at the driveline site, with or without systemic manifestations of infection, usually are present.

Pump pocket infection is a second infection presentation and can be a complication of driveline infection. Local pain or discomfort with systemic manifestations is present, and abnormal fluid collection is demonstrated on ultrasound examination or CT. Fluid aspiration or surgical drainage procedures yield purulent material.

LVAD-associated IE is the least often diagnosed of the three presentations, but some cases may go undiagnosed (or may be diagnosed only at autopsy) because diagnostic tools such as TEE lack sensitivity. This diagnosis should be considered in all patients with sustained bloodstream infection and no other cardiovascular device that could serve as a nidus for sustained bacteremia or fungemia.

Microbiology

Staphylococcal species are the predominant causes of LVAD infection,[97,98] and oxacillin resistance is common. Less often, a panoply of other bacteria, encompassing enterococci (including VRE) and *Pseudomonas* spp., and fungi (*Candida* spp.) are identified as pathogens. Treatment options, particularly as oral therapy, usually are limited because of the multidrug-resistant profiles of these pathogens.

Management

The medical management of LVAD infections is difficult. Ideally, the device would be completely removed, but this approach requires surgical intervention and is associated with considerable morbidity and mortality. Therefore, antimicrobial therapy is the mainstay of management and often is used for prolonged periods on a recurrent basis. In addition, antimicrobial selection is difficult because of the characteristic multidrug resistance of infecting pathogens and the underlying comorbidities that increase

the likelihood of drug toxicity (e.g., chronic renal failure and colistin or aminoglycoside use for multidrug-resistant *Pseudomonas aeruginosa* infection).

Regardless of site of device infection, blood culture specimens should be obtained in every case of LVAD infection. Positive blood cultures can occur in patients without systemic signs of infection and can indicate the presence of a more complicated infection (e.g., IE rather than only driveline infection) or infection of another cardiovascular device, such as a prosthetic valve or CIED.

A variety of surgical interventions are used in the management of LVAD infection. Such interventions range from local soft tissue débridement for driveline infection to heart transplantation with LVAD removal in an effort to control refractory LVAD endocarditis and its associated complications.

Prevention

Placebo-controlled trials indicating the efficacy of antibiotic prophylaxis at LVAD placement (surgical site prophylaxis) are lacking. Nevertheless, the adoption of this practice is universal,[97,98] and multiple (up to five) antimicrobials often are administered, typically including some combination of vancomycin, rifampin, cefepime, ciprofloxacin, and fluconazole. The duration of antimicrobial prophylaxis after LVAD implantation also has varied widely, with 24 hours as a minimal duration. In some centers, nasal mupirocin also is used for a variable duration both before and after LVAD implantation.

Meticulous daily care at the driveline exit site is advocated. Patient and family education and serial visits with specialized caregivers are critical in infection prevention and in securing an early diagnosis.

Coronary Stent Infections

Although coronary stent infection is exceedingly rare, in view of the millions of coronary stents placed worldwide, questions often arise about the possibility of such infection in patients with bloodstream infection. This section reviews the current knowledge on this cardiac device infection syndrome.

Clinical Presentation

Coronary stent infections are rare. Patients present with fever that begins less than 1 month (often within 7 days) after stent placement.[99] Chest pain is frequent and may be caused by a variety of complications, including myocardial infarction, suppurative pericarditis, and pericardial empyema. The short incubation period between stent placement and onset of fever is consistent with the predominant pathogen, *S. aureus*, which can cause sepsis and its complications. *P. aeruginosa* and coagulase-negative staphylococci also have been documented to cause coronary artery stent infection.

Diagnosis

Diagnostic procedures usually include TEE to rule out myocardial abscess formation and coronary artery aneurysm or pseudoaneurysm. CT or MRI angiography should be done if TEE findings are negative or if surgical intervention is planned.

Management

Because of the extreme rarity of cases, no optimal management strategy has been defined. Moreover, with only approximately 24 cases described in the literature,[99,100] consensus-based recommendations are difficult to provide. With a reported mortality rate approaching 50%, management strategies to date have been unacceptable. *S. aureus* is the predominant pathogen, and device removal appears to be necessary for attempted cure. Therefore, early surgical intervention should be considered, including stent resection, vascular repair, and possibly vascular grafting. Antimicrobial therapy based on pathogen identification and susceptibility results should be administered parenterally for approximately 6 weeks.

Guidelines

Infective Endocarditis

Larry M. Baddour, William K. Freeman, Rakesh M. Suri, Walter R. Wilson, and Robert O. Bonow

The American Heart Association (AHA) guidelines for prevention of infective endocarditis (IE) have been evolving for the past 50 years, with the most recent key updates providing recommendations for antibiotic prophylaxis published in 2007.[1] The updated AHA scientific statement regarding the recommendations for diagnosis and management of this condition were published in 2015.[2] Other guidelines with recommendations relevant to this condition include the American College of Cardiology/American Heart Association (ACC/AHA) guidelines for management of patients with valvular heart disease, revised most recently in 2014,[3] and the European Society of Cardiology (ESC) guidelines on the prevention, diagnosis, and treatment of IE.[4]

Prevention

The 2007 AHA guidelines represented a marked departure from 1997 recommendations and greatly reduced the patient population for whom prophylactic antibiotics are recommended. The 2007 guidelines noted that previous recommendations were based on research showing that antimicrobial prophylaxis is effective for prevention of experimental endocarditis in animal models, but also acknowledge the lack of clinical trial evidence that antimicrobial prophylaxis is effective in humans for prevention of endocarditis after dental, gastrointestinal, or genitourinary procedures. The expert committee also considered the complexity of prior guidelines, which required stratification of patients and procedures on their IE risk.

The 2007 AHA guidelines committee concluded that only an extremely small number of cases of IE might be prevented by antibiotic prophylaxis for dental procedures even if such prophylaxis were 100% effective. Accordingly, the revised guidelines recommend IE prophylaxis for dental procedures only for patients with underlying cardiac conditions associated with the highest risk of adverse outcomes from IE (**Table 73G.1**). These new recommendations were incorporated in the 2014 ACC/AHA guidelines.[3] The guidelines, however, also included the following statement regarding individualization of preventive strategies based on physician and patient preference:

TABLE 73G.1

Cardiac Conditions and Dental Procedures for Which Antibiotic Prophylaxis Is Recommended

Cardiac Conditions Associated With the Highest Risk of Adverse Outcome From Endocarditis for Which Prophylaxis with Dental Procedures Is Recommended (Class I, Level of Evidence: B)
Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
Previous infective endocarditis
Congenital heart disease (CHD)
Unrepaired cyanotic CHD, including those with palliative shunts and conduits
Completely repaired CHD with prosthetic material or device either by surgery or catheter intervention during the first 6 months after the procedure*
Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
Except for the conditions listed above, antibiotic prophylaxis is no longer recommended for any other form of CHD
Cardiac transplantation recipients who develop cardiac valvulopathy
Dental Procedures for Which Endocarditis Prophylaxis Is Recommended for High-Risk Patients (see above)
All dental procedures and events that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa *except* the following: • Routine anesthetic injections through noninfected tissue • Taking dental radiographs • Placement of removable prosthodontic or orthodontic appliances • Adjustment of orthodontic appliances • Placement of orthodontic brackets • Shedding of deciduous teeth and bleeding from trauma to the lips or oral mucosa

*It is reasonable to stop prophylaxis after 6 months because endothelialization of prosthetic material occurs within 6 months after the procedure.

From Wilson W et al. Prevention of infective endocarditis. Recommendations by the American Heart Association. Circulation 2007;116:1736; and Nishimura RA et al. 2014 AHA/ACCF guideline for the management of patients with valvular heart disease. A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. Circulation 2014;129:e521-e643.

The committee recognizes that decades of previous recommendations for patients with most forms of valvular heart disease and other conditions have been abruptly changed by the new AHA guidelines. Because this may cause consternation among patients, clinicians should be available to discuss the rationale for these new changes with their patients, including the lack of scientific evidence to demonstrate a proven benefit for infective endocarditis prophylaxis. In select circumstances, the committee also understands that some clinicians and some patients may still feel more comfortable continuing with prophylaxis for infective endocarditis, particularly for those with bicuspid aortic valve or coarctation of the aorta, severe mitral valve prolapse, or hypertrophic obstructive cardiomyopathy. In those settings, the clinician should determine that the risks associated with antibiotics are low before continuing a prophylaxis regimen. Over time, and with continuing education, the committee anticipates increasing acceptance of the new guidelines among both provider and patient communities.

For patients with conditions in which antibiotic prophylaxis is recommended, the antibiotics are intended for dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa. The guidelines recommend a single oral dose of amoxicillin as the preferred prophylactic agent for patients who do not have a history of type I hypersensitivity reactions to a penicillin. For those who do have a history of such reactions, alternative recommendations include clindamycin, azithromycin, and clarithromycin. For patients who demonstrate a non–type I allergic reaction to a penicillin, a first-generation oral cephalosporin can be used.

Antibiotic administration is not recommended for patients undergoing genitourinary or gastrointestinal tract procedures solely for the purpose of preventing endocarditis. This recommendation is in contrast with previous guidelines that recommended endocarditis antibiotic prophylaxis before selected procedures. Antibiotic prophylaxis for bronchoscopy is not recommended, unless the procedure involves

incision of the respiratory tract mucosa.

Indications for Echocardiography

Echocardiography is strongly supported in virtually all patients with suspected or known IE[2,3] (**Table 73G.2**). The guidelines urge use of transesophageal echocardiography (TEE) when specific questions are not adequately addressed by an initial transthoracic echocardiography (TTE) evaluation, such as when the TTE study is of poor quality or yields negative findings despite a high level of clinical suspicion for endocarditis, if a prosthetic valve is involved, or if the clinical picture is strongly suggestive of IE, such as in a patient with staphylococcal bacteremia or in an elderly patient with valvular abnormalities, making TTE diagnosis difficult.

TABLE 73G.2

ACC/AHA Guidelines for Echocardiography and Computed Tomography in Infective Endocarditis (IE)

INDICATION	CLASS	RECOMMENDATION	LOE
Transthoracic echocardiography (TTE)	I	In patients with suspected IE to identify vegetations, characterize hemodynamic severity of valvular lesions, assess ventricular function and pulmonary pressures, and detect complications.	B
		Reevaluation of patients with IE who have a change in clinical signs or symptoms (e.g., new murmur, embolism, persistent fever, heart failure, abscess, or atrioventricular heart block) and in patients at high risk of complications (e.g., extensive infected tissue/large vegetation on initial echocardiogram or staphylococcal, enterococcal, or fungal infections).	B
Transesophageal echocardiography (TEE)	I	In all patients with known or suspected IE when TTE is nondiagnostic, when complications have developed or are clinically suspected, or when intracardiac device leads are present.	B
		Reevaluation of patients with IE who have a change in clinical signs or symptoms (e.g., new murmur, embolism, persistent fever, heart failure, abscess, or atrioventricular heart block) and in patients at high risk of complications (e.g., extensive infected tissue or large vegetation on initial echocardiogram or staphylococcal, enterococcal, or fungal infections).	B
		Intraoperative TEE for patients undergoing valve surgery for IE.	B
	IIa	Diagnose possible IE in patients with persistent staphylococcal bacteremia without a known source.	B
		Diagnose IE of a prosthetic valve in the presence of persistent fever without bacteremia or a new murmur.	B
	IIb	Detection of concomitant staphylococcal IE in nosocomial *Staphylococcus aureus* bacteremia with a known portal of entry from an extracardiac source.	B
Computed tomography (CT)	IIa	Evaluate morphology and anatomy in the setting of suspected paravalvular infections when the anatomy cannot be clearly delineated by echocardiography.	B

LOE, Level of evidence.

From Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACCF guideline for the management of patients with valvular heart disease. A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. Circulation 2014;129:e521-e643.

Diagnosis of prosthetic valve endocarditis with TTE is more difficult than diagnosis of endocarditis of native valves. Thus the AHA scientific statement and the ACC/AHA guidelines suggest a lower threshold for performance of TEE in patients with prosthetic valves and suspected endocarditis[2,3] (**Table 73G.2**).

Surgery for Active Endocarditis

The AHA scientific statement, the ACC/AHA guidelines for valvular heart disease, and the ESC guidelines support performance of surgery for patients with life-threatening congestive heart failure or cardiogenic shock related to active endocarditis.[2-4] Indications for surgery for patients with stable endocarditis are considered to be less clear (**Table 73G.3** and **73G.4**).

TABLE 73G.3

ACC/AHA Guidelines for Surgery in Infective Endocarditis (IE)

INDICATION	CLASS	RECOMMENDATION	LOE
Surgery for IE	I	Decisions regarding timing of surgical intervention should be determined by a multispecialty heart valve team of cardiology, cardiothoracic surgery, and infectious disease specialists.	B
		Early surgery (during initial hospitalization before completion of full therapeutic course of antibiotics):	
		In patients with IE who present with valve dysfunction resulting in heart failure symptoms	B
		In patients with left-sided IE caused by *Staphylococcus aureus*, fungal, or other highly drug-resistant organisms	B
		In patients with IE complicated by heart block, annular or aortic abscess, or destructive penetrating lesions	B
		In patients with evidence of persistent infection as manifested by persistent bacteremia or fever lasting longer than 5 to 7 days after onset of appropriate antimicrobial therapy	B
		Patients with PVE and relapsing infection (defined as recurrence of bacteremia after a complete course of appropriate antibiotics and subsequently negative blood cultures) without other identifiable source for portal of infection are candidates for surgery.	C
		Complete removal of pacemaker or defibrillator systems, including all leads and the generator, should be part of the early management plan in patients with IE in patients with documented infection of the device or leads	B
	IIa	Complete removal of pacemaker or defibrillator systems, including all leads and the generator, is reasonable in patients with valvular IE caused by *S. aureus* or fungi even without evidence of device or lead infection.	B
		Complete removal of pacemaker or defibrillator systems, including all leads and the generator, is reasonable in patients undergoing valve surgery for valvular IE.	C
		Early surgery (during initial hospitalization before completion of full therapeutic course of antibiotics) is reasonable in patients with IE who present with recurrent emboli and persistent vegetations despite appropriate antibiotic therapy.	B
	IIb	Early surgery (during initial hospitalization before completion of a full therapeutic course of antibiotics) may be considered in patients with NVE who exhibit mobile vegetations >10 mm.	B

LOE, Level of evidence.

From Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACCF guideline for the management of patients with valvular heart disease. A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. Circulation 2014;129:e521-e643.

TABLE 73.G4

European Society of Cardiology Guidelines for Surgery in Infective Endocarditis

RECOMMENDATIONS: INDICATIONS FOR SURGERY	TIMING	Class	LOE
Heart Failure			
Aortic or mitral NVE or PVE with severe acute regurgitation, obstruction, or fistula causing refractory pulmonary edema or cardiogenic shock.	Emergency	I	B
Aortic or mitral NVE or PVE with severe regurgitation or obstruction causing symptoms of heart failure or echocardiographic signs of poor hemodynamic tolerance.	Urgent	I	B
Uncontrolled Infection			
Locally uncontrolled infection (abscess, false aneurysm, fistula, enlarging vegetation).	Urgent	I	B
Infection caused by fungi or multiresistant organisms.	Urgent/elective	I	C
Persisting positive blood cultures despite appropriate antibiotic therapy and adequate control of septic metastatic foci.	Urgent	IIa	B
PVE caused by staphylococci or non-HACEK gram-negative bacteria.	Urgent/elective	IIa	C
Prevention of Embolism			
Aortic or mitral NVE or PVE with persistent vegetations >10 mm after one or more embolic episode despite appropriate antibiotic therapy.	Urgent	I	B
Aortic or mitral NVE with vegetations >10 mm, associated with severe valve stenosis or regurgitation, and low operative risk.	Urgent	IIa	B
Aortic or mitral NVE or PVE with isolated, very large vegetations (>30 mm).	Urgent	IIa	B
Aortic or mitral NVE or PVE with isolated large vegetations (>15 mm) and no other indication for surgery.*	Urgent	IIb	C

*Surgery may be preferred if a procedure preserving the native valve is feasible.

LOE, level of evidence; HACEK, *Haemophilus parainfluenzae, H. aphrophilus, H. paraphrophilus, H. influenzae*; *Actinobacillus actinomycetemcomitans*; *Cardiobacterium hominis*; *Eikenella corrodens*; *Kingella, kingae, K. denitrificans*; *NVE,* native valve endocarditis; *PVE,* prosthetic valve endocarditis.

Rheumatic Fever

Bongani M. Mayosi

Rheumatic fever is the leading cause of acquired heart disease in children and young adults worldwide. Initiated by a pharyngeal infection with group A beta-hemolytic streptococci (GAS) and following a latent period of approximately 2 to 3 weeks, the illness is characterized by acute inflammation of the heart, joints, skin, subcutaneous tissue, and central nervous system. Pathologically, the inflammatory process causes damage to collagen fibrils and connective tissue ground substance (i.e., fibrinoid degeneration), and thus rheumatic fever is classified as a connective tissue or collagen vascular disease.

The destructive effect on the heart valves leads to the chronic sequelae of the disease—rheumatic heart disease (RHD)—with serious hemodynamic disturbances causing cardiac failure, and other complications such as stoke and infective endocarditis. Referring to the fleeting arthritis and damaging carditis characteristic of rheumatic fever, the French physician Ernst-Charles Lasègue famously said in 1884, “Pathologists have long known that rheumatic fever licks at the joints, but bites at the heart.” Almost all cases of rheumatic fever and RHD and associated deaths are entirely preventable.

Epidemiology

The burden of rheumatic fever and RHD has been characterized by at least four changing patterns over the past 150 years (**Fig. 74.1**). The first pattern represents the preantibiotic fall in incidence of rheumatic fever that is typical of industrialized countries (curve A, **Fig. 74.1**). For example, in the United States the incidence per 100,000 population was 100 at the start of 20th century, 45 to 65 between 1935 and 1960, and is currently estimated to be less than 10 cases per 100,000.[1] The decrease in rheumatic fever incidence preceded the introduction of antibiotics in the 1940s and is almost certainly the result of improved socioeconomic standards, less overcrowded housing, and improved access to medical care.

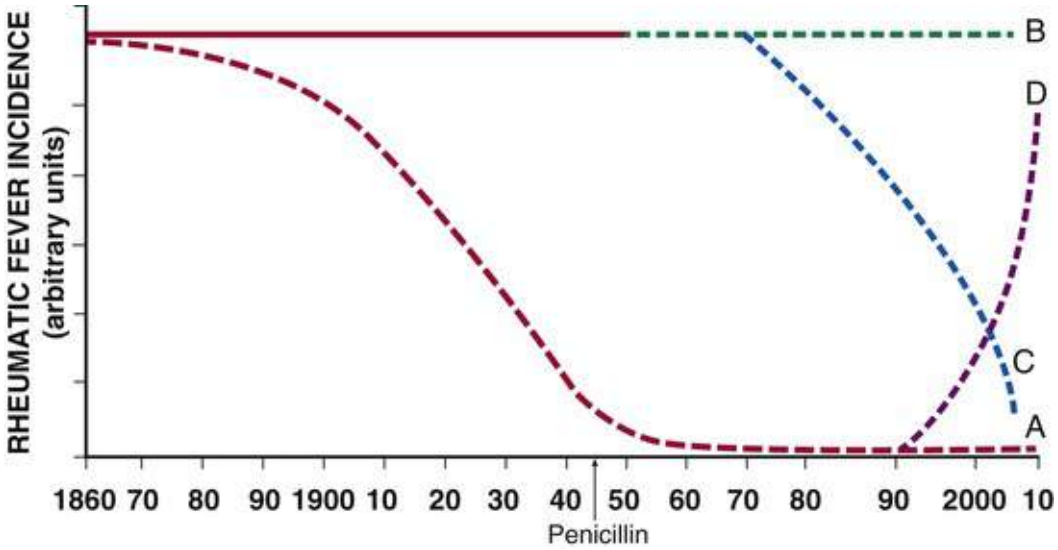

FIGURE 74.1 Incidence of rheumatic fever: four patterns over the past 150 years. Curve A represents the preantibiotic fall in the incidence of rheumatic fever that is typical of industrialized countries. Curve B is typical of the persistent high incidence of rheumatic fever in regions of the world with no comprehensive program for prevention, such as Africa and south Asia. Curve C shows the postantibiotic fall in the incidence of rheumatic fever in countries that instituted comprehensive programs for primary and secondary prevention of rheumatic fever, such as Cuba, Costa Rica, Martinique, and Guadeloupe. Curve D shows the fall and rise in the incidence of rheumatic fever in the formerly Soviet republics of central Asia. (Modified from Parry E, Godfrey R, Mabey D, Gill G, editors. Principles of Medicine in Africa. 3rd ed. Cambridge: Cambridge University Press; 2004, p 861.)

The second pattern is characterized by a persistently high incidence of rheumatic fever in developing regions and among indigenous populations of some developed countries, such as Australia and New Zealand (curve B, **Fig. 74.1**). The incidence of rheumatic fever among 5-to 14-year-old indigenous Australian children is as high as 162 per 100,000 per year in males, and 228 per 100,000 per year in females.[2] This hyperendemic pattern of rheumatic fever affects the majority of the population of the world who live in Africa, Middle East, Asia, eastern Europe, South America, and indigenous communities of Australasia.[3]

Third, some developing countries, such as Cuba, Costa Rica, the French Islands of Martinique and Guadeloupe, and Tunisia, have experienced a falling incidence of rheumatic fever following the implementation of comprehensive public health programs of primary and secondary prevention of rheumatic fever[4] (curve C, **Fig. 74.1**). By contrast, African countries that have not implemented public health programs for prevention of rheumatic fever continue to experience a high incidence of rheumatic fever and RHD.[5]

Outbreaks of rheumatic fever have been reported in affluent communities of the United States and Italy[6] (see Classic References, Veasy). The epidemiologic transition in the former Soviet Union has been associated not only with an increase in mortality rates from atherosclerotic diseases and trauma in Russia, but also in a sustained resurgence of rheumatic fever and RHD in central Asia.[7] The incidence of rheumatic fever fell in central Asia to the same levels as Japan in the middle 1970s, but rose sharply in the post-Soviet period to levels associated with developing countries (curve D, **Fig. 74.1**). Among developing countries, Kyrgyzstan probably has the highest incidence of rheumatic fever and RHD, approximately 543 per 100,000 population per year, thus earning the central Asian republics the dubious distinction of being the rheumatic fever "hot spot" of the world. The resurgence of rheumatic fever in the formerly Soviet republics may reflect the weakening of the primary health care system and the economic crisis of the post-Soviet period (see Classic References, Tulchinsky and Varavikova).

Pathogenesis

Rheumatic fever is a multifactorial disease that follows GAS pharyngitis (the agent) in a susceptible individual (the host) who lives under deprived social conditions (the environment). The theory of *molecular mimicry* holds that GAS pharyngitis triggers an autoimmune response to epitopes in the organism that cross-react with similar epitopes in the heart, brain, joints and skin, and repeated episodes of rheumatic fever lead to RHD[1,8] (**Fig. 74.2**).

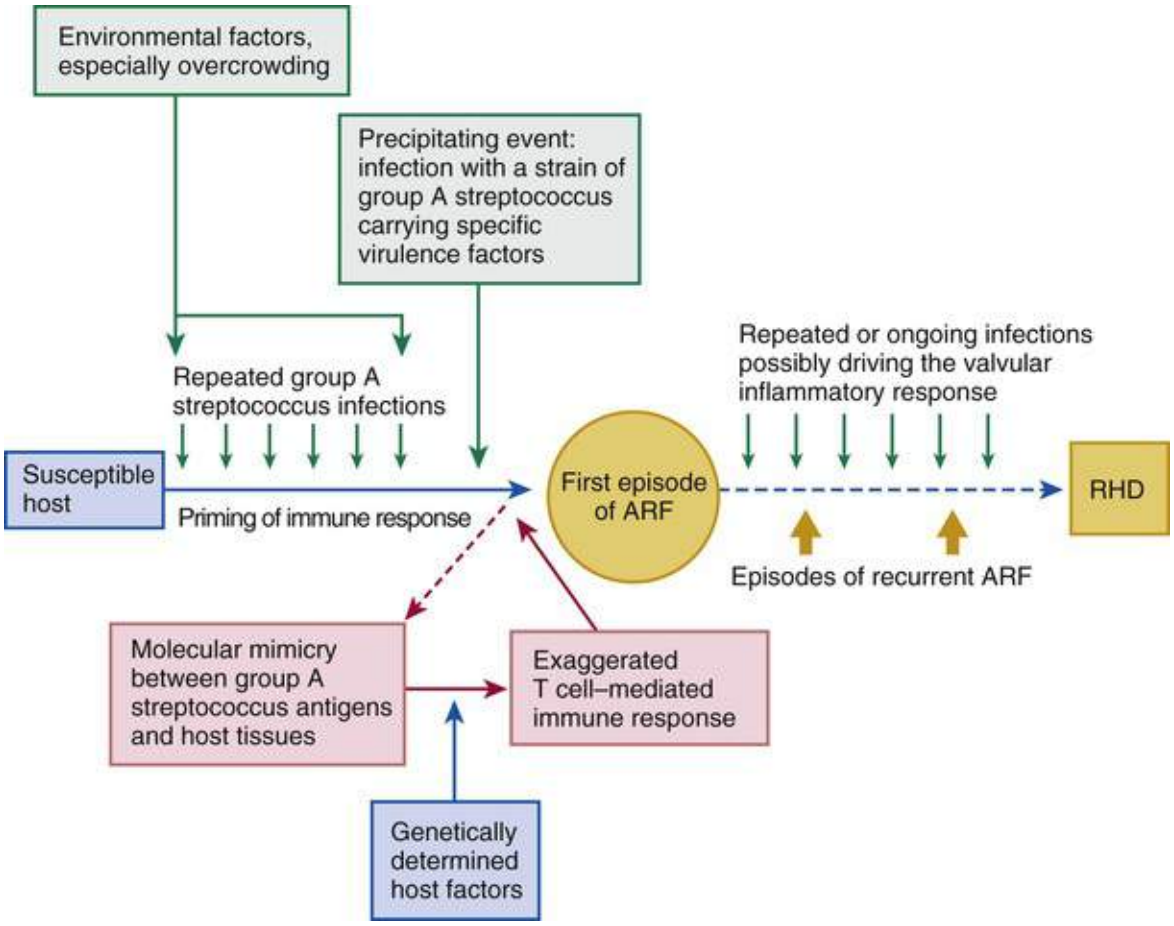

FIGURE 74.2 Pathogenesis of acute rheumatic fever (ARF) and rheumatic heart disease (RHD). (From Carapetis J, McDonald M, Wilson NJ. Acute rheumatic fever. Lancet 2005;366:155.)

The Agent

Epidemiologic and immunologic observations together with the preventive effect of antibiotic treatment for pharyngitis demonstrated in clinical trials strongly support the causative role of untreated GAS pharyngitis in rheumatic fever.[9] Streptococcal skin infection is believed not to cause rheumatic fever. However, a report of rheumatic fever following streptococcal wound infection (see Classic References, Popat and Riding), as well as the high prevalence of pyoderma with relative paucity of streptococcal pharyngitis in aboriginal communities of Australasia with a high incidence of rheumatic fever, raised questions about the link between streptococcal skin infection and rheumatic fever.[10] Although effective antibiotic treatment substantially reduces the risk of rheumatic fever, in situations of untreated epidemic GAS pharyngitis, up to 3% of patients develop the disease.[11]

The hypothesis of molecular mimicry in the pathogenesis of rheumatic fever has been reviewed.[1,9] There is evidence that patients with RHD have cross-reactive autoantibodies that target the dominant GAS epitope of the group A carbohydrate, *N*-acetyl-beta-D-glucosamine (GlcNAc), and laminin and laminar basement membrane in heart valve endothelium. T cells in peripheral blood and heart valves of patients with RHD cross-react with streptococcal M protein and cardiac myosin. Furthermore, autoantibodies against the GAS carbohydrate epitope GlcNAc and cardiac myosin appear during progression of RHD. In addition, autoantibodies against collagen that are not cross-reactive may form because of the release of collagen from damaged valves.

The *two-hit hypothesis* for the initiation of disease proposes that antibody attack of valve endothelium facilitates the extravasation of T cells through activated epithelium into valve tissue, leading to the

formation of granulomatous nodules called Aschoff bodies that are characteristic of rheumatic myocarditis. The area of central necrosis is surrounded by a ring of plump histiocytes called Anitschkow cells (**Fig. 74.3**). These nodules were discovered independently by Ludwig Aschoff and Paul Rudolf Geipel and thus are occasionally called Aschoff-Geipel bodies.

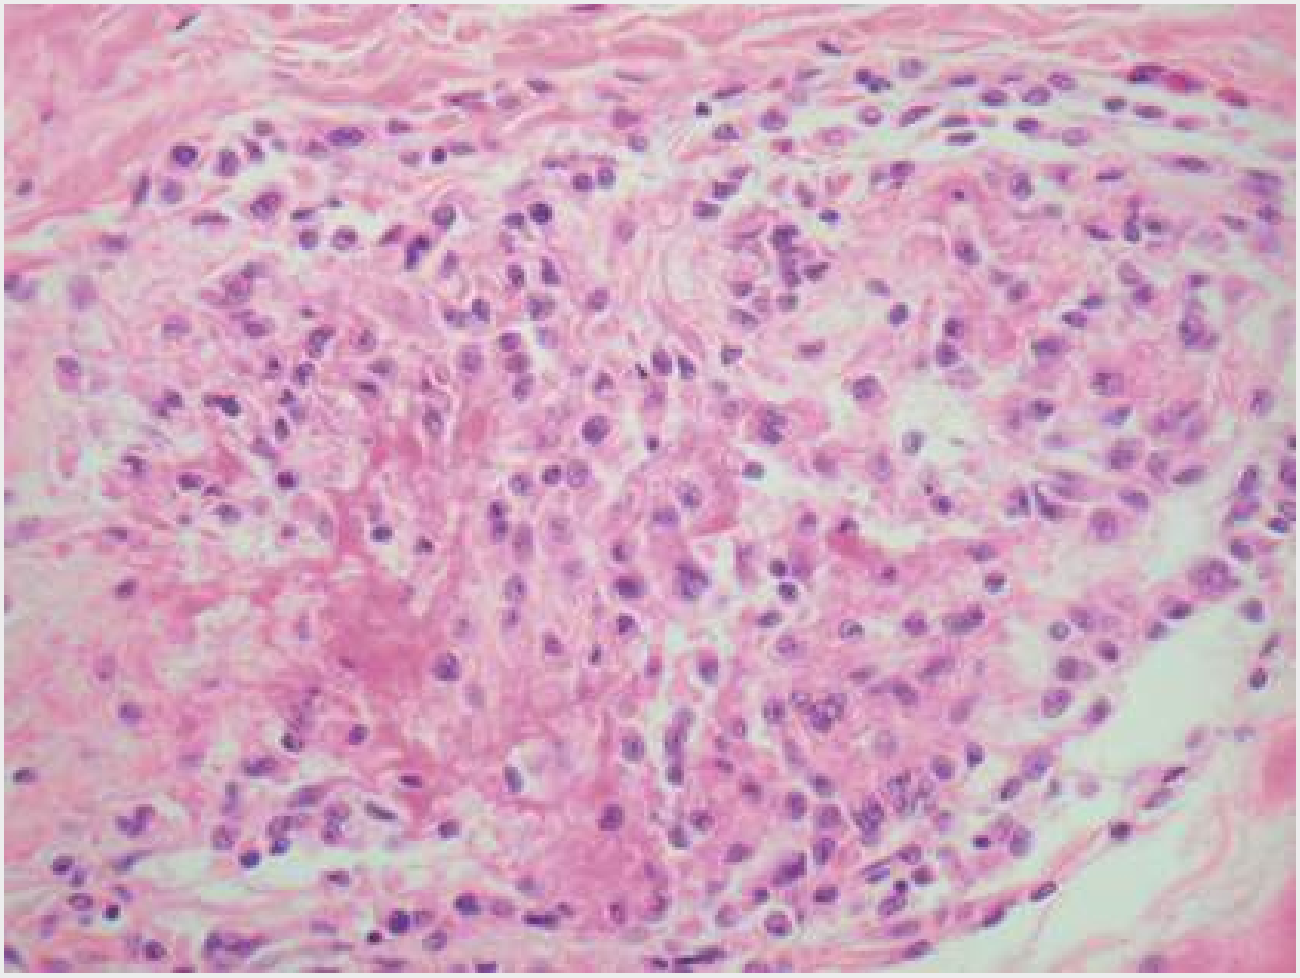

FIGURE 74.3 The Aschoff body of rheumatic fever. Photomicrograph of an Aschoff nodule from the heart in a case of acute rheumatic fever. The nodule is composed of Anitschkow cells; these have clear nuclei with a central bar of chromatin, said to resemble a caterpillar. There is a central area of fibrin. This central necrosis is further surrounded by a mononuclear cell infiltrate. Myocardial fibers adjacent to the Aschoff body are undergoing destruction. (From Sebire NJ, Ashworth M, Malone M, Jacques TS, editors. Diagnostic Pediatric Surgical Pathology. London: Churchill Livingstone; 2010.)

In *Sydenham chorea*, human monoclonal antibodies (mAbs) derived from patients with disease target GlcNAc, gangliosides, and dopamine receptors are found on the surface of neuronal cells in the brain. Human mAbs and autoantibodies in Sydenham chorea activate calcium/calmodulin-dependent protein kinase II (CaMKII) in neuronal cells and recognize the intracellular protein biomarker tubulin. Therefore the theme of molecular mimicry in rheumatic fever is characterized by the recognition of targeted intracellular biomarker antigens (cardiac myosin and brain tubulin), while targeting extracellular membrane antigens (laminin on valve surface endothelium or lysoganglioside and dopamine receptors in the brain).[1,9]

The Host

Several lines of epidemiologic evidence support the role of hereditary factors in susceptibility to rheumatic fever. First, the lifetime cumulative incidence of rheumatic fever in populations exposed to

rheumatogenic GAS infection is constant at 3% to 6% regardless of geography or ethnicity.[12] This suggests that the proportion of susceptible individuals is the same in all continental populations of the world.[13] Second, the familial aggregation of rheumatic fever was reported by Cheadle as far back as 1889.[13] Cheadle reported that the chance of an individual with a family history of rheumatic fever acquiring the disease is "nearly 5 times as great as that of an individual who has no such hereditary taint." The familial aggregation of RHD has been supported by a study of children raised separately from parents with RHD, who had a relative risk of 2.93 for the development of rheumatic fever compared with children whose parents did not have RHD.[13] Also, a study of 435 twin pairs found that the risk of rheumatic fever in a monozygotic twin when the co-twin previously had rheumatic fever is more than six times greater than that in dizygotic twins. The heritability of rheumatic fever is 60%, which highlights the importance of heredity as a major susceptibility factor of the disease.[14]

Numerous studies have been conducted to search for specific genetic susceptibility factors in rheumatic fever.[15] Several genes controlling the adaptive immune response (e.g., HLA class II alleles, cytotoxic T cell lymphocyte antigen 4), the innate immune response (e.g., ficolin 2, mannose-binding lectin 2, receptor for Fc fragments of IgG, Toll-like receptor 2), cytokine genes (e.g., tumor necrosis factor alpha, transforming growth factor beta, interleukin-1 receptor A, interleukin-10), and B cell alloantigens have been implicated in the development of the disease. Although significant associations have been found between genetic factors and rheumatic fever, study results either conflict with each other or are not replicated.[13] Therefore, it is not possible at present to predict the individuals who are at risk of developing rheumatic fever following an episode of untreated streptococcal pharyngitis.

The Environment

It is well known that rheumatic fever is generally associated with low socioeconomic status. The incidence of rheumatic fever has been falling consistently in industrialized countries since the mid-19th century, independently of the advent of penicillin, possibly because of less crowding, improved housing and nutritional conditions, higher levels of parental employment, and better access to health care (curve A, **Fig. 74.1**). In New Zealand, the risk of rheumatic fever is linked to high levels of deprivation based on household income, access to telephone and car, education level, and housing.[16] The impact of the social gradient has also been illustrated in Uganda, where an increased risk of RHD is associated with overcrowding and unemployment. Furthermore, there was interaction between overcrowding and distance from the nearest health center, suggesting that the effect of overcrowding on the risk of acquiring RHD increases with every kilometer increase from the nearest health center.[17] In addition, schoolchildren of lower socioeconomic status have a higher prevalence of disease and more advanced disease in an echocardiographic screening study of RHD in Uganda.[18]

Clinical Features

The typical attack of rheumatic fever follows an episode of streptococcal pharyngitis after a latent period of 2 to 3 weeks. During the latent period there is no clinical or laboratory evidence of active inflammation. However, as many as one third of patients who develop rheumatic fever do so after asymptomatic GAS, and in outbreaks, up 58% of patients have no symptoms of pharyngitis. This is one of the potential barriers to the effectiveness of primary prevention of rheumatic fever solely with antibiotic treatment of GAS pharyngitis and provides the justification for the development of an anti-GAS vaccine as one of the strategies for the control of rheumatic fever and other streptococcal diseases.

Rheumatic fever occurs most frequently in children between ages 4 and 15 years. In developing

countries such as Saudi Arabia and India, juvenile mitral stenosis may occur at age 3 to 5 years.[19] The prevalence of the various clinical features varies in different studies depending on whether the patients are studied prospectively or in retrospect. The illness usually begins with a high fever, but in some patients the fever may be low grade or absent. The most common of the major criteria is *polyarthritis*, which occurs in two thirds to three quarters of the patients, followed by carditis and chorea.

Arthritis

Joint involvement is more common (almost 100%), and more severe in young adults than in teenagers (82%) and children (66%).[20] The joint pain is typically described as "migratory," which refers to the sequential involvement of joints, with inflammation resolving in one joint and then beginning in another joint. In some cases the joint involvement may be additive rather than migratory, with simultaneous involvement of several joints. In untreated patients the number of joints involved may vary from 6 to 16.[20]

The affected joint may be inflamed for only a few days to 1 week before the inflammation subsides. The polyarthritis is severe for approximately 1 week in two thirds of patients and may last another 1 to 2 weeks in the remainder before it resolves completely. If joint swelling persists after 4 weeks, it becomes necessary to consider other conditions, such as juvenile idiopathic arthritis or systemic lupus erythematosus (SLE).[20]

At the onset of the illness the joint involvement is asymmetric and usually affects the lower limbs initially before spreading to the upper limbs. Monoarthritis has been reported in 17% to 25% of patients.[21] The large joints such as the knees, ankles, elbows, and wrists are most frequently involved. The hip, shoulder, and small joints of the hands and feet are less frequently involved. Analysis of the synovial fluid has shown the presence of sterile inflammatory fluid. There may be a reduction in complement components C1q, C3, and C4, suggesting their consumption by immune complexes. Radiographs may show features of a joint effusion, but no other abnormalities are noted.[20]

Jaccoud arthritis or arthropathy (or chronic post–rheumatic fever arthropathy) is a rare manifestation of rheumatic fever characterized by deformities of the fingers and toes (**Fig. 74.4**). The condition may occur after repeated attacks of rheumatic fever and results from recurrent inflammation of the fibrous articular capsule. There is ulnar deviation of the fingers, especially the fourth and fifth fingers, flexion of the metacarpophalangeal joints, and hyperextension of the proximal interphalangeal joints (i.e., swan neck deformity). The hand is usually painless, and there are no signs of inflammation. The deformities are usually correctible but may become fixed in the later stages. There are no true erosions on radiography, and the rheumatoid factor is usually negative. A similar form of arthropathy is seen in patients with SLE.[20]

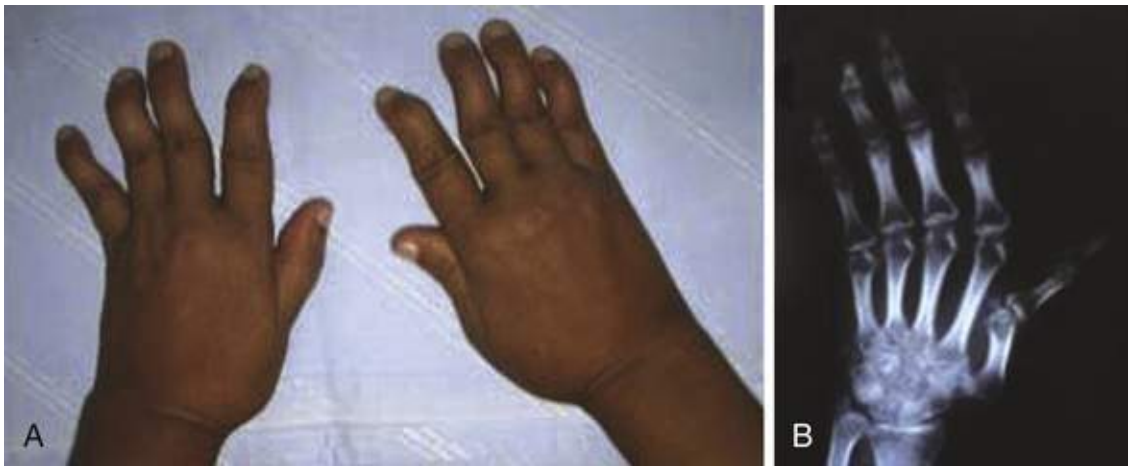

FIGURE 74.4 Post–rheumatic fever Jaccoud arthropathy. **A,** Swan neck deformity in Jaccoud arthropathy, with ulnar deviation and metacarpophalangeal subluxation. **B,** Plain radiograph of left hand showing deformities but not erosions. (From Santiago MB: Jaccoud's arthropathy. Best Prac Res Clin Rheumatol 2011;25:715.)

The arthritis of rheumatic fever responds promptly to nonsteroidal anti-inflammatory drugs, and thus the classic presentation of a migratory polyarthritis may be infrequent where self-medication with NSAIDs, or their prescription without considering the diagnosis, is common. The apparent fall in incidence of rheumatic fever in some developing countries may be related to indiscriminate use of NSAIDs without considering a diagnosis of rheumatic fever.[22] The differential diagnosis of polyarticular arthritis in children and adolescents includes poststreptococcal reactive arthritis, other autoimmune diseases, septic arthritis, infective endocarditis, Lyme disease, lymphoma/leukemia, viral arthropathy and sickle cell disease.

Poststreptococcal reactive arthritis is diagnosed in patients who have an arthritis that is not typical of rheumatic fever but who have evidence of recent streptococcal infection. This condition is said to occur after a shorter latent period than rheumatic fever, is less responsive to NSAIDs, may be associated with renal manifestations, and evidence of carditis is usually not seen. The distinction between poststreptococcal reactive arthritis and rheumatic fever is unclear, and many would recommend that a diagnosis of poststreptococcal reactive arthritis not be made in populations in whom rheumatic fever is common. Even if the diagnosis is considered, it is appropriate to offer a period of secondary penicillin prophylaxis, as for episodes of acute rheumatic fever (ARF), in such populations.[23]

Carditis

Carditis is the most serious manifestation of rheumatic fever because it may lead to chronic RHD with its attendant complications of atrial fibrillation, stroke, heart failure, infective endocarditis, and death. In some patients the carditis may be asymptomatic and is detected during clinical examination of a patient with arthritis or chorea. The incidence of carditis during the initial attack of rheumatic fever varies from 40% to 91% depending on the selection of patients and whether the diagnosis is made on clinical assessment alone or combined with echocardiography.[23]

The incidence of carditis in rheumatic fever varies with the age of the patient. It is reported in 90% to 92% of children under age 3 years, in 50% of children age 3 to 6 years, in 32% of teenagers age 14 to 17 years, and only in 15% of adults with a first attack of rheumatic fever.[20] In a 1951 review of 1000 patients, 65% were diagnosed as having carditis (see Classic References, Bland and Duckett Jones), and in the 1987 report of a Utah outbreak in the United States, 91% had carditis when clinical examination was combined with echocardiography (see Veasy).

The symptoms and signs of carditis depend on whether there is involvement of the pericardium, myocardium, or heart valves. The clinical diagnosis of carditis is based on the detection of an organic murmur that was not previously present (to indicate endocarditis), presence of a pericardial friction rub or signs of pericardial effusion (to indicate pericarditis), or cardiomegaly or congestive heart failure (CHF) (to indicate myocarditis).

Myocarditis in the absence of valvulitis is unlikely to be rheumatic in origin. It should be accompanied by an apical systolic or basal diastolic murmur. Patients with myocarditis may develop cardiomegaly and CHF, which may be severe and life threatening. Myocardial damage may manifest with electrocardiographic changes, which include varying degrees of heart block. Patients with first-degree heart block are usually asymptomatic. Patients with second- and third-degree heart block may be symptomatic and require a pacemaker if they develop CHF.[20] CHF may be caused by myocarditis or severe involvement of one or more heart valves. It occurs in 5% to 10% of the initial episodes and is more frequent during recurrences of rheumatic fever.

Pericarditis is associated with anterior chest pain (**see Chapter 83**), and a pericardial friction rub may be detected on clinical examination. Pericarditis can be detected clinically in about 10% of patients. The pericardial effusion may sometimes be large, but cardiac tamponade is rare, and constrictive pericarditis does not occur.

The most common valvular lesion is mitral regurgitation causing an apical pansystolic murmur. Aortic regurgitation is less common. Stenotic lesions are uncommon in the early stages of the disease, but a transient apical mid-diastolic murmur (Carey-Coombs) may occur in association with the murmur of mitral regurgitation. In patients with a history of previous RHD, a change in the character of the murmurs or the appearance of a new murmur will indicate the presence of acute rheumatic carditis.

Echocardiography is more sensitive and specific than cardiac auscultation for the detection of acute rheumatic carditis, such that it is recommended that all patients with suspected or definite rheumatic fever should undergo echocardiography[24] (see Classic References, Vasan). **Table 74.1** outlines the minimum echocardiographic criteria of the World Heart Federation for the diagnosis of pathologic regurgitation caused by rheumatic valvulitis.[25] The advent of portable echocardiography has increased the availability of cardiac ultrasound to many people in developing countries, resulting in its increasing use in screening for subclinical rheumatic heart valve disease.

TABLE 74.1

World Heart Federation Minimum Echocardiographic Criteria for Diagnosis of Pathologic Valvular Regurgitation Caused by Rheumatic Carditis

Pathologic Mitral Regurgitation*
1. Seen in at least two views.
2. In at least one view, jet length is ≥2 cm.†
3. Peak velocity ≥3 meters/second.
4. Pansystolic jet in at least one envelope.
Pathologic Aortic Regurgitation*
1. Seen in at least two views.
2. In at least one view, jet length is ≥1 cm.†
3. Peak velocity ≥3 meters/second.
4. Pandiastolic jet in at least one envelope.

*All four Doppler criteria must be met.

†A regurgitant jet length should be measured from the vena contracta to the last pixel of regurgitant color (blue or red) on nonmagnified (nonzoomed) images.

From Reményi B, Wilson N, Steer A, et al. World Heart Federation criteria for echocardiographic diagnosis of rheumatic heart disease: an evidence-based guideline. Nat Rev Cardiol 2012;9:297-309.

Sydenham Chorea

Chorea may be the only presenting manifestation of rheumatic fever. It is more common in females, and after puberty there is an even greater female predominance. The latent period between the episode of streptococcal pharyngitis and the development of chorea is considerably longer (6 to 8 weeks) than for arthritis and carditis. Chorea is characterized by the presence of involuntary, purposeless, jerky movements of the hands, arms, shoulders, feet, legs, face, and trunk associated with hypotonia and weakness. The purposeless movements interfere with voluntary activity and disappear during sleep. Initially, chorea may be confined to the face or one arm and sometimes may be unilateral (hemichorea).

Patients also show motor impersistence by intermittently, involuntarily withdrawing the tongue when attempting to protrude it for 30 seconds (jack-in-the-box tongue). Motor impersistence may also be demonstrated by asking the patient to squeeze the examiner's hand. This results in repetitive, irregular squeezes called the “milking sign.” Emotional lability manifests in personality changes, with inappropriate behavior, restlessness, outbursts of anger or crying, and learning difficulties.

Chorea may last for 1 week to 2 years but usually lasts 8 to 15 weeks. When chorea occurs alone, the erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and streptococcal antibody titers may be normal because of the long latent period and resolution of the original infection. Chorea does not occur simultaneously with arthritis but may coexist with carditis. Some patients with chorea may have a cardiac murmur, whereas others may only later manifest involvement of the mitral valve.

Sydenham chorea with motor tics may overlap with the involuntary jerks of Tourette syndrome. The term *pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections* (PANDAS) has been used for a subgroup of children with tic or obsessive-compulsive disorders triggered by GAS infection with no associated cardiac valve damage.[26] However, the evidence supporting the existence of PANDAS as a distinct clinical entity has been questioned, leading to the recommendation that, in populations at high risk for rheumatic fever, clinicians should rarely, if ever, make a diagnosis of PANDAS; rather, they should err on the side of diagnosis of rheumatic fever and secondary prophylaxis.[24]

Subcutaneous Nodules

The subcutaneous nodules of rheumatic fever resemble the nodules of rheumatoid arthritis and may be detected over the occiput, elbows, knees, ankles, and Achilles tendons. In rheumatic fever the nodules around the elbow tend to occur over the olecranon, whereas rheumatoid nodules tend to occur more distally along the extensor aspect of the upper forearm. They are usually firm, painless, and freely movable over the subcutaneous tissue. The nodules vary in size from 0.5 to 2 cm and tend to occur in crops (**Fig. 74.5**). They are usually smaller, more discrete, and less persistent than rheumatoid nodules. The nodules were detected in only 1.5% of patients in a series of 786 patients, although a higher prevalence was reported in earlier studies.[20] Nodules are usually seen in children with prolonged active carditis rather than in the early stages of rheumatic fever. They may persist for a few weeks but seldom more than 1 month. Multiple crops of nodules may be related to the severity of the rheumatic carditis.

FIGURE 74.5 Subcutaneous nodules of rheumatic fever over the bony prominences of the elbow. (From Beerman, LB, Kreutzer J, Allada V. Cardiology. In Zitelli BJ, McIntire SC, Nowalk AJ, editors. Atlas of Pediatric Physical Diagnosis. 6th ed. Philadelphia: Saunders; 2012.)

Erythema Marginatum

Erythema marginatum is a less common manifestation of rheumatic fever and occurs on the upper arms or trunk but not the face (**Fig. 74.6**). It has a characteristic appearance and is therefore helpful in the diagnosis of rheumatic fever but is not pathognomonic of the disease. The rash is evanescent, pink, and nonpruritic. It extends centrifugally while the skin at the center returns to normal and has an irregular, serpiginous border. The rash may also become more prominent after a hot shower. Erythema marginatum usually occurs in patients with carditis and may occur early or later in the course of the disease.

FIGURE 74.6 Erythema marginatum in acute rheumatic fever. The pen mark shows the location of the rash approximately 60 minutes previously. (From Cohen J, Powderly WG. Infectious Diseases. 2nd ed. St Louis: Mosby; 2004.)

Other Manifestations

The temperature is usually raised during attacks of rheumatic fever and ranges from 38.4°C to 40°C. When temperature is used as a minor diagnostic criterion, however, a cutoff value of higher than 37.5°C would allow the diagnosis of fever in 90% of suspected cases of rheumatic fever in endemic communities, such as indigenous Australians. The temperature usually decreases within 1 week and rarely lasts more than 4 weeks.

Abdominal pain may be severe and may mimic acute appendicitis. Epistaxis was reported as a common manifestation in the past but is now uncommon. Rapid sleeping pulse rate, tachycardia out of proportion to fever, malaise, and anemia may be noted in patients with ARF. Rheumatic pneumonia is uncommon and is difficult to distinguish from pulmonary edema and other causes of alveolitis.

Diagnosis

Although no specific clinical, laboratory, or other test exists to confirm conclusively a diagnosis of rheumatic fever, the diagnosis is usually made using the clinical criteria first formulated in 1944 by T. Duckett Jones. Since then the criteria have undergone multiple modifications, with the most recent revision by the American Heart Association (AHA) in 2015[13,27] (**Table 74.2**). The initial diagnosis of ARF is made if, in the presence of preceding GAS infection, two major criteria or one major and two minor criteria are present. The diagnosis of *recurrent* ARF requires two major, one major and two minor, or three minor criteria in the presence of preceding GAS infection. Evidence of preceding GAS infection, essential for the diagnosis, may be obtained from throat swab culture (only positive in approximately 11%

of patients at diagnosis of rheumatic fever) or by demonstrating a rising titer of antistreptococcal antibodies, either antistreptolysin O (ASO) or anti–deoxyribonuclease B (anti-DNase B), or by a positive rapid group A streptococcal carbohydrate antigen test in a child whose clinical presentation suggests a high pretest probability of streptococcal pharyngitis.[13,28]

TABLE 74.2

2015 AHA-Revised Jones Criteria for Diagnosis of Rheumatic Fever*

MAJOR CRITERIA	
Low-Risk Populations	**Moderate- and High-Risk Populations**
Carditis (clinical or subclinical†) Arthritis (polyarthritis only) Chorea Erythema marginatum Subcutaneous nodules	Carditis (clinical or subclinical) Arthritis (including polyarthritis, monoarthritis, or polyarthralgia‡) Chorea Erythema marginatum Subcutaneous nodules
MINOR CRITERIA	
Low-Risk Populations	**Moderate- and High-Risk Populations**
Polyarthralgia Fever (≥38.5°C) ESR ≥60 mm in the first hour and/or CRP ≥3.0 mg/dL Prolonged PR interval, after accounting for age variability (unless carditis is a major criterion)	Monoarthralgia Fever (≥38°C) ESR ≥30 mm in the first hour and/or CRP ≥3.0 mg/dL§ Prolonged PR interval, after accounting for age variability (unless carditis is a major criterion)

*Annual acute rheumatic fever (ARF) incidence of ≤2 per 100,000 school-aged children or all-age rheumatic heart disease (RHD) prevalence of ≤1 per 1000 people per year.

†Defined as echocardiographic valvulitis, as defined in Table 74.1.

‡Polyarthralgia should only be considered as a major manifestation in moderate- and high-risk populations after exclusion of other causes.

§C-reactive protein (CRP) value must be greater than the normal laboratory upper limit. In addition, because the erythrocyte sedimentation rate (ESR) might evolve during the course of ARF, peak ESR values should be used.

Joint manifestations are only considered in either the major or the minor category, but not in both categories in the same patient.

There are three main changes in the 2015 revised Jones criteria. First, subclinical valvulitis detected by echocardiography (as defined in **Table 74.1**) is accepted as a major criterion for the diagnosis of ARF in all patient populations. Second, there is recognition that the clinical utility of the Jones criteria is determined by the pretest probability and background disease prevalence in a population. To avoid overdiagnosis in low-incidence populations and underdiagnosis in high-risk populations, variability in applying diagnostic criteria in low-risk versus high-risk populations has been introduced in line with the Australian guidelines.[13,24] Low-risk communities are defined as having an ARF incidence of less than 2 per 100,000 school-aged children (usually 5 to 14 years old) per year, or an all-age prevalence of RHD of 1 or more per 1000 population per year. In moderate- to high-risk communities, monoarthritis and polyarthralgia have been added as major criteria to polyarthritis, and a temperature of 38°C and monoarthralgia are the revised minor criteria (**see Table 74.2**).

The addition of monoarthritis or polyarthralgia as a major criterion and the inclusion of a fever higher than 38°C and monoarthralgia as a minor criteria have increased the sensitivity of the modified Jones criteria in communities with hyperendemic levels of ARF.[24]

The 2015 Jones criteria also recognize the clinical entity of “possible” rheumatic fever. It is appropriate for clinical judgment to be applied in parts of the world where rheumatic fever remains common and where it is not possible to fulfill the Jones criteria because of a lack of laboratory facilities to conduct the recommended investigations of a patient with suspected rheumatic fever, as listed in **Table 74.3**.[23,24] When a diagnosis of possible rheumatic fever is made in a high-incidence setting, it is reasonable to consider offering 12 months of secondary prophylaxis, followed by reevaluation based on

history, physical examination, and repeat echocardiogram.

TABLE 74.3
Investigations in Suspected Rheumatic Fever

Recommended for All Cases
White blood cell count
Erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP)
Throat swab before giving antibiotics for GAS culture
Blood culture, if febrile
Antistreptococcal serology: both antistreptolysin O (ASO) and anti-DNase B titers (repeat after 10 to 14 days if first test is not confirmatory)
Electrocardiogram
Chest radiograph
Echocardiogram
Tests for Alternative Diagnoses, Depending on Clinical Features
Repeated blood cultures with temperature spikes if infective endocarditis is suspected
Joint aspirate for possible septic arthritis (microscopy and culture)
Copper, ceruloplasmin, antinuclear antibody, and drug screen for choreiform movements
Serology and autoimmune markers for arboviral, autoimmune, or reactive arthritis
Peripheral blood smear for sickle cell disease

GAS, Group A beta-hemolytic streptococci.

From RHD Australia (ARF/RHD writing group), National Heart Foundation of Australia and Cardiac Society of Australia and New Zealand. Australian guideline for prevention, diagnosis and management of acute rheumatic fever and rheumatic heart disease. 2nd ed. Darwin, Australia: Menzies School of Health Research; 2012.

Treatment

The aim of treatment of a proven attack of rheumatic fever is (1) to suppress the inflammatory response and thus minimize the effects of inflammation on the heart and joints, (2) to eradicate the GAS from the pharynx, (3) to provide symptomatic relief, and (4) to commence secondary prophylaxis.

The longstanding recommendation of bed rest would appear to be appropriate mainly to lessen joint pain. The duration of bed rest should be individually determined, but ambulation can usually be started once the fever has subsided and acute-phase reactants are returning to normal. Strenuous exertion should be avoided, especially for those with carditis.

Even though throat swabs taken during the acute attack of rheumatic fever are rarely positive for GAS, it is advisable for patients to receive an intramuscular (IM) dose of benzathine benzylpenicillin (or erythromycin if allergic to penicillin). Although conventional, this strategy is untested. Thereafter, secondary prophylaxis should be commenced (see Classic References, Manyemba and Mayosi).

The choice of anti-inflammatory agent is among salicylates, NSAIDs, and corticosteroids. A systematic review of randomized controlled trials (RCTs) compared anti-inflammatory agents (e.g., aspirin, corticosteroids, immunoglobulins, pentoxifylline) with placebo or controls, or compared any of the anti-inflammatory agents with one another, in adults and children with rheumatic fever diagnosed according to the Jones or modified Jones criteria.[28] The presence of cardiac disease 1 year after treatment was the major outcome criterion selected. Eight RCTs involving 996 people were included. Several steroidal agents (corticotrophin, cortisone, hydrocortisone, dexamethasone, prednisone) and intravenous (IV) immunoglobulin were compared to aspirin, placebo, or no treatment in the various studies. Six of the trials were conducted between 1950 and 1965, one study in 1990, and the final study in 2001. Overall, there was no significant difference in the risk of cardiac disease at 1 year between the corticosteroid-treated and aspirin-treated groups (six studies, 907 participants; relative risk [RR], 0.87; 95% confidence interval [CI] 0.66 to 1.15). Similarly, use of prednisone (two studies, 212 participants; RR, 1.13; 95% CI 0.52 to 2.45) compared to aspirin did not reduce the risk of developing heart disease after 1 year. The

three studies reporting adverse events all found substantial adverse events. Thus, there is little evidence of benefit from using corticosteroids or IV immunoglobulins to reduce the risk of heart valve lesions in patients with ARF.[28]

These trials may be criticized on at least two grounds. First, the method used to assess cardiac involvement was clinical, with the development or persistence of an apical systolic murmur the usual criterion. It could be argued that observer error and interobserver variability of clinical methodology could invalidate the results, and that the question should be reexamined using modern, noninvasive techniques such as echocardiography. It has been shown, however, that at least during the acute phase of the illness, transthoracic two-dimensional echocardiography with color flow imaging does not add significantly to the clinical evaluation of the degree of cardiac involvement. The second point relates to the duration of follow-up. Lack of clinical evidence of cardiac involvement at 1 or 2 years after the initial attack of ARF is no guarantee that the important sequelae of valvular incompetence or stenosis will not develop in the ensuing decades.

The appropriate dosages of anti-inflammatory agents are aspirin, 100 mg/kg/day in four or five divided doses, and prednisone, 1 to 2 mg/kg/day. The duration of therapy must be gauged from the severity of the attack, presence of carditis, and rate of response to treatment. Milder attacks with little or no carditis may be treated with salicylates for approximately 1 month or until inflammation has subsided, as assessed by clinical and laboratory evidence. More severe cases may require 2 to 3 months of corticosteroid therapy before this can be gradually weaned. Up to 5% of patients may still have rheumatic activity despite treatment at 6 months. Occasionally a “rebound” of inflammatory activity can occur when anti-inflammatory therapy is reduced and may require salicylate treatment.

In patients whose initial attack of rheumatic fever is inadequately treated, there is a high risk that the rheumatic activity will continue and result in valvular incompetence, most often of the mitral valve. The end result of an ongoing rheumatic process with deteriorating valvular function is heart failure. Experience has shown that in such cases, prompt surgical management is the sole option and can result in the survival of up to 90% of patients.[29] It has been suggested that the reduction in cardiac workload following valve surgery results in a settling of the rheumatic process, similar to the beneficial effect observed for bed rest.[30]

Prevention

There are three levels of prevention of rheumatic fever: primordial prevention, based on removal of the social determinants of risk for rheumatic fever; primary prevention of the initial attack; and secondary prevention of recurrent attacks.

Primordial Prevention

Primordial prevention consists of measures to minimize future hazards to health and thus inhibit the establishment factors (environmental, economic, social, behavioral, cultural) known to increase the risk of disease. It addresses broad health determinants rather than preventing personal exposure to risk factors, which is the goal of primary prevention. In the case of rheumatic fever, the improvement of social conditions and increasing access to primary health care have been associated with a dramatic fall in the incidence of the disease even before the discovery of antibiotics (curve A, **Fig. 74.1**). Therefore the prevention of rheumatic fever primarily requires the improvement of socioeconomic status of people at high risk of developing rheumatic fever.

Primary Prevention

Antibiotic treatment of proven or presumed GAS pharyngitis is effective in reducing the attack rate of rheumatic fever by 70%. IM penicillin appears to reduce the attack rate by as much as 80%. There is one fewer case of rheumatic fever for every 50 to 60 patients treated with antibiotics.[11] **Table 74.4** presents the drug regimen of choice.[27]

TABLE 74.4

Drug Regimen of Choice for Primary Prevention of Rheumatic Fever

ANTIBIOTIC	ADMINISTRATION	DOSE
Benzathine benzylpenicillin	Single intramuscular injection	1.2 million units; 50% if <30 kg in weight
Phenoxymethylpenicillin (penicillin VK)	Oral for 10 days	250-500 mg three times daily for 10 days
Erythromycin ethylsuccinate	Oral for 10 days	Varies with the formulation

Data from World Health Organization. Rheumatic fever and rheumatic heart disease: report of a WHO expert panel. WHO Technical Report Series No. 923. Geneva: WHO; 2004.

The treatment of proven or presumed GAS pharyngitis is directed toward eradication of the bacteria from the upper respiratory tract. The infection can usually be eradicated by a single IM injection of benzathine benzylpenicillin or by 10 days' treatment with oral penicillin.[11] Although the use of IM penicillin to prevent rheumatic fever is supported by clinical trials, few trials have been done to test the efficacy of oral penicillin for the primary prevention of rheumatic fever. However, there is resistance to using IM penicillin in some developing countries because of the perceived higher risk of anaphylaxis and the dangers associated with the potential reuse of needles. Concerns over safety of IM penicillin have resulted in government orders prohibiting penicillin injections in hospitals and clinics. Government regulations in response to some of these concerns are warranted, particularly in the area of infection control by preventing needle reuse. However, with respect to the dangers of anaphylaxis, more than 60 years of experience with penicillin has shown that, although toxic reactions to IM penicillin have been reported, severe reactions are exceedingly rare, especially in children. Therefore, when given under sterile conditions with an appropriate injection technique, concern regarding the use of parenteral penicillin is unwarranted.[11]

Three major controversies surround the primary prevention of rheumatic fever. The first concerns the role of active ascertainment of cases of sore throat in school-based primary prevention programs. This strategy has been tested in a cluster randomized trial of 53 schools (approximately 22,000 students) from a high-incidence rheumatic fever setting (approximately 60/100,000/year) in Auckland, New Zealand.[31] The control group received routine general practice care. The intervention was a school-based sore throat clinic program with free nurse-observed oral penicillin treatment of GAS pharyngitis. This study involving 86,874 person-years showed no significant reduction of rheumatic fever in the school-based sore throat clinic programs.

The second controversy relates to the utility of primary prevention as a public health measure for the prevention of rheumatic fever.[4] Although there are no RCTs of this strategy, there are several examples of the successful application of primary prevention in the context of a comprehensive public health program for the prevention of rheumatic fever in Cuba, Costa Rica, and the French islands of Martinique and Guadeloupe (curve C, **Fig. 74.1**).[4,16]

Third, the cost-effectiveness of primary prevention as a public health strategy for the prevention of rheumatic fever has been questioned.[4,8] A study conducted in South Africa shows that a strategy of using a clinical decision rule to diagnose GAS pharyngitis without culturing and providing treatment with a single IM injection of penicillin is a cost-effective strategy for the primary prevention of rheumatic fever

in a high-risk community.[32] A strategy of culturing all children is prohibitively expensive. Taken together with the clinical trial evidence,[11] the evidence suggests that primary prevention by treatment of symptomatic cases of GAS pharyngitis diagnosed on clinical grounds may be a cost-effective public heath strategy for the prevention of rheumatic fever in the context of a comprehensive national program for prevention of the disease.[27]

Secondary Prevention

A systematic review of the effectiveness of antibiotics in the secondary prevention of rheumatic fever shows two principal findings (see Classic References, Manyemba and Mayosi). First, the evidence from clinical trials is strongly in support of the superiority of IM compared to oral penicillin in the prevention of rheumatic fever recurrences. Second, more frequent injections are more effective in preventing rheumatic fever recurrence than injections every 4 weeks. The evidence is strong for injections every 2 weeks, with an almost 50% reduction in the risk of rheumatic fever recurrence compared to injections every 4 weeks. The evidence for injections every 3 weeks is less strong and may be even weaker if the analysis takes into account the systematic error introduced by inadequate randomization and allocation concealment in the studies. Despite this evidence, the World Health Organization (WHO)[27] recommends intervals of 3 to 4 weeks for the secondary prevention of rheumatic fever (**Table 74.5**).

TABLE 74.5

Drug Regimen of Choice for Secondary Prevention of Rheumatic Fever

ANTIBIOTIC	ADMINISTRATION	DOSE
Benzathine benzylpenicillin	Single intramuscular injection every 3-4 weeks	For adults and children ≥30 kg in weight: 1,200,000 units For children <30 kg in weight: 600,000 units
Penicillin V	Oral	250 mg twice daily
Sulfonamide*	Oral	For adults and children ≥30 kg in weight: 1 g daily For children <30 kg in weight: 500 mg daily
Erythromycin	Oral	250 mg twice daily

*Including sulfadiazine, sulfadoxine, and sulfisoxazole.

Data from World Health Organization. Rheumatic fever and rheumatic heart disease: report of a WHO expert panel. WHO Technical Report Series No. 923. Geneva: WHO; 2004.

Recommendations regarding the duration of secondary prophylaxis are largely empiric and based on observational studies. The duration of prophylaxis should be individualized and take into account the socioeconomic conditions and risk of exposure to GAS for that patient. Individuals who have had carditis, with or without valvular involvement, are at higher risk for recurrent attacks and should receive prophylaxis well into adulthood and perhaps for life. If valvular heart disease persists, prophylaxis should be lifelong. Patients who have not had rheumatic carditis may receive prophylaxis until 21 years of age or 5 years after the last attack[27] (**Table 74.6**).

TABLE 74.6

Duration of Secondary Prophylaxis for Rheumatic Fever

CATEGORY OF PATIENT	DURATION OF PROPHYLAXIS
Patient without proven carditis	For 5 years after last attack or until 18 years of age (whichever is longer)
Patient with carditis (mild mitral regurgitation or healed carditis)	For 10 years after last attack or at least until 25 years of age (whichever is longer)
More severe valvular disease	Lifelong
After valve surgery	Lifelong

Data from World Health Organization. Rheumatic fever and rheumatic heart disease: report of a WHO expert panel. WHO Technical Report Series No. 923. Geneva: WHO; 2004.

Future Perspectives

The key challenge to the control of rheumatic fever is related to the identification and removal of barriers to the translation of existing knowledge into policy, programs, and practice. There is good evidence that a comprehensive national program that includes primary and secondary prevention interventions is effective in reducing the incidence of rheumatic fever and rheumatic heart disease in endemic countries.[4] Therefore a need exists for cardiovascular practitioners and other partners in endemic countries to work with their ministries of health to establish national public health programs of prevention, as recommended by WHO in 2001.[27]

The efforts to prevent and control rheumatic fever will be facilitated by improvement of access to and development of better formulations of penicillin, identification of the 3% to 5% of individuals with genetic susceptibility to rheumatic fever, and development of an effective vaccine for GAS infection. Benzathine penicillin is a WHO essential drug, but it is not available to all who need it in affected countries. Furthermore, the current formulations of injectable penicillin require frequent administration and follow-up, which impose a heavy burden on fragile primary health care systems in developing countries. Therefore it is necessary not only to improve access to high-quality benzathine penicillin, but also to develop new, long-acting formulations that will improve adherence and the effectiveness of prevention programs.

An understanding of the molecular genetic mechanisms underlying host susceptibility can provide important insights into the pathogenesis of rheumatic fever, which in turn can inform diagnosis, new treatments, and vaccine development. Currently, the syndromic Jones criteria are not very sensitive or specific in countries with a high incidence, and a test for susceptibility may increase specificity. The identification of all genetic susceptibility factors for rheumatic fever through whole-genome analysis may lead to the development of a useful predictive genetic risk score for the disease and an improvement of the Jones criteria in the future.[14]

A safe, effective, and affordable vaccine designed to prevent GAS infections could have a major impact on the health of millions of people at risk of developing rheumatic fever. Research over several decades has yielded a number of different candidate vaccines in various stages of preclinical and clinical development. Vaccine development efforts have been hampered by several obstacles, which can be overcome through global collaborative efforts to identify key activities and secure financial resources that will accelerate the process, leading to the successful introduction of a safe, effective vaccine for the entire world.[33]

OUTLINE

75

Congenital Heart Disease in the Adult and Pediatric Patient

Gary D. Webb, Jeffrey F. Smallhorn, Judith Therrien, Andrew N. Redington

General Considerations

This chapter has been written for the practicing adult cardiologist in the developed world and is compatible with the existing expert management recommendations for the care of adult patients with congenital cardiac defects. (An update on the ACC/AHA guidelines is available online on ExpertConsult.) The discussion will be concentrated on the issues of late adolescence and adulthood; such issues can best be appreciated in the setting of an understanding of the anatomy, physiology, and events during childhood, and these will be discussed in each section when appropriate. Additional information can be found in other sources.[1-3] *Congenital cardiovascular disease* is defined as an abnormality in cardiocirculatory structure or function that is present at birth, even if it is discovered much later. Congenital cardiovascular malformations usually result from altered embryonic development of a normal structure or failure of such a structure to progress beyond an early stage of embryonic or fetal development. The aberrant patterns of flow created by an anatomic defect may, in turn, significantly influence the structural and functional development of the remainder of the circulation. For instance, the presence of mitral atresia in a fetus may prohibit normal development of the left ventricle, aortic valve, and ascending aorta. Similarly, constriction of the fetal ductus arteriosus may result in right ventricular dilation and tricuspid regurgitation in the fetus and newborn.

Postnatal events can markedly influence the clinical presentation of a specific "isolated" malformation. Infants with Ebstein malformation of the tricuspid valve may improve dramatically as the magnitude of tricuspid regurgitation diminishes with the normal fall in pulmonary vascular resistance after birth; and infants with pulmonary atresia or severe stenosis may not become cyanotic until normal spontaneous closure of a patent ductus arteriosus (PDA) occurs. Ductal constriction many days after birth also may be a central factor in some infants in the development of coarctation of the aorta. Still later in life, patients with a ventricular septal defect (VSD) may experience spontaneous closure and develop right ventricular outflow tract obstruction and/or aortic regurgitation with increasing duration of follow-up. These selected examples serve to emphasize that anatomic and physiologic changes in the heart and circulation can continue to evolve from the prenatal period to late adult life.

Incidence in Childhood.

The true incidence of congenital cardiovascular malformations is difficult to determine accurately, partly because of differences in definitions. The incidence in fetal life exceeds that of early childhood, as very complex lesions are associated with early nonviability or later in utero death. Consequently, approximately 0.8% of live births are complicated by a cardiovascular malformation. This figure does not take into account what may be the two most common cardiac anomalies: the congenital, functionally normal bicuspid aortic valve and prolapse of the mitral valve.

Specific defects can show a definite gender preponderance: PDA, Ebstein anomaly of the tricuspid valve, and secundum atrial septal defect (ASD) are more common in females, whereas aortic valve stenosis, coarctation of the aorta, hypoplastic left heart syndrome, pulmonary and tricuspid atresia, and transposition of the great arteries (TGA) are more common in males.

Extracardiac anomalies occur in approximately 25% of infants with significant cardiac disease, and their presence may significantly increase the mortality rate. The extracardiac anomalies are often

multiple. One third of infants with both cardiac and extracardiac anomalies have some established syndrome.

The Adult Patient.

Thanks to the great successes of pediatric cardiac care, the overall number of adult patients with congenital heart disease (CHD) is now greater than the number of pediatric cases. Indeed, more than 90% of patients born in 1990 in Belgium survived to at least age 18 years In the United States, 40,000 babies are born each year with congenital heart defects.[4] More than 35,000 of these will reach age 18 and beyond. There are now approximately 1.3 million American adults with congenital heart defects, more than 50% of which are classified as complex, and in need of lifelong expert surveillance. These moderately complex to very complex patients are at significant risk of premature death, reoperation, or future complications of their conditions and their treatments. Many patients, especially those with moderately complex to very complex conditions, should see a specialist trained in the care of adult CHD. At present, there are not enough such practitioners or facilities to always make this possible. Adult patients should have been taught in adolescence about their condition, their future outlook, and the possibility of further surgery and complications, if appropriate, and they also should have been advised about their responsibilities in ensuring self-care and professional surveillance. Copies of operative reports should accompany patients being transferred for adult care, along with other key documents from the pediatric file.

Table 75.1 lists the types of patients who should be considered as having “simple” CHD and who are suitable for community care. **Tables 75.2 and 75.3** show the diagnoses for moderately complex and very complex patients. Moderately complex and very complex patients should be monitored throughout their lives in a specialized center.

TABLE 75.1

Types of Adult Patients with Simple Congenital Heart Disease*

Native Disease
Isolated congenital aortic valve disease
Isolated congenital mitral valve disease (except parachute valve, cleft leaflet)
Isolated patent foramen ovale or small atrial septal defect
Isolated small ventricular septal defect (no associated lesions)
Mild pulmonic stenosis
Repaired Conditions
Previously ligated or occluded ductus arteriosus
Repaired secundum or sinus venosus atrial septal defect without residua
Repaired ventricular septal defect without residua

*These patients can usually be cared for in the general medical community.

From Webb G, Williams R, Alpert J, et al: 32nd Bethesda Conference: Care of the Adult with Congenital Heart Disease, October 2-3, 2000. J Am Coll Cardiol 37:1161, 2001.

TABLE 75.2

Types of Adult Patients with Congenital Heart Disease of Moderate Severity*

Aorto–left ventricular fistulas
Anomalous pulmonary venous drainage, partial or total
Atrioventricular septal defects (partial or complete)
Coarctation of the aorta
Ebstein anomaly
Infundibular right ventricular outflow obstruction of significance
Ostium primum atrial septal defect
Patent ductus arteriosus (not closed)
Pulmonary valve regurgitation (moderate to severe)
Pulmonic valve stenosis (moderate to severe)
Sinus of Valsalva fistula/aneurysm
Sinus venosus atrial septal defect
Subvalvular or supravalvular aortic stenosis (except hypertrophic obstructive cardiomyopathy)
Tetralogy of Fallot
Ventricular septal defect with the following:
Absent valve or valves
Aortic regurgitation
Coarctation of the aorta
Mitral disease
Right ventricular outflow tract obstruction
Straddling tricuspid/mitral valve
Subaortic stenosis

*These patients should be seen periodically at regional adult congenital heart disease centers.

From Webb G, Williams R, Alpert J, et al: 32nd Bethesda Conference: Care of the Adult with Congenital Heart Disease, October 2-3, 2000. J Am Coll Cardiol 37:1161, 2001.

TABLE 75.3

Types of Adult Patients with Congenital Heart Disease of Great Complexity*

Conduits, valved or nonvalved
Cyanotic congenital heart (all forms)
Double-outlet ventricle
Eisenmenger syndrome
Fontan procedure
Mitral atresia
Pulmonary atresia (all forms)
Pulmonary vascular obstructive diseases
Single ventricle (also called *double-inlet* or *double-outlet, common,* or *primitive ventricle*)
Transposition of the great arteries
Tricuspid atresia
Truncus arteriosus/hemitruncus
Other abnormalities of atrioventricular or ventriculoarterial connection not included above (i.e., crisscross heart, isomerism, heterotaxy syndromes, ventricular inversion)

*These patients should be seen regularly at adult congenital heart disease centers.

From Webb G, Williams R, Alpert J, et al: 32nd Bethesda Conference: Care of the Adult with Congenital Heart Disease, October 2-3, 2000. J Am Coll Cardiol 37:1161, 2001.

CHD in the adult is not simply a continuation of the childhood experience. The patterns of many

lesions change in adult life. Arrhythmias are more frequent and of a different character (**see Chapter 32**). Cardiac chambers often enlarge, and ventricles tend to develop systolic dysfunction. Bioprosthetic valves, prone to early failure in childhood, last longer when implanted at an older patient age. The comorbidities that tend to develop in adult life often become important factors needing attention. As a result, the needs of adult CHD patients are often best met by a physician or a team familiar with both pediatric and adult cardiology issues. For the best results, congenital heart surgery and interventional catheterization procedures should be performed at centers with adequate surgical and institutional volumes of congenital heart cases at any age. Patients undergoing surgery in a nonspecialist environment, even when operated upon by a congenital heart surgeon, suffer a three-fold increased mortality rate compared with those treated in specialized congenital heart centers.[5] In most cases, the specialist environment is a children's hospital; this model will probably not be sustainable for optimal care as the population with CHD expands.

Echocardiographic studies, diagnostic heart catheterizations, electrophysiologic studies, magnetic resonance imaging (MRI), and other imaging modalities of complex cases (**see Chapters 14 to 19**) are best done where qualified staff has relevant training, experience, and equipment. Ideally, patients should be cared for by a multidisciplinary team. Special cardiology and echocardiography skills are essential, but individuals with other special training, experience and interest should also be accessible. These include congenital heart surgeons and their teams, nurses, reproductive health staff, mental health professionals, medical imaging specialists, respiratory consultants, and others.

Etiology

Congenital cardiac malformations can occur with mendelian inheritance directly as a result of a genetic abnormality, be strongly associated with an underlying genetic disorder (e.g., trisomy), be related directly to the effect of an environmental toxin (e.g., maternal diabetes, alcohol), or result from an interaction between multifactorial genetic and environmental influences too complex to allow a single definition of cause (e.g., CHARGE syndrome [see Syndromes in Congenital Heart Disease later]). The latter group is shrinking as genetic research identifies new genetic abnormalities underlying many conditions.

Genetic Considerations.

A single gene mutation can be causative in the familial forms of ASD with prolonged atrioventricular (AV) conduction; mitral valve prolapse; VSD; congenital heart block; situs inversus; pulmonary hypertension; and the syndromes of Noonan, LEOPARD, Ellis–van Creveld, and Kartagener (see Syndromes in Congenital Heart Disease later). The genes responsible for several defects have now been identified (e.g., long-QT syndrome, Holt-Oram syndrome, Marfan syndrome, hypertrophic cardiomyopathy, supravalvular aortic stenosis), and contiguous gene defects on the long arm of chromosome 22 underlie the conotruncal malformations of DiGeorge and velocardiofacial syndromes. However, at present, less than 15% of all cardiac malformations can be accounted for by chromosomal aberrations or genetic mutations or transmission (**see Chapters 7 and 33**).

It is interesting to note, but unexplained, that several different gene defects may lead to the same cardiac malformation (e.g., AV septal defect). Furthermore, the finding that, with some exceptions, only one of a pair of monozygotic twins is affected by CHD indicates that most cardiovascular malformations are not inherited in a simple manner. However, this observation may have led, in the past, to an underestimation of the genetic contribution because most recent twin studies reveal more than double the incidence of heart defects in monozygotic twins but usually in only one of the pair. Family studies indicate a 2-fold to 10-fold increase in the incidence of CHD in siblings of affected patients or in the

offspring of an affected parent. Malformations are often concordant or partially concordant within families. Routine fetal cardiac screening of subsequent pregnancies should be performed in such circumstances.

Environmental Considerations.

Maternal diabetes, maternal rubella infection, ingestion of thalidomide and isotretinoin early during gestation, and chronic maternal alcohol abuse are environmental insults known to interfere with normal cardiogenesis in humans. For example, the incidence of tetralogy of Fallot with pulmonary atresia is increased 10-fold in the offspring of diabetic mothers. Rubella syndrome consists of cataracts; deafness; microcephaly; and, either singly or in combination, PDA, pulmonary valve and/or arterial stenosis, and ASD. Thalidomide exposure is associated with major limb deformities and, occasionally, with cardiac malformations without a predilection for a specific lesion. Tricuspid valve anomalies are associated with ingestion of lithium during pregnancy. Fetal alcohol syndrome consists of microcephaly, micrognathia, microphthalmia, prenatal growth retardation, developmental delay, and cardiac defects (often defects of the ventricular septum) in approximately 45% of affected infants.

Prevention

Physicians who treat pregnant women should be aware of the effects of known teratogens, as well as drugs (e.g., angiotensin-converting enzyme [ACE] inhibitors and fetal renal development), that may have a functional rather than a structural damaging influence on the fetal and newborn heart and circulation. They should also recognize that information about the teratogenic potential of many drugs is inadequate. Appropriate radiologic equipment and techniques for reducing gonadal and fetal radiation exposure should always be used to reduce the hazards of this potential cause of birth defects.

Detection of genetic abnormalities during fetal life is becoming an increasing reality. Fetal cells are obtained from amniotic fluid or chorionic villus biopsy. Many fetuses in whom CHD is detected will undergo genetic testing, and fetal echocardiography is frequently indicated when a chromosomal abnormality is diagnosed due to other reasons. Many social, religious, and legal considerations influence whether termination of pregnancy is performed under these circumstances, but the improved outcomes for even the most complex CHDs frequently argue against the cardiac condition being used as the sole reason. Immunization of children with rubella vaccine has been one of the most effective preventive strategies against fetal rubella syndrome and its associated congenital cardiac abnormalities.

Anatomy

Normal Cardiac Anatomy

The key to understanding CHD is an appreciation of the segmental approach to the diagnosis of both simple and complex lesions.

Cardiac Situs

Cardiac situs refers to the status of the atrial appendages. The normal left atrial appendage is a finger-like structure with a narrow base and pectinate muscles that are confined to the appendage, and a smooth vestibule that is confluent with the smooth-walled body of the left atrium. On the other hand, the right atrial appendage is broad based and the pectinate muscles extend all the way around the vestibule and reach to the cardiac crux. Situs ambiguus refers to hearts with two morphologic left or right atrial appendages. These are dealt with in the section on isomerism and have implications with regard to

associated intracardiac and extracardiac abnormalities.

Atrioventricular Connections

Atrioventricular (AV) connections are the connections between the atria and ventricles. The AV connections are said to be concordant if the morphologic left atrium is connected to the morphologic left ventricle via the mitral valve, and the morphologic right atrium is connected to the morphologic right ventricle via a tricuspid valve. The connections are said to be discordant in other circumstances, such as congenitally corrected TGA (cc-TGA) and univentricular circulations, when both atria are connected predominantly to one of the ventricles.

Ventriculoarterial Connections

Ventriculoarterial connections are the connections between the semilunar valves and the ventricles. Ventriculoarterial concordance occurs when the morphologic left ventricle is connected to the aorta and the morphologic right ventricle is connected to the pulmonary artery. Ventriculoarterial discordance occurs when the morphologic left ventricle is connected to the pulmonary artery, and the aorta is connected to the morphologic right ventricle. A double-outlet right ventricle is present when more than 50% of both great arteries are connected to the morphologic right ventricle. A single-outlet heart has only one great artery connected to the heart.

Atria

Designating an atrium as a morphologic left atrium or right atrium is determined by the morphology of the atrial appendages and not by the status of the systemic or pulmonary venous drainage. The right atrial appendage is broad and triangular, whereas the left is smaller and finger like. The internal architecture is the key feature to an accurate diagnosis, with the right atrium having extensive pectinate muscles that run around the vestibule of the atrium, unlike its left atrial counterpart. Although the pulmonary veins usually drain into a morphologic left atrium and the systemic veins drain into a morphologic right atrium, this is not always the case.

Atrioventricular Valves

The morphologic mitral valve is a bileaflet valve with the anterior or aortic leaflet in fibrous continuity with the noncoronary cusp of the aortic valve. The mitral valve leaflets are supported by two papillary muscle groups located in the anterolateral and posteromedial positions. Each papillary muscle supports the adjacent part of both valve leaflets, with considerable variation in the morphology of the papillary muscles.

The tricuspid valve is a trileaflet valve. It is frequently difficult to identify all three leaflets because of the variability in the anteroposterior commissure. With close inspection, the commissural chordae that arise from the papillary muscles may permit the identification of the three leaflets. The three leaflets occupy a septal anterior, superior, and inferior position. The commissures between the leaflets are the anterior septal, anterior inferior, and inferior commissures. The papillary muscles supporting the valve leaflets arise mostly from the trabeculoseptomarginalis and its apical ramifications.

Morphologic Right Ventricle

The morphologic right ventricle is a triangular-shaped structure with inlet, trabecular, and outlet

components. The inlet component of the right ventricle has attachments from the septal leaflet of the tricuspid valve. Inferior to this is the moderator band, which arises at the base of the trabeculoseptomarginalis, with extensive trabeculations toward the apex of the right ventricle. The outlet component of the right ventricle consists of a fusion of three structures (i.e., the infundibular septum separating the aortic valve from the pulmonary valve, the ventriculoinfundibular fold separating the tricuspid valve from the pulmonary valve, and, finally, the anterior and posterior limbs of the trabeculoseptomarginalis).

Morphologic Left Ventricle

The morphologic left ventricle is an elliptical-shaped structure with a fine trabecular pattern, with absent septal attachments of the mitral valve in the normal heart. It consists of an inlet portion containing the mitral valve and a tension apparatus, with an apical trabecular zone that is characterized by fine trabeculations and an outlet zone that supports the aortic valve.

Semilunar Valves

The aortic valve is a trileaflet valve, with the left and right cusps giving rise to the left and right coronary arteries, respectively, with the noncoronary cusp lacking a coronary artery connection. Of note, the noncoronary cusp is in fibrous continuity with the anterior leaflet of the mitral valve. The aortic valve has a semilunar attachment to the junction of the ventricular outlet and its great arteries. The aortic cusps have a main core of fibrous tissue with endocardial linings on each surface. The cusps are thickened at the midpoint to form a nodule. The characteristics of the pulmonary valve are similar to those of its aortic counterpart, noting the absence of the coronary ostia arising at the superior portion of the sinuses.

Aortic Arch and Pulmonary Arteries

In the normal heart, the aortic arch usually points to the left, with the first branch, the innominate artery, giving rise to the right carotid artery and right subclavian artery. In general, the left carotid and left subclavian arteries arise separately from the aortic arch. By definition the ascending aorta is proximal to the origin of the innominate artery, with the transverse aortic arch extending from the innominate artery to the origin of the left subclavian artery. The aortic isthmus is the area between the left subclavian artery and a PDA or ligamentum arteriosum.

Systemic Venous Connections

In the normal heart, the superior caval vein connects to the roof of the right atrium. The inferior caval vein connects to the inferior portion of the morphologic right atrium, with hepatic veins joining the inferior caval vein before its insertion into the atrium. The coronary veins drain into the flow of the coronary sinus, with the latter running in the posterior AV groove and terminating in the right atrium. The inferior caval vein is guarded by the eustachian valve, which may vary in size among hearts.

Pulmonary Venous Drainage in the Normal Heart

The pulmonary veins drain to the left-sided atrium. Usually three pulmonary veins arise from the trilobed right lung and two pulmonary veins from the bilobed left lung. The pulmonary veins drain into the left atrium in superior and inferior locations. There is a short segment of extraparenchymal pulmonary vein before it disappears into the adjacent hila of the lungs.

Anatomic Variations in the Fetus and Their Implications in Children, Adolescents, and Adults

CHD is being diagnosed with increasing frequency during fetal life. Our ability to modify the evolution of structural (by fetal intervention) and physiologic (by drug therapy) heart disease is increasing. Knowledge of the changes in cardiovascular structure, function, and metabolism that occur during fetal development is perhaps more important today than at any time in the past.

The rapid somatic growth rates of infancy and adolescence are periods of rapid hemodynamic change. Stenotic lesions that may be relatively slowly progressive throughout early childhood need more frequent surveillance during adolescence. Childhood and adolescence is a time to begin educating patients, not just their parents, about their heart disease and the responsibilities that go with it. Issues such as the need for compliance with medications, avoidance of smoking and illicit drug use, and pregnancy and contraception counseling are by no means exclusively issues of the adult with CHD and increasingly require discussion in the pediatric cardiac clinic.

Indeed, the early teenage years should be regarded as part of the transition process before transfer to adult follow-up. The management of the older adolescent and follow-up of adults with newly discovered or previously treated CHD is a burgeoning new subspecialty that will continue to require careful planning to ensure that there are adequate resources for the increasing number of adult “graduates” of pediatric programs. A coordinated approach with specialists in an affiliated adult congenital clinic is clearly desirable.

Adult patients, and often their family members, should understand the cardiac condition both in terms of what has been done so far and what could happen in the future. This is important for a young patient “graduating” into the adult world. Patients need information and should become partners in their own care.

Potential long-term complications in adults with CHD (such as arrhythmias, ventricular failure, conduit obstruction, and endocarditis) should be explained to patients who are at relatively high risk for these issues. The possible need for future therapy, whether medical (antiarrhythmics, anticoagulation, heart failure therapy), catheter based (valve dilation, stents, arrhythmia ablation), or surgical (redo surgery, transplantation), should be discussed if the patient may require any such treatment in the near or intermediate-term future. Day-to-day issues of concern for these young adults need to be addressed, such as exercise prescriptions, driving restrictions, and traveling limitations. Many young people with CHD need advice regarding career choices, entering the work force, insurability, and life expectancy.

Many will want to start a family, and reproductive issues will need to be addressed. Discussion of appropriate contraception methods for any given patient should be offered. Counseling before conception as to the risk to the mother and the fetus for any given pregnancy should be done by specialized physicians. They will take into account the maternal cardiac anatomy, maternal functional status, maternal life expectancy, risk of CHD transmission to the offspring, and risk of premature birth. High-risk patients (e.g., a patient with Marfan syndrome with aortic root dilation; severe pulmonary hypertension; New York Heart Association [NYHA] class III or IV symptoms; and severe aortic stenosis) should be advised against pregnancy. Intermediate-risk patients (e.g., a patient with cyanosis; a patient requiring warfarin because of a mechanical valve or other conditions; or a patient with moderate left ventricular outflow tract obstruction or moderate left ventricular dysfunction) need to know that pregnancy, although possible, may be complicated, and they will require careful follow-up.

Last, but not least, comorbidities such as obesity, smoking, high blood pressure, diabetes, and high

cholesterol measurements add new levels of complexity to these adults as they age, and their consideration must be part of the mandate of the patient's cardiologist.

Pathologic Consequences of Congenital Cardiac Lesions

Congestive Heart Failure

Although the basic mechanisms of cardiac failure are similar for all ages, the common causes, time of onset, and, often, approach to treatment vary with age (**see also Chapters 21 to 31**). Fetal echocardiography now allows the diagnosis of intrauterine cardiac failure. The cardinal findings of *fetal heart failure* are scalp edema, ascites, pericardial effusion, and decreased fetal movements. In *preterm infants*, especially those with a birth weight of less than 1500 g, persistent patency of the ductus arteriosus is the most common cause of cardiac decompensation, and other forms of structural heart disease are uncommon. In *full-term newborns*, the earliest important causes of heart failure are hypoplastic left heart syndrome and aortic coarctation syndrome, sustained tachyarrhythmia, cerebral or hepatic arteriovenous fistula, and myocarditis. Among the lesions commonly producing heart failure *beyond age 1 to 2 weeks*, when diminished pulmonary vascular resistance allows substantial left-to-right shunting, are VSDs and AV septal defects, TGA, truncus arteriosus, and the total anomalous pulmonary venous connection. *Infants younger than 1 year* who have cardiac malformations account for 80% to 90% of pediatric patients who develop congestive failure. In *older children*, heart failure is often due to acquired disease or is a complication of surgical or interventional procedures. In the acquired category are rheumatic and endomyocardial diseases, infective endocarditis, hematologic and nutritional disorders, and severe cardiac arrhythmias.

Congestive heart failure is not common in adult congenital heart practice, although prevention of myocardial dysfunction is a common concern. The adult patient with CHD may develop heart failure in the presence of a substrate (e.g., myocardial dysfunction, valvular regurgitation) and a precipitant (e.g., sustained arrhythmia, pregnancy, or hyperthyroidism). Patients prone to congestive failure include those with long-standing volume loads (e.g., valvular regurgitation and left-to-right shunts) and those with a primary depression of myocardial function (e.g., systemic right ventricles, ventricles damaged during surgery or because of late treatment of ventricular pressure or volume overload). Treatment depends on a clear understanding of the elements contributing to decompensation and on addressing each of the treatable components. Standard adult heart failure regimens are frequently used and may include ACE inhibitors, angiotensin receptor blockers, beta blockers, diuretics, resynchronization pacing, transplantation, and other novel therapies. The evidence for the effectiveness of these strategies is relatively lacking, and many of the proven therapies used for heart failure in acquired heart disease have failed to have a demonstrable benefit in heart failure patients with CHD.

CHD accounts for 40% of pediatric heart transplants, but only 2% of adult heart transplants. Adult CHD heart transplant recipients have a mean survival time of 11 years, similar to that of patients with other forms of heart disease. Patients who have had Fontan surgery tend to have worse outcomes, presumably because they have multiorgan disease. About one third of heart-lung transplants are done for CHD. The 3-year survival rate is about 50%; the rate is even better in patients with Eisenmenger syndrome.

Cyanosis

Central cyanosis refers to arterial oxygen desaturation resulting from the shunting or mixing of systemic venous blood into the arterial circulation. The magnitude of shunting and mixing and the amount of pulmonary blood flow determines the severity of desaturation.

Morphology

Cardiac defects that result in central cyanosis can be divided into two categories: (1) those with increased pulmonary blood flow and (2) those with decreased pulmonary blood flow (**Table 75.4**).

TABLE 75.4

Cardiac Defects Causing Central Cyanosis*

Transposition of the great arteries	Ebstein anomaly
Tetralogy of Fallot	Eisenmenger physiology
Tricuspid atresia	Critical pulmonary stenosis or atresia
Truncus arteriosus	Functionally single ventricle
Total anomalous pulmonary venous return	

*Note 5 Ts and 2 Es.

Pathophysiology

Hypoxemia increases the renal production of erythropoietin, which in turn stimulates bone marrow production of circulating red blood cells, enhancing the oxygen-carrying capacity. Secondary erythrocytosis should be present in all cyanotic patients because it is a physiologic response to tissue hypoxia.[6] The improved tissue oxygenation that results from this adaptation may be sufficient to reach a new equilibrium at a higher hematocrit. However, adaptive failure can occur if the increased whole-blood viscosity rises so much that it impairs oxygen delivery.

Clinical Features

Although erythrocytosis is now rare because of the diminishing prevalence of untreated cyanotic CHD in developed countries, it may cause *hyperviscosity syndrome*. Its symptoms include headaches, faintness, dizziness, fatigue, altered mentation, visual disturbances, paresthesias, tinnitus. and myalgias. Iron deficiency, a common finding in cyanotic adult patients if repeated phlebotomies are done or excessive bleeding occurs, must be treated because it can increase the risk of complications.[8]

Hemostatic abnormalities have been documented in cyanotic patients with erythrocytosis and can occur in up to 20% of patients. A bleeding tendency can be mild and superficial, leading to easy bruising, skin petechiae, and mucosal bleeding, or it can be moderate or life threatening with hemoptysis or intracranial, gastrointestinal, or postoperative bleeding. An elevated prothrombin and partial thromboplastin time; decreased levels of factors V, VII, VIII, and IX; qualitative and quantitative platelet disorders; increased fibrinolysis; and systemic endothelial dysfunction from increased shear stress have all been implicated. Paradoxically, a thrombotic tendency has also been recently described, with 47% of cyanotic patients having an asymptomatic cerebral infarct and 31% having pulmonary thrombosis.[7]

Neurologic complications, including cerebral hemorrhage, can occur secondary to hemostatic defects and can be seen in patients taking anticoagulants. Patients with right-to-left shunts are at risk for paradoxical cerebral emboli, especially if they are iron deficient. A brain abscess should be suspected in a cyanotic patient with a new or different headache or new neurologic symptoms. Air filters should be

used in peripheral and central venous lines in cyanotic patients to avoid paradoxical emboli through a right-to-left shunt.

Renal dysfunction in patients with cyanotic CHD can be manifested as proteinuria, hyperuricemia, or renal failure. Pathologic studies at the level of the glomeruli show evidence of vascular abnormalities, as well as increased cellularity and fibrosis. Hyperuricemia is common and is thought to be due mainly to the decreased reabsorption of uric acid rather than to overproduction associated with erythrocytosis. Urate nephropathy, uric acid nephrolithiasis, and gouty arthritis may occur.

Rheumatologic complications of cyanotic CHD include *gout* and, especially, *hypertrophic osteoarthropathy*, which is thought to be responsible for the arthralgias and bone pain affecting up to one third of cyanotic patients. In patients with right-to-left shunting, megakaryocytes released from the bone marrow can bypass the lung. The entrapment of megakaryocytes in the systemic arterioles and capillaries induces the release of platelet-derived growth factor, promoting local cell proliferation. New osseous formation with periostitis ensues and gives rise to arthralgia and bony pain.

Patients with central cyanosis usually display dilated *coronary arteries*; atherosclerotic narrowing is unusual. Their level of total cholesterol is also lower than that of the general population.

Interventional Options and Outcomes

Complete Repair Procedures

Physiologic or anatomic repair results in total or near-total separation of the pulmonary and systemic circulations in complex cyanotic lesions that leads to relief of cyanosis and shunting. Such procedures should be performed whenever feasible. Complete repairs rarely are without long-term sequelae, despite the inference in the name, and both physicians and patients should be made aware of the need for regular lifelong care in nearly all cases.

Palliative Surgical Interventions

Palliative surgical interventions can be performed in patients with cyanotic lesions to increase pulmonary blood flow while allowing cyanosis to persist. Palliative surgical shunts are summarized in **Table 75.5**. Blalock-Taussig-Thomas, central, and Glenn (also called *cavopulmonary*) shunts are still in use today. Blalock-Taussig-Thomas shunts seldom caused pulmonary hypertension compared with central (Waterston and Potts) shunts and were less prone to causing pulmonary artery distortion. Glenn shunts have the advantage of increasing pulmonary flow without imposing a volume load on the systemic ventricle. Glenn shunts require low pulmonary artery pressures to work, and they may be associated with the development over time of pulmonary arteriovenous fistulas, which can worsen cyanosis.

TABLE 75.5

Palliative Systemic-to-Pulmonary Shunts

Arterial
Blalock-Taussig-Thomas shunt (subclavian artery to PA)
Classic: end-to-side, no or reduced ipsilateral arm pulses
Current: side-to-side tubular grafts, preserved arm pulses
Central shunt (side-to-side tubular graft, aorta to PA)
Potts shunt (descending aorta to LPA)
Waterston shunt (ascending aorta to RPA)
Venous
Glenn shunt (SVC to ipsilateral PA without cardiac or other PA connection)
Bidirectional cavopulmonary (Glenn) shunt (end-to-side SVC to LPA and RPA shunt)

LPA, left PA; *PA*, pulmonary artery; *RPA*, right PA; *SVC*, superior vena cava.

Transplantation

Transplantation of the heart or one or both lungs with surgical cardiac repair, and heart-lung transplantation have been performed in cyanotic patients with or without palliation who were no longer candidates for other forms of intervention (**see Chapter 28**). Pulmonary vascular obstructive disease precludes isolated heart transplantation. An increasing number of CHD patients with previous palliation and ventricular failure are successfully undergoing cardiac transplantation. Timing of transplantation in these patients remains difficult.

Other Management Measures for Cyanosis

The goal of *phlebotomy* is symptom control. When patients have troubling symptoms of hyperviscosity, are iron replete (normal MCV, hematocrit > 65%), and are not dehydrated, removal of 250 to 500 mL of blood over 30 to 45 minutes should be performed with concomitant quantitative volume replacement. The procedure may be repeated every 24 hours if necessary until symptomatic improvement occurs or the hemoglobin level has fallen below 18 to 19 g/dL. Phlebotomy is not indicated for asymptomatic patients.

If iron deficiency anemia is found, *iron supplements* should be prescribed.[8] Cyanotic patients should avoid iron deficiency, which can cause functional deterioration and is associated with an increased risk of stroke and adverse cardiovascular outcomes.

Platelet transfusions, fresh frozen plasma, vitamin K, cryoprecipitate, and desmopressin can be used to treat severe *bleeding*. Given the inherent tendency of cyanotic patients to bleed, aspirin, heparin, and warfarin should be avoided unless the risks of treatment are outweighed by the risks of no treatment. Likewise, nonsteroidal antiinflammatory drugs should be avoided to prevent gastrointestinal bleeding.

Symptomatic hyperuricemia and *gouty arthritis* can be treated as needed with standard therapies.

Reproductive Issues

Pregnancy in a cyanotic CHD patient (excluding a patient with Eisenmenger syndrome) results in a 32% incidence of maternal cardiovascular complications and a 37% incidence of fetal prematurity. Pregnant women with a resting oxygen saturation of more than 85% fare better than women with an oxygen saturation of less than 85% (**see Chapter 90**).

Follow-Up

Although their numbers have dramatically fallen in developed countries, all cyanotic patients should be followed by a CHD cardiologist, and particular attention should be paid to the underlying heart condition; symptoms of hyperviscosity; systemic complications of cyanosis; change in exercise tolerance; change in saturation levels; and prophylaxis against endocarditis, influenza, and pneumococcal infections. The clinician should remember to measure oxygen saturation only after the patient has been resting for at least 5 minutes, and measure blood pressure in the contralateral arm to the side used for an aortopulmonary shunt. In stable cyanotic patients, yearly follow-up is recommended and should include annual flu shots, pneumococcal vaccination, yearly blood work (complete blood count, ferritin, clotting profile, renal function, uric acid), and regular Doppler echocardiographic studies. Home oxygen therapy may occasionally have a role.

Pulmonary Hypertension

Once common because of delayed diagnosis or treatment, severe pulmonary hypertension is a less and less common accompaniment of congenital cardiac lesions in the developed world. When present, the status of the pulmonary vascular bed is often the principal determinant of the clinical manifestations, the course, and whether corrective treatment is feasible (**see Chapter 85**). A recent consensus statement provides important information on this general topic.[9,10] Increases in pulmonary arterial pressure result from elevations of pulmonary blood flow and/or resistance, the latter sometimes caused by an increase in vascular tone but usually the result of underdevelopment and/or obstructive or obliterative structural changes within the pulmonary vascular bed. Although pulmonary hypertension usually affects the entire pulmonary vascular bed, it may occur focally. For example, unilateral pulmonary hypertension may occur in an overshunted lung (the other lung perhaps protected and fed by a cavopulmonary Glenn shunt) or in lung segments supplied by aortopulmonary collateral flow.

Pulmonary vascular resistance normally falls rapidly immediately after birth because of the onset of ventilation and subsequent pulmonary vasodilation. Subsequently, and gradually, the medial smooth muscle of pulmonary arterial resistance vessels thins. This latter process is often delayed by several months in infants with large aortopulmonary or ventricular communications, at which time levels of pulmonary vascular resistance are still somewhat elevated. In patients with high pulmonary arterial pressures from birth, failure of normal growth of the pulmonary circulation may occur, and anatomic changes in the pulmonary vessels in the form of proliferation of intimal cells and intimal and medial thickening often progress, so vascular resistance in an older child or adult ultimately may become relatively fixed by obliterative changes in the pulmonary vascular bed. Quite likely, injury to pulmonary vascular endothelial cells initiates a cascade of events that involve the release or activation of factors that alter the extracellular matrix, induce hypertrophy, cause proliferation of vascular smooth muscle cells, and promote connective tissue protein synthesis. Considered together, these may permanently alter vessel structure and function.

Mechanisms of Development

Intimal damage appears to be related to shear stresses because endothelial cell damage occurs at high shear rates. A reduction in pulmonary arteriolar lumen size due to either thickened medial muscle or vasoconstriction increases the velocity of flow. Shear stress also increases as blood viscosity rises; therefore, infants with hypoxemia and high hematocrit levels, as well as increased pulmonary blood flow,

are at increased risk of developing pulmonary vascular disease. In patients with left-to-right shunts, pulmonary arterial hypertension, if not present in infancy or childhood, may never occur or may not develop until the third or fourth decade or later. Once developed, intimal proliferative changes with hyalinization and fibrosis are not reversible by repair of the underlying cardiac defect. In severe pulmonary vascular obstructive disease, arteriovenous malformations may develop and predispose to sometimes massive hemoptysis.

Most vexing is the variability among patients with the same or similar cardiac lesions in both the time of appearance and the rate of progression of their pulmonary vascular obstructive process. Although genetic influences may be operative (an example is the apparent acceleration of pulmonary vascular disease in patients with CHD and trisomy 21), evidence is now accumulating for important genetic, prenatal, and postnatal modifiers of the pulmonary vascular bed that appear, at least in part, to be lesion dependent. Thus a quantitative variability exists in the pulmonary vascular bed related to the number, not just the size and wall structure, of arterial vessels within the pulmonary circulation, all of which may be modified by coexisting CHD.

Eisenmenger Syndrome

Diminishingly common in the developed world, but still common where early cardiac treatment is unavailable, *Eisenmenger syndrome*, a term coined by Paul Wood, is defined as pulmonary vascular obstructive disease that develops as a consequence of a large preexisting left-to-right shunt such that pulmonary artery pressures approach systemic levels and the direction of the flow becomes bidirectional or predominantly right to left. Congenital heart defects that can result in Eisenmenger syndrome include “simple” defects, such as ASD, VSD, and PDA, as well as more “complex” defects, such as AV septal defect, truncus arteriosus, aortopulmonary window, and univentricular heart. The high pulmonary vascular resistance is usually established in early childhood (often by age 4 years, except in ASD) and is sometimes present from birth.

Natural History of the Unoperated Patient

Patients with defects that allow free communication between the pulmonary and systemic circuits at the aortic or ventricular levels usually have a fairly healthy childhood and gradually become overtly cyanotic during their second or third decade. Exercise intolerance (dyspnea and fatigue) is proportional to the degree of hypoxemia or cyanosis. In the absence of complications, these patients generally have a good functional capacity up to their third decade and thereafter usually experience a slowly progressive decline in their physical abilities. Most patients survive to adulthood, with reported survival rates of 77% at 15 years of age and 42% at 25 years of age.

Congestive heart failure in patients with Eisenmenger syndrome usually occurs after 40 years of age. The most common modes of death are sudden death (≈30%), congestive heart failure (≈25%), and pulmonary hemorrhage (≈15%). Pregnancy, perioperative death at the time of noncardiac surgery, and infectious causes (brain abscesses and endocarditis) account for most of the remainder.

Clinical Manifestations

Patients can present with the following complications: those related to their cyanotic state; palpitations, which occur in nearly half of patients; atrial fibrillation or flutter in ≈35%, ventricular tachycardia in up to ≈10%); hemoptysis, which occurs in approximately 20%; pulmonary thromboembolism, angina,

syncope, and endocarditis, each of which occurs in approximately 10%; and congestive heart failure. Hemoptysis is usually due to bleeding bronchial vessels or pulmonary infarction.

Physical examination reveals central cyanosis and clubbing of the nail beds. Patients with Eisenmenger PDA can have pink nail beds on the right hand (more than the left hand) and cyanosis and clubbing of both feet, or so-called differential cyanosis. This occurs because venous blood shunts through the ductus and enters the aorta distal to the subclavian arteries. The jugular venous pressure in patients with Eisenmenger syndrome can be normal or elevated, especially with prominent *v* waves when tricuspid regurgitation is present. Signs of pulmonary hypertension (a right ventricular heave, palpable and loud P_2, and a right-sided S_4) are typically present. In many patients, a pulmonary ejection click and a soft and scratchy systolic ejection murmur, attributable to dilation of the pulmonary trunk, and (less often) a high-pitched decrescendo diastolic murmur of pulmonary regurgitation (Graham Steell murmur) are audible. Peripheral edema is absent until right-sided heart failure ensues.

Laboratory Investigations

Electrocardiography (ECG).

Peaked P waves consistent with right atrial overload and evidence of right ventricular hypertrophy with right axis deviation are the rule on an ECG. Atrial arrhythmias can be present.

Chest Radiography.

Chest radiography shows dilated central pulmonary arteries with rapid tapering of the peripheral pulmonary vasculature (the radiographic hallmarks of Eisenmenger syndrome). Pulmonary artery calcification may be seen and is diagnostic of long-standing pulmonary hypertension. Eisenmenger syndrome due to VSD or PDA usually has a normal or only slightly increased cardiothoracic ratio. Eisenmenger syndrome due to an ASD typically has a large cardiothoracic ratio because of right atrial and ventricular dilation, along with an inconspicuous aorta, reflecting a low lifelong cardiac output. Calcification of the arterial duct may be seen in Eisenmenger PDA.

Echocardiography.

The intracardiac defect should be seen readily, along with bidirectional shunting. A pulmonary hypertensive PDA is not easily seen. Evidence of pulmonary hypertension is found. Assessment of right ventricular function adds prognostic value.

Cardiac Catheterization.

Cardiac catheterization not only provides direct measurement of the pulmonary artery pressure, documenting the existence of severe pulmonary hypertension, but can also allow assessment of the reactivity of the pulmonary vasculature. Administration of pulmonary arterial vasodilators (O_2, nitric oxide, prostaglandin I_2 [epoprostenol]) can determine which patients have contraindications to surgical repair and which patients have reversible pulmonary hypertension and may benefit from surgical or even catheter repair. Radiographic contrast material may cause hypotension and worsening cyanosis and should be used cautiously.

Open-Lung Biopsy.

Open-lung biopsy is seldom used in the current era, and should be considered only when reversibility of the pulmonary hypertension is uncertain from the hemodynamic data. An expert opinion will be necessary to determine the severity of the changes, often using the Heath-Edwards classification.

Indications for Intervention

Historically, the underlying principle of clinical management in patients with Eisenmenger syndrome was to avoid any factors that may destabilize the delicately balanced physiology. Until the last decade or so, an approach of nonintervention has been recommended. The widespread use of pulmonary vasodilators in Eisenmenger patients began in 2006, after the publication of the BREATHE-5 randomized controlled trial (see below). Since then, a number of trials of agents in various classes have provided evidence of benefit from these "advanced therapies."[11]

In addition to or instead of advanced therapies (which are quite expensive), the therapeutic focus is directed toward preventing complications (e.g., flu shots and pneumococcal vaccine to reduce the morbidity of respiratory infections) or restoring the physiologic balance (e.g., iron replacement for iron deficiency, antiarrhythmic management of atrial arrhythmias, and diuretics for right-sided heart failure). As a general rule, the first episode of hemoptysis should be considered an indication for investigation. Bed rest is usually recommended; although usually self-limiting, each such episode should be regarded as potentially life threatening, and a treatable cause should be sought. When patients are severely incapacitated from severe hypoxemia or congestive heart failure, the main intervention available is lung transplantation (plus repair of the cardiac defect) or, with somewhat better results, heart-lung transplantation. This is generally reserved for individuals without contraindications who are thought to have a 1-year chance of survival of less than 50%. Such assessment is fraught with difficulty because of the unpredictability of the time course of the disease and the risk of sudden death.

Noncardiac surgery should be performed only when absolutely necessary because of its high associated mortality rates. Eisenmenger syndrome patients are particularly vulnerable to alterations in hemodynamics induced by anesthesia or surgery, such as a minor decrease in systemic vascular resistance that can increase right-to-left shunting and possibly potentiate cardiovascular collapse. Local anesthesia should be used whenever possible. Avoidance of prolonged fasting and, especially, dehydration, the use of antibiotic prophylaxis when appropriate, and careful intraoperative monitoring are recommended. The choice of general versus epidural or spinal anesthesia is controversial. An experienced cardiac anesthetist with an understanding of Eisenmenger syndrome physiology should administer anesthesia. Additional risks of surgery include excessive bleeding, postoperative arrhythmias, and deep venous thrombosis with paradoxical emboli. An "air filter" or "bubble trap" should be used for most intravenous lines in cyanotic patients. Early ambulation is recommended. Postoperative care in an intensive care unit setting is optimal.

Interventional Options and Outcomes

Oxygen

Supplemental nocturnal oxygen has been shown to have no impact on exercise capacity or on survival rates in adult patients with Eisenmenger syndrome. Supplemental oxygen during commercial air travel is often recommended, but the scientific basis for this recommendation is lacking.

Transplantation

Lung transplantation may be undertaken in association with repair of existing cardiovascular defect(s). Alternatively, heart-lung transplantation may be required if the intracardiac anatomy is not correctable. The 3-year survival rate after heart-lung transplantation for CHD is approximately 50%. The subgroup of patients with Eisenmenger syndrome may do better, with a 50% 5-year survival rate. These procedures

offer the best hope to individuals with end-stage CHD who are confronting death and have an intolerable quality of life.

Medical Therapy

In 2006, the BREATHE-5 trial was published, demonstrating that bosentan could be safely given to patients with Eisenmenger syndrome. It improved their 6-minute walk distance. Since then, several trials have demonstrated improved outcomes of various types in Eisenmenger patients using the three different drug classes of pulmonary vasodilators: endothelin receptor antagonists; phosphodiesterase inhibitors; and prostacyclins. A recent review article proposed a treatment algorithm for such patients (**Fig. 75.1**).

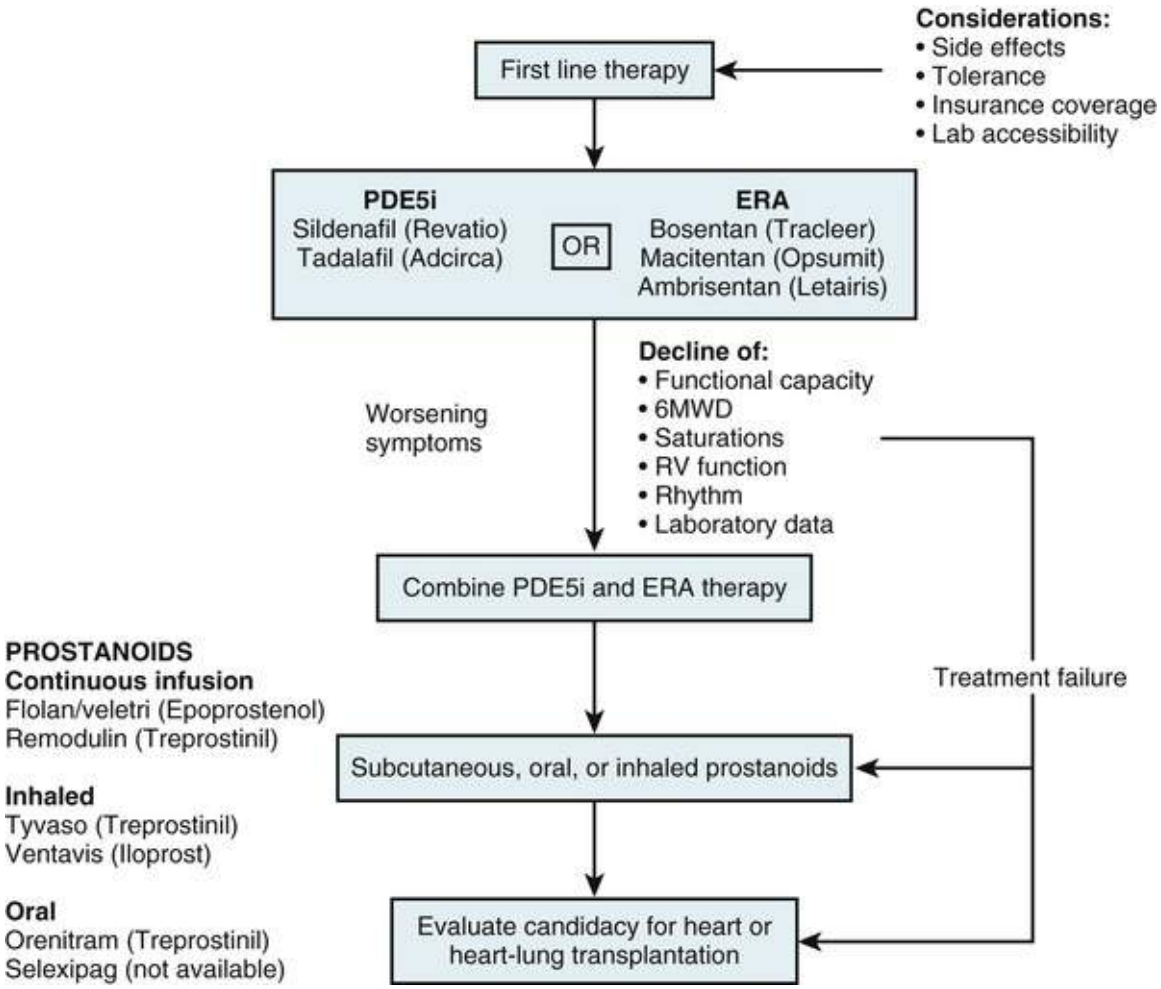

FIGURE 75.1 Suggested treatment algorithm for pulmonary arterial hypertension and Eisenmenger syndrome. *6MWD*, 6-minute walk distance. (From Roth TS, Aboulhosn JA: Pulmonary Hypertension And Congenital Heart Disease. Cardiol Clin 2016;34(3):391-400.)

Follow-Up

Patient education is critical. Avoidance of over-the-counter medications, dehydration, smoking, high-altitude exposure, and excessive physical activity should be stressed. Avoidance of pregnancy with appropriate contraceptive methods is of paramount importance. Annual flu shots, a single dose of pneumococcal vaccine, and use of endocarditis prophylaxis together with proper oral hygiene are recommended. A yearly assessment of the complete blood cell count and uric acid, creatinine, and ferritin levels should be done to monitor treatable causes of deterioration.

Cardiac Arrhythmias

Most arrhythmias encountered in teenagers and young adults are in association with previously operated CHD (**see also Chapters 32 to 38**). Arrhythmias can be a major clinical challenge in adolescent and adult congenital heart patients. They are the most frequent reason for emergency department visits and hospital admissions, and they are usually recurrent and may worsen or become less responsive to treatment with time. Treatment may be challenging.

Atrial Arrhythmias

Atrial flutter and, to a lesser degree, atrial fibrillation are the most common arrhythmias (**see Chapter 38**). Atrial flutter tends to reflect right atrial abnormalities, and atrial fibrillation, left atrial abnormalities. Atrial flutter in such patients is often atypical in appearance and behavior and is better called *intraatrial reentrant tachycardia.* Recognition of atrial flutter can be difficult, and the observer must be vigilant in recognizing 2 : 1 conduction masquerading as sinus rhythm (typically with a resting heart rate of ≈ 100 beats/min). Recurrence is likely and should not necessarily be assumed to represent failure of the management strategy. The conditions in which atrial flutter is most likely are Mustard/Senning repairs of TGA, repaired or unrepaired ASDs, repaired tetralogy of Fallot, and Ebstein anomaly of the tricuspid valve; it is also likely after a Fontan operation. Atrial flutter may reflect hemodynamic deterioration in patients who have had Mustard, Senning, tetralogy of Fallot, or Fontan repairs. Its onset is usually associated with more symptoms and functional limitation.

The pharmaceutical agents most commonly used in therapy are warfarin, beta blockers, amiodarone, sotalol, propafenone, and digoxin. As a rule, patients with good ventricular function can receive sotalol or propafenone, whereas those with depressed ventricular function should receive amiodarone. Other therapies, including pacemakers, ablative procedures, and innovative surgery, are being both applied and refined. Sustained ventricular tachycardia or ventricular fibrillation occurs less often, usually in the setting of ventricular dilation, dysfunction, and scarring. Although sudden death is common in several conditions, the mechanism is poorly understood.

Ventricular Tachycardia

Ventricular tachycardia can be seen as a manifestation of proarrhythmic effects of various agents; in patients with acute myocardial injury or infarction; and in CHD patients with severe ventricular dysfunction. In particular, sustained ventricular tachycardia has occurred in patients with repaired tetralogy of Fallot, where it is seen as a manifestation of hemodynamic problems (usually severe pulmonary regurgitation) requiring repair; as a reflection of right ventricular dilation and dysfunction; and in relation to ventricular scarring.

Sudden Death

Unlike adults, children seldom die suddenly and unexpectedly of cardiovascular disease. Nonetheless, sudden death at any age has been reported with arrhythmias, aortic stenosis, hypertrophic obstructive cardiomyopathy, idiopathic pulmonary arterial hypertension, Eisenmenger syndrome, myocarditis, congenital complete heart block, primary endocardial fibroelastosis, and when there are specific anomalies of the coronary artery origin and course (**see also Chapter 42**).[12]

Atrioventricular Block

First-degree AV block is commonly seen in patients with AV septal defects, Ebstein anomaly, or complete TGA (D-TGA) and in the older ASD patient. Complete heart block may develop in patients with cc-TGA and may develop postoperatively in these and other patients. When pacing is required, epicardial leads are usually placed in cyanotic patients because of the risk of paradoxical embolism. Many adult patients with CHD are prone to problems of vascular access because of prior surgeries, catheter procedures, and pacing leads.

Infective Endocarditis

Infective endocarditis complicating CHD is uncommon before 2 years of age, except in the immediate postoperative period (**see also Chapter 73**). Recent guidelines for endocarditis prophylaxis have substantially altered clinical practice. Maintenance of excellent oral hygiene is encouraged most strongly. Antibiotic prophylaxis prior to dental procedures is recommended for patients with prosthetic heart valves; prosthetic material used for cardiac valve repair; a prior history of infective endocarditis; persistently cyanotic CHD; residual defects that are adjacent to a prosthetic patch or prosthetic device; and for the first 6 months after placement of prosthetic material or a device for CHD and for cardiac transplant recipients who develop cardiac valvulopathy.

Chest Pain

Angina pectoris is an uncommon symptom of congenital cardiac disease, although when there is typical pain a full surveillance for coronary abnormalities (e.g., abnormal origin and course, ostial stenosis, myocardial bridging) is required. Pain caused by pericarditis is commonly of acute onset and associated with fever, and can be identified by specific physical, radiographic, and echocardiographic findings. Most commonly, late postoperative chest pain is musculoskeletal in origin and may be reproduced on upper extremity movement or by palpation. **See also Chapter 56**.

Syndromes in Congenital Heart Disease

The acronym ALCAPA in *ALCAPA syndrome* stands for *a*nomalous *l*eft *c*oronary *a*rtery *a*rising from the *p*ulmonary *a*rtery. It is also called *Bland-White-Garland syndrome* (Videos 75.1 to 75.3).

Alagille syndrome is an autosomal dominant syndrome consisting of intrahepatic cholestasis, characteristic facies, butterfly-like vertebral anomalies, and varying degrees of peripheral pulmonary artery stenoses or diffuse hypoplasia of the pulmonary artery and its branches. It is most commonly caused by point mutations in the *JAG1* gene on chromosome 20p and is less frequently caused by deletions of chromosome 20p (7% of cases) or point mutations in *NOTCH2* (1% of cases).

22q11 deletion syndrome is caused by a microdeletion at chromosome 22q11, resulting in a wide clinical spectrum. It is also known as DiGeorge or velocardiofacial or Takao syndrome. Cardiac defects include conotruncal defects such as interrupted aortic arch, tetralogy of Fallot, truncus arteriosus, and double-outlet right ventricle.

The CHARGE in *CHARGE syndrome* is an acronym for ocular *c*oloboma, congenital *h*eart defects, choanal *a*tresia, *r*etardation of growth and development, *g*enital hypoplasia, and *e*ar anomalies associated with deafness. The phenotype is highly variable. Congenital heart defects seen in the CHARGE association are tetralogy of Fallot with or without other cardiac defects, AV septal defect,

double-outlet right ventricle, double-inlet left ventricle, TGA, interrupted aortic arch, and others. A majority of cases are caused by mutations or deletions of a gene encoding a chromatin remodeling protein, *CHD7*.

Down syndrome is the most common genetic malformation and is caused by trisomy 21. Most of the patients (95%) have complete trisomy of chromosome 21; some have translocation or mosaic forms. The phenotype is diagnostic (short stature, characteristic facial appearance, mental retardation, brachydactyly, atlantoaxial instability, and thyroid and white blood cell disorders). Congenital heart defects are frequent (40%), with AV septal defect, VSD, and PDA being the most common. Patients with Down syndrome are prone to earlier and more severe pulmonary vascular disease than otherwise expected as a result of the lesions identified. Health supervision guidelines for patients with Down syndrome provide management and screening recommendations.[13]

Ellis–van Creveld syndrome is an autosomal recessive skeletal dysplasia syndrome in which common atrium, primum ASD, and partial AV septal defects are the most common cardiac lesions. This syndrome is one of a growing class of "ciliopathies" and is caused by mutations in *EVC1* or *EVC2*.

Holt-Oram syndrome is an autosomal dominant syndrome consisting of radial abnormalities of the forearm and hand associated with secundum ASD (most common); VSD; or, rarely, other cardiac malformations. It is caused by mutations in *TBX5* and is characterized by phenotypic variability within and between families.

LEOPARD syndrome is an autosomal dominant condition. It is a close "cousin" of Noonan syndrome, and it shares a similar genetic substrate (deletion of the *PTPN-11* gene). It includes *l*entigines, *E*CG abnormalities, *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormal genitalia, *r*etardation of growth, and *d*eafness. Rarely, cardiomyopathy or complex CHD may be present.

Noonan syndrome is an autosomal dominant syndrome phenotypically somewhat similar to Turner syndrome but with a normal chromosomal complement. Noonan syndrome is caused by mutations in the *PTPN-11* gene, as well as the *KRAS*, *SOS-1*, *NRAS*, and *RAF-1* genes, leading to the idea that RAS pathway genes contribute to Noonan and related syndromes. Noonan syndrome is associated with congenital cardiac anomalies, especially dysplastic pulmonary valve stenosis, pulmonary artery stenosis, and ASD. Hypertrophic cardiomyopathy is less common. Congenital lymphedema is a commonly associated anomaly.

Rubella syndrome was once a serious condition, but it has largely been eradicated where there are vaccination programs. It is a wide spectrum of malformations caused by rubella infection early in pregnancy, including cataracts, retinopathy, deafness, CHD, bone lesions, and mental retardation. The spectrum of congenital heart lesions is wide and includes pulmonary artery stenosis, PDA, tetralogy of Fallot, and VSD.

Scimitar syndrome (Videos 75.4 and 75.5) is a constellation of anomalies, including a total or partial anomalous pulmonary venous connection (PAPVC) of the right lung to the inferior vena cava, often associated with hypoplasia of the right lung and right pulmonary artery. The lower portion of the right lung (sequestered lobe) tends to receive an additional arterial supply from the abdominal aorta. The name of the syndrome derives from the appearance on a posteroanterior chest radiograph of the shadow formed by the anomalous pulmonary venous connection that resembles a Turkish sword, or scimitar.

SHONE complex (syndrome) is an association of multiple levels of left ventricular inflow and outflow obstruction (subvalvular and valvular left ventricular outflow tract obstruction, coarctation of the aorta, and mitral stenosis [parachute mitral valve and supramitral ring] (Video 75.6). The genetic basis of left-sided lesions, including mitral stenosis, aortic stenosis, left ventricular hypoplasia, and coarctation, is shared, but for the most part causal genes have not been found. *NOTCH-1* mutations are associated

with aortic stenosis.

Turner syndrome is a clinical syndrome resulting from the 45 XO karyotype in about 50% of cases, and from various other X chromosome abnormalities in the remainder. There is a characteristic but variable phenotype, an association with congenital cardiac anomalies, especially postductal coarctation of the aorta and other left-sided obstructive lesions, as well as PAPVC without ASD. The female phenotype varies with the age of presentation and is somewhat similar to that of Noonan syndrome.

Williams syndrome is a contiguous gene syndrome associated with inherited or sporadic deletions at chromosome 7q11.23. The cardiovascular features are caused by the loss of function of ELASTIN, one of the approximately 30 genes in the deletion. Williams syndrome is associated with intellectual deficit, infantile hypercalcemia, characteristic phenotype, and CHD, especially supravalvular aortic stenosis and multiple peripheral pulmonary stenoses. Isolated familial supravalvar aortic stenosis is seen in otherwise phenotypically and intellectually normal families that carry ELASTIN mutations, but not the full deletion.

Evaluation of the Patient With Congenital Heart Disease

Physical Examination

Although the advances in technology have profoundly improved our diagnostic abilities, there is still a role for a detailed clinical examination in the assessment and follow-up of patients with unoperated, palliated, and repaired CHD. The relevant findings pertaining to specific abnormalities are outlined in the appropriate sections that follow, but some general principles bear consideration (**see also Chapter 10**).

Physical Assessment

The presence of characteristic facial or somatic features of an underlying syndrome may be a strong clue to the type of heart disease (e.g., Williams syndrome, Noonan syndrome, Down syndrome) at any age. Central cyanosis can be difficult to diagnose clinically when mild but should be actively excluded by oximetry in any patient with suspected CHD. One should assess both cardiac and visceral situs and not assume the heart will be left sided. Performing careful surveillance of the chest wall for scars is also important in older patients and adults, who do not always know or report the type and sequence of their surgical or catheter interventions.

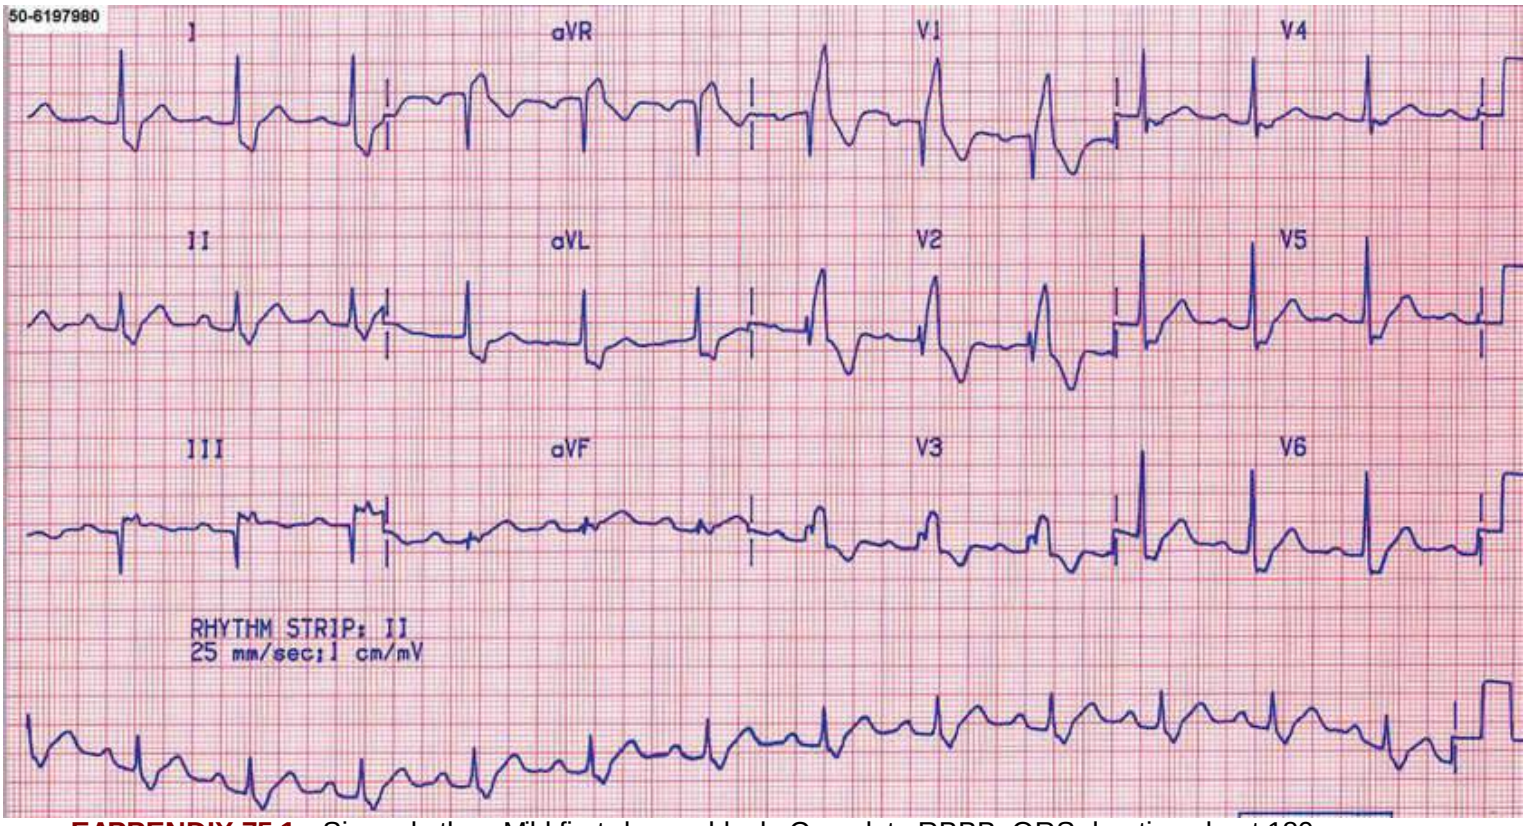
Examination of the upper and lower limb peripheral pulses is important. Delay, absence, or reduction of a pulse is an important clue to the presence of arterial obstruction and its site. The left brachial pulse is often compromised by surgery for coarctation, and blood pressure measurements should not be taken in only the left arm. Similarly, other palliative procedures (Blalock-Taussig-Thomas shunt, interposition grafts) may affect either or both upper limb pulses. Assessing the femoral and carotid pulses in addition to the upper limb pulses is important in such patients. Just as in acquired disease, the pulse volume and character also provide important information regarding the severity of obstructive or regurgitant left heart disease. A low-volume pulse (usually with a narrow pulse pressure) reflects a low cardiac output. Pulsus alternans signifies severe systemic ventricular dysfunction. Pulsus paradoxus points to cardiac tamponade. In adolescents and adults, the jugular venous pressure examination is often important. It may give an indication of cardiac decompensation, cardiac chamber hypertrophy or restriction, valvular regurgitation or stenosis, arrhythmia or conduction disturbance, cardiac tamponade, pericardial constriction, and other phenomena.

Auscultation

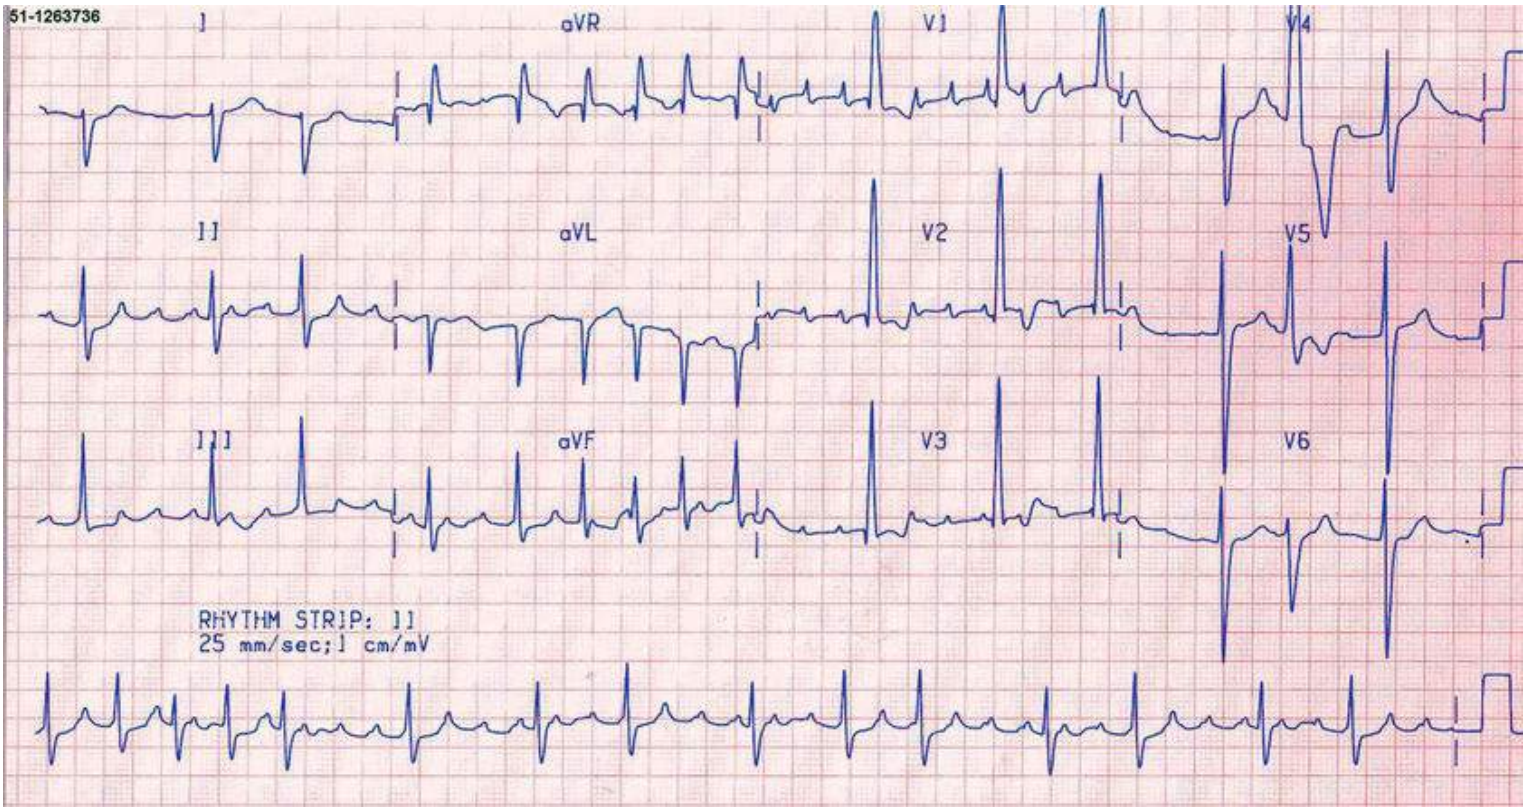
The rules of auscultation follow those developed for acquired heart disease. However, cardiac and vascular malposition may significantly affect the appreciation of heart sounds and murmurs. For example, in TGA treated by an atrial switch procedure, the aorta remains anterior to the pulmonary artery. Consequently, the aortic component of the second sound can be exceptionally loud, and the pulmonary component may be virtually inaudible, making it difficult to estimate the pulmonary artery pressure clinically under such circumstances. Conversely, when there is a valved conduit between the right ventricle and pulmonary artery, the pulmonary closure sound may be extremely loud, even though the pulmonary artery diastolic pressure is low. This is because the conduit is frequently adherent to the chest wall, assisting sound transmission to the stethoscope placed close to it. Calcification of semilunar valves is relatively unusual in childhood and early adult life, making the differentiation of valve stenosis from subvalve or supravalve narrowing, by the presence of an ejection click, more precise in these patients. The differentiation of multiple murmurs is sometimes a challenge. Systolic and/or diastolic murmurs in an individual may have several causes, and supplementary clinical information may be required to establish their significance in some cases. Auscultation over the entire anterior and posterior chest wall is important. The continuous murmurs of aortoaortic collateral arteries in coarctation may be audible only between the shoulder blades posteriorly, for example, and similarly the presence of a localized distal pulmonary artery stenosis or an aortopulmonary collateral artery may be detected only in a localized area of the chest wall.

The Electrocardiogram

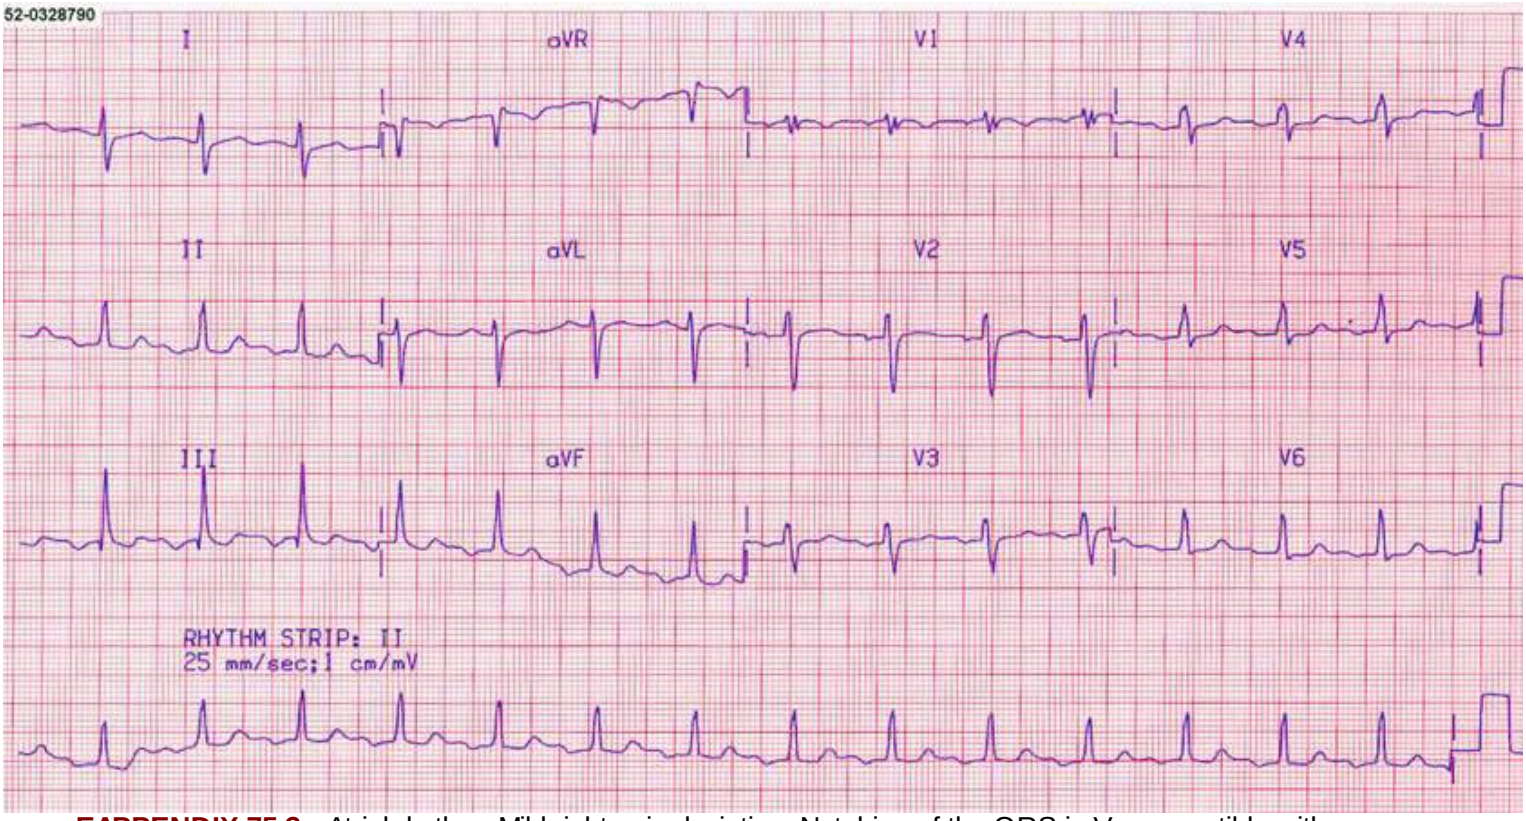
The ECG remains an important tool in the assessment of CHD. The heart rhythm and rate, as well as the AV conduction, can be evaluated (**see Chapter 12** and the ECG figures in the eAppendix). The dominant theme that runs through ECGs in CHD is the prevalence of right heart disease. This often takes the form of right axis deviation along with right atrial and right ventricular hypertrophy. Right ventricular hypertrophy may reflect pulmonary hypertension, right ventricular outflow tract obstruction, or a subaortic right ventricle. Incomplete right bundle branch block often indicates right ventricular hypertrophy due to pressure (e.g., pulmonary hypertension or pulmonary stenosis) or volume (e.g., ASD) overload. Right ventricular volume overload is likely when the r″ in V_1 is less than 7 mm. Very wide QRS complexes should be seen as possible manifestations of dilated and dysfunctional ventricles, most specifically in patients with a combination of repaired tetralogy, complete right bundle branch block, and severe pulmonary regurgitation. The ECG may be uninterpretable in patients with abnormal cardiac or visceral situs unless it is clear where the leads were placed.



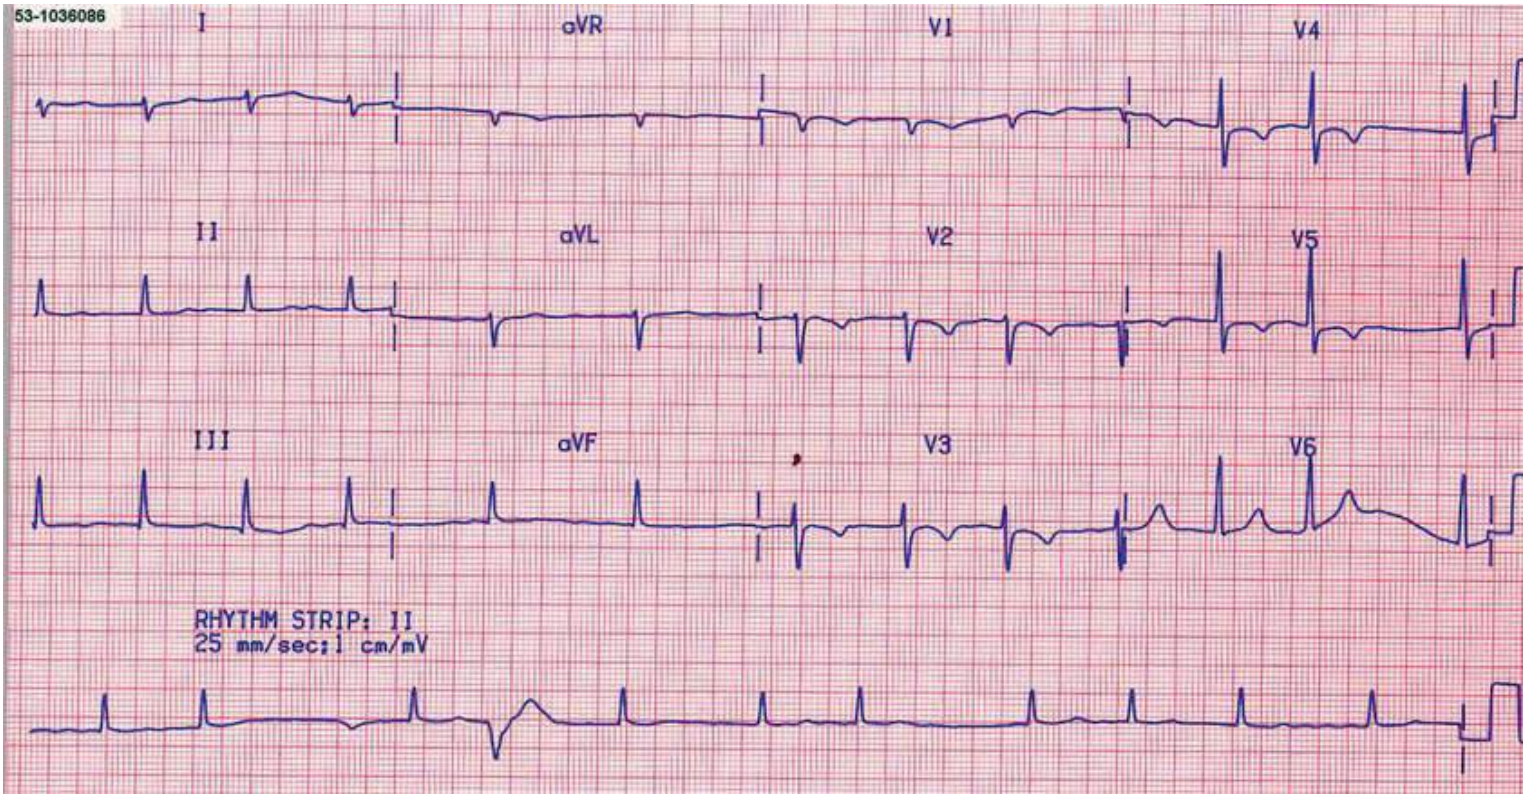
EAPPENDIX 75.1 Sinus rhythm. Mild first-degree block. Complete RBBB. QRS duration about 180 ms. CLINICAL DX: Repaired tetralogy of Fallot. Severe pulmonary regurgitation. Age 50.



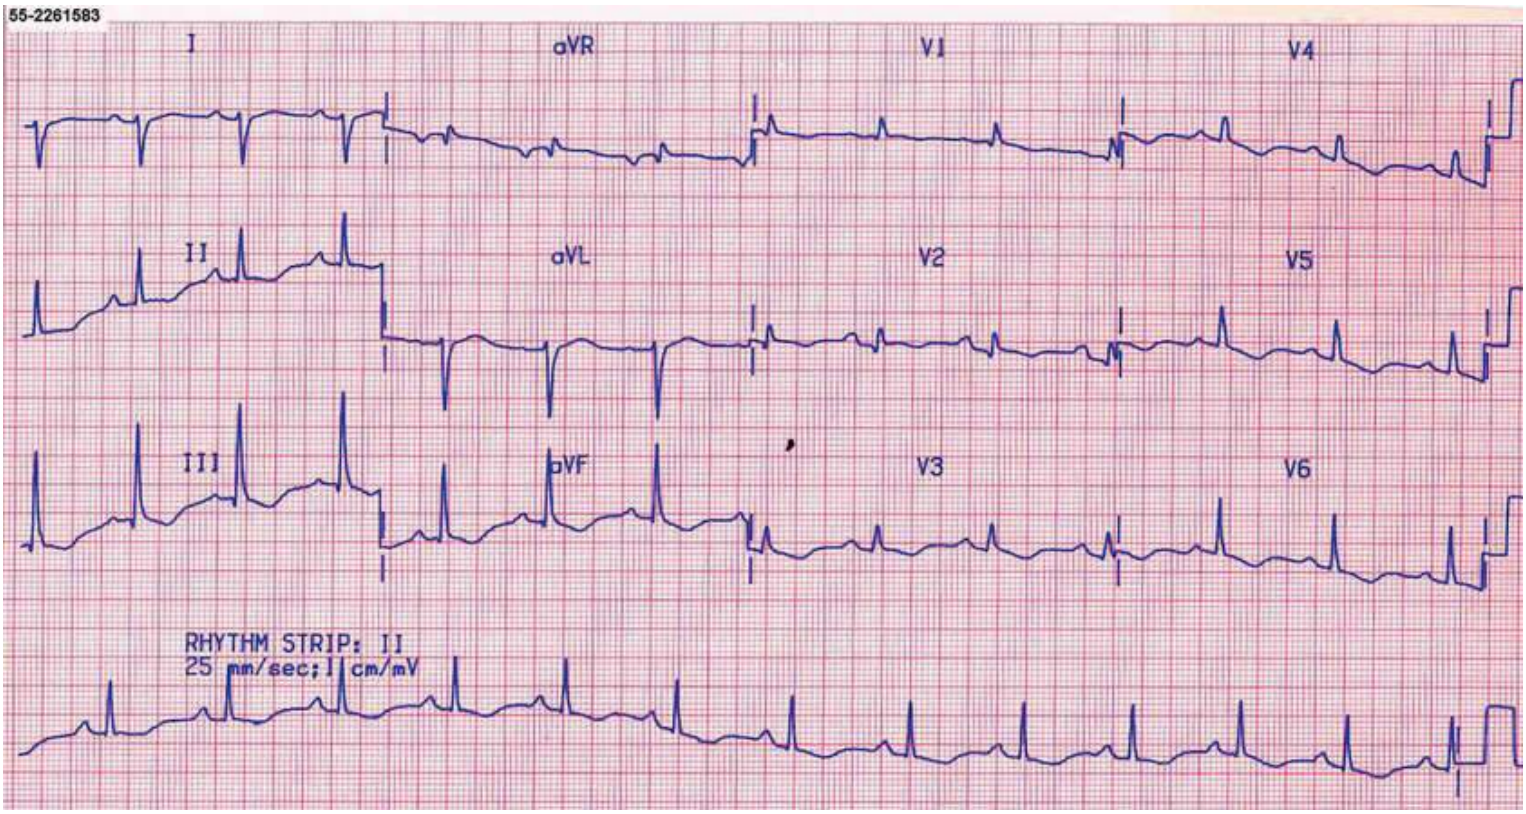
EAPPENDIX 75.2 Atrial flutter at a rate of about 230 bpm. Irregular ventricular response at a rate of about 80 bpm. Marked right-axis deviation and evidence of marked right ventricular hypertrophy in the precordial leads. Nonspecific repolarization changes. CLINICAL DX: Prior Mustard repair of TGA. Paroxysmal “atrial flutter.” Age 24.



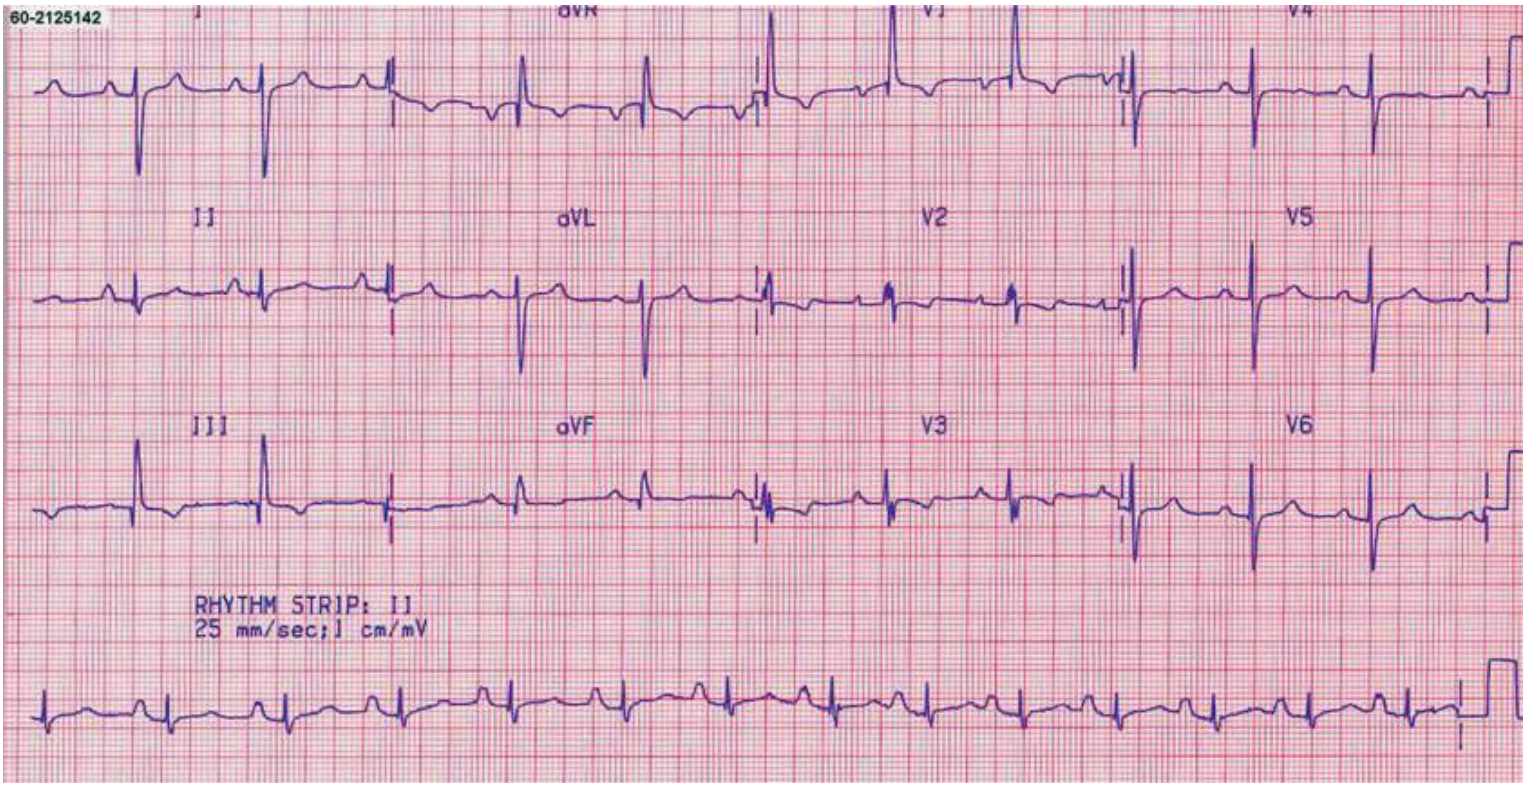
EAPPENDIX 75.3 Atrial rhythm. Mild right-axis deviation. Notching of the QRS in V_1 compatible with an ASD. CLINICAL DX: Prior patch closure of a sinus venosus ASD and partial anomalous pulmonary venous connection. Age 38.



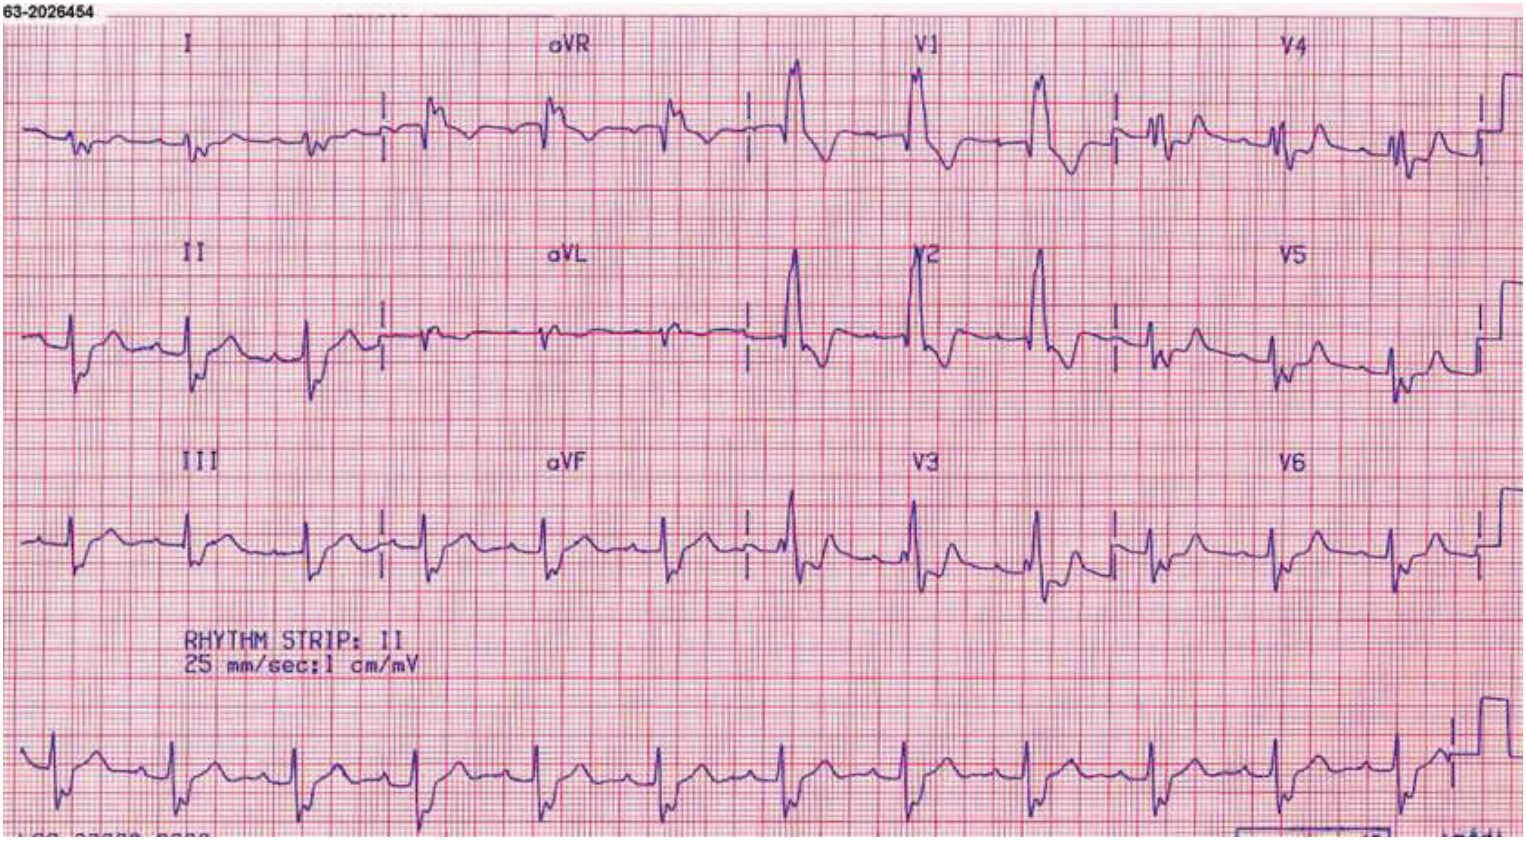
EAPPENDIX 75.4 Atrial fibrillation with an irregular ventricular rate of about 80 bpm. Mild right-axis deviation. Repolarization abnormalities in V_1 to V_5. One ventricular premature beat. CLINICAL DX: Ebstein anomaly. Chronic atrial fibrillation. Age 38.



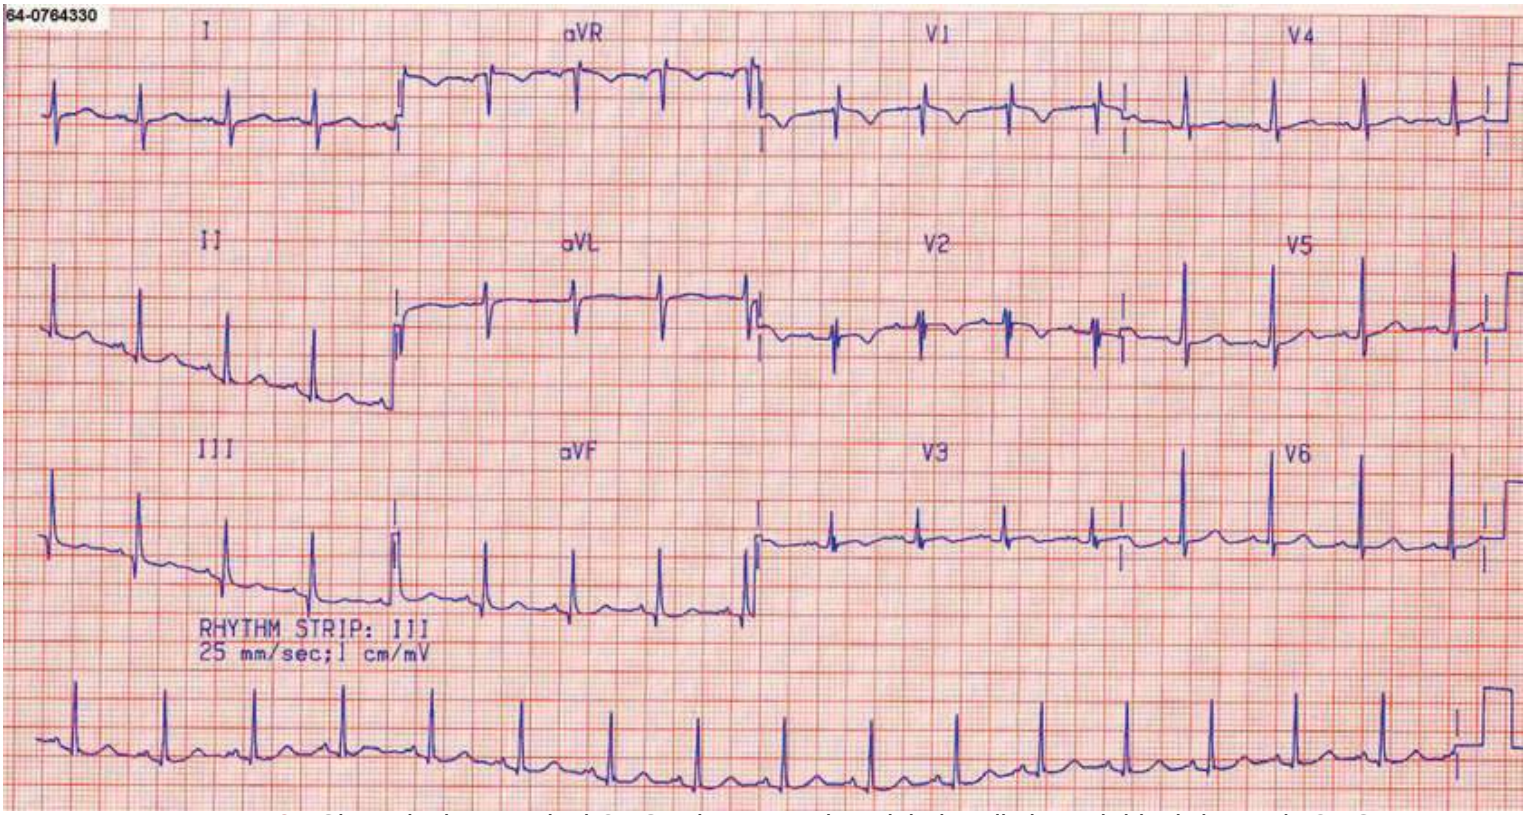
EAPPENDIX 75.5 Sinus rhythm. Marked right-axis deviation. V_1 pattern suggestive of right ventricular volume overload. Widespread nonspecific repolarization abnormalities. CLINICAL DX: Ebstein anomaly. Paroxysmal atrial flutter. Age 20.



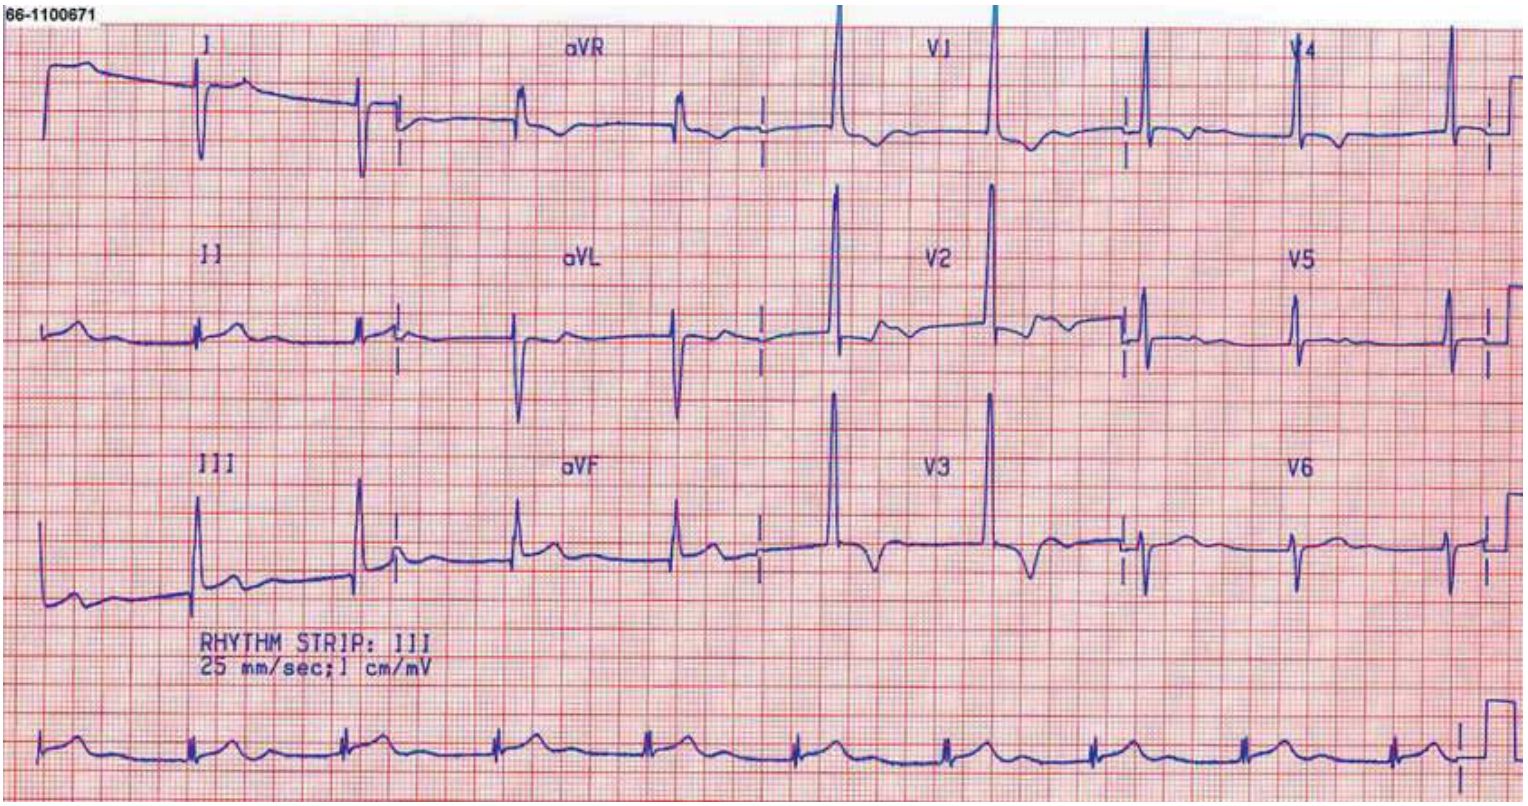
EAPPENDIX 75.6 Sinus rhythm. Possible right atrial overload. Marked right-axis deviation. Marked right ventricular hypertrophy with a strain pattern in V_1 to V_3. CLINICAL DX: Eisenmenger syndrome. Complete unrepaired AV septal defect. Down syndrome. Age 30.



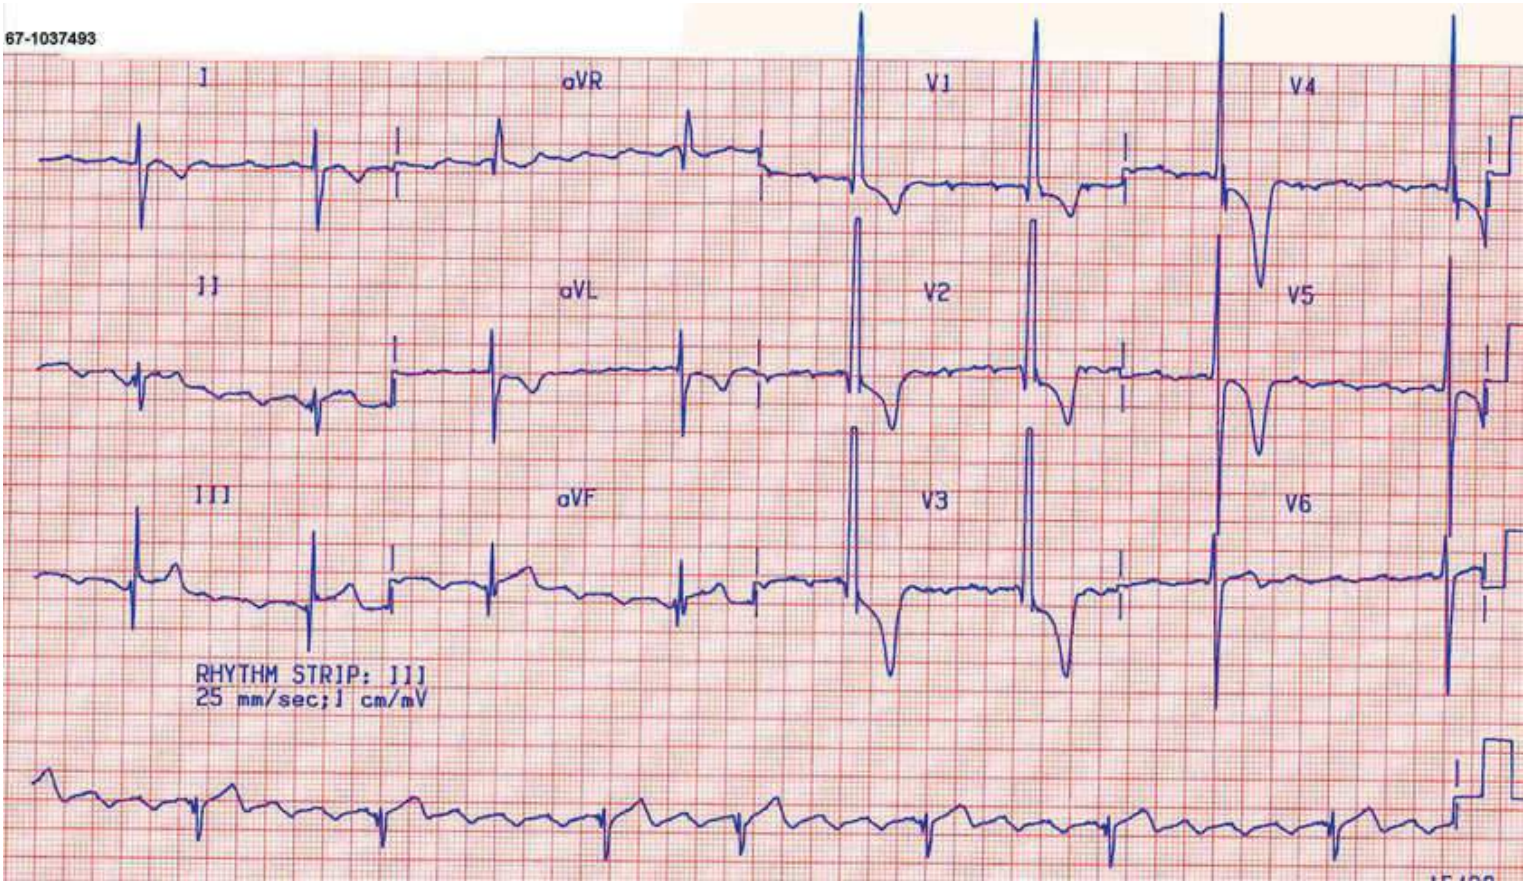
EAPPENDIX 75.7 Sinus rhythm. Borderline first-degree block. Left-axis deviation of initial forces. Complete right bundle branch block (RBBB) with a wide QRS complex approaching 200 ms. CLINICAL DX: Repaired tetralogy with a bioprosthetic pulmonary valve replacement for severe pulmonary regurgitation. Age 32.



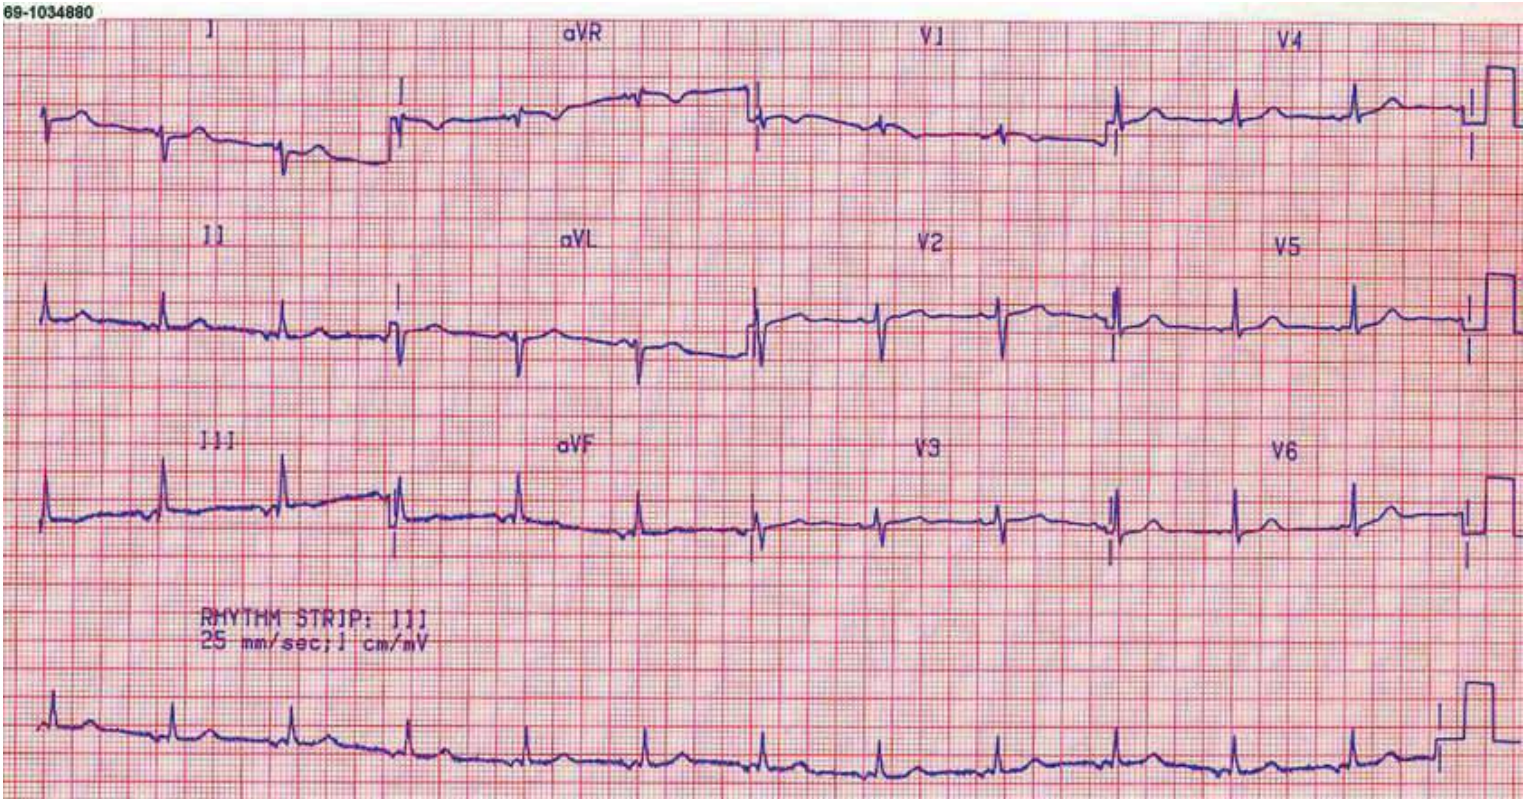
EAPPENDIX 75.8 Sinus rhythm. Vertical QRS axis. Incomplete right bundle branch block (RBBB). QRS notching in V_2. CLINICAL DX: Postoperative secundum ASD repair. Age 21.



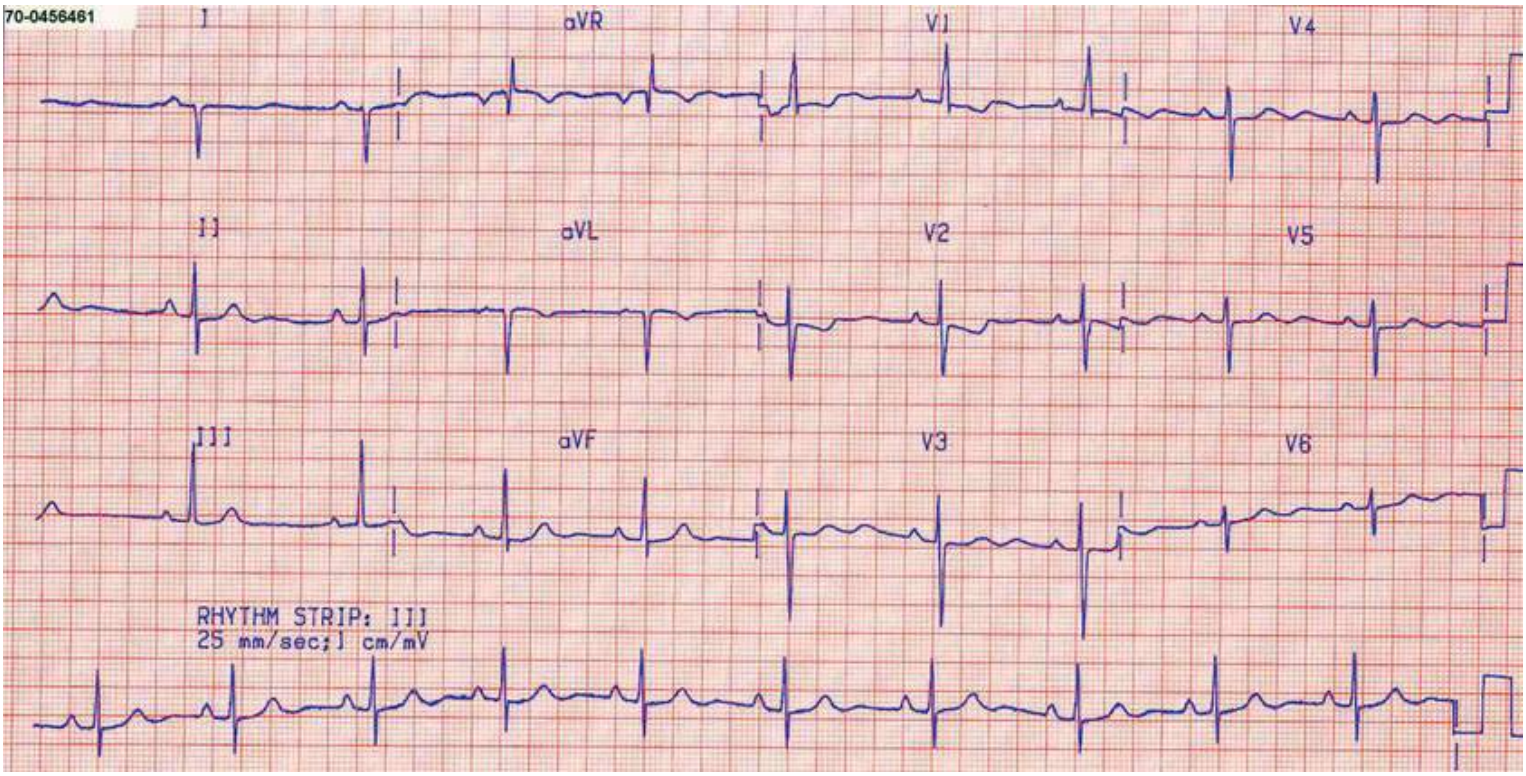
EAPPENDIX 75.9 Junctional rhythm at about 50 bpm. Marked right-axis deviation. Marked right ventricular hypertrophy (RVH) with strain. CLINICAL DX: Mustard repair of TGA. Age 19.



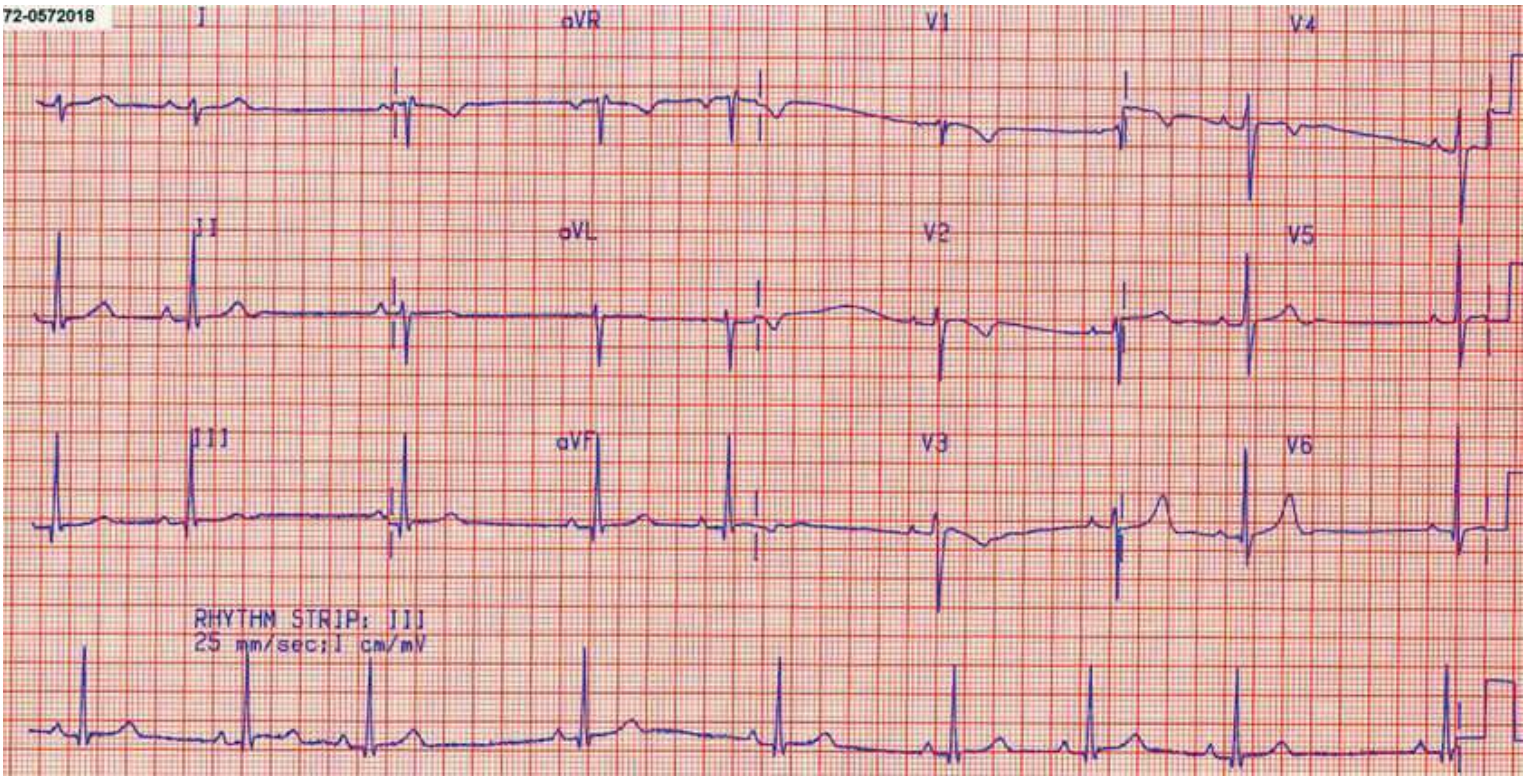
EAPPENDIX 75.10 Atrial flutter with an atrial rate of about 200 bpm and a ventricular rate of about 50 bpm. Marked right-axis deviation. Marked right ventricular hypertrophy (RVH) with strain. CLINICAL DX: Mustard repair of TGA. Age 20.



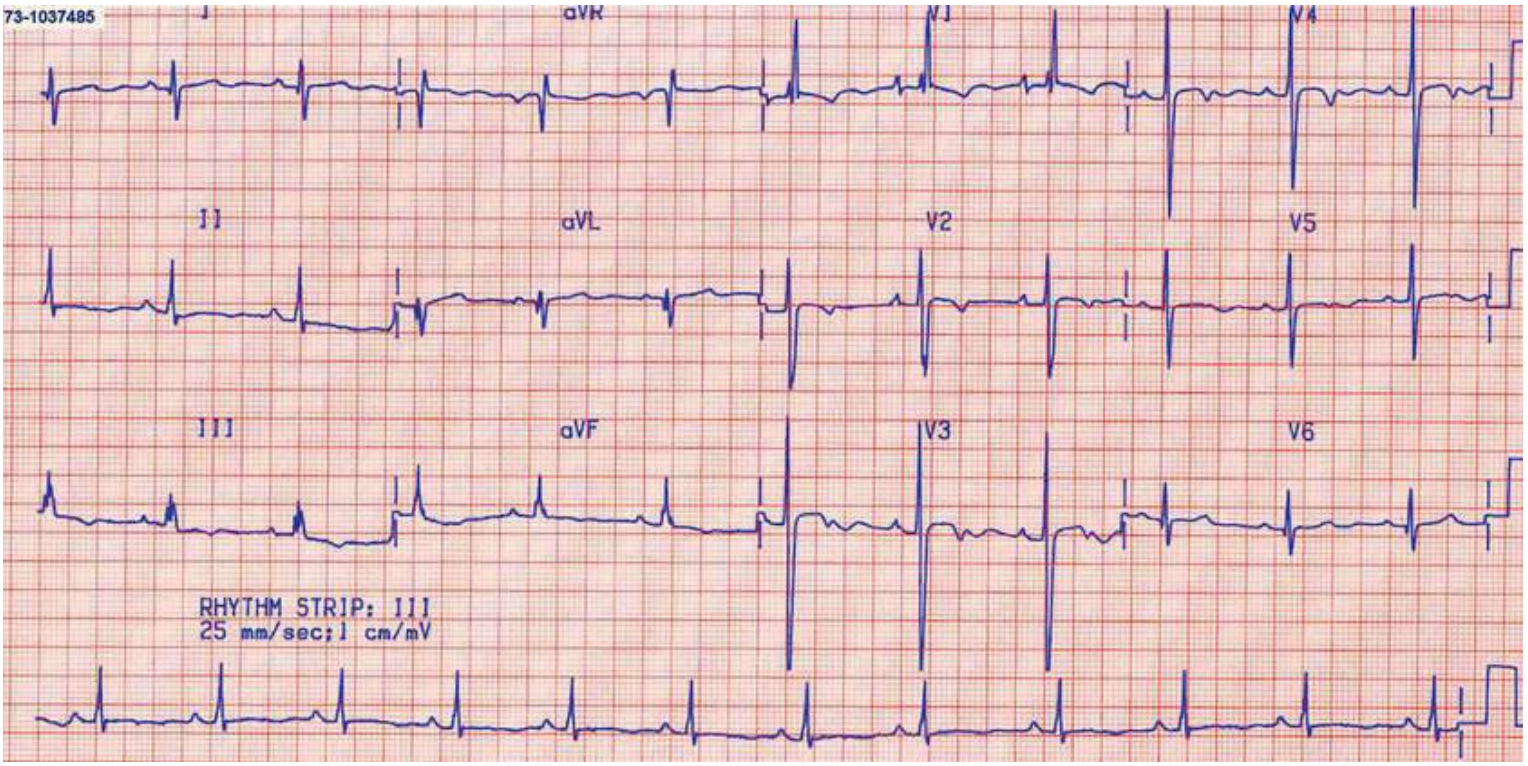
EAPPENDIX 75.11 Atrial rhythm. Moderate right-axis deviation. CLINICAL DX: Repaired sinus venosus ASD and PAPVD. Age 34.



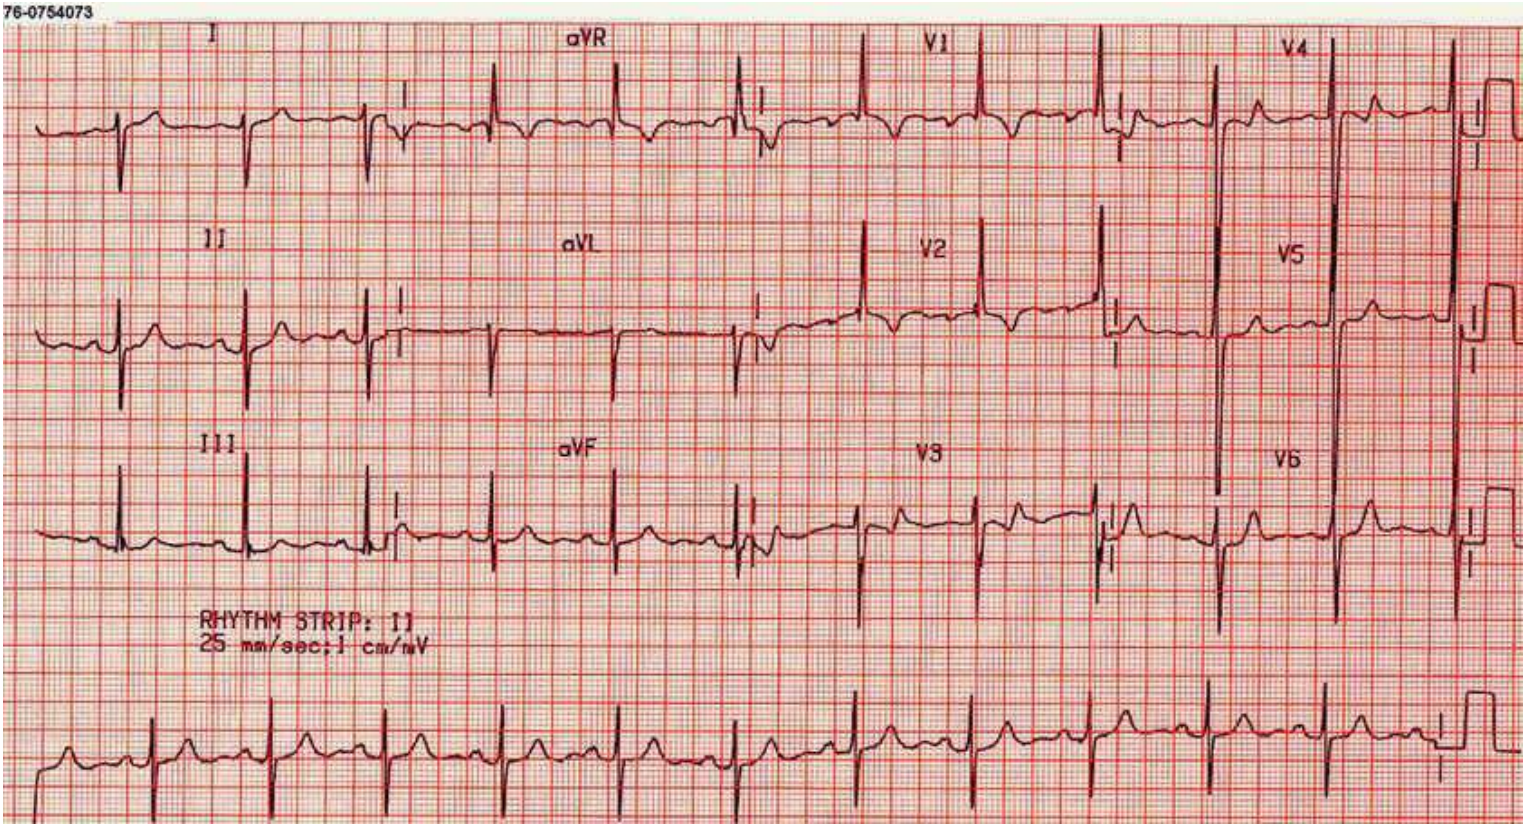
EAPPENDIX 75.12 Sinus bradycardia. Marked right-axis deviation. Voltage evidence of right ventricular hypertrophy (RVH) with strain. CLINICAL DX: Eisenmenger VSD, age 30.



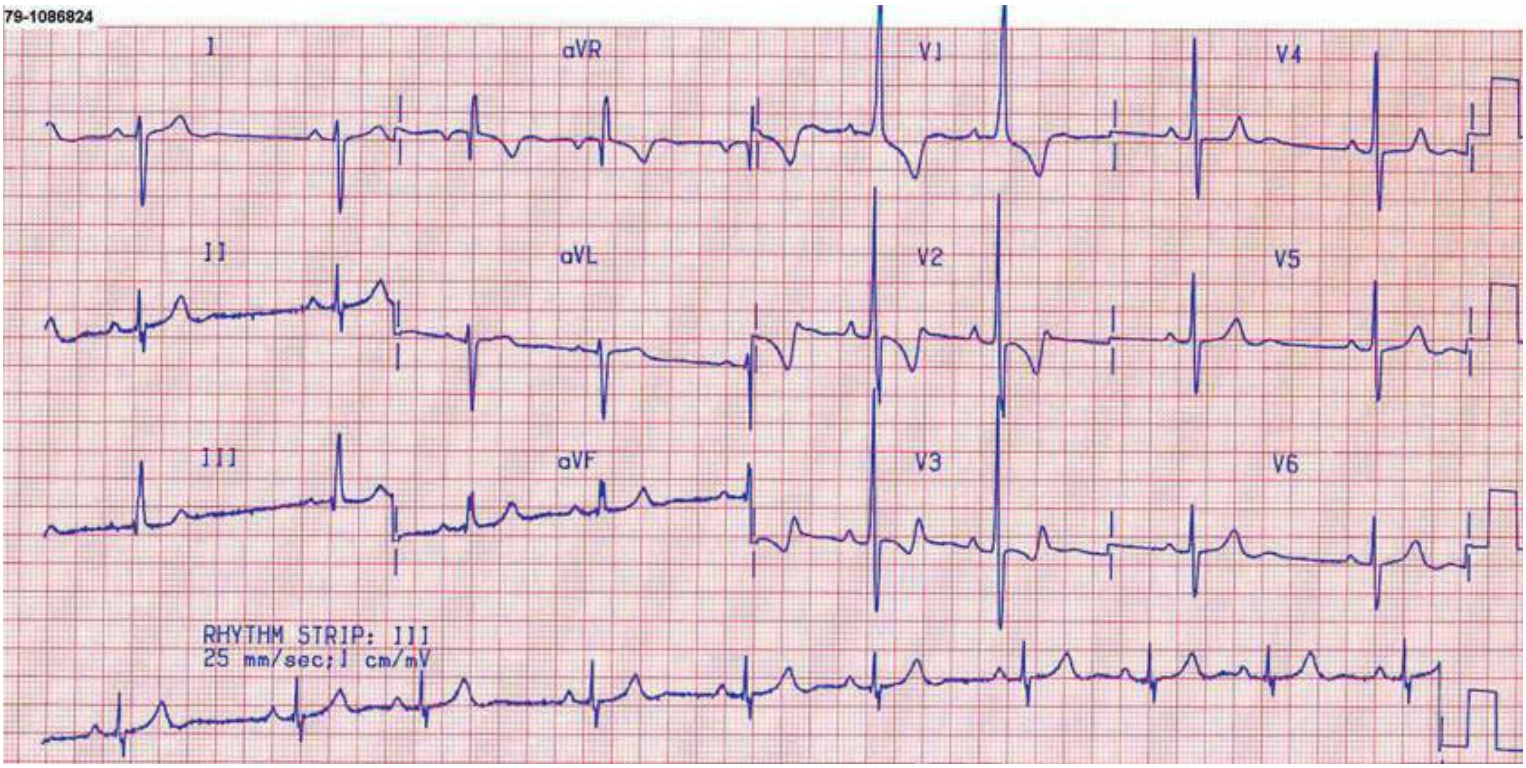
EAPPENDIX 75.13 Sinus rhythm with sinus arrhythmia. Very mild right-axis deviation. QRS notching in V_1. T inversion in V_1 to V_4. CLINICAL DX: Small secundum ASD. Age 22.



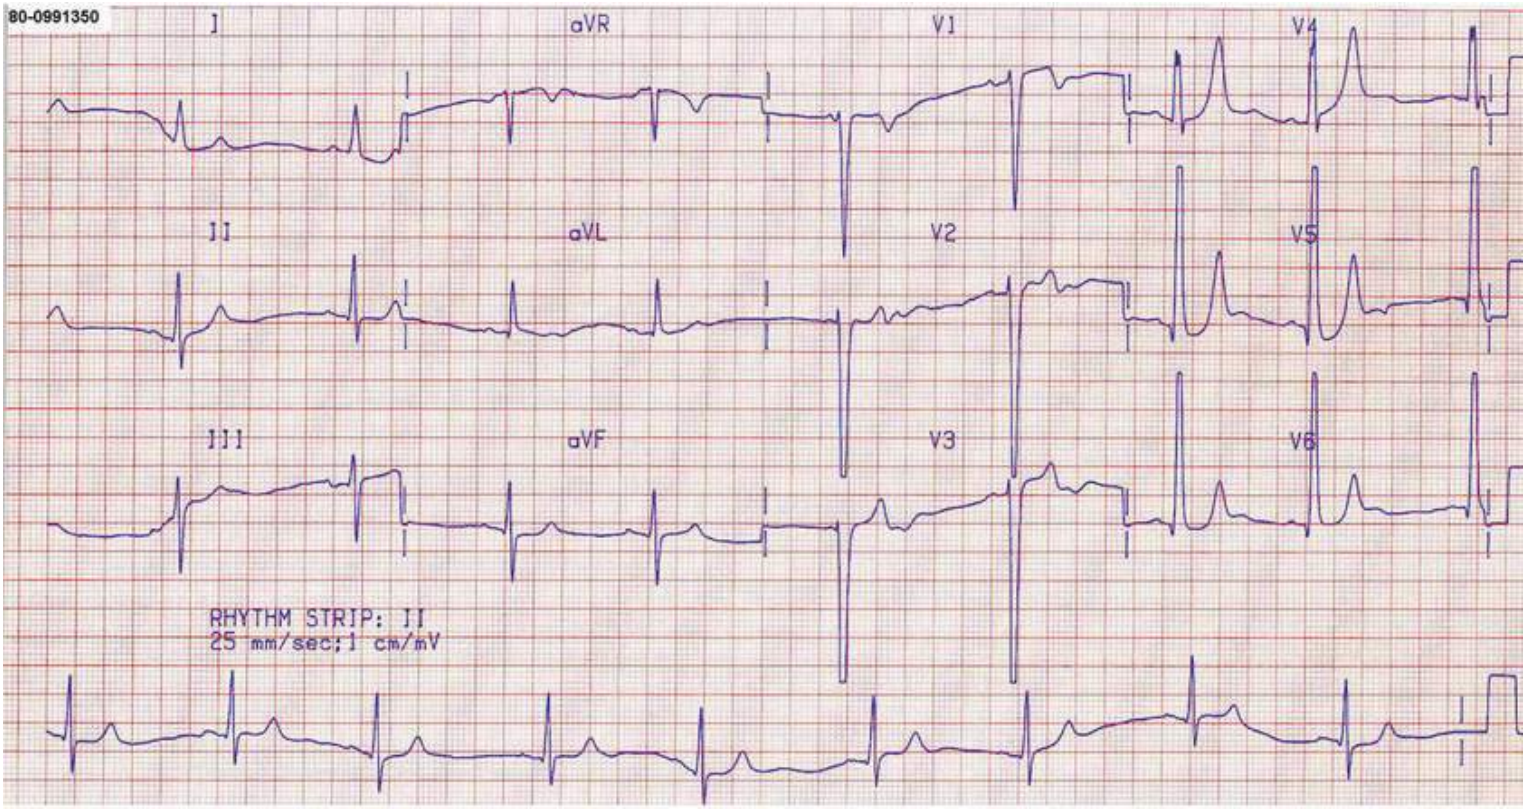
EAPPENDIX 75.14 Sinus rhythm. Mild right-axis deviation. Right atrial overload in V_1. Voltage evidence of right ventricular hypertrophy (RVH) with some strain. CLINICAL DX: Unrepaired tetralogy. Age 22.



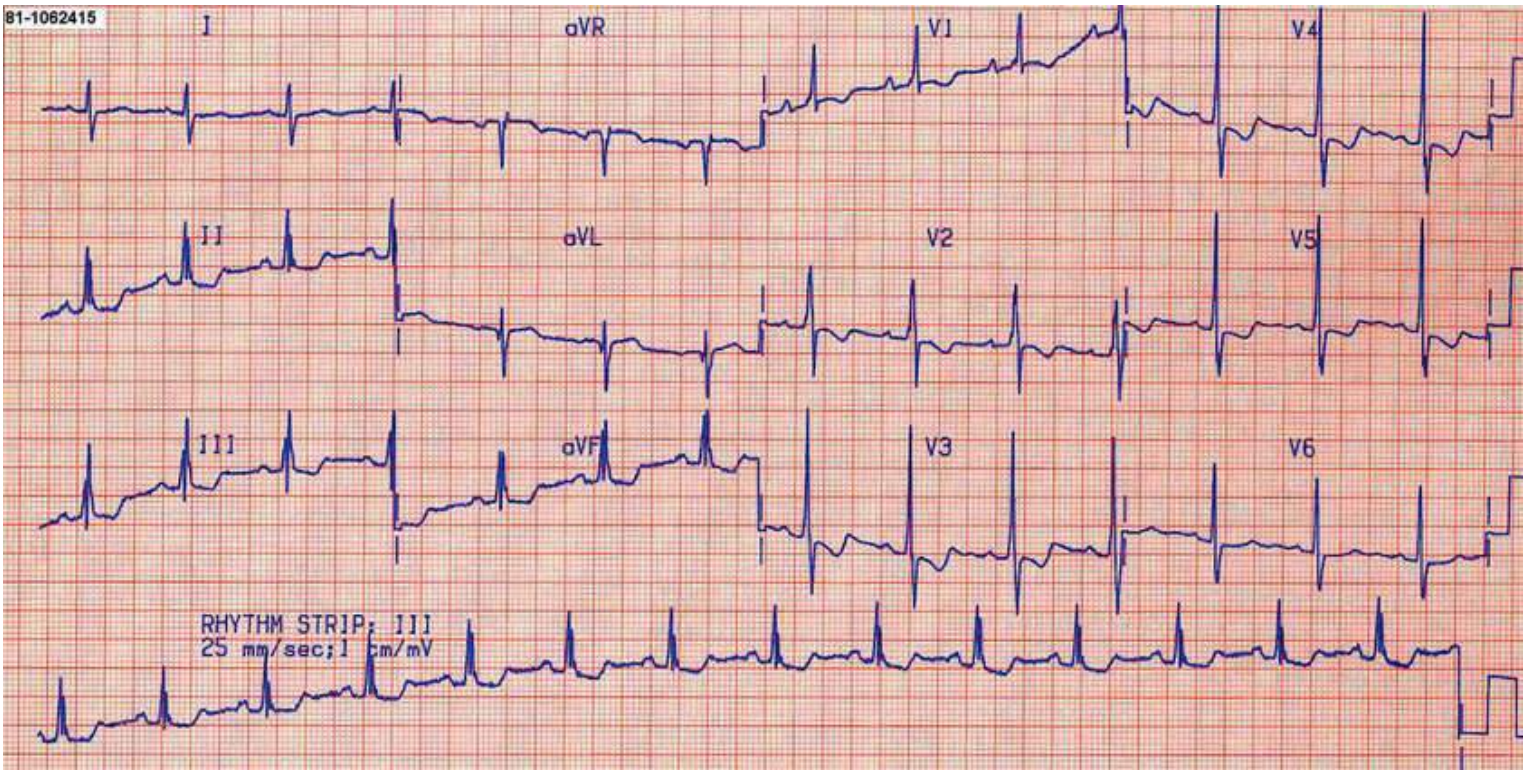
EAPPENDIX 75.15 Sinus rhythm. Indeterminate QRS axis. Marked right ventricular hypertrophy (RVH) with strain. CLINICAL DX: Mustard repair of complete TGA. Age 22.



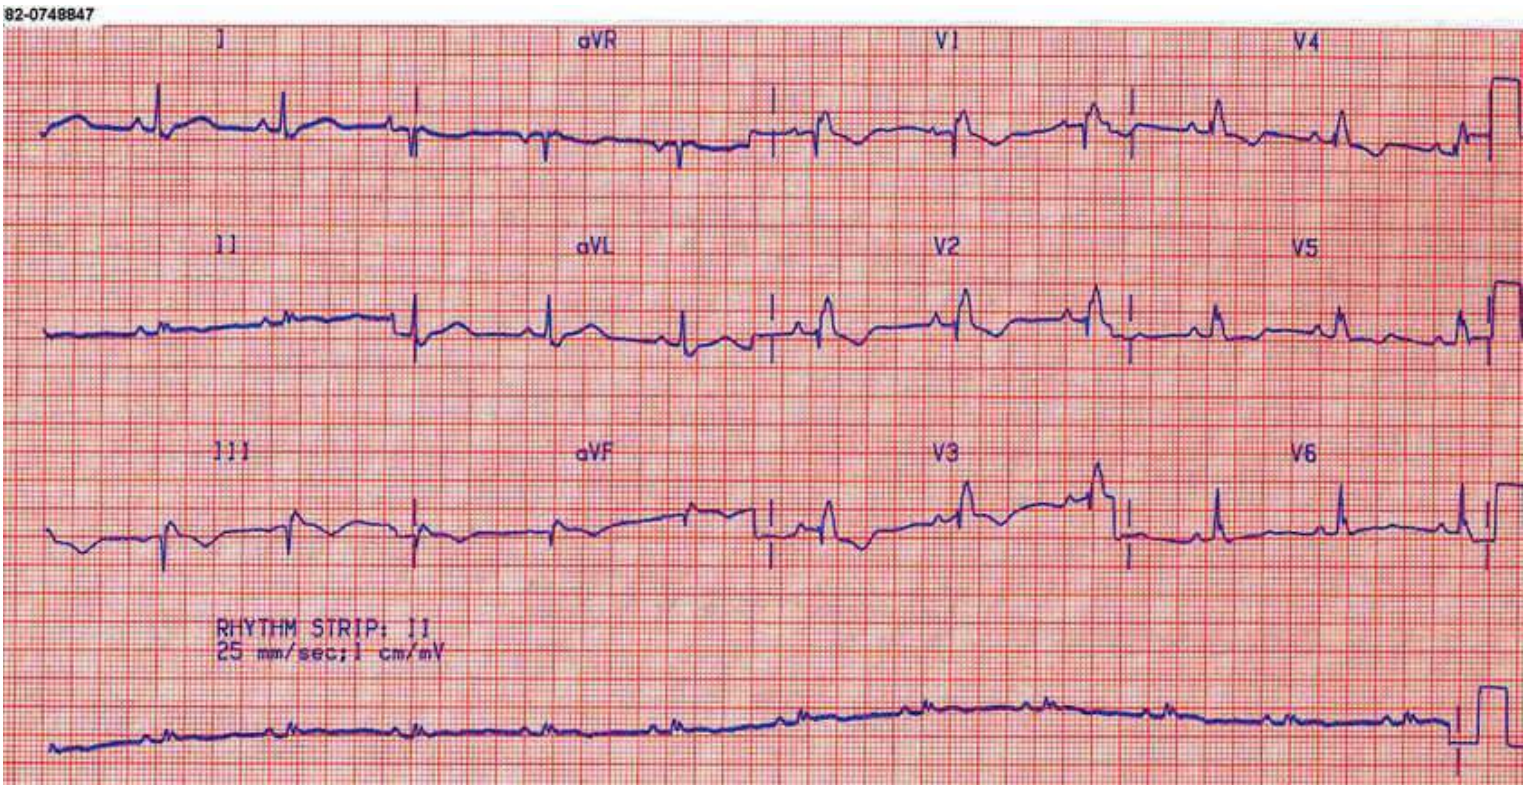
EAPPENDIX 75.16 Sinus rhythm. Marked right-axis deviation. Marked voltage evidence of right ventricular hypertrophy (RVH) with strain. CLINICAL DX: Eisenmenger VSD, age 27.



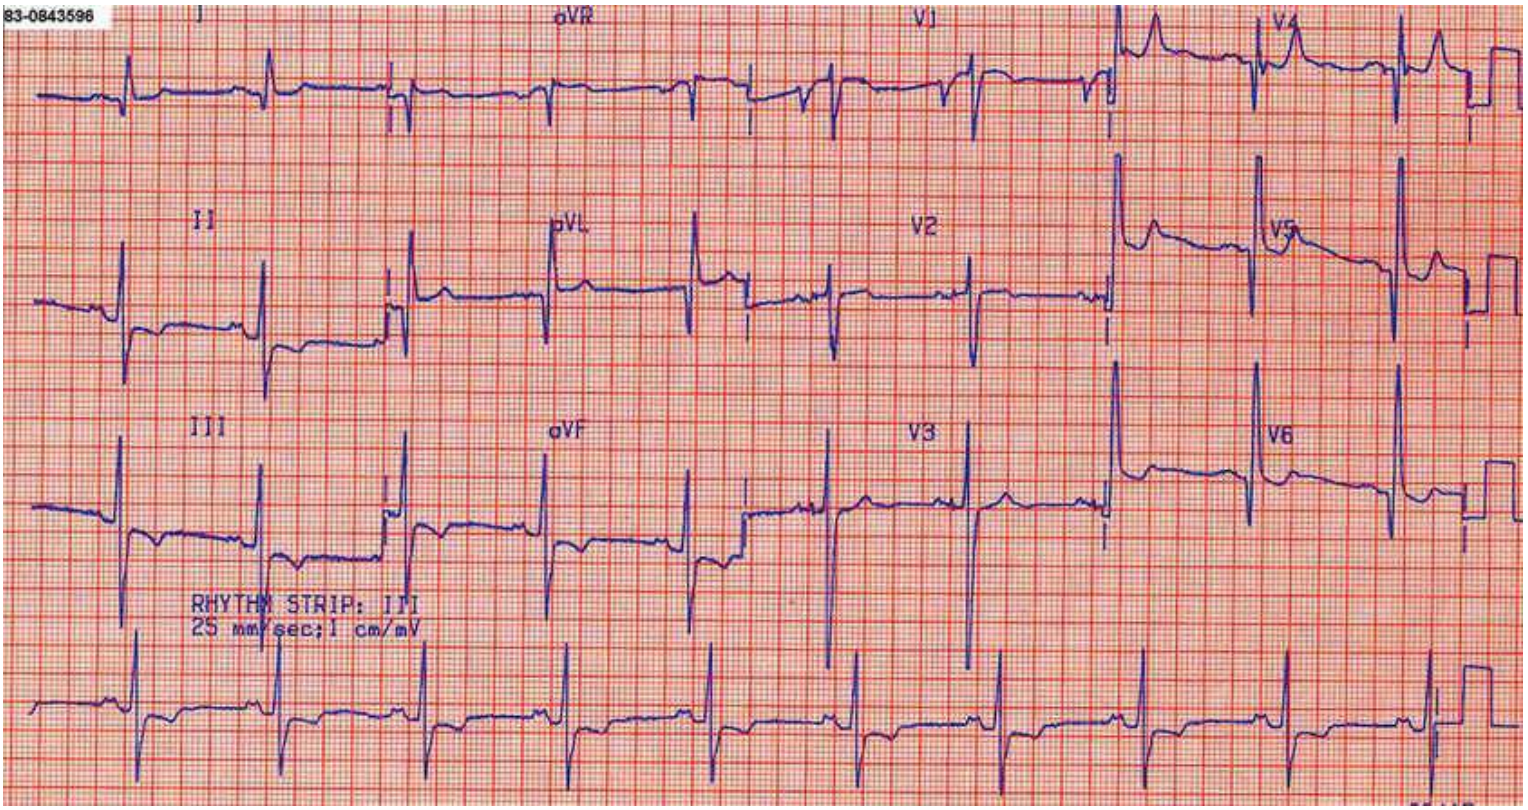
EAPPENDIX 75.17 Sinus rhythm. Voltage evidence of left ventricular hypertrophy (LVH) with QRS prolongation. Somewhat prominent Q waves in V_5 to V_6, with tall T waves in the left chest leads. CLINICAL DX: Severe aortic regurgitation. Age 20.



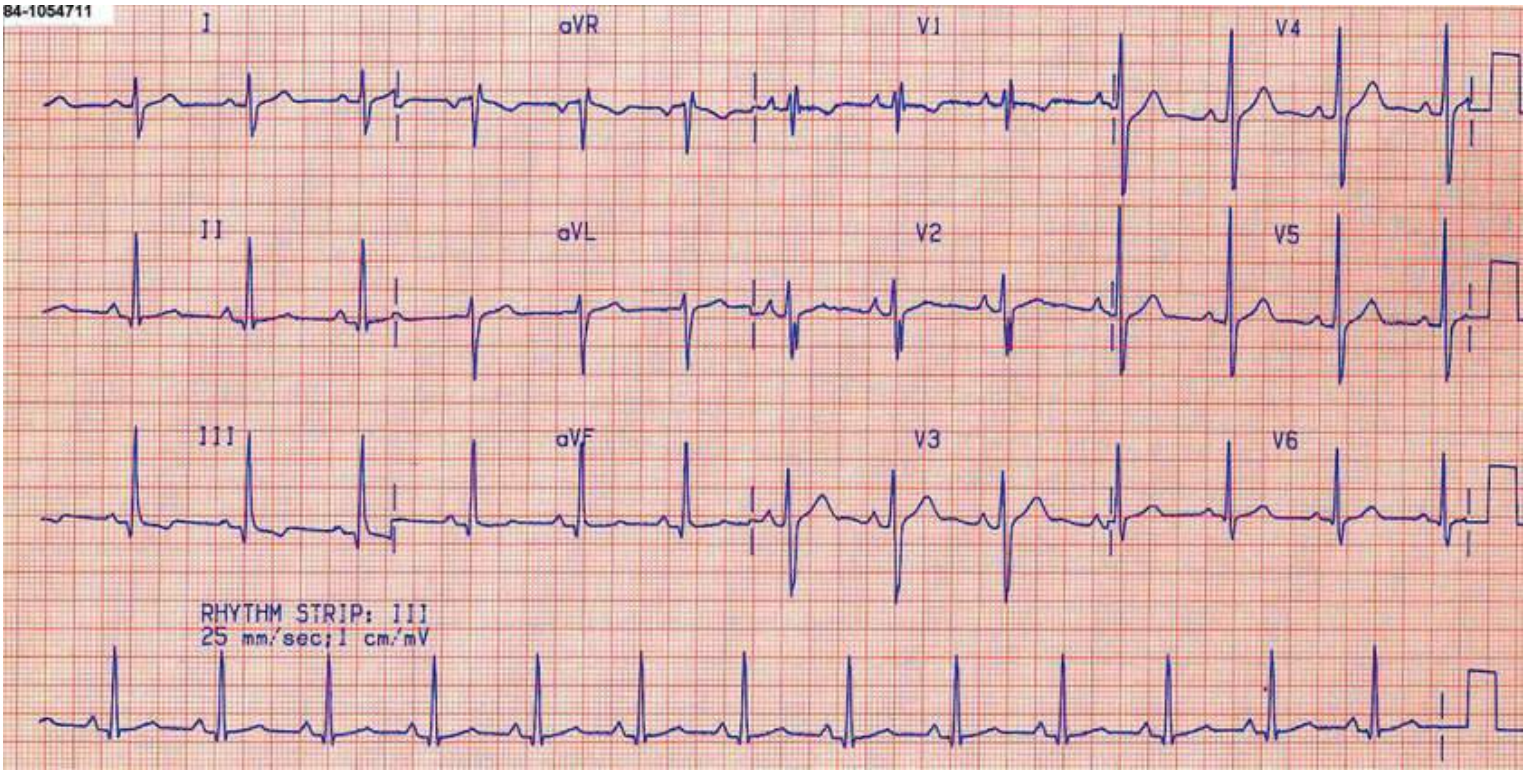
EAPPENDIX 75.18 Sinus rhythm. Slight right-axis deviation. Q wave of 9 mm in V_1 indicative of RVH with an extensive right ventricular strain pattern. Nonspecific repolarization changes in the inferior leads. CLINICAL DX: Unrepaired secundum ASD with modest pulmonary hypertension. Age 58.



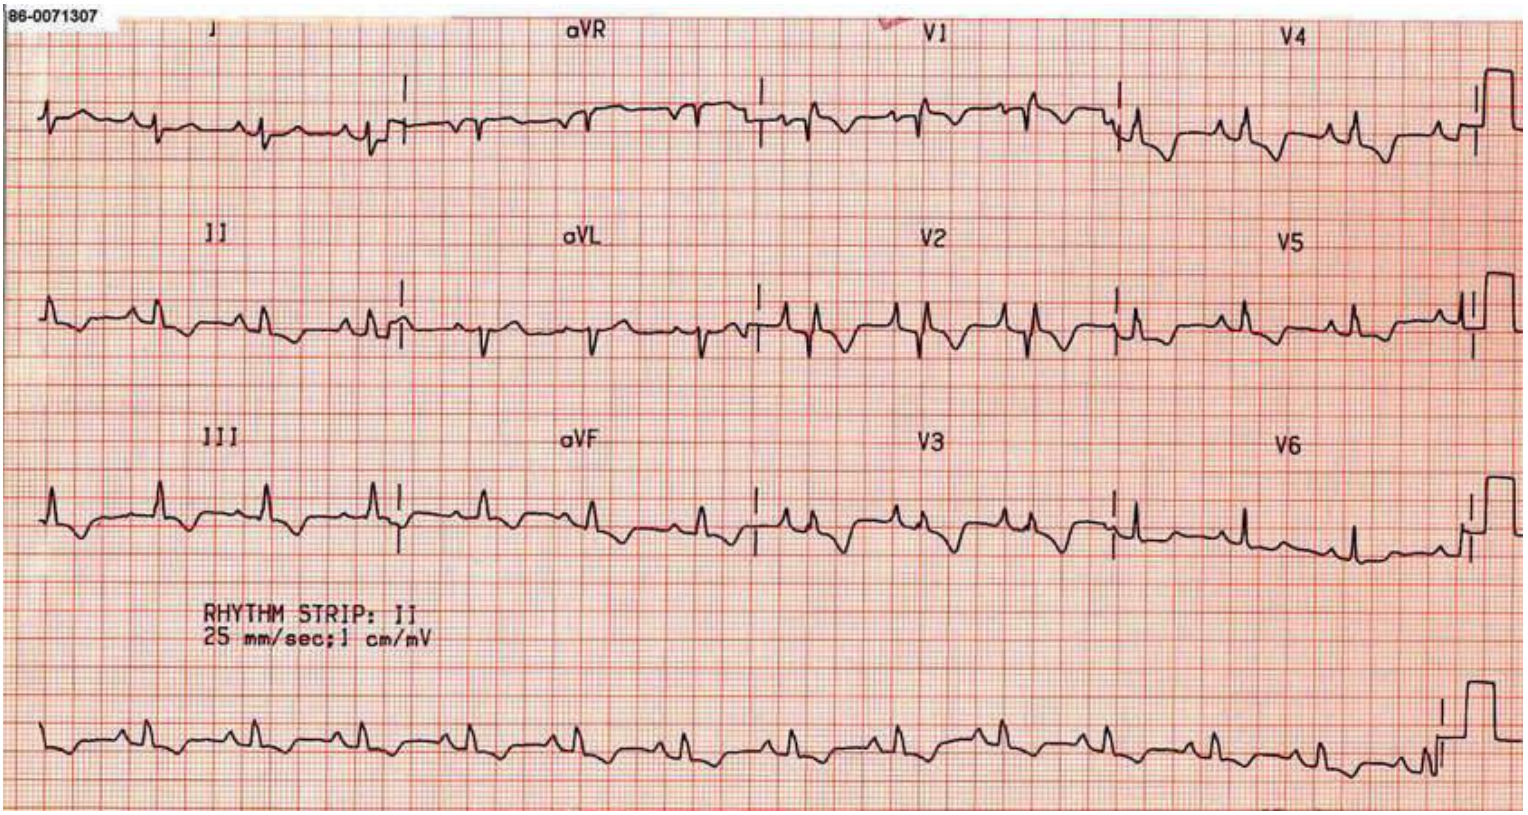
EAPPENDIX 75.19 Sinus rhythm. Leftward axis. Complete RBBB. CLINICAL DX: Repaired Ebstein anomaly. Age 26.



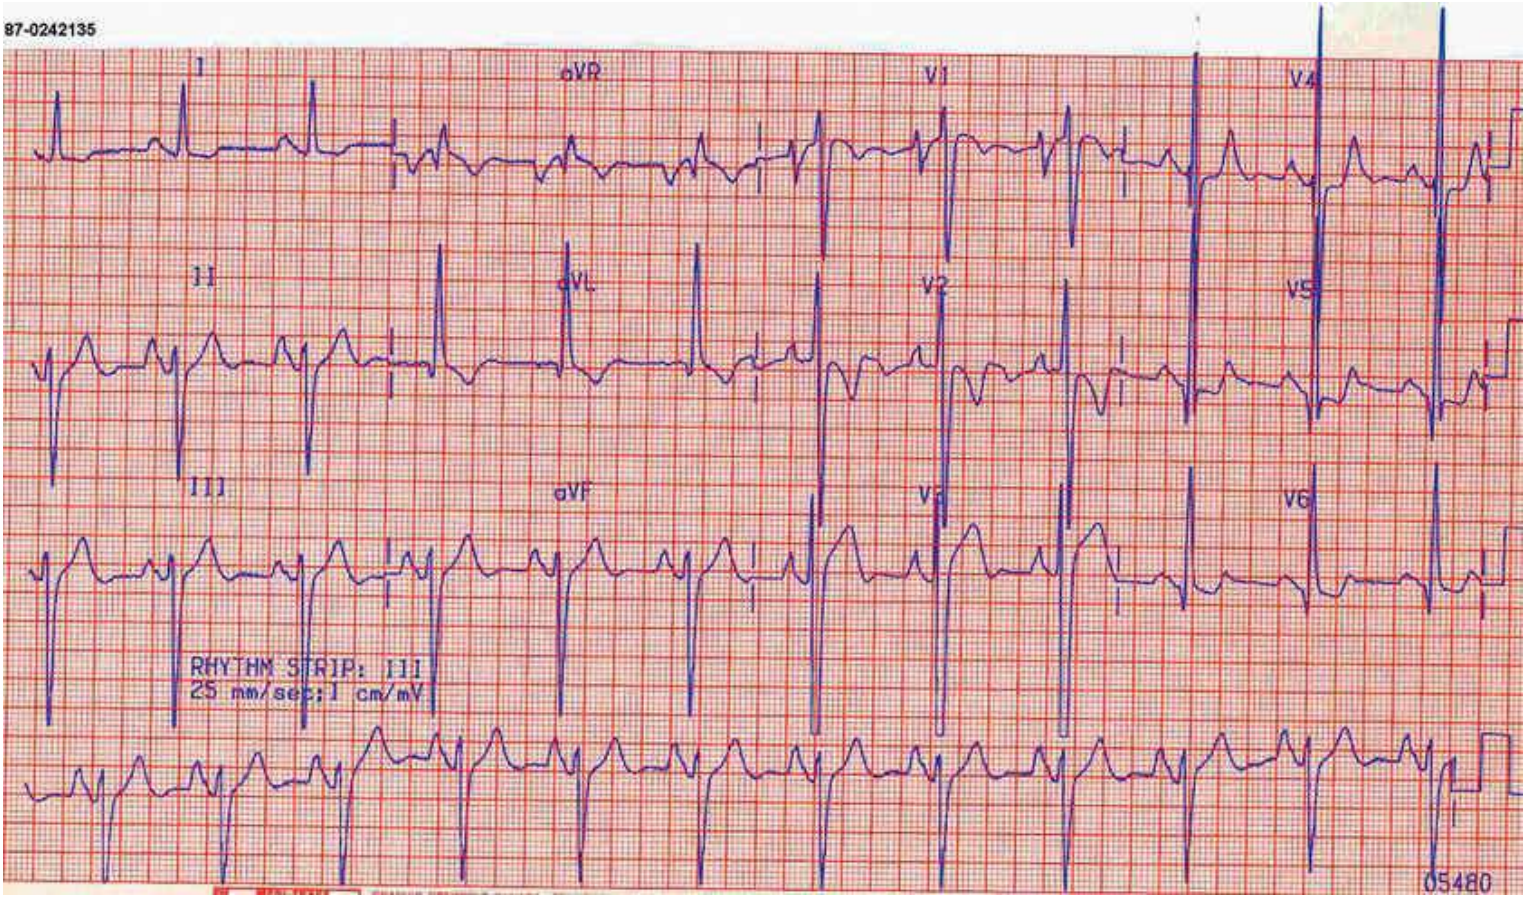
EAPPENDIX 75.20 Sinus rhythm with both right and left atrial overload. Left-axis deviation. Deep Q waves in V_4 to V_6 compatible with left ventricular volume overload in a young person. Repolarization abnormalities. CLINICAL DX: Tricuspid atresia and pulmonary stenosis palliated with a Blalock-Taussig-Thomas shunt. Age 31.



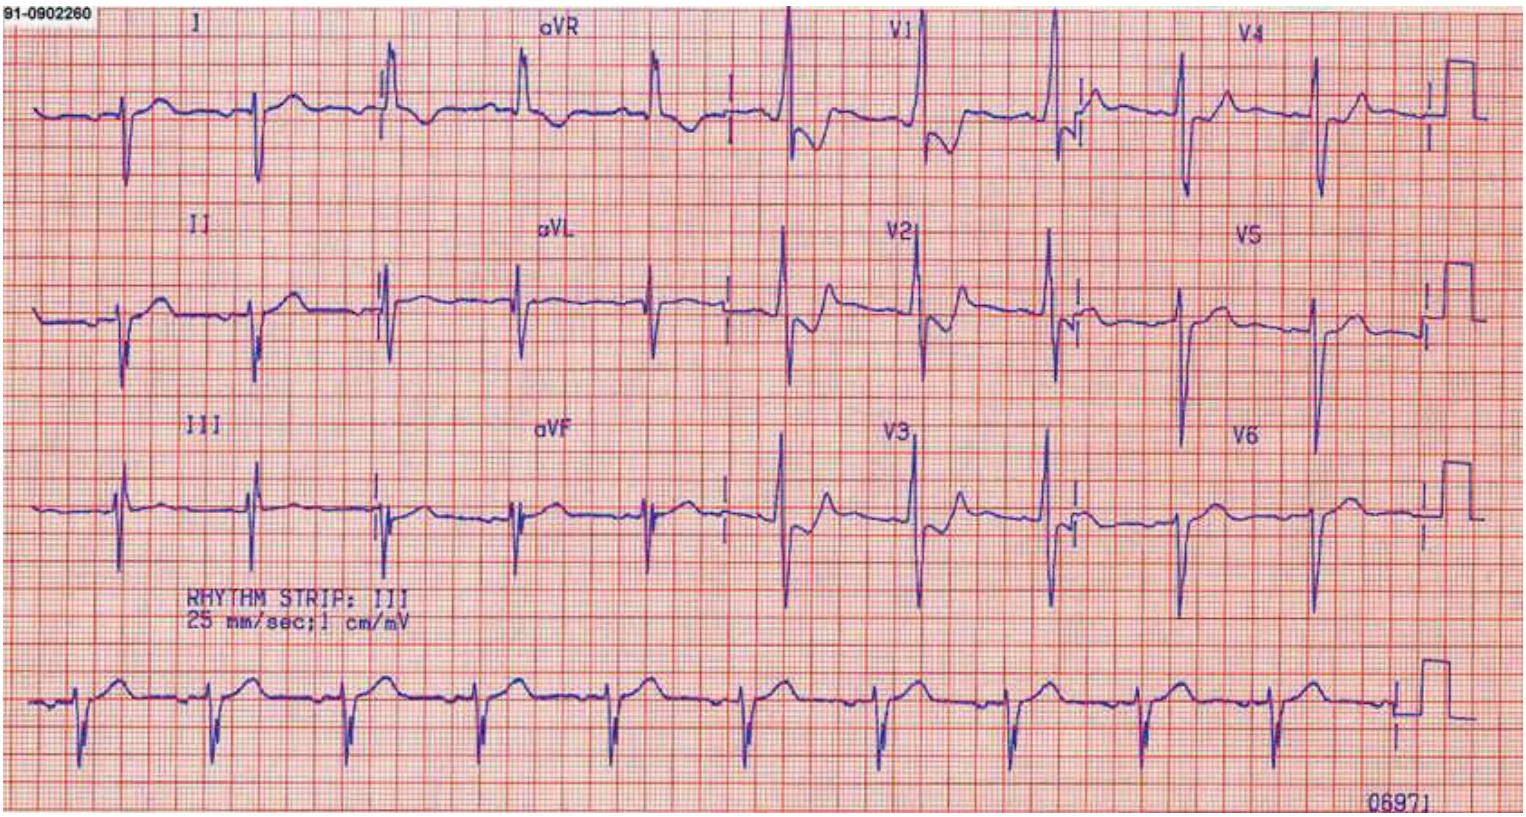
EAPPENDIX 75.21 Sinus rhythm. Mild right-axis deviation. Incomplete RBBB with notching of the QRS complex in leads V_1 and V_2. Mild right atrial overload. CLINICAL DX: Repaired secundum ASD. Age 22.



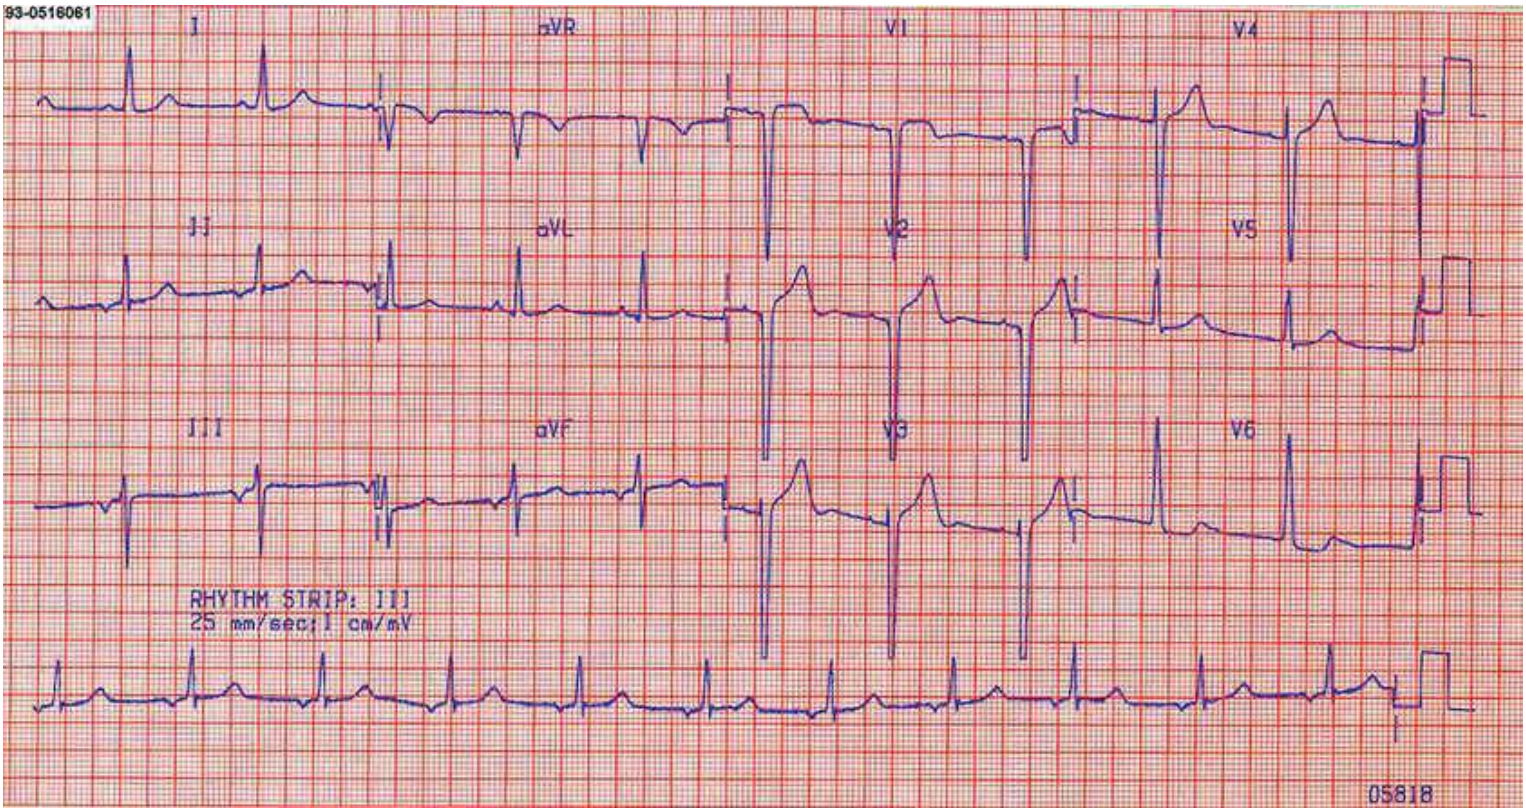
EAPPENDIX 75.22 Sinus rhythm. Right atrial overload most notable in the precordial leads. Low QRS voltage. Incomplete RBBB with a widespread right ventricular strain pattern. CLINICAL DX: Ebstein anomaly. Age 38.



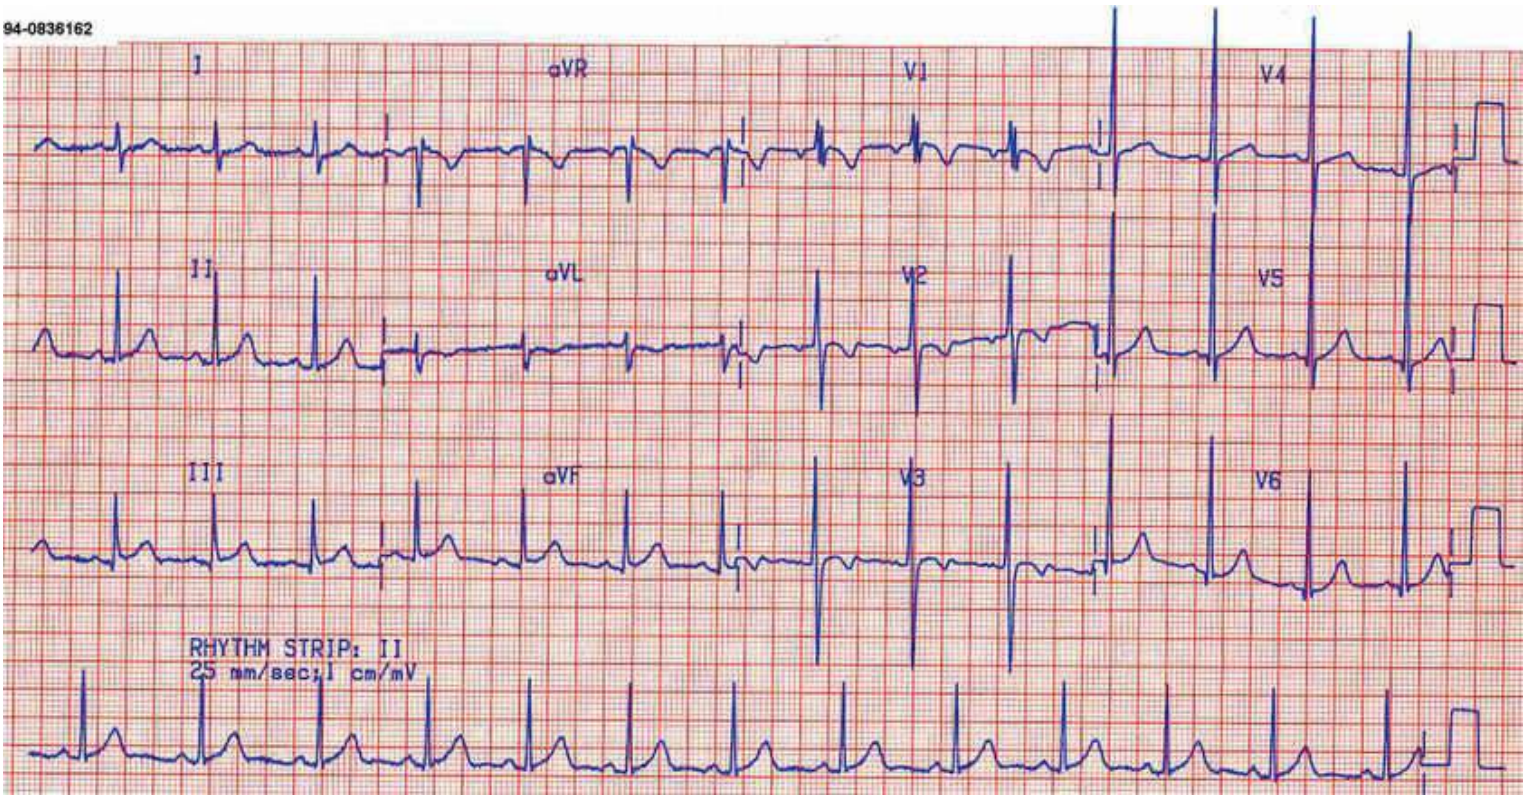
EAPPENDIX 75.23 Sinus rhythm. Left and right atrial overload. Left-axis deviation. Left ventricular hypertrophy. CLINICAL DX: Tricuspid atresia palliated by Blalock-Taussig-Thomas shunts. Age 33.



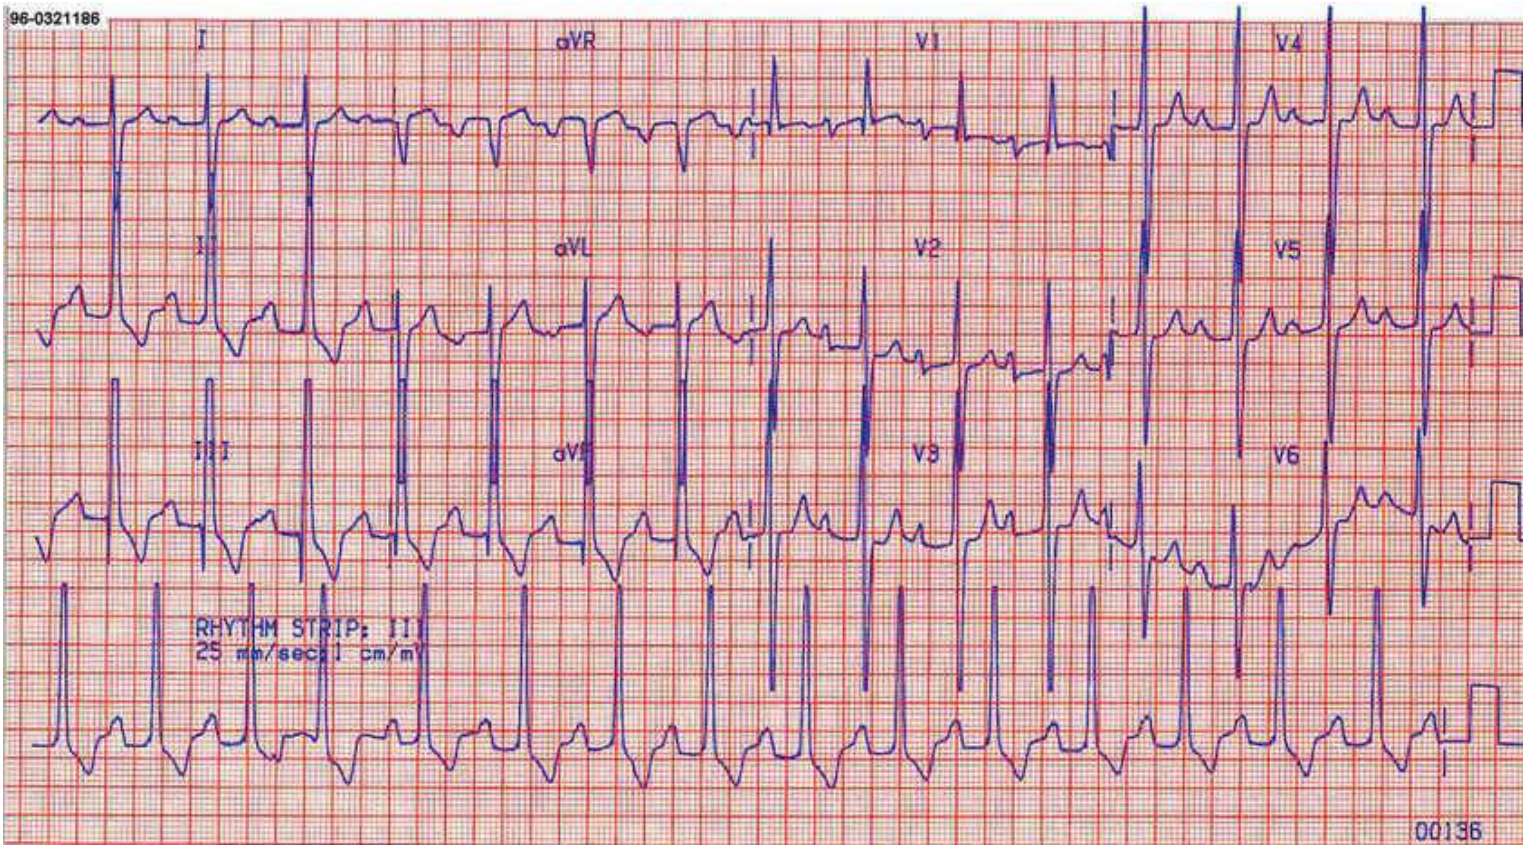
EAPPENDIX 75.24 Atrial rhythm. Left-axis deviation. RVH with strain. CLINICAL DX: Complete AV septal defect with pulmonary stenosis. Still cyanotic, palliated by a cavopulmonary shunt and a Blalock-Taussig-Thomas shunt. Age 19.



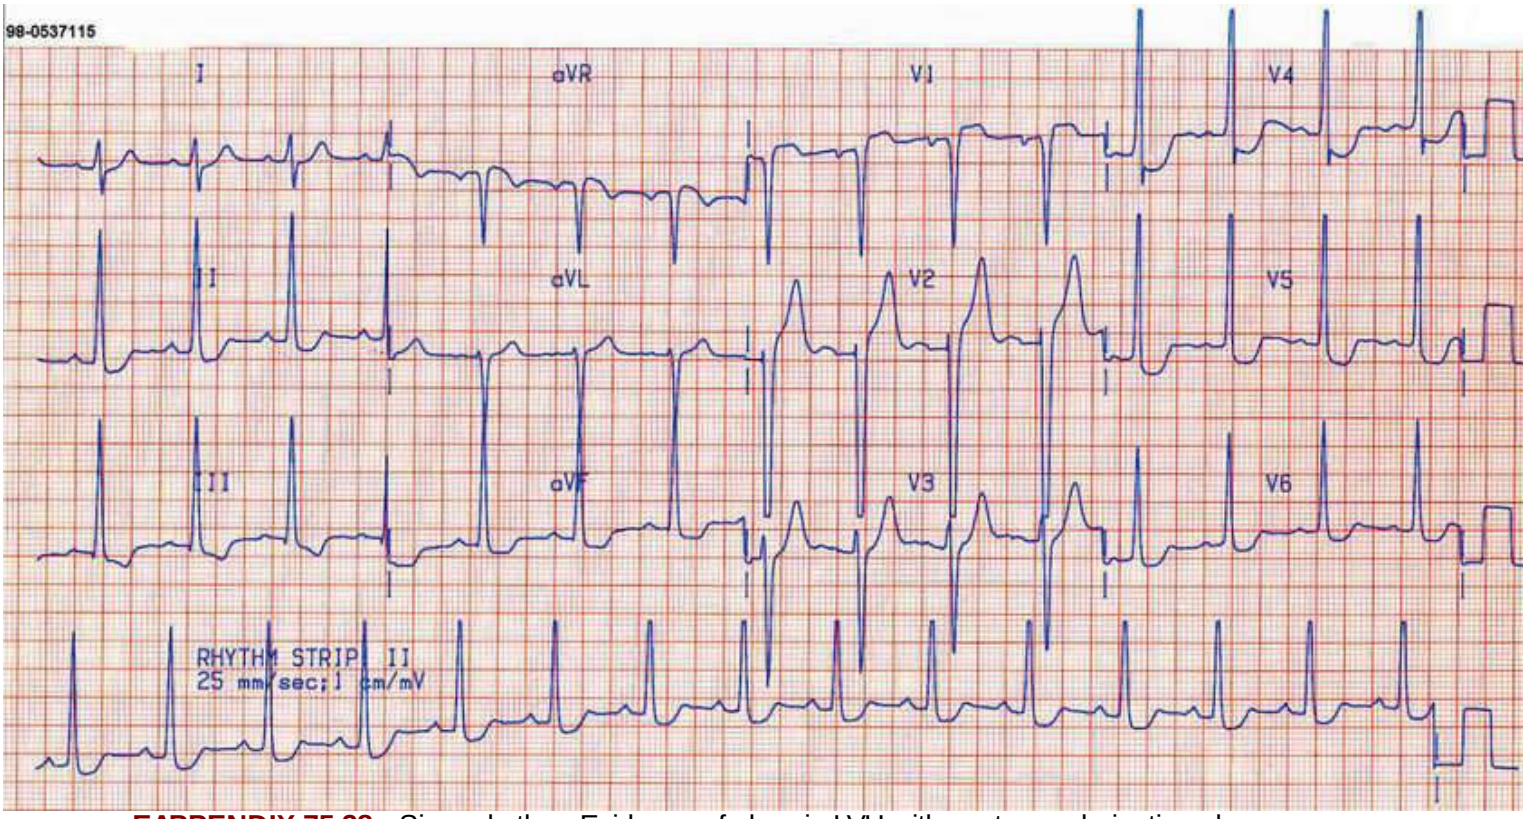
EAPPENDIX 75.25 Atrial rhythm. Incomplete LBBB reflecting LVH with Q waves in V_1 and V_2 and absent Q waves in the left chest leads. CLINICAL DX: Prior repair of coarctation and fibromuscular subaortic stenosis. Age 19.



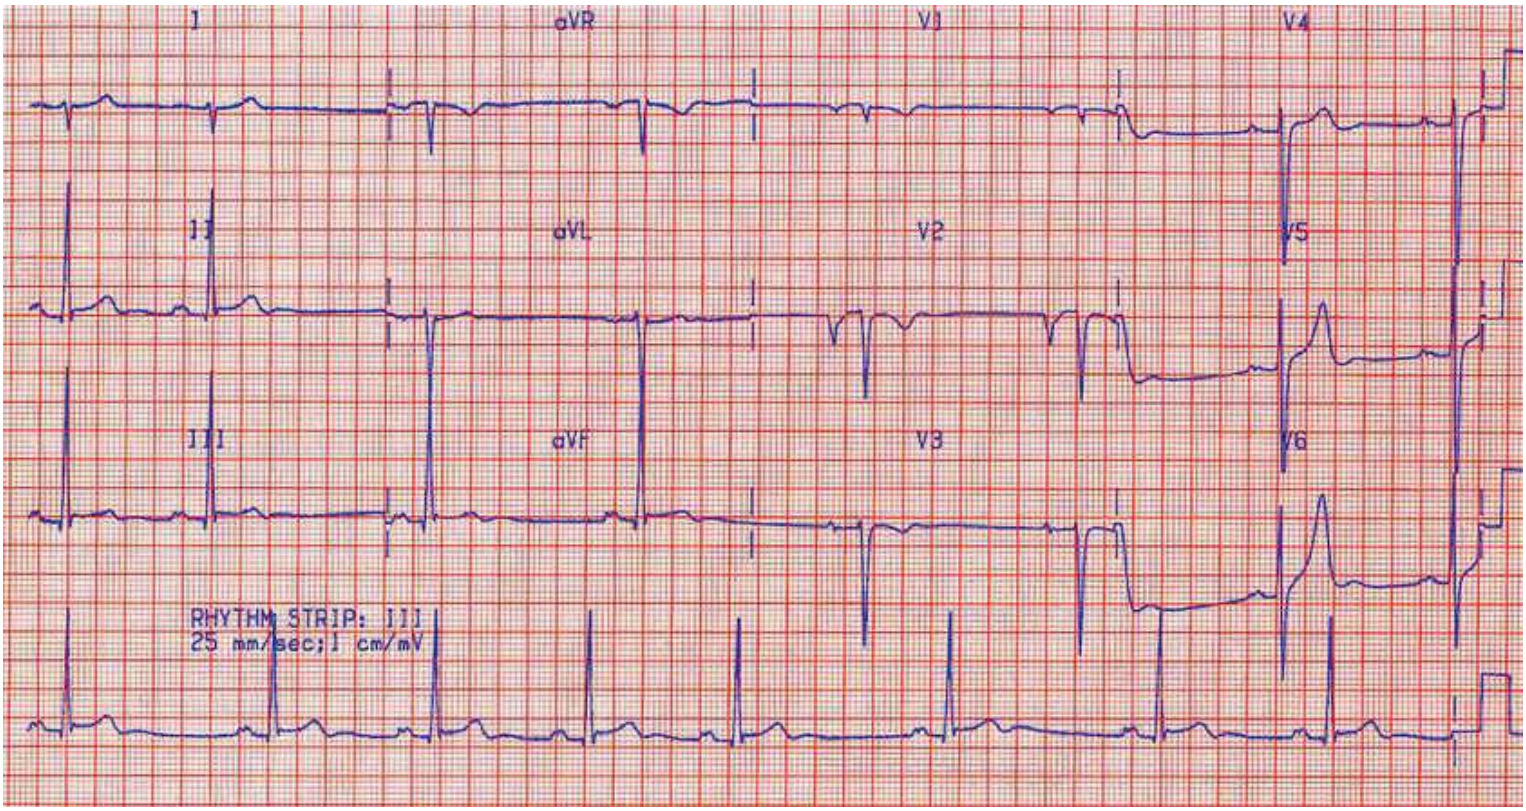
EAPPENDIX 75.26 Sinus rhythm. Normal QRS axis. Prominent R waves in V_1 or with QRS notching. T wave inversion in V_1 to V_3 possibly reflecting "RV strain." CLINICAL DX: Unrepaired secundum ASD, age 19.



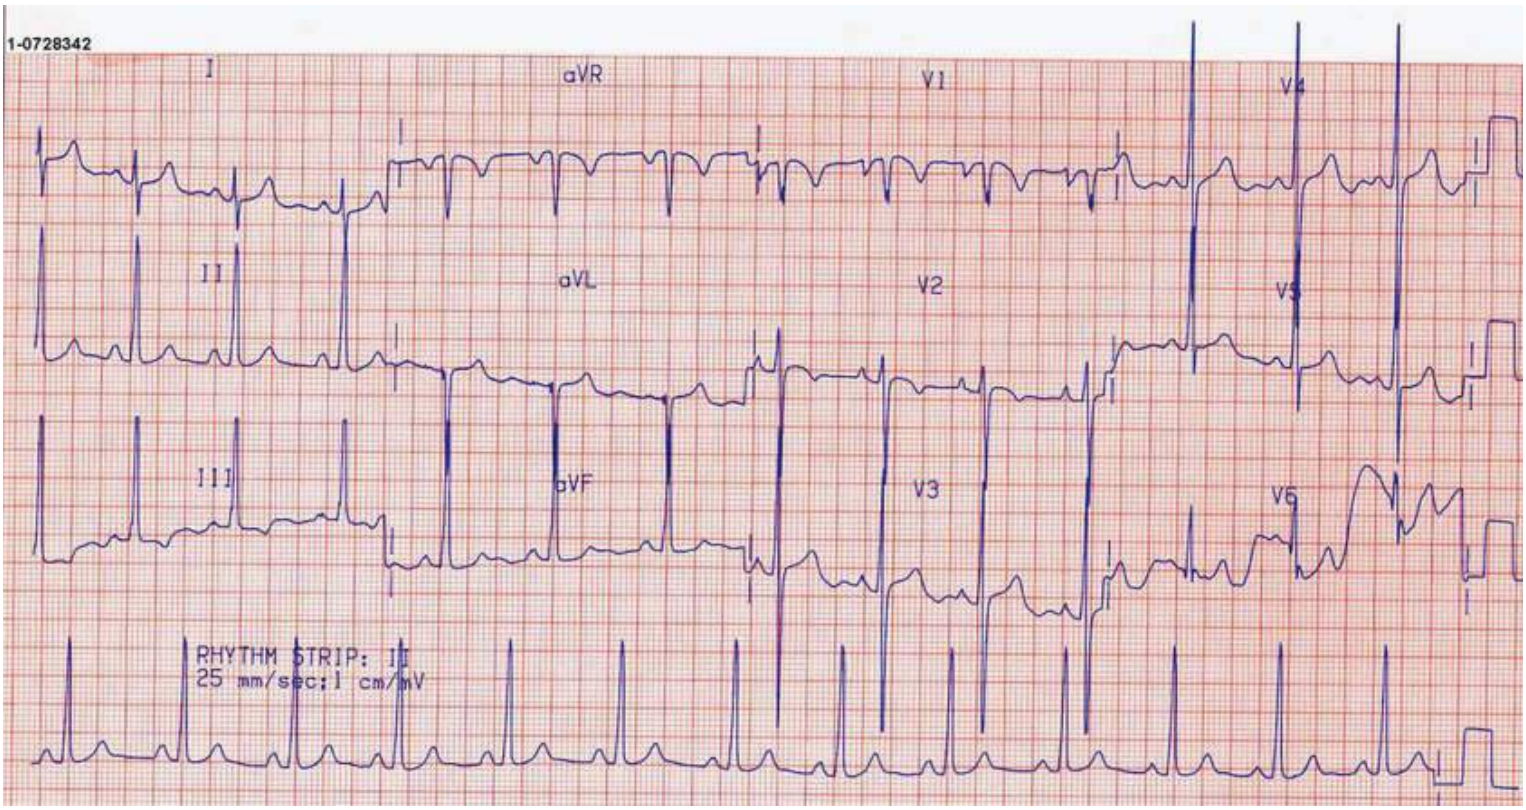
EAPPENDIX 75.27 Sinus rhythm with first-degree block. Probable left and right atrial overload. Right-axis deviation. Prominent R waves in V_1 suggesting elevated subpulmonary pressure. Q wave in V_1 with an absent Q wave in V_5 and V_6. CLINICAL DX: cc-TGA (L-TGA) with single ventricle, pulmonary hypertension, and tricuspid valve stenosis. Age 27.



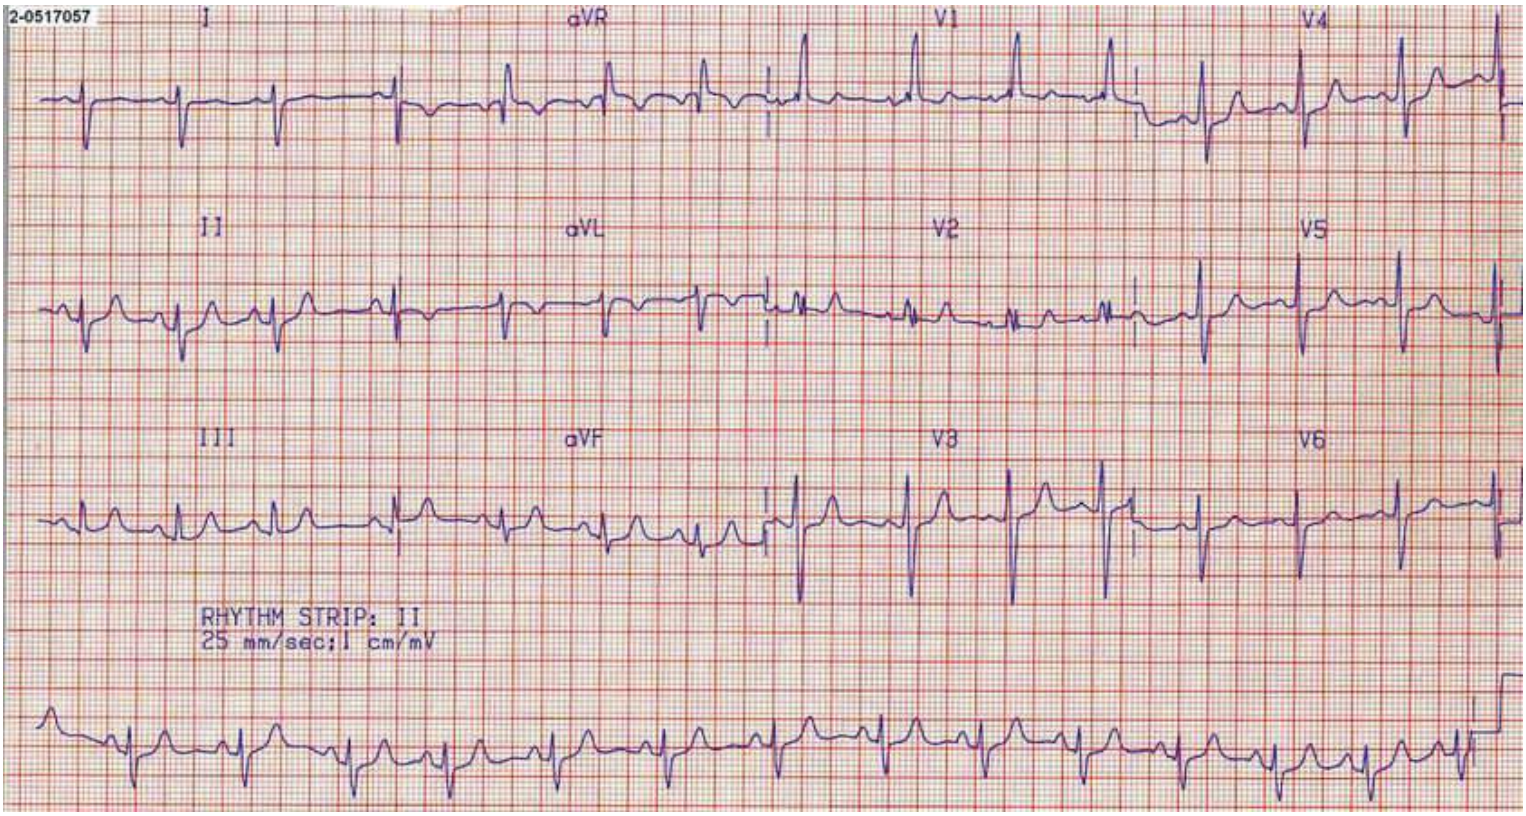
EAPPENDIX 75.28 Sinus rhythm. Evidence of chronic LVH with acute repolarization changes resembling ischemia. CLINICAL DX: Young man with an acutely regurgitant aortic bioprosthesis with mild heart failure and normal coronary arteries. Age 24.



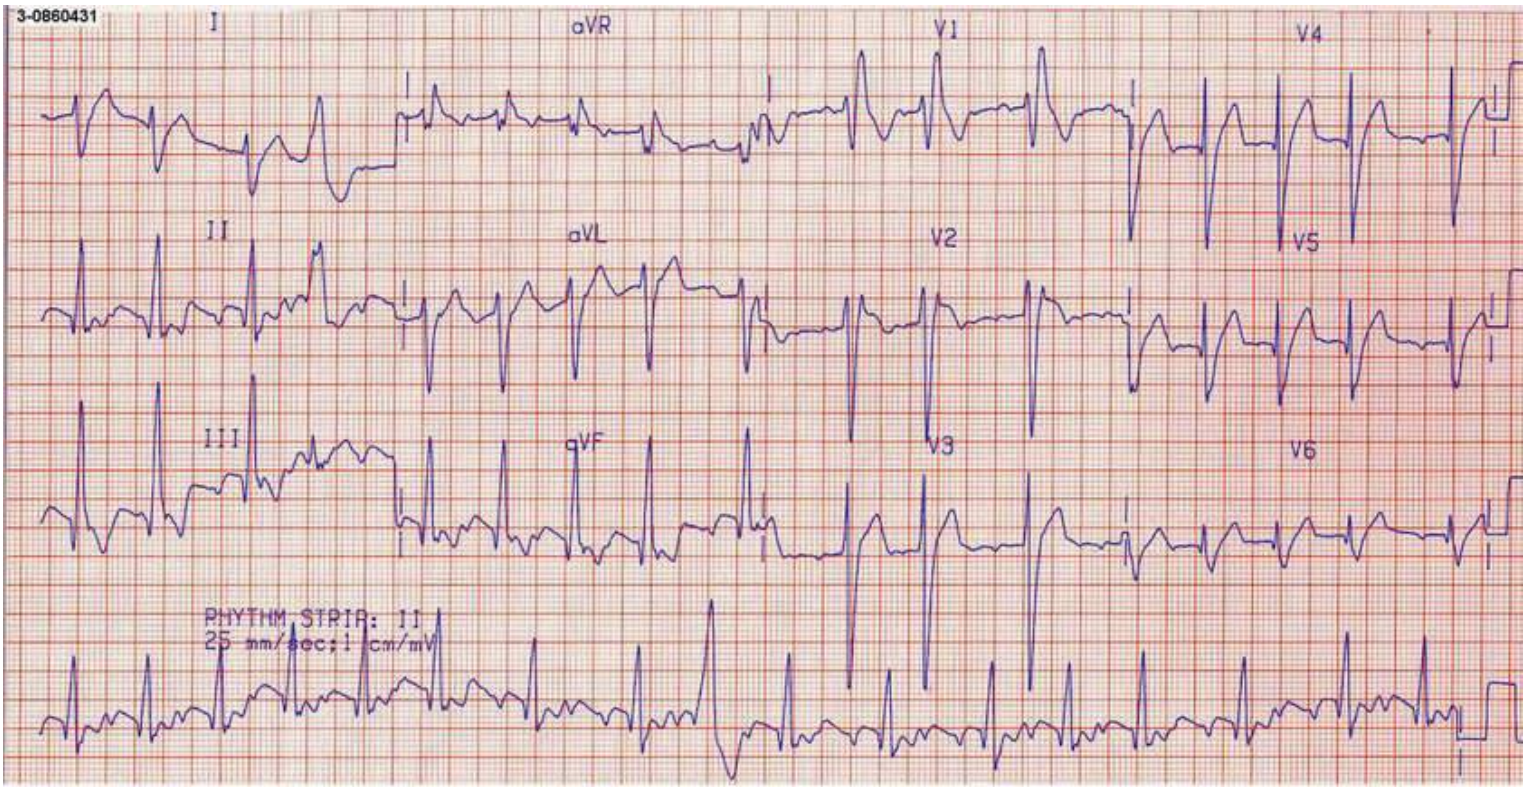
EAPPENDIX 75.29 Sinus rhythm with sinus arrhythmia. Mild right-axis deviation. Markedly prominent and peaked P wave in lead V_2. Mild T wave inversion in the right precordial leads. CLINICAL DX: A 22-year-old person with Marfan syndrome with severe pectus excavatum and moderate mitral regurgitation. The deeply inverted P waves are due to the pectus, and not to right atrial overload.



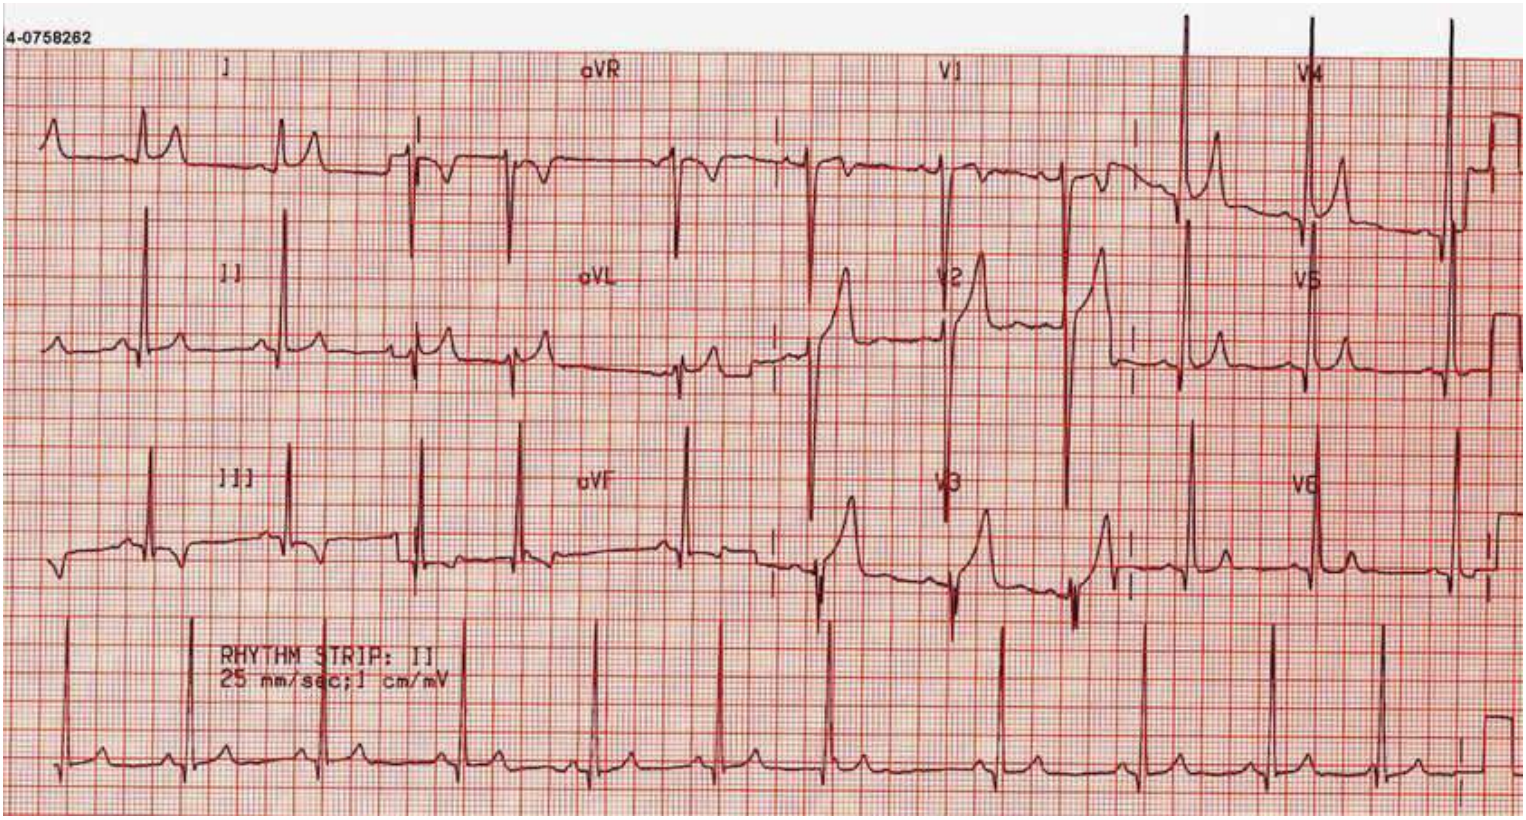
EAPPENDIX 75.30 Sinus rhythm. Vertical axis. Probable right atrial overload (deep P wave inversion in V_1 and peaked P wave in V_2.). CLINICAL DX: Tetralogy of Fallot palliated by a Blalock-Taussig-Thomas shunt. Age 22.



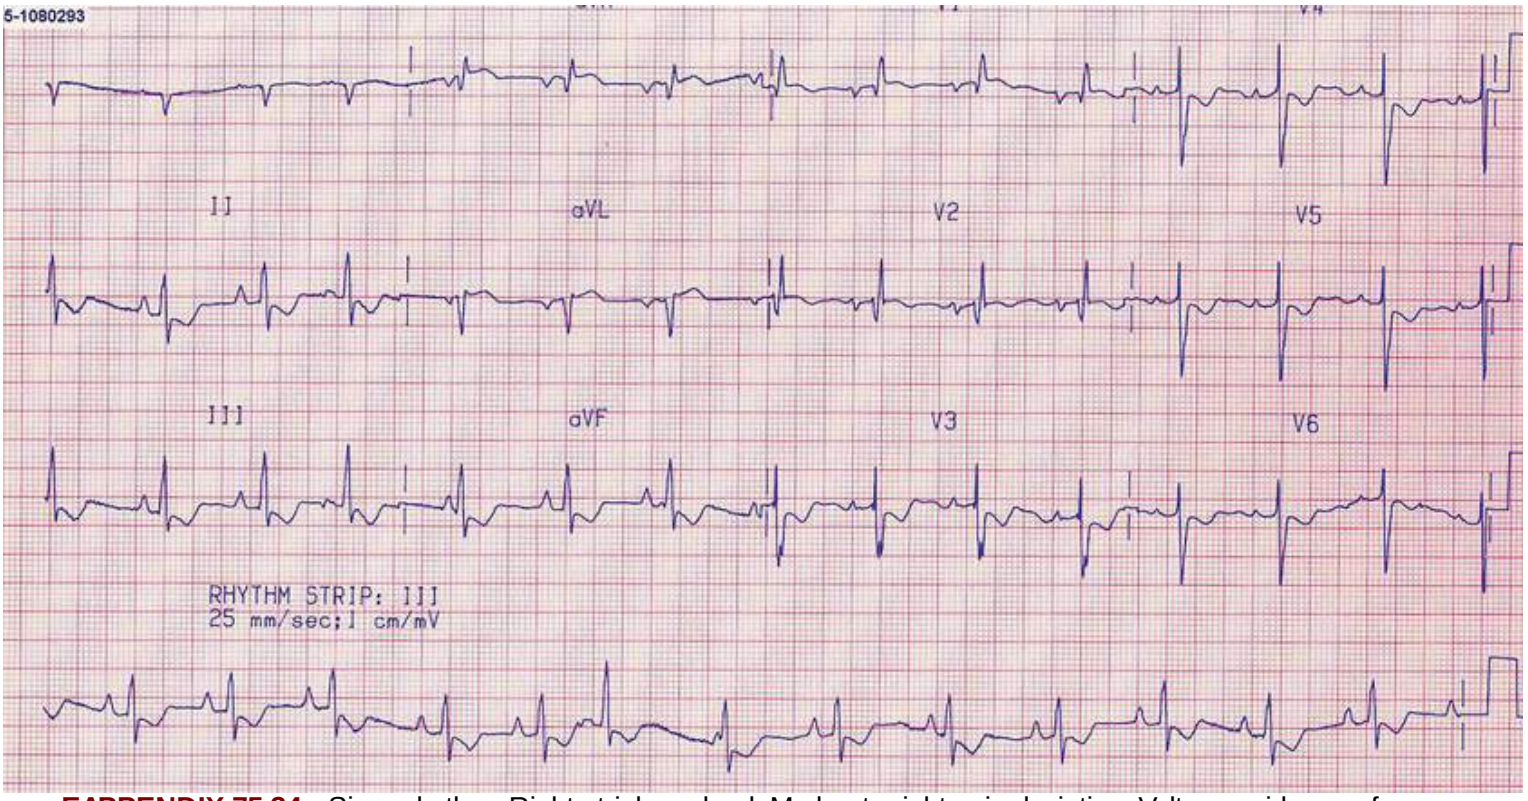
EAPPENDIX 75.31 Sinus rhythm. Marked right-axis deviation. Voltage evidence of RVH. CLINICAL DX: Eisenmenger VSD. Age 27.



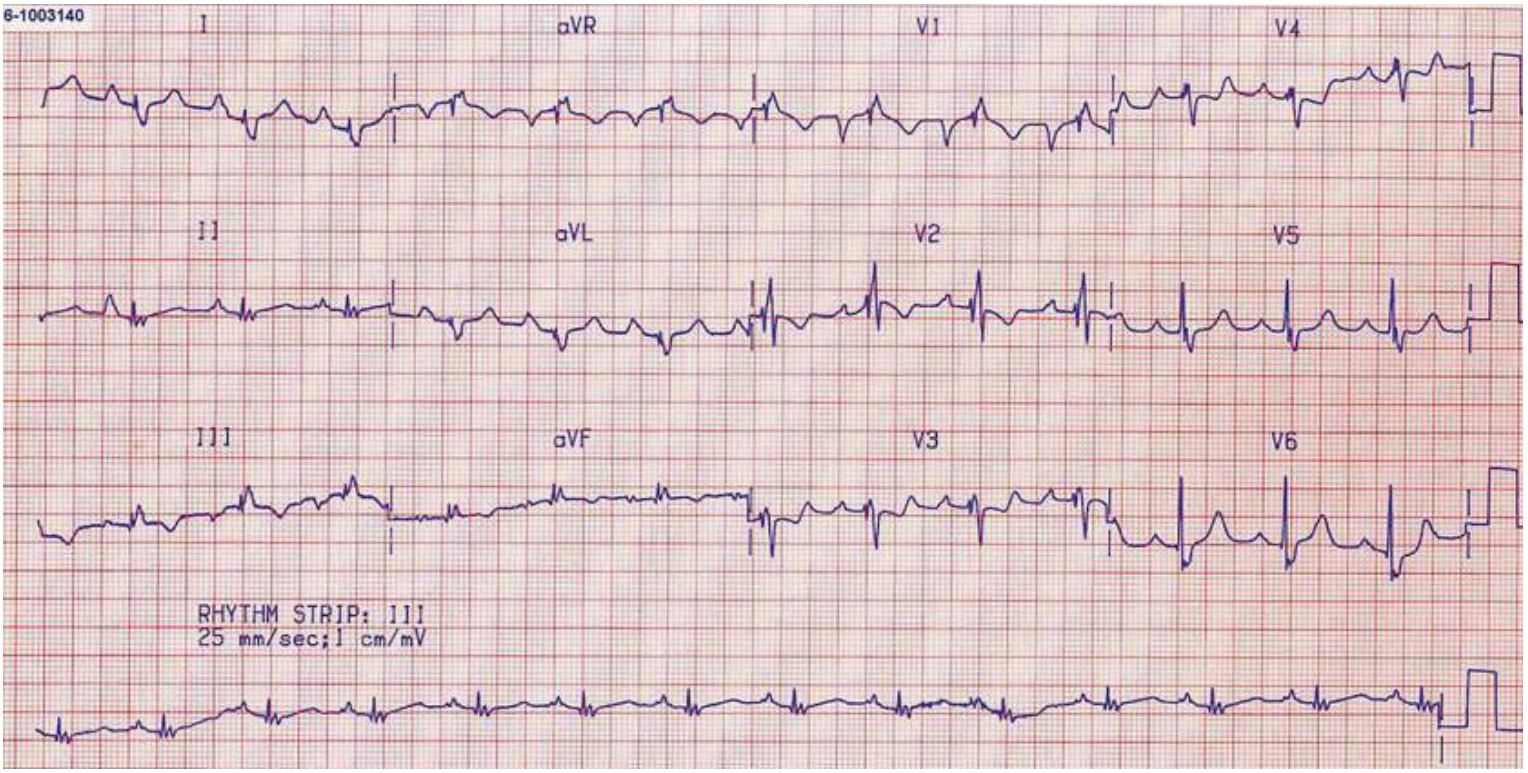
EAPPENDIX 75.32 Atypical atrial flutter with a ventricular rate of about 100 bpm. Right-axis deviation of initial forces. Terminal RBBB. One ventricular premature beat. CLINICAL DX: Repaired tetralogy with residual VSDs and severe tricuspid regurgitation. Age 32.



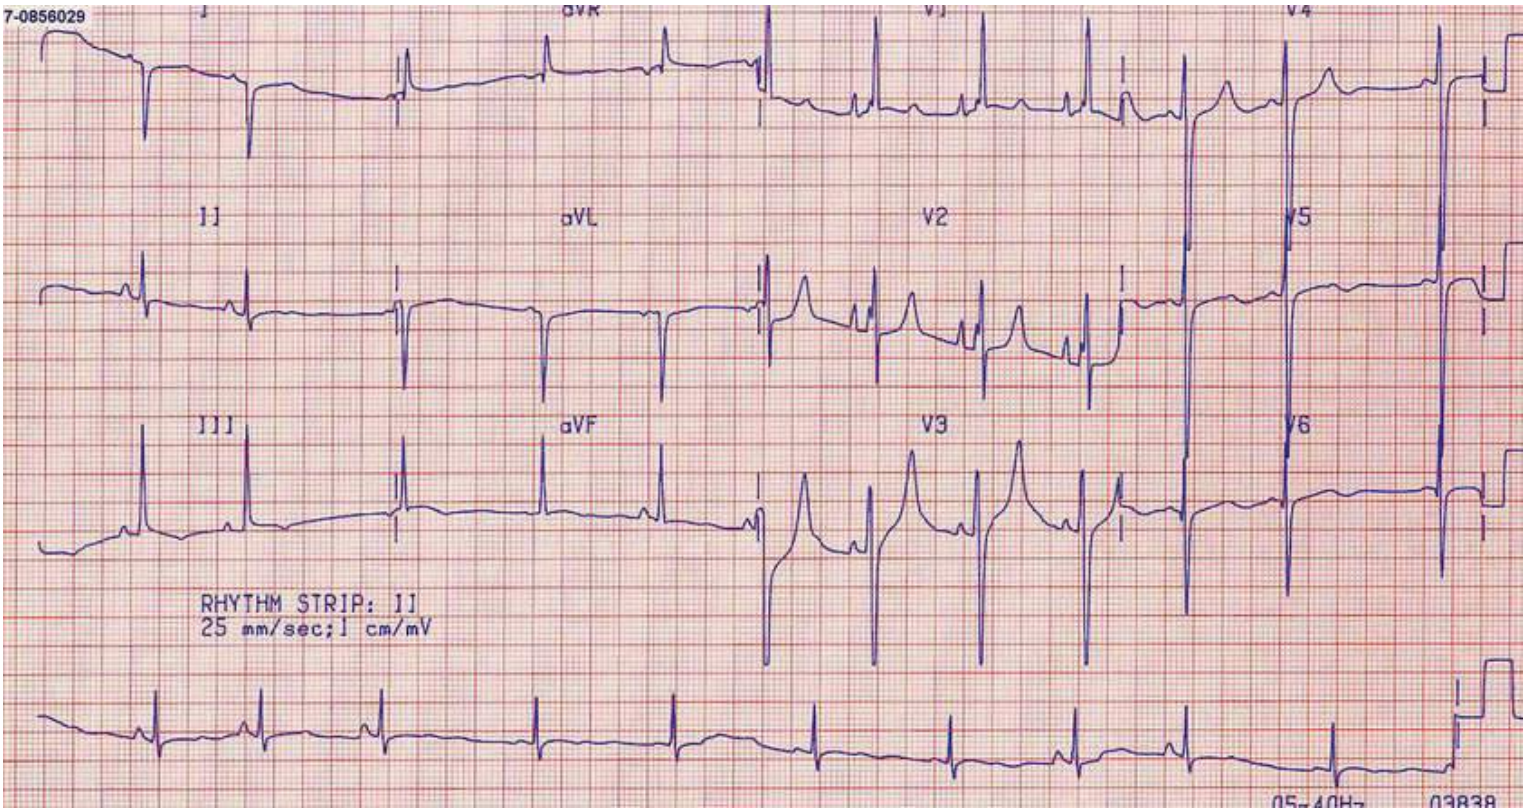
EAPPENDIX 75.33 Sinus rhythm. Possible/probable LVH depending on age. Prominent Q waves in the left chest leads with very tall precordial T waves (the so-called left ventricular volume overload pattern sometimes seen in young people). CLINICAL DX: Severe aortic regurgitation on a bicuspid aortic valve. Age 20.



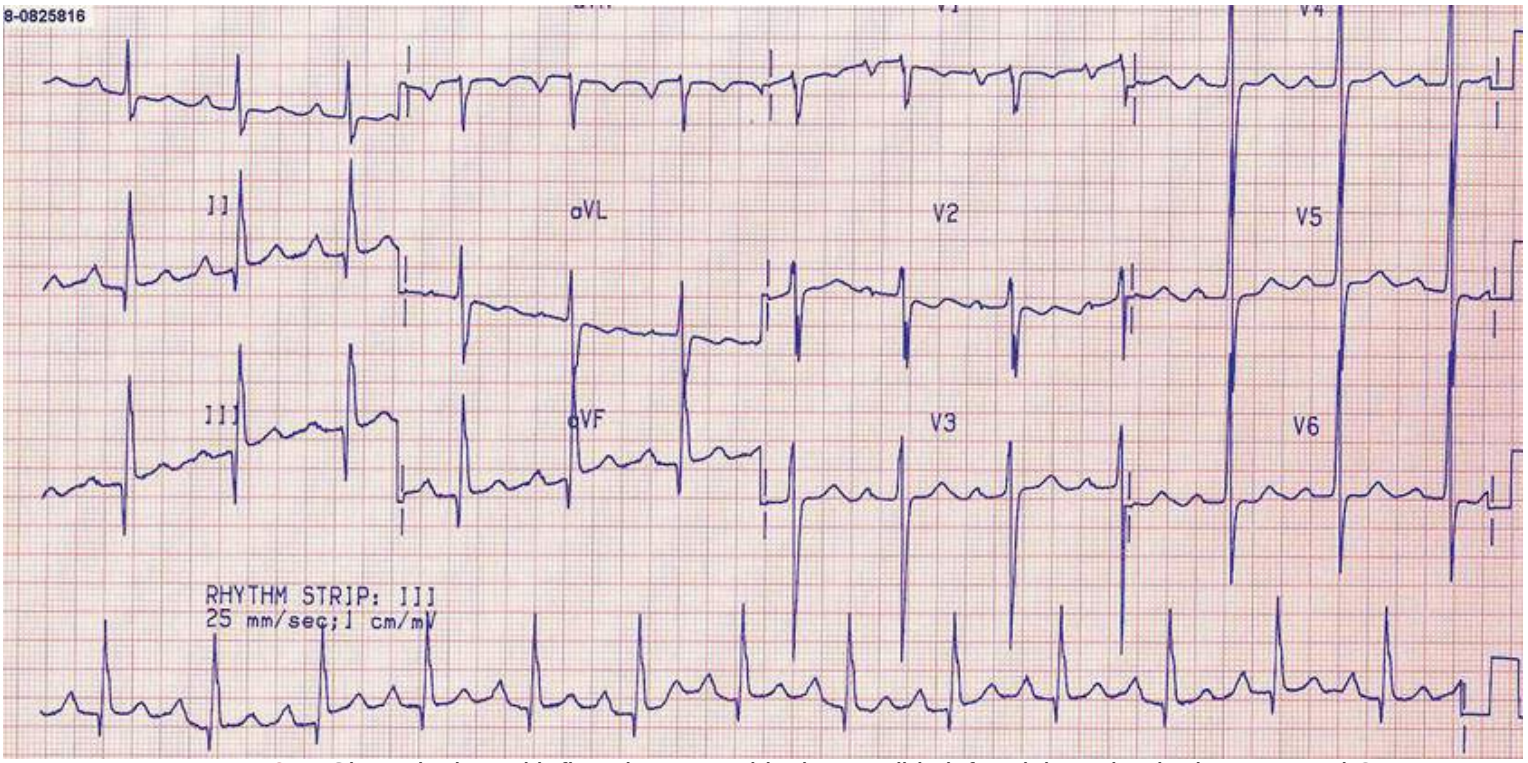
EAPPENDIX 75.34 Sinus rhythm. Right atrial overload. Moderate right-axis deviation. Voltage evidence of RVH with a right ventricular strain pattern. CLINICAL DX: Pulmonary hypertensive ASD. Age 47.



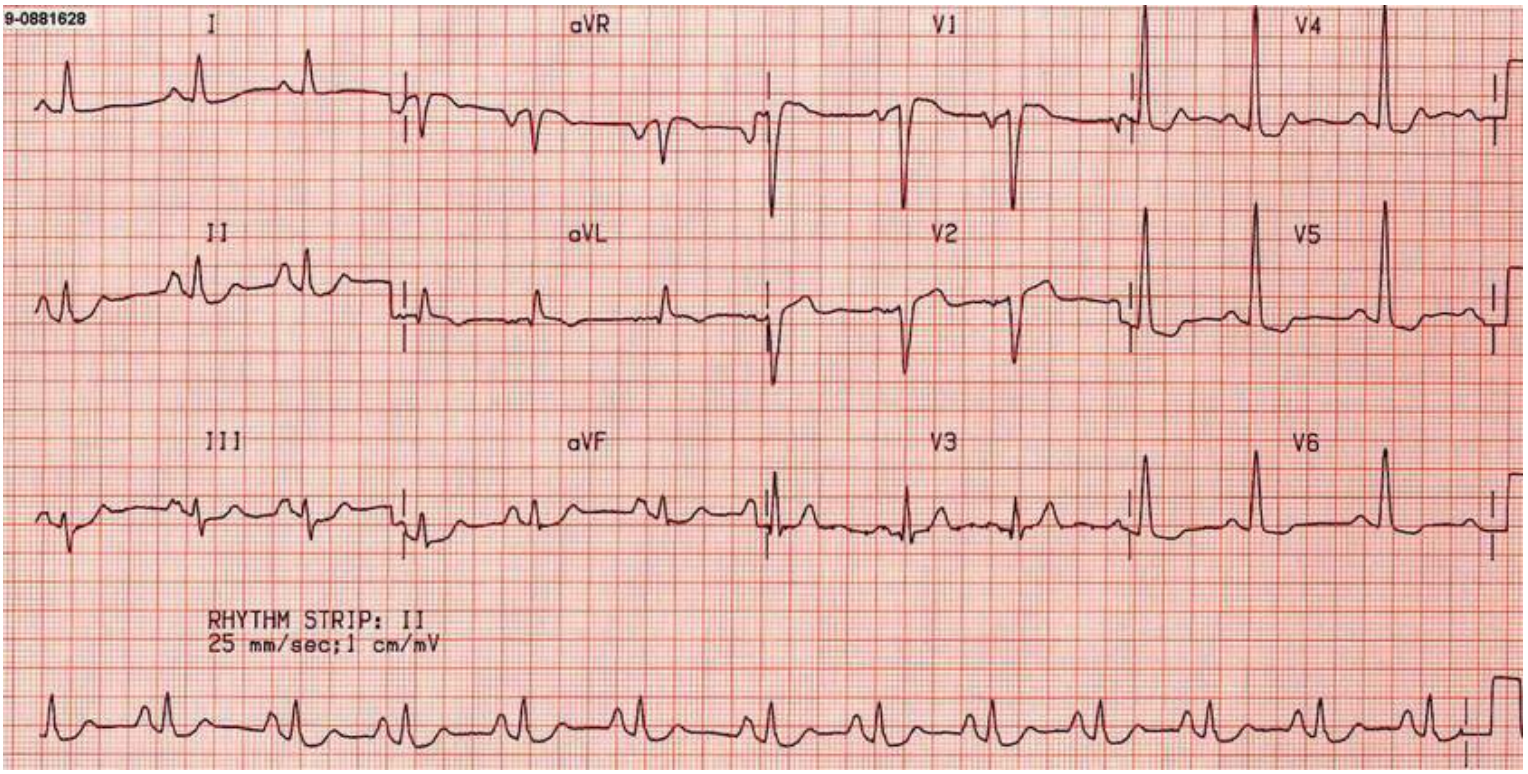
EAPPENDIX 75.35 Sinus rhythm. First-degree AV block. Low-voltage QRS complexes. Right atrial overload (V_1). Abnormal QRS notching in V_2 and V_3. Incomplete RBBB. CLINICAL DX: Ebstein anomaly. Age 19.



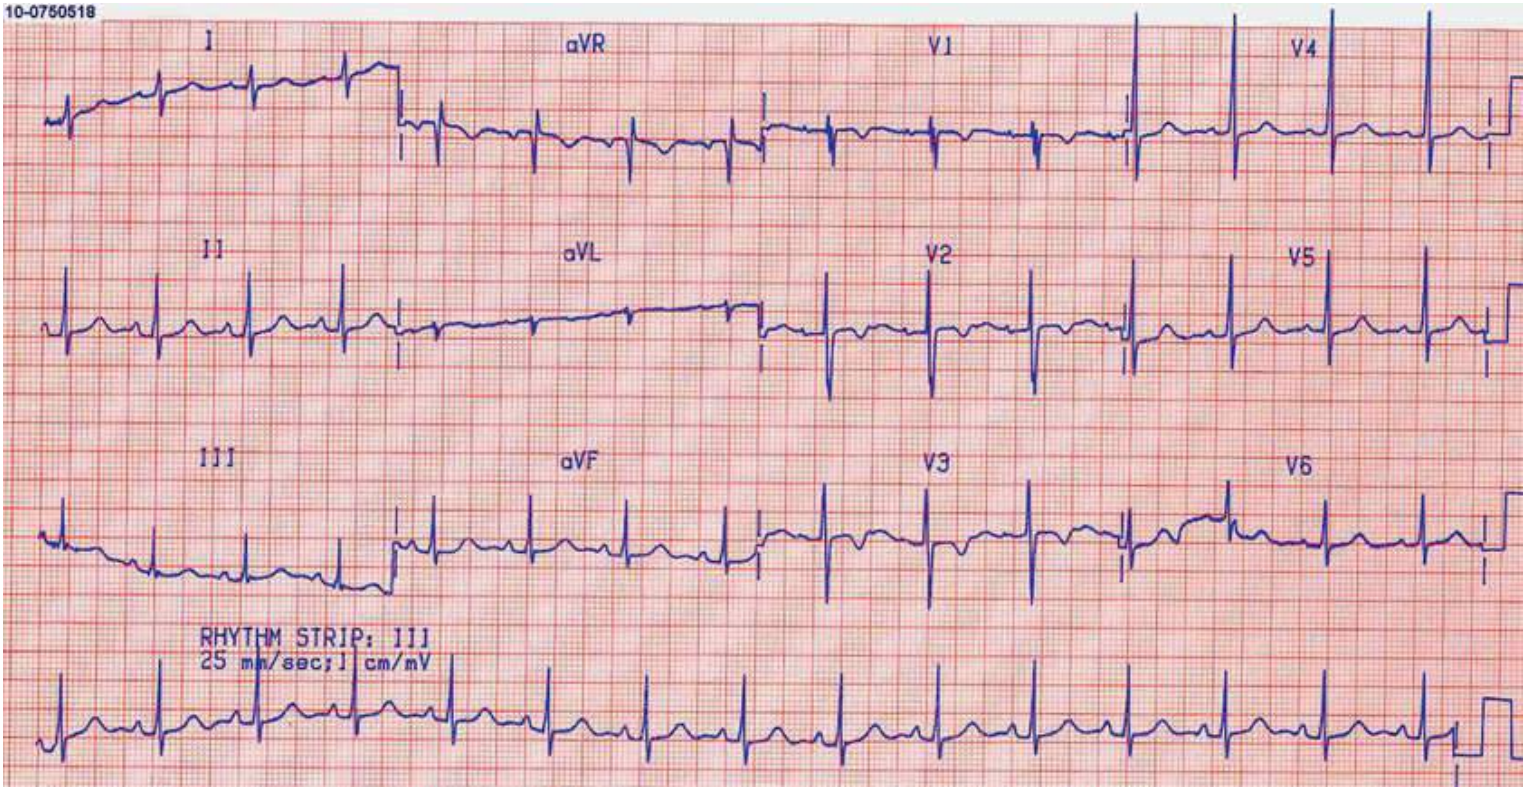
EAPPENDIX 75.36 Sinus rhythm with marked sinus arrhythmia. Marked right atrial overload. Marked right-axis deviation. Marked voltage evidence of RVH. CLINICAL DX: Eisenmenger syndrome due to a large Waterston shunt (ascending aorta to right pulmonary artery) in a patient with tetralogy. Age 21.



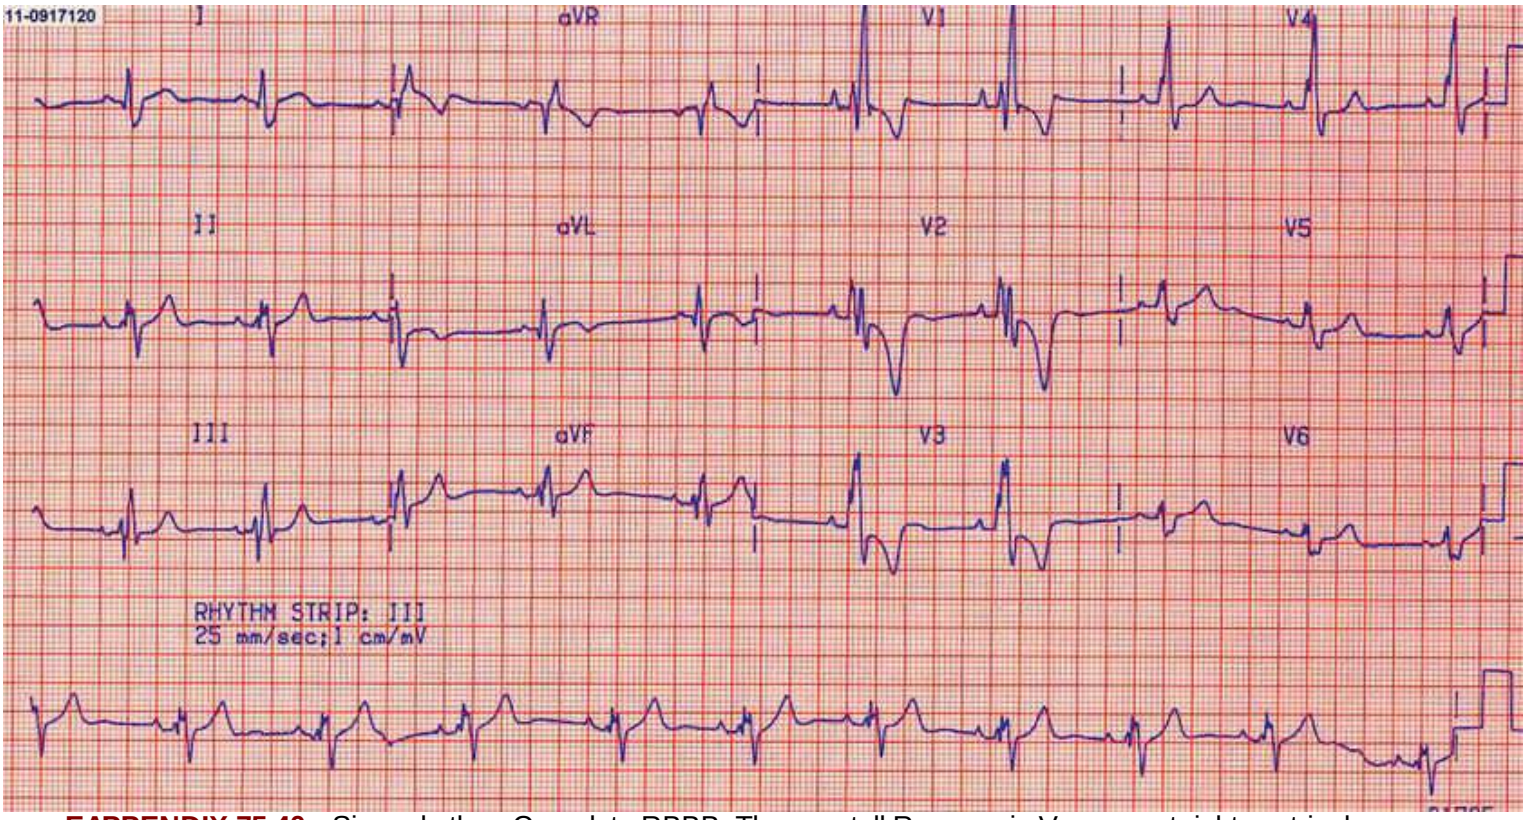
EAPPENDIX 75.37 Sinus rhythm with first-degree AV block. Possible left atrial overload. Absent septal Q waves in leads V_5 and V_6. Prominent inferior Q waves of uncertain significance. CLINICAL DX: Congenitally corrected TGA with severe systemic tricuspid regurgitation. Age 34.



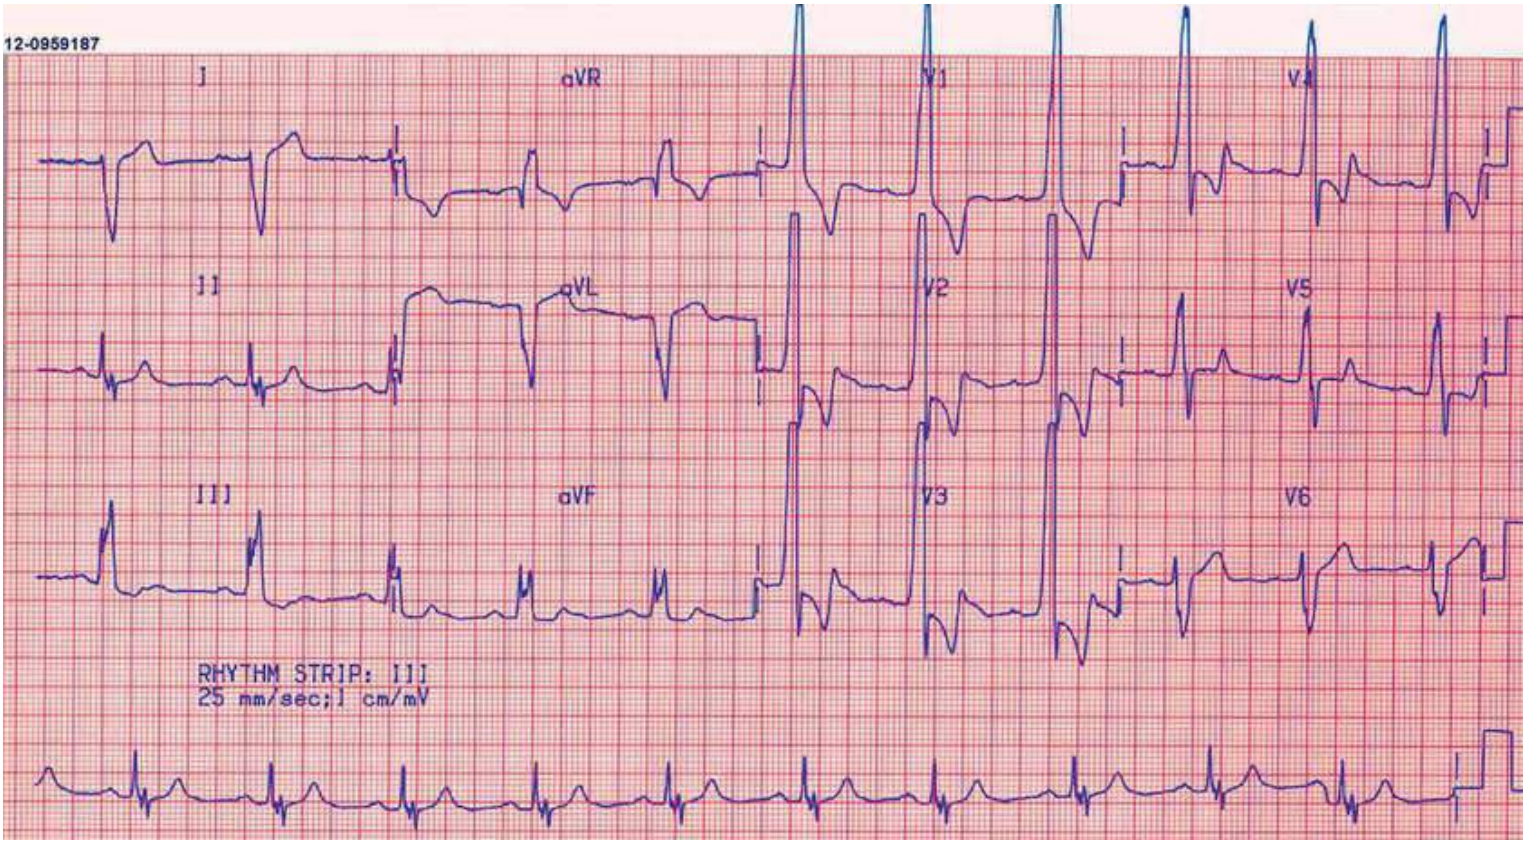
EAPPENDIX 75.38 Sinus rhythm. Right and possibly left atrial overload. Incomplete LBBB with possible left ventricular strain pattern. Possible digoxin effect. CLINICAL DX: Tricuspid atresia with a Blalock-Taussig-Thomas shunt. Age 35.



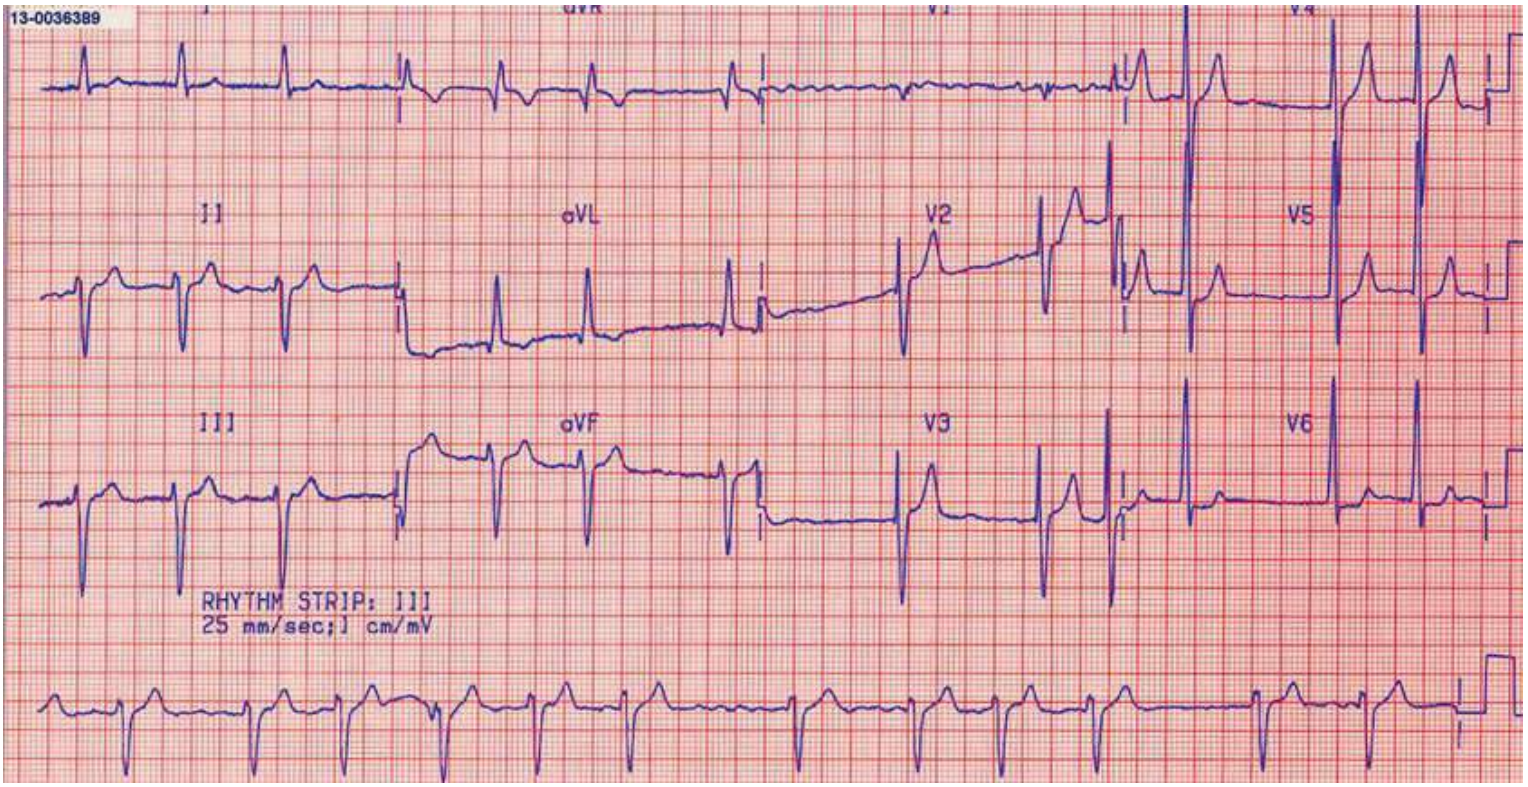
EAPPENDIX 75.39 Sinus rhythm. Vertical axis or mild right-axis deviation. QRS notching in V_1, often seen in secundum ASDs and not changing after repair. T wave inversion in V_1 to V_3 compatible with a right ventricular abnormality. CLINICAL DX: Postoperative secundum ASD repair. Age 29



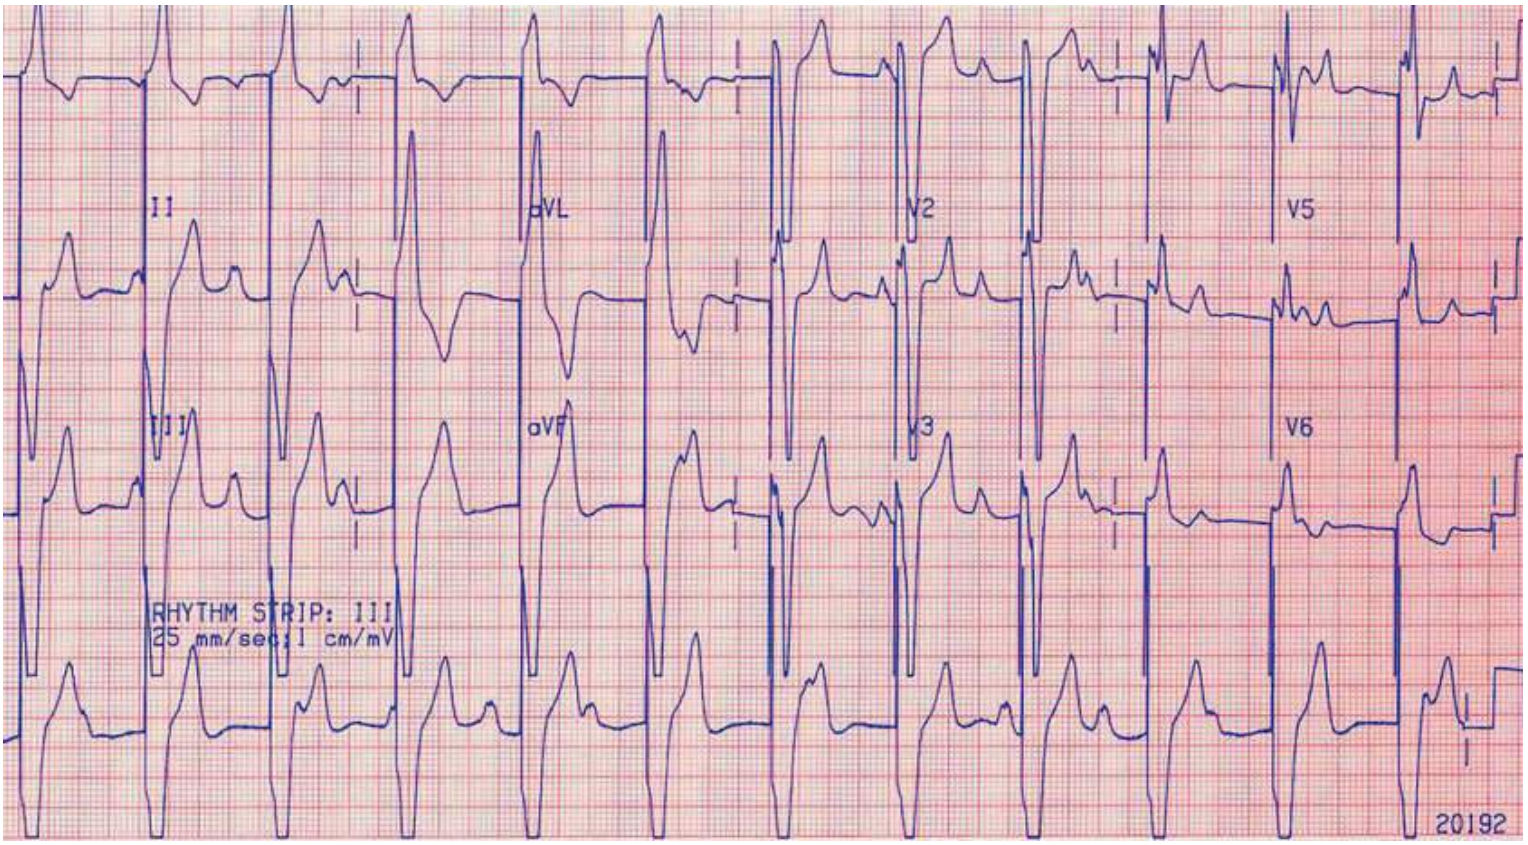
EAPPENDIX 75.40 Sinus rhythm. Complete RBBB. The very tall R waves in V_1 suggest right ventricular hypertension. Right atrial overload in V_1. CLINICAL DX: Complicated repaired tetralogy. Residual pulmonary hypertension following a prior Waterston shunt. VSD patch leak. Age 21.



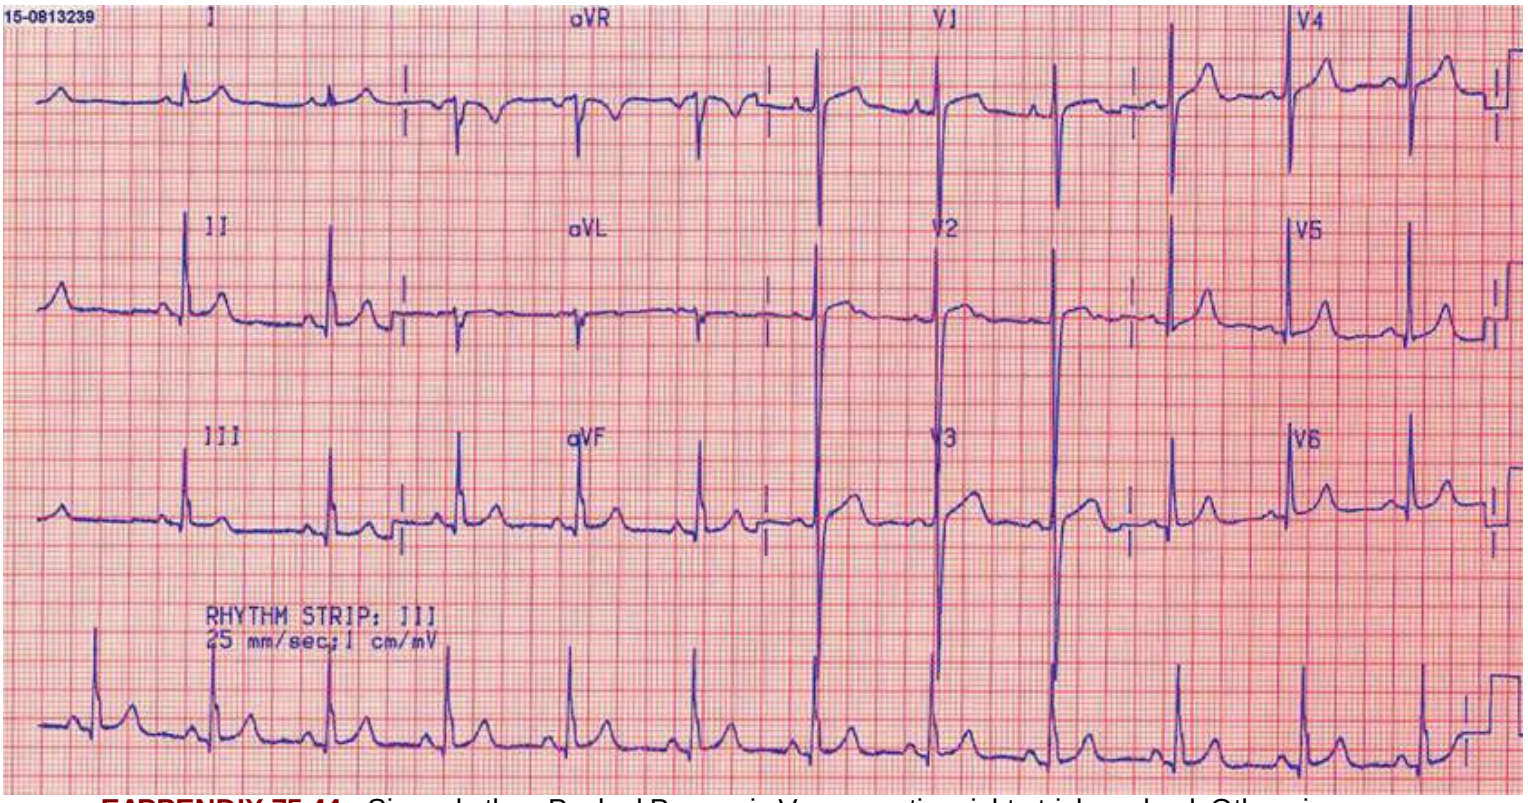
EAPPENDIX 75.41 Sinus rhythm with first-degree AV block. Marked right-axis deviation of initial forces with terminal complete RBBB. No right atrial overload. CLINICAL DX: Mustard repair of TGA, age 17.



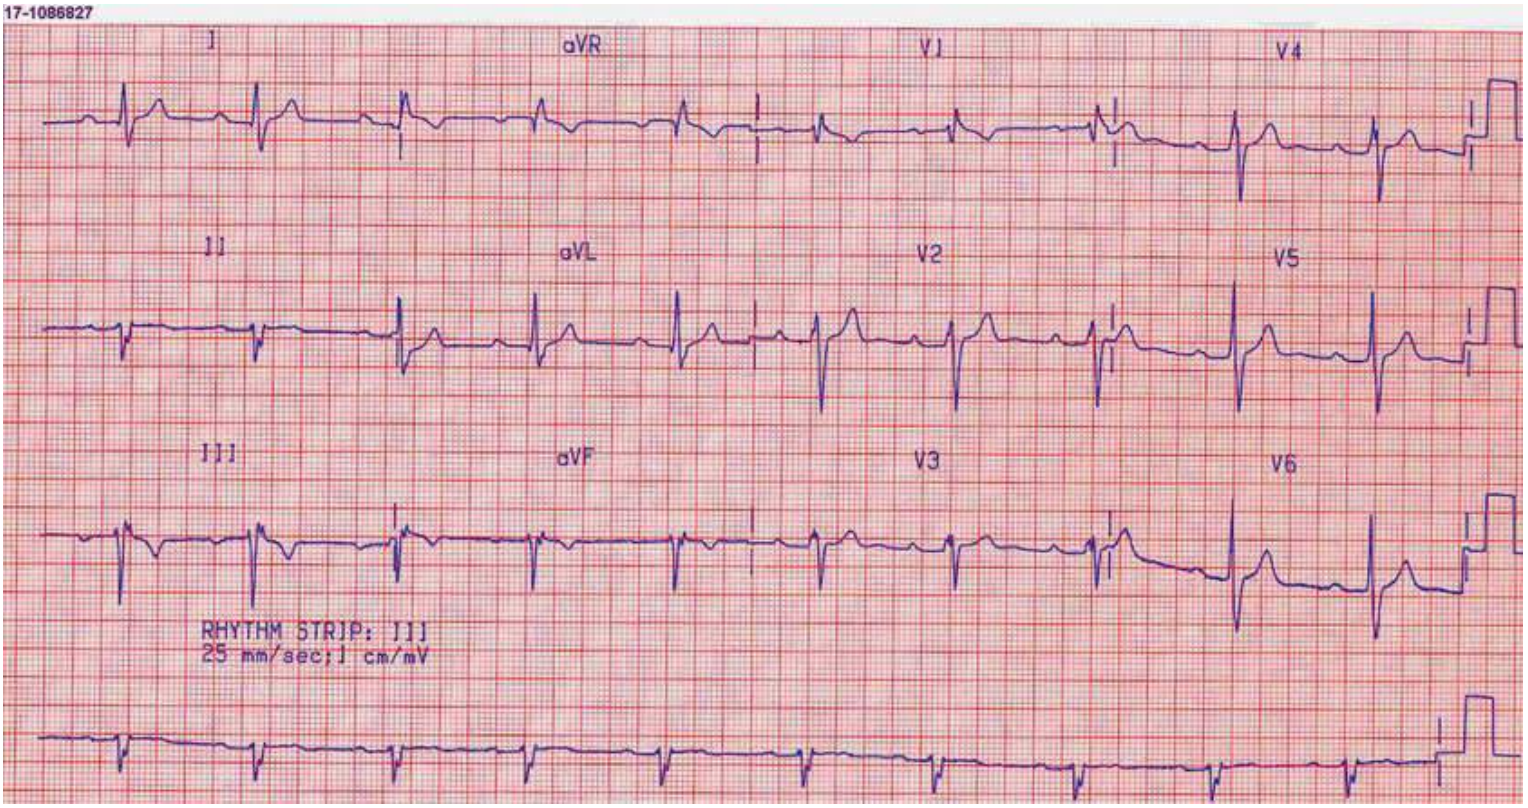
EAPPENDIX 75.42 Atrial fibrillation with a ventricular rate of 80 bpm. Marked left-axis deviation. CLINICAL DX: Repaired ostium primum ASD and mitral repair, still having substantial mitral regurgitation. On digoxin.



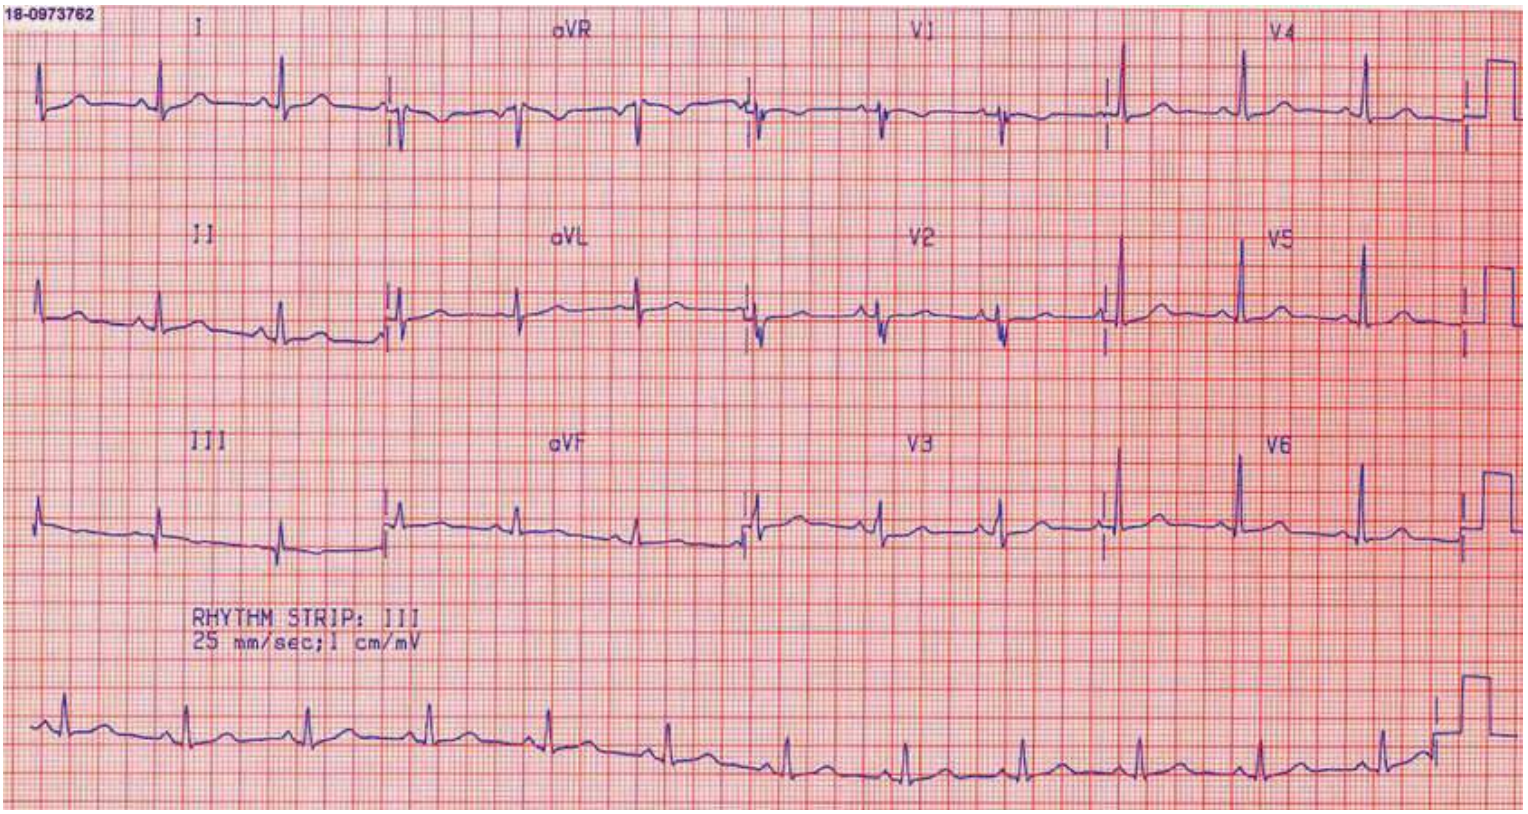
EAPPENDIX 75.43 Sinus rhythm at a rate of about 85 bpm. Complete heart block with ventricular pacing. Marked right atrial overload. CLINICAL DX: Congenitally corrected TGA with a VSD and substantial pulmonary stenosis.



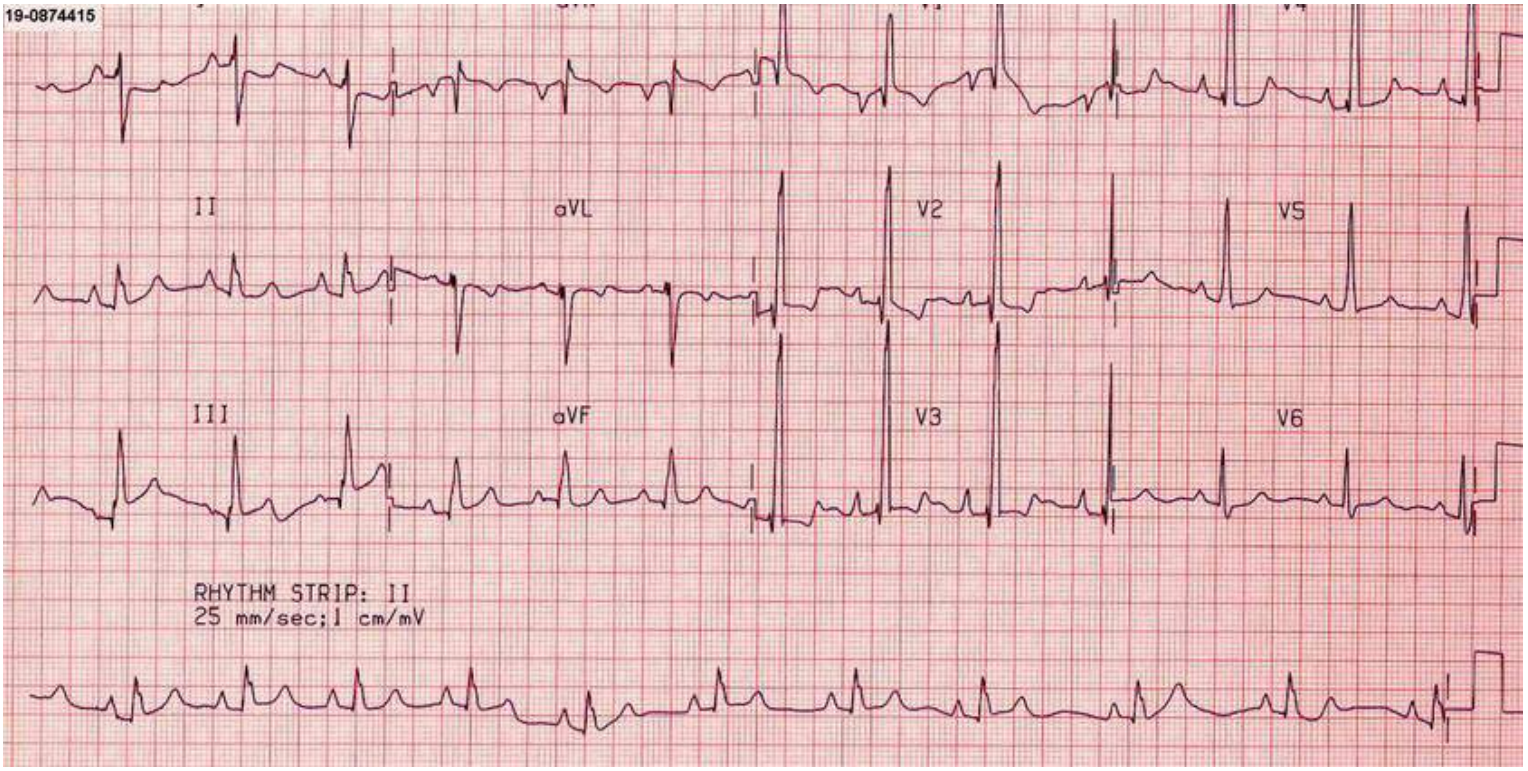
EAPPENDIX 75.44 Sinus rhythm. Peaked P wave in V_1 suggesting right atrial overload. Otherwise normal ECG. CLINICAL DX: Mild pulmonary stenosis. Age 21.



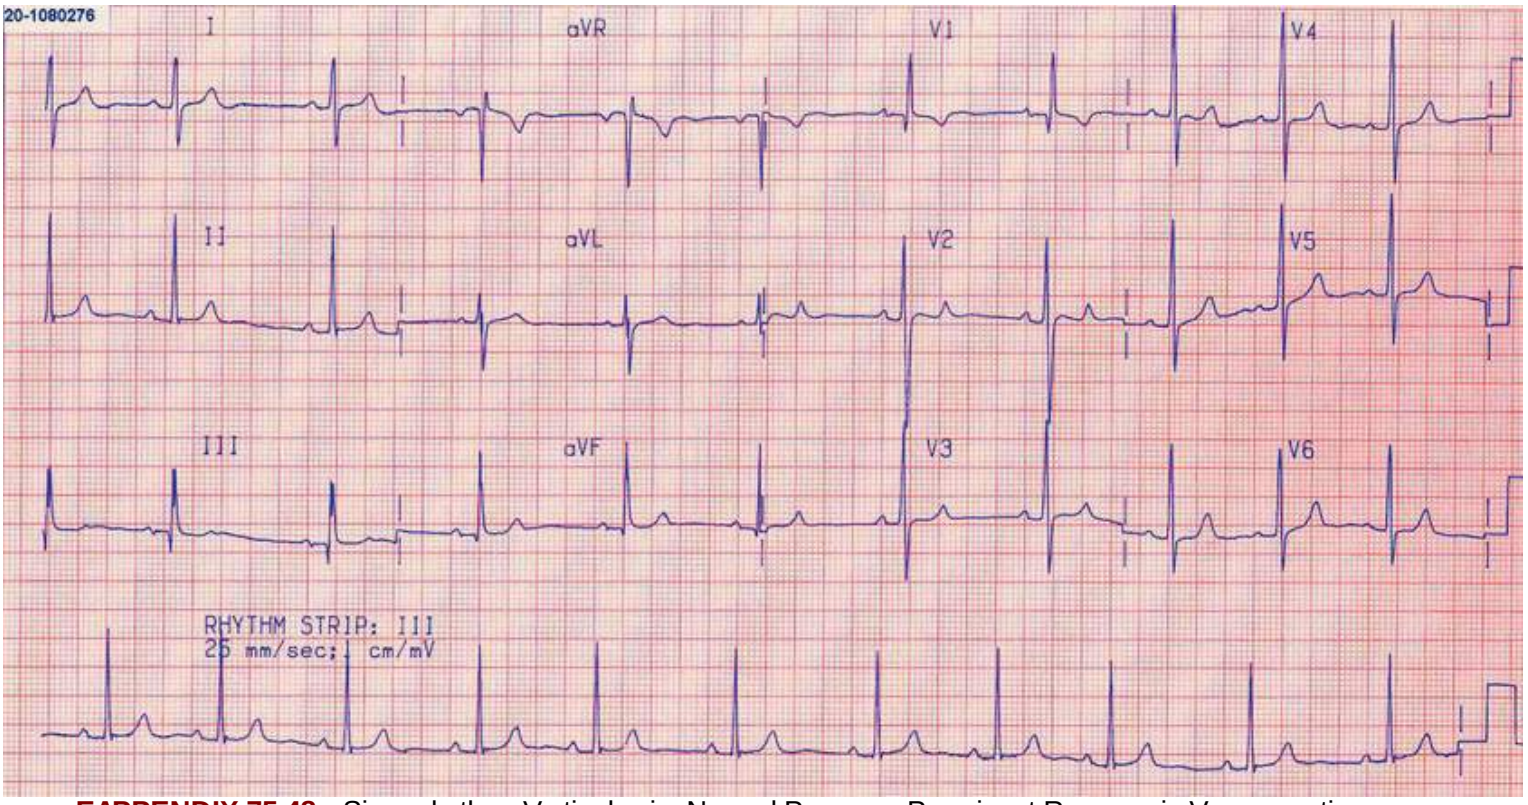
EAPPENDIX 75.45 Sinus rhythm with first-degree AV block. Left-axis deviation. Incomplete RBBB. No left atrial overload pattern. CLINICAL DX: Ostium primum ASD. Age 27.



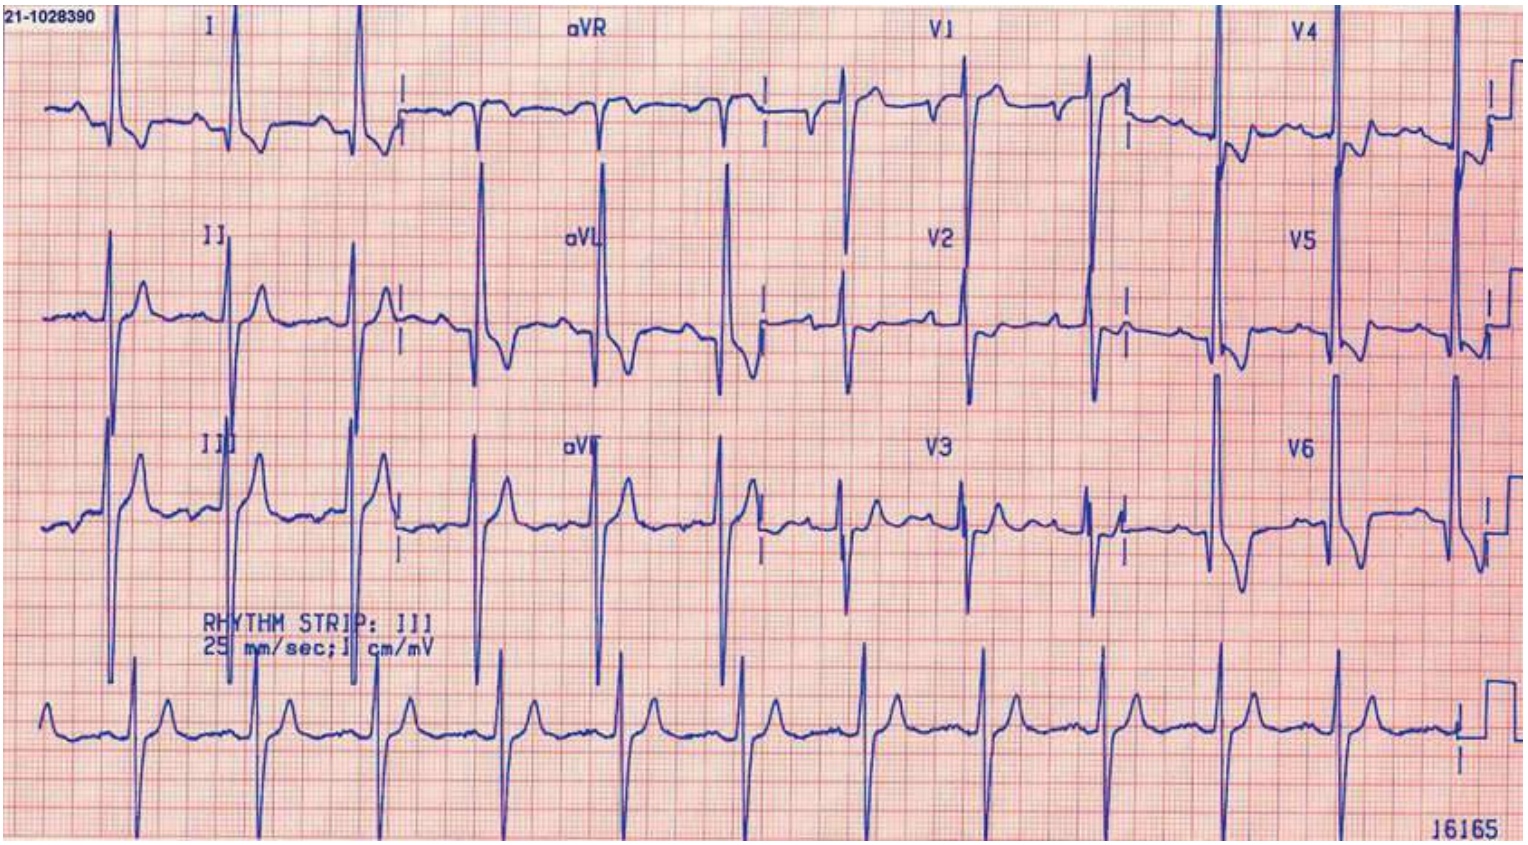
EAPPENDIX 75.46 Sinus rhythm. Peaked P waves in V_2 and V_3 not meeting voltage criteria for right atrial overload. QRS notching in V_1 and V_2 possibly suggestive of an ASD. CLINICAL DX: Ebstein anomaly. Age 46.



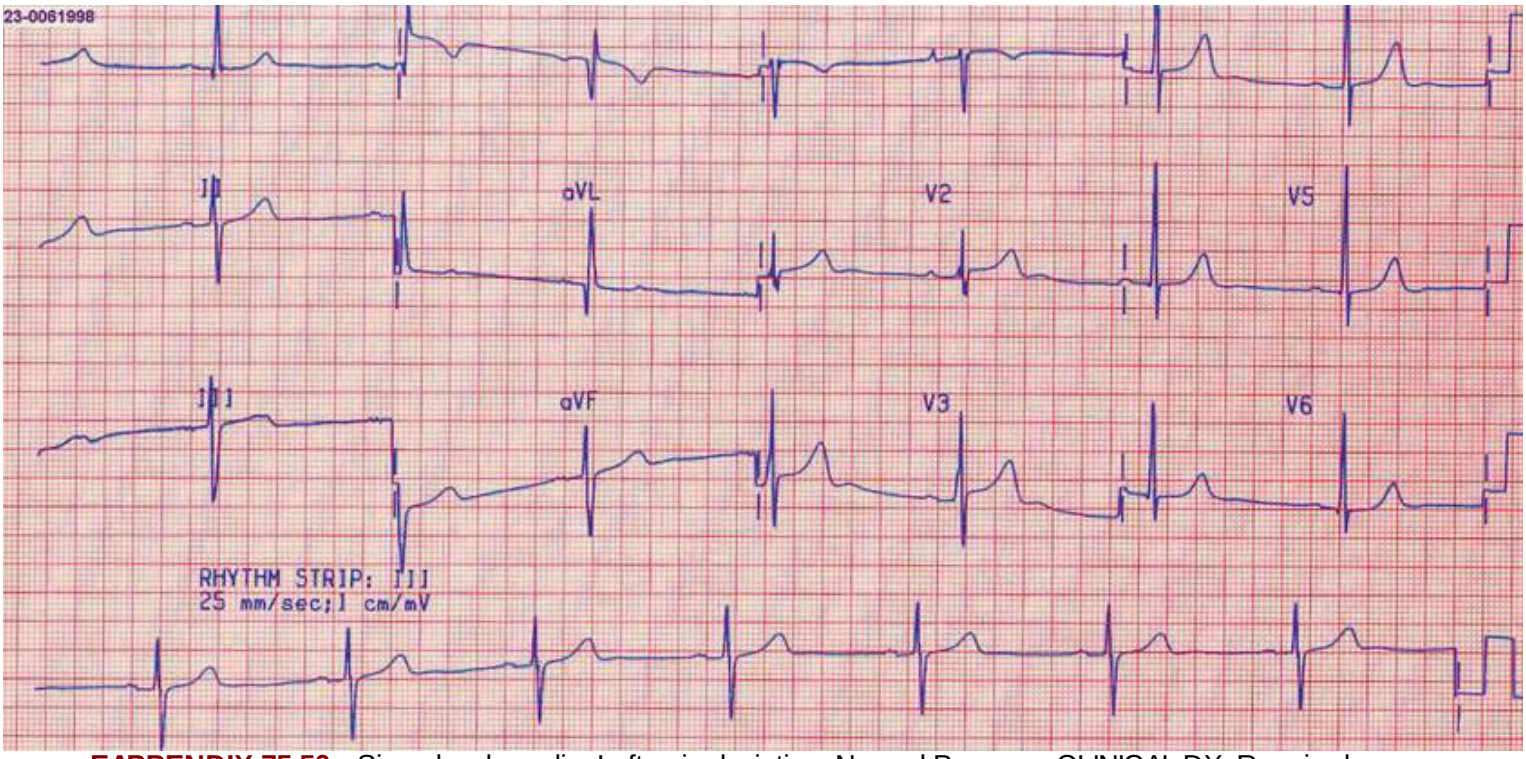
EAPPENDIX 75.47 Sinus rhythm. Right atrial enlargement. Right-axis deviation of initial forces. Voltage evidence of RVH with RV strain. CLINICAL DX: Tetralogy palliated by a Blalock-Taussig-Thomas shunt. Age 21.



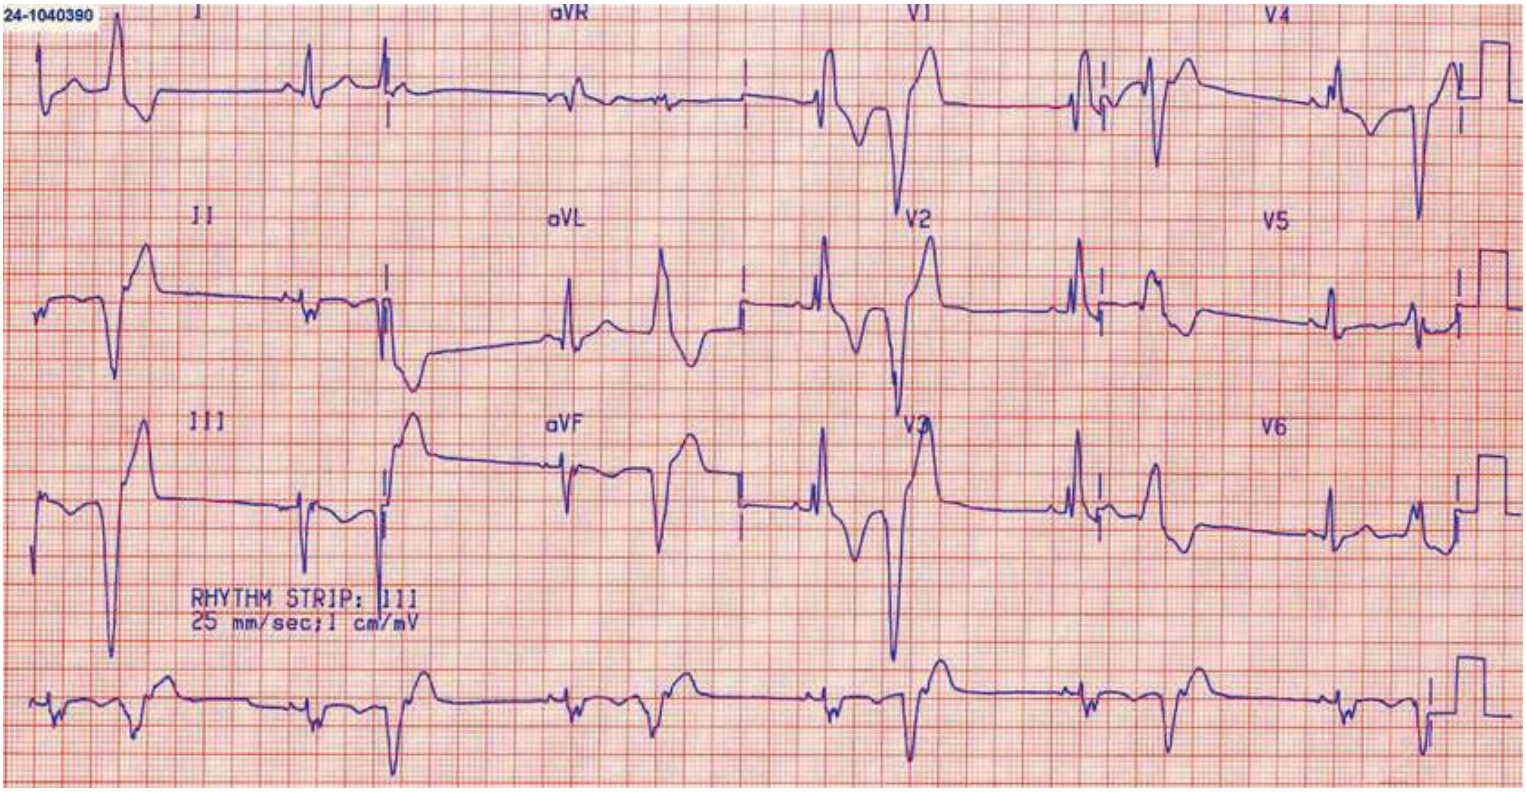
EAPPENDIX 75.48 Sinus rhythm. Vertical axis. Normal P waves. Prominent R waves in V_1 suggesting RV pressure overload. CLINICAL DX: Unrepaired tetralogy. Age 19.



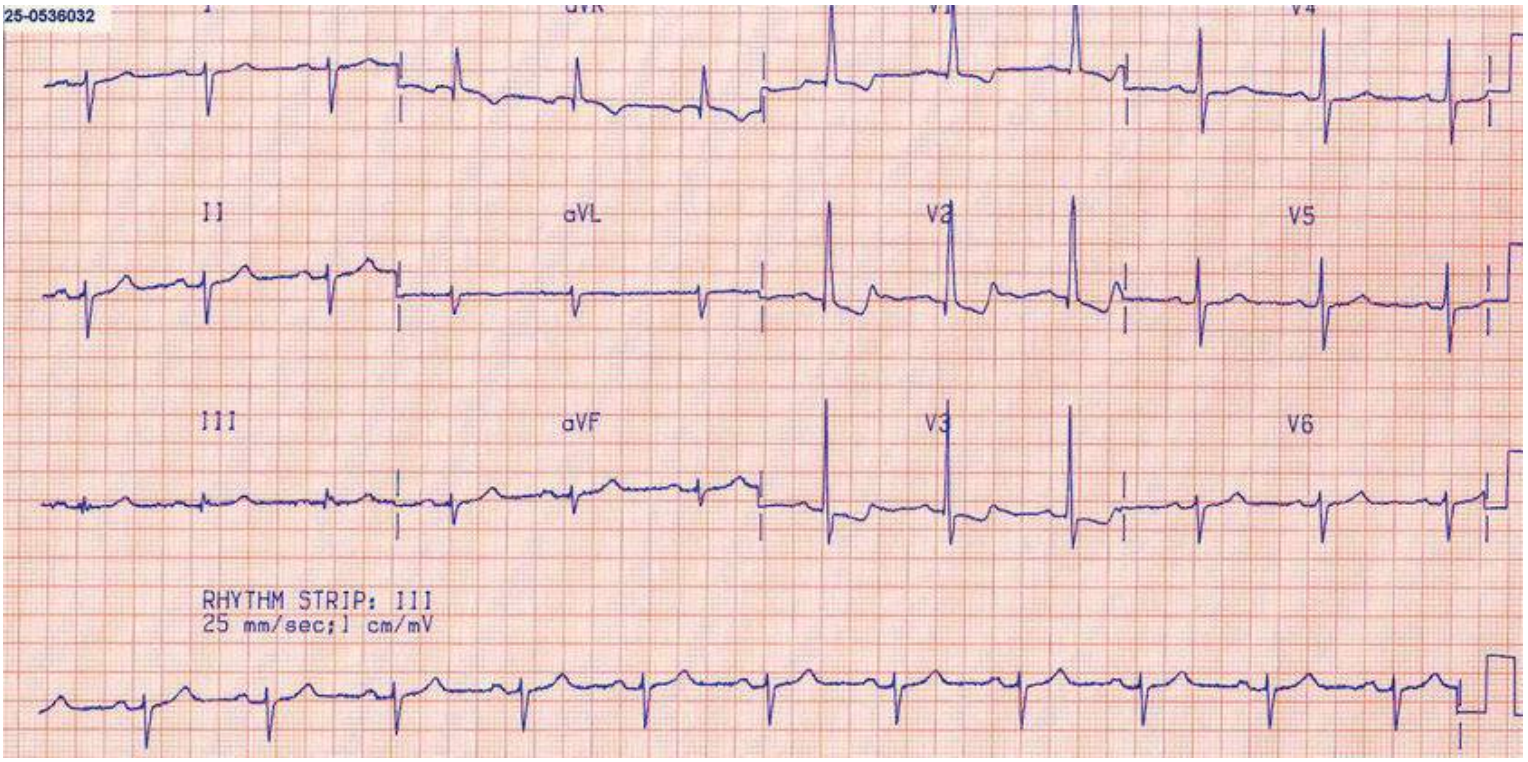
EAPPENDIX 75.49 Sinus rhythm with both left and right atrial overload. Left-axis deviation. Prominent Q waves in the lateral leads. Possible LV strain pattern. Possible digoxin effect. CLINICAL DX: Tricuspid atresia with a VSD and PS palliated with a cavopulmonary (Glenn) shunt and a large Potts shunt. Age 20.



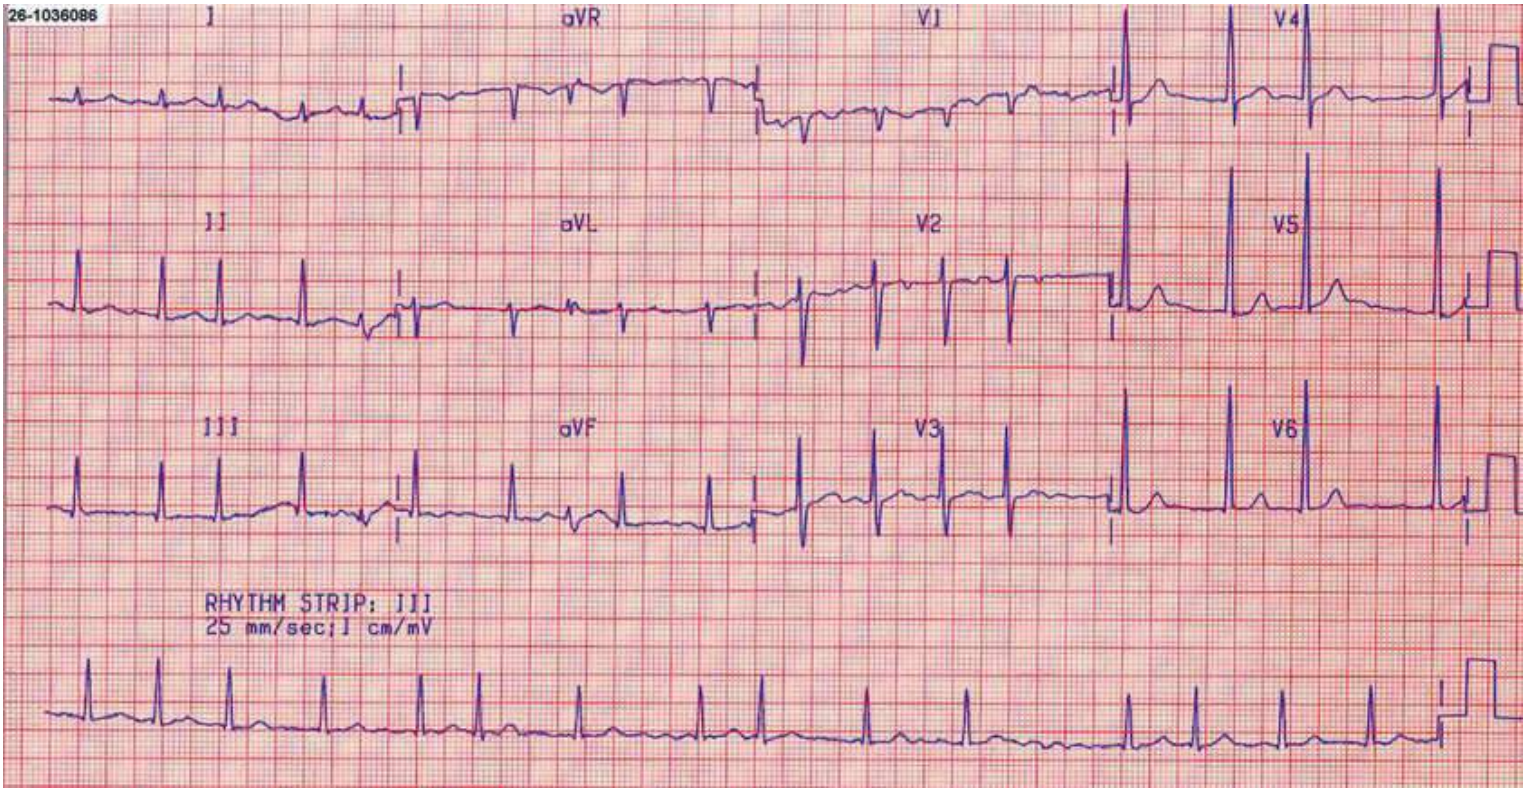
EAPPENDIX 75.50 Sinus bradycardia. Left-axis deviation. Normal P waves. CLINICAL DX: Repaired ostium primum ASD. Cleft mitral leaflet with mild regurgitation. Age 39.



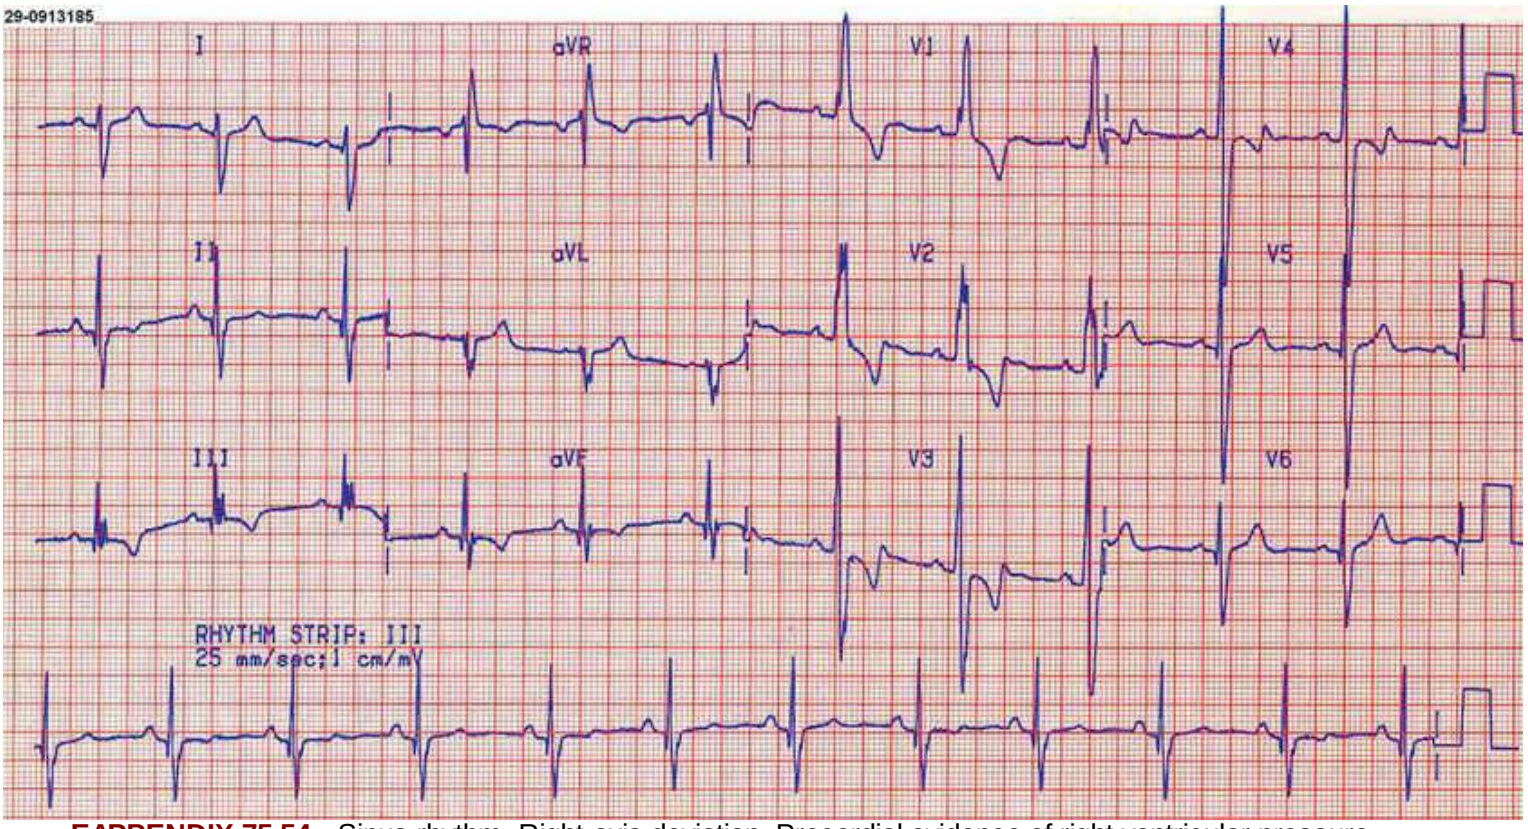
EAPPENDIX 75.51 Sinus rhythm with ventricular bigeminy. VPBs arise in the right ventricle (LBBB pattern). Complete RBBB. CLINICAL DX: Repaired tetralogy. Age 32.



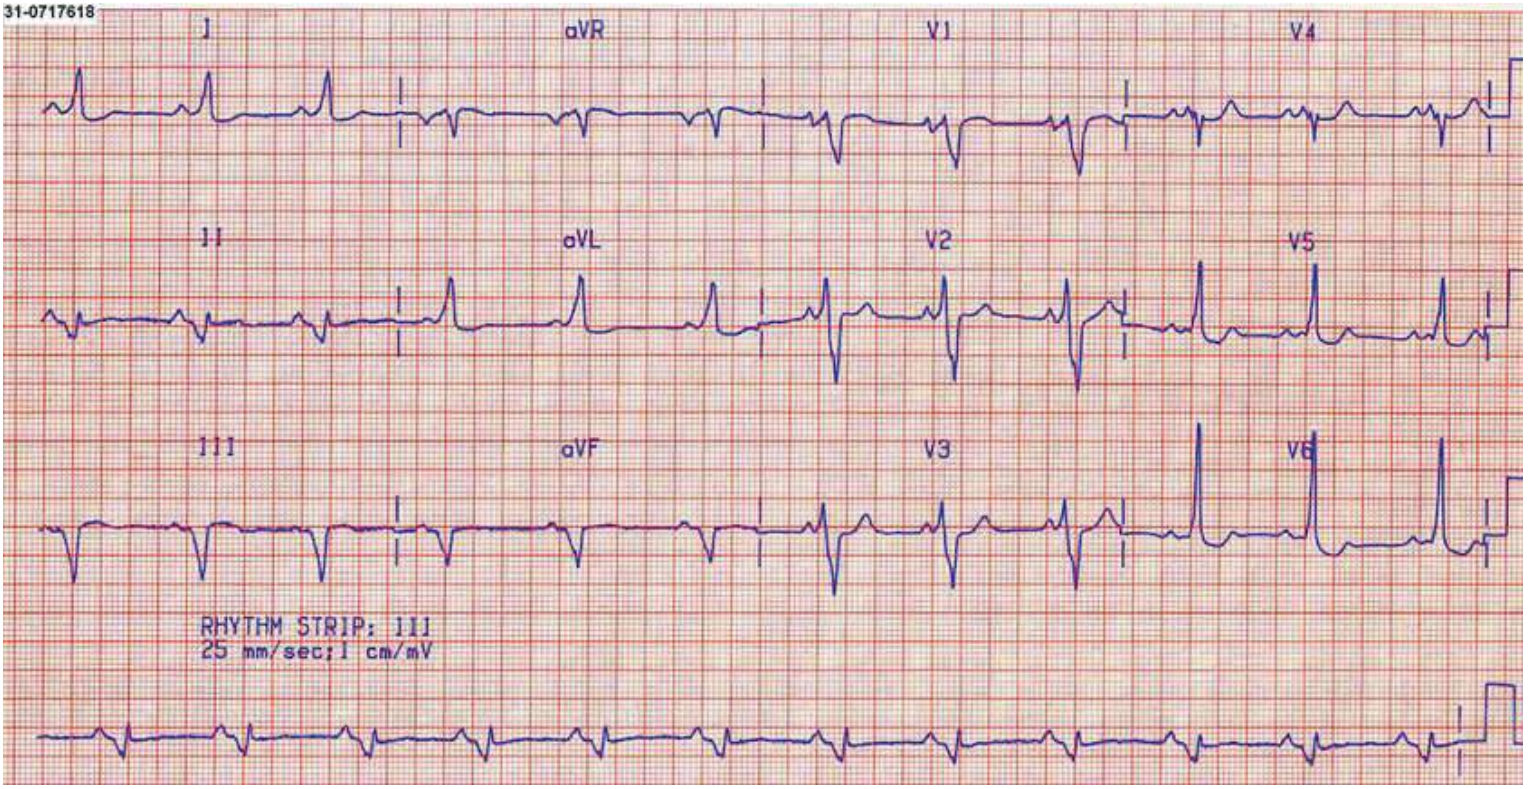
EAPPENDIX 75.52 Sinus rhythm. Marked right-axis deviation. Marked precordial evidence of right ventricular pressure overload. Indeterminate QRS axis. CLINICAL DX: Mustard repair of TGA. Age 32.



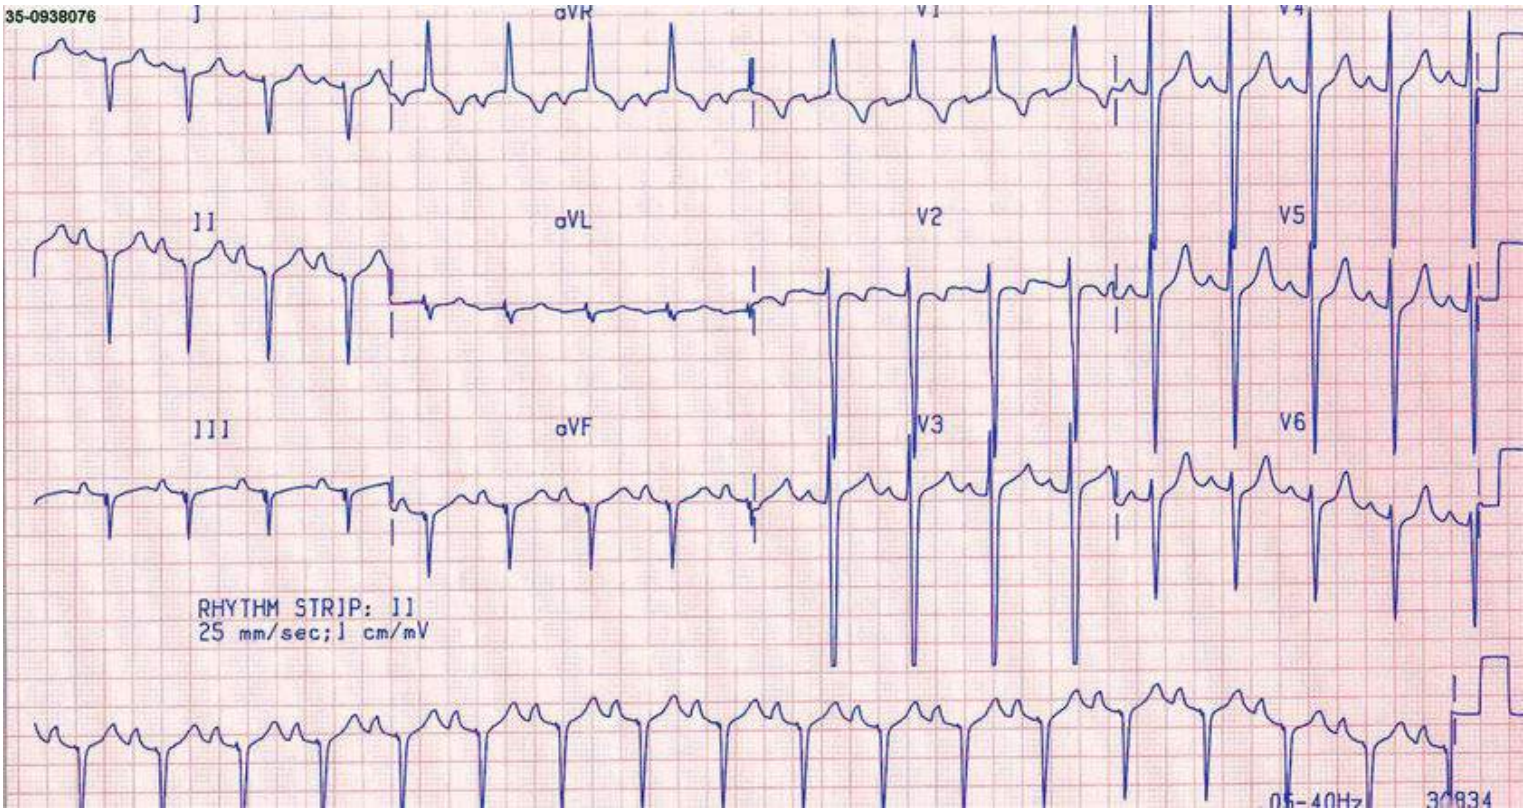
EAPPENDIX 75.53 Atrial fibrillation with ventricular rate of 90 bpm. Normal QRS axis. CLINICAL DX: Ebstein anomaly. Age 33.



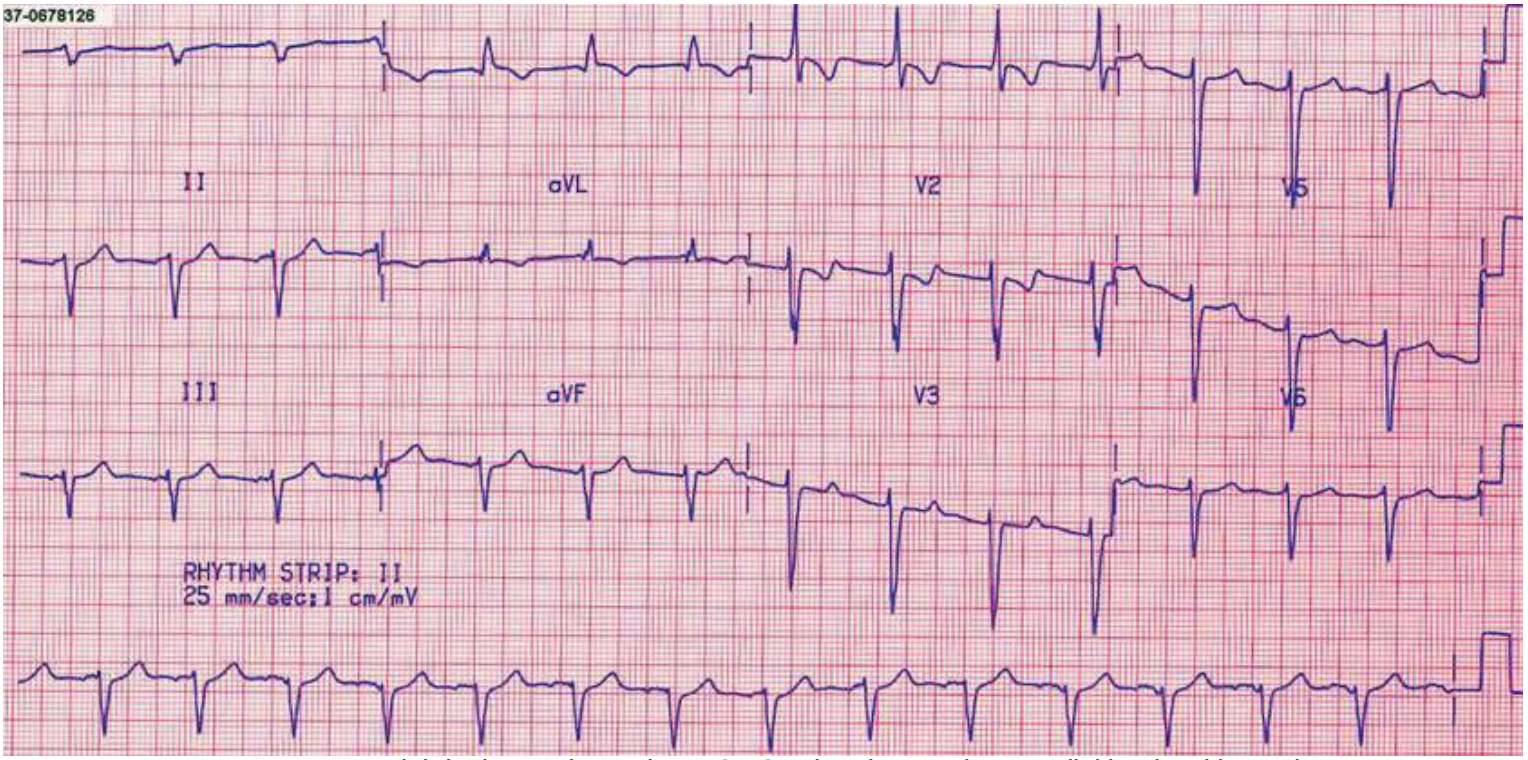
EAPPENDIX 75.54 Sinus rhythm. Right-axis deviation. Precordial evidence of right ventricular pressure overload. RV strain pattern V_1 to V_4. CLINICAL DX: Eisenmenger VSD. Age 20.



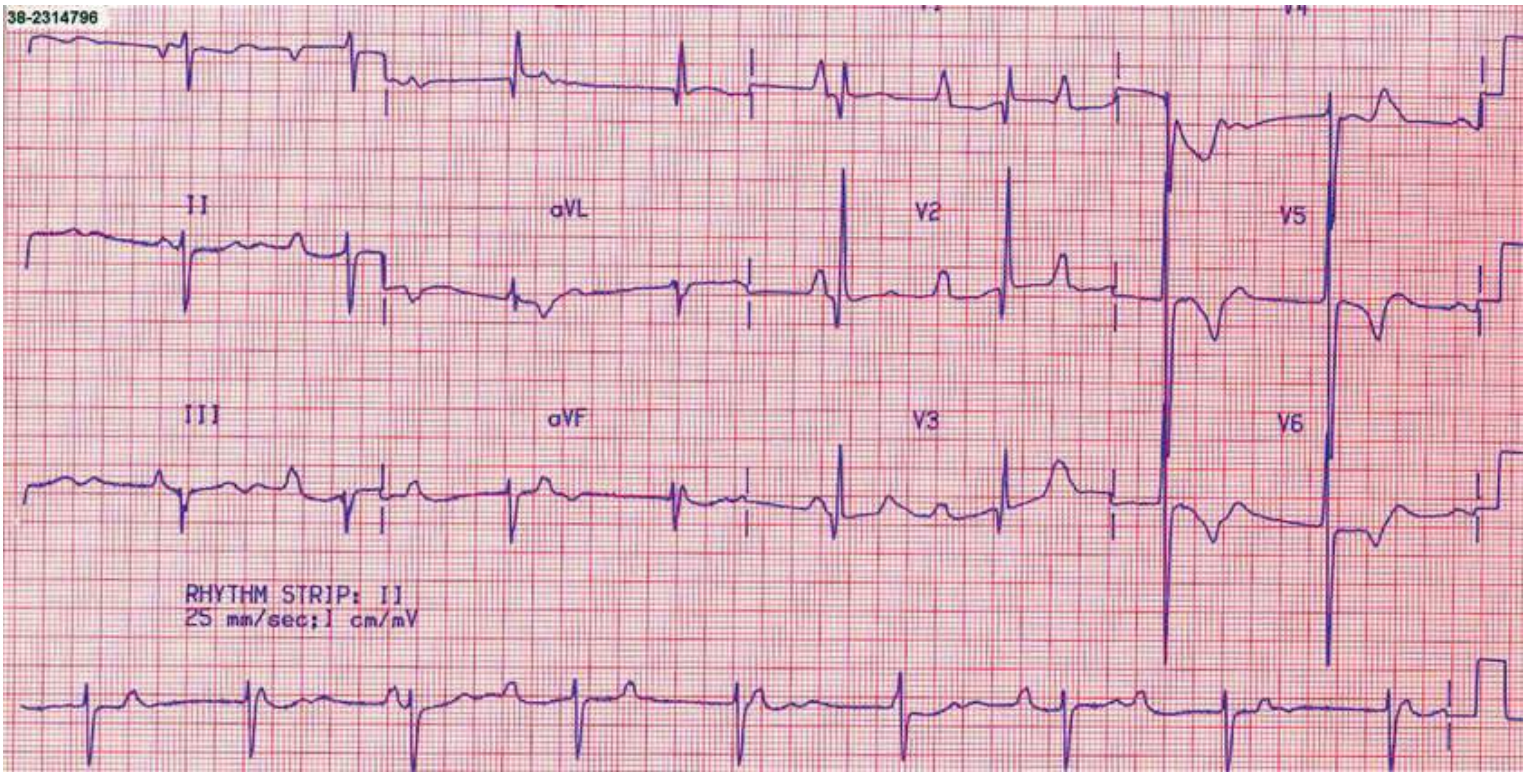
EAPPENDIX 75.55 Sinus rhythm. Short PR interval. Delta waves present. No right atrial overload. CLINICAL DX: Ebstein anomaly. Wolff-Parkinson-White pattern syndrome. Age 25.



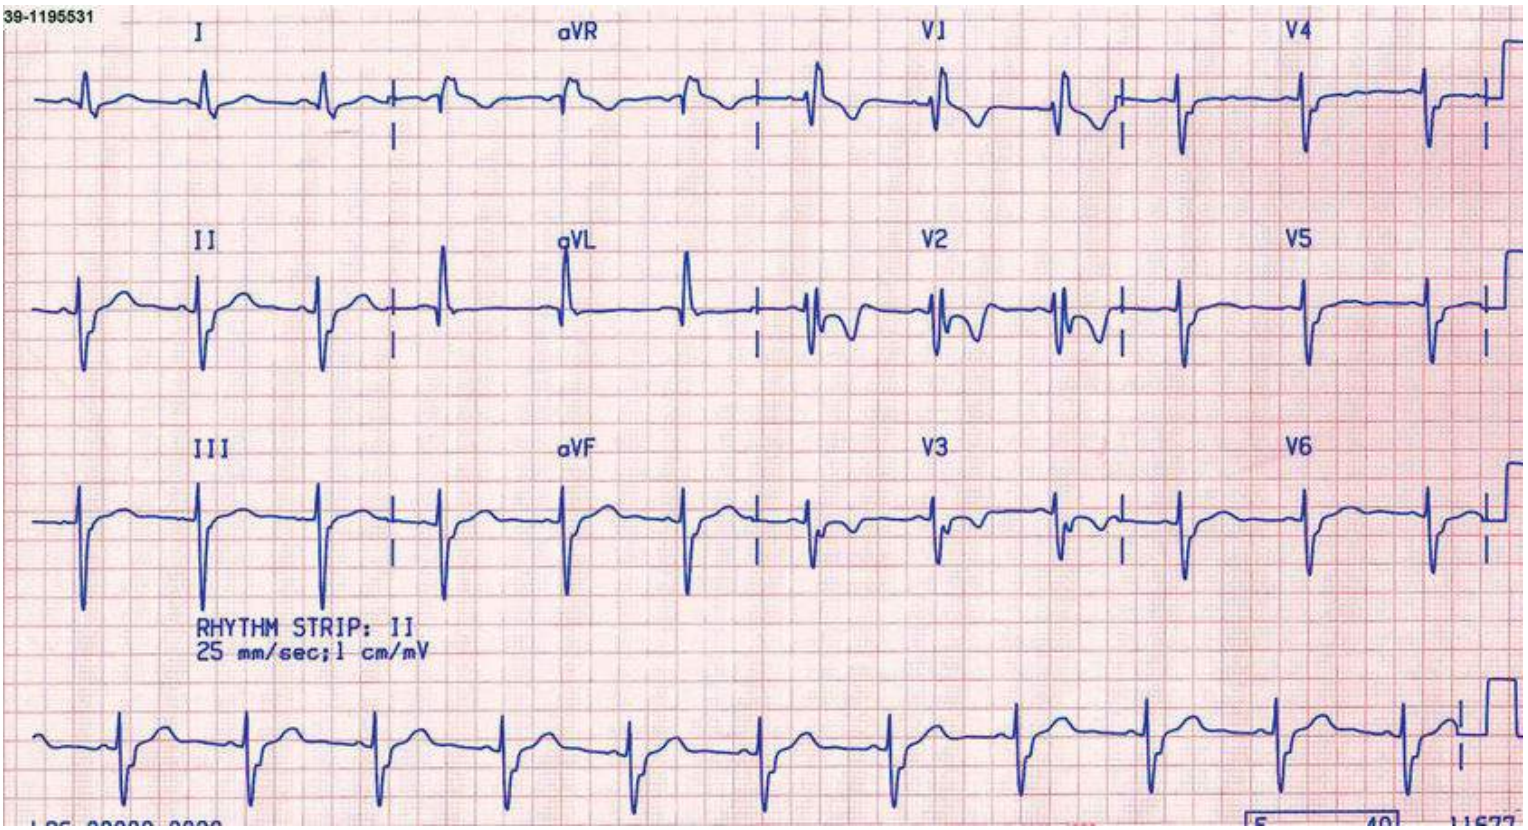
EAPPENDIX 75.56 Sinus tachycardia. Indeterminate QRS axis. Inferior Q waves of uncertain significance. Marked precordial evidence of RVH. Possible right atrial enlargement in lead II. CLINICAL DX: Eisenmenger VSD. Age 34.



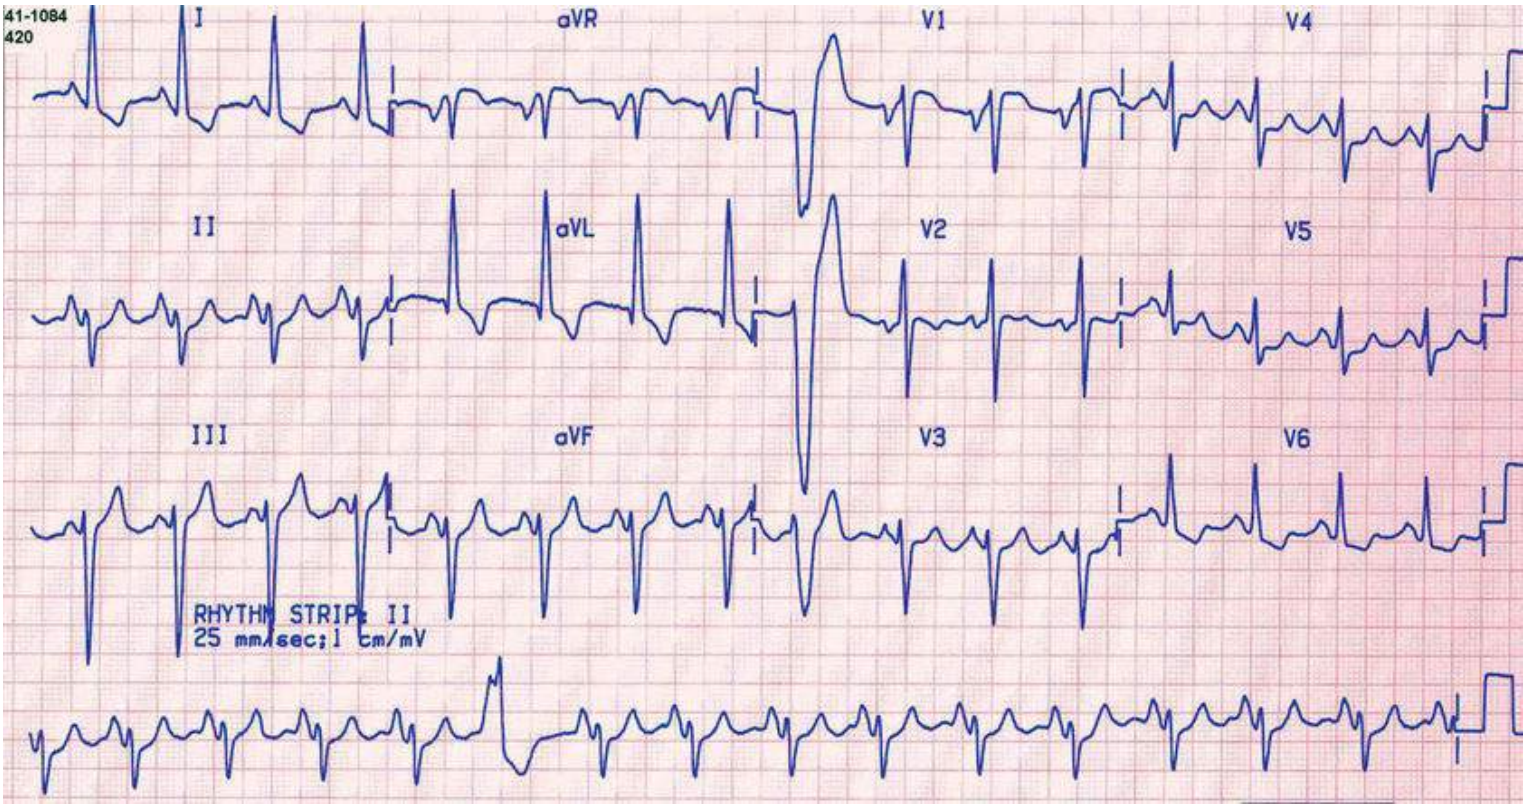
EAPPENDIX 75.57 Atrial rhythm. Indeterminate QRS axis. Abnormal precordial leads without clear significance. CLINICAL DX: Left atrial isomerism with a Fontan procedure. Age 31. Left atrial isomerism means that there is no sinus node in either atrium; thus the abnormal P wave axis.



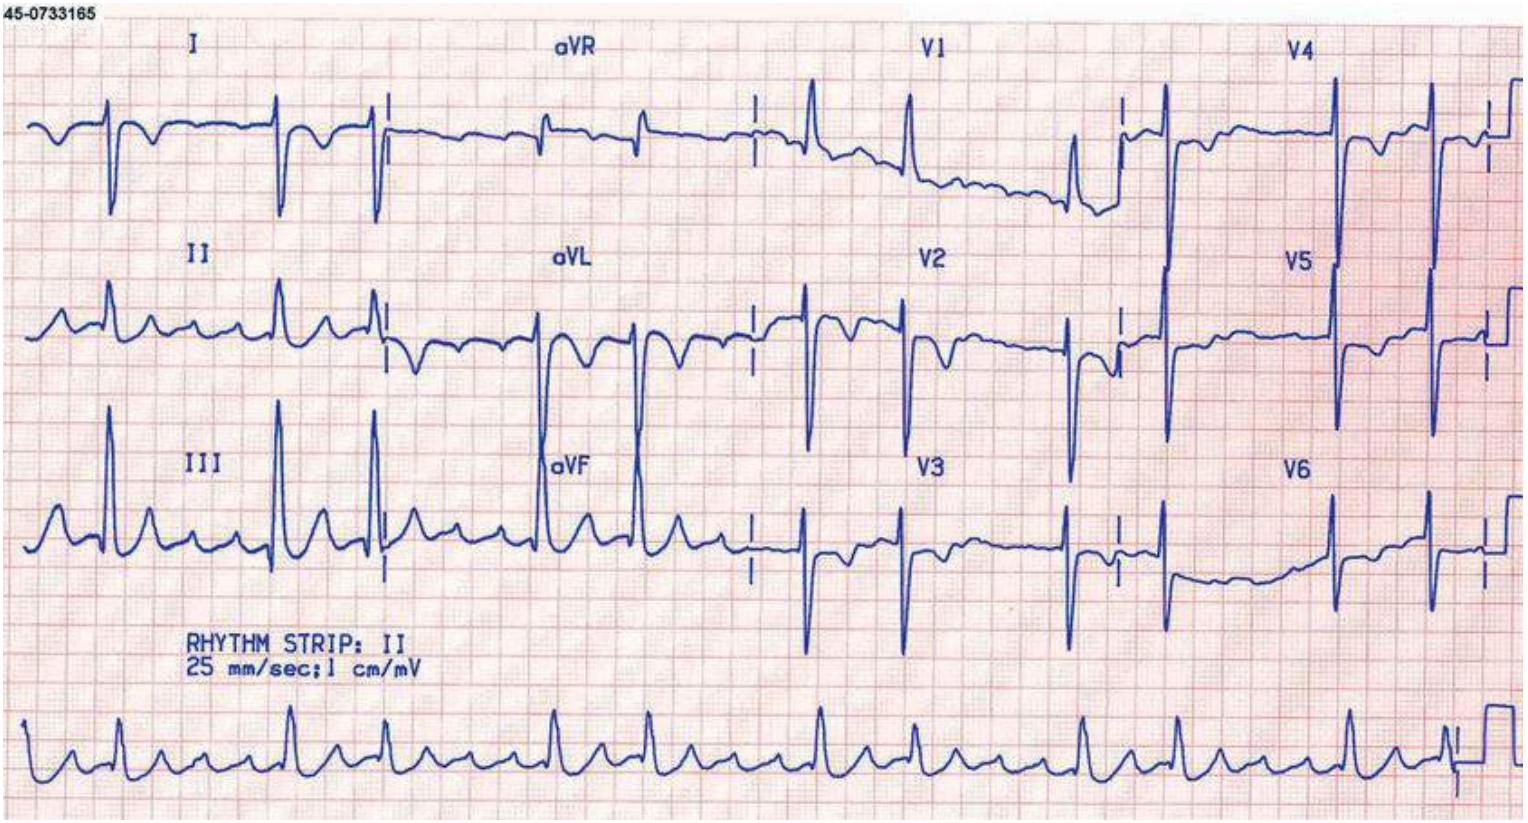
EAPPENDIX 75.58 Atrial rhythm at a rate of about 60 bpm. Complete heart block with a ventricular rate of about 55 bpm. Marked right atrial overload (V_1 and V_2). Q waves in V_1 to V_3 of uncertain significance. Abnormal precordial repolarization pattern. CLINICAL DX: Left atrial isomerism. Complete AV septal defect. Pulmonary hypertension. Age 21.



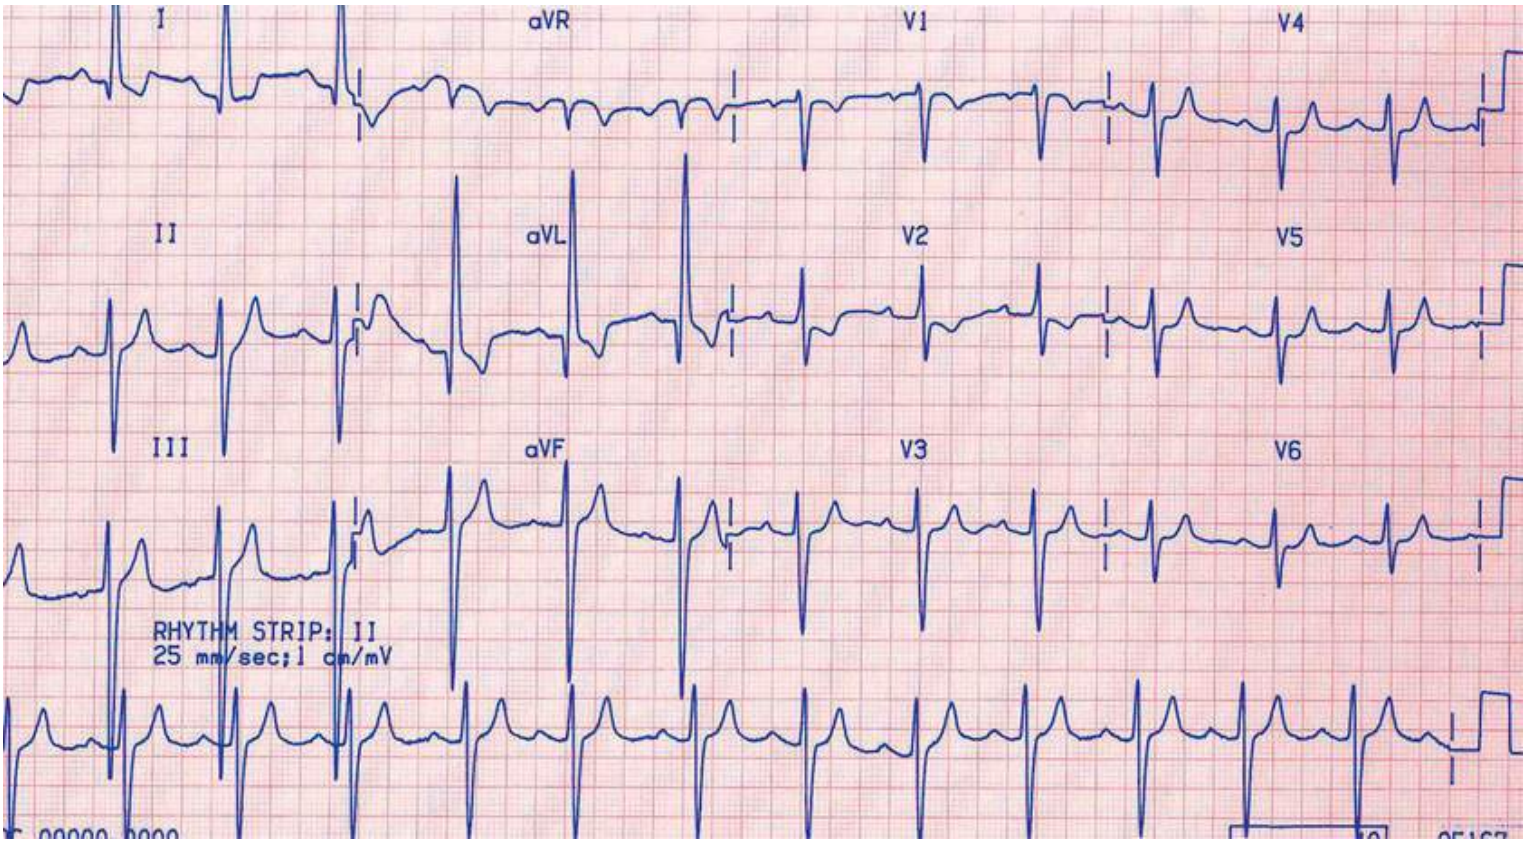
EAPPENDIX 75.59 Sinus rhythm. Left-axis deviation. Complete RBBB. CLINICAL DX: Repaired tetralogy. Age 22.



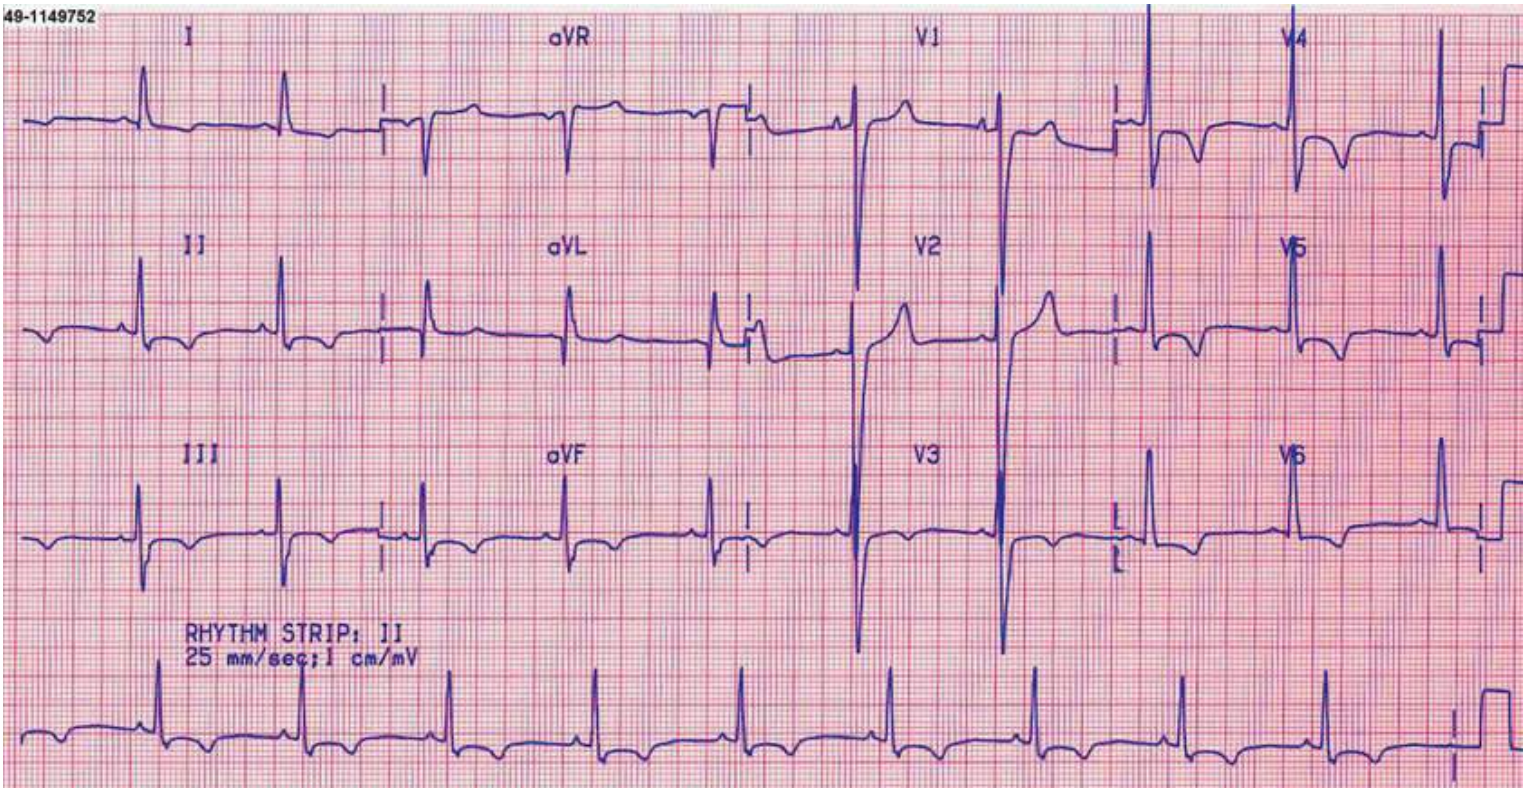
EAPPENDIX 75.60 Sinus rhythm with a ventricular rate of 100 bpm. Left-axis deviation. Possible right atrial overload. Occasional VPBs. Nonspecific repolarization abnormalities. CLINICAL DX: Tricuspid atresia with pulmonary atresia palliated with a Glenn shunt and a Potts shunt. Age 23.



EAPPENDIX 75.61 Atypical atrial flutter with a ventricular rate of about 75 bpm. Marked right-axis deviation. Voltage evidence of RVH with RV strain. CLINICAL DX: Fontan procedure for functionally single ventricle. Age 39.



EAPPENDIX 75.62 Sinus rhythm. Marked left-axis deviation. Possible voltage evidence of LVH in the standard and limb leads. CLINICAL DX: Tricuspid and pulmonary atresia palliated by a Glenn shunt (cavopulmonary shunt to the right lung) and Potts shunt to the left lung. Age 25.



EAPPENDIX 75.63 Sinus rhythm. Normal QRS axis. Probable LVH. T wave inversion in several leads. CLINICAL DX: Fontan procedure. Age 26. Fontan ECGs are difficult to interpret. The important thing is to compare them with the prior ECGs for the same patient.

Atrial flutter (often in an atypical form, or so-called *intraatrial reentrant tachycardia*) is much more

common in young patients than is atrial fibrillation. First-degree block is often seen in AV septal defects, cc-TGA, and Ebstein anomaly. Complete heart block is most often seen in patients with cc-TGA, as well as those with VSD repairs that had been performed in an earlier era.

Left atrial overload may reflect increased pulmonary blood flow, as well as AV valve dysfunction and myocardial failure. Left axis deviation should make one think of an AV septal defect, a univentricular heart, and/or a hypoplastic right ventricle. Deep Q waves in the left chest leads can be caused by left ventricular volume overload in a young person with aortic or mitral regurgitation. Pathologic Q waves can be evidence of the anomalous origin of the left coronary artery from the pulmonary artery.

The Chest Radiograph

The chest radiograph is another valuable tool for the discerning physician caring for patients with congenital heart defects (**see Chapter 15**). Although more recent technologies have rightly attracted much attention, there is value in learning how to interpret the chest radiograph. Some teaching points can be made that may anchor the interpretation of chest radiographs of some CHD patients. The following sections provide a number of clinical and radiographic differential diagnoses.

Criteria for Shunt Vascularity

The criteria for shunt vascularity include (1) uniformly distributed vascular markings with absence of the normal lower lobe vascular predominance; (2) a right descending pulmonary artery diameter that exceeds 17 mm; and (3) a pulmonary artery branch that is larger than its accompanying bronchus (best noted in the right parahilar area). Prominent vascularity is apparent only if the pulmonary-to-systemic flow ratio is greater than 1.5 to 1. As a rule, overt cardiac enlargement implies a shunt greater than 2.5 to 1. Patients with anemia, thyrotoxicosis, or a pulmonary AV fistula and pregnant patients may mimic shunt vascularity.

The group of *cyanotic patients with shunt vascularity* include those with a single ventricle with transposition, persistent truncus arteriosus, tricuspid atresia without significant pulmonary outflow obstruction, total anomalous pulmonary venous connection, double-outlet right ventricle, and a common atrium.

Disorders in *cyanotic patients with a VSD and normal or decreased pulmonary vascularity* include tetralogy of Fallot; tricuspid atresia with pulmonary stenosis; single ventricle and pulmonary stenosis; D-TGA with pulmonary stenosis; cc-TGA with pulmonary stenosis; double-outlet right ventricle with pulmonary stenosis; pulmonary atresia; and asplenia syndrome.

Causes of retrosternal filling on lateral chest radiograph include right ventricular dilation, TGA, ascending aortic aneurysm, and noncardiovascular masses (e.g., lymphoma, thymoma, teratoma, and thyroid masses).

Causes of a straight left heart border include right ventricular dilation, left atrial dilation, cc-TGA, pericardial effusion, Ebstein anomaly, and congenital absence of the left pericardium.

Cardiovascular diseases associated with scoliosis include cyanotic CHD, Eisenmenger syndrome, Marfan syndrome, and occasionally mitral prolapse.

Causes of large central pulmonary arteries include increased pulmonary flow (main pulmonary artery and branches), increased pulmonary pressure (main pulmonary artery and branches), valvular pulmonary stenosis (main and left pulmonary arteries), and idiopathic dilation of the pulmonary artery

(main pulmonary artery).

Situs solitus with cardiac dextroversion is associated with CHD in more than 90% of cases. Up to 80% have a congenitally corrected transposition with a high incidence of associated VSD, pulmonary stenosis, and tricuspid atresia. *Situs inversus with dextrocardia* has a low incidence of CHD, whereas s*itus inversus with levocardia* is virtually always associated with severe CHD.

Cardiovascular Magnetic Resonance Imaging

Cardiac MRI (**see Chapter 17**) in adolescents and adults with CHD has become of ever-increasing importance in the past decade. MRI can circumvent the echocardiographic problem of suboptimal visualization of the heart in adult patients, especially those who have had surgery. This technique can generate information never previously available and do so more easily or more accurately than any other means. New MRI image acquisition methods are faster and provide improved temporal and spatial resolution. Major advances in hardware design, new pulse sequences, and faster image reconstruction techniques now permit rapid high-resolution imaging of the complex cardiovascular anatomy. MRI can produce quantitative measures of the ventricular volumes, mass, and ejection fraction. MRI can quantify blood flow in any vessel.

Cardiac MRI is of particular value when transthoracic echocardiography cannot provide the needed diagnostic information; as an alternative to diagnostic cardiac catheterization; and for MRI's unique capabilities, such as myocardial characterization, deformation imaging by tissue tagging, and vessel-specific flow quantification. The value of MRI compared with echocardiography in the evaluation of the right ventricle has become increasingly appreciated. The capability of MRI to assess the right ventricle is of great importance because the right ventricle is a key component of many of the more complex CHD lesions. In addition, MRI can measure valve regurgitation and delineate postoperative systemic and pulmonary venous pathways, Fontan pathways, and the great vessels. MRI should be considered the best imaging modality in adolescents and adults with repaired tetralogy of Fallot, TGA, a Fontan procedure, and diseases of the aorta. Late gadolinium enhancement can demonstrate myocardial scarring in both preoperative and postoperative CHD, and is increasingly reported to be related to functional and arrhythmic outcomes. In the near future, we will see real-time MRI used to guide interventional procedures, and molecular imaging that will further expand MRI's capabilities.

Echocardiography

Fetal Echocardiography

Fetal echocardiography has “graduated” from being a special area of interest for some pediatric cardiologists to one of standard care. It should be offered to all mothers with increased risk of a fetal cardiac anomaly, including those with, or who have a partner with, CHD, and those with a strong family history. As early as 16 weeks' gestation, excellent images of the fetal cardiac structures can be obtained by the transabdominal route, along with an appreciation of cardiac and placental physiology through the use of Doppler technology. Transvaginal ultrasound is a newer approach that permits the echocardiographer to obtain images at approximately 13 to 14 weeks' gestation. Data are beginning to emerge as to the benefit of this approach, though current opinion would support a follow-up cardiac screening at 18 weeks' gestation. Although it has some application for cases with a higher risk of recurrent CHD (e.g., obstructive left-sided lesions), its accuracy has yet to be determined. This is in part because of the limited number of views that are possible with the relatively fixed position of the

transducer.

Impact of Fetal Echocardiography

Most major structural congenital heart defects are now accurately categorized through fetal echocardiography. Once the abnormalities are identified, families and obstetric caregivers can be counseled as to the impact of the abnormality both on the fetus and the family. Decisions appropriate to the family and fetus can then be made. Although termination of pregnancy is one of the consequences of prenatal diagnosis, it is not the main objective. In fact, data are starting to appear in the literature indicating that prenatal diagnosis of some major cardiac malformations has a direct impact on the outcome, from the vantage points of survival rates, morbidity rates, and costs. This is in part due to the fact that when a prenatal diagnosis is made, subsequent caregivers are prepared for the immediate postnatal effects of the defect. For example, in hypoplastic left heart syndrome and other duct-dependent lesions, prostaglandin E_1 can be started immediately after birth, hopefully in a hospital within or attached to a pediatric cardiology facility.

Fetal echocardiography has also permitted an improved understanding of the evolution of certain congenital cardiac malformations. For example, although the fetal heart is fully formed by the time a prenatal scan is performed, tremendous growth of the cardiac structures still must occur. Therefore, in some circumstances a cardiac chamber that may appear only mildly hypoplastic at 16 weeks' gestation may be profoundly affected at the time of birth. This has a major impact on the management of the newborn as well as the counseling process at 16 weeks' gestation.

Direct Fetal Intervention

The next step is direct intervention for specific cardiac lesions. Intervention has initially involved obstructive lesions, thus far mainly being limited to the left ventricle. The rationale behind this therapy is based on the notion that the relief of obstructive outflow tract lesions will permit growth of the affected ventricle, potentially changing a neonatal pathway from univentricular to biventricular. Cardiac surgery for the fetus is also a future option, and indeed there is already a considerable amount of research on the impact of this in fetal animal models.

Segmental Approach to Echocardiography in Congenital Heart Disease

The following four echocardiographic steps of segmental analysis are crucial in any patient with CHD. Starting from a standard subcostal view, one should determine the position of the apex and the situs of the atria, as well as the AV and ventriculoarterial relationships.

1 Apex

From a standard subcostal view, determine if the apex of the heart is pointing to the right (dextrocardia), to the left (levocardia), or to the middle (mesocardia) (**Fig. 75.2**) (Videos 75.7 to 75.9).

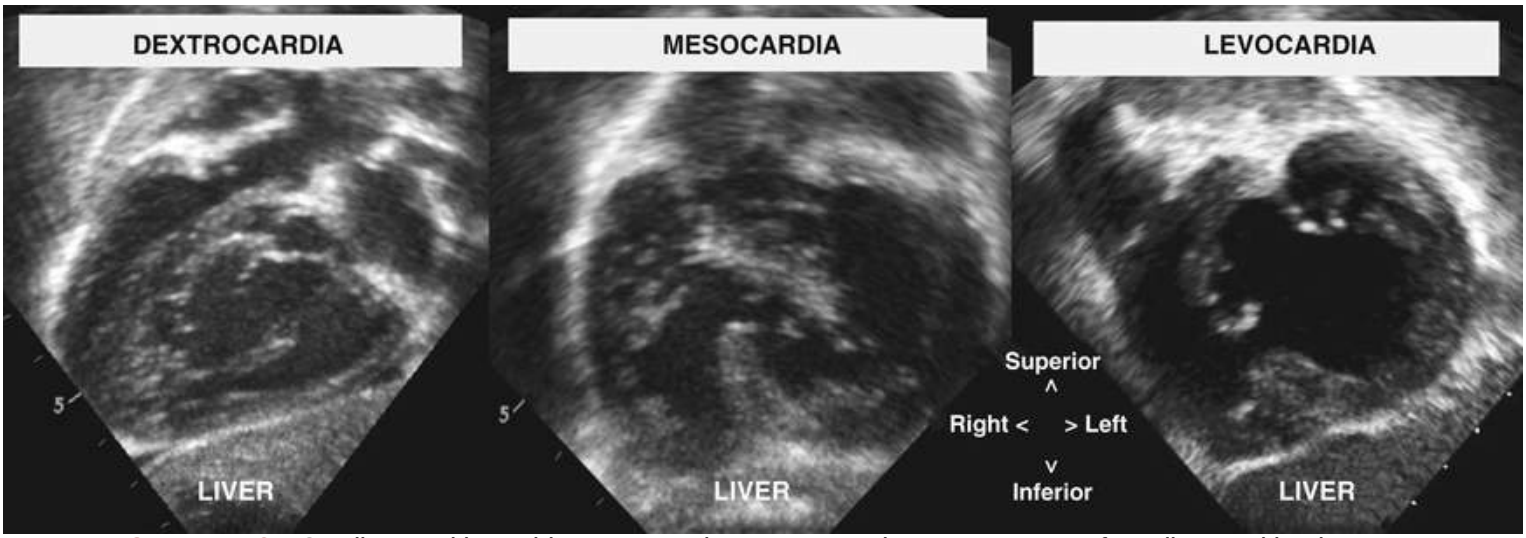


FIGURE 75.2 Cardiac position: This montage demonstrates the assessment of cardiac position in patients with complex congenital heart disease, as obtained from the subcostal position in a coronal plane. This is the optimal plane for determining the position of the apex of the heart.

2 Situs of the Atria *(Fig. 75.3)*

The right and left atria differ morphologically with regard to their appendages. A morphologic right atrium has a broad right atrial appendage, whereas a morphologic left atrium has a narrow left atrial appendage. Right and left atrial appendages, however, are difficult to visualize by transthoracic echocardiography, and one often has to rely on the abdominal situs to determine the atrial situs. The atrial situs follows the abdominal situs in 70% to 80% of cases. From a standard subcostal view with the probe pointing at a right angle to the spine, one can visualize the abdominal aorta, as well as the inferior vena cava and the spine at the back. When the aorta is to the left of the spine and the inferior vena cava to the right of the spine, there is abdominal situs solitus and, in all probability, corresponding atrial situs solitus (meaning the morphologic right atrium is on the right side and the morphologic left atrium is on the left side, the so-called “usual” atrial arrangement). In this setting the usual situation is for the systemic veins to connect to the morphologic right atrium, with the pulmonary veins to the left (**Fig. 75.4**); however, systemic and pulmonary venous drainage does not define the atrial morphology.

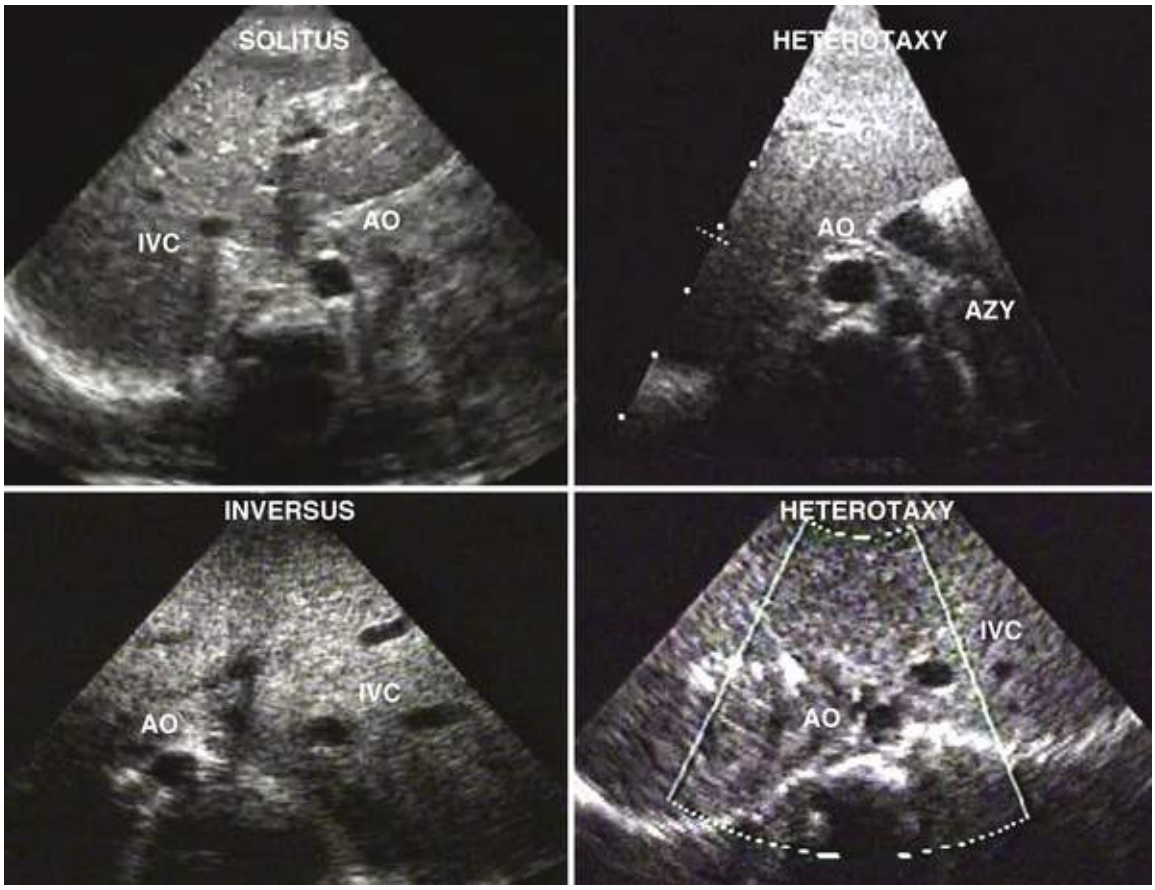

FIGURE 75.3 Montage of the different types of situs as seen by a subcostal echocardiographic scan. Note that situs solitus and inversus are just the mirror images of each other. The upper right picture is in the setting of heterotaxy with an interrupted intrahepatic inferior vena cava, with azygos continuation on the left. This is seen more frequently in left atrial isomerism. The lower right picture is also in the setting of heterotaxy with an intrahepatic inferior vena cava that is positioned closer to the aorta than in solitus or inversus. Note also the midline liver. This pattern is seen more commonly in right atrial isomerism. *AO*, aorta; *AZY*, azygos; *IVC*, inferior vena cava.

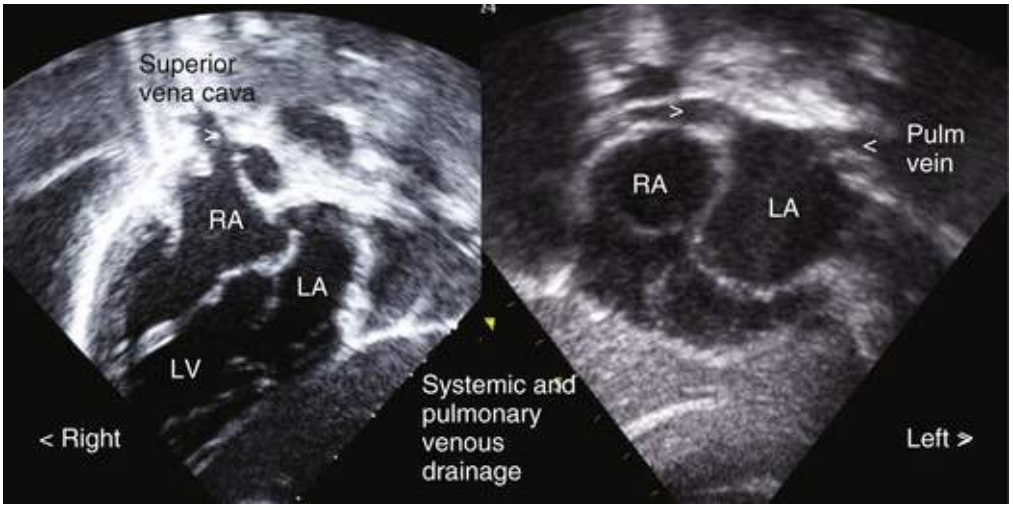

FIGURE 75.4 Systemic and pulmonary venous drainage: This montage demonstrates the systemic and pulmonary venous drainage in a heart with dextrocardia and double-inlet left ventricle. The image on the left shows the superior vena cave connecting to the right-sided atrium. The right-sided panel shows the pulmonary veins draining to the left-sided atrium in the same case. *LA*, left atrium; *LV*, left ventricle; *RA*, right atrium.

When the aorta is to the right of the spine and the inferior vena cava is to the left of the spine, there is abdominal situs inversus and, in all probability, corresponding atrial situs inversus (morphologic right

atrium on the left side and morphologic left atrium on the right side [i.e., mirror-image atrial arrangement]). When both the aorta and inferior vena cava are on the same side of the spine, there is usually abdominal and atrial right isomerism (two morphologic right atria). Left atrial isomerism (two morphologic left atria) is usually suspected when the intrahepatic inferior vena cava is interrupted, with the presence of azygos continuation in the paravertebral gutter, on either the left or right side.

3 Atrioventricular Relationship

Once the situs of the atria is determined, one must assess the position of the ventricles in relation to the atria. The morphologic right ventricle has four characteristic features that distinguish it from the morphologic left ventricle: (1) a trabeculated apex, (2) a moderator band, (3) septal attachment of the tricuspid valve, and (4) lower (apical) insertion of the tricuspid valve. The tricuspid valve is always "attached" to the morphologic right ventricle (**Fig. 75.5**, and see Video 75.8**).** The morphologic left ventricle has the following characteristics: (1) a smooth apex, (2) no moderator band, (3) no septal attachment of the mitral valve, and (4) a higher (basal) insertion of the mitral valve. The mitral valve is always "attached" to the morphologic left ventricle (**see Fig. 75.5**). Once the position of the ventricles is determined, one can establish the AV relationship. When the morphologic right atrium empties into the morphologic right ventricle and the morphologic left atrium empties into the morphologic left ventricle, there is AV concordance. When the morphologic right atrium empties into the morphologic left ventricle, and the morphologic left atrium empties into the morphologic right ventricle, there is AV discordance (**see Fig. 75.5**) (Video 75.10; see Video 75.9).

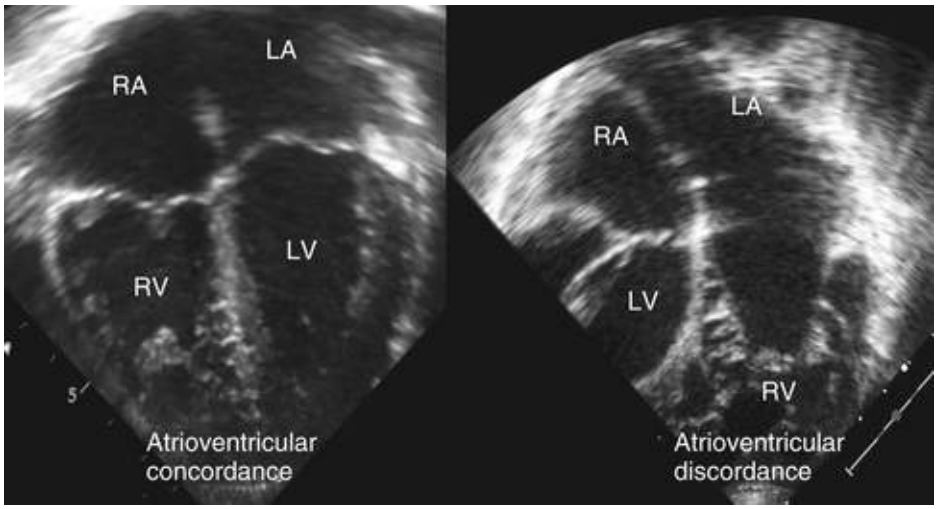

FIGURE 75.5 AV concordance and AV discordance: The image on the left is from a heart with AV concordance. Note that the tricuspid valve is inserted at a lower level than the mitral valve. Also note the heavily trabeculated right ventricle with evidence of the moderator band. The image on the right is from a heart with AV discordance. Note in this image that the left-sided tricuspid valve is inserted at a lower level than its mitral counterpart. Also the right-sided interventricular septum is smooth, with no septal attachments from the right-sided mitral valve. *LA*, left atrium; *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle.

The *morphologic right ventricle* is a triangular-shaped structure with an inlet, a trabecular, and an outlet component. The inlet component of the right ventricle has attachments from the septal leaflet of the tricuspid valve. Inferior to this is the moderator band, which arises at the base of the trabeculoseptomarginalis, with extensive trabeculations toward the apex of the right ventricle. The outlet component of the right ventricle consists of a fusion of three structures (i.e., the infundibular septum

separating the aortic from the pulmonary valve, the ventriculoinfundibular fold separating the tricuspid valve from the pulmonary valve, and, finally, the anterior and posterior limbs of the trabeculoseptomarginalis).

The *morphologic left ventricle* is an elliptical-shaped structure with a fine trabecular pattern, with absent septal attachments of the mitral valve in the normal heart. It consists of an inlet portion containing the mitral valve and a tension apparatus, with an apical trabecular zone that is characterized by fine trabeculations and an outlet zone that supports the aortic valve.

What happens when these basic rules do not apply? This is encountered in hearts where both atria are predominantly connected to one ventricle (univentricular AV connection), either by one or two AV valves. There has been recent consensus in the nomenclature, so that a heart such as this is referred to as a *functionally single ventricle*. In general, these are hearts where both ventricular chambers cannot be used to support the systemic and pulmonary venous circulations, such that the only option is a Fontan approach. This approach has been the Rosetta stone of morphology, connecting the European and North American classifications. Of note, in these hearts the apex can be left sided, at the midline, or on the right; none of these placements impacts the classification of a functionally single ventricle. They can also coexist with all types of situs, that is, solitus, inversus, or isomeric. The type of ventriculoarterial connection does not influence this classification. It is possible to have normally related great arteries, discordant arterial connections, or a single outlet, with either aortic or pulmonary atresia. When there are two ventricles, they are usually connected by a VSD, which in the majority of cases is muscular in nature.

In hearts with a *double-inlet ventricle*, both atria are mainly connected to one ventricular chamber, either by two valves or a common AV valve. This is dictated by the 50% rule, whereby more than 50% of the total annular circumference is committed to one ventricular mass, this being independent of the status of the AV valves (**Fig. 75.6**) (Videos 75.11 to 75.17). Of note, the designation of double inlet is not dictated by the morphology or size of the connecting AV valves. They can connect mainly into a ventricle of left or right ventricular morphology, and rarely one ventricle, the morphology of which can be difficult to determine (**Fig. 75.7**) (Video 75.18). The morphology of the ventricles is determined in part by some of the same features described above, but in a ventricular chamber without a connecting AV valve the position of that chamber, relative to the larger one, is an important key to determining its status as a left or right ventricle. For example, a smaller ventricle lying posterior to a larger one is almost always a morphologic left ventricle. A smaller ventricle lying anterior to a larger one is a morphologic right ventricle (**Fig. 75.8**) (Video 75,19).

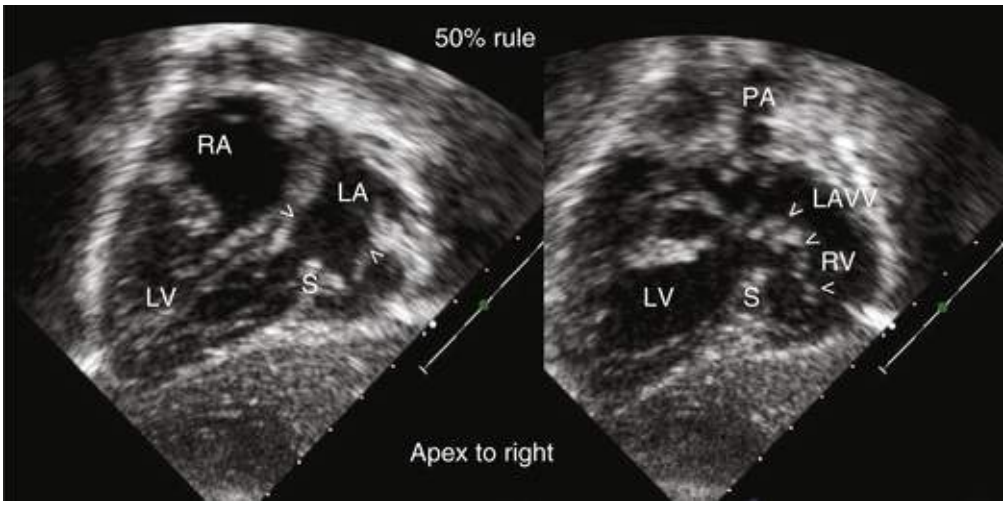

FIGURE 75.6 Fifty percent rule straddling left atrioventricular valve: These two images are from a heart with dextrocardia and a double-inlet left ventricle. Note in the left-hand panel the left-sided AV valve annulus (as indicated by the *white arrows*) overrides the interventricular septum by at least 50%. If the overriding were less than 50%, the designation would be AV discordance. There is straddling of the left-sided AV valve, as indicated by the *white arrows*. The valve has a foot in both ventricles. This demonstrates one of the flaws in the nomenclature; that is, determining in this heart the precise amount of overriding. Of importance, the presence of the straddling valve plays no role in the designation of the AV connection. *LA*, left atrium; *LAVV*, left atrioventricular valve; *LV*, left ventricle; *PA*, pulmonary artery; *RA*, right atrium; *RV*, right ventricle; *S*, interventricular septum.

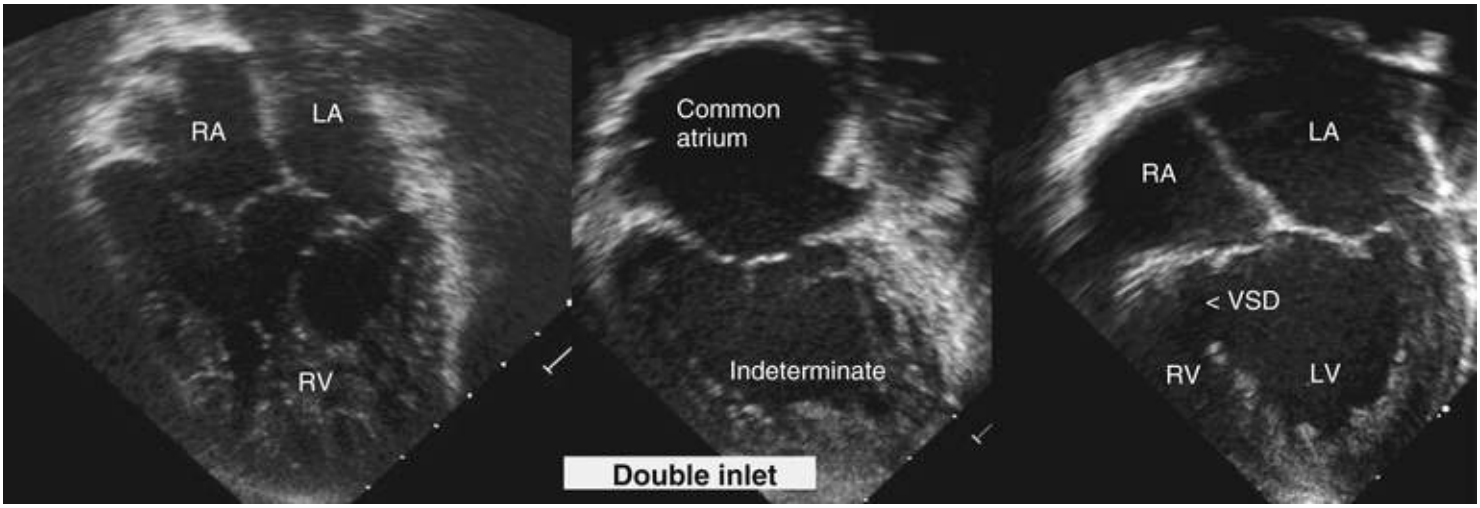

FIGURE 75.7 Double-inlet labels: These three images are from hearts with a double inlet. The one on the left is from a heart with a double-inlet right ventricle (note the coarse trabeculations) with two AV valves that are totally committed to the large right ventricle. The image on the far right is from a heart with a double-inlet left ventricle and two AV valves. Note the hypoplastic right ventricle on the right, and the large VSD. The image in the middle is from a heart with a double inlet and a common AV valve with an associated common atrium (often seen in hearts with isomerism). There was no second chamber in the heart, and the designation of a morphologic left or right ventricle is difficult. *LA*, left atrium; *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle; *VSD*, ventricular septal defect.

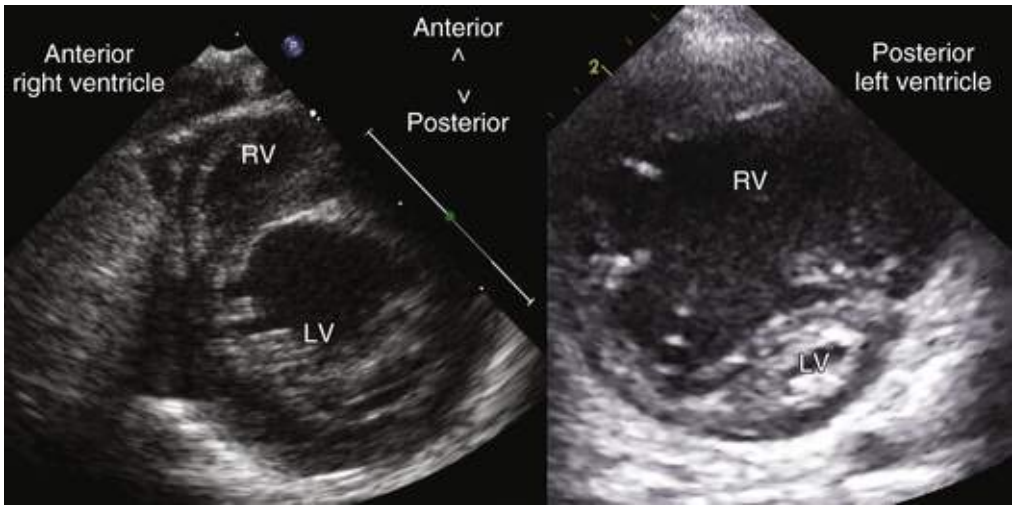

FIGURE 75.8 Chamber position: These two images show how the position of the ventricles can help determine their morphology. On the left-hand side, the larger chamber is posterior and the smaller one anterior; thus the larger chamber is the morphologic left ventricle. The right-hand panel demonstrates the opposite, that is, a dominant right ventricle with a smaller posterior left ventricle. *LV*, left ventricle; *RV*, right ventricle.

Ventricular looping is also an important consideration. For example, in a double-inlet left ventricle, an L loop is more common with the morphologic left ventricle situated on the right of the hypoplastic morphologic right ventricle. In a D loop, the morphologic left ventricle is on the left of the hypoplastic morphologic right ventricle (**Fig. 75.9**) (Videos 75.20 and 75.21).

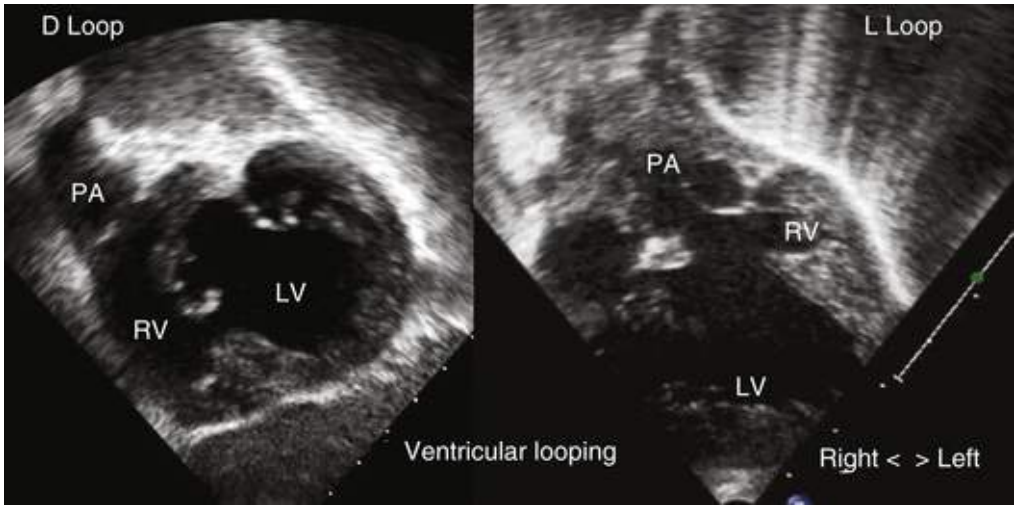

FIGURE 75.9 Ventricular looping: The image on the left taken from the subcostal position shows a heart with levocardia, a D-loop, and a double-inlet left ventricle (i.e., the morphologic left ventricle is on the right and the hypoplastic right ventricle is on the right). The panel on the right, also taken from the subcostal position, is also from a heart with levocardia and a double-inlet left ventricle; however, there is an L-loop, with the morphologic right ventricle being to the left and anterior of the larger morphologic left ventricle. Of note, in the left-hand panel the pulmonary artery arises from the right-sided right ventricle, whereas it arises from the morphologic left ventricle in the right-hand panel. *LV*, left ventricle; *PA*, pulmonary artery; *RV*, right ventricle.

In a *heart with an absent connection*, there is absence of either the left-sided or right-sided AV valve, and a solitary valve connects both atria to the main ventricular mass. This disorder is often referred to as mitral or tricuspid atresia, terms that are still in common use (**Fig. 75.10**) (Videos 75.22 and 75.23; see also Video 75.7). Although the remaining AV valve is often referred to as a mitral or tricuspid valve, this can be misleading, because in some instances the valve morphology does differ from the classic

description in the normal heart. Of importance, the floor of the absent connection consists of sulcus tissue, such that if a pin were to be passed from the right atrium through that tissue, it would end up outside the heart, and not in the hypoplastic left or right ventricle.

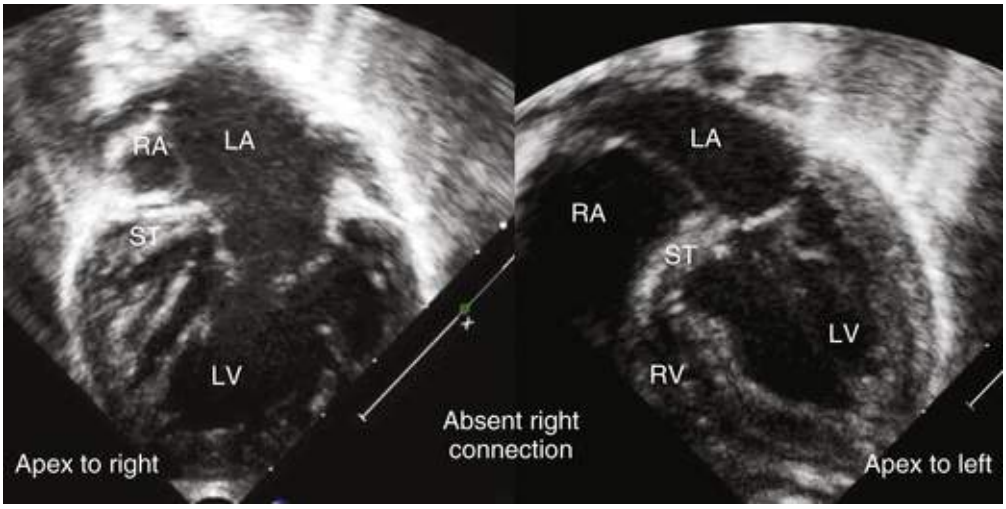

FIGURE 75.10 Absent right connection labels: These two images are from hearts with an absent right connection, the one on the left with associated dextrocardia, and the one on the right with levocardia. Note the pulmonary veins draining into the left atrium and the wedge of sulcus tissue between in the floor of the right atrium as seen in both images. If a pin were passed from the right atrium through the sulcus tissue, it would end up outside the heart in the AV groove, differentiating the condition pictured from an imperforate valve. Also note the hypoplastic right ventricle on the right of the dominant left ventricle in the right-hand panel. *LA*, left atrium; *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle; *ST*, sulcus tissue.

If a heart has a *functionally single ventricle in the setting of AV concordance or discordance, but with associated hypoplasia of one ventricle, it requires a Fontan, or single-ventricle, palliation, because the smaller ventricle is incapable of supporting either the systemic or pulmonary venous circulations. This includes hearts with the classic hypoplastic left heart syndrome, pulmonary atresia with an intact ventricular septum (***Fig. 75.11***) (*Videos 75.24 and 75.25*), unbalanced AV septal defects, and corrected transposition with hypoplasia of one or the other ventricle. Again, this classification is not affected by the status of the connecting AV valves, nor of the ventriculoarterial connections.*

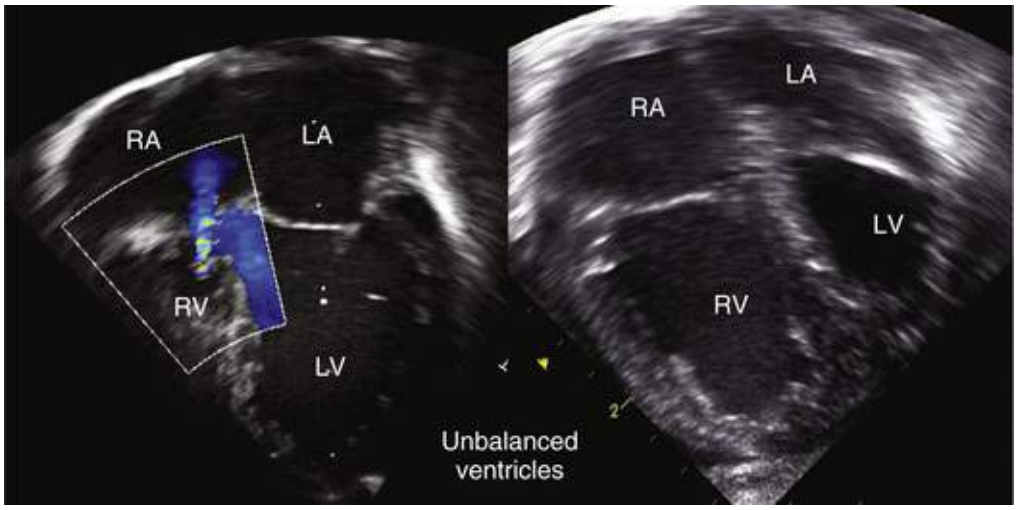

FIGURE 75.11 Unbalanced ventricles: The image on the left is from a heart with AV concordance, but a hypoplastic morphologic right ventricle. Note that the tricuspid valve is perforate because the color Doppler image shows some tricuspid valve regurgitation. This heart is from a case with pulmonary atresia intact ventricular septum. The heart on the right is from a case with hypoplastic left heart syndrome, with a hypoplastic left-sided morphologic left ventricle. The AV connection is concordant. Both cases are referred to as having a "functionally single ventricle" because the small chamber cannot support either the systemic or pulmonary arterial circulation. *LA*, left atrium; *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle.

4 Ventriculoarterial Relationship

Once the AV relationship has been determined, one should assess the position of the great artery(s) in relation to the ventricles (**Figs. 75.12 and 75.13**; (see also Videos 75.10, 75.15, 75.16, and 75.20). It is possible to have an aorta and a pulmonary artery, or a solitary outlet from either ventricle, with the other artery being atretic. Also, in some cases, the solitary outlet can be a solitary trunk, which gives rise to the head and neck vessels and the pulmonary and coronary arteries. The pulmonary artery can be distinguished by its early branching pattern into the left and right pulmonary arteries; the pulmonary valve is always "attached" to the pulmonary artery. Similarly, the aorta can be distinguished by its "candy cane" shape and the take-off of its three head and neck vessels (innominate, carotid, and subclavian arteries). The aortic valve is always "attached" to the aorta. Once the position of the great arteries is determined, one can establish the ventriculoarterial relationship. When the morphologic right ventricle ejects into the pulmonary artery and the morphologic left ventricle ejects into the aorta, there is ventriculoarterial concordance. When the morphologic right ventricle ejects into the aorta and the morphologic left ventricle ejects into the pulmonary artery, there is ventriculoarterial discordance. When more than 50% of both great arteries exit from one ventricle (right or left), this is called a *double-outlet* (right or left) *ventricle*.

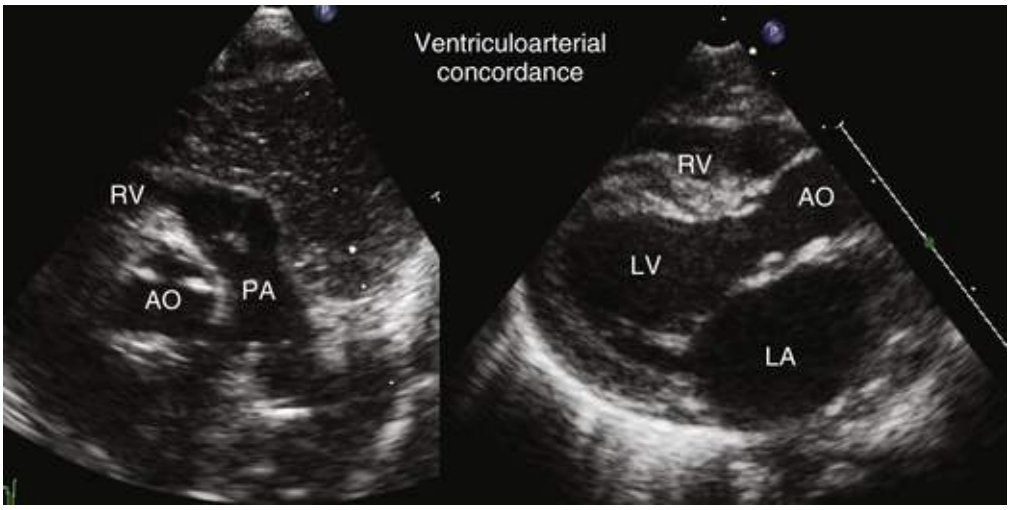

FIGURE 75.12 Ventriculoarterial concordance: These two images are from a heart with an absent right connection (tricuspid atresia) and ventriculoarterial concordance. That is, the aorta arises from the morphologic left ventricle and the pulmonary artery from the more anterior morphologic right ventricle. *AO*, aorta; *LA*, left atrium; *LV*, left ventricle; *PA*, pulmonary artery; *RV*, right ventricle.

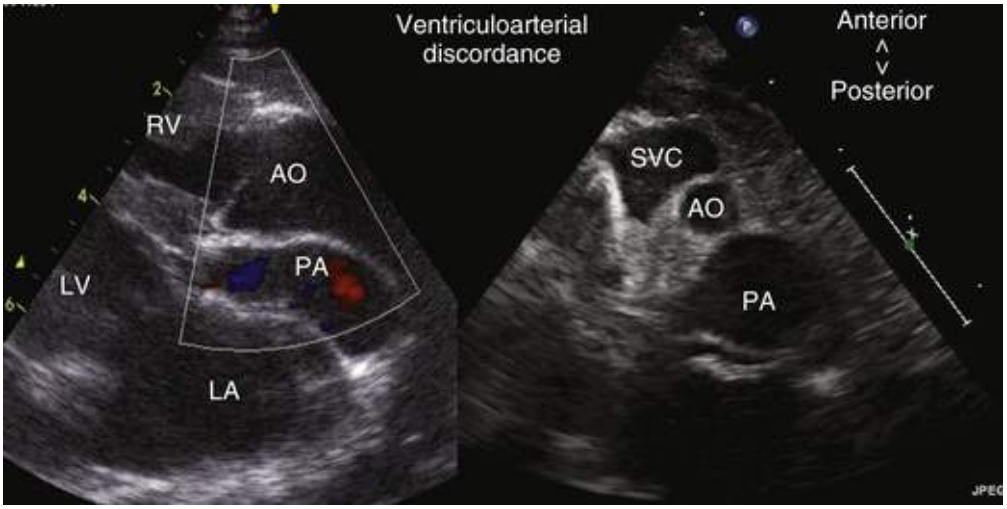

FIGURE 75.13 Ventriculoarterial discordance: These two images are from different hearts, one with a hypoplastic aorta (right-hand panel) and the other with a hypoplastic main pulmonary artery (left-hand panel). Note in both cases the aorta is anterior to the posterior pulmonary artery. The image on the left shows the two great arteries that are parallel to each other, unlike in the image on the right, where the more anterior pulmonary artery crosses the aorta. The image on the right is taken in the short axis plane. *AO*, aorta; *LA*, left atrium; *LV*, left ventricle; *PA*, pulmonary artery; *RV*, right ventricle; *SVC*, superior vena cava.

Once segmental analysis has been completed, one can proceed to the usual echocardiographic windows to determine the nature of the specific lesions, as well as their hemodynamic relevance.

Other Echocardiographic Imaging Modalities

Transesophageal and Three-Dimensional Echocardiography

Transesophageal echocardiography (TEE) offers a better two-dimensional (2D) resolution than transthoracic echocardiography. This is especially important in adult patients who have undergone multiple previous cardiac operations and in whom adequate transthoracic windows are often difficult to obtain.

TEE should be used whenever transthoracic echocardiography or MRI does not provide adequate anatomic or functional information. The addition of real-time three-dimensional (3D) TEE has opened up a new diagnostic window. It can be used in specific cases to (1) depict the spatial relationship of the various structures within the heart, (2) quantify the chamber size, mass, and function, as well as (3) help guide transcatheter procedures.[14] Transthoracic 3D echocardiography has been limited in the adult CHD population because of the size of the patients being imaged and the number of prior operations they may have undergone; its TEE counterpart can play a major role in diagnostic evaluation, however. TEE should be considered in the setting of the conditions discussed in the following sections.

In *secundum atrial septal defect*, use TEE for the assessment of device closure feasibility, measuring ASD size, assessing the adequacy of margins for device anchoring, and ruling out an anomalous pulmonary venous connection. This information can be enhanced by real-time 3D imaging, which provides precise anatomic detail of the ASD (**Fig. 75.14**).

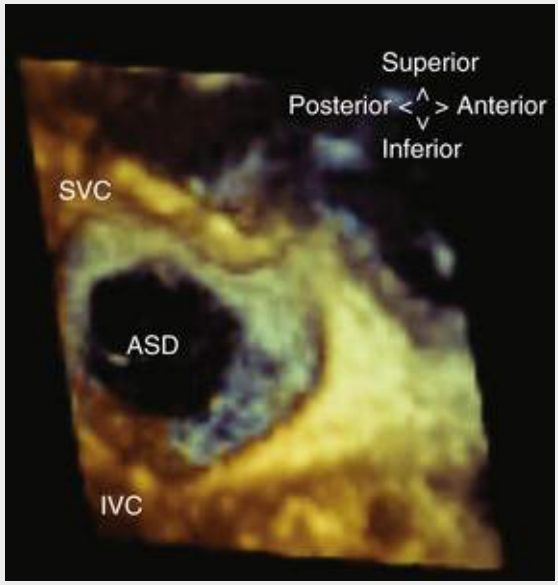

FIGURE 75.14 Three-dimensional secundum ASD: This real-time 3D echocardiographic image obtained by T EE demonstrates the rims of a large secundum atrial septal defect, as seen from the right atrium. ASD, atrial septal defect; IVC, inferior vena cava; SVC, superior vena cava.

In *atrioventricular valve regurgitation*, use TEE for preoperative evaluation of mitral valve leaflet morphology and suitability for mitral valve repair versus replacement. Real-time 3D TEE is rapidly becoming the reference standard for evaluating mitral valve form and function prior to surgical or catheter intervention. As well, this imaging is invaluable in those cases with complex CHD with abnormalities of one or another AV valve. Lesions such as postoperative AV septal defect, corrected transposition (**Fig. 75.15**, and Videos 75.26 and 75.27), or Fontan hearts with a regurgitant systemic AV valve frequently require further intervention. Real-time 3D TEE has been disappointing for tricuspid valve assessment in those with normal connections and no ventricular hypoplasia. This has not been the case in hearts following the Fontan procedure, however, because invariably, the valve being evaluated is more perpendicular to the ultrasound beam (unlike the normal tricuspid valve, the oblique position of which affects the image resolution). Preoperative planning, using imaging plus real-time 3D color Doppler echocardiography, is essential for an optimal repair (**Fig. 75.16** and Video 75.28). Color

Doppler assessment of the site of regurgitation is more sensitive than standard saline testing,[15] and so should be used routinely.

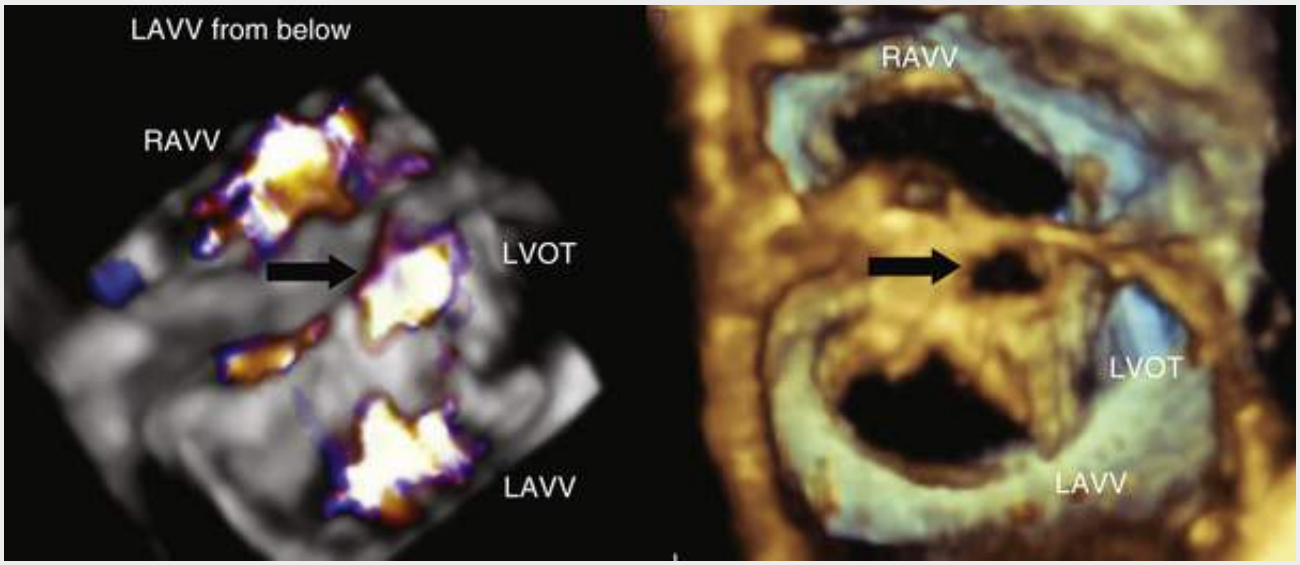

FIGURE 75.15 Three-dimensional postoperative AV septal defect: This TEE real-time 3D image is taken from below in a case following repair of an AV septal defect. It images the left AV valve from below and demonstrates two mechanisms of regurgitation, one from an area of dehiscence of the valve indicated by the *black arrow*, with the second located centrally because of poor coaptation of the leaflets. *LAVV*, left atrioventricular valve; *LVOT*, left ventricular outflow tract; *RAVV*, right atrioventricular valve.

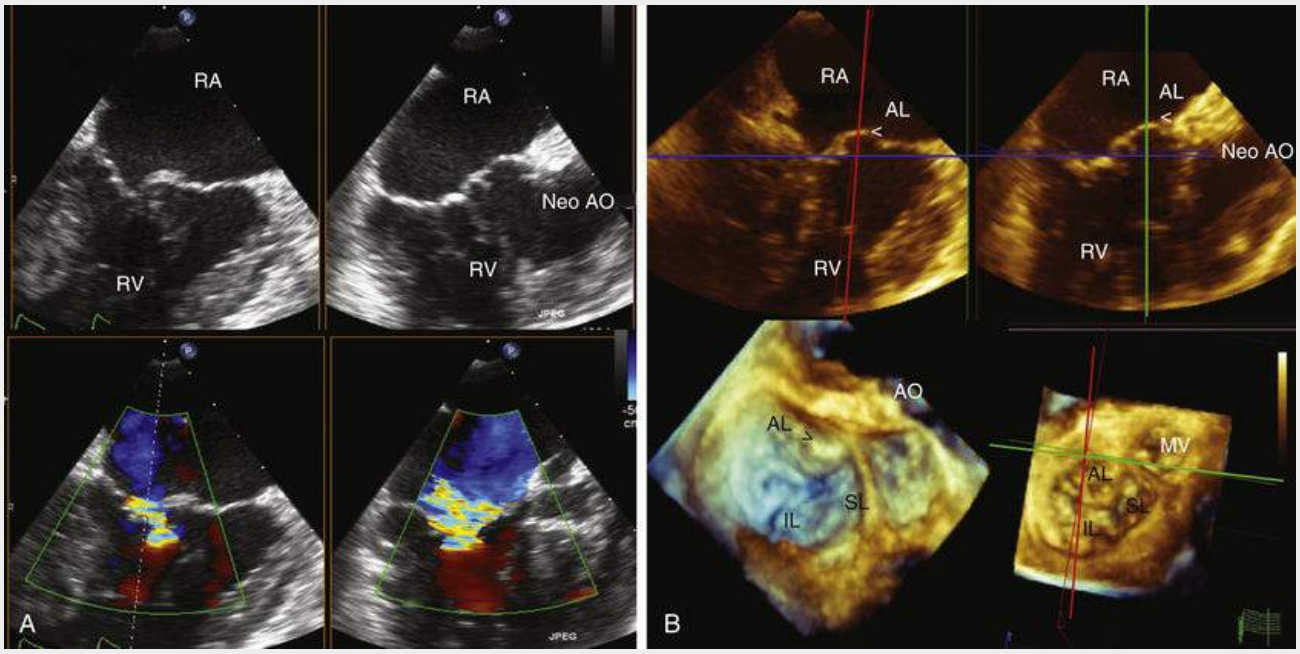

FIGURE 75.16 Three-dimensional tricuspid valve following Fontan procedure. The TEE image labeled A demonstrates moderate tricuspid valve regurgitation following a Fontan procedure in a patient with hypoplastic left heart syndrome and dextrocardia. Although the moderate regurgitation is evident from the color Doppler signal, the precise mechanism and location are unclear. The real-time 3D echocardiography image labeled B displays the tricuspid valve in the MPR mode (multiplane reformatting), as well as a surgical en face view of the tricuspid valve. The *red* and *green lines* are at right angles to each other and show that the main problem is prolapse of the anterior leaflet of the tricuspid valve. The lower right-hand image is taken in the exact same spatial location as the upper two images; the lower left-hand image has been angled to show the prolapse in more detail. Although not seen from the surgical en face view, the position of the aorta has been noted to help with orientation. *AL*, anterior leaflet; *AO*, aorta; *IL*, inferior leaflet; *MV*, mitral valve; *SL*, septal leaflet.

With *Ebstein anomaly*, use TEE for preoperative assessment of the tricuspid valve morphology and the potential for tricuspid valve repair. Thus far, real-time -3D echocardiography has been disappointing for this lesion, because the leaflets are often so thin that there are too many areas of dropout in the images.

In *clot assessment*, use TEE when a right atrial clot is suspected following the Fontan procedure on clinical grounds or by transthoracic echocardiography, or when circuit obstruction is suspected.

Precardioversion.

For any patient who is not adequately anticoagulated, presenting with atrial flutter or fibrillation longer than 24 hours, TEE should be performed before chemical or electrical cardioversion. Patients with a Fontan circuit should undergo TEE irrespective of the duration of atrial tachyarrhythmia to rule out a right or left atrial thrombus.

Guidance of Therapeutic Interventions.

Both standard 2D TEE and, more recently, real-time 3D TEE can be instrumental in helping to guide therapy at the time of transcatheter or surgical procedures. TEE is particularly helpful in the following situations.

Percutaneous Device Closure.

TEE is performed at the time of percutaneous device closure (i.e., transcatheter ASD closure to assist ASD-stretched balloon sizing and device deployment), unless intracardiac echocardiography (ICE) (see later) is available.

Ventricular Volume Assessment.

Real-time 3D echocardiography has already been shown to provide accurate data with regard to left

ventricular volumes and function, and more recently, albeit in younger patients, the same technology has been applied quite successfully to the right ventricle, in particular in persons who have had tetralogy of Fallot.

Intracardiac Echocardiography

Intracardiac echocardiography (ICE) uses lower-frequency transducers that have been miniaturized and mounted into catheters capable of percutaneous insertion into the heart. ICE not only provides high-resolution 2D and hemodynamic data with full Doppler capabilities but also eliminates the need for general anesthesia, which is often required for TEE.

Current applications of ICE include the following:

Percutaneous ASD Device Closure.

ICE supports percutaneous ASD device closure by adequately sizing the defect and assisting device positioning while avoiding the need for general anesthesia. More recently, real-time 3D TEE is being used not only to assess the size and suitability of ASD device closure, but also to monitor the procedure, either in an interventional setting or surgically using robotic procedures.

Electrophysiologic Studies.

ICE assists electrophysiologic procedures by guiding transseptal puncture, enabling endocardial visualization, and ensuring electrode-tissue contact at the time of ablative procedures. Recently, a forward-looking imaging and ablation probe has been developed, which will enable precise localization of energy delivery to an arrhythmogenic focus (**See Chapter 34**).

Cardiac Catheterization

With the development of cross-sectional echocardiography and the subsequent introduction of MRI and fast computed tomographic methods, truly diagnostic cardiac catheterization (**see Chapter 19**) is becoming rare. “Diagnostic” catheterization is reserved for resolving unanswered questions from the less-invasive techniques, and measuring hemodynamics. A good example of this is the assessment of major aortopulmonary collateral arteries in tetralogy of Fallot with pulmonary atresia; the presence and distribution of the arteries may be shown beautifully by MR angiography, but cardiac catheterization may be required to demonstrate the presence of communications with the central pulmonary arteries and measure the pressure within them. There is no adequate substitute for cardiac catheterization to measure ventricular end-diastolic pressures or pulmonary artery pressures and resistance with the precision required to plan for, or assess, the Fontan circulation. Furthermore, diagnostic testing may also be needed to evaluate possible coronary artery disease, especially before heart surgery in adults.

Therapeutic Catheterization

Balloon atrial septostomy was the first catheter intervention that proved useful in treating heart disease, and it remains the standard initial palliation in many infants with D-TGA. Many transcatheter techniques are now used successfully to treat CHD: blade atrial septostomy; device or coil closure of PDA; closure of ASD and patent foramen ovale (PFO); transluminal balloon dilation of pulmonary and aortic valve stenosis; radiofrequency perforation of pulmonary valve atresia; balloon-expandable intravascular stents for right ventricular outflow tract, pulmonary artery, aortic coarctation, and other vascular stenoses; and device occlusion of unwanted collateral vessels and AV fistulas. These have all become treatments of choice in centers with these capabilities. Some are universally accepted as the standard of care (e.g., balloon pulmonary valvuloplasty), whereas debate continues for other interventions (e.g., unoperated

coarctation). One of the most exciting new developments has been that of transcatheter valved stents for the treatment of right ventricular outflow stenosis and regurgitation in patients with congenital defects, a procedure that also has led to an explosion of transcatheter valve techniques for acquired disease. Going along with the extraordinary expansion of interventional techniques for the treatment of structural abnormalities, ablative techniques for the treatment of tachycardias are now performed routinely in centers with congenital heart electrophysiology programs and are crucial to the management of adults with operated and unoperated CHD, in whom arrhythmias are such a burden in terms of their morbidity, as well as a significant cause of late death. The indications, outcomes, and current status of each of these techniques are discussed later in detail in the sections concerning specific lesions.

Specific Cardiac Defects

Left-to-Right Shunts

Atrial Septal Defect and Partial Anomalous Pulmonary Venous Drainage

Morphology

It is important to distinguish between an “atrial septal defect” and an interatrial communication. To understand this problem, a brief review of the embryologic development of the atrial septum is essential. The primary septum grows down from the roof of the developing atria, develops, and breaks down superiorly to form the secondary foramen. The leading edge of the primary septum, or mesenchymal cap, fuses with the superior cushion, with the only communication between the atria being via the secondary foramen. When first formed, the secondary foramen has no upper rim and is flat. At this stage, there is a single orifice that connects the left atrium to the pulmonary veins. Later, after separation into the left and right pulmonary veins and incorporation of their orifices as separate openings, a fold develops superiorly; it had previously been called the septum secundum but at this point it is recognized as the fibrofatty fold. The true atrial septum is a relatively small component of the left and right atria.

Four types of interatrial communications exist: ostium primum, ostium secundum, sinus venosus, and coronary sinus defects (**Fig. 75.17A and D** and Videos 75.29 to 75.31). (Ostium primum is discussed in the section on AV septal defect.) Ostium secundum defects are the only true ASDs; all the others are atrial-level shunts, not being surrounded by true atrial septal tissue. Secundum defects have varying degrees of deficiency of the primary septum during embryologic development. Some are discrete defects, and others represent a series of fenestrations in the primary septum (foramen flap).

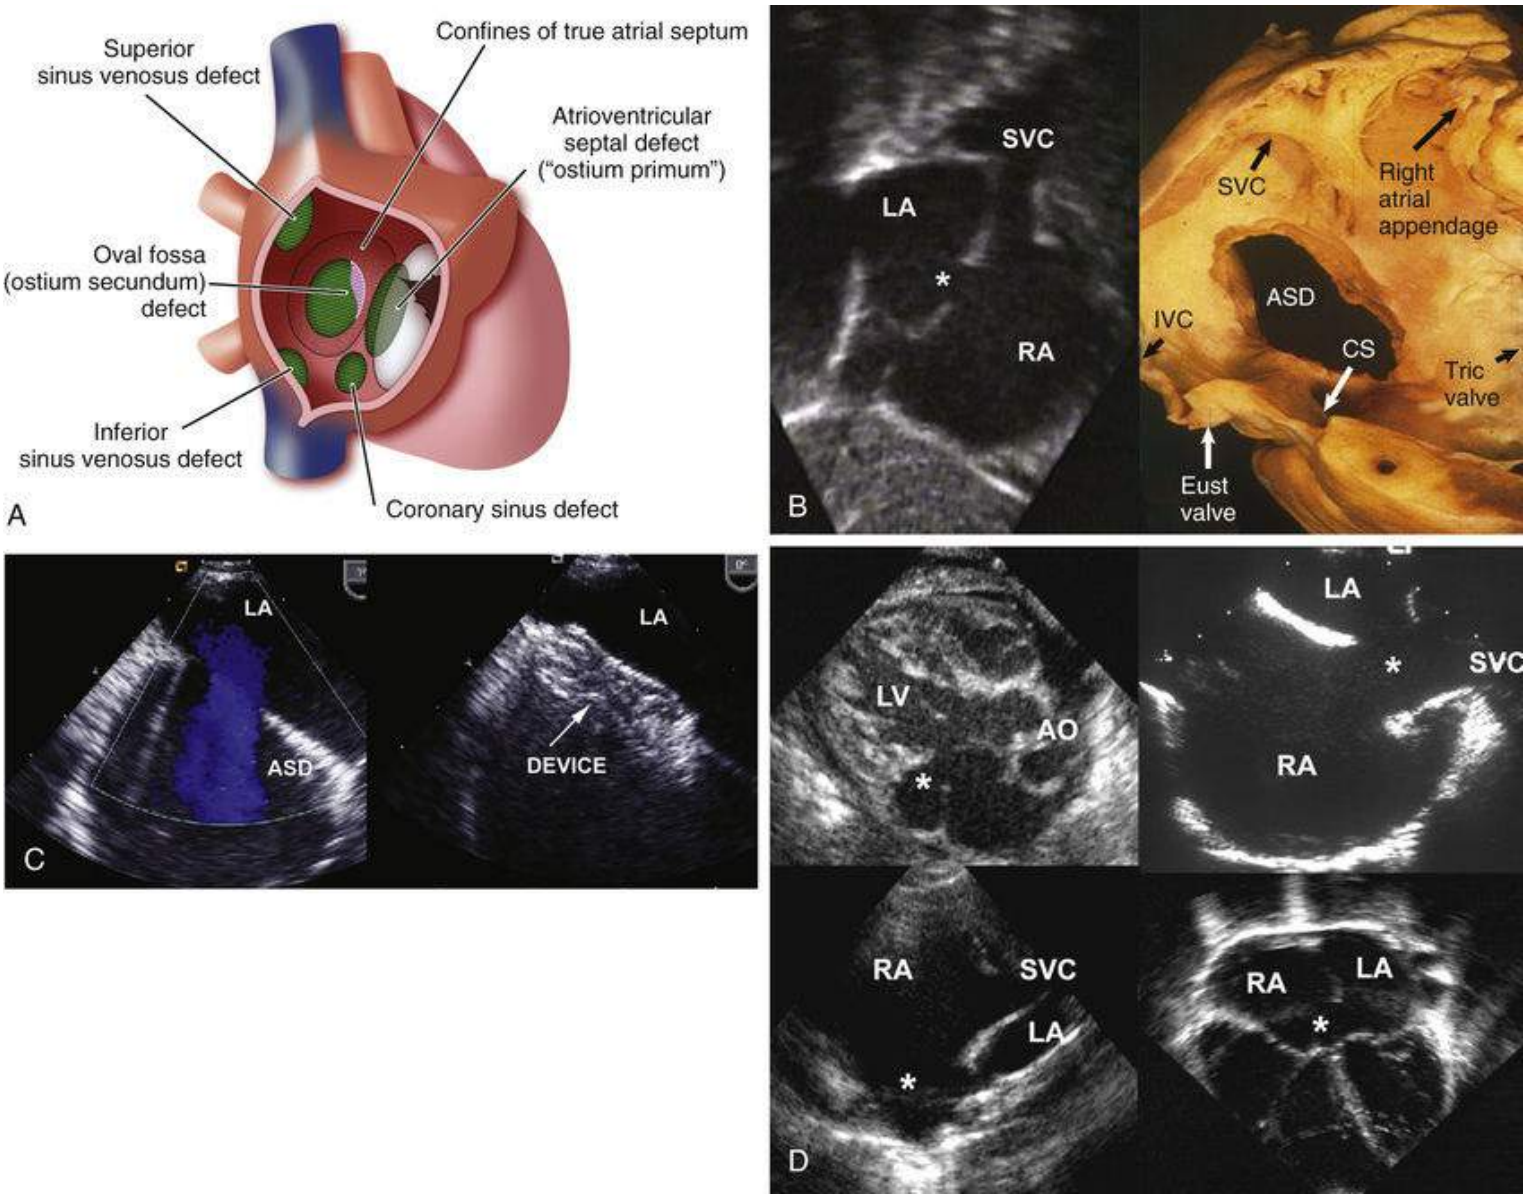

FIGURE 75.17 **A,** Schematic diagram outlining the different types of interatrial shunting that can be encountered. Note that only the central defect is suitable for device closure. **B,** Subcostal right anterior oblique view of a secundum ASD (*asterisk*) that is suitable for device closure. The right panel is a specimen as seen in a similar view, outlining the landmarks of the defect. **C,** The left image is a transesophageal echocardiogram with color flow before device closure, whereas the right side has been taken following release of an Amplatzer device. **D,** Montage of interatrial communications that are not ASDs (*asterisks*) and therefore not suitable for device closure. The upper left image shows a coronary sinus defect due to unroofing; the top right image, a superior sinus venosus defect; the bottom left image, an inferior sinus venosus defect; and the bottom right image, an ASD in the setting of an AV septal defect. *AO*, aorta; *ASD*, atrial septal defect; *CS*, coronary sinus; *Eust*, eustachian; *IVC*, inferior vena cava; *LA*, left atrium; *LV*, left ventricle; *RA*, right atrium; *SVC*, superior vena cava; *Tric*, tricuspid.

Sinus venosus defects of the superior vena caval type are due to a deficiency between the superior vena cava and, usually, the right upper and middle pulmonary veins. In these hearts, there is often partial erosion of the fibrofatty fold, but the true atrial septum is intact, although there can be a separate secundum ASD. These hearts have a superior vena cava–pulmonary vein–left atrial connection, unlike a partial anomalous pulmonary venous connection to the superior vena cava, which connects at a higher point, above the right pulmonary artery, and does not have an atrial connection. Rarely, sinus venosus defects drain to the azygos vein posteriorly. Inferior sinus venosus defects result from a breakdown between the right atrial wall and the inferior right-sided pulmonary veins. Coronary sinus septal defects are rare and occur when there is either a partial or complete deficiency of the roof of the coronary sinus, such that it is possible to have atrial-level shunting at the mouth of the coronary sinus but the true

interatrial septum is intact.

In other situations, there is a partial anomalous pulmonary venous connection; most frequently, the connection is with all of the pulmonary veins or with the left upper lobe pulmonary vein only, draining to the innominate vein; this can coexist with a true ASD. Less frequently, there is a partial anomalous pulmonary venous connection to the coronary sinus or inferior vena cava; the latter is called *scimitar syndrome*. In scimitar syndrome, the primary abnormality is a partial anomalous pulmonary venous connection to the inferior vena caval–atrial junction, but it can occur in association with right lung hypoplasia, sequestration of the right lung, and aortopulmonary collateral circulation. It can be seen in some patients with a secundum ASD, as well as in association with many other forms of CHD.

Pathophysiology

In any type of atrial-level shunt, the degree of left-to-right atrial shunting depends on the size of the defect and the relative diastolic filling properties of the two ventricles. Any condition causing reduced left ventricular compliance (e.g., systemic hypertension, cardiomyopathy, myocardial infarction) or increased left atrial pressure (e.g., mitral stenosis and/or regurgitation) tends to increase the left-to-right shunt. If similar forces are present in the right heart, this will diminish the left-to-right shunt and promote right-to-left shunting.

Natural History

Most large, true secundum ASDs (pulmonary artery blood flow relative to systemic blood flow [Qp/Qs] > 2.0/1.0) are dealt with during childhood by surgical or device closure. An undetected ASD with a significant shunt (Qp/Qs > 1.5/1.0) probably causes symptoms over time in adolescence or adulthood, and symptomatic patients usually become progressively more physically limited as they age. Effort dyspnea is seen in about 30% of patients by the third decade and more than 75% of patients by the fifth decade. Exercise intolerance on cardiopulmonary testing is even more common, reflecting the fact that such patients often do not know what “normal” feels like. Supraventricular arrhythmias (atrial fibrillation or flutter) and right-sided heart failure develop by 40 years of age in about 10% of patients and become more prevalent with aging. Paradoxical embolism resulting in a transient ischemic attack or stroke can call attention to the diagnosis. The development of pulmonary hypertension, although probably not as common as originally thought, can occur at an early age. If pulmonary hypertension is severe, a second causative diagnosis should be sought. The life expectancy is clearly reduced in ASD patients, although not as severely as was quoted in earlier papers because, in them, only statistics on patients with large ASDs were reported.

Clinical Features

The most common presenting symptoms in adults are exercise intolerance (exertional dyspnea and fatigue) and palpitations (typically from atrial flutter, atrial fibrillation, or sick sinus syndrome). Right ventricular failure can be the presenting symptom in older patients. The presence of cyanosis should alert one to the possibility of shunt reversal and Eisenmenger syndrome or, alternatively, to a prominent eustachian valve directing the inferior vena caval flow to the left atrium via a secundum ASD or sinus venosus ASD of the inferior vena caval type. The clinical findings in those with PAPVC/PAPVD are similar to those with an ASD; the primary clinical diagnosis is usually an ASD, with subsequent investigations identifying the precise pathology.

On examination, there is “left atrialization” of the jugular venous pressure (*a* wave = *v* wave). A

hyperdynamic right ventricular impulse may be felt at the left sternal border at the end of expiration or in the subxiphoid area on deep inspiration. A dilated pulmonary artery trunk may be palpated in the second left intercostal space. A wide, fixed split of S_2 is the auscultatory hallmark of ASD, although it is not always present. A systolic ejection murmur, usually grade 2 and often scratchy, is best heard at the second left intercostal space, and a middiastolic rumble, from increased flow through the tricuspid valve, may be present at the left lower sternal border. When right ventricular failure occurs, a pansystolic murmur of tricuspid regurgitation is common.

Laboratory Investigations

ECG.

A sinus rhythm or atrial fibrillation or flutter may be present. The QRS axis is typically rightward in secundum ASD and PAPVD/PAPVC, and there may be crochetage of the QRS complex in the inferior leads. Negative P waves in the inferior leads indicate a low atrial pacemaker often seen in superior sinus venosus defects, which are located in the area of the sinoatrial node and render it deficient. Complete right bundle branch block appears as a function of age. Tall R or R′ waves in V_1 suggest pulmonary hypertension.

Chest Radiography.

The classic radiographic features are of cardiomegaly (from right atrial and right ventricular enlargement), dilated central pulmonary arteries with a pulmonary plethora, indicating increased pulmonary flow, and a small aortic knuckle (reflecting a chronic low cardiac output state). Those with scimitar syndrome often have hypoplasia of the right hemithorax, and some have the classic *scimitar sign*, which represents the course of the right-sided pulmonary veins.

Echocardiography (Videos 75.32 and 75.33).

Transthoracic echocardiography documents the type(s) and size(s) (defect diameter) of the ASD(s), the direction(s) of the shunt(s) (**see Fig. 75.17B**), and sometimes the presence of an anomalous pulmonary venous return. The functional importance of the defect can be estimated by the size of the right ventricle and the presence or absence of right ventricular volume overload (paradoxical septal motion). If the size of the ASD is out of keeping with the size of the right ventricle, suspect an associated abnormality of the pulmonary venous drainage or connection. Indirect measurement of the pulmonary artery pressure can be obtained from the Doppler velocity of the tricuspid regurgitation jet. A dilated coronary sinus is seen in PAPVC to the coronary sinus. In scimitar syndrome, the abnormal pulmonary vein can be seen from the subcostal position during evaluation of the inferior vena cava. Associated stenosis of the pulmonary vein may exist. In adolescents and adults, TEE may also be useful in assessing not only the size of a true ASD, but also any associated PAPVD/PAPVC.

TEE permits better visualization of the interatrial septum and is usually required when device closure is contemplated, partly to ensure that the pulmonary venous drainage or connection is normal. Intracardiac echocardiography (ICE) can be used instead of TEE during device closure to help guide device insertion, reducing the fluoroscopy and procedural time and forgoing the need for general anesthesia.

MRI.

Although TEE can be used with a considerable degree of accuracy in older patients who have poor ultrasound windows, MRI is a less invasive means of obtaining data. MRI provides superb images of the

connecting veins seen more distally and their connections with the hilum of the lung. The pulmonary-to-systemic flow ratio can be calculated for any atrial-level shunt, usually obviating the need for hemodynamic evaluation. The pulmonary-to-systemic flow ratio can also be estimated by radionuclide techniques.

Indications for Intervention

Shunt fractions are now rarely measured and are reserved for "borderline" cases. Hemodynamically insignificant ASDs (Qp/Qs < 1.5) usually do not require closure; a possible exception is when trying to prevent paradoxical emboli in older patients after a stroke. "Significant" ASDs (Qp/Qs > 1.5, or ASDs associated with right ventricular volume overload) should be closed, especially if device closure is available and appropriate. For patients with pulmonary hypertension (pulmonary artery pressure higher than two thirds of the systemic arterial blood pressure, or pulmonary arteriolar resistance higher than two thirds of the systemic arteriolar resistance), closure can be recommended if there is a net left-to-right shunt of at least 1.5 : 1, or evidence of pulmonary artery reactivity when challenged with a pulmonary vasodilator (e.g., oxygen or nitric oxide).

Device Closure.

Device closure of secundum ASDs percutaneously under fluoroscopy and TEE guidance or with intracardiac echocardiographic guidance is the therapy of choice when appropriate (**see Fig. 75.17C** and Video 75.34). Indications for device closure are the same as for surgical closure, but the selection criteria are stricter. Depending on the device, this technique is available only for patients with a secundum ASD with a stretched diameter of less than 36 to 40 mm and with adequate rims (> 5 mm) to enable secure deployment of the device.[16] An anomalous pulmonary venous connection or proximity of the defect to the AV valves or coronary sinus or systemic venous drainage usually precludes the use of this technique. It is a safe and effective procedure in experienced hands; major complications (e.g., device embolization, atrial perforation, thrombus formation) occur in less than 1% of patients, and clinical closure is achieved in more than 80%. Device closure of an ASD improves the functional status in symptomatic patients no matter what their age[17,18] and the exercise capacity in asymptomatic and symptomatic patients. Intermediate follow-up data have proved ASD device closure to be safe and effective,[19] with better preservation of right ventricular function and lower complication rates than surgery. Its cost is also lower than surgery.[20]

Surgery.

Device closure is not an option for those with sinus venosus or ostium primum defects or with secundum defects with unsuitable anatomy. Surgical closure of ASDs can, depending on size and shape, be performed by primary suture closure or by using a pericardial or synthetic patch. The procedure is usually performed via a midline sternotomy, but the availability of a minimally invasive, inframammary, or minithoracotomy approach to a typical secundum ASD should be made known to cosmetically sensitive and other patients. The mortality rate in adult surgical patients without pulmonary hypertension should be less than 1%. Surgical closure of an ASD improves the functional status and exercise capacity in symptomatic patients and improves (but usually does not normalize) survival rates; it also improves or eliminates congestive heart failure, especially when patients are operated on at a young age (e.g., < 25 years). However, surgical closure of ASDs in adult life does not prevent atrial fibrillation or flutter or stroke, especially when patients are operated on after the age of 40 years. The role of a concomitant Cox

maze procedure in patients with a history of atrial flutter or fibrillation should be considered (**see Chapters 34 and 35**). In the setting of preexisting atrial tachyarrhythmias, surgical as well as device closure of an ASD does decrease the incidence of postoperative atrial tachyarrhythmia.[21-23]

Surgery is not necessary when a single anomalously draining vein has not produced right ventricular volume loading. In those with right ventricular volume loading, the surgical technique depends on the nature of the abnormal connection; the goal is to reroute the pulmonary venous blood back to the left atrium. In those with PAPVD to the right atrium, the atrial patch is placed such that the right-sided pulmonary veins drain back to the left atrium. In a superior sinus venosus defect, the deficiency between the superior vena cava and right pulmonary veins is closed.

Reproductive Issues

Pregnancy is well tolerated in patients after ASD closure. Pregnancy is also well tolerated in women with unrepaired ASDs, but the risk of paradoxical embolism is increased (it is still very low) during pregnancy and in the postpartum period. Pregnancy is contraindicated in Eisenmenger syndrome because of the high mortality rates for the mother (≈50%) and fetus (≈60%).

Follow-Up

After device closure, patients require 6 months of aspirin and endocarditis prophylaxis until the device endothelializes, following which, assuming there is no residual shunt, they do not require any special precautions or endocarditis prophylaxis. Patients with sinus venosus defects are at risk of developing caval and/or pulmonary vein stenosis and should be kept under intermittent review. Patients who have had surgical or device repair as adults, patients with atrial arrhythmias preoperatively or postoperatively, and patients with ventricular dysfunction should have long-term cardiology surveillance. Indeed, all patients who have had device closure should probably have an echocardiogram every 5 years or so because of the possibility of late issues, especially erosion. The outcome of patients undergoing PAPVC/PAPVD surgery is invariably excellent, although the precise number of veins that become stenotic after repair is currently unclear. The main issue is that postrepair echocardiography is an unreliable modality for determining the patency of individual veins, and most patients do not undergo MRI follow-up, because they are asymptomatic with a right ventricle that has returned to normal size.

Patent Foramen Ovale

Anatomy

The foramen ovale is a tunnel-like space between the overlying septum secundum and septum primum. It closes in 75% of people at birth. In utero, the foramen ovale is necessary for blood flow across the fetal atrial septum. Oxygenated blood from the placenta returns to the inferior vena cava, crosses the foramen ovale, and enters the systemic circulation. In approximately 25% of people, a patent foramen ovale (PFO) persists into adulthood. PFOs may be associated with atrial septal aneurysms (a redundancy of the interatrial septum), eustachian valves (a remnant of the sinus venosus valve), and Chiari networks (filamentous strands in the right atrium).

Pathophysiology

PFOs have been scrutinized for their implications in the mechanism of cryptogenic stroke. Many of the basic tenets linking PFO and stroke seem plausible but have not been demonstrated. The current views may be summarized as follows. PFOs may serve as either a conduit for paradoxical embolization from the venous side to the systemic circulation or, because of their tunnel-like structure and propensity to stagnant flow, may serve as a nidus for in situ thrombus formation. Variations in PFO size, the status of the right atrial anatomy, varying hemodynamic conditions, and the development of venous thrombi may all contribute to the chances of paradoxical embolization. The risk of a cryptogenic stroke seems increased for larger PFOs. The presence of an interatrial septal aneurysm in combination with a PFO also increases the risk of an adverse event, perhaps because of increased in situ thrombus formation in the aneurysmal tissue or simply because PFOs associated with an interatrial septal aneurysm tend to be larger. Eustachian valves and a Chiari network may direct blood flow from the inferior vena cava toward the atrial septum, encouraging right-to-left shunting in the presence of an interatrial communication. Physiologic (Valsalva maneuvers) and pathologic conditions that increase the right ventricular pressure will raise the right atrial pressure, favoring right-to-left shunting. Finally, pelvic vein thrombi are found more frequently in young patients with cryptogenic stroke than in patients with a known cause of stroke and may provide the source of venous thrombi.

PFOs have also been implicated in the pathophysiology of decompression sickness (arterial gas embolism from the venous side), as well as in the pathogenesis of migraine headaches. *Platypnea-orthodeoxia syndrome* (dyspnea and arterial desaturation when a patient is in the upright position and improvement when the patient is lying down) has also been attributed to the presence of a PFO (Video 75.35).

Clinical Impact

The cause-and-effect relationship between PFO and cryptogenic stroke is still tentative. The recent body of literature would suggest a strong association, if not a causative link, especially in younger patients. Indeed, young patients with cryptogenic stroke have a significantly higher incidence of PFO (36% to 54%) than normal controls (15% to 25%). The association is more controversial in the older patient population. Older patients often have more risk factors for stroke, and the causative role of a PFO in these patients is more difficult to establish.

When a patient presents with a stroke and a PFO is discovered, the usual causes of stroke must first be eliminated. Potential causes of strokes include carotid artery disease, ascending aortic atherosclerosis, atrial fibrillation, neurovascular abnormalities, and/or prothrombotic tendencies. If after an exhaustive investigation (see later) no other cause of the stroke can be found, the PFO may be seen to have possibly had a causative role. The diagnosis of a PFO as a cause of cryptogenic stroke is, at best, a diagnosis of exclusion.

Investigations

A PFO is usually detected by transthoracic echocardiography, TEE, or transcranial Doppler imaging. TEE is the most sensitive test, especially when performed with contrast media injected during a cough or Valsalva maneuver. A PFO is judged to be present if microbubbles are seen in the left-sided cardiac chambers within three cardiac cycles from the maximum right atrial opacification.

Screening for prothrombotic states (e.g., protein C or S deficiency, antithrombin III, or lupus anticoagulant), atrial fibrillation, significant carotid atherosclerosis by carotid Doppler imaging, and neurovascular abnormalities by brain MRA must be undertaken in each patient before a PFO can be

considered a possible culprit.

Therapeutic Options

Once the presumptive diagnosis of a cryptogenic stroke caused by a PFO is determined, treatment modalities to prevent recurrent events include antiplatelet or anticoagulant agents, percutaneous device closure, or surgical PFO closure. Medical therapy for secondary prevention of stroke with warfarin or antiplatelet agents is often used as first-line therapy with similar efficacy (i.e., a yearly stroke recurrence rate of about 2%). Patients with PFO and atrial septal aneurysm who have had strokes seem to be at higher risk of recurrent stroke (≤ 15% per year), and a preventive strategy other than aspirin or warfarin should perhaps be considered. Device closure is safe and seems effective, with a recurrence rate of stroke between nil and 3.8% per year. Surgical closure of PFO is usually performed when cardiac surgery is required for other reasons.

Three recent randomized clinical trials in which device closure was compared with medical treatment (ASA or warfarin) for a patient with a PFO after a stroke, did not show a significant difference between the two treatment arms in the recurrent stroke rate at a mean follow-up time of 2 to 4 years.[24-26]

However, a recent metaanalysis of transcatheter closure versus medical therapy, pooling the data of the three aforementioned studies, suggests that the recurrence rate of a stroke in patient with cryptogenic stroke and PFO is low (1%/year) but that device closure reduces the recurrence risk by half.[27] Further studies will be required to determine the best treatment strategy for patients with PFO and cryptogenic stroke.[28]

Atrioventricular Septal Defect

The terms *atrioventricular septal defect*, *atrioventricular canal defect*, and *endocardial cushion defect* can be used interchangeably to describe this group of defects. The variable components of these lesions are explained in the following sections.

Morphology

The basic morphology of AV septal defect is common to all types and is independent of the presence or absence of an atrial or ventricular communication. These common features (**Figs. 75.18 and 75.19**) are a common AV junction with absence of the membranous and muscular AV septum (resulting in the AV valves being at the same level on echocardiography); inlet and outlet disproportion (resulting in an elongated left ventricular outflow tract); abnormal lateral rotation of the posteromedial papillary muscle; and abnormal configuration of the AV valves. The left AV valve is a trileaflet valve made of superior and inferior bridging leaflets separated by a mural leaflet. The space between the superior and inferior leaflets as they bridge the interventricular septum is called the *cleft* in the left AV valve (Videos 75.36 to 75.39).

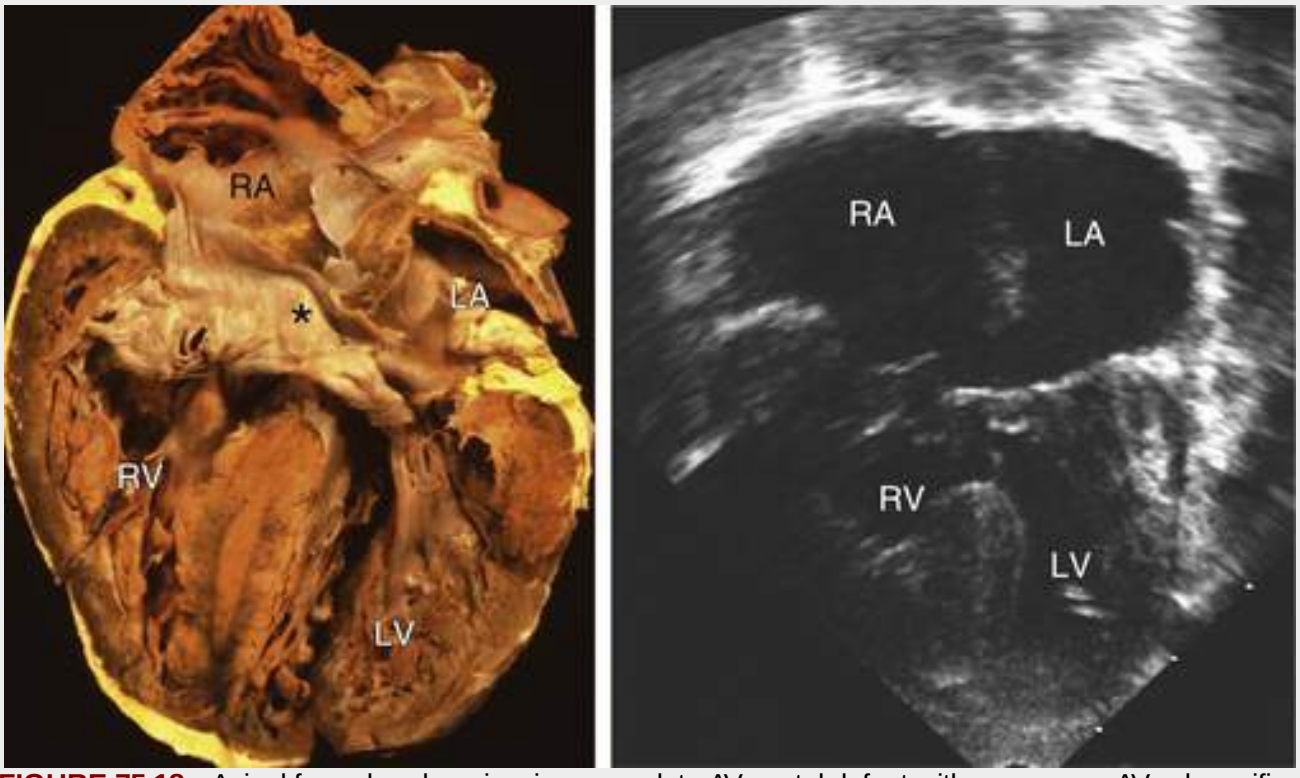

FIGURE 75.18 Apical four-chamber view in a complete AV septal defect with a common AV valve orifice (*). Note the large interatrial and interventricular communications and the large free-floating superior bridging leaflet. *LA*, left atrium; *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle.

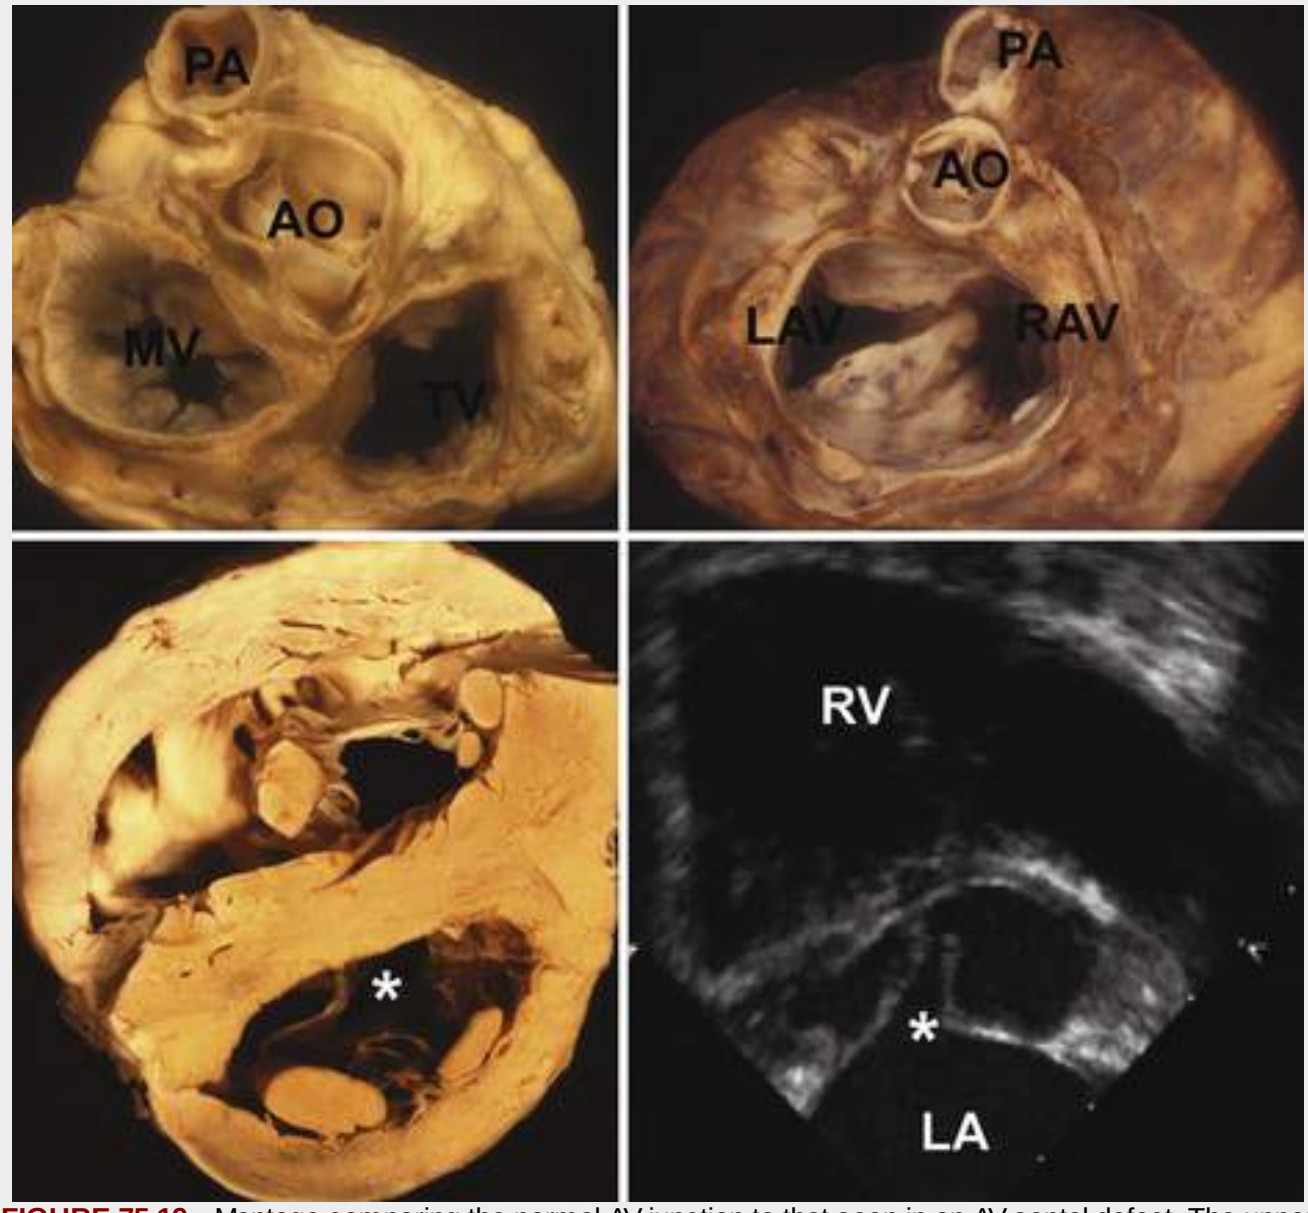

FIGURE 75.19 Montage comparing the normal AV junction to that seen in an AV septal defect. The upper left picture is the normal AV junction as seen from above. Note the normal morphology of the mitral and tricuspid valves, with the aorta wedged between them. The upper right picture is a similar view in an AV septal defect. Note the unwedged aorta, the trileaflet left AV valve, and the cleft between the superior and inferior bridging leaflets. The lower left picture is a specimen of an AV septal defect demonstrating the cleft. The lower right picture is an echocardiogram showing the cleft. *AO*, aorta; *LA*, left atrium; *LAV*, left atrioventricular valve; *MV*, mitral valve; *PA*, pulmonary artery; *RAV*, right atrioventricular valve; *RV*, right ventricle; *TV*, tricuspid valve.

The other feature common to all hearts with an AV septal defect is a "sprung" AV junction (**Fig. 75.20**); this is the cause of the aorta not being wedged between the left and right AV junction, but sitting above it.

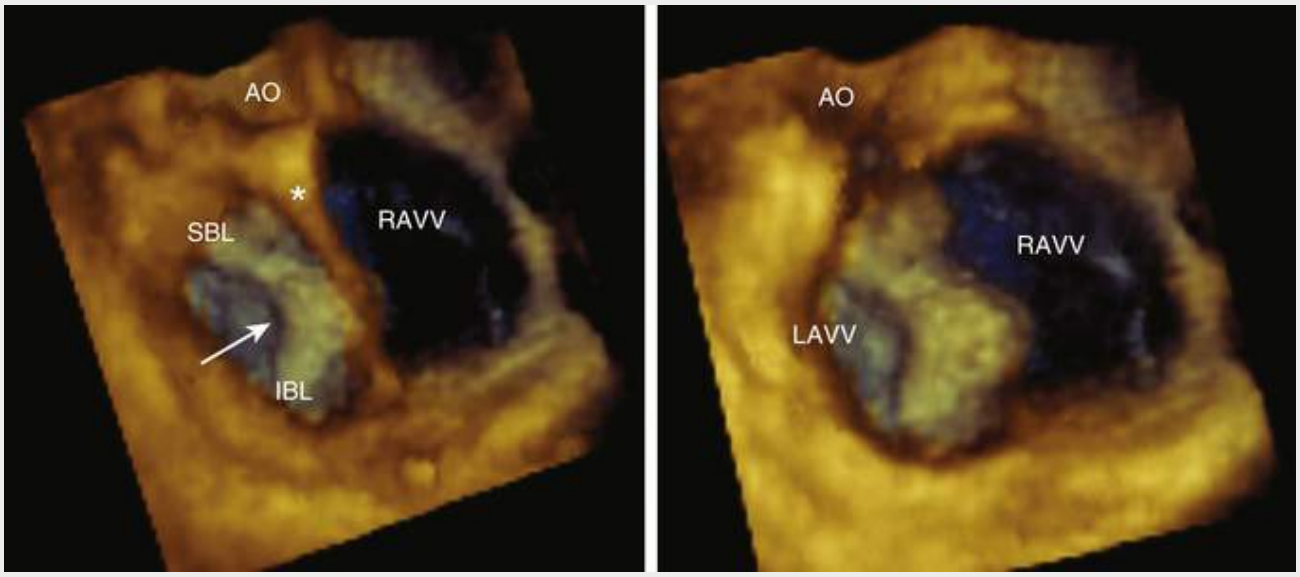

FIGURE 75.20 These images demonstrate the sprung AV junction as seen from above in a heart with an AV septal defect and partitioned orifices. Note the unwedged position of the aorta and the connecting tongue between the superior and inferior bridging leaflets. *AO*, aorta; *LAVV*, left atrioventricular valve; *IBL*, inferior bridging leaflet; *RAVV*, right atrioventricular valve; *SBL*, superior bridging leaflet.

The bridging leaflets may be completely adherent to the crest of the interventricular septum, free floating, or attached by a chordal apparatus. It is possible to have an interventricular communication beneath one, but not the other, bridging leaflet. The degree of chordal attachment beneath the superior and inferior bridging leaflets is also variable.

Partitioned Versus Complete Atrioventricular Septal Defects.

A *partitioned* orifice is one in which the superior and inferior leaflets are joined by a connecting tongue of tissue as they bridge the interventricular septum. This partitions the valve into separate left and right orifices. A *common* AV valve orifice is one in which there is no such connecting tongue, resulting in one large orifice that encompasses the left-sided and right-sided components. Interatrial (ostium primum) and interventricular defects are common in AV septal defect Although most interventricular communications occur in those with a common AV valve orifice, it is possible to have ventricular-level shunting beneath the "connected" bridging leaflets in those with partitioned orifices. The interatrial communication is not a true deficiency of the atrial septum, but is failure of fusion of the leading edge of the primitive primum septum with the AV cushions. As well, a true secundum ASD can coexist with shunting through a primum defect.

By its very nature, the left ventricular outflow tract is elongated in all hearts with an AV septal defect. This exacerbates the multiple potential causes of subaortic stenosis, often with several mechanisms coexisting in the same heart. Potential mechanisms are an isolated fibromuscular shelf, accessory tissue tags, tunnel narrowing due to the inherently elongated outflow tract, abnormal location of the anterolateral papillary muscle, and accessory papillary muscles.

A *double-orifice* left AV valve is a risk factor for repair and subsequent postoperative regurgitation. The second orifice is more often located in the vicinity of the posteromedial papillary muscle. The papillary muscles are closer together than normal, and in some instances there is a single, or parachute, papillary muscle. In others there is dominance of one of the papillary muscles, usually the anterolateral muscle, which is frequently associated with shortened and fused chordae with a blunted superior-mural commissure. This finding can have long-term implications with regard to left AV valve function.[29] The term *unbalanced AV septal defect* refers to cases in which one ventricle is hypoplastic (Videos 75.40 to 75.42). This is seen more commonly in patients with heterotaxy and those with left-sided obstructive

defects.

Pathophysiology

The *native pathophysiology* of those with an isolated shunt at the atrial level (commonly referred to as a *primum defect*) is similar to that of a large secundum ASD, with unrestricted left-to-right shunting through the primum defect, leading to right-sided atrial and ventricular volume overload. Chronic left AV valve regurgitation may produce left-sided ventricular and atrial volume overload. Adults with unrepaired complete AV septal defect usually have irreversible pulmonary vascular disease and are inoperable.

After correction, the medium- and long-term issues regarding pathology are related to left AV valve regurgitation, which increases in frequency with each passing decade, and left ventricular outflow tract obstruction (5% of cases). The latter is more common in those with a primum defect and no interventricular communication, or those with partitioned orifices and an interventricular communication. Also, a single papillary muscle in the left ventricle, or a double-orifice left AV valve, is associated with greater long-term regurgitation. Some develop fibromuscular subaortic stenosis that was not present at the initial repair; in others, it is due to residual anatomic features that were present at the primary repair but were not of sufficient severity at that time to address. Residual significant left AV valve regurgitation may occur and cause significant left atrial, as well as left ventricular, dilation. Left AV valve stenosis from overzealous repair of the valve may also be seen.

Natural History

Patients with an isolated primum ASD have a course similar to that of those with large secundum ASDs, although symptoms may appear sooner when significant left AV valve regurgitation is present. Patients may be asymptomatic until the third or fourth decade, but progressive symptoms related to congestive heart failure, atrial arrhythmias, complete heart block, and variable degrees of pulmonary hypertension develop in virtually all of them by the fifth decade.

Most patients with complete AV septal defect have had surgical repair in infancy. When presenting unrepaired, most adults have established pulmonary vascular disease.

Clinical Issues

In patients with *Down syndrome*, the rate of AV septal defect is 35%. These patients more commonly have a complete AV septal defect with a common AV valve orifice and a large associated VSD. In the current era, most are repaired within the first 6 months of life, so that there is a lower resulting incidence of long-term pulmonary hypertension.

In *patients who do not have Down syndrome*, the clinical presentation depends on the presence and size of the atrial-level and ventricular-level shunts and on the competence of the left AV valve. A large left-to-right shunt gives rise to symptoms of heart failure (exertional dyspnea or fatigue) or pulmonary vascular disease (exertional syncope or cyanosis). In adulthood, palpitations from atrial arrhythmias are common. Cardiac findings on physical examination for patients with an isolated shunt at the atrial level are similar to those of patients with secundum ASD, with the important addition of a prominent left ventricular apex and pansystolic murmur when significant left AV valve regurgitation is present. Cases with a primum defect and a restrictive ventricular-level shunt have similar findings, but with the addition of a pansystolic murmur heard best at the left sternal border. Complete AV septal defects have a single S_1 (common AV valve), a middiastolic murmur from augmented AV valve inflow, and findings of pulmonary

hypertension and/or a right-to-left shunt.

Laboratory Investigations

ECG.

Most patients have left axis deviation. Complete AV block and/or atrial fibrillation or flutter can be present in older patients. Partial or complete right bundle branch block is usually associated with right ventricular dilation or prior surgery.

Chest Radiography.

If the defect has not been repaired, chest radiography demonstrates cardiomegaly with right atrial and right ventricular prominence with increased pulmonary vascular markings. In patients with a small interatrial communication and important left AV valve regurgitation, there is cardiomegaly due to left ventricular enlargement and normal pulmonary vascular markings. Findings of Eisenmenger syndrome are also possible. If the defect has been repaired, the heart and lungs may appear normal.

Echocardiography.

Echocardiography has replaced angiography in assessing virtually all patients with AV septal defect. The cardinal and common features discussed in the morphology section are readily recognized by echocardiography. In the four-chamber view, the AV valve(s) appear at the same level, irrespective of the presence or absence of a ventricular-level shunt beneath the bridging leaflets. The typical inferior primum defect is seen in this view. The degree of associated AV valve regurgitation, the left-to-right shunt, and the estimated right ventricular systolic pressure should be determined. When using the right AV valve to assess right ventricular pressure, care must be taken to ensure that the jet is not contaminated by an obligatory left ventricle–to–right atrial shunt. Three-dimensional echocardiography is very useful in the planning of surgical intervention because it increases our understanding of the complex anatomy, in particular commissural abnormalities, and shows the precise location of the sites of AV valve regurgitation.

Cardiac Catheterization.

Cardiac catheterization has mostly been replaced by echocardiography for the evaluation of patients with an AV septal defect. The one role it still has is in the evaluation of the patient who presents late and may have associated pulmonary vascular or coronary disease.

Indications for Intervention

The patient with an unoperated or newly diagnosed AV septal defect and significant hemodynamic defects requires surgical repair. Equally, patients with persistent left AV valve regurgitation (or stenosis from a previous repair) that is causing symptoms, patients with an atrial arrhythmia or deterioration in ventricular function, and patients with significant subaortic obstruction (a mean gradient > 50 mm Hg at rest) require surgical intervention.

In the presence of severe pulmonary hypertension (pulmonary artery pressure higher than two thirds of the systemic blood pressure or pulmonary arteriolar resistance higher than two thirds of the systemic arteriolar resistance), there must be a net left-to-right shunt of at least 1.5 : 1, or evidence of pulmonary artery reactivity when challenged with a pulmonary vasodilator (e.g., oxygen, nitric oxide, and/or prostaglandins).

Interventional Options and Outcomes

Isolated Shunt at Atrial Level (Primum Atrial Septal Defect).

Pericardial patch closure of the primum ASD with concomitant suture (with or without annuloplasty) of the cleft left AV valve is usually performed. When left AV valve repair is not possible, replacement may be necessary. In the short term, the results of repair of partial AV septal defect are similar to those following closure of secundum ASD, but sequelae of left AV ("mitral") valve regurgitation, subaortic stenosis, and AV block may develop or progress. A subsequent repair of the left AV valve is more challenging in adults because the leaflets are usually less pliable than in children.

Complete Atrioventricular Septal Defect.

The "staged approach" (pulmonary artery banding followed by intracardiac repair) has been supplanted by primary intracardiac repair in infancy. The goals of intracardiac repair are ventricular and atrial septation with adequate left and right AV valve reconstruction. Single-patch, double-patch, and no-patch techniques for closing atrial-level and ventricular-level shunts have been described with comparable results. The "Australian" technique is also used in complete AV septal defects; the common leaflets are sewn directly onto the crest of the interventricular septum, and the primum defect is closed with a patch. Patients with a single papillary muscle or double-orifice left AV valve have a higher frequency of ongoing left AV valve regurgitation. Occasionally, left AV valve replacement is necessary when valve repair is not possible. The intermediate- and long-term results following repair are good in terms of the survival rates; with each decade, however, there is an increasing incidence of patients who require further surgery to address progressive left AV valve regurgitation. Those with a simple primum defect or a small interventricular communication are at greater risk of developing significant left AV valve regurgitation, compared with patients with a common AV valve and a large ventricular component. This is related to more deficient leaflet tissue in those with a pure primum defect or small interventricular communication.

Reproductive Issues

Pregnancy is well tolerated in patients with complete repair and no significant residual lesions. Women in NYHA classes I and II with an unoperated, isolated primum ASD usually tolerate pregnancy well. Pregnancy is contraindicated in Eisenmenger syndrome because of the high mortality rates for the mother (≈50%) and fetus (≈60%).

Follow-Up

All patients who have a repair require periodic follow-up by an expert cardiologist because the 5-year freedom rate from reoperation is only 74%.[30] Long-term complications include patch dehiscence or residual septal defects (1%), development of complete heart block (3%), late atrial fibrillation or flutter, significant left AV valve dysfunction (10%), and subaortic stenosis (5% to 10%). Left AV valve regurgitation requiring left AV valve repair or replacement occurs in least 10% to 20% of patients.[31,32] Subaortic stenosis develops or progresses in 5% to 10% of patients after repair, particularly in patients with primum ASD, especially if the left AV ("mitral") valve has been replaced. Particular attention should be paid to patients who have pulmonary hypertension before operation. Antibiotic prophylaxis is only necessary in the first 6 months following surgery unless there is a residual patch leak or a prosthetic valve has been used.

Isolated Ventricular Septal Defect

Morphology

The ventricular septum can be divided into three major components, the inlet, trabecular, and outlet components, all abutting a small membranous septum lying just underneath the aortic valve. VSDs (**Fig. 75.21**) are classified into three main categories according to their locations and margins (**Fig. 75.22**). *Muscular VSDs* are bordered entirely by myocardium and can have a trabecular, inlet, or outlet location. *Membranous VSDs* often have inlet, outlet, or trabecular extension and are bordered in part by fibrous continuity between the leaflets of an AV valve and an arterial valve. *Doubly committed subarterial VSDs* are more common in Asian and South American patients, are situated in the outlet septum, and are bordered by fibrous continuity of the aortic and pulmonary valves (Videos 75.43 to 75.45). This section deals with VSDs occurring in isolation from major associated cardiac anomalies.

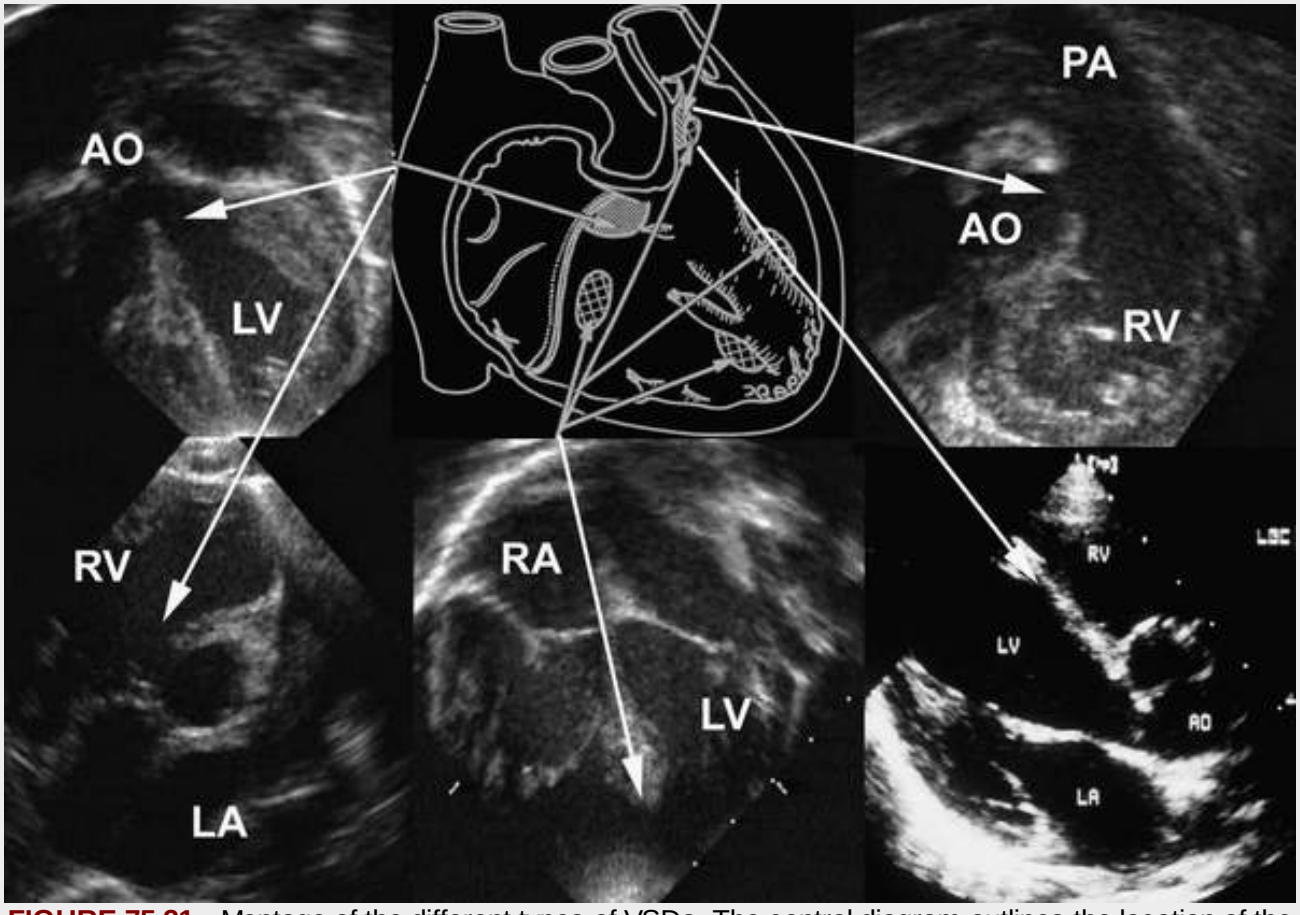

FIGURE 75.21 Montage of the different types of VSDs. The central diagram outlines the location of the various types of defects as seen from the right ventricle. The two left images show a perimembranous VSD as seen in the five-chamber and short axis views. Note the defect is roofed by the aorta and is next to the tricuspid valve. The bottom middle echocardiogram shows a muscular apical defect. The upper right image is a right anterior oblique view in a doubly committed VSD. The lower right image is a short axis view showing an outlet VSD with prolapse of the right coronary cusp. *AO*, aorta; *LV*, left ventricle; *PA*, pulmonary artery; *RA*, right atrium; *RV*, right ventricle; *VSD*, ventricular septal defect.

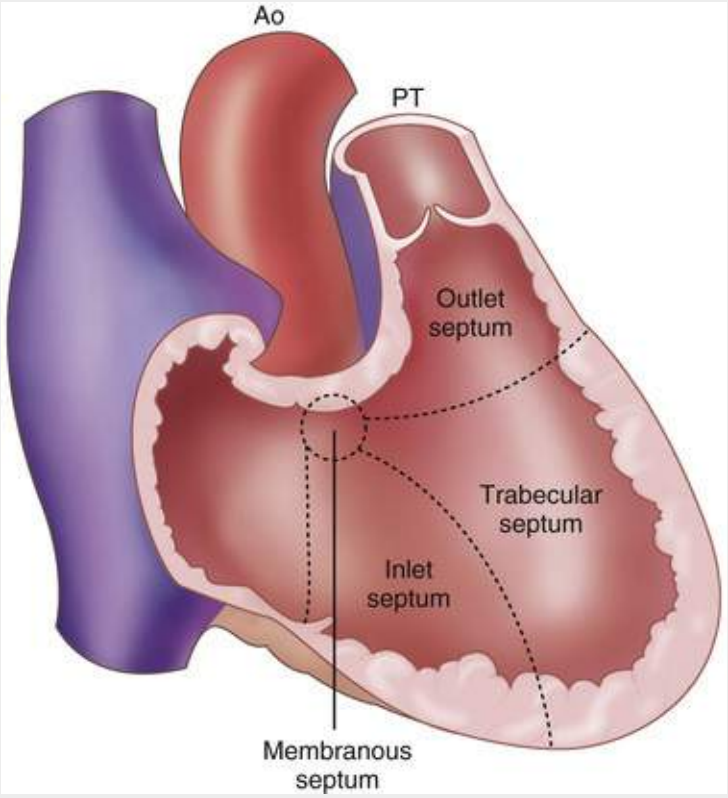

FIGURE 75.22 Four components of the ventricular septum shown here from the right ventricular aspect are now described by Anderson and associates as inlet and outlet components of the right ventricle because these areas do not correspond to septal structures as initially suggested. *Ao*, aorta; *PT*, pulmonary trunk. (Modified from Anderson RH, Becker AE, Lucchese E, et al: Morphology of congenital heart disease. Baltimore, University Park Press, 1983.)

Pathophysiology

A *restrictive VSD* is a defect that produces a significant pressure gradient between the left ventricle and the right ventricle (pulmonary-to-aortic systolic pressure ratio < 0.3) and is accompanied by a small (≤1.4/1) shunt. A *moderately restrictive VSD* is accompanied by a moderate shunt (Qp/Qs of 1.4 to 2.2/1) with a pulmonary-to-aortic systolic pressure ratio of less than 0.66. A large or *nonrestrictive VSD* is accompanied by a large shunt (Qp/Qs > 2.2) and a pulmonary-to-aortic systolic pressure ratio of greater than 0.66. An *Eisenmenger VSD* has a systolic pressure ratio of 1 and a Qp/Qs of less than 1 : 1, or a net right-to-left shunt.

Natural History

A *restrictive VSD* does not cause significant hemodynamic derangement and may close spontaneously during childhood and sometimes even in adult life. A perimembranous defect in an immediately subaortic position, or any doubly committed VSD, may be associated with significant aortic regurgitation. Late development of subaortic and subpulmonary stenosis (see double-chambered right ventricle), as well as the formation of a left ventricular–to–right atrial shunt, is well described and should be excluded at follow-up. A *moderately restrictive VSD* imposes a hemodynamic burden on the left ventricle, which leads to left atrial and ventricular dilation and later dysfunction, as well as a variable increase in pulmonary vascular resistance. A *large or nonrestrictive VSD* in the absence of obstruction to pulmonary blood flow features left ventricular volume overload early in life, with a progressive rise in pulmonary artery pressure and a fall in left-to-right shunting. In turn, this leads to higher pulmonary vascular resistance and eventually to Eisenmenger syndrome.

Clinical Features

Like patients with ASDs and AV septal defect, most patients with significant defects will undergo closure in childhood in developed societies. Large VSDs will usually produce symptoms in early infancy, and closure at 3 to 6 months of age is the norm. The role of "prophylactic" VSD closure in children with a substrate for the development of aortic regurgitation is controversial, with most units waiting for at least mild to moderate aortic regurgitation to develop before advising surgery (which usually reverses or stabilizes its progression). Most adult patients with a small *restrictive VSD* are asymptomatic. Physical examination reveals a harsh or high-frequency pansystolic murmur, usually grade 3 to 4, heard with maximal intensity at the left sternal border in the third or fourth intercostal space. Patients with a *moderately restrictive VSD* often present with dyspnea in adult life, perhaps triggered by atrial fibrillation. Physical examination typically reveals a displaced cardiac apex with a similar pansystolic murmur, and occasionally an apical diastolic rumble and third heart sound at the apex from the increased flow through the mitral valve. Patients with large *nonrestrictive Eisenmenger VSDs* present as adults with central cyanosis and clubbing of the nail beds. Signs of pulmonary hypertension (i.e., a right ventricular heave, palpable and loud P_2, and right-sided S_4) are typically present. A pulmonary ejection click, a soft and scratchy systolic ejection murmur, and a high-pitched decrescendo diastolic murmur of pulmonary regurgitation (Graham Steell murmur) or aortic regurgitation may be audible. Peripheral edema usually reflects right-sided heart failure.

Laboratory Investigations

ECG.

The ECG mirrors the size of the shunt and the degree of pulmonary hypertension. *Small, restrictive VSDs* usually produce a normal tracing. *Moderate-sized VSDs* produce a broad, notched P wave characteristic of left atrial overload, as well as evidence of left ventricular volume overload, namely deep Q waves and tall R waves, with tall T waves in leads V_5 and V_6, and perhaps eventually atrial fibrillation. Following repair of perimembranous defects, there is usually right bundle branch block.

Chest Radiography.

The chest radiograph reflects the magnitude of the shunt, as well as the degree of pulmonary hypertension. A *moderate-sized shunt* causes signs of left ventricular dilation with some pulmonary plethora.

Echocardiography.

Transthoracic echocardiography can identify the location, size, and hemodynamic consequences of the VSD, as well as any associated lesions (aortic regurgitation, right ventricular outflow tract obstruction, or left ventricular outflow tract obstruction) (Videos 75.46 to 75.52).

Cardiac Catheterization.

Cardiac catheterization may be required when the hemodynamic significance of a VSD is questioned or when the assessment of pulmonary artery pressures and resistances is necessary. In some centers or countries, therapeutic catheterization is performed for percutaneous closure (see later).

Indications for Intervention

The presence of a significant VSD (symptoms; significantly increased left ventricular and left atrial size;

or deteriorating left ventricular function) in the absence of irreversible pulmonary hypertension warrants closure. If severe pulmonary hypertension (see ASD section) is present, closure is seldom feasible. Other relative indications for VSD closure include the presence of a perimembranous or outlet VSD with more than mild aortic regurgitation or a history of recurrent endocarditis.

Interventional Options and Outcomes

Surgery.

Surgical closure by direct suture or with a patch has been used for more than 50 years with a low perioperative mortality rate, even in adults, and a high closure rate. Patch leaks are not uncommon but seldom need reoperation.

Device Closure.

Successful transcatheter device closure of trabecular (muscular) and perimembranous VSDs has been reported. Trabecular VSDs have proven more amenable to this technique because of their relatively straightforward anatomy and the presence of a muscular rim to which the device attaches well; therefore, the closure rates are excellent and the procedural mortality rate is low. Immediate- as well as short-term results are good. The closure of perimembranous VSDs is technically more challenging due to their proximity to valve structures; careful patient selection is required. The procedure has not gained widespread acceptance, and should be performed only in centers with appropriate expertise. Short-term follow-up data show complete closure in 96% of patients; aortic and/or tricuspid regurgitation or complete heart block develops in less than 15% of patients.

Reproductive Issues

Pregnancy is well tolerated in women with small or moderate VSDs and in women with repaired VSDs. Pregnancy is contraindicated in Eisenmenger syndrome because of the high mortality rates for the mother (≈50%) and fetus (≈60%).

Follow-Up

For patients with a good to excellent functional class and good left ventricular function before surgical closure, the life expectancy after surgical correction is close to normal. The risk of progressive aortic regurgitation is reduced after surgery, as is the risk of endocarditis, unless a residual VSD persists. Yearly cardiac evaluation is suggested for patients with right ventricular outflow tract obstruction, left ventricular outflow tract obstruction, and aortic regurgitation not undergoing surgical repair; patients with Eisenmenger syndrome; and adults with significant atrial or ventricular arrhythmias. Cardiac surveillance is also recommended for patients who had late repair of moderate or large defects, which are often associated with left ventricular impairment and elevated pulmonary artery pressure at the time of surgery.

Patent Ductus Arteriosus

Morphology

The ductus arteriosus derives from the left sixth primitive aortic arch and connects the proximal left pulmonary artery to the descending aorta, just distal to the left subclavian artery.

Pathophysiology

The ductus is widely patent in the normal fetus, carrying unoxygenated blood from the right ventricle through the descending aorta to the placenta, where the blood is oxygenated. Functional closure of the ductus from vasoconstriction occurs shortly after a term birth, whereas anatomic closure from intimal proliferation and fibrosis takes several weeks to complete. Some patients have a "ductus-dependent" physiology as neonates. This means their circulation depends on the ductus for pulmonary blood flow, as in severe aortic coarctation, hypoplastic left heart syndrome, and, sometimes, D-TGA. If spontaneous closure of the ductus occurs in such neonates, clinical deterioration and death usually follow quickly.

Isolated PDAs, the subject of this section, are often categorized according to the degree of left-to-right shunting, which is determined by both the size and length of the duct and the difference between the systemic and pulmonary vascular resistances, as follows:

- Silent: tiny PDA detected only by nonclinical means (usually echocardiography)
- Small: continuous murmur common; Qp/Qs < 1.5/1
- Moderate: continuous murmur common; Qp/Qs of 1.5 to 2.2/1
- Large: continuous murmur present; Qp/Qs > 2.2/1
- Eisenmenger syndrome: continuous murmur absent; substantial pulmonary hypertension, differential hypoxemia, and differential cyanosis (pink fingers, blue toes)

Clinical Features

A *small* audible duct usually causes no symptoms but may rarely present as an endovascular infection. Physical examination may reveal a grade 1 or 2 continuous murmur peaking in late systole and best heard in the first or second left intercostal space. Patients with a *moderate-sized* duct may present with dyspnea or palpitations from atrial arrhythmias. A louder continuous or "machinery" murmur in the first or second left intercostal space is typically accompanied by a wide systemic pulse pressure from aortic diastolic runoff into the pulmonary trunk and signs of left ventricular volume overload, such as a displaced left ventricular apex and sometimes a left-sided S_3 (meaningful in adults only). With a moderate degree of pulmonary hypertension, the diastolic component of the murmur disappears, leaving a systolic murmur. Adults with a *large* uncorrected PDA eventually present with a short systolic ejection murmur, hypoxemia in the feet more than the hands (differential cyanosis), and Eisenmenger physiology.

Laboratory Investigations

ECG.

The ECG reflects the size and degree of shunting occurring through the duct. A *small* duct produces a normal ECG. A *moderate* duct may show left ventricular volume overload with broad, notched P waves together with deep Q waves, tall R waves, and peaked T waves in V_5 and V_6. A *large* duct with Eisenmenger physiology produces findings of right ventricular hypertrophy.

Chest Radiography.
A *small* duct produces a normal chest radiograph. A *moderate-sized* duct causes moderate cardiomegaly with left-sided heart enlargement, a prominent aortic knuckle, and increased pulmonary perfusion. Ring calcification of the ductus may be seen through the soft tissue density of the aortic arch or pulmonary trunk in older adults. A *large* PDA produces an Eisenmenger appearance with a prominent aortic knuckle.

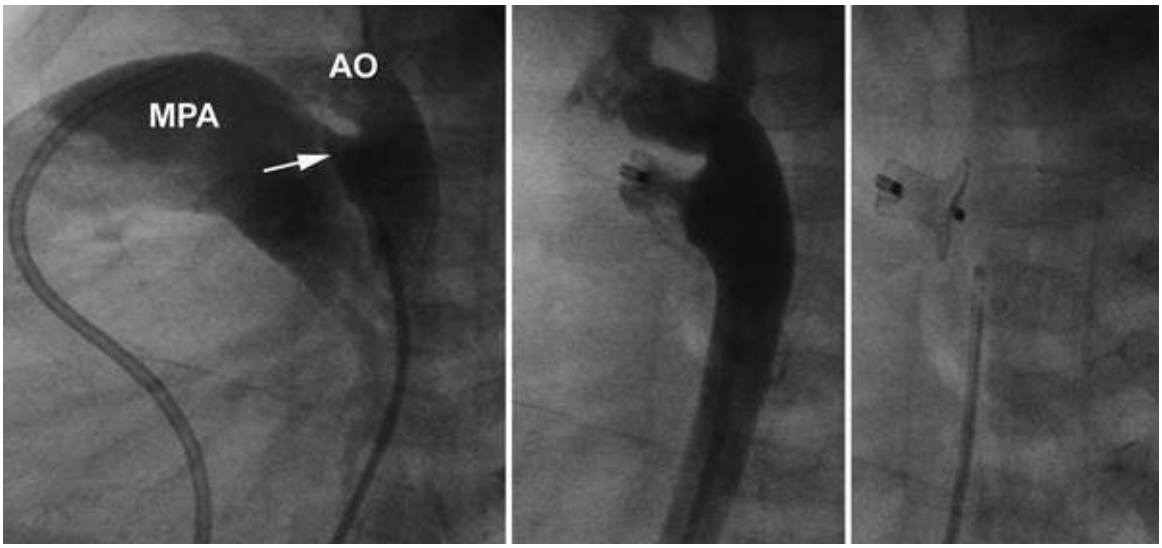
Echocardiography.
Echocardiography allows determination of the presence, size, and degree of shunting and the physiologic consequences of the shunt. The PDA is seen with difficulty in an Eisenmenger context. A bubble study will show the communication.

Indications for Intervention

There is no debate about the desirability of closing a hemodynamically important PDA, with significant left-to-right shunting, at any age. There is ongoing debate about the merits of closing an inaudible or small PDA strictly to reduce the risk of endarteritis, and likely it is not warranted.[33] In the presence of severe pulmonary hypertension (see Atrial Septal Defect earlier), closure is seldom indicated. Contraindications to ductal closure include irreversible pulmonary hypertension or active endarteritis.

Interventional Options and Outcomes

Transcatheter Treatment (eFig. 75.1).



EFIGURE 75.1 Montage of a patent arterial duct (*arrow*), before and after device occlusion. *AO*, aorta; *MPA*, main pulmonary artery.

Over the past 20 years, the efficacy and safety of transcatheter device closure for ducts smaller than 8 mm have been established, with complete ductal closure achieved in more than 85% of patients by 1 year following device placement, at a mortality rate of less than 1%.[34] In centers with appropriate resources and experience, transcatheter device occlusion should be the method of choice for ductal closure.

Surgical Treatment.

Surgical closure, by ductal ligation and/or division, has been performed for more than 50 years with a

marginally greater closure rate than device closure but somewhat higher rates of morbidity and mortality. Immediate clinical closure (no shunt audible on physical examination) is achieved in more than 95% of patients. Surgical closure is a low-risk procedure in children. The surgical mortality rate in adults is 1% to 3.5% and relates to the presence of pulmonary arterial hypertension and difficult ductal morphology (calcified or aneurysmal) often seen in adults. Surgical closure should be reserved for those in whom the PDA is too large for device closure or at centers without access to device closure.

Reproductive Issues

Pregnancy is well tolerated in women with silent and small PDAs and in patients who were asymptomatic before pregnancy. In women with a hemodynamically important PDA, pregnancy may precipitate or worsen heart failure. Pregnancy is contraindicated in Eisenmenger syndrome because of the high mortality rates for the mother (≈50%) and fetus (≈60%).

Follow-Up

Patients with device occlusion or after surgical closure should be examined periodically for possible recanalization. Silent residual shunts may be found by transthoracic echocardiography. Endocarditis prophylaxis is recommended for 6 months following PDA device closure or for life if any residual defect persists following device closure. Patients with a silent or small PDA do not require endocarditis prophylaxis or follow-up.

Persistent Truncus Arteriosus

Morphology

Persistent truncus arteriosus is an anomaly in which a single vessel forms the outlet of both ventricles and gives rise to the systemic, pulmonary, and coronary arteries. It is always accompanied by a VSD and frequently by a right-sided aortic arch. The truncal valve is usually tricuspid but is quadricuspid in about one third of patients. Truncal valve regurgitation and truncal valve stenosis are each seen in 10% to 15% of patients. There can be a single coronary artery.

Truncus arteriosus is classified anatomically according to the mode of origin of pulmonary vessels from the common trunk. In the commonest type (type I), a partially separate pulmonary trunk of variable length exists and gives rise to left and right pulmonary arteries. In type II, each pulmonary artery arises separately but close to the other from the posterior aspect of the truncus. In type III, each pulmonary artery arises separately from the lateral aspect of the truncus. Less commonly, one pulmonary artery branch may be absent, with aortopulmonary collateral arteries supplying the lung that does not receive a pulmonary artery branch from the truncal artery.

Pathophysiology

Pulmonary blood flow is governed by the size of the pulmonary arteries and the pulmonary vascular resistance. In infancy, pulmonary blood flow is usually excessive because pulmonary vascular resistance is not greatly increased. Thus, in the neonate, only minimal cyanosis is present. With time, the pulmonary vascular resistance increases, relieving the left ventricular volume load but at the price of increasing cyanosis. When pulmonary vascular resistance reaches systemic levels, Eisenmenger physiology and bidirectional shunting occur. Significant truncal valve regurgitation produces a volume load on both the

right and left ventricles because of the biventricular origin of the truncal artery.

Natural History

Most deaths from congestive heart failure occur before 1 year of age. Unoperated patients who survive past 1 year will most likely present with established pulmonary hypertension. The prevalence of truncal valve regurgitation increases with age.

Clinical Features

Infants with truncus arteriosus usually present with mild cyanosis coexisting with the cardiac findings of a large left-to-right shunt. This is the result of excessive pulmonary blood flow due to a low pulmonary vascular resistance. Symptoms of heart failure and poor physical development usually appear in the first weeks or months of life. The most frequent physical findings include cardiomegaly, collapsing peripheral pulses, a loud single second heart sound, a harsh systolic murmur preceded by an ejection click, and a low-pitched middiastolic rumbling murmur and bounding pulses. A decrescendo diastolic murmur suggests associated truncal valve regurgitation.

DiGeorge syndrome may be seen with truncus arteriosus. Facial dysmorphism, a high incidence of extracardiac malformations (particularly of the limbs, kidneys, and intestine), atrophy or absence of the thymus gland, T-lymphocyte deficiency, and a predilection to infection also may be features of the clinical presentation.

The physical findings are different if pulmonary blood flow is restricted by a high pulmonary vascular resistance: cyanosis is prominent, and only a short systolic murmur may be heard in association with an ejection click. Pulmonary vascular obstruction usually does not restrict pulmonary blood flow before 1 year of age.

Adults presenting with an unrepaired truncus arteriosus can be expected to have Eisenmenger syndrome and its typical findings.

Laboratory Investigations in Unrepaired Truncus Arteriosus

ECG.

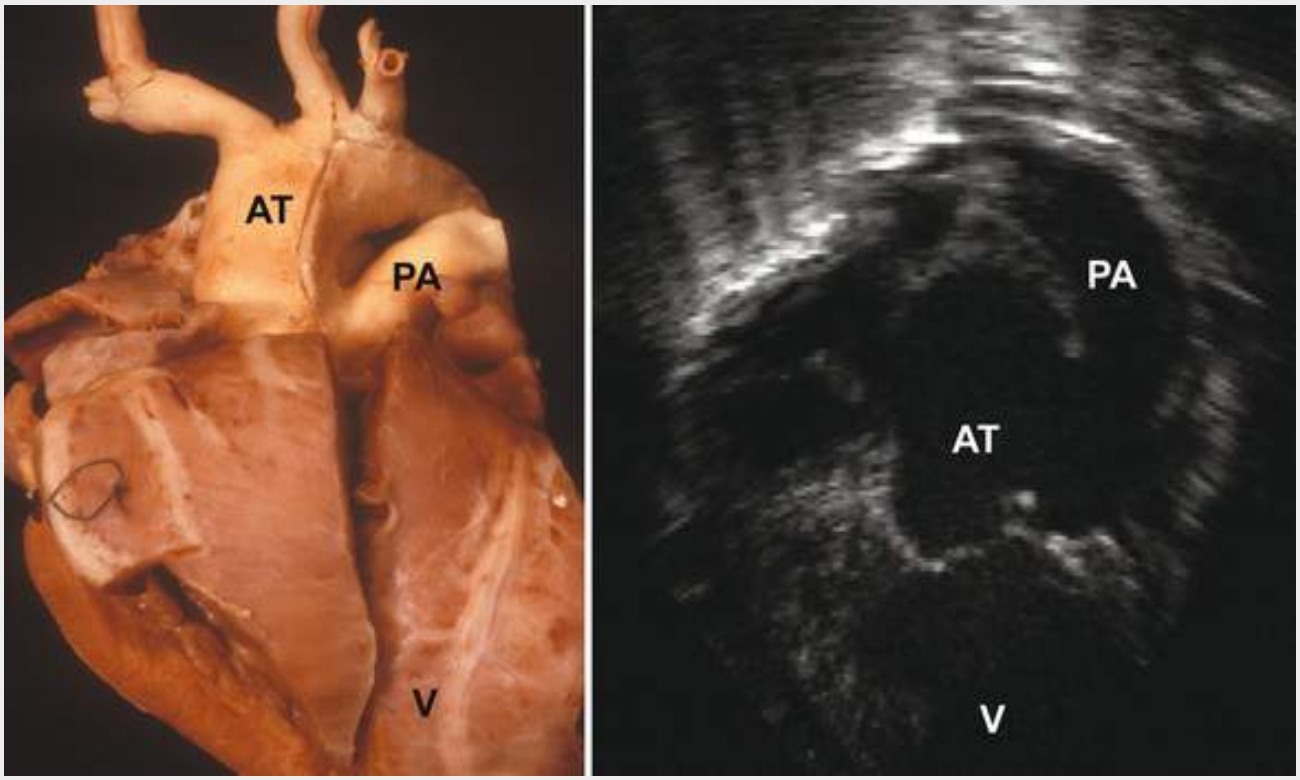
This demonstrates biventricular hypertrophy with strain as the pulmonary resistance rises.

Chest Radiography.

This demonstrates cardiomegaly with prominent pulmonary arterial markings and unusually high hilar areas. A right aortic arch occurs in 50% of cases.

Echocardiography.

In most cases, 2D echocardiography provides a complete diagnosis (**eFig. 75.2**). The study should demonstrate the overriding truncal root, the origin of the pulmonary arteries, the number of truncal cusps, the origin of the coronary arteries, the functional status of the truncal valve, and the VSD size.



EFIGURE 75.2 View of the origin of the pulmonary artery in truncus arteriosus. Note the lateral origin of the pulmonary artery. *AT*, ascending trunk; *PA*, pulmonary artery; *V*, ventricle.

Cardiac Catheterization and Angiography.
Cardiac catheterization and angiography are rarely necessary and in fact carry a risk of both morbidity and death. In general, significant arterial desaturation in the absence of branch pulmonary artery stenosis indicates that the lesion cannot be repaired.

Indications for Intervention

Early surgical intervention, within the first 2 months of life, is indicated in almost all cases. In the presence of severe pulmonary hypertension (see ASD section), surgical intervention is not performed.

Interventional Options and Outcomes

Operation consists of closure of the VSD, leaving the aorta arising from the left ventricle; excision of the pulmonary arteries from their truncal origin; and the placement of a valve-containing prosthetic conduit or aortic homograft valve conduit between the right ventricle and the pulmonary arteries to establish circulatory continuity. Truncal valve regurgitation is a challenging problem and may require valve replacement or repair.

Important risk factors for perioperative death are severe truncal valve regurgitation, an interrupted aortic arch, coronary artery anomalies, and age at initial operation older than 100 days. Patients with only one pulmonary artery are especially prone to early development of severe pulmonary vascular disease.

Reproductive Issues

Patients with a repaired truncus arteriosus and no hemodynamically important residual lesions should tolerate pregnancy well. Patients with significant conduit obstruction and/or important truncal valve regurgitation need prepregnancy counseling, with consideration of correction of the lesions before pregnancy and/or careful follow-up throughout pregnancy. Pregnancy is contraindicated in patients with

Eisenmenger syndrome, given its 50% maternal mortality rate.

Follow-Up

Patients operated on early (< 1 year of age) generally do well. However, conduit change is often indicated within the first few years after repair as the patient outgrows its size.[35] Those patients with significant truncal valve stenosis and/or regurgitation may eventually require truncal valve replacement. Patients operated on late (> 1 year of age) require careful follow-up for any signs of progression of pulmonary hypertension. Endocarditis prophylaxis is required in all patients.

Cyanotic Heart Disease

Tetralogy of Fallot (Including Tetralogy with Pulmonary Atresia)

Morphology

The four components of tetralogy of Fallot are an outlet VSD, obstruction to right ventricular outflow, overriding of the aorta (<5%), and right ventricular hypertrophy (**Figs. 75.23 and 75.24**). The fundamental abnormality contributing to each of these features is anterior and cephalad deviation of the outlet septum, which is malaligned with respect to the trabecular septum. Thus tetralogy may occur in the setting of double-outlet right ventricle (aortic override > 50%) and may coexist with an AV septal defect. Right ventricular outflow tract obstruction is of variable severity. Often a stenotic, bicuspid pulmonary valve with supravalvular hypoplasia exists. The dominant site of obstruction is usually at the subvalve level. In some cases the outflow tract is atretic, and the heart can be diagnosed as having tetralogy of Fallot with pulmonary atresia (also known as *complex pulmonary atresia* when major aortopulmonary collateral arteries are present). The management and outcome for patients with major aortopulmonary collateral arteries differ significantly than in those with less extreme forms of tetralogy and are discussed separately at the end of this section.

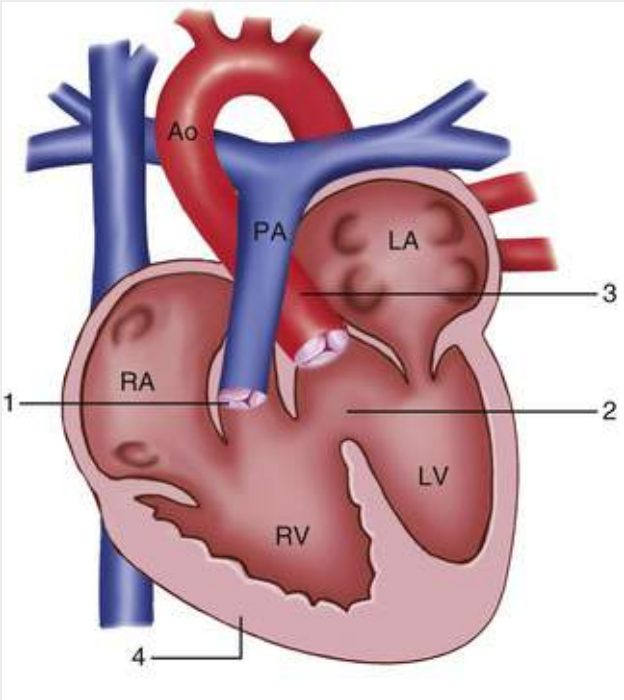


FIGURE 75.23 Diagrammatic representation of tetralogy of Fallot. 1, pulmonary stenosis; 2, ventricular septal defect; 3, overriding aorta; 4, right ventricle hypertrophy. *Ao*, aorta; *LA*, left atrium; *LV*, left ventricle; *PA*, pulmonary artery; *RA*, right atrium; *RV*, right ventricle. (From Mullins CE, Mayer DC: Congenital heart disease: a diagrammatic atlas. New York, Wiley-Liss, 1988.)

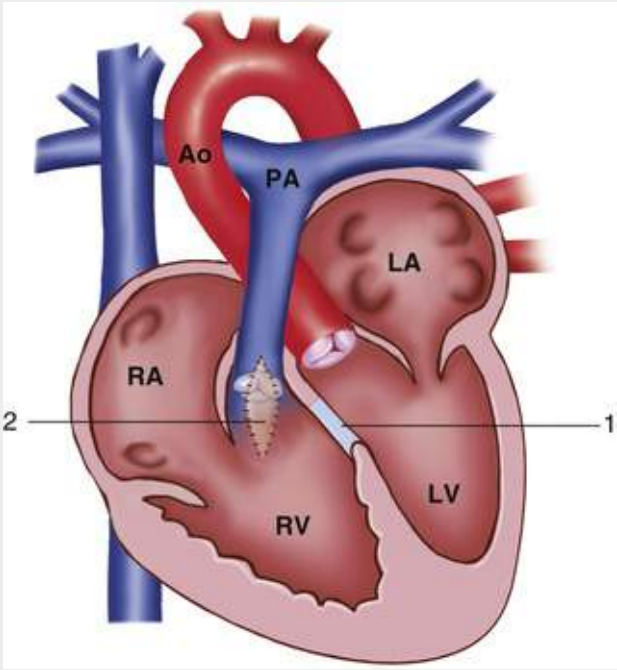

FIGURE 75.24 Diagrammatic representation of the surgical repair of tetralogy of Fallot. 1, patch closure of ventricular septal defect; 2, right ventricular outflow/main pulmonary artery outflow patch (transannular patch). *Ao*, aorta; *LA*, left atrium; *LV*, left ventricle; *PA*, pulmonary artery; *RA*, right atrium; *RV*, right ventricle. (From Mullins CE, Mayer DC: Congenital heart disease: a diagrammatic atlas. New York, Wiley-Liss, 1988.)

Associated Anomalies

A right aortic arch occurs in about 25% of patients, and abnormalities of the course of the coronary arteries occur in approximately 5%. The most common coronary anomaly is when the anterior descending artery originates from the right coronary artery and courses anteriorly to cross the infundibulum of the right ventricle. Furthermore, the origin of the left main stem is often rotated clockwise, increasing the risk of coronary compression during later right ventricular outflow tract stenting or stent-valve placement. *Absent pulmonary valve syndrome* is a rare form of tetralogy in which stenosis and regurgitation of the right ventricular outflow tract are due to a markedly stenotic pulmonary valve ring with poorly formed or absent valve leaflets. The pulmonary arteries are usually markedly dilated or aneurysmal and may produce airway compression at birth, a poor prognostic feature.

Pathophysiology

In the absence of alternative sources of pulmonary blood flow, the degree of cyanosis reflects the severity of right ventricular outflow tract obstruction. There is right-to-left shunting across the VSD. In the unoperated patient, a *tetralogy "spell"* is an acute fall in arterial saturation due to dynamic subpulmonary obstruction, and it may be life threatening. Its treatment is aimed at relieving obstruction and increasing systemic resistance. Relief of hypoxia with oxygen and morphine, intravenous propranolol, and systemic vasoconstriction (e.g., squatting, knee-chest position, vasoconstrictor drugs) usually reverses the cyanosis.

Natural History

Progressive hypoxemia in the first years of life is expected. Survival to adult life is rare without palliation or correction. The presence of additional sources of a blood supply (see later) modifies the rate of progression of cyanosis and its complications.

Clinical Features

Unoperated Patients.

Variable cyanosis exists. A right ventricular impulse and systolic thrill are often palpable along the left sternal border. An early systolic ejection sound that is aortic in origin may be heard at the lower left sternal border and apex; the second heart sound is usually single. The intensity and duration of the systolic ejection murmur vary inversely with the severity of subvalve obstruction—the opposite of the relationship that exists in patients with pulmonary valve stenosis. With extreme outflow tract stenosis or pulmonary atresia and during an attack of paroxysmal hypoxemia, no murmur or only a short, faint murmur may be detected. A continuous murmur faintly audible over the anterior or posterior chest reflects flow through aortopulmonary collateral vessels or a duct.

After Palliative Surgery.

Progressive cyanosis with its complications can result from worsening right ventricular outflow tract obstruction, gradual stenosis and occlusion of palliative aortopulmonary shunts (**see Table 75.5**), or the development of pulmonary hypertension (sometimes seen after Waterston or Potts shunts have been used). Progressive ascending aortic dilation and aortic regurgitation can occur. Central cyanosis and clubbing are invariably present.

After Reparative Surgery.

After intracardiac repair, more than 85% of patients are asymptomatic on follow-up, although objective testing will usually demonstrate a reduction in maximal exercise performance. Palpitations from atrial and ventricular arrhythmias and exertional dyspnea from progressive right ventricular dilation secondary to chronic pulmonary regurgitation or severe residual right ventricular outflow tract obstruction occur in 10% to 15% of patients within 20 years after initial repair. An ascending aortic aneurysm and significant aortic regurgitation from a dilated aortic root may occasionally be present. A parasternal right ventricular lift and a soft and delayed, or absent, P_2 with a low-pitched diastolic murmur from pulmonary regurgitation may exist. A systolic ejection murmur from right ventricular outflow tract obstruction, a high-pitched diastolic murmur from aortic regurgitation, and a pansystolic murmur from a VSD patch leak may also be heard.

Tetralogy of Fallot with Pulmonary Atresia and Major Aortopulmonary Collateral Arteries

This subgroup represents one of the greatest challenges in CHD. The aim of unifocalization surgery is to amalgamate all the sources of pulmonary blood flow and establish unobstructed right ventricular–to–pulmonary artery continuity while achieving a normal pulmonary artery pressure and a closed ventricular septum. When this is not possible, a combined interventional catheterization and surgical approach may be indicated. Balloon dilation and stenting of stenosed arteries and anastomoses can “rehabilitate” the segmental supply and allow subsequent VSD closure; if the VSD has already been closed, it can reduce the right ventricular pressure (Video 75.53).

Laboratory Investigations

ECG.
In adults with repaired tetralogy of Fallot, a complete right bundle branch block following repair has been the rule. The QRS width may reflect the degree of right ventricular dilation and, when extreme (>180 msec) or rapidly progressive, may be a risk factor for sustained ventricular tachycardia and sudden death.

Chest Radiography.
Characteristically, the unrepaired patient has a normal-sized, boot-shaped heart (*coeur en sabot*) with prominence of the right ventricle and a concavity in the region of the underdeveloped right ventricular outflow tract and main pulmonary artery. After repair, the right ventricle is often prominent, and the left heart border tends to be straightened by a dilated right ventricular outflow tract. The aortic arch may be on the right side (25%). The ascending aorta is sometimes prominent.

Echocardiography (Fig. 75.25).
In the *unoperated* patient, the complete diagnosis can usually be established by echocardiography alone. The study should identify the malaligned and nonrestrictive VSD and overriding aorta (< 50% override) and the presence and degree of right ventricular outflow tract obstruction (infundibular, valvular, and/or pulmonary arterial stenosis). Cardiac catheterization is now rarely required before corrective surgery. The exception to this rule is when there are additional sources of pulmonary blood flow.

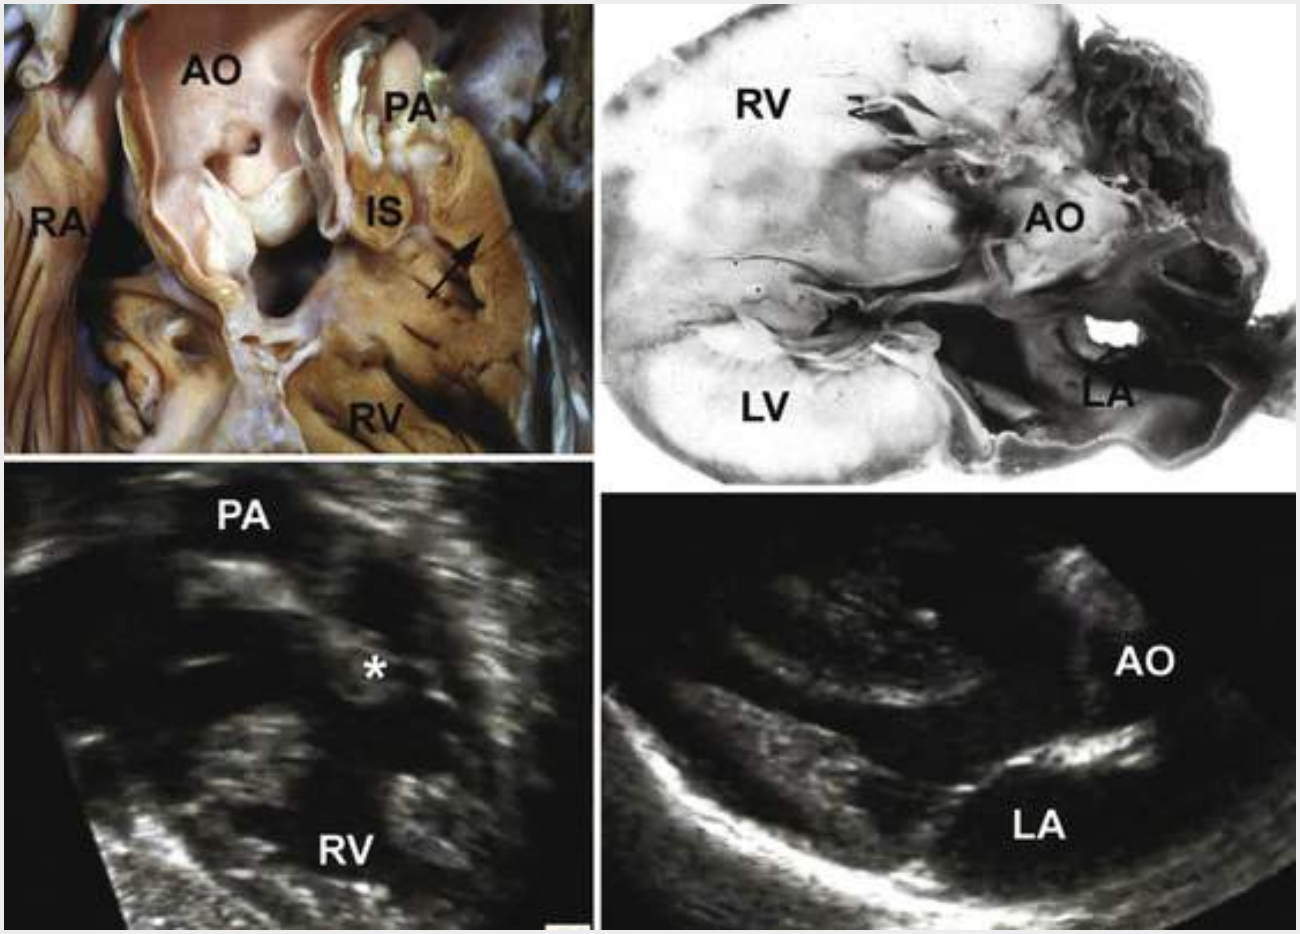

FIGURE 75.25 Montage of tetralogy of Fallot. The two left images are in the right anterior oblique view that demonstrates the anteriorly deviated infundibular septum (*asterisk*) and the VSD. The *arrow* on the specimen points to the hypertrophied septoparietal trabeculations. The right images demonstrate the overriding aorta and the VSD. *AO*, aorta; *IS*, infundibular septum; *LA*, left atrium; *PA*, pulmonary artery; *RA*, right atrium; *RV*, right ventricle.

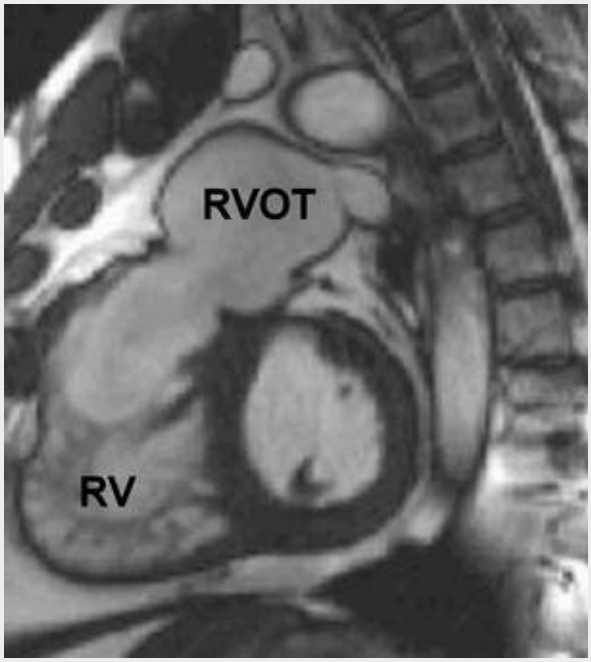
In patients with *repaired* tetralogy of Fallot, the residual pulmonary stenosis and regurgitation, residual VSD, right and left ventricular size and function, aortic root size, and degree of aortic regurgitation should be assessed.

Cardiac Catheterization and Angiocardiography.

Although echocardiography, MRA, and fast computed tomography (CT) may delineate the presence and proximal course of the pulmonary blood vessels, the preoperative assessment of tetralogy with pulmonary atresia with major aortopulmonary collateral arteries usually includes delineation of the arterial supply to both lungs by selective catheterization and angiography to show the course and segmental supply from the collateral arteries and central pulmonary arteries. Major aortopulmonary collateral arteries usually arise from the descending aorta at the level of the tracheal bifurcation.

MRI.

The goals of MRI examination after tetralogy of Fallot repair include the quantitative assessment of the left and, particularly, right ventricular volumes, stroke volumes, and ejection fraction; imaging of the anatomy of the right ventricular outflow tract (**eFig. 75.3**), pulmonary arteries, aorta, and aortopulmonary collaterals; and quantification of pulmonary, aortic, and tricuspid regurgitation.



EFIGURE 75.3 This MRI image after tetralogy repair demonstrates its use in imaging right ventricular outflow tract aneurysms, and in assessing right ventricular volumes. *RV*, right ventricle; *RVOT*, right ventricular outflow tract.

Indications for Intervention

Children.

Symptomatic infants are now repaired at any age, and elective repair in asymptomatic infants during the first 6 months is advocated by many. This is often at the expense of a transannular patch enlargement of the right ventricular outflow tract, which is a risk factor for later reintervention. Marked hypoplasia of the pulmonary arteries, small body size, and prematurity are relative contraindications for early corrective operation; these patients may be successfully palliated by balloon dilation of the right ventricular outflow

tract (with or without stenting) and pulmonary arteries (Video 75.54).

Adults, Unoperated.

For unoperated adults, surgical repair is still recommended because the results are gratifying and the operative risk is comparable to that of pediatric series provided there is no serious coexisting morbidity.

Palliated Patients.

Palliation was seldom intended as a permanent treatment strategy, and most of these patients should undergo surgical repair. In particular, palliated patients with increasing cyanosis and erythrocytosis (from gradual shunt stenosis or development of pulmonary hypertension), left ventricular dilation, or aneurysm formation in the shunt should undergo intracardiac repair with takedown of the shunt unless irreversible pulmonary hypertension has developed.

Repaired Patients.

The following situations *may* warrant intervention after repair: a residual VSD with a shunt greater than 1.5/1; residual pulmonary stenosis (either the native right ventricular outflow or valved conduit if one is present) with right ventricular systolic pressure two thirds or more of systemic pressure; or severe pulmonary regurgitation associated with substantial right ventricular dilation or dysfunction (i.e., right ventricular diastolic volume index > 150 to 170 mL/m^2 or a right ventricular ejection fraction < 45%),[36] exercise intolerance, or sustained arrhythmias. The coexistence of substantial left ventricular dysfunction or a QRS duration of more than 180 msec offers additional support when other indications are present. The development of major cardiac arrhythmias increases over time, and most commonly includes atrial flutter or fibrillation (present in ≤ 20% of patients) or sustained ventricular tachycardia (present in ≤ 14% of patients).[37] The presence of arrhythmias usually reflects hemodynamic deterioration from the right and/or left heart,[37] and should be treated accordingly. Surgery is occasionally necessary for significant aortic regurgitation associated with symptoms or progressive left ventricular dilation and for aortic root enlargement of 55 mm or more. Rapid enlargement of a right ventricular outflow tract aneurysm needs surgical attention.

Interventional Options

Surgery.

Reparative surgery involves closing the VSD with a Dacron patch and relieving the right ventricular outflow tract obstruction. The latter may involve resection of infundibular muscle and insertion of a right ventricular outflow tract or transannular patch (i.e., a patch across the pulmonary valve annulus that disrupts the integrity of the pulmonary valve and causes important pulmonary regurgitation). When an anomalous coronary artery crosses the right ventricular outflow tract and precludes a patch, an extracardiac conduit is placed between the right ventricle and pulmonary artery, bypassing the right ventricular outflow tract obstruction. A PFO or secundum ASD may be closed. Additional treatable lesions such as muscular VSDs, PDAs, and aortopulmonary collaterals may also be addressed at the time of surgery.

Reoperation is necessary in 10% to 15% of patients after reparative surgery over a 20-year follow-up. For persistent right ventricular outflow tract obstruction, resection of a residual infundibular stenosis or placement of a right ventricular outflow or transannular patch, with or without pulmonary arterioplasty, can be performed. Occasionally, an extracardiac valved conduit may be necessary. Pulmonary valve

replacement (either homograft or xenograft) is used to treat severe pulmonary regurgitation. Concomitant tricuspid valve annuloplasty may be performed for moderate or severe tricuspid regurgitation. Concomitant cryoablation may be performed at the time of surgery for patients with preexisting atrial or ventricular arrhythmias.

Transcatheter Valve Replacement.

Percutaneous pulmonary valve replacement (Videos 75.55 and 75.56) can be performed. Compared with surgical pulmonary valve replacement, the mortality rates are similar; the hemodynamic short- and intermediate-term results are favorable; and the morbidity rates are lower. Percutaneous replacement should be done only in CHD centers with expertise in the procedure, however. At present, these therapies are reserved primarily for patients with circumferential right ventricle–pulmonary artery conduits (i.e., homografts, valved conduits) measuring less than 22 mm, although transcatheter pulmonary valve replacements have been performed in patients with native right ventricular outflow tracts.[38] Significant branch pulmonary artery stenosis can be managed with balloon dilation and usually stent insertion.

Implantable Cardioverter-Defibrillator.

When a patient presents with aborted sudden death or sustained ventricular tachycardia, implantable cardioverter-defibrillator (ICD) placement should be considered as a secondary prevention measure,[39] unless there is compelling evidence that a hemodynamic issue could correct the risk for subsequent events. The selection of appropriate candidates for primary prevention ICDs remains controversial. ICDs are probably best reserved for those with a high annual risk of adverse events (≥ 3.5%/year), a group that includes patients with combinations of a prior palliative shunt, QRS higher than 180 msec, inducible ventricular tachycardia, and raised left ventricular end-diastolic pressure.

Interventional Outcomes

The overall survival rate of patients who have had an initial operative repair is excellent, provided the VSD has been closed and the right ventricular outflow tract obstruction has been relieved. A 25-year survival rate of 94% has been reported. Pulmonary valve replacement for chronic pulmonary regurgitation or right ventricular outflow tract obstruction after initial intracardiac repair can be done safely; the mortality rate is 2%. Pulmonary valve replacement, when it is performed for significant pulmonary regurgitation, leads to an improvement in exercise tolerance as well as favorable right ventricular remodeling.[36] Sudden death can occur. Ventricular tachycardia can originate at the site of the right ventriculotomy, from VSD patch sutures, or from the right ventricular outflow tract. Patients at high risk for sudden death include those with right ventricular dilation and a QRS duration of 180 msec or more on the ECG. Moderate-to-severe left ventricular dysfunction is another risk factor for sudden death.[37,39,40] The reported incidence of sudden death is approximately 5%, which accounts for approximately one third of late deaths during the first 20 years of follow-up.

Reproductive Issues

Patients with repaired tetralogy of Fallot can go through pregnancy relatively safely, with an adverse cardiovascular event rate of between 8% and 17%.[23,40] The events are mainly arrhythmias and a worsening NYHA class resulting from right heart failure.[41] The outcome of the offspring relates to the maternal cardiovascular status prior to pregnancy, as well as cardiovascular events during pregnancy. Women with repaired tetralogy of Fallot should be followed diligently during pregnancy. Chromosomal

abnormalities in a parent, such as the CATCH 22 syndrome, have a 50% chance of transmission to the offspring.

Follow-Up

All patients should have expert cardiologic follow-up every 1 to 2 years.

Lesions That Require the Fontan Procedure

The next four sections describe lesions usually or often treated with a Fontan procedure. These include tricuspid atresia, hypoplastic left heart syndrome, double-inlet ventricle, and isomerism. The *Fontan procedure* has become a generic term to describe a palliative surgical procedure that redirects the systemic venous return directly to the pulmonary arteries without passing through a subpulmonary ventricle. It is performed in patients having a functionally single ventricle or in those for whom a biventricular intracardiac repair is not possible, even though there are two good-sized ventricles. Although undoubtedly imperfect, the Fontan circuit restores an in-series pulmonary-to-systemic circulation, removing the chronic volume load of the systemic ventricle previously supporting a parallel circuit of pulmonary and systemic circulations. The earliest iteration of the Fontan procedure was a simple “atriopulmonary” connection, whereby the right atrium or its appendage was anastomosed to the pulmonary arteries. Because of the long-term problems of atrial dilation, arrhythmia, and thrombosis, this procedure has been abandoned in favor of hemodynamically superior versions. In the early 1990s, the total cavopulmonary anastomosis or lateral-tunnel Fontan procedure was introduced. This consisted of a direct, end-to-side superior cavopulmonary anastomosis (bidirectional Glenn operation) in combination with an intraatrial baffle or tube connection of the inferior vena cava to the underside of the confluent pulmonary arteries. More recently, the inferior vena cava has been directed to the pulmonary arteries via an extracardiac conduit, completely excluding the atrium from the circuit. It remains to be seen whether these modifications will have the desired effect of reducing late morbidity, and all patients will require regular and careful review in special centers.

Tricuspid Atresia (Absent Right Atrioventricular Connection)

Morphology

Classic tricuspid atresia is best described as absence of the right AV connection (**Figs. 75.26 and 75.27**, and see Videos 75.22 and 75.23). Consequently, there must be an ASD. There is usually hypoplasia of the morphologic right ventricle, which communicates to the dominant ventricle via a VSD. Patients may be subdivided into those with concordant ventriculoarterial connections and normally related great arteries (70% to 80% of cases) and those with discordant connections, where the aorta arises from the small right ventricle and is fed via the VSD. Associated lesions in the latter group include subaortic stenosis and aortic arch anomalies.

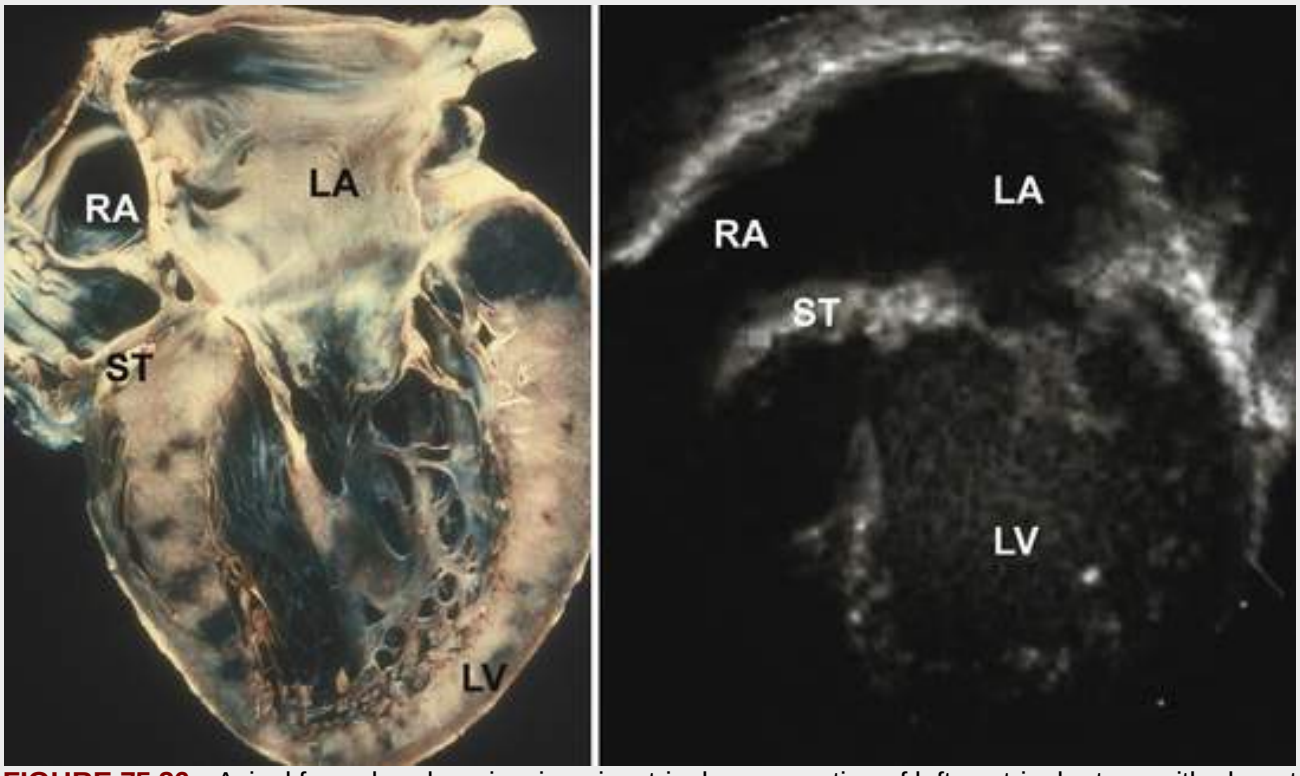


FIGURE 75.26 Apical four-chamber view in univentricular connection of left ventricular type with absent right connection (tricuspid atresia). Note the wedge of sulcus tissue in the floor of the right atrium. *LA*, left atrium; *LV*, left ventricle; *RA*, right atrium; *ST*, sulcus tissue.

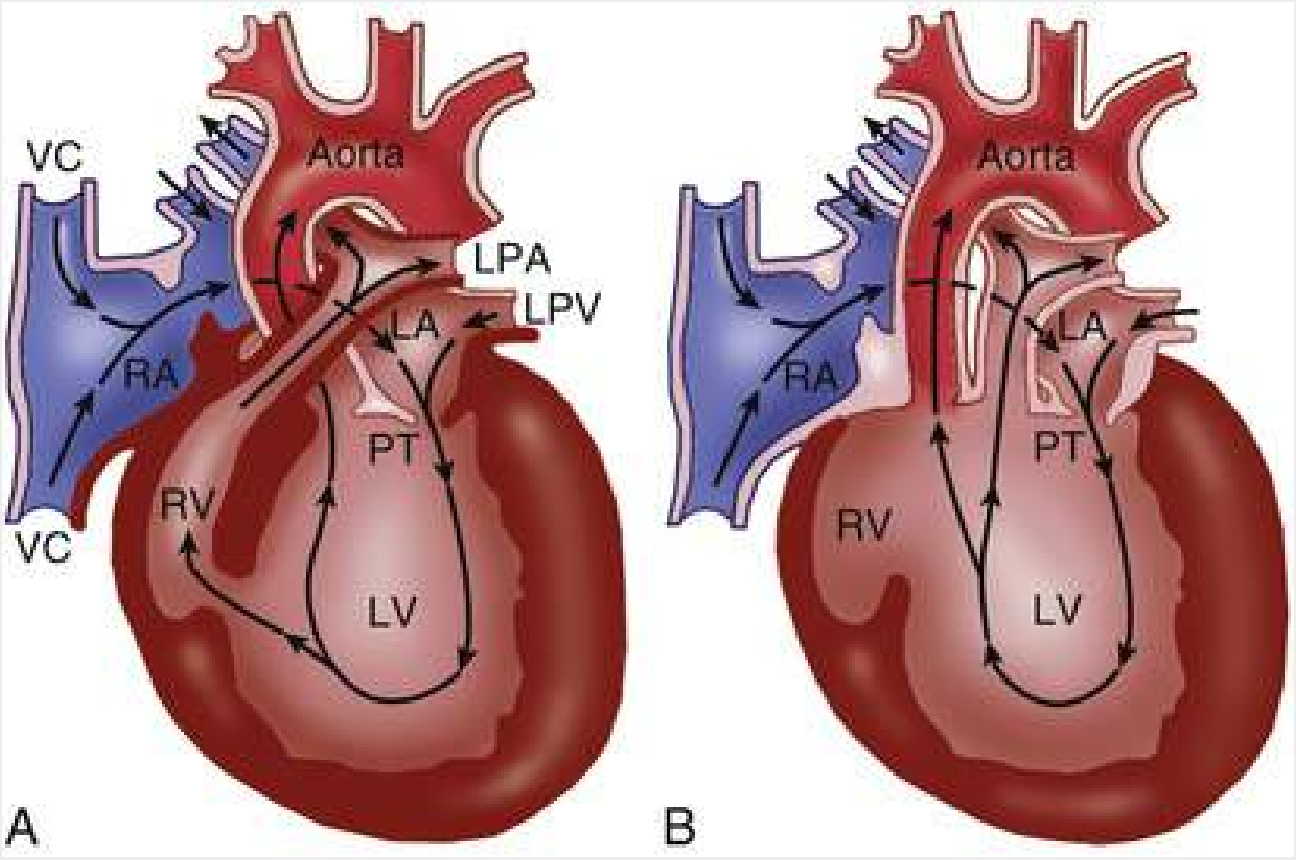

FIGURE 75.27 **A,** Tricuspid atresia with normally related great arteries, a small VSD, diminutive right ventricular chamber, and narrowed outflow tract. **B,** An example of tricuspid atresia and complete transposition of the great arteries in which the left ventricular chamber is essentially a common ventricle, with the aorta arising from an infundibular component (RV) of the common ventricle. *LA*, left atrium; *LPA*, left pulmonary artery; *LPV*, left pulmonary vein; *LV*, left ventricle; *PT*, pulmonary trunk; *RA*, right atrium; *RV*, right ventricle; *VC*, vena cava. (**A** and **B,** Modified from Edwards JE, Burchell HB: Congenital tricuspid atresia: classification. Med Clin North Am 33:1177, 1949.)

Pathophysiology

The clinical picture and management are dominated by issues related to the ventriculoarterial connections. All patients have “mixing” of atrial blood, and thus their degree of cyanosis is governed by the amount of pulmonary blood flow and systemic venous saturations. Patients with concordant ventriculoarterial connections tend to be more cyanosed (depending on the size of the VSD), whereas those with discordant connections are pinker and tend to develop heart failure (because the unobstructed pulmonary circulation arises directly from the left ventricle). Some present with a critical reduction of systemic blood flow because of obstruction at the VSD and/or associated aortic arch anomalies and behave much like patients with hypoplastic left heart syndrome.

Laboratory Investigations

ECG.

Left axis deviation, right atrial enlargement, and left ventricular hypertrophy often occur. Left atrial enlargement may be present if the pulmonary flow is high.

Chest Radiography.

Situs solitus, levocardia, and a left-sided aortic arch usually occur. The heart size and pulmonary vascular markings vary with the amount of pulmonary blood flow. The main pulmonary trunk is inapparent. A right aortic arch exists in 25% of patients.

Echocardiography.

This establishes the full segmental diagnosis. The size of the ASD, VSD, and aortic arch all must be carefully assessed.

Cardiac Catheterization.

This is rarely required for the initial diagnosis or management. It can be useful to assess the degree of subaortic stenosis (by assessing the change in left ventricle–to–aorta pressure gradient while performing an isoprenaline or dobutamine challenge) and is usually performed to measure the pulmonary artery pressure and resistance prior to venopulmonary connections.

Management Options.

In patients with concordant ventriculoarterial connections and severe cyanosis, a systemic-to-pulmonary shunt is performed in the first 6 to 8 weeks of life. In older children, a primary bidirectional Glenn procedure can be considered. In infants with discordant arterial connections, early palliation ranges from pulmonary artery banding to reduce pulmonary blood flow when there is no subaortic narrowing to a full Norwood stage 1 procedure in patients presenting with severe stenosis and a hypoplastic ascending aorta and arch.

The aim of early palliation is to prepare for a Fontan procedure. This should be performed only when there is good ventricular function, unobstructed systemic blood flow, and minimal AV valve regurgitation. Candidates for these corrective procedures must also have a low pulmonary resistance, a mean pulmonary artery pressure of less than 15 mm Hg, and pulmonary arteries of adequate size.

Hypoplastic Left Heart Syndrome

Hypoplastic left heart syndrome is a generic term used to describe a group of closely related cardiac anomalies characterized by underdevelopment of the left cardiac chambers, in association with atresia or stenosis of the aortic and/or the mitral orifices, and hypoplasia of the aorta. The term should be restricted to those with normally connected hearts with concordant AV and ventriculoarterial connections. Hypoplastic left heart syndrome (**Fig. 75.28**) is characterized by duct-dependent systemic blood flow and so tends to present with severe symptoms within the first week of life, as ductal constriction occurs. Untreated, the disease is almost uniformly fatal in infancy. In the past, many infants would present with severe acidemic circulatory collapse, but this is becoming less frequent as fetal ultrasound screening for cardiac anomalies becomes more generally available and successful. Fetal diagnosis allows for a planned delivery and institution of prostaglandin therapy from birth and has now been proven to reduce subsequent preoperative morbidity rates and perioperative mortality rates during the first stage of surgical repair.

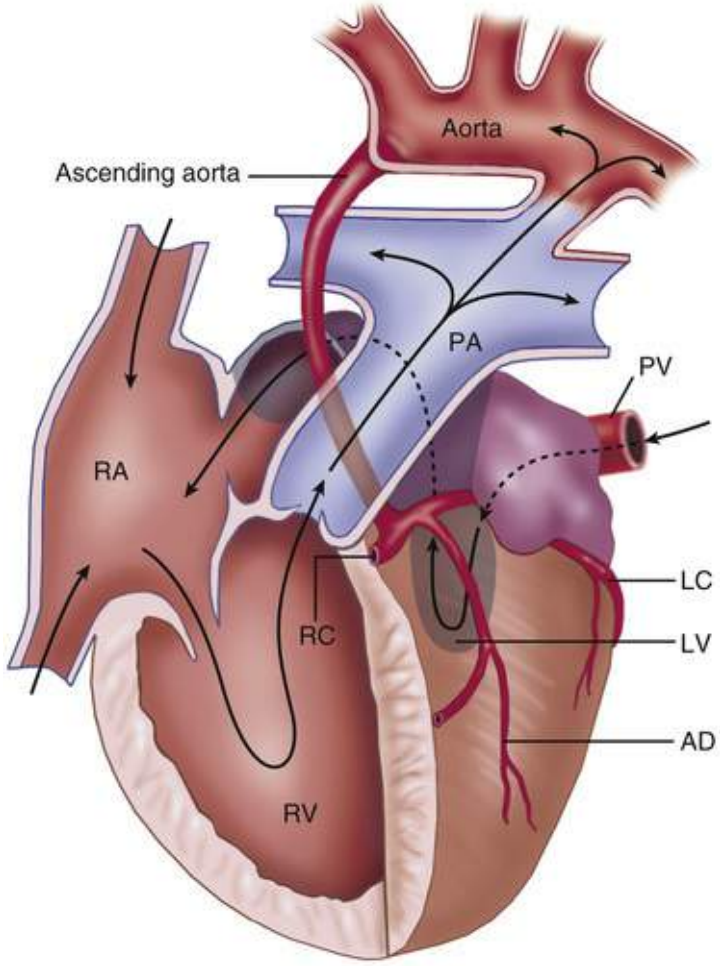

FIGURE 75.28 Hypoplastic left heart with aortic hypoplasia, aortic valve atresia, and a hypoplastic mitral valve and left ventricle. AD, anterior descending; LC, left circumflex; LV, left ventricle; PA, pulmonary artery; PV, pulmonary vein; RA, right atrium; RC, right coronary artery; RV, right ventricle. (From Neufeld HN, Adams P Jr, Edwards JE, et al: Diagnosis of aortic atresia by retrograde aortography. Circulation 25:278, 1962.)

Pathophysiology

It remains uncertain whether hypoplastic left heart syndrome reflects a primary myocardial disease or is a consequence of a structural or hemodynamic abnormality. There is no doubt that in some patients, an apparently isolated dilated cardiomyopathy in early fetal life may evolve (as a result of a subsequent lack of left ventricular growth) into hypoplastic left heart syndrome later in gestation. Congenital structural abnormalities clearly play a significant role as well. This is exemplified by the effect of isolated valvular stenosis to produce a continuum of hypoplastic left heart syndrome to critical aortic stenosis with a normal-sized left ventricle. Therefore, hypoplastic left heart syndrome is likely multifactorial in origin.

Clinical Features.

The diagnosis should be considered in any infant with a sudden onset of circulatory collapse and severe lactic acidosis. As such, it must be distinguished from neonatal sepsis and metabolic disorders. Until excluded, any child presenting in this way should be treated with prostaglandin, which may have a dramatically positive effect if there is an underlying cardiac abnormality and little effect if there is not.

Laboratory Investigations

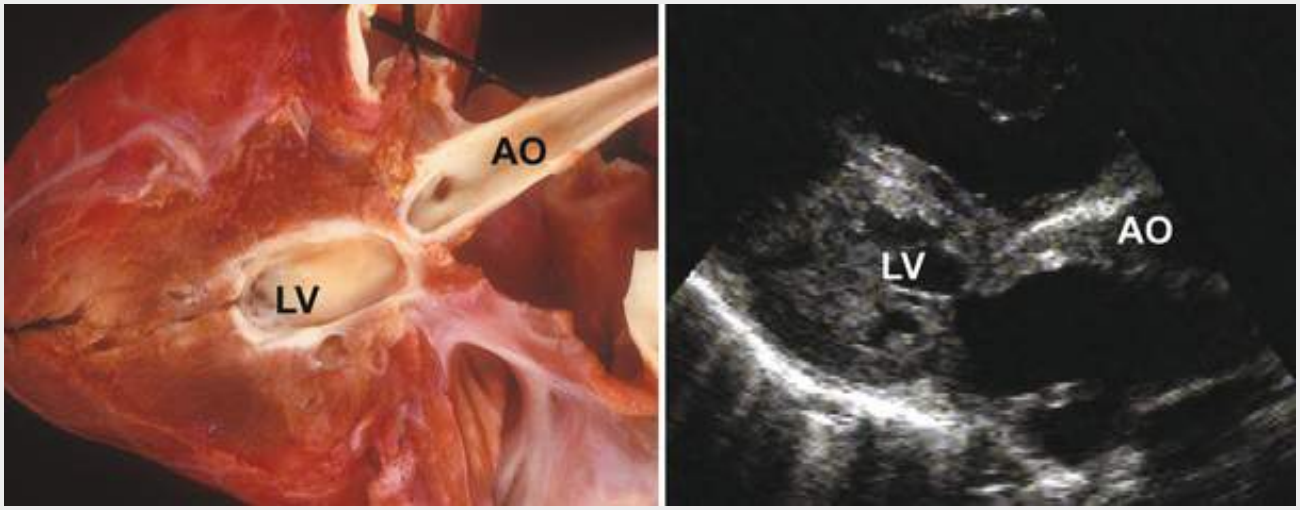
ECG.

This frequently shows right axis deviation, right atrial and ventricular enlargement, and ST and T wave abnormalities in the left precordial leads.

Chest Radiography.

This usually shows some cardiac enlargement shortly after birth, but with clinical deterioration there may be marked cardiomegaly and increased pulmonary venous and arterial vascular markings.

Echocardiography (eFig. 75.4).



EFIGURE 75.4 Long axis view of the left ventricle and aorta in hypoplastic left heart syndrome. Note the associated endocardial fibroelastosis in the specimen. *AO*, aorta; *LV*, left ventricle.

Cross-sectional echocardiography provides a full segmental diagnosis. In its classic form, the left ventricular cavity is small, with a diminutive mitral valve. The myocardium may be thinned or be of normal thickness, but the endocardium is usually thickened, consistent with endocardial fibroelastosis. There may be fistulous communications between the left ventricular cavity and the coronary arteries, a feature much more likely when the mitral valve is patent and the aortic valve atretic. The aortic root is usually diminutive, less than 4 to 5 mm in diameter at the level of the sinuses of Valsalva, and narrowed in its ascending portion. The aortic arch is usually larger, but there is often a juxtaductal coarctation. The duct varies in size according to treatment, and assessment of this and the size of the interatrial communication is crucial to management. There may be profound desaturation and rapid demise (because of a combination of reduced pulmonary blood flow and pulmonary edema) in children with an intact atrial septum or restrictive PFO.

Management Options.

Early treatment with prostaglandin is mandatory. Patients presenting in shock require paralysis, mechanical ventilation, and inotropic support. Crucial to managing these patients is maintenance of a balanced pulmonary and systemic blood flow. The cardiac output is fixed and is distributed according to the relative magnitude of the systemic and pulmonary vascular resistance. Thus measures to elevate the pulmonary resistance (by imposing hypercapnia or by alveolar hypoxia) and reduce the systemic

resistance (using vasodilators) are frequently required.

Staged *surgical management* now provides long-term palliation to most patients with hypoplastic left heart syndrome. The first stage, often referred to as the *Norwood procedure*, now has many versions, but its essence is the creation of an unobstructed communication between the right ventricle and an unobstructed aorta. The right ventricular–to–aortic connection is accomplished by direct connection between the transected proximal pulmonary trunk and ascending aorta, usually with a patch extending around the augmented aortic arch. Pulmonary blood flow is established via a systemic-to-pulmonary shunt or the more recently introduced right ventricle–to–pulmonary artery conduit. The PDA is ligated, and a large interatrial communication is created. Early results of this procedure were poor, but survival rates higher than 85% have recently been published. Institutional variations, the interval mortality rate, and cases in which a patient is unsuitable for progression to stage 2 must be taken into account, however, and in some centers, the preferred operation is cardiac transplantation.

Stage 2 consists of an end-to-side superior vena cava–to–pulmonary artery connection (bidirectional Glenn procedure) or a hemi-Fontan procedure (incorporating the roof of the atrium into the pulmonary artery anastomosis). This is performed at approximately 6 months of age as an intermediate step before stage 3, a Fontan operation. A newer innovation is the so-called hybrid procedure, whereby at the first stage each pulmonary artery is banded separately and then, to maintain ductal patency, a stent is placed by the interventional cardiologist, either directly via the main pulmonary artery in concert with the surgeon or percutaneously. The second stage combines the surgical aortopulmonary anastomosis with the bidirectional Glenn procedure. It remains to be seen whether this approach confers a survival or physiologic advantage.

The *adult survivors* of the early attempts at staged Norwood palliation are now entering adult life. Their issues are likely to be common to all late survivors of Fontan palliation with a systemic right ventricle (see below).

Double-Inlet Ventricle

The double-inlet connection falls under the umbrella of univentricular AV connections. In these hearts, more than 50% of each AV connection is attached to a dominant ventricle. In practice this usually means the whole of one junction and more than 50% of the alternative junction are connected to either a left or right ventricle. When there is a common junction, more than 75% of the junction must be connected to the dominant ventricle.

Morphology

In about 75% of patients, the dominant ventricle is a left ventricle that is separated from the right ventricle by a VSD. In 20%, the dominant ventricle is a right ventricle, and the small, incomplete ventricle is of left ventricular apical morphology. In only 5% of cases is there truly only one ventricle in the ventricular mass. In double-inlet left ventricle, the most common ventriculoarterial connection is discordant. Thus the aorta arises from the small right ventricle and is fed via the VSD, and the generally unobstructed pulmonary artery arises from the left ventricle. Aortic and aortic arch anomalies are frequent in these patients.

Pathophysiology

The basic circulatory physiology of *double-inlet left ventricle* is identical to that of tricuspid atresia.

Common mixing of systemic and pulmonary venous blood occurs, and the blood is then ejected from the left ventricle into the pulmonary artery (with discordant connections) or aorta (with concordant connections). In the former the blood must pass through the VSD to gain egress to the aorta. Subaortic stenosis, aortic hypoplasia, and arch anomalies are therefore common. In *double-inlet right ventricle*, it is those patients with concordant ventriculoarterial connections who are at particular risk of systemic outflow obstruction. One or the other, or both, of the two AV valves (when present) may be stenotic, atretic, or regurgitant. Under these circumstances the integrity of the atrial septum becomes important. If there is left or right atrial outflow obstruction, a septectomy or septostomy will be required.

Clinical Features.

When there is critical reduction of systemic outflow, infants may be duct dependent and present with acidemic shock. Conversely, when pulmonary blood flow is reduced, the presentation may be with severe cyanosis or with duct-dependent pulmonary blood flow. Other patients may not present in the neonatal period and will develop heart failure because of increased pulmonary blood flow. Patients undergo the same surgical algorithms as those with tricuspid atresia and so ultimately will undergo a Fontan operation. Their clinical issues are typical of any patient after this procedure.

Laboratory Investigations

ECG.

This is highly variable. Ventricular hypertrophy appropriate to the dominant ventricle is expected.

Chest Radiography.

This is similarly variable and rarely diagnostic.

Echocardiography (Fig. 75.29 and see Videos 75.11 through 75.13)

A full segmental diagnosis should be possible in all patients. Particular attention should be paid to defining AV valve anomalies and the presence and anatomy of any subaortic obstruction. Obstruction may develop even if it is not present at birth, and surveillance for it should be part of the routine examination of these patients.

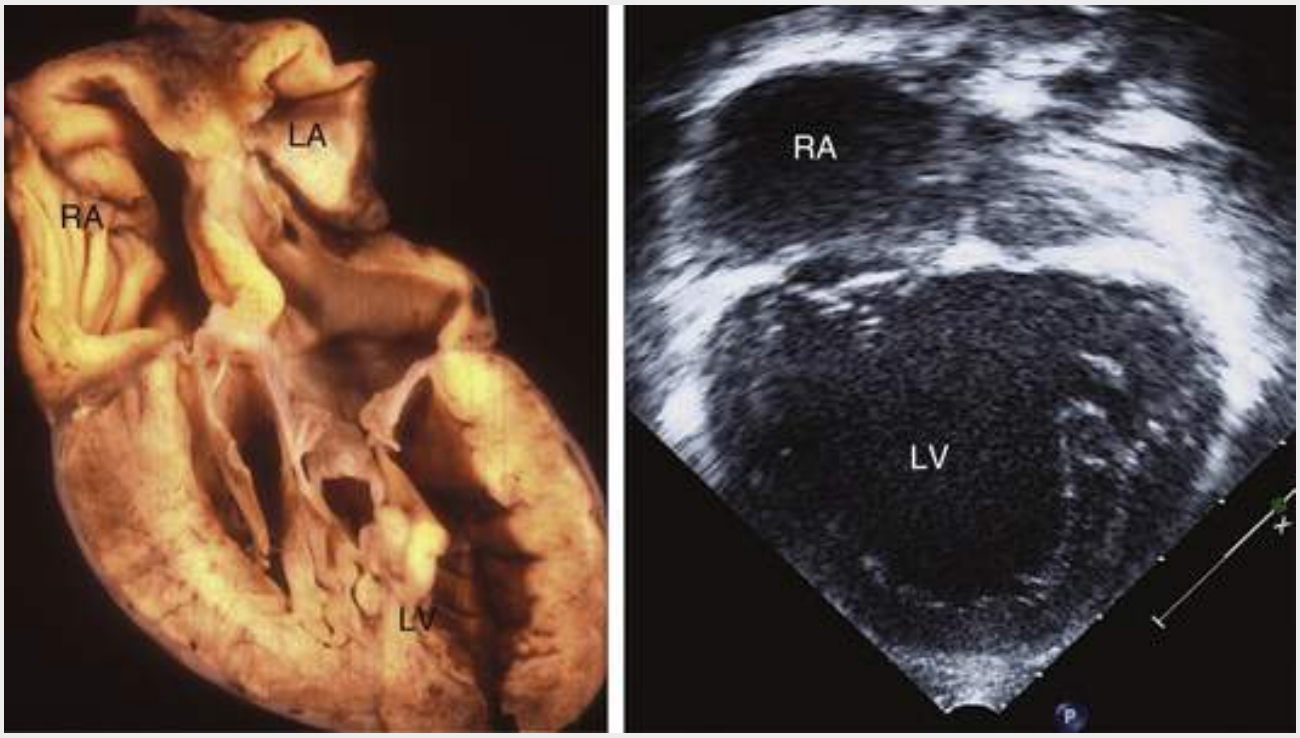


FIGURE 75.29 Apical four-chamber view in a double-inlet univentricular connection of left ventricular type with two AV valves. *LA*, left atrium; *LV*, left ventricle; *RA*, right atrium.

Indications and Options for Intervention.

Survival times without intervention may be prolonged, but at the expense of increasing cyanosis (when there is restriction to pulmonary blood flow) or pulmonary vascular disease (when there is unrestricted pulmonary blood flow). Those born with restricted systemic blood flow require urgent surgical intervention; they usually undergo a Norwood-type repair to establish the pulmonary valve as the unobstructed systemic outflow tract. Pulmonary artery banding is only offered to those infants with pulmonary overcirculation, heart failure, and unobstructed systemic outflow. Subsequently, and sometimes as the primary procedure, a bidirectional Glenn anastomosis is performed as a prelude to a Fontan procedure.

Follow-Up.

These patients should be reviewed frequently and in a center conversant with the issues of the Fontan operation.

Isomerism

For the purposes of illustrating the cardiac manifestations, isomerism describes the situation in which both atrial appendages have either left or right anatomic features (i.e., bilateral right or bilateral left atrial appendages).

Morphology

In left isomerism it is not unusual to have a biventricular AV connection, with separate AV junctions. A common junction (with an AV septal defect) is seen in approximately 30% of cases of left isomerism and more than 90% of hearts with right isomerism. Concordant ventriculoarterial connections predominate in

left isomerism, and a double-outlet right ventricle with an anterior aorta is most frequently seen when there is right isomerism. The venous connections are variable. These variations significantly affect the clinical and interventional management of these patients.

Isomerism of the Right Atrial Appendages

Clinical Features.

Bilateral "right-sidedness" results in a pattern of visceral abnormalities sometimes described as *asplenia syndrome*. The liver is at the midline, both lungs are trilobed with symmetrically short bronchi on the chest radiograph, and the spleen is hypoplastic or absent. The latter mandates immunization against pneumococcal infection and continuous penicillin prophylaxis against gram-positive sepsis. The diagnosis can be inferred from the bronchial pattern on the chest radiograph but most often is established by cross-sectional echocardiography because of early presentation with severe CHD. Abdominal scanning shows an ipsilateral arrangement of the aorta and an anterior inferior vena cava. The intracardiac anatomy is most often that of an AV septal defect with varying degrees of right ventricular dominance, and frequently there is an associated double-outlet right ventricle with an anterior aorta, and subpulmonary stenosis or atresia. Thus cyanosis is the most common presentation. The inferior vena cava may connect to either right atrium, and superior venae cavas are often lateralized and separate. It is the pulmonary venous drainage that is crucial to the presentation and outcome of these children. By definition, the pulmonary veins are draining anomalously to one or the other right atrium, but frequently this is indirect and/or obstructed. Adequate repair of the latter is fundamental to the outcome of these children, who almost uniformly ultimately require a Fontan procedure.

Management Options and Outcomes.

Initial palliation is usually directed toward regulating pulmonary blood flow and dealing with anomalies of pulmonary venous connection. Subsequently these patients (even when there are equal-sized ventricles) are treated along a Fontan algorithm. This is because repair of a complete AV septal defect in the setting of abnormal ventriculoarterial connections is technically difficult or impossible. Thus a unilateral or bilateral superior cavopulmonary anastomosis is performed at approximately 6 months of age, followed when possible by a Fontan procedure at age 2 to 4 years.

The long-term outcome of surgery for right isomerism, however, has been poor, and relatively few patients will be seen in adult CHD clinics. However, improved early palliation and a staged approach toward the Fontan procedure have led to improved results, and more patients with extremely complex underlying disease can be expected to survive into adult life.

Isomerism of the Left Atrial Appendages

Clinical Features.

These patients have bilateral "left-sidedness." Hence they have two left lungs and bronchi, tend to have polysplenia, and frequently have malrotation of the gut. The cardiac abnormalities tend to be less severe than those of right isomerism. These patients are particularly prone to develop atrial arrhythmias because, in them, the normal sinoatrial node is a right atrial structure and is usually absent. The ECG often shows an abnormal P wave axis or wandering pacemaker. Complete heart block may also occur. The anatomic diagnosis is usually established by echocardiography. The abdominal great vessels are both to the right or left of the spine, as with right isomerism, but in left isomerism the vein is a posterior azygos vein that

continues to connect to a left- or right-sided superior vena cava. The intrahepatic inferior vena cava is absent in 90% of patients, and under these circumstances the hepatic veins drain directly to the atria. The pulmonary venous connection needs to be defined precisely before any surgical intervention. Pulmonary arteriovenous malformations are not infrequently seen in patients with left isomerism. These can lead to cyanosis in unoperated or operated patients. The intracardiac anatomy varies from essentially normal to complex. Again, AV septal defect (partial and complete) is overrepresented but with less frequent ventricular imbalance and abnormalities of ventriculoarterial connection.

Management Options.

A biventricular repair is achieved in many more of these patients, albeit with the need for complex atrial baffle surgery to separate the systemic and pulmonary venous returns. The long-term outcome for patients with left isomerism is therefore much better than for those with right isomerism. The issues are much like those related to the type of surgery, but monitoring for arrhythmia needs to be even more intense than usual.

The Fontan Patient (Fig. 75.30)

As stated in the introduction to this section, the uncertain nature of the Fontan circulation and the frequency of its failure require that all patients be followed regularly in a specialized center for CHD, and new symptoms should prompt early reevaluation in such a center.

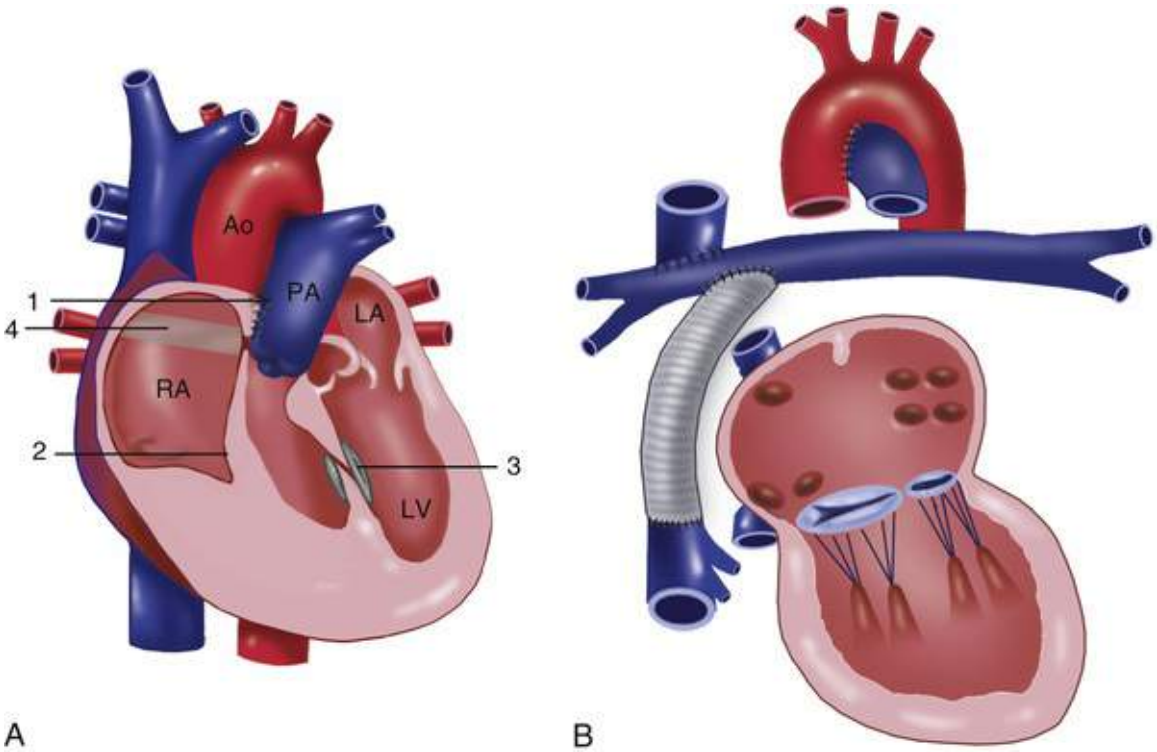

FIGURE 75.30 Modification of the Fontan operation. **A,** Direct atriopulmonary connection (1) for tricuspid valve atresia (2); VSD, oversewn (3); patch closure of ASD (4). **B,** Extracardiac conduit made of a Dacron graft bypassing the right atrium, connecting the inferior vena cava to the inferior aspect of the right pulmonary artery. Superior vena cava is anastomosed to the superior aspect of the right pulmonary artery. *Ao*, aorta; *LA*, left atrium; *LV*, left ventricle; *PA*, pulmonary artery; *RA*, right atrium. (**A,** From Mullins CE, Mayer DC: Congenital heart disease: a diagrammatic atlas. New York, Wiley-Liss, 1988; **B,** from Marcelletti C: Inferior vena cava–pulmonary artery extracardiac conduit: a new form of right heart bypass. J Thorac Cardiovasc Surg 100:228, 1990.)

Since its description for the surgical management of tricuspid atresia in 1971, the Fontan procedure has

become the definitive palliative surgical treatment when a biventricular repair is not possible. The principle is diversion of the systemic venous return directly to the pulmonary arteries without passing through a subpulmonary ventricle. Over the years, many modifications of the original procedure have been described and performed, namely, direct atriopulmonary connection, total cavopulmonary connection, and extracardiac conduit. Fenestration (4 to 5 mm in diameter) of the Fontan circuit into the left atrium is sometimes performed in high-risk patients at the time of surgery, permitting right-to-left shunting and decompression of the Fontan circuit.

Pathophysiology

Elevation of the central venous pressure and a reduced cardiac output (sometimes at rest but always during exercise) are inevitable consequences of the Fontan procedure. Small adverse changes in ventricular function (particularly diastolic); circuit efficiency (elevated pulmonary resistance, obstruction, thrombosis); or the onset of arrhythmia all potentially lead to major symptomatic deterioration.

Although it is reasonable to describe patients after the Fontan procedure as existing in a form of chronic heart failure (because their central venous pressure must be high), this is seldom due to marked systolic dysfunction. Indeed, a small elevation in ventricular diastolic pressure may be much more harmful. Thus it may be incorrect to treat these patients with traditional heart failure medications. *Indeed, in a randomized, blinded placebo-controlled study, ACE inhibition failed to improve ventricular function*[42] *or functional performance, and exercise cardiac output worsened.*

The more "streamlined" Fontan circulations (total cavopulmonary anastomosis, extracardiac conduit) that exclude the right atrium from the circulation have demonstrably better fluid dynamic properties and improved functional performance. Physical obstruction at any or all of the surgical anastomoses, the distal pulmonary arteries, or pulmonary veins (often due to compression by a dilated right atrium) reduces the circulatory efficiency, however. Similarly, elevated pulmonary arteriolar resistances have adverse effects. This is because pulmonary vascular resistance is the single biggest contributor to impairment of venous return and elevation of venous pressure. Relatively little is known about pulmonary vascular resistance late after the procedure, but it has been shown to be elevated in a significant number of patients and to be reactive to inhaled nitric oxide, suggesting pulmonary endothelial dysfunction.

Recently, beneficial effects on exercise performance were shown with bosentan[43] *and sildenafil*[44] *treatment, but this remains to be confirmed in larger studies.*

Clinical Features

The majority of patients (≈90%) present with functional class I to II disease at 5 years' follow-up after a Fontan procedure. Progressive deterioration of functional status with time is the rule. Supraventricular arrhythmias such as atrial tachycardia, flutter, and fibrillation are common. Physical examination in an otherwise uncomplicated patient reveals an elevated, usually nonpulsatile, jugular venous pulse, hepatomegaly early, and a smaller cirrhotic liver later, a quiet apex, a normal S_1, and a single S_2 (the pulmonary artery having been tied off). A heart murmur should not be present, and its identification may suggest the presence of systemic AV valve regurgitation or subaortic obstruction. Generalized edema and ascites may be a sign of protein-losing enteropathy (see later).

Complications and Sequelae

Although often associated with marked symptomatic decline, atrial *arrhythmias* tend to reflect the consequences of the abnormalities of ventricular function and circulatory efficiency described earlier. The massively dilated right atrium after an atriopulmonary connection is commonly associated with atrial flutter and fibrillation (15% to 20% at 5 years' follow-up). Atrial flutter or fibrillation carries a significant rate of morbidity,[45] can be associated with profound hemodynamic deterioration, and needs prompt medical attention. The combination of atrial incisions and multiple suture lines at the time of Fontan surgery along with increased right atrial pressure and size probably explains the high incidence of atrial arrhythmias in such patients. Patients at greater risk for atrial tachyarrhythmias are those who were operated on at an older age, with poor ventricular function, systemic AV valve regurgitation, or increased pulmonary artery pressure. It has been suggested that the exclusion of the right atrium from elevated systemic venous pressure (as in total cavopulmonary connections or extracardiac conduits) leads to a decrease in the incidence of atrial arrhythmias.[46] This apparent benefit may, however, be due exclusively to the shorter length of follow-up in this group of patients. Sinus node dysfunction and complete heart block can occur and require pacemaker insertion.

The reported incidence of *thromboembolic complications, including stroke,* in the Fontan circuit varies from 6% to 25%, depending on the diagnostic method used and the length of follow-up. Thrombus formation may relate to the presence of supraventricular arrhythmias, right atrial dilation, right atrial “smoke,” and the presence of artificial material used to construct the Fontan circuit. Systemic arterial embolism in patients with and without a fenestrated Fontan circuit has also been reported. Protein C deficiency has been reported in these patients and may explain in part their propensity to thromboembolism. There is continuing debate as to the role of anticoagulation or antiplatelet therapy, or both, in the long-term management of these patients,[47] but most receive some form of therapy.

Protein-losing enteropathy, defined as severe loss of serum protein into the intestine, occurs in 4% to 13% of patients after a Fontan procedure. Patients present with generalized edema, ascites, pleural effusion, and/or chronic diarrhea. Protein-losing enteropathy is thought to result principally from chronically elevated systemic venous pressure causing intestinal lymphangiectasia with consequent loss of albumin, protein, lymphocytes, and immunoglobulin into the gastrointestinal tract. The diagnosis is confirmed by finding low serum albumin and protein levels; a low plasma $alpha_1$-antitrypsin level and lymphocyte counts; and, most important, a high $alpha_1$-antitrypsin stool clearance. It carries a dismal prognosis, with a 5-year survival rate of 46% to 59%.

Right pulmonary vein obstruction or compression can occur from the enlarged right atrium or the atrial baffle bulging into the left atrium and can lead to a vicious spiral of increased pulmonary artery pressure with further dilation of the right atrium.

Stenosis or partial obstruction of the Fontan connection leads to exercise intolerance, atrial tachyarrhythmias, and right-sided heart failure. Sudden total obstruction (usually thrombotic) can present as sudden death (Video 75.57).

Progressive deterioration of systemic ventricular function, with or without progressive AV valve regurgitation, is common. Patients with morphologic systemic right ventricles may fare less well than those with morphologic left ventricles.

Mildly raised hepatic transaminase levels from hepatic congestion are frequent but seldom clinically important.[48] *Cirrhosis* due to chronic venous hypertension is increasingly recognized, and monitoring for complications of cirrhosis should be initiated.

Worsening *cyanosis* may relate to worsening ventricular function, the development of venous collateral

channels draining to the left atrium, or the development of pulmonary arteriovenous malformations (especially if a classic Glenn procedure remains as part of the Fontan circulation). In Fontan patients with cirrhosis, the hepatopulmonary syndrome may occur.

Laboratory Investigations

ECG.

Sinus rhythm, atrial flutter, junctional rhythm, or complete heart block may be present on the ECG. The QRS complex reflects the basic underlying cardiac anomaly.

Chest Radiography.

Mild bulging of the right lower heart border from a dilated right atrium is often seen in patients with an atriopulmonary connection.

Echocardiography.

The presence or absence of right atrial stasis, thrombus, patency of a fenestration, and Fontan circuit obstruction should be sought. Superior and inferior vena caval flow is usually phasic with respiration and of low velocity. Assessment of the pulmonary venous flow pattern is important in detecting pulmonary vein obstruction (right pulmonary vein > left pulmonary vein), sometimes caused by an enlarged right atrium. Concomitant assessment of systemic ventricular function and AV valve regurgitation can be readily accomplished. TEE may be required if there is inadequate visualization of the Fontan anastomosis or to exclude thrombus in the right atrium.

MRI.

The objectives of MRI in Fontan patients include assessment of the pathways from the systemic veins to the pulmonary arteries for obstruction and thrombus; detection of Fontan baffle fenestration or leaks; evaluation of the pulmonary veins for compression; assessment of the systemic ventricular volume, mass, and ejection fraction; imaging of the systemic ventricular outflow tract for obstruction; quantitative assessment of the AV and semilunar valve(s) for regurgitation; and quantitative assessment of the aorta for obstruction or an aneurysm and for aortopulmonary, systemic venous, or systemic-to-pulmonary venous collateral vessels.

Diagnostic Catheterization.

Complete heart catheterization is advised if surgical reintervention is planned or if adequate assessment of the hemodynamics is not obtained by noninvasive means.

Management Options and Outcomes

Patient selection for the Fontan procedure is of utmost importance and has a major impact on the clinical outcome. The long-term survival rate in “ideal” candidates is 81% at 10 years, compared with 60% to 71% in “all comers.” Death occurs mostly from congestive heart failure and atrial arrhythmias. The Fontan procedure remains a palliative, not curative, procedure. A more radical approach to the failing atriopulmonary Fontan circulation, including surgical revision of the circuit to an extracardiac conduit, in combination with a Cox maze procedure and, frequently, simultaneous epicardial pacemaker insertion has recently been shown to provide good early and midterm palliation. Ultimately, cardiac transplantation may be required by some of these patients, although their outcomes are less favorable.

Atrial tachyarrhythmias are quite difficult to manage and should quickly raise the thought of long-term anticoagulation. When *atrial flutter* or *fibrillation* is present, an underlying hemodynamic cause should

always be sought, and, in particular, evidence for obstruction of the Fontan circuit needs to be excluded. Prompt attempts should be made to restore the sinus rhythm. Antiarrhythmic medications, alone or combined with an epicardial antitachycardia pacing device, and radiofrequency catheter ablation techniques have had limited success. Surgical conversion from an atriopulmonary Fontan connection to a total cavopulmonary connection with concomitant atrial cryoablation therapy at the time of surgery has been reported with good medium-term success. Epicardial pacemaker insertion for sinus node dysfunction and/or complete heart block may be necessary. Epicardial AV sequential pacing should be employed whenever possible.

The use of *prophylactic long-term anticoagulation* is a contentious issue.[47] Experts recommend that patients with a history of documented arrhythmias, fenestration in the Fontan connection, or spontaneous contrast (smoke) in the right atrium on echocardiography be anticoagulated. For established thrombus, thrombolytic therapy versus surgical removal of the clot and conversion of the Fontan circuit have been described, both with high mortality rates (Video 75.58).

Treatment modalities for *protein-losing enteropathy* include a low-fat, high-protein, medium-chain–triglyceride diet to reduce intestinal lymphatic production; albumin infusions to increase intravascular osmotic pressure; and/or the introduction of diuretics, afterload-reducing agents, and positive inotropic agents to lower the central venous pressure. Most often these therapies are ineffective and should not be continued, if indeed tried at all. Catheter-based interventions such as balloon dilation of pathway obstruction or creation of an atrial fenestration, as well as surgical interventions from conversion or takedown of the Fontan circuit to cardiac transplantation, have also been advocated. Other reportedly effective treatment modalities include subcutaneous heparin, octreotide treatment, and steroid therapy. All therapies have a similar failure rate of about 50%.

When *right pulmonary vein compression or obstruction* is hemodynamically significant, Fontan conversion to a total cavopulmonary connection or extracardiac conduit may be recommended.

Surgical revision of an obstructed Fontan connection (i.e., obstructed right atrium–to–pulmonary artery or superior and inferior venae cava–to–pulmonary artery connection) is recommended, usually with an extracardiac Fontan procedure. Alternatively, balloon angioplasty with or without stenting may be used when appropriate and feasible (Videos 75.59 and 75.60).

For *ventricular failure and valvular regurgitation*, ACE inhibitors are of unproven benefit[42] and do not appear to enhance exercise capacity. Patients with systemic AV valve regurgitation may require AV valve repair or replacement. Cardiac transplantation should also be considered.

If *cyanosis* occurs in the setting of a fenestrated Fontan procedure, surgical or, preferably, transcatheter closure of the fenestration can be attempted. Pulmonary arteriovenous fistulas from a classic A Glenn shunt may be improved by surgical conversion to a bidirectional Glenn connection.

Reproductive Issues

The rather fixed cardiac output and low flow state of a Fontan circuit makes pregnancy rather problematic in these patients. Cardiovascular complications, including arrhythmias and venous congestion, as well as obstetric complications, such as preterm labor and intrauterine growth retardation, mandate that a multidisciplinary high-risk pregnancy team follow these patients once they are pregnant.

Follow-Up

Close and expert follow-up is recommended, with particular attention to ventricular function and systemic AV valve regurgitation. The development of atrial tachyarrhythmia should instigate a search for possible

obstruction at the Fontan anastomosis, right pulmonary vein obstruction, or thrombus within the right atrium. Some institutions have developed multidisciplinary Fontan clinics to advance both clinical research and patient care.

Total Anomalous Pulmonary Venous Connection

A total anomalous pulmonary venous connection is a situation in which all pulmonary veins fail to connect directly to the morphologic left atrium. As a result, all of the systemic and pulmonary venous return usually drains to the right atrium, albeit using varied routes.

Morphology

The anatomic varieties of a total anomalous pulmonary venous connection may be subdivided, depending on the path of the abnormal drainage (**Fig. 75.31**). The anomalous connection is most often supradiaphragmatic, connecting via a vertical vein to the left brachiocephalic vein, directly to the right atrium, to the coronary sinus, or directly to the superior vena cava. In about 10% to 15% the pathway is below the diaphragm. The anomalous trunk then connects to the portal vein or one of its tributaries; to the ductus venosus; or, rarely, to the hepatic or other abdominal veins.

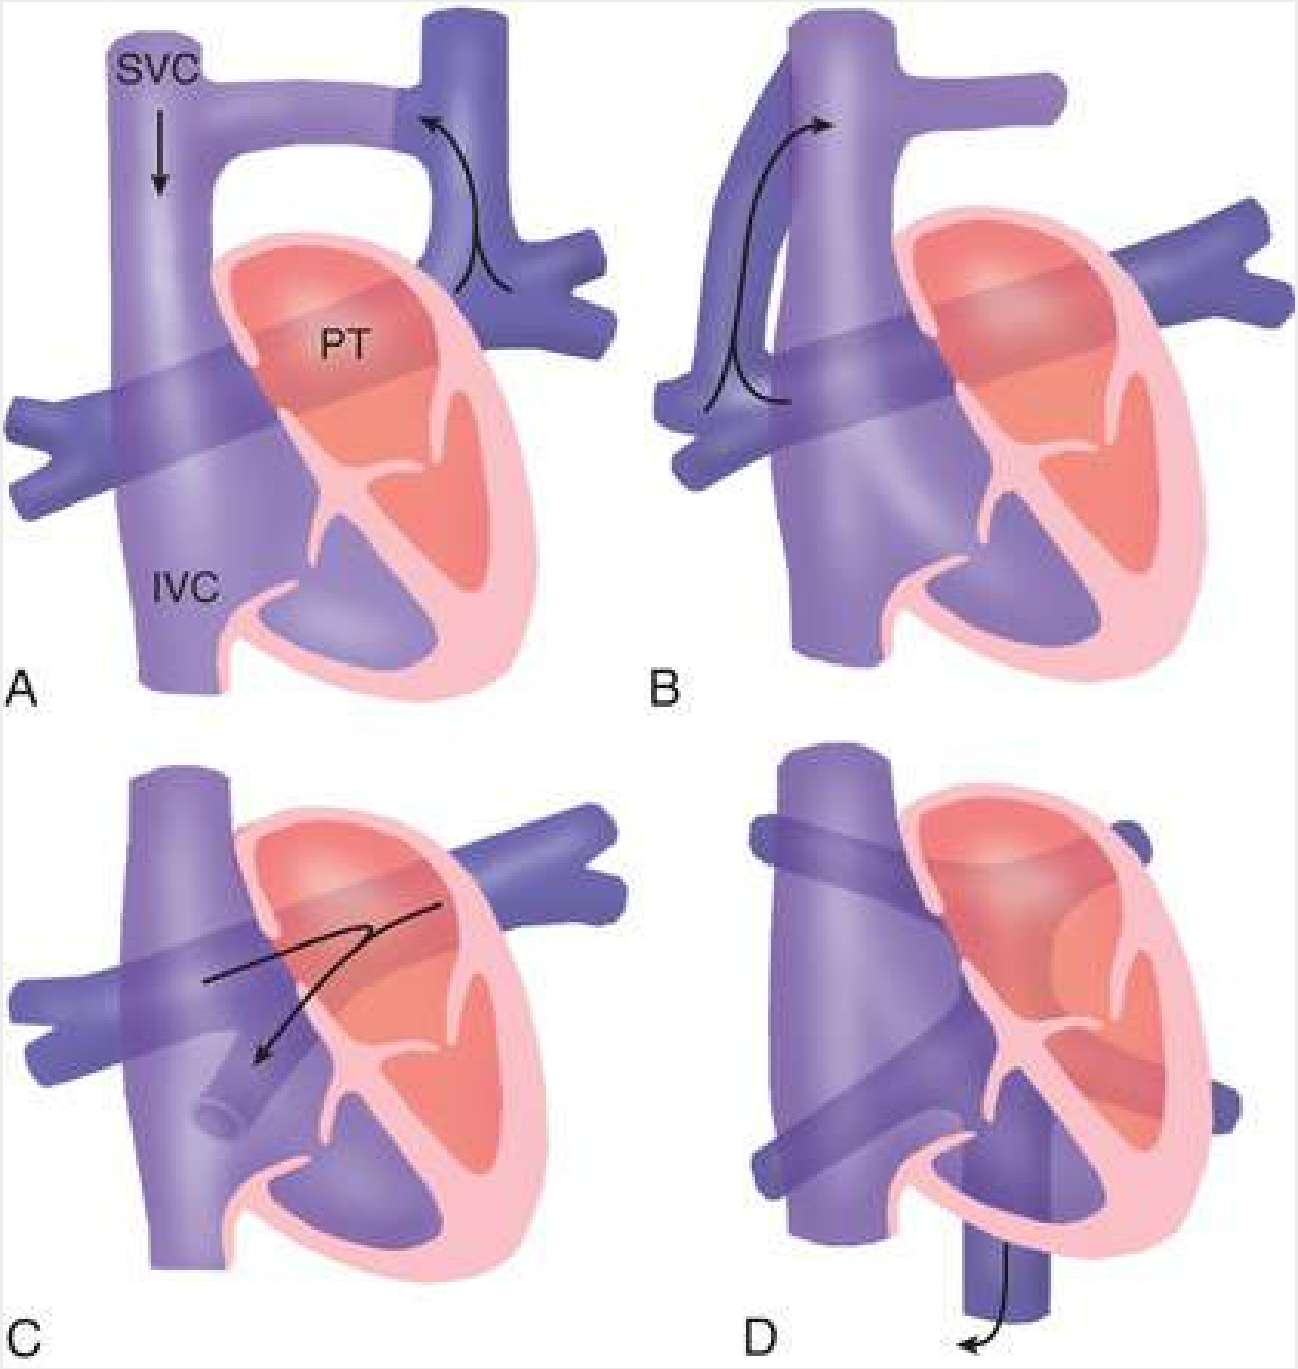

FIGURE 75.31 Anatomic types of total anomalous pulmonary venous return: supracardiac, in which the pulmonary veins drain either via the vertical vein to the anomalous vein **(A)** or directly to the superior vena cava (SVC), with the orifice close to the orifice of the azygos vein **(B)**. **C,** Drainage into the right atrium via the coronary sinus. **D,** Infracardiac drainage via a vertical vein into the portal vein or the inferior vena cava (IVC). *PT*, pulmonary trunk. (**A** to **D,** From Stark J, de Leval M: Surgery for congenital heart defects, 2nd ed. Philadelphia, WB Saunders, 1994, p 330.)

Natural History

Most patients with total anomalous pulmonary venous connection have symptoms during the first year of life and undergo repair, such that this entity is rarely seen in late adolescent and adult patients. If it is the patient has classic signs of an ASD, but with associated cyanosis, because of right-to-left shunting at the atrial level. Older unrepaired patients are also at risk for having elevated pulmonary artery pressure.

Laboratory Investigations

ECG.

This usually shows right axis deviation and right atrial and right ventricular hypertrophy.

Chest Radiography.

In the unrepaired older patient with an abnormal connection to the coronary sinus or a left vertical vein, there is cardiomegaly with increased pulmonary blood flow. The right atrium and ventricle are dilated and hypertrophied, and the pulmonary artery segment is enlarged. The so-called figure-of-8, or snowman, heart is due to enlargement of the heart and the presence of a dilated right superior vena cava, innominate vein, and left vertical vein.

Echocardiography (Fig. 75.32).

This usually shows marked enlargement of the right ventricle and a small left atrium. Demonstrating the entire pathway of pulmonary venous drainage is usually possible in younger patients, and in that group cardiac catheterization (which may be hazardous) is almost never performed. An echo-free space representing the pulmonary venous confluence can usually be seen behind the left atrium. The drainage of all four pulmonary veins and their connections must be identified.

FIGURE 75.32 **A,** Subcostal view demonstrating total anomalous pulmonary drainage to the coronary sinus. Note the dilated coronary sinus in both images. The echocardiogram also demonstrates an associated confluence that connects to the coronary sinus. **B,** Suprasternal view demonstrating total anomalous pulmonary venous drainage to a left vertical vein. Note the direction of flow in the vertical vein that differentiates it from a left superior vena cava. **C,** Total anomalous pulmonary venous drainage below the diaphragm. The specimen shows the pulmonary veins as they enter the confluence, whereas the echocardiogram demonstrates the descending veins as they enter the liver. Note that the direction of flow is away from the heart. *AO*, aorta; *CS*, coronary sinus; *DA*, descending aorta; *DV*, descending vein; *LVV*, left vertical vein; *PA*, pulmonary artery; *PV*, pulmonary vein; *PVC*, pulmonary venous confluence; *RA*, right atrium.

MRI.

MRI may be helpful in older patients to delineate the site of connections of total anomalous pulmonary venous return when there are multiple mixed sites, and to detect stenosis in postoperative patients.

Intervention and Outcomes

Surgery is usually performed during childhood, most often at presentation. Historically, surgical repair of restenosis was disappointing. However, the sutureless technique, whereby the pulmonary veins are opened widely into the retroatrial space, has markedly improved the results of such surgery. Adult patients have almost always had surgical repair in childhood. As a rule, they function normally and are not too prone to arrhythmias or other problems. They are seen as low-risk adults.

Follow-Up

Early follow-up should be frequent and aimed at early detection of stenosis of the pulmonary veins or the surgical anastomosis. If not present within the first year, stenosis is rare.

Transposition Complexes

The key anatomic feature that characterizes this group of diagnoses is discordant ventriculoarterial connections. This is most commonly seen in the context of AV concordance, also known as *complete transposition* or *dextro-transposition* (*D-TGA)*. The second condition discussed in this section is the combination of ventriculoarterial discordance with AV discordance, commonly referred to as *congenitally corrected TGA* or *levo-transposition* (*L-TGA)*. More complicated arrangements are not considered here.

Complete Transposition of the Great Arteries

Definition and Natural History.

This is a common and potentially lethal form of heart disease in newborns and infants. The malformation consists of the origin of the aorta from the morphologic right ventricle and that of the pulmonary artery from the morphologic left ventricle. Consequently, the pulmonary and systemic circulations are connected in parallel rather than the normal in-series connection. In one circuit, systemic venous blood passes to the right atrium, the right ventricle, and then to the aorta, and back to the systemic veins. In the other, pulmonary venous blood passes through the left atrium and ventricle to the pulmonary artery and then back to the pulmonary veins. This situation is incompatible with life unless mixing of the two circuits occurs.

Approximately two thirds of patients have no major associated abnormalities (*"simple"*

transposition), and one third have associated abnormalities (*"complex" transposition*). The most common associated abnormalities are VSD and pulmonary or subpulmonary stenosis. It is increasingly being diagnosed in utero. Without treatment, about 30% of these infants die within the first week of life, and 90% die within the first year.

Morphology

Some communication between the two circulations must exist after birth to sustain life. Two thirds have a PDA, and about one third have an associated VSD. If there is no significant intracardiac shunt or communication, a balloon atrial septostomy is performed.

Pathophysiology

The degree of tissue hypoxia, the nature of the associated cardiovascular anomalies, and the anatomic and functional status of the pulmonary vascular bed determine the clinical course. Infants with D-TGA are particularly susceptible to the early development of pulmonary vascular obstructive disease even in the absence of a PDA and even with an intact ventricular septum.

Clinical Features.

All adult patients with TGA will have had some type of surgical repair.

Surgical Management Option.

Although neonatal balloon atrial septostomy is often lifesaving, it is palliative and anticipates "corrective" surgery. Atrial redirection procedures were developed in the 1950s and 1960s but were replaced by the arterial switch operation, which became widely adopted in the 1980s.

Atrial Switch Procedure.

The most common surgical procedure in patients who are older adults is the atrial switch operation (**Fig. 75.33**). Patients will have had either a Mustard or a Senning procedure. Blood is redirected at the atrial level using a baffle made of Dacron or pericardium (Mustard operation) or atrial flaps (Senning operation), achieving physiologic correction. Systemic venous return is diverted through the mitral valve into the subpulmonary left ventricle, and the pulmonary venous return is rerouted through the tricuspid valve into the subaortic right ventricle. By virtue of this repair, the morphologic right ventricle supports the systemic circulation.

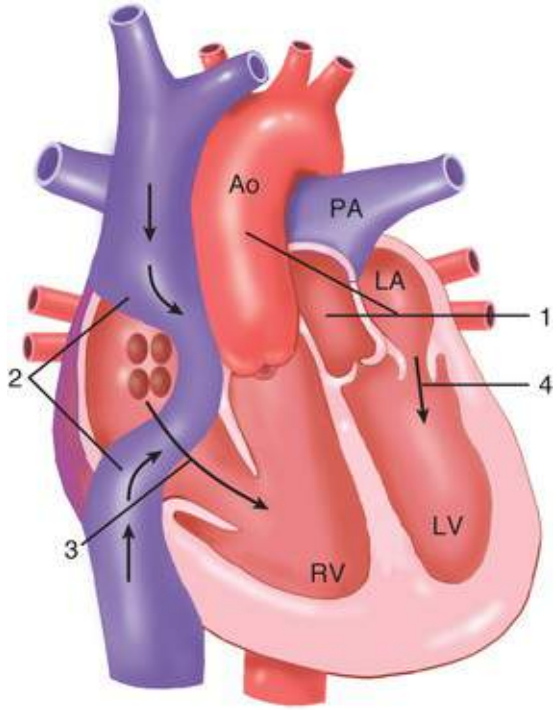

FIGURE 75.33 Diagrammatic representation of atrial switch surgery (Mustard/Senning procedure). Superior vena cava (SVC) and inferior vena cava (IVC) blood is redirected into the morphologic left ventricle (LV), which pumps blood into the pulmonary artery (PA), whereas the pulmonary venous blood flow is rerouted to the morphologic right ventricle (RV), which empties into the aorta (Ao). *LA*, left atrium; *RA*, right atrium; *1*, transposition of the great arteries; *2*, atrial baffles; *3*, pulmonary vein blood flow through tricuspid valve to RV; *4*, IVC and SVC blood flow through mitral valve to LV. (From Mullins CE, Mayer DC: Congenital heart disease: a diagrammatic atlas. New York, Wiley-Liss, 1988.)

Palliative Atrial Switch Procedure *(Videos 75.61 to 75.65)*.

Uncommonly, in patients with a large VSD and established pulmonary vascular disease, a palliative atrial switch operation is done to improve systemic oxygenation. The VSD is left open or enlarged at the time of atrial baffle surgery. These patients resemble patients with Eisenmenger VSDs and should be managed as such.

Arterial Switch Operation.

In the arterial switch operation the arterial trunks are transected and reanastomosed to the contralateral root (**FIg. 75.34**). If present, a VSD is closed. The coronary arteries must be transposed to the neoaorta. This is the most challenging part of the procedure and accounts for most of the deaths. Nonetheless, this rate has fallen to less than 2% in most large centers. The major advantages of the arterial switch procedure, when compared with the atrial switch procedure, are restoration of the left ventricle as the systemic pump and the potential for long-term maintenance of sinus rhythm.

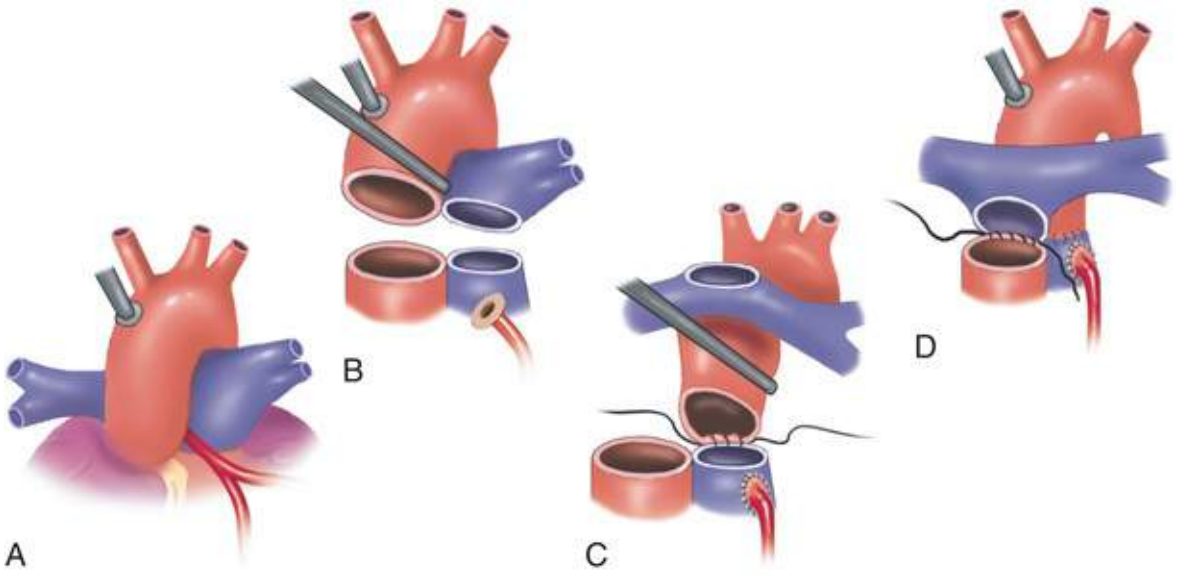

FIGURE 75.34 Complete transposition of the great arteries, corrected by a modified arterial switch operation **(A).** The aorta and pulmonary artery are transected, and the orifices of the coronary arteries are excised with a rim of adjacent aortic wall **(B).** The aorta is brought under the bifurcation of the pulmonary artery, and the pulmonary artery and the aorta are anastomosed without necessitating graft interposition. The coronary arteries are transferred to the pulmonary artery **(C).** The mobilized pulmonary artery is directly anastomosed to the proximal aortic stump **(D).** (**A** to **D,** From Stark J, de Leval M: Surgery for congenital heart defects. New York, Grune & Stratton, 1983, p 379.)

Follow-up studies after the arterial switch operation have demonstrated good left ventricular function and normal exercise capacity. Potential sequelae of the operation include coronary occlusion; supravalvular pulmonary stenosis (which may be treated by either reoperation or balloon angioplasty); supravalvular aortic stenosis; ascending aortic aneurysms; and neoaortic regurgitation, usually mild. Long-term patency and growth of the coronary arteries appear satisfactory, but the very long term results are yet to be defined.

Rastelli Procedure *(Videos 75.66 to 75.68)*.

Infants with TGA plus a VSD and left ventricular outflow tract obstruction may require an early systemic-to-pulmonary artery shunt when a pronounced diminution in pulmonary blood flow exists. A later corrective procedure for these patients bypasses the left ventricular outflow obstruction with an extracardiac conduit between the right ventricle and the distal end of a divided pulmonary artery and uses an intracardiac ventricular baffle to tunnel the left ventricle to the aorta (Rastelli procedure). The late outcomes for the Rastelli procedure are particularly poor (see below), and in recent years another procedure, the Nikaidoh operation, has replaced the Rastelli procedure for some forms of TGA with VSD and pulmonary stenosis. In this operation the pulmonary outflow tract is resected and the aorta translocated posteriorly to sit more “anatomically” above the left ventricle, making subsequent left ventricular outflow tract obstruction less likely. Just as in the Rastelli procedure, the right ventricular outflow tract is reconstructed with a conduit in this operation, but because of the backward translocation of the aorta, there is more space behind the sternum, and the hope is that conduit longevity will be enhanced. The REV (reparation a l'etage ventriculaire) procedure has also been introduced as an alternative treatment for D-TGA with VSD and pulmonary stenosis where the pulmonary outflow tract is repaired without the need for a conduit.

Management Outcomes

Atrial Switch Procedure.

After atrial baffle surgery, most patients who reach adulthood are in NYHA classes I and II, but in many, abnormalities of ventricular filling due to the abnormal atrial pathways may be of more direct importance to the functional capacity than right ventricular performance issues. Some present have symptoms of congestive heart failure (2% to 15%). Echocardiographic evidence of moderate or severe systemic right ventricular dysfunction is present in up to 40% of patients. More than mild systemic tricuspid regurgitation is present in 10% to 40%, both reflecting and exacerbating right ventricular dysfunction. Palpitations and near-syncope or syncope from rhythm disturbances are fairly common. Atrial flutter occurs in 20% of patients by 20 years of age, and sinus node dysfunction is seen in half of the patients by that time. These rhythm disturbances are a consequence of direct and indirect atrial and sinus node damage at the time of atrial baffle surgery.

A shortened life expectancy is the rule, with the survival rate being 70% to 80% at 20 to 30 years' follow-up. Patients with “complex” TGA in general fare worse than those with “simple” TGA. Sudden cardiac death may occur in these patients and may be related to systemic right ventricular dysfunction, the presence of atrial flutter, and/or pulmonary hypertension. The role of primary ICDs in these patients remains fully to be defined.[49] Significant pulmonary vascular disease can develop over time and is related to an older age at the time of the atrial switch operation, particularly in patients with a substantial VSD, as well as in those with long-standing left-to-right shunts through a baffle leak. Superior vena cava or inferior vena cava baffle obstruction often goes undetected because collateral drainage through the azygos vein prevents systemic venous congestion. Pulmonary venous baffle obstruction causes elevated pulmonary artery pressure, and patients can present with dyspnea and pulmonary venous congestive features.[50]

Physical examination of a patient whose condition is otherwise uncomplicated reveals a right ventricular parasternal lift, a normal S_1, a loud single S_2 (P_2 is often not heard because of its posterior location), a pansystolic murmur from tricuspid regurgitation (if present, best heard at the left lower sternal border, but not increasing with inspiration), and a right-sided S_3 when severe systemic ventricular dysfunction is present.

Arterial Switch Procedure.

Data on long-term complications in adults who have undergone the arterial switch procedure are emerging.[51-54] The development of progressive neoaortic valve regurgitation from neoaortic root dilation is the most common long-term sequela. It is time dependent and as such requires periodic follow-up. Supraneopulmonary artery stenosis is a frequent finding[55] but rarely has clinical consequences. The development of ostial coronary artery disease has also been described in some patients. Arrhythmia promises to be less of a problem in this group of patients. Cardiac examination in uncomplicated patients is normal.

Rastelli Procedure.

Compared with either the arterial switch or Mustard procedure, the survival rate after the Rastelli procedure is poor, and the need for repeat intervention is high. Progressive right ventricular–to–pulmonary artery conduit obstruction can cause exercise intolerance or right ventricular angina. Left ventricular tunnel obstruction is frequent, and can present as exertional dyspnea or syncope. Conduit replacement or transcatheter stent or stent-valve implantation is inevitably required in surviving patients.[56] Physical examination in uncomplicated patients reveals, in contrast to those after the atrial

switch procedure, no right ventricular lift, a systolic ejection murmur from the conduit, and two components to the S_2. Long-term comparative outcome studies on the Nikaidoh and REV procedures are lacking.[56]

Laboratory Investigations

ECG.

Sinus bradycardia or junctional rhythm (without a right atrial overload pattern) with evidence of marked right ventricular hypertrophy is characteristically present in patients after the atrial switch procedure. The ECG is typically normal in patients after the arterial switch procedure. The ECG typically shows right bundle branch block after a Rastelli procedure.

Chest Radiography.

On the posteroanterior film, a narrow vascular pedicle with an oblong cardiac silhouette ("egg on side") is typically seen in patients after the atrial switch procedure. On the lateral view, the anterior aorta may be seen to fill the retrosternal space. For the arterial switch, normal mediastinal borders are present. After the Rastelli procedure, the chest radiograph may be normal unless the conduit becomes calcified.

Echocardiography (Videos 75.69 to 75.71).

After the atrial switch procedure, parallel great arteries are the hallmark of TGA (**Fig. 75.35**). They are best visualized from a parasternal long axis view (running side by side) or from a parasternal short axis view (seen en face, with the aorta anterior and rightward). Qualitative assessment of systemic right ventricular function, the degree of systemic tricuspid regurgitation, and the presence or absence of subpulmonary left ventricular obstruction (dynamic or fixed) is important. Assessment of baffle leak or obstruction (**Fig. 75.36**) is best done using color and Doppler flow imaging. Normal baffle flow should be phasic in nature and vary with respiration, with a peak velocity of less than 1 m/sec. After the arterial switch procedure, neoaortic valve regurgitation, supraneopulmonary valve stenosis, and a segmental wall motion abnormality from ischemia due to coronary ostial stenosis should be sought. In patients who have undergone the Rastelli operation, left ventricular–to–aorta tunnel obstruction, as well as right ventricular–to–pulmonary artery conduit degeneration (stenosis or regurgitation), must be assessed.

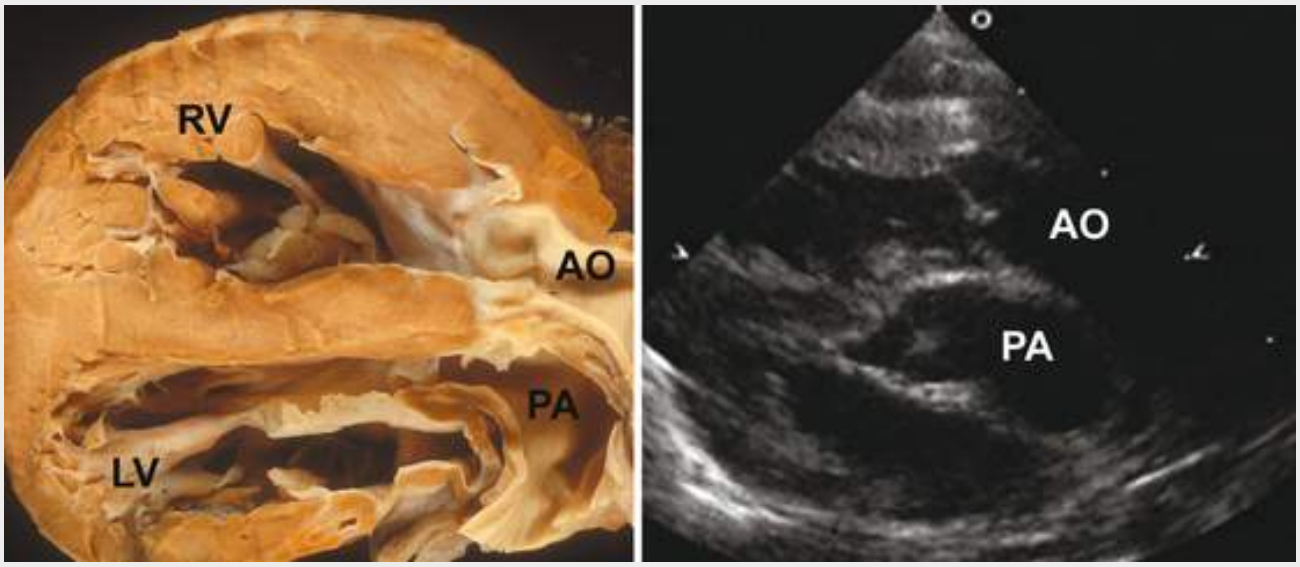

FIGURE 75.35 Parasternal long axis view in transposition of the great arteries. Note the parallel nature of the aorta and pulmonary artery. *AO*, aorta; *LV*, left ventricle; *PA*, pulmonary artery; *RV*, right ventricle.

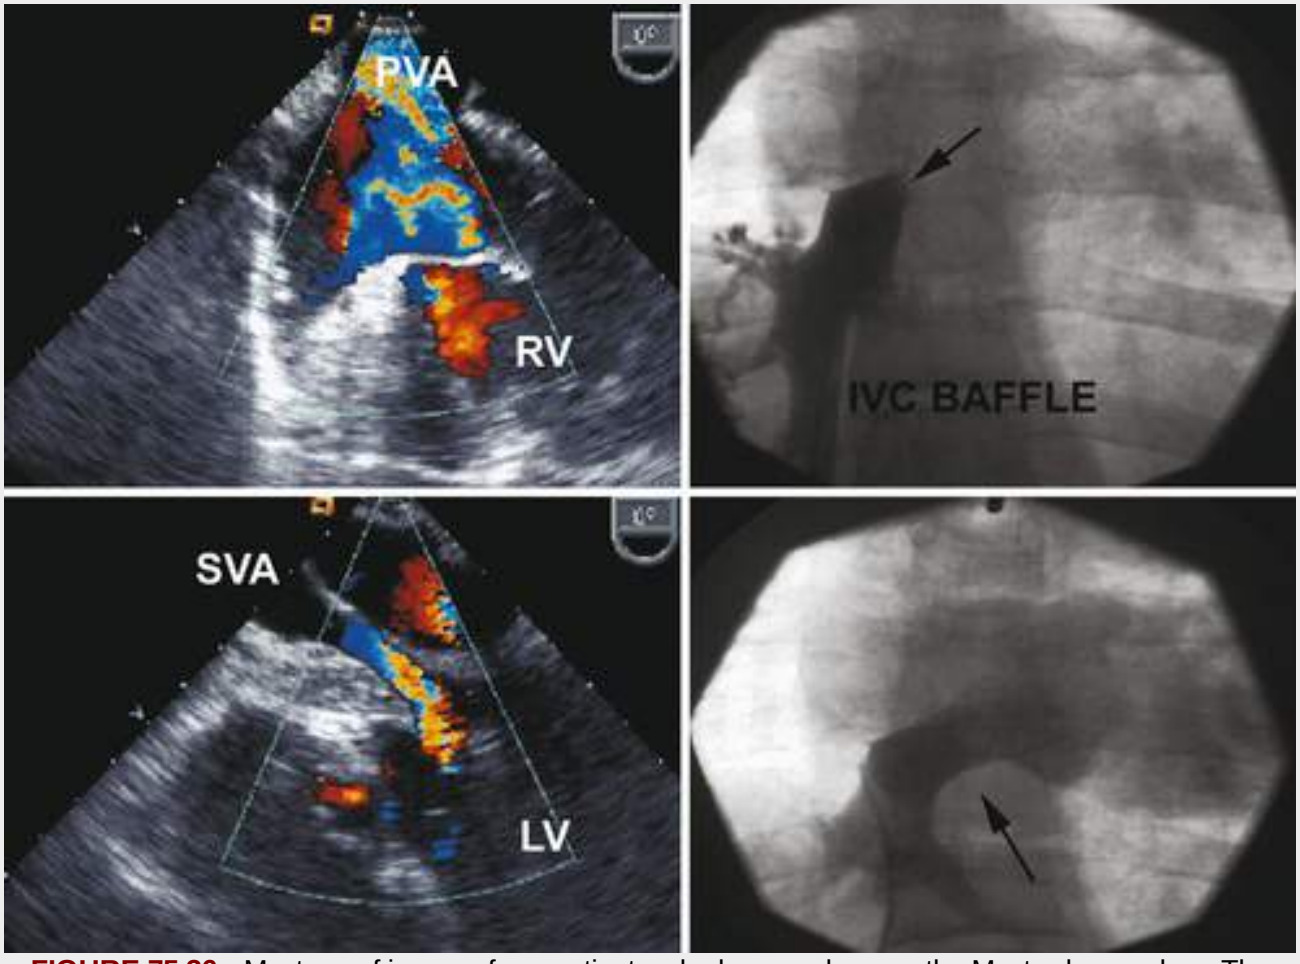

FIGURE 75.36 Montage of images from patients who have undergone the Mustard procedure. The angiogram on the right upper panel shows complete obstruction of the inferior limb of the systemic venous baffle, whereas the lower right panel shows the same case after stenting. The upper left image is a TEE showing the pulmonary venous baffle with some mild flow acceleration in its midpoint. The lower left panel shows the systemic venous baffle at its left ventricular end. *IVC*, inferior vena cava; *LV*, left ventricle; *PVA*, pulmonary venous atrium; *RV*, right ventricle; *SVA*, systemic venous atrium.

MRI.

The major role of MRI in patients who have undergone the atrial switch procedure is to evaluate the

baffles and systemic right ventricular volume and ejection fraction. As a rule, MRI better reports the right ventricular size and function than does echocardiography. For patients who are claustrophobic or have a pacemaker, a CT angiogram may serve as a substitute.

Cardiac Catheterization.

Diagnostic cardiac catheterization may be required for assessing the presence or severity of systemic or pulmonary baffle obstruction, baffle leak, and pulmonary hypertension; coronary ostial stenosis; or tunnel or conduit obstruction when not adequately assessed by noninvasive means.

Indications for Reintervention.

After the *atrial switch procedure,* severe symptomatic right ventricular dysfunction may warrant surgical treatment in the form of a *two-stage arterial switch procedure* or cardiac transplantation. Tricuspid valve repair or replacement is rarely performed for severe systemic (tricuspid) AV valve regurgitation, but may be appropriate if it is due to a flail leaflet or cusp perforation, providing right ventricular function is adequate. A baffle leak resulting in a significant left-to-right shunt (>1.5/1), any right-to-left shunt, or attributable symptoms requires surgical or transcatheter closure. Superior vena cava or inferior vena cava pathway obstruction may require intervention (Video 75.72). Superior vena cava stenosis is usually benign, whereas inferior vena cava stenosis may have greater hemodynamic consequences, depending on the adequacy of alternative routes of venous return, usually via the azygos vein to the superior vena cava. Balloon dilation of superior vena cava or inferior vena cava stenosis is an option in expert hands. Stenting usually relieves the stenosis completely.

Pathway obstruction after the Senning operation is usually more amenable to balloon dilation and stenting (see Video 75.72). Pulmonary venous obstruction, although usually seen early and reoperated on in childhood, may present in adulthood. Symptomatic bradycardia warrants permanent pacemaker implantation, whereas tachyarrhythmias may require catheter ablation, an antitachycardia pacemaker device, or medical therapy. After an atrial switch procedure, transvenous pacing leads must traverse the upper limb of the baffle to enter the morphologic left ventricle. Active fixation is required because of the tightly packed fine apical trabeculations in the morphologic left ventricle. Transvenous pacing should be avoided in patients with residual intracardiac communications because paradoxical emboli can occur.

After an *arterial switch procedure,* significant right ventricular outflow tract obstruction at any level (gradient > 50 mm Hg or right-to-left ventricular pressure ratio > 0.6) may require surgical or catheter augmentation of the right ventricular outflow tract. Myocardial ischemia from coronary artery obstruction may require coronary artery bypass grafting, preferably with arterial conduits. Significant neoaortic valve regurgitation may warrant aortic valve replacement.

In patients who have had the *Rastelli procedure,* significant right ventricle–to–pulmonary artery conduit stenosis (> 50 mm Hg withdrawal gradient or mean echocardiography gradient) or significant regurgitation necessitates intervention. Subaortic obstruction across the left ventricle–to–aorta tunnel necessitates left ventricle–to–aorta baffle reconstruction. A significant residual VSD (shunt > 1.5/1) may require surgical closure.

Reintervention Options.

In patients who have undergone an atrial switch procedure, *medical therapy* is uncertain. The role of afterload reduction with ACE inhibitors, angiotensin receptor blockers,[57] or a beta blockade to preserve the systemic right ventricular function is debatable, and short- to medium-term studies have shown no benefit.[57]

Following an atrial switch procedure, patients with severe, symptomatic, systemic (right) ventricular dysfunction with or without severe systemic (tricuspid) AV valve regurgitation may require consideration of a *heart transplantation*.

Reproductive Issues.

Severe systemic ventricular dysfunction or intractable arrhythmias may be a contraindication to pregnancy, and baffle obstruction should, ideally, be relieved before pregnancy. Women who have undergone an atrial switch procedure usually tolerate pregnancy well, but about 15% will develop worsening right ventricular function or systemic tricuspid regurgitation during the pregnancy.[58] In half of these cases, the problem does not improve after delivery. Pregnancy following an arterial switch procedure is better tolerated, assuming there are no significant hemodynamic lesions prior to pregnancy.[59]

Follow-Up.

Regular follow-up by physicians with special expertise in CHD is recommended.

Atrial Switch Procedure.

Serial follow-up surveillance of systemic right ventricular function is warranted. Asymptomatic baffle obstructions and leaks should be sought with echocardiography or MRI. Regular Holter monitoring is recommended to diagnose unacceptable bradyarrhythmias or tachyarrhythmias.

Arterial Switch and Rastelli Procedures.

Regular follow-up with echocardiography is recommended. As patients advance in age, the MRI is more suited to assess the branch pulmonary arteries after the LeCompte maneuver (bringing the pulmonary artery anterior to the aorta), because this is a challenging area to see with echocardiography (**eFig. 75.5**).

EFIGURE 75.5 This MRI demonstrates the use of branch pulmonary artery imaging after the LeCompte maneuver as part of the arterial switch procedure. *AO*, aorta; *LPA*, left pulmonary artery; *MPA*, main pulmonary artery; *RPA*, right pulmonary artery.

For the Rastelli procedure, regular follow-up with echocardiography is recommended. Particular attention should be paid to the right ventricular–to–pulmonary artery conduit, as well as the left ventricular–to–aorta tunnel.

Congenitally Corrected Transposition of the Great Arteries

The term *congenitally corrected transposition of the great arteries (cc-TGA)* describes hearts in which there are discordant AV connections in combination with discordant ventriculoarterial connections.

Morphology

cc-TGA is a rare condition, accounting for less than 1% of all CHDs (**Fig. 75.37**). When there is the usual atrial arrangement, systemic venous blood passes from the right atrium through a mitral valve to a left ventricle and then to the posteriorly located pulmonary artery. Pulmonary venous blood passes from the left atrium through a tricuspid valve to a left-sided right ventricle and then to an anterior, left-sided aorta. The circulation is thus "physiologically" corrected, but the morphologic right ventricle supports the systemic circulation. Associated anomalies occur in up to 95% of patients and consist of a VSD (75%), pulmonary or subpulmonary stenosis (75%), and left-sided (tricuspid and often "Ebstein-like") valve anomalies (75%).

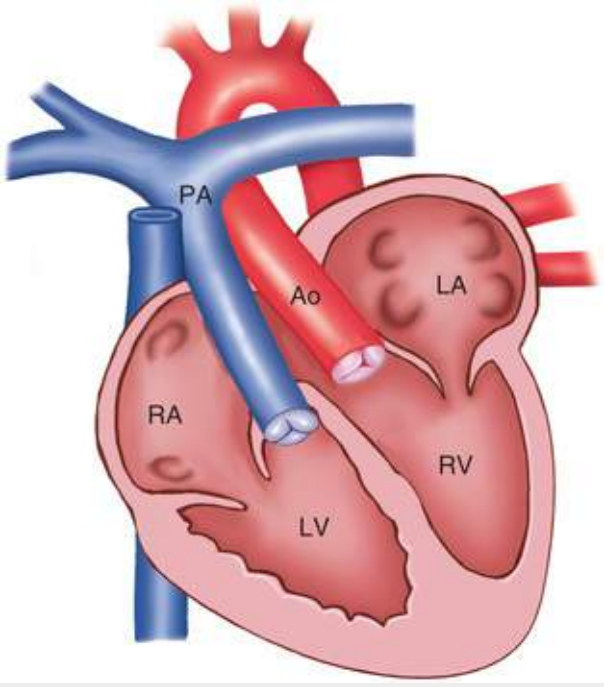

FIGURE 75.37 Diagrammatic representation of congenitally corrected transposition of the great arteries. *Ao*, aorta; *LA*, left atrium; *LV*, left ventricle; *PA*, pulmonary artery; *RA*, right atrium; *RV*, right ventricle. (From Mullins CE, Mayer DC: Congenital heart disease: a diagrammatic atlas. New York, Wiley-Liss, 1988.)

Because of the inherently abnormal conduction system, 5% of patients with cc-TGA are born with a congenital complete heart block and approximately 25% will develop it later in life, spontaneously or as a consequence of surgery.

Pathophysiology

Patients with no associated abnormalities ("isolated" cc-TGA) can exceptionally survive until the

seventh or eighth decade. Progressive systemic (tricuspid) AV valve regurgitation and systemic (right) ventricular dysfunction tend to occur from the fourth decade onward, whereas atrial tachyarrhythmias are more common from the fifth decade onward. In addition to those born with congenital complete heart block, acquired complete AV block continues to develop at a rate of 2% per year, concentrated mainly at the time of cardiac surgery. Patients with associated anomalies (VSD, pulmonary stenosis, left-sided [tricuspid] valve anomaly) often have undergone surgical palliation (systemic-to-pulmonary artery shunt for cyanosis) or repair of the associated anomalies (see Surgical Procedures), but a significant number of patients are naturally balanced by a combination of their VSD and subpulmonary left ventricular outflow tract obstruction. Although cyanosed, they often remain well, with no intervention for many years.

Clinical Features

Unoperated Patients.

Patients with no associated defects can be asymptomatic until late adulthood. Dyspnea, exercise intolerance from developing congestive heart failure, and palpitations from supraventricular arrhythmias most often arise in the fifth decade. Patients with well-balanced VSD and pulmonary stenosis can present with paradoxical emboli or cyanosis, especially if pulmonary stenosis is severe. Physical examination of a patient whose condition is otherwise uncomplicated reveals a somewhat more medial apex due to the side-by-side orientation of the two ventricles. The A_2 is often palpable in the second left intercostal space due to the anterior location of the aorta. A single S_2 (A_2) is heard, with P_2 often being silent due to its posterior location. The murmur of an associated VSD or of left AV valve regurgitation may be heard. The murmur of pulmonary stenosis radiates upward and to the right, given the rightward direction of the main pulmonary artery. If there is complete heart block, cannon "A waves" with an S_1 of variable intensity are present.

VSD Patch and Left Ventricular–to–Pulmonary Artery Conduit Repair.

Most patients are in functional class I at 5 to 10 years after surgery despite the common development of systemic tricuspid regurgitation and systemic right ventricular dysfunction after surgical repair. Dyspnea, exercise intolerance, and palpitations from supraventricular arrhythmia often occur in the fourth decade. Physical examination reflects the basic cardiac malformation with or without residual coexisting anomalies.

Laboratory Investigations

ECG.

An abnormal direction of initial (septal) depolarization from right to left causes reversal of the precordial Q wave pattern (Q waves are often present in the right precordial leads and absent in the left). First-degree AV block occurs in about 50%, and complete AV block occurs in up to 25% of patients. Atrial arrhythmias may be seen.

Chest Radiography.

Chest radiography characteristically reveals absence of the normal pulmonary artery segment in favor of a smooth convexity of the left supracardiac border produced by the left-sided ascending aorta. The main pulmonary trunk is medially displaced and absent from the cardiac silhouette; the right pulmonary hilum

is often prominent and elevated compared with the left, producing a right-sided "waterfall" appearance.

Echocardiography (Fig. 75.38, and Videos 75.73 to 75.75)

Echocardiography permits the identification of the basic malformation, as well as any associated anomalies. The right-sided morphologic left ventricle is characterized by its smooth endocardial surface and is guarded by a bileaflet AV (mitral) valve with no direct septal attachment. The morphologic right ventricle is recognized by its apical trabeculation and moderator band and is guarded by a trileaflet, apically displaced AV valve (tricuspid valve) with direct attachment to the septum. The AV valves therefore show reversed offsetting, a strong clue to the diagnosis. Ebstein-like malformation of the left (tricuspid) AV valve is defined by excessive (> 8 mm/m^2 body surface area) apical displacement of the left (tricuspid) AV valve, with or without dysplasia (Videos 75.76 to 75.80).

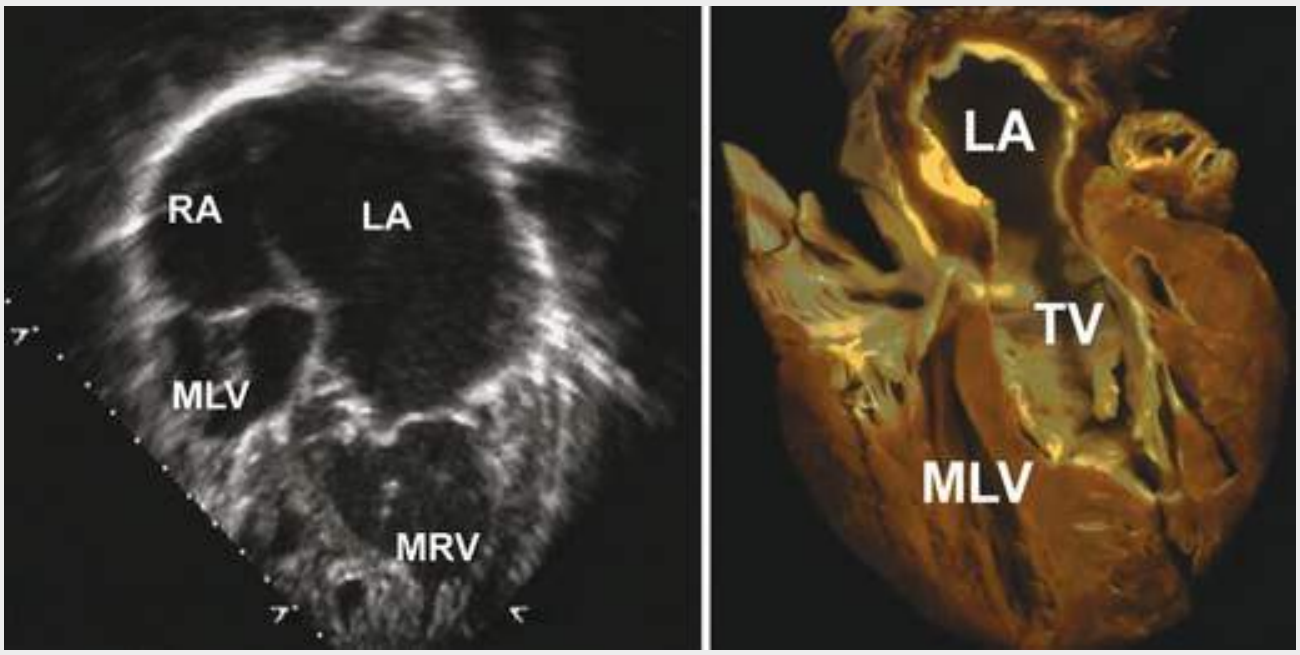

FIGURE 75.38 Four-chamber view in cc-TGA with dysplasia and displacement of the morphologic left-sided tricuspid valve. *LA*, left atrium; *MLV*, morphologic left ventricle; *MRV*, morphologic right ventricle; *RA*, right atrium; *TV*, tricuspid valve.

MRI.

The major role of MRI in cc-TGA patients is to evaluate the systemic right ventricular volume and ejection fraction. It does so better than echocardiography can at present. For claustrophobic patients or those with a pacemaker, a high-quality radionuclide angiogram or a CT angiogram with volume estimates may serve as a substitute. MRI can evaluate other issues, as well, including conduit function and AV valve regurgitation.

Cardiac Catheterization.

This is rarely required for diagnosis but may be indicated before surgical repair to demonstrate the coronary artery anatomy, as well as ventricular end-diastolic and pulmonary artery pressures.

Indications for Intervention and Reintervention.

If moderate or severe systemic (tricuspid, left) AV valve regurgitation develops, valve replacement should be considered. Left AV valve replacement should be performed before systemic right ventricular function deteriorates, namely, at an ejection fraction of 45% or more. When tricuspid regurgitation is

associated with poor systemic (right) ventricular function, the double-switch procedure should perhaps be considered. Patients with end-stage symptomatic heart failure should be referred for cardiac transplantation. The presence of a hemodynamically significant VSD (Qp/Qs > 1.5/1) or residual VSD with significant native or postsurgical (conduit) pulmonary outflow tract stenosis (echocardiography mean or catheter gradient > 50 mm Hg) may require surgical correction, although the latter is sometimes best left alone because it can maintain a neutral septal position and minimize systemic tricuspid regurgitation. Left AV valve replacement at the time of VSD and pulmonary stenosis surgery should be considered if concomitant left AV valve regurgitation is present. Pacemaker implantation is usual when complete AV block is present. The optimal pacing modality is DDD. Active fixation electrodes are required because of the lack of apical trabeculation in the morphologic left ventricle. Transvenous pacing should be avoided if there are intracardiac shunts because paradoxical emboli may occur. Epicardial leads are preferred under these circumstances.

Interventional Options.

Medical therapy with ACE inhibitors, angiotensin receptor blockers, or beta-blocker therapy for patients with systemic ventricular dysfunction may be intuitive, but no benefit has yet been demonstrated[60]

Conduit replacement or repair is inevitably required in survivors of this type of initial surgery. Fortunately, it is now possible in some patients and in many countries to repair a failing conduit with a percutaneously delivered stented valve.

Valve repair is usually unsuccessful because of the abnormal, often Ebstein-like, anatomy of the valve. Consequently, for significant regurgitation, *tricuspid valve replacement* is preferable to repair, but it carries a higher risk if there is significant right ventricular dysfunction (ejection fraction < 45%).

The *double-switch procedure* has been successfully performed in children[61,62] and carefully selected adults. It should be considered for patients with severe tricuspid regurgitation and systemic ventricular dysfunction. Its purpose is to relocate the left ventricle into the systemic circulation and the right ventricle into the pulmonary circulation, achieving physiologic correction. An atrial switch procedure (Mustard or Senning), together with either an arterial switch procedure (when pulmonary stenosis is not present) or a Rastelli-type repair, the so-called *Ilbawi procedure* (left ventricle tunneled to aorta and right ventricle–to–pulmonary artery valved conduit when VSD and pulmonary stenosis are present), can be performed after adequate left ventricular retraining, leaving the regurgitant tricuspid valve and failing right ventricle on the pulmonary side.

Patients with deteriorating systemic (right) ventricular function should be treated aggressively with medical therapy but may need to be considered for *cardiac transplantation*.

Interventional Outcomes.

After conduit repair and VSD patching, the median survival time of patients reaching adulthood is 40 years. The usual causes of death are sudden death (presumed arrhythmic) or, more commonly, progressive systemic right ventricular dysfunction with systemic (tricuspid) AV valve regurgitation. The major predictor of a poor outcome is the presence of left AV (tricuspid) valve regurgitation. Reoperation is common (15% to 25%), with left AV valve replacement usually being the primary reason. Data in adults using the double-switch procedure are lacking, and this procedure should be considered experimental in this patient population.

Reproductive Issues.

Severe systemic ventricular dysfunction or intractable arrhythmias may be a contraindication to

pregnancy, and severe systemic tricuspid regurgitation or conduit problems should, ideally, be relieved before pregnancy. In women with a good functional capacity, pregnancy is usually well tolerated, but worsening tricuspid regurgitation or ventricular dysfunction or arrhythmias may occur and be poorly tolerated.

Follow-Up.

All patients should have at least annual follow-up visits with a cardiologist who has expertise in the care of patients with congenital cardiac defects. Regular assessment of systemic (tricuspid) AV valve regurgitation by serial echocardiographic studies and systemic ventricular function by MRI or radionuclide angiography should be done. Holter recording can be useful if paroxysmal atrial arrhythmias or transient complete AV block is suspected.

Double-Outlet Right Ventricle

The term *double-outlet right ventricle* describes hearts in which more than 50% of each semilunar valve arises from the morphologic right ventricle. It may coexist with any form of atrial arrangement or AV connection and is independent of the infundibular (conal) anatomy.

Morphology (Fig. 75.39)

Few morphologic descriptors have invoked more discussion and controversy than double-outlet right ventricle. The definition given above is flawed but pragmatic. To some extent this anatomic definition is less important than the understanding of the relationship between the great vessels and the VSD and the anatomy of the outlets to the great vessels, both of which are crucial determinants of clinical presentation and management.

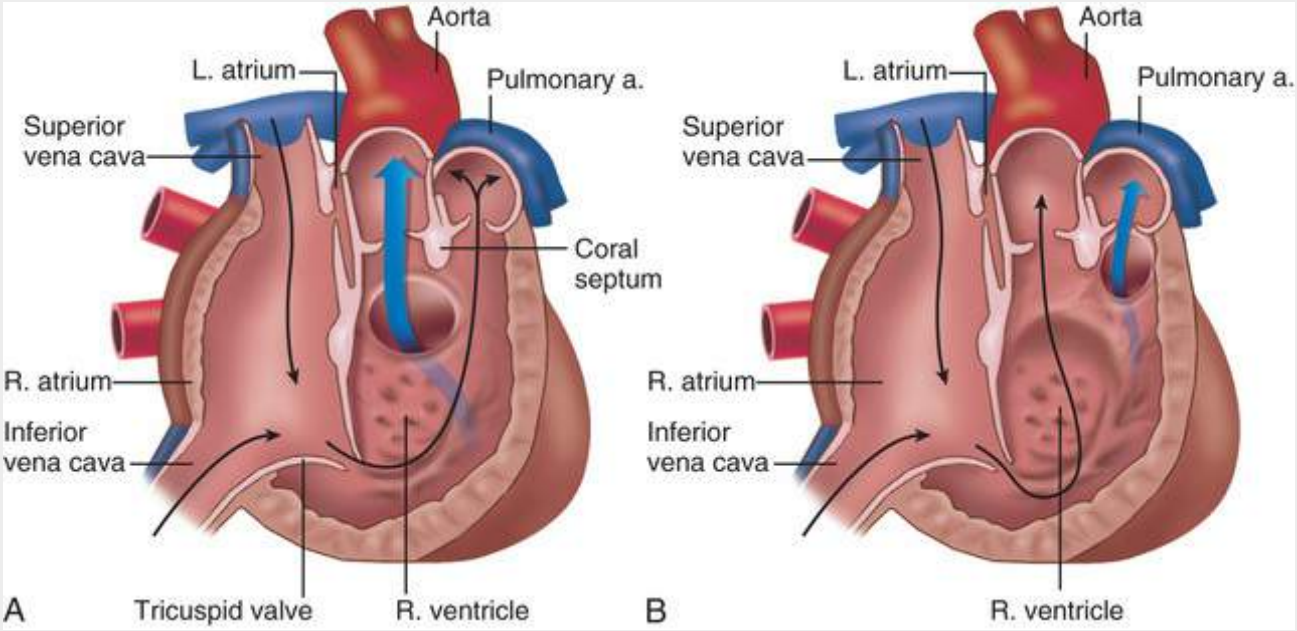

FIGURE 75.39 Double-outlet right ventricle with side-by-side relationship of great arteries is illustrated in both panels. **A,** A subaortic VSD below the crista supraventricularis favors delivery of left ventricular blood to the aorta. **B,** Subpulmonary location of the VSD above the crista favors streaming to the pulmonary trunk. (**A** and **B,** From Castañeda A, Jonas RA, Mayer JE, et al: Cardiac surgery of the neonate and infant. Philadelphia, WB Saunders, 1994, p 446.)

Clinical Features

Three main categories of double-outlet right ventricle exist: (1) double-outlet right ventricle with a subaortic VSD, (2) double-outlet right ventricle with a subpulmonary VSD, and (3) double-outlet right ventricle with a noncommitted VSD.

When present, the anatomy of the infundibular septum further modifies the hemodynamics. Taking double-outlet right ventricle with a *subaortic VSD* as an example, where the aorta and its semilunar valve are closest to, or overriding, the trabecular septum, anterior deviation of the outlet septum causes subpulmonary stenosis, and the clinical scenario and management algorithm are similar or identical to that of tetralogy of Fallot. Conversely, if the outlet septum is deviated posteriorly, there will be subaortic stenosis, often with a coexisting abnormality of the aortic arch. The presentation and management of this variation are therefore entirely different. If there is no deviation of the outlet septum, and no outlet obstruction, the clinical scenario will be that of a simple VSD. Double-outlet right ventricle with a *subpulmonary VSD* (Taussig-Bing anomaly) can be considered along with TGA. This is because the usual position of the pulmonary artery (posterior to and leftward of the aorta) means that the streaming of deoxygenated and oxygenated blood is similar to that of transposition, even though most of the pulmonary valve is connected to the right ventricle. Anterior deviation of the outlet septum causes subaortic stenosis and aortic anomalies, and posterior deviation causes subpulmonary stenosis and limits pulmonary blood flow. It is also important to recognize double-outlet right ventricle with a *noncommitted VSD*. This defines hearts in which the VSD is remote from the outlets, making surgical management particularly difficult.

Associated Lesions

More than half of patients with double-outlet right ventricles have associated anomalies of the AV valves. Mitral valve stenosis or atresia, associated with a hypoplastic left ventricle, is common. Ebstein anomaly of the tricuspid valve, complete AV septal defect, and overriding or straddling of either AV valve may

occur.

Laboratory Investigations

Because of the diversity of the underlying anatomies, discussion of the ECG and radiographic features is not included here.

Echocardiography.

This is the mainstay of diagnosis. The commitment of the semilunar valves to the ventricles is ascertained. When present, deviation of the outlet septum beneath a semilunar valve likely has implications for downstream development of the great vessels. For example, when there is subaortic stenosis, the echocardiographic examination is incomplete until abnormalities of the aortic arch have been excluded. Preoperative evaluation must also take into account potential AV valve anomalies and straddling, in particular.

Indications for Intervention

The goals of operative treatment are to establish continuity between the left ventricle and aorta, create adequate right ventricle–to–pulmonary continuity, and repair associated lesions. Palliative surgery is reserved for those in whom biventricular repair is not possible and in those with markedly reduced pulmonary blood flow. In the latter, an aortopulmonary shunt may be placed to temporize before complete correction. For most of the remainder, complete repair is now performed as a primary procedure. In double-outlet right ventricle with a subaortic VSD, repair is accomplished by creating an intraventricular baffle that conducts left ventricular blood to the aorta. If there is coexisting subpulmonary stenosis, the repair is similar to that of tetralogy of Fallot. When the VSD is subpulmonary, but without subpulmonary stenosis, repair is accomplished by closure of the VSD and the arterial switch procedure. Subpulmonary stenosis is frequently present in a double-outlet right ventricle with a subpulmonary VSD. In these cases the aorta is connected to the left ventricle using an intraventricular baffle, and a right ventricle–to–pulmonary artery conduit is placed to complete the repair (Rastelli procedure). Classic surgical approaches cannot be used when the VSD is remote and uncommitted to either semilunar orifice. Occasionally the VSD can be baffled toward the aorta, but when this is not possible, the right ventricle may be used as the systemic ventricle. This requires a Mustard or Senning atrial redirection procedure, closure of the VSD, and placement of a conduit between the left ventricle and the pulmonary trunk.

Interventional Options and Outcomes

The late follow-up of the surgical procedures described earlier (e.g., tetralogy of Fallot repair, arterial switch procedure, Rastelli procedure) tends to be less satisfactory when there is a double-outlet right ventricle than when more classic indications were present. The development of subaortic stenosis is more likely because of the abnormal geometry of the left ventricular outflow tract that often results after correction. Similarly, right ventricle–to–pulmonary artery conduit obstruction is more likely because of the spatial difficulties imposed on placement of the conduit, with respect to the position on the right ventricle and the sternum. Because of these considerations, the options for catheter interventions are often fairly limited. However, recurrent arch obstruction and distal pulmonary artery obstruction are amenable to balloon dilation with or without stenting.

Follow-Up

All of these patients require at least annual review by a congenital cardiologist.

Left Ventricular Outflow Tract Lesions (Fig. 75.40)

Coarctation of the Aorta

Aortic arch obstruction may be divided into (1) localized coarctation in close proximity to a PDA or ligamentum, (2) tubular hypoplasia of some part of the aortic arch, and (3) aortic arch interruption.

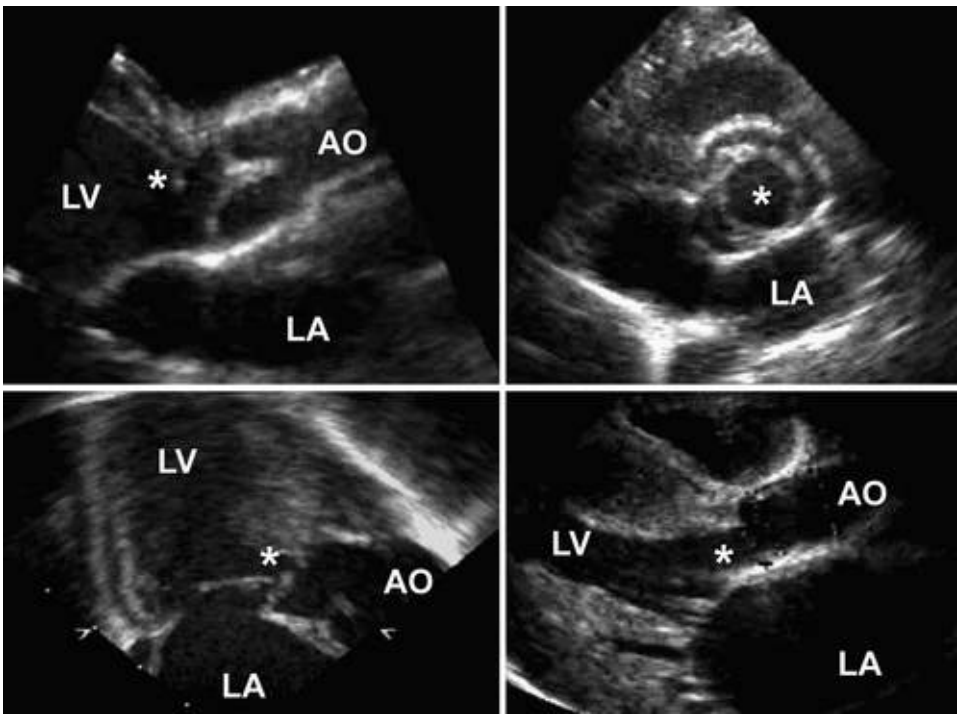

FIGURE 75.40 Montage demonstrating the different types of left ventricular outflow tract obstruction (*asterisks*). The upper left image shows isolated fibromuscular obstruction; the upper right, stenosis due to a bicuspid aortic valve; the lower left, obstruction because of chordal apparatus from the anterior mitral leaflet; and the lower right, obstruction due to tunnel narrowing at the valvular, annular, and subvalvular level. *AO*, aorta; *LA*, left atrium; *LV*, left ventricle.

Localized Aortic Coarctation

Morphology

This lesion consists of a localized shelf in the posterolateral aortic wall opposite the ductus arteriosus. Associated isthmic hypoplasia, which is common in the infant presentation, has important long-term implications, because persistent arch hypoplasia, even in the absence of a discrete obstruction, is one of the mechanisms of ongoing hypertension.

Clinical Features.

Coarctation occurs two to five times more commonly in males, and there is a high degree of association with gonadal dysgenesis (Turner syndrome) and bicuspid aortic valve (≥50%). Other common associated

anomalies include VSD and mitral stenosis or regurgitation. Additional lesions have an impact on the outcome.

Beyond the neonatal period the majority of patients with isolated coarctation are asymptomatic, with the findings of reduced femoral pulses and/or hypertension. Heart failure is uncommon because the left ventricle has a chance to become hypertrophied, thus maintaining a normal wall stress. Complaints of headache, cold extremities, and leg fatigue with exercise may be noted in the older patient.

Presentation in adulthood again may be entirely asymptomatic, and picked up during routine health checks, usually because of the discovery of a murmur or unexplained hypertension. Indeed, coarctation of the aorta should be excluded in all new cases of hypertension, by clinical examination of the pulses and upper and lower limb blood pressure measurements (see below). In some adolescents and adults, presentation is with symptoms of functional decline, in the setting of concentric left ventricular hypertrophy, or in more extreme cases, left ventricular dilation and dysfunction. Associated abnormalities include intracranial aneurysms (most commonly of the circle of Willis) in 2% to 10% and acquired intercostal artery aneurysms. One definition of *significant aortic coarctation* requires a gradient of more than 20 mm Hg across the coarctation site at angiography with or without proximal systemic hypertension. A second definition of significant aortic coarctation requires the presence of proximal hypertension in the company of echocardiographic or angiographic evidence of aortic coarctation. If there is an extensive collateral circulation there may be a minimal pressure gradient or no gradient at all and acquired aortic atresia.

Death in patients who do not undergo repair is most often due to heart failure (usually in patients > 30 years of age), coronary artery disease, aortic rupture or dissection, concomitant aortic valve disease, infective endarteritis or endocarditis, or cerebral hemorrhage. Of Turner syndrome patients, 35% have aortic coarctation.

Leg claudication (pain) is rare unless there is concomitant abdominal aortic coarctation. A thorough clinical examination reveals upper limb systemic hypertension, as well as a differential systolic blood pressure of at least 10 mm Hg (brachial artery > popliteal artery pressure). Radial-femoral pulse delay is evident unless significant aortic regurgitation coexists. Auscultation may reveal an interscapular systolic murmur emanating from the coarctation site and a widespread crescendo-decrescendo systolic murmur throughout the chest wall from the intercostal collateral arteries. Funduscopic examination can reveal “corkscrew” tortuosity of retinal arterioles.

Laboratory Investigations

ECG.

This reveals left ventricular hypertrophy of various degrees, depending on the height of arterial pressure above the obstruction and the patient's age. Coexisting right ventricular hypertrophy usually implies a complicated lesion.

Chest Radiography.

The characteristic posteroanterior film feature is the so-called figure-3 configuration of the proximal descending thoracic aorta due to both prestenotic and poststenotic dilation. Rib notching (unilateral or bilateral, second to ninth ribs) is present in 50% of cases. Rib notching is unilateral if the right or left subclavian arteries arise from the aorta distal to the coarctation. Rib notching is noted as an erosion of the undersurface of a posterior rib, usually at its outer third, with a sclerotic margin.

Echocardiography.

This demonstrates a posterior shelf, a well-expanded isthmus and transverse aortic arch (in most cases), and a high-velocity jet with diastolic persistence through the coarctation site. Interestingly, a slow upstroke is observed on the abdominal aortic velocity profile compared with that seen in the ascending aorta.

MRI.

This provides detailed information in this age-group and may be performed before intervention,[63] particularly if balloon dilation is the treatment of choice. This is the best tool for postintervention imaging surveillance[64] and has become routine in many centers.

Angiocardiography.

This is reserved for delineating the coarctation at the time of balloon dilation or stent placement (Videos 75.81 to 75.83).Primary management in those cases with a well-expanded isthmus and transverse aortic arch invariably involves balloon dilation and/or stent placement (Video 75.84).

Interventional Outcomes.

Surgical repair of simple coarctation usually relieves the obstruction, with a minimal mortality rate (1%). Paraplegia due to spinal cord ischemia is uncommon (0.4% or perhaps less)[65] and may occur in patients who do not have a well-developed collateral circulation. The prevalence of recoarctation reported in the literature varies widely, from 7% to 60%, but is probably about 10% depending on the definition used, the length of follow-up, and the age at surgery. The appropriateness of the surgical repair for a given anatomy is probably the main factor dictating the chance of recoarctation rather than the type of surgical repair itself. True aneurysm formation at the site of coarctation repair is also a well-recognized entity, with a reported incidence of between 2% and 27%. Aneurysms are particularly common after Dacron patch aortoplasty and usually occur in the native aorta opposite the patch. Late dissection at the repair site is rare, but false aneurysms, usually at the suture line, can occur. Long-term follow-up after surgical correction of coarctation of the aorta still reveals an increased incidence of premature cardiovascular disease and death, mainly resulting from prevalent associated risk factors (i.e., male sex, hypertension, and hyperlipidemia).[66] The respective roles of stent therapy and surgery over balloon dilation of aortic coarctation are becoming better defined.[67]

The outcomes of *transcatheter techniques* may involve complications. After balloon dilation (**Fig. 75.41**), aortic dissection, restenosis, and aneurysm formation at the site of coarctation all have been documented. These complications have been reduced with the now increasing if not exclusive use of primary stenting in the adults with native coarctation as well as recoarctation.[68] Medium-term outcomes of stent therapy in children have also been favorable.[69] The significance of aneurysm formation is often unknown, and longer-term data are necessary.

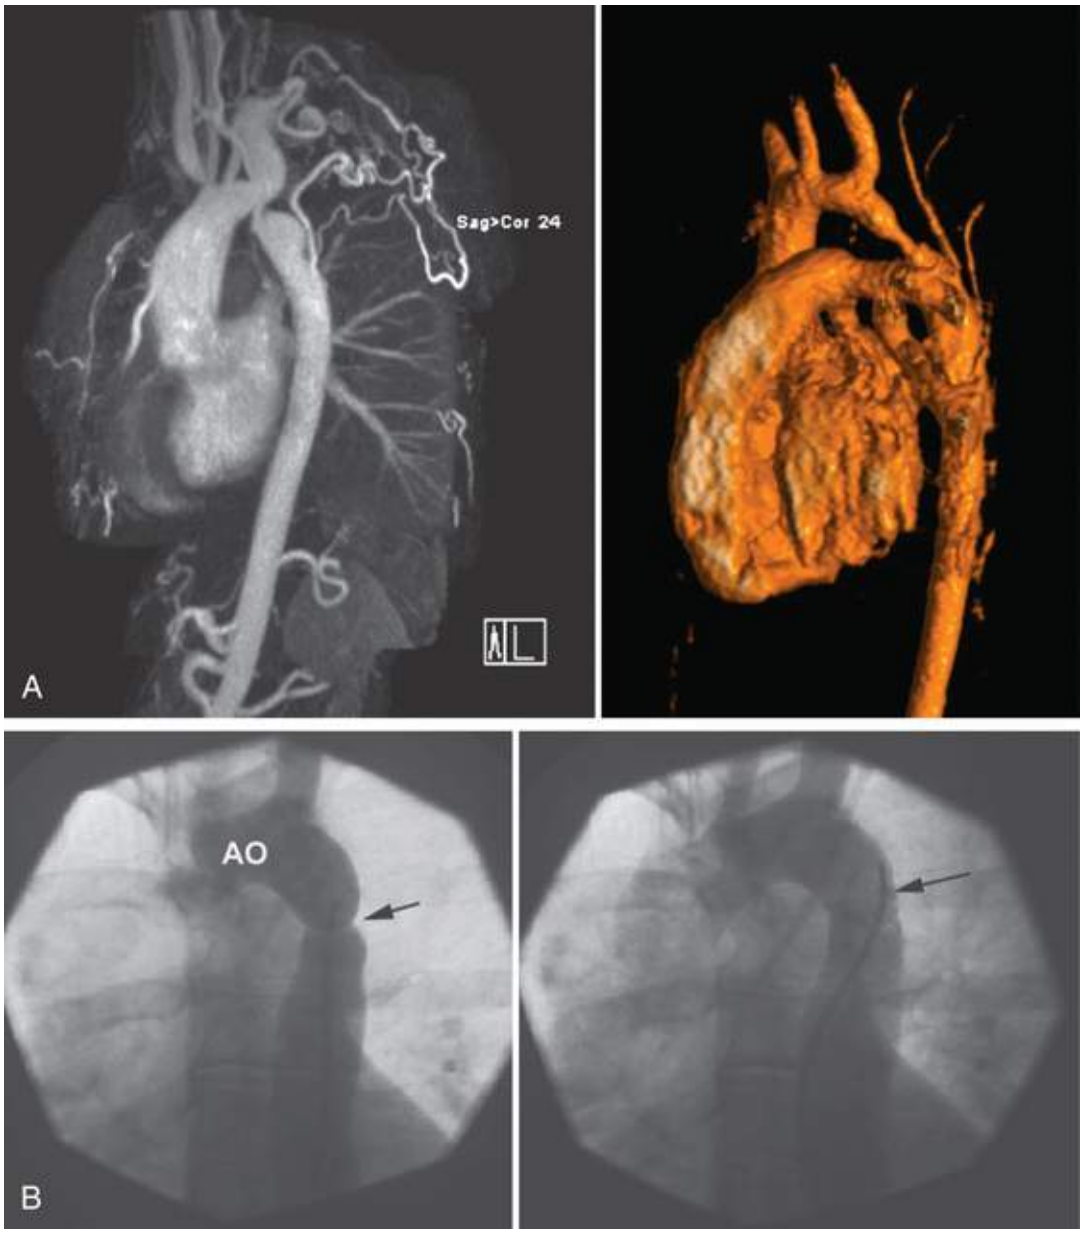

FIGURE 75.41 **A,** Montage of coarctation of the aorta. The left image shows the site of the posterior shelf. The right image is from an MRI and shows the posterior shelf and some associated transverse arch hypoplasia. **B,** Angiogram of coarctation of the aorta, before and after stenting. *AO*, aorta.

Prior hypertension resolves in up to 50% of patients but may recur later in life, especially if the intervention is performed at an older age.[70] In some of these patients, this may be essential hypertension, but a hemodynamic basis should be sought and blood pressure control should be attained. Systolic hypertension is also common with exercise and is not a surrogate marker for recoarctation of the aorta.[70,71] It may be related to residual arch hypoplasia or to increased renin and catecholamine activity from residual functional abnormalities of the precoarctation vessels. The criteria for and significance of exertional systolic hypertension are controversial, but its presence may predict the future development of chronic hypertension.[71] Late cerebrovascular events occur, notably in patients undergoing repair as adults and in those with residual hypertension. Endocarditis or endarteritis can occur at the coarctation site or on intracardiac lesions; if this occurs at the coarctation site, embolic manifestations are restricted to the legs.

Reproductive Issues.

Patients with repaired aortic coarctation usually tolerate pregnancy well unless they have hemodynamically significant residual lesions, such as severe recoarctation or aortic stenosis from a bicuspid aortic valve. A greater propensity to develop hypertension during pregnancy has, however, been

reported.[72]

Follow-Up.

All patients should have a follow-up examination every 1 to 3 years. Particular attention should be directed toward residual hypertension; heart failure; intracardiac disease such as an associated bicuspid aortic valve, which can become stenotic or regurgitant later in life; or an ascending aortopathy sometimes seen in the presence of a bicuspid aortic valve. Complications at the site of repair such as restenosis and aneurysm formation should also be sought using clinical examination, chest radiography, echocardiography, and periodic MRI or CT scanning.[64] Patients with a Dacron patch repair should probably undergo an MRI or a spiral CT examination every 3 to 5 years or so to detect subclinical aneurysm formation. Hemoptysis from a leaking or ruptured aneurysm is a serious complication requiring immediate investigation and surgery. New or unusual headaches raise the possibility of berry aneurysms. It has long been said that coarctation patients are prone to premature coronary artery disease, but a recent study did not confirm this suspicion.[66] There is substantial evidence of a generalized arteriopathy in coarctation patients that is not addressed by relief of the obstruction.[73]

Aortic Arch Interruption.

Aortic arch interruption is a rare lesion, but one where surgical success has resulted in an ever-growing number of older children, adolescents, and, now, adults with a history of surgical intervention. Of importance, it is associated with DiGeorge syndrome with microdeletion of chromosome 22. Interruptions distal to the left subclavian artery (type A) occur almost as frequently as interruptions distal to the left common carotid artery (type B). The right subclavian artery is of variable origin, frequently arising from the descending aortic segment distal to the interruption.

Virtually all patients have associated intracardiac anomalies, typically either a VSD (80% to 90% of cases) or an aorticopulmonary window (10% to 20%). As well, muscular left ventricular outflow tract obstruction is a common association in those with a VSD, this being due to posterior deviation of the outlet septum. Other complex intracardiac malformations such as TGA, aortopulmonary window, and truncus arteriosus are common.

Primary repair at the time of presentation is the main mode of treatment, and includes a direct connection between the interrupted segments in conjunction with closure of the VSD. Surgical resection of the posteriorly deviated outlet septum is dealt with at the time of primary repair in some centers, whereas others address it at a later date.

The medium- and long-term outcomes are reasonable,[74] but there may be a need for reintervention for left ventricular outflow tract obstruction and recurrent arch obstruction.

Congenital Aortic Valve Stenosis

Congenital aortic valve stenosis is a relatively common anomaly. It occurs much more frequently in males, with a gender ratio of 4 : 1. Associated cardiovascular anomalies have been noted in up to 20% of patients. PDA and coarctation of the aorta occur most frequently with aortic valve stenosis; all three of these lesions may coexist. As well, congenital abnormalities of the mitral valve and endocardial fibroelastosis are encountered more frequently in early presentations, but the clinical sequelae may persist into adulthood.

Morphology

The basic malformation consists of thickening of the valve tissue with various degrees of commissural fusion. Despite the fusion of the leaflets, in most cases there are still three sinuses. The valve is most commonly bicuspid; in most cases, this is the result of fusion of two leaflets, rather than an actual absence of one of the leaflets. The fusion usually involves the two coronary sinuses, or the right and noncoronary sinus. In some patients (usually newborns), the stenotic aortic valve is unicuspid and dome shaped, with no attachment or just one lateral attachment to the aorta at the level of the orifice. In infants and young children with severe aortic stenosis, the aortic valve annulus may be relatively underdeveloped. Aortopathy is a common association and results in associated dilation of the ascending aorta and sinuses.

Clinical Presentation

For the adult cardiologist, a history of aortic valve stenosis in a newborn is relevant because it shows that this population invariably does not have isolated aortic valve pathology. It is common for them to have associated endocardial fibroelastosis, as well as abnormalities of their mitral valves. These patients as newborns often present in heart failure, are usually managed with balloon dilation at the time of presentation, and invariably have ongoing aortic valve issues in the form of residual stenosis and/or regurgitation. Many require reintervention in their younger years in the form of further balloon dilation or aortic valve replacement. These patients are surviving into their adolescent and young adult years, and will have more ongoing issues than those who present at a later date. In older children, adolescents, and adults, the diagnosis is usually made following the detection of a murmur. Symptomatic functional decline, presyncope, and syncope are rarely the first presenting features. Natural history studies performed several years ago demonstrated that a more rapid progression of aortic valve stenosis is more likely to happen within the first 2 years of life, following which the rate of progressive obstruction is more uniform.

Clinical Findings

In general most patients beyond the neonatal period are asymptomatic, having normal peripheral pulses if the stenosis is less severe, and low-volume, slow-rising pulses when it progresses. Exercise fatigue and chest pain occur only when the stenosis is severe. With severe stenosis there is a systolic thrill in the same area that can also be felt in the suprasternal notch and carotid arteries. Beyond the newborn period there is usually an ejection click at the apex that precedes the murmur. The second heart sound is usually normal in children, with reversed splitting seen only in older patients with severe stenosis. A systolic ejection murmur is heard along the left sternal border, with radiation into the right infraclavicular area. Associated aortic regurgitation may be heard.

Laboratory Investigations

ECG.

Left ventricular hypertrophy with or without strain is the hallmark feature.

Chest Radiography.

The overall heart size is normal unless left ventricular remodeling is severe or there is important associated valvar regurgitation. Dilation of the ascending aorta can be seen in those with an associated aortopathy.

Echocardiography.

Two-dimensional echocardiography provides detailed information about the morphology of the valve, the left ventricular function, and the presence of associated left-sided lesions. Doppler echocardiography can be used to determine the severity of stenosis and the presence or absence of associated aortic regurgitation. Doppler imaging provides peak instantaneous gradients that are higher than the peak-to-peak gradients determined from cardiac catheterization. Mean gradients as derived from Doppler imaging and catheterization correlate closely and can be used in the decision process for patients outside the pediatric age-group. The aortic valve area (determined by the modified Gorlin equation, which provides accurate information on valve areas) is used in the adult population. Whatever the absolute number chosen to work with, the additional finding of left ventricular hypertrophy on ECG and echocardiography provides supportive data regarding the timing for intervention. The pediatric community generally agrees that a peak-to-peak gradient of 60 mm Hg or more probably warrants intervention even in the absence of symptoms, although clearly the thresholds for intervention are different in adults.[75]

Cardiac Catheterization.

Cardiac catheterization is now rarely used to establish the site and severity of obstruction to the left ventricular outflow. Instead, catheterization is undertaken when therapeutic interventional balloon aortic valvuloplasty is indicated in children and young adults, and to determine if associated coronary artery disease is present in the adult population.

Cardiac MRI.

In older patients, providing an adequate evaluation of the ascending aorta can be difficult with echocardiography; MRI overcomes this limitation, providing data that can help determine if aortic root surgery is necessary, either independently or at the time of aortic valve intervention.

Management Options

In this era, balloon dilation has almost completely replaced primary surgical valvotomy in the pediatric population (Video 75.85). Balloon valvuloplasty retains a place in the management of adolescents and young adults, but with increasing age it becomes a less attractive option; it is rarely successful in those with sclerotic and calcified valves, at any age. A 2012 paper compared the results of surgical versus balloon therapy for congenital aortic stenosis.[76] Another described the midterm outcomes of the Ross procedure in infants.[77]

Genetic Implications

The incidence of bicuspid aortic valve in first-degree relatives is such that when a new index case is diagnosed, family members should be screened. This usually involves the parents and any siblings. This is important because some individuals with a bicuspid aortic valve have neither significant stenosis nor regurgitation, but do have associated aortopathy with progressive dilation of the aortic root that may lead to aortic dissection.

Follow-Up

Follow-up studies indicate that aortic valvotomy in children and adolescents is a safe and effective means of palliative treatment with excellent relief of symptoms. Aortic regurgitation can occasionally be progressive and require valve replacement. Moreover, after commissurotomy, the valve leaflets remain

somewhat deformed, and further degenerative changes including calcification will likely lead to significant stenosis in later years. Thus prosthetic aortic valve replacement is required in approximately 35% of patients within 15 to 20 years of the original operation. For those children and adolescents requiring aortic valve replacement, the surgical options include replacement with a mechanical aortic valve, an aortic homograft, or a pulmonary autograft in the aortic position (Ross procedure). Accumulating evidence shows that the Ross procedure may ultimately be preferable to the aortic homograft. In the pulmonary autograft, the patient's pulmonary valve is removed and used to replace the diseased aortic valve, and the right ventricular outflow tract is reconstructed with a pulmonary valve homograft. This approach appears to confer a survival advantage in the younger age-group, where repeated mechanical valve replacement is associated with an increased mortality rate. Despite this advantage, caution is necessary when the approach is used for patients with a bicuspid aortic valve and aortic regurgitation. This is due to associated aortic root dilation, which is inherent to this lesion and may complicate the long-term durability of the Ross procedure. This surgical approach can be performed in patients of any age, from neonates to adults. Neither homografts nor autografts require anticoagulation.

Subaortic Stenosis

Morphology

Discrete Fibromuscular Lesions.

Such lesions consist of a ridge or fibrous ring encircling the left ventricular outflow tract at varying distances from the aortic valve. The subvalvular fibrous ridge may extend onto the aortic valve cusps and almost always makes contact with the ventricular aspect of the anterior mitral leaflet at its base. In cases with fibrous discontinuity between the mitral and aortic valves, it forms more of a tunnel obstruction.

Focal Muscular Lesions.

Rarely there is a focal muscular obstruction on the crest of the interventricular septum; in some patients, this is a variant of hypertrophic cardiomyopathy, and in others it is not. The way to differentiate the two is through genetic testing, or if that is negative, with echocardiographic follow-up.

Hypoplasia of the Left Ventricular Outflow Tract.

In some cases, valvular and subvalvular aortic stenoses coexist with hypoplasia of the aortic valve annulus and thickened valve leaflets, producing a tunnel-like narrowing of the left ventricular outflow tract. Additional findings often include a small ascending aorta.

Discrete Subaortic Stenosis and VSD.

This combination is frequently encountered in the pediatric age-group, with the fibromuscular component often being absent at the initial echocardiographic evaluation. The association should be suspected in VSDs with some associated anterior malalignment of the aorta and a more acute aortoseptal angle. These hearts will also develop a double-chambered right ventricle from hypertrophied right ventricular muscle bundles. In a different subset of patients with aortic arch interruption and a VSD, there is muscular subaortic stenosis due to posterior deviation of the infundibular septum.

Clinical Features

These types of obstruction are not truly “congenital” because they are rarely present at birth, but are acquired later, in an otherwise normal heart or when there are associated VSDs or aortic arch obstruction.

Most patients have a systolic murmur and consequently are referred for evaluation. It is a systolic ejection murmur best heard along the lower left sternal border with the absence of an ejection click. There is often a carotid thrill, however.

Laboratory Investigations

ECG.

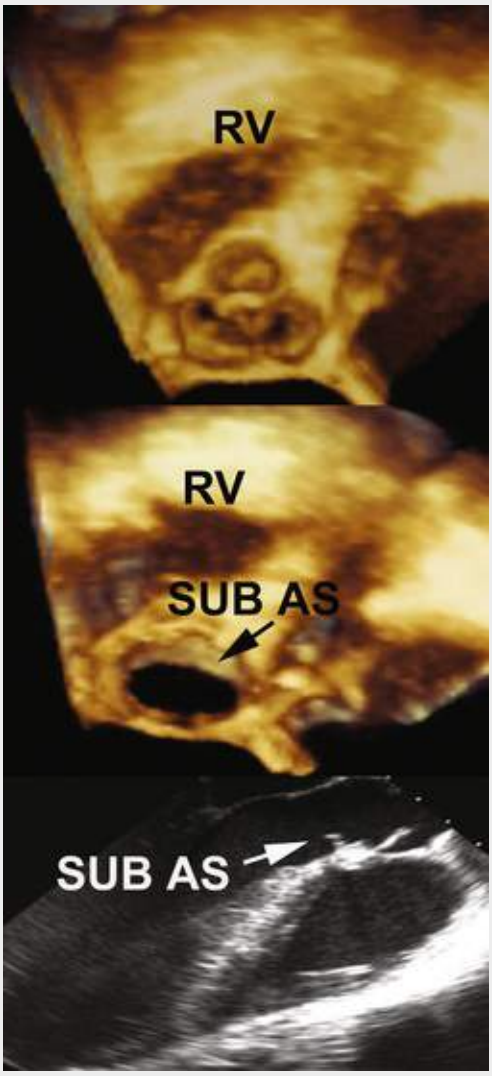
In patients with associated defects, the ECG reflects the major abnormality rather than the associated left ventricular outflow tract obstruction. With isolated forms of left ventricular outflow tract obstruction where the obstruction is significant, there may be left ventricular hypertrophy.

Chest Radiography.

This is usually unhelpful in these patients.

Echocardiography (Videos 75.86 to 75.88).

Echocardiography is the standard diagnostic tool in this lesion. Not only can it permit an accurate delineation of the mechanisms of obstruction, but it provides detailed data regarding associated lesions. In all forms the parasternal long axis view is key to providing an accurate diagnosis. The presence of mitral aortic discontinuity, the relationship of a fibromuscular ridge to the aortic valve, the presence of accessory obstructive tissue, and the dimensions of the aortic annulus and root all are well imaged in this view. In addition, color flow mapping permits the identification of associated aortic valve regurgitation and provides hemodynamic evidence of the site of onset of obstruction. The extension of a fibromuscular ridge onto the anterior mitral leaflet is best appreciated in the apical five-chamber view. This also provides the best site for pulsed or continuous-wave Doppler assessment of the maximum gradient across the left ventricular outflow tract. In the older patient TEE plays an important role in delineating the pathology. Real-time 3D echocardiography provides additional information, particularly in patients with complex mechanisms of left ventricular outflow tract obstruction (**eFig. 75.6**).



EFIGURE 75.6 These images demonstrate fibromuscular subaortic stenosis as seen by 3D echocardiography. The upper two panels show the aortic valve as seen by the surgeon; the middle image is just distal to that and shows the crescent-shaped subaortic membrane. The lower image shows the fibromuscular ridge as seen by transesophageal 2D echocardiography. *RV*, right ventricle; *SUB AS*, subaortic stenosis.

Cardiac Catheterization.

This technique is no longer of importance in evaluating this lesion. Balloon dilation of discrete fibrous ridges has recently been reported from one center to have had favorable long-term outcomes,[78] although it is rarely the treatment of choice.

MRI.

In general, MRI is unnecessary unless there are problems obtaining the needed information by echocardiography.

Interventional Options

Surgical intervention is indicated either at the time of the repair of the underlying primary lesion or in those patients with discrete obstruction when the obstruction is severe enough to raise concerns.

Discrete Subaortic Stenosis (Fibrous and Muscular Stenosis).

The rate of progression is varied and may be slow. In general the approach to the latter group has been to intervene when there is a mean echocardiography gradient across the left ventricular outflow tract of greater than 30 mm Hg to avoid future aortic leaflet damage and minimize recurrence. Surgery involves a

fibromyectomy, with the approach being through the aortic root, with care taken to avoid damage to the aortic valve or to create an iatrogenic VSD. There is a recurrence rate of subaortic stenosis requiring reoperation in up to 20% percent of patients.· In some cases the recurrence is in the form of a fibrous ridge, whereas in others there is acquired pathology of the aortic valve in the form of stenosis and/or regurgitation. Reoperation may just involve repeat resection of a recurrent fibrous ridge or, in patients with significant aortic regurgitation, it may involve surgery on the aortic valve.

Complex Forms of Left Ventricular Outflow Tract Obstruction and an Intact Ventricular Septum.

In patients with an intact ventricular septum, the indications for intervention are similar to those with discrete obstruction. The difference lies in the fact that the surgical approach must be modified according to the underlying pathology, and that reoperation is more frequent. Resection of any fibromuscular component or accessory tissue (provided it is not a primary support mechanism for the mitral valve); a valve-sparing Konno operation; and, in those cases with a hypoplastic aortic annulus, a classic Konno procedure with aortic valve replacement are the potential surgical options.

Left Ventricular Outflow Tract Obstruction and Complex Forms of Chd.

In general, surgery on the left ventricular outflow tract is part of the general repair of the lesion and is not dependent on the precise degree of obstruction across this site.

Outcomes

Immediate complications related to surgery include complete AV block, inadvertent creation of a VSD, or mitral regurgitation from intraoperative damage to the mitral valve apparatus. Long-term complications include recurrence of fibromuscular subvalvular left ventricular outflow tract obstruction (≤20%), clinically important aortic regurgitation, and valvular aortic stenosis (especially in the context of a bicuspid aortic valve or aortic coarctation).[79,80] In some patients with predominant acquired aortic valve stenosis, balloon dilation has been the treatment of choice.

Follow-Up

Particular attention should be paid to patients with residual or recurrent subaortic stenosis or those with an associated bicuspid aortic valve or important aortic regurgitation because they are most likely to require surgery eventually. Reoperation is more likely in patients with complex forms of obstruction, those who are younger at the time of operation, and those who had incomplete relief of obstruction at the initial procedure. Patients with bioprosthetic aortic valves in the aortic position (following the Konno procedure) or the pulmonary position (following the Ross-Konno procedure) need close follow-up. Endocarditis prophylaxis should be used for patients with prosthetic valves.

Supravalvular Aortic Stenosis

Morphology

Three anatomic types of supravalvular aortic stenosis are recognized, although some patients may have findings of more than one type. Most common is the hourglass type, in which marked thickening and

disorganization of the aortic media produce a constricting annular ridge at the superior margin of the sinuses of Valsalva. The membranous type is the result of a fibrous or fibromuscular semicircular diaphragm with a small central opening stretched across the lumen of the aorta. Diffuse hypoplasia of the ascending aorta characterizes the third type.

Because the coronary arteries arise proximal to the site of outflow obstruction in supravalvular aortic stenosis, they are subjected to the elevated pressure that exists within the left ventricle. These vessels are often dilated and tortuous, and premature coronary atherosclerosis has been described. Moreover, if the free edges of some or all of the aortic cusps adhere to the site of the supravalvular stenosis, coronary artery inflow may be compromised. The left ventricle may have a "ballerina foot" configuration, which can result in muscular left ventricular outflow tract obstruction, particularly when associated with significant supravalvular obstruction.

Clinical Features

The clinical picture of supravalvular obstruction differs in major respects from that observed in the other forms of aortic stenosis. Chief among these differences is the association of supravalvular aortic stenosis with Williams syndrome.

Williams Syndrome

The designation *supravalvular aortic stenosis syndrome*, *Williams syndrome*, or *Williams-Beuren syndrome* has been applied to the distinctive picture produced by the coexistence of the cardiac features in the setting of a multisystem disorder. Beyond infancy in these patients, a challenge with vitamin D– or calcium-loading tests unmasks abnormalities in the regulation of circulating 25-hydroxyvitamin D.

The entire spectrum of clinical manifestations includes auditory hyperacusis, inguinal hernia, a hoarse voice, and a typical personality that is outgoing and engaging. Other manifestations of this syndrome include intellectual impairment, "elfin facies," narrowing of peripheral systemic arteries (beware of coexistent renal artery stenosis) and pulmonary arteries, strabismus, and abnormalities of dental development consisting of microdontia, enamel hypoplasia, and malocclusion.

In an older child or adult, progressive joint limitation and hypertonia may become a problem. Adult patients are usually handicapped by their developmental disabilities.

Williams syndrome was previously considered to be nonfamilial; however, most patients have anomalies in the elastin gene on chromosome 7q11.23. Elastin is an important component of the arterial wall, but precisely how mutations in elastin genes cause the phenotypes of supravalvular aortic stenosis is not known.

Familial Autosomal Dominant Presentation

Occasionally the aortic anomaly and peripheral pulmonary arterial stenosis are also found in familial and sporadic forms not associated with the other features of the syndrome. Affected patients have normal intelligence and are normal in facial appearance. Genetic studies suggest that when the anomaly is familial, it is transmitted as autosomal dominant with variable expression. Some family members may have peripheral pulmonary stenosis either as an isolated lesion or in combination with the supravalvular aortic anomaly.

Clinical Features

Patients with Williams syndrome are intellectually challenged (**eFig. 75.7**). The typical appearance is similar to that of the elfin facies observed in the severe form of idiopathic infantile hypercalcemia and is characterized by a high prominent forehead, stellate or lacy iris patterns, epicanthal folds, an underdeveloped bridge of the nose and mandible, an overhanging upper lip, strabismus, and anomalies of dentition.

EFIGURE 75.7 Typical elfin facies in three patients with supravalvular aortic stenosis. (From Friedman WF, Kirkpatrick SE: Congenital aortic stenosis. In Adams FH, Emmanouilides GC, Riemenschneider TA, et al [editors]: Moss' heart disease in infants, children, and adolescents, 4th ed. Baltimore, Williams & Wilkins, 1989.)

Prior studies of the natural history of the principal vascular lesions in these patients—supravalvular aortic stenosis and peripheral pulmonary artery stenosis—indicate that the aortic lesion is usually progressive, with an increase in the intensity of obstruction related often to poor growth of the ascending aorta. This has recently been questioned in a longitudinal single-center study, where those with smaller gradients at presentation appeared to have evidence of regression of their stenosis. Those with pulmonary branch stenosis, whether associated with the aortic lesion or not, tend to show no change in or a reduction in right ventricular pressure with time.

With few exceptions, the major *physical findings* resemble those observed in patients with aortic valve stenosis. Among these exceptions are accentuation of aortic valve closure due to elevated pressure in the aorta proximal to the stenosis, an absent ejection click, and the especially prominent transmission of a thrill and murmur into the jugular notch and along the carotid vessels. The narrowing of the peripheral pulmonary arteries may produce a late systolic or continuous murmur heard best in the lung fields and is usually accentuated by inspiration. Another hallmark of supravalvular aortic stenosis is that the systolic pressure in the right arm is usually higher than in the left arm. This pulse disparity may relate to the tendency of a jet stream to adhere to a vessel wall (*Coanda effect*) and selective streaming of blood into the innominate artery.

Laboratory Investigations

ECG.

There will be left ventricular hypertrophy when the obstruction is severe. Biventricular or even right ventricular hypertrophy may be found if there is significant narrowing of peripheral pulmonary arteries.

Chest Radiography.
In contrast to valvular stenosis, dilation of the ascending aorta or pulmonary artery is absent.

Echocardiography.
This is a valuable technique for localizing the site of obstruction to the supravalvular area. Most often the sinuses of Valsalva are dilated and the ascending aorta and arch appear small or of normal size. The diameter of the aortic annulus is always greater than that of the sinotubular junction. The proximal coronary arteries may become aneurysmal. Doppler examination determines the location of obstruction but usually overestimates the gradient compared with that obtained at cardiac catheterization. This results from the obstruction being lengthy, and the Doppler gradient is overestimated due to the phenomenon of pressure recovery.

Angiocardiography.
This is necessary to define an accurate hemodynamic gradient across the left ventricular outflow tract, as well as to determine the status of the coronary arteries. Echocardiography alone provides inadequate imaging of the coronary arteries, and in some instances there is no clinical evidence of coronary compromise prior to surgery due to the high proximal coronary perfusion pressure, which becomes evident in the immediate or early postoperative period, when the perfusion pressure falls because of the relief of the obstruction.

Usually it also involves an assessment of the branch pulmonary arteries, as well as the brachiocephalic, renal, and mesenteric arteries, all of which can be stenotic. Because of the nature of the anatomic defect, transcatheter balloon angioplasty, with or without stenting, is not an effective treatment option.

Interventional Options and Outcomes

Surgical intervention for supravalvular aortic stenosis has been successful in most cases, with good medium- and long-term results. A variety of surgical procedures may be performed, all of which are tailored to the type of pathology. The use of a Y patch, resection with end-to-end anastomosis, or a Ross procedure are the main techniques employed. Additional procedures including osteoplasty or coronary bypass of ostial stenosis, aortic valvuloplasty, and subaortic resection, may be necessary in some cases.

The cardiac prognosis is good, with some patients requiring further surgery for recurrent supravalvular stenosis.[81] Because peripheral pulmonary artery stenosis tends to improve with time, there is a reluctance to attempt intervention, either surgical or via balloon angioplasty. Long-term behavioral and intellectual problems persist.

Congenital Mitral and Tricuspid Valve Anomalies

Congenital Mitral Stenosis

Morphology
Anatomic types of mitral stenosis include the parachute deformity of the valve, in which shortened chordae tendineae converge and insert into a single large papillary muscle, or into one dominant muscle with a few chordae inserting into a second smaller papillary muscle (see Video 75.6); thickened leaflets with shortening and fusion of the chordae tendineae; an anomalous arcade of obstructing

papillary muscles; accessory mitral valve tissue; and a supravalvar circumferential ridge or “ring” of connective tissue arising at the base of the atrial aspect of the mitral leaflets. Associated cardiac defects are common, including endocardial fibroelastosis, coarctation of the aorta, PDA, and left ventricular outflow tract obstruction (Videos 75.89 and 75.90). An association between persistence of the left superior vena cava and obstructive left-sided lesions also exists.

Clinical Features.

In most cases the findings are incidental at the time of evaluation of another left-sided obstructive lesion, such as coarctation of the aorta or aortic valve stenosis. The classic auscultatory findings seen with rheumatic mitral valve stenosis are often absent in the congenital form. Typical findings include a normal S_1, a middiastolic murmur with or without some presystolic accentuation, and no opening snap.

Laboratory Investigations

ECG.

In milder forms this is usually normal, or there may be left atrial hypertrophy, with or without right ventricular hypertrophy due to associated pulmonary hypertension.

Chest Radiography.

This is normal in milder forms, with evidence of pulmonary edema in those cases with more severe obstruction.

Echocardiography.

Two-dimensional and, more recently, 3D echocardiography, combined with Doppler studies, usually provides a complete analysis of the anatomy and function of congenital mitral stenosis. The status of the papillary muscles is best appreciated in the precordial short axis view. If two papillary muscles are present, they are usually closer together than is seen in the normal heart. The precordial long axis view permits identification of a supravalvular mitral ring, as well as the degree of mobility of the valve leaflets. In some instances, the supravalvar ring starts at the annular level, but extends somewhat distally onto the leaflets. Color-flow Doppler imaging allows identification of the level of the obstruction, as well as the presence of mitral valve regurgitation. Pulsed or continuous-wave Doppler imaging provides an accurate assessment of the mean gradient across the mitral valve. The advantage of the pressure half-time lies in the fact that it is independent of cardiac output, unlike the mean gradient across the mitral valve. An indirect assessment of pulmonary artery pressure is also important and is included in the decision process of whether or not to intervene.

Interventional Options and Outcomes.

In asymptomatic cases clinical and echocardiographic follow-up is all that is necessary. The presence of a single papillary muscle in itself does not predict progressive stenosis. If the patient starts to develop pulmonary hypertension or symptoms, surgical intervention is usually indicated. Mitral valve balloon dilation is usually not as successful as it is in rheumatic mitral valve stenosis. Surgery usually involves removing a supramitral ring when present, and splitting both papillary muscles and the fused chordal apparatus in those patients with more common forms of congenital mitral stenosis.[82,83] In general, surgical intervention provides temporary relief, with many operated cases requiring valve replacement later in life.[84,85]

Congenital Mitral Regurgitation

Morphology

Isolated Congenital Mitral Valve Regurgitation.

This is usually due either to an isolated cleft of the anterior mitral valve leaflet or is the result of leaflet dysplasia. In the latter cases there is evidence of shortened chordae in conjunction with dysplastic valve leaflets. In those with an isolated mitral valve *cleft*, the deficiency in the anterior mitral leaflet points toward the left ventricular outflow tract, unlike those cases with an AV septal defect. In general the larger the cleft in the anterior mitral leaflet, the greater the degree of regurgitation.

In cases with a *dysplastic* mitral valve, the chordal apparatus is shortened, with varying degrees of dysplasia of the leaflets.

Complex Congenital Mitral Valve Regurgitation.

This is seen more frequently in association with abnormalities of the ventriculoarterial connection, such as double-outlet right ventricle, transposition and VSD, and corrected transposition. In the first two there is often a cleft in the anterior mitral valve leaflet, with some chordal support apparatus that renders the valve less regurgitant than in those patients with an isolated cleft. In cc-TGA the morphologic mitral valve may have an associated cleft, be dysplastic, or have multiple papillary muscles, all of which increase the tendency for it to be regurgitant.

Clinical Features.

The presence of symptoms relates to the severity of the regurgitation in patients in whom the pathology is isolated to the valve. Exercise intolerance, combined with a pansystolic murmur at the apex, with or without a middiastolic murmur are the cardinal clinical features.

Laboratory Investigations

ECG.

This is either normal or demonstrates left atrial and left ventricular hypertrophy.

Chest Radiography.

This demonstrates cardiomegaly predominantly involving the left ventricle and atrium.

Echocardiography.

Doppler echocardiography and 2D and 3D echocardiography provide an accurate evaluation of the mechanisms and degree of valvular regurgitation. The cleft in the anterior mitral valve leaflet is best seen in the precordial short axis view, pointing toward the left ventricular outflow tract (Videos 75.91 to 75.96). Three-dimensional echocardiography evaluation helps by determining the extent of the cleft. Patients with a dysplastic mitral valve lack mobility of the valve leaflets and have shortened chordae, resulting in the appearance of tethering and poor coaptation. Color Doppler interrogation helps in locating the site of regurgitation. The severity of regurgitation is assessed in the standard fashion. Three-dimensional echocardiography permits a comprehensive evaluation of the mechanisms of regurgitation, with additional information being obtained regarding commissural length, leaflet area, and

sites of regurgitation from color-flow Doppler imaging.

Angiocardiography and MRI.
These procedures are seldom helpful in management planning.

Interventional Options and Outcomes.

The need for intervention depends on the severity of regurgitation and its impact on left ventricular function. Surgery should not be delayed until patients become symptomatic. Surgery involves suture of an isolated cleft, with or without associated commissuroplasties. In those patients with a dysplastic mitral valve, leaflet extension in conjunction with an annuloplasty and commissuroplasty usually results in effective control of the regurgitation in the short and medium term. Despite this, many of these patients end up with a mitral valve replacement at some stage in the future.

Ebstein Anomaly

Morphology

The common feature in all cases of Ebstein anomaly is apical displacement of the septal tricuspid leaflet in conjunction with leaflet dysplasia (**Fig. 75.42**). Many, but not all, have associated displacement of the posterior mural leaflet, with the anterior leaflet never being displaced. Although the anterior leaflet is never displaced apically, it may be adherent to the free wall of the right ventricle, causing right ventricular outflow tract obstruction. The displacement of the tricuspid valve results in “atrialization” (functioning as an atrial chamber) of the inflow tract of the right ventricle and consequently produces a variably small functional right ventricle. Associated anomalies include PFO or ASD in approximately 50% of patients; accessory conduction pathways in 25% (usually right sided); and, occasionally, varying degrees of right ventricular outflow tract obstruction, VSD, aortic coarctation, PDA, or mitral valve disease. Left ventricular abnormalities resembling noncompaction syndrome have also been described.

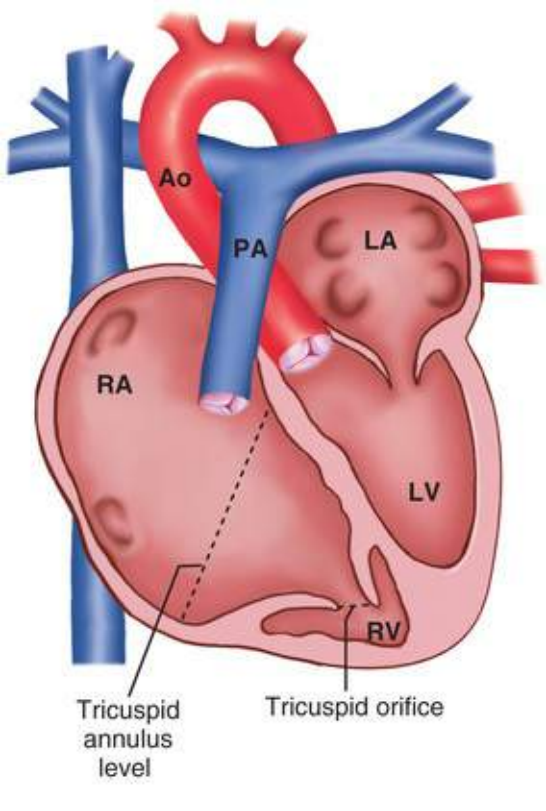


FIGURE 75.42 Diagrammatic representation of Ebstein anomaly. *Ao*, aorta; *LA*, left atrium; *LV*, left ventricle; *PA*, pulmonary artery; *RA*, right atrium; *RV*, right ventricle. (From Mullins CE, Mayer DC: Congenital heart disease: a diagrammatic atlas. New York, Wiley-Liss, 1988.)

Pathophysiology

Varying degrees of tricuspid regurgitation (or exceptionally tricuspid stenosis) result from the abnormal tricuspid leaflet morphology with consequent further right atrial enlargement. Right ventricular volume overload from significant tricuspid regurgitation and infundibular dilation can also be present. Right-to-left shunting through a PFO or ASD occurs if the right atrial pressure exceeds the left atrial pressure (which is often the case when severe tricuspid regurgitation is present).

Natural History.

The natural history of patients with Ebstein anomaly depends on its severity. When the tricuspid valve deformity and dysfunction are extreme, death in utero from hydrops fetalis is the norm. When the tricuspid valve deformity is severe, symptoms usually develop in newborn infants. Patients with moderate tricuspid valve deformity and dysfunction usually develop symptoms during late adolescence or young adult life. Adults with Ebstein anomaly can occasionally remain asymptomatic throughout life if the anomaly is mild; exceptional survival to the ninth decade has been reported.

Clinical Features.

With severe tricuspid valve deformity, newborns and infants present with failure to thrive and right-sided congestive heart failure. In general, children who present after the neonatal period remain asymptomatic until late adolescence or early adult life. Most adult patients present with exercise intolerance (exertional dyspnea and fatigue), palpitations of supraventricular origin, or cyanosis from a right-to-left shunt at the atrial level. Occasionally, a paradoxical embolus resulting in a transient ischemic attack or stroke can call attention to the diagnosis. Right-sided cardiac failure from severe tricuspid regurgitation and right ventricular dysfunction is possible. Sudden death (presumed to be arrhythmic in nature) is described.

Physical examination typically and surprisingly reveals a normal jugular venous pressure because of the large and compliant right atrium and atrialized right ventricle; a widely split S_1 with a loud tricuspid component (the “sail sound”); a widely split S_2 from a right bundle branch block; and a right-sided third heart sound. A pansystolic murmur (typically increasing on inspiration) from tricuspid regurgitation is best heard at the lower left sternal border. Cyanosis from a right-to-left shunt at the atrial level may or may not be present.

Laboratory Investigations

ECG.

The ECG presentation of Ebstein anomaly varies widely. Low voltage is typical. Peaked P waves in leads II and V_1 reflect right atrial enlargement. The PR interval is usually prolonged, but a short PR interval and a delta wave from early activation through an accessory pathway can be present. An rsr′ pattern consistent with right ventricular conduction delay is typically seen in lead V_1, and right bundle branch block is common in adults. Atrial flutter and fibrillation are common. The ECG may be normal.

Chest Radiography.

A rightward convexity from an enlarged right atrium and atrialized right ventricle coupled with a leftward convexity from a dilated infundibulum give the heart a “water bottle” appearance on chest radiography. Cardiomegaly, highly variable in degree, is the rule. The aortic knuckle and the pulmonary trunk are inconspicuous. The pulmonary vasculature is usually normal to reduced.

Echocardiography.

The diagnosis of Ebstein anomaly is usually made by echocardiography (**Fig. 75.43**). Apical displacement of the septal leaflet of the tricuspid valve by 8 mm/m^2 or more, combined with an elongated sail-like appearance of the anterior leaflet, confirms the diagnosis. The size of the atrialized portion of the right ventricle (identified between the tricuspid annulus and the ventricular attachment of the tricuspid valve leaflets) and the systolic performance of the functional right ventricle can be estimated. The degree of tricuspid regurgitation (and rarely stenosis) can be assessed. Associated defects such as ASDs, as well as the presence and direction of shunting, can also be identified (Videos 75.97 to 75.100).

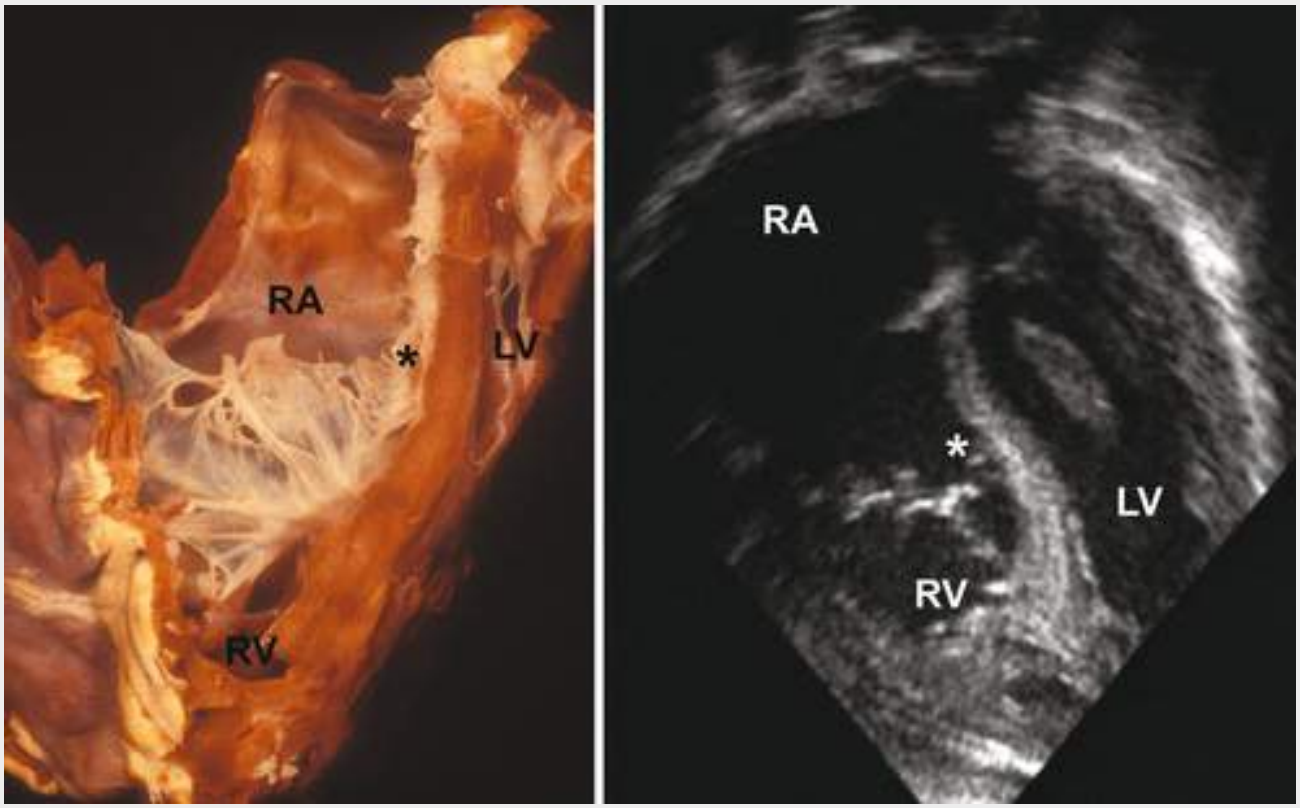

FIGURE 75.43 Apical four-chamber view in Ebstein malformation of the tricuspid valve. Note the significant displacement of the septal tricuspid valve leaflet (*asterisk*), with associated valve dysplasia. *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle.

Angiography.
Cardiac catheterization is required mainly when concomitant coronary artery disease is suspected and to determine if pulmonary artery pressures are elevated. When performed, selective right ventricular angiography shows the extent of tricuspid valve displacement, the size of the functional right ventricle, and the configuration of its outflow tract.

MRI.
This investigation can offer insights into functional right ventricular volume and function.

Indications for Intervention.

Indications for intervention include substantial cyanosis, right-sided heart failure, poor functional capacity, and perhaps the occurrence of paradoxical emboli. Recurrent supraventricular arrhythmias not controlled by medical or ablation therapy and asymptomatic substantial cardiomegaly (cardiothoracic ratio > 60%) are relative indications.[86,87,88]

Interventional Options.

Tricuspid valve repair when feasible is preferable to tricuspid valve replacement. The feasibility of tricuspid valve repair depends primarily on the experience and skill of the surgeon, as well as the adequacy of the anterior leaflet of the tricuspid valve to form a monocusp valve or a cone-like structure.[89] Tricuspid valve repair is possible when the edges of the anterior leaflet of the tricuspid valve are not severely tethered down to the myocardium and when the functional right ventricle is of adequate size (> 35% of the total right ventricle). If the tricuspid valve is irreparable, valve replacement will be necessary, usually with a bioprosthetic tricuspid valve.

For “high-risk” patients (those with severe tricuspid regurgitation, an inadequate functional right

ventricle [because of size or function], and/or chronic supraventricular arrhythmias), a bidirectional cavopulmonary connection can be added to reduce the right ventricular preload if pulmonary artery pressures are low (this procedure in adults is controversial, however, because it may lead to superior vena cava syndrome).[90] Occasionally a Fontan operation may be the best option in patients with tricuspid stenosis and/or a hypoplastic right ventricle. A concomitant right atrial or biatrial maze procedure at the time of surgery should be considered in patients with chronic atrial flutter or fibrillation. If an accessory pathway is present, this should be mapped and obliterated either at the time of surgical repair or preoperatively in the catheter laboratory. Recurrent arrhythmias following ablation do occur because of the multiple pathways and difficult anatomy and may require repeat catheter ablation.[91] An atrial communication, if present, should be closed. In occasional patients with a resting oxygen saturation of more than 90% and exercise intolerance caused by worsening hypoxemia, closure of the PFO/ASD may be indicated without addressing the tricuspid valve itself.

With satisfactory valve repair, the medium- and long-term prognoses are good.[92] Right ventricular remodeling usually occurs[93] and symptomatic improvement is the norm.[94] Late arrhythmias can occur, however. With valve replacement, results are just as satisfactory. Valve re-replacement may be necessary because of a previous failing repair, bioprosthesis, or thrombosed mechanical valve.

Reproductive Issues.

In the absence of maternal cyanosis, right-sided heart failure, or arrhythmias, pregnancy is usually well tolerated.[95]

Follow-Up.

All patients with Ebstein anomaly should have regular follow-up, the frequency being dictated by the severity of their disease. Particular attention should be paid to patients with cyanosis, substantial cardiomegaly, poor right ventricular function, and recurrent atrial arrhythmias. Patients with substantial tricuspid regurgitation following tricuspid valve repair need close follow-up, as do patients with recurrent atrial arrhythmias, degenerating bioprostheses, or dysfunctional mechanical valves.

Valvular and Vascular Conditions (see Chapters 63, 67–70)

Sinus of Valsalva Aneurysm and Fistula

Morphology

The malformation consists of a separation, or lack of fusion, between the media of the aorta and the annulus fibrosus of the aortic valve. The receiving chamber of a right aortic sinus aortocardiac fistula is usually the right ventricle, but occasionally, when the noncoronary cusp is involved, the fistula drains into the right atrium. Approximately 5% to 15% of aneurysms originate in the posterior or noncoronary sinus. The left aortic sinus is seldom involved. Associated anomalies are common and include VSD, bicuspid aortic valve, and aortic coarctation.

Clinical Features

The deficiency in the aortic media appears to be congenital. Reports in infants are exceedingly rare, and they are infrequent in children because progressive aneurysmal dilation of the weakened area develops

but may not be recognized until the third or fourth decade of life, when rupture into a cardiac chamber occurs. A congenital aneurysm of an aortic sinus of Valsalva, particularly the right coronary sinus, is an uncommon anomaly that occurs three times more often in males. An unruptured aneurysm usually does not produce a hemodynamic abnormality. Rarely, myocardial ischemia may be caused by coronary arterial compression. Rupture is often of abrupt onset, causes chest pain, and creates continuous arteriovenous shunting and acute volume loading of both right and left heart chambers, which promptly results in heart failure. An additional complication is infective endocarditis, which may originate either on the edges of the aneurysm or on those areas in the right side of the heart that are traumatized by the jet-like stream of blood flowing through the fistula.

The presence of this anomaly should be suspected in a patient with a combination of chest pain of sudden onset; resting or exertional dyspnea; bounding pulses; and a loud, superficial, continuous murmur accentuated in diastole when the fistula opens into the right ventricle, as well as a thrill along the right or left lower sternal border.

Laboratory Investigations

ECG.

This may show biventricular hypertrophy, or it may be normal.

Chest Radiography.

This may demonstrate generalized cardiomegaly and usually heart failure after the fistula develops.

Echocardiography.

Studies based on 2D and pulsed Doppler echocardiography may detect the walls of the aneurysm and disturbed flow within the aneurysm or at the site of perforation. TEE may provide more precise information than the transthoracic approach.

Cardiac Catheterization.

This reveals a left-to-right shunt at the ventricular or, less commonly, the atrial level; the diagnosis may be established definitively by retrograde thoracic aortography.

Management Options and Outcomes

Preoperative medical management consists of measures to relieve cardiac failure and to treat coexistent arrhythmias or endocarditis, when present. At operation the aneurysm is closed and amputated, and the aortic wall is reunited with the heart, either by direct suture or with a prosthesis. All efforts should be made to preserve the aortic valve in children because patch closure of the defect combined with prosthetic valve replacement greatly increases the risk of operation in small patients. Late results of surgical repair have been excellent.[96] Successful device closure of the ruptured aneurysm has also been reported.

Vascular Rings and Compression

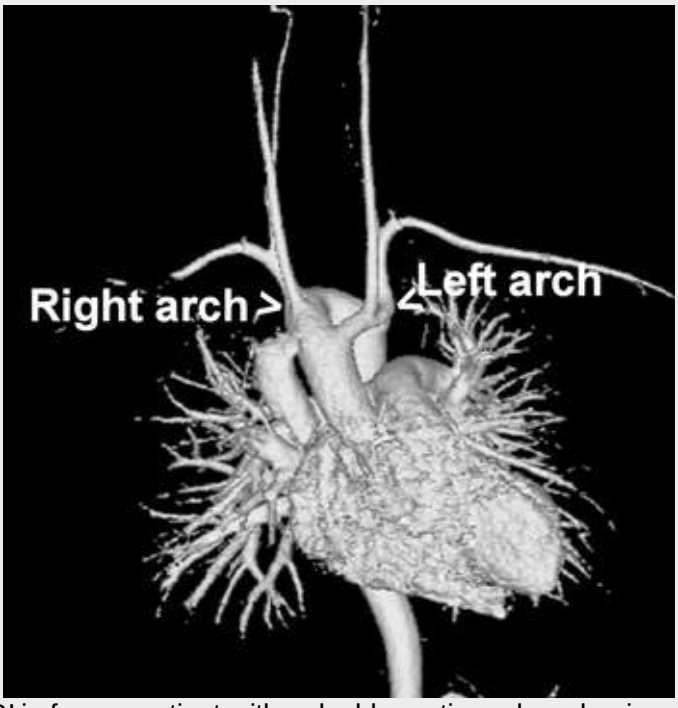
Morphology

The term *vascular ring* is used for those aortic arch or pulmonary artery malformations that exhibit an

abnormal relation with the esophagus and trachea, often causing dysphagia and/or respiratory symptoms.

Double Aortic Arch.

The most common vascular ring is produced by a double aortic arch in which both the right and left fourth embryonic aortic arches persist (**eFig. 75.8**). In the most common type of double aortic arch, there is a left ligamentum arteriosum or occasionally a ductus arteriosus. Although both arches may be patent at the time of diagnosis, invariably the left arch distal to the left subclavian artery is atretic and is connected to the descending aorta by a fibrous remnant that completes the ring. In the setting where both arches are patent, the right arch is typically larger than the left. This usually occurs as an isolated lesion, with the respiratory symptoms being caused by tracheal compression and frequently associated laryngomalacia, usually in the neonate and young infant.



EFIGURE 75.8 This MRI is from a patient with a double aortic arch, a dominant posterior right arch, and a hypoplastic but patent left aortic arch.

Right Aortic Arch.

A right aortic arch with a left ductus or ligamentum arteriosum connecting the left pulmonary artery and the upper part of the descending aorta is the next most frequent vascular ring seen. Although all cases with this lesion have a vascular ring, not all cases are symptomatic. Indeed, those patients who are symptomatic usually have an associated diverticulum of Kommerell. This is a large outpouching at the distal takeoff of the left subclavian artery from the descending aorta. It is the combination of the diverticulum and the ring that causes the airway compression. Other cases without a diverticulum of Kommerell have a loose vascular ring, made up of the aberrant left subclavian artery and a left ligamentum.

Anomalous Origin of a Right Subclavian Artery.

Anomalous origin of a right subclavian artery is one of the most common abnormalities of the aortic arch. Although the aberrant right subclavian artery runs posterior to the esophagus, it does not form a vascular ring unless there is an associated right-sided ductus or ligamentum to complete the ring. During adulthood about 5% of patients with an aberrant right subclavian artery (and a left ductus) develop symptoms

(usually dysphagia rather than respiratory symptoms) owing to rigidity of the aberrant vessel.

Retroesophageal Descending Aorta.

This is a rarer but more problematic type of vascular compression. In this setting there may be either an ascending left and descending right aorta or an ascending right and descending left aorta. The retroesophageal component of the descending aorta causes esophageal, and sometimes tracheal, compression, in conjunction with the left- or right-sided ligamentum.

Pulmonary Artery Sling.

This is usually made up of the left pulmonary artery arising from the right pulmonary artery, which runs posterior to the trachea but anterior to the esophagus. This is usually seen in isolation and can be associated with significant hypoplasia of the tracheobronchial tree, which is the predominant cause of the airway symptoms.

Clinical Features

The symptoms produced by vascular rings depend on the tightness of anatomic compression of the trachea and esophagus and consist principally of respiratory difficulties, including stridor and dysphagia. Not all patients with a vascular ring are symptomatic, and cases with an aberrant left subclavian artery are frequently detected at the time of evaluation for associated CHD such as tetralogy of Fallot. Although most patients with a true ring and some airway compression present early in life, others present later with dysphagia and still others escape diagnosis forever.

Laboratory Investigations

ECG.

This appears normal unless associated cardiovascular anomalies are present.

Chest Radiography.

If there is evidence of a right aortic arch in a symptomatic patient, a vascular ring should be suspected. In some instances, there is evidence of some airway narrowing. The barium esophagogram is a useful screening procedure. Prominent posterior indentation of the esophagus is observed in many of the common vascular ring arrangements, although the pulmonary artery vascular sling produces an anterior indentation.

Echocardiography.

Although echocardiography is a sensitive tool for evaluating the laterality of the aortic arch, including a detailed assessment of the associated brachiocephalic vessels, MRI is rapidly becoming the preferred mode of investigation prior to intervention. This technique has the added advantage of imaging the more posterior structures that run behind the esophagus and trachea. In general, if there is normal branching of the innominate artery, to the right for a left aortic arch and to the left for a right, along with the correct "sidedness" of the descending aorta, then a vascular ring can be excluded. *Most cases with a double aortic arch* have a dominant right arch, with the descending aorta appearing to dip posteriorly as it runs behind the esophagus. A patent ductus or ligamentum can usually be identified by echocardiography. When both arches are patent, a frontal plane sweep from inferior to superior demonstrates both patent arches, as well as their brachiocephalic vessels. *A right aortic arch with an aberrant left subclavian artery* is suspected when it is not possible to identify normal branching of the left-sided innominate artery. *A retroesophageal descending aorta* should be suspected when the ascending aorta and its

brachiocephalic arteries are readily identified but there is difficulty in identifying the descending aorta as it traverses behind the esophagus. *A left pulmonary artery sling* is suspected when the normal branching pattern of pulmonary arteries cannot be identified. In this setting color Doppler imaging permits the identification of the left pulmonary artery as it arises from the right pulmonary artery and runs in a posterior and leftward direction.

MRI and CT.

MRI and CT play a major role in the evaluation of patients with a vascular ring. In fact, MRI has become the gold standard for the evaluation of the aorta and its branches. The only disadvantage for infants is that general anesthesia is often required to achieve a successful examination. On the other hand, spiral CT is a technique that is fast and provides better definition of the affected airways. This latter technique is particularly valuable for patients with a pulmonary artery sling, where the vascular ring often plays a secondary role to the airway abnormalities. The advantages of these techniques are that, unlike echocardiography, they permit a precise assessment of the more posterior vascular structures and their relationships to the esophagus and airways. These techniques are particularly valuable in the more complex forms, such as a retroesophageal descending aorta.

Management Options and Outcomes

The severity of symptoms and the anatomy of the malformation are the most important factors in determining treatment. Patients, particularly infants, with respiratory obstruction require prompt surgical intervention. A left thoracotomy is the surgical approach in most patients with a vascular ring. Operative repair of the double aortic arch requires division of the minor arch (usually the left) and the ligamentum. Patients with a right aortic arch and a left ductus or ligamentum arteriosum require division of the ductus or ligamentum and/or ligation and division of the left subclavian artery, which is the posterior component of the ring. Video-assisted thoracoscopy is an alternative to open thoracotomy for management. In patients with a pulmonary artery vascular sling, surgery consists of detachment of the left pulmonary artery at its origin and anastomosis to the main pulmonary artery directly or by way of a conduit with its proximal end brought anterior to the trachea. The addition of tracheal narrowing that requires surgical intervention adds to the mortality rate in this group of patients, as does the association with intracardiac malformations.

Pulmonary Stenosis with Intact Ventricular Septum

This lesion exists as a continuum, ranging from some patients with an isolated valvular stenosis to others in whom there is complete atresia of the pulmonary outflow tract (**Fig. 75.44 and eFig. 75.9**). The pulmonary valve may vary from a well-formed trileaflet valve with varying degrees of commissural fusion to an imperforate membrane.

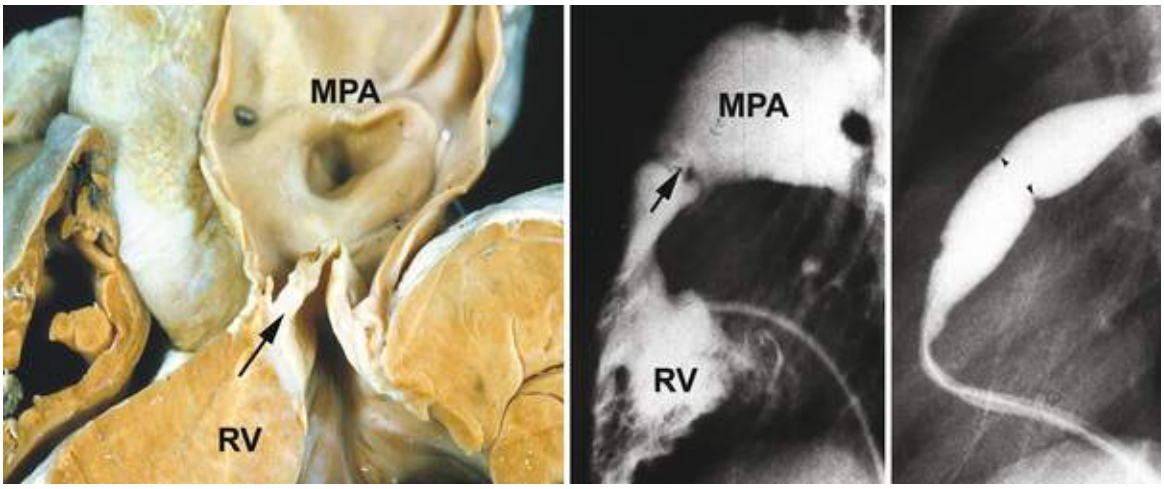


FIGURE 75.44 Montage of pulmonary valve stenosis demonstrating typical pathology (**left,** *arrow*) with a thickened pulmonary valve and obstruction due to commissural fusion. Note the poststenotic dilation. The angiogram demonstrates a case before (**middle,** *arrow*) and during (**right**) balloon dilation. *MPA*, main pulmonary artery; *RV*, right ventricle.

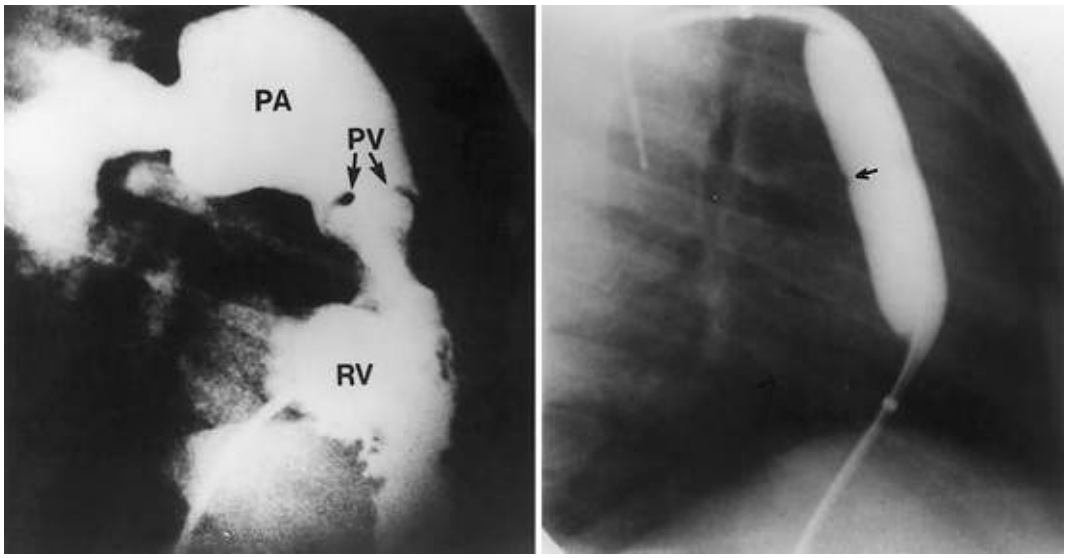


EFIGURE 75.9 Right ventriculogram (RV) in the lateral projection **(left)** from a patient with valvular pulmonic stenosis. The pulmonary valve (PV) is thickened and domes in systole (*arrows*). Poststenotic dilation of the pulmonary artery (PA) is seen. At **right**, successful balloon valvuloplasty shows almost complete disappearance of the stenotic waist (*arrow*). (Courtesy of Dr. Thomas G. DiSessa.)

In pulmonary valve stenosis due to valvular dysplasia, the obstruction is caused not by commissural fusion but by a combination of thickened and dysplastic pulmonary valve leaflets in combination with varying degrees of supravalvular pulmonary stenosis. The supravalvular stenosis is classically at the distal part of the pulmonary valve sinuses, and there is usually no poststenotic pulmonary artery dilation. This entity is associated with Noonan syndrome, which in turn may be associated with hypertrophic cardiomyopathy.

In those with isolated pulmonary valvular stenosis who present beyond the neonatal period, the right ventricle and tricuspid valve are usually normal. However, cases with valvular stenosis presenting in the newborn period very often have abnormalities of the tricuspid valve, in particular some leaflet dysplasia and an associated shortened chordal support apparatus.

The other group, those with pulmonary valve atresia, have varying degrees of right ventricular hypoplasia, varying from a tripartite right ventricle to conditions with associated infundibular atresia,

with intrinsic myocardial abnormalities that persist for life. Those with the smallest right ventricle often have primitive coronary artery–to–right ventricular connections (sometimes termed *sinusoids*), which in some instances are responsible for myocardial perfusion via the suprasystemic right ventricle (so-called *ventricular dependency*). There is frequently associated endocardial fibroelastosis of the right ventricle. The tricuspid valve is invariably abnormal, usually with thickened dysplastic leaflets and varying degrees of leaflet tethering due to a shortened chordal apparatus.

The importance of understanding the right ventricular and tricuspid valve abnormalities is that these persist throughout life and have a significant impact on right ventricular and tricuspid valve function in patients who end up with a biventricular circulation. As well, those with the smallest right ventricle may have persistent coronary artery abnormalities that eventually result in both left and right ventricular myocardial perfusion issues.

Two modes of presentation exist. The first mode is seen in patients who present in the neonatal period, usually with associated pathology of the tricuspid valve, right ventricle, and/or coronary arteries. The second mode is seen beyond the neonatal period, when the valvular stenosis is usually isolated.

Clinical Features

Patients who present beyond the neonatal period with isolated mild to moderate right ventricular outflow tract obstruction of any type usually have no symptoms. Patients with severe right ventricular outflow tract obstruction may present with exertional fatigue, dyspnea, lightheadedness, and chest discomfort (right ventricular angina). Physical examination may reveal a prominent jugular *a* wave, a right ventricular lift, and possibly a thrill in the second left intercostal space. Auscultation reveals a normal S_1, a single or split S_2 with a diminished P_2, and a systolic ejection murmur best heard in the second left intercostal space. When the pulmonary valve is thin and pliable, a systolic ejection click that decreases on inspiration is heard. As the severity of the pulmonary stenosis progresses, the interval between S_1 and the systolic ejection click becomes shorter, S_2 becomes more widely split, P_2 diminishes or disappears, and the systolic ejection murmur lengthens and peaks later in systole, often extending beyond A_2. An ejection click seldom occurs with dysplastic pulmonary stenosis. Cyanosis may be present when a PFO or ASD permits right-to-left shunting.

Adult patients with trivial and mild valvular right ventricular outflow tract obstruction do not become worse with time. Moderate valvular right ventricular outflow tract obstruction can progress in 20% of unoperated patients, especially in adults because of calcification of the valve, and may require intervention. Some of these patients can also become symptomatic, particularly in later life, because of atrial arrhythmias resulting from right ventricular pressure overload and tricuspid regurgitation. Patients with severe valvular right ventricular outflow tract obstruction will have had balloon or surgical valvotomy to survive to adult life. Long-term survival in patients with repaired pulmonary valve stenosis is similar to that of the general population, with excellent to good functional class at long-term follow-up in most patients. A few patients have severe pulmonary regurgitation, and some will require pulmonary valve replacement. Because of the restrictive nature of the right ventricle, most patients do not develop progressive right ventricular dilation, even if they have free pulmonary regurgitation.

Outside the newborn period and early infancy, patients with *Noonan syndrome* have short stature, webbed necks, and broad-shaped chests in a fashion similar to Turner syndrome. Noonan syndrome is inherited as an autosomal dominant disorder, and in 85% to 90% of patients there is a gene mutation (*PTPN11* in 50%, *SOS1* in 10% to 15%, and *RAF1* and *RIT1* in 5% of cases). Noonan syndrome affects both sexes equally. Noonan syndrome is often difficult to diagnose in the neonate, and in some instances

the diagnosis of the dysplastic pulmonary valve is the first clue to the diagnosis.

Laboratory Investigations

ECG.

In the *newborn* period, in patients with significant right ventricular hypoplasia or in patients with Noonan syndrome findings of an associated hypertrophic cardiomyopathy, an ECG may show left-axis deviation and left ventricular dominance. Other patients may have a normal QRS axis. Right atrial overload is present in those with increased right atrial pressure. In the *infant*, *child*, and *adult*, the findings depend on the severity of the stenosis. In milder cases the ECG should be normal. As the stenosis progresses, evidence of right ventricular hypertrophy appears. Right atrial overload is associated with moderate to severe pulmonary stenosis.

Chest Radiography.

In the *infant*, *child*, and *adult* with mild or moderate pulmonary stenosis, chest radiography often shows a heart of normal size and normal pulmonary vascularity. Poststenotic dilation of the main and left pulmonary arteries is often seen, unless there is pulmonary valve dysplasia. Right atrial and right ventricular enlargement is observed in patients with severe obstruction and right ventricular failure. The pulmonary vascularity is usually normal in the absence of a right-to-left atrial shunt but may be reduced in patients with severe stenosis and right ventricular failure.

Echocardiography (Videos 75.101 to 75.103).

Two-dimensional echocardiographic and continuous-wave Doppler examination characterizes the anatomic valve abnormality and its severity and has essentially eliminated the requirement for diagnostic cardiac catheterization. Although traditionally, maximum instantaneous gradients have been used to select patients for balloon valvuloplasty, recent data would suggest the contrary. Mean Doppler gradients appear to correlate better with catheter-derived peak-to-peak gradients, with a value of 50 mm Hg being the cut point for intervention.

The right ventricular size is currently best assessed indirectly from the tricuspid annular dimension. In the absence of a VSD there is an excellent correlation between the two. Right ventricular pressure can be assessed indirectly from the tricuspid regurgitation gradient. Tricuspid valve morphology and function and the status of the interatrial septum all need to be addressed. Three-dimensional echocardiography is helpful in patients for whom surgery is contemplated for associated tricuspid valve regurgitation.

Those with pulmonary valve dysplasia have a thickened fleshy pulmonary valve, lack of poststenotic dilation, and varying degrees of supravalvular pulmonary stenosis (Video 75.103). The associated diagnosis of hypertrophic cardiomyopathy can be confirmed or excluded. If the initial echocardiogram does not demonstrate hypertrophic cardiomyopathy, further studies should be performed throughout childhood and adolescence, particularly in cases with left axis deviation.

Interventional Options and Outcomes

Presentation after the neonatal period usually implies that a well-developed right ventricle and valve are present, and elective balloon dilation of the pulmonary valve is the therapeutic procedure of choice, with excellent short- and medium-term results. The same approach applies to those with a dysplastic pulmonary valve, though in many instances only partial relief of the gradient is possible, with surgery being required when the gradient increases. In those patients, partial pulmonary valvectomy, or patch

insertion, is usually necessary to relieve the obstruction, in some cases in conjunction with relief of supravalvar stenosis. The long-term results are very good in this group, though ongoing issues with hypertrophic cardiomyopathy affect patients with this association.

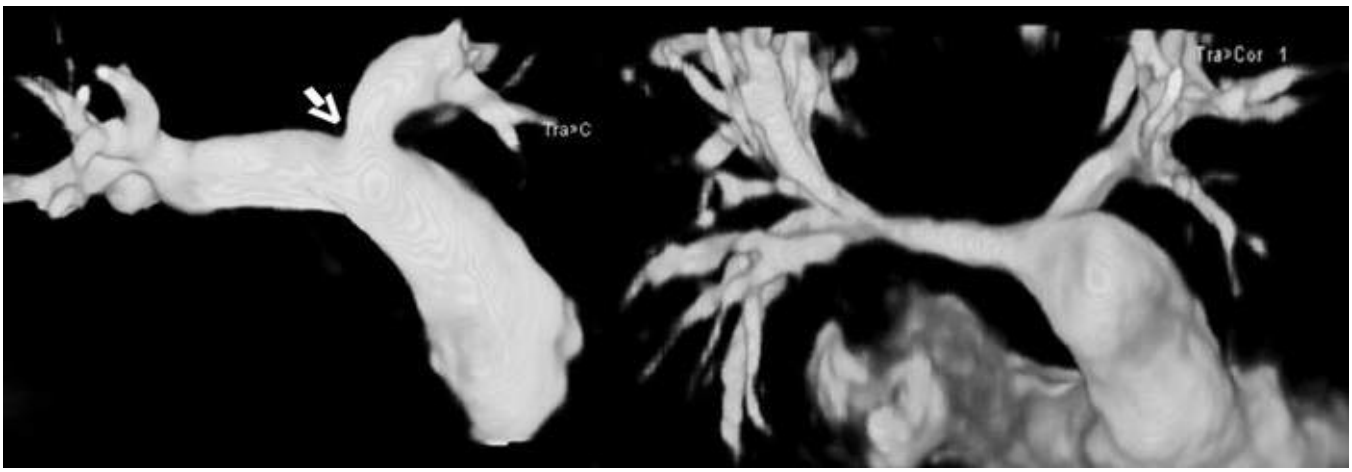
Despite the excellent survival results from the second natural history study (survival rate after surgical valvotomy of 95.7%, compared with sex-matched controls of 96.6%), recent long-term data suggest that this patient population faces ongoing challenges. In one series, after a mean follow-up period of 33 years, 53% of patients had required further intervention and 38% had either atrial or ventricular arrhythmias. In another series after balloon valvotomy, there was a 26% reintervention rate at 20 years, usually for restenosis. A 2012 paper compared outcomes after surgical intervention and balloon pulmonary valvuloplasty.[97] Although the outcomes were very good over the first 20 years, those in the surgical group appeared to have a higher need for surgical reintervention 20 to 40 years after the procedure, compared with those undergoing balloon dilation.

In those with pulmonary atresia and an intact ventricular septum, there is a complex algorithm for determining whether the right ventricle is large enough for an eventual biventricular circulation (sometimes achieved solely by radiofrequency perforation and dilation of the pulmonary valve in the neonatal period) (Video 75.104), or whether a Fontan procedure is the most appropriate approach. In others who had undergone perforation of the pulmonary valve, but who had a persistently small right ventricle, a one-and-a-half ventricle approach is used, which adds a bidirectional cavopulmonary shunt to the circulation.

Although a small percentage of patients follow a late course identical to those with “simple” valve stenosis, many patients with pulmonary atresia and an intact ventricular septum have higher rates of late morbidity and mortality and arrhythmias primarily related to abnormalities of the tricuspid valve, and they also may have consequences of palliative surgery.[98]

Peripheral Pulmonary Artery Stenosis

In patients with peripheral pulmonary artery stenosis, both peripheral pulmonary artery stenosis and an intact ventricular septum are seen (**eFig. 75.10**). It excludes those with an associated VSD, which is dealt with in the sections on tetralogy of Fallot and pulmonary atresia with a VSD. Also excluded is Noonan syndrome.



EFIGURE 75.10 This panel shows two cases with peripheral pulmonary artery stenosis as seen by MRI. The one on the left shows a central proximal left pulmonary artery stenosis, and the right panel shows a case with diffuse stenosis of both branch pulmonary arteries.

Cause

In the past, the most important cause of significant pulmonary artery stenoses producing symptoms in newborns was maternal *rubella infection during pregnancy*.

Peripheral pulmonary artery stenosis is associated with supravalvular aortic stenosis in patients with *Williams syndrome*, which is discussed in the section on supravalvular aortic stenosis.

Peripheral pulmonary artery stenosis is a component of *Alagille syndrome*, with some cases having a *JAG1* mutation.

Isolated branch pulmonary artery stenosis is encountered mainly in the proximal left pulmonary artery and is invariably related to a sling of ductal tissue that causes stenosis when the ductus arteriosus closes after birth. In most cases this is fairly mild, but a significant obstruction resulting in failure of distal growth of the left pulmonary artery may also be seen.

Morphology

Apart from the isolated form mentioned earlier, the stenoses are usually diffuse and bilateral and extend into the mediastinal, hilar, and intraparenchymal pulmonary arteries.

Clinical Features

The degree of obstruction is the principal determinant of clinical severity. The type of obstruction determines the feasibility of intervention. Most patients are asymptomatic. A systolic ejection murmur heard at the upper left sternal border and well transmitted to the axilla and back is most common. No pulmonary ejection click is heard. The pulmonic component of the second heart sound may be accentuated and is loud only if there is proximal pulmonary hypertension. A continuous murmur is often audible in patients with significant branch stenosis. The murmurs in the lung fields are typically increased by inspiration.

Laboratory Investigations

ECG.

Right ventricular hypertrophy is seen when obstruction is severe. Left-axis deviation with counterclockwise orientation of the frontal QRS vector is common in rubella syndrome and when there is also supravalvular aortic stenosis.

Chest Radiography.

Mild or moderate stenosis usually produces normal findings. Detectable differences in vascularity between regions of the lungs or dilated pulmonary artery segments are uncommon. When obstruction is bilateral and severe, right atrial and ventricular enlargement may be seen.

Echocardiography.

Echocardiography is helpful in making the diagnosis and excluding associated lesions; however, it is limited in its ability to image the distal pulmonary arteries beyond the hilum of the lung. Right ventricular pressure assessment may help if there is associated tricuspid valve regurgitation.

MRI and Spiral CT.

These are valuable diagnostic tests because they permit a more distal evaluation of the branch pulmonary

arteries. The advantage of spiral CT in young children is that it can be performed without the need for either heavy sedation or general anesthesia. Although most patients require cardiac catheterization and angiography, these other techniques are excellent for the initial evaluation and for following the progress of the lesions.

Radionuclide Quantitative Lung Perfusion Scan.
This is valuable in cases with unilateral stenosis to determine whether intervention is necessary. Similar flow estimates can now be obtained by MRI.

Cardiac Catheterization and Angiocardiography.
This permits the assessment of right ventricular pressure and the pressures in the pulmonary arterial tree. Angiocardiography is the key to precisely assessing the extent and severity of the stenoses.

Interventional Options and Outcomes

For those cases with isolated left pulmonary artery stenosis where there is less than 30% of flow to the lung, balloon dilation with or without stent insertion is effective in relieving the obstruction. In those cases with more diffuse bilateral stenoses, the indications for intervention depend on the right ventricular pressure. Because the natural history of diffuse peripheral pulmonary artery stenosis in Williams syndrome is one of potential regression over time, intervention is in general reserved for those cases with systemic or suprasystemic right ventricular pressure. Intervention also depends in part on the extent of the stenosis and the dilation capability of the lesions, with or without stenting. In some cases, several attempts at dilation are required to achieve any improvement in vessel caliber. High-pressure balloons are usually necessary, but some lesions cannot be dilated even with such balloons. Recently, improved results have been reported using “cutting” balloons, which may assist dilation in a stenosis that is otherwise not dilatable. As a rule, surgery has little to offer patients with diffuse peripheral pulmonary artery stenoses and can indeed make the situation worse.

Subpulmonary Right Ventricular Outflow Tract Obstruction (Anomalous Muscle Bundles or a Double-Chambered Right Ventricle)

Morphology

A double-chambered right ventricle is formed by right ventricular obstruction due to anomalous muscle bundles. Although this can occur in isolation, it is more frequently part of a combination of lesions that includes right ventricular muscle bundles, a perimembranous-outlet VSD, and subaortic stenosis with or without aortic valve prolapse.

Clinical Features

Most cases are discovered as an incidental finding during the routine follow-up of a VSD. In some cases there may be only a systolic ejection murmur. If the obstruction is isolated, there is a systolic ejection murmur that is heard best in the upper left sternal border. If the VSD is the predominant lesion, the right ventricular outflow tract murmur may not be appreciated. Before the routine use of echocardiography, the diagnosis was often made during follow-up for a VSD when the pansystolic murmur decreased in intensity and a systolic ejection murmur emerged. The patients are usually pink unless there is progression

of the subpulmonary stenosis in the setting of a VSD. The diagnosis may be more problematic in adults.

Laboratory Investigations

ECG.

The ECG is similar to those with isolated pulmonary valve stenosis beyond the newborn period. In cases with a nonrestrictive VSD and mild subpulmonary stenosis, the ECG typically shows biventricular hypertrophy resulting from a left-to-right shunt and associated pulmonary hypertension. If the stenosis is more severe, right ventricular hypertrophy will be seen. Those with a restrictive VSD may have a normal ECG or left ventricular hypertrophy, the latter of which is replaced with right ventricular hypertrophy if the stenosis increases in severity.

Chest Radiography.

This is usually normal in those with isolated subpulmonary stenosis, whereas those with a VSD may have increased or reduced pulmonary blood flow, depending on the severity of the obstruction.

Echocardiography (see Videos 75.48 to 75.52).

Doppler and 2D echocardiography usually provide a complete diagnosis. The level of subpulmonary obstruction is appreciated best in a combination of subcostal right anterior oblique and precordial short axis views. These views permit the identification of the relationship of the VSD to the muscle bundles, as well as the degree of anterior malalignment of the infundibular septum in those with a VSD. The precordial short axis view is best for evaluating the presence of possible subpulmonary stenosis and aortic cusp prolapse. Color and pulsed or continuous-wave Doppler evaluation usually allows differentiation of the VSD flow jet from that originating from the muscle bundles. This permits an accurate assessment of the hemodynamic effect of the subpulmonary obstruction.

Cardiac Catheterization and Angiocardiography.

This technique is rarely necessary. In older patients in whom the echocardiographic images of the subpulmonary region may be suboptimal, a combination of MRI and echocardiography is all that is generally necessary.

Management Options and Outcomes

Management is dictated by the severity of the obstruction and the presence of associated defects. In patients with isolated subpulmonary stenosis, surgery is indicated when the right ventricular pressure is more than 60% of the systemic pressure. This involves resection of the muscle bundles through the right atrium. For those cases with an associated VSD, the decision is based on the size of the VSD, the presence of associated subaortic stenosis, the presence of aortic valve prolapse, and the severity of the right ventricular obstruction. These patients tend to have progressive disease, so many cases that are followed conservatively for several years will eventually require surgery. In general the outcome is excellent, with a low rate of recurrence after surgical resection of obstructive muscle bundles. Infrequently, recurrence of the subaortic obstruction may occur.

Miscellaneous Lesions

Cor Triatriatum

Morphology

In this malformation, failure of resorption of the common pulmonary vein results in a left atrium divided by an abnormal fibromuscular diaphragm into a posterosuperior chamber receiving the pulmonary veins and an anteroinferior chamber giving rise to the left atrial appendage and leading to the mitral orifice. The communication between the divided atrial chambers may be large, small, or absent, depending on the size of the opening(s) in the diaphragm, which determines the degree of obstruction to pulmonary venous return. Elevations of both pulmonary venous pressure and pulmonary vascular resistance may result in severe pulmonary artery hypertension.

Clinical Features

Cor triatriatum is often detected as an incidental finding in a patient who has an echocardiogram for another reason. In general these represent the unobstructed form that requires no early intervention. Patients with more severe obstruction present in a fashion similar to patients with congenital pulmonary vein stenosis.

Laboratory Investigations

ECG.

In unobstructed cases this is normal, whereas in those with significant obstruction there is right ventricular hypertrophy due to the associated pulmonary hypertension.

Chest Radiography.

This may be normal in those with mild obstruction or demonstrate pulmonary edema with significant obstruction.

Echocardiography.

The diagnosis is established by 2D echocardiography or TEE, with further insight from 3D reconstruction. The obstructive diaphragm is visualized in the parasternal long- and short axis and four-chamber views and can be distinguished from a supravalvular mitral ring by its position superior to the left atrial appendage, which forms part of the distal chamber. Also present is diastolic fluttering of the mitral leaflets and high-velocity flow detected by Doppler examination in the distal atrial chamber and at the mitral orifice (Videos 75.105 to 75.107).

Cardiac Catheterization and Angiocardiography.

This technique is usually unnecessary, unless there are concerns regarding the hemodynamic consequences.

Management Options and Outcomes

Surgical resection of the membrane is the treatment of choice for patients with significant obstruction. This results in symptom relief and a reduction of pulmonary artery pressure. In general the outcome following surgery is good. With the advent of more routine use of echocardiography, a subset of cases with typical but nonobstructive forms has been recognized. Thus far these cases appear to remain asymptomatic, with an infrequent need for surgical intervention.

Pulmonary Vein Stenosis

Congenital pulmonary vein stenosis may occur as a focal stenosis at the atrial junction or as generalized hypoplasia of one or more pulmonary veins. The incidence of associated cardiac malformations is extremely high, including VSD, ASD, tetralogy of Fallot, tricuspid and mitral atresia, and AV septal defect. In other cases the pulmonary vein stenosis is acquired after surgical intervention for a total anomalous pulmonary venous connection. Children frequently present with recurrent respiratory infections, whereas adults exhibit exercise intolerance. Pulmonary hypertension is one of the consequences of pulmonary vein stenosis, whether it is congenital or acquired. In cases with unilateral pulmonary vein stenosis, clinical symptoms are frequently absent because there is pulmonary blood flow redistribution away from the affected lung.

Laboratory Investigations

ECG.

The ECG is usually normal unless there is evidence of pulmonary hypertension, in which case right ventricular hypertrophy may be seen.

Chest Radiography.

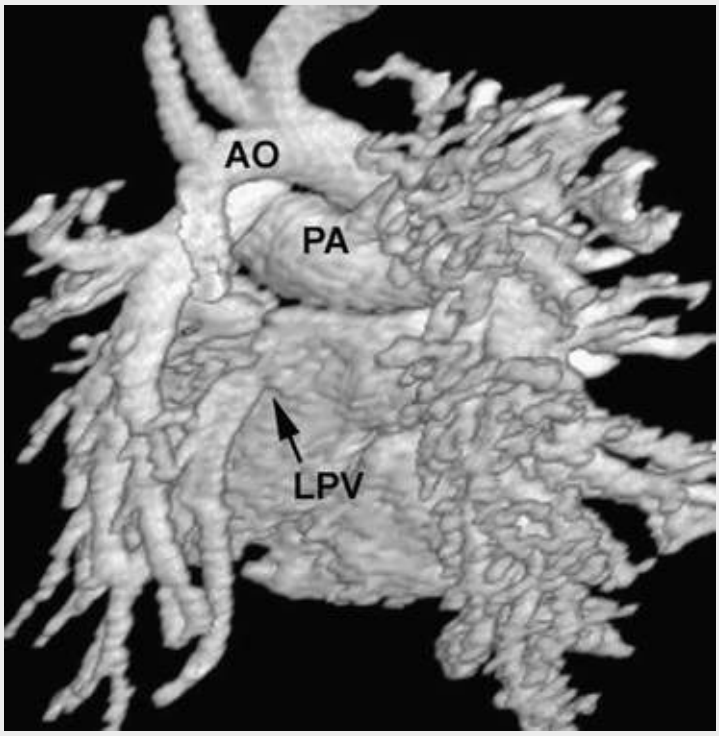
With unilateral pulmonary vein stenosis there is oligemia of the affected lung and increased flow to the contralateral side. If the obstruction is bilateral, pulmonary edema may be seen.

Echocardiography.

This can usually exclude or confirm the diagnosis of pulmonary vein stenosis. Assessment of pulmonary artery pressure from tricuspid or pulmonary valve regurgitation is possible. Doppler color flow assessment of the right- and left-sided pulmonary veins is the best screening tool. If there is evidence of turbulence or aliasing in the color flow pattern, then spectral analysis with pulsed Doppler imaging will help confirm the diagnosis. Usually pulmonary venous flow is of low velocity and phasic. If the pattern is of high velocity and turbulent, there is disturbed pulmonary venous flow. Absolute Doppler gradients may or may not be helpful for two reasons. First, the absolute velocity depends on the amount of pulmonary blood flow to that segment of lung. Second, it is often difficult to obtain a parallel line of interrogation of the pulmonary veins that will affect gradient assessment. The absolute velocity is less important than the diagnosis of pulmonary vein stenosis and its effect on pulmonary artery pressure.

MRI.

MRI has now become the gold standard for the diagnosis of pulmonary vein stenosis (**eFig. 75.11**). It permits a detailed assessment of the pulmonary veins and pulmonary blood flow. Velocity assessment is now possible, though this is in the actual veins themselves rather than at the venoatrial junction, which is the site assessed by Doppler echocardiography.



EFIGURE 75.11 Three-dimensional MRI demonstrating stenosis of the left lower lobe pulmonary vein. *AO*, aorta; *LPV*, left pulmonary vein; *PA*, pulmonary artery.

Cardiac Catheterization and Angiography.
In general a combination of echocardiography and MRI makes invasive procedures unnecessary, unless transcatheter therapy is contemplated.

Management Options and Outcomes

If the patient has unilateral pulmonary vein stenosis and normal pulmonary artery pressure, no treatment may be necessary. Continued follow-up is important because this is often a progressive disease that can subsequently affect both sides. In cases with bilateral stenoses the outlook in the past was believed to be hopeless, with a virtually 100% mortality rate. Stents usually provided only temporary relief. More recently a pericardial reflection procedure (the “sutureless” repair) using native tissue has resulted in some early success for this lesion. This involves using native atrial tissue, pericardium, and pleura to form a pocket around the surgically resected stenotic region.

Pulmonary Arteriovenous Fistula

Abnormal development of the pulmonary arteries and veins in a common vascular complex is responsible for this congenital anomaly. A variable number of pulmonary arteries communicate directly with branches of the pulmonary veins. Most patients have an associated Weber-Osler-Rendu syndrome or complex CHD (e.g., left isomerism); associated problems include bronchiectasis and other malformations of the bronchial tree, as well as absence of the right lower lobe. Pulmonary AV fistulas may also complicate classic Glenn shunts used in the palliation of cyanotic CHD and are believed to be due to the absence of “hepatic factor” in the venous blood feeding the superior vena cava–pulmonary artery connection. Hepatopulmonary syndrome may also be associated with substantial right-to-left intrapulmonary shunting. The amount of right-to-left shunting depends on the extent of the fistulous communications and may result in cyanosis. Paradoxical emboli or a brain abscess may result and cause major neurologic deficits. Patients with hereditary hemorrhagic telangiectasia are often anemic because of repeated blood loss and

may have less obvious cyanosis because of anemia. Systolic and continuous murmurs may be audible over areas of the fistula. Rounded opacities of various sizes in one or both lungs on chest radiography may suggest the presence of the lesion.

Laboratory Investigations

Echocardiography is helpful in the initial diagnostic process with the use of a saline contrast injection into a systemic vein. With pulmonary arteriovenous malformations, there is early pulmonary venous return to the left atrium, but not as quickly as for patients with a PFO or ASD and right-to-left atrial shunting. More recently, CT and MRI techniques have provided valuable diagnostic information. Pulmonary angiography reveals the site and extent of the abnormal communication.

Management Options

Unless the lesions are widespread throughout both lungs, surgical treatment aimed at removing the lesions with preservation of healthy lung tissue is commonly indicated to avoid the complications of massive hemorrhage, bacterial endocarditis, and rupture of arteriovenous aneurysms. Transcatheter balloon or plug or coil occlusion embolotherapy may prove to be the therapeutic procedure of choice in some patients. In patients with underlying CHD, redirecting hepatic venous return to the affected lung can reverse the arteriovenous malformations and improve the hypoxemia.

Coronary Arteriovenous Fistula

Morphology

A coronary arteriovenous fistula is a communication between one of the coronary arteries and a cardiac chamber or vein. The right coronary artery (or its branches) is the site of the fistula in about 55% of patients; the left coronary artery is involved in about 35%; and both coronary arteries are involved in a few. Connections between the coronary system and a cardiac chamber appear to represent persistence of embryonic intertrabecular spaces and sinusoids. Most of these fistulas drain into the right ventricle, right atrium, or coronary sinus. Coronary–to–pulmonary artery fistulas are an occasional and usually incidental finding during coronary angiography.

Clinical Features

The shunt through the fistula is usually small, and myocardial blood flow is not compromised. Potential complications include pulmonary hypertension and congestive heart failure if a large left-to-right shunt exists, bacterial endocarditis, rupture or thrombosis of the fistula or of an associated arterial aneurysm, and myocardial ischemia distal to the fistula due to a “myocardial steal.”

Most pediatric patients are asymptomatic and are referred because of a cardiac murmur that is loud, superficial, and continuous at the lower or midsternal border. The site of maximal intensity of the murmur is related to the site of drainage and is usually away from the second left intercostal space, which is the classic site of the continuous murmur of persistent ductus arteriosus.

Laboratory Investigations

ECG.

This is usually normal unless there is a large left-to-right shunt.

Chest Radiography.

Radiographic findings are often normal and seldom show selective chamber enlargement.

Echocardiography.

Coronary artery fistulas are now recognized with a high degree of accuracy with the advent of routine coronary artery evaluation during most pediatric echocardiography examinations. A significantly enlarged feeding coronary artery can be detected, and the entire course and site of entry of the arteriovenous fistula can be traced by Doppler color-flow mapping. The shunt entry site is characterized by a continuous turbulent systolic and diastolic flow pattern. Multiplane TEE also accurately defines the origin, course, and drainage site of the fistula.

Cardiac Catheterization and Angiocardiography.

If echocardiography demonstrates a significant coronary artery fistula, hemodynamic evaluation and possible intervention are warranted. Standard retrograde thoracic aortography, balloon occlusion angiography of the aortic root with a 45-degree caudal tilt of the frontal camera ("laid back" aortogram), or coronary arteriography can be used reliably to identify the size and anatomic features of the fistulous tract.

Management Options and Outcomes

Small fistulas have an excellent long-term prognosis. Untreated larger fistulas may predispose the individual to premature coronary artery disease in the affected vessel. Coil embolization at the time of cardiac catheterization is rapidly becoming the treatment of choice (Video 75.108). Surgical treatment is still required in some instances.

Catheter-Based Treatment of Congenital Heart Disease in Adults

John M. Lasala, David T. Balzer

The number of adults living with congenital heart disease has been steadily increasing, with recent estimates suggesting that adults now outnumber children with the disease (**see Chapter 75**). As this population continues to grow, the number of adults requiring intervention for the disease increases. Congenital heart disease is extremely variable and involves all aspects of cardiovascular physiology such that specialized training has become a necessity for anyone caring for these patients. Indeed, the most recent American College of Cardiology/American Heart Association (ACC/AHA) guidelines state that interventions for adults must be performed at regional adult congenital heart disease centers of excellence by providers with “expertise in the surgical and transcatheter management of patients with congenital heart disease.”[1] In addition, because of the complexity of disorders in these patients, any site undertaking the care of adults with congenital heart disease must have a well-established multidisciplinary team that includes congenital cardiothoracic surgeons, cardiac anesthesiologists, cardiac intensivists, and congenital cardiologists.[1] Pediatric interventional cardiologists are also key persons on the team, and

partnerships between adult congenital interventionalists and pediatric interventional cardiologists are mandatory. As the capabilities of the congenital catheterization laboratory continue to evolve, the line between surgical and catheter-based interventions will become more and more blurred. Many interventions already take place in highly specialized hybrid operating suites in which interventional cardiologists work alongside their cardiothoracic surgery colleagues. This combined model of intervention will continue to be adapted for adult congenital interventions, and it is this ongoing evolution that makes the field so exciting. Furthermore, as interventional approaches change, the indications for intervention become a "moving target." As a result, national guidelines may become outdated sooner than in decades past; therefore, interventional cardiologists who treat adults must remain knowledgeable about the ever-changing medical literature on this topic. In this chapter we review major areas in which catheter-based interventions have become well established for adults with congenital heart disease. The topic of congenital heart disease in adults is reviewed in **Chapter 75**.

Valvular Interventions

The first static pulmonary balloon valvuloplasty was performed in 1982; successful catheter-based interventions have since been performed on all types of cardiac valves.[2] Although valvuloplasty defined the early era of congenital interventional catheterization, valve replacement is defining the current era.

Pulmonary Valvuloplasty

In "typical" pulmonary valve stenosis, there are normal valve leaflets with limited valve excursion resulting from partial fusion. Static pulmonary valvuloplasty, which aims to separate the fused leaflets, was first performed in the early 1980s and has since replaced surgical valvotomy as the initial intervention in cases of typical isolated valvar pulmonary stenosis.[3] Valvuloplasty for thick and/or dysplastic valves is less successful; moreover, balloon dilation will be unsuccessful in relieving any muscular subvalvar stenosis. Indications for pulmonary valvuloplasty in adults with congenital heart disease has been outlined elsewhere (**see Chapter 75**).[1] Before pulmonary valvuloplasty is performed, a complete right heart catheterization should be performed, followed by right ventricular (RV) angiography, to profile the right ventricular outflow tract (RVOT). Angiographic measurements of the pulmonary annulus allow for selection of the appropriately sized balloon, which is approximately 120% of the measured pulmonary annulus. Successful balloon valvuloplasty can usually be achieved with hand inflation of the selected balloon. After dilation of the pulmonary valve, repeat angiography should be performed to rule out vascular injury and assess the degree of pulmonary regurgitation.

Outcomes and Complications

Case selection is critical for optimizing outcomes. Patients with typical pulmonary valve stenosis will have relatively thin leaflets with partial fusion and will respond well to balloon valvuloplasty.[4] The most common complication for pulmonary valvuloplasty is pulmonary regurgitation (<10% with 2+ or greater pulmonary regurgitation), which is usually well tolerated. Major adverse events or unplanned surgeries were not reported for patients with typical valvar stenosis in the most recent report from the National Cardiovascular Data Registry (NCDR).[4]

Pulmonary Valve Replacement

The pulmonary valve is a semilunar valve separating the right ventricle from the main pulmonary artery. It allows for unobstructed right ventricular ejection while maintaining pulmonary arterial diastolic pressure via competent leaflet coaptation. Unfortunately, many patients with congenital heart disease have pulmonary valve disease involving stenosis or regurgitation, or a combination of both. Furthermore, bioprosthetic valves that are implanted in infants to reconstruct the right ventricular outflow tract will invariably fail. The largest anatomic subcategory of "severe" congenital heart disease in adults is tetralogy of Fallot,[5] in which the surgical repair leaves patients with severe pulmonary regurgitation and variable degrees of RVOT obstruction. Over time, pulmonary valve disease will be manifested by symptoms (e.g., exercise intolerance, congestive heart failure, dysrhythmias) heralding significant RV dysfunction. In an effort to avoid such dysfunction, relief of stenosis and placement of a competent valve are warranted. Determining the optimal timing for pulmonary valve replacement continues to be an issue; there are currently several indications in symptomatic[1] and asymptomatic[6] patients with pulmonary valve disease (**see Chapter 75**).

Pulmonary Valve Systems

There are currently two available valve systems approved by the Food and Drug Administration (FDA) for use in the pulmonary valve: Melody Transcatheter Pulmonary Valve (Medtronic, Inc., Minneapolis) and SAPIEN XT Pulmonic Valve (Edwards Lifesciences, Irvine, CA). Each has its own unique strengths and weaknesses.

Melody Valve

Developed by Dr. Philipp Bonhoeffer in conjunction with Medtronic, the Melody valve (**Fig. 76.1**) has a bovine jugular vein valve sutured to a platinum-iridium stent frame and is deployed by the proprietary Ensemble delivery system. The valve is available in two sizes, approved for use in circumferential right ventricular–pulmonary artery (RV-PA) conduits with original implant diameters of 16 to 22 mm. Numerous reports have described its off-label use in native RVOTs and failed bioprosthetic valves,[7,8] and some authors have demonstrated good valve function at implant diameters of up to 24 mm.[9] With a maximal implant diameter of 24 mm, the Melody valve's most significant limitation is size. In addition, because the valve is harvested and not manufactured, there are natural limitations to its supply. The strength of the valve is primarily in the design of the Ensemble delivery system, which covers the valve until it is positioned in the RV-PA conduit and employs a balloon-in-balloon catheter, making delivery easy to control and predictable.

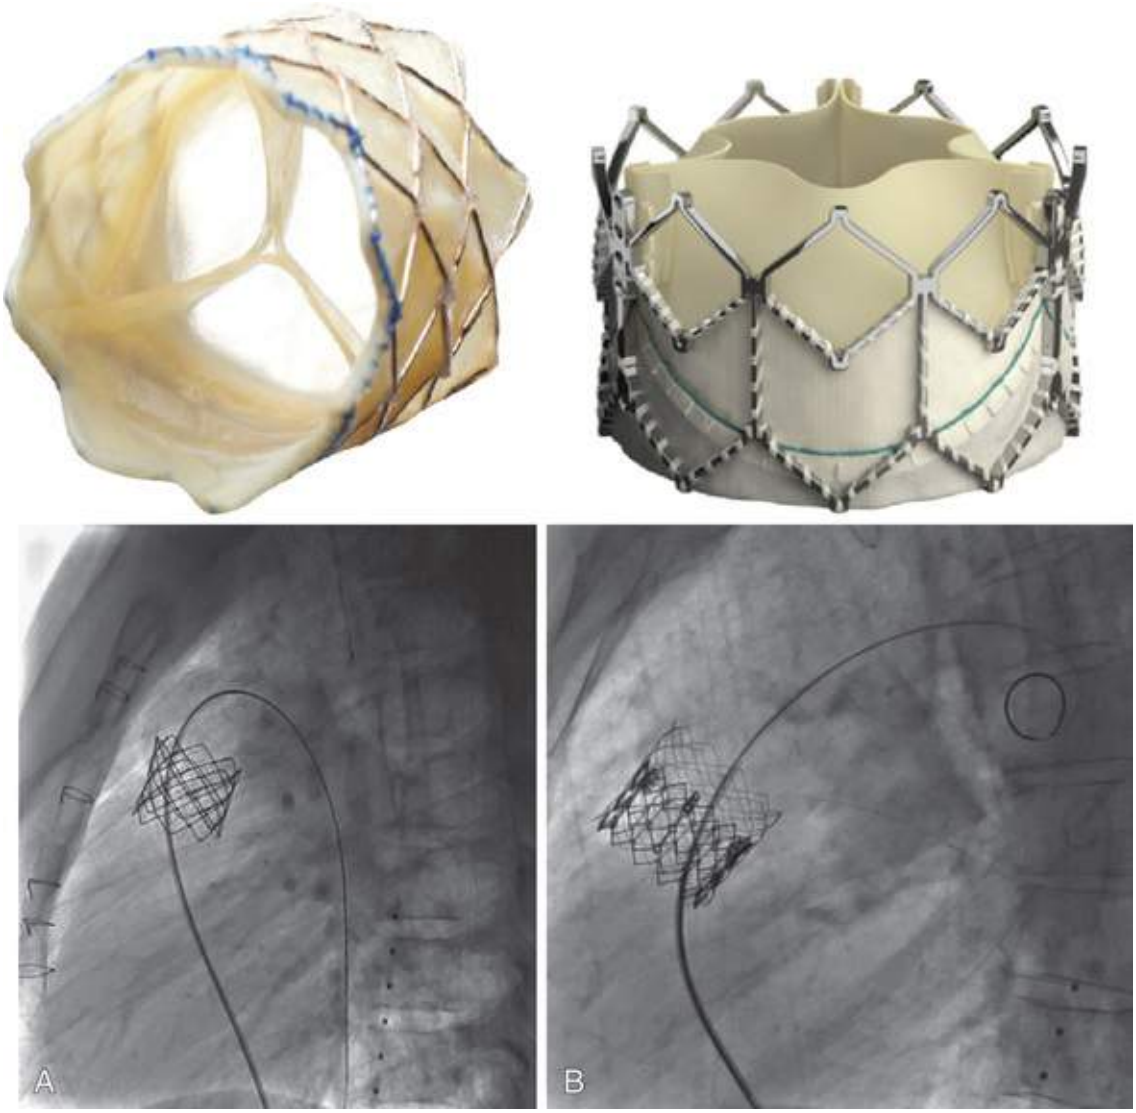

FIGURE 76.1 FDA-approved transcatheter valves and fluoroscopic appearances on lateral projection. **A,** Melody valve (Medtronic, Minneapolis). **B,** Edwards SAPIEN XT valve (Edwards Lifesciences LLC, Irvine, CA).

SAPIEN Valve

Originally designed for the treatment of aortic valve disease and validated in the PARTNER trial,[10] the SAPIEN XT transcatheter balloon expandable prosthesis (**see Fig. 76.1**) has only recently been approved for use in the pulmonary position. Since its introduction in the early 2000s, the valve has undergone modifications to improve its safety profile and procedural outcomes.[11] The SAPIEN 3 valve is the newest iteration; it is characterized by a trileaflet valve created with bovine pericardium and treated with the same patented ThermaFix process as the Carpentier-Edwards surgical valves. In contrast to the Melody system, the Edwards family of valves have demonstrated superior radial strength and a wider range of sizes (approved for use in conduits with a diameter of 18 to 28 mm), but their delivery systems are more difficult to maneuver.

Outcomes and Complications

The Melody valve has been approved by the FDA since 2010. Early[12] and intermediate[13] outcome data have demonstrated excellent procedural success and freedom from RVOT reintervention at rates of 98% at 3 years and 91% at 5 years. SAPIEN valves have had similarly good early outcomes[14] and have had favorable comparisons with the Melody valve.[15] Important procedural complications include vascular

injury, conduit disruption, pulmonary artery perforation, stent or valve embolization, coronary artery compression, ventricular arrhythmias, and tricuspid valve injury.[8] Long-term complications include stent frame fracture, valve dysfunction, and endocarditis.[8,13,16,17]

Arterial Interventions

The pathologic “arterial” conditions encountered most frequently by congenital interventionalists are related to anatomic lesions in the pulmonary arterial tree, followed by coarctations of the aorta. As in other interventional areas, technologic advances have increased the breadth of catheter-based treatments for congenital heart disease, as well as the quality and durability of the outcomes. In adult patients, stenting has become a well-established companion to angioplasty, and has improved acute and long-term outcomes.

Pulmonary Angioplasty

A myriad of congenital heart lesions involve pulmonary artery disorders; moreover, many congenital heart surgeries involve RV-PA conduits, systemic-pulmonary arterial shunts, and pulmonary artery (PA) bands that distort the normal PA anatomy. As a result, many patients are left with fixed obstructions to the pulmonary blood flow. Depending on the location of the obstruction, these lesions can result in elevated RV pressure or significant flow discrepancies between lung segments. Over time, these obstructions can have deleterious effects on RV function and the pulmonary vasculature. Indications for pulmonary arterial intervention have been described elsewhere (**see Chapter 75**).[1] There are currently no stents approved by the FDA for use in pulmonary arteries; however, Palmaz Genesis stents (Cordis, Milpitas, CA) and the EV3 family of stents (Covidien/Medtronic, Minneapolis) have been used and have shown good radial strength, a low profile, and achievable diameters. In children or in small or distal pulmonary arteries in adults, it is reasonable to use premounted stents.

Outcomes and Complications

The heterogeneous nature of pulmonary arterial disease has resulted in a wide spectrum of clinical outcomes following catheter-based interventions. Both the anatomic location of the stenosis and its circumstances of formation as a congenital or postoperative feature have contributed importantly to the differences in clinical outcomes. Complications include vascular tears, stent embolization or malpositioning, pulmonary edema, and the need for unanticipated procedures or surgeries; some patients may not survive. Several reviews from Boston Children's Hospital have described the differences between proximal and distal lesions,[18] as well as the effectiveness of using cutting and/or high-pressure balloons for resistant lesions.[19] A report from the NCDR revealed reasonable safety; in 245 procedures across all age-groups, adverse events were reported in 13.2% of cases and major adverse events in 1.2% of cases, and two patients died.[4]

Stenting for Coarctation of the Aorta

Coarctation of the aorta is a narrowing in the normal dimensions of the aortic arch (**see Chapter 75**). Coarctations usually occur around the isthmus of the aorta, where the ductus arteriosus was once inserted. The increase in afterload imposed by the coarctation can result in left ventricular (LV) dysfunction and

cardiogenic shock, which often develop in early infancy. More frequently, the body develops extensive collaterals through the chest wall, which minimize the increase in afterload and preserve systolic function. Over time, patients with coarctation will develop hypertension to varying degrees and, eventually, coronary artery disease and LV diastolic dysfunction.[20] Treatment of coarctation has traditionally required cardiothoracic surgery; however, catheter-based treatments have been evolving. Coarctation stenting is typically performed in a retrograde approach via the femoral artery. After measuring the baseline gradient, angiography is performed and measurements are taken of the distal aortic arch and thoracic aorta (at the level of the diaphragm). The covered Cheatham pulmonary (CP) stent (NuMED, Inc., Hopkinton, NY) is approved by the FDA for use in coarctation, but other stents have been frequently used off-label. The diameter of the implanted balloon should be no larger than that of the surrounding aorta or 3.5 times the narrowest dimension.[21] Stents are most frequently placed by balloon-in-balloon catheters because of the improved control. Once a stiff guidewire is positioned across the coarctation, a long sheath is positioned above the narrowed area and a mounted stent advanced into position at the site of coarctation. The stent is uncovered and deployed with inflation of the balloon catheter. After successful placement of the stent, additional serial dilations of any residual waist may be considered. Follow-up angiography should be performed to rule out dissection or aneurysm before measuring the final pressure gradient. Indications for coarctation intervention are discussed elsewhere (**see Chapter 75**).[1] Comparisons between balloon angioplasty, aortic stenting, and surgical resection have been done, and catheter-based stenting has emerged as the preferred treatment modality for older children and adults.[20]

Outcomes and Complications

Coarctation stenting is safe and compares favorably with surgery in regard to elimination of the pressure gradient.[4,20-23] The NCDR report noted more frequent stenting in older children and adults, with nearly 84% of stented patients achieving a postprocedural gradient of less than 10 mm Hg.[4] Complications include access injuries, vascular tears or dissections, stent embolization or malpositioning, restenosis, and aneurysm; death may result. For adults in the NCDR, 8.6% experienced an adverse event, but only one major adverse event occurred in 92 patients.[4] Long-term follow-up will continue to reveal the true risk of late aneurysm and restenosis in these patients. For children who are not fully grown, future dilations to keep pace with somatic growth should be anticipated.

Septal Interventions

Techniques for Closure of Atrial Septal Defects

Atrial septal defects (ASDs) are the third most common form of congenital heart disease. They occur in 56 to 100 live births per 100,000 infants.[24] Isolated ASDs will result in left-to-right shunting, with the magnitude of the shunt determined by ventricular compliance and atrioventricular valve stenosis. Significant left-to-right shunts result in RV dilation; if they are left unrepaired, they may ultimately result in pulmonary arterial muscularization and elevations in the pulmonary vascular resistance by the sixth decade of life.[24] In an effort to avoid irreversible changes in pulmonary vascular resistance, early closure of significant ASDs has become standard practice.[24] Transcatheter devices and techniques have evolved substantially since the first case was reported in 1976 by King and colleagues. The currently available devices each have unique strengths and weaknesses (**Fig. 76.2**).[24] Indications for intervention have been previously outlined.[1]

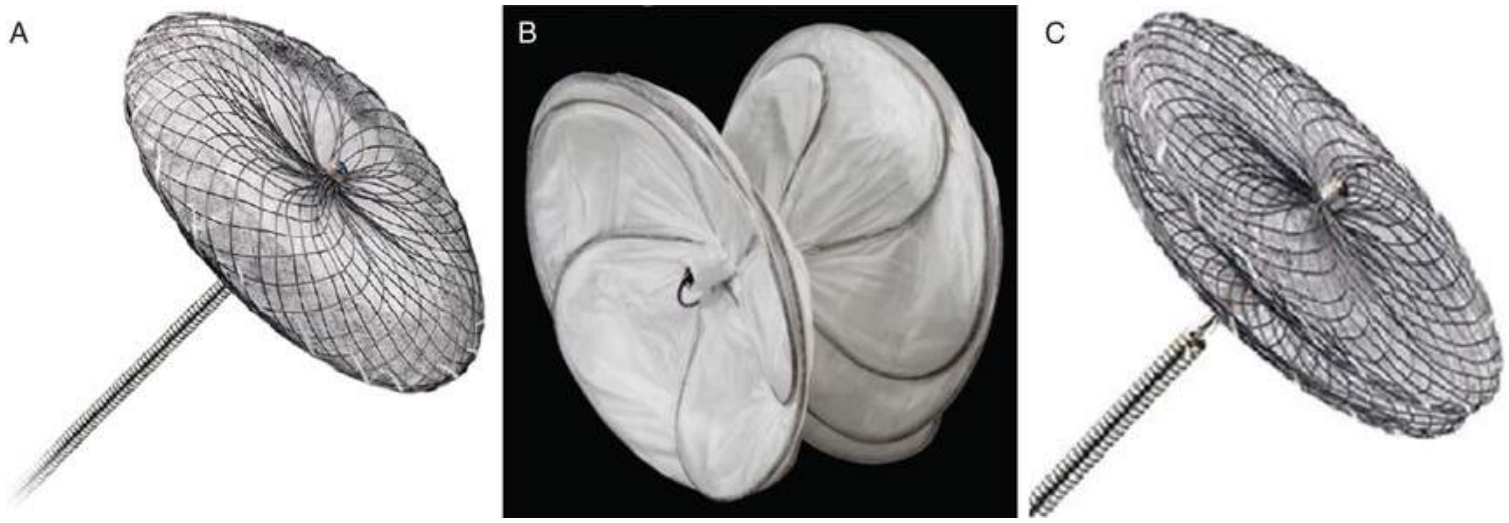

FIGURE 76.2 Various closure devices for atrial septal defects. **A,** Amplatzer Cribriform device (St. Jude Medical, St. Paul). **B,** GORE Cardioform Septal Occluder (W.L. GORE and Associates, Inc., Flagstaff, AZ). **C,** Amplatzer Septal Occluder (St. Jude Medical, St. Paul).

Amplatzer Devices

Originally introduced in the mid-1990s, the Amplatzer Septal Occluder (ASO) (St. Jude Medical, Inc., St. Paul) has been used in thousands of cases across the globe. The ASO is made of woven Nitinol wire that forms a self-centering device, with left and right atrial discs and a central waist. The device is filled with interwoven Dacron polyester fibers to facilitate platelet aggregation and endothelialization. The device is secured to a delivery cable and introduced into the left atrium via the appropriately sized, proprietary TorqVue sheath. ASOs can treat ASDs of many sizes as long as the atrial septal rim is substantial enough that the device can be placed securely. If the septal rim is deficient (<5 mm in contiguous zones), stable positioning will be more difficult to achieve and at times may not be possible. Numerous deployment techniques can be used if the septal rim is deficient, but they are outside the scope of this chapter and are described elsewhere.[25-27] Shortly after the introduction of the ASO, Amplatzer developed the Multi-Fenestrated Septal Occluder, or Cribriform device. In contrast to the ASO, the Cribriform device does not have a waist and is therefore not self-centering. Its primary benefit, therefore, is that it can be placed in a small central defect and also covers numerous satellite defects. Its deployment is identical to that of the ASO, using the same TorqVue sheaths and delivery cables.

Outcomes and Complications

When compared with surgery in the US Pivotal Trial, the ASO demonstrated superior safety and statistically similar closure rates. The postmarket approval study and multicenter community use trial have further solidified the ASO's position as a safe and effective device for transcatheter closure of an ASD or a patent foramen ovale.[28,29] Major adverse events reported include arrhythmias, device embolization, device erosion, device fracture, stroke, and left arterial thrombus. One of the most significant adverse events is device erosion. After the first reported case in 2002, AGA/St. Jude revised the ASO instructions for use, but erosions continued to be reported to the Manufacturer and User Facility Device Experience (MAUDE) database. In response to ongoing erosion reports (<0.05% of worldwide sales, estimated to be ≈ 0.1% of implants), the FDA and AGA/St. Jude made additional changes to the instructions for use in an effort to minimize the erosion risk, and recommended closer follow-up with more frequent echocardiograms. In addition to erosion, several case reports in children and adults have demonstrated delayed endothelialization in the setting of endocarditis, and concerns have been raised

regarding the optimal length of time for subacute bacterial endocarditis prophylaxis following device placement.[30]

GORE Devices

The GORE Helex device (no longer commercially available) was approved in 2006. It was not self-centering and therefore was relatively limited with regard to the sizes of defects it could effectively treat (i.e., the device had to be two times the diameter of the defect). The original Helex delivery system was cumbersome, and the device was arguably too flexible, so GORE redesigned its septal occluder system. It is now marketed as the GORE Cardioform Septal Occluder (GSO) (W.L. Gore and Associates, Flagstaff, AZ). The new device consists of a five-wire Nitinol frame, which adds radial strength and improves structural integrity, and it is covered with the same expanded polytetrafluoroethylene (ePTFE) membrane as the original Helex device. The redesigned delivery system is much more intuitive, and it maintains its novel retention cord mechanism. Because of its non–self-centering design, the GSO can only close defects up to 18 mm in diameter.

Outcomes and Complications

The GSO was approved by the FDA in 2012 and has demonstrated comparable safety and efficacy to the ASO in closure of patent foramen ovale and ASD.[31-33] GORE is currently conducting a prospective, randomized, multicenter, multinational trial (REDUCE Clinical Study [NCT00738894]) comparing the risk of recurrent cryptogenic stroke in patients who undergo patent foramen ovale closure with the GSO and are also given antiplatelet medications versus patients who receive antiplatelet medications only. In contrast to the ASO, there has never been a report of device erosion following implantation of a GORE device. Overall, percutaneous device placement has established itself as the preferred intervention for ASDs because of its excellent outcomes and safety record.[34]

Techniques for Closure of Ventricular Septal Defects

Ventricular septal defects (VSDs) are the most common congenital heart defects and can range in size from tiny pinholes to near absence of the septum (**see also Chapter 75**).[35] VSDs can be an isolated finding or associated with other complex congenital heart diseases, primarily conotruncal defects (e.g., tetralogy of Fallot, double-outlet right ventricle, transposition of the great arteries). The ventricular septum has four primary regions: inlet, outlet, perimembranous area, and muscular area, and defects can occur in any location and extend to adjacent regions. The shunt through a VSD is predicated on ventricular outflow obstruction and downstream vascular resistance. The management of VSD is a complex topic beyond the scope of this chapter, and indications for intervention have been previously described (**see Chapter 75**).[1] Catheter-based device closure of muscular, traumatic, postoperative residual, and postinfarct VSDs has become a reasonable alternative to surgery. Perimembranous VSD remains controversial because of the associated risk of heart block. Inlet VSDs are not amenable to transcatheter techniques, because there is no circumferential tissue on which to securely “land” a device.[35,36]

Outcomes and Complications

Complications specific to transcatheter device closure of VSDs include aortic regurgitation, tricuspid regurgitation, rhythm disturbances, and atrioventricular (AV block); death occurs rarely. In a review of the European registry of transcatheter VSD devices, Carminati and associates[37] found that VSDs in the

perimembranous location were at increased risk for developing complete AV block. When similar devices have been used, others have found similar rates of AV block, ranging from 2% to 6%.[38-40] Interestingly, a lower risk of AV block has been seen in some cases when the first-generation Amplatzer ductal occluders have been used.[41]

Treatment of Patent Ductus Arteriosus

Patent ductus arteriosus is a frequent congenital heart defect that is most commonly detected in infancy because of the associated murmur (**see also Chapter 75**). The ductus arteriosus is a fetal remnant of the sixth arch connecting the pulmonary artery to the lesser curvature of the aortic arch; it directs the RV output preferentially into the descending aorta. After birth, several important physiologic changes (loss of circulating placental prostaglandins and increased oxygen tension) lead to early functional closure of the ductus followed by anatomic closure in the following weeks to months. For patients in whom the ductus remains patent, the elevation in systemic vascular resistance and drop in peripheral vascular resistance promotes a left-to-right shunt with resultant pulmonary overcirculation and left heart dilation. Left untreated, a patent ductus arteriosus (PDA) can lead to significant heart failure, atrial arrhythmias (secondary to atrial hypertension), and pulmonary hypertension. Rarely, the PDA can be a site for infective endarteritis.[42] Prior to catheter-based interventions, significant PDAs were ligated surgically via posterolateral thoracotomy. Indications for intervention have been outlined elsewhere.[1] From the earliest reports of catheter-based closure in 1967, numerous devices have been introduced to treat the various morphologic differences in ductal anatomy. From coils, to vascular plugs, to dedicated occlusion devices, the interventionalist has multiple options for PDA occlusion (**Fig. 76.3**). There is consensus regarding the indication for closure in a large PDAs with associated left heart dilation, but there is current controversy with respect to the need for closing "silent" PDAs.[43]

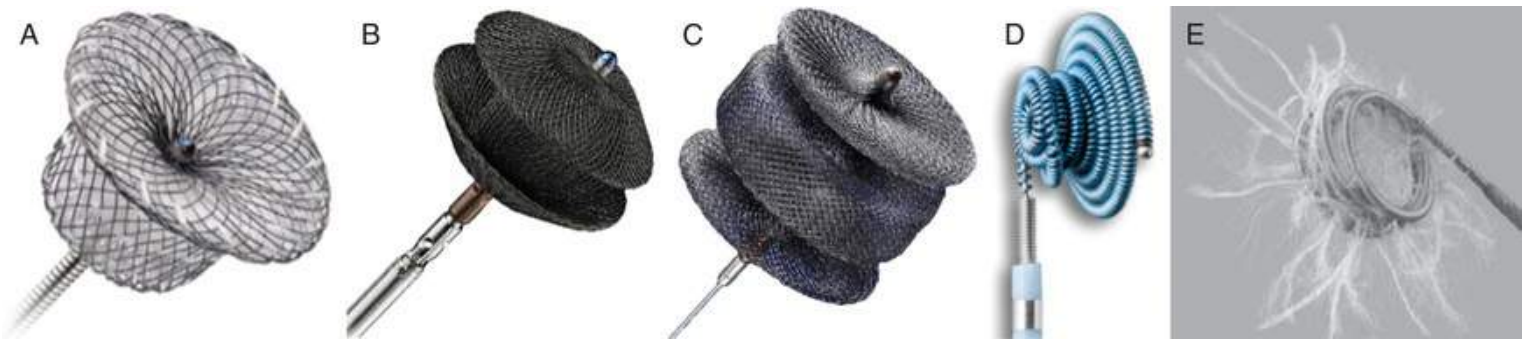

FIGURE 76.3 Various closure devices for patent ductus arteriosus. **A,** Amplatzer Ductal Occluder (St. Jude Medical, St. Paul). **B,** Amplatzer Ductal Occluder II (St. Jude Medical, St. Paul). **C,** Amplatzer Vascular Plug II (St. Jude Medical, St. Paul). **D,** Nit-Occlud PDA Occluder (PFM Medical AG, Köln, Germany).

Amplatzer Duct Occluders (First- and Second-Generation)

The ADO-I device is made of a Nitinol wire mesh packed with Dacron polyester fabric to facilitate platelet aggregation and endothelialization. The second-generation ADO-II has symmetric retention skirts, which allow it to be placed in an antegrade or a retrograde fashion. The ADO-II is not packed with polyester fibers, because the Nitinol wire weave is tighter than in the ADO-I.

Amplatzer Vascular Plugs (Second- and Fourth-Generation)

In patients with long, tubular ducts, a vascular plug may be the optimal occlusion device. The vascular plugs have a conveniently low profile and work well in ducts with sufficient length to ensure that the left pulmonary artery and aorta are not obstructed. The AVP-II has a wide assortment of sizes (3 to 22 mm). The AVP-IV has fewer available sizes (4 to 8 mm) and is slightly longer than AVP-II, but it offers an even lower profile, so that it can navigate tortuous anatomy with ease.

Nit-Occlud Device

The Nit-Occlud device (PFM Medical, Carlsbad, CA) has a single Nitinol wire coil, which can be wound in a funnel shape when it is advanced from the catheter. The Nit-Occlud device can be delivered via a 4 Fr guide catheter with a controlled-release mechanism. The Nit-Occlud comes in multiple sizes with variable levels of wire stiffness.

Standard Coiling

After small ducts have been crossed, they can be reliably occluded with simple coils or detachable coils.

Outcomes and Complications

Transcatheter closure of PDA has become a reliable procedure with excellent technical success and good efficacy.[4] Numerous articles have reviewed the outcomes of detachable coils and the Amplatzer devices and found the overall closure rate to be approximately 94%.[43] Chinese reviews of 1500 patients have reported technical success rates of 99% and occlusion rates of 100% at 6-month follow-up.[44] Serious adverse events are extremely rare.[4] Minor complications, including vascular injuries, device embolization, residual shunts, blood loss requiring transfusion, hemolysis, and aortic or pulmonary artery narrowing not requiring intervention, occur in the youngest patients, but rarely in adults.[4]

Future Perspectives

The transcatheter management of structural congenital heart disease in adults has undergone rapid advances over the past decade. Pulmonary valve implants have become a mainstay of therapy for patients with pulmonic valve stenosis and/or regurgitation. Valve-in-valve implants appear likely to play an important role in managing degenerative bioprosthetic valves.

These therapies can be expected to evolve rapidly, as can other new, unexpected, and sophisticated approaches to the transcatheter management of structural heart disease. Current trials regarding the Edwards valve-in-valve registry for mitral and aortic valves are ongoing. The Medtronic Evolute R has approval for aortic valve-in-valve procedures.

Acknowledgment

The authors gratefully acknowledge the contribution of Dr. Toby A. Rockefeller in the writing of this chapter.

The Dilated, Restrictive, and Infiltrative Cardiomyopathies

Rodney H. Falk, Ray E. Hershberger

There is, at present, no universal definition of cardiomyopathy. Even though it is now agreed that myocardial disease secondary to atherosclerotic coronary artery disease, valvular disease, congenital heart disease, and systemic hypertension should not be classified as a cardiomyopathy, opinion differs as to whether the condition should be defined on the basis of morphology and whether molecular disturbances such as the channelopathies should be included. An American Heart Association definition[1] describes cardiomyopathies as "a heterogeneous group of diseases of the myocardium associated with mechanical and/or electrical dysfunction that usually (but not invariably) exhibit inappropriate ventricular hypertrophy or dilation and are due to a variety of causes and frequently are genetic. Cardiomyopathies either are confined to the heart or are part of a generalized systemic disorder often leading to cardiovascular death or progressive heart failure–related disability." This classification includes patients with predominantly electrical dysfunction of the heart, a group not included in a European Working Group definition.[2] Both U.S. and European experts, however, have recognized the growing importance of genetics in patients with cardiomyopathy since these position papers were released.

The ability to combine genetic information with phenotypic information regarding both left ventricular (LV) and right ventricular (RV) structure and function forms the basis of cardiovascular genetic medicine (**Fig. 77.1**). Clinical genetic testing in patients with cardiomyopathies not only benefits asymptomatic patients and family members through proper cascade risk assessment, but may also enhance the care of symptomatic patients, as it is likely that in the near future, genomic information will both predict the natural history and guide therapy. The expansion of clinical genetic testing that has been made possible by next-generation sequencing also brings new challenges in terms of knowing which tests to order, how to conduct pretest counseling and obtain consent, and how to interpret molecular genetic test results. **Table 77.1**[3,4] presents an overview of the classification of cardiomyopathies based on phenotypic (the "phenome") and genetic information. The phenome includes data on cardiac morphology, physiology, and cellular and molecular pathology, as well as on other aspects of the environment relevant to the specific disease in question.[5] Despite the integration of genetics and genomics, the phenotypic information derived from information about LV and RV chamber size and function remains highly relevant in terms of clinical care despite the absence of universally accepted cardiomyopathy definitions. Numerous genes, having had rare variants reported in association with one or more of the genetic cardiomyopathies, have now been noted, and some genes have been reported to cause more than one phenotype (**Fig. 77.2**) Although this chapter focuses primarily on nonsyndromic cardiomyopathies, there are multiple syndromes in which a cardiomyopathy develops in concert with multiorgan system involvement. Hypertrophic cardiomyopathy (HCM; **see Chapter 78**) is also mentioned briefly herein because of its significant genetic overlap with dilated cardiomyopathy (DCM) and restrictive cardiomyopathy (RCM). It is also important to recognize that although myocardial dysfunction as a result of hypertension and ischemic heart disease must be differentiated from the cardiomyopathies, the diseases often coexist and may aggravate an underlying primary cardiomyopathy.

FIGURE 77.1 Interaction of genome and phenome. The *arrow* depicts the bimodal interaction between genes and the environment, or the genome and phenome. The goal of human genetic studies has always been to understand genomic variation and its impact on phenotypes, and vice versa. Genetic and genomic effects in cardiovascular diseases are now becoming integrated into the practice of cardiovascular medicine.

TABLE 77.1

Classification of the Cardiomyopathies by Phenome and Genome

TYPE	PHENOME			GENOME		
	Morphology	Physiology	Pathology	Systemic Conditions, Clinical Features, Risk Factors	Nonsyndromic, Usually Single Gene	Syndromic
Dilated (DCM)	Dilation of LV and RV with minimal or no wall thickening	Reduced contractility is the primary defect; variable degree of diastolic dysfunction	Myocyte hypertrophy; scattered fibrosis	Hypertension; alcohol; thyrotoxicosis, myxedema; persistent tachycardia; toxins (e.g., chemotherapy, especially anthracyclines); radiation	Diverse gene ontology (**see Fig. 77.2**) with >30 genes implicated (**see also eTable 77.1**)	Diverse array of associated conditions, especially muscular dystrophies: Emery-Dreifuss muscular dystrophy, limb-girdle muscular dystrophy, Duchenne/Becker muscular dystrophy; Laing distal myopathy; Barth syndrome; Kearns-Sayre syndrome; others[3,4]
Restrictive (RCM)	Usually normal chamber sizes; minimal wall thickening	Contractility normal or near-normal with a marked increase in end-diastolic filling pressure	Specific to type, diagnosis: amyloid, iron, glycogen storage disease, others	Endomyocardial fibrosis, amyloid, sarcoid, scleroderma, Churg-Strauss syndrome, cystinosis, lymphoma, pseudoxanthoma elasticum, hypereosinophilic syndrome, carcinoid	If not associated with systemic genetic disease, genetic cause usually from sarcomeric gene mutations (**see eTable 77.1**)	Gaucher disease, hemochromatosis, Fabry disease, familial amyloidosis; mucopolysaccharidoses, Noonan syndrome
Hypertrophic (HCM)	Usually normal or reduced internal chamber dimension; wall thickening pronounced, especially septal hypertrophy	Systolic function increased or normal	Myocyte hypertrophy, classically with disarray	Severe hypertension can confound clinical, morphologic diagnosis	Mutations of genes encoding sarcomeric proteins (**see Chapter 78; also see eTable 77.1**)	Noonan syndrome, LEOPARD syndrome, Danon syndrome, Fabry disease, Wolff-Parkinson-White syndrome, Friedreich ataxia, MERRF, MELAS (**see Chapter 97**)
Arrhythmogenic right ventricular cardiomyopathy (ARVC)	Scattered fibrofatty infiltration, classically of RV but also of LV; dilation of RV or LV, or both, is common but not universal	Ventricular arrhythmias (VT, VF) early or late, reduced contractility with progressive disease; can mimic DCM	Islands of fatty replacement; fibrosis	Palmoplantar keratoderma, wooly hair in Naxos syndrome	Mutations of genes encoding proteins of desmosome (**see Fig. 77.2, eTable 77.1, and eFig. 77.4**)	Naxos syndrome
Left ventricular noncompaction (LVNC)	Ratio of noncompacted to compacted myocardium increased with normal LV or RV or any other phenotype	Normal to reduced systolic function	Myocardium normal and ranging to findings consistent with other coexisting cardiomyopathies	Phenotype observed in setting of other types of cardiomyopathy	Various cardiomyopathy genes associated, but uncertain whether genetic cause or developmental defect during organogenesis; see text	
Infiltrative	Usually thickened walls; occasional dilation	Restrictive physiology; systolic function usually mildly reduced	Specific to type, diagnosis: amyloid, iron, glycogen storage disease, others		See RCM, above	See RCM, above
Inflammatory	Normal or dilated without hypertrophy	Reduced systolic function	Inflammatory infiltrates	Hypereosinophilic syndrome (see text), acute myocarditis (**see Chapter 79**)		
Ischemic	Normal or dilated without hypertrophy	Reduced systolic function	Areas of infarcted myocardium	Hypercholesterolemia, hypertension, diabetes, cigarette smoking, family history	Familial hypercholesterolemia; other heritable lipid disorders	Familial hypercholesterolemia
Infectious	Normal or dilated without hypertrophy	Reduced systolic function	Specific to infection	Viral (especially acute myocarditis); protozoal (e.g., Chagas disease); bacterial, direct infection (e.g., Lyme disease) or from acute cellular toxicity as result of systemic toxins (e.g., *Streptococcus*, gram-negative, others) (**see Chapter 79**)	Genetic predisposition to infection and/or variable response to infective agent	

LV, left ventricle; *MELAS*, mitochondrial encephalopathy, lactic acidosis, and strokelike symptoms; *MERRF*, myoclonic epilepsy associated with ragged-red fibers; *RV*, right ventricle; *VF*, ventricular fibrillation; *VT*, ventricular tachycardia.

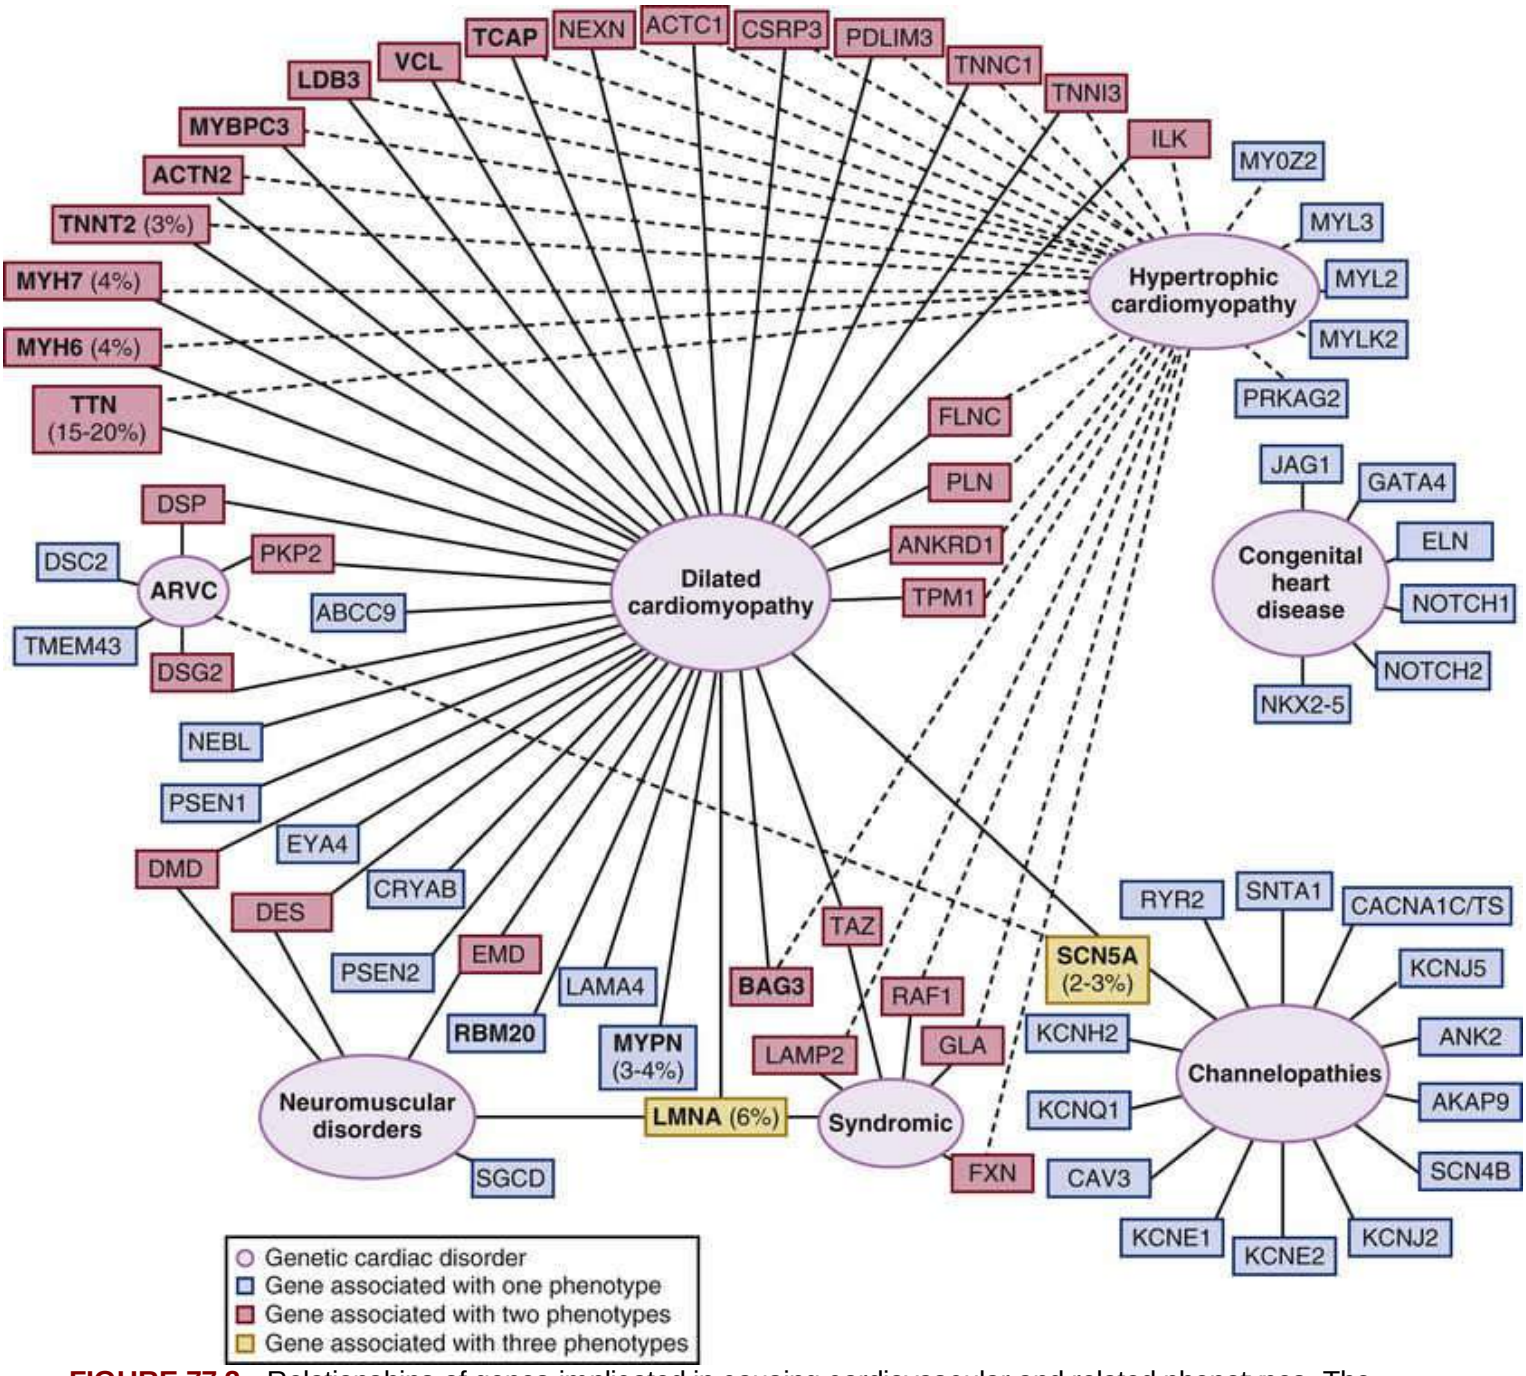

FIGURE 77.2 Relationships of genes implicated in causing cardiovascular and related phenotypes. The gene relationships for several cardiovascular phenotypes are shown, with the principal focus on DCM genetics. Common cardiac phenotypes are shown in the *purple ovals,* and *lines* connect each phenotype to the gene or genes (shown in a box) of which rare variants have been implicated in causing the phenotype. The gene boxes are color-coded according to the number of phenotypes with which they are associated: *blue* indicates one phenotype, *red* indicates two phenotypes, and *orange* indicates three phenotypes (as shown in the lower left corner of the figure). For a gene causing 3% or more of familial DCM cases, the frequency is included with its name. HCM gene associations are indicated by *dotted lines.* Well-established HCM genes include two sarcomere genes (*MYH7* and *MYBPC3*) that together account for 80% of HCM cases for which a genetic cause can be identified. Three other sarcomere genes (*TNNT2*, *TNNI3*, and *TPM1*) account for an additional 15% of such cases. The other numerous genes implicated have caused only one or a few reported cases. The evidence in support of rare variants in the genes shown and their relevance for the specified cardiomyopathy varies considerably.

The Dilated Cardiomyopathies

A dilated cardiomyopathy (DCM) is characterized by a dilated left ventricle with systolic dysfunction that is not caused by ischemic or valvular heart disease. A large number of genetic causes of DCM should be

considered (**see Fig. 77.2 and eTable 77.1**) before labeling the cardiomyopathy as "idiopathic," which is a term that reflects our inability to make a specific diagnosis. A latent period of asymptomatic LV systolic dysfunction often occurs before the development of clinical symptoms in patients with DCM (**Fig. 77.3**). Patients with DCM are also at risk for ventricular arrhythmias and may occasionally initially be seen because of aborted sudden cardiac death (**see also Chapter 42**).

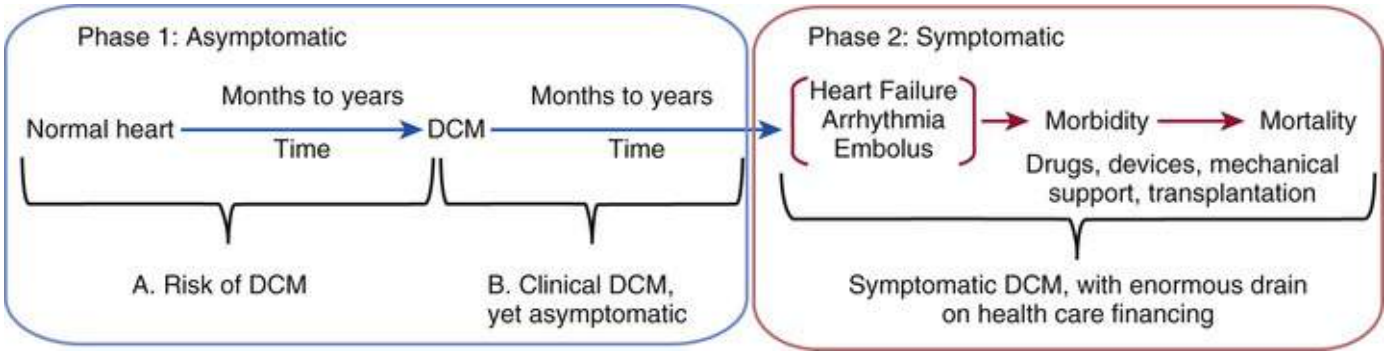

FIGURE 77.3 Asymptomatic and symptomatic phases of DCM. Phase 1 includes two periods, both asymptomatic. In the first period (1A), individuals who harbor one or more rare DCM variants have a risk of developing DCM over time. During this phase, genetic information identifies the individuals who would benefit from periodic clinical screening to detect early clinical disease. In phase 1B, DCM is present but asymptomatic, at times for years, and may evade detection unless periodic clinical cardiovascular imaging efforts detect it. Once disease has been detected, medical therapy can be initiated in an effort to prevent progression to phase 2. In phase 2, late-stage disease becomes symptomatic, with heart failure, arrhythmia, or embolus, the presenting features of DCM. (From Morales A, Hershberger RE: The rationale and timing of molecular genetic testing for dilated cardiomyopathy. Can J Cardiol 2015;31:1309-12.)

ETABLE 77.1

Genes Reported to Harbor Rare Variants in Association with Nonsyndromic Cardiomyopathy

GENE*	PROTEIN	FUNCTION	OMIM	DCM†	RCM†	ARVC†	LVNC†	HCM†
TTN	Titin	Sarcomere structure/extensible scaffold for other proteins	188840	18% to 25%				CR
LMNA	Lamin A/C	Structure/stability of inner nuclear membrane; gene expression	150330	6%			CR	
MYH7	Beta-myosin heavy chain	Sarcomeric protein; muscle contraction	160760	4%	CR		CR	40%
TNNT2	Cardiac troponin T	Sarcomeric protein; muscle contraction	191045	3%	CR		CR	5%
SCN5A	Sodium channel	Controls sodium ion flux	600163	2%				
MYH6	Alpha-myosin heavy chain	Sarcomeric protein; muscle contraction	160710	1% to 2%				CR
MYPN	Myopalladin	Sarcomeric protein, Z-disc	608517	1% to 2%				
MYBPC3	Myosin-binding protein C	Sarcomeric protein; muscle contraction	600958	1%			CR	40%
RBM20	RNA binding protein 20	RNA binding protein of a spliceosome		1% to 2%				
ANKRD1	Ankyrin repeat domain, containing protein 1	Cardiac ankyrin repeat protein (CARP); localized to myopalladin/titin complex	609599	1%				
LAMA4	Laminin a-4	Extracellular matrix protein	600133	<1%				
VCL	Metavinculin	Sarcomere structure; intercalated discs	193065	<1%				
LDB3	Cypher	Cytoskeletal assembly; targeting/clustering of membrane proteins	605906	<1%			CR	
TCAP	Titin-cap or telethonin	Z-disc protein that associates with titin; aids sarcomere assembly	604488	<1%				
PSEN1/2	Presenilin 1/2	Transmembrane proteins, gamma-secretase activity	104311/ 600759	<1%				
ACTN2	Alpha-actinin-2	Sarcomere structure; anchor for myofibrillar actin	102573	<1%				CR
CRYAB	Alpha B crystallin	Cytoskeletal protein	123590	<1%				
TPM1	Alpha-tropomyosin	Sarcomeric protein; muscle contraction	191010	<1%	CR		CR	2%
ABCC9	SUR2A	Kir6.2 regulatory subunit, inwardly rectifying cardiac K_{ATP} channel	601439	<1%				
ACTC1	Cardiac actin	Sarcomeric protein; muscle contraction	102540	<1%	CR		CR	<1%
PDLIM3	LIM domain protein 3	Cytoskeletal protein	605889	<1%				
ILK	Integrin-linked kinase	Intracellular serine-threonine kinase; interacts with integrins	602366	<1%				
TNNC1	Cardiac troponin C	Sarcomeric protein; muscle contraction	191040	<1%			CR	CR
TNNI3	Cardiac troponin I	Sarcomeric protein, muscle contraction; also seen as recessive	191044	<1%	CR			5%
PLN	Phospholamban	Sarcoplasmic reticulum Ca^{2+} regulator; inhibits SERCA2 pump	172405	<1%			CR	CR
DES	Desmin	DAGC; transduces contractile forces	125660	<1%				
SGCD	Delta-sarcoglycan	DAGC; transduces contractile forces	601411	<1%				
NEBL	Nebulette	Binds actin; Z-disc assembly	605491	<1%				
NEXN	Nexilin	Cardiac Z-disc	613122	<1%				
CSRP3	Muscle LIM protein	Sarcomere stretch sensor/Z-discs	600824	<1%				CR
EYA4	Eyes-absent 4	Transcriptional coactivators (Six and Dach)	603550	CR				
DMD‡	Dystrophin	Dystrophin-associated glycoprotein complex, transduces contractile force	300377	?				
TAZ‡	Tafazzin	Unknown	300394	CR			CR	
MYL2	Regulatory myosin light chain	Sarcomeric protein; stabilizes long helical neck of myosin head	160781	CR	CR			<1%
MYL3	Essential myosin light chain	Sarcomeric protein; stabilizes long helical neck of myosin head	160790		CR			1%
PKP2	Plakophilin 2	Desmosomal protein	602861	<1%	CR	10% to 40%		
DSG2	Desmoglein	Desmosomal protein	125671	CR	CR	10% to 40%		
DSP	Desmoplakin	Desmosomal protein	125647	<1%	CR	5% to 15%		
DSC2	Desmocollin	Desmosomal protein	125645	CR	CR	2%		
JUP	Junction plakoglobin	Desmosomal protein	173325		CR	CR		
TMEM43	Transmembrane protein 43	Nuclear envelope protein	612048	CR	CR	CR		
TGFB3	Transforming growth factor-beta-3	Growth factor, differentiation, and proliferation	190230	CR	CR	CR		
RYR2	Ryanodine receptor 2	Calcium handling for myocyte contraction	180902	CR	CR	CR		

*Gene symbol.

†Percentages; the fraction of probands carrying mutations of that gene for the phenotypes shown based on primary and secondary reports.

ATP, adenosine triphosphate; *CR*, case reports with insufficient data to estimate the frequency within the phenotype.

When investigating a patient with DCM, a full history, including risk factors for coronary artery disease, should be acquired. Unless the patient is questioned in detail, the duration of symptoms may be significantly underestimated. Angina may occur, even in the absence of epicardial coronary disease, but

symptoms suggestive of angina should raise the possibility of coronary artery disease, either as a coexistent disease or as a major causative factor. Patients should be questioned carefully about alcohol consumption (**see Chapter 80**), both present and past. If a spouse is available, that person's input may be of great value because underreporting of heavy alcohol intake is common. A family history is essential, not only of symptoms suggestive of heart failure but also of sudden cardiac death, which may be referred to by the patient as "death from a massive heart attack." Occasionally, the constellation of symptoms may allow an astute clinician to detect an uncommon cause; for example, the combination of deafness, maternally inherited diabetes, and heart failure in a relatively young patient suggests a mitochondrial cardiomyopathy.

Findings on clinical examination reflect the biventricular dysfunction present in DCM (**see Chapter 21**). Electrocardiography frequently reveals LV hypertrophy, nonspecific ST-T wave changes, or bundle branch block (**see Chapter 21**). Pathologic Q waves may be present, although their presence should raise the possibility of advanced atherosclerotic heart disease rather than primary cardiomyopathy. In advanced cases with extensive fibrosis, low-voltage limb leads may be seen.

Echocardiography (**see also Chapter 14**) reveals biventricular dilation, which can range from mild to severe, as can LV systolic dysfunction (**Fig. 77.4**). LV wall thickness is usually within the normal range, but the LV mass is almost invariably increased. Most commonly, global LV hypokinesis is present, but regional wall motion abnormalities may also be seen, particularly septal dyskinesis in those with left bundle branch block. Disproportionate thinning of a dyskinetic wall should raise the possibility of coronary artery disease rather than primary cardiomyopathy. Mitral and tricuspid regurgitation is frequently present and may be severe, even when the clinical examination does not reveal a loud murmur. Other than impaired leaflet coaptation, the mitral and tricuspid valves appear to be structurally normal, and structural abnormalities suggest primary valvular disease rather than cardiomyopathy. Diastolic function in DCM ranges from normal to restrictive (**see also Chapter 26**). A restrictive pattern is most commonly seen in patients with volume overload in "decompensated" heart failure and often improves with initiation of diuretic or vasodilator therapy.

FIGURE 77.4 Echocardiogram in a patient with dilated cardiomyopathy. The end-diastolic frame **(left)** and end-systolic frame **(right)** in a 40-year-old man with severe DCM (ejection fraction < 20%) are shown. Note the globular LV shape, typical of advanced DCM. Despite the severe reduction in LV ejection fraction, he had only mild symptoms, attributable, in part, to preservation of stroke volume because of the marked increase in LV end-diastolic volume.

Coronary angiography (**see Chapter 20**) should be considered in all patients who have risk factors

for coronary artery disease or who are of an age at which this may be a causative factor. Alternatively, computed tomography (CT) coronary angiography (**see Chapter 18**) may be used, although it does not allow hemodynamic study, which may be useful in some patients. Because coronary artery disease is common, the functional significance of any obstructive coronary lesions found should be carefully evaluated insofar as their presence may be coincidental to DCM.

Cardiac magnetic resonance imaging (CMR) (**see also Chapter 17**) can be helpful in evaluating cardiomyopathies. A pattern of nontransmural delayed gadolinium enhancement in a noncoronary distribution in a dilated left ventricle suggests a nonischemic cause. Certain conditions, such as sarcoidosis, may have a rather typical appearance.[6] CMR is able to evaluate the extent of myocardial fibrosis in DCM and may provide information complementary to that obtained with cardiac biopsy. Unless a specific condition is suspected, cardiac biopsy is often unrewarding in the evaluation of DCM, but it may occasionally provide an unexpected diagnosis.[7] The risk for perforation during heart biopsy should be weighed against the small likelihood of finding a treatable cause with it.

Genetics of Dilated Cardiomyopathy

In a significant proportion of patients with DCM, no obvious cause can be found even with a comprehensive evaluation; these patients are assigned a diagnosis of *idiopathic DCM*. Family-based studies have shown that if clinical screening with an electrocardiogram (ECG) and/or echocardiogram is conducted in the first-degree family members of patients with DCM, evidence of DCM will be found in at least 20% to 35% of them, thereby establishing a diagnosis of *familial DCM*.[8] Familial DCM is now thought to have a genetic basis of diverse ontology (**see Fig. 77.2**).[9] Recent studies in families with familial DCM suggest that a genetic cause can be identified in at least 30% of cases and perhaps in as many as 40%, as extrapolated from studies of individual genes or small numbers of genes in gene discovery publications (**see eTable 77.1**). Truncating variants in the giant scaffolding protein titin (*TTN*) have been shown to be the most common, associated with 15% to 20% of cases of DCM (**Fig. 77.5**).[10,11] The proportion of rare variants thought to be causative of DCM attributed to any specific gene is much smaller, usually ranging from less than 1% to 2% to 3% (**see eTable 77.1**). Even though familial DCM is now considered a genetic disease, the issue of whether idiopathic DCM has a genetic basis in cases in which there is no evidence of familial DCM has not been resolved. Patients with DCM typically have an asymptomatic phase for many years before symptomatic heart failure, an arrhythmia, or an embolic event develops later in the course of the disease (**see Fig. 77.3**).[12] Occasionally, asymptomatic but clinically detectable DCM is discovered serendipitously during routine or preprocedural medical screening, usually prompted by subtle abnormalities on an ECG that lead to an echocardiogram. The time span needed for clinical disease to develop illustrates the remarkable ability of the myocardium to maintain normal—or close to normal—cardiac output and filling pressure for years despite clinically detectable asymptomatic DCM. This principle underlies the observation that the family history is much less sensitive than clinical screening via echocardiography in detecting DCM among family members of an individual with a new diagnosis of idiopathic DCM and emphasizes the necessity of clinical screening of all first-degree family members when a new diagnosis of any cardiomyopathy has been made (**Fig. 77.6**).

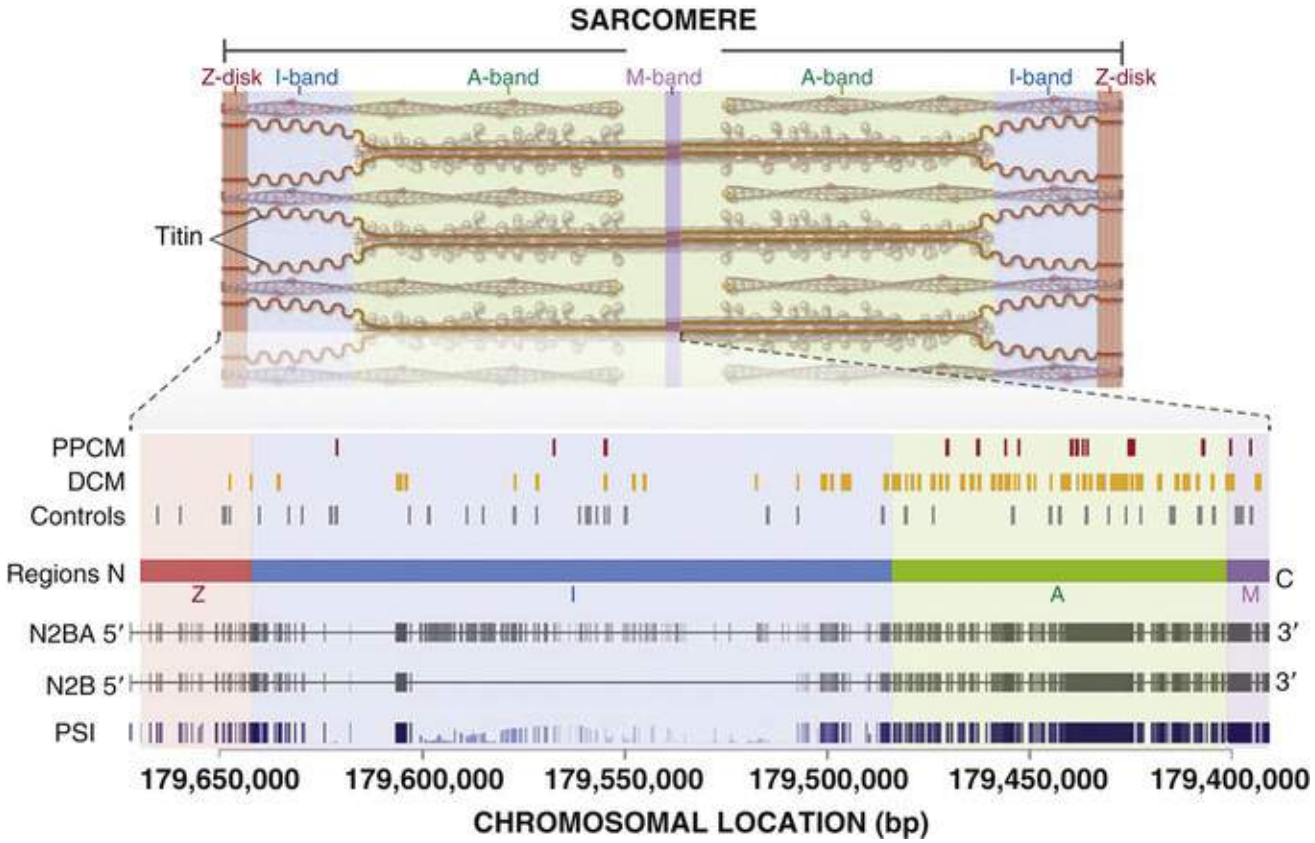

FIGURE 77.5 The giant protein titin and its involvement in DCM. Titin, the largest protein in the body, which is made up of more than 35,000 amino acids, is encoded by *TTN*, which acts as a scaffolding protein for sarcomere assembly. The large size of *TTN* made investigation extremely challenging prior to the development of next-generation sequencing strategies. Recent work has implicated truncating variants of *TTN* in 15% to 25% of familial DCM patients and 10% to 15% of nonfamilial DCM patients. Truncating variants include nonsense, frameshift, splice site, or other variants that cause the protein to be truncated. The upper part of the diagram shows the protein structure, with sarcomeric regions labeled (Z-disk and I, A, and M bands). The lower portion shows the locations of truncating variants in peripartum cardiomyopathy (PPCM), DCM, or controls. The exons of the primary two cardiovascular transcripts expressed (N2BA, N2B) are shown, along with their proportions spliced in (PSI). (From Ware JS, Li J, Mazaika E, et al: Shared genetic predisposition in peripartum and dilated cardiomyopathies. N Engl J Med 2016;374:233-41.)

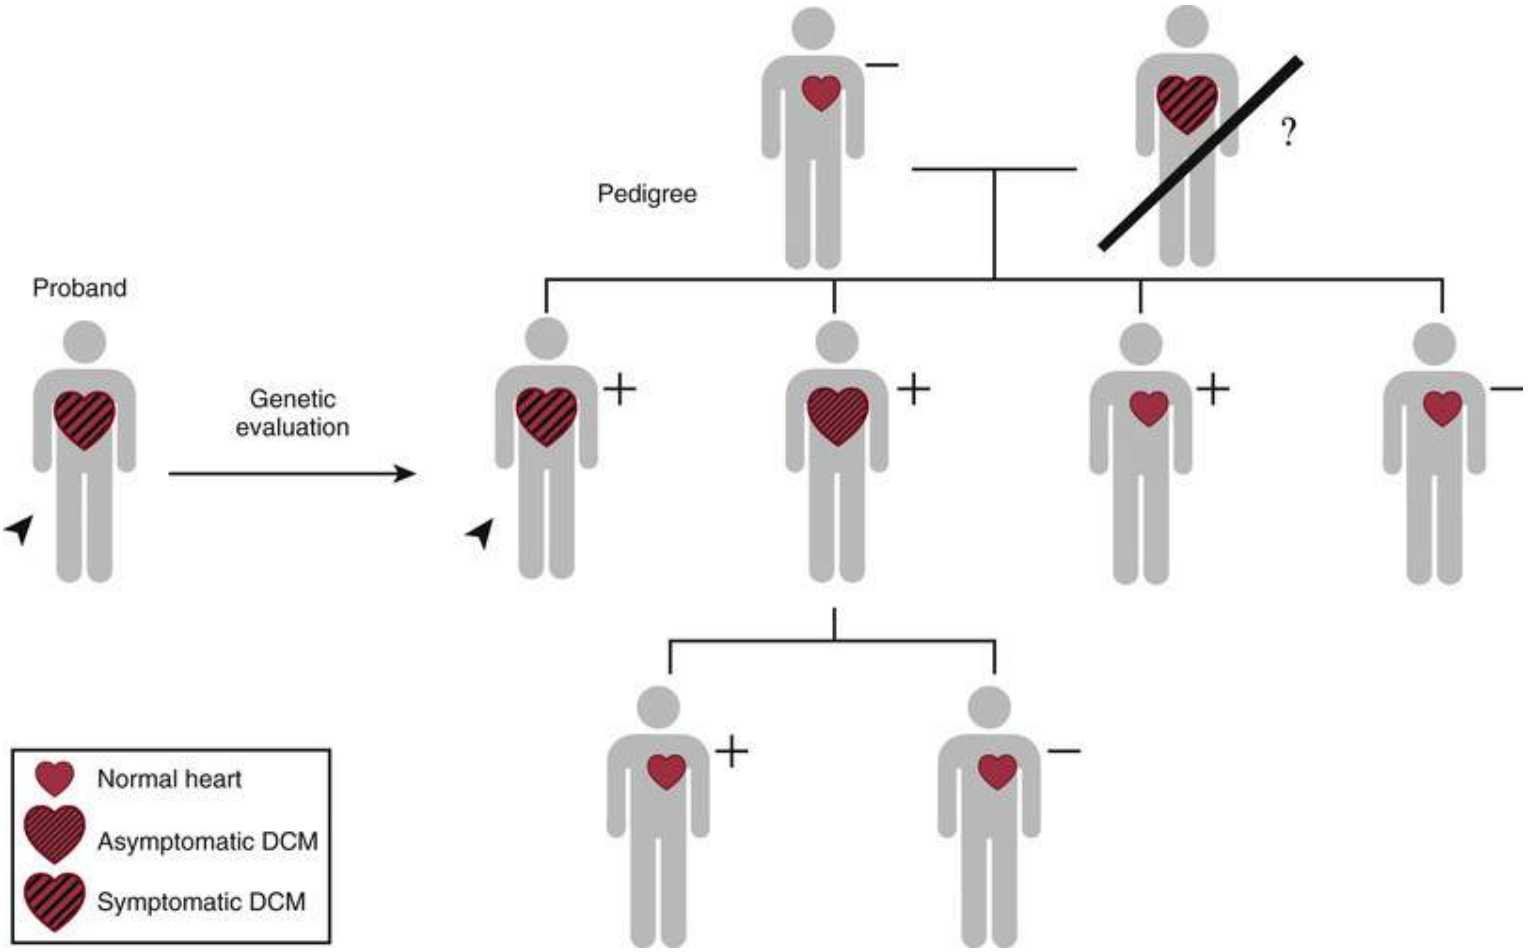

FIGURE 77.6 Genetic evaluation for cardiomyopathy. The goal of a genetic evaluation is to assess genetic risk of the proband and the proband's at-risk family members. The proband is the first patient identified with the trait or disease of interest, here depicted as an individual with DCM and shown as an enlarged heart. The at-risk relatives can be shown by a pedigree, or a graphical depiction of the family relationships. A genetic evaluation includes a comprehensive family history for three generations or more and genetic and family counseling for all patients and families. In this example, the proband's mother died with a known diagnosis of DCM, but neither a genetic evaluation nor family screening was undertaken. With a new diagnosis of cardiomyopathy, clinical screening of first-degree relatives is indicated. In this example, the proband's three siblings are clinically evaluated. One is found to have asymptomatic DCM; the other two do not have clinical evidence of DCM. Because DCM has been found in one sibling, the sibling's children also have undergone clinical cardiovascular screening. A genetic evaluation is also indicated. In most cases, genetic testing should be undertaken for the one clearly affected person in a family to facilitate family screening and management. In this case, the proband is sequenced first, and a pathogenic mutation is identified. This permits sequencing of the at-risk family members. The affected sibling is a mutation carrier, as is one unaffected sibling, who will be advised to have ongoing surveillance with clinical screening for early-onset DCM so that treatment can be initiated prior to the development of symptomatic DCM. One sibling is shown to not carry the mutation, so that individual can be released from clinical surveillance. The affected sibling's offspring can now also undergo genetic testing to assess risk. The one who is a mutation carrier will need clinical surveillance for development of DCM, with early intervention to attempt to prevent symptomatic disease. In this pedigree, the negative genetic testing result of the unaffected individual in the first generation indicates that the mutation, inherited by multiple individuals in the second generation, was transmitted from the affected individual in the first generation. The finding that three affected family members all carried the same mutation builds the evidence that the variant indeed is the pathogenic variant in this family. The *solid diagonal line* in the first generation depicts a deceased individual.

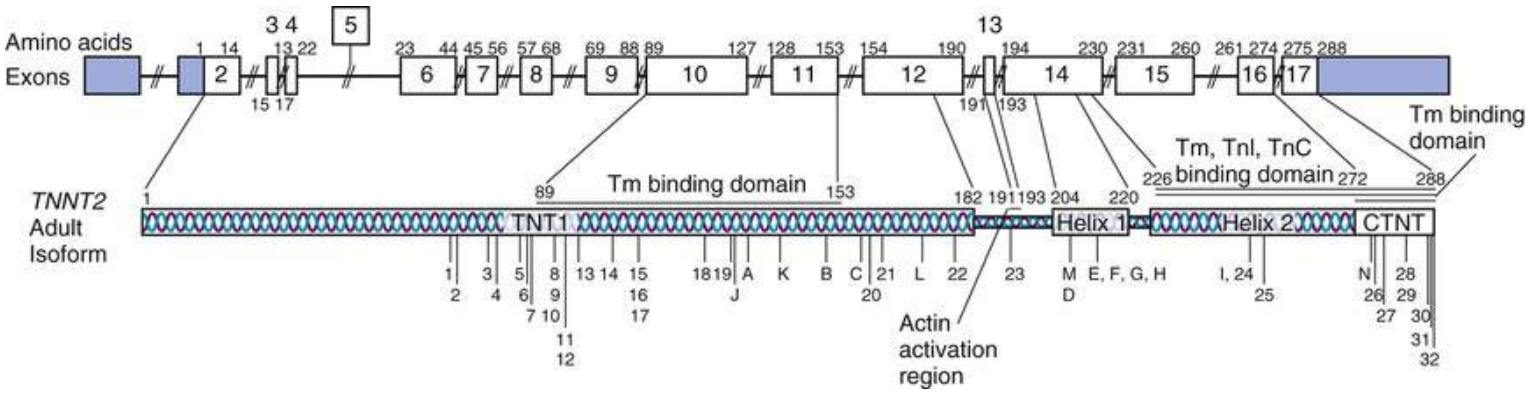
Genetics of Familial Dilated Cardiomyopathy

The genes shown to cause familial DCM are classified by subcellular location (gene ontology). As shown in **Fig. 77.2** and **eTable 77.1**, most of the implicated genes encode sarcomere, Z-disk, or cytoskeleton proteins. The broad representation of other genes encoding a wide variety of proteins demonstrates the

diverse pathways that can lead to a final phenotype of DCM.[9] Presumably, other yet unknown pathways may also be relevant in the pathogenesis of DCM. More than 30 genes have been identified to cause DCM (referred to as locus heterogeneity). The diverse subcellular locations of genes implicated in DCM differentiate this form of cardiomyopathy from HCM (**see also Chapter 78**) and arrhythmogenic right ventricular cardiomyopathy (ARVC), which are caused by variants in genes encoding sarcomeric or desmosomal proteins, respectively (**see Fig. 77.2**). In addition to locus heterogeneity, the molecular genetics of DCM is also characterized by allelic heterogeneity; that is, mutations commonly occur at many locations in a DCM gene, and many mutation sites in genes shown to cause both DCM and HCM are specific to that cardiomyopathy (**see eFig. 77.1**). So-called overlap phenotypes are not uncommon, particularly for sarcomeric genes, wherein mutations that have been shown to cause DCM, HCM, and RCM may be seen in an extended pedigree. Indeed, all three phenotypes (HCM, RCM, DCM) have been reported with the same mutation in an extended family.[13]



EFIGURE 77.1 Molecular genetic allelic heterogeneity**.** An example of molecular genetic allelic heterogeneity is shown for *TNNT2*, which encodes cardiac troponin T, a key sarcomeric protein involved in both DCM and HCM. The mutations known to cause DCM (letters A through N) or HCM (numbers 1 through 32) are shown. The genomic structure of *TNNT2* is presented in the **upper** part of the figure with exons numbered through 17; amino acids are also numbered by exon. The **lower** portion shows the adult troponin T protein isoform and its key domains. (From Hershberger RE, Pinto JR, Parks SB, et al: Clinical and functional characteristics of *TNNT2* mutations identified in patients with dilated cardiomyopathy. Circ Cardiovasc Genet 2009;2:306.)

Clinical Genetics of Familial Dilated Cardiomyopathy

Familial DCM is characterized by a relatively unitary final phenotype[9] of "generic" DCM. That is, for almost all genes implicated in DCM, there are no unique or distinguishing genotypic or phenotypic features that have been associated with specific gene mutations. The only general phenotypic variation that has been noted[8,14] is "DCM with prominent conduction system disease," a phenotype that is observed in lamin A/C (LMNA) DCM and in some cases of sodium channel (SCN5A) and desmin (DES) DCM (**see eTable 77.1**). Occasionally, a clinically mild muscular dystrophy phenotype can be identified in patients with LMNA cardiomyopathy and a new diagnosis of DCM. However, if the muscular dystrophy is prominent, in most cases it will have been identified in a neuromuscular clinic, with DCM being an incidental finding at the time of evaluation. Regardless of the setting, when a new diagnosis of idiopathic DCM is made, vigilance in detecting syndromic disease is essential, with particular attention being directed to neuromuscular phenotypes.

Most cases of familial DCM are transmitted via autosomal dominant inheritance, with the offspring of a mutation carrier having a 50% chance of inheriting the mutation. Autosomal recessive disease has been

reported, particularly in consanguineous families. X-linked DCM resulting from mutations in the gene for Duchenne muscular dystrophy (DMD) in patients without any findings of muscular dystrophy has been reported both in males and in carrier females, although the prevalence of DMD-DCM in cohorts of patients with idiopathic DCM has not been studied systematically. Mitochondrial DCM has also been reported, particularly in the setting of syndromic disease.[3]

Familial DCM is characterized by age-dependent penetrance, which means that an individual harboring a DCM-causing allele will manifest evidence of the DCM phenotype with increasing age.[8,14] Most genetic DCM cases become evident in the fourth to seventh decades, although DCM occurring in adolescence, childhood, or infancy is not uncommon. Variations in the age at onset of DCM are common across families with mutations in the same DCM gene, at times marked, and even in family members of an extended pedigree with the same mutation. Penetrance in familial DCM is commonly incomplete; that is, an individual with a disease-causing allele may not manifest any aspect of the disease phenotype. Also, expression is variable in that the clinical features and the phenotype can vary significantly between individuals in the same family or between families with the same mutation. Both incomplete penetrance and variable expressivity confound the assessment of familial DCM in family pedigrees. This is particularly relevant for a newly discovered or novel candidate mutation in a family because full segregation of the candidate mutation with the disease phenotype in one or more extended families is one of the most helpful approaches for determining the pathogenicity of such variants.[15]

Incomplete penetrance and variable expressivity at times result in marked phenotypic variability within and between families with DCM, even with the same mutation. The explanation for this phenomenon is not clear. Both environmental and genetic factors have been postulated and range from intrinsic (e.g., hypertension) and extrinsic phenomic components (e.g., toxins, viruses, adverse or favorable drug exposure) to a combination of various genomic variants resulting in a different genetic milieu (e.g., a second mutation in a different disease gene, risk alleles in the same or other relevant DCM pathways, variability in epigenetics or gene expression, and others).

Allelic heterogeneity, in which mutations in one gene can give rise to different and distinct phenotypes seemingly unrelated to one another (**see Fig. 77.2 and eFig. 77.1**), is also observed with some DCM genes, and knowledge of these allelic variants can be critical when considering a genetic diagnosis of DCM. One of the most remarkable examples is *LMNA*, which encodes the proteins lamin A and lamin C, key components of the inner nuclear membrane. For example, mutations in *LMNA* cause a distinctive DCM phenotype in which conduction system disease and arrhythmia occur before the onset of DCM. Mutant lamin proteins also cause a variety of syndromic diseases spanning striated muscle, adipose, nerve, and vascular tissues. These phenotypes, collectively termed the *laminopathies*, include skeletal myopathies (autosomal dominant Emery-Dreifuss muscular dystrophy, limb-girdle muscular dystrophy type 1B, and others [**see Chapter 97**]), lipodystrophy syndromes, peripheral neuropathy, and accelerated aging syndromes, most notably Hutchinson-Gilford progeria.

Approach to Clinical Genetic Evaluation, Including Genetic Testing

Guidelines for evaluation and clinical genetic testing for DCM, applicable to all cardiomyopathies with a possible genetic cause (**see Fig. 77.6**), include a comprehensive three- to four-generation search of the family history for any evidence of any type of cardiomyopathy, muscular dystrophy, or other evidence of syndromic disease that may have a cardiomyopathy component.[4,16] However, as noted earlier, even if it is obtained by a skilled professional, the family history might be negative because DCM may be

asymptomatic in family members. Accordingly, cardiovascular clinical screening of all first-degree relatives is essential; history taking, a physical examination, an ECG, and echocardiography should be acquired at a minimum. If evidence of DCM is identified in a relative, screening of that relative's first-degree relatives is indicated (i.e., stepwise or cascade clinical screening). Genetic testing, within the context of genetic counseling, is indicated with any evidence of familial disease because identification of a disease-associated mutation (in one or more clearly affected family members) can permit molecular genetic testing of other at-risk family members with preclinical disease and thereby aid in their risk stratification. Those who test negative for the family mutation should have a significantly reduced risk for the development of DCM; those with a family DCM mutation should undergo enhanced clinical screening to detect early DCM, with the rationale that early intervention, usually with angiotensin-converting enzyme (ACE) inhibitors or beta blockers, may delay or prevent progression of the disease.

Genetic testing is now conducted by next-generation sequencing in panels of DCM genes ranging from 20 to 30 or more and has recently been advocated for individuals with cardiomyopathy regardless of results of family clinical cardiovascular screening results.[12] Pancardiomyopathy panels now also contain more than 50 genes, and their competitive cost structure suggests that large test panels will quickly become the norm. Genetic testing should always be conducted within the context of genetic counseling, the goals of which are to review the genetic inheritance patterns and clinically relevant facts regarding idiopathic and familial DCM and ensure that a comprehensive family history has been completed and properly interpreted, including identification of at-risk relatives. Counseling is also essential to provide information regarding the risks, benefits, and limitations of clinical genetic testing, including the possible consequences of uncertain or inconclusive results or the discovery of heritable disease and its potential psychological implications. These processes are time-consuming and require specialized knowledge; guidelines suggest that referral of patients to individuals or centers with experience should be considered if local resources for completion of the process are not available.[4]

The recommendation for genetic testing recognizes that with the greater number of genes being tested in pancardiomyopathy panels, a greater number of variants of unknown or uncertain significance may be encountered.[12] Clinicians ordering clinical genetic testing must understand this concept and be prepared to deal with this reality as the results become available. The emergence of next-generation sequencing of panels of genes has fueled an extremely active period for reevaluation of testing strategies, including approaches to interpreting large numbers of variants. All of this will require careful, comprehensive translational research to understand the optimal testing strategies, including large databases of disease-associated variants.

Therapy for Dilated Cardiomyopathy

Therapy for DCM is similar to that for all types of heart failure with a reduced ejection fraction, and is discussed in detail in **Chapter 25**. Attention should be paid to treatment of atrial arrhythmias (see Tachycardia-Induced Cardiomyopathy, later). In selected patients, cardiac resynchronization therapy should be considered (**see Chapter 27**), and/or referral for a ventricular assist device or cardiac transplantation may be also needed (**see also Chapters 28 and 29**).

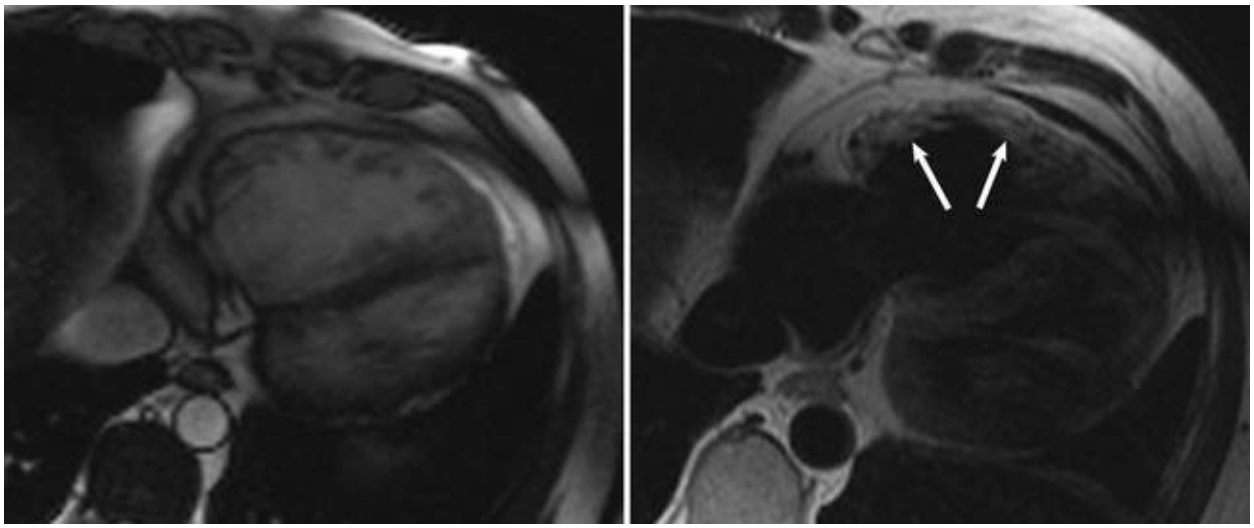
Alcoholic and Diabetic Cardiomyopathies

Excessive alcohol intake is cardiotoxic and may be manifested as DCM, and is discussed in detail in **Chapter 80**.[17] The importance of obtaining as accurate an alcohol history as possible in assessing patients

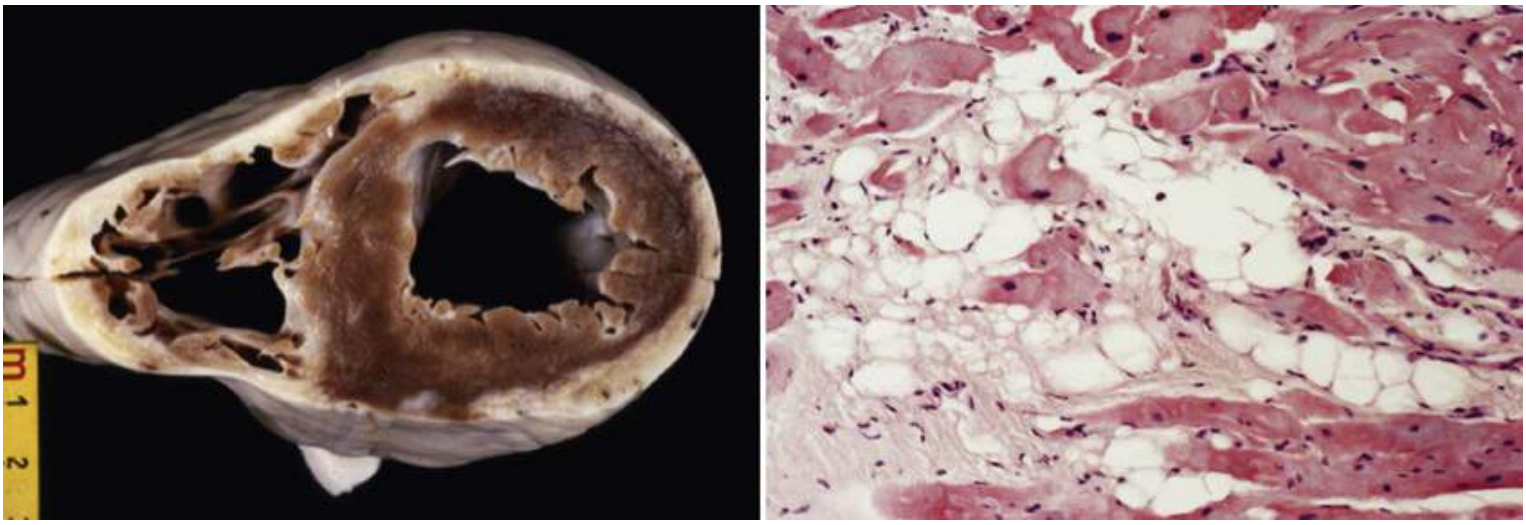
with DCM cannot be overstated. The existence of a specific diabetic cardiomyopathy independent of the effect of diabetes on the vasculature is debated, both in terms of its existence and, among those who believe it to exist, in the form that it takes.[18] Subtle abnormalities in both systolic and diastolic function do seem to be prevalent in diabetic patients, but their clinical relevance to the development of overt disease is unclear. Nevertheless, data do support good glycemic control as a preventative against the development of heart failure[19](**see Chapter 51**).

Arrhythmogenic Right Ventricular Cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is a genetically determined cardiomyopathy characterized by fibrofatty replacement of the myocardium. The right ventricular nomenclature is preserved to reflect the current medical literature, even though biventricular involvement occurs in up to 50% of cases and a small proportion of cases affect predominantly the left ventricle (**eFigs. 77.2 and 77.3**). The disorder is conceptualized as having three stages: an early subclinical phase in which imaging studies are negative but during which sudden cardiac death can still occur; next, a phase in which (usually) RV abnormalities are obvious without any clinical manifestation of RV dysfunction but with the development of a symptomatic ventricular arrhythmia; and, finally, progressive fibrofatty replacement and infiltration of the myocardium leading to severe RV dilation and aneurysm formation and associated right-sided heart failure (**see eFig. 77.2**). LV dilation and failure may also arise at this stage or may occur later (sometimes referred to as phase 4).[20]



EFIGURE 77.2 MRI in a 46-year-old man with arrhythmogenic right ventricular cardiomyopathy and abnormal findings on an ECG. **Left,** Steady-state precision image showing marked dilation of the right ventricle. **Right,** T1-weighted image showing extensive fatty infiltration of the RV wall (*arrows*). These appearances are typical of arrhythmogenic cardiomyopathy. (From Murphy DT, Shine SC, Cradock A, et al: Cardiac MRI in arrhythmogenic right ventricular cardiomyopathy. AJR Am J Roentgenol 2010;194:W299.)



EFIGURE 77.3 Arrhythmogenic right ventricular cardiomyopathy. **Left,** Autopsy specimen from a 39-year-old man with ARVC who died suddenly. The specimen shows fatty replacement of the RV free wall. There is also involvement of the subepicardial region of the LV free wall, which demonstrates the biventricular nature of ARVC in some patients. **Right,** Typical histologic appearance of a patient with advanced ARVC showing fatty replacement of the myocardium. (**Left,** From Rizzo S, Pilichou K, Thiene G, Basso C. The changing spectrum of arrhythmogenic right ventricular cardiomyopathy. Cell Tissue Res 2012;348:319; **right,** from Leone O, Veinot JP, Angelini A, et al: 2011 Consensus statement on endomyocardial biopsy from the Association for European Cardiovascular Pathology and the Society for Cardiovascular Pathology. Cardiovasc Pathol 2012;21:245.)

The electrical manifestations of ARVC are a reflection of the pathologic disturbance. In the early stage, slow conduction and electrical uncoupling may lead to a fatal arrhythmia. As the disease progresses, fibrofatty infiltration results in inhomogeneous activation and a further delay in conduction. The predominant site of cardiac involvement, known as the triangle of dysplasia, was believed to involve the RV outflow tract, an area below the tricuspid valve, and the RV apex. However, recent data suggest that the RV apex is only involved in advanced disease and that an area involving the basal inferior and anterior right ventricle and the posterolateral left ventricle may be most commonly involved.[21] Patients with ARVC exhibit a typical monomorphic ventricular tachycardia (VT) characterized by left bundle branch block morphology with a superior axis[22] and typical T wave inversions extending to V_3 or beyond. A classic “epsilon wave” in the right precordial leads is a specific but insensitive finding (**Fig. 77.7**).

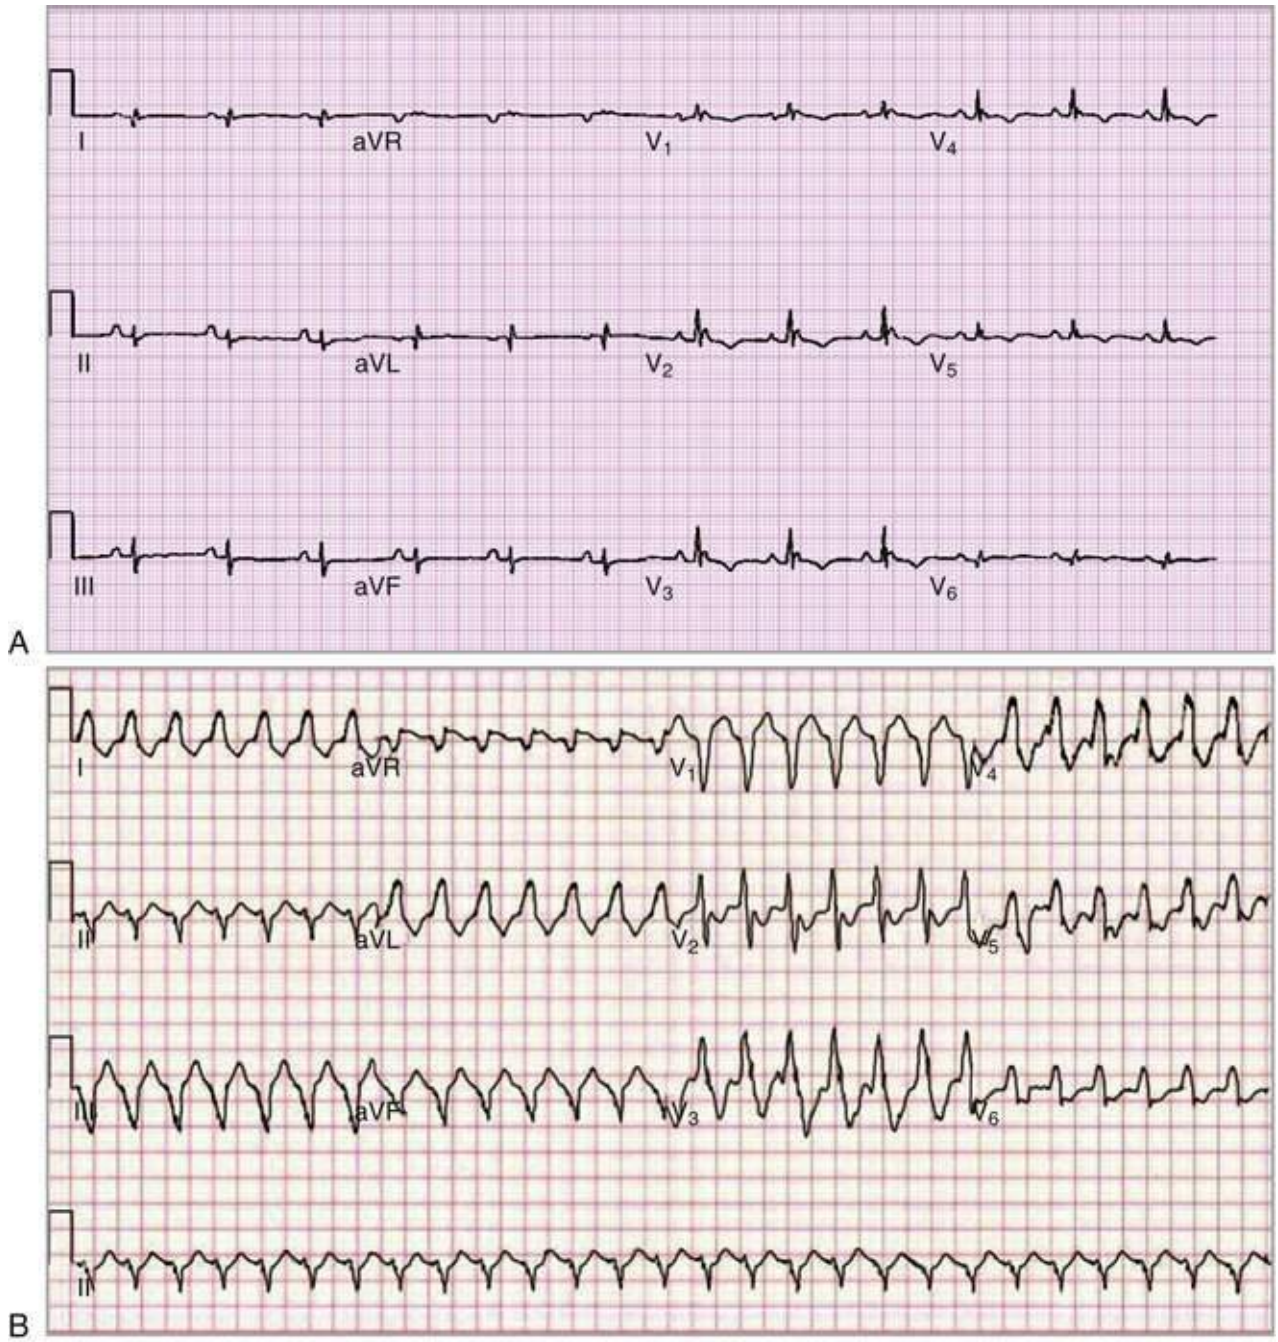


FIGURE 77.7 Arrhythmogenic right ventricular cardiomyopathy. **A,** ECG of a patient with ARVC. A typical ECG shows inverted T waves in the anterior precordial leads and an "epsilon potential" early during ventricular repolarization representing a "late potential" caused by delayed depolarization of an area of the right ventricle. **B,** Ventricular tachycardia in a patient with ARVC. There are left bundle branch block morphologic findings with a leftward axis. (From Hauer RN, Cox MG, Groeneweg JA: Impact of new electrocardiographic criteria in ARVC. Front Physiol 2012;3:352.)

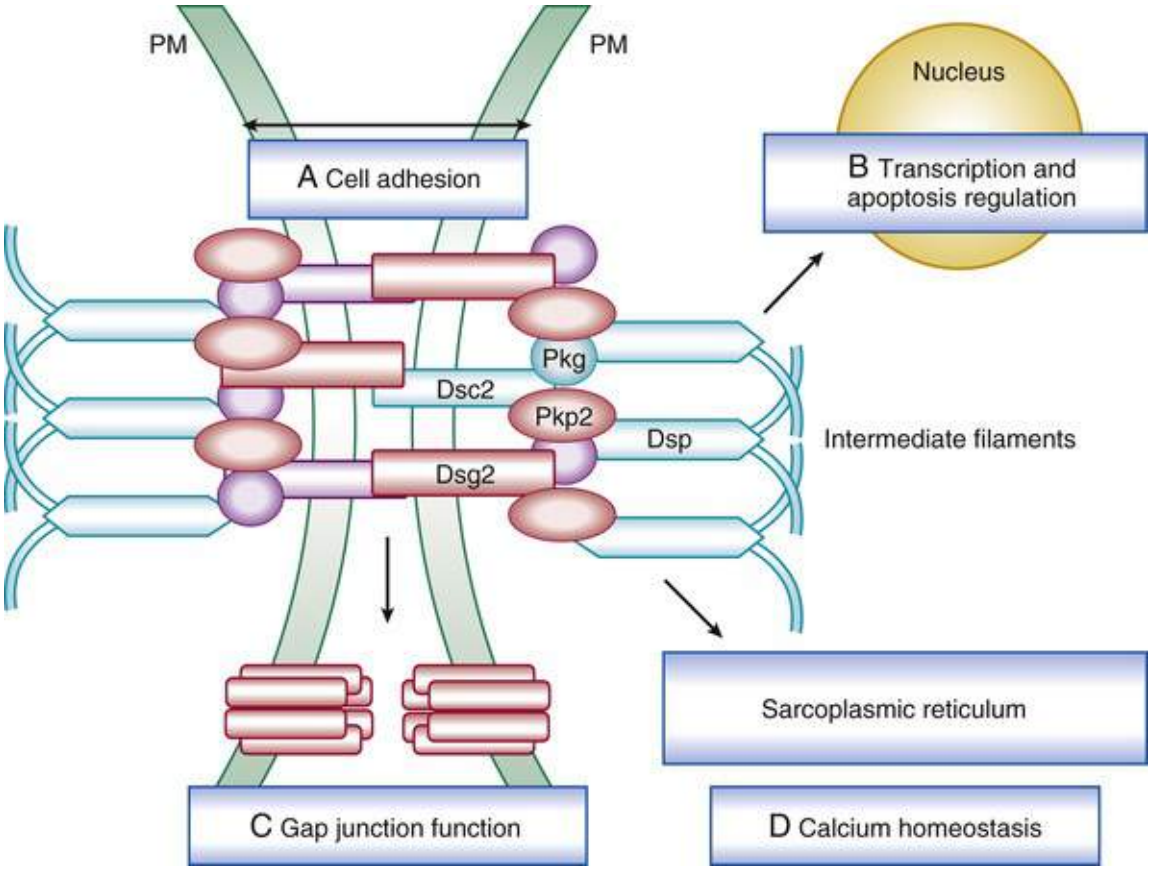
Genomic Cause of Arrhythmogenic Right Ventricular Cardiomyopathy

Unlike genetic DCM, which has a final common phenotype despite its extensive locus heterogeneity, ARVC is driven by molecular alterations in genes encoding proteins that are key for cell-to-cell adhesion (**eFig. 77.4**).[23] Extensive work over the past decade has implicated genes encoding the desmosome, one of three key components of the intercalated disc, the end-to-end connection between ventricular myocytes,[23] in the pathogenesis of ARVC. In addition to desmosomes, the intercalated disc includes gap junctions mediating small-molecule communications. Mechanical coupling is mediated through the desmosome and adherens junctions (**see Chapter 22**), and disruptions of desmosomal proteins have been associated with ARVC. The classic hallmark of ARVC, fibrofatty replacement, is now understood to be related to aberrant

Wnt signaling of desmosomal proteins, as well as direct plakoglobin signaling, which transforms myocytes into adipocytes with disease progression.[23]



EFIGURE 77.4 Desmosomal proteins relevant for arrhythmogenic right ventricular cardiomyopathy. The cardiac desmosome and proposed roles of the desmosome in supporting structural stability through cell-cell adhesion *(A),* regulating transcription of genes involved in adipogenesis and apoptosis *(B),* and maintaining proper electrical conductivity through regulation of gap junctions *(C)* and calcium homeostasis *(D)* are presented. *Dsc2*, desmocollin-2; *Dsg2*, desmoglein-2; *Dsp*, desmoplakin; *Pkg*, plakoglobin; *Pkp2*, plakophilin 2; *PM*, plasma membrane. (From Awad MM, Calkins H, Judge DP: Mechanisms of disease: molecular genetics of arrhythmogenic right ventricular dysplasia/cardiomyopathy. Nat Clin Pract Cardiovasc Med 2008;5:258.)

Molecular Genetics.

When a genetic cause can be identified, mutations in the genes encoding plakophilin 2 (*PKP2*), desmoglein 2 (*DSG2*), and desmoplakin (*DSP*) account for most genetic causes of ARVC (**see eTable 77.1 and Fig. 77.2**). Other genes encoding desmosomal proteins (desmocollin [*DSC2*], junction plakoglobin [*JUP*]) or affecting desmosomal physiology (e.g., transmembrane protein [*TMEM*]) have been implicated (**see eTable 77.1**). The degree of locus heterogeneity is similar for HCM and ARVC, in which five or fewer genes contribute to most of the identifiable genetic causes. However, as for DCM and HCM, the genes implicated in ARVC show extensive allelic heterogeneity.

Clinical Genetics.

The autosomal recessive syndromic *Naxos disease*, so named because it was discovered on the Greek island of Naxos, is manifested as ARVC cosegregating with palmoplantar keratoderma and wooly hair. Molecular genetic analysis has shown a homozygous two–base pair frameshift deletion of *JUP*, which encodes plakoglobin. This observation first implicated the desmosome in ARVC and prompted the

molecular genetic discovery of other desmosomal proteins. Other mutations in *JUP* have also been associated with cutaneous disease or wooly hair phenotypes, although cardiovascular phenotypes have not been identified in most of these allelic variants.[23] A second autosomal recessive syndromic disease, *Carvajal syndrome*, resembles Naxos disease in that individuals have palmoplantar keratoderma and wooly hair, but individuals with Carvajal syndrome manifest DCM, not ARVC. Carvajal syndrome is caused by a frameshift mutation in *DSP*, which encodes desmoplakin.[23] Other mutations in *DSP* have been identified with only ARVC or with only skin or hair manifestations. Even though reduced penetrance and variable expressivity are commonly observed in all genetic cardiomyopathies, these features may be particularly prominent in ARVC, in part because of the difficulty of assessing the phenotype and also because the arrhythmia component may be the only feature of the disease in some individuals long before structural changes can be identified.

Diagnosis

The more advanced the disease, the easier the diagnosis, but recognition of earlier stages, which may be manifested as aborted sudden death without detectable structural abnormalities, can be difficult. In addition, with increasing use of CMR for the diagnosis of cardiac pathology, a trend toward overdiagnosis of ARVC is now being recognized (**see also Chapter 17**). Although, in experienced hands, CMR is a useful tool for both diagnosis and evaluation of the extent of structural abnormalities in ARVC, early disease may not be apparent despite ventricular arrhythmia,[24] and overdiagnosis of the disease by less-experienced CMR readers has been recognized.[25] Endomyocardial biopsy for ARVC is one of the diagnostic criteria but is rarely undertaken nowadays because of the potential for higher major complication rates and for false-negative findings.[26] The diagnosis of ARVC currently rests primarily on the combination of clinical, electrocardiographic, and genetic findings, which are divided into major and minor diagnostic criteria as proposed in a 2010 consensus statement (**eTable 77.2**).

ETABLE 77.2

Revised Task Force Criteria for the Diagnosis of Arrhythmogenic Right Ventricular Cardiomyopathy

Diagnostic Terminology for Revised Criteria
• Definite diagnosis: 2 major criteria, or 1 major and 2 minor criteria, or 4 minor criteria from different categories • Borderline: 1 major criterion and 1 minor criterion, or 3 minor criteria from different categories • Possible: 1 major criterion, or 2 minor criteria from different categories
I. Global and/or Regional Dysfunction and Structural Alterations
Major Criteria
By two-dimensional echocardiography: Regional RV akinesia, dyskinesia, or aneurysm *and* one of the following (end diastole): Parasternal long-axis view of RVOT (PLAX) ≥32 mm (≥19 mm/m^2) Parasternal short-axis view of RVOT (PSAX) ≥36 mm (≥21 mm/m^2) *or* Fractional area change <33% By MRI: Regional RV akinesia, dyskinesia, or dyssynchronous RV contraction *and* one of the following: Ratio of RVEDV to BSA ≥110 mL/m^2 (male) or ≥100 mL/m^2 (female) *or* RVEF ≤40% By RV angiography: Regional RV akinesia, dyskinesia, or aneurysm
Minor Criteria
By two-dimensional echocardiography: Regional RV akinesia or dyskinesia and one of the following (end diastole): PLAX RVOT ≥29 to <32 mm (≥16 to <19 mm/m^2) PSAX RVOT ≥32 to <36 mm (≥18 mm to <21 mm/m^2) *or* Fractional area change >33% to ≤40% By MRI: Regional RV akinesia, dyskinesia, or dyssynchronous RV contraction *and* one of the following: Ratio of RVEDV to BSA ≥100 to <110 mL/m^2 (male) or ≥100 to <110 mL/m^2 (female) *or* RVEF <40% to ≤45%
II. Tissue Characterization of Wall
Major Criteria
Residual myocytes <60% by morphometric analysis (or <50% if estimated), with fibrous replacement of RV free wall myocardium in at least one sample, with or without fatty replacement of tissue seen on endomyocardial biopsy
Minor Criteria
Residual myocytes 60% to 75% by morphometric analysis (or 50% to 65% if estimated), with fibrous replacement of RV free wall myocardium in at least one sample, with or without fatty replacement of tissue seen on endomyocardial biopsy
III. Repolarization Abnormalities
Major Criteria
Inverted T waves in right precordial leads (V_1, V_2, and V_3) or beyond in individuals >14 years of age (in absence of complete right bundle branch block QRS ≥120 msec)
Minor Criteria
Inverted T waves in leads V_1 and V_2 in individuals >14 years of age (in absence of complete right bundle branch block) or in V_4, V_5, or V_6
Inverted T waves in leads V_1, V_2, V_3, and V_4 in individuals >14 years of age in presence of complete right bundle branch block
IV. Depolarization/Conduction Abnormalities
Major Criteria
Epsilon wave (reproducible low-amplitude signals between end of QRS complex to onset of T wave) in right precordial leads (V_1 to V_3)
Minor Criteria
Late potentials by signal-averaged ECG in at least 1 of 3 parameters in absence of QRS duration ≥110 msec on standard ECG
Filtered QRS duration ≥114 msec
RMS voltage of terminal 40 msec <20 μV
Terminal activation duration of QRS ≥55 msec measured from nadir of S wave to end of QRS complex, including R′ in V_1, V_2, or V_3 in absence of complete right bundle branch block

BSA, body surface area; *PLAX*, parasternal long-axis; *PSAX*, parasternal short-axis; *RVEDV*, RV end-diastolic volume; *RVEF*, RV ejection fraction; *RVOT*, RV outflow tract.

Approach to Clinical Genetic Evaluation, Including Clinical Genetic Testing

Current studies estimate that a plausible genetic cause can be identified in approximately half of ARVC cases.[27-29] The impact of multiple mutations in desmosomal genes has been emphasized, as well as the impact of the revised task force clinical criteria, which has increased the sensitivity of molecular genetic testing.[28] A recent study of 439 index patients and their 562 family members showed an earlier onset of

disease in those who were positive for the mutation, although clinical characteristics were similar for both groups with disease onset.[30] For clear-cut cases of ARVC, genetic testing is indicated so that cascade testing of at-risk family members can be accomplished. This is particularly relevant for ARVC insofar as arrhythmias, especially sudden cardiac death, can occur before other phenotypic features become evident. The genes involved in ARVC show significant allelic heterogeneity, thus making it difficult to discern pathogenic variants from uncommon polymorphisms, as is the case for clinical genetic testing for all cardiomyopathies.[29] Pancardiomyopathy testing, especially for a phenotype of prominent VT, ventricular fibrillation, or sudden cardiac death with biventricular dilation and systolic dysfunction of unknown cause otherwise consistent with DCM, may also yield rare variants in the genes associated with ARVC. Even though conventional recommendations currently discourage the use of genetic testing for the diagnosis of ARVC, molecular genetic testing will probably be used more frequently in the near future to assist in making the diagnosis, especially as genetic testing proliferates and is used more commonly for all cardiomyopathies regardless of phenotype.

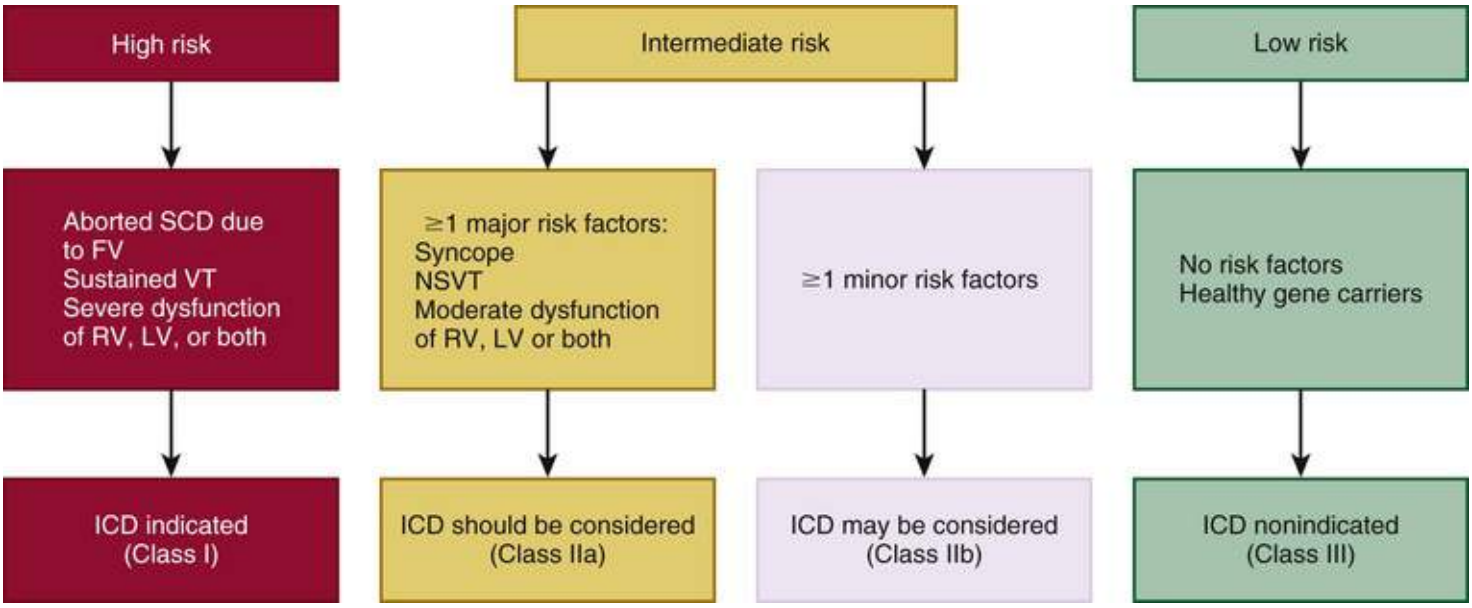
Differential Diagnosis

The differential diagnosis of ARVC in the early stages (before the onset of visible structural abnormalities) includes idiopathic and RV outflow tract VTs. The morphology of the classic ARVC-related VT differs from these entities, and in the presence of precordial T-wave inversion during sinus rhythm, ARVC should be the initial diagnosis. Cardiac sarcoidosis may occasionally mimic ARVC morphologically and be indistinguishable, even with multiple imaging modalities. Cardiac biopsy in patients with sarcoidosis often fails to show the pathognomonic granulomas but may reveal extensive fibrosis, which may also be confused with ARVC.

Treatment

Currently, the mainstay of therapy for ARVC is suppression and prevention of ventricular arrhythmias and the risk for sudden cardiac death, and prevention of disease progression. There is evidence that intense physical exertion is associated with an earlier onset of symptoms and an increased risk of sustained VT, and therefore patients with a definite diagnosis of ARVC are advised not to participate in athletic activity.[31,32] The classic monomorphic VT in ARVC with predominant RV involvement is generally well tolerated, even at a rapid rate, possibly because of preserved LV function in most patients. Nevertheless, VT of a different morphology may occur and sudden death is not uncommon. Antiarrhythmic drugs may suppress a symptomatic arrhythmia but have not been shown to prevent sudden death. Beta-blocking agents may suppress catecholamine-triggered arrhythmia and slow progression of ventricular dysfunction and have been recommended as potentially valuable in all patients with ARVC.[32] An implantable defibrillator (ICD) is recommended in patients with aborted sudden death, syncope, or decreased LV function and may be considered in other patients (**eFig. 77.5**). Catheter ablation has not been shown to reduce sudden death but is valuable in a patient with an ICD and frequent arrhythmias or in occasional patients with very well tolerated single-morphology VT. Ablation appears to be most successful when lesions are made in both the epicardial and endocardial surfaces of the heart; it should be performed only at centers experienced in the technique, either as a combined procedure or with epicardial ablation reserved for recurrence after endocardial ablation.[33] Heart failure may occur in advanced ARVC and is treated with standard drugs. Because a history of vigorous sustained exercise among carriers of a pathogenic ARVC desmosome mutation is associated with an earlier onset of symptoms and a higher prevalence of VT or ventricular fibrillation,[31] there is a task force recommendation that persons with

definite or suspected ARVC should not compete in most competitive sports.[34]



EFIGURE 77.5 Recommendations for implantable defibrillator in ARVC. (Corrado D, Wichter T, Link MS, et al: Treatment of arrhythmogenic right ventricular cardiomyopathy/dysplasia: an International Task Force Consensus Statement. Circulation 2015;132:441-53.)

Left Ventricular Noncompaction

Whether LV noncompaction (LVNC) should be classified as a distinct cardiomyopathy has been debated extensively, as LVNC is a morphologic trait that is shared by many cardiomyopathies as well as by other conditions, such as the channelopathies and congenital heart disease. Underlying this debate is the lack of adverse outcomes of the LVNC itself, so that published accounts of adverse events stem from an otherwise defined cardiomyopathy or arrhythmia phenotype. Whether LVNC is a marker of another genetically driven cardiovascular pathologic condition remains uncertain. When combined with the absence of any unique LVNC gene ontology, the question of phenotype versus cardiomyopathy remains unresolved, although mounting evidence has increased to favor the phenotype.[35] In 2006, LVNC was included as a genetic cardiomyopathy in an AHA scientific statement.[1] In 2008, the European Society of Cardiology questioned whether LVNC should be classified as a cardiomyopathy or "merely a congenital or acquired morphologic trait that is shared by many phenotypically distinct cardiomyopathies."[2] LVNC does not have its own gene ontology but intersects with those of DCM, HCM, and ARVC (**see eTable 77.1**). In support of its heritable basis, one recent systematic study of families of probands in whom LVNC was diagnosed showed familial disease in 32 of 50 probands (64%), with the phenotypes of many family members also being limited to LVNC (i.e., without DCM or HCM). Interestingly, in 41% of these (23 of 56) patients, plausible mutations in sarcomeric genes were identified, even though nonpenetrance of LVNC among family members carrying these mutations was common.[36]

Defining the LVNC phenotype has been confounded by various echocardiographic or CMR approaches that have led to an estimate of its frequency in a population-based study of as high as 23%; furthermore, the concordance of three different echocardiographic diagnostic schemata was congruent in only 30% of cases.[37] These diagnostic criteria have been summarized and include four echocardiographic-based and two cardiac CMR–based (**eTable 77.3**). The criteria used to define LVNC use ratios of compacted to

noncompacted myocardium and LV size and function are not components of the diagnosis. Echocardiographic-based approaches differ as to whether measurements are obtained at end-systole or end-diastole, and the ratio of compacted to noncompacted myocardium varies. CMR approaches measure either the ratio of trabeculated to compact myocardium (T/M ratio of > 2.3 is considered LVNC) or the ratio of the mass of noncompacted to compacted myocardium (trabeculations > 20% are considered LVNC). The population-based Multi-Ethnic Study of Atherosclerosis evaluated the range of normal LV wall thicknesses in eight ventricular wall regions in 1000 participants using a T/M ratio of 2.3.[38] In 323 fully evaluable individuals without cardiac disease or hypertension, 140 (43%) had a T/M ratio of greater than 2.3 in at least one LV region, and in 20 (6%) the T/M ratio was greater than 2.3 in more than two regions. No associations were identified with age, sex, ethnicity, height, or weight.

ETABLE 77.3

Echocardiographic and Magnetic Resonance Imaging Diagnostic Criteria for Left Ventricular Noncompaction

Echocardiographic Criteria
Chin, et al. (California criteria)*
LVNC is defined by an X/Y ratio ≤0.5
These criteria evaluate trabeculae at the LV apex on the parasternal short-axis and apical views and by using the LV free wall thickness at end-diastole
Jenni, et al. (Zurich criteria)†
Bilayered myocardium consisting of a thin C layer and a much thicker NC layer with deep endomyocardial recesses: NC/C > 2
Predominant location of the pathology is midlateral, midinferior, and at the apex
Evidence of intertrabecular recesses filled with blood from the LV cavity
Acquisition of image views: short axis with measurement of the NC/C ratio performed at end-systole
Stöllberger and Finsterer (Vienna criteria)‡
Four or more trabeculations protruding from the LV wall, located apical to the papillary muscles and visible in one imaging plane
Trabeculations with the same echogenicity as the myocardium and synchronous movement with ventricular contractions
Perfusion of the intertrabecular recesses from the LV cavity
Acquisition of images in the apical four-chamber view; atypical views to obtain the best-quality image for differentiation between false chords, aberrant bands, and trabeculations
Paterick, et al. (Milwaukee criteria)§
Evaluation of trabeculation sizes (NC myocardium) in relation to C wall thicknesses in multiple imaging windows and at different ventricular levels throughout the cardiac cycle
Identification of the bilayered myocardium (C and NC) in short-axis views at the mid and apical levels and in the apical two- and four-chamber and apical long-axis views
Thicknesses of the C and NC sections of the myocardium are best measured in short-axis views at end-diastole, with an NC/C ratio > 2 being diagnostic of LVNC
Magnetic Resonance Criteria
Petersen, et al.‖
Ratio between NC and C layers > 2.3 at end-diastole
Jacquier, et al.¶
Trabeculated LV mass > 20% of global LV mass (measurements made at end-diastole)

Molecular and Clinical Genetics of Left Ventricular Noncompaction

LVNC has been observed in all cardiomyopathy phenotypes.[39] Although some studies suggest that LVNC

with normal LV systolic function, physiology, and chamber dimension engenders an increased risk for the later development of systolic dysfunction, as well as an ongoing increased risk for thromboembolism related to the marked increase in noncompacted (trabecular) mass, it has been difficult to estimate the disease-related risk that is specific to LVNC and independent of the underlying cardiomyopathy itself. Mutations in approximately a dozen genes known to cause familial DCM or HCM have also been identified in individuals with familial LVNC,[36] but these variants have no unique characteristics that predict an LVNC phenotype.

Approach to Clinical Genetic Evaluation, Including Clinical Genetic Testing, for Left Ventricular Noncompaction

If LVNC is identified in concert with another cardiomyopathy (DCM, HCM, RCM), the approach to the primary cardiomyopathy will drive the genetic evaluation process, as outlined earlier. This should include appropriate imaging modalities (echocardiography or CMR) as needed to define the phenotype in at-risk family members. For probands in whom LVNC has been identified but who are completely asymptomatic and have a normal cardiovascular phenotype except for the LVNC, family-based screening has not been studied and has not been recommended.

Clinical Management of Left Ventricular Noncompaction

It is not clear that any specific management is indicated for LVNC if it is identified independent of another cardiovascular diagnosis. When LVNC is diagnosed in concert with another cardiomyopathy (e.g., DCM, HCM, RCM, ARVC), the specific cardiomyopathy diagnosis will direct the surveillance and any treatment approaches, as per conventional guidelines. Whether the stroke rate is increased in patients with LVNC and normal cardiac function is uncertain, and no primary prevention recommendations are available. Case reports suggest that thromboembolic disease may occur in cases in which only LVNC has been identified, especially with extensive evidence of noncompaction. In clinical situations with clear evidence suggesting transient ischemic events, reversible neurologic deficits, or stroke without other obvious cause, secondary prevention should be considered and combined with an evaluation for a hypercoagulable condition.

Tachycardia-Induced Cardiomyopathy

Tachycardia for a prolonged period can result in diastolic and systolic ventricular dysfunction, even in the absence of other cardiac diseases. This condition is known as tachycardia-induced cardiomyopathy.[40] It is a diagnosis that can be made only retrospectively when correction of an arrhythmia is associated with improved ventricular function. However, it should be considered in any patient with tachycardia and LV systolic dysfunction who is not in sinus rhythm. The cardiomyopathy may be manifested either as an isolated condition or in association with preexisting cardiac disease. Thus a patient with mild DCM in whom atrial fibrillation develops may have a tendency for the development of decompensated heart failure, not only because of the loss of atrial function but also because the rapid, irregular rate of atrial fibrillation leads to further systolic dysfunction. Hyperthyroidism should be ruled out because it may cause both tachycardia and, rarely, an independent DCM. The “purest” form of tachycardia-induced cardiomyopathy is probably that caused by incessant or extremely frequent atrial tachycardia or permanent reciprocating junctional tachycardia, often in a child or young patient with systolic dysfunction.[41] However, almost any arrhythmia can cause tachycardia-induced cardiomyopathy, including

very frequent premature ventricular contractions (PVCs) or recurrent nonsustained VT.[42] Incessant atrial tachycardia causing tachycardia-induced cardiomyopathy may be mistaken for sinus tachycardia. If a previous ECG is available, comparison may be helpful, with specific attention being paid to subtle differences in P-wave morphology.

The duration of the arrhythmia, more than the heart rate, is probably a critical factor in tachycardia-induced cardiomyopathy. Among 30 patients with incessant atrial tachycardia and tachycardia-induced cardiomyopathy, the mean duration of symptoms was 6 years. The mean ventricular response was just 117 beats/min, and rate control (primarily by ablation) was associated with normalization of the ejection fraction in all but one patient.[41] A decreased ejection fraction in the presence of atrial fibrillation may occasionally improve after the restoration of sinus rhythm. If the ventricular rate is well controlled, improvement of LV systolic function in atrial fibrillation with a reduced ejection fraction is uncommon, but it is important to assess ventricular rate control with 24-hour monitoring to confirm control during both exercise and rest. Most patients with PVC-associated tachycardia-induced cardiomyopathy have more than 20,000 PVCs over a 24-hour period, but the condition has also been described with a lesser frequency of arrhythmia.[33] Catheter ablation of PVCs, if possible, is generally associated with improvement in ventricular function in these patients.

Most cases of tachycardia-induced cardiomyopathy improve within 3 to 6 months after correction of the arrhythmia, but occasional patients have been seen with late improvement, up to 1 year. Because the rapid, irregular ventricular response to atrial fibrillation is associated with marked beat-to-beat variation in the ejection fraction, the most accurate way to determine whether an improvement in systolic function has really occurred is to evaluate the ejection fraction early after restoration of sinus rhythm and then compare it with a reevaluation 3 to 6 months later.

Following restoration of sinus rhythm, subtle abnormalities in LV function may remain, such as mild LV dilation despite normalization of the ejection fraction, and recurrence of arrhythmia can be associated with deterioration of LV function.[43] In an animal model, tachycardia was associated with diastolic dysfunction often before a decrease in systolic function. Tachycardia-induced LV diastolic dysfunction may occur in humans in the presence of a normal ejection fraction. Although poorly studied, it may be responsible for the symptoms of heart failure in some patients with arrhythmia and a preserved LV ejection fraction.[44] Few data on improvement in diastolic dysfunction following correction of arrhythmia are available.

Peripartum Cardiomyopathy

Peripartum cardiomyopathy (PPCM) is a DCM that occurs in a temporal relationship to pregnancy (**see also Chapter 90**). The incidence and clinical features of PPCM may differ among geographic regions, with the U.S. incidence estimated to be between 1 in 1150 and 1 in 3200 live births, as compared with 1 in 1000 live births in South Africa and 1 in 300 live births in Haiti. In the United States, PPCM is disproportionately found in black patients. Older age and multiple-fetus pregnancies appear to be risk factors. A genetic basis for PPCM, has support from two studies, which show that in at least some proportion of cases, a rare variant genetic cause, similar to that of familial DCM (reviewed earlier), is at play.[45,46] From a database of 520 DCM probands, all those or their family members with DCM who met the formal criteria for PPCM were identified, and rare variant mutations in known DCM genes (*MYH7*, *SCN5A*, *PSEN2*, *MYH6*, *TNNT2*, and *MYBPC3*) were present in 6 of 19 women who had sequence information available.[45] In a second earlier study, among 90 families with DCM, 6% were found to have at least one member with PPCM, and genetic screening of relatives of three patients with PPCM who

failed to show complete recovery revealed undiagnosed DCM in all three families.[46] From this study comes the recommendation that if DCM occurs during or following pregnancy, the same guidelines for idiopathic DCM presented earlier should be followed, namely, obtaining a comprehensive family history and performing clinical screening of first-degree relatives, including echocardiography (**see Fig. 77.6**). With evidence of familial disease, clinical genetic testing is indicated as for idiopathic DCM. A more recent study[11] provided more definitive evidence of the rare variant genetic basis of PPCM, where 172 women with PPCM underwent sequencing for DCM genes, with *TTN* truncating variants (TTNtv's) identified in 26 of the 172 (15%), similar to prior studies of TTNtv's in idiopathic DCM. This genetic evidence, combined with that of the prior studies, provides substantial evidence pointing to a rare-variant genetic cause of PPCM similar to other forms of DCM.

Clinical Features

In patients with PPCM, symptoms and signs of heart failure develop during pregnancy or after delivery, similar to those of any patient with heart failure caused by LV systolic dysfunction. Most diagnoses are made in the 4 months following delivery; prepartum diagnoses are most commonly made in the last month of pregnancy. However, the disorder has also been described in early pregnancy (pregnancy-associated cardiomyopathy). Because symptoms similar to those of heart failure (dyspnea, fatigue, and edema) may occur in normal pregnancy, it is possible that a proportion of cases have a delayed diagnosis. Furthermore, because spontaneous resolution of LV dysfunction is known to occur, mild cases in the peripartum period may be overlooked. Given the rarity of the disease, it is not possible to precisely determine the incidence of PPCM in subsequent pregnancies of patients who have had a previous episode. However, recurrence appears to be related to the degree of recovery from the initial episode; PPCM seems less likely to recur in women who enter a second pregnancy with a normal ejection fraction than in those with a persistent reduction in the ejection fraction.[47]

In approximately 50% of patients with PPCM who are given standard medical therapy, the LV ejection fraction returns to normal, although the patients may still be at risk for recurrent PPCM. The remainder are often stabilized with medical therapy; however, a proportion of patients may experience progressive heart failure. Following delivery, treatment of PPCM is the same as for other causes of systolic dysfunction. However, if heart failure occurs during pregnancy, ACE inhibitors or angiotensin-receptor blockers are contraindicated because of the risk for fetotoxic effects. Diuretics should be used with caution, and metoprolol should be used rather than carvedilol. Eplerenone should be avoided, but spironolactone can be used cautiously later in pregnancy.

Elevated prolactin occurs in nursing mothers, and the cleaved 16kDa N-terminal fragment of prolactin has been shown in experimental studies to produce marked endothelial damage and cardiomyocyte dysfunction. In addition, full-length prolactin promotes inflammation in peripartum cardiomyopathy. This has led to the clinical use of bromocriptine in PPCM, with a small pilot study showing a greater rate of LVEF normalization compared to controls.[47a] Although this disorder has a variable prevalence and outcome in different racial groups,[47b] the use of a short course of bromocriptine early in peripartum cardiomyopathy is strongly advocated in Europe.[47c] Despite lack of evidence from larger controlled trials it appears to be safe and should be considered in cases of PPCM. Heart transplantation has been performed in patients with severe PPCM. In the United States, approximately 5% of all women undergoing cardiac transplantation have PPCM as their primary indication; it represents the fourth most common cause in women. Posttransplantation outcomes of PPCM are similar to those for other indications.

Takotsubo Cardiomyopathy

Takotsubo cardiomyopathy (TC) (referred to as Takotsubo syndrome in Europe),[48] or stress-induced cardiomyopathy, is an acute, reversible condition first recognized in the 1990s. A recent European task force proposed a uniform definition (**Table 77.2**). It is estimated that in 2012, about 5500 patients were admitted to U.S. hospitals with TC, with an even greater number developing the condition while they were in the hospital secondary to a comorbid condition or stress. In an International Takotsubo Registry of 1750 patients, 89.8% were women, the vast majority postmenopausal.[49] Chest pain was the predominant symptom in 76%, dyspnea in 47%, and syncope in 7.7%. A preceding physical trigger occurred in 36% and an emotional trigger in 28%, and troponin values were elevated in 87%, with ST elevation shown on the ECG in almost half of the patients.

TABLE 77.2

Definition of Takotsubo Syndrome/Cardiomyopathy According to the Position Statement From the Taskforce on Takotsubo Syndrome of the Heart Failure Association of the European Society of Cardiology

1. Transient regional wall motion abnormalities of LV or RV myocardium occur and are frequently, but not always, preceded by a stressful trigger (emotional or physical).
2. The regional wall motion abnormalities usually[a] extend beyond a single epicardial vascular distribution and often result in circumferential dysfunction of the ventricular segments involved.
3. There is an absence of culprit atherosclerotic coronary artery disease, including acute plaque rupture, thrombus formation, and coronary dissection or other pathologic conditions, to explain the pattern of temporary LV dysfunction observed (e.g., hypertrophic cardiomyopathy, viral myocarditis).
4. New and reversible electrocardiography (ECG) abnormalities (ST segment elevation, ST depression, LBBB,[b] T-wave inversion, and/or QTc prolongation) are seen during the acute phase (first 3 months).
5. Significantly elevated levels of serum natriuretic peptide (BNP or NT-proBNP) are seen during the acute phase.
6. A positive but relatively small elevation in cardiac troponin can be measured with a conventional assay (i.e., disparity between the troponin level and the amount of dysfunctional myocardium present).[c]
7. Recovery of ventricular systolic function is apparent on cardiac imaging at follow-up (3 to 6 months).[d]

[a]Acute, reversible dysfunction of a single coronary territory has been reported.

[b]Left bundle branch block may be permanent after Takotsubo syndrome, but its presence should alert clinicians to exclude other cardiomyopathies. T-wave changes and QTc prolongation may take many weeks to months to normalize after recovery of LV function.

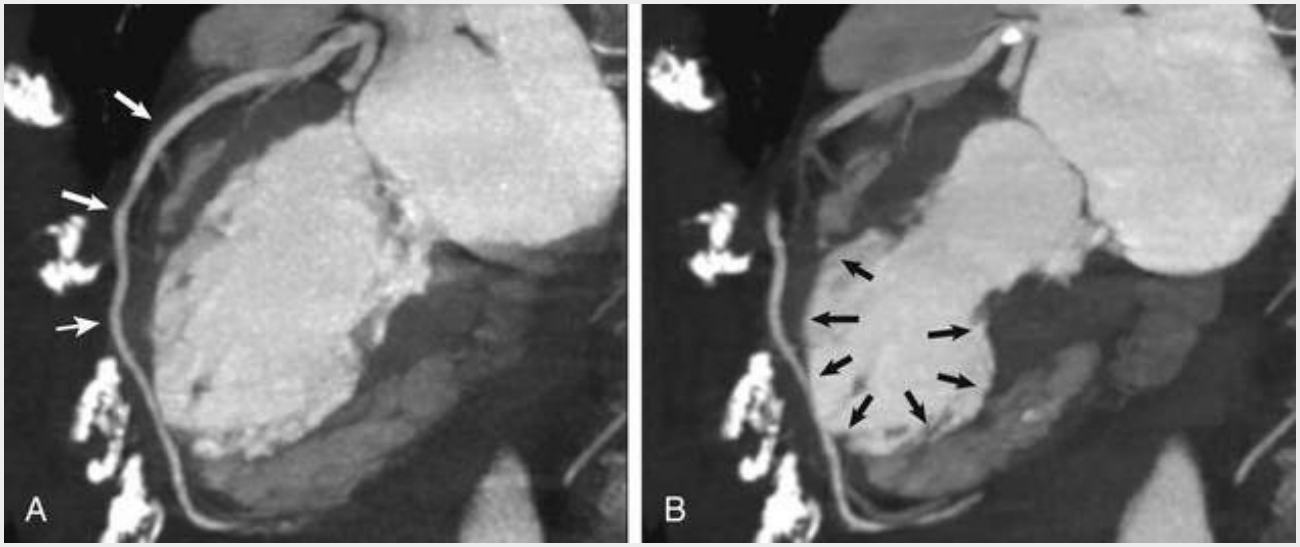
[c]Troponin-negative cases have been reported but are atypical.

[d]Small apical infarcts have been reported. Bystander subendocardial infarcts have also been reported, involving a small proportion of the acutely dysfunctional myocardium. These infarcts are insufficient to explain the acute regional wall motion abnormality observed.

From Lyon AR, Bossone E, Schneider B, et al: Current state of knowledge on Takotsubo syndrome: a Position Statement from the Taskforce on Takotsubo Syndrome of the Heart Failure Association of the European Society of Cardiology. Eur J Heart Fail 2016;18:8-27.

LV contractile abnormalities in TC are prominent, and although they involve the LV apex (resulting in the synonym of “apical ballooning syndrome”) in more than 80% of patients, (**eFig. 77.6**), regional wall motion abnormalities may be limited to the midventricular wall or other LV walls in a minority of patients. The wall motion abnormalities are characterized by their lack of a single coronary artery distribution, and coronary angiography reveals no evidence of acute obstructive coronary disease. Compensatory hyperdynamic contraction of the basal LV segments with associated apical LV dyskinesis may result in acute LV outflow tract obstruction because of systolic anterior motion of the mitral valve with an associated outflow tract gradient and hypotension. Although the long-term prognosis is good, an in-hospital mortality rate of 4.1% has been reported, primarily because of irreversible cardiogenic

shock, LV rupture, or embolization of LV thrombi. Malignant ventricular arrhythmia, particularly torsades de pointes associated with Takotsubo-related QT prolongation, may occur, as (rarely) may complete heart block.[50]



EFIGURE 77.6 Cardiac MRI in a patient with Takotsubo cardiomyopathy. **A,** Cardiac MRI (diastolic frame) demonstrating a patent left anterior descending artery (*arrows*). **B,** Classic apical ballooning (*arrows*) of the left ventricle (systolic frame) in the same patient as in **A.** (From Sanz J: Evolving diagnostic and prognostic imaging of the various cardiomyopathies. Ann N Y Acad Sci 2012;1254:123.)

The mechanism of myocardial dysfunction in stress-induced cardiomyopathy has not been fully elucidated, but a leading hypothesis suggests that a catecholamine surge results in regional microvascular dysfunction in susceptible patients, accompanied by cellular calcium overload.[51] Recurrence of Takotsubo cardiomyopathy is uncommon and is estimated to occur in in 1.5% to 2% of cases annually, with some recurrences occurring early after the initial event and others after many years.[52] Recurrence may be associated with dyskinesis in an area of the heart that is different from the area affected in the initial manifestation.

Therapy

Takotsubo cardiomyopathy is a self-limited disorder, usually with rapid resolution of the symptoms and LV dysfunction. The European task force position statement suggests classification into lower-risk and higher-risk categories, with the latter based on an LV ejection fraction of less than 45%, hypotension and an outflow tract gradient of greater than 40 mm Hg, and/or the presence of an arrhythmia.[48] Consideration of an ACE inhibitor and/or a beta blocker is recommended in the higher-risk groups. Because of the occasional association with acute QT prolongation, care should be taken to avoid using QT-prolonging medications, such as macrolide antibiotics or certain antiarrhythmic agents. In patients with hypotension associated with Takotsubo cardiomyopathy, pressors should be used with caution because LV outflow tract obstruction may be precipitated. Occasionally, thrombus formation may occur in the dyskinetic segment. Even though a visualized thrombus mandates anticoagulation, routine anticoagulation for dyskinesis without thrombus is not recommended, because of the rapid resolution of the condition. Although the occurrence of a catecholamine trigger might be a reason to use a beta blockade in all patients to prevent recurrence, the rarity of recurrence plus the description of de novo and recurrent Takotsubo cardiomyopathy in patients receiving beta blockers has reduced enthusiasm for this approach.

Restrictive and Infiltrative Cardiomyopathies

The restrictive cardiomyopathies (RCMs) are a heterogeneous group of diseases characterized by a nondilated left ventricle, often with a well-preserved ejection fraction. The predominant manifestation is diastolic dysfunction as a result of myocardial disease, and although severe hypertensive disease, aortic stenosis, and some cases of HCM may feature restrictive pathophysiology, these conditions are not classified as RCMs. Some infiltrative cardiac diseases such as amyloidosis produce an RCM, whereas others, such as sarcoidosis, have an infiltrative component but are predominantly manifested as DCMs. Thus, just as DCM is a morphologic condition that encompasses several causes of cardiomyopathy, the terms *restrictive cardiomyopathy* and *infiltrative cardiomyopathy* are pathophysiologic and anatomic definitions of cardiomyopathies that have overlaps with several well-defined conditions.

Approach to Identifying a Cause of Restrictive Cardiomyopathy

Because RCM is not always an isolated cardiac disease but may arise secondary to other acquired or genetic diseases, the diagnostic approach is challenging for the cardiovascular specialist (**see Table 77.1**). Endomyocardial biopsy may be much more relevant for the diagnosis of a specific cause in patients with RCM than in those with DCM or HCM insofar as RCM may be caused by an infiltrative cardiac process without systemic involvement or with subclinical involvement of other organs.[53] When a cause cannot be identified, the condition is known as *idiopathic RCM*. Unlike with DCM, *familial RCM* is distinctly uncommon. Regardless of whether a cause can be found, a comprehensive family history should always be obtained and clinical screening of first-degree relatives should be strongly considered.[3,54] If the family history is suggestive or screening of first-degree relatives shows a related myocardial abnormality, a genetic cause can be sought by following the cardiomyopathy guidelines (**see Fig. 77.6**).

Clinical and Molecular Genetics of Restrictive Cardiomyopathy

The clinical genetic features of familial RCM are similar to those of DCM in that reduced penetrance and a variable age at onset are commonly observed. Genes with rare variants implicated in the cause of idiopathic and nonsyndromic RCM are in most cases ones that encode sarcomeric proteins (**see eTable 77.1**).[13,55,56] Although some locus heterogeneity is apparent, it is much less so than with DCM (**see eTable 77.1**). Because cardiac hemodynamic findings commonly exhibit restrictive physiology in HCM, the genetic similarity of HCM and RCM suggests that in these cases the RCM phenotype can be viewed as a minimally hypertrophic HCM phenotype with prominent restrictive physiology. As noted earlier, at times "overlap" or "crossover" phenotypes of RCM and HCM have been observed in families with mutations in sarcomeric genes that demonstrate this principle.[13,55,56]

Clinical Features of Idiopathic Restrictive Cardiomyopathy

Idiopathic RCM has been described in individuals from infancy to late adulthood; it usually carries a poor prognosis, especially in children.[57] The disease is rare, and the largest adult series contains only 91 cases seen over a 17-year period.[58] In one series of 32 unrelated patients with end-stage disease, RCM was considered to be genetically determined either by the identification of pathogenic mutations (60%) or by evidence of familial disease without a known pathogenic mutation (in an additional 5 patients), for a total of 75% of these patients with a genetic cause.[59] Symptoms of idiopathic RCM are nonspecific and

reflect the presence of heart failure. Dyspnea is an initial complaint in most patients, edema occurs in approximately half, and palpitations, fatigue, and orthopnea are reported by 22% to 33%. Physical examination is usually consistent with biventricular heart failure, with jugular venous distention noted in most patients but ascites and significant edema being found in advanced cases. Atrial fibrillation is common, and a third heart sound is heard in one in four patients; murmurs are not a feature. The ECG has normal voltage, with only a minority of patients showing intraventricular conduction delay.

Echocardiography reveals a typical pattern of biatrial enlargement and nondilated ventricles with a normal LV ejection fraction and LV wall thickness (**Fig. 77.8**). At cardiac catheterization, both RV and LV filling pressure is elevated. Endomyocardial biopsy demonstrates nonspecific findings such as myocyte hypertrophy, interstitial fibrosis, and, not uncommonly, endocardial fibrosis. The survival rate is reduced in comparison with that of an age- and sex-matched population; the observed survival rate from the time of diagnosis is 64% at 5 years and 37% at 10 years.[60] Most deaths are associated with cardiac causes, either suddenly or secondary to heart failure, although a third die of noncardiac causes related to progressive age.

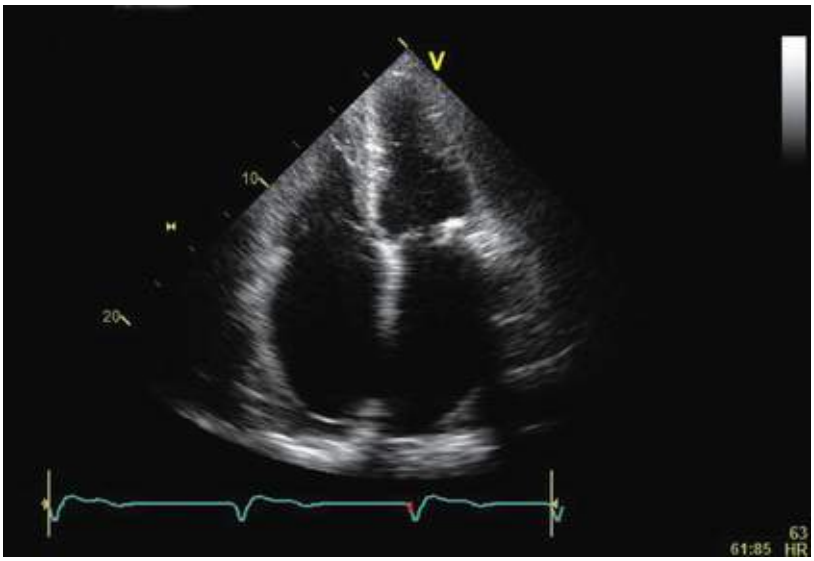


FIGURE 77.8 Echocardiogram showing restrictive cardiomyopathy**.** An apical four-chamber view is shown in an 80-year-old man with long-standing RCM. The LV ejection fraction was normal, with evidence of severe diastolic dysfunction on echocardiography and cardiac catheterization. Note the massive biatrial enlargement and normal LV wall thickness.

The differential diagnosis of idiopathic RCM includes the infiltrative cardiomyopathies, such as amyloidosis, or constrictive pericarditis. Unlike idiopathic RCM, amyloidosis is associated with increased LV wall thickness and subtle abnormalities in LV systolic function, with specific findings on cardiac biopsy. Constrictive pericarditis is more difficult to differentiate from RCM because most of the clinical features overlap between the two disorders. A thickened pericardium noted on echocardiography, CT, or CMR in a patient with heart failure and a preserved ejection fraction without wall thickening suggests constrictive pericarditis; however, it bears emphasis that 18% of patients with constrictive pericarditis have normal pericardial thickness.[61] Advanced echocardiographic techniques may be of help in distinguishing constrictive pericarditis from RCM (**see also Chapter 14**), but endomyocardial biopsy may be required unless an alternative diagnosis is clear. Treatment of idiopathic RCM is generally limited to medical treatment of heart failure, but in selected advanced cases, cardiac transplantation has been performed with similar outcomes as in those with nonrestrictive cardiomyopathy.[58]

Cardiac Amyloidosis

Cardiac amyloidosis is an infiltrative cardiomyopathy that in some forms is associated with a toxic component. The term *amyloid* refers to a proteinaceous material derived from misfolded products of a variety of precursor proteins. On electron microscopy, amyloid fibrils are seen as extracellular, nonbranching fibrils 7 to 10 nm in diameter. Amyloid deposits also contain a serum amyloid P component, as well as several other common constituents such as heparan and dermatan sulfate proteoglycans and glycosaminoglycans, apolipoprotein E, type IV collagen, and laminin.

The type of amyloidosis is defined by the precursor protein. The four most common precursor proteins associated with cardiac amyloidosis are light chains produced by a plasma cell dyscrasia (amyloid light-chain [AL] amyloidosis), amyloid derived from wild-type transthyretin (TTRwt) (previously referred to as senile systemic amyloidosis) or mutant TTR (ATTRm, or familial amyloidosis), and localized atrial amyloid deposits derived from atrial natriuretic peptide. Secondary (AA) amyloidosis, in which the deposits are derived from the inflammatory protein serum amyloid A, rarely involves the heart (**Table 77.3**).

TABLE 77.3

Features of Cardiac Amyloidosis Based on Amyloid Type

TYPE OF AMYLOIDOSIS	PRECURSOR PROTEIN	USUAL AGE AT ONSET	MAIN ORGANS INVOLVED	AVERAGE SURVIVAL TIME IN UNTREATED PATIENTS	SPECIFIC TREATMENT
AL (primary)	Abnormal light chains	50+	All except central nervous system; heart involved in 50% of cases	Noncardiac disease, 24 months; disease with heart failure, < 9 months	Chemotherapy aimed at plasma cells
Familial (ATTR)	Mutant TTR	20-70+ (partially dependent on mutation)	Peripheral and autonomic neuropathy; heart	7 to 10 years for neuropathy	Liver transplantation. Investigational agents to stabilize TTR (tafamidis) or suppress its production
Senile systemic amyloidosis (SSA)	Wild-type TTR	70+	Heart	5 to 7 years	Investigational agents to stabilize TTR (tafamidis) or suppress its production
Isolated atrial amyloidosis (IAA)	Atrial natriuretic peptide	Unknown	Cardiac atria (particularly in already diseased hearts)	No effect on survival	None needed
AA (secondary amyloidosis)	Serum amyloid A (SAA), an inflammatory protein	Teens upward, depending on underlying inflammatory condition	Liver, kidney; heart rarely	10+ years	Treatment of underlying inflammatory condition

The clinical pattern and prognosis of cardiac amyloidosis differ among the different types; AL amyloidosis is often a multiorgan disease; ATTRm amyloidosis affects the heart or the peripheral or autonomic nervous system, or both; and ATTRw predominantly affects the heart. Individual types of cardiac amyloidosis are described in the following sections.

Amyloid Light-Chain Amyloidosis

The precursor protein of AL amyloidosis is an abnormal light chain produced by dysfunctional plasma cells. AL amyloidosis is closely related to multiple myeloma, may overlap with it, and is treated with similar drugs. Of all the amyloidoses, AL amyloidosis affects the most organs, with almost every organ system potentially being involved except for the central nervous system. Approximately 50% of patients with AL amyloidosis have evidence of cardiac involvement at the initial evaluation, which is clinically significant in about 75%.[62] The clinical manifestation of AL cardiac amyloidosis is rapidly progressive heart failure, often associated with evidence of systemic disease elsewhere. Although the heart failure is biventricular, right-sided signs frequently predominate, with prominent peripheral edema and occasional ascites. At times patients may have typical angina because of amyloid infiltration of small vessels.

Postural syncope may be due to autonomic dysfunction, but recurrent exertional syncope or presyncope may indicate severe cardiac disease with a fixed, low cardiac output.

Physical examination usually reveals sinus rhythm or, less commonly, atrial fibrillation with a normal- to low-volume pulse. Jugular venous pressure may be markedly elevated, and a Kussmaul sign is frequently present. The apex beat is often impalpable and heart sounds are generally normal. An unusual feature of cardiac amyloidosis, particularly AL amyloidosis, is the absence of a fourth heart sound despite the small stiff ventricle. This corresponds to atrial systolic dysfunction secondary to atrial infiltration. If a third heart sound is present, it usually indicates RV dysfunction. A pleural effusion is often detected on physical examination and may be large, particularly if pleural amyloid infiltration is also present. Congested hepatomegaly is common and ascites may be detected. Evidence of noncardiac involvement is a useful clue to the presence of a systemic disorder and may include periorbital purpura (virtually pathognomonic of AL amyloidosis), heavy proteinuria, peripheral or autonomic neuropathy, macroglossia, or cachexia.

The *ECG* frequently shows low-voltage limb leads, often with an unusually rightward axis (**Fig. 77.9A**). First-degree AV block is common, and Q waves are frequently seen in leads V_1 to V_3. Left bundle branch block is rare in AL amyloidosis.

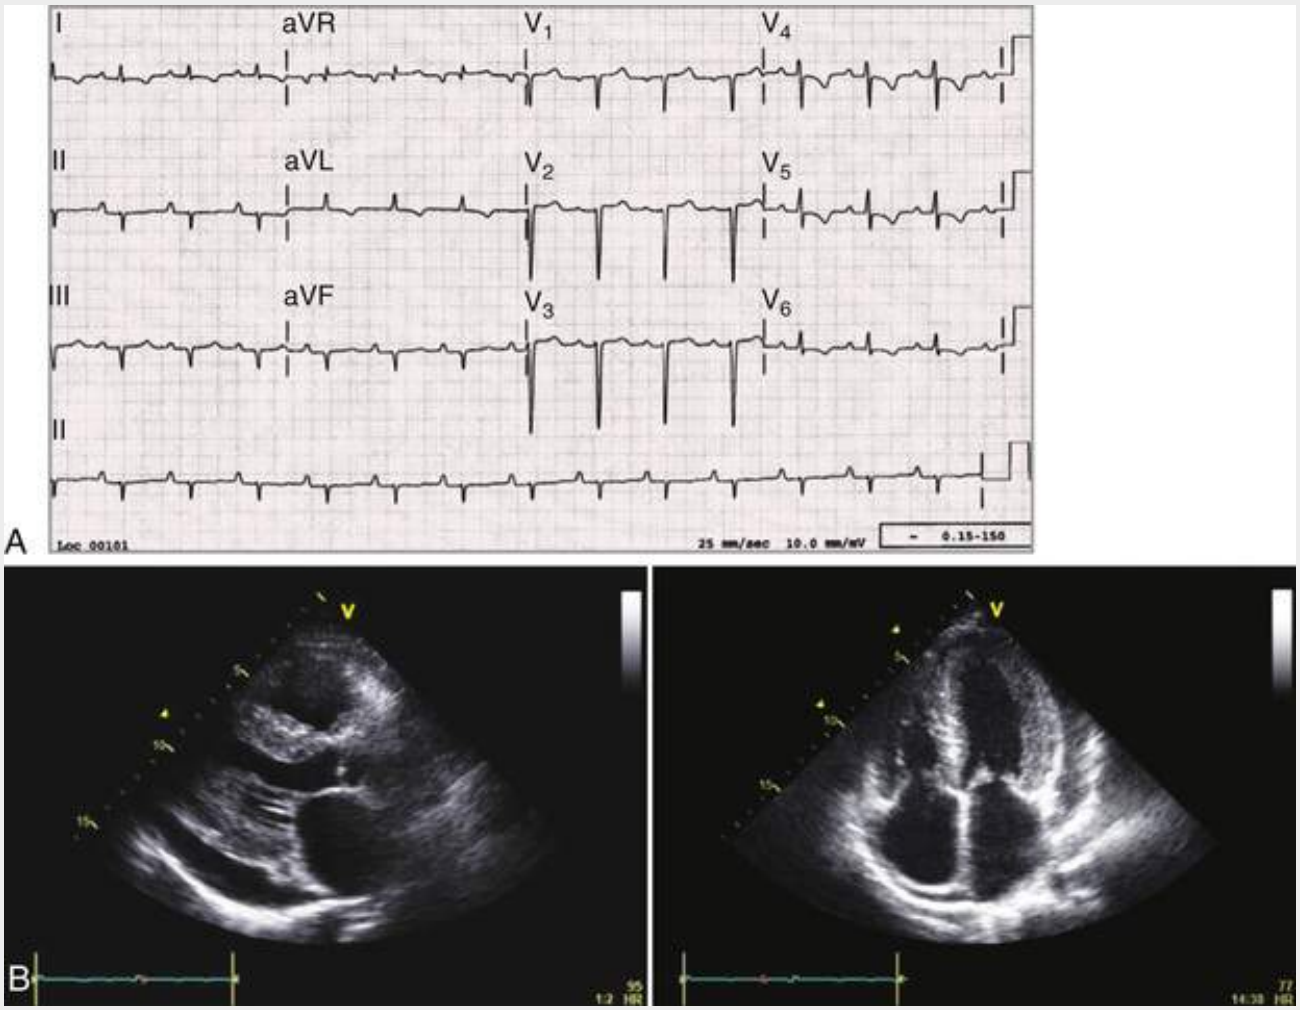

FIGURE 77.9 Cardiac amyloidosis. **A,** ECG in a patient with AL amyloidosis. Note the low-voltage limb leads with an unusual axis, pseudomyocardial infarction pattern in the inferior and septal leads, and T wave inversions. **B,** Echocardiogram in a patient with AL amyloidosis. Parasternal **(left)** and apical four-chamber **(right)** views in the same patient as in **A** are shown. Concentric wall thickening and biatrial enlargement with a pericardial effusion are evident. The patient was in severe heart failure and received a heart transplant followed by chemotherapy and autologous stem cell transplantation.

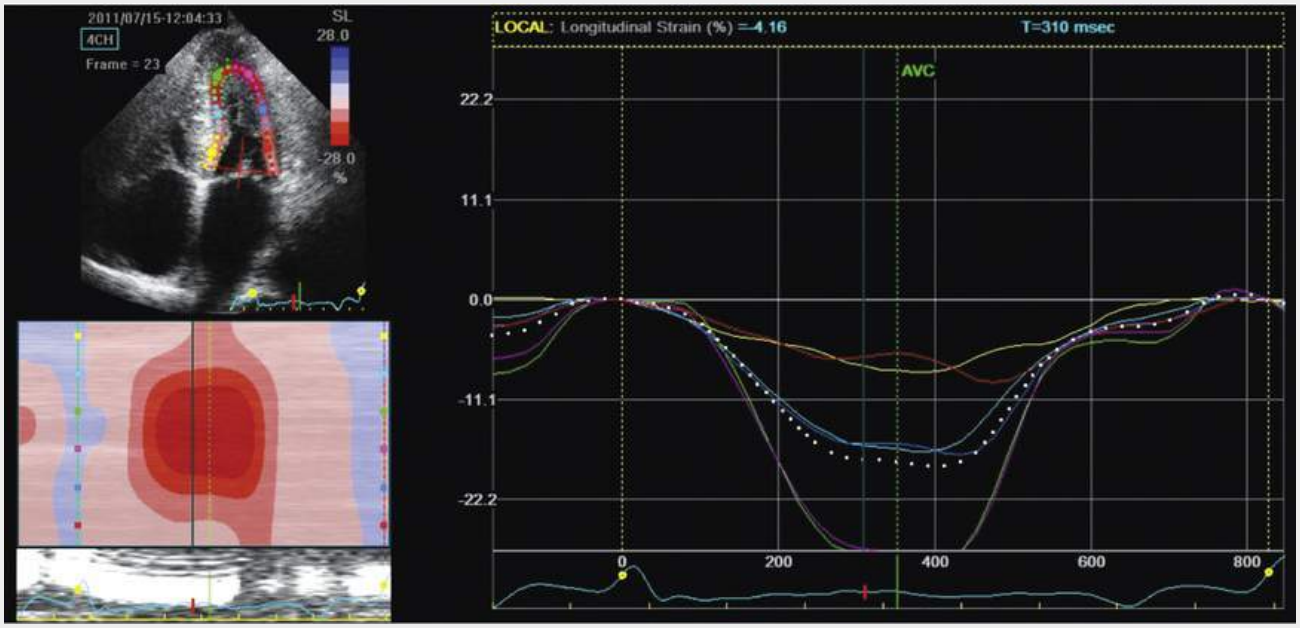
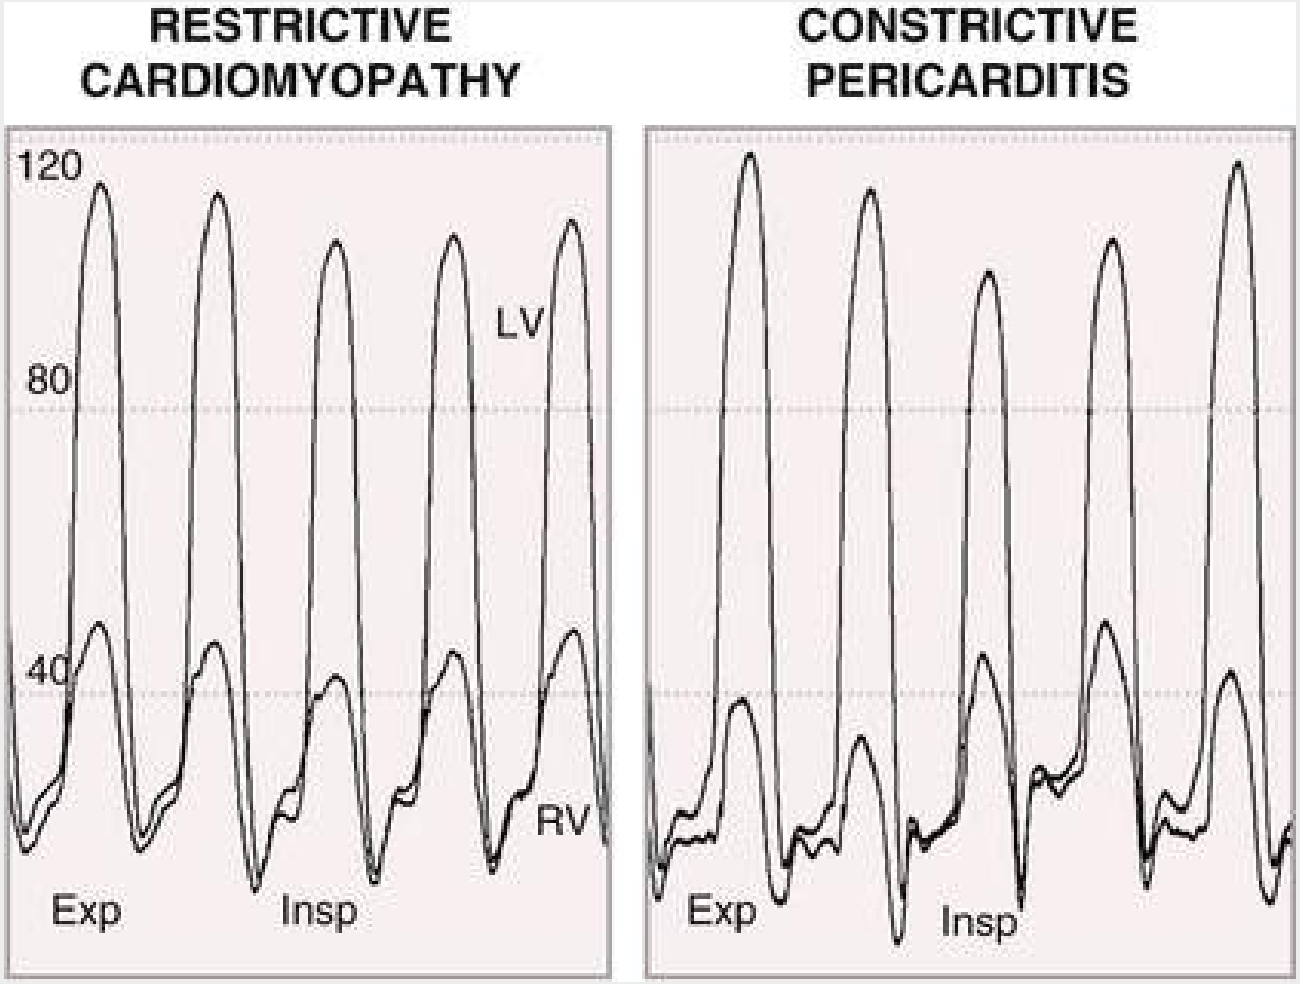
Echocardiography generally reveals a pattern strongly suggestive of an infiltrative cardiomyopathy, and is similar in all types of cardiac amyloidosis. The LV cavity is normal to small, LV and, often, RV wall thickness is increased, and there may be increased myocardial echogenicity (**Fig. 77.9B**). Mitral regurgitation, if present, is rarely more than moderate, and the aortic valve seldom shows any significant amyloid-related dysfunction. Doppler tissue imaging frequently suggests elevated LV filling pressure and severely impaired longitudinal LV systolic function, even with a near-normal LV ejection fraction. Speckle tracking shows a classic appearance of regional longitudinal dysfunction characterized by relative apical sparing and prolonged diastolic relaxation[63] (**see eFig. 77.7**). Occasionally, asymmetric septal thickening with an LV outflow tract gradient may be present and mimic HCM. Cardiac catheterization shows bilateral elevation of filling pressures, and a dip-and-plateau tracing is often seen; unlike in constrictive pericarditis, however, equalization of diastolic pressures is uncommon. Careful evaluation of simultaneously recorded LV and RV pressures during respiration demonstrates concordant changes in systolic pressures in amyloidosis and other restrictive cardiomyopathies, as opposed to a discordance (inspiratory increase in RV systolic pressure with a simultaneous decrease in LV pressure) seen in constrictive pericarditis (**see eFig. 77.8**).[64]



EFIGURE 77.7 Echocardiographic strain imaging in amyloid cardiomyopathy. The “bulls-eye” appearance of the longitudinal strain pattern from an echocardiographic apical four-chamber view is shown in a patient with familial amyloid cardiomyopathy and a normal ejection fraction. The appearance represents a gradient of longitudinal strain from the apex to the base with relatively well-preserved apical strain and severely impaired basal strain. In contrast, normal subjects have no significant strain gradient from the apex to the base. This appearance, a useful diagnostic finding, is seen in more than 80% of patients with cardiac amyloidosis, regardless of the precursor amyloid protein.



EFIGURE 77.8 Hemodynamics of restrictive cardiomyopathy and constrictive pericarditis. Differentiation of RCM **(left)** and constrictive pericarditis **(right)** can be achieved by examination of simultaneously measured RV and LV systolic pressure responses to respiration. In constrictive pericarditis, inspiration is associated with an increase in RV systolic pressure and a concordant decrease in LV systolic pressure (ventricular interdependence). This is not seen with RCM. *Exp*, expiration; *Insp*, inspiration. (From Nishimura RA, Carabello BA: Hemodynamics in the cardiac catheterization laboratory of the 21st century. Circulation 2012;125:2138.)

CMR is a useful diagnostic tool for all forms of cardiac amyloidosis. The classic features of cardiac amyloidosis (**Fig. 77.10**) include biventricular thickening with normal cavity size, as well as atrial septal thickening. With the use of gadolinium, there is often difficulty in nulling the myocardium, and late gadolinium enhancement typically shows diffuse or patchy subendocardial enhancement, which often involves the atrium. This combination of findings is unusual in other cardiomyopathies and strongly suggests cardiac amyloidosis.

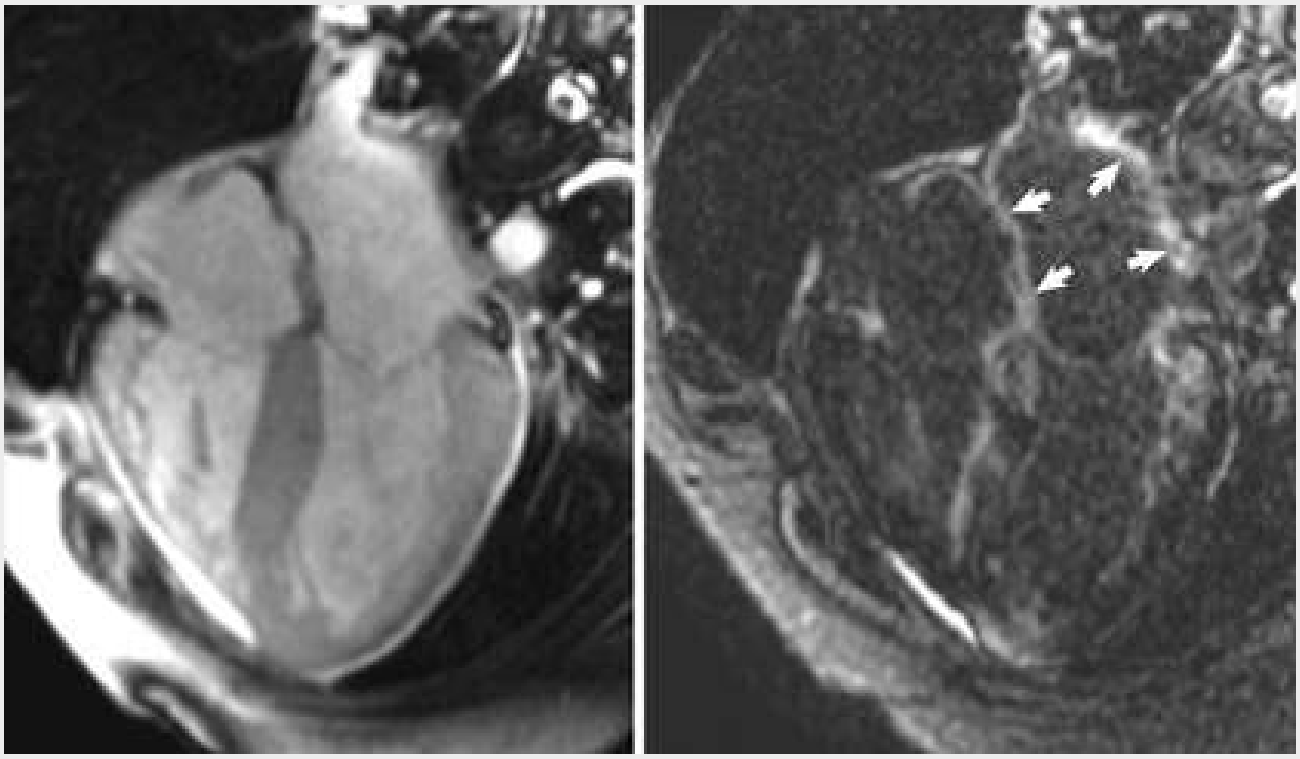


FIGURE 77.10 Cardiac MRI in a patient with amyloid cardiomyopathy. The **left panel** shows a thickened left ventricle with biatrial enlargement and a thickened atrial septum. The **right panel** is from the same patient and shows extensive delayed gadolinium enhancement involving not only the ventricles but also the atria extensively (*arrows*). Atrial amyloid deposition is associated with impaired atrial contraction and intraatrial thrombus formation.

Nuclear imaging using standard isotopes, such as sestamibi, is generally negative for ischemia, even in a patient with angina. Positron emission tomography (PET) with vasodilator stress such as adenosine may show widespread stress-induced subendocardial ischemia related to the small-vessel disease; early studies with the amyloid-avid agent florbetapir, approved for Alzheimer imaging, may show avid myocardial uptake. As discussed in **Chapter 21**, ^{99m}technetium pyrophosphate (^{99m}Tc-PYP) scanning shows promise in diagnosing AL amyloidosis.

Familial and Senile Systemic Amyloidosis

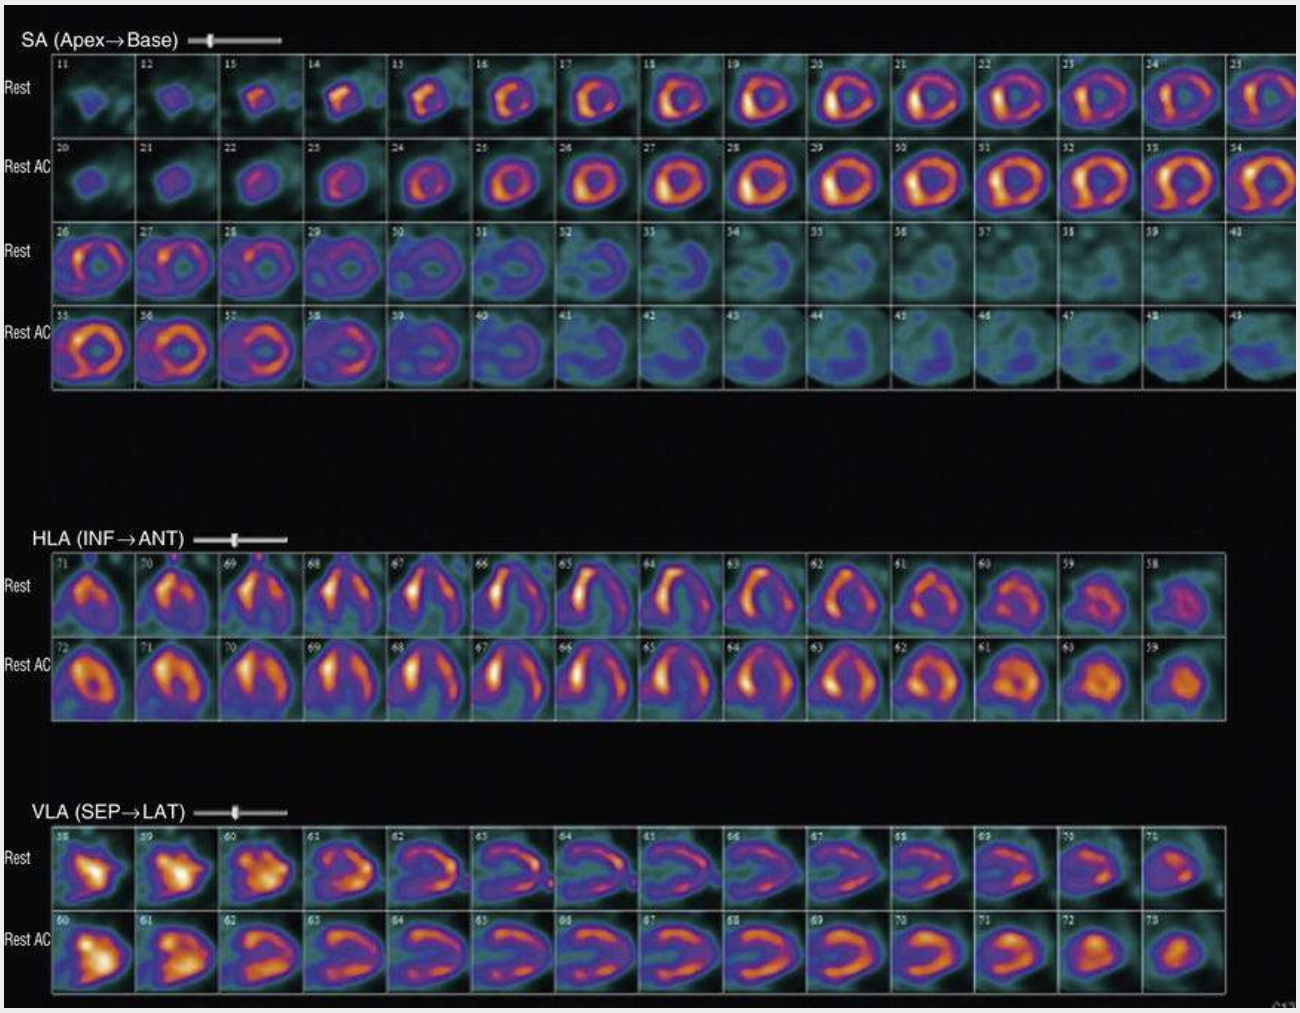
Familial amyloidosis is an autosomal dominant disease with relatively high penetrance. It is usually due to a point mutation in the hepatically expressed protein TTR encoded by the gene *TTR*. TTR is a 55-kDa protein that serves as a carrier of the thyroid hormone thyroxine (T_4) and retinol-binding protein bound to retinol; hence the acronym ***t***ransports ***t***hyroxine and ***r***etinol. Approximately 100 *TTR* point mutations are known, almost all of which produce an unstable protein that causes cardiac and/or peripheral or autonomic nervous system dysfunction. The two most common mutations are Val30Met and Val122Ile. Val30Met has been described worldwide, with several endemic areas in Japan, Brazil, Sweden, and Portugal. In younger patients, the disease is predominantly manifested as a neuropathy, and cardiac involvement, if it occurs, consists of sinus node dysfunction and mild cardiac infiltration. In contrast, when the disease occurs after middle age, cardiomyopathy tends to predominate. Val122Ile is a relatively common cause of amyloid cardiomyopathy. Approximately 3.4% of the U.S. black population and the Afro-Caribbean population in the United Kingdom are heterozygous for the Val122Ile mutation, which can result in amyloid cardiomyopathy in the sixth and seventh decades of life. The mutation is associated with an increased risk of developing heart failure even if an overt amyloid cardiomyopathy is not present.[65] Val122Ile is almost never associated with neuropathy, other than carpal tunnel syndrome.[66]

Wild-type ATTRwt is due to the deposition of amyloid derived from normal TTR. The heart is the only major organ to be clinically involved, but deposits of amyloid are frequently also found at autopsy in the lungs and gastrointestinal tract.[67] ATTRwt tends to occur from the end of the seventh decade onward and is predominantly a disease of men, with a male-to-female ratio of approximately 20 : 1.[67] Although small deposits of amyloid derived from wild-type TTR are commonly seen on pathologic examination of aged hearts, patients with clinically apparent ATTRwt have extensive deposits leading to cardiac dysfunction. The disease is characterized by progressive biventricular failure without neuropathy. Previously considered a rarer disease than ATTRm or AL amyloidosis, it is probably the commonest form of amyloid cardiomyopathy.

Distinctive Clinical Features.

In contrast to the low voltage of AL amyloidosis, the ECG in TTR amyloidosis frequently shows normal voltage with nonspecific conduction disturbance and ST-T wave changes. Left bundle branch block is more common, and particularly in ATTRwt, high-degree AV block may occur as the disease progresses. The echocardiographic appearance of TTR cardiomyopathy, whether caused by a mutant protein or wild-type protein, is similar to that of AL amyloidosis described earlier. Nonetheless, the course is more indolent, and if left untreated, the survival rate is considerably longer in ATTRwt than in untreated AL amyloidosis, with survival in ATTRm being somewhere between the other two.[68] This observation gave rise to a hypothesis that in AL amyloidosis, in addition to damage from infiltration, a toxic component from circulating free light chains may exist. Subsequent observations showing rapid clinical improvement in heart failure after treatment of AL amyloidosis, as well as compelling laboratory data demonstrating light chain toxicity, appear to have confirmed the initial hypothesis.[69]

Technetium pyrophosphate scanning (DPD scanning in Europe) has emerged as an extremely useful diagnostic tool for patients with suspected TTR amyloidosis. The finding of a strongly positive scan is virtually pathognomonic for TTR amyloidosis, with patients with AL amyloidosis having little or no uptake of the isotope in myocardium. A strongly positive scan in a patient with a typical echocardiographic appearance of amyloidosis and no evidence of a plasma cell dyscrasia is considered diagnostic of TTR amyloidosis and may obviate the need for a tissue biopsy (**eFig. 77.9**).[70,71]



EFIGURE 77.9 Technetium pyrophosphate scan in an 81-year-old patient with wild-type amyloidosis (ATTRwt.). Paired sets of images with nonattenuation-corrected images are labeled "rest," and corresponding CT-based attenuation-corrected images are labeled "rest AC." The patient had heart failure and marked wall thickening on his echocardiogram; he did not have any evidence of a plasma cell dyscrasia. The heart avidly took up the isotope (a normal heart exhibits no uptake). This is virtually pathognomonic of TTR amyloidosis. In this case, it was later confirmed by biopsy. Genetic testing for a *TTR* mutation was negative. *AC*, attenuation corrected; *HLA*, horizontal long axis; *SA*, short axis; *VLA*, vertical long axis. (Courtesy Dr. Sharmila Dorbala, Brigham and Women's Hospital, Boston.)

Isolated atrial amyloid cannot be diagnosed other than on a biopsy specimen. Its predominant manifestation is an increased prevalence of atrial fibrillation, and its main significance lies in the recognition that if it is found in an operative biopsy specimen from an excised atrial appendage, it is not associated with ventricular amyloidosis.

Diagnosis

The diagnosis of amyloidosis relies on clinical awareness of and suspicion for the disease, clinical features, blood and tissue analysis, and positive findings on biopsy. In patients with AL amyloidosis, serum and/or urine immunofixation generally reveals a monoclonal gammopathy. Measurement of serum free kappa and lambda light chains demonstrates an excess of either kappa or lambda in more than 90% of cases of AL amyloidosis and is a very useful test for monitoring the response to therapy. Patients with TTR amyloidosis do not have a disease-related monoclonal gammopathy and have a normal serum free light chain ratio. However, an unrelated monoclonal gammopathy of unknown significance is present in more than 5% of patients older than 70 years and may confuse the picture if found in a patient with TTR amyloidosis. Bone marrow biopsy in patients with AL amyloidosis usually reveals an excess of plasma cells, often in the range of 10% to 20% of the total cellularity. Plasma cell cellularity in the marrow in

excess of 30% suggests an overlap syndrome with multiple myeloma.

A definitive diagnosis of the amyloidoses usually requires biopsy. Subcutaneous fat pad aspiration may show amyloid deposits in more than 80% of patients with AL amyloidosis, but experience in staining the small deposits is needed to avoid false-positive or false-negative results. The yield of fat pad biopsy is lower in TTR amyloidoses. Endomyocardial biopsy is almost universally positive in cardiac amyloidosis, unlike many other cardiomyopathies. It also offers the advantage of being able to measure right-sided heart pressures at the time of the biopsy and, in skilled hands, carries a low complication rate.

It is not sufficient simply to make a tissue diagnosis of amyloidosis without precise typing of the amyloid, because treatment differs greatly, depending on the underlying precursor protein. Immunohistochemistry, ideally performed on a fresh tissue specimen, has moderate specificity, but inaccuracies still occur even in skilled hands. Molecular analysis of the amyloid type may be needed in cases in which the clinical pattern is equivocal, and laser microdissection of amyloid deposits with subsequent proteomic analysis is now considered the "gold standard."[72]

Treatment

The aim of treatment is twofold: treatment of the heart failure and management of the underlying amyloidogenic protein. In AL amyloidosis, diuretics are the mainstay of heart failure therapy. Hypotension is frequently present (often because of a combination of autonomic dysfunction and low cardiac output), and ACE inhibitors are poorly tolerated; they can precipitate worsening hypotension even with low doses. There is no evidence that beta blockade (even if tolerated) affects the outcome (although in low doses it may be helpful for control of the ventricular rate in atrial fibrillation), and calcium channel blockers are contraindicated because they frequently worsen heart failure. For severe heart failure, an intravenous infusion of diuretics with renal-dose dopamine may help mobilize fluid, but the role of inotropes is unclear. In TTR amyloidosis without autonomic neuropathy, ACE inhibitors in low doses are better tolerated than in AL. If high-degree AV block develops and necessitates pacing, biventricular pacing should be attempted because RV pacing in the stiff small-cavity ventricle appears to be detrimental.

Treatment of the plasma cell dyscrasia causing AL amyloidosis requires careful coordination between the cardiologist and a hematologist skilled in treating the disease, and consists of chemotherapy directed against plasma cells. High-dose chemotherapy with autologous stem cell transplantation is generally poorly tolerated in patients with cardiac amyloidosis, but bortezomib-based regimens are showing great promise in rapidly controlling the underlying plasma cell dyscrasia and stabilizing the patient.[73] Long-term survival is increasingly common. In many patients, normalization of serum free light chains is associated with significant improvement in heart failure despite the apparently unchanged appearance on echocardiography, most likely because of removal of the cardiotoxic effects of the amyloid precursor.[74]

In ATTRm amyloidosis, removal of the source of the amyloidogenic protein requires liver transplantation. Unfortunately, some patients with cardiac amyloidosis due to ATTRm have progression of the infiltrative cardiomyopathy even after liver transplantation; this is believed to be due to continued amyloid deposition derived from wild-type (as opposed to mutant) TTR. A combined liver-heart transplant needs to be considered in some patients, particularly if neuropathy and cardiomyopathy coexist. Some ATTRm patients, particularly those with Val122Ile, may benefit from isolated heart transplantation, because significant amyloid does not seem to recur in the transplanted heart. Heart transplantation for AL amyloidosis has successfully been performed and requires a carefully selected patient with clinically isolated cardiac amyloidosis who after transplantation is also willing to undergo intensive chemotherapy to abolish the plasma cell dyscrasia. Although many patients with ATTRwt are outside the usual age range

for cardiac transplantation, it has been performed successfully with a good long-term outcome. Because ATTRwt patients do not produce a mutant TTR, there is no role for liver transplantation. Unlike the dilated and ischemic cardiomyopathies, the role of an ICD in amyloidosis is far less clear. Many patients with amyloidosis who have had an ICD implanted still die suddenly with pulseless electrical activity, and use of an ICD should probably be limited to patients with aborted sudden death or syncope clearly caused by a ventricular arrhythmia. The Transthyretin-Associated Amyloidoses Outcome Survey (THAOS; NCT00628745) is a global, multicenter, longitudinal observational survey with a minimum duration of 10 years that is designed to better understand and characterize the natural history of the disease by studying a large and heterogeneous patient population.

Sarcoid Cardiomyopathy

Sarcoidosis is a multisystem disorder of unknown cause characterized histologically by noncaseating granulomas. In the United States the disease is most commonly seen in the black population and is more common in women than in men. Sarcoid has a higher incidence in Scandinavia and Japan. Cardiac involvement takes the form of ventricular dysfunction, heart block, and/or ventricular arrhythmias. Despite frequently being described as an RCM, the most common phenotype of sarcoid heart disease is a DCM, occasionally with aneurysm formation. Although most patients with sarcoid cardiomyopathy also have evidence of noncardiac disease, particularly lung disease, clinically isolated cardiac sarcoidosis is increasingly being recognized as a cause of heart block and ventricular arrhythmias. Sudden death, presumably from a ventricular arrhythmia, may be the first manifestation either of sarcoidosis itself or of heart disease in a patient with known pulmonary or systemic sarcoid. The prevalence of cardiac involvement in patients with pulmonary sarcoidosis was previously thought to be no more than 5%, but autopsy studies indicate a much higher prevalence, and recent cardiac imaging studies have demonstrated abnormalities in at least 25% of patients with pulmonary sarcoidosis.[75] With advanced imaging studies and a high index of suspicion, cardiac sarcoidosis is being diagnosed with increasing frequency in the absence of clinically apparent noncardiac disease.

Pathology

The pathology of sarcoid heart disease raises puzzling questions about the cause of the systolic dysfunction, which can be severe. Noncaseating granulomas, the hallmark of the disease, are patchily distributed even in severe disease and thus cannot alone account for the severe systolic dysfunction. Granulomatous lesions are associated with edema and inflammation, and widespread myocardial fibrosis is seen late in the disease (**Fig. 77.11**). The patchy nature of granulomatous infiltration and the sometimes extensive fibrosis render cardiac biopsy a low-yield procedure for detecting diagnostic histology in cardiac sarcoidosis, and finding granulomas may be difficult even at autopsy, because end-stage disease is characterized predominantly by fibrosis.[76] Occasionally, the right ventricle may be severely and predominantly involved, and several cases of apparent ARVC with a typical appearance on multimodality imaging have been described that are later found to be due to cardiac sarcoidosis.[77] RV function can be impaired in patients with severe pulmonary sarcoidosis and pulmonary hypertension, even in the absence of direct sarcoid involvement of the heart.

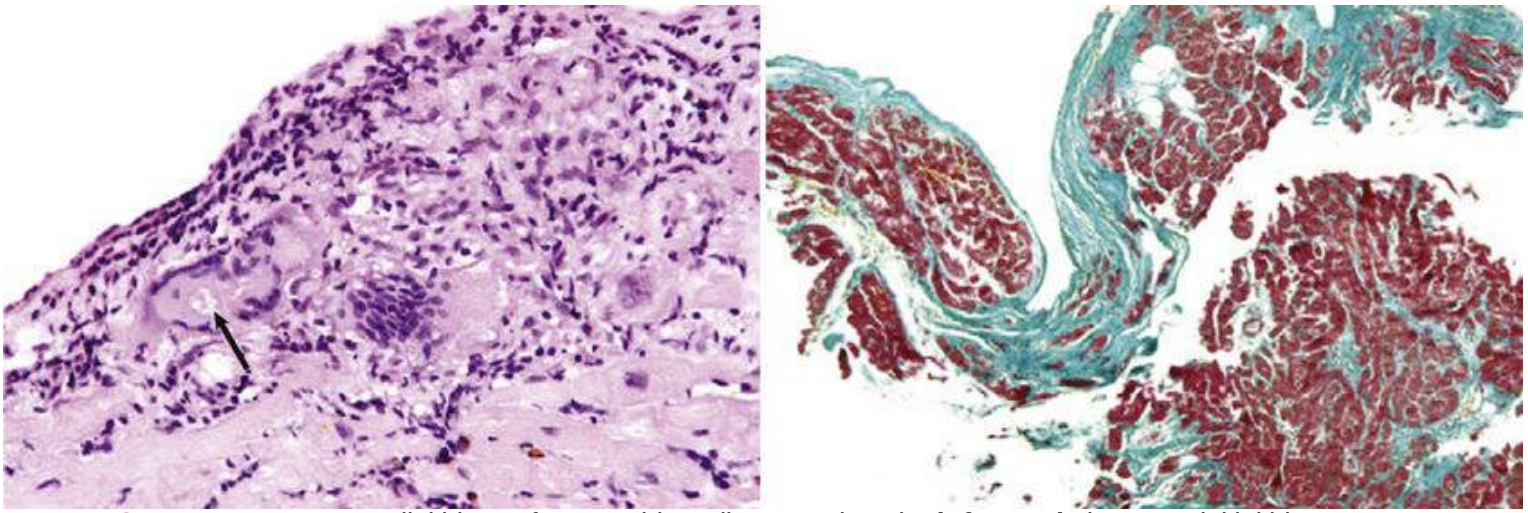


FIGURE 77.11 Myocardial biopsy for sarcoid cardiomyopathy. The **left panel** shows an initial biopsy specimen (hematoxylin-eosin staining) with an inflammatory noncaseating granuloma typical of sarcoid. The *arrow* points to an "asteroid body" in the cytoplasm of the giant cell; this is a common finding in various granulomatous diseases. The **right panel** shows a follow-up biopsy specimen (Masson trichrome stain, initial magnification 100×) in the same patient. No granulomas are present, and there is now extensive interstitial fibrosis (*green-staining area*). This demonstrates how granulomas may be missed on biopsy, particularly in advanced sarcoid cardiomyopathy, when fibrosis is extensive. (From Leone O, Veinot JP, Angelini A, et al: 2011 Consensus statement on endomyocardial biopsy from the Association for European Cardiovascular Pathology and the Society for Cardiovascular Pathology. Cardiovasc Pathol 2012;21:245.)

Clinical Features

The most common noncardiac site of sarcoid involvement is the lungs, with approximately half of patients having overt parenchymal disease and the remainder having isolated bilateral hilar lymphadenopathy. Other findings, in decreasing order of frequency, are hepatic and gastrointestinal involvement, ocular sarcoidosis, and neurologic sarcoidosis. Skin involvement in sarcoidosis is not uncommon, and lesions appear to have a predilection for scars and tattoos. In patients with established extracardiac sarcoid, LV systolic dysfunction is almost always due to associated cardiac sarcoidosis.

The most common clinical feature of cardiac sarcoidosis is biventricular heart failure. Mitral regurgitation, often caused by papillary muscle involvement in addition to LV dilation, may be severe. Sarcoid granulomas have a predilection for the cardiac conduction system, and high-degree AV block may occur, either as an initial manifestation of cardiac sarcoidosis or later in the disease (**Fig. 77.12**). Both atrial and ventricular arrhythmias are common, the latter arising from either ventricle. Once causes such as Lyme disease have been ruled out, complete heart block in a young patient suggests sarcoidosis, especially if ventricular arrhythmias are present, and imaging should be pursued in all such cases. Sudden cardiac death is almost always associated with grossly visible scarring and fibrosis at autopsy. A rare manifestation of cardiac sarcoidosis is acute sarcoid myocarditis, characterized by high-degree AV block, malignant ventricular arrhythmia, and heart failure. It may be difficult to distinguish this from giant cell myocarditis unless systemic features of sarcoid are also present.

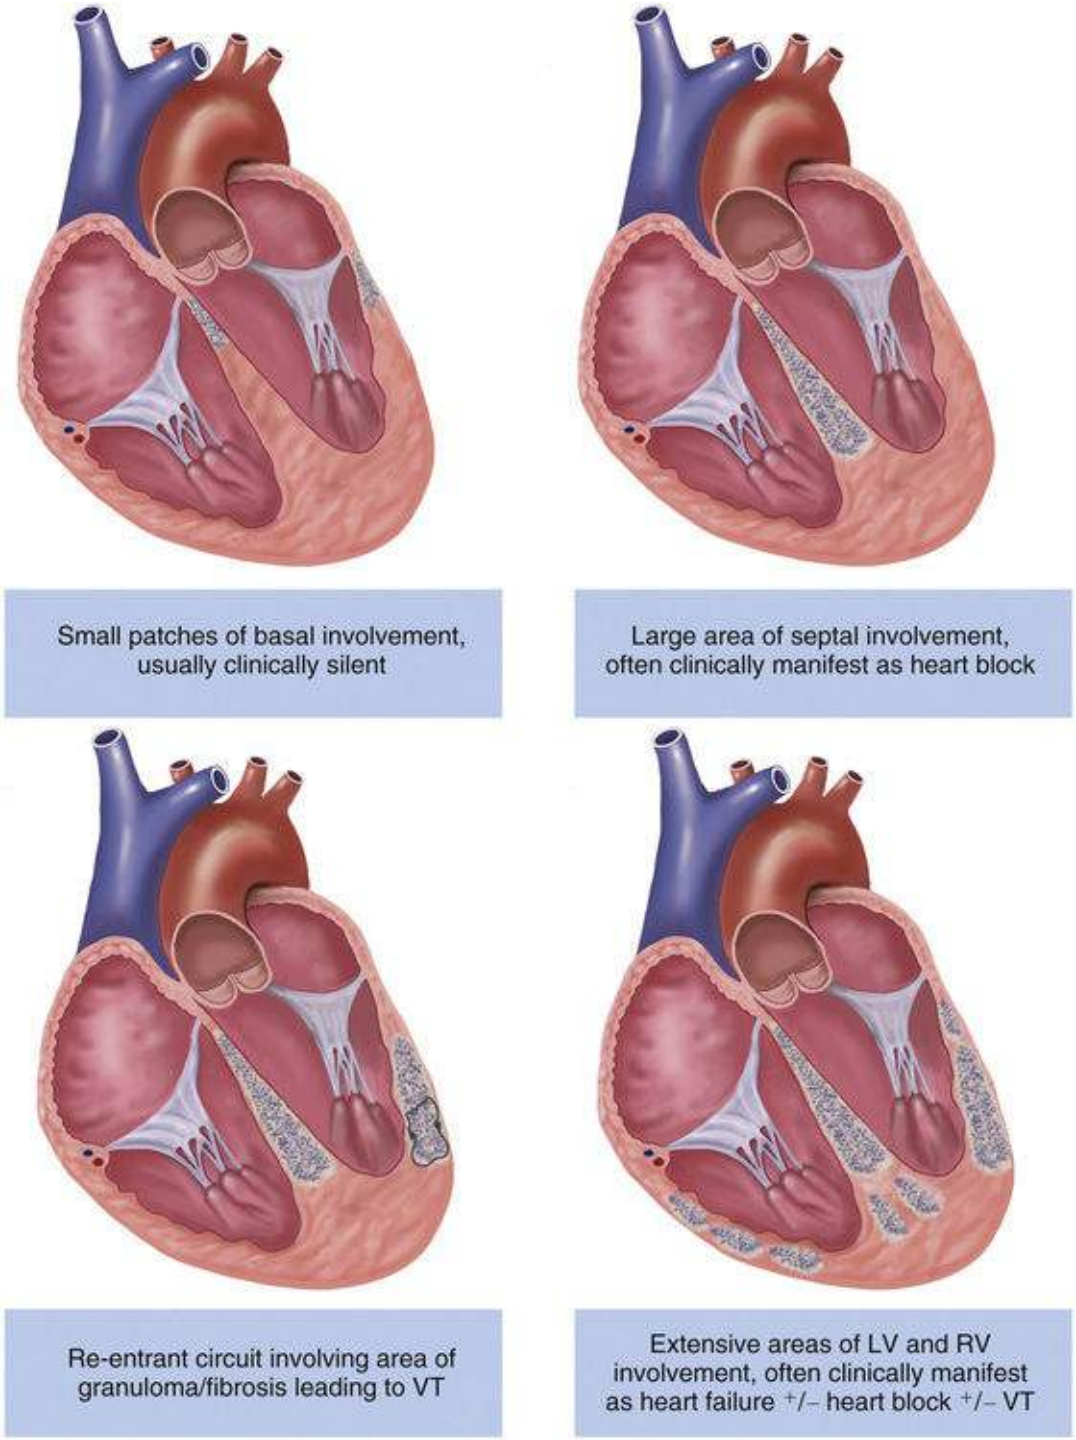

FIGURE 77.12 Illustrative examples of the extent of cardiac sarcoid pathologic changes in relation to clinical manifestations of the disease. (From Birnie DH, Nery PB, Ha AC, Beanlands RS. Cardiac sarcoidosis. *J Am Coll Cardiol.* 2016;68:411-21.)

Diagnosis

Laboratory testing for sarcoidosis is generally unrewarding. An elevated sedimentation rate may be present but is nonspecific, as is a finding of elevated immunoglobulins. Hypercalcemia (believed to be due to activation of vitamin D by macrophages in sarcoid granulomas), although uncommon, is a useful clue. Although elevation of serum ACE may be helpful for diagnosis, there is a wide range in the normal population because of a polymorphism in the *ACE* gene. Normal ACE levels may be seen in patients with untreated sarcoidosis, and serial ACE levels do not appear to correlate with treatment response.

CMR with gadolinium enhancement (**see also Chapter 17**) is a sensitive test for detecting abnormalities in cardiac sarcoidosis (**Fig. 77.13**). Delayed gadolinium enhancement may be found in

either a coronary or noncoronary distribution, is usually nontransmural, and has a predilection for the basal and/or midventricular septum.[75] The finding of myocardial late gadolinium enhancement by CMR in a patient with proven extracardiac sarcoidosis is a marker for subsequent major cardiac events, including sudden death, and the risk of major events is proportional to the amount of late gadolinium enhancement.[78] In the acute stage, T2-weighted imaging may show myocardial edema, which is characterized by focal areas of thickening and increased signal intensity on T2-weighted and early gadolinium-enhanced images.[79]

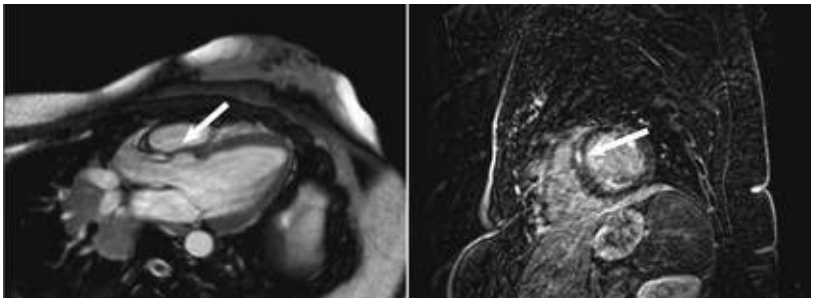

FIGURE 77.13 Cardiac MRI in a patient with sarcoidosis. Heart failure developed late in pregnancy and was initially diagnosed as PPCM. Echocardiography revealed a reduced ejection fraction with the basal septal thinning typical of sarcoidosis. The appearance was confirmed on MRI (**left panel**, *arrow*). Delayed gadolinium uptake showed midmyocardial gadolinium uptake (**right panel**, *arrow*) consistent with sarcoidosis, which was subsequently confirmed on a biopsy specimen.

^{18}F-fluorodeoxyglucose (FDG) PET scanning (**see also Chapter 16**) is complementary to CMR in patients with sarcoidosis; it reveals areas of inflammation in active disease, permits serial evaluation of response to therapy, and is becoming an important tool for the diagnosis and management of cardiac disease.[80] An example of a combined PET-CT scan in a patient with cardiac amyloidosis is shown in **Fig. 77.14**.

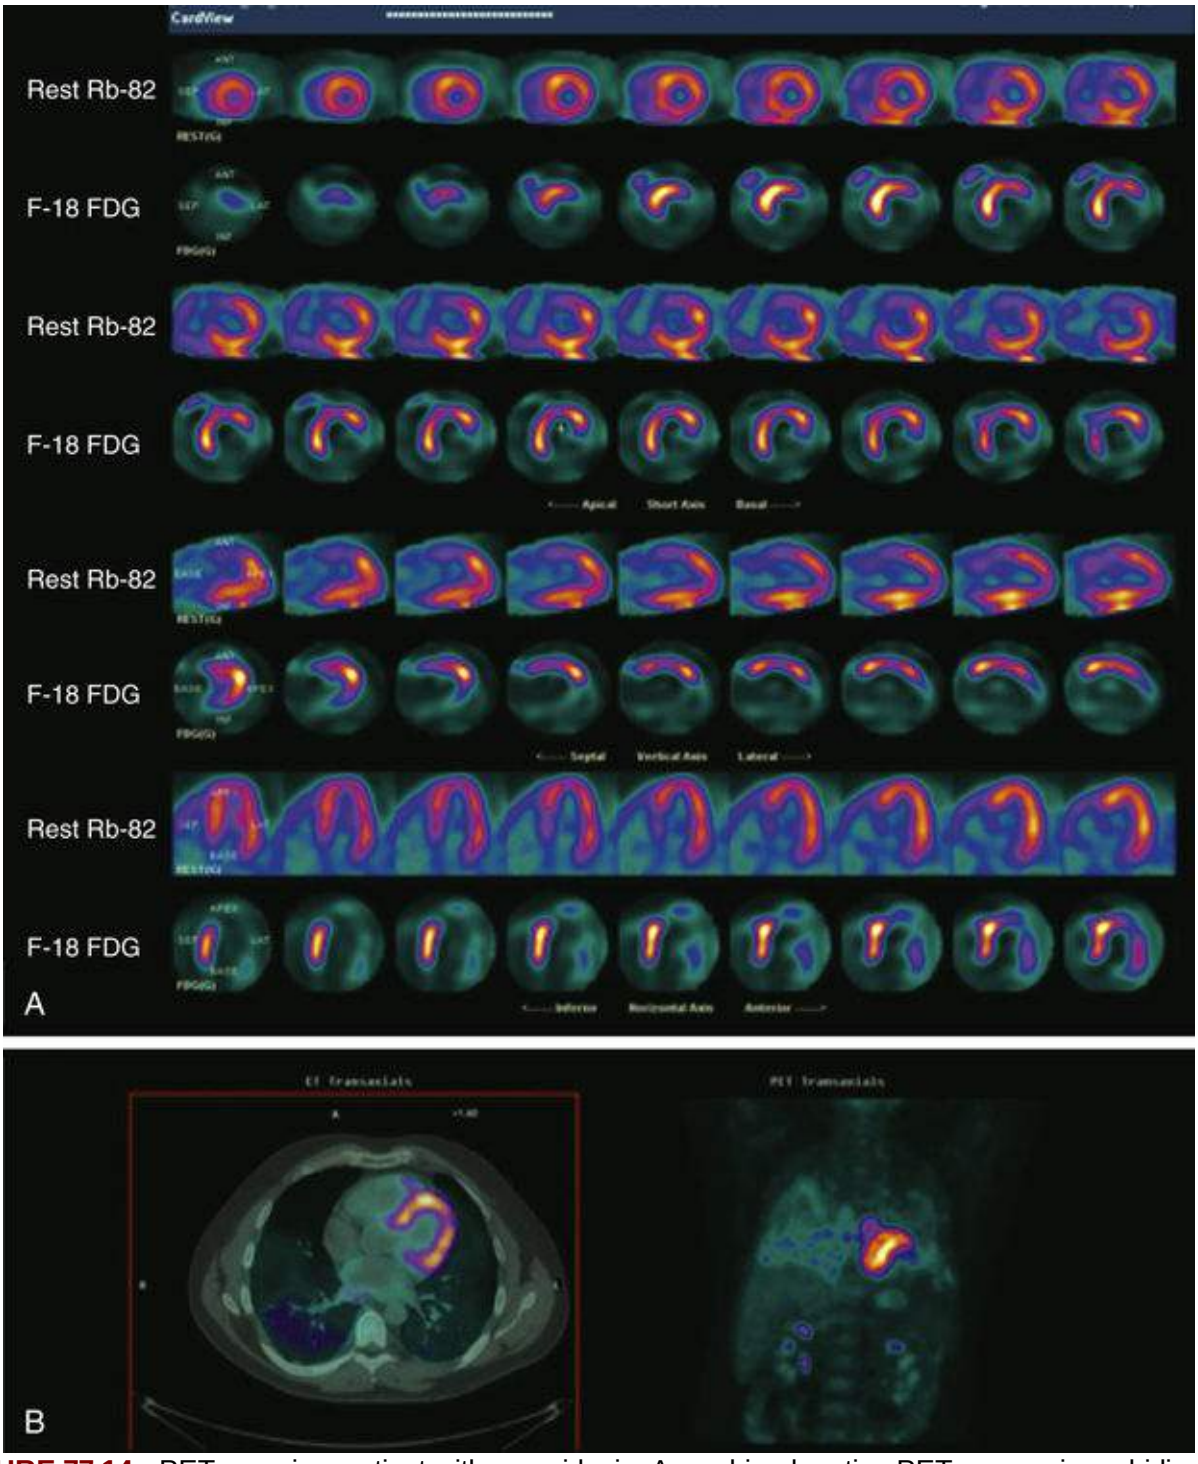

FIGURE 77.14 PET scan in a patient with sarcoidosis. A combined resting PET scan using rubidium-82 and ^{18}F-FDG (a glucose analogue) is shown for a 53-year-old man with a history of pulmonary sarcoidosis who had palpitations and atrial flutter. **A,** From the top, each pair of images represents the rubidium-82 scan and, underneath it, the corresponding ^{18}F-FDG image. The scans show a basal and midanteroseptal perfusion defect with intense FDG uptake in these regions suggestive of myocardial inflammation. Normal myocardium does not exhibit any FDG uptake because it is using free fatty acids. **B,** Combined CT-PET images in the same patient demonstrating the intense cardiac uptake. (Courtesy Dr. Sharmila Dorbala, Brigham and Women's Hospital, Boston. From Dubrey SW, Falk RH: Diagnosis and management of cardiac sarcoidosis. Prog Cardiovasc Dis 2010;52:336.)

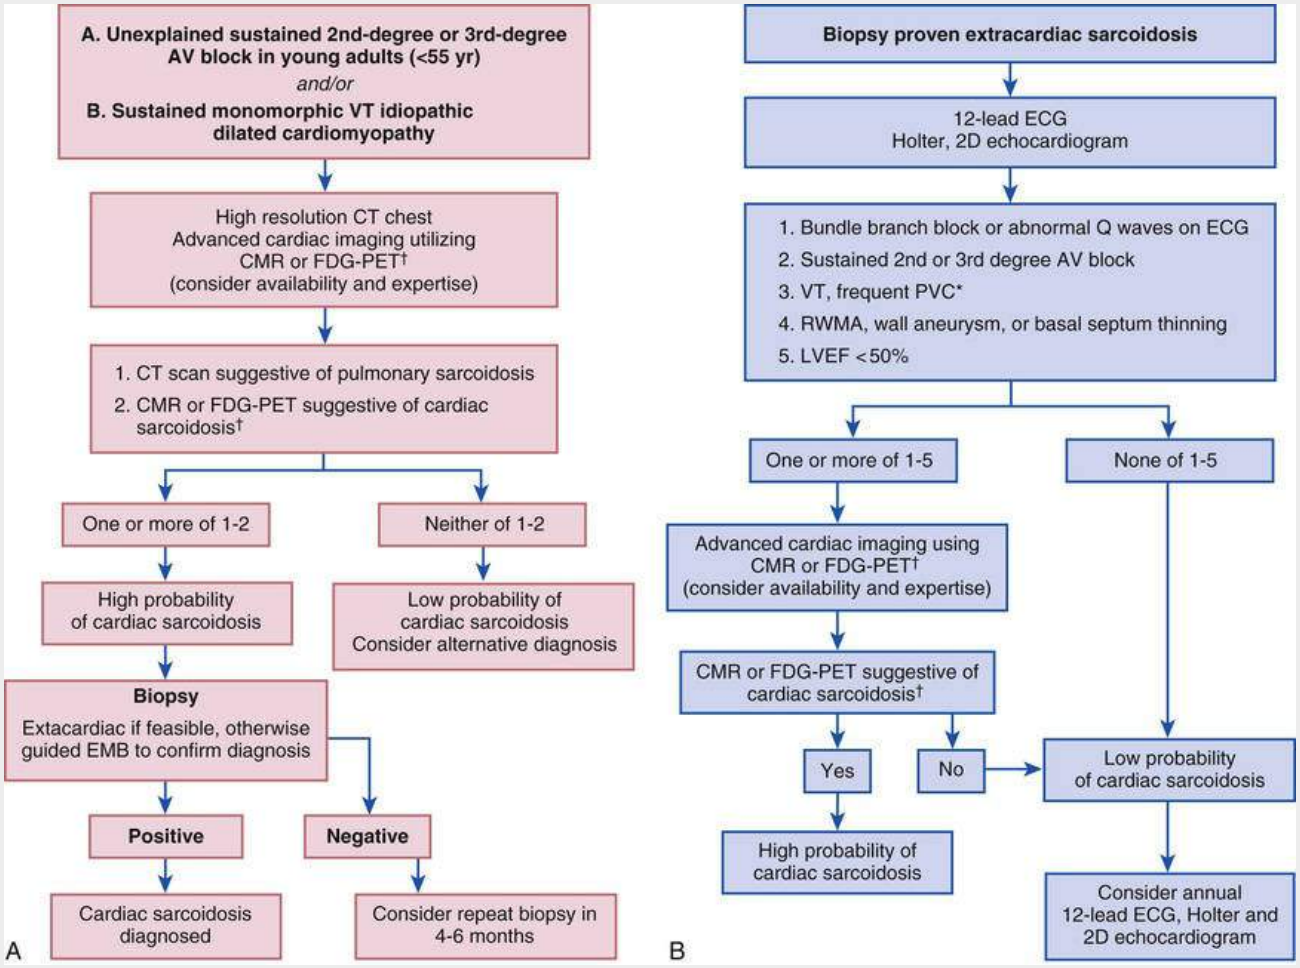
Tissue Biopsy.

A positive cardiac biopsy showing noncaseating granulomas is diagnostic of cardiac sarcoidosis if giant cell myocarditis is ruled out. However, the patchy nature of the granulomatous infiltration results in a low

yield of positive biopsies. Targeted biopsy of another organ, such as enlarged hilar lymph nodes, may give a higher yield, or alternatively, biopsy of an area of definite abnormality seen on PET or CMR may be valuable. Although the 2006 recommendations of the Japanese Society of Sarcoidosis and of the Granulomatous Disorders suggest diagnosis by a combination of major and minor criteria, including myocardial biopsy, PET-CT and CMR are more sensitive and are playing an increasing role. An algorithm for the diagnosis of cardiac sarcoidosis is presented in **eFig. 77.10**.



EFIGURE 77.10 Diagnostic algorithm for cardiac sarcoidosis. The diagnostic approach differs according to the clinical findings, including conduction system disease and/or ventricular arrhythmia **(A)** or biopsy-proven extracardiac sarcoidosis **(B).** *In the absence of coronary artery disease, defined as more than 1000 PVCs per 24 hours. †Gallium-67 scintigraphy or technetium-based myocardial perfusion imaging are reasonable alternatives if FDG-PET or CMR is not available. *CMR*, cardiac magnetic resonance; *EMB*, endomyocardial biopsy; *LVEF*, LV ejection fraction; *RWMA*, regional wall motion abnormality. (From Youssef G, Beanlands RS, Birnie DH, Nery PB: Cardiac sarcoidosis: applications of imaging in diagnosis and directing treatment. Heart 2011;97:2078.)

Treatment

No randomized clinical trials of the treatment of cardiac sarcoidosis have been published. Standard heart failure therapy should be instituted if heart failure is present, but in addition, steroid therapy is often given, particularly in patients with newly diagnosed sarcoidosis and systolic dysfunction. Steroids are frequently effective in noncardiac sarcoidosis, and nonrandomized data suggest a benefit in patients with cardiac sarcoid complicated by heart failure, particularly early in the disease when irreversible fibrosis has not yet developed. Prednisone is generally initiated in doses between 1 mg/kg and 40 mg daily and

tapered gradually over a period of several months with careful monitoring.[81] Methotrexate is often used as a second agent if steroid therapy is unsuccessful,[82] and several recent case reports have shown promising responses to anti-TNF monoclonal antibodies.

Management of arrhythmia often requires a pacemaker and/or implantable defibrillator. On the assumption that high-degree AV block in systemic sarcoidosis is a marker of associated myocardial sarcoidosis, use of a pacemaker-ICD has been recommended for any patient with sarcoidosis who requires pacing. Prophylactic use of an ICD based on a reduced ejection fraction, similar to other patients with heart failure with a depressed ejection fraction, is also appropriate (**see also Chapter 27**), but the role of an ICD in a patient with sarcoidosis and mild cardiac disease but no high-degree AV block or frequent ventricular arrhythmia is less clear.[83] The 2014 Heart Rhythm Society Consensus Recommendations for ICD implantation in patients with cardiac sarcoidosis are a useful guide, and suggest incorporation of advanced imaging and possible electrophysiologic study in such patients (**eTable 77.4**).[84] Cardiac transplantation may be undertaken in patients with severe cardiac sarcoidosis after careful evaluation for noncardiac involvement. Less than 0.2% of transplants in the United States are performed for cardiac sarcoidosis; outcomes are at least equivalent to those of other cardiac transplant patients.[85]

ETABLE 77.4

Heart Rhythm Society Recommendations for Management of Arrhythmia in Cardiac Sarcoidosis

Diagnosis and Screening	
It is recommended that patients with biopsy-proven extracardiac sarcoidosis should be asked about unexplained syncope/presyncope/significant palpitations.	I
It is recommended that patients with biopsy-proven extracardiac sarcoidosis should be screened for cardiac involvement with a 12-lead electrocardiogram.	I
Screening for cardiac involvement with an echocardiogram can be useful in patients with biopsy-proven extracardiac sarcoidosis.	IIa
Advanced cardiac imaging, CMR, or FDG-PET at a center with experience in CS imaging protocols can be useful in patients with one or more abnormalities detected on initial screening by symptoms/ECG/echocardiogram.	IIa
Screening for CS in patients age < 60 years with unexplained second-degree (Mobitz II) or third-degree atrioventricular block can be useful.	IIa
Advanced cardiac imaging, CMR, or FDG-PET is not recommended for patients without abnormalities on initial screening by symptoms/ECG/echocardiogram.	III
Management of Conduction Abnormalities	
Device implantation can be useful in CS patients with an indication for pacing, even if the atrioventricular block reverses transiently.	IIa
Immunosuppression can be useful in CS patients with second-degree (Mobitz II) or third-degree atrioventricular block.	IIa
ICD implantation can be useful in patients with CS and an indication for permanent pacemaker implantation.	IIa
Management of Ventricular Arrhythmias	
Assessment of myocardial inflammation with FDG-PET can be useful in CS patients with ventricular arrhythmias.	IIa
Immunosuppression can be useful in CS patients with ventricular arrhythmias and evidence of myocardial inflammation.	IIa
Antiarrhythmic drug therapy can be useful in patients with ventricular arrhythmias refractory to immunosuppressive therapy.	IIa
Catheter ablation can be useful in patients with CS and ventricular arrhythmias refractory to immunosuppressive *and* antiarrhythmic therapy.	IIa
Risk Stratification for Sudden Cardiac Death	
An electrophysiologic study for the purpose of sudden death risk stratification may be considered in patients with LVEF > 35%, despite optimal medical therapy and a period of immunosuppression (if there is active inflammation).	IIb
CMR for the purpose of sudden death risk stratification may be considered	IIb
ICD Implantation	
Spontaneous sustained ventricular arrhythmias, including prior cardiac arrest	I
LVEF ≤ 35% despite optimal medical therapy and a period of immunosuppression (if there is active inflammation)	I
ICD implantation can be useful in patients with CS, independent of ventricular function and one or more of the following: 1. An indication for permanent pacemaker implantation 2. Unexplained syncope or near-syncope, felt to be arrhythmic in etiology 3. Inducible sustained ventricular arrhythmias.	IIa
ICD implantation may be considered in patients with an LVEF 36% to 49% and/or an RV ejection fraction < 40%, despite optimal medical therapy for heart failure and a period of immunosuppression (if there is active inflammation).	IIb

CMR, cardiac magnetic resonance; *CS*, cardiac sarcoidosis; *ECG*, electrocardiogram; *FDG-PET*, fluorodeoxyglucose-positron emission tomography; *ICD*, implantable cardioverter-defibrillator; *LGE*, late gadolinium enhancement; *LVEF*, left ventricular ejection fraction; *RV*, right ventricular.

Fabry Disease

Fabry disease is caused by progressive lysosomal accumulation of neutral glycosphingolipids, primarily globotriaosylceramide; it results from deficiency of the enzyme alpha-galactosidase A, which is encoded by *GLA* on the X chromosome.[86] As an X-linked condition, most disease occurs in males with transmission by female carriers, although significant disease in later years can also be seen in women.[86-88] The disease phenotype encompasses diverse signs and symptoms with the following major manifestations: angiokeratomas, acroparesthesias, anhidrosis, ocular changes, and eventually cardiovascular, cerebrovascular, and renal disease, all largely related to the central pathophysiology of small-vessel vascular disease from the deposition of glycosphingolipid and consequent vascular insufficiency. The hallmark of the classic early-onset disease in males in childhood is episodic crises of severe pain in the extremities (acroparesthesias), characterized by burning pain in the distal end of the extremities, triggered by a variety of stressors, and resulting in ischemia of peripheral nerves from small-vessel disease. Angiokeratomas, red and purple punctate dermal lesions involving the lower midsection, buttocks, thighs, and upper part of the legs, may be one of the earliest signs of the disease and accumulate progressively with age. Anhidrosis is also an early finding in most cases. A survey of the phenotypic characteristics derived from a Fabry registry[87] showed that the age at onset and phenotypic variability were related to the degree of alpha-galactosidase A deficiency, with less than 1% of the activity associated with the earliest and most aggressive disease (**eTable 77.5**).[86-88]

ETABLE 77.5

Age at Onset of Fabry Disease in Early-Onset Classic Disease and in Renal and Cardiac Variant Cases

MANIFESTATION	CLASSIC	RENAL VARIANT	CARDIAC VARIANT
Age at onset	4 to 8 years	>25 years	>40 years
Average age at death	41 years	>60 years	>60 years
Angiokeratoma	++	–	–
Acroparesthesias	++	–/+	–
Hypohidrosis/anhidrosis	++	–/+	–
Corneal/lenticular opacity	+	–	–
Heart	LVH, ischemia	LVH	LVH, cardiomyopathy
Brain	TIA, stroke	–	–
Kidney	ESRD	ESRD	Proteinuria
Residual alpha-galactosidase A enzyme activity	<1%	>1%	>1%

ESRD, end-stage renal disease; *LVH*, left ventricular hypertrophy; *TIA*, transient ischemic attack.

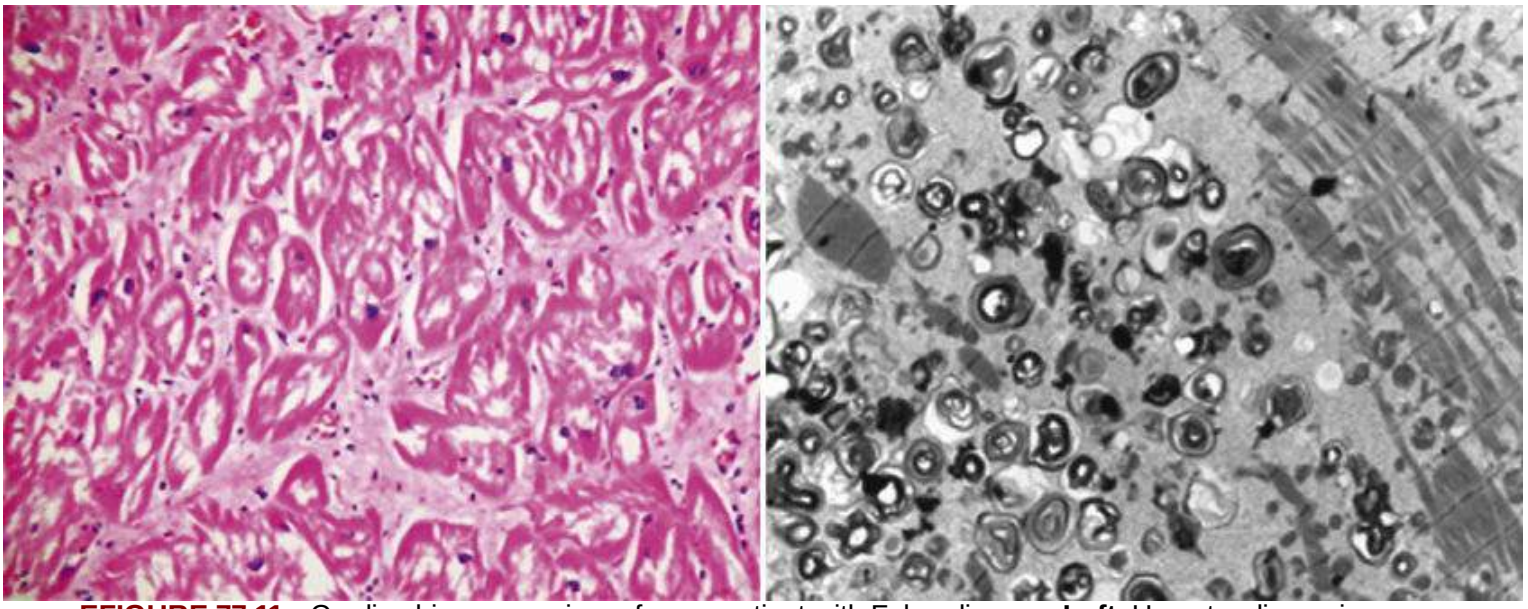
Modified from Mehta A, Hughes DA: Fabry disease. In Pagon RA, Adam MP, Ardinger HH, et al. Gene Reviews. Seattle: University of Washington. Initial posting August 5, 2002; last update January 5, 2017.

Most morbid and mortal manifestations of Fabry disease are related to cardiovascular, cerebrovascular, and renal disease and occur in men in midlife who have had the classic phenotype and onset in early life, although the age at onset of advanced disease is variable and in some cases it may occur in the second and third decades. Cerebrovascular issues related to small-vessel disease include transient ischemic attacks and thrombosis resulting in stroke in up to a quarter of patients in a variety of locations, most commonly the posterior circulation. Cardiovascular involvement is not usually clinically apparent until the third or fourth decade, but eventually some manifestation of cardiovascular disease occurs in most patients. The most common finding is LV hypertrophy on echocardiography, although the degree of hypertrophy is mild in many cases in the third decade but is progressive with age. Worsening LV hypertrophy is associated with angina that occurs consequent to small-vessel disease, and epicardial coronary disease is uncommon. Findings on the ECG initially include a short PR interval and LV

hypertrophy, with later evidence of heart block. Nonspecific intraventricular conduction delays are also seen. Bradycardia is common and a few patients will require pacemakers. Nonspecific ST-T changes are also common. Echocardiographic features range from mild to severe LV hypertrophy, the latter being more common in older patients, and mild to significant diastolic dysfunction. In most cases systolic function is normal, although heart failure has been reported with advanced disease. Palpitations and arrhythmia also occur.

Atypical phenotypes of Fabry disease have been categorized as cardiac or renal variants. Although most classic Fabry disease is syndromic, as noted earlier, and in the vast majority of cases a diagnosis of Fabry disease will be established before referral for cardiovascular or renal consultation, occasionally patients will be referred to cardiovascular or renal specialists for organ-specific disease before the diagnosis of Fabry disease is made. The atypical cardiac variant phenotype has few or none of the classic signs and symptoms but rather may be manifested as unexplained LV hypertrophy in the sixth to eighth decades, at times accompanied by cardiomyopathy, mitral insufficiency, and mild proteinuria but minimal or no renal dysfunction. Because of its protean manifestations, the frequency of Fabry disease in patients who have unexplained LV hypertrophy consistent with a diagnosis of HCM has been investigated. In a study of 1386 patients at 13 European centers that included men and women older than 35 and 40 years, respectively, all with diagnoses of HCM, systematic screening for Fabry disease was performed by searching for *GLA* mutations, and when identified, it was confirmed by alpha-galactosidase A levels.[89] Seven individuals (0.5%) were identified, 4 of the 7 being women 45 to 72 years of age, all with significant LV hypertrophy (ranging from 15 to 22 mm). Only 3 had other signs of Fabry disease, most commonly angiokeratomas. Exclusion of mutations in other genes encoding sarcomeric proteins known to cause HCM was not reported in this study, but comprehensive molecular (panel) testing for HCM would now identify sarcomeric variants, as well as *GLA* variants.

The diagnosis of Fabry disease rests on showing reduced alpha-galactosidase A activity and molecular genetic testing for mutations in *GLA*. An endomyocardial biopsy specimen showing inclusions in vascular endothelial cytoplasm on light or electron microscopy can also lead to the diagnosis (**eFig. 77.11**). Because the cardiovascular findings in adults with Fabry disease almost always include LV hypertrophy and in many cases a diagnosis of HCM is considered, genetic testing with gene panels now includes *GLA* to ensure that atypical cases of Fabry disease will not be missed.



EFIGURE 77.11 Cardiac biopsy specimen from a patient with Fabry disease. **Left,** Hematoxylin-eosin staining (200×) demonstrating hypertrophied vacuolated myocytes. **Right,** Transmission electron microscopy (10,000×) showing intracytoplasmic lamellar bodies within myocytes. (From Leone O, Veinot JP, Angelini A, et al: 2011 Consensus statement on endomyocardial biopsy from the Association for European Cardiovascular Pathology and the Society for Cardiovascular Pathology. Cardiovasc Pathol 2012;21:245.)

Importantly, treatment of Fabry disease is available as enzyme replacement, which can arrest the deposition of globotriaosylceramide and in some cases reverse the disease phenotype, ameliorate symptoms, and restore organ function. For this reason, the diagnosis of Fabry disease, even though rarely encountered by most physicians, is important.

Gaucher Disease and Glycogen Storage Diseases

Gaucher disease is an autosomal recessive glycogen storage disease that results from deficient beta-glucocerebrosidase enzyme activity caused by homozygous or compound heterozygous mutations in *GBA*.[90] The clinical spectrum of disease varies greatly and ranges from a lethal acute perinatal form and a subacute juvenile form, both of which share major central nervous system disease, to a mostly asymptomatic adult form; all forms share splenomegaly, hepatomegaly, cytopenia, and pulmonary disease because of deposition of glucosylceramide in reticuloendothelial cells, including peripheral blood leukocytes. Cardiac involvement is uncommon to rare but has been reported in patients with allelic variants, with mitral and aortic valve calcification leading to valvular insufficiency and stenosis in the setting of corneal opacification and splenomegaly. Recurrent pericarditis resulting in constriction, as well as DCM with systolic dysfunction, has also been reported. Enzyme replacement therapy is now available and in most cases will stabilize or reverse the disease process, thus accentuating the relevance of identifying Gaucher disease.

Hemochromatosis

Hemochromatosis is a disease caused by iron overload in which iron infiltrates major organs, especially the liver, heart, thyroid, gonads, skin, and pancreatic islet cells, to give the characteristic clinical findings of advanced disease that include cirrhosis, cardiomyopathy, diabetes, and endocrine disease. Hemochromatosis is categorized as hereditary (or primary) when arising from genetic disease or as secondary when caused by increased absorption associated with the thalassemias, sickle cell disease, or

the sideroblastic anemias or when related to excess blood transfusions for myelodysplasia or aplastic anemia. The content and distribution of iron are tightly regulated because of its toxicity and the inability of the body to excrete iron. Recent progress has been made in further understanding the molecular mechanisms of iron adsorption, use, storage, and recycling.[91]

HFE (hemochromatosis gene)-associated hereditary hemochromatosis is an autosomal recessive disease that in almost all cases results from the homozygous mutation Cys282Tyr, although 3% to 8% of cases are compound heterozygotes for Cys282Tyr and His63Asp. The carrier frequency of the Cys282Tyr variant ranges as high as 11% in individuals of European descent, although the disease is twice as likely to develop in women and penetrance varies even with Cys282Tyr homozygotes.[92] The onset of clinical disease from iron overload is insidious, and signs and symptoms are insensitive and nonspecific. Screening tests include serum ferritin and percent transferrin saturation, with the accepted level being 200 ng/mL in women and 300 ng/mL in men or 45% in women and 50% in men. If both tests are negative, iron overload is effectively excluded. With elevated transferrin saturation, molecular genetic testing for *HFE* is indicated. With elevated transferrin saturation and ferritin levels higher than 1000, iron removal, usually by phlebotomy, is indicated, and evaluation of liver and cardiac function is indicated.

The cardiovascular findings of hemochromatosis, regardless of cause, are similar and may bring the patient to medical attention before diagnosis because of other organ system involvement in a minority of cases, so clinicians always need to consider hemochromatosis in the differential diagnosis of a nondilated cardiomyopathy with mild to moderate systolic dysfunction. Cardiovascular dysfunction begins with a restrictive nondilated phenotype that with advancing disease progresses to systolic dysfunction, mild to moderate LV dilation consistent with DCM, and then advanced disease and eventual heart failure.[93] In most cases, arrhythmias and conduction system disease accompany the progressive myocardial dysfunction and include AV and bundle branch blocks and bradyarrhythmias and tachyarrhythmias, some of which may result in syncope and sudden cardiac death. CMR has evolved to become a sensitive noninvasive diagnostic modality. A definitive tissue-based diagnosis of iron overload causing cardiac dysfunction can also be made by endomyocardial biopsy, which may be particularly useful if other testing is inconclusive or the degree of cardiovascular involvement by hemochromatosis is confounded by other cardiovascular disease (e.g., coronary disease). Definitive treatment is centered on iron removal, usually by phlebotomy in *HFE*-associated hereditary hemochromatosis, and as iron stores are depleted, cardiac function will improve in most cases, sometimes to a dramatic degree. Cardiac transplantation can be avoided in most patients with timely diagnosis and phlebotomy.

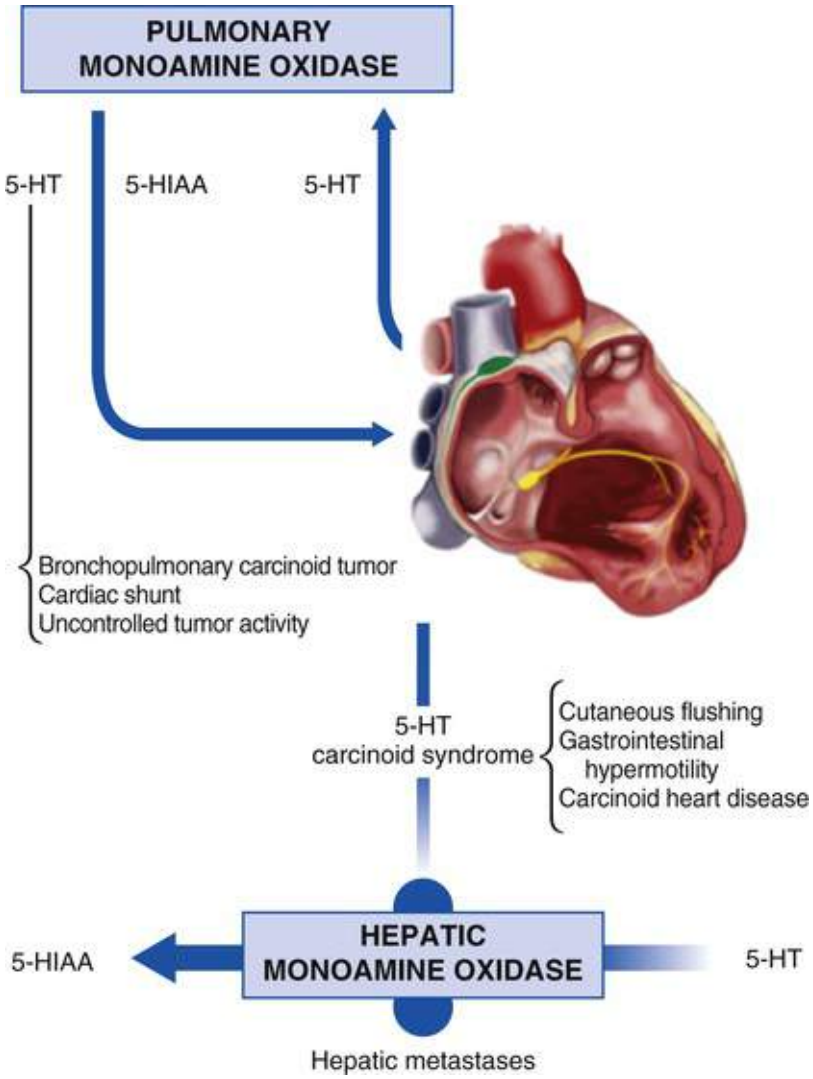
Endomyocardial Disease

The endomyocardial diseases, another cause of RCM, are unified by the finding of endocardial fibrosis. Several conditions share the pathologic end phenotype of fibrosis of the endocardium, but no unifying hypothesis for this pathology has emerged, and each condition may have its own distinctive cause. *Endomyocardial fibrosis* (EMF), a disease first described in Uganda in 1948 (initially termed tropical endocardial disease or endocardial fibroelastosis), may well be the most common cause of RCM worldwide. Although only rarely observed in North America, related conditions that pathologically resemble EMF include Löffler endocarditis, usually observed in adults, or the distinctly different onset of *neonatal endocardial fibroelastosis* (EFE) associated with hypoplastic left-heart syndrome and other congenital heart disease or in utero mumps infection. EFE, recently recapitulated in a model system,[94] can be differentiated from EMF by its epidemiology and more diffuse involvement of the left ventricle, whereas endocardial fibrosis more involves the RV and LV apices and subvalvular apparatus. Neonatal

EFE has been observed in a few families, and a genetic cause has been considered (see Online Mendelian Inheritance in Man [OMIM] 226000), and the X-linked *Barth syndrome* (see OMIM 302060) is categorized as a DCM with associated EFE, a proximal skeletal myopathy, and growth retardation. At times, noncompaction has also been observed in Barth syndrome.

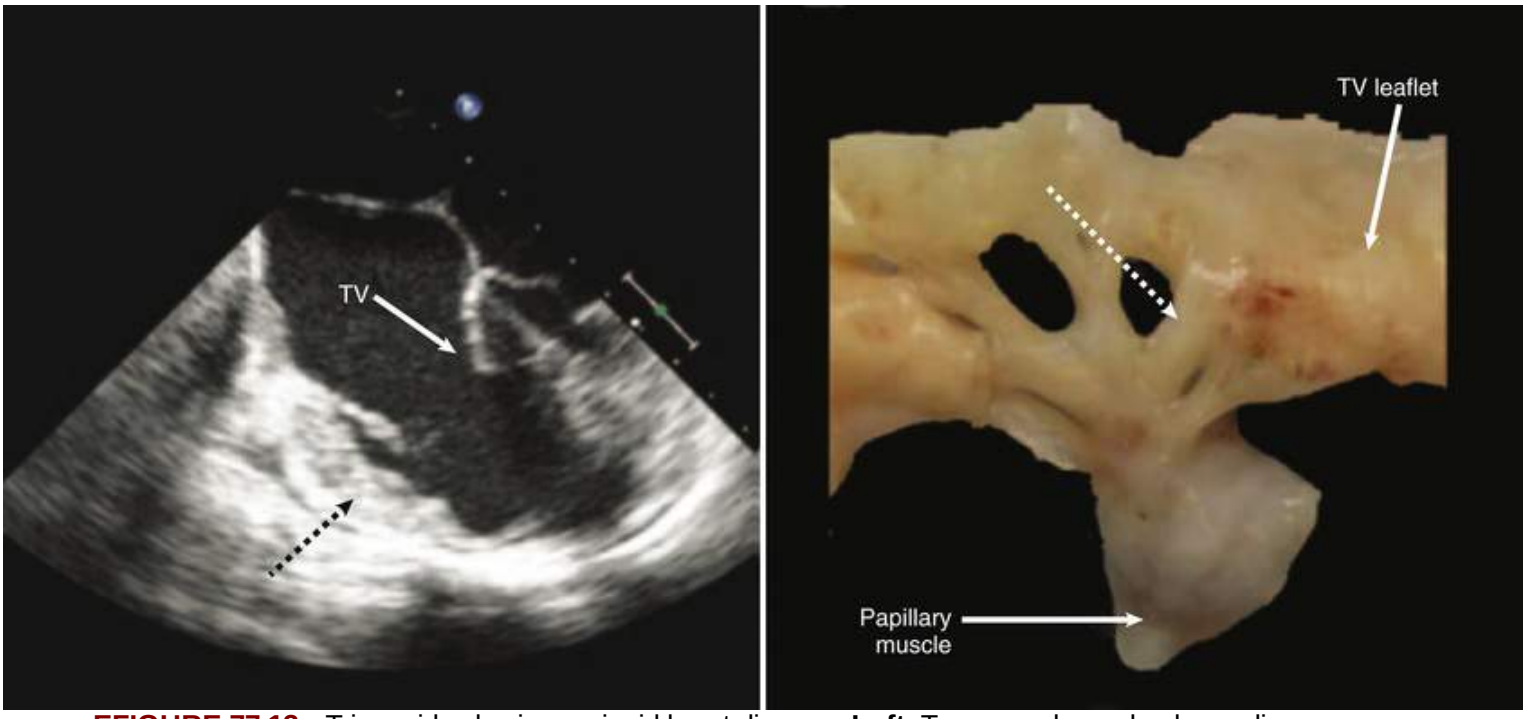
Carcinoid Heart Disease

Carcinoid heart disease is a rare condition that occurs as part of carcinoid syndrome, a systemic disorder mediated by elevated circulating levels of vasoactive substances, including serotonin (5-hydroxytryptamine [5-HT]), 5-hydroxytryptophan, histamine, bradykinin, tachykinins, and prostaglandins produced by a rare metastatic neuroendocrine malignancy, carcinoid.[95] *Carcinoid syndrome* is characterized by a triad of symptoms—flushing, diarrhea, and bronchospasm—that occur in association with hepatic metastases. The metastases produce high levels of these vasoactive substances, particularly 5-HT, which reaches the systemic circulation via the hepatic vein. High levels in the right side of the heart cause progressive fibrotic endocardial plaque[96] (**eFig. 77.12**). Inactivation in the lung to hydroxyindoleacetic acid (5-HIAA) generally protects the left-sided heart structures, but these structures may become involved if levels are very high or if a patent foramen ovale allows right-to-left shunting.[97] Carcinoid heart disease has very rarely also been described in association with nonmetastatic ovarian cancer.



EFIGURE 77.12 Mechanism of carcinoid syndrome. Serotonin (5-HT) is usually metabolized in the liver to 5-HIAA, but in the presence of carcinoid metastases the amount of 5-HT produced exceeds the degradation capacity of the liver, enters the hepatic vein, and passes through the right side of the heart. 5-HT is metabolized in the lung and does not cause left-sided heart damage unless there is a large amount, a patent foramen ovale, or, rarely, additional production by a bronchopulmonary carcinoid. (From Castillo JG, Silvay G, Solis J: Current concepts in diagnosis and perioperative management of carcinoid heart disease. Semin Cardiothorac Vasc Anesth 2013;17:212.)

The characteristic pathologic features of carcinoid heart disease are right-sided valve thickening and retraction resulting from myofibroblast proliferation along with deposition of collagen and smooth muscle cells. Tricuspid annular and subvalvar involvement and pulmonary root constriction also occur, thereby adding to the valvular dysfunction. Very rarely the heart is involved directly by carcinoid metastases.[95,96] Physical examination reveals evidence of RV volume and pressure overload with murmurs of tricuspid and pulmonary regurgitation and stenosis. In the late stage of the disease, peripheral edema and ascites with low cardiac output occur, although the valvular disease may be hemodynamically severe before significant clinical deterioration takes place. Symptoms of right-sided heart failure in the setting of known carcinoid syndrome are highly suggestive of carcinoid heart disease, but cardiac involvement may occasionally be the initial feature of carcinoid syndrome. Chest radiography and electrocardiography are generally unrevealing in carcinoid heart disease. Elevation of urinary 5-HIAA levels is highly specific and moderately sensitive for the diagnosis of carcinoid syndrome, and the echocardiographic and CMR features of thickened immobile tricuspid and pulmonary valves with combined stenosis and regurgitant lesions are highly suggestive of carcinoid heart disease[98] (**eFig. 77.13**).



EFIGURE 77.13 Tricuspid valve in carcinoid heart disease. **Left,** Transesophageal echocardiogram showing thickened tricuspid valve (TV) leaflets and endocardial thickening as a result of carcinoid plaque (*dashed arrow*). **Right,** Surgical specimen of the TV showing thickened, retracted papillary muscle as a result of carcinoid plaque and thickened chordae (*dashed arrow*). (From Bhattacharyya S, Toumpanakis C, Burke M, et al: Features of carcinoid heart disease identified by 2- and 3-dimensional echocardiography and cardiac MRI. Circ Cardiovasc Imaging 2010;3:103.)

Untreated patients with carcinoid syndrome have a median survival time of 3 to 4 years, and the presence of carcinoid heart disease shortens this to less than 1 year.[95] Therapy is not generally curative and includes debulking the hepatic metastases by embolization or partial hepatic resection and by the use of octreotide, a somatostatin analogue that binds to somatostatin receptors on the surface of carcinoid tumor cells and inhibits the secretion of vasoactive substances. Although the development and progression of carcinoid heart disease are associated with increasing 5-HIAA levels,[99] a decrease in 5-HIAA levels afterward does not appear to cause a change in the cardiac valvular lesions, and they may even progress.[95] Valve replacement in carcinoid heart disease can be performed successfully[100] but carries unique challenges, such as the development of an *acute carcinoid crisis* characterized by profound hypotension, severe flushing bronchoconstriction, and arrhythmias. Thus a surgical and anesthetic team knowledgeable about the condition and working with an endocrinologist, both intraoperatively and perioperatively, is of critical importance. Once advanced carcinoid valve disease is recognized on echocardiography, surgery is recommended even in the absence of significant right-sided heart dysfunction; patients who have undergone surgery are believed to be likely to have a more favorable outcome.[95]

Löffler (Eosinophilic) Endocarditis

Löffler endocarditis occurs within the spectrum of the hypereosinophilic conditions in which increased numbers of eosinophils invade and damage tissues in a variety of organs, including the endocardium and myocardium, by releasing highly active biologic substances. The cause of the eosinophilia in Löffler endocarditis includes known and idiopathic causes, such as a broad spectrum of helminthic or other parasitic infections, malignancy including carcinoma or eosinophilic leukemia, and allergy including drug reactions, all of which may have associated hypereosinophilia, as well as idiopathic hypereosinophilia

syndrome. Hypereosinophilia has been defined as either a chronic absolute eosinophil count higher than 1500 cells/mL for at least 1 month, although hypereosinophilia persisting for 6 months or longer is common, or pathologic evidence of hypereosinophilic tissue invasion. One family has been reported with autosomal dominant transmission linked to 5q31-q33, and more recently, hypereosinophilia syndrome in the setting of myeloproliferative disease has responded to tyrosine kinase inhibitors, but a unifying genetic or environmental hypothesis is not yet available.

Hypereosinophilic syndromes affecting the heart, although rare, when present cause considerable morbidity and mortality. Some cases of myocardial hypereosinophilic disease may be identified at endomyocardial biopsy during evaluation for idiopathic RCM, and in such situations a thorough evaluation for an underlying cause should be completed. Regardless of cause, eosinophilic-mediated cardiac disease has been categorized into three stages: acute, intermediate, and fibrotic. In the acute phase, usually characterized by few or no signs or symptoms, eosinophils invade the myocardium, degranulate, and aided by lymphocytes, cause intense myocardial inflammation and eventually myocardial necrosis. Even though findings on echocardiography may be normal during this phase, contrast-enhanced CMR can detect disease,[101,102] and myocardial biomarkers may be elevated to variable degrees. In the second stage, thrombus favoring the apices covers the affected endocardium. Symptoms include chest pain or dyspnea. Other evidence of disease includes mitral or tricuspid valvular regurgitation, cardiomegaly, and heart failure. Embolism of endocardial thrombus to the brain or other organs is common and may be the initial feature of the disease. The ECG may show T wave inversions, and imaging studies will reveal mural thrombus in affected areas, at times so extensive that large portions of the myocardial chamber are obliterated with clot. The third fibrotic phase progresses with diffuse scarring that results in endocardial fibrosis and RCM. The scar process commonly involves the mitral and tricuspid subvalvular structures; it impairs their mobility and leads to valvular regurgitation. Valve leaflet scarring can also occur. If disease can be identified in the first stage, therapy is focused on treatment of the underlying condition. Corticosteroids and cytolytic therapies have been used with some response. The fibrotic stage needs to be addressed surgically by valve release, repair, or replacement and by resection of the endocardial scar to mitigate the restrictive nature of the endocardial fibrosis.

Endomyocardial Fibrosis

Endomyocardial fibrosis (EMF), an unusual disease in North America but common in Africa, is characterized by fibrosis of the LV and RV apical endocardium causing an RCM. First reported in Uganda, it has been found in tropical regions of Africa, the south Asian subcontinent, and Brazil, although it is also found in subtropical Africa and some cases occur rarely in moderate climates, including North America. A population prevalence of approximately 20% in rural Mozambique has been reported,[103] with more males affected than females (23% versus 17%). In addition, family clustering was identified in this study, although whether this was related to environmental exposure common to the family units selected for study, to a genetic predisposition, or to both was not addressed. A bimodal peak in age has been noted in several studies, with onset in the first decade and a second peak occurring in the second to fourth decades of life.

The cause of EMF remains unknown, but its pathology resembles that of other conditions in North America that are more commonly encountered, such as eosinophilic cardiomyopathy or hypereosinophilic syndrome, discussed earlier. However, elevated eosinophil counts in peripheral blood or cardiac tissue from endomyocardial biopsy have seldom been observed in EMF. Although one or more infectious agents could be causal, no consistent unifying infectious cause has been established. Environmental exposure to

cerium, a rare element present in affected areas, has also been considered. Family-based disease has been observed in several reports, but whether familial predisposition is related to environmental or genetic causes, or to both, remains unknown.

In most cases heart failure symptoms from left or right restrictive physiology predominate the clinical findings and include dyspnea on exertion, paroxysmal nocturnal dyspnea, and edema. Ascites, at times a prominent feature, is common to all the endomyocardial diseases. Cardiovascular imaging shows restrictive filling with apical fibrosis that commonly involves the mitral and tricuspid subvalvular apparatus, accompanied by atrial enlargement. As noted earlier, successful surgical resection of the endocardial fibrosis with valve repair or replacement can have a dramatic effect on symptoms and survival, although the operation itself is associated with a significant risk for morbidity and mortality.

Future Perspectives

Enormous progress has recently been made in understanding the genetic basis of cardiomyopathy, accelerated in large part by next-generation sequencing strategies. Sequencing of the exome, defined as the 1% to 2% of the human genome that encodes the approximately 19,000 genes, has greatly facilitated progress in understanding the genomic basis of the cardiomyopathies. The genomic information reviewed herein, limited in most cases by mutation surveys of one or a few candidate genes, will give way to comprehensive genome-wide strategies to identify and understand rare and common variants relevant to disease susceptibility and cause, including structural and other nonprotein coding genomic variants, in much larger populations of patients with cardiomyopathy. This will enable a more comprehensive and insightful understanding of the genomic basis of human disease, including that affecting the myocardium. Our present rudimentary understandings of “mendelian genetics,” an oversimplified concept of “single-gene” genetics, is rapidly evolving into much greater complexity.

Hypertrophic Cardiomyopathy

Barry J. Maron, Martin S. Maron, Iacopo Olivotto

Hypertrophic cardiomyopathy (HCM), the most common of the genetic cardiovascular diseases, is characterized by heterogeneous clinical expression, distinctive pathophysiologic features, and a diverse natural history.[1-5] It is caused by a multitude of mutations in genes encoding proteins of the cardiac sarcomere.[6-10] Although many patients with HCM have a normal life span, HCM has been regarded as the most common cause of sudden death (SD) in the young, including competitive athletes.[11-13] It also constitutes a risk for atrial fibrillation (AF), and it is responsible for heart failure–related disability at virtually any age.[9,14-16] Since the modern description of HCM was developed more than 50 years ago, our understanding of the clinical complexity and spectrum of this disease has evolved dramatically.[17] Most importantly, contemporary cardiovascular treatments have now reduced HCM-related mortality rates significantly.[18-22] This chapter offers an updated summary of HCM with respect to its diagnosis, natural history, and management.

Definition, Prevalence, and Nomenclature

HCM is characterized by a thickened but nondilated left ventricle in the absence of another cardiac or systemic condition (e.g., aortic valve stenosis, systemic hypertension, and some expressions of physiologic athlete's heart) capable of producing the magnitude of left ventricular (LV) hypertrophy evident (**Figs. 78.1 and 78.2**).[1,3,23,24] Several epidemiologic studies report the prevalence of the HCM phenotype in the general population at 1 : 500, equivalent to approximately 700,000 affected people in the United States. More recent estimates, which take into account genetic and imaging diagnostic modalities, place the prevalence closer to 1 : 200.[25] This frequency in the general population exceeds the number of diagnosed patients in cardiovascular practice (estimated at 100,000),[26] suggesting that most affected individuals remain unrecognized during their lifetime and usually do not have symptoms or suffer cardiovascular events.

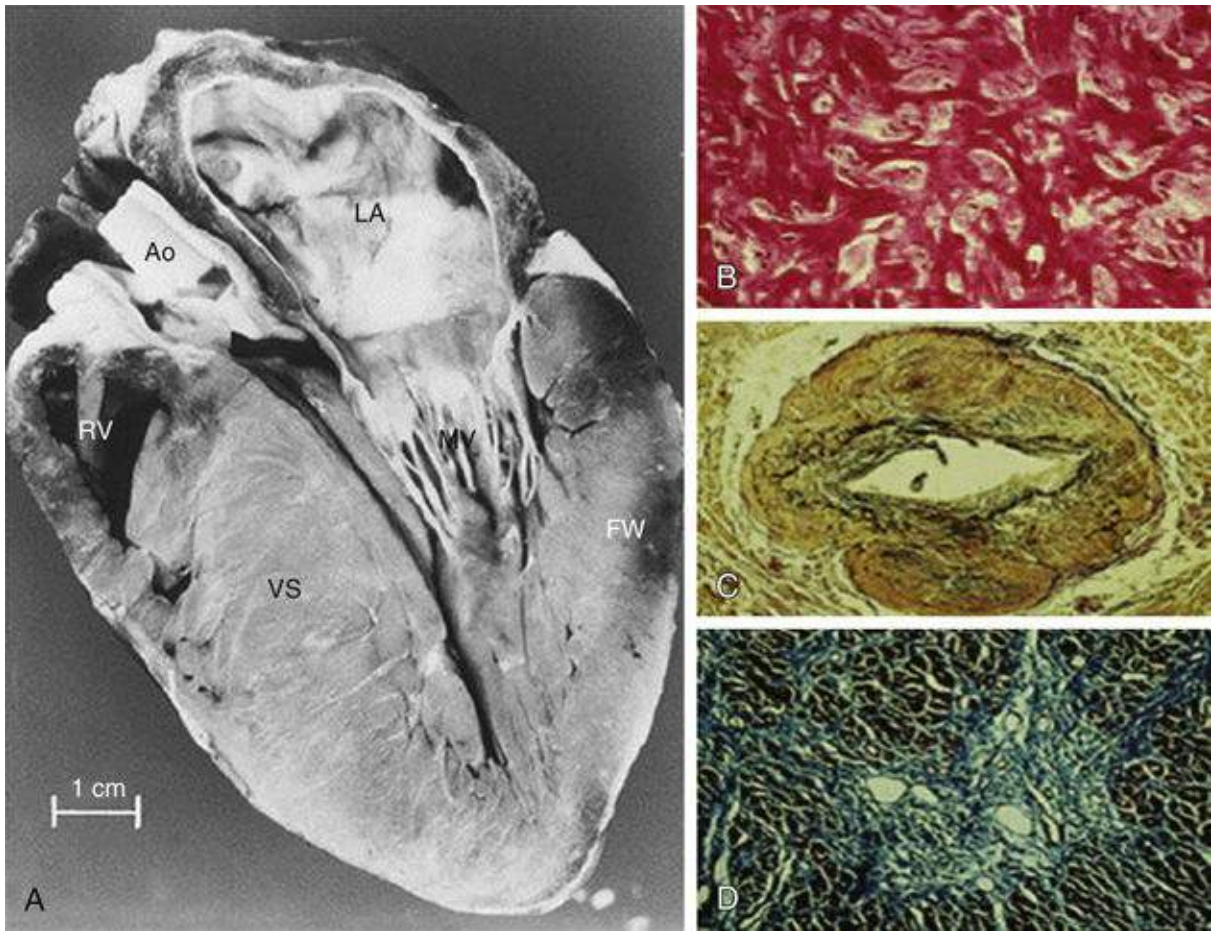

FIGURE 78.1 Gross morphology and histopathology of HCM. **A,** Gross heart specimen shown in a cross-sectional plane similar to that of the echocardiographic (parasternal) long axis; pattern of LV hypertrophy is asymmetric, disproportionately involving the ventricular septum (VS), which typically bulges into the LV outflow tract. *Ao*, aorta; *FW*, free wall of left ventricle; *LA*, left atrium; *RV*, right ventricle. **B,** Histopathology characteristic of left ventricle in HCM, with septal myocardium showing markedly disordered architecture with adjacent hypertrophied cardiac muscle cells arranged at perpendicular and oblique angles. **C,** Intramural coronary artery with narrowed lumen and thickened wall, due primarily to medial (M) hypertrophy. **D,** Scar in VS, representing repair process following clinically silent ischemia and myocyte death. (From Maron BJ: Sudden death in hypertrophic cardiomyopathy. J Cardiovasc Transl Res 2009;2:368-80.)

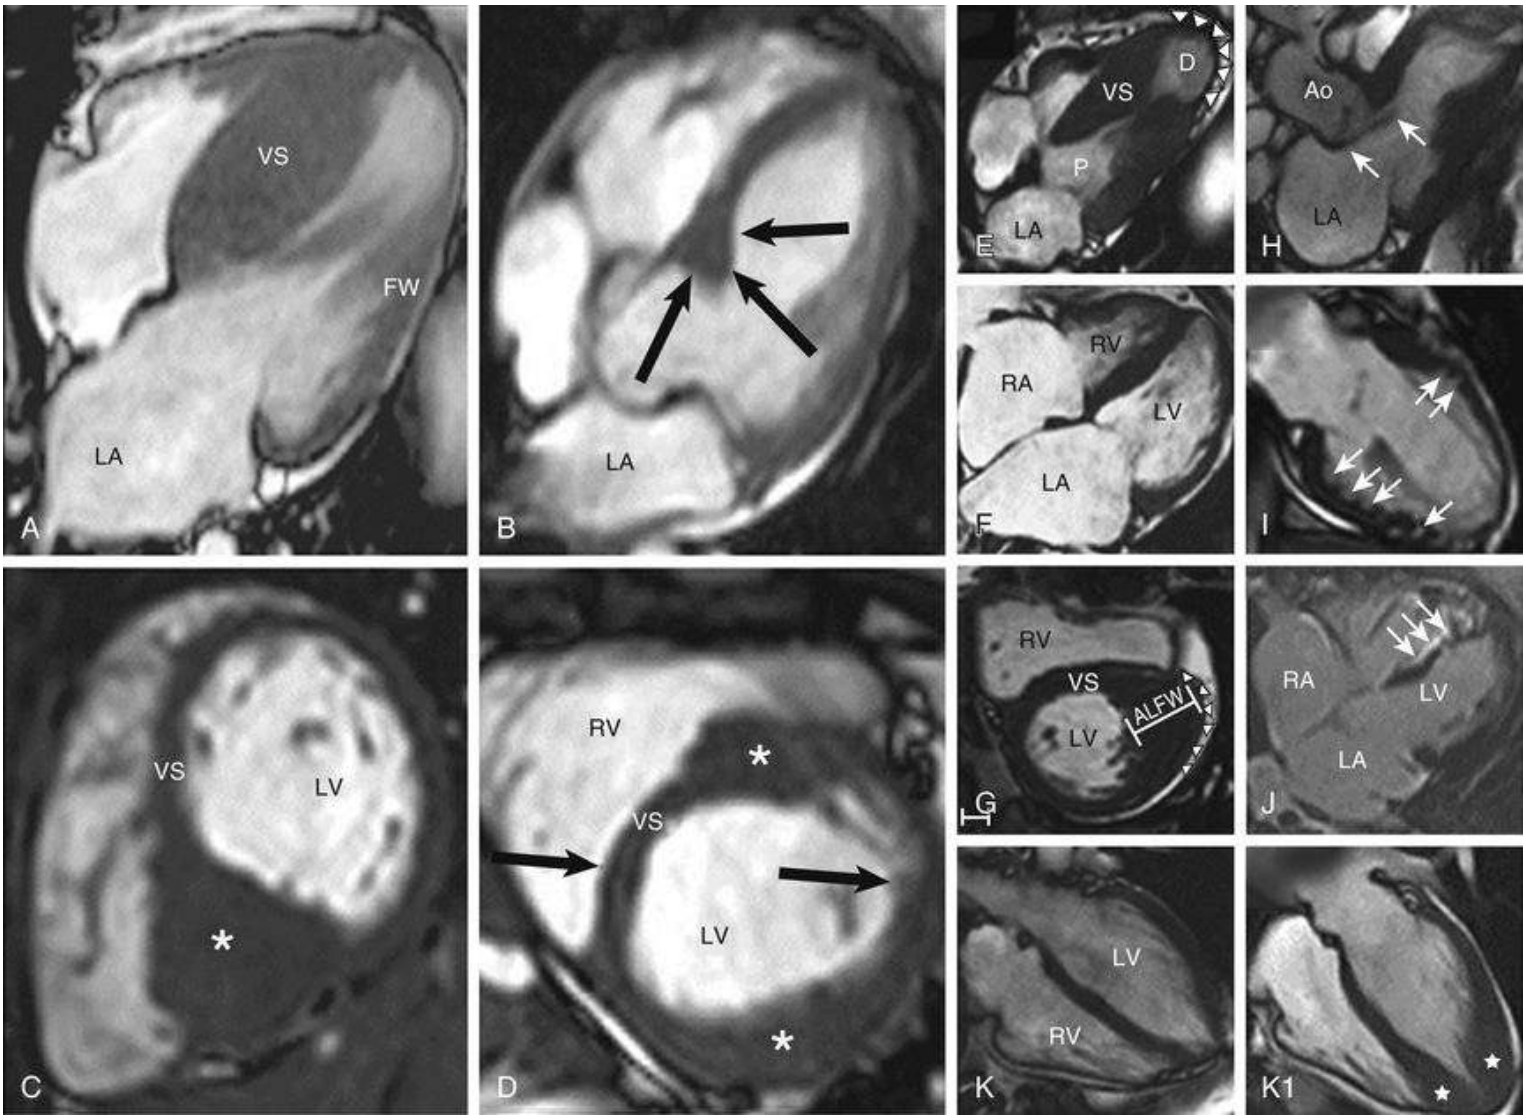

FIGURE 78.2 CMR in HCM. Spectrum of the phenotype. **A,** Hypertrophy involving the ventricular septum (VS) and sparing LV free wall (FW). **B,** Focal area of hypertrophy sharply confined to basal anterior septum (*arrows*), **C,** Extreme thickness of 33 mm in the posterior ventricular septum (*asterisk*). **D,** Noncontiguous segmental areas of hypertrophy involving the basal anterior septum and posterior free wall (*asterisks*) separated by regions of normal LV thickness (*arrows*). **E,** LV apical aneurysm (*arrowheads*) with midcavity muscular obstruction. **F,** "End-stage" remodeling with enlargement of LV cavity (and atria) and wall thinning, associated with systolic dysfunction (ejection fraction < 50%). **G,** Massive hypertrophy (wall thickness 34 mm) confined to anterolateral LV free wall (ALFW). **H, I, J,** Morphologic abnormalities in the absence of LV hypertrophy in genetically affected patients. **H,** Primary elongation of anterior mitral leaflet (*arrows*). **I,** Multiple LV myocardial crypts (*arrows*). **J,** LGE indicative of replacement myocardial fibrosis (*arrows*). **K and K1,** De novo phenotypic conversion at advanced age. **K,** Absent LV hypertrophy at age 46 years. **K1,** At age 51 years, apical HCM (*stars*) is now evident. (**A** to **D** from Maron BJ, Maron MS: Hypertrophic cardiomyopathy. Lancet 2013;381:242. **E** to **K1** from Maron BJ, Haas TS, Kitner C, et al: Onset of apical hypertrophic cardiomyopathy in adulthood. Am J Cardiol 2011;108:1783.)

HCM is a global disease, reported in more than 50 countries from all continents.[1,2] The first contemporary reports of HCM in 1958 were from Brock (in the cardiac catheterization laboratory) and from Teare (at autopsy), describing "asymmetrical hypertrophy of the heart" as being responsible for SD in a small group of young people. This disease rapidly acquired a confusing array of names, with most emphasizing the highly visible feature of LV outflow obstruction.[27] However, because obstruction to LV outflow is not always present and about one third of patients have the nonobstructive form of HCM, the preferred and generally accepted name for this condition is hypertrophic cardiomyopathy (HCM), with or without outflow obstruction.[1-4,19,23]

Gender and Race.

As an autosomal dominant disease, HCM is expected to occur with equal frequency in men and women.[4,23] The predominance of men with HCM reported in the literature probably reflects an underdiagnosis in women, who achieve clinical recognition less frequently and at older ages than men. Women may be at greater risk than men for progression to advanced heart failure (usually associated with outflow obstruction), although there is no relationship between gender and SD risk or overall HCM-related mortality rates. HCM has been reported in many races; it appears to be underrecognized in African- Americans, and most competitive athletes who die suddenly of HCM are previously undiagnosed black men.[11-13] The clinical expression, presentation, and course of HCM, as well as the phenotypic expression, are similar throughout the world, although the morphologic form characterized by hypertrophy confined to the LV apex may be more common in Japan.[1,2]

Genetic Basis and Testing.

HCM is transmitted as a mendelian trait with an autosomal dominant pattern of inheritance (**see also Chapter 7**); every offspring of an affected relative has a 50% chance of inheriting the disease.[1-3,23] Molecular studies, conducted intensively over two decades, have provided access to a laboratory-based diagnosis by identifying disease-causing (pathogenic) mutations, and providing in the process important insights into the broad clinical expression of HCM, including identification of individuals with pathogenic mutations but without evidence of the disease phenotype (LV hypertrophy).

HCM is known to be caused by mutations in 11 or more genes encoding proteins of the thick and thin contractile myofilament components of the cardiac sarcomere or the adjacent Z-disc (**Figs. 78.3 and 78.4**). Two sarcomere genes, β-myosin heavy chain (*MYH7*) and myosin-binding protein C (*MYBPC3*) are by far the most common, accounting for 70% of patients for whom genotyping has been successful. Troponin T *(TNNT2*), troponin I (*TNNI3*), and several other genes are each responsible for 5% or fewer cases. Underscoring the vast genetic heterogeneity of HCM is the recognition of over 1500 individual mutations (largely missense), most of which are unique to individual families.[6,28-32]

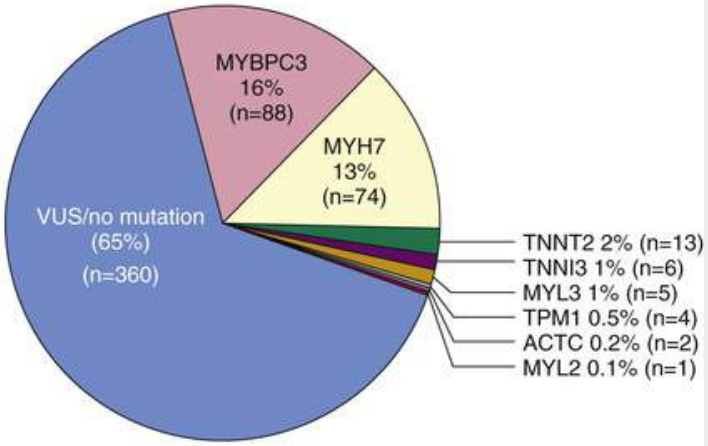

FIGURE 78.4 Genetic substrate in HCM. **Left,** Genes known to be associated with HCM. **Right,** Distribution of genes encoding proteins of the cardiac sarcomere identified in unrelated HCM probands undergoing clinical genetic testing. A variety of laboratories report a wide range in mutational yield (24% to 63%), leaving a significant proportion of the HCM population genotype-negative. However, based on current commercial genetic testing, only about 35% of families are genotyped to a pathogenic mutation. *VUS,* Variant of uncertain significance. (From Maron BJ, Maron MS, Semsarian C: Genetics of hypertrophic cardiomyopathy after 20 years: clinical perspectives. J Am Coll Cardiol 2012;60:705.)

In clinical practice, the greatest advantage of commercially available genetic testing (**Fig. 78.5**) is the opportunity to identify or exclude an affected status in family members without LV hypertrophy.[6,29] This strategy first requires identification of a pathogenic mutation in a relative (proband) with clinically expressed HCM. With current commercial genetic testing, however, a genotype for a disease-causing mutation can be identified in only about 35% of families; this is a major obstacle to performing cascade screening of family members. Genetic testing not infrequently identifies novel but ambiguous sequence variants for which the pathogenicity is unresolved (variants of unknown significance; VUSs) and which have no application to clinical family screening. This issue and the not uncommon phenomenon of reclassification, in which pathogenic mutations can be down-graded to VUSs (or vice versa) with time, underscore the challenges remaining in translating complex molecular science to patient care. The possibilities offered by next-generation techniques, including whole-exome and whole-genome analysis, may be considerable because they may provide enhanced screening capabilities and reduced costs, but they will also increase the frequency with which VUSs are recognized.[32]

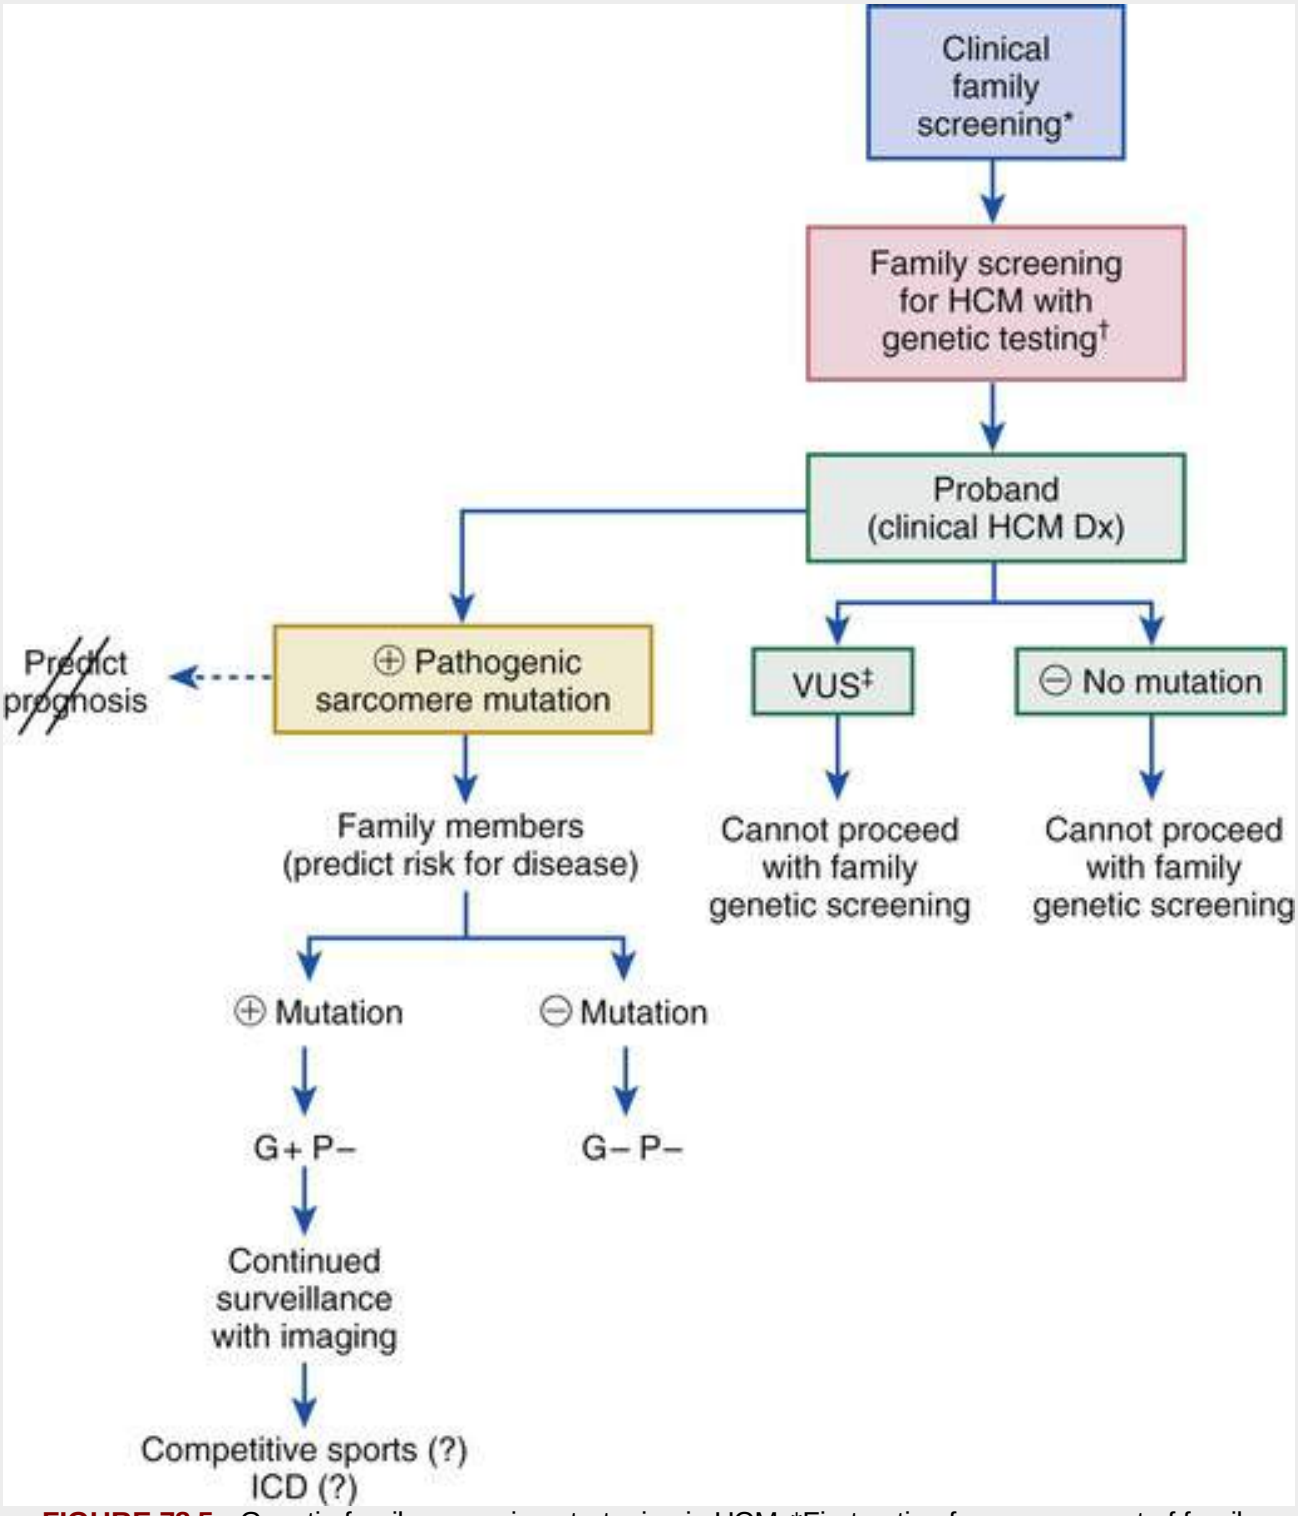

FIGURE 78.5 Genetic family screening strategies in HCM. *First option for assessment of family members would be a clinical screening evaluation with imaging tests and ECG; †the option of genetic testing is triggered largely for those relatives without LV hypertrophy, with indeterminate clinical testing and imaging. *Dx*, diagnosis; *ICD*, implantable cardioverter-defibrillator; *VUS,* variant of uncertain significance. (From Maron BJ, Maron MS, Semsarian C: Genetics of hypertrophic cardiomyopathy after 20 years: clinical perspectives. J Am Coll Cardiol 2012;60:705.)

Notably, despite early aspirations, predicting the prognosis and risk for SD in individual HCM patients based on specific sarcomere mutations has proved unreliable, and therefore patient management decisions are not determined by genetic testing results.[2,4,30] Population-based association studies have demonstrated a more severe course in gene-positive patients than gene-negative patients, as well as in patients with thick-filament mutations (*MYBPC3* and *MYH7*) compared with those with thin-filament mutations (*TNNT2* and *TNNI3*).[8,10,31] In HCM, there is inconsistent evidence for whether multiple pathogenic sarcomere mutations coexisting in the same patient lead to early disease onset and/or a more

severe clinical profile.[6]

Genetic testing is crucial for clarifying the diagnosis in patients with metabolic and storage disorders for which the clinical presentation and pattern of LV hypertrophy can mimic sarcomeric HCM but for which the pathophysiology, natural history, and management are dissimilar.[24] For example, *LAMP2* cardiomyopathy is associated with a lethal natural history refractory to defibrillation therapy (with survival uncommon beyond 25 years) and requires early recognition and likely heart transplant,[33] and Fabry disease requires enzyme replacement therapy.[34]

Morphologic Findings and the Role of Cardiac Imaging

Phenotype and Left Ventricular Hypertrophy

The clinical diagnosis of HCM has conventionally been made with two-dimensional echocardiography. However, cardiovascular magnetic resonance (CMR) imaging has emerged with an expanded role in the diagnosis (and management) of HCM patients by virtue of its high-resolution tomographic imaging capability (**see Fig. 78.2**). CMR also allows for quantification of late gadolinium enhancement (LGE), a marker for myocardial fibrosis. CMR is complementary to echocardiography by resolving technically ambiguous LV wall thicknesses or visualizing relevant areas of hypertrophy blind to echocardiography (e.g., in the anterolateral free wall, posterior (inferior) septum, or apical left ventricle).[35-40]

Cardiac imaging in clinically identified adults and children with HCM typically documents an absolute increase in LV wall thickness of 15 mm or more (21 to 22 mm on average, and up to > 50 mm), although any LV wall thicknesses (including those within normal range) are consistent with a genetically affected status.[40] Borderline LV wall thicknesses of 13 to 14 mm can create diagnostic ambiguity, particularly in the differential diagnosis of physiologic athlete's heart (**eTable 78.1**).

Diverse and myriad patterns of asymmetric LV hypertrophy are characteristic of HCM (**see Fig. 78.2**), even in related patients (although identical twins share the same morphology). Typically, one or more regions of the LV chamber are of greater thickness than other areas, often with a sharp demarcation at the point of transition in thickness, or there are noncontiguous patterns of segmental hypertrophy (**see Fig. 78.2**), as well as extension into the right ventricular (RV) wall, in some patients. No single morphologic form of HCM is considered “classic” or typical.

ETABLE 78.1

Distinguishing Hypertrophic Cardiomyopathy from Athlete's Heart When Left Ventricular Hypertrophy Is Within the "Gray Zone" of Overlap*

	PATHOLOGIC LV HYPERTROPHY (HCM)	PHYSIOLOGIC LV HYPERTROPHY (ATHLETE'S HEART)

ECG, electrocardiogram; *HCM*, hypertrophic cardiomyopathy; *LV*, left ventricular; *VO_2* peak oxygen consumption; +, present; 0, absent.

From Maron BJ, Maron MS. Hypertrophic cardiomyopathy. Lancet 2013;381, 242-255.

Hypertrophy is frequently extensive, involving the ventricular septum and LV free wall. In a sizeable minority, wall thickening is limited to segmental areas, including the most distal portion of the LV chamber (i.e., apical HCM); this is a distinctive morphologic form associated with marked T-wave negativity on ECG,[1,33,40] which is part of the HCM clinical spectrum caused by sarcomere mutations.[9] Indeed, in 20% of patients, the LV mass calculated by CMR may be normal or near-normal because of hypertrophy localized to small areas of the left ventricle.[38]

Usually, the HCM phenotype remains incomplete until adolescence, when accelerated growth and maturation are accompanied by spontaneous (often striking) increases in LV wall thickness and a more extensive distribution of hypertrophy. Occasionally, these structural changes may not occur until midlife or even later (late-onset adult LV hypertrophy) (**see Fig. 78.2**), although not usually associated with the development of symptoms or arrhythmic events.[1] In genetically affected family members without LV hypertrophy (i.e., those who are gene positive but phenotype negative), a variety of clinical and imaging findings have been reported, including subclinical diastolic dysfunction, blood-filled myocardial crypts, mitral valve leaflet elongation, collagen precursor biomarkers and myocardial scarring, or 12-lead ECG abnormalities (**see Fig. 78.2**).[28,36,41] A minority of athletes with marked repolarization abnormalities on ECG (but normal LV wall thickness) may progress to clinical and phenotypic evidence of HCM.

Mitral Valve Apparatus

Primary structural abnormalities of the mitral apparatus responsible for LV outflow obstruction are part of the phenotypic expression of HCM (**see Fig. 78.2**). The mitral valve may be more than twofold the normal size due to elongation of both leaflets, or there may be segmental enlargement of only the anterior or posterior leaflet, more frequently observed in younger patients.[41] In older patients, outflow obstruction often occurs in the presence of a particularly small LV outflow tract, mitral leaflets of normal length, and mitral-septal contact created by a modest anterior excursion of the valve combined with posterior motion of the septum.

Histopathology

In HCM, hypertrophied cardiac muscle cells (myocytes) in both the ventricular septum and LV free wall have bizarre shapes and are often arranged in a chaotic and disorganized architectural pattern (**see Fig. 78.1**).[1] At autopsy, areas of cellular disarray are evident in 95% of HCM patients; they usually occupy substantial portions of both hypertrophied and nonhypertrophied LV myocardium.

The vast majority of HCM patients also exhibit structurally abnormal intramural coronary arterioles with thickened vessel walls caused by media smooth muscle hyperplasia. These microvascular changes cause narrowing of the vessel lumen, which is likely responsible for an impaired vasodilator response and blunting of the coronary flow reserve (**see Fig. 78.1**). These abnormalities are believed to cause "small-vessel" ischemia, which, over extended periods of time, results in myocyte death and a repair process characterized by replacement myocardial fibrosis (**see Fig. 78.1**).[1,2,37] The volume of the interstitial (matrix) collagen compartment, constituting the structural framework of the LV myocardium, is greatly expanded.

The combination of disorganized cellular architecture, microvascular ischemia, and replacement fibrosis predisposes to disordered patterns and increased dispersion of electrical depolarization and repolarization, in turn serving as an unstable electrophysiologic substrate predisposing to reentry ventricular tachyarrhythmias and a likely mechanism for SD.

Pathophysiology

Left Ventricular Outflow Tract Obstruction

HCM is predominantly a disease of mechanical obstruction, in which the majority of patients (70%) have the propensity to develop impedance to LV outflow with dynamic gradients of 30 mm Hg or more, either at rest or with physiologic exercise.[1-4,27,42] Long-standing outflow obstruction is the most relevant clinical determinant of HCM-related progressive heart failure symptoms (**Figs. 78.6 and 78.7**).[18,19] Alternatively, only a weak relationship has been demonstrated between outflow obstruction and SD risk.

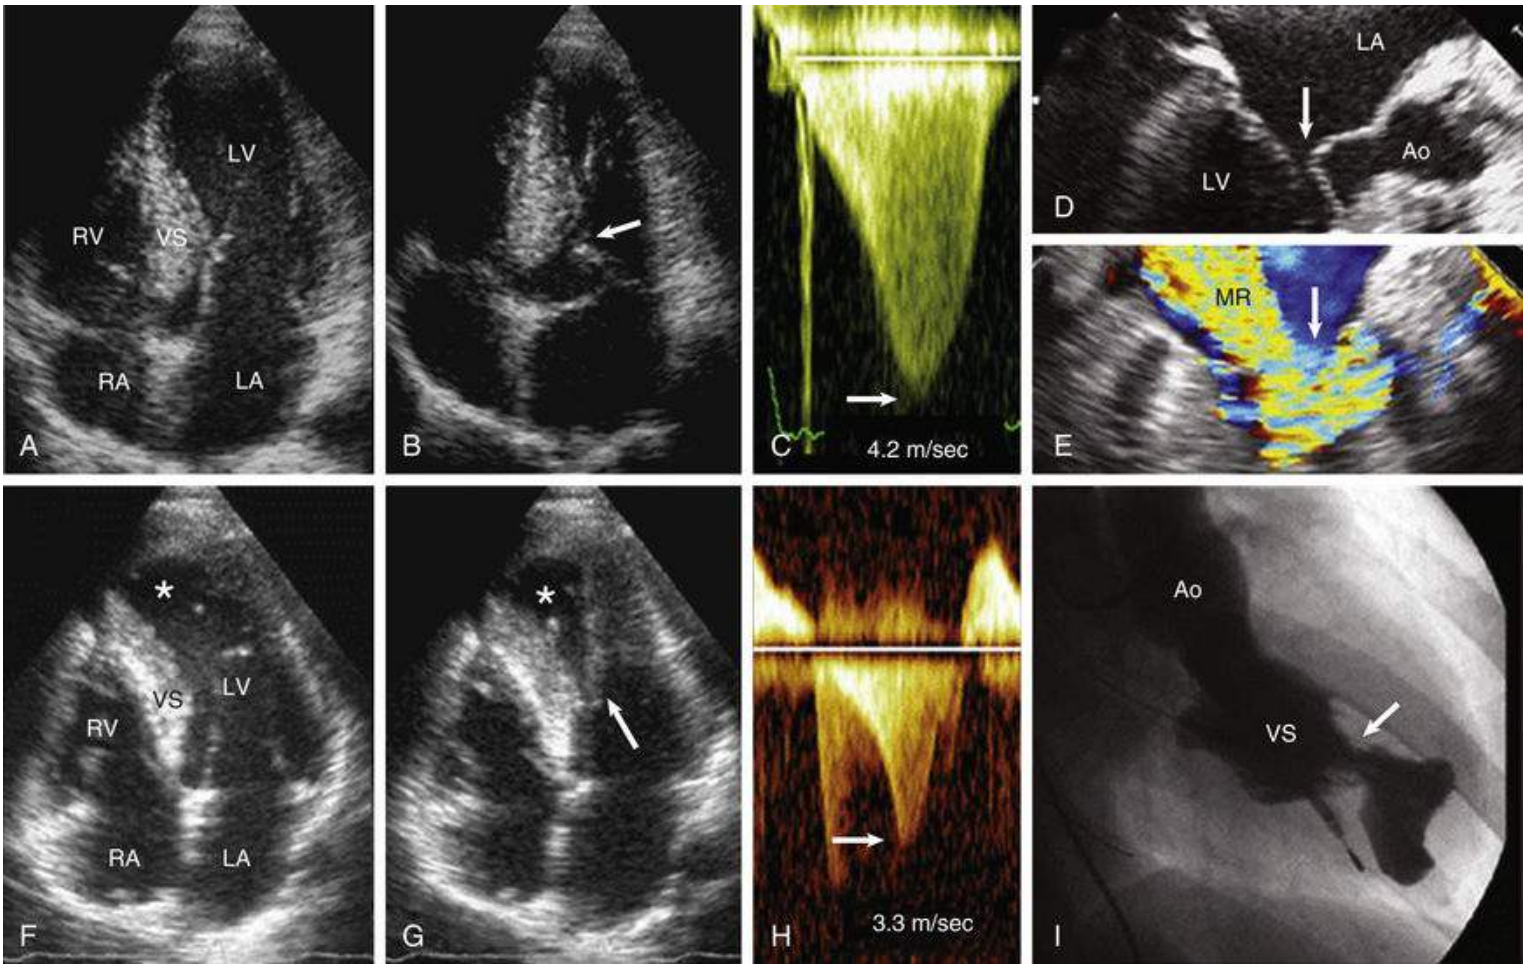

FIGURE 78.6 Dynamic LV outflow obstruction. **A** to **E,** Subaortic obstruction due to systolic anterior motion (SAM) of the mitral valve. Echocardiographic apical four-chamber view at **(A)** end-diastole and at **(B)** end-systole as the anterior mitral leaflet bends acutely with septal contact (*arrow*). **C,** Continuous-wave (CW) Doppler interrogation of the LV outflow tract showing the typical late-peaking waveform, with velocity of 4.2 m/s in midsystole, estimating a gradient of 70 mm Hg (*arrow*). **D** and **E,** transesophageal echo plane showing incomplete mitral leaflet coaptation during SAM (*arrow*), producing posteriorly directed mitral regurgitation (MR) jet. **F** to **I,** Midventricular obstruction. Echocardiographic apical four-chamber view at end-diastole **(F)** and end-systole, showing hypertrophied anterolateral papillary muscle appearing to insert directly into anterior mitral leaflet, creating midventricular muscular obstruction **(G)** (*arrow*). **H,** CW Doppler interrogation of LV outflow tract showing late-peaking waveform with peak velocity of 3.3 m/s, estimating a gradient of 45 mm Hg (*arrow*). **I,** LV ventriculogram showing hourglass contour of chamber associated with midventricular obstruction (*arrow*). *Ao*, aorta; *LA*, left atrium; *LV*, left ventricular; *MR*, mitral regurgitation; *RA*, right atrium; *RV*, right ventricle; *VS*, ventricular septum. (From Yacoub MH, El-Hamamy I, Said K, et al. The left ventricular outflow in hypertrophic cardiomyopathy: from structure to function. J Cardiovasc Transl Res 2009;2:510-517; Olivotto I, Girolami F, Nistri S, et al. The many faces of hypertrophic cardiomyopathy: from developmental biology to clinical practice. J Cardiovasc Transl Res 2009;2:349-67.)

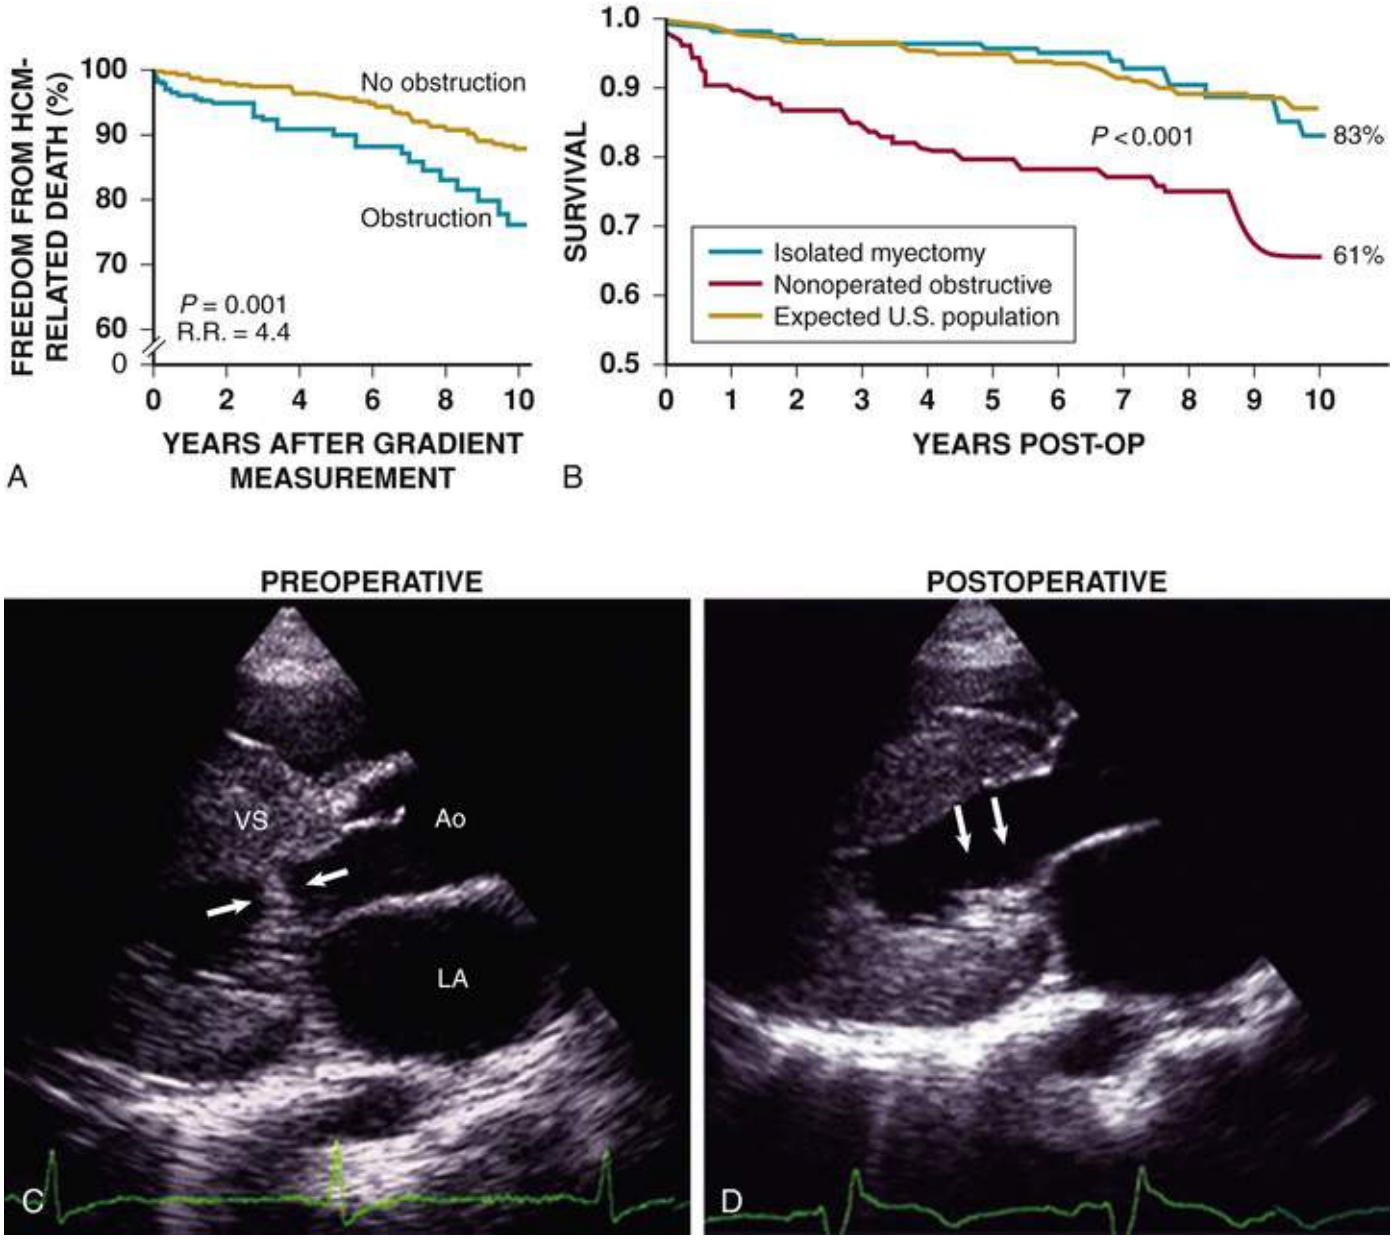

FIGURE 78.7 Clinical significance of LV outflow tract obstruction in HCM. **A,** Probability of severe progressive heart failure (NYHA class III or IV), or stroke in patients with LV outflow obstruction significantly exceeds that in patients without obstruction (relative risk, 4.4; $P < 0.001$). **B,** After myectomy, with relief of LV outflow obstruction and normalization of intraventricular pressures, showing survival free from all-cause mortality compared with age- and gender-matched U.S. population, and also nonoperated patients with obstruction ($P < 0.001$). Before surgical myectomy **(C)** echocardiographic parasternal long-axis end-systolic frames from 26-year-old woman with HCM and dynamic LV obstruction due to SAM and septal contact (*arrows*). After myectomy **(D)** with both SAM and obstruction obliterated (*arrows*). (**A** from Maron MS, Olivotto I, Betocchi S, et al: Effect of left ventricular outflow tract obstruction on clinical outcome in hypertrophic cardiomyopathy. N Engl J Med 2003;348:295. **B** from Ommen SR, Maron BJ, Olivotto I, et al: Long-term effects of surgical septal myectomy on survival in patients with obstructive hypertrophic cardiomyopathy. J Am Coll Cardiol 2005;46:470.)

Dynamic subaortic obstruction in HCM is usually produced by systolic anterior motion (SAM) of the mitral valve in which elongated leaflets bend sharply, contacting the ventricular septum in midsystole by means of a drag effect, i.e., pushing force of flow directly on the leaflets, producing markedly increased intraventricular systolic pressures that over time increase the myocardial wall stress and oxygen demand (**see Fig. 78.6**).[43] The magnitude of the outflow gradient, which is reliably estimated noninvasively with continuous-wave Doppler imaging, is directly related to the duration of mitral valve–septal contact, with posteriorly directed mitral regurgitation a secondary consequence (**see Fig. 78.6**). A central or anteriorly directed mitral regurgitation jet usually suggests an intrinsic mitral valve abnormality (e.g., with myxomatous degeneration). A congenital anomaly of the anterolateral papillary muscle insertion directly

into the anterior leaflet (without interposition of chordae tendineae) can produce midcavity muscular obstruction and is identifiable by both echocardiography and CMR.[35,36]

Subaortic gradients (and associated systolic ejection murmurs) can be spontaneously variable, reduced, or abolished by interventions, which decrease myocardial contractility (e.g., beta-adrenergic blocking drugs) or increase ventricular volume or arterial pressure (e.g., squatting, isometric handgrip, phenylephrine). Alternatively, gradients can be augmented by circumstances in which the arterial pressure or ventricular volume is reduced (e.g., Valsalva maneuver, administration of nitroglycerin or amyl nitrite, blood loss, dehydration) or when LV contractility is increased (as with premature ventricular contractions, infusion of isoproterenol or dobutamine, or physiologic exercise).[3,4] Consumption of a heavy meal or small amounts of alcohol can also transiently increase subaortic gradients.

Provocable physiologic gradients are associated with severe heart failure symptoms in some patients who become candidates for septal reduction therapy.[2,42] In asymptomatic or mildly symptomatic HCM patients, such latent gradients can be predictive of progression in heart failure symptoms over time. Provocable gradients can be blunted by inhibition of sympathetic stimulation with beta blockers.

Nonobstructive Hypertrophic Cardiomyopathy; Diastolic Dysfunction

Uncommonly (in ≈ 10%), patients with the nonobstructive form of HCM (gradient < 30 mm Hg at rest and with physiologic exercise) experience progressive heart failure to New York Heart Association (NYHA) class III or IV, at which point they may become candidates for heart transplant, with (or without) systolic dysfunction. Nonobstructive HCM patients are almost five times less likely to develop NYHA class III or IV disease than are patients with obstruction.[19] Therefore, asymptomatic and mildly symptomatic nonobstructive HCM patients make up a substantial proportion of the overall HCM clinical spectrum (at least one third), a subgroup previously underrecognized in the natural history of this disease (**Fig. 78.8**).

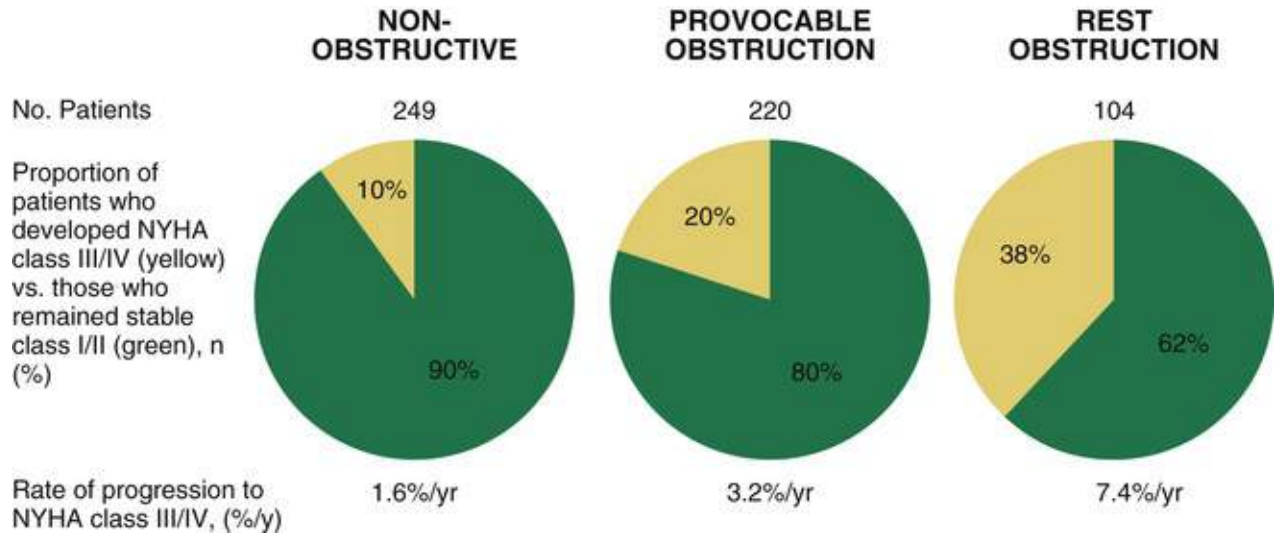

FIGURE 78.8 Comparative frequency of advanced and progressive heart failure (to NYHA classes III and IV) among the three hemodynamic subgroups. The proportion of patients who develop severe heart failure (and the rate of progression) is much less among nonobstructive patients than in patients with provocable or rest obstruction. (From Maron MS, Rowin EJ, Olivotto I, et al: Contemporary natural history and management of nonobstructive hypertrophic cardiomyopathy. J Am Coll Cardiol 2016;67:1399.)

Evidence of impaired LV relaxation and filling, by pulsed and tissue Doppler imaging or strain

techniques, is present in most HCM patients, probably contributing to symptoms of exertional dyspnea, although unrelated to the severity of LV hypertrophy.[1-3,44] In particular, diastolic dysfunction (**see also Chapter 26**) is the likely cause of limiting symptoms in patients with nonobstructive disease; it represents the mechanism by which progressive heart failure develops in the presence of preserved LV systolic function, which is occasionally refractory to medical management and ultimately requires heart transplant.[19,45] The most commonly observed pattern is delayed relaxation, characterized by a prolonged rapid filling phase associated with a decreased rate and volume of LV filling and (in sinus rhythm) a compensatory increase in the contribution of atrial systole to overall filling.

Reduced ventricular compliance in HCM probably results largely from those factors determining the passive elastic properties of the LV chamber, such as hypertrophy, replacement scarring, interstitial fibrosis, abnormal microvascular blood flow, and disorganized cellular architecture. Furthermore, abnormal energetic handling and diastolic calcium overload, occurring possibly as a result of abnormalities in the late sodium current, have been shown to contribute to diastolic dysfunction,[8] Unfortunately, few echocardiographic measurements of diastolic dysfunction available in clinical practice reliably predict the prognosis, symptoms, or filling pressures in the individual HCM patient, with the possible exceptions of reduced mitral annulus E′ velocity on tissue Doppler imaging[44] and restrictive filling patterns.[46]

Microvascular Dysfunction

Myocardial ischemia due to microvascular dysfunction appears to be an important pathophysiologic component of the HCM disease process, promoting adverse LV remodeling and ultimately affecting the clinical course.[47] Positron emission tomography (PET) is the technique most useful in the assessment of microvascular function, although it has not penetrated into routine clinical cardiovascular practice. A marked reduction in coronary reserve demonstrated with PET early in the clinical course has been reported to be a determinant of the prognosis.

Clinical Features

Physical Examination

In HCM, findings on physical examination (**see also Chapter 10**) vary related largely to the hemodynamic state. Patients with LV outflow obstruction characteristically have a medium-pitch systolic ejection murmur at the lower left sternal border and apex that varies in intensity with the magnitude of the subaortic gradient; it increases with the Valsalva maneuver, during or immediately after exercise, or on standing. Such variability, together with the characteristic lack of radiation of the murmur to the neck, aids in differentiating dynamic subaortic obstruction from fixed aortic stenosis. Most HCM patients with loud murmurs of at least grade 3/6 are likely to have LV outflow gradients of more than 30 mm Hg; arterial pulses may rise rapidly with the bisferiens pulse contour.

Initial clinical suspicion of HCM may occur with recognition of a heart murmur on routine or preparticipation sports examinations, although most patients are identified by virtue of symptom onset or cardiac events. Physical findings in patients without subaortic gradients are more subtle, with only a soft systolic murmur or no murmur at all, although a forceful apical systolic thrust may raise the suspicion of HCM.

Symptoms

Symptoms of heart failure may develop at any age, with functional limitation predominantly resulting from exertional dyspnea and fatigue; orthopnea or paroxysmal nocturnal dyspnea occasionally occurs in advanced stages. Such disability can be exacerbated by large meals or ingestion of alcohol and is frequently accompanied by chest pain, either typical or atypical of angina, possibly related to structural microvasculature abnormalities. Patients may also experience impaired consciousness with syncope or near-syncope and light-headedness explained by arrhythmias or outflow obstruction. Palpitations are common and may be linked to a variety of tachyarrhythmias, most frequently supraventricular, including AF and, less commonly, ventricular ectopy. The nature of symptoms in HCM is usually similar in patients with or without outflow obstruction.[1-4,19]

Electrocardiographic Findings

In HCM, the 12-lead ECG pattern (**see also Chapter 12**) is abnormal in about 90% of probands and in about 75% of asymptomatic relatives.[1-4] ECGs show a wide variety of abnormal patterns, some of which are distinctly abnormal or even bizarre, but none are pathognomonic of the disease or can be used alone to predict the outcome. The most common abnormalities include increased voltages consistent with LV hypertrophy, ST-T changes (including marked T-wave inversion in the lateral precordial leads), left atrial enlargement, deep and narrow Q waves, and diminished R waves in the lateral precordial leads.

Normal ECG patterns are more commonly associated with mild LV hypertrophy and a favorable clinical course, but do not exclude the possibility of future SD events. Increased voltages (tall R waves or deep S waves) are only weakly correlated with the magnitude of LV hypertrophy and do not reliably distinguish obstructive from nonobstructive HCM.

Cardiac Imaging

Cardiac imaging of HCM by two-dimensional echocardiography is discussed in **Chapter 14** and cardiac magnetic resonance imaging in **Chapter 17**.

Family Screening Strategies.
Clinical screening of relatives in HCM families is performed with two-dimensional echocardiography, CMR, and 12-lead electrocardiography, in addition to history taking and physical examination (**Table 78.1**). Clinical screening evaluations are usually performed on a 12- to 18-month basis, beginning at the age of about 12 years. If these studies do not show the HCM phenotype by the time full growth is achieved (18 to 21 years), it is more likely that a mutation that might cause HCM is absent. Morphologic conversion to LV hypertrophy can be delayed well into adulthood, however, and therefore it is not possible to provide reassurance that a normal echocardiogram at maturity unequivocally defines an unaffected genetic status. In such clinical circumstances, it may be prudent to selectively extend echocardiographic surveillance into adulthood at 5-year intervals or, alternatively, pursue genetic testing.[1-4]

TABLE 78.1

Proposed Clinical Family Screening Strategies With Echocardiography or Cardiovascular Magnetic Resonance (and 12-Lead Electrocardiography) for Detection of HCM with Left Ventricular Hypertrophy*

Age < 12 years
Optional unless:
Malignant family history of premature death from HCM, or other adverse complications
Competitive athlete in an intense training program
Onset of symptoms
Other clinical suspicion of early left ventricular hypertrophy
Age 12 to 21 years†
Every 12 to 18 months
Age > 21 years
Imaging at onset of symptoms, or possibly at 5-year intervals at least through midlife; more frequent intervals for imaging are appropriate in families with malignant clinical course or history of late-onset HCM

*In family members who had not undergone genetic testing, or in whom testing was unresolved or indeterminant.

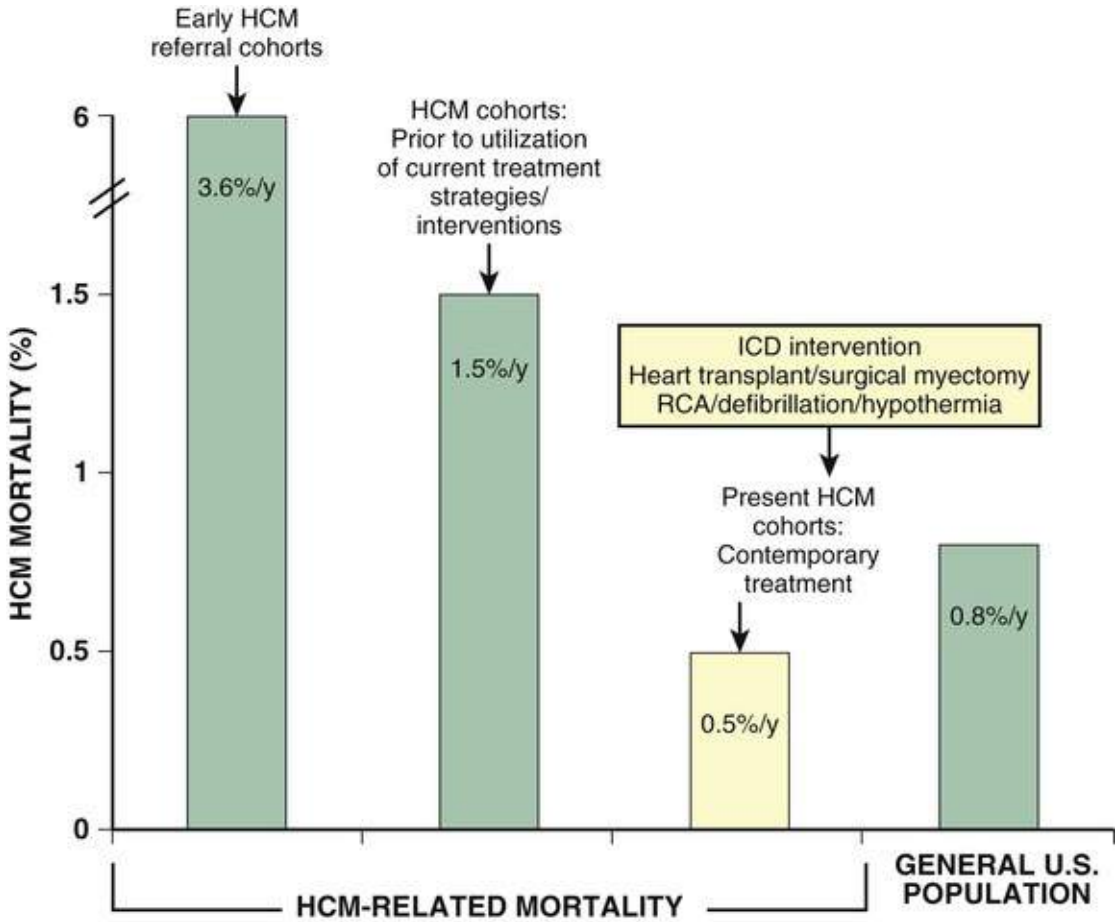
†Age range takes into consideration individual variability in achieving physical maturity, and in some patients screening may be justified at an earlier age; initial evaluation should be performed no later than early pubescence.

From Maron BJ, Maron MS, Semsarian C: Genetics of hypertrophic cardiomyopathy after 20 years: clinical perspectives. J Am Coll Cardiol 60:705, 2012.

Clinical Course

Natural History

HCM is perhaps unique among cardiovascular diseases in having the potential for clinical presentation during all phases of life, from infancy to old age.[1-4,17-22] Affected patients at either extreme of this age range appear to have the same basic disease process, although not necessarily the same clinical course. During the last decade, greater clarity has emerged regarding the natural history and clinical course of HCM. For example, cohort studies now report overall HCM-related mortality rates of less than 1% per year with the use of contemporary treatment options (**eFig. 78.1**), contrasting sharply with the older HCM literature. The now obsolete annual mortality rates of 4% to 6% were derived from highly selected cohorts at tertiary centers incorporating substantial patient referral bias skewed toward high-risk patients, and were reported in the era before implanted cardioverter-defibrillators (ICDs), surgical myectomy, and transplants for HCM were available to many patients.



EFIGURE 78.1 Historical 50-year reduction in HCM-related mortality rates. With contemporary management strategies, a mortality rate of 0.5% per year now is achievable, in contrast to data from older eras. *ICD*, implantable cardioverter-defibrillator; *OHCA*, out-of-hospital cardiac arrest. (From Maron BJ, Rowin EJ, Casey SA, et al: Hypertrophic cardiomyopathy associated with low cardiovascular mortality with contemporary management strategies. J Am Coll Cardiol 65:1915, 2015.)

In most patients, HCM is compatible with a normal life expectancy and a good quality of life with little or no disability; major therapeutic interventions are not necessary to achieve that outcome.* Indeed, not uncommonly, adults with HCM survive into their 70s, 80s, and even 90s, often with no or mild symptoms,[48-50] achieving longevity rates statistically similar to those of an age- and sex-matched general U.S. population. This recognition underscores the important principle that most HCM patients deserve a large measure of reassurance regarding their prognosis.[1,2,4,19-22]

Specific subgroups also exist within the expansive HCM population who are at higher risk for important disease complications and premature death. Such patients may proceed along specific adverse pathways (**Figs. 78.9 and 78.10**), punctuated by clinical events that alter their natural history and ultimately dictate targeted treatment strategies: (1) sudden and unexpected death; (2) progressive heart failure with exertional dyspnea and functional limitation (with or without obstruction); and (3) repetitive, persistent, permanent AF, with the risk for embolic stroke. Among these major disease end-points, which are treatable with contemporary interventions (e.g., ICDs, septal myectomy, heart transplant, and defibrillation), progressive heart failure now predominates; arrhythmic SD events are the least common. Approximately 40% of patients referred to tertiary HCM centers will experience one of these end-points, although the risk of incurring two of these complications in any single patient is uncommon (<10%).

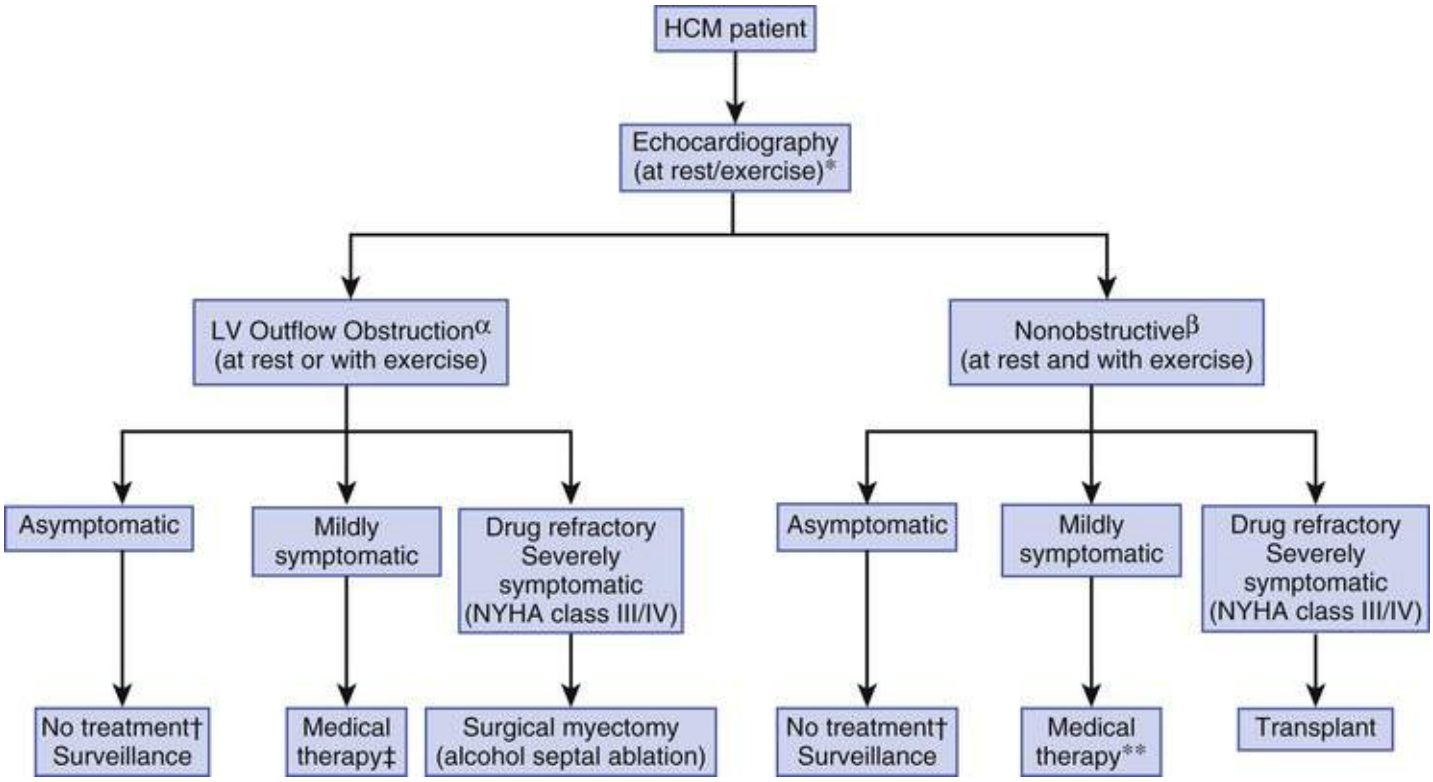


FIGURE 78.9 Heart failure management strategies starting with echocardiography. *Patients without LV outflow tract gradient (<30 mm Hg) at rest should undergo stress (exercise) echocardiography. †No data on benefit of pharmacologic therapy, although beta blockers are often administered prophylactically in clinical practice. **Beta blockers, calcium channel antagonists, and possibly diuretics administered judiciously. ‡Usually, beta blockers or calcium channel antagonists (verapamil), or disopyramide. α, generally regarded, by definition, as ≥ 30 mm Hg outflow gradient, but ≥ 50 mm Hg when septal reduction intervention is considered (i.e., septal myectomy; alcohol ablation), β, no or trivial (< 30 mm Hg) outflow gradient at rest and with exercise. (From Maron BJ, Ommen SR, Semsarian C, et al: State-of the Art Review: hypertrophic cardiomyopathy: present and future, with translation into contemporary cardiovascular medicine. J Am Coll Cardiol 2014;64:83.)

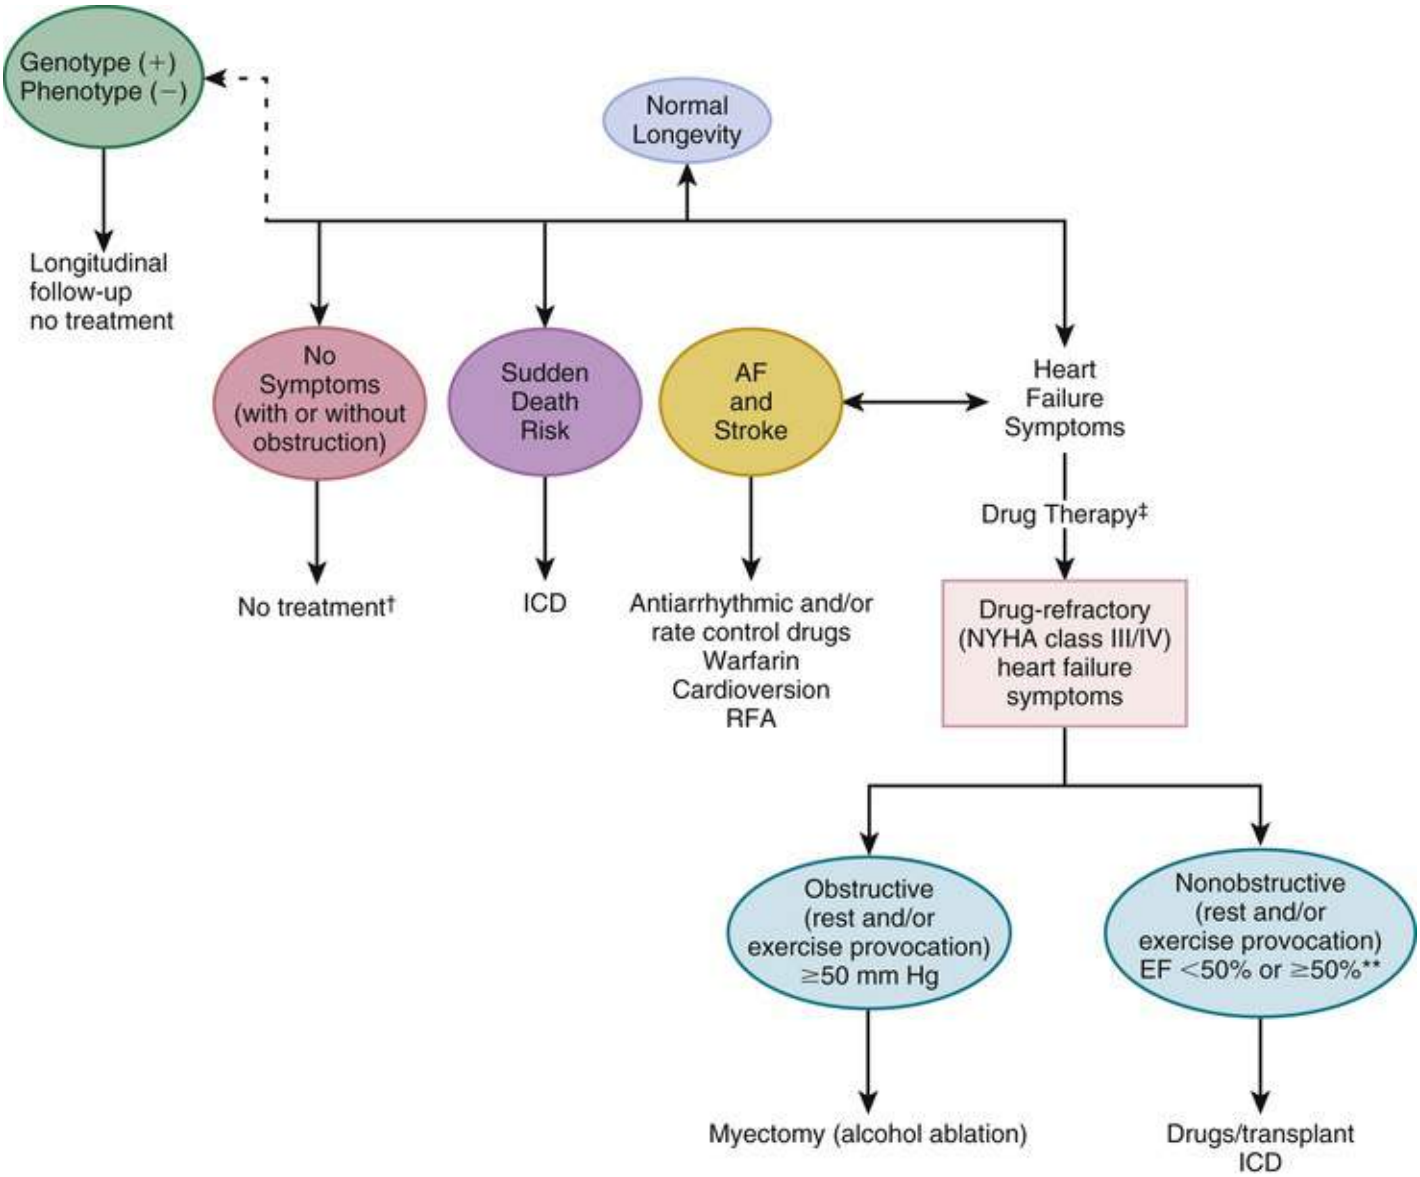

FIGURE 78.10 Prognostic pathways and treatment strategies for HCM. The majority of HCM patients probably experience a benign and stable clinical course without the need for major treatment interventions. Adverse pathways (i.e., sudden death, heart failure, and atrial fibrillation) are not necessarily mutually exclusive, because patients may progress along more than one. NYHA, New York Heart Association. Patients identified as genotype-positive, phenotype-negative may or may not develop morphologic conversion to LV hypertrophy during adolescence. †No data are available on benefit of drug treatment for asymptomatic patients, although in clinical practice, β-blockers or calcium channel blockers are sometimes administered prophylactically. ‡Usually, β-blockers and calcium channel blockers, occasionally disopyramide, and possibly diuretics (administered judiciously). **Patients in this subgroup are eligible for heart transplant with ejection fraction of < 50% or ≥ 50%. (From Maron BJ, Maron MS: Hypertrophic cardiomyopathy. Lancet 2013;381:242.)

Heart Failure

Some element of heart failure (**see also Chapters 25 and 26**) with exertional dyspnea is common in HCM, with the principal determinants of progressive heart failure attributable to LV outflow obstruction; diastolic dysfunction in the absence of obstruction is less often the primary mechanism (**see Fig. 78.9**).[1-3,18,19,21,22]

About 2% to 3% of HCM patients at referral centers develop advanced (end-stage) heart failure, usually associated with systolic LV dysfunction (ejection fraction < 50%), a consequence of small-vessel–mediated myocardial ischemia and diffuse transmural scarring (**eFig. 78.2 and see Fig. 78.2**).[2,4,54-

[57] The most reliable risk marker for evolution to end-stage disease appears to be a family history of HCM with systolic dysfunction. This profound expression of heart failure is associated with adverse LV remodeling, often resulting in LV wall thinning or chamber enlargement, or both. It usually leads to progressive heart failure over several years and requires heart transplant at a relatively young age (43 ± 13 years), and earlier than in other non-HCM patients. A potential premonitory end-stage phase has been identified in some patients with nonobstructive HCM and a low to normal ejection fraction (i.e., 50% to 60%) associated with substantial LGE (**Figs. 78.10 and 78.11 and eFig. 78.2**).[39] HCM end-stage disease has a variable genetic substrate not consistently related to any specific disease-causing gene or mutation; it is indistinguishable from end-stage disease with a preserved ejection fraction except for a higher frequency of multiple sarcomere mutations.[45]

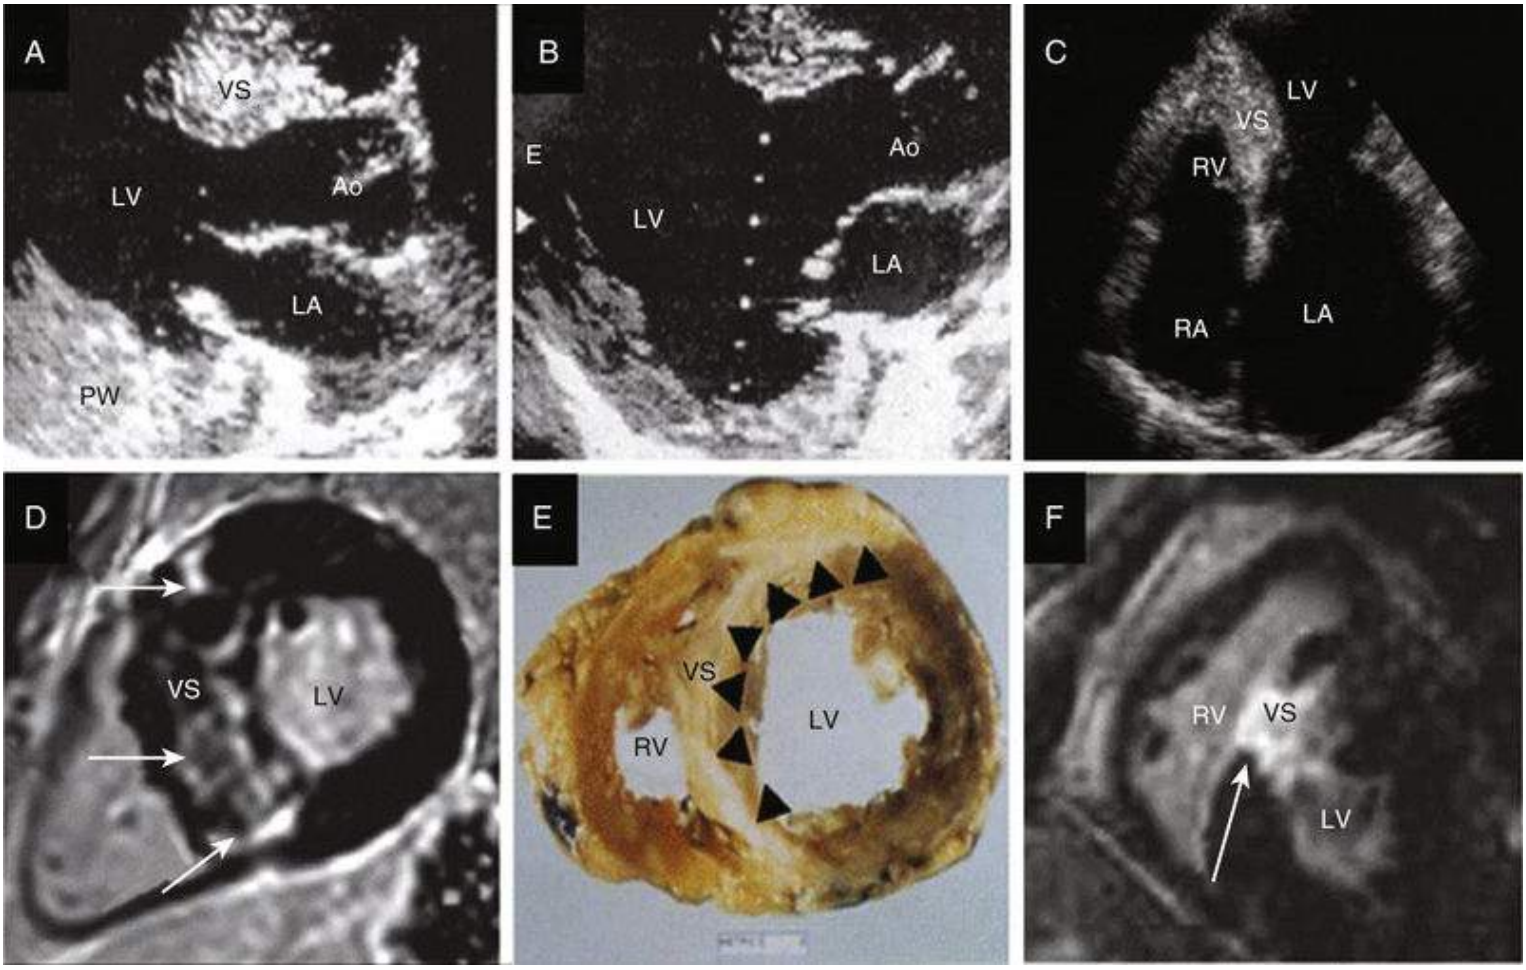

FIGURE 78.11 Myocardial scarring and outcome in HCM. **A** to **C,** End-stage HCM. **A,** Parasternal long-axis echocardiographic image in 37-year-old man showing hypertrophied ventricular septum and left ventricular posterior wall, reduced cavity size, and normal ejection fraction. **B,** Same patient shown with later conversion to end-stage disease and systolic dysfunction with remodeling in the form of septal and free wall thinning, and left ventricular cavity enlargement. **C,** Restrictive form with biatrial enlargement, small ventricular cavities, and normal ejection fraction, often associated with myocardial scarring. **D,** Contrast-enhanced MRI in a high-risk 32-year-old man, showing transmural ventricular septal LGE occupying more than 15% of LV mass (*arrows*) associated with multiple bursts of nonsustained ventricular tachycardia on ambulatory (Holter) ECG. **E,** "End-stage" heart showing extensive, transmural scarring involving septum and extending into anterior wall (*arrowheads*). **F,** Large transmural ventricular septal scar (*arrowheads*) produced by alcohol septal ablation procedure. *Ao*, aorta; *LA*, left atrium; *LV*, left ventricle; *PW*, posterior wall; *RV*, right ventricle; *VS*, ventricular septum. Circulation 130:484, 2014.)

Epidemiology of Sudden Death; Risk Stratification Strategies

Sudden death (**see also Chapter 42**) events in HCM may occur at a wide range of ages, most commonly in adolescents and adults younger than 30 years of age, but also not infrequently in midlife (**see Figs. 78.10 and 78.11 and eFig. 78.2**).[20,22] The underlying electrical substrate is unpredictably unstable, and SD may be the initial clinical manifestation of the disease unidentified in asymptomatic (or mildly symptomatic) patients.[1-4] Although the risk for SD can extend into midlife, it is significantly less common in patients 60 years of age or older, suggesting that in a genetic disease such as HCM, the potential for

lethal ventricular tachyarrhythmias is mitigated at the more advanced ages (even in the presence of conventional risk markers), as if at some point the disease declares itself to be largely free of adverse clinical events (**Fig. 78.12**).[50] Indeed, about 75% of deaths in HCM patients are unrelated to HCM, particularly in older patients.[49]

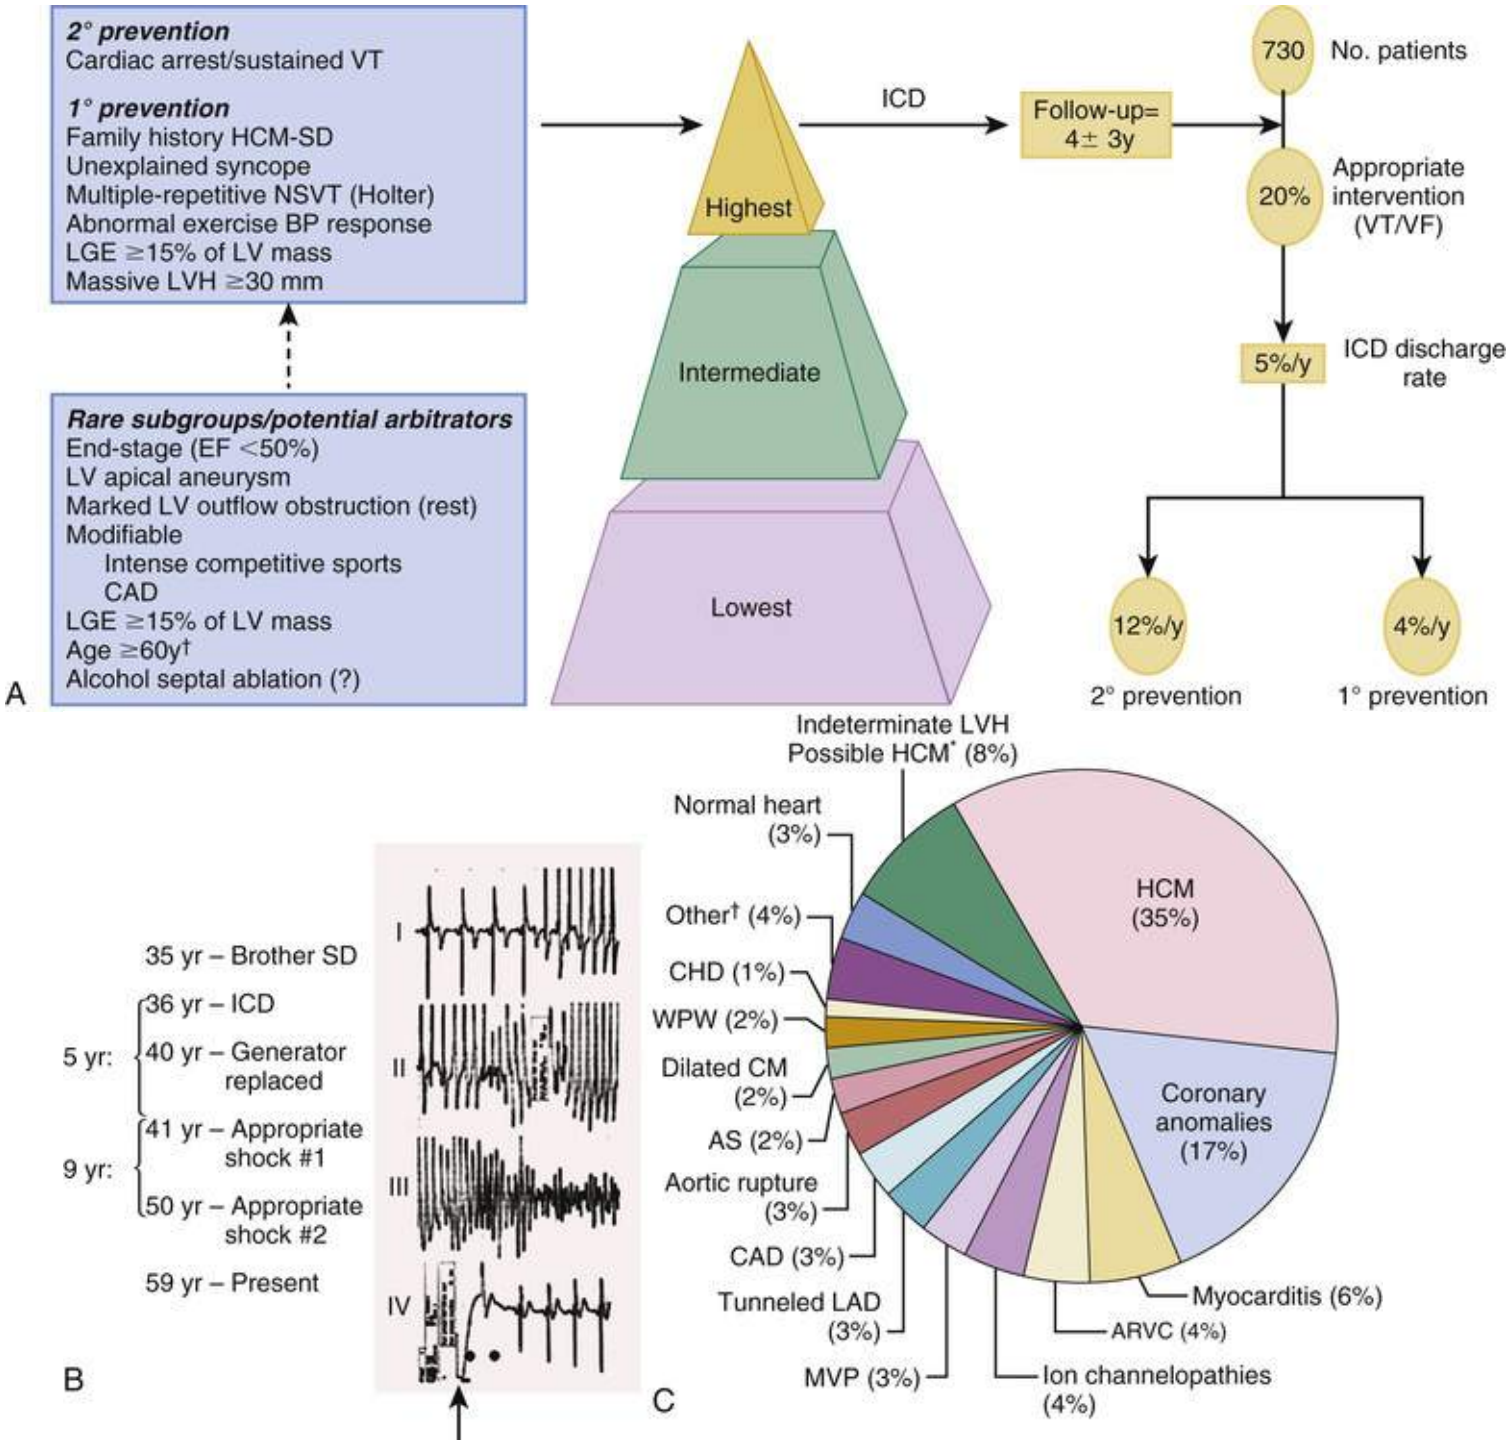

FIGURE 78.12 Prevention of sudden death. **A,** Flow-diagram summarizing HCM risk markers (to left) and ICD-related outcome in 730 high-risk children and adults from the HCM international and multicenter ICD registry studies (to right). **B,** Intracardiac electrogram obtained at 1 : 20 AM (while asleep) 5 years after implant from a 35-year-old man with HCM who received a prophylactic ICD because of a family history of SD and marked ventricular septal thickness (31 mm). Tracing I: Ventricular tachycardia (VT) at 200 bpm begins abruptly; II: Defibrillator senses VT and charges; III: VT deteriorates to ventricular fibrillation (VF); IV: Defibrillator issues a 20-J shock (*arrow*), restoring sinus rhythm. A virtually identical sequence occurred 9 years later during sleep; this patient is now 56 years old and asymptomatic. **C,** HCM is the single most common cause of sudden death in young competitive athletes in the United States, although several other largely genetic heart diseases also account for many of these events. ARVC, arrhythmogenic right ventricular cardiomyopathy; AS, aortic valve stenosis; CAD, coronary artery disease; CHD, congenital heart disease; CM, cardiomyopathy; LAD, left anterior descending; LVH, left ventricular hypertrophy; MVP, mitral valve prolapse; WPW, Wolff-Parkinson-White syndrome. *Regarded as possible (but not definitive) evidence for HCM at autopsy with mildly increased LV wall thicknesses (18 ± 4 mm) and heart weight (447 ± 76 g). (**B** from Maron BJ, Spirito P, Shen W-K, et al: Implantable cardioverter-defibrillators and prevention of sudden cardiac death in hypertrophic cardiomyopathy. JAMA 298:405, 2007. **C** from Maron BJ. Historical perspectives on sudden death in young athletes with evolution over 35 years. Am J Cardiol 116:1461, 2015.)

Whereas most SDs occur during sedentary or modest physical activities, such events are not uncommonly associated with vigorous exertion; this is consistent with the long-standing observation that HCM is the most common cardiovascular cause of SD in competitive athletes, including high school, college, and postgraduate participants (**see Fig. 78.12**).[12,13] This association of HCM with exercise-related SD is the basis for the prudent recommendations by the 36th Bethesda Conference (and subsequently by AHA/ACC guidelines) to disqualify young athletes with HCM from intense competitive sports to reduce risk.[11]

Among the broad HCM population, the greatest SD risk is associated with specific clinical markers (**see Fig. 78.12**):

Secondary Prevention: Patients who have had a prior cardiac arrest and have sustained ventricular tachycardia (VT) must have an ICD implanted for secondary prevention.

Primary Prevention: Patients with one or more of the following markers are candidates for primary prevention (the markers assume greater weight in patients younger than 50 years of age) for whom an ICD can be considered):* (1) a family history of one or more premature HCM-related deaths, particularly if the death was sudden or occurred in close relatives; (2) unexplained syncope, especially if it was recent and in a young patient; (3) a hypotensive or attenuated blood pressure response to exercise; (4) multiple, repetitive (or prolonged), nonsustained bursts of VT on serial ambulatory ECGs; (5) massive LV hypertrophy (wall thickness ≥ 30 mm Hg) (**see Fig. 78.2**), as well as LV apical aneurysms (**Table 78.2**). The risk for SD is unrelated to the pattern or location of the LV hypertrophy. In contrast to the risk for SD, greater LV wall thickness is not associated with an increased likelihood of progressive heart failure symptoms.

TABLE 78.2

Risk Factors for Sudden Death in Hypertrophic Cardiomyopathy

Secondary Prevention
Cardiac arrest or sustained VT
Conventional Primary Prevention Risk Markers
Family history of sudden death due to HCM
Unexplained recent syncope
Multiple or repetitive nonsustained VT (on ambulatory ECG)
Hypotensive or attenuated blood pressure response to exercise
Massive LV hypertrophy (wall thickness ≥ 30 mm*)
Extensive or diffuse late gadolinium enhancement (contrast-enhanced CMR)
Potential High-Risk Subsets for Primary Prevention
End-stage phase (ejection fraction < 50%)
LV apical aneurysm with scarring
Potential Arbitrators for Primary Prevention†
Substantial LV outflow gradient at rest
Extensive or diffuse late gadolinium enhancement
Transmural scar associated with alcohol septal ablation
Multiple sarcomere mutations
Modifiable
Intense competitive sports
Atherosclerotic coronary artery disease

*Or the equivalent in children according to body size.

†To arbitrate decision making regarding prophylactic implantable defibrillators in patients for whom risk level remains ambiguous after assessment by the conventional risk factor algorithm.

CMR, cardiovascular magnetic resonance; ECG, electrocardiogram; HCM, hypertrophic cardiomyopathy; LV, left ventricular; VT, ventricular tachycardia.

From Maron BJ, Maron MS: Hypertrophic cardiomyopathy. Lancet 381:242, 2013.

The presence of one or more major risk factors in the individual patient's clinical profile justifies consideration for primary prevention with an ICD, particularly when a family history of SD, unexplained syncope, or massive LV hypertrophy is present (these are also the most reliable markers for assessing the risk in children with HCM). This current risk stratification strategy for HCM, based on United States/Canada (ACC/AHA) guidelines, expert consensus panels and other data and experience, reliably identifies most high-risk patients and has been shown to be largely responsible for a reduction in HCM-related mortality rates to 0.5% per year (**see eFig. 78.1**).[18-22] Resolving complex risk assessment dilemmas involving primary SD prevention therapy may require a shared decision-making strategy that takes into account the desires of a fully informed patient and the experience and judgment of the individual clinician.

This risk algorithm is incomplete, however, and a minority of patients without any of the conventional primary prevention risk factors remain susceptible to SD.[58] In this regard, extensive LGE on contrast-enhanced CMR (particularly when it is present in 15% or more of the LV mass) has been shown to be associated with an increased SD risk; it is a new marker and independent predictor of SD, even in the absence of conventional risk factors, and its presence would lead to consideration of a prophylactic ICD (**see Table 78.2 and Fig. 78.12**).[37] Therefore, extensive LGE expands the risk stratification algorithm to incorporate patients not otherwise considered at an unacceptably high risk, and also is a marker for progression to the end-stage phase with systolic dysfunction (**see Figs. 78.2 and 78.11**). Absent or focal LGE denotes a lower risk, as does LGE localized to the junctional areas of RV attachment to the septum.

In 2014, the European Society of Cardiology proposed a novel mathematical/statistical risk score model[3] to identify patients who may benefit from ICD therapy or who do not require primary prevention implants.[59] Determination of the precise role for this scoring strategy in the clinical arena is ongoing.[60]

A number of other disease features can be regarded as potential arbitrators for prophylactic ICD decisions in individual patients when the level of risk is judged to be ambiguous based on conventional markers (**see Table 78.2**). These include subgroups within the heterogeneous HCM disease spectrum (i.e., thin-walled akinetic LV apical aneurysms with regional myocardial scarring often associated with midcavity muscular obstruction (**see Fig. 78.2**),[61] extensive LGE of 15% or more of the LV mass on CMR, coexistent obstructive atherosclerotic coronary artery disease, marked LV outflow obstruction at rest, evolution to systolic dysfunction (**see Figs. 78.2 and 78.11**), and transmural infarction from percutaneous alcohol septal ablation (**see Fig. 78.11**).[62-67]

There is no compelling evidence that particular ECG patterns, T-wave alternans, or myocardial bridging of the left anterior descending coronary artery (although more frequent in HCM than the general population) predict SD risk in HCM.[68] Furthermore, the prognosis appears benign in gene carriers without LV hypertrophy, and there is little evidence to justify disqualification of such individuals from most competitive sports or employment opportunities.[11]

Management

Prevention of Sudden Death

The ICD has altered the natural history of HCM for many patients by virtue of effectively and reliably aborting potentially lethal ventricular tachyarrhythmias, both for secondary prevention after cardiac arrest (12% per year) and primary prevention (4% per year), based on risk factor analysis (**see Fig. 78.12**).* Defibrillator intervention rates are similar in children, adolescents, and adults with HCM. Appropriate ICD interventions in high-risk patients occur with similar frequency in those implanted for one, two, three, or more risk factors (patients with one risk factor account for 35% of ICD interventions).[18,20,21,69] The timing of these ICD events shows a measure of unpredictability, as evidenced by the absence of a distinctive circadian pattern, the extended periods of time that can elapse between the clinical decision to implant an ICD and the time at which the device is required to intervene and terminate ventricular tachyarrhythmias, and the infrequency of recurrence following cardiac arrest. Notably, after an appropriate ICD intervention, progression of heart failure symptoms rarely occurs, different from the clinical circumstances in ischemic heart disease after ICD shocks. Older patients (≥ 60 years) are less often considered for primary prevention devices, given that HCM-related SD is uncommon in this age-group (**see Fig. 78.12**).[50] Decisions regarding prophylactic implantable defibrillators must also take into account the not inconsequential risk of transvenous ICD-related complications (5% per year)[70,71] and psychosocial consequences of long-term device therapy, particularly in children and adolescents. Subcutaneous ICDs could be an attractive alternative for young HCM patients to avoid the potentially deleterious impact of chronically implanted transvenous leads on the vascular system.[72] However, uncertainty persists with regard to SD prevention, given the limited experience with spontaneous VT termination outside the laboratory setting and the absence of antitachycardia pacing capability with these devices.

Pharmacologic treatment with amiodarone or other antiarrhythmic drugs for primary prevention of SD in high-risk patients is an obsolete strategy; it lacks the proven efficacy of the ICD, and there is a likelihood of important side effects occurring during the long risk period typically experienced by young

HCM patients.[20] Recurrent ventricular tachyarrhythmias triggering the ICD are uncommon in HCM; radiofrequency ablation is an unproven treatment strategy due to a diffusely abnormal substrate, with the exception of patients with LV apical aneurysms in whom an arrhythmic focus can be abolished.[61]

Treatment of Heart Failure

Drugs

Limiting symptoms of heart failure (i.e., exertional dyspnea with or without chest pain) is attributable to diastolic dysfunction, outflow tract obstruction, mitral regurgitation, microvascular ischemia, or any combination of these pathophysiologic variables (**see Fig. 78.9**).[1,2] Symptom relief with medical treatment can be highly variable, and drug administration is often empirically tailored to requirements of individual patients. Since the mid-1960s, beta-adrenergic receptor blocking drugs have been used extensively to relieve symptoms of heart failure in HCM by slowing the heart rate, thereby decreasing myocardial oxygen consumption and augmenting ventricular filling, as well as mitigating exercise-induced outflow gradients by reducing the force of the LV contraction.

Verapamil has the potential to improve symptoms and exercise capacity, largely in patients without obstruction to LV outflow. This is likely because it can provide heart rate control and improved ventricular relaxation and filling, and it serves as a potential treatment for chest pain by increasing the myocardial blood flow.[1,2] Although beta blockers are usually the first drug option, there is no evidence that combining beta blockers and verapamil is advantageous; also, together these drugs may lower the heart rate and/or blood pressure excessively.

Disopyramide is a third option (in combination with an AV nodal blocking agent) to ameliorate gradient and symptoms in patients with outflow obstruction when other drugs fail to control symptoms, although its use can be limited by parasympathetic side effects.[73] Diuretic agents, administered judiciously and used predominantly in patients with nonobstructive disease, can relieve pulmonary congestion and LV filling pressures. Novel agents currently under investigation to mitigate symptoms in HCM include small-molecule, allosteric myosin inhibitors.[5]

Medical therapeutic strategies for patients with systolic dysfunction and advanced heart failure are similar to those for congestive heart failure in non-HCM cardiac diseases, including the administration of beta blockers, angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARB), and diuretics, or spironolactone (**see Fig. 78.9**). The role of biventricular pacing for treatment of heart failure in end-stage HCM remains uncertain. HCM patients may also have severe refractory heart failure with preserved systolic function, an absence of extensive scarring, residual marked LV hypertrophy, and nondilated ventricular chambers.

End-stage HCM, with or without systolic dysfunction, and with severely limiting heart failure symptoms is virtually the sole indication for heart transplant in HCM.[1-4] Survival rates after transplant in HCM are similar to (or possibly more favorable) than those in other cardiac diseases (75% at 5 years; 60% at 10 years).[56]

Surgical Myectomy

Heart failure caused by LV outflow obstruction is reversible by septal reduction (i.e., myectomy or selective alcohol septal ablation). On the basis of extensive worldwide experience spanning over 50 years, and substantiated in guidelines and expert consensus panel recommendations from all major international cardiovascular societies, septal myectomy has been judged the preferred and primary

management option for disabled patients with severe drug-refractory symptoms (i.e., NYHA functional class III or IV disease [or the equivalent in children] due to obstruction to LV outflow under basal conditions or with physiologic exercise [i.e., gradient ≥ 50 mm Hg]) (**see Fig. 78.9**).[1-4,23,74-80]

Transaortic ventricular septal myectomy (Morrow procedure) involves resecting a small portion of muscle (usually 3 to 10 g) from the basal septum. Many surgeons now perform a more aggressive myectomy with muscular resection extending more distally within the septum to the base of the papillary muscles, and reorienting abnormally displaced papillary muscles judged as contributing to obstruction. Cutting of mitral valve chordae (in association with a shallow septal resection) has been advanced for patients with mild septal hypertrophy to effectively achieve gradient relief.[77] Of note, the expected operative mortality rate has decreased steadily and is now less than 1% at experienced HCM centers, making myectomy potentially the safest open heart procedure.[75,78]

The primary objective of surgical myectomy is reduction in heart failure symptoms and improvement in the quality of life, by virtue of relieving the outflow obstruction (and SAM) and associated mitral regurgitation, resulting in normalization of the LV pressures (**see Fig. 78.7**). Indeed, long-term follow-up studies report that 90% to 95% of patients undergoing myectomy experience both permanent abolition of the basal outflow gradient, without compromise in global LV function, and relief of symptoms over periods of up to 25 years, substantiating the likelihood of reversing heart failure due to outflow obstruction in HCM.[2,74,76,78]

In addition to substantial improvement in the quality of life, there is evidence from nonrandomized studies that myectomy is associated with extended survival rates equivalent to those expected in the age- and sex-matched general population and superior to those of nonoperated patients with outflow obstruction, including also a possible reduction in SD rate.[74] Surgical myectomy is not recommended for asymptomatic (or mildly symptomatic) patients, because conclusive evidence is lacking that prophylactic relief of obstruction is advantageous or necessary, while even the very low operative mortality rate could exceed the risk of the disease for some patients.

Alcohol Septal Ablation

Percutaneous alcohol septal ablation, an alternative to myectomy in selected patients, involves injection of 1 to 3 mL of 95% alcohol into a major septal perforator coronary artery to create necrosis and a permanent transmural myocardial infarction in the proximal ventricular septum.[62-67] The scar, which occupies approximately 10% of the LV wall (≤ 30% of the septum), causes progressive thinning and restricted basal septal excursion, outflow tract enlargement, and, in most patients, a reduced LV outflow tract gradient and mitral regurgitation.[20]

Alcohol ablation substantially improves heart failure symptoms in many patients, although long-term prognostic and efficacy data comparable to surgery are not yet available.[62-67] Nonrandomized data show that gradient and symptom relief after alcohol ablation are similar to myectomy, although less consistent; in patients over 65 years of age, symptom improvement with myectomy may be superior to that with ablation. Approximately 10% to 20% of patients incur high-degree AV block after alcohol ablation requiring permanent pacing or multiple procedures to obtain a satisfactory clinical result. Even in experienced centers, alcohol ablation may be associated with procedural mortality and complication rates similar to those of myectomy.

Remaining incompletely resolved is the important issue of the clinical consequences of the alcohol-induced transmural scar, which represents a potentially unstable electrical substrate and a nidus for lethal ventricular tachyarrhythmias that could raise the risk for SD in susceptible patients. There is evidence to support an increased level of arrhythmogenicity directly attributable to the alcohol-induced transmural

myocardial infarct (**see Fig. 78.11**), exceeding that expected following myectomy. The long-term risk associated with alcohol ablation remains unresolved, because a randomized trial of myectomy versus ablation is not feasible. Decisions regarding prophylactic ICD implants after alcohol ablation are individualized.[20,63-67,75]

All consensus and guideline panels regard alcohol ablation as an alternative treatment strategy for patients with obstructive HCM who are not considered optimal myectomy candidates (e.g., those of particularly advanced age, with significant comorbidities and potentially increased operative risk, or with a strong personal aversion to surgery) (**see Fig. 78.9**). Furthermore, alcohol septal ablation should not be performed in HCM patients with concomitant conditions, including intrinsic mitral valve disease or coronary artery disease necessitating bypass grafting, and should be discouraged in patients with extreme hypertrophy and/or complex abnormalities of the submitral valve apparatus.[4]

Dual-Chamber Pacing

Approximately 25 years ago, permanent dual-chamber pacing was promoted as an alternative to surgical myectomy for obstructive HCM patients with heart failure symptoms.[4] However, the role for pacing in HCM has become exceedingly limited, as several randomized studies demonstrated that the subjectively perceived symptomatic benefit associated with pacing appeared to be largely a placebo effect.

Treatment of Atrial Fibrillation

Symptomatic AF is the most common sustained arrhythmia in HCM, frequently accounting for unexpected hospital admissions, lost productivity, and impaired quality of life.[1-4,14,15,81-91] AF is not associated with increased HCM-related mortality or a promoter of progressive heart failure symptoms. Paroxysmal, persistent, or permanent AF occurs in 20% to 25% of HCM patients, increasing in incidence with age and related to left atrial enlargement and dysfunction. Symptomatic paroxysmal AF can adversely impact the quality of life, with frequent visits to the emergency room for cardioversion. However, the mortality rate specifically attributable to AF with HCM is low (<1% per year) and primarily due to embolic stroke in the absence of anticoagulation. No HCM gene has been linked to AF.[85]

Because of the potential for clot formation and embolization, patients with AF require anticoagulant therapy (**see Fig. 78.10**).[2-4,81,82] Although the vitamin K antagonist warfarin remains widely employed, novel oral anticoagulants are reasonable alternatives in HCM patients. Anticoagulation decisions are tailored to individual patients after consideration of lifestyle modifications, hemorrhagic risk, and expectations for compliance. The CHA_2DS_2-VASc score is neither validated nor relevant to HCM, and the number of episodes necessary to initiate treatment is unresolved, although a low threshold is prudent. Although data specifically in HCM are limited, amiodarone is regarded as the most effective drug in reducing AF recurrences; beta blockers and verapamil are usually administered to control the heart rate in patients with persistent or permanent AF.

In relatively small studies, only partial and short-term success has been achieved in controlling drug-refractory recurrent paroxysmal AF with radiofrequency catheter ablation (pulmonary vein isolation).[83,84,87] Short-term outcome in HCM is 40% of patients experiencing freedom from AF for 1 year. The long-term outcome is largely unresolved, with not inconsequential rates of repeat procedures and arrhythmic recurrences. Patients with a history of AF, undergoing surgical myectomy, should be considered for an adjunctive MAZE procedure.

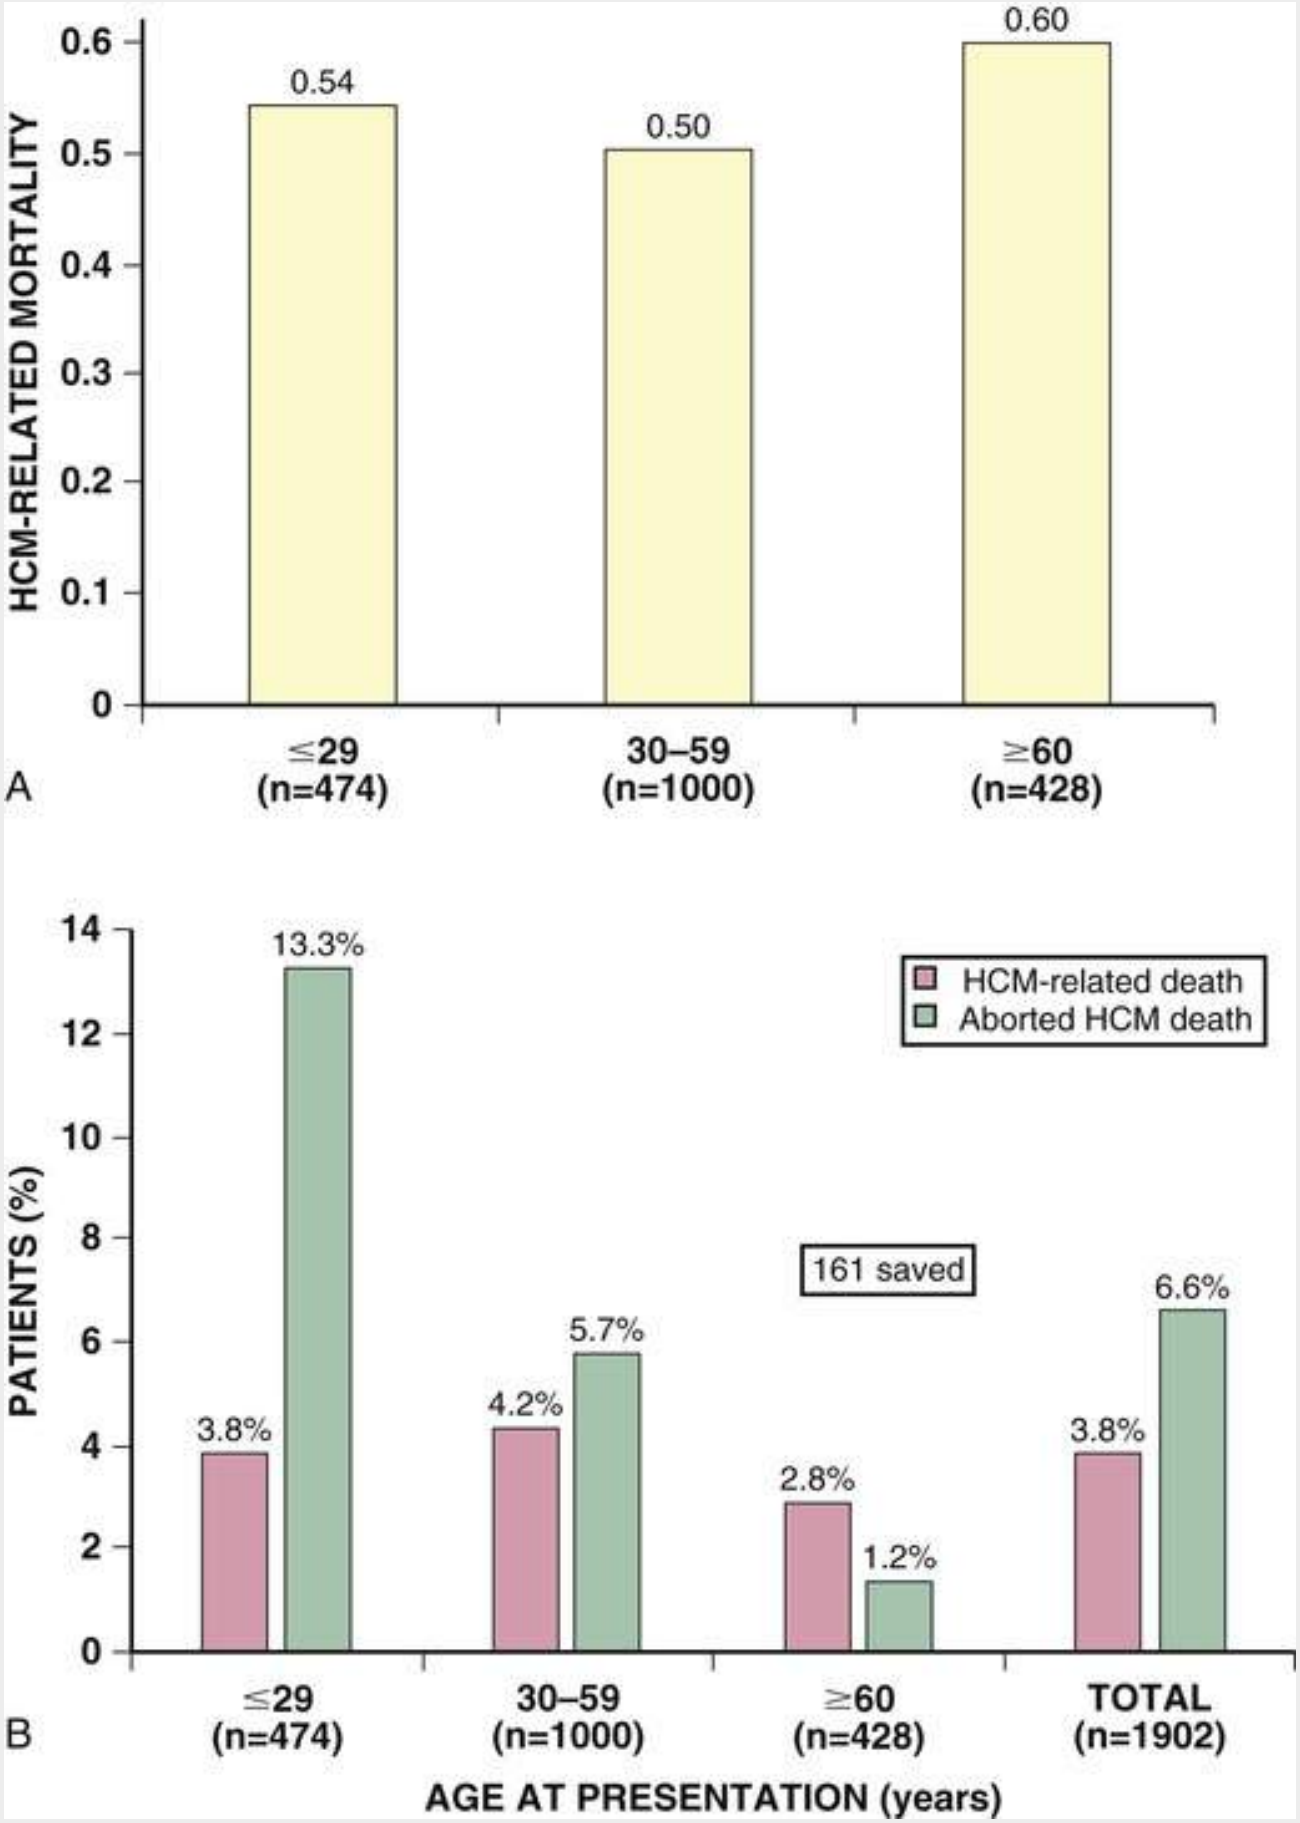
Other Management Issues

There is no evidence that HCM patients are generally at increased risk during pregnancy and delivery. Maternal morbidity and mortality rates appear to be confined to an extremely small subset of symptomatic women with high-risk clinical profiles (e.g., severe heart failure, ventricular tachyarrhythmias, or LV outflow obstruction), who deserve specialized and preventive obstetric care. Otherwise, most women with HCM undergo normal (vaginal) delivery, without a necessity to consider cesarean section.

Bacterial endocarditis is an uncommon but potentially profound complication of HCM (prevalence < 1%), with vegetations most commonly involving the anterior mitral leaflet or septal endocardium at the site of mitral valve contact. Preventive antimicrobial prophylaxis remains a prudent strategy before dental or surgical procedures, particularly for HCM patients with outflow obstruction.[88]

Outcomes; Hypertrophic Cardiomyopathy–Related Mortality Rates.

Over the last 15 years, with the emergence of dedicated HCM centers of excellence,[89] comprehensive HCM-related diagnostic and management strategies have evolved substantially in accordance with the U.S./Canada (ACC/AHA) guidelines.[4] They include an expanded risk stratification algorithm with greater appreciation for at-risk patients. The emergence of contemporary treatment advances has changed the clinical course of the disease for many patients and resulted in a significant reduction in deaths related to HCM in tertiary center cohort analyses.[17-22,90] By virtue of employing contemporary treatment strategies (e.g., ICDs for primary prevention of SD, transplant for refractory heart failure in nonobstructive disease, surgical myectomy to reverse severe heart failure due to LV outflow obstruction, modern defibrillation techniques associated with therapeutic hypothermia), the mortality rates for HCM can be reduced to as low as 0.5% per year, independent of patient age at presentation (**eFig. 78.3 and see eFig. 78.1**). These data redefine the mortality risk and alter the historical perception of HCM as a grim, relentless, progressive disease.[90]



EFIGURE 78.3 **A,** HCM-related mortality rates with contemporary treatment interventions are similar (about 0.5% per year) at all ages of presentation. **B,** Deaths averted by such treatments with a total of 161 lives saved. (From Maron BJ, Rowin EJ, Casey SA, et al: How hypertrophic cardiomyopathy became a contemporary treatable genetic disease with low mortality: shaped by 50-years of clinical research and practice. JAMA Cardiol 1:98, 2016.)

Athlete's Heart

Additional content on athlete's heart and HCM is presented in an online supplement for this chapter entitled Athlete's Heart and Hypertrophic Cardiomyopathy.

Future Perspectives

The last decade has witnessed a greatly increased understanding of the diagnosis, clinical profile, and natural history of HCM, and most notably has produced crucial advances in management. Indeed, HCM has been transformed from a disease with a seemingly unfavorable prognosis to one compatible with normal life expectancy, in which all major complications are associated with a potentially effective treatment option. A list of classic references in the field is presented in the online supplement for this chapter entitled Classic Hypertrophic Cardiomyopathy References.

Nevertheless, future investigative efforts are necessary, including development of even more precise risk stratification strategies to reliably identify all patients at unacceptably high risk for SD deserving of consideration for ICD therapy, but also limiting the number of unnecessary device implants. There will also be continuing efforts to define the proper role of alcohol ablation relative to surgical myectomy in the management of symptomatic patients with outflow obstruction, as well as a more complete understanding regarding the use of commercial genetic testing, the impact of next-generation sequencing, and further clarification of genotype-phenotype relationships.

Finally, as advanced heart failure continues to emerge as an increasingly common complication of HCM, a major unmet need will be more reliable prospective identification of at-risk patients and the development of novel, targeted, disease-specific pharmacologic options to relieve heart failure symptoms, particularly in the absence of outflow obstruction. Active research and clinical trials are ongoing to identify disease-specific drugs targeting HCM pathophysiology.

Athlete's Heart and Hypertrophic Cardiomyopathy

Intensive and long-term athletic training can increase the LV diastolic cavity dimension, wall thickness, and calculated mass, creating a physiologic entity known as athlete's heart.[1] Such absolute increases in LV wall thickness are usually modest and evident in only some athletes, but can be more common and substantial in elite and highly trained individuals, particularly those participating in rowing and cycling. They are not associated with participation in purely isometric sports such as weightlifting. Diagnostic dilemmas may arise in distinguishing clinically benign and physiologic LV hypertrophy (as a consequence of athletic training) from pathologic conditions such as HCM (**eTable 78.1**).[1] Clinical parameters that favor the diagnosis of HCM in trained athletes in the ambiguous “gray zone” of overlap between the two conditions (when the maximum LV wall thicknesses is 13 to 15 mm) include identification of a disease-causing sarcomeric mutation or recognition of HCM in a relative; finding of a transmitral Doppler waveform consistent with altered LV relaxation and filling; an LV end-diastolic cavity dimension of less than 45 mm, and LGE by CMR. Parameters favoring physiologic athlete's heart include regression of LV wall thickness on serial CMR studies after a short (4- to 6-week) period of deconditioning and an enlarged LV cavity size (> 55 mm).

Preparticipation Screening

Detection of cardiovascular abnormalities with the potential for unexpected and unpredictable SD associated with intense physical training and competition is a major objective of preparticipation screening for high school and college-aged sports participants. In the United States, the customary screening practice dictates a personal and family history and physical examination.[2] Although HCM can

be suspected and identified by this process, it may remain unrecognized given that many affected individuals do not have a heart murmur or historical clues (e.g., syncope or a family history of HCM). Mandatory incorporation of the ECG into a national screening program for competitive athletes is not feasible or recommended within the current U.S. health care system for several reasons: the unfavorable cost-efficacy with insufficient resources, the substantial possibility of borderline and false-positive test results (and the uncertainty that accompanies these circumstances), the variability in ECG patterns with respect to race, and the possibility of false-negative testing in about 10% of those with clinically expressed HCM,[3] On the other hand, a national ECG screening program for detection of cardiovascular disease in competitive athletes has achieved some success in Italy.[4] Broad-based screening of athlete populations with echocardiography appears to be an even less practical strategy.

Myocarditis

Leslie T. Cooper Jr, Kirk U. Knowlton

Overview and Definition

In its broadest sense, *myocarditis* refers to any inflammation of the myocardium. Inflammation can be

found after any form of injury to the heart, including ischemic damage, mechanical trauma, and genetic cardiomyopathies. More specifically, however, *classic myocarditis* refers to inflammation of the heart muscle occurring as a result of exposure to either discrete external antigens, such as viruses, bacteria, parasites, toxins, or drugs, or internal triggers, such as autoimmune activation against self-antigens. Although viral infection remains the most commonly identified cause of myocarditis, drug hypersensitivity and toxic drug reactions, other infections, and peripartum cardiomyopathy also can lead to myocarditis.

The pathogenesis of myocarditis is a classic paradigm of cardiac injury followed by immunologic response from the host as cardiac inflammation. The relative incidence of viral causes is continually evolving as new diagnostic tools based on molecular epidemiology become available. Indeed, more than 20 viruses have been associated with myocarditis, and the most frequent are currently parvovirus B19 (B19V) and human herpesvirus 6.[1] Historically, enteroviruses such as coxsackievirus B were the most commonly identified pathogens, and strains of enterovirus remain widely used in rodent models of the disease.[2] If the host immune response is overwhelming or inappropriate, the inflammation may destroy the heart tissue acutely or may linger, producing cardiac remodeling that leads to dilated cardiomyopathy (DCM), heart failure, or death. Fortunately for most patients, clinical myocarditis often is self-limited if proper support and follow-up care are available. In many cases the virus is cleared successfully, and the immune response is down-modulated. In some patients, however, an autoimmune reaction to endogenous antigens lingers beyond this phase and can cause persistent cardiac dysfunction. Sometimes viral genomes persist in the heart with or without acute inflammation.[3] Viral genomes commonly are detected in endomyocardial biopsy (EMB) specimens from patients with DCM and may signal a disease-related infection. As discussed in this chapter, with new insights into the understanding of the pathophysiology of myocarditis and new therapies for this condition, the outlook for affected patients is continuing to improve.

Epidemiology

Globally, the number of cases of myocarditis in 2015 was approximately 2.2 million, an increase from approximately 1.48 million cases in the 2013 world population.[4] In 2015 there were approximately 200,000 deaths in men and 150,000 deaths in women from both myocarditis and cardiomyopathy, with a death rate of between 5 and 6 per 100,000 in males and between 4 and 5 per 100,000 in females (**Fig. 79.1**). The burden of myocarditis as a percentage of prevalent heart failure varies by age and region from approximately 0.5% to 4.0%.[5]

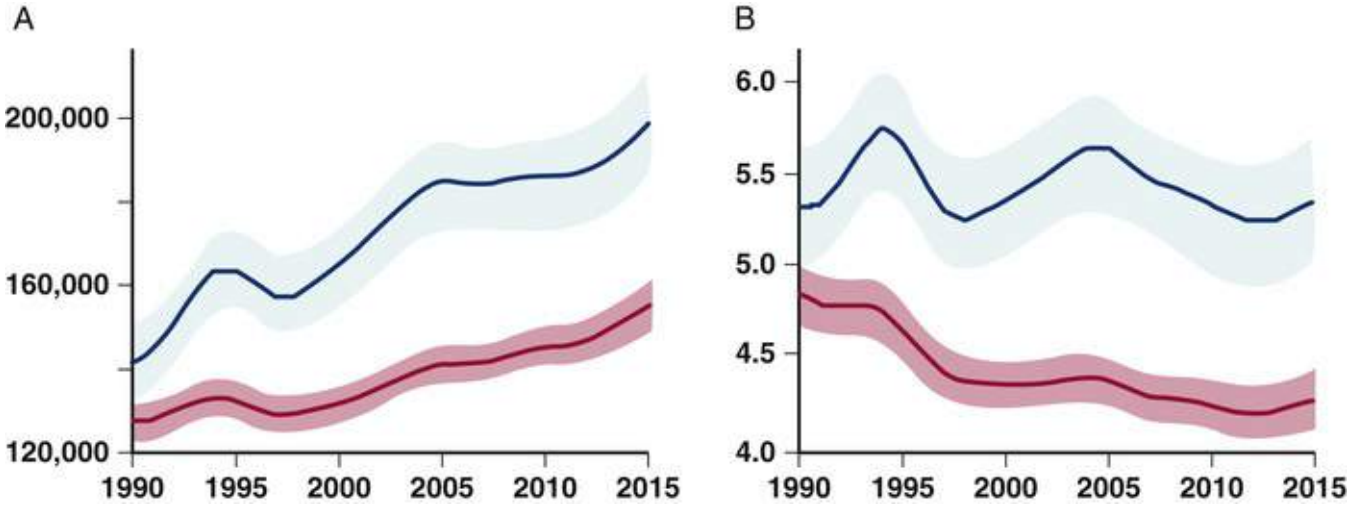

FIGURE 79.1 **A,** Number of global deaths with 95% uncertainty interval for women (*red*) and men (*blue*) due to cardiomyopathy and myocarditis from 1990 to 2015. **B,** The global death rate per 100,000 people with 95% uncertainty interval for women (*red*) and men (*blue*) due to cardiomyopathy and myocarditis from 1990 to 2015. (From the Global Burden of Disease Project, Institute for Health Metrics and Evaluation database. Image provided by Greg A. Roth, MD, MPH, and Catherine O. Johnson, Division of Cardiology, University of Washington, Institute for Health Metrics and Evaluation. Heymans S, Eriksson U, Lehtonen J, Cooper LT Jr: The quest for new approaches in myocarditis and inflammatory cardiomyopathy. J Am Coll Cardiol 2016;68:2348-64.)

In clinical case series of sudden death, myocarditis often is the third leading cause after hypertrophic cardiomyopathy and congenital and atherosclerotic coronary artery disease. Myocarditis is responsible for sudden cardiovascular death in approximately 2% of infants, 5% of children, and 5% to 14% of young athletes.[6,7] The overall rate of myocarditis was 3% (6 of 200) in autopsies of patients experiencing sudden death in Japan.[8] This rate should be seen in the context of the unselected diagnosis rate of myocarditis, 0.11% of 377,841, in autopsies registered in Japan from 1958 to 1977.

Myocarditis is responsible for a substantial minority of DCM cases (**see also Chapters 21 and 77**). In a review of DCM case series from 1978 to 1995 in which EMB was performed, the incidence of biopsy-proven myocarditis varied widely, ranging from 0.5% to 67%, with an average of 10.3%. Data from the U.S. Pediatric Cardiomyopathy Registry, in which 46% (222/485) of children with an identified cause of DCM had myocarditis, are illustrative of recent reports. As in most DCM case series, only a minority of children in this series, 34% of 1426, had a specific cause of DCM identified.[9]

Most case series show a male predominance, which may be mediated by sex hormones. The prevalence of myocarditis as a cause of cardiomyopathy is relatively high in the first year of life, declines from age 2 to 11 years, and rises again from puberty to about age 40 years. The population-based prevalence of myocarditis is likely higher, because the diagnostic test, EMB, is infrequently performed outside of referral medical centers.

The differing histologic criteria used to define myocarditis are responsible for some of the variation in the reported prevalence of myocarditis. The standard Dallas criteria define idiopathic myocarditis as an inflammatory infiltrate of the myocardium with necrosis and/or degeneration of adjacent myocytes not typical of the ischemic damage associated with coronary artery disease (**Fig. 79.2A** and **Table 79.1**).[10] These criteria have been criticized because of interreader variability in interpretation, lack of prognostic value, and low sensitivity due in part to sampling error. Specific immunohistochemical stains that detect cellular antigens, such as anti-CD3 (T lymphocytes), anti-CD68 (macrophages), and class I and II human leukocyte antigens (**Fig. 79.2B**), may have greater sensitivity for small infiltrates than that of hematoxylin-eosin stain. Markers of complement activity such as C4d also are commonly found in native cardiomyopathic hearts. Newer immunohistochemical stains have a greater predictive value for cardiovascular events than the Dallas criteria.[11]

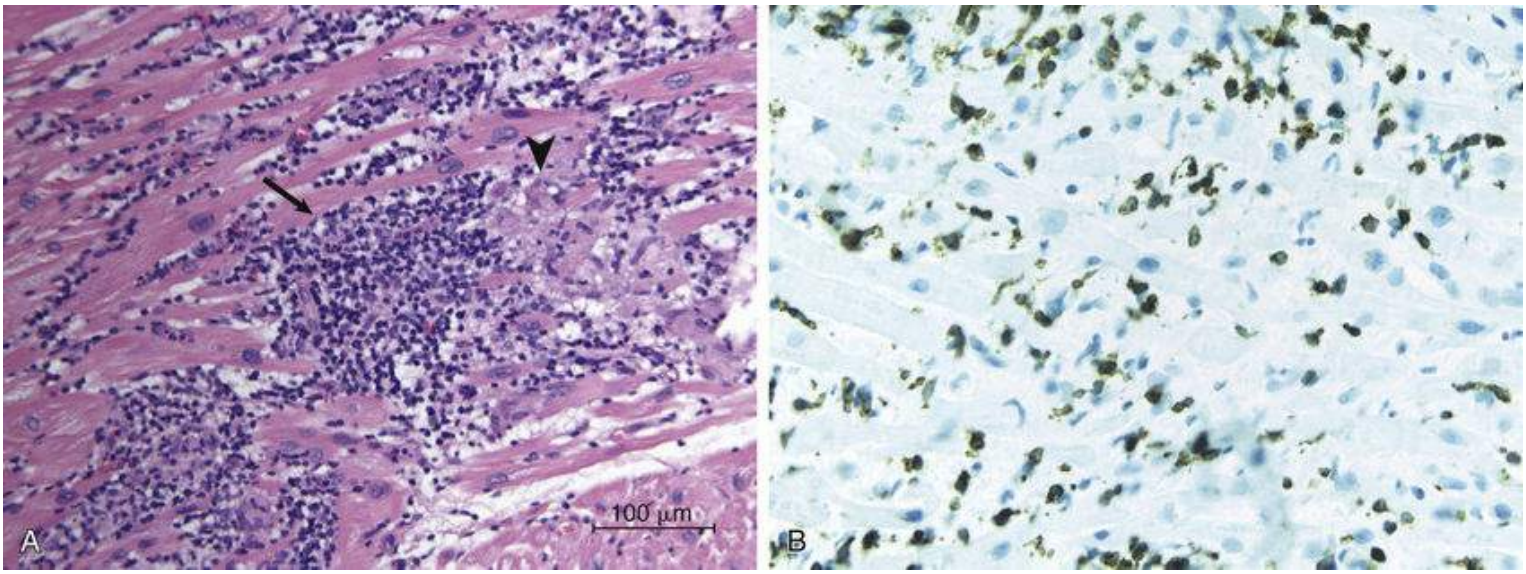

FIGURE 79.2 **A,** Acute myocarditis with widespread lymphocytic and histiocytic infiltrate (*arrow*) and associated myocyte damage (*arrowhead*). **B,** CD3 immunostaining of T lymphocytes in a patient with acute myocarditis. TABLE 79.1

Endomyocardial Biopsy Diagnosis of Myocarditis: the Dallas Criteria

DEFINITION		
Idiopathic *myocarditis*: "an inflammatory infiltrate of the myocardium with necrosis and/or degeneration of adjacent myocytes not typical of the ischemic damage associated with coronary artery disease"		
CLASSIFICATION		
First biopsy • Myocarditis with or without fibrosis • Borderline myocarditis (repeat biopsy may be indicated) • No myocarditis Subsequent biopsy • Ongoing (persistent) myocarditis with or without fibrosis • Resolving (healing) myocarditis with or without fibrosis • Resolved (healed) myocarditis with or without fibrosis		
DESCRIPTORS		
	INFLAMMATORY INFILTRATE	**FIBROSIS**
Distribution	Focal, confluent, diffuse	Endocardial, interstitial
Extent	Mild, moderate, severe	Mild, moderate, severe
Type	Lymphocytic, eosinophilic, granulomatous, giant cell, neutrophilic, mixed	Perivascular, replacement

Modified from Leone O, Veinot JP, Angelini A, et al: 2011 Consensus statement on endomyocardial biopsy from the Association for European Cardiovascular Pathology and the Society for Cardiovascular Pathology. Cardiovasc Pathol 2012;21:245.

The presence of viral genomes in heart tissue may indicate an active infectious myocarditis. In the posttransplantation setting, the presence of viral genomes in myocardial biopsy material predicts future rejection episodes and graft loss in children.[12] Viruses for which testing is commonly done in the setting of suspected myocarditis are B19V, adenovirus, cytomegalovirus, enterovirus, Epstein- Barr virus, hepatitis C virus, herpes simplex viruses 1, 2, and 6, and influenza viruses A and B. New diagnostic criteria that rely on higher B19V copy numbers or evidence of active viral replication have been proposed.[2] For epidemiologic studies in which universal EMB is not feasible, diagnostic classifications that rely on clinical syndromes, biomarkers, and/or imaging abnormalities have been used[13] (**Table 79.2**).

TABLE 79.2

Three-Tiered Clinical Classification for Diagnosis of Myocarditis by Level of Diagnostic Certainty

DIAGNOSTIC CATEGORY	CRITERIA	HISTOLOGIC CONFIRMATION	BIOMARKER, ECG, OR IMAGING ABNORMALITIES CONSISTENT WITH MYOCARDITIS	TREATMENT NEEDED
Possible subclinical acute myocarditis	In the clinical context of possible myocardial injury *without* cardiovascular symptoms but with at least one of the following: Biomarkers of cardiac injury raised ECG findings suggestive of cardiac injury Abnormal cardiac function on echocardiogram or CMR	Absent	Required	Not known
Probable acute myocarditis	In clinical context of possible myocardial injury *with* cardiovascular symptoms and at least one of the following: Biomarkers of cardiac injury raised ECG findings suggestive of cardiac injury Abnormal cardiac function on echocardiogram or CMR	Absent	Required	Per clinical syndrome
Definite myocarditis	Histologic or immunohistologic evidence of myocarditis	Present	Not required	Tailored to specific cause

CMR, cardiac magnetic resonance imaging.

Modified from Sagar S, Liu PP, Cooper LT, Jr: Myocarditis. Lancet 2012;379:738.

Specific Etiologic Agents

In most cases, myocarditis is triggered by an inciting event, such as infection or exposure to a drug or toxin that activates the immune response. A subset of cases is due to primary immunologic abnormalities in the affected patient. Advanced techniques in virology, immunology, and molecular biology have demonstrated that there are many potential causes of myocarditis. Almost any infectious agent has been associated with myocarditis. In clinical practice, however, it is often difficult to identify a specific etiologic agent.

Viruses

Viral infection has been implicated as one of the most common infectious causes of myocarditis (**Table 79.3**). The earliest evidence of virus infection and its association with myocarditis and pericarditis was acquired during outbreaks of influenza, poliomyelitis, measles, and mumps, and in cases of pleurodynia associated with enterovirus infection.[14] Modern virologic and molecular techniques have demonstrated that adenoviruses, enteroviruses, and parvovirus are among the most commonly identified infectious agents in myocarditis. The precise incidence caused by these agents varies geographically and temporally. Nevertheless, in metaanalyses, polymerase chain reaction (PCR) studies in patients with clinically suspected myocarditis or cardiomyopathy who subsequently underwent heart biopsy demonstrated that virus could be identified 3.8 times more frequently in patients with myocarditis than in control subjects. Additional evidence indicates that persistence of the viral genome in patients with cardiomyopathy is associated with increased ventricular dysfunction and worse outcome during follow-up.

TABLE 79.3

Causes of Myocarditis

VIRUSES AND VIRAL DISORDERS	BACTERIA AND BACTERIAL DISORDERS	CARDIOTOXINS	HYPERSENSITIVITY MEDIATORS AND FACTORS
Adenovirus*	*Chlamydia*	Anthracycline drugs*	Cephalosporins
B19V	Cholera	Arsenic	Clozapine
CVB*	Leptospirosis	Carbon monoxide	Diuretics
Cytomegalovirus*	Lyme disease	Catecholamines	Hypereosinophilia
Epstein-Barr virus	*Mycoplasma*	Chagas disease	Insect bites
Hepatitis C virus	*Neisseria*	Cocaine*	Kawasaki disease
Herpes simplex virus	Relapsing fever	Copper	Lithium
HIV*	*Salmonella*	Ethanol*	Sarcoidosis
Influenza virus	Spirochete	Heavy metals	Snake bites
Mumps	*Staphylococcus*	Lead	Sulfonamides
Poliovirus	*Streptococcus*	Leishmaniasis	Systemic disorders
Rabies	Syphilis	Malaria	Tetanus toxoid
Rubella	Tetanus	Mercury	Tetracycline
Varicella-zoster virus	Tuberculosis	Protozoa	Wegener granulomatosis
Yellow fever			

*Frequent cause of myocarditis.

Modified from Elamm C, Fairweather D, Cooper LT: Pathogenesis and diagnosis of myocarditis. Heart J 2012;98:835.

Enteroviruses, Including Coxsackieviruses.

Coxsackievirus is a member of the Enterovirus genus, Picornaviridae family. It is a nonenveloped lytic virus. Its capsid proteins harbor a single, positive-strand RNA genome of 7.4 Kb. Throughout the history of studies that address the causes of myocarditis, enteroviruses such as coxsackievirus B3 or echovirus are commonly identified in a subset of patients at a higher frequency than in control subjects. Using molecular techniques such as PCR and in situ hybridization, the enterovirus genome has been identified in the heart of 15% to 30% of patients with myocarditis and 7% to 30% of specimens with DCM, although the incidence in different studies varies considerably. Coxsackievirus infection meets the criteria of Koch's postulates as a cause of myocarditis in humans: It can be regularly found in the lesions of the disease; it has been isolated in pure culture from patients with myocarditis; and when inoculated into a mouse it can recapitulate the disease, after which the virus can be recovered from the heart of the infected mouse.

Coxsackievirus is a close relative of the poliovirus and rhinovirus, viruses that have been studied extensively. Although the disease phenotypes are different, the many similarities in viral replication cycles have facilitated an understanding of the mechanisms by which coxsackievirus can cause disease. Coxsackievirus typically enters the host through the gastrointestinal or respiratory system. It uses the coxsackievirus-adenovirus receptor (CAR), a transmembrane adhesion protein, as its primary receptor for cell entry. It can cause a broad range of clinical syndromes, including meningitis, skin rashes, acute respiratory illness, skeletal myositis, and myocarditis.

Most recently, evaluation of patients with myocarditis has demonstrated a decrease in the prevalence of enteroviruses in the myocardium. This is particularly evident in Western Europe. The reason for this decrease is not clear, but it may be related to a herd immunity that occurs after a period of prolonged exposure to the virus. The lower incidence also may be confounded by seasonal outbreaks of enterovirus infections, thereby making the exact incidence dependent on the outbreaks.

Adenovirus.

Adenoviruses are nonenveloped DNA viruses that also use CAR (adenovirus types 2 and 5), as well as

integrins, as receptors for entry into the target cell. The adenovirus capsid harbors a double-stranded DNA genome. Adenoviruses commonly infect mucosal surfaces. The adenovirus genome is consistently identified in a subset of patients with myocarditis. The incidence in myocarditis patients has been recorded to be as high as 23% and as low as less than 2%.[15] Although mechanisms of adenoviral infection have been studied in considerable detail in cell culture and other diseases, it has been challenging to study adenovirus-mediated myocarditis, in the face of difficulties identifying an appropriate mouse model using the same adenoviruses that affect humans.

Parvovirus.

Considerable attention during the last decade has focused on the role of parvovirus B19 (B19V) of the genus Erythrovirus in the pathogenesis of myocarditis because of the high prevalence of B19V DNA in hearts of patients with myocarditis. Parvovirus is a nonenveloped, nonlytic virus with a single-strand, positive-strand DNA genome of approximately 5.6 Kb. Humans are the only known host for B19V, making it challenging to study in animal models, but examples of myocarditis in mice stimulated with the capsid protein VP1 or antibodies against VP1 have been reported.[15] Its primary receptor is globoside, also known as group P antigen. This antigen is found primarily on erythroid progenitors, erythroblasts, and megakaryocytes. It also has been shown to be expressed on endothelial cells. This finding may be important for its role in the pathogenesis of myocarditis. The infection is thought generally to be spread by the respiratory route. The incidence of infection in the general population is high, with evidence of B19V infection demonstrated in approximately 50% of children at age 15 years, and detectable IgG directed against B19V found in as many as 80% of elderly patients.[16] With PCR studies, the PVB genome has been identified in 11% to 56% of patients with myocarditis and in 10% to 51% of patients with DCM.

In keeping with the high prevalence of B19V in the general population, the pathogenic role of B19V continues to be clarified. In one study, B19V was assessed by immunohistochemistry and PCR assay. The investigators found that B19V was detectable by immunohistologic analysis in 65% of patients with myocarditis, 35% of patients with DCM, and 8% of noninflamed control hearts. The viral load was assessed by genome copy numbers in the samples that were positive for B19V on immunohistologic analysis. The viral load was significantly higher in patients with acute myocarditis, followed by those with DCM, and it was lowest in the patients with normal hearts without inflammation.[17] In addition, viral RNA replicative intermediates were detected only in patients with inflamed hearts. It has also been determined that evidence of viral transcription is associated with an anomalous host myocardial transcriptome.[18] These findings indicate that the amount of B19V viral DNA is associated with the disease phenotype. Of importance, the virus was found in endothelial cells and not myocardial cells. Other studies have suggested a bystander role for B19V in adult myocarditis,[16] with persistence of low-level B19V titers a frequent finding, but unrelated to ongoing myocardial injury. Additional experimentation is needed to determine mechanisms by which B19V could contribute to myocarditis and cardiomyopathy.

Human Immunodeficiency Virus.

The improved survival rate of patients with human immunodeficiency virus (HIV) infection (**see also Chapter 82**) has affected the incidence of heart disease in this population, There has been a shift from myocardial and pericardial disease to a higher incidence of coronary artery disease. In retrospective series and autopsy studies in patients infected with HIV, the incidence of cardiac involvement ranged from 25% to 75%. Clinical cardiovascular presentations associated with HIV infection include myocarditis, pericarditis, DCM, arrhythmias, and vascular diseases. Myocarditis with lymphocytic

infiltration has been reported in 40% to 52% of patients who die of acquired immunodeficiency syndrome (AIDS). The incidence of myocardial disease, however, appears to have decreased with increased antiretroviral therapy. This is especially true as it relates to DCM, pericardial disease, and arrhythmias. The incidence of cardiomyopathy, myocarditis, and pericardial diseases correlates with the severity of the HIV infection as measured by a low $CD4^+$ count or high viral titers. Owing to ongoing changes in therapy for HIV infection, the exact incidence of myocardial diseases is not clear, but it continues to be a problem. In addition, many patients in developing regions of the world do not receive highly active antiretroviral therapy and may present with cardiac disease. Although HIV infection can be associated with ventricular dysfunction, the mechanisms by which this occurs have not been fully elucidated; however, activation of cytokines and alteration of immune cells that affect cardiac function are likely to be involved. Convincing evidence that HIV directly infects the myocardium is lacking. The pathogenesis of HIV-associated cardiomyopathy is complicated by infection with pathogens that are associated with immunosuppression, malnutrition, and other confounding effects. In the post–antiretroviral therapy era, acute coronary syndromes and coronary artery disease are the major cardiovascular diseases that occur in HIV-infected patients in the United States.[19]

Hepatitis C Virus.

Hepatitis C virus infection appears to be mainly associated with cardiomyopathy in Asian countries such as Japan. A low incidence of hepatitis C virus antibodies (4.4%) was identified in patients who were studied in the Myocarditis Treatment Trial. This occurrence rate was nevertheless higher than that (1.8%) in the general U.S. population. Perhaps the higher incidence of hepatitis C virus infection in DCM is related to the overall higher incidence of this infection in Asia. Myocardial biopsy samples from patients with cardiomyopathy have demonstrated the presence of the hepatitis C viral genome, and a rise in serum antibody titers has been documented in patients so affected. The phenotype associated with hepatitis C virus also has been reported to include hypertrophic cardiomyopathy, suggesting that hepatitis C may have a direct effect on growth and hypertrophy of the myocardial cells. Symptomatic myocarditis generally is observed in the first to third weeks of illness. It has been reported that heart function can return to normal with clearance of the virus.

Influenza Virus.

Influenza A virus infection is a well-recognized cause of myocarditis, and this association should be kept in mind during periodic outbreaks of influenza A. The exact incidence of myocarditis with influenza A outbreaks is not known, but it generally is considered to be in the 5% range. During pandemics such as the 2009 H1N1 pandemic, myocarditis was reported in 5% to 15% of cases as diagnosed by changes on the electrocardiogram (ECG) and the presence of cardiac symptoms. Some cases manifested with fulminant myocarditis. Histopathologic examination usually demonstrates the presence of the inflammatory infiltrate that is typical of myocarditis.[20]

Bacteria

Nonviral pathogens such as bacteria and parasites can affect the heart and, in some cases, activate an immune reaction in the heart. Virtually any bacterial agent can cause myocardial dysfunction, but it does not necessarily mean that the bacterium has infected the myocardium. In the case of sepsis or other severe bacterial infections, the myocardial dysfunction generally is attributed to activation of inflammatory mediators (**see Chapter 23**). Of note, however, bloodstream infection by virtually any bacterial infection can result in metastatic foci in the myocardium. This finding is most commonly associated with bacterial endocarditis. Some bacterial infections are well known to have specific effects on the heart that can be

mediated by direct infection or activation of inflammatory mechanisms. The most common of these include diphtheria, rheumatic heart disease, and streptococcal infections.

Corynebacterium Infection.

Myocardial involvement with *Corynebacterium diphtheriae* is a serious complication and is the most common cause of death in diphtheria. In up to one half of fatal cases, evidence of cardiac involvement can be found. Studies from the last decade indicate that there is evidence of myocardial involvement in 22% to 28% of patients. The overall incidence has decreased in developed countries because of vaccination, but recently, there have been a growing number of unprotected individuals in developed countries as well. This may be related to vaccine avoidance. *C. diphtheriae* produces an exotoxin that severely damages the myocardium and the cardiac conduction system. Cardiac damage is due to the liberation of this exotoxin, which inhibits protein synthesis by interfering with host translational mechanisms. The toxin appears to have an affinity for the cardiac conduction system. Both antitoxin therapy and antibiotics are important in the treatment of diphtheria.

Streptococcal Infection.

The most commonly detected cardiac complication after beta-hemolytic streptococcal infection is acute rheumatic fever, which is followed by rheumatic valve disease in approximately 60% of patients. Rarely, involvement of the heart by the streptococcus may produce a nonrheumatic myocarditis distinct from acute rheumatic carditis. This clinical entity is characterized by the presence of an interstitial infiltrate composed of mononuclear cells with occasional polymorphonuclear leukocytes, which may be focal or diffuse. In contrast with rheumatic heart disease, streptococcal myocarditis usually occurs coincident with the acute infection or within a few days of the pharyngitis. Electrocardiographic abnormalities, including ST elevation and prolongation of the PR and QT intervals, are common. Rare sequelae may include sudden death, conduction disturbances, and arrhythmias.

Tuberculosis.

Involvement of the myocardium by Mycobacterium tuberculosis (not tuberculous pericarditis) is rare. Tuberculous involvement of the myocardium occurs by means of hematogenous or lymphatic spread or may arise directly from contiguous structures and may cause nodular, miliary, or diffuse infiltrative disease. On occasion, it may lead to arrhythmias, including atrial fibrillation and ventricular tachycardia, complete atrioventricular block, heart failure, left ventricular aneurysms, and sudden death.

Whipple Disease.

Although overt involvement is rare, intestinal lipodystrophy, or Whipple disease, is not uncommonly associated with cardiac involvement. Periodic acid–Schiff–positive macrophages can be found in the myocardium, pericardium, coronary arteries, and heart valves of patients with this disorder. Electron microscopy has demonstrated rod-shaped structures in the myocardium similar to those found in the small intestine, representing the causative agent of the disease, *Tropheryma whipplei*, a gram-negative bacillus related to the actinomycetes. An inflammatory infiltrate and foci of fibrosis also may be present. The valvular fibrosis may be severe enough to result in aortic regurgitation and mitral stenosis. Although it usually is asymptomatic, nonspecific electrocardiographic changes are most common; systolic murmurs, pericarditis, complete heart block, and even overt congestive heart failure may occur. Antibiotic therapy appears to be effective in treatment of the basic disease, but relapses can occur, often more than 2 years after the initial diagnosis.

Lyme Carditis.

Lyme disease is caused by a tick-borne spirochete (*Borrelia burgdorferi*). It usually begins during the summer months with a characteristic rash (erythema chronicum migrans), followed by acute neurologic, joint, or cardiac involvement, usually with few long-term sequelae. Early studies indicated that up to 10% of untreated patients with Lyme disease demonstrated evidence of transient cardiac involvement, the most common manifestation being atrioventricular block of variable degree. With the early use of antibiotics, however, Lyme carditis is now considered to be a rare manifestation.[21] Of patients with Lyme disease reported to the Centers for Disease Control (CDC), only 1.1% were identified as having Lyme carditis.[22] Syncope due to complete heart block is frequent with cardiac involvement because of the commonly associated depression of ventricular escape rhythms. Diffuse ST-segment and T-wave abnormalities are transient and usually asymptomatic. An abnormal gallium scan is compatible with cardiac involvement, and the demonstration of spirochetes in myocardial biopsy specimens of patients with Lyme carditis suggests a direct cardiac effect. Patients with second-degree or complete heart block should be hospitalized and undergo continuous electrocardiographic monitoring. Temporary transvenous pacing may be required for a week or longer in patients with a high-grade block. It is thought that antibiotics can prevent subsequent complications and may shorten the duration of the disease; therefore, they are used routinely in patients with Lyme carditis. Intravenous antibiotics are suggested, although oral antibiotics can be used when only mild cardiac involvement is present. Corticosteroids may reduce myocardial inflammation and edema, which in turn can shorten the duration of the heart block. It is thought that treatment of the early manifestations of the disease will prevent development of late complications.

Protozoa

Chagas disease is one of the major causes of nonischemic cardiomyopathy throughout the world, although the incidence is changing. In a remarkable tale of discovery at the beginning of the 20th century, Carlos Chagas almost single-handedly identified the parasite, *Trypanosoma cruzi*, which causes the entity now known as Chagas disease. He also elucidated the relatively complex life cycle of the parasite in poor, rural areas of Brazil.[23] The parasite resides in and replicates in an infected host such as an armadillo or a domestic cat. The parasite then infects triatomine insects, including the hematophagous reduviid bug that feeds on the blood of infected vertebrate carriers. The triatomine acts as the vector of infection when it bites a human, depositing the parasite in its feces in the area of the bite wound, conjunctiva, or other mucous membranes. Once within the now-infected individual, the parasite replicates and infects target organs such as the heart. Parasitic infection of cardiac myocytes and activation of the associated immune function damage the heart and other organs and lead to the clinical manifestations of Chagas disease; **Fig. 79.3** shows the life cycle.[24]

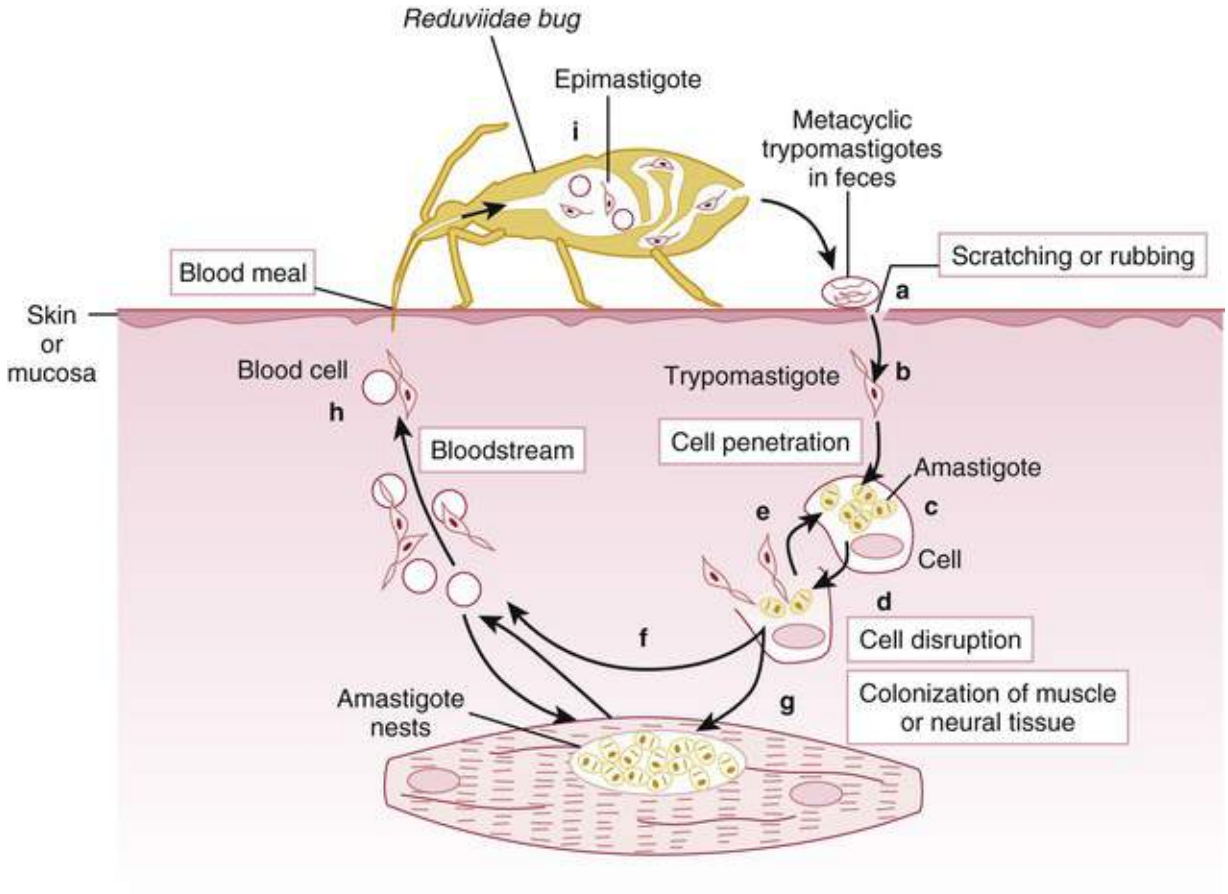

FIGURE 79.3 The life cycle of *Trypanosoma cruzi.* Reduviid bugs transmit *T. cruzi.* While partaking of a blood meal **(A),** the insect defecates on the host's skin, releasing the infective trypomastigote form of the parasite. The trypomastigotes penetrate the host's skin or mucous membrane through abrasions caused by scratching or rubbing the bitten area **(B)**. Trypomastigotes can infect host cardiac, skeletal, smooth muscle, or neural cells, subsequently giving rise to the round amastigote form that can replicate intracellularly **(C)**. Amastigotes can give rise to trypomastigotes that can lyse cells **(D)**. Amastigotes and trypomastigotes released from dying cells can propagate the infection or reenter the circulation (**E** to **G**). Insects can pick up the parasite when consuming a blood meal **(H)**; it develops into the epimastigote form that replicates in the insect gut **(I)**. (From Macedo AM, Oliveira RP, Pena SD: Chagas' disease: role of parasite genetic variation in pathogenesis. Expert Rev Mol Med 2002;4:1.)

Chagas disease is endemic in poor, rural areas of Central and South America (**see eFig. 79.1**). The distribution of Chagas disease is changing to include more urban and traditionally nonendemic areas because of migration of infected individuals from the rural to urban areas. Vector control initiatives in the endemic areas and aggressive screening of the blood supply has reduced the overall incidence of Chagas disease. In the 1980s, 17.4 million people were infected in 18 endemic countries.[25] By 2010, it was estimated that the number of infected persons had dropped to nearly 5.7 million. In 1990, it was estimated that 700,000 new cases were diagnosed each year. In 2010, that number had decreased to 29,925. Similarly, the number of annual deaths from Chagas disease has decreased, from 50,000 per year in 1990 to approximately 12,500 per year.[24,26] However, at the same time that Chagas disease is decreasing worldwide, the incidence in the developed world is increasing because of immigration from endemic areas. It is currently estimated that approximately 238,000 people in the United States are infected with *T. cruzi*.[27] This has important implications in relation to blood transfusion and organ donation, because the infectious agent can be transferred from donor to recipient; this is a particularly important consideration in the immunocompromised transplant recipient.

EFIGURE 79.1 Distribution of Chagas disease in the Americas. (Modified from Acquatella H: Chagas' disease. *In* Abelmann WH, Braunwald E [editors]: Atlas of Heart Disease: Cardiomyopathies, Myocarditis, and Pericardial Disease. Philadelphia, Current Medicine, 1995, pp 8.1-8.18; and Liu PP, Schultheiss HP: Myocarditis. *In* Libby P, Bonow RO, Mann DL, Zipes DP [editors]: Braunwald's Heart Disease. Philadelphia, Saunders, 2008.)

Symptoms from *T. cruzi* infection typically begin 1 to 2 weeks after a bite from an infected triatomine or can occur up to a few months after transfusion of infected blood. The parasite load can affect the severity of clinical presentation. The acute phase is accompanied by the presence of parasites in the blood smear. The acute phase of *T. cruzi* infection lasts for 4 to 8 weeks. During the acute phase of parasite infection, most affected patients are either asymptomatic or have a mild, subacute febrile illness. Other potential manifestations include adenopathy, hepatomegaly, myocarditis, and meningoencephalitis. Cardiovascular abnormalities during the acute phase might include nonspecific ECG changes, first-degree atrioventricular block, and cardiomegaly on chest x-ray examination. Death occurs from myocarditis or meningoencephalitis in less than 5% to 10% of symptomatic patients. In up to 90% of patients, the symptoms of disease resolve spontaneously. Of these, approximately 60% to 70% never develop chronic Chagas disease manifestations even in the absence of treatment with trypanocidal drugs, but these patients will remain seropositive throughout life. Aside from seropositivity for *T. cruzi,* the patients without manifestations of disease exhibit no signs or laboratory findings of Chagas disease, as described further on. The other 30% to 40% of patients ultimately develop more typical manifestations of the chronic form of Chagas disease. Treatment with antiparasite drugs such as benznidazole usually can cure the patient during the acute illness.[23,24] The chronic phase of *T. cruzi* infection continues throughout the infected host's life. The 30% to 40% of patients with acute illness that go on to develop chronic Chagas disease usually manifest the disease within 5 to 15 years after the initial infection. However, less than 1% of patients with chronic Chagas disease report a history of symptoms of acute Chagas disease. The

chronic form is characterized by myocardial fibrosis, destruction of the conduction system, ventricular dilation, thinning of the apex of the heart, and formation of a thrombus in the apex of the heart. These changes lead to heart failure, arrhythmia, atrioventricular and bundle branch block, and possible thromboembolism. Gastrointestinal disturbances also can be a prominent part of the presentation. It is reported that 50% to 90% of patients with chronic Chagas disease remain asymptomatic despite ongoing pathologic processes.[23,24]

Congenital transmission of the parasite to a fetus from the mother is another important mechanism of transmission of the parasite. Conversely, the parasite can be passed from the mother to the infant at the time of birth. *T. cruzi* also has been shown to infect the placenta and subsequently infect the fetus in utero. Congenital transmission occurs in 1% to 5% of pregnancies when the mother has chronic Chagas disease. Congenital transmission of this disease results in spontaneous abortion, premature birth, or infection of organs in the fetus.[23,24]

The goal of treatment in all forms of Chagas disease is to eradicate the parasite. Antitrypanosomal treatment is strongly recommended for all patients with acute, congenital, and reactivated infections. It also is recommended for all children who have chronic *T. cruzi* infection who are 18 years of age or younger. Therapy should be offered to patients 19 to 50 years of age without advanced heart disease. Strong consideration should be given for treatment of persons who have not previously been treated but have acquired HIV infection or are being considered for organ transplantation. Chagas disease is associated with both active persistent parasite infection and an immune response that may be directed against the parasite or may be a response of autoimmune origin.[28] Antiparasite treatment generally is not indicated in patients with advanced heart failure from Chagas disease.

Helminths

Echinococcosis (Hydatid Cyst)

Echinococcosis is endemic in many sheep-raising areas of the world, particularly Argentina, New Zealand, Greece, North Africa, and Iceland; however, cardiac involvement in patients with hydatid disease is uncommon (<2%). The usual host of *Echinococcus granulosus* is the dog, but humans may serve as intermediate hosts if they accidentally ingest ova from contaminated dog feces. When cardiac involvement is present, the cysts usually are intramyocardial, located in the interventricular septum or left ventricular free wall.

A myocardial cyst can degenerate and calcify, develop daughter cysts, or rupture. Rupture of the cyst is the most dreaded complication; rupture into the pericardium can result in acute pericarditis, which may progress to chronic constrictive pericarditis. Rupture into the cardiac chambers can result in systemic or pulmonary emboli. Rapidly progressive pulmonary hypertension can occur with rupture of right-sided cysts, with subsequent embolization of hundreds of scolices, fragments of the tapeworm, into the pulmonary circulation. The liberation of hydatid fluid into the circulation can produce profound, fatal circulatory collapse as a result of an anaphylactic reaction to the protein constituents of the fluid. It is estimated that only approximately 10% of patients with cardiac hydatid cysts experience clinical symptoms. The ECG may reflect the location of the cyst. Chest pain usually is due to rupture of the cyst into the pericardial space with resultant pericarditis. Large cystic masses sometimes produce right-sided obstruction. The chest radiograph may show an abnormal cardiac silhouette or a calcified lobular mass adjacent to the left ventricle. Two-dimensional echocardiography, computed tomography, or cardiac

magnetic resonance (CMR) imaging may aid in the detection and localization of heart cysts. Eosinophilia, when present, is a useful adjunctive finding. The Casoni skin test or serologic evaluation for echinococcus has a limited role in cardiac diagnosis. In terms of therapy, despite the availability of effective drugs such as mebendazole and albendazole, surgical excision generally is recommended, even for asymptomatic patients. This is because of the significant risk of rupture of the cyst and its attendant serious and sometimes fatal consequences.

Trichinosis

Infection with *Trichinella spiralis* is common after ingestion of infected meat, usually pork. The parasite typically infects skeletal muscle. Reports of the incidence of clinically detectable cardiac involvement average around 25% of infected patients worldwide. Cardiomyopathy and arrhythmias may develop in some patients and constitute the most common cause of death in this infection. Less frequently, death is due to pulmonary embolism secondary to venous thrombosis or neurologic complications. Although the parasite can invade the heart, it does not usually encyst there, and a finding of larvae or larval fragments in the myocardium is rare. The heart may be dilated and flabby, and a pericardial effusion may be present. A prominent focal infiltrate composed primarily of eosinophils can be found, with occasional microthrombi in the intramural arterioles. Areas of muscle degeneration and necrosis are present.

The clinical myocarditis in trichinosis may be mild and go unnoticed, but in a subset of cases it is manifested by heart failure and chest pain, usually appearing around the third week of the disease. Electrocardiographic abnormalities are detected in approximately 20% of patients with trichinosis and parallel the time course of clinical cardiac involvement, initially appearing in the second or third week and usually resolving by the seventh week. The most common electrocardiographic abnormalities are repolarization abnormalities and ventricular premature complexes. The diagnosis usually is based on the demonstration of indirect immunofluorescent antibody in a patient with the clinical features of trichinosis. Eosinophilia, when present, is a supportive finding. The skin test result is usually but not invariably positive. Treatment is with anthelminthics and corticosteroids; dramatic improvement in cardiac function has been reported after completion of an appropriate regimen of these agents.

Physical Agents, Including Adverse Drug Effects

A wide variety of substances other than infectious agents can act on the heart and damage the myocardium. In some cases, the damage is acute, transient, and associated with evidence of an inflammatory myocardial infiltrate with myocyte necrosis (e.g., with the arsenicals and lithium). Other agents that damage the myocardium can lead to chronic changes with resulting histologic evidence of fibrosis and a clinical picture of a dilated or restrictive cardiomyopathy. Numerous chemicals and drugs (both industrial and therapeutic) can lead to cardiac damage and dysfunction. Several other physical agents (e.g., radiation, excessive heat) also can contribute directly to myocardial damage. Additional content on this this topic is discussed in an online supplement for this chapter titled Additional Physical Agents That Cause Myocarditis.

Additional Physical Agents That Cause Myocarditis

Physical Agents

A wide variety of substances other than infectious agents can act on the heart and damage the myocardium.

In some cases, the damage is acute, transient, and associated with evidence of an inflammatory myocardial infiltrate with myocyte necrosis (e.g., with the arsenicals and lithium). Other agents that damage the myocardium can lead to chronic changes with resulting histologic evidence of fibrosis and a clinical picture of a dilated or restrictive cardiomyopathy. Numerous chemicals and drugs (both industrial and therapeutic) can lead to cardiac damage and dysfunction. Several physical agents (e.g., radiation and excessive heat) also can contribute directly to myocardial damage.

Radiation

The cardiac effects of radiation therapy are discussed in **Chapter 81**. Briefly, radiation therapy can lead to a variety of cardiac complications that arise long after the completion of the therapy, including pericarditis with effusion, tamponade, or constriction; coronary artery fibrosis and myocardial infarction; valvular abnormalities; myocardial fibrosis; and conduction disturbances. Although irradiation probably results in some degree of tissue damage in all patients, clinically significant cardiac involvement occurs in the minority of patients, usually long after the treatment has ended. Radiation-induced cardiac damage is related to the cumulative dose of the radiation and the mass of heart irradiated. The late cardiac damage that may follow irradiation appears to result from a long-lasting injury of the capillary endothelial cells, which leads to cell death, capillary rupture, and microthrombi. Because of this damage to the microvasculature, ischemia results and is followed by myocardial fibrosis. In addition to microvascular damage, the major epicardial coronary arteries can become narrowed, especially at the ostia.

Occasionally a patient will develop acute cardiac complications after radiation therapy. This typically manifests as acute pericarditis. A mild, transient, asymptomatic depression of left ventricular function is sometimes seen early after radiation therapy. The more common clinical expressions of heart disease occur months or years after the exposure. The pericardium is the most common site of clinical involvement, with findings of chronic pericardial effusion or pericardial constriction (**see Chapter 83**). Myocardial damage occurs less frequently and is characterized by myocardial fibrosis with or without endocardial fibrosis or fibroelastosis. Left and/or right ventricular dysfunction at rest or with exercise appears to be a common, albeit usually asymptomatic, finding 5 to 20 years after radiation therapy. Often there is a latent period of a decade or more between the radiation exposure and the development of ventricular dysfunction or valvular deformity. ECG abnormalities, heart block, accelerated atherosclerosis, and a variety of arrhythmias may be seen months or years after therapeutic radiation, although the ultimate clinical significance is unclear.

Heat Stroke

Heat stroke results from failure of the thermoregulatory center following exposure to a high ambient temperature. It is manifested principally by hyperpyrexia, renal insufficiency, disseminated intravascular coagulation, and central nervous system dysfunction. However, ECG abnormalities appear to be common in heat stroke; pulmonary edema and transient right and/or left ventricular dysfunction may occur, along with hypotension and circulatory collapse. Pathologic changes include dilation of the right side of the heart, particularly the right atrium. Hemorrhages of the subendocardium and the subepicardium are frequently seen at necropsy and often involve the interventricular septum and posterior wall of the left ventricle. Histologic findings include degeneration and necrosis of muscle fibers, as well as interstitial edema. Sinus tachycardia is invariably present, whereas atrial and ventricular arrhythmias usually are absent. Transient prolongation of the QT interval may be seen, along with ST-segment and T wave

abnormalities. It can take up to several months for these repolarization abnormalities to resolve. Serum enzyme levels can be elevated and may reflect myocardial damage, at least in part, although concomitant rhabdomyolysis often is present.

Hypothermia

Low temperatures also can result in myocardial damage. Cardiac dilation can occur, with epicardial petechiae and subendocardial hemorrhages. Microinfarcts are found in the ventricular myocardium, presumably related to abnormalities in the microcirculation. The lesions are not caused by the low temperature per se but appear to be the result of the circulatory collapse, hemoconcentration, capillary slugging, and depressed cellular metabolism that accompany hypothermia. Clinical manifestations of hypothermia include sinus bradycardia, conduction disturbances, atrial (and occasionally ventricular) fibrillation, hypotension, a fall in cardiac output, reversible myocardial depression, and a characteristic deflection of the terminal portion of the QRS pattern (Osborn wave). Treatment includes core warming (often using extracorporeal blood warming), cardiopulmonary resuscitation, and management of pulmonary, hematologic, and renal complications. Notwithstanding its potential cardiac risks, mild therapeutic hypothermia appears to improve the neurologic outcome after cardiac arrest and is a currently accepted practice.

Drugs

Drug-induced hypersensitivity syndrome may involve the heart and be associated with myocarditis. The syndrome usually emerges within 8 weeks of the initiation of a new drug but can occur at any time after drug consumption. Common agents include antiepileptics, antimicrobials, allopurinol, and sulfa-based drugs. Dobutamine, often used for hemodynamic support in patients with failing hearts, may be associated with eosinophilic myocarditis, and the drug should be stopped when eosinophilia appears or when an unexpected decline in left ventricular function is noted. Presenting characteristics may include a rash (unless the patient is immunologically compromised), fever, and multiorgan dysfunction (including hepatitis, nephritis, and myocarditis). Diffuse myocardial involvement may result in systemic hypotension and thromboembolic events. CMR imaging and measurement of cardiac biomarkers may help identify patients with cardiac involvement. EMB may demonstrate eosinophils, histiocytes, lymphocytes, myocardial necrosis, and occasionally granuloma and vasculitis. Myocardial involvement is patchy, so a definitive diagnosis is made only when the biopsy findings are positive. Corticosteroids and drug withdrawal usually resolve this syndrome; however, some patients may display a prolonged and relapsing course.

Clozapine is an effective antipsychotic medication that is used to treat severe, refractory schizophrenia. Myocarditis is a rarely reported side effect of clozapine therapy, with the initial incidence reported at between 0.01% and 0.001%. More recent observations, however, have found an incidence of myocarditis in 1% to 10% of patients. Perhaps the increased incidence is related to an increased awareness of the risk. Myocarditis can develop at any time during treatment but occurs most frequently within the first 4 days to 22 weeks after initiation of clozapine. The peak incidence is at around 19 to 21 days. Clozapine-related myocarditis probably is the result of a hypersensitivity reaction. It may be accompanied by eosinophilia, with eosinophilic infiltration seen in myocardial biopsy material. Clozapine also is a potent anticholinergic compound, and high levels associated with altered metabolism from CYP450 enzymes also could contribute to the cardiac effects. With clear evidence of myocarditis in a patient taking this drug, immediate discontinuation is indicated.[29]

Vaccination for smallpox among uniformed service members has been demonstrated to be associated with myopericarditis. In a prospective assessment of myocarditis following smallpox vaccination, clinical myopericarditis and subclinical myocarditis were noted at an incidence of 463 and 2868 per 100,000 subjects, respectively (in a healthy cohort the incidence was 2.2 clinical myopericarditis patients per 100,000). There were no cases of clinical myopericarditis or subclinical myocarditis in a control group that received trivalent influenza vaccination.[30]

As new chemotherapeutic agents are developed to target specific pathways in the heart, it is becoming increasingly apparent that cancer chemotherapy can induce cardiomyopathy (**see also Chapter 81**).[31] Fulminant myocarditis has been described in two patients that were receiving combination immune checkpoint blockade using ipilimumab and nivolumab.[32] Future attention to the mechanisms by which chemotherapeutic agents induce cardiomyopathy may give additional insight into mechanisms of myocarditis.

Pathogenesis

Much of the current understanding of the pathogenesis of myocarditis is derived from mouse models of enteroviral infection, particularly coxsackievirus B3, and rodent models of autoimmune myocarditis.[33] The principles derived from these models have been applied to human myocarditis of different causes.[2] The description of the pathogenesis draws from cellular animal and human data. The pathogenesis of viral myocarditis can be divided into three major components: viral infection and replication, immunologic response (innate and adaptive immune response), and, ultimately, a phase of chronic cardiac remodeling (**Fig. 79.4**). MicroRNAs have also been shown to have a role in myocarditis (see online supplement for details on MicroRNAs in Myocarditis).

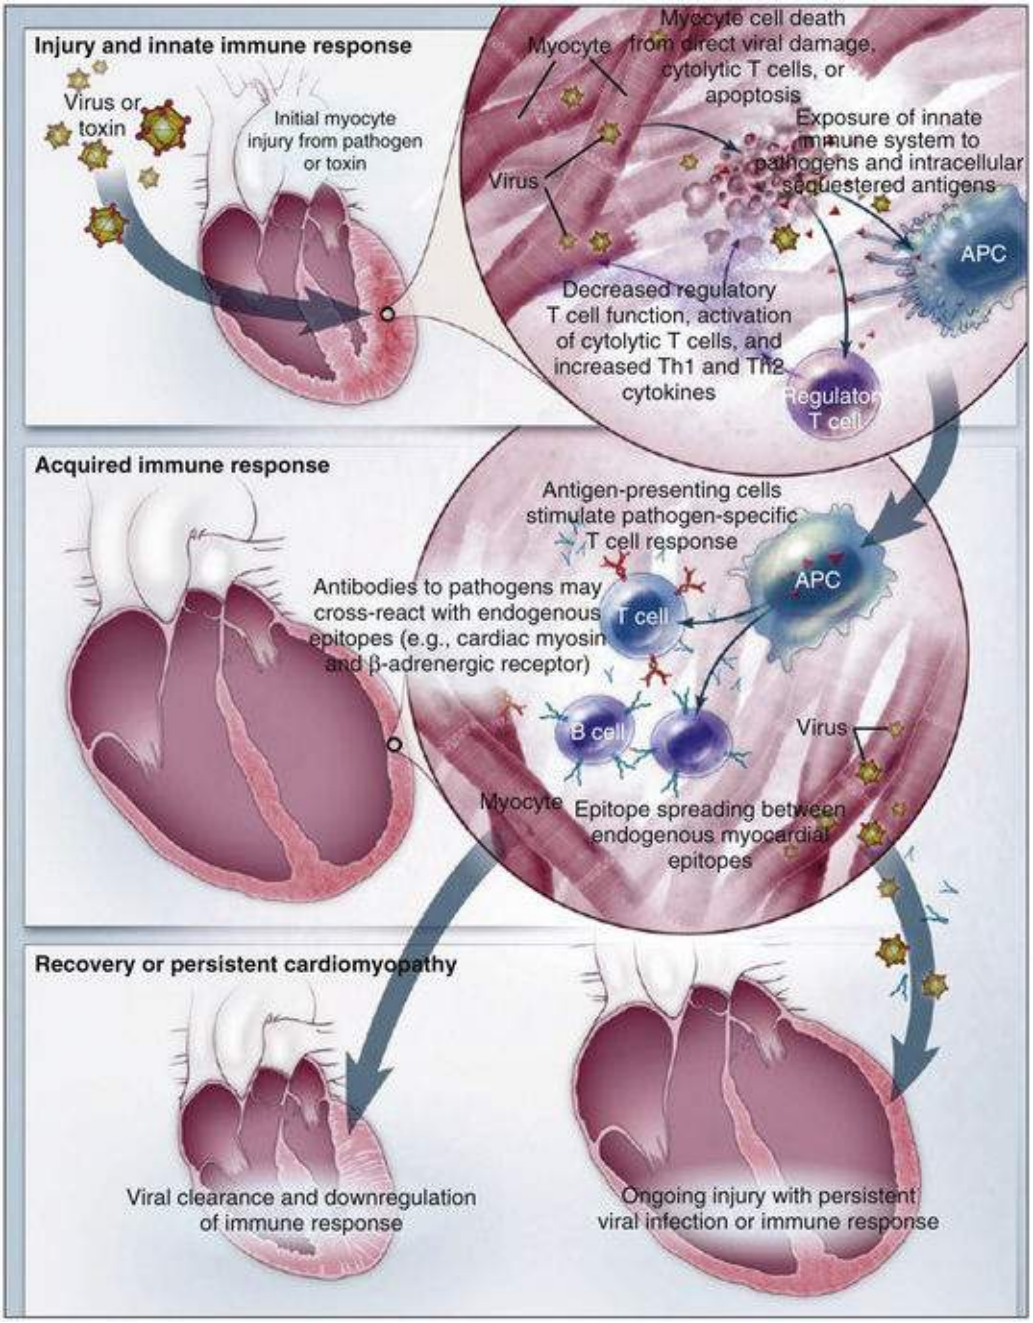

FIGURE 79.4 Pathogenesis of myocarditis. The current understanding of the cellular and molecular pathogenesis of postviral and autoimmune myocarditis is based solely on animal models. In these models, the progression from acute injury to chronic DCM may be simplified into a three-stage process. Acute injury leads to cardiac damage, exposure of intracellular antigens such as cardiac myosin, and activation of the innate immune system. Over weeks, specific immunity that is mediated by T lymphocytes and antibodies directed against pathogens and similar endogenous heart epitopes causes robust inflammation. In most patients, the pathogen is cleared and the immune reaction is down-regulated, with few sequelae. In other patients, however, the virus is not cleared, and it causes continued myocyte damage; heart-specific inflammation may persist because of mistaken recognition of endogenous heart antigens as pathogenic entities. *APC*, antigen-presenting cell. (Reprinted from Cooper LT: Myocarditis. N Engl J Med 2009;360:1526.)

Micro RNAs in Myocarditis

Microribonucleic acids (miRNAs) have been shown to have a role in myocarditis and in limiting viral replication.[1,2] miR-208b and miR-499 can be detected in the plasma of myocarditis patients. Interestingly, plasma miRNA levels reflect myocardial damage but not inflammation in acute viral myocarditis.[3] miR-21 and miR-146b have been shown to be involved in murine myocarditis through regulation of Th-17

differentiation. Inhibition of miR-21 and miR-146b decreased the severity of myocarditis.[4] miR-203 increases in murine myocarditis and increases cell viability, thus enhancing coxsackievirus B3 replication.[5] miR-141 can inhibit host protein synthesis by targeting the RNA cap binding protein eukaryotic initiation factor 4E.[6] miR-126 is up-regulated with coxsackievirus infection and activates the protein kinase C/transcription factor AP-1 pathway that is an important signaling molecule for coxsackievirus replication.[7] miR-10a* targets the three-dimensional RNA sequence of CVB3 and increases its synthesis.[8] miR-221 and miR-222 are significantly elevated in myocarditis, but act in a defensive manner by affecting proteins that are needed for efficient viral replication.[9]

Viral Infection

Viruses enter the host through a variety of locations, including the gastrointestinal system and respiratory system. The virus may undergo initial replication in the host in organs such as the liver, spleen, and pancreas. Ultimately, the virus reaches the heart via dissemination through the blood or lymphatic vessels. The steps include attachment of the virus to its receptor, entry of the virus into the cell, replication of the virus within the affected cell in the heart, and for lytic viruses, exit of the virus from the cell to allow infection of other cardiac cells. In the case of coxsackievirus, the virus infects the cardiac myocyte. In addition, however, viruses such as B19V may infect other cells in the heart; B19V has been demonstrated to infect the cardiac endothelial cell and is not found in the cardiac myocyte.[18]

Initially, the virus binds to a viral receptor, ultimately resulting in internalization of the virus (**Fig. 79.5**). This process includes entry of the viral capsid proteins and the viral genome. In the case of coxsackieviruses and adenoviruses, the receptor is a transmembrane molecule, CAR, named for these two viruses, which are known to use it as a receptor.[34] Genetic deletion of CAR in the cardiac myocyte

markedly inhibits infection of the heart and development of myocarditis.[35] In addition to CAR, coxsackievirus infection can be facilitated by interaction with the decay-accelerating factor (DAF), or CD55. CAR acts as a receptor in both human and mouse cells. CAR is a tight junction protein in noncardiac cells and is expressed at high levels in the intercalated disc of myocardial cells. Entry of the virus through the receptor activates a signaling complex that includes $p56^{lck}$, Abl, and Fyn kinase.[34]

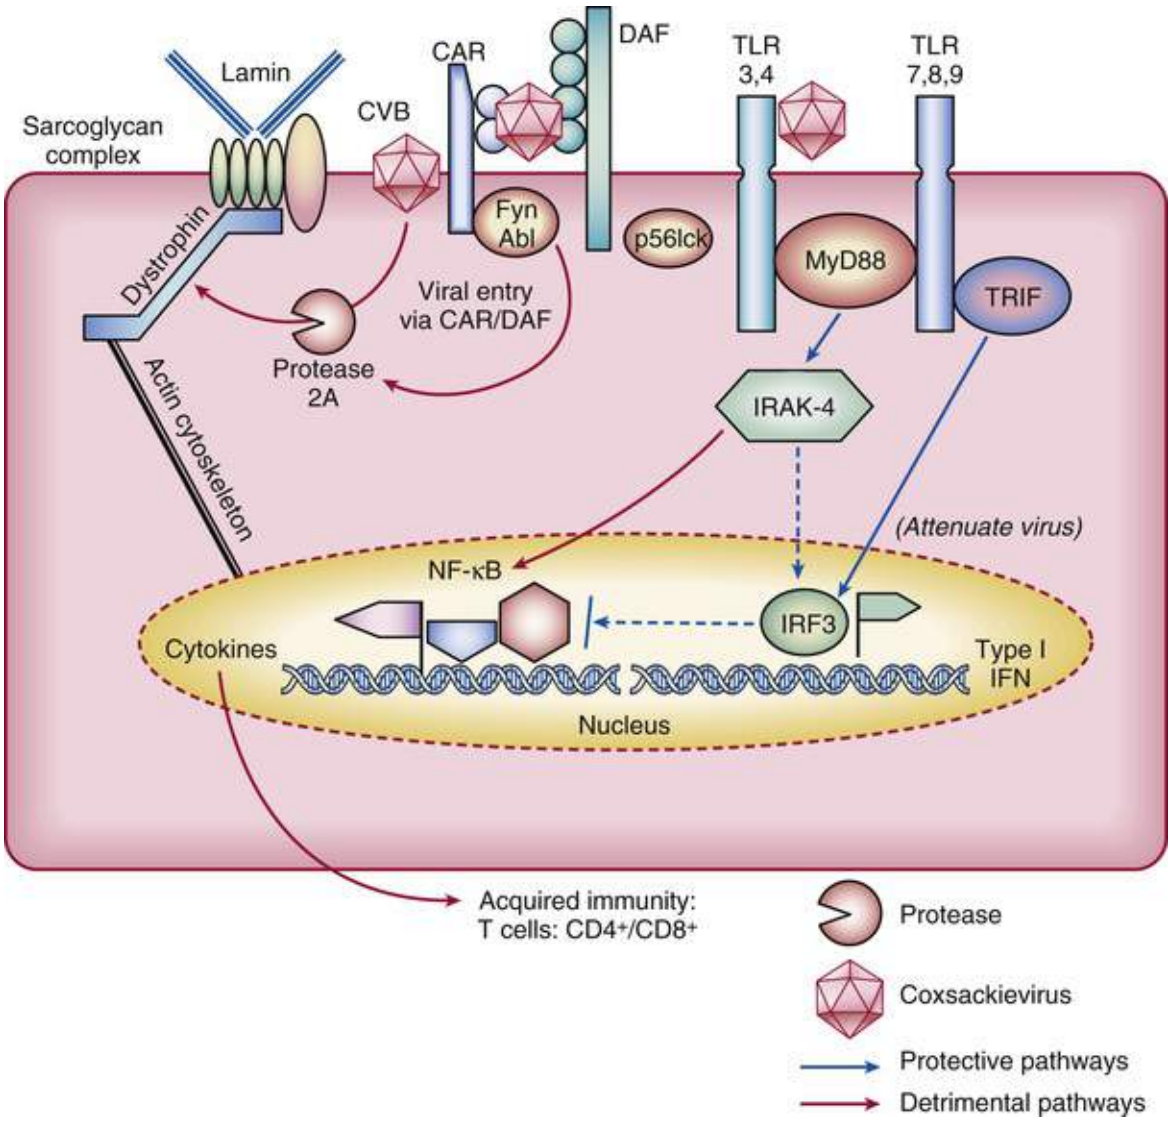

FIGURE 79.5 The pathogenesis of viral myocarditis, such as that caused by coxsackievirus. The virus enters the cell membrane through internalization receptors of the coxsackievirus-adenovirus receptor (CAR), which in turn can trigger receptor-associated kinases such as p56lck, Fyn, and Abl to alter host myocyte cytoskeleton to facilitate viral entry. Viruses such as coxsackievirus B (CVB) can directly produce enzymes such as protease 2A that can disassemble the important cytoskeletal components such as dystrophin-sarcoglycan complex, leading to myocyte remodeling and destruction. Engagement of the receptor also activates tyrosine kinases, which are important for T-cell clonal expansion and linking between the innate and acquired immune systems. The virus also activates innate immunity by engaging Toll-like receptors (TLRs) through adaptors such as MyD88 and TRIF (Toll/interleukin-1 [IL-1] receptor domain–containing adaptor-inducing interferon-β). Activation and translocation of NF-κB, on the one hand, will produce cytokines and trigger acquired immunity such as $CD4^+/CD8^+$ T-cell mobilization. On the other hand, this can be attenuated by the activation of IRF3 and type I interferon (IFN) production. The latter may be protective through multiple mechanisms, including attenuation of the virus. *DAF*, decay-accelerating factor (CVB coreceptor); *IRAK*, interleukin receptor–associated kinase (a signaling protein in innate immune pathway); *IRF*, interferon regulatory factor.

On entry of the enterovirus into the cell, the positive, single-strand RNA is released from the

icosahedral capsid and translated using host translational mechanisms. The viral RNA is translated as a single, monocistronic polyprotein, which is cleaved into its separate peptides by the viral proteases 2A and 3C; through an autocatalytic cleavage process, VP0 is cleaved into VP2 and VP4. This results in generation of capsid and nonstructural proteins, including an RNA-dependent RNA polymerase that is required for replication of the viral genome. The other nonstructural proteins also are required for replication of the positive-strand RNA through a negative-strand intermediate. Once the numbers of viral capsid proteins have been amplified and the positive-strand RNA has replicated, the positive-strand RNA is encapsidated into the newly formed viral capsid proteins VP1, VP2, VP3, and VP4. The encapsidated coxsackievirus RNA is released from the myocardial cell through a process of cell lysis and disruption of the sarcolemmal membrane.

Several mechanisms are recognized to affect membrane integrity, thus affecting in turn release of the replicated virus. Muscle cells rely on the subsarcolemmal protein dystrophin and the associated proteins in the dystrophin-glycoprotein complex to maintain the integrity of the sarcolemmal membrane. Hereditary absence of dystrophin in Duchenne muscular dystrophy, for example, causes cardiac and skeletal muscle dysfunction. In enterovirus-induced murine myocarditis, it has been demonstrated that one of the nonstructural proteins, protease 2A, is able to directly cleave dystrophin, thus disrupting the dystrophin-glycoprotein complex. This decreases the sarcolemmal membrane integrity and facilitates the release of the virus from the myocardial cell. When dystrophin is not present in the mouse heart, as occurs in Duchenne muscular dystrophy, coxsackievirus is released more efficiently from the myocyte to infect adjacent cells.[36] However, when a dystrophin protein is expressed that cannot be cleaved by protease 2A, viral replication and the extent of myocardial damage is decreased.[37] Proteases 2A and 3C can cleave other host proteins that are involved in the maintenance of membrane integrity, initiation of translation of host proteins, regulation of apoptosis, innate immune response, and serum response fator.[38] Other lytic viruses use similar mechanisms. For example, adenovirus expresses a proteinase that cleaves the cytoskeletal protein cytokeratin 18.

Generally, the activation of the innate and adaptive, antigen-specific immune response eliminates or greatly reduces the replication of the virus within the host cell. In some instances, however, the virus can persist within the myocardium. In keeping with the presence of the enteroviral genome in a subset of patients with DCM, it is thought that persistence of the enteroviral genome could contribute to the ongoing remodeling that occurs with DCM. The feasibility of this concept has been shown in a mouse model, in which low-level, cardiac-specific expression of a replication-defective enteroviral genome can cause cardiomyopathy. However, the proportion of patients in whom the enteroviral genome can be identified with reverse transcriptase PCR (rtPCR) or in situ hybridization techniques generally is less than 10%. The early phases of enteroviral infection and intramyocardial innate immunity can now be studied in human induced pluripotent stem cells that are differentiated to cardiac myocytes.

Other types of viruses also have been detected in cardiac biopsy specimens from patients with DCM. These viruses include B19V, herpesvirus, cytomegalovirus, hepatitis C virus, and others.[15] Distinguishing whether the presence of a viral genome in each patient is causative or an incidental finding in cardiomyopathy has not been trivial. For example, the B19V viral genome can be detected in a high percentage of patients independent of whether they have cardiomyopathy. It has been demonstrated that only 15.9% of patients that have evidence of B19V DNA on EMB have evidence of B19V mRNA. Interestingly, there is a significant difference in expression profiling in the biopsies that show transcriptionally active B19V, suggesting that transcriptional activity of the B19V may have a role in the pathogenesis.[18]

Innate Immunity

Innate immunity is effective during the earliest stages of virus infection. It is an antigen-independent defense mechanism that protects the host from a broad range of microbial pathogens. Innate immunity is initiated in the first days of enteroviral infection and is the major immune mechanism responsible for inhibiting viral infection and replication during the first 4 to 5 days after infection. In addition to innate immune mechanisms in noncardiac organs, important innate immune responses also are activated in the cardiac myocyte.[36] One of the classic and best-characterized examples of innate immunity is the activation of interferon signaling that occurs with viral infection. The two broad classes of interferons use different receptors: Type I interferons bind to the IFN-α receptor and include interferon-α and interferon-β, whereas IFN-γ is the sole type II interferon member. Both types of interferons are effective at limiting viral replication when added to infected cells or when administered to a coxsackievirus-infected mouse.[36] The absence of type I interferon receptors or interferon-β in mice is associated with a marked increase in mortality rates but has less effect on early viral replication in the heart. In a phase II clinical trial, it has been demonstrated that administration of interferon-β to virus-positive patients with symptoms of heart failure caused significant clearance or reduction of the virus load and improvement in the New York Heart Association (NYHA) functional class and quality of life. In enterovirus-positive patients, interferon-β may improve survival rates.[39] Additional content on this this topic is discussed in an online supplement for this chapter titled The Role of Innate Immunity in Myocarditis.

The Role of Innate Immunity in Myocarditis

Toll-Like Receptors

Toll-like receptor (TLR) activation is among the most common and earliest innate immune mechanisms. Multiple TLRs (TLR2, TLR3, TLR4, TLR7, and TLR9) have been implicated in inflammatory heart disease and myocarditis.[1] The receptors recognize pathogen-associated molecular patterns activating a defense against the invading pathogens. TLRs do not have the high specificity conferred by the antigen-specific B and T cells and thus react more quickly. Stimulation of the TLRs by foreign ribonucleic acids, DNA, or proteins leads to activation of signaling and transcriptional mechanisms, which result in increases in cytokines and interferon regulatory factors that increase expression of interferons and other antiviral signaling pathways. TLR signaling uses adaptor molecules and kinases such as MyD88 and interleukin receptor–associated kinases (IRAKs). Both TLR3 and TLR4 are abundant in the myocardium. TLR3 recognizes double-stranded RNA, whereas TLR7 and TLR8 can be activated by single-stranded RNA. Both single- and double-stranded RNA are generated as part of the coxsackievirus replication cycle. TLR4 recognizes bacterial lipopolysaccharides. Disruption of TLR3 was shown to augment encephalomyocarditis virus–induced heart disease in the mouse. A similar effect is observed with CVB3 infection. Also, TLR4 disruption increases the pathogenesis of coxsackievirus B3–induced myocarditis.

The downstream molecules of TLR signaling have been shown to have a significant effect on coxsackievirus B3 infection. One of the better-studied of these molecules is MyD88, which binds to TLR4, and the endosomal molecules TLR7 to TLR9. When mice with a global knockout of MyD88 are infected, a marked reduction is seen in the susceptibility to viral infection, indicating that the absence of MyD88 confers host protection, potentially through direct activation of IRF-3 and interferon-β. The absence of MyD88 also controls the induction of α-myosin heavy chain–stimulated autoimmune myocarditis through defective induction of dendritic cell–mediated TNF-α.[2]

Other Innate Immune Mechanisms

Other innate immune responses are important in the control of the initial phases of viral infection. For example, inhibition of glycoprotein 130 (gp130) signaling by transgenic expression of the suppressor of cytokine signaling (SOCS)-1 or -3 results in a marked increase in the susceptibility to viral infection in the mouse. In addition, the relevance of RNA helicases in the activation of innate immunity against viral infection has been demonstrated. dsRNA can be recognized by the RNA helicases, retinoic acid–induced protein (RIG-I), and melanoma differentiation–associated gene 5 (MDA-5). These RNA helicases can interact with mitochondrial antiviral signaling (MAVS), activating signaling cascades that ultimately increase type I interferons.[3,4] The importance of MAVS after infection with RNA viruses was confirmed in MAVS-knockout mice.[3,4]

Activation of inflammasomes has been demonstrated to occur in patients with acute viral myocarditis within the first 4 weeks of the onset of the disease. The inflammasome is a macromolecular complex that is activated during myocardial injury. It stimulates processing of IL-1β and IL-18, which are important in the innate immune response against viral infection. It is thought that inflammasome activation can limit viral replication, though it could also damage the cell. Evasion of the inflammasome process might decrease myocardial cell damage, but might also contribute to viral persistence.[5,6]

Macrophages have been shown to have an important role in the early innate immune response. They act as scavengers, microbicidal effector cells, and regulatory cells in the onset of cardiac inflammation. Early recruitment of inflammatory macrophages ($Ly6C^{hi}$) occurs following cardiac injury. Chemokine (C-C motif) receptor 2 (CCR2) has been implicated in having a role in macrophage infiltration in the heart of CVB3 infected mice. Although macrophages are involved in the early response to injury, they are also responsive to T cells. CD4+ T (type 1 T helper [Th1]) cells influence the differentiation of monocytes toward proinflammatory M1 macrophages. The interferon-γ secreted by Th1 cells potentiates microbicidal activity of macrophages. $Ly6C^{low}$ M2 macrophages blunt the inflammatory response and predominate during myocardial healing.[7]

Acquired Immunity

Acquired immunity becomes a prominent manifestation of viral myocarditis beginning approximately 4 to 5 days after the viral infection, although the peak and pattern of activation are variable. The acquired immune response is an antigen-specific response that is directed to a single antigen and is mediated by T and B cells. T cells are targeted to infected cells and attempt to limit infection by destroying the host cell through secretion of cytokines or perforins. These can contribute to the death of the infected cell through necrotic and/or apoptotic mechanisms. Thus, although T cell–mediated immune mechanisms are important for controlling and limiting viral replication, they also can have detrimental effects on the infected organ by stimulating cell death mechanisms in the infected host. Appropriately limiting the T-cell and B-cell immune mechanisms could limit damage to the heart, but such inhibition needs to be balanced by the need to inhibit viral replication.[40]

The acquired immune process is initiated when the variable region of the T-cell receptor binds to peptides with specific amino acid sequences that are recognized as foreign to the host. When $CD4^+$ T cells interact with antigen-presenting cells such as dendritic cells, the $CD4^+$ cells can differentiate into different effector cell subsets, such as the classic Th1 and Th2 cell subtypes: Th17 and T regulatory (Treg) cells. Cytokines in the cellular microenvironment can control how the cells differentiate. The precise cellular signaling cascades and pattern of cytokine production that are associated with differentiation of these distinct T-cell subtypes has been reviewed elsewhere.[40,41] Appropriate regulation of effector T cells is needed to control infections and at the same time avoid inappropriate immunologic destruction of host tissue such as myocardial cells. Activation of T cells also leads to B-cell activation, which results in secretion of antigen-specific antibodies directed against the invading pathogen. After initial activation, the immune cells undergo clonal expansion to attack the source of antigen, which could include a viral coat protein or, in some cases, proteins in the cardiac myocyte such as myosin. There is evidence that cross reaction with the host may occur because of “molecular mimicry” between the virus and the host. Treg cells have important functions for the suppression of Th1-cell and Th2-cell immune responses and were previously identified as T helper cells. They are characterized by the expression of the forkhead transcription factor, Foxp3, and are defined as $CD4^+CD25^+Foxp3^+$. The classic model held that commitment of $CD4^+$ cells to the different effector lineages involved stable programs of gene expression and that once differentiated, they maintained that effector phenotype even as changes in the microenvironment occurred. This model, however, has evolved, because of evidence that $CD4^+$ T cells have an element of plasticity in that they can alter their functional programs and in this way change the balance between Treg cells and cytokine-producing T cells and the type of cytokines that they produce.[40] This plasticity may be important as new therapeutic strategies are developed. The activation of T cells is highly dependent on an interaction with the innate immune-signaling cascade. For example, the T cell receptor downstream signaling uses p56lck. It is interesting that p56lck also has been shown to bind to the CAR-DAF receptor complex and that it is involved in viral entry. When p56lck is genetically deleted from the mouse, typical myocarditis is almost eliminated, with no significant mortality rates after infection.[42]

Alterations in any of the pathogenic mechanisms just described could, theoretically, affect the susceptibility to viral infection. For example, alterations in the mechanism of viral entry and replication, innate or acquired immune-signaling mechanisms, or the integrity of the sarcolemmal membrane could affect the susceptibility to develop myocarditis on exposure to a given virus. Nutrition is also likely to have an effect on the susceptibility to viral infection. It is thought that a deficiency of selenium can increase the risk of myocarditis, as has been described in the Keshan province in China. When selenium deficiency was prevented, the incidence of myocarditis and DCM decreased. Furthermore, selenium deficiency in mice also increased the susceptibility to enteroviral myocarditis. The number of

mechanisms known to affect the susceptibility to myocarditis in humans is far from complete.

Cardiac Remodeling

Remodeling of the heart after cardiac injury (**see also Chapter 23**) can significantly affect cardiac structure and function, and the degree of such remodeling may mean the difference between appropriate healing and the development of DCM. The virus can directly enter the endothelial cells and myocytes and effect changes that lead to direct cell death or hypertrophy. The virus also can modify the myocyte cytoskeleton, as mentioned earlier, leading to DCM. The inflammatory process outlined earlier for both innate and acquired immunity can lead to cytokine release and activation of matrix metalloproteinases that digest the interstitial collagen and elastin framework of the heart (**see Chapter 23**).

Clinical Syndromes

Myocarditis has a wide-ranging array of potential clinical presentations, a feature that contributes to the difficulties in diagnosis and classification. The clinical picture may be one of asymptomatic electrocardiographic or echocardiographic abnormalities or may include signs and symptoms of chest pain, cardiac dysfunction, arrhythmias or heart failure, and/or hemodynamic collapse. Transient electrocardiographic or echocardiographic abnormalities have been observed frequently during community viral outbreaks or influenza epidemics, but most patients remain asymptomatic from a cardiac standpoint and have few long-term sequelae. Chest pain from myocarditis may resemble typical angina and be accompanied by ECG changes, including ST-segment elevation. Coronary vasospasm, demonstrated using intracoronary acetylcholine infusion, is one cause for chest pain in patients with clinical signs of myocarditis in the absence of significant coronary atherosclerosis.[43] Chest pain also may mimic that in pericarditis, suggesting epicardial inflammation with adjacent pericardial involvement. The outcome of myopericarditis generally is good, with only two sudden deaths reported from four published case series (N = 128) (**Table 79.4**). Additional content on clinical syndromes is presented in an online supplement for this chapter entitled Specific Clinical Presentations of Myocarditis.

TABLE 79.4

Outcome of Myopericarditis and Perimyocarditis in Recent Clinical Series

STUDY	SETTING	TROPONIN (PEAK)	FOLLOW-UP	MORTALITY RATES
Imazio et al, 2008	Myopericarditis/adult (40 patients)	TnI: 7.7 ± 6.7 μg/L (1.5-22.5)	12 months	0%; normalization of parameters in 97.5%
Machado et al, 2010	Myopericarditis/adult (14 patients)	TnI: 7.3 μg/L (4.4-10.2)	20 months	21.4%
Kobayashi et al, 2012	Myopericarditis/pediatric (12 patients)	TnI: 4.75 μg/L (1.35-9.72)	2 months (2 weeks to 3 years)	0%; normal LVEF and function
Buiatti et al, 2012	Perimyocarditis/adult (62 patients)	TnI: 10.5 ± 17.0 μg/L	4.5 ± 0.8 years	0%; normalization of echo features in 100%

Myocarditis typically has a bimodal distribution in terms of age in the population, with the acute or fulminant presentation more commonly seen in young children and teenagers. By contrast, the presenting symptoms are more subtle and insidious, often with DCM and heart failure, in the older adult population. The difference in presentation probably is related to the maturity of the immune system, whereby the young tend to mount an exuberant response to the initial exposure of a provocative antigen. By contrast, older persons would have developed a greater degree of tolerance and show a chronic inflammatory

response only to the chronic presence of a foreign antigen or with a dysregulated immune system that predisposes to autoimmunity. Myocarditis probably is responsible for 10% to 50% of new-onset cases of idiopathic DCM, a rate that varies depending on the criteria used for diagnosis. Viral myocarditis has been associated with heart failure from both systolic and isolated diastolic dysfunction.[44]

The presentation of myocarditis varies by cause. For example, B19V frequently causes chest pain from endothelial dysfunction, whereas ventricular arrhythmias and heart block are more common in giant cell myocarditis (GCM).[44] Associated physical examination findings point to specific causes for myocarditis. Enlarged lymph nodes with hilar adenopathy on the chest radiograph may suggest systemic sarcoidosis. A pruritic, maculopapular rash with an elevated eosinophil count suggests a hypersensitivity reaction to a drug or toxin. Patients who present with DCM complicated by sustained or symptomatic ventricular tachycardia or high-grade heart block are at high risk for having GCM or cardiac sarcoidosis. A study of 72 young Finnish patients with initially unexplained atrioventricular block revealed that 25% had either cardiac sarcoidosis (19%) or GCM (6%). Of these 18 patients, 7 (39%) experienced sustained ventricular tachycardia or cardiac death or required transplantation over an average follow-up period of 48 months (**Fig. 79.6**).[45] A prospective study of 12 patients with biopsy-proven GCM revealed that 25% of patients with a cardiomyopathy of less than 6 months' duration that failed to respond to usual care or was complicated by ventricular tachycardia or high-grade heart block had GCM.[46] In patients who fail to recover from an acute episode of myocarditis, the persistence of left ventricular dysfunction can sometimes be due to ongoing immune activation or chronic myocarditis.[1] Failure to clear virus from the heart has been postulated to underlie some cases of persistent heart failure. Recognition of endogenous proteins, such as cardiac myosin, as “foreign” may contribute to ongoing inflammation even after successful viral clearance.[47,48] In clinical practice, the distinction between a noninflammatory DCM and a chronic inflammatory DCM with or without viral infection requires EMB. As discussed further on, the lack of positive large-scale trial data supporting either immunosuppression or antiviral therapy currently limits the application of EMB in this setting.

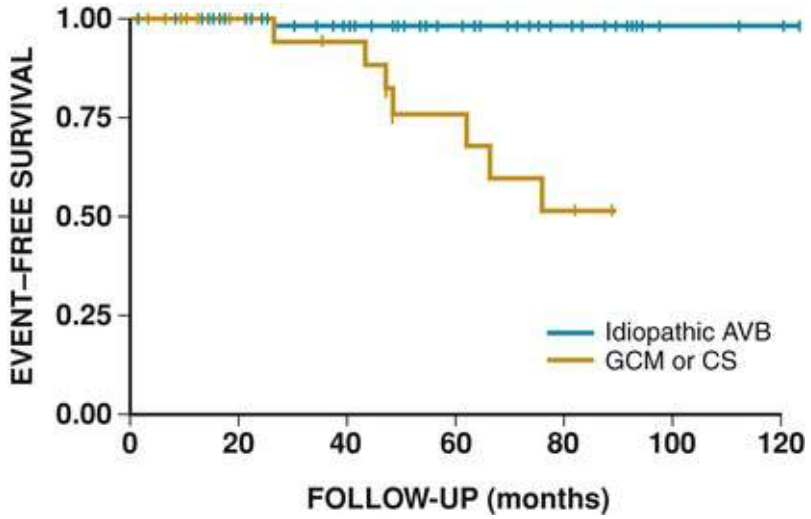

FIGURE 79.6 Kaplan-Meier curves for survival free of major adverse cardiac events (cardiac death, cardiac transplantation, ventricular fibrillation, or treated sustained ventricular tachycardia) in patients with pacemaker implantation for atrioventricular block that remained idiopathic or atrioventricular block due to cardiac sarcoidosis (CS) or GCM. (From Kandolin R, Lehtonen J, Kupari M: Cardiac sarcoidosis and giant cell myocarditis as causes of atrioventricular block in young and middle-aged adults. Circ Arrhythm Electrophysiol 2011;4:303.)

Specific Clinical Presentations of Myocarditis

Acute Myocarditis

Classically, patients with myocarditis present with nonspecific symptoms related to the heart. In a recent series of 245 patients with clinically suspected myocarditis, the most common symptoms included fatigue (82%), dyspnea on exertion (81%), arrhythmias (55%, both supraventricular and ventricular), palpitations (49%), and chest pain at rest (26%).[1] These can be difficult to distinguish from acute ischemic syndromes because they result in release of troponin, ST-segment elevation on electrocardiography, and segmental wall motion abnormalities on echocardiography. Therefore, the symptoms can be quite nonspecific, although some symptoms indicate cardiac involvement. The viral prodrome of fever, chills, myalgias, and constitutional symptoms occurs in 20% to 80% of the cases and can be readily missed by the patient; thus, they cannot be relied on for a diagnosis.

Many cases of myocarditis present with de novo onset of heart failure, particularly when the patient is middle aged or older. When the health care team fails to identify other causes of heart failure, viral myocarditis, along with idiopathic dilated cardiomyopathy (DCM), becomes the diagnosis of exclusion. To distinguish myocarditis from idiopathic DCM, almost one third of the cases of viral myocarditis will recover to normal cardiac function with appropriate supportive therapy, which is less frequent in genetic DCM.

Fulminant Myocarditis

Approximately 10% of patients with biopsy-proven myocarditis display fulminant myocarditis. This entity is characterized by an abrupt onset, usually within 2 weeks of a viral illness. Patients have hemodynamic compromise and hypotension, often requiring pressors or mechanical support. The echocardiogram reveals diffuse global hypofunction, rarely, cardiac dilation, and typically, thickening of the ventricular wall, probably due to myocardial edema from myocardial inflammation and cytokine release. Endomyocardial biopsy (EMB) reveals typical and diffuse myocarditis in virtually each histologic section, making it a reliable source of confirmation. On follow-up, 93% of the original cohort were alive and transplant free 11 years after the initial biopsy, compared with only 45% of those with chronic myocarditis.[2] This underscores the importance of supporting patients with fulminant myocarditis as aggressively as needed to maximize the time for recovery.

Giant Cell Myocarditis

Another distinctive clinicopathologic form of myocarditis is giant cell myocarditis (GCM). This disorder is more subtle in onset than fulminant myocarditis and may not be distinguishable from other forms of myocarditis initially. Patients may present with heart failure, arrhythmia, or heart block, which despite standard medical therapy fails to improve. The survival time for this population is less than 6 months; it is improved with the use of immunosuppressive therapy.[3] Preliminary data suggest that high-dose multiagent immunosuppression may improve the prognosis; however, there are no prospective randomized trials to confirm this approach. Early discontinuation of immunosuppression may lead to recurrence. EMB reveals a distinctive pattern of giant cells with active inflammation and scar tissue. Currently, cardiac transplantation, often preceded by mechanical circulatory support, remains the only alternative for most patients with this disorder. Early recognition and immunosuppressive therapy may alter this approach.

Patients with GCM often have other autoimmune disorders, including thymoma and Crohn disease. The pathophysiologic mechanism remains unknown but is suspected to be autoimmune in nature.

Chronic Active Myocarditis

Patients in this group are mostly older adults with myocarditis, and the onset is often insidious and difficult to pinpoint. The patient presents with symptoms compatible with moderate ventricular dysfunction, such as fatigue and dyspnea. Pathologic examination of a myocardial biopsy specimen may show active myocarditis, but more frequently it is only borderline or generalized chronic myopathic changes with fibrosis and myocyte dropout. Some may progress to diastolic dysfunction with predominantly fibrosis; this condition ultimately resembles a restrictive cardiomyopathy.

This category encompasses 60% to 70% of patients with active or borderline myocarditis who present with DCM of unknown cause. Use of newer imaging approaches, such as magnetic resonance imaging with gadolinium enhancement and positron emission tomography–computed tomography (PET-CT), molecular diagnosis by immunohistopathologic analysis, assessment of up-regulation of immune markers, and molecular testing, including PCR and in situ hybridization, may expand this population significantly.

Eosinophilic Myocarditis

The eosinophil may be associated with myocardial inflammation in three distinct forms. *Allergic eosinophilic myocarditis* is caused by a hypersensitivity reaction to a foreign antigen, almost always a drug. This form of myocarditis requires a high degree of suspicion (related to the initiation of new agents) and subtle declines in left ventricular function. Withdrawal of the offending agent and administration of corticosteroids usually result in resolution. The heart may be inflamed in association with systemic eosinophilic disorders, resulting in myocardial, endocardial, and valvular involvement (*Löffler endocarditis*). The outcome is dependent on control of the underlying condition. Finally, *fulminant necrotic myocarditis* presents in a fashion similar to fulminant myocarditis, has no clear cause, and requires aggressive medical immunosuppression and occasional mechanical support.

Peripartum Cardiomyopathy

Peripartum cardiomyopathy is characterized by the onset of left ventricular dysfunction in the last month of pregnancy or within 5 months of delivery, with no preexisting cardiac dysfunction and no recognized cause of the cardiomyopathy. There is evidence that patients submitted to EMB early after presentation have a high frequency of myocarditis.[4] Because most patients with this disorder recover with standard therapy, biopsy is recommended only for those with persistent left ventricular dysfunction and symptoms despite heart failure management.

Diagnostic Approaches

The diagnosis of myocarditis traditionally has required a histologic diagnosis according to the classic Dallas criteria. However, because of low sensitivity due to the patchy nature of the inflammatory infiltrates in the myocardium and the reluctance of clinicians to perform an invasive diagnostic procedure, myocarditis is severely underdiagnosed. Because the incidence of the disease is likely to be much higher than is appreciated, a high level of clinical suspicion, together with hybrid clinical and laboratory criteria and new imaging modalities, may help secure the diagnosis without necessarily resorting to biopsy in all cases (**see Table 79.2**).[2] Although clinical and imaging criteria have been used to estimate the myocarditis prevalence in various cohorts without EMB confirmation, such criteria probably sacrifice diagnostic specificity.

Laboratory Testing

The role of cardiac injury biomarkers in screening for myocarditis in patients with acute viral illness has been investigated in accordance with the hypothesis that a diagnosis of heart damage in this setting may indicate a greater risk of arrhythmias or cardiomyopathy. In this regard, elevated cardiac troponin values help to confirm cases of suspected myocarditis. Whereas older studies suggested that the sensitivity of troponins for myocarditis was low, more recent studies using more sensitive assays in less chronic disease support the value of troponin. For example, troponin levels predicted the severity of myocarditis and short-term prognosis in a case series of 65 children with recent-onset myocarditis. Fulminant myocarditis was associated with higher levels of cardiac troponins I and T (cTnI and cTnT) than acute myocarditis, and a higher cardiac troponin level was associated with a lower left ventricular ejection fraction.[49] In a case series of adults hospitalized with acute or fulminant myocarditis, creatine kinase–MB concentrations of greater than 29.5 ng/mL predicted in-hospital death with a sensitivity of 83% and a specificity of 73%. A growing literature also supports a role for TnI as an autoantigen as well as a biomarker for diagnosis.[50]

During the influenza A epidemic (H3N2) in Japan from 1998 to 1999, the myosin light-chain concentration was raised in 11.4% of patients without cardiac symptoms.[51] Recently, Renko and associates prospectively measured cTnI levels in 1009 children to determine the incidence of myocarditis in children hospitalized for an acute infection. TnI levels exceeded the screening limit (0.06 µg/L) in only six children, none of whom had electrocardiographic or echocardiographic abnormalities. Thus the incidence of acute myocarditis during childhood viral infections appears to be low, so routine TnI screening for asymptomatic myocarditis in unselected children without cardiac symptoms probably is not indicated.[52] The rate of asymptomatic increases in troponin after smallpox vaccination is as high as 28.7 per 1000.[30] The risk of acute cardiomyopathy appears low in the first year after smallpox vaccination, but the longer-term significance of a troponin rise in this setting is not known.[53]

A variety of other biomarkers have demonstrated prognostic value in acute myocarditis. In children with fulminant myocarditis, higher serum creatinine, lactate, and aspartate transaminase (AST) levels are associated with increased in-hospital mortality rates.[54] N-terminal pro–B type (brain) natriuretic peptide (NT-pro-BNP) is predictably elevated in children with acute DCM due to myocarditis and generally

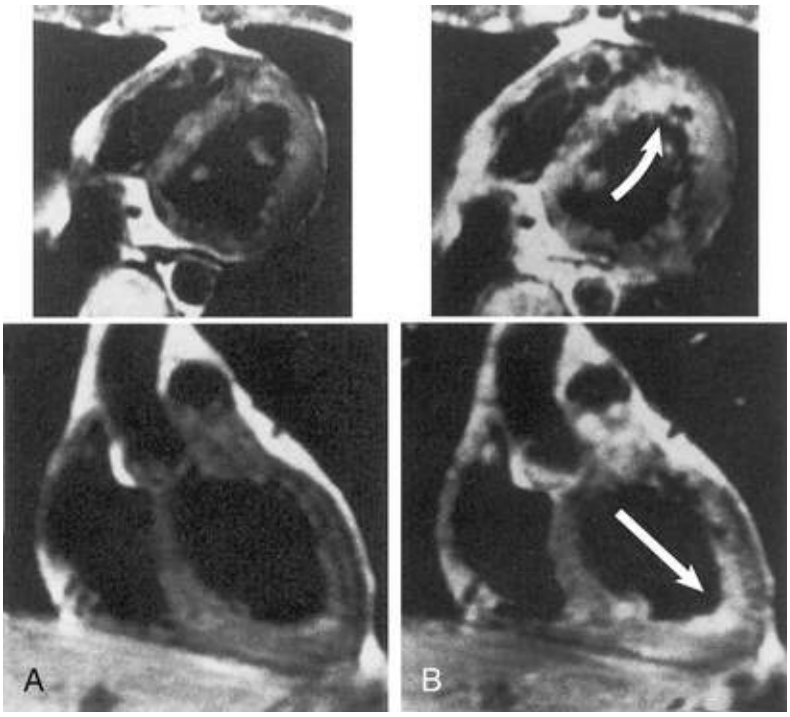
declines rapidly in children who recover left ventricular function.[55] In adults, higher interleukin-10 and soluble Fas concentrations are associated with an increased risk of death. Anti–heart antibodies have been reported to predict an increased risk of death or need for transplantation.[56] However, few anti–heart antibody tests are standardized or available in clinical laboratories. Nonspecific biomarkers of inflammation, such as the leukocyte count, C-reactive protein, erythrocyte sedimentation rate, and leukocyte count have low specificity. Circulating viral antibody titers do not correlate with tissue viral genomes and are rarely of diagnostic use in clinical practice.[57]

Pathognomonic ECG findings are lacking in acute myocarditis, but nonspecific repolarization changes and sinus tachycardia are common (**see also Chapter 12**). PR-segment depression and diffuse ST-segment elevation may accompany a clinical presentation of myopericarditis.[58] The presence of a QRS width greater than 120 milliseconds in duration and Q waves is associated with a great risk of cardiac death or need for heart transplantation.[59]

Cardiac Imaging

An assessment of left ventricular function is essential in all cases of suspected myocarditis, accomplished by means of cardiac imaging (**see also Chapters 14 to 17**). Echocardiography is an excellent choice for imaging, although there are no specific echocardiographic features of myocarditis. In patients who have an acute cardiomyopathy, the most common pattern is a dilated, spherical ventricle with reduced systolic function. Patients with heart failure due to fulminant myocarditis typically present with small cardiac chambers and mild and reversible ventricular hypertrophy from inflammation. Right ventricular dysfunction is less common and heralds a poor prognosis. Of interest, segmental wall motion abnormalities often are present early and may mimic the regional changes seen in a myocardial infarction. A pericardial effusion usually signifies myopericarditis.

CMR can distinguish most cases of ischemic from nonischemic cardiomyopathy, and certain patterns of signal abnormality strongly suggest acute myocarditis (**eFig. 79.2**).[60] Furthermore, the T1-weighted, myocardial delayed enhancement technique can quantitate regions of damage and possibly predict the risk of cardiovascular death and ventricular arrhythmias after myocarditis.[61] Abnormalities on delayed enhancement imaging also correlate with myocarditis in patients who present with chest pain and normal coronary arteries. However, the T2-weighted, short tau inversion recovery (STIR) and T1-weighted delayed postcontrast signal abnormalities seen in acute myocarditis usually decrease with time. In a recent study the sensitivity and specificity of CMR in suspected myocarditis more than 14 days after symptom onset were poor (sensitivity, 63%; specificity, 40%).[62] Thus, CMR performs best in the setting of acute cardiomyopathy or chest pain with elevated troponin. Both T1- and T2-weighted sequences should be used, to optimize the sensitivity and specificity.[63] T2 mapping has been used recently to decrease artifacts that are common with T2-weighted sequences.



EFIGURE 79.2 **A,** Precontrast T1-weighted transaxial (*upper*) and coronal (*lower*) magnetic resonance images through the left ventricle in a patient with myocarditis. **B,** Postcontrast magnetic resonance images at the same levels after injection of contrast material. Note enhancement of the myocardial signal in the septum and apical region (*arrows*). (From Matsouka H, Hamada M, Honda T, et al: Evaluation of acute myocarditis and pericarditis by Gd-DTPA enhanced magnetic resonance imaging. Eur Heart J 1994;15:283.)

Although most nuclear imaging techniques are ancillary in the evaluation of suspected myocarditis, positron emission tomography (PET) imaging remains useful for diagnosing cardiac sarcoidosis.[64] Isiguzo and colleagues recently showed a significant association of metabolism-perfusion mismatch by rubidium-FDG PET with clinically active disease in cardiac sarcoidosis patients.[65] Case control series suggest that patients with cardiomyopathy or ventricular arrhythmias due to cardiac sarcoidosis may benefit from steroid therapy.

Endomyocardial Biopsy

EMB remains essential for the diagnosis of specific forms of myocarditis.[66] The rate of major complications with EMB is less than 1 in 1000 when the procedure is done by experienced operators.[67] In children with suspected myocarditis, EMB demonstrating myocarditis can identify responders to medical treatment. Because myocarditis may only involve regions of one ventricle, several large-volume cardiac centers are routinely performing left as well as right ventricular biopsy. In these centers, the safety of left ventricular biopsy is equivalent to that of right ventricular biopsy, and the diagnostic yield is greater.[68,69]

The clinical scenarios in which EMB is most useful are suspected GCM and fulminant lymphocytic myocarditis (**Fig. 79.7**).[70,71] GCM should be considered in acute DCM that fails to respond to usual care or is complicated by high-grade heart block or sustained ventricular tachycardia. The use of immunosuppressive therapy that includes cyclosporine probably increases the transplant-free survival rate in patients with GCM whose symptoms are of less than 6 months' duration.[46,72] Histologically, GCM is defined by a diffuse or multifocal inflammatory infiltrate of lymphocytes and multinucleated giant cells in the absence of granuloma. In contrast with cardiac sarcoidosis, in which the giant cells are located within the granuloma, the giant cells often are located at the edges of the inflammation, where myocyte damage is present. Eosinophils are significantly more common in GCM, whereas fibrosis is significantly more common in cardiac sarcoidosis. Immunohistochemistry may be beneficial in differentiating GCM

from cardiac sarcoidosis.

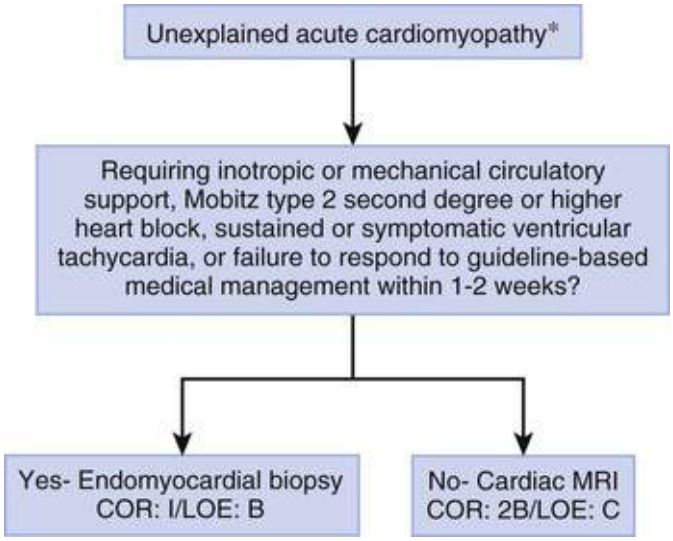


FIGURE 79.7 Algorithm for the evaluation of suspected myocarditis in the setting of unexplained acute cardiomyopathy. *COR,* class of recommendation; *LOE,* level of evidence; *MRI,* magnetic resonance imaging. *Usually a DCM. Fulminant myocarditis may have normal end-diastolic diameter with mildly thickened walls. Exclude ischemic, hemodynamic (valvular, hypertensive), metabolic, and toxic causes of cardiomyopathy as indicated clinically. (From Yancy CW, Jessup M, Bozkurt B, et al. 2016 ACC/AHA/HFSA Focused Update on New Pharmacological Therapy for Heart Failure: An Update of the 2013 ACCF/AHA Guideline for the Management of Heart Failure: A Report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines and the Heart Failure Society of America. Circulation. 2016;134:e282-93.)

Prognosis

The prognosis for patients with acute myocarditis varies in relation to the clinical scenario and degree of left ventricular dysfunction at presentation.[73] Patients who present with myopericarditis or chest pain suggestive of an acute coronary syndrome usually do well if their left ventricular function is normal or near normal.[74] However, approximately 15% of patients with myopericarditis may develop recurrent myopericarditis. In acute DCM, the risk of death or need for cardiac transplantation is increased in those myocarditis patients with lower left ventricular function, lower right ventricular function, and higher pulmonary artery pressures. In children, the time course of left ventricular functional recovery extends to at least 8 years, and the overall risk of death or requirement for transplantation approaches 30% (**Fig. 79.8**).[75,76] In patients with a recent onset of DCM who were bridged to recovery with a left ventricular assist device, myocardial inflammation was present but fibrosis was less evident.[77] There is a risk of late heart failure due to diastolic dysfunction years after the apparent resolution of acute myocarditis.[44]

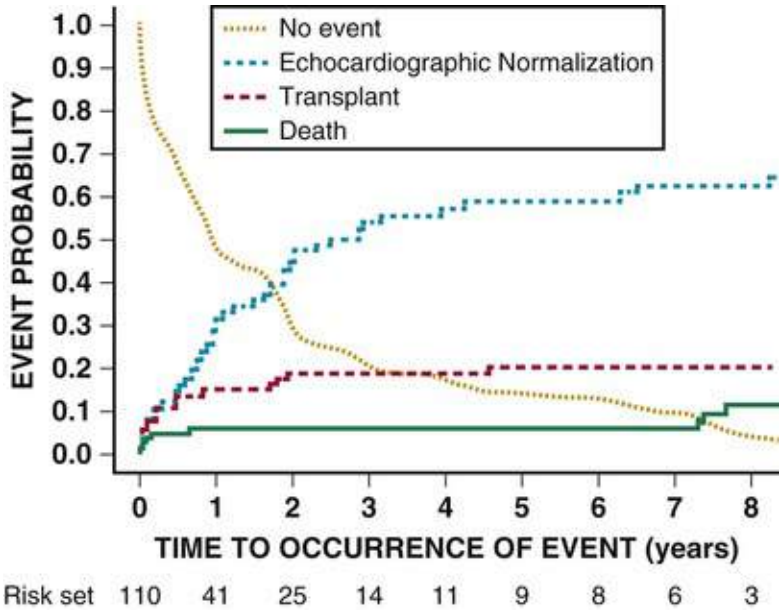

FIGURE 79.8 Crude cumulative incidence rates of echocardiographic normalization, cardiac transplantation, and death among children with biopsy-confirmed myocarditis. (From Foerster SR, Canter CE, Cinar A, et al: Ventricular remodeling and survival are more favorable for myocarditis than for idiopathic dilated cardiomyopathy in childhood: an outcomes study from the Pediatric Cardiomyopathy Registry. Circ Heart Fail 2010;3:689.)

In chronic DCM, the presence of inflammatory cells on EMB may define a subset of patients who will improve with a short course of immunosuppression. Some investigators have demonstrated that the presence of active myocarditis defined by immunohistology, but not conventional Dallas criteria, predicts the risk of death or need for transplantation. The presence of viral genomes on EMB may portend a poor outcome. Older clinical data for enteroviruses in acute cardiomyopathy were mostly consistent with this conclusion, but in recent years, the impact of viral genomes on the outcome has been questioned. Possibly the variable findings with respect to viral genomes may be due to a changing spectrum of viruses, from enteroviruses to B19V and human herpesvirus 6. In addition, genetic background differences in study populations, and possibly unmeasured environmental toxins or nutritional deficiencies, may account for differences in study outcomes. Recently, studies that have evaluated the impact of CMR imaging–associated delayed gadolinium enhancement on the cardiovascular risk following acute myocarditis generally support an association between delayed gadolinium enhancement and subsequent arrhythmic events.[63]

Treatment

The first-line therapy for all patients with myocarditis and heart failure is supportive care (**see Chapter 25**). A small proportion of patients will require hemodynamic support that ranges from vasopressors (**see Chapter 24**) to intraaortic balloon pump and ventricular assist devices (**see Chapter 29**) (**Fig. 79.9**). Guidelines for myocarditis management have been published by the American Heart Association,[78] Japanese Circulatory Society, and European Society of Cardiology (ESC) working group on myocarditis and pericarditis.[66] In patients who present with an acute DCM and a syndrome of heart failure, the current American College of Cardiology/American Heart Association (ACC/AHA) guidelines for heart failure care should be followed (**see Chapter 25**, Guidelines: Management of Heart Failure with a Reduced Ejection Fraction).[79] Clinical experience suggests that standard pharmacotherapy is effective in myocarditis, although trials of heart failure management in myocarditis have not been done.

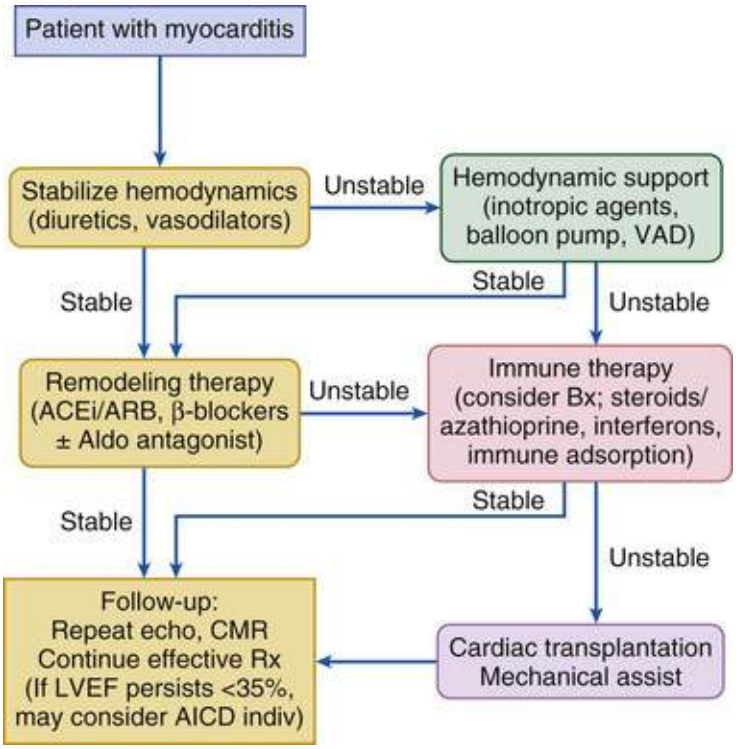

FIGURE 79.9 Treatment algorithms for patients with myocarditis, depending on hemodynamic stability and response to general supportive and remodeling treatment regimen at each step. All patients require aggressive support and appropriate follow-up. Immune therapy at present is still indicated mainly to support those who have failed to improve spontaneously. *ACEi,* angiotensin-converting enzyme inhibitor; *AICD,* automatic implantable cardioverter-defibrillator; *Aldo,* aldosterone; *ARB,* angiotensin receptor blocker; *Bx,* biopsy; *CMR,* cardiac magnetic resonance; *echo,* echocardiography; *indiv,* based on individual assessment of risk versus benefit; *LVEF,* left ventricular ejection fraction; *VAD,* ventricular assist device.

Routine treatment of mild to moderately severe acute myocarditis with immunosuppressive drugs is not recommended for adults. These data are based on the U.S. Myocarditis Treatment Trial, in which immunosuppression with prednisone and either azathioprine or cyclosporine effected similar changes in the left ventricular ejection fraction and transplant-free survival rates compared with placebo. Significant exceptions are recognized, including those of patients with GCM, cardiac sarcoidosis, eosinophilic myocarditis, and myocarditis associated with inflammatory connective tissue disorders. Also, the data from case-controlled series regarding the use of intravenous immunoglobulin (IVIG) and immunosuppressive drugs are neutral to favorable in the pediatric literature. Treatment of viral infection may be helpful in the management of posttransplantation viral heart disease in children.[12] However, in adult patients with chronic DCM and viral genomes detected by PCR assay on heart biopsy tissue, only one trial series suggests that 6 mIU of interferon-β three times per week can improve enteroviral or adenoviral heart infection.[39] There may be a role for a short course of immunosuppression in patients with chronic DCM who fail to respond to guideline-based heart failure management. In the Tailored Immunosuppression in Inflammatory Cardiomyopathy trial, 85 patients with chronic inflammatory cardiomyopathy without persistent viral infection were randomly assigned to receive either prednisone and azathioprine or placebo.[80] Immunosuppressive treatment was associated with an increase in the left ventricular ejection fraction from 26% to 46% and an improved quality of life. Larger, multicenter trials are needed to assess whether immunosuppression will affect clinically meaningful end points such as the risk of death or admission to hospital in this population.

Patients with ventricular arrhythmias or heart block due to acute myocarditis should be hospitalized for electrocardiographic monitoring. Arrhythmias usually resolve after several weeks. The ACC/AHA/ESC guidelines for the management of arrhythmias recommended that acute arrhythmia emergencies be

managed conventionally in the setting of myocarditis. Generally, the indications for an implantable cardiac-defibrillator (ICD) are the same as with nonischemic DCM. In the setting of GCM or cardiac sarcoidosis, the high rate of ventricular arrhythmias may warrant early consideration for an ICD. In patients with suspected lymphocytic myocarditis and nonsustained ventricular tachycardia, a temporary external defibrillator vest may be used while it is determined whether the arrhythmias will persist after the acute inflammatory phase.

Mechanical circulatory support (**see also Chapter 29**) or extracorporeal membrane oxygenation may allow a bridge to transplantation or recovery in patients with cardiogenic shock despite optimal medical care. In those patients who recover, the time to recovery in acute myocarditis varies, ranging from a few weeks to a few months. Transplantation also is an effective therapy for patients with myocarditis who have refractory heart failure despite optimal medical therapy and mechanical circulatory support. Survival rates after transplantation for myocarditis are similar to survival rates for other causes of cardiac transplantation. However, the risk of graft loss may be greater in children who undergo transplantation.

Future Perspectives

One of the major gaps in the management of myocarditis is the lack of a sensitive and specific noninvasive test. In this regard, diagnostic techniques are evolving to identify novel blood-based biomarkers reflecting cardiac inflammation through microarray and proteomic analysis of tissues from both laboratory models and patient samples.[38] Moreover, with improved understanding of pathophysiologic mechanisms, new therapies also are being developed and evaluated in clinical trials. These new treatments, including cell-based therapies that selectively inhibit T cell responses, induce apoptosis of activated T cells, and increase Treg cells, will be evaluated in planned clinical trials. Such prospective investigations should be designed specifically to establish efficacy in women. Translational studies focused on genomic markers in biopsy samples and peripheral blood should help refine risk assessments and target therapies to the populations at highest need.

Cardiomyopathies Induced by Drugs or Toxins

Richard A. Lange, L. David Hillis

Many toxins, some used by a substantial fraction of the population, may affect the heart adversely, so it is important to understand the myriad ways in which these substances may influence the cardiovascular system. This chapter focuses on environmental exposures and commonly prescribed pharmacologic agents, as well as frequently used illicit drugs, including cocaine and amphetamines. **Chapter 81** discusses the toxicities of various chemotherapeutic agents in greater detail.

Ethanol

An estimated two thirds of Americans occasionally consume ethanol, and approximately 10% are considered heavy consumers. Although ingestion of a moderate amount of ethanol (usually defined as three to nine drinks per week) is associated with a reduced risk for cardiovascular disease (**Fig. 80.1**),[1] binge drinking and the consumption of excessive amounts have the opposite effect. When ingested in substantial amounts, ethanol may cause ventricular systolic and/or diastolic dysfunction, systemic arterial hypertension, angina pectoris, coronary vasospasm, arrhythmias, stroke, and even sudden cardiac death.

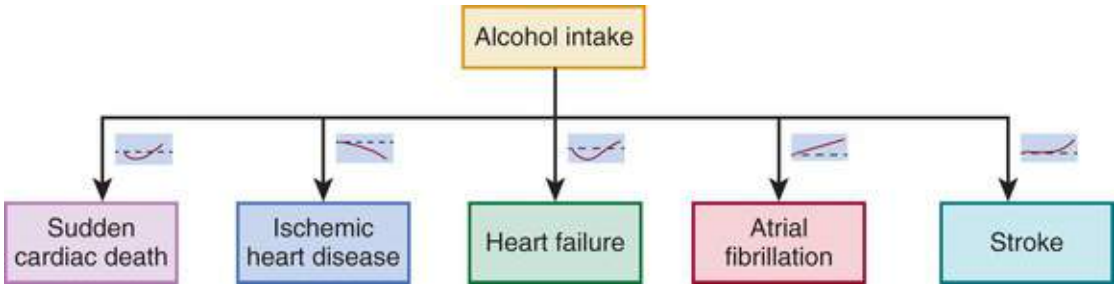

FIGURE 80.1 Schematic illustration of the relationships between alcohol intake and several major cardiovascular disease outcomes. The *small boxes* represent the approximate relationship between alcohol intake and the corresponding cardiovascular end point; the *dashed line* indicates the risk among nondrinkers as the reference group. (From Conen D. Alcohol consumption and incident cardiovascular disease; not just one unifying hypothesis. Eur Heart J 2015;36:897.)

Effects of Ethanol on Cardiac Myocyte Structure and Function

Ethanol may cause myocardial damage via several mechanisms (**Table 80.1**).[2,3] First, ethanol and its metabolites acetaldehyde and acetate may exert a direct toxic effect on the myocytes. Second, deficiencies of certain vitamins (e.g., thiamine), minerals (e.g., selenium), or electrolytes (e.g., magnesium, phosphorus, or potassium), which sometimes occur in heavy ethanol consumers, may adversely affect myocardial function. Third, certain substances that sometimes contaminate alcoholic beverages, such as lead (often found in “moonshine” alcohol) or cobalt, may damage the myocardium.

TABLE 80.1

Mechanisms of Ethanol-Induced Myocardial Injury

Direct Toxic Effects
Uncoupling of the excitation/contraction system
Reduced calcium sequestration in the sarcoplasmic reticulum
Inhibition of the sarcolemmal adenosine triphosphate–dependent Na^+/K^+ pump
Reduction in the mitochondrial respiratory ratio
Altered substrate uptake
Increased interstitial/extracellular protein synthesis
Myocyte apoptosis
Toxic Effect of Metabolites
Acetaldehyde
Ethyl esters
Nutritional or Trace Metal Deficiencies
Thiamine
Selenium
Electrolyte Disturbances
Hypomagnesemia
Hypokalemia
Hypophosphatemia
Toxic Additives
Cobalt
Lead
Arsenic

Ethanol impairs excitation-contraction coupling, calcium handling and sensitivity, mitochondrial oxidative phosphorylation, and cardiac contractility by adversely affecting the function of the sarcolemmal membrane, sarcoplasmic reticulum, mitochondria, and contractile proteins. Electron microscopic studies of the hearts of experimental animals in close temporal proximity to heavy ethanol ingestion demonstrate dilated sarcoplasmic reticula and swollen mitochondria, along with fragmented cristae and glycogen-filled vacuoles. With sustained exposure to ethanol, myofibrillar degeneration and replacement fibrosis appear. In addition to the effects of ethanol on the myocardial contractile apparatus, acute or chronic consumption may adversely influence myofibrillar protein synthesis and apoptosis. Microscopically, the hearts of chronic heavy consumers of ethanol manifest an increased accumulation of collagen in the extracellular matrix, as well as increased intermolecular cross-links.

Ethanol and Heart Failure

Chronic heavy ethanol ingestion may induce left ventricular diastolic and/or systolic dysfunction.[3] Diastolic dysfunction, which is caused, at least in part, by interstitial fibrosis of the myocardium, is often demonstrable in heavy consumers of ethanol even in the absence of symptoms or obvious signs. About half of asymptomatic chronic alcoholics have echocardiographic evidence of left ventricular hypertrophy with preserved systolic performance. By Doppler echocardiography (**see also Chapter 14**), the left ventricular relaxation time is often prolonged, the peak early diastolic velocity is reduced, and the acceleration of early diastolic flow is slowed—all manifestations of left ventricular diastolic dysfunction. Even small amounts of alcohol are associated with an acute worsening of diastolic function, as assessed by early diastolic velocity (E′), its ratio to late diastolic velocity (E′/A′), and the ratio of mitral to myocardial early diastolic velocity (E/E′).[4] Abnormal increases in left ventricular filling pressure during volume or pressure loading may be observed.

Ethanol may induce asymptomatic left ventricular systolic dysfunction even when it is ingested by healthy individuals in relatively small quantities, as occurs in subjects who are considered “social” drinkers. As many as 30% of asymptomatic chronic alcoholics have echocardiographic evidence of left

ventricular systolic dysfunction. With continued heavy ethanol ingestion, symptoms and signs of heart failure often develop (**see also Chapter 21**) as a result of dilated cardiomyopathy. In fact, ethanol abuse is the leading cause of nonischemic dilated cardiomyopathy in industrialized countries; it accounts for approximately half of those with this diagnosis. The likelihood of ethanol-induced dilated cardiomyopathy developing correlates with the amount of ethanol that is consumed in a lifetime: most men in whom it develops have consumed more than 80 g of ethanol (i.e., 1 liter of wine, eight standard-sized beers, or one-half pint of hard liquor) per day for at least 5 years. Women appear to be even more susceptible than their male counterparts to ethanol's cardiotoxic effects in that dilated cardiomyopathy may develop in women following the consumption of a smaller amount of ethanol per day and per lifetime.

Although heavy intake of ethanol is associated with nonischemic dilated cardiomyopathy, individuals with light to moderate ethanol consumption (5 to 25 g/day) actually have a lower incidence of congestive heart failure than do those who do not drink at all.[5,6] In patients with left ventricular dysfunction, light to moderate ethanol ingestion does not exacerbate heart failure.[7] In subjects with ischemic cardiomyopathy, light to moderate ethanol consumption may reduce mortality rates.[8,9]

Subjects with markedly symptomatic ethanol-induced dilated cardiomyopathy may manifest a substantial improvement in left ventricular systolic function and symptoms of heart failure with complete abstinence or a dramatic reduction in ethanol consumption (i.e., to less than 60 g of ethanol per day or the equivalent of four standard drinks). Although most of this improvement occurs in the first 6 months of abstinence, it often continues for as long as 2 years of observation.

Ethanol and Systemic Arterial Hypertension

Experts estimate that ethanol has causal importance in up to 11% of men with hypertension (**see Chapter 46**). Individuals who consume more than two drinks daily are 1.5 to 2 times more likely to have hypertension than are age- and sex-matched nondrinkers. This effect is dose related and most prominent when daily ethanol intake exceeds two drinks (i.e., 30 g of ethanol).[10] “Social” ethanol consumption is associated with a modest rise in systolic arterial pressure, whereas heavy consumption and binge drinking may lead to a substantial increase. Although the mechanism by which ethanol induces a rise in systemic arterial pressure is not completely understood, studies have demonstrated that ethanol consumption increases plasma levels of catecholamines, renin, cortisol, and aldosterone, each of which may cause systemic arterial vasoconstriction. In individuals with ethanol-induced hypertension, abstinence often normalizes systemic arterial pressure.

Ethanol and Lipid Metabolism

Ethanol consumption inhibits the oxidation of free fatty acids by the liver, which stimulates hepatic triglyceride synthesis and the secretion of very low density lipoprotein cholesterol. Most commonly, therefore, ethanol consumption causes hypertriglyceridemia. In addition, heavy ingestion may cause an increase in the serum concentrations of total cholesterol and low-density lipoprotein (LDL) cholesterol. Regular ethanol consumption increases the serum concentration of high-density lipoprotein (HDL) cholesterol.[11] Subjects with hyperlipidemia should be encouraged to limit their ethanol intake.

Coronary Artery Disease

Heavy ethanol use is associated with an increased incidence of atherosclerotic coronary artery disease and resultant cardiovascular morbidity and mortality (**see also Chapter 61**). This rise may result, at least in part, from the increased likelihood that heavy ethanol consumers (versus nondrinkers) have systemic arterial hypertension, increased left ventricular muscle mass (with concomitant diastolic and/or systolic dysfunction), and hypertriglyceridemia (**Table 80.2**). Conversely, light to moderate ethanol intake (two to seven drinks per week) is associated with a decreased risk for myocardial infarction and cardiovascular morbidity and mortality in both men and women.[12–15] Even in men already at low risk for cardiovascular disease on the basis of body mass index, physical activity, smoking, and diet, moderate alcohol intake is associated with a reduced risk for myocardial infarction (MI) (**Fig. 80.2**).[16] This lower risk for cardiovascular morbidity and mortality in consumers of moderate amounts of ethanol than in nondrinkers or heavy consumers is supported by numerous retrospectively and prospectively conducted studies. The French were noted to have a reduced incidence of coronary artery disease when compared with inhabitants of other countries despite high smoking rates and a diet high in fat (the so-called *French paradox*). Although this diminished incidence was initially attributed to the antioxidant and hemostatic properties of red wine, similar findings were subsequently reported in mild to moderate consumers of other alcoholic beverages and in other study populations. Several prospectively performed cohort studies have demonstrated that drinkers of moderate amounts of ethanol are 30% to 70% less likely than nondrinkers or heavy consumers to manifest coronary artery disease or ischemic stroke.[17] Some studies have suggested that the consumption of all alcoholic beverages exerts such an effect, whereas others have reported that this so-called *cardioprotection* is strongest with the consumption of wine.[18] The mechanism or mechanisms by which the consumption of moderate amounts of ethanol reduces cardiovascular risk appear to be multifactorial in that moderate consumption exerts several beneficial effects, including (1) an increase in the serum concentrations of HDL cholesterol, apolipoprotein A-I, and adiponectin; (2) inhibition of platelet aggregation; (3) decreased serum fibrinogen concentration; (4) increased antioxidant activity (from the phenolic compounds and flavonoids contained in red wine); (5) antiinflammatory effects (with lower concentrations of white blood cells and C-reactive protein); (6) improved fibrinolysis (resulting from increased concentrations of endogenous tissue plasminogen activator and a concomitant decrease in endogenous plasminogen activator inhibitor activity); and (7) improved insulin sensitivity (**Fig. 80.3**).[2,19]

TABLE 80.2

Qualitative Effects of Light to Moderate and Heavier Alcohol Intake on Cardiovascular Risk Factors and Outcomes

CARDIOVASCULAR RISK FACTORS AND OUTCOMES	LIGHT TO MODERATE ALCOHOL INTAKE (<2 DRINKS PER DAY)	HEAVIER ALCOHOL INTAKE (>2 DRINKS PER DAY)
Blood pressure	↔	↑↑
HDL cholesterol	↑↑	↑↑↑
Triglycerides	↑	↑↑
LDL cholesterol	↔ or ↓	↑
Platelet aggregability/coagulability	↓	↓↓
Systemic inflammation	↓	↑
Congestive heart failure	↓	↑↑
Coronary artery disease (angina, nonfatal MI)	↓↓	↔ or ↑
Atrial fibrillation	↔	↑↑
Stroke	↓	↑↑
Sudden cardiac death	↓↓	↑

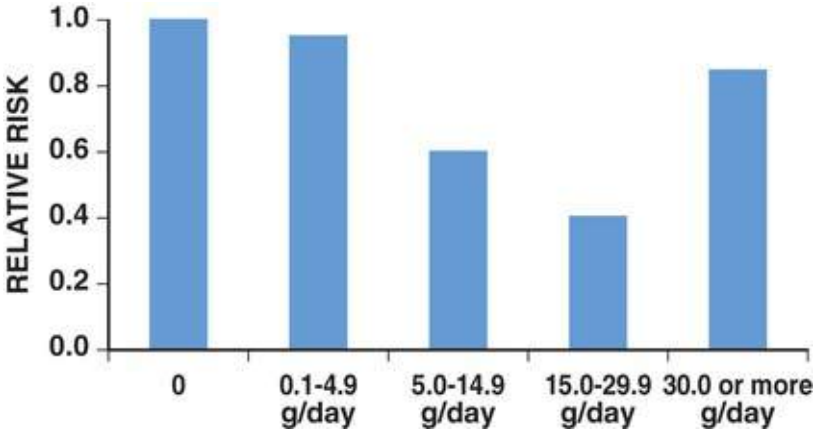

FIGURE 80.2 Relative risk for myocardial infarction (MI) according to daily alcohol intake in men already at low risk for cardiovascular disease on the basis of body mass index, physical activity, smoking, and diet. Moderate alcohol intake is associated with a lower risk for MI.

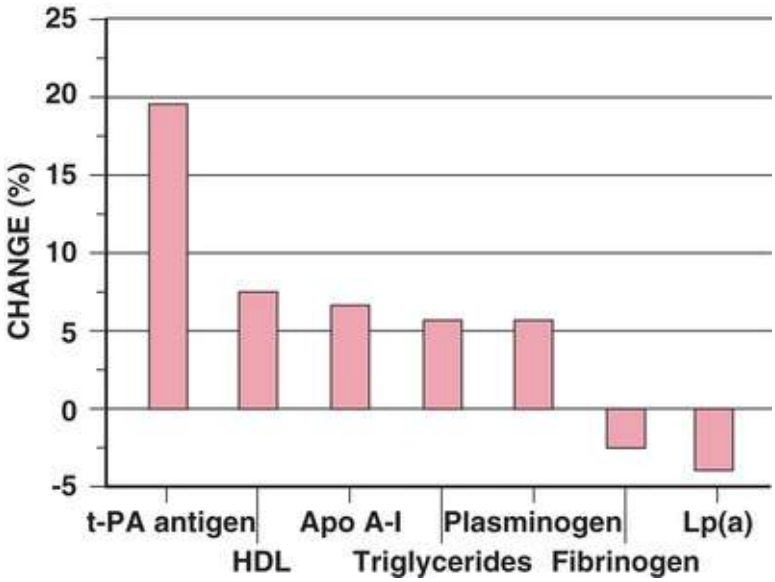

FIGURE 80.3 Percentage of change in various serologic variables caused by ethanol ingestion. Ingestion of ethanol, 30 g daily for 1 to 9 weeks, was associated with increased serum concentrations of tissue plasminogen activator (t-PA) antigen, HDL cholesterol, apolipoprotein A-I (Apo A-I), serum triglycerides, and serum plasminogen, as well as decreased concentrations of serum fibrinogen and lipoprotein(a) [Lp(a)]. The reduced risk for cardiovascular events seen in subjects who consume moderate amounts of ethanol may be caused, at least in part, by these beneficial changes in serologic variables.

Men and women manifest a difference in the cardioprotective effect of alcohol (**Fig. 80.4**). The maximal beneficial effect of ethanol occurs at lower doses for women than for men, and the range of alcohol consumption at which it is protective is wider for men than for women. In addition, the relative cardioprotective effect of ethanol is greater for middle-aged and elderly individuals than for young adults.[20] Light to moderate ethanol consumption is associated with similar reductions in risk for coronary artery disease in diabetic and nondiabetic men and women.[21] In survivors of MI, moderate ethanol consumption appears to reduce the risk of subsequent mortality.[8,22,23] In patients suffering an acute MI, those with light or moderate alcohol use have a better prognosis than do heavy drinkers or abstainers, even though recent ingestion of ethanol does not appear to reduce infarct size or the propensity for the subsequent appearance of arrhythmia or heart failure.

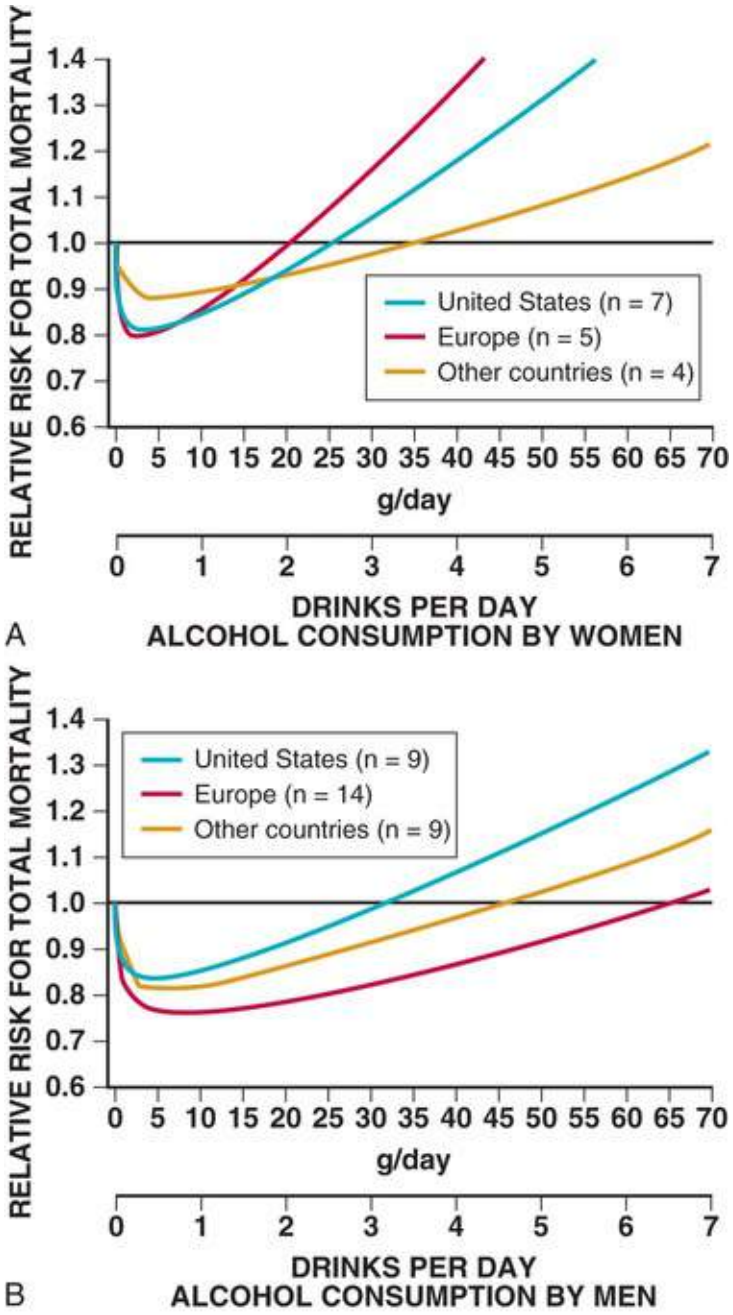

FIGURE 80.4 Relative risk for total mortality and alcohol intake in women **(A)** and men **(B)** in the United States, Europe, and other countries (Australia, Japan, and/or China). A J-shaped relationship between alcohol consumption and total mortality is observed in both men and women. Consumption of alcohol, up to four drinks per day in men and two drinks per day in women, is inversely associated with total mortality. Higher doses of alcohol were associated with increased mortality. The inverse association in women disappears at doses lower than in men.

Arrhythmias

Ethanol consumption is associated with a variety of atrial and ventricular arrhythmias, most commonly (1) atrial or ventricular premature beats, (2) supraventricular tachycardia, (3) atrial flutter, (4) atrial fibrillation, (5) ventricular tachycardia, or (6) ventricular fibrillation (**see also Chapters 35, 38, 39**). The most common ethanol-induced arrhythmia is atrial fibrillation. Ethanol is of causal importance in about a third of subjects with new-onset atrial fibrillation; in those younger than 65 years it may be responsible in as many as two thirds. Most episodes occur after binge drinking, usually on weekends or holidays—hence the term “holiday heart.” Electrophysiologic testing in humans without cardiac disease has shown that ethanol enhances vulnerability to the induction of atrial flutter and fibrillation. Treatment

of these ethanol-induced arrhythmias is abstinence.

Ethanol may be arrhythmogenic via several mechanisms. In many ethanol consumers, concomitant factors may predispose to arrhythmias, including cigarette smoking, electrolyte disturbances, metabolic abnormalities, hypertension, and sleep apnea. Acute ethanol ingestion induces diuresis, which is accompanied by the concomitant urinary loss of sodium, potassium, and magnesium. The presence of myocardial interstitial fibrosis, ventricular hypertrophy, cardiomyopathy, or autonomic dysfunction may also enhance the likelihood of dysrhythmias. Prolongation of the QT interval, decreased heart rate variability, diminished vagal modulation, and reduced baroreflex sensitivity have also been noted in patients with alcohol use or withdrawal.[24]

Sudden Death

In subjects without known cardiac disease, the decrease in cardiovascular mortality rates that is associated with moderate ethanol intake results largely from a reduction in the incidence of sudden death (**Fig. 80.5**) (**see also Chapter 42**). Of the more than 21,000 men in the Physicians Health Study,[25] those who consumed two to four or five to six drinks per week had a significantly reduced risk for sudden death (relative risks, 0.40 and 0.21, respectively) when compared with those who rarely or never drank. In contrast, heavy ethanol consumption (i.e., six or more drinks per day) or binge drinking was associated with an increased risk for sudden death. Heavy ethanol consumption is associated with an increased incidence of sudden death independent of the presence of coronary artery disease. The incidence of ethanol-induced sudden death increases with age and the amount of ethanol that is ingested. For example, daily ingestion of more than 80 g of ethanol is associated with a threefold increased incidence of mortality when compared with daily consumption of a lesser amount.

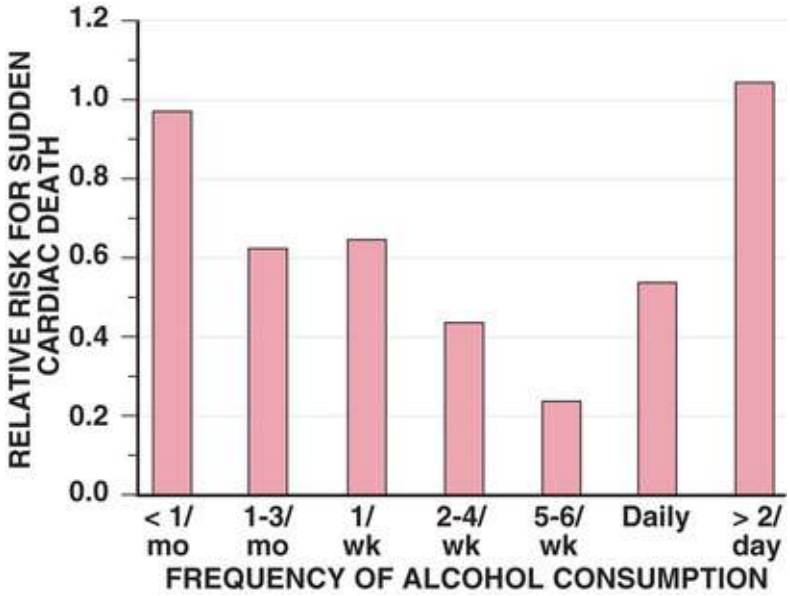

FIGURE 80.5 Ethanol consumption and risk for sudden cardiac death in U.S. male physicians. In comparison to those who had less than one drink per month (*far left bar*), those who consumed small or moderate amounts of ethanol (*middle bars*) had a reduced risk for sudden cardiac death. In contrast, those who consumed at least two drinks per day (*far right bar*) had an increased risk.

Cocaine

Cocaine is currently the most commonly used illicit drug in subjects seeking care in hospital emergency departments, and it is the most frequent cause of drug-related deaths reported by medical examiners in the United States. Its use is associated with a number of cocaine-related cardiovascular complications, including angina pectoris, MI, cardiomyopathy, aortic dissection, and sudden death (**Table 80.3**).

TABLE 80.3

Endocarditis
Aortic dissection

Pharmacology and Mechanisms of Action

Cocaine (benzoylmethylecgonine) is an alkaloid extracted from the leaf of the *Erythroxylon coca* bush, which grows primarily in South America. It is available in two forms: the hydrochloride salt and the "freebase." Cocaine *hydrochloride* is prepared by dissolving the alkaloid in hydrochloric acid to form a water-soluble powder or granule, which can be taken orally, intravenously, or intranasally (so-called chewing, mainlining, or snorting, respectively). The *freebase* form is manufactured by processing the cocaine with ammonia or sodium bicarbonate (baking soda). Unlike the hydrochloride form, "freebase" cocaine is heat stable, so it can be smoked. It is known as "crack" because of the popping sound that it makes when heated.

Cocaine hydrochloride is well absorbed through all mucous membranes; therefore users may achieve a high blood concentration with intranasal, sublingual, vaginal, or rectal administration. The route of administration determines the rapidity of onset and duration of action. The euphoria associated with smoking crack cocaine occurs within seconds and is short-lived. Crack cocaine is considered the most potent and addictive form of the drug. Cocaine is metabolized by serum and liver cholinesterases to water-soluble metabolites (primarily benzoylecgonine and ecgonine methyl ester), which are excreted in urine. Because cocaine's serum half-life is just 45 to 90 minutes, it is detectable in blood or urine only for several hours after use. However, its metabolites persist in blood or urine for 24 to 36 hours after administration.

When applied locally, cocaine acts as an anesthetic by virtue of its inhibition of membrane permeability to sodium during depolarization, thereby blocking the initiation and transmission of electrical signals. When given systemically, it blocks the presynaptic reuptake of norepinephrine and dopamine, thereby producing an excess of these neurotransmitters at the site of the postsynaptic receptor (**Fig. 80.6**). In short, cocaine acts as a powerful sympathomimetic agent.

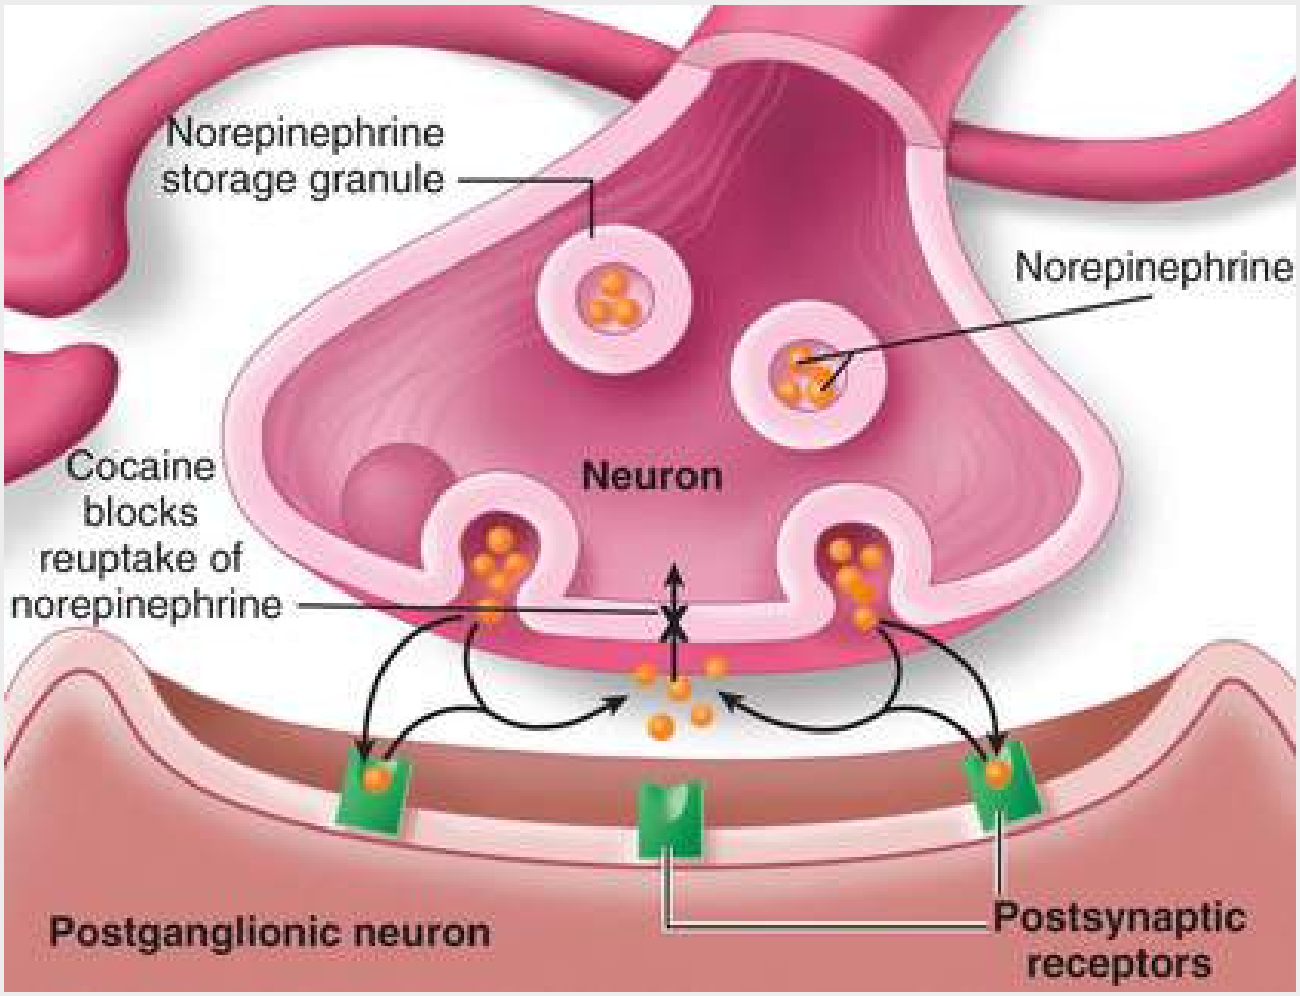

FIGURE 80.6 Mechanism by which cocaine alters sympathetic tone. Cocaine blocks the reuptake of norepinephrine by the preganglionic neuron (X), thereby resulting in excess amounts of this neurotransmitter at postganglionic receptor sites.

Cocaine-Related Myocardial Ischemia and Infarction

Since 1982, numerous reports have associated cocaine use with myocardial ischemia and infarction (**see also Chapters 57, 59, and 60**).[26] Cocaine-related myocardial ischemia or infarction may result from (1) increased myocardial oxygen demand in the setting of a limited or fixed oxygen supply, (2) marked coronary arterial vasoconstriction, and (3) enhanced platelet aggregation and thrombus formation (**Fig. 80.7**).

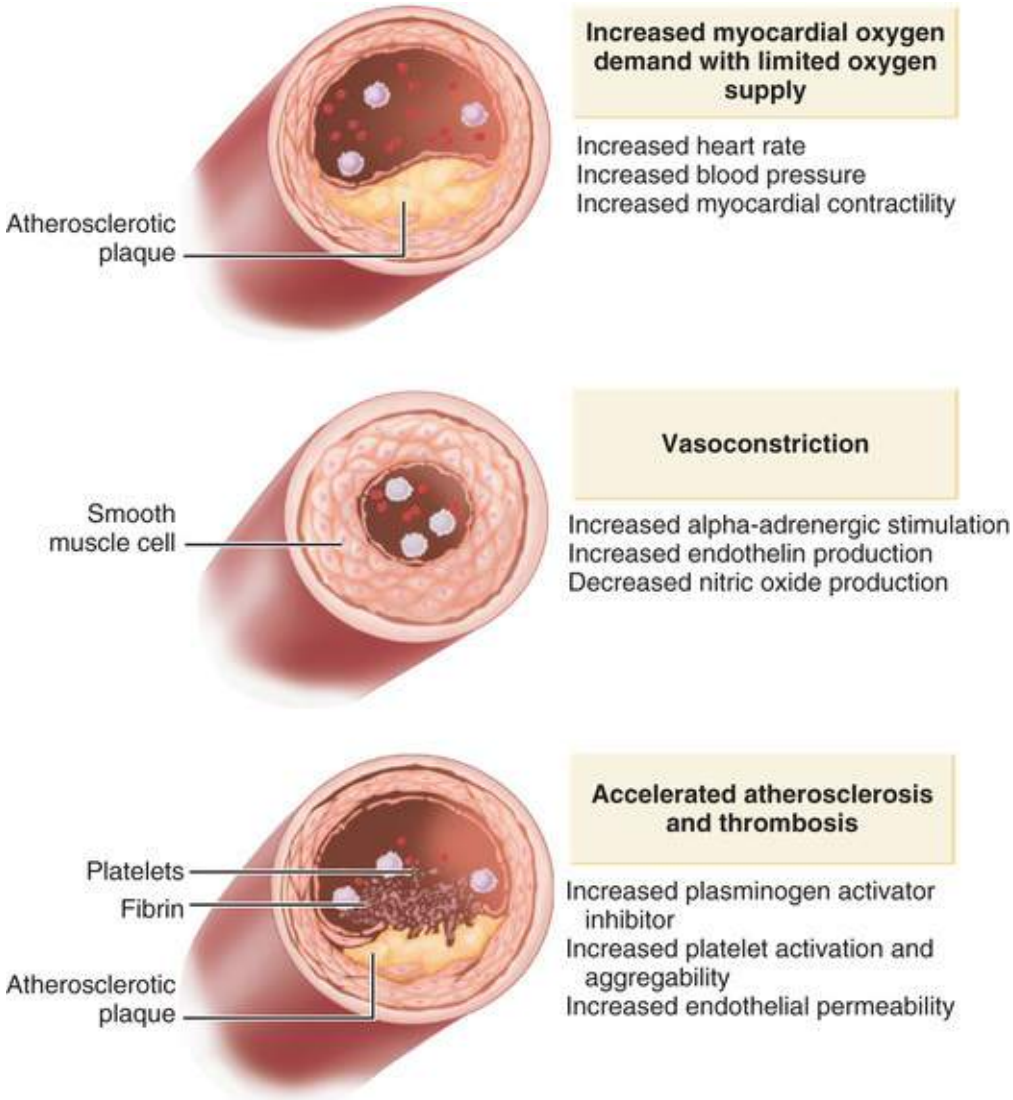

FIGURE 80.7 Mechanisms by which cocaine may induce myocardial ischemia or infarction. Cocaine may induce myocardial ischemia or infarction by increasing the determinants of myocardial oxygen demand in the setting of limited oxygen supply (*top*), thereby causing intense coronary arterial vasoconstriction (*middle*) or inducing accelerated atherosclerosis and thrombosis (*bottom*).

By virtue of its sympathomimetic effects, cocaine increases the three major determinants of myocardial oxygen demand: heart rate, left ventricular wall tension, and left ventricular contractility. At the same time, ingestion of even small amounts of the drug causes vasoconstriction of the epicardial coronary arteries (so-called *inappropriate vasoconstriction*) in that the myocardial oxygen supply decreases as the demand increases. Cocaine induces vasoconstriction in normal coronary arteries but exerts a particularly marked vasoconstrictive effect in diseased segments. As a result, cocaine users with atherosclerotic coronary artery disease probably have an especially high risk for an ischemic event after cocaine use. Cocaine-induced coronary arterial vasoconstriction results primarily from the stimulation of coronary arterial alpha-adrenergic receptors because it is reversed by phentolamine (an alpha-adrenergic antagonist) and exacerbated by propranolol (a beta-adrenergic antagonist). In addition, cocaine causes increased endothelial production of endothelin (a potent vasoconstrictor) and decreased production of nitric oxide (a potent vasodilator), which may also promote vasoconstriction.

Cocaine use may enhance platelet activation and aggregability, as well as increase concentrations of plasminogen activator inhibitor and von Willebrand factor released from endothelial cells, which may promote thrombus accumulation. The presence of premature atherosclerotic coronary artery disease, as observed in postmortem studies of long-term cocaine users, may provide a nidus for thrombosis. In vitro studies have shown that cocaine causes structural abnormalities in the endothelial cell barrier—it

increases its permeability to LDL and enhances the expression of endothelial adhesion molecules (thereby favoring leukocyte migration), all of which are associated with atherogenesis.

Chest pain is the most common cardiovascular complaint of patients seeking medical assistance following cocaine use. Approximately 6% of those who come to the emergency department with cocaine-associated chest pain have enzymatic evidence of myocardial necrosis. Most subjects with cocaine-related MI are young, nonwhite, male cigarette smokers without other risk factors for atherosclerosis who have a history of repeated cocaine use (**Table 80.4**). The deleterious effects of cocaine on the myocardial oxygen supply and demand are substantially exacerbated by concomitant cigarette smoking, which by itself induces coronary arterial vasoconstriction through an alpha-adrenergic mechanism. Following concomitant cocaine use and smoking, the heart rate and systemic arterial pressure increase markedly, and coronary arterial vasoconstriction is more intense than with either alone.

TABLE 80.4

Characteristics of Patients with Cocaine-Induced Myocardial Infarction

Dose of Cocaine
5-6 lines (150 mg) to as much as 2 g Serum concentration, 0.01-1.02 mg/L
Frequency of Use
Reported in chronic, recreational, and first-time users
Route of Administration
Occurs with all routes of administration 75% of reported MIs occurred after intranasal use
Age
Mean, 34 years (range, 17-71 years) 20% younger than 25 years
Sex
80%-90% male
Timing
Often within minutes of cocaine use Reported as late as 5-15 hours after use

In subjects who are otherwise considered to be at low risk for MI, the risk for infarction increases 24-fold during the 60 minutes after cocaine use. The occurrence of MI after cocaine use appears to be unrelated to the amount ingested, its route of administration, and the frequency of its use: cocaine-related infarction has been reported with doses ranging from 200 to 2000 mg, after ingestion by all routes, and in habitual and first-time users. About half the patients with cocaine-related MI have no angiographic evidence of atherosclerotic coronary artery disease. Therefore, when subjects with no or few risk factors for atherosclerosis, particularly those who are young or have a history of substance abuse, are seen with acute MI, urine and blood samples should be analyzed for cocaine and its metabolites.

Cardiovascular complications resulting from cocaine-related MI are relatively uncommon, with ventricular arrhythmias occurring in 4% to 17%, congestive heart failure in 5% to 7%, and death in less than 2%. This low incidence of complications is caused, at least in part, by the young age and absence of extensive multivessel coronary artery disease in most patients with cocaine-related infarction. If complications develop, most occur within 12 hours of hospitalization. Following hospital discharge, continued cocaine use and recurrent chest pain are common. Occasionally, a patient has recurrent nonfatal or fatal MI.

Cocaethylene

In individuals who use cocaine in temporal proximity to the ingestion of ethanol, hepatic transesterification leads to the production of a unique metabolite, cocaethylene. Cocaethylene is often detected postmortem in subjects who are presumed to have died of cocaine and ethanol toxicity. Similar to cocaine, cocaethylene blocks the reuptake of dopamine at the synaptic cleft, thereby possibly potentiating the systemic toxic effects of cocaine. In experimental animals, in fact, cocaethylene is more lethal than cocaine. In humans, the combination of cocaine and ethanol causes a substantial increase in myocardial oxygen demand. The concomitant use of cocaine and ethanol is associated with a higher incidence of disability and death than use of either agent alone. Individuals presumably dying of a combined cocaine-ethanol overdose have much lower blood cocaine concentrations than do those presumably dying of a cocaine overdose alone, thus suggesting an additive or synergistic effect of ethanol on the catastrophic cardiovascular events that are induced by cocaine.

Cocaine-Induced Myocardial Dysfunction

Long-term cocaine abuse has been associated with left ventricular hypertrophy, as well as with left ventricular diastolic and/or systolic dysfunction. In a recent study,[26] cardiac magnetic resonance imaging detected cardiac abnormalities in 71% of asymptomatic consecutive cocaine abusers. The main findings were a decrease in systolic function of left and right ventricles, an increase of left ventricular mass, and the presence of focal fibrosis (late gadolinium enhancement). There was a significant association between years of cocaine use and probability of left ventricular systolic dysfunction. Aside from the effects of long-term cocaine use on myocardial performance, it may cause an acute deterioration in left ventricular systolic and/or diastolic function or transient apical ballooning (also called Takotsubo cardiomyopathy or “broken heart syndrome”) (**see also Chapter 25**). Cocaine may adversely affect left ventricular systolic function by several mechanisms. First, as noted previously, cocaine may induce myocardial ischemia or infarction. Second, the profound repetitive sympathetic stimulation induced by cocaine is similar to that observed in patients with pheochromocytoma; either may result in cardiomyopathy and characteristic microscopic changes of subendocardial contraction band necrosis. Third, the concomitant administration of adulterants or infectious agents may cause myocarditis, which has been seen on occasion in intravenous cocaine users studied after death. Fourth, studies in experimental animals have shown that cocaine increases the production of reactive oxygen species, alters cytokine production in the endothelium and in circulating leukocytes, stimulates the transcription of genes responsible for changes in the composition of myocardial collagen and myosin, and induces myocyte apoptosis.

Arrhythmias

Although cardiac dysrhythmias may occur with cocaine (**Table 80.5**), its precise arrhythmogenic potential is poorly defined. In many cases the dysrhythmias ascribed to cocaine occur in the setting of profound hemodynamic or metabolic derangements, such as hypotension, hypoxemia, seizures, or MI. Nonetheless, because of cocaine's sodium and potassium channel–blocking properties and its ability to enhance sympathetic activation, it is considered a probable cause of cardiac arrhythmias.[28] The development of lethal arrhythmias with cocaine use may require an underlying substrate of abnormal myocardium. Life-threatening arrhythmias and sudden death in association with cocaine use occur most often in individuals with myocardial ischemia or infarction or in those with nonischemic myocellular damage. Long-term cocaine use is associated with increased left ventricular mass and wall thickness, which are known risk

factors for ventricular dysrhythmias.

Cardiac Dysrhythmias and Conduction Disturbances Reported with Cocaine Use

Sinus tachycardia
Sinus bradycardia
Supraventricular tachycardia
Bundle branch block
Complete heart block
Accelerated idioventricular rhythm
Ventricular tachycardia
Ventricular fibrillation
Asystole
Torsades de pointes
Brugada pattern (right bundle branch block with ST-segment elevation in leads V1, V2, and V3)

Cocaine may affect the generation and conduction of cardiac impulses by several mechanisms. First, its sympathomimetic properties may increase ventricular irritability and lower the threshold for fibrillation. Second, it inhibits action potential generation and conduction (i.e., it prolongs the QRS and QT intervals) as a result of its sodium channel–blocking effects. In so doing, it acts in a manner similar to that of a class I antiarrhythmic agent. Accordingly, Brugada-type electrocardiographic features and torsades de pointes have been observed following cocaine use. Third, cocaine increases the intracellular calcium concentration, which may result in afterdepolarizations and triggered ventricular arrhythmias. Fourth, it reduces vagal activity, thereby potentiating its sympathomimetic effects.

Aortic Dissection

Because aortic dissection or rupture has been temporally related to cocaine use, it should be considered a possible cause of chest pain in cocaine users (**see also Chapter 63**). Cocaine has been implicated as a causative factor in 0.5% to 37% of cases of aortic dissection, with an average interval from cocaine use to the onset of symptoms of 12 hours (range, 0 to 24).[29] Dissection probably results from a cocaine-induced increase in systemic arterial pressure. In addition to aortic rupture, cocaine-related rupture of mycotic and intracerebral aneurysms has been reported.

Amphetamines

Amphetamines were previously prescribed for the treatment of obesity, attention deficit disorder, and narcolepsy; at present, their use is strictly limited. The most frequently abused amphetamines are dextroamphetamine, methcathinone, methamphetamine, methylphenidate, ethylphenidate, ephedrine, propylhexedrine, phenmetrazine, and 3,4-methylene-dioxymethamphetamine (MDMA, also known as *Ecstasy*). Recently, many deaths have been reported from exposure to paramethoxymethamphetamine (PMMA, also known as *Death* and *Dr. Death*), an amphetamine similar in structure MDMA but substantially more toxic.[30] *Ice* is a freebase form of methamphetamine that can be inhaled, smoked, or injected. Because amphetamines are sympathomimetic agents, their use has been associated with systemic arterial hypertension, premature coronary artery disease, acute coronary syndromes, MI, myocardial damage consistent with catecholamine excess, aortic dissection, and lethal arrhythmias.[31] Similar to cocaine, amphetamines may induce intense coronary arterial vasoconstriction with or without thrombus formation. Finally, dilated cardiomyopathy can develop following repetitive amphetamine use, with recovery of cardiovascular function occurring after drug discontinuation. Although initial case reports

suggested that stimulants prescribed for the treatment of attention-deficit/hyperactivity disorder (ADHD) were linked to adverse cardiovascular events (which prompted the Food and Drug Administration to issue a black box warning in 2006), subsequent studies have shown that the use of ADHD medications is not associated with an increased risk for serious cardiovascular events in children[32] (**Fig. 80.8**) or young and middle-aged adults.[33]

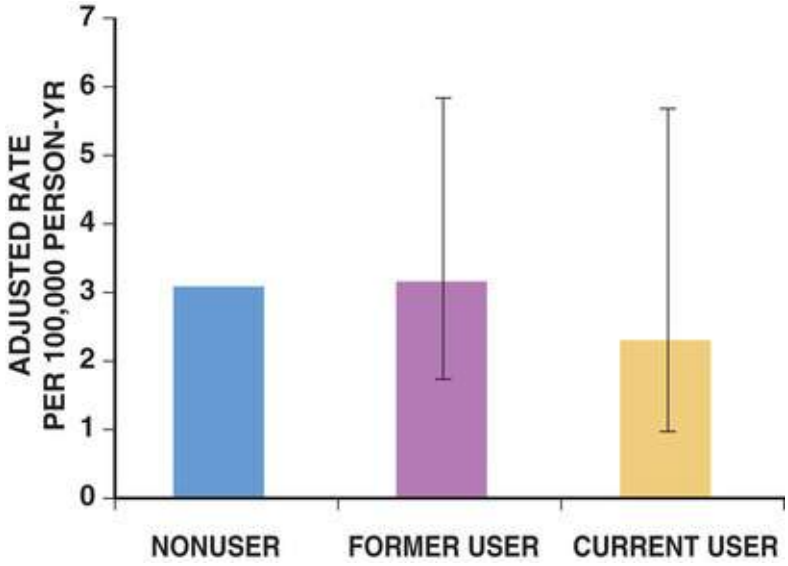

FIGURE 80.8 Adjusted rates of serious cardiovascular events according to use of ADHD drugs. Use of ADHD medications is not associated with an increased risk for serious cardiovascular events. (From Cooper WO, Habel LA, Sox CM, et al: ADHD drugs and serious cardiovascular events in children and young adults. N Engl J Med 2011;365:1896.)

Cathinones

Cathinones bind to monoamine transporters for dopamine, serotonin, and norepinephrine, which accounts for their sympathomimetic properties. Like cocaine and amphetamines, these substances produce stimulant effects and are therefore sometimes used as substitutes for the traditional illicit drugs.

The leaves of khat (*Catha edulis*) are chewed for the central stimulant action of their cathinone content. Khat use is highly prevalent in East African and Middle Eastern countries, in particular, Somalia and Yemen, and it is an emerging problem in Australia and Europe. Khat chewing has been linked to MI, dilated cardiomyopathy, vascular disease (such as hypertension and stroke), and thromboembolism.[34] Khat chewing is an independent risk factor for acute MI: moderate khat chewers were shown to be at high risk (odds ratio, 7.6), and heavy khat chewers were at even higher risk (odds ratio, 22.3).[35]

Many synthetic cathinones (mephedrone, methylenedioxypyrovalerone [MDPV], and methylone), colloquially known on the street as *meow*, have gained renewed popularity as designer drugs of abuse, particularly among young people.[36] These compounds are marketed as “bath salts” or “plant food” and labeled “not for human consumption” to circumvent regulatory restrictions on drugs of abuse. They are used by the oral route, nasal insufflation (“snorting”), intramuscular or intravenous injection, and rectal insertion, with most ingestion occurring by nasal insufflation or oral ingestion (or both). Synthetic cathinones have been associated with myocarditis and sudden death.

Synthetic Cannabinoids

These drugs consist of psychoactively inert dry plant material sprayed with synthetic cannabinoid receptor agonists. Marketed as incense and best known by the street names “spice” and “K2,” when smoked they provide a marijuana-like effect; their use has been associated with MI in adolescents.[37,38]

Ma Huang (Ephedra)

The dietary supplement ephedra, also known as ma huang, contains ephedrine and its enantiomer pseudoephedrine. Ma huang increases catecholamines at synaptic areas in the brain and heart and directly stimulates alpha- and beta-adrenergic receptors. As a result, it typically induces an increase in heart rate, blood pressure, cardiac output, and peripheral resistance. Its use has been associated with stroke, MI, sudden death, and cardiomyopathy.

Catecholamines and Beta-Adrenergic Receptor Agonists

Catecholamines, administered exogenously or secreted by a neuroendocrine tumor (e.g., pheochromocytoma or neuroblastoma), may produce acute myocarditis (with focal myocardial necrosis and inflammation), cardiomyopathy, tachycardia, and arrhythmias. Similar abnormalities have been described with the excessive use of beta-adrenergic agonist inhalants and methylxanthines in patients with severe pulmonary disease. The administration of beta-adrenergic receptor agonists or catecholamines (i.e., dobutamine or epinephrine, respectively) has been associated with the appearance of transient left ventricular apical dyskinesis and anterior electrocardiographic T-wave inversions; this entity is known as *takotsubo* or *stress cardiomyopathy* (**see also Chapter 25**). Several mechanisms may be responsible for the acute and chronic myocardial damage associated with catecholamines. They may exert a direct toxic effect on the myocardium through changes in autonomic tone, enhanced lipid mobility, calcium overload, free radical production, or increased sarcolemmal permeability. Alternatively, myocardial damage may be secondary to a sustained increase in myocardial oxygen demand and/or a decrease in myocardial oxygen supply (the latter caused by catecholamine-induced coronary arterial vasoconstriction or platelet aggregation).

Energy Drinks

Emergency department visits related to energy drinks have more than doubled to more than 20,000 visits annually. Cardiovascular complications reported after energy drink ingestion include arrhythmias (i.e., atrial fibrillation, supraventricular tachycardia, ventricular fibrillation, torsades de pointes), MI, and cardiac arrest, often in young persons.[39] Adverse effects and toxicities associated with energy drinks have been attributed to (1) the high caffeine content and the fact that the drinks are often consumed in an excessive or rapid manner; (2) consumption by young individuals who may be caffeine naïve and prone to consume large quantities; (3) mixture with alcohol and other substances; and (4) other ingredients in the drinks that may increase the cardiovascular risks.

Inhalants

The inhalants may be classified as organic solvents, organic nitrites (such as amyl nitrite or amyl butyl), and nitrous oxide. Organic solvents include toluene (airplane glue, rubber cement, and paint thinner), Freon, kerosene, gasoline, carbon tetrachloride, acrylic paint sprays, shoe polish, degreasers (trichloroethylene), nail polish remover, typewriter correction fluid, adhesives, permanent markers, room fresheners, deodorants, dry-cleaning agents, and lighter fluid. These solvents are most often inhaled by children or young adolescents (so-called huffing, sniffing, or dusting). Acute or chronic inhalant use has occasionally been reported to induce cardiac abnormalities, most commonly dysrhythmias; rarely, inhalant use has been associated with myocarditis, MI, and sudden death. The inhalation of Freon, for example, can sensitize the myocardium to catecholamines; in such individuals, fatal arrhythmias have been reported to occur when the user is startled during inhalation.

Antiretroviral Agents

Subjects treated with highly active antiretroviral therapy (HAART) have been observed to have severe hypertriglyceridemia (serum triglycerides >1000 mg/dL), marked elevations in lipoprotein(a) and hypercholesterolemia, increased LDL and decreased HDL cholesterol levels, and insulin resistance. Not surprisingly, therefore, patients treated with these agents have an increased risk for atherosclerosis (**see also Chapter 82**). Epidemiologic studies have linked certain antiretroviral medications (some nucleoside reverse transcriptase inhibitors [i.e., abacavir or didanosine-containing regimens] and protease inhibitors [i.e., indinavir and lopinavir-ritonavir]) with a higher risk for coronary heart disease. Conversely, nonnucleoside reverse transcriptase inhibitors, entry inhibitors, and integrase inhibitors do not appear to increase the risk for coronary heart disease.[40]

Serotonin Agonists

The medicinal use of serotonin agonists, such as ergotamine and methysergide (migraine therapy), bromocriptine, cabergoline, and pergolide (Parkinson disease therapy), and fenfluramine and dexfenfluramine (appetite suppressants) has been associated with left- and right-sided valvular disease (**Table 80.6**). Recreational and regular use of MDMA (*Ecstasy*) has also been associated with valvular disease.[41] The echocardiographic and histopathologic findings resemble those described in patients with carcinoid syndrome. Grossly, the valve leaflets and chordae tendineae are thickened and have a glistening white appearance. Histologically, the leaflet architecture is intact, but a plaquelike encasement of the leaflets and chordal structures occurs, and proliferative myofibroblasts surrounding an abundant extracellular matrix are observed.

TABLE 80.6

Serotonin Agonists Associated with Valvular Disease

DRUGS	AFFECTED VALVES	DOSE DEPENDENCY
Ergotamine	AV, MV, and TV	Not reported
Methysergide	AV and MV	Not reported
(Dex)Fenfluramine	AV, MV, and TV	Yes
Pergolide	AV, MV, and TV	Yes
Cabergoline	AV, MV, and TV	Yes
Bromocriptine	AV, MV, and TV	Yes
MDMA *(Ecstasy)*	AV and MV	Not reported
Benfluorex	AV, MV, and TV	Yes

AV, aortic valve; *MV*, mitral valve; *TV*, tricuspid valve.

Two medications used to treat subjects with migraine headaches, ergotamine and triptans, have been associated with acute MI.[42] Ergotamine causes vasoconstriction of the intracerebral and extracranial arteries; rarely, its use has been associated with coronary arterial vasospasm and acute MI. Its vasoconstrictor effects are exaggerated by concomitant caffeine ingestion or use of beta-adrenergic blockers. Triptans, selective 5-hydroxytryptamine agonists, also exert their therapeutic effects by inducing cerebral arterial vasoconstriction. Several reports have appeared of patients in whom coronary vasospasm and acute MI occurred following the administration of therapeutic doses of sumatriptan or zolmitriptan; some of these MIs were complicated by ventricular tachycardia/fibrillation and sudden cardiac death. Following oral sumatriptan, electrocardiographic changes consistent with cardiac ischemia (in the absence of atherosclerotic CAD), QT prolongation, and torsades de pointes have been observed.

Chemotherapeutic Agents

Several chemotherapeutic agents may adversely affect cardiac function, and some have been reported to induce hypertension, acute cardiomyopathy, myocardial ischemia or infarction, pericarditis, dysrhythmias, QT interval prolongation, and/or sudden death (**see Chapter 81**).

Environmental Exposures

Exposure to environmental pollutants and/or toxins can occur by three different routes: inhalation, ingestion, or dermal absorption. The physiologic response to a given exposure to an environmental pollutant may vary between individuals because of differences in their underlying health status or polymorphisms in the genes encoding detoxifying enzymes, as well as other factors. In the section that follows we will review the cardiovascular effects of metal pollutants and other environmental toxins. The effects of air pollution on cardiovascular disease are discussed in **Chapter 52**.

Metal Pollutants

Epidemiologic and experimental studies both suggest that metals (e.g., cadmium and lead) and metalloids (e.g., arsenic) are associated with the development of cardiovascular disease.

Cobalt

In the mid-1960s, an acute and fulminant form of dilated cardiomyopathy was described in heavy beer drinkers. It was suggested that the cobalt chloride that was added to beer as a foam stabilizer was the

causative agent; therefore, its addition was discontinued. Subsequently, this acute and severe form of cardiomyopathy disappeared. More recently, several reports of dilated cardiomyopathy after occupational exposure to cobalt have appeared; in these individuals, high concentrations of cobalt were demonstrated in endomyocardial biopsy specimens.

Lead

Environmental exposure to lead can occur from air and dust, and sometimes from drinking water and food. Although public health interventions that banned the use of lead in gasoline, paint, and solder have reduced the overall lead exposure, both children and adults have continued lead exposure because of its use in batteries and toys and its release through industrial sources, as well as the persistence of lead in house paint, plumbing fixtures, and soil. Prospective and cross-sectional studies have demonstrated an association between the current levels of lead exposure and the risk of adverse cardiovascular outcomes. The relative risks of death from MI and stroke for individuals with the highest tertile of blood lead levels were approximately 2- to 2.5-fold greater, respectively, than in patients with the lowest tertile of blood lead levels. Moreover, in cross-sectional studies, blood lead levels were associated with peripheral arterial disease. Moderate to high levels of lead exposure are nephrotoxic, whereas low levels of lead exposure can lead to the development and progression of chronic kidney disease. Patients with lead poisoning typically have complaints that are referable to the gastrointestinal and central nervous systems. On occasion, subjects with lead poisoning have electrocardiographic abnormalities, atrioventricular conduction defects, and overt congestive heart failure; rarely, myocardial involvement may contribute to or be the principal cause of death.[43]

Cadmium

Cadmium is a by-product of the mining and refining of zinc, lead, and copper ores. The use of cadmium has increased dramatically through applications such as nickel-cadmium batteries and metal coatings. Cadmium from industrial sources and phosphate fertilizers containing cadmium fertilizers contaminate the soil. Leafy green and root vegetables concentrate cadmium bound to organic matter in soil, leading to a major cadmium exposure pathway through diet and tobacco smoking. Other dietary sources include shellfish and organ meats (liver and kidney). Epidemiologic studies suggest there is an association between exposure to cadmium and cardiovascular and kidney disease. Increased levels of cadmium in blood or urine are associated with a higher incidence of death from coronary heart disease, heart failure, and stroke.

Mercury

Occupational exposure to metallic mercuric vapor may cause systemic arterial hypertension and myocardial failure. Although some studies have suggested that high mercury content in fish may counteract the beneficial effects of its omega-3 fatty acids, thereby increasing the risk for atherosclerotic cardiovascular disease, more recent assessments have not supported an association between total mercury exposure and the risk for coronary artery disease.

Antimony

Various antimony compounds have previously been used for the treatment of patients with schistosomiasis. Their use is often associated with electrocardiographic abnormalities, including prolongation of the QT interval and T-wave flattening or inversion. Rarely, chest pain, bradycardia,

hypotension, ventricular arrhythmias, and sudden death have been reported.

Arsenic

The main sources of inorganic arsenic exposure are drinking water obtained in regions where ground water is contaminated by industrial sources or naturally occurring arsenic, as well as in food (rice, grains, and some juices). The intake of arsenic associated with the consumption of fish does not have the level of toxicity attributed to inorganic arsenic or its metabolites. Although occupational exposure to sources of arsenic has decreased over the past several decades, exposure to arsenic in drinking water still remains a global environmental health problem. Approximately 10 million individuals in the United States live in areas where arsenic levels in drinking water exceed the World Health Organization and Environmental Protection Agency recommended limit of 10 µg/L. Prospective studies evaluating arsenic exposure have reported an association between low to moderate arsenic levels and the occurrence of cardiovascular disease, especially coronary artery disease. Arsenic exposure is associated with ECG abnormalities, pericardial effusion, and myocarditis, as well as established cardiovascular risk factors such as hypertension, diabetes, and abnormal renal function (estimated glomerular filtration rate or albuminuria), supporting a causal role for arsenic in the development of cardiovascular disease.[43]

Other Environmental Toxins

Aluminum Phosphide.

Aluminum phosphide (AP) is an inorganic phosphide that is commonly used as an insecticide and rodenticide in grain storage and grain-processing facilities. Inhalation or ingestion of AP results in the generation of phosphine gas, which produces widespread organ toxicity and mortality in 37% to 100% of subjects. Cardiac toxicity from AP poisoning is characterized by myocarditis, refractory heart failure, and cardiac arrhythmias, including ventricular tachycardia.[44]

Thallium.

Thallium salts are toxic when inhaled, ingested, or absorbed through the skin. Gastrointestinal and neurologic symptoms of poisoning occur within 12 to 24 hours of a single toxic dose (>1 g in adults). Several weeks after acute exposure, individuals are predisposed to cardiac arrhythmias and sudden death.

Cardenolides.

Cardenolides are naturally occurring plant toxins that act primarily on the heart and cause serious dysrhythmias—including second- or third-degree heart block—and cardiac arrest. Poisoning with the digitalis cardenolides (digoxin and digitoxin) is reported worldwide. Cardiotoxicity from other cardenolides—such as the yellow, pink, or white oleander; sea mango tree; and coconut crabs—is a major problem in southern Asia. In India and Sri Lanka, yellow oleander has become a popular means of self-harm, with tens of thousands of ingestions annually and a case fatality ratio of 5% to 10%. Prolonged hospitalization and observation are recommended because the occurrence of dangerous dysrhythmias may be delayed for up to 72 hours after ingestion.

“Mad Honey.”

Honey produced from the nectar of rhododendrons growing on mountains of the eastern Black Sea region of Turkey may contain grayanotoxins, which bind to voltage-dependent sodium channels in the heart and thereby lead to bradycardia and atrioventricular block. Poisoning may present with ST elevation and

symptoms mimicking acute MI. Symptoms of “mad honey” poisoning (i.e., nausea, vomiting, hypotension, and syncope) occur a few minutes to several hours after ingestion of the honey, with the severity of the poisoning being dependent on the amount ingested. Grayanotoxins are metabolized and excreted rapidly, so the toxic effects of honey poisoning are rarely fatal and typically resolve in 2 to 9 hours.

Aconitine (Monkshood).

Aconite roots, most commonly from the monkshood plant, are commonly used in Chinese and Japanese herbal medications for treating subjects with musculoskeletal pain. Aconitine blocks the conduction of voltage-sensitive sodium channels in cardiac and nerve tissue, which results in the rapid onset of various gastrointestinal, neurologic, and cardiac symptoms, including paresthesias, muscle weakness, vomiting, hypotension, ventricular dysrhythmias, and refractory cardiovascular collapse. Enhancement of the transmembrane inward sodium current during the plateau phase of the action potentially prolongs repolarization in cardiac myocytes and results in afterdepolarizations with triggered automaticity, which underlies the ventricular dysrhythmias. Although ventricular arrhythmia is the most common electrocardiographic finding in acute aconitine poisoning, frequent ventricular ectopic beats, bundle branch block, sinus tachycardia, and sinus bradycardia have also been reported.

Scombroid.

Acute severe myocardial dysfunction secondary to histamine poisoning has been reported within 1 hour of the ingestion of spoiled scombroid fish, such as tuna or bonito. The flesh of these fish is rich in histidine, which is metabolized by gastrointestinal flora to histamine. The diagnosis is based mainly on clinical findings, but it can be documented by determination of histamine concentrations in the ingested fish or increased plasma histamine levels in the patient within 4 hours of fish ingestion.

Envenomations.

Black widow spider, bee, wasp, jellyfish, cobra, and scorpion envenomations have been associated with cardiac complications, including MI, acute cardiac failure, myocarditis, bradyarrhythmias, heart block, ventricular tachyarrhythmias, and sudden death. The mechanism or mechanisms by which these adverse outcomes occur include systemic release of catecholamines, cardiac ion channel modulation, coronary arterial vasoconstriction, and direct myotoxic effects.

Future Directions

Although adverse cardiovascular events have been associated with various medications, recreational drugs, and toxins, the precise mechanism of their effects is often unknown, and as a result, effective treatment is not established. This information is essential to avoid agents that interfere with specific molecular pathways that regulate cardiac function and to develop therapy that limits cardiotoxicity. When new medications are approved for use, postmarketing studies should be required to identify any cardiotoxic effects that may occur infrequently—and hence are not evident when the drug is studied in limited numbers of subjects—or only in the presence of concomitant conditions. For specific agents, such as chemotherapeutic compounds and antiretroviral agents, effective approaches to the identification of early (i.e., days to weeks) and late (months to years) cardiotoxic effects should be defined.

Cardio-Oncology

Bonnie Ky

Cardiovascular (CV) disease and cancer are two disease states that are associated with a substantial public health burden. There are an estimated 15 million people with CV disease and 14 million with a history of cancer, and there are risk factors and common biologic mechanisms shared by both of these disease states. The intersection of CV disease and cancer has led to the burgeoning discipline of cardio-oncology. This multidisciplinary field encompasses the care of patients with CV disease who develop cancer; cancer patients and survivors who are at risk for the development of CV disease secondary to cancer therapy; and cancer patients and survivors who develop overt CV disease. CV disease related to cancer therapy is often termed *cardiotoxicity*. The diseases encompassed by the term are not only heart failure (HF) and left ventricular (LV) dysfunction (the latter sometimes referred to as cancer therapeutics

cardiac dysfunction, or CTRCD),[1] but also a myriad of others, including hypertension (HTN) (**see Chapter 47**), myocardial ischemia (**see Chapter 61**), arrhythmia (**see Chapter 32**), pulmonary HTN (**see Chapter 85**), pericardial disease (**see Chapter 83**), valvular disease (**see Chapter 67**), peripheral vascular disease (**see Chapter 64**), and venous and arterial thrombosis.

The incidence and, thus, significance of cardiotoxicity with cancer therapy are believed to be growing. There are several reasons for this increase. First, cancer patients are living longer because they are receiving improved treatment regimens, so the observed "late effects" of cancer therapies are increasing. Second, cancer therapies are rapidly evolving, and new drug development has led to the increasing use of "targeted" strategies, many of which also affect fundamental signaling pathways that are necessary for cardiomyocyte and endothelial cell function and homeostasis. **Chapter 81** reviews the epidemiology, clinical manifestations, and pathophysiology of CV disease with commonly used chemotherapeutic agents, targeted therapies, hormonal therapy, and radiation therapy (RT) (**Table 81.1**). Care of the CV patient prior to, during, and after therapy and strategies to mitigate cardiotoxicity are also discussed.

TABLE 81.1

Cardiotoxic Effects of Cancer Therapies

AGENT	REPORTED CARDIOTOXIC EFFECTS	COMMENTS
Anthracyclines		
Doxorubicin, daunorubicin, epirubicin, idarubicin, mitoxantrone	Cardiac arrhythmias, CM, HF	Risk factors include cumulative dose, although genetic variation may confer increased risk at lower dosages; conventional CV risk factors and disease; additional cardiotoxic therapies, including RT or trastuzumab
Taxanes		
Paclitaxel	Arrhythmia, myocardial ischemia	May exacerbate risk of anthracycline cardiotoxicity secondary to pharmacokinetic effects
Alkylating and Alkylating-Like Agents		
Cyclophosphamide	Myopericarditis, arrhythmias	Rare; CV complications reported only at high dosages
Cisplatin, carboplatin, oxaliplatin	Endothelial dysfunction, arterial vasospasm, HTN	
Antimetabolites		
5-Fluorouracil, capecitabine	Coronary vasospasm, myocardial ischemia, infarction, arrhythmias, ECG changes, sudden death	May be related to endothelial injury, vasoconstriction, and vasospasm; typically managed with nitrates and calcium channel blockers
Monoclonal Antibody Tyrosine Kinase Inhibitors		
Bevacizumab	HTN, CM, HF, thrombosis	Low risk of CM or HF
Trastuzumab	CM, HF	Increased risk of CM and HF with anthracyclines; HTN, obesity, and borderline normal baseline LVEF are also established risk factors; many LVEF declines are reversible, but in approximately 20% of patients, reversibility is not seen
Pertuzumab	CM, HF	Risk of CM and HF remains incompletely defined, but thus far, it has been modest
Proteasome Inhibitors		
Bortezomib	CM, HF, edema	Reversible proteasome inhibitor
Carfilzomib	CM, HF, edema	Irreversible proteasome inhibitor; cardiotoxicity rates greater
Small-Molecule Tyrosine Kinase Inhibitors		
Sunitinib	HTN, CM, HF, thrombosis	Risk of HTN that tends to occur early; relationship between afterload and CM risk remains to be determined
Sorafenib	HTN, CM, ischemia, thrombosis	Risk of HTN; also associated with ischemia
Imatinib	CM, edema, pericardial effusion	Risk of CM very low
Nilotinib	Peripheral vascular disease, ischemic heart disease	
Ponatinib	Peripheral vascular disease, ischemic heart disease	
Dasatinib	Pulmonary HTN, pericardial effusion	
Immune-Modulating Agents		
Thalidomide	Edema, thrombosis, arrhythmia	
Lenalidomide	Edema, thrombosis, arrhythmia	
Immune check-point inhibitors	Myocarditis	
Androgen-Deprivation Therapy		
Leuprolide, goserelin, triptorelin, flutamide, bicalutamide	Metabolic syndrome, ischemia, coronary artery disease	
Estrogen-Receptor Modulators		
Tamoxifen	Thrombosis	Favorable effects on lipids
Aromatase inhibitors (anastrozole, letrozole, exemestane)	Hypercholesterolemia, HTN, combined end point of dysrhythmia, valvular disease, and pericarditis	
Radiation Therapy	Valvular disease, pericardial disease, vascular disease, ischemia, coronary artery disease, CM, HF	Major CV events tend to occur late, although early abnormalities in cardiac function and perfusion are observed

CM, cardiomyopathy; *CV*, cardiovascular; *ECG*, electrocardiogram; *HF*, heart failure; *HTN*, hypertension; *RT*, radiation therapy.

Epidemiology, Clinical Manifestations, and Pathophysiology of Cancer Therapy Cardiotoxicity

Traditional Chemotherapeutic Agents

Anthracyclines

Anthracyclines have been in use since the 1950s, are used widely in both adults and children, and are clearly associated with an increased risk of cardiotoxicity, primarily manifested as HF and LV

dysfunction. The American College of Cardiology and American Heart Association Heart Failure Guidelines have classified exposure to cardiotoxic therapies, such as anthracyclines, as stage A HF.[2] Reports of the incidence of anthracycline-associated cardiotoxicity have varied widely in the literature; in part, this may be because of variability in the definition of CV outcomes across retrospective analyses and the lack of systematic and rigorously ascertained longitudinal follow-up data, particularly in adults. Historically, cardiotoxicity has been classified as acute, subacute, or chronic,[3] although more recent studies have challenged this paradigm. Acute cardiotoxicity tends to occur early, during therapy, and is typically rare (≈1%), manifesting as arrhythmias, electrocardiogram changes, pericarditis, or possibly even myocarditis and HF. Estimates for subacute cardiotoxicity, which typically occurs within 1 year of therapy, and chronic (or late-onset) cardiotoxicity suggest a more frequent occurrence, with a reported incidence in the literature that varies widely, from 1.6% to 23%. Late-onset cardiotoxicity may occur 10 to 20 years after therapy, possibly in the setting of an additional stressor (i.e., a “second hit”). On an individual patient level, implicating cardiotoxic cancer therapy exposure as the cause of late-onset cardiomyopathy (CM) and HF often remains a diagnosis of exclusion.

More recent data have suggested an alternative paradigm regarding late cardiotoxicity.[4] A study of 2625 patients treated with anthracyclines followed over a median of 5.2 years (interquartile range [IQR] 2.6 to 8.0) with serial echocardiography monitoring (baseline, every 3 months during chemotherapy and the first year after chemotherapy, every 6 months for the following 4 years, and yearly afterward) noted the following. The overall incidence of cardiotoxicity, defined as a decrease in the LV ejection fraction (LVEF) of more than 10% from baseline to less than 50%, was 9%. In 98% of cases, cardiotoxicity was detected within the first year after chemotherapy had been completed, with a median time between the last dose of anthracyclines and the development of cardiotoxicity of 3.5 months (IQR, 3 to 6). In five patients, cardiotoxicity was detected after 5.5 years. The LVEF at the completion of chemotherapy and the cumulative anthracycline dose were independently associated with a risk of cardiotoxicity. A very small number of patients were hospitalized; the majority were managed as outpatients. HF therapy was initiated in all patients who developed cardiotoxicity, and 82% of the patients recovered their LVEF, either fully or partially. Overall, these findings might suggest a need for increased screening after completion of chemotherapy, and they challenge the notion of irreversible LVEF declines with early pharmacologic intervention.

Risk factors for cardiotoxicity include the dosage of the anthracycline. Retrospective analyses suggest an incidence of HF, as defined by clinical signs and symptoms, of 1.7% at a cumulative dose of 300 mg/m^2, 4.7% at 400 mg/m^2, 15.7% at 500 mg/m^2, and 48% at 650 mg/m^2.[3] It is notable that standard errors for many of these estimates are large, given the small sample sizes. More recent data from childhood cancer survivors also indicate that genetic variations in single-nucleotide polymorphisms modify the association between the anthracycline dose and CM risk.[5] In adults, additional clinical risk factors for anthracycline-induced cardiotoxicity include age (**Fig. 81.1**), traditional CV risk factors (HTN, diabetes, obesity, and hyperlipidemia), the presence of coronary artery disease or CM, prior chest RT, or additional cardiotoxic therapy.[5]

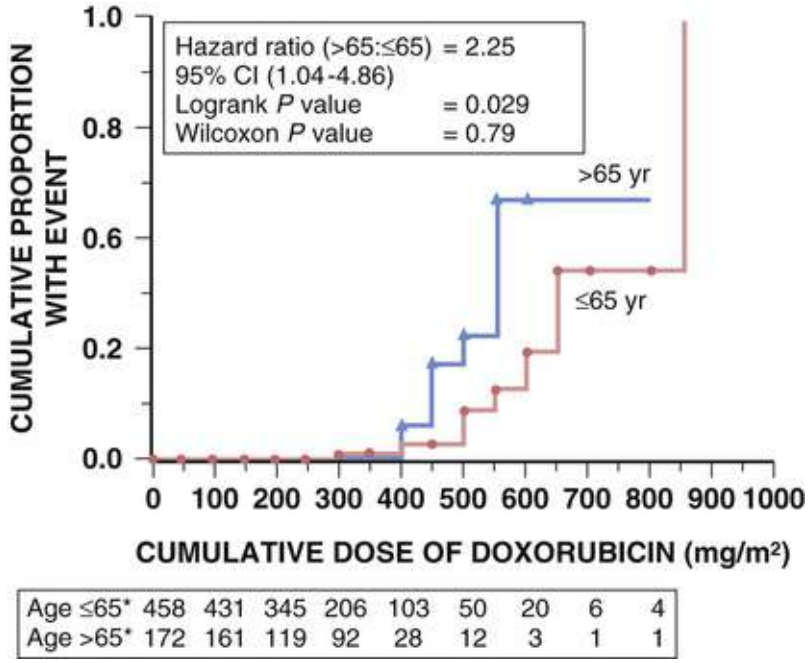

FIGURE 81.1 Risk of doxorubicin-associated heart failure by patient age and cumulative dose. The figure graphically depicts the cumulative doxorubicin dose at the onset of doxorubicin-associated heart failure in 630 patients according to patient age older or younger than 65 years. (From Swain SM, Whaley FS, Ewer MS: Congestive heart failure in patients treated with doxorubicin: a retrospective analysis of three trials. Cancer 2003;97:2869.)

Several basic mechanisms have been proposed to explain anthracycline-induced cardiotoxicity. The first is formation of reactive oxygen species (ROS) and increased oxidative stress via redox cycling of the quinone moiety of doxorubicin, formation of anthracycline-iron complexes, and topoisomerase-2β (Top2β) inhibition (**Fig. 81.2**).[6] Furthermore, anthracyclines have been shown to cause impaired calcium signaling and intracellular sequestration affecting myocardial relaxation; a decrease in cardiac progenitor cells; and alterations in neuregulin (NRG)/ErbB signaling.[6,7] Of these potential mechanisms, the most widely cited and accepted mechanism is the formation of ROS, leading to oxidative stress and subsequent injury to cardiac myocytes and endothelial cells.[6,7] The quinone moiety of the anthracycline enters cells and undergoes redox cycling, generating free radicals via both an enzymatic pathway involving the mitochondrial respiratory chain and also via a nonenzymatic pathway involving direct interactions between anthracyclines and intracellular iron. Toxic hydroxyl radicals from anthracycline-iron complexes act as cytotoxic messengers. This results in impaired mitochondrial function, cellular membrane damage, and cytotoxicity. Nitric oxide synthase (NOS) also contributes to the generation of anthracycline-mediated reactive nitrogen species, worsening nitrosative stress.

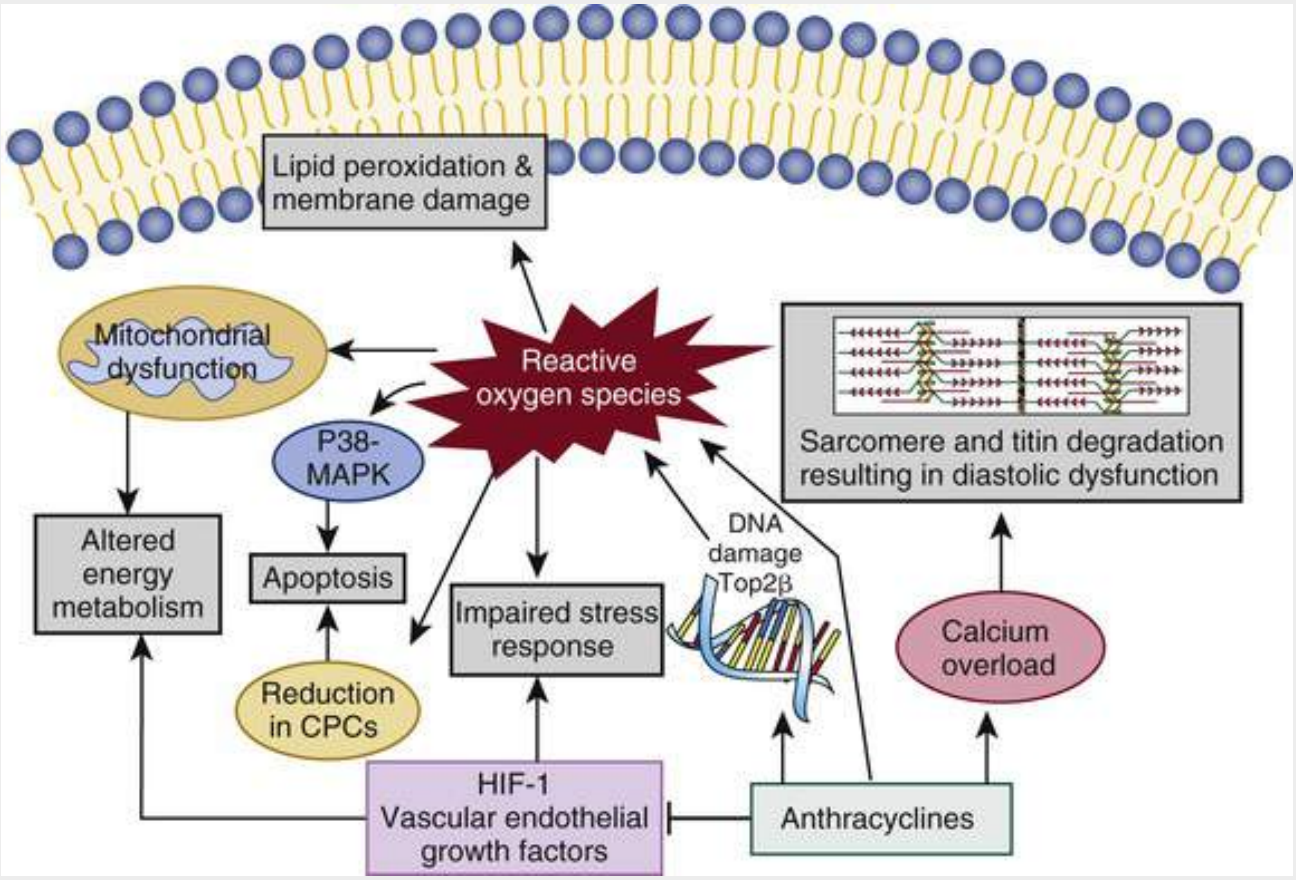

FIGURE 81.2 Proposed mechanisms of anthracycline cardiotoxicity. Using anthracyclines results in the generation of reactive oxygen species (ROS), potentially via topoisomerase 2β inhibition, as well as calcium overload, reduction in cardiac progenitor cells (CPCs), and hypoxia-inducible factor (HIF) inhibition.

More recent data suggest that the formation of ROS also occurs via the isozyme Top2, and, more specifically, Top2β, in cardiomyocytes.[6] Mice lacking Top2β are protected from anthracycline-induced DNA damage, cardiomyocyte death, and declines in cardiac function. These findings need to be further validated, but even now they suggest that this pathway may be a mechanism for engineering therapies that are less cardiotoxic and may be a tool for better stratifying the risk for individual patients. Interestingly, as discussed below, dexrazoxane, an iron chelator and cardioprotectant, binds to Top2β and results in Top2β degradation.

Data derived from in vitro and in vivo animal models support the hypothesis that anthracyclines also affect the population of cardiac progenitor cells, resulting in an impaired response to pathologic stress and injury repair. Anthracycline chemotherapy may also render cardiomyocytes more susceptible to alterations in NRG-1 and ErbB signaling and downstream prosurvival pathways.[6,7] NRG-1 administration is cardioprotective in the setting of anthracycline-induced cardiotoxicity, and conversely, NRG-1 heterozygotes have decreased survival rates and cardiac function with doxorubicin exposure as compared with wild types. A recent investigation using a modified bivalent NRG-1β demonstrated the potential for engineering NRG-1β to exploit its cardioprotective effects in the setting of doxorubicin cardiotoxicity, while reducing its possible proneoplastic effects.[7] In vitro studies have demonstrated an inhibitory effect of doxorubicin on hypoxia-inducible factor (HIF) and downstream pathways. Anthracyclines have been shown to result in impaired diastolic relaxation via calpain-dependent titin proteolysis.

Taxanes

The taxanes, paclitaxel (Taxol) and its semisynthetic analogue docetaxel (Taxotere), disrupt microtubular networks as their mechanism of antitumor activity. Used alone, these drugs have relatively little cardiotoxicity; there may be predominantly asymptomatic bradycardia and atrioventricular block.[8] However, when paclitaxel was given in close combination with high-dose doxorubicin, high rates of HF were observed (21%). This is believed to be secondary to alterations in doxorubicin metabolism when they are given with taxanes. Subsequent studies have demonstrated that limiting the doxorubicin dosages and separating the paclitaxel infusion time from the doxorubicin infusion time substantially decreased the risk of HF. Docetaxel given with anthracyclines is also reported to only mildly increase the risk of HF, again related to alterations in the pharmacokinetics and pharmacodynamics of anthracyclines.

Alkylating and Alkylating-Like Agents

Cyclophosphamide, used in the treatment of breast cancer and hematologic malignancies, is typically well tolerated. At higher dosages, greater than 100 mg/kg, there have been case reports of hemorrhagic myocarditis, tachyarrhythmias, HF, and pericardial disease.

Platinum-based agents, often considered alkylating-like agents, are commonly used in germ-cell testicular cancer, as well as ovarian, lung, and breast cancers and other solid tumors. Platinum cardiotoxicity has been perhaps most well studied in the testicular cancer population. Testicular cancer has high cure rates, and survivors often live 30 to 50 years after treatment, but they suffer from an increased long-term risk of CV events believed to be related to platinum therapy exposure. One epidemiologic study with a median observation time of 19 years reported a 5.7-fold increased risk of coronary artery disease and 2.3-fold increased risk of atherosclerotic disease as defined by coronary disease, cerebrovascular disease, and peripheral arterial disease in patients receiving platinum-based chemotherapy regimens compared with patients receiving no chemotherapy.[9] These effects were worsened in patients who received concomitant RT, and patients also had abnormal androgen levels. Some studies have also suggested that platinum is associated with endothelial damage, because plasma platinum levels remain detectable in patients up to 20 years after therapeutic exposure.

Antimetabolites

5-Fluorouracil (5FU) is used in the treatment of many solid tumors, including gastrointestinal, breast, head and neck, and pancreatic cancers. Specific CV effects include myocardial ischemia, which is the most common, as well as cardiac arrhythmias, HTN, hypotension, CM, and cardiac arrest. In vitro and in vivo studies suggest that 5FU is associated with endothelial injury, vasospasm and vasoconstriction, and interstitial fibrosis.

In one prospective study of 106 patients treated with 5FU, 9% (8.5%) had symptoms of cardiotoxicity, presenting primarily as angina and electrocardiographic changes.[10] Elevations in cardiac biomarkers such as N-terminal probrain natriuretic peptide (NT-proBNP) were also observed. These symptoms, often treatable with nitrates and calcium channel blockers, have historically been attributed to vasospasm, although the mechanism and pathophysiology remain poorly defined. The oral agent capecitabine (Xeloda), which is metabolized to fluorouracil, has also been associated with a 6.5% incidence of cardiac events, defined by angina in 4.6%, myocardial infarction, ventricular tachycardia, and sudden death.[8]

Additional Cancer Therapies

Proteasome Inhibitors

Proteasome inhibitors, such as bortezomib and carfilzomib, are used in the treatment of relapsed or refractory and newly diagnosed cases of multiple myeloma, a disorder characterized by an excess of bone marrow cells and monoclonal protein. Strategies to treat myeloma include the use of ubiquitin proteasome inhibitors; proteasome complexes are responsible for the degradation of the majority of regulatory proteins, including those that control cell-cycle progression, apoptosis, and DNA repair.[5] Cancer cells generally have higher levels of proteasome activity compared with normal cells, and are thus believed to be particularly susceptible to the proapoptotic effects of proteasome inhibitors. Protein homeostasis, however, is also hypothesized to play a role in the maintenance of cardiac function.[11] In patients with dilated CM, for example, oligomeric protein deposits are found in cardiomyocytes and are associated with increased cardiac stress. Both bortezomib, which results in reversible inhibition, and carfilzomib, an irreversible inhibitor, are associated with an incidence of HF of 4% and 7%, respectively; the incidence of cardiotoxicity is greater with carfilzomib.[5] Additional cardiotoxicities, such as HTN, diastolic dysfunction, increases in pulmonary pressures, elevations in natriuretic peptides, and worsened dyspnea, have also been observed with these therapies.

Immune-Modulating Agents

Immune modulatory agents such as thalidomide and lenalidomide are used in the treatment of multiple myeloma.[12] These agents are primarily associated with an increased risk of venous thromboembolic events, on the order of 2% to 4%, secondary to antiangiogenic effects and alterations in factors including thrombomodulin, von Willebrand factor antigen, and factor VIII. Reportedly, this incidence increases significantly when the agents are used in combination with other agents such as dexamethasone or anthracyclines. To mitigate the risk of thromboembolism, the International Myeloma Working Group recommends the use of aspirin, low-molecular-weight heparin, or warfarin with combination therapy, with the exact agent dependent upon the risk factor profile and the individual patient.

Immune check-point inhibitors are a newer class of agents used in a variety of solid tumors. These agents have been associated with a very low, but clinically significant, risk of myocarditis. Case reports of patients treated with both anti-CTLA-4 and anti-PD1 antibodies have described case fatalities secondary to marked cardiac compromise.

Targeted Therapies

The treatment of a number of malignant neoplasms has changed radically during the past few years with the advent of so-called targeted therapies. As opposed to traditional chemotherapeutics, which target basic cellular processes present in most cells, these therapies target factors that are specifically dysregulated in cancerous cells. It was hoped that this approach would reduce toxicities typical of standard chemotherapeutics (e.g., alopecia, gastrointestinal toxicity, myelotoxicity) and at the same time be more effective at treating the cancer. In some situations, this has been the case, but concerns about cardiotoxicity have surfaced for several agents.

ErbB Antagonists (Trastuzumab, Pertuzumab, T-DM1)

Trastuzumab is a humanized monoclonal antibody that binds subdomain IV of human epidermal growth factor receptor 2 (HER2)/neu, also known as ErbB2. Trastuzumab exerts its antitumor effects by blocking

HER2 cleavage, resulting in antibody-dependent, cell-mediated cytotoxicity and inhibition of ligand-independent, HER2-mediated signaling affecting the following downstream pathways: phosphoinositide 3-kinase (PI3K), serine/threonine-specific protein kinase Akt, mitogen-activated protein kinase (MAPK), and extracellular-signal–regulated kinase 1/2 (ERK1/2), and the mechanistic target of rapamycin (mTOR).[6] Trastuzumab also exerts antiangiogenic effects. First approved by the Food and Drug Administration (FDA) in 1998 for advanced metastatic cancer, it received expanded indications for early-stage HER2+ breast cancer in 2007.[13]

Phase III clinical trials with trastuzumab suggest that the risk of severe HF is low, on the order of 1.7% to 4.1%, but the risk of declines in LVEF are greater, on the order of 7.1% to 18.6%.[3,14,15] As a result, the FDA recommends cardiac monitoring every 3 months during trastuzumab therapy. Studies suggest that adherence to cardiac monitoring may be low, and some clinicians favor the notion that monitoring be performed only in high-risk individuals.[16] However, retrospective analyses from various large data sources, including the Surveillance, Epidemiology, and End Results (SEER) Program, the Cancer Research Network, and the Canadian health care system databases, indicate that the incidence of HF and CM development may be higher.[3] For example, analyses of SEER patients reported an incidence of HF of 41.9% at 3 years following combination therapy with anthracyclines and trastuzumab.[17] In the Cancer Research Network, there was a 20.1% incidence of HF and/or CM with combination therapy.[3] Data from the Ontario Cancer Registry suggest a 3- to 5-year risk of major cardiac events (HF hospitalization, urgent visit, outpatient diagnosis, or CV death) on the order of 4.8% to 5.2%.[18] As with anthracycline cardiotoxicity, hospital-based HF events occur less frequently, but patients treated with sequential anthracyclines and trastuzumab therapy are observed to have an increased risk (hazard ratio [HR], 3.96; 95% confidence interval [CI], 3.01 to 5.22), as do patients treated with trastuzumab alone (HR, 1.76; 95% CI, 1.19 to 2.60). The risk of HF and CM is greatest in the setting of sequential anthracycline and trastuzumab exposure, and additional risk factors for trastuzumab cardiotoxicity include the presence of obesity, a lower baseline LVEF, HTN, or diabetes; antihypertensive therapy; and increased patient age.

Importantly, LVEF declines with trastuzumab are largely reversible and occur during therapy. As a consequence, trastuzumab-associated cardiotoxicity was initially termed type II dysfunction by many, to distinguish it from anthracycline-associated cardiotoxicity, which was termed type I dysfunction.[3] This classification has largely fallen out of favor because of its oversimplification of the situation and because of the lack of strong evidence that the biologic underpinnings and clinical manifestations of anthracycline and trastuzumab cardiotoxicity are fundamentally distinct and do not overlap. Moreover, the reversibility of LVEF declines with trastuzumab is not universally observed. In the HERceptin Adjuvant (HERA) Trial, a phase III randomized trial of trastuzumab, approximately 20% to 30% of patients did not demonstrate LVEF recovery, and some patients suffered a subsequent decline in LVEF even after an initial recovery was noted.[14] Conversely, as noted above, LVEF recovery is observed with anthracyclines.[4]

Dose delays and interruptions have also been shown to be associated with worse overall survival rates, emphasizing the importance of the delivery of cancer therapy. The clinical determinants of LV recovery, as defined by an improvement in LVEF, have not been rigorously defined with trastuzumab, but observations suggest that temporary cessation of therapy and/or institution of cardiac medications (e.g., angiotensin-converting enzyme [ACE] inhibitors and beta blockers) are associated with recovery. Longitudinal data defining the changes in cardiac size and function over time suggest that measures of LV size, primarily end-systolic volumes; contractility (longitudinal and circumferential strain); and ventricular-arterial coupling (afterload) are independently associated with LVEF decline and recovery.

It is widely speculated that the cardiac dysfunction observed with trastuzumab is a direct consequence of ErbB2 inhibition in cardiomyocytes, but this remains to be definitively proven (**Fig. 81.3**).[6,7] Basic studies have been limited, in part, by the lack of robust systems to study the in vitro and in vivo effects of trastuzumab, a humanized antibody. The NRG/ErbB system functions as a paracrine and juxtacrine system between microvascular endothelial cells and cardiomyocytes. NRG-1 is expressed in vascular endothelial cells, and ErbB2 and ErbB4 are expressed in cardiomyocytes and endothelial cells. Recombinant NRG-1β activates ErbB2 and ErbB4 receptor phosphorylation in cardiomyocytes in vitro. Important downstream mediators, as noted above, include PI3K/Akt, MAPK/ERK, steroid receptor activator (Src)/focal adhesion kinase, and NOS. All of these pathways are fundamental for cardiac homeostasis, cell survival, mitochondrial function, cell growth, and focal adhesion formation. Mice with a cardiac-specific deletion of ErbB2 develop dilated CM and demonstrate exaggerated systolic dysfunction after pressure overload compared with wild-type mice. ErbB2 and ErbB4 expression is preserved during compensated hypertrophy, but it declines in the early stages of systolic dysfunction in mice subjected to pressure overload. Overall, these findings suggest that perturbations in ErbB receptor signaling are important in the maintenance of cardiac function. More recent data suggest that disruption of ErbB2 signaling results in endothelial dysfunction and an altered vascular phenotype, potentially contributing to the cardiomyopathic phenotype.

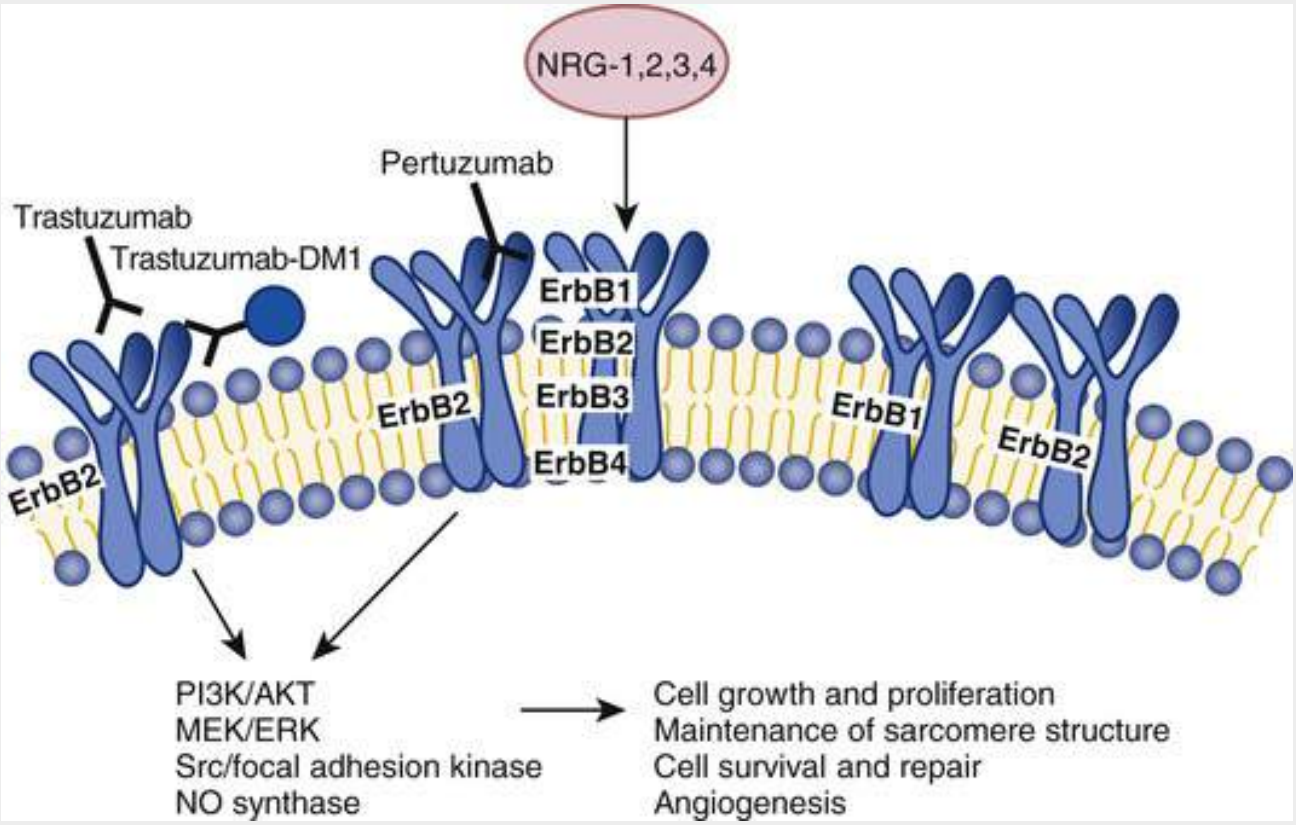

FIGURE 81.3 Proposed mechanisms of trastuzumab cardiotoxicity. Trastuzumab is hypothesized to result in perturbations of the neuregulin (NRG)/ErbB signaling pathway; this results in inhibition of fundamental cardiovascular signaling pathways, which are responsible for cell growth, maintenance of cardiomyocyte structure, cell survival, and angiogenesis.

There are a number of newer ErbB antagonists, including pertuzumab and ado-trastuzumab emtansine.

Pertuzumab is a humanized monoclonal antibody that binds HER2 at subdomain II of the HER2 extracellular domain[3]; it is administered in conjunction with trastuzumab. Pertuzumab also stimulates antibody-dependent, cell-mediated cytotoxicity, and prevents dimerization to other ligand-activated HER receptors, especially HER3. As with trastuzumab, clinical guidelines for pertuzumab suggest monitoring of cardiac function every 3 months. Although the CV effects are still being elucidated, clinical data to date have not demonstrated a substantial cardiotoxic signal. In the CLEOPATRA study of patients with HER2-positive metastatic breast cancer, the rate of LV dysfunction according to the Common Terminology Criteria for Adverse Events (CTCAE) was 6.6% in the pertuzumab group, compared with 8.6% in the control group. In the pertuzumab group, there was one event of symptomatic LV dysfunction that occurred at 40 months and resolved after 3 months with discontinuation of trastuzumab and pertuzumab. In the remainder of patients who suffered from declines in LVEF, the condition was largely reversible in most, but not all.

Trastuzumab emtansine (T-DM1) is an antibody-drug conjugate used in the treatment of metastatic breast cancer. The maytansine-derived cytotoxic agent, which is able to inhibit cell division and induce tumor cell death, is attached to trastuzumab by a stable thioether linker. The design facilitates the intracellular delivery of the drug to HER2 tumor cells. To date, no major signal for dose-limiting cardiotoxicity has been observed, although long-term data with larger numbers of patients are needed to define the risk of cardiotoxicity with greater certainty.

Tyrosine Kinase Inhibitors and Monoclonal Antibodies

Many of the targeted cancer therapeutics inhibit the activity of tyrosine kinases. Tyrosine kinases (TKs) attach phosphate groups to tyrosine residues of other proteins, thereby changing the activity, subcellular localization, and rate of degradation of the proteins. In the normal cell, these wild-type (i.e., normal) TKs play many roles in regulating basic cellular functions. However, in leukemias and cancers, the gene encoding the causal (or contributory) TK is amplified (leading to overexpression) or mutated, leading to a constitutively activated state that drives proliferation of the cancerous clonal cells or blocks their normal death.

Vascular Endothelial Growth Factor Receptor Inhibitors

Vascular endothelial growth factor receptor (VEGFR) signaling pathway inhibitors are used in the treatment of metastatic renal cell cancers; gastrointestinal stromal tumors; and thyroid, hepatocellular, and colon cancers; they are under active investigation for many additional indications. Bevacizumab is a humanized recombinant anti-VEGF antibody. The CV risks associated with bevacizumab include HTN; a low incidence of HF (on the order of 1.6%, but with a relative risk of 4.7 compared with placebo); and an increased incidence of arterial thromboembolic events (7.1% with bevacizumab versus 2.5% with chemotherapy alone). Sorafenib is a small-molecule TK inhibitor that blocks VEGFR, platelet-derived growth factor (PDGFR), and rapidly accelerated fibrosarcoma (Raf); it is used in the treatment of metastatic renal cell, thyroid, and hepatocellular cancers and other solid tumors. Sorafenib is associated with cardiac ischemia and HTN. Both bevacizumab and sorafenib have less pronounced cardiotoxic effects than sunitinib.

Sunitinib is a multitargeted oral TK inhibitor used in the treatment of metastatic renal cell carcinoma, gastrointestinal stromal tumors, and neuroendocrine tumors.[19,20] Recent studies have suggested its potential effectiveness in the adjuvant renal cell carcinoma setting. Axitinib and pazopanib are other small-molecule TK inhibitors that also affect the VEGFR signaling pathway. These antiangiogenic TK

inhibitors have been associated with HTN, CM and HF, cardiac ischemia, and arterial thrombotic events. Of these agents, we focus on describing the epidemiology and basic mechanisms of sunitinib, because it is the most well studied agent to date and is used widely in clinical practice. This discussion is also relevant to other TK inhibitors that have off-target effects on the VEGFR and PDGFR.

Sunitinib results in HTN, as well as declines in LVEF. In phase III trials and subsequent clinical experience, the incidence of HTN ranges from 5% to 47% and the incidence of significant LVEF declines is estimated to be on the order of 10%.[7] HTN secondary to sunitinib tends to occur early, with the median time to HTN (defined as a systolic blood pressure of ≥ 140 mm Hg or diastolic blood pressure of ≥ 90 mm Hg) occurring within 1 to 20 days of the first two cycles of sunitinib therapy. The incidence of systolic HTN in one pooled analysis was 58%, and of diastolic HTN was 48% by the end of cycle 1.[21] By the end of cycle 2, 80% had systolic HTN and 68% had diastolic HTN. The median (range) blood pressures were 160 (140 to 220) mm Hg over 98 (90 to 129) mm Hg in those with a history of HTN and 130 (100 to 139) mm Hg over 82 (59 to 89) mm Hg without a history of HTN. Prospective observational data suggest that the rate of LV dysfunction in the metastatic renal cell cancer population, as defined by declines in LVEF, is on the order of 10%. The majority of these events occur early after the initiation of therapy, primarily within the first 3 months, with a low risk of late cardiotoxicity. LVEF declines have also been observed to be reversible, although predictors of LVEF recovery remain to be defined. As sunitinib and other TK inhibitors gain more widespread use, maximizing tolerability and minimizing toxicity has become increasingly critical. The mechanisms of sunitinib cardiotoxicity are believed to be secondary to the inhibition of key signaling pathways critical to CV homeostasis, energy compromise, and increased afterload,[7] although the relative importance of each of these mechanisms remains unknown. Additional content on the mechanisms of sunitinib toxicity are presented in the online supplement titled Sunitinib Cardiotoxicity.

Bcr-Abl Targeted Therapies

Imatinib, the first targeted small-molecule TK inhibitor of the fusion protein Bcr-Abl, which arises from the chromosomal translocation that creates the Philadelphia chromosome, revolutionized the treatment of chronic myeloid leukemia. In vitro and in vivo murine studies first suggested a relationship between imatinib and CM.[22] Clinically, imatinib is associated with a low incidence of HF. Newer Bcr-Abl TK inhibitors have raised more substantive concerns. Dasatinib, with more potent activity than imatinib against Bcr-Abl, has been associated with significant pulmonary HTN that is observed to be largely reversible with cessation of the drug.[22] This finding prompted the FDA to recommend that patients be evaluated for cardiopulmonary disease prior to and during dasatinib treatment. Nilotinib and ponatinib have both been associated with peripheral vascular disease and ischemic heart disease. Moreover, nilotinib has been associated with cardiometabolic effects, including hyperglycemia and hyperlipidemia, and ponatinib with HTN likely related to VEGFR1-3 inhibition. Retrospective studies suggest the incidence of peripheral arterial disease is on the order of 1.3% to 6.2%, and the incidence of combined CV events, including ischemic heart disease, ischemic cerebrovascular disease, and peripheral arterial disease, may be on the order of 10% to 15.9%. The biologic mechanisms of cardiotoxicity remain unknown. Comprehensively deciphering the mechanisms of these kinase inhibitors remains challenging given their nonselectivity; they typically affect more than 30 different kinases.

Hormonal Therapy

Androgen Deprivation Therapy

In prostate cancer, androgen deprivation therapy (ADT) is used to reduce levels of androgens in the circulation and decrease prostate cell growth. Potential agents include gonadotropin-releasing hormone (GnRH) agonists, such as leuprolide, goserelin, and triptorelin, and antiandrogens, such as flutamide and bicalutamide. These therapies have adverse metabolic effects, and observational studies suggest that they result in increased body weight, decreased insulin sensitivity, and dyslipidemia. Changes in body composition occur early, within the first few months of therapy. Multiple cohort studies indicate an increased risk of CV events in men, including coronary disease, myocardial infarction, sudden cardiac death, or death due to CV disease.[23] Not all studies corroborate this effect, however, and this has resulted in the consensus amongst experts that it is "reasonable to state that there may be a relationship between ADT and CV events."[23] Recent literature suggests that the CV risk in patients treated with ADT may vary according to the comorbidity status, with ADT having a greater and worse impact on CV survival rates in patients who have greater CV and overall comorbidities.

Selective Estrogen Receptor Modulators and Aromatase Inhibitors

Tamoxifen is a selective estrogen receptor modulator widely used in adjuvant therapy for estrogen receptor–positive breast cancer. Data regarding the cardioprotective effect of tamoxifen have been conflicting. Tamoxifen does exert a favorable effect on lipids, with a reduction in total cholesterol and LDL levels. Some studies demonstrate a potential effect on decreasing the ischemic heart disease incidence, with a relative risk of 0.76 (95% CI, 0.60 to 0.95; $P = 0.02$),[24] although other studies demonstrate no significant effect. An increased risk of thromboembolic events, however, is well established; they occur largely during the first 2 years of exposure and in older women. A metaanalysis from the Early Breast Cancer Trialists' Collaborative Group confirmed a significant, but small, increased risk in venous thromboembolism with tamoxifen.

Aromatase inhibitors (e.g., anastrozole, letrozole, exemestane) block the conversion of androgens to estrogen. The two major classes that are currently in use differ according to their ability to bind reversibly versus irreversibly to aromatase. Data regarding the potential CV effects of aromatase inhibitors have been conflicting, but it is hypothesized that these agents inhibit the beneficial effects of estrogen related to the regulation of lipids, coagulation, antioxidant systems, and nitric oxide production. Aromatase inhibitors are associated with worse hypercholesterolemia and HTN, and a longer duration of exposure is associated with an increased risk of CV disease. Pooled data analyses from multiple large cohort studies suggest that there is a modestly increased risk of CV disease, as defined by myocardial infarction, angina, or HF, with aromatase inhibitors compared with tamoxifen (odds ratio [OR], 1.26; 95% CI, 1.10 to 1.43; $P < 0.001$).[25] A recent retrospective analysis of 13,273 postmenopausal women with hormone receptor–positive breast cancer without prior CV disease with a maximum follow-up of 21 years determined that compared with tamoxifen, aromatase inhibitors were not associated with an increased risk of cardiac ischemia or stroke. However, there was a nonsignificant association with HF and CM and a significant association with a combined outcome of dysrhythmia, valvular dysfunction, and pericarditis.[26]

Radiation Therapy

In the United States, where nearly 3 million women live with breast cancer, radiation therapy (RT) has been critical for improved cancer control and survival rates.[27] Despite these gains, incidental irradiation

to cardiac structures results in an increased risk of CV morbidity and mortality. The clinical manifestations of RT cardiotoxicity include coronary disease, CM and HF, valvular disease, arrhythmia, and pericardial disease. Increasing data suggest that early subclinical changes, including cardiac perfusion defects and cardiac strain abnormalities, occur earlier, within 6 months of RT, even with the use of modern techniques.

In a metaanalysis of over 23,000 women with breast cancer, there was an excess of deaths not resulting from breast cancer as early as 5 years following RT, principally due to CV disease and lung cancer.[28] Subsequent epidemiologic studies support these results. Retrospective analyses of 4456 women treated between 1954 and 1984 who had survived at least 5 years after breast cancer treatment were evaluated an average of 28 years after cancer therapy. A total of 3075 of these women had received RT, and 6% had chemotherapy exposure as well. Cardiac and vascular diseases were defined by ICD codes, and included pericarditis, myocarditis, valvular disease, ischemic heart disease, conduction disorders, HF, hypertensive disease, pulmonary heart disease, vasculocerebral disease, diseases of the arteries, and diseases of the circulatory system. In this study, RT was associated with a 1.76-fold increased risk of cardiac mortality and a 1.33-fold increased risk of vascular mortality. Patients with left-sided disease had a 1.56-fold increased risk of cardiac mortality compared with those with right-sided disease. SEER cancer registry analyses of 308,861 U.S. women with early breast cancer and RT also confirmed an increased risk of death in patients with left-sided versus right-sided disease.[28] A breast cancer study from 2013 suggests that the rate of major CV events increased linearly by 7.4% for each Gray (Gy) increase in mean RT dose to the heart.[29]

Similar studies in Hodgkin lymphoma survivors corroborate an association between the RT dose to the heart and the risk of CV disease that is progressive over time, increasing the risk of CV complications 3- to 5-fold compared with the general population. In a single-center, retrospective analysis of 1279 Hodgkin lymphoma survivors treated with mediastinal radiation, the cumulative incidence of cardiac disease increased from 2.2% at 5 years to 16% at 20 years.[30] Relative to healthy age-matched controls, the standard incidence ratio was 3.19 for coronary artery bypass surgery, 1.55 for percutaneous revascularization, 9.19 for valve surgery, 12.91 for pericardial stripping or pericardiocentesis, and 1.9 for defibrillator or pacemaker placement.

In addition to the cumulative RT dose, which represents a critical determinant of the development of cardiac disease, additional risk factors include the radiation field, younger age, higher number of fractions, concomitant chemotherapy (anthracyclines), CV risk factors (diabetes, tobacco use, obesity, HTN, and hypercholesterolemia), and preexisting CV disease.

Irradiation results in valvular disease with leaflet thickening, fibrosis, and calcification.[31] Left-sided valves are more commonly affected, particularly the aortic valve, followed by the mitral and tricuspid valves. Fibrosis and calcification of the aortic root, aortic valve annulus, aortic valve leaflets, aortic-mitral intervalvular fibrosa, mitral valve annulus, and the base and mid portions of the mitral valve leaflets typically occur. Sparing of the mitral valve tips and commissures has been noted, and used as a feature to distinguish radiation-induced valvular disease from other disease states, such as rheumatic heart disease. Regurgitation is more commonly encountered than stenosis, with the exception of the aortic valve, where stenotic lesions are reported to be more common. The reported incidence of significant valve disease is 1% at 10 years, 5% at 15 years, and 6% at 20 years, with the incidence increasing significantly at more than 20 years after radiation exposure. This risk is related to the RT dose. The pathophysiology of radiation-induced heart disease is believed to be associated with an increase in TGF-β and osteogenic factors, including bone morphogenetic protein 2, osteopontin, and alkaline phosphatase.

RT is also associated with the development of HF and CM. Diffuse myocardial fibrosis and

microvascular and macrovascular injury result in systolic and diastolic dysfunction, and can manifest as a restrictive CM phenotype. Regional wall motion abnormalities have also been noted. However, most imaging-based studies evaluating the longitudinal changes over time with RT remain small; the way in which microvascular disease and macrovascular disease impact the development of overt CM and the type of CM occurring remain unknown. On a microvascular level, irradiation results in endothelial cell loss and dysfunction, increased inflammation, and decreased capillary density. On a macrovascular level, there is proximal (ostial) involvement of coronary arteries, and lesions are fibrous, fibrocalcific, fibrofatty, and laden with cholesterol and lipid. A higher prevalence of perfusion abnormalities has been observed in left-sided compared with right-sided breast cancer patients, with an increase in disease in the left anterior descending artery territory. Irradiation also results in autonomic dysfunction, defined by an elevated resting heart rate and abnormal heart rate recovery. These abnormalities can lead to impaired exercise tolerance and an increased risk of death, independent of ischemic heart disease or LV dysfunction. Radiation-induced pericardial disease can occur acutely, as pericarditis and pericardial effusions. Pericardial thickening and constrictive pericarditis have also been noted, and can be delayed several weeks to years after radiotherapy.

Cardiovascular Care of the Cancer Patient

The approach to the CV care of an oncology patient is often classified as a continuum across three stages: prior to cancer therapy, during cancer therapy, and after completion of cancer therapy.[32] At each of these stages, priorities in cardio-oncology include the safe and effective delivery of oncologic therapy through the identification of patients at high risk for CV disease, the optimization of CV risk factors, and the careful management of CV disease (**Fig. 81.4**). Guidelines set forth by the American Society of Clinical Oncology (ASCO) recommend that prior to the initiation of therapies that can result in HF, clinicians should perform a comprehensive assessment that includes history taking and a physical examination, screening for and optimization of CV disease risk factors (HTN, diabetes, dyslipidemia, obesity, and smoking), and evaluation of cardiac function by echocardiography (**eTable 81.1**).

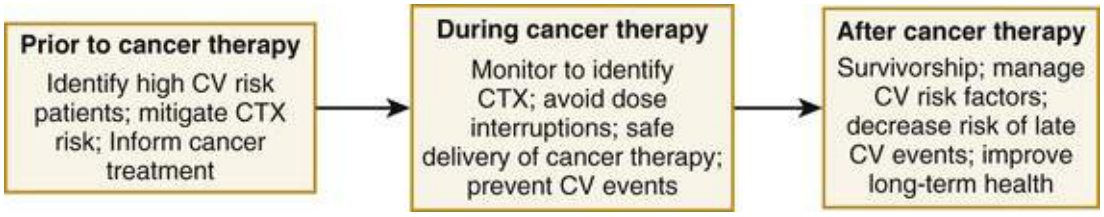

FIGURE 81.4 Approach to the cardiovascular care of the cancer patient. Care occurs along a continuum prior to, during, and after cancer therapy. At each of these stages, the goals are to minimize cardiovascular toxicity and maximize the effectiveness of oncologic therapy. *CTX*, cardiotoxicity; *CV*, cardiovascular.

Recommendations for Prevention and Monitoring of Cardiac Dysfunction in Survivors of Adult Cancers: ASCO Clinical Practice Guideline

RECOMMENDATION	EVALUATION OF EVIDENCE
Guideline Question 1: Which cancer patients are at increased risk for developing cardiac dysfunction?	

Recommendation 1.1
It is recommended that cancer patients who meet any of the following criteria should be considered at increased risk for developing cardiac dysfunction.
Treatment that includes any of the following:
• High-dose anthracycline (e.g., ≥ 250 mg/m^2 doxorubicin, ≥ 600 mg/m^2 epirubicin)
• High-dose (≥30 Gy) radiotherapy where the heart is in the treatment field
• Lower-dose anthracycline (e.g., < 250 mg/m^2 doxorubicin, < 600 mg/m^2 epirubicin) in combination with lower-dose radiotherapy (<30 Gy) where the heart is in the treatment field
• Treatment with lower-dose anthracycline (e.g., < 250 mg/m^2 doxorubicin, < 600 mg/m^2 epirubicin) or trastuzumab alone, and the presence of any of the following risk factors:
  • Multiple (≥2) cardiovascular risk factors, including smoking, HTN, diabetes, dyslipidemia, obesity during or after completion of therapy
  • Older (≥ 60 years) age at cancer treatment
  • Compromised cardiac function (e.g.. borderline low LVEF [50% to 55%], history of myocardial infarction, moderate or more severe valvular heart disease) at any time prior to or during treatment
• Treatment with lower-dose anthracycline (e.g., < 250 mg/m^2 doxorubicin, < 600 mg/m^2 epirubicin) followed by trastuzumab (sequential therapy)
	Evidence-based; benefits outweigh harms;
	evidence quality: intermediate;
	strength of recommendation: moderate

Recommendation 1.2 No recommendation can be made on the risk of cardiac dysfunction in cancer patients with any of the following treatment exposures: • Lower-dose anthracycline (e.g., < 250 mg/m^2 doxorubicin, < 600 mg/m^2 epirubicin) *or* trastuzumab alone, and no additional risk factors (as defined in 1.1) • Lower-dose radiotherapy (<30 Gy) where the heart is in the treatment field, and no additional cardiotoxic therapeutic exposures or risk factors (as defined in 1.1) • Kinase inhibitors	Evidence-based; evidence quality: low
Guideline Question 2: Which preventive strategies minimize the risk prior to initiation of therapy?	
Recommendation 2.1 Avoid or minimize the use of potentially cardiotoxic therapies if established alternatives exist that would not compromise cancer-specific outcomes.	Consensus-based; benefits outweigh harms; strength of recommendation: strong
Recommendation 2.2 Clinicians should perform a comprehensive assessment in cancer patients that includes a history and physical examination, screening for cardiovascular disease risk factors (HTN, diabetes, dyslipidemia, obesity, smoking), and an echocardiogram prior to initiation of potentially cardiotoxic therapies.	Evidence- and consensus-based; benefits outweigh harms; evidence quality: high; strength of recommendation: strong
Guideline Question 3: Which preventive strategies are effective in minimizing the risk during the administration of potentially cardiotoxic cancer therapy?	
Recommendation 3.1 Clinicians should screen for and actively manage modifiable cardiovascular risk factors (smoking, HTN, diabetes, dyslipidemia, obesity) in all patients receiving potentially cardiotoxic treatments.	Informal consensus– and evidence-based; benefits outweigh harms; evidence quality: insufficient; strength of recommendation: moderate
Recommendation 3.2 Clinicians may incorporate a number of strategies, including use of the cardioprotectant dexrazoxane, or continuous infusion, or liposomal formulation of doxorubicin for prevention of cardiotoxicity in patients planning to receive high-dose (e.g., ≥ 250 mg/m^2 doxorubicin, ≥ 600 mg/m^2 epirubicin) anthracyclines.	Evidence-based; benefits outweigh harms; evidence quality: intermediate; strength of recommendation: moderate
Recommendation 3.3 For patients who require mediastinal radiation therapy that might impact cardiac function, clinicians should select lower radiation doses when clinically appropriate, and use more precise or tailored radiation fields, with exclusion of as much of the heart as possible. These goals can be accomplished through use of advanced techniques, including: • Deep inspiration breath holding for patients with mediastinal tumors or breast cancer in which the heart might be exposed. • Intensity-modulated radiation therapy that varies the radiation energy while treatment is delivered in order to precisely contour the desired radiation distribution and avoid normal tissues.	Evidence- and informal consensus–based; benefits outweigh harms; evidence quality: intermediate; strength of recommendation: strong
Guideline Question 4: What are the preferred surveillance or monitoring approaches during treatment in patients at risk for cardiac dysfunction?	
Recommendation 4.1 Clinicians should complete a careful history and physical examination in patients who are receiving potentially cardiotoxic treatments.	Informal consensus–based; benefits outweigh harms; evidence quality: insufficient; strength of recommendation: strong
Recommendation 4.2 In individuals with clinical signs or symptoms concerning for cardiac dysfunction during routine clinical assessment, the following strategy is recommended: • Echocardiogram for diagnostic workup	Evidence-based; benefits outweigh harms; evidence quality: intermediate; strength of recommendation: strong
• Cardiac magnetic resonance imaging (MRI) or multigated acquisition (MUGA) scan if echocardiogram is not available or technically feasible (e.g., poor image quality), with preference given to cardiac MRI	• Evidence-based; benefits outweigh harms; evidence quality: intermediate; strength of recommendation: moderate
• Serum cardiac biomarkers (troponins, natriuretic peptides) or echocardiography-derived strain imaging, in conjunction with routine diagnostic imaging	• Evidence-based; benefits outweigh harms; evidence quality: intermediate; strength of recommendation: moderate
• Referral to a cardiologist based on findings	Informal consensus–based; benefits outweigh harms; evidence quality: insufficient; strength of recommendation: strong
Recommendation 4.3 Routine surveillance imaging may be offered during treatment in asymptomatic patients considered to be at increased risk (Recommendation 1.1) of developing cardiac dysfunction. In these individuals, echocardiography is the surveillance imaging modality of choice that should be offered. Frequency of surveillance should be determined by health care providers based upon clinical judgment and patient circumstances.	Evidence-based; benefits outweigh harms; evidence quality: intermediate; strength of recommendation: moderate
Recommendation 4.4 No recommendations can be made regarding continuation or discontinuation of cancer therapy in individuals with evidence of cardiac dysfunction. This decision, made by the oncologist, should be informed by close collaboration with a cardiologist, fully evaluating the clinical circumstances, and considering the risks and benefits of the continuation of therapy responsible for the cardiac dysfunction.	Informal consensus–based; benefits outweigh harms; evidence quality: insufficient
Recommendation 4.5 Clinicians may use routine echocardiographic surveillance in patients with metastatic breast cancer continuing to receiving trastuzumab indefinitely. The frequency of cardiac imaging for each patient should be determined by health care providers, based	Evidence- and informal consensus–based; benefits outweigh harms; evidence quality: low; strength of recommendation:

upon clinical judgment and patient circumstances.	moderate
Guideline Question 5: What are the preferred surveillance and monitoring approaches after treatment in patients at risk for cardiac dysfunction?	
Recommendation 5.1 Clinicians should complete a careful history and physical examination in cancer survivors previously treated with potentially cardiotoxic therapies.	Informal consensus–based; benefits outweigh harms; evidence quality: insufficient; strength of recommendation: strong
Recommendation 5.1.1 In individuals with clinical signs or symptoms concerning for cardiac dysfunction, the following approaches should be offered as part of recommended care:	Evidence-based; benefits outweigh harms; evidence quality: intermediate; strength of recommendation: strong
• Echocardiogram for diagnostic workup	
• Cardiac MRI or MUGA if echocardiogram is not available or technically feasible (e.g., poor image quality), with preference given to cardiac MRI	• Evidence-based; benefits outweigh harms; evidence quality: intermediate; strength of recommendation: moderate
• Serum cardiac biomarkers (troponins, natriuretic peptides)	• Evidence-based; benefits outweigh harms; evidence quality: intermediate; strength of recommendation: moderate
• Referral to a cardiologist based on findings	Informal consensus–based; benefits outweigh harms; evidence quality: insufficient; strength of recommendation: strong
Recommendation 5.2 An echocardiogram may be performed between 6 and 12 months after completion of cancer-directed therapy in asymptomatic patients considered to be at increased risk (Recommendation 1.1) of cardiac dysfunction.	Evidence-based; benefits outweigh harms; evidence quality: intermediate; strength of recommendation: moderate
Recommendation 5.2.1 Cardiac MRI or MUGA may be offered for surveillance in asymptomatic individuals if an echocardiogram is not available or technically feasible (e.g., poor image quality), with preference given to cardiac MRI.	Evidence-based; benefits outweigh harms; evidence quality: intermediate; strength of recommendation: moderate
Recommendation 5.3 Patients identified to have asymptomatic cardiac dysfunction during routine surveillance should be referred to a cardiologist or a health care provider with cardio-oncology expertise for further assessment and management.	Informal consensus–based; benefits outweigh harms; evidence quality: insufficient; strength of recommendation: strong
Recommendation 5.4 No recommendations can be made regarding the frequency and duration of surveillance in patients at increased risk (Recommendation 1.1) who are asymptomatic and have no evidence of cardiac dysfunction on their 6- to 12-month posttreatment echocardiograms.	Informal consensus–based; relative balance of benefits and harms; evidence quality: insufficient
Recommendation 5.5 Clinicians should regularly evaluate and manage cardiovascular risk factors such as smoking, HTN, diabetes, dyslipidemia, and obesity in patients previously treated with cardiotoxic cancer therapies. A heart-healthy lifestyle, including the role of diet and exercise, should be discussed as part of long-term follow-up care.	Evidence- and consensus-based; benefits outweigh harms; evidence quality: intermediate; strength of recommendation: moderate

Identifying Cancer Patients at Risk for Cardiovascular Disease

A growing body of research is focused on developing prediction tools to identify patients at increased risk of cardiotoxicity prior to overt disease.[33] It is widely accepted that exposure to potentially cardiotoxic therapies represents stage A HF, and as such, many of the clinical and research efforts have focused on mitigating the risk of development of overt HF and CM, and more specifically, early risk stratification.[2] In the following section, we will elaborate on the current data related to clinical and treatment risk factors, that is, the use of genetics, circulating biomarkers, and imaging indices prior to therapy. Clinical and treatment factors associated with a risk of CM and HF in cancer patients have been noted above (**see also Chapter 25**). Briefly, these include high-dose anthracyclines; high-dose chest RT; a combination of lower doses of anthracyclines and chest RT; CV risk factors, including tobacco use, HTN, diabetes, dyslipidemia, older age, and a history of CV disease; a borderline low LVEF (50% to 55%); and greater-than-moderate valvular disease.[3,14,34] Although this is an area of active investigation, there are no validated clinical risk prediction algorithms currently used to identify high-risk patients prior to the initiation of cancer therapy.

An additional tool that holds promise for identifying high-risk patients and can aid in our understanding of disease mechanisms is the use of genetic markers. Much of our current understanding of the genetics of anthracycline-induced cardiotoxicity has come from the study of childhood survivors; these studies implicate that polymorphisms in carbonyl reductase (CBR) and hyaluronan synthase 3 (*HAS3*) are independent modifiers of the anthracycline-related CM risk.[35] CBRs catalyze the reduction of anthracyclines to cardiotoxic alcohol metabolites, whereas the *HAS3* gene encodes for hyaluronan (HA),

a ubiquitous component of the extracellular matrix that plays a role in the tissue response to injury. Additional studies in childhood cancer survivors have identified polymorphisms in genes that regulate intracellular transport (*SLC28A3*, *SLC28A1*) of anthracyclines as independent predictors of CM risk.[36] A study of adult hematopoietic cell transplantation patients treated with anthracyclines identified an association between a polymorphism in the doxorubicin efflux transporter (*ABCC2*) and cardiotoxicity, suggesting an important role for alterations in anthracycline metabolism in the development of cardiotoxicity.[37] This study also identified *RAC2*, involved in free radical generation, and *HFE*, a regulator of iron metabolism, as risk modifiers. The causal role of genes implicated in familial dilated CM remains an area of active investigation, as does the use of patient-specific, human-induced, pluripotent stem cell–derived cardiomyocytes to characterize the genetic basis of anthracycline-induced cardiotoxicity.

Biomarkers, including established CV biomarkers such as troponin (Tn) and NT-proBNP, and more novel biomarkers, both individually and in combination, hold promise as aids for risk stratification (**see also Chapter 21**), but they are not yet recommended routinely or standardly evaluated prior to cancer therapy.[5] Imaging tools, such as echocardiography and multigated acquisition (MUGA) scanning, are used widely to screen for abnormalities in LVEF prior to cardiotoxic cancer therapies, because the baseline LVEF is associated with subsequent cardiotoxicity in studies of patients with breast cancer who are receiving anthracyclines and trastuzumab. Newer measures of cardiac mechanics, including strain imaging, with a large focus on longitudinal strain, and three-dimensionally derived measures of cardiac structure and function, have also been recommended by expert consensus groups as monitoring strategies prior to therapy, with a focus on evaluating the change over time as discussed below (**see also Chapter 14**).[1] Although baseline abnormalities in measures of longitudinal strain, prior to any cancer therapy, have not been demonstrated to be associated with a subsequent decline in LVEF, there are data to suggest that baseline abnormalities in circumferential strain and ventricular-arterial coupling are associated with subsequent cardiac dysfunction.[38] Studies in populations who do not have cancer have suggested that abnormalities in circumferential strain reflect an inherent vulnerability to cardiac dysfunction. These modalities are further described in the following section.

Cardiovascular Care of the Cancer Patient During Therapy

Multiple strategies, including cardiac biomarkers and imaging modalities, are used during cancer therapy to monitor patients. Cardiac troponins are sensitive and specific markers of myocardial injury and play an important role in the diagnosis of acute coronary syndromes. In cardio-oncology, troponin has been the most widely studied biomarker. The largest study to date has been of 703 patients treated with high-dose chemotherapy.[5] Here, patients underwent frequent TnI monitoring at multiple time points with each cycle of treatment (immediately after each cycle and 12, 24, 36, and 72 hours after each cycle) and 1 month after chemotherapy. The pattern of TnI elevation identified patients at various levels of risk for cardiotoxicity. Specifically, the highest cardiotoxicity event rate was observed among patients with early (within 72 hours) TnI elevation (≥ 0.08 ng/mL) that persisted at 1 month after treatment. A similar study performed in patients treated with trastuzumab demonstrated that elevated TnI was associated with a lack of LVEF recovery despite HF therapy. There have also been multiple reports on the use of TnI as a marker of cardiotoxicity with other treatment exposures (e.g., sunitinib, sorafenib, lapatinib). Validation of these findings in additional cohorts is an area of active investigation, and will be of absolute necessity prior to the widespread use of Tn as a standardized monitoring strategy in cancer patients undergoing cardiotoxic therapies. High-sensitivity Tn assays that provide superior diagnostic accuracy for acute coronary

syndromes are also under investigation for the early detection of cardiotoxicity. The natriuretic peptides brain-type natriuretic peptide (BNP) and NT-proBNP are standard biomarkers used in clinical practice for the diagnosis and management of HF.[2] However, conclusions regarding the role of natriuretic peptides for the prediction and diagnosis of cancer therapy cardiotoxicity remain conflicting. Some studies have demonstrated a significant association with cardiotoxicity, but others have not.

The 2016 European Society of Cardiology position statement suggests that biomarkers during cardiotoxic chemotherapy may be considered, although it also identified challenges in understanding the timing of laboratory assessment, use of different assays, definition of upper limit of normal, and interpretation and management strategies of abnormal values.[5] Moreover, the group noted that data are still needed to validate the use of biomarkers as a robust strategy for preventing or improving longer-term toxicity events. The ASCO guidelines has suggested that cardiac biomarkers (troponins, natriuretic peptides) be used in conjunction with routine diagnostic imaging in the evaluation of patients at risk for LV dysfunction during cancer therapy, noting that the benefits outweigh the harms and the quality of the evidence was intermediate (**see eTable 81.1**).[32] There is an ongoing body of work that evaluates the role of newer biomarkers in risk prediction. These include markers of oxidative and nitrosative stress, such as myeloperoxidase (MPO)[39] and asymmetric dimethylarginine (ADMA), and immunoglobulin E (IgE) in the study of anthracycline and trastuzumab cardiotoxicity.

As it pertains to the application of imaging tools for understanding the changes in cardiac function that occur with cancer therapy, there have been many small studies. Some have evaluated changes in conventional measures of diastolic function, which have not been shown to be strongly predictive of subsequent systolic dysfunction, although these studies are not definitive given the marked limitations in sample size.[1] Additional research has focused on imaging tools such as speckle tracking–derived longitudinal strain. Longitudinal strain has demonstrated promise as a measure of subclinical cardiotoxicity, and multiple small studies have reported that a decline in longitudinal strain is associated with a subsequent decline in LVEF.[1] Changes in circumferential strain are also associated with subsequent LVEF decline, with moderate discriminative ability.[38] The American Society of Echocardiography (ASE) expert consensus group has recommended the use of global longitudinal strain (GLS) for the early detection of cardiac dysfunction in patients with cancer undergoing cardiotoxic therapy, with a particular focus on change over time (**see also Chapter 14**).[1] There remains concern about variability in data, lack of robust cut points, limitations in technique (e.g., through plane motion), and lack of adequate expertise across clinical centers.[5] However, this is an area of active research, with ongoing studies aimed at understanding its prognostic and predictive value.

Cardiac magnetic resonance (CMR) imaging is another imaging modality used in the clinical and research evaluation of patients with cancer (**see also Chapter 17**).[1] CMR provides accurate and reproducible LV size and function assessment without ionizing electromagnetic radiation. CMR can also be used in the detection of myocardial masses and pericardial disease. An active body of research is evaluating the use of relaxation times (T1, T2, and T2*) to gain insight into changes in the myocardium in cancer patients exposed to cardiotoxic therapy.

Cardioprotective Strategies Before and During Therapy

There have been a number of studies evaluating the use of cardioprotective pharmacologic therapies prior to, during, and immediately after cancer therapy, in children and in adults, primarily anthracycline and/or trastuzumab therapy. An agent specific to the mechanisms of anthracycline cardiotoxicity (i.e., dexrazoxane, a derivative of the chelating agent ethylenediaminetetraacetic acid [EDTA]), is used as a

prophylactic strategy, largely in pediatric populations, although it is not currently approved by the FDA for this indication. Dexrazoxane may exert cardioprotective effects via a number of mechanisms. One long-standing hypothesis has been that dexrazoxane prevents ROS generation by binding and removing free and bound iron from the doxorubicin-iron complex. More recently, it has also been postulated that dexrazoxane inhibits Top2β, which, as described above, has been recently implicated as a mediator of anthracycline cardiotoxicity. Multiple clinical trials in children as well as adults have evaluated the use of dexrazoxane, with data overall suggesting a decrease in the incidence of HF and LVEF or a fractional shortening decline. However, its use has been limited by concerns over an increased risk of subsequent hematologic malignancies, including acute myeloid leukemia and myelodysplastic syndromes.

There are numerous ongoing studies evaluating the potential cardioprotective, prophylactic effects of conventional HF and CV pharmacologic therapies, including beta blockers, angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), aldosterone antagonists, and 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors.[34] These therapies have been administered prior to, during, or after anthracyclines or trastuzumab in adults and children. Again, most of the data related to these therapies are derived from small studies. Carvedilol and nebivolol have been studied in small, placebo-controlled randomized control trials of patients treated with anthracyclines.[40] Here, treatment with beta blockers was associated with an attenuation of the LVEF decline that was observed in the placebo group exposed to anthracyclines. Metoprolol individually has not been shown to have an effect in small studies, but in combination with ACE inhibitors, there was a modest beneficial effect on mitigating LVEF declines in patients with malignant hemopathies. Enalapril did not prevent LVEF declines when administered during chemotherapy but did decrease the risk of cardiac events when administered 1 month after high-dose chemotherapy in patients with TnI positivity. Two randomized, placebo-controlled studies of ARBs in breast cancer patients receiving anthracyclines with or without trastuzumab were recently published. One smaller, single-center study of 130 participants receiving anthracycline chemotherapy suggested that candesartan attenuated a very modest decline in LVEF (≈2% absolute percentage points) that had been observed in the group not receiving candesartan.[40] Another study of 206 breast cancer patients receiving anthracyclines and trastuzumab did not demonstrate any significant difference in cardiac events or LVEF in patients treated with candesartan as compared with patients given placebo.[41] Spironolactone was associated with a beneficial effect on LVEF and diastolic function measures in a small study of patients treated with anthracycline. HMG-CoA reductase inhibitors are associated with an attenuation of LVEF declines in patients with hematologic malignancies, and a trial in cancer patients treated with anthracycline is ongoing.

Limitations of these studies largely include a small sample size; lack of a consensus on the definition of a clinically relevant cardiotoxicity outcome; lack of generalizability; and questions about optimal timing of pharmacologic administration. As such, no expert consensus group currently recommends the use of prophylactic therapy without another CV indication (e.g., ACE inhibitor in a diabetic patient with HTN).[5] The potential cardioprotective effect of nonpharmacologic therapies, such as exercise and dietary modification, are also under active investigation. Although no specific exercise or diet-based guidelines exist in cardio-oncology, there is a biologic basis for the protective effects of exercise. One retrospective analysis suggested that a higher metabolic equivalent tasks-hour per week in cancer patients was associated with a lower risk of CV events.[42]

Cardiovascular Care of Cancer Survivors

Epidemiologic data from large cohort studies suggest that there are still an excess number of deaths

secondary to CV or circulatory causes in cancer survivors, although this risk is decreasing over time. Additional content on the epidemiology of cancer survivors is presented in the online supplement titled Care of Cancer Survivors. The Children's Oncology Group currently recommends CM and HF screening guidelines for survivors of childhood cancer based upon age, anthracycline dosage, and RT exposure.[43] They recommend screening by echocardiography or MUGA annually, biannually, or every 5 years, depending upon exposure (**Table 81.2**). Although the appropriateness of screening in survivors is widely accepted, the population and frequency of screening has recently been called into question given concerns about overutilization and cost-effectiveness. As a result, there have been efforts to harmonize recommendations for cardiomyopathy surveillance for survivors of childhood cancer.[44] The ASCO Guidelines on Survivorship Care recommend that clinicians regularly evaluate and manage CV risk factors such as smoking, HTN, diabetes, dyslipidemia, and obesity in patients previously treated with cardiotoxic cancer therapies (**see eTable 81.1**).[32] A heart-healthy lifestyle, including the role of diet and exercise, should be discussed as part of long-term follow-up care. The guidelines recommend that an echocardiogram be performed at 6 to 12 months after completion of cancer therapy in asymptomatic patients at increased risk for CV disease, but make no recommendations regarding continued surveillance. This recommendation is based largely on data described above, suggesting that most episodes of cardiotoxicity occur within the first year after anthracycline completion.[4]

TABLE 81.2

Children's Oncology Group Recommendations for Cardiac Monitoring

AGE AT TREATMENT	IRRADIATION WITH POTENTIAL IMPACT TO HEART	ANTHRACYCLINE DOSAGE (BASED UPON DOXORUBICIN)	RECOMMENDED FREQUENCY OF ECHOCARDIOGRAM OR MUGA SCAN
< 1 year old	Yes	Any	Every year
	No	< 200 mg/m^2	Every 2 years
		≥ 200 mg/m^2	Every year
1-4 years old	Yes	Any	Every year
	No	< 100 mg/m^2	Every 5 years
		≥ 100 to < 300 mg/m^2	Every 2 years
		≥ 300 mg/m^2	Every year
≥ 5 years old	Yes	< 300 mg/m^2	Every 2 years
		≥ 300 mg/m^2	Every year
	No	< 200 mg/m^2	Every 5 years
		≥ 200 to < 300 mg/m^2	Every 2 years
		≥ 300 mg/m^2	Every year
Any age with decrease in serial function			Every year

MUGA, multigated acquisition scanning.

Children's Oncology Group: Long-Term Follow-Up Guidelines for Survivors of Childhood, Adolescent, and Young Adult Cancers. Version 4.0., 2013. http://www.survivorshipguidelines.org/pdf/LTFUGuidelines_40.pdf.

Recent data from the St. Jude Lifetime Cohort Study of 1820 adult survivors of childhood cancer exposed to anthracycline chemotherapy or chest-directed RT, or both, suggest a high prevalence of subclinical dysfunction, with abnormal GLS (8%) and diastolic dysfunction (9.7%) despite a normal LVEF.[45] Abnormalities in GLS were associated with treatment exposure, including chest RT (dose response on the order of an increased RR of 1.38 to 2.39 with increasing dose), anthracycline dosages of more than 300 mg/m^2 (RR, 1.72), metabolic syndrome (RR, 1.94), and diastolic dysfunction (RR, 1.68). Another St. Jude study of 1853 survivors of childhood cancers with a median age of 31 years suggested that CM, as defined by an LVEF of less than 50%, was identified in 7.4%, coronary artery disease in 3.8%, and

arrhythmia in 4.6%.[46] Male sex, anthracycline dosages of 250 mg/m^2 or higher, cardiac radiation exposure or more than 1500 cGy, and HTN were associated with an increased risk of CM.

Management of HF or CM once it ensues largely follows established CV guidelines, including the use of various diagnostic and therapeutic strategies, such as pharmacologic and device therapies (**see guidelines for Chapter 25**).[2] Randomized clinical trials examining therapies specifically in cancer patients with CM have not yet been performed, and as such, the effectiveness of certain CV medications over others in this patient population remains largely unknown, as does the optimal duration of therapy. Of note, in one retrospective analysis of 201 cancer patients treated with anthracyclines who developed CM with a subsequent LVEF of 45% or less, institution of ACE inhibitors and beta blockers in combination was associated with a greater likelihood of recovery of the LVEF, as was institution of cardiac medications within 6 months of the detection of LV dysfunction.[47] Guidelines for the management of CV risk factors largely follow established CV guidelines, with no specific recommendations in cancer survivors. However, these are needed, because the observational data described above suggest that CV risk factors pose a markedly additive risk of CV disease in cancer patients as compared with controls.[2,48]

Future Perspectives

The field of cardio-oncology continues to evolve. The need for the dedicated CV care of cancer patients will continue to grow as both cancer and CV disease remain highly prevalent; as there is a growing population of survivors; and as newer cancer therapies affect fundamental CV signaling pathways, resulting in both subclinical and overt cardiotoxic effects. With this growth comes a call to (1) advance our understanding of the basic pathophysiologic mechanisms; (2) translate these findings to improve upon cancer therapeutics and cardioprotective strategies; (3) understand the epidemiology and natural history of cardiotoxicity and CV remodeling with cancer therapies; (4) develop robust mechanisms to identify high-risk CV patients; and (5) personalize the delivery of therapy to maximize its oncologic effectiveness and minimize its cardiotoxic potential. There is a great need for continued clinical and research education and expertise and collaborative efforts among cardiologists, oncologists, industry partners, patient advocates, and officials of the National Institutes of Health and FDA[33] so that a framework can be built to address gaps in knowledge and personalize the delivery of therapy by means of robust, evidence-based medicine.

Sunitinib Cardiotoxicity

Sunitinib blocks signaling pathways that play a crucial role in the maintenance of vascular and cardiac energy homeostasis, such as VEGFR 1-3, PDGFR α/β, c-Kit, and fms-like tyrosine kinase-3 (Flt3) pathways. The direct effects of vascular toxicity and increased afterload on cardiac function in the setting of sunitinib remain speculative to date. VEGF, a downstream target of HIF-1α, is a critical stress-induced cardioprotective mechanism.[1] The blockade of VEGF-VEGFR signaling in mice subjected to pressure overload results in a reduction in capillary density, impaired compensatory hypertrophy, LV dilation, and contractile dysfunction. In animal models of nonischemic CM, overexpression of VEGF led to attenuation of apoptosis and proapoptotic signaling pathways and delayed progression to HF after tachypacing. Exposure to sunitinib in animal models results in increased expression of genes involved in the hypoxia response, including cardiac prolyl hydroxylase domain–containing protein 3 (PHD3), which is important in the regulation of HIF-1α.

Sunitinib also inhibits PDGFR, which plays a critical role in cell survival and cardioprotection in the setting of pathologic stress.[2-4] In animal models, PDGFR-β is up-regulated in the setting of pressure overload stress, and mice with cardiac-specific deletion of PDGFR-β exposed to marked increases in afterload after transaortic constriction, suffered from greater LV dilation, worsened cardiac function, and pulmonary congestion compared with controls. The PDGFR-β knockout mice also show impaired activation of prosurvival signaling pathways and increased apoptosis after pressure overload, and decreased expression of proangiogenic genes. In vivo, sunitinib treatment led to coronary microvascular dysfunction, postulated to be secondary to a loss of pericytes. PDGFR inhibition impairs the growth and survival of pericytes, a type of cell that is closely associated with the microvasculature.

Sunitinib has also been shown to inhibit the stem cell growth factor receptor known as c-Kit or CD117, which is expressed by precursors for hematopoietic stem cells and endothelial progenitor cells, and is important for mobilization of these cells to sites of injury.[4,5] Reduced c-Kit kinase activity impairs injury repair after myocardial infarction.

In vitro and in vivo animal studies suggest that sunitinib therapy results in compromised myocyte energy homeostasis and inhibits the compensatory up-regulation of adenosine monophosphate–activated protein kinase (AMPK), which is critical in maintaining favorable myocardial energetics.[1] Sunitinib inhibits AMPK activity in mice; in cardiomyocyte culture, restoration of AMPK activity reduced cell death. Whether these findings translate to mechanisms in humans remain to be elucidated.

Care of Cancer Survivors

The British Childhood Cancer Survivor Study included 34,489 5-year survivors of childhood cancer diagnosed from 1940 to 2006, who were followed until 2014. These data suggest that there were 64.2 excess deaths per 100,000 person-years due to circulatory causes, a standardized mortality ratio of 3.8 (95% CI, 3.4 to 4.3), and an absolute excess risk of 3.6 (95% CI, 3.0 to 4.1).[1] In childhood cancer survivors age 60 years or older, circulatory causes exceeded secondary neoplasms as the cause for excess deaths (37% vs 31%).

Data from the Childhood Cancer Survivor Study (CCSS) indicate that the cumulative incidence of all-cause deaths in patients with cancer was 10.7% for those diagnosed in the 1970s, 7.9% for those diagnosed in the 1980s, and 5.8% for those diagnosed in the 1990s.[2] The cumulative incidence of death from a cardiac cause at 15 years decreased from 0.5% in patients treated from 1970 to 1974 to 0.1% in patients treated from 1990 to 1994. Although it is unknown if these reductions are attributable to safer delivery of cancer therapy and reduced exposure to cardiotoxic therapies or delayed presentation of CV disease, a reduction in treatment exposure was associated with a reduction in overall mortality rates in the CCSS data. Greater follow-up time is necessary to better understand the validity of this observation.[1]

The impact of CV risk factors in cancer survivors has been well studied. Traditional CV risk factors have been shown to have a more significant effect in survivors on the subsequent development of overt CV disease, as compared with controls who do not have cancer. Data from the CCSS suggested that in 10,724 5-year cancer survivors, the incidence of National Cancer Institute Common Terminology Criteria for Adverse Events (CTCAE) for grade 3 to 5 CV events, including coronary artery disease, HF, valvular disease, and arrhythmia, by 45 years of age was 5.3%, 4.8%, 1.5%, and 1.3%, respectively.[3] Siblings, in contrast, had a very low risk of any events, each less than 1%. The prevalence of CV risk factors such as HTN and dyslipidemia was also higher in survivors, as compared with siblings. HTN alone increased the risk of all CV events, and the combinations of risk factors that included HTN resulted in the highest rate ratios (e.g., HTN and diabetes rate ratio of 23.5 for coronary disease; 35.3 for HF). The excess risk secondary to cardiotoxic therapeutic exposure (anthracyclines, chest RT) was also most marked in survivors who developed HTN. The relative excess risk due to an interaction between HTN and chest radiotherapy was 27.9 for coronary disease and 18.3 for HF, and was also increased for valvular disease and arrhythmia. There was also a significant interaction between HTN and anthracyclines and the risk of HF. Additional studies in adult cancer survivors corroborate that there is a significant interaction between the association of CV risk factors and subsequent CV disease and death in cancer survivors compared with controls.[4]

Risk prediction algorithms, primarily based upon demographic variables and treatment characteristics, have been derived and validated by CCSS investigators.[5] Similar proof-of-principle risk scores have been developed in breast cancer patients with the use of SEER Medicare data to predict the 3-year risk of HF or CM by integrating clinical factors (including age; treatment regimen [anthracyclines, trastuzumab]; and the presence of HTN, diabetes, coronary artery disease, atrial fibrillation, and renal disease) for the prediction of subsequent HF and CM.[6] Other cardiac risk scores, incorporating only age and LVEF, have also been developed in breast cancer patients treated with adjuvant anthracyclines and trastuzumab to predict the 5-year risk of cardiac events (definite or probable cardiac death or HF associated with an absolute decrease in LVEF of > 10% from baseline to < 55% or a decrease of > 5% to a value < lower limit of normal).[7] Many of these risk scores relevant to the breast cancer population, in particular, have not yet been externally validated and are not in routine clinical use.

Cardiovascular Abnormalities in HIV-Infected Individuals

Priscilla Y. Hsue, David D. Waters

More than 37,000,000 people, including 2,400,000 in Europe and North America, were living with human immunodeficiency virus (HIV) infection or acquired immunodeficiency syndrome (AIDS) in 2015.[1] The introduction of highly active antiretroviral therapy (ART) beginning in 1996 dramatically decreased the HIV-related mortality rates, and the trend toward decreasing mortality rates has persisted since then.[2] As a consequence, by 2015 half of all HIV/AIDS patients in the United States were age 50 years or older. Projections from European cohorts such as the Dutch ATHENA Cohort predict that by the year 2030, 73% of individuals living with AIDS will be age 50 years and older and 84% of HIV-infected individuals will have an age-related noncommunicable comorbidity, such as cardiovascular (CV) disease, diabetes, kidney disease, osteoporosis, or cancers not related to AIDS. With improving longevity, non-AIDS conditions are now accounting for the majority of deaths among individuals receiving ART, and CV disease has become an increasingly significant problem in the HIV population. Deaths due to CV disease among individuals living with HIV have ranged from 6.5% to 15% of total deaths, depending on the cohort studied.[3,4]

The mechanisms underlying CV disease in HIV patients are largely poorly understood but are known to be multifactorial. They include many traditional risk factors and also factors related to HIV, such as the side effects of antiretroviral medication. These effects are significant and include metabolic issues, immune activation, chronic inflammation, microbial translocation, and coinfection with other viral pathogens such as cytomegalovirus.[5] Such mechanisms are ongoing even when HIV infection has been treated; the CD4 count and HIV viral load may be controlled, but the infection has not been cured. Viral replication continues within HIV reservoirs, leading to a continued need for ART and continued abnormal immune function and chronic inflammation; all of these factors underlie CV disease as well as other comorbidities observed in HIV infection.[6]

This review will focus on CV manifestations of HIV infection, with particular emphasis on CV risk factors and coronary heart disease (CHD). In developed countries, ART has transformed HIV infection into a chronic disease state; cardiologists should be aware of HIV-associated CV diseases, along with the unique issues they pose in this clinical setting.

Cardiovascular Risk Factors in HIV Patients

Traditional coronary risk factors are more common in HIV patients, particularly those receiving ART, than in noninfected persons (**see Chapter 10**). Dyslipidemia, metabolic syndrome, hypertension, and cigarette smoking are all more prevalent in HIV patients, leading to higher calculated 10-year Framingham Risk Scores in this group than in noninfected controls. In a Danish cohort, age-associated comorbidities, including hypertension, angina pectoris, myocardial infarction (MI), peripheral arterial disease, and CV disease, were all significantly more common among HIV-infected individuals than controls.[7]

Lipid Abnormalities

The early stages of untreated HIV infection are characterized by lipid abnormalities (**see Chapter 48**), such as low- levels of high-density lipoprotein (HDL) cholesterol, hypertriglyceridemia, and low- levels of low-density lipoprotein (LDL) cholesterol with predominantly small, dense LDL cholesterol particles.[8] After initiation of ART, LDL and total cholesterol levels increase but HDL cholesterol levels remain low, particularly if protease inhibitors are used.[9] In the Swiss HIV Cohort Study, hypercholesterolemia and hypertriglyceridemia were 1.7 to 2.3 times more common among patients taking protease inhibitors than

in patients not taking them. Thus, the overall effect on lipids of HIV infection is an atherogenic lipid profile with a reduction in HDL cholesterol and an increase in triglycerides, oxidized LDL cholesterol, and small, dense LDL cholesterol. The prevalence of hyperlipidemia in HIV patients is 28% to 80% in different studies, with the commonest abnormality being hypertriglyceridemia.

Most HIV drugs have the potential to increase LDL cholesterol levels, but important differences exist among drug classes and among drugs within classes.[10] Protease inhibitors increase triglyceride levels, with ritonavir being the worst culprit; in some cases it may cause extreme hypertriglyceridemia exceeding 1000 mg/dL. The lower doses of ritonavir used nowadays result in less hypertriglyceridemia, but increased triglyceride levels are also seen with ritonavir-saquinavir and ritonavir-lopinavir combinations. Atazanavir has less effect on triglyceride levels. Second-generation protease inhibitors, the integrase inhibitor raltegravir and the entry inhibitor maraviroc, have favorable effects on lipid profiles, particularly in comparison with older forms of ART.[10] Tenofovir alafenamide (TAF), a newer formulation of tenofovir disoproxil fumarate (TDF) that was approved by the Food and Drug Administration (FDA) in November of 2015, has been associated with higher levels of total cholesterol, LDL cholesterol, and HDL cholesterol than those in individuals treated with TDF; total cholesterol/HDL ratios remain unchanged.[11]

Lipodystrophy and the Metabolic Syndrome

Lipodystrophy is a syndrome characterized by fat accumulation in the dorsocervical region and an increase in or preservation of visceral fat, with subcutaneous and peripheral fat loss, resulting in relative central adiposity (**see Chapter 49**). Lipodystrophy develops in 20% to 35% of patients after initiation of ART, particularly in those who have taken protease inhibitors and the nucleoside reverse-transcriptase inhibitors stavudine and didanosine. Newer protease inhibitors such as atazanavir do not appear to induce lipodystrophy.

Lipodystrophy in HIV patients is commonly associated with features of the metabolic syndrome (**see Chapter 49**). Specifically, these features are insulin resistance, impaired glucose tolerance, elevated triglycerides, low HDL cholesterol levels, and hypertension. The reported prevalence of the metabolic syndrome in HIV patients has varied from 8.5% to 52%, with rates at the higher end of this range reported in Latin American countries and rates at the lower end in multicenter studies where patients had less exposure to ART.[12] Progression to metabolic syndrome is common in the first 3 years after initiation of an ART regimen that includes stavudine or lopinavir/ritonavir, but is less common with newer drugs. Most studies indicate that the presence of metabolic syndrome is a predictor for CV disease and death in HIV patients.[12]

Diabetes

Whether HIV infection is associated with an increased incidence of diabetes has been controversial (**see Chapter 51**). The protease inhibitors indinavir and lopinavir/ritonavir can cause insulin resistance, as do the thymidine analogs, particularly stavudine.[12] However, these drugs are no longer recommended for initial treatment of HIV because of their toxicities. In a recent large cohort study from Denmark, the risk of diabetes irrespective of ART use reported from 1996 to 1999 was nearly three times that of the general population; this increased risk was no longer seen from 1999 to 2010, however.[13] The study found that indinavir, saquinavir, stavudine, and didanosine were associated with an increased risk of diabetes, a finding that could partly explain the difference in risk in the two periods. These drugs are rarely part of modern ART.

Another recent study, from the South Carolina Medicaid system, found little difference in the incidence of diabetes in 6816 patients infected with HIV and an equal number of uninfected adults matched for age, sex, and race between 1994 and 2003; from 2004 to 2011, however, HIV patients had a lower incidence of diabetes than uninfected controls.[14] Exposure to protease inhibitors was associated with a higher risk of diabetes (adjusted relative risk, 1.35; 95% confidence interval [CI], 1.03 to 1.78). Other factors may play a role in the development of diabetes, including chronic inflammation, worsened control of HIV disease, hepatitis C virus coinfection, and autoimmune destruction, along with demographic factors such as older age and male gender.

Smoking

Smoking is common among HIV patients. In a recent large cohort study from Denmark, nearly half of HIV patients were current smokers, compared with one fifth of noninfected individuals.[15] Rates of death from all causes, including factors not related to AIDS, were substantially increased among smoking HIV patients compared with nonsmoking HIV patients. A 35-year-old HIV patient had a median life expectancy of 62.6 years (95% CI, 59.9 to 64.6) if a smoker and 78.4 years (95% CI, 70.8 to 84.0) if a nonsmoker. More life-years were lost in association with smoking than with HIV (12.3 life-years [95% CI, 8.1 to 16.4] compared with 5.1 life-years [95% CI, 1.6 to 8.5]). The population-attributable risk of death associated with smoking was 61.5% among HIV patients and 34.2% among controls. Studies modeling the impact of risk factor modification among individuals with HIV have demonstrated that smoking cessation, plus reduced lipid levels and reduced blood pressure, decrease the relative risk of CV disease; there is also an increase in risk associated with age.[16]

Smoking cessation strategies appear to have the same modest success rates in HIV patients as in noninfected individuals. A metaanalysis of eight trials in 1822 HIV smokers showed that behavioral interventions increased abstinence with a moderate effect size (relative risk [RR],1.51; 95% CI, 1.17 to 1.95).[17] Potential drug-drug interactions of ART with pharmacotherapies for smoking cessation have not been completely evaluated in HIV-infected individuals. An alternate approach is to train HIV care physicians to provide smoking cessation counseling and treatment. In one center in the Swiss HIV Cohort Study, all medical staff competed a structured half-day workshop on treatment for nicotine dependence.[18] Subsequently, rates of smoking cessation were significantly increased and rates of smoking relapse reduced relative to comparison institutions, with cessation rates higher among individuals with CV risk factors.

Hypertension and Chronic Kidney Disease

The prevalence rates of hypertension (**see Chapter 47**) and chronic kidney disease (**see Chapter 98**) have been reported to be higher in HIV patients than in the general population; this finding is not consistent, however, and may be influenced by a variety of factors, including the type of ART a patient is taking. Both hypertension and prehypertension have been shown to increase the risk of MI in HIV patients, just as they do in uninfected persons.[19] A prospective cohort study demonstrated that among individuals with normal renal function,[20] the incidence of chronic kidney disease increased among individuals exposed to TDF or one of two protease inhibitor regimens, atazanavir/ritonavir or lopinavir/ritonavir.[21] Similarly, chronic kidney disease expressed as either albuminuria or a depressed glomerular filtration rate (GFR) has been associated with an increased risk of CV events in HIV-infected individuals.[22] As in individuals without HIV, the baseline impaired eGFR is strongly related to CV disease, as demonstrated

in a cohort of more than 35,000 HIV-infected individuals.[20] A risk score model for development of chronic kidney disease among HIV-infected individuals has been proposed; it includes both HIV-related and traditional components.[23]

Atherosclerosis in HIV Patients

The underlying mechanism whereby HIV infection accelerates atherogenesis is incompletely understood, but it appears to be a combination of direct viral effects, effects of ART and associated metabolic changes, immune activation and chronic inflammation, and coinfection with other viral pathogens, along with traditional risk factors (**Fig. 82.1**). Regarding direct viral effects, low-level transcription of HIV genes may continue even after years of ART.[24] The HIV-encoded proteins transactivator of transcription (tat) and negative factor (nef) induce inflammation and endothelial dysfunction. Additionally, the HIV envelope protein gp-120 has been linked to higher endothelin-1 levels. Thus, the HIV virus itself may promote atherogenesis by releasing low levels of proteins. Only one controversial report has demonstrated the presence of HIV in the endothelium; in contrast, most studies show that the impact of HIV on the endothelium is likely due to downstream effects of the virus, such as chronic inflammation.

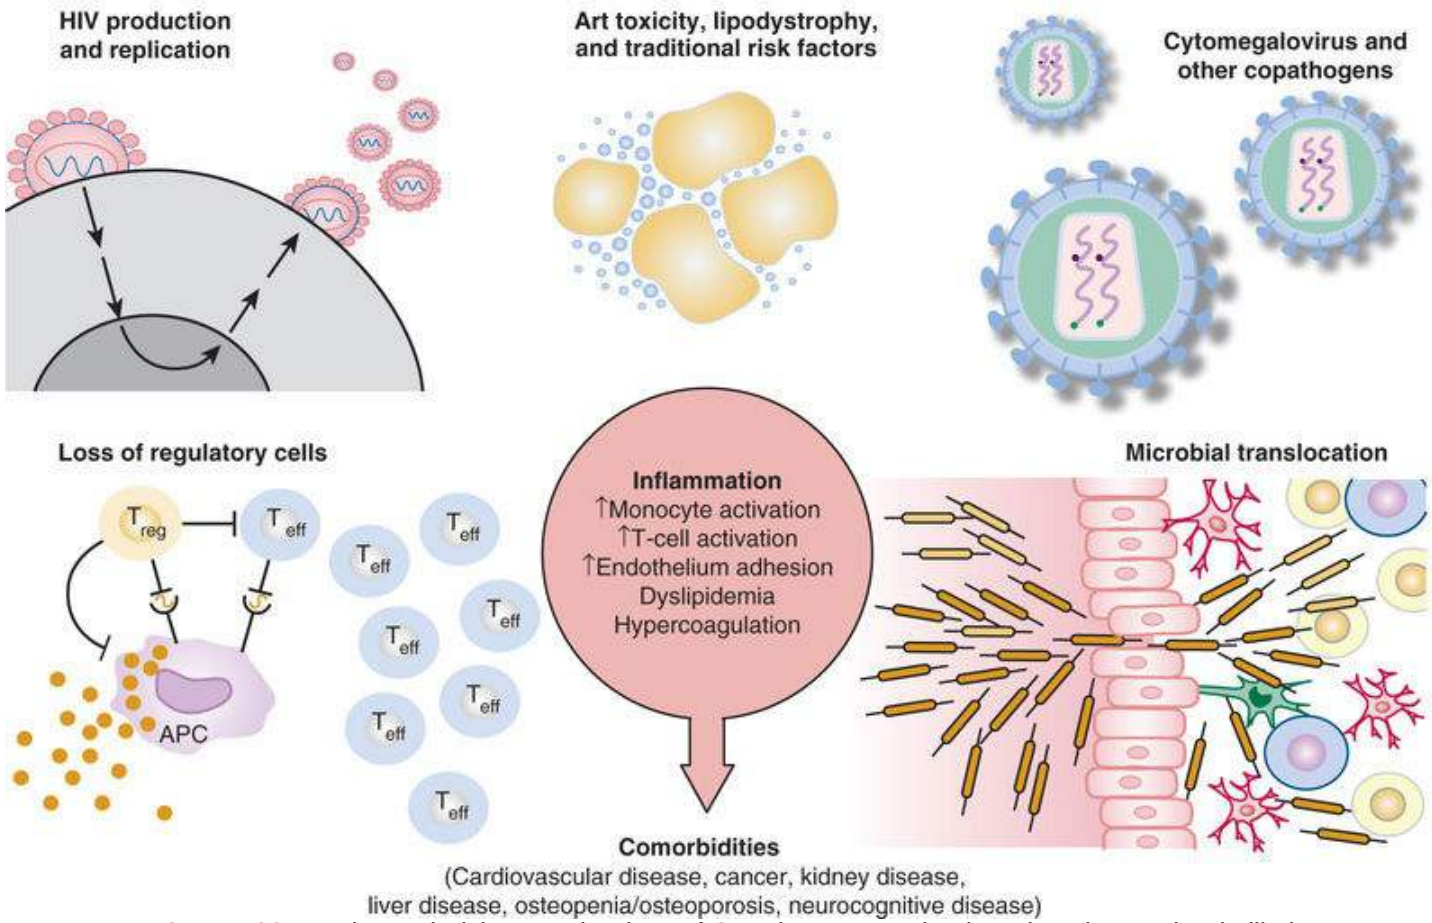

FIGURE 82.1 The underlying mechanism of CVD in HIV remains largely unknown but is likely multifactorial, as shown in the figure. It includes ongoing viral replication, side effects from ART, traditional risk factors, coinfection with other viral pathogens, immune activation, and microbial translocation in the gut. All of these factors may increase inflammation in the setting of treated and suppressed HIV disease, resulting in monocyte activation, dyslipidemia, hypercoagulability, vascular disease function, and end-organ disease, not only in the heart but in other systems, as shown above. (From Deeks SG, Lewin SR, Havlir DV:. The end of AIDS: HIV infection as a chronic disease. Lancet 2013;382(9903):1525-33.)

ART drugs, particularly the older drugs, may promote atherosclerosis by mechanisms in addition to dyslipidemia. Protease inhibitors induce reactive oxygen species and endothelial cell apoptosis.[24] Nucleoside reverse-transcriptase inhibitors increase platelet reactivity, and non-nucleoside reverse-transcriptase inhibitors cause monocytes to adhere to the vascular endothelium.

Chronic inflammation and T-cell activation play a central role in the development of atherosclerosis.[5,25] Untreated HIV-infected individuals have very high levels of T cells, and even after successful treatment with ART, higher-than-normal T-cell levels persist. T-cell activation leads to higher levels of inflammatory markers, such as interleukin-6, D-dimer, and high-sensitivity C-reactive protein. As established by the Strategies for Management of Antiretroviral Therapy (SMART) Study (a study of continuous vs. intermittent ART), these higher levels of inflammatory and coagulation markers are independent predictors of CV events[26] and fatal CV disease in the setting of treated HIV infection.[27]

Monocytes and macrophages are critical to the pathogenesis of HIV disease,[28] as well as atherosclerosis; for this reason, they may also play a unique role in HIV-associated CV disease. Activated monocytes have been shown to accelerate the progression of carotid atherosclerosis, and their presence predicts the progression of coronary artery calcium (CAC) in HIV.[29] In a study where aortic inflammation was assessed by ^{18}fluorine-2-deoxy-D-glucose positron emission tomography (18F-FDG-PET), HIV patients had higher levels of aortic inflammation than controls and the degree of aortic inflammation

correlated with a circulating marker of monocyte and macrophage activation, sCD163.[30] Monocytes from HIV patients and from patients without HIV infection but with an acute coronary syndrome have been shown to share a procoagulant phenotype; this suggests another mechanism whereby monocytes in HIV patients might drive atherosclerosis.[31]

The CD4 count and viral load also influence the CV risk. The CD4 count nadir predicts subclinical carotid atherosclerosis, and a low CD4 count with ART has been associated with an increased risk of CV disease. A low CD4 count was independently associated with an increased prevalence of carotid plaques in one study, and in another, the CD4 nadir of 350 cells/mm^3 or less was correlated with arterial stiffness. Such data suggest that earlier initiation of ART may be beneficial (see Strategic Timing of AntiRetroviral Treatment [START] Study below). Other studies have shown that initiation of HIV medication improves endothelial function but does not restore it to normal and that higher viral loads correlate with worsened endothelial dysfunction as measured by brachial artery flow–mediated dilation.

In the current era of HIV management, the link between immune depression and CV events may be attenuated. For example, no association was found between immune depression, a lower CD4 count, and CV events in a recent report from the Data Collection on Adverse Events of Anti-HIV Drugs (D:A:D) Study.[32]

Many biomarkers predictive of CV events in uninfected cohorts are elevated in HIV patients, reflecting endothelial dysfunction, procoagulant changes, fibrinolytic effects, increased activation of platelets, and inflammation. Levels of endothelial cell–derived markers such as von Willebrand factor antigen are elevated, particularly in patients with a high viral burden or advanced disease. Circulating levels of intercellular adhesion molecule-1 (ICAM-1) and vascular adhesion molecule-1 (VCAM-1) are elevated in HIV patients compared with uninfected controls; levels were directly related to the degree of inflammation as assessed by soluble receptor type 2 for TNF-alpha (s-TNFR2). Increased inflammation as assessed by cytomegalovirus-specific T-cell responses is associated with higher levels of carotid intima–media thickness (IMT).

HIV infection is associated with high levels of interleukin-6, D-dimer, and high-sensitivity C-reactive protein; levels remain elevated in treated and suppressed HIV disease,[33] a finding demonstrated in multiple studies of different cohorts. These biomarkers are strong predictors of non-AIDS events,[34] including increased rates of CV events,[26] increased risk of CV disease[35] and deaths due to CV disease,[27] and increased rates of all other causes of mortality, in HIV patients.[36] Markers of myocardial stress, such as ST2, growth differentiation factor (GDF)-15, and N-terminal pro–B-type natriuretic peptide (NT-proBNP), also are predictors of mortality in HIV patients.[37]

Chronic activation of the immune system in HIV infection may also be due to microbial translocation in the gastrointestinal tract, leading to elevated levels of circulating microbial products such as lipopolysaccharide. Residual microbial translocation during suppressive ART is associated with the degree of immune reconstitution, as reflected by CD4 T-cell count recovery. A marker of the monocyte response, sCD14, has been linked to increased mortality rates in HIV patients.[38] Therapies that reduce the impact of microbial gut translocation, specifically rifaximin and sevelamer, have failed to show a significant effect on microbial translocation in HIV patients.[39,40]

Because HIV and CV disease have such a multifactorial impact on a patient, it has been difficult to determine, and is still unclear, which biomarker may be best for predicting the CV risk in HIV infection.

Features of Coronary and Carotid Atherosclerosis That May Be Unique to HIV Patients

Atherosclerosis in HIV patients may be a distinctive pathologic entity from the atherosclerosis seen in the general population (**see Chapter 48**). Autopsy studies have reported that coronary atherosclerosis in young HIV patients resembles transplant vasculopathy (**see Chapter 28**), or that it is characterized by diffuse, circumferential vessel involvement with proliferation of smooth muscle cells mixed with abundant elastic fibers. In addition, calcification of the internal elastic media has been described in HIV patients.

Cardiac computed tomography (**see Chapter 18**) has provided insight into the features of coronary disease in HIV patients.[41] The prevalence of coronary artery calcification by cardiac computed tomography was not higher in HIV patients than in controls across seven studies. However, CT angiographic studies reveal that noncalcified plaques are much more common in HIV patients.[42] In a metaanalysis of nine studies that included 1229 HIV patients and 1029 controls, the prevalence of coronary stenosis (> 30% or > 50%) or calcified plaques did not differ between the two groups.[43] However, noncalcified plaques were more than three times more likely to be present in HIV patients (58% compared with 17%). Noncalcified plaques are more likely to be lipid laden, inflammatory, and prone to rupture. High-risk features of plaque have also been reported in the setting of HIV.[44]

In non-HIV cohorts, carotid IMT is associated with prevalent CV disease and risk factors, as well as an increased risk of future stroke and MI. Many observational studies have measured carotid IMT in individuals with HIV and in controls. As shown in **Fig. 82.2**, the carotid IMT of individuals with HIV was, on average, 0.04 mm thicker (95% CI, 0.02 to 0.06 mm; $P < 0.001$) than that of uninfected controls in a metaanalysis.[41] This conclusion should be viewed with caution because of differences among the studies in population characteristics, study designs, sample sizes, length of follow-up, and ultrasound techniques used. Carotid plaque has also been found to be more common in HIV patients compared with uninfected controls across six studies.[41] Interestingly, carotid IMT has been shown to be an independent predictor of mortality in HIV.[45]

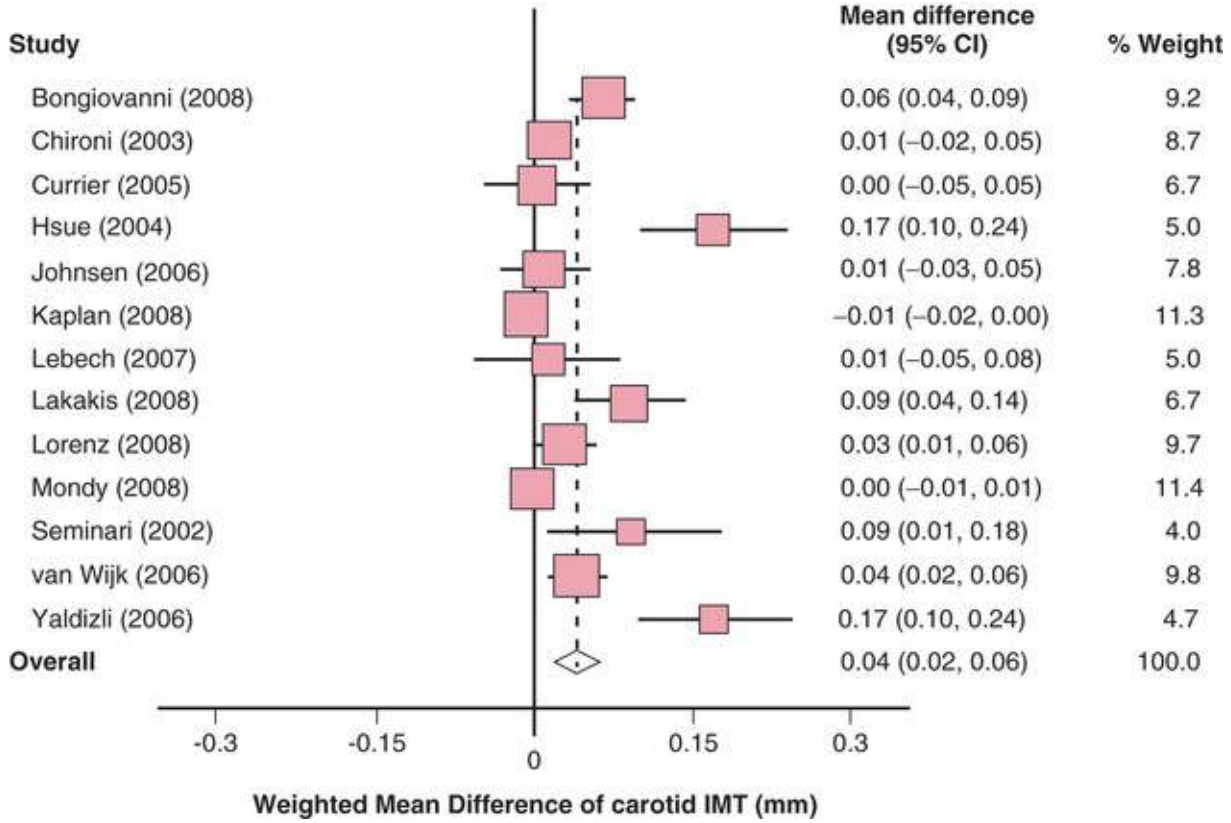

FIGURE 82.2 Differences in carotid IMT by HIV status. Metaanalysis of 13 studies evaluating the associations between HIV status and carotid intima–media thickness (IMT). The carotid IMT of individuals with HIV infection was, on average, 0.04 mm thicker (95% CI, 0.02 to 0.06 mm; $P < 0.001$) than that of individuals without HIV infection. *WMD*, weighted mean difference. Coronary Disease in HIV Patients

Epidemiology

The first case reports of MI in HIV-infected patients taking ART began to appear in 1998 (**see Chapter 58**). Since these initial reports, many observational studies have reported higher rates of CHD among HIV-infected individuals. For example, the Veterans Aging Cohort Study followed 55,109 uninfected and 27,350 HIV-infected persons for 5.9 years.[46] The risk of MI was increased in HIV-infected patients for each decade of age from the 30s to the 70s. After adjusting for Framingham risk factors, comorbidities, and substance use, HIV-positive veterans had an increased risk of MI compared with uninfected veterans (hazard ratio [HR], 1.48; 95% CI, 1.27 to 1.72). An excess risk remained among virally suppressed patients compared with uninfected veterans (HR, 1.39; 95% CI, 1.17 to 1.66). The impact of HIV on risk was comparable to traditional risk factors, including hypertension, diabetes, and hyperlipidemia. Many other observational studies confirm an increased risk of CHD in HIV-infected individuals of about 1.5- to 2-fold when compared with uninfected controls.

The risk of ischemic stroke (**see Chapter 65**) was also increased in HIV-infected men compared with uninfected persons in the Veterans Aging Cohort Study (incidence rate ratio [IRR] 1.25; 95% CI, 1.09 to 1.43; $P < 0.01$).[47] After adjusting for demographic factors, ischemic stroke risk factors, comorbid diseases, and substance use, the risk of ischemic stroke was attenuated but still higher among HIV-infected men (HR, 1.17; 95% CI, 1.01 to 1.36; $P = 0.04$).

The relative contributions of HIV infection itself and the adverse effects of ART to CHD risk have been

a topic of controversy. There is general agreement that the risk of CV events increases with increasing duration of ART. On the other hand, a randomized trial clearly demonstrated that continuous ART was associated with fewer CV events than intermittent ART. Initiation of ART in treatment-naïve patients improves markers of atherosclerosis such as endothelial function. The increased risk of CV events with intermittent ART and the improvement in markers of risk with initiation of therapy strongly suggest that HIV itself increases the risk for CV disease. However, the risk remains elevated in virally suppressed individuals, either because of the consequences of infection or of ART, or both.

Individual antiretroviral drugs have been linked to an increased risk of CV events, specifically, indinavir, lopinavir-ritonavir, didanosine, and abacavir.[48] The nucleoside reverse-transcriptase inhibitor abacavir has been particularly controversial in this regard. In 2008 the D:A:D Study reported a 90% increase in MI risk in HIV-positive individuals receiving ART regimens that included abacavir. This risk was particularly evident among current or recent abacavir users. In more than a dozen studies published since then, most, but not all, have confirmed an association. In a recent report of 49,717 D:A:D participants, abacavir use was still associated with an increase in MI rate (RR, 1.98; 95% CI, 1.72 to 2.29).[49] This effect has been attributed to the propensity of the drug to induce platelet hyperreactivity. Other mechanisms have been postulated, which include endothelial dysfunction and leukocyte and endothelial cell interactions. Atazanavir, which causes hyperbilirubinemia, was associated with lower IMT progression compared with other HIV regimens.[50]

Clinical Presentation

The clinical presentation of acute coronary syndrome differs in HIV patients compared with uninfected individuals (**see Chapters 59 and 60**). HIV patients are on average more than a decade younger than uninfected persons and are more likely to be men, to be current smokers, and to have low HDL cholesterol levels. Their risk scores tend to be lower and they are more likely to have single-vessel than multiple-vessel coronary artery disease. In general, HIV patients hospitalized with acute coronary syndrome have excellent immediate outcomes.

In earlier studies, HIV patients had substantially higher rates of restenosis after percutaneous coronary interventions with bare metal stents, compared with uninfected patients. Restenosis in HIV patients has been associated with higher C-reactive protein levels and higher levels of CD8+ T cells.[51] More recent studies, in which most patients received drug-eluting stents, show similar medium-term outcomes between HIV patients and matched controls.[52] A report from the Nationwide Inpatient Sample detected no increase in in-hospital mortality rates among 9771 HIV-infected patients undergoing cardiac surgery, including coronary bypass, compared with matched uninfected controls.[53] Long-term outcome studies after coronary bypass surgery have not been reported in large cohorts of HIV patients. Using a U.S. inpatient discharge database, the Nationwide Inpatient Sample, the percentage of HIV-infected individuals undergoing CV surgeries increased from 0.09% to 0.23%, and individuals with HIV were not at increased risk for death while inpatients, although they were more likely to require blood transfusion and have postoperative complications.[53]

Some data indicate that HIV patients with acute coronary syndromes have been less likely than uninfected patients to receive investigations and treatments that have been shown in uninfected patients to reduce mortality rates and recurrent events. For example, in a U.S. Nationwide Inpatient Sample from 1997 to 2006, comparing nearly 6000 HIV MI patients with more than 2.5 million uninfected MI patients, only 48% of HIV patients underwent coronary arteriography, compared with 63% of noninfected patients.[54] This discrepancy occurred despite a younger age and more comorbidity in the HIV group. It is

likely that HIV patients with acute coronary syndromes likely now receive more aggressive treatment; indeed, in the large D:A:D database, mortality rates from CHD declined between 1999 and 2000 and 2009 and 2011.[2] In addition, the type of MI may be distinct in HIV. Using type I (atherothrombotic) and type II (demand-related) classifications for MI, more than 40% of MIs in a North American cohort of HIV-infected individuals were classified as type II,[55] a finding that may underlie some of the conflicting data regarding patient characteristics, outcomes, and predictors in the setting of HIV that have been reported in the literature.

As with acute coronary syndromes, the clinical features of ischemic stroke differ in HIV patients compared with uninfected individuals. HIV stroke patients tend to be younger and to be male. The risk factors for ischemic stroke in the general population (i.e., hypertension, diabetes, smoking, and dyslipidemia) are also risk factors for stroke in HIV patients.

Treatment

The treatment of CHD in HIV-infected individuals should largely be guided by existing recommendations for uninfected patients because clinical trial data for treatment in HIV patients is insufficient. However, two aspects specific to HIV-infected patients deserve mention: (1) the potential contribution of ART to CV disease and (2) the treatment of hyperlipidemia in HIV disease, for which separate recommendations have been devised.

Antiretroviral Therapy and Cardiovascular Disease

Since ART first became available in the 1990s, the indications for treatment and specific drug regimens have evolved rapidly. In earlier years, when the benefits of ART were more limited and treatment-related adverse effects were more common, it was recommended that the drugs not be used until patients were at increased risk of immunosuppression. More recent studies suggest that the chronic immune stimulation and inflammation that accompany early asymptomatic HIV infection can result in long-term morbidity. Thus, whereas treatment was initially restricted to patients with low CD4 counts, it is now widely accepted that treatment should be started in all individuals with HIV infection with detectable viremia irrespective of the CD4 cell count.[56] Initiation of ART is recommended as soon as possible in the setting of acute HIV infection because initiation prior to the development of HIV antibody positivity reduces the size of the latent HIV reservoir, reduces immune activation, and may protect against infection of central memory T cells. Early initiation of ART as compared with deferred initiation has been beneficial with respect to AIDS-related and non-AIDS–related events; this benefit did not reach significance for CV outcomes, however.[57] The impact of early ART on CV disease and CV risk in HIV remains unknown.

Planned discontinuation of early ART after a specific treatment duration is not recommended, because the benefits do not persist and the subsequent viral rebound is associated with increased clinical events and the potential for transmission.[56] Initiation of ART in “elite controllers” (defined as patients with confirmed HIV infection and persistent undetectable HIV RNA without ART) remains controversial.

What combinations of drugs are recommended for initial therapy? The integrase strand transfer inhibitor agents (InSTIs) have taken a key role as first-line therapy because they are highly effective, with higher, more rapid rates of virologic suppression compared with protease inhibitors and non-nucleoside reverse-transcriptase inhibitors, the previous mainstays of ART. InSTIs have the additional advantage of being extremely well tolerated. The relative advantages and disadvantages of the three available InSTIs are listed in **Table 82.1**.

TABLE 82.1

Integrase Strand Transfer Inhibitors

	DOLUTEGRAVIR	ELVITEGRAVIR	RALTEGRAVIR
FDA Approval	2013	2012	2007
Advantages	Superior to efavirenz and ritonavir-boosted darunavir Once-daily dosing Pill size is small Lowest risk of resistance with virologic failure Relatively few drug interactions Can be taken with or without food Superior to raltegravir in treatment-experienced patients	Superior to ritonavir-boosted atazanavir in HIV-infected women Once-daily dosing	Superior to ritonavir-boosted atazanavir and ritonavir-boosted darunavir Longest safety record Fewest drug interactions Can be taken with or without food
Disadvantages	Raises serum creatinine due to inhibition of tubular secretion of creatinine Higher rates of insomnia and headache than comparators in some studies	Requires pharmacokinetic boosting with cobicistat or ritonavir for once-daily dosing Most drug interactions Cobicistat raises serum creatinine due to inhibition of tubular secretion of creatinine Should be taken with food	Must be taken twice daily Not coformulated as part of a complete regimen

Adapted from Nordell AD, McKenna M, Borges ÁH, et al: Severity of cardiovascular disease outcomes among patients with HIV is related to markers of inflammation and coagulation. J Am Heart Assoc 2014;3(3):e000844.

Recommended initial ART regimens for most patients are dolutegravir/abacavir/ lamivudine, dolutegravir plus TAF/emtricitabine, elvitegravir/

cobicistat/TAF/emtricitabine, and raltegravir plus TAF/emtricitabine (a slash separating components indicates that the components are available as coformulations.).[56] Up to 96% of patients who remain in care and receive ART have undetectable plasma HIV RNA levels.

Abacavir is a component of the recommended regimen of dolutegravir/ abacavir/lamivudine. Approximately half of individuals who are positive for the HLA-B*5701 allele experience a hypersensitivity reaction to abacavir that may be life threatening. In one large prospective study, PREDICT-1, 5.6% of patients tested positive. It is recommended that HLA-B*5701 testing be performed prior to abacavir use and those who test positive should not be given abacavir.[56]

An association between abacavir and an increased risk of MI is supported by several, but not all, studies.[49] Thus, current guidelines recommend that abacavir be used with caution in patients who have or are at high risk for CV disease.[56]

Several non–InSTI-containing regimens suppress HIV RNA in most patients who adhere to therapy. These regimens may be optimal for a given patient based on individual clinical features, preferences, or financial considerations or where InSTIs are not available. These regimens are recommended therapeutic options: (1) darunavir (boosted with cobicistat or ritonavir) plus TAF/emtricitabine, TDF/emtricitabine, or abacavir/lamivudine, (2) efavirenz/TDF/emtricitabine, or (3) rilpivirine/TAF (or TDF)/emtricitabine. Each of these combinations has advantages and disadvantages. Option 1 has a low risk of resistance with virologic failure, even with poor adherence; option 2 exhibits high efficacy in patients with a baseline HIV RNA measurement of higher than 100,000 copies/mL; and option 3 has the lowest risk of metabolic adverse effects.[56]

Modifications to ART are needed in pregnant patients and in those with hepatitis B and C coinfection or opportunistic infections.[56] Osteoporosis and fractures are increased with HIV infection. During the first year or two after initiation of ART, patients may lose 2% to 6% of their bone mineral density. Regimens containing TDF are associated with a greater initial decline in bone mineral density than regimens containing TAF or abacavir; thus, TDF is not recommended for patients with osteopenia or osteoporosis.[56]

Monitoring of kidney function with eGFR, urinalysis, and testing for glycosuria and albuminuria or

proteinuria is recommended when ART is initiated or changed and every 6 months (along with HIV RNA) once HIV RNA is stable. TDF, especially with a boosted protease inhibitor, increased the risk of chronic kidney disease in cohort studies and thus is not recommended for patients with an eGFR of less than 60 mL/min. Long-term data on TAF in patients with preexisting renal disease are limited. TDF or TAF should be discontinued if renal function worsens, particularly if there is evidence of proximal tubular dysfunction.[56]

With improvements in ART, there has been less need for patients taking it to switch drugs because of virologic failure and drug resistance. Some patients who have virologic suppression but are taking older regimens that are less convenient or have more adverse effects may benefit from switching to the improved ART drugs, however. Reasons for considering switching therapy in such patients include the development of adverse effects, the benefits of reducing dosages or the number of pills to be taken, or the occurrence of drug-drug interactions. Switching therapy may also be considered for pregnant patients. Some patients may benefit from switching even if they are doing well on their current treatment. For instance, switching is reasonable for patients taking regimens containing stavudine, didanosine, or zidovudine because of long-term toxic effects or regimens of older protease inhibitors that have higher pill burdens and greater metabolic toxicities than darunavir or atazanavir. Some drugs that are no longer recommended for initial use may be safely continued for patients who are tolerating them. For example, although nevirapine and efavirenz have substantial early toxic effects, they are safe and tolerable over the long term.[56]

Recommendations for laboratory monitoring can be summarized as follows. As close to the time of HIV diagnosis as possible and before ART is begun, the following factors should be measured: CD4 cell count; plasma HIV RNA level; serologic studies for hepatitis A, B, and C; serum chemistries; estimated creatinine clearance; complete blood cell count; and urine glucose and protein. Genotypic resistance assays for reverse-transcriptase and protease should be ordered for all patients. Routine pretreatment screening for integrase resistance is not currently routinely recommended. Screening for syphilis and mucosal nucleic acid amplification testing for chlamydial infection and gonorrhea should also be done at the time of HIV diagnosis, and a lipid profile should be obtained. Other laboratory assessments should be individualized, in keeping with current guidelines. If ART is initiated on the first visit, all laboratory specimens should be drawn before the first dose is started.

Worldwide, the number of HIV patients receiving ART has increased from 7,500,000 in 2010 to 17,000,000 in 2015.[1] Even so, only 46% of HIV-infected individuals are receiving ART, and 20,000,000 patients are untreated. Improving ART coverage is a United Nations priority.

Initiation of ART in the very early stages of HIV infection preserves immunologic function and reduces inflammation; it might also be expected to curtail the potential of HIV infection to induce atherosclerosis, although this has not been proven in the setting of randomized clinical trials. In addition, newer ART drugs do not carry the adverse metabolic consequences of older therapies. These considerations provide hope that current HIV patients may experience a lower risk of CV events compared with patients from 10 to 15 years ago.

Treatment of Hyperlipidemia in HIV Patients

The Infectious Diseases Society of America and Adult AIDS Clinical Trials Group published specific guidelines in 2003 for the evaluation and management of ART-related hyperlipidemia (**see Chapter 48**). These recommendations were largely based on National Cholesterol Education Program Adult Treatment Panel III guidelines (ATP III), and advocated LDL cholesterol targets according to the level of CV risk based on the Framingham Risk Score predictions for 10 years. In 2013 the American College of

Cardiology (ACC) and the American Heart Association (AHA) produced new guidelines on the treatment of cholesterol for reducing the atherosclerotic CV risk in adults, which replaced the outdated ATP III guidelines.[58] The ACC/AHA guidelines recommend treatment with moderate- or high-intensity statins for patients with established atherosclerotic CV disease, patients with an LDL cholesterol level of 190 mg/dL or higher, patients with diabetes who are 40 to 75 years of age and have an LDL cholesterol level of 70 to 189 mg/dL, and patients with a 10-year CV risk of 7.5% or more who are 40 to 75 years of age and have an LDL cholesterol level of 70 to 189 mg/dL.[58]

Some evidence suggests that the guidelines are not accurate in detecting HIV patients who should be treated with statins. For example, in a recent study, high-risk coronary plaque morphology was shown by CT angiography in 36% of 108 HIV-infected patients, but statins would be recommended for only 19% of them by the 2013 guidelines and 7% by the ATP III guidelines.[59] Furthermore, compliance with guidelines appears to be suboptimal. In the HIV Outpatient Study of 2005 patients, one fifth had a 10-year CV risk of more than 20%, and yet a large percentage of at-risk patients who were eligible for pharmacologic treatment did not receive recommended interventions and did not reach recommended treatment goals.[60]

Specific drug-drug interactions are important to consider when initiating lipid-lowering therapy in HIV patients. Both protease inhibitors and non-nucleoside reverse-transcriptase inhibitors can affect cytochrome P450 isoforms. In general, all protease inhibitors inhibit CYP3A4, with the highest level of inhibition with ritonavir, followed by indinavir, nelfinavir, amprenavir, and saquinavir. Delavirdine, a non-nucleoside reverse-transcriptase inhibitor, is also an inhibitor of CYP3A4, whereas nevirapine and efavirenz result in induction of the enzyme.

Both simvastatin and lovastatin blood levels increase dramatically with protease inhibitor use, and thus these statins are contraindicated with protease inhibitors because of the risk of rhabdomyolysis. Atorvastatin blood levels increase to a lesser extent, so that it may be used at lower doses. Pravastatin and fluvastatin are safe because they are not metabolized by CYP3A4, but their capacity to reduce LDL cholesterol levels is limited. Rosuvastatin has minimal P450 metabolism, although levels appear to be increased when it is used in combination with atazanavir/ritonavir and lopinavir/ritonavir, so limiting doses to 10 mg with those drugs is advised. A metaanalysis of 18 studies of antiretrovirally treated HIV-infected individuals receiving statin therapy reported that statin therapy significantly lowered the total cholesterol, LDL cholesterol, and triglyceride levels, with limited efficacy for HDL levels.[61] Statin therapy, when dose adjusted for drug-drug interactions, was associated with low rates of adverse events.

The 2003 HIV guidelines for the treatment of hyperlipidemia recommended diet and exercise interventions, which have been shown to decrease total cholesterol levels by 11% to 25% in HIV populations. Pravastatin 20 to 40 mg/day or atorvastatin 10 mg/day was recommended as starting therapy for elevated LDL cholesterol levels in patients taking any protease inhibitor or delavirdine. Fluvastatin 20 to 40 mg/day was considered an alternative second-line agent.

The 2003 guidelines are somewhat antiquated because contemporary ART interferes much less often with statin metabolism compared with older forms of ART. Additionally, trials done in non-HIV populations since 2003 have demonstrated that more potent statins at higher doses provide more CV event reduction than lower doses of weaker statins. This evidence is reflected in the treatment recommendations of the 2013 ACC/AHA guidelines. In light of these considerations, it seems reasonable to treat HIV patients who are not taking ART metabolized by the hepatic CYP3A4 enzyme system more aggressively, perhaps in line with the current ACC/AHA recommendations. Of note, the European Society of Cardiology Guidelines recommend that individuals with HIV and dyslipidemia be treated to achieve the LDL goal as it is defined for high-risk individuals.[62]

Hypertriglyceridemia is common in HIV patients and can be treated with fibrates (gemfibrozil 600 mg

twice a day or micronized fenofibrate 54 to 160 mg daily) when triglyceride levels exceed 500 mg/dL. Fibrates and statins have a drug-drug interaction and should be used only at low doses when combined. Niacin and bile acid sequestrants are not recommended for use in HIV patients. Ezetimibe appears safe and effective when added to maximally tolerated doses of a statin; it lowers LDL cholesterol levels modestly when used alone in HIV patients. PCSK9 inhibitors profoundly lower LDL cholesterol levels and are being investigated in large clinical trials to determine whether they also reduce CV events. PCSK9 inhibitors might be advantageous for certain HIV patients, but they have not yet been investigated in this population. Elevated PCSK9 levels have been reported in the setting of coinfection with HIV and hepatitis C virus; of note, PCSK9 levels increased in a stepwise fashion, along with IL-6 levels.[63]

Whether statins reduce CV events in HIV-infected patients to the same extent as in noninfected subjects is uncertain. It has been suggested in some studies that statins reduce LDL cholesterol levels less in HIV patients than in uninfected patients. Although HIV infection is characterized by high levels of inflammatory markers, statins may reduce these markers less in HIV-infected than in noninfected subjects.[64] As previously noted, coronary plaques in HIV patients are more likely to be of the soft, noncalcified variety. In a recent placebo-controlled trial, atorvastatin decreased the volume of such noncalcified plaques and also decreased their high-risk features, but no impact on vascular inflammation or inflammatory markers was demonstrated.[64]

Screening for Coronary Risk Factors in HIV Patients

The traditional CV risk factors appear to cluster in the HIV population.

The increase in CV risk with increasing numbers of risk factors is more logarithmic than linear, such that a large proportion of HIV patients are at high risk. Thus, smoking cessation, diet and exercise recommendations, and guideline-based treatment of diabetes and hypertension should all be aggressively pursued in HIV patients. As previously noted, a young HIV-infected smoker loses more life-years to continued smoking than to HIV disease.[15] Addressing CV risk factors in HIV patients is often difficult because of the burden of concomitant medical conditions, including HIV, and a correspondingly large pill burden.

Risk Assessment Models

None of the multivariate models for calculating the CV risk in the general population have been validated in HIV-infected cohorts. The most widely used screening tool is the Framingham Risk Score, which appears to underestimate the risk in HIV patients who are smokers, are receiving ART, or have an intermediate or higher 10-year predicted risk. It seems important to use a risk assessment tool that that has been validated in the population to which the patient belongs, particularly one that takes into account HIV-specific features that may alter the CV risk.

A new prediction model for CV events was recently published, based upon 1010 events occurring in 32,663 HIV-positive persons from Australia and 20 countries in Europe.[65] The model included age, gender, systolic blood pressure, smoking status, family history of CV disease, diabetes, total cholesterol, HDL cholesterol, CD4 lymphocyte count, cumulative exposure to protease and nucleoside reverse-transcriptase inhibitors, and current use of abacavir. A reduced model omitted ART. The model performed better than the Framingham Risk Score, even after the Framingham score had been recalibrated to the HIV population.

Other risk prediction models have been developed for HIV populations. Studies comparing different

models have yielded quite different results with less overlap than would be expected. For practical purposes, until a generally accepted, easy-to-use, well-validated risk assessment tool for HIV populations becomes available, it seems reasonable to use risk assessment tools such as the Framingham Risk Score and to accept the results with the expectation that they are underestimates of the true risk.

Biomarkers and Signs of Coronary Disease in HIV Patients

Clinicians should be aware that symptoms of coronary disease may develop in relatively young HIV-infected patients and may be atypical (**see Chapter 10**). The sensitivity and specificity of exercise or pharmacologic stress testing have not been established in HIV disease, so that use of these tests currently follows guidelines for the general population.

Several biomarkers have been reported to be higher in HIV-infected patients who develop coronary disease compared with those who do not, including soluble CD163, soluble CD14, monocyte chemoattractant protein 1 (markers of monocyte activation), D-dimer, interleukin-6, intercellular adhesion molecule-1, soluble-tumor necrosis factor-α receptor I and II, C-reactive protein, and osteoprotegerin.[26,27,33,66] Other biomarkers have been reported to be lower in HIV-infected patients who develop coronary disease compared with those who do not, including adiponectin, soluble receptor activator of nuclear factor-κB ligand, and vitamin D. None of these markers have been developed to the point where they are used clinically to aid in the diagnosis of coronary disease. The biomarker profile predictive of CV disease in HIV is likely distinct from that in the noninfected population; this suggests that HIV infection has a role in the disease process.

Screening for CAC may have diagnostic value in the assessment of HIV patients. Middle-aged patients with HIV infection are more likely to have CAC than are noninfected controls of a similar age; in at least one study, long-term ART increased the probability of CAC. CAC scores tend to be higher in HIV-infected patients compared with uninfected controls. During a 5-year follow-up in the Multicenter AIDS Cohort Study, 21% of HIV-infected men developed CAC compared with 16% of uninfected men, an association that persisted after adjustment for traditional and HIV-associated risk factors (HR, 1.64; 95% CI, 1.13 to 3.14).[67] The presence of coronary calcium in HIV patients is predictive of future CV events, just as it is in the general population.[68]

Chest CT imaging (**see Chapter 18**) allows for the measurement of epicardial adipose tissue (EAT) thickness. HIV-infected individuals have thicker EAT than noninfected persons; increased EAT is predictive of CV events in HIV patients, as it is in noninfected individuals.[68] EAT overlies the coronary arteries and has been postulated to accelerate coronary atherosclerosis by secreting proinflammatory substances. Thicker EAT is associated with a longer duration of ART, thicker carotid IMT, and the presence of coronary plaque.[69]

A limitation of screening for CAC in HIV patients is that noncalcified plaques are much more common in this population than in uninfected patients.[43] The CAC score may thus underestimate the severity of coronary disease. In addition, if all plaques are noncalcified, the diagnosis of coronary disease would be missed. In the Multicenter AIDS Cohort Study, noncalcified plaques were more prevalent in HIV patients compared with controls (prevalence ratio, 1.28; 95% CI, 1.13 to 1.45), a difference that remained statistically significant even after adjustment for coronary risk factors.[42] In addition, more than a third of HIV-infected individuals had a significantly elevated carotid IMT of 1 mm or more despite having no CAC, suggesting that a negative CAC scan does not rule out CV risk in HIV.[70]

Coronary CT angiography (**see Chapter 20**) detects noncalcified coronary plaques and thus is often a useful diagnostic test in HIV-infected patients, depending upon the clinical circumstances. In the

Multicenter AIDS Cohort Study, coronary artery stenosis of more than 50% was more frequently found in HIV patients than in uninfected controls.[42] The detection of coronary plaques in an HIV-infected patient should lead to initiation or intensification of treatment for CV risk factors. Statin therapy, smoking cessation, and aggressive control of hypertension and diabetes become mandatory in this setting. Coronary lesions have been shown to improve with statin therapy in HIV-infected patients.[64]

Carotid ultrasound (**see Chapter 14**), performed for measuring the carotid IMT and determining whether coronary plaques are present and, if so, their severity, has been useful in research about atherosclerosis related to HIV infection.[71] Changes in the carotid IMT over time can be challenging to assess because of measurement variations. The presence of carotid plaques or an abnormally thickened carotid IMT should lead to more aggressive control of risk factors. Brachial artery flow–mediated dilation is useful for assessing the role of the endothelium in HIV-associated CV disease and for evaluating responses to interventions, but it may be challenging to perform in the clinical setting. Increased fibrosis has been shown in HIV-infected individuals by means of cardiac MRI.[72]

Although few studies have addressed the topic, cardiac screening has been shown to be cost-effective in HIV patients at intermediate risk for coronary disease.[73] Depending on the clinical features of a patient, screening for CAC and IMT or stress testing could be considered an appropriate first step. An ECG should be obtained in all HIV-infected adults, and an echocardiogram is reasonable because of the high prevalence of left ventricular hypertrophy and left ventricular dysfunction present in HIV patients (discussed below).

Chronic Inflammation and Cardiovascular Disease

Chronic inflammation and immune activation are thought to be important contributors to HIV-associated CV disease.[5] Although the mechanisms underlying CV disease in HIV are multifactorial, as shown in **Fig. 82.1**, chronic inflammation is thought to underlie CV disease in HIV, as well as in other non-AIDS conditions, including renal disease, neurologic disease, and cancers. Many different therapies are being evaluated as proof-of-concept interventions for reducing inflammation; they include therapies used in cardiology, such as statins, aspirin, ACE inhibitors, and aldosterone-receptor antagonists. Additionally, trials evaluating agents used in other inflammatory states such as rheumatoid arthritis are being studied, including low-dose methotrexate, TNF-alpha inhibitors, IL-6 inhibitors, and IL-1β inhibitors. The impact of these differing interventions on relieving inflammation and lowering the risk for CV diseases is unknown, and their safety for use in HIV patients and effects on CV end points are also unknown at this time.

Other Cardiovascular Conditions in HIV Patients

Pulmonary Hypertension

The prevalence of idiopathic pulmonary hypertension (PH) in the general population is estimated to be one to two persons per million, but in HIV-infected patients a prevalence of 0.5%, several thousand times higher, has been consistently reported (**see Chapter 85**). This prevalence has remained constant with the advent of ART; for example, a survey from France published in 2008 reported a prevalence of 0.46%. An evaluation of the prevalence of pulmonary arterial hypertension in HIV patients at hospital discharge or following death was lower than the previous and consistently reported prevalence, suggesting that this diagnosis may be underrecognized.[74] Studies of HIV patients screened with Doppler echocardiography

suggest that many more have mild, asymptomatic PH and that the true prevalence is considerably higher than 0.5%. For example, in our study of 106 HIV-infected patients, 87 had a pulmonary artery systolic pressure of 30 mm Hg or higher on echocardiographic studies; PH was confirmed by right heart catheterization in 16 of the 65 who underwent this procedure.[75] In another recent study, PH was detected by echocardiography in 23 of 374 HIV-infected patients (6.1%), of whom only 3 had symptoms of PH.[76]

The pathology of PH associated with HIV infection is similar to that in PH patients without HIV. It includes intimal thickening of small pulmonary arteries with plexogenic lesions in the media, leading ultimately to obstruction of small pulmonary arteries. Severe PH leads to worsening dyspnea, curtailed exercise capacity, right heart failure, and sudden cardiac death. PH may occur at any stage of HIV infection and does not appear to be related to the CD4 count, type of ART used, or other HIV-related factors.

PH is a harbinger of early death in HIV-infected patients. In older studies, the mean survival time of HIV patients with PH was 6 months. The survival time is likely much better if asymptomatic patients are included and may also be improved in patients who are given contemporary therapy for PH. In a series of 77 HIV-infected PH patients treated at a specialized French center between 2000 and 2008, the overall survival rate was 88% at 1 year and 72% at 3 years.[77] Predictors of the survival rate were a cardiac index of more than 2.8 L/min/m^2 and a CD4 lymphocyte count of more than 200 cells/µL. In HIV patients with symptomatic PH, death is almost always caused by the PH rather than other complications of HIV.

As with idiopathic PH, no single cause of HIV-associated PH has been identified, but many potential contributing factors have been implicated. Increased levels of inflammatory markers such as vascular endothelial growth factor-A, platelet-derived growth factor, and interleukin 1 and 6 have been demonstrated in HIV-associated pulmonary arterial hypertension. Certain HIV proteins have been shown to activate endothelial cells indirectly, such as the envelope glycoprotein-120, which is associated with higher levels of endothelin-1. Levels of endothelin-1 have been correlated with pulmonary artery systolic pressure among HIV-infected patients with PH,[76] suggesting that this potent vasoconstrictor plays a central role in the pathogenesis of HIV PH. Another potential mechanism is asymmetric dimethylarginine (ADMA)–induced endothelial dysfunction; elevated ADMA levels have been reported in HIV-associated PH.[78] Finally, a genetic predisposition to HIV-associated PH has been suggested, and some evidence indicates that autoimmunity may contribute.

Optimal treatment for HIV-associated PH remains unclear. ART does not appear to be beneficial. Pulmonary vasodilator testing reveals that a small minority of HIV-infected PH patients respond to calcium channel blockers.[79] The drug-drug interaction between calcium channel blockers and protease inhibitors means that the dose of the calcium channel blocker should be limited. The dual endothelin-receptor antagonist bosentan has been shown to improve pulmonary vascular resistance and exercise tolerance over 1 year of treatment, similar to the response expected in uninfected PH patients. Of note, the recommended dose of bosentan for individuals taking protease inhibitors is 62.5 mg/day or every other day instead of the usual dose of 125 mg twice daily. Studies of the selective endothelin-receptor antagonists ambrisentan and sitaxsentan have not been reported in the setting of HIV.

The phosphodiesterase type-5 inhibitors sildenafil, tadalafil, and vardenafil have been shown in clinical trials to improve hemodynamics and exercise tolerance in PH patients without HIV infection. No such trials have been reported in HIV-associated PH; however, isolated case reports suggest similar improvements should be expected in HIV PH patients.[79] Sildenafil is metabolized by the 3A4 isoform of the cytochrome P450 system, and interactions have been described with the protease inhibitors saquinavir, ritonavir, and indinavir. Because of these drug-drug interactions, the dose of sildenafil in HIV-infected individuals who are concurrently taking protease inhibitors should be carefully monitored. The

other phosphodiesterase type-5 inhibitors share this problem.

Several small series demonstrate that prostacyclin analogues induce hemodynamic benefit in HIV patients with PH.[79] Subcutaneous treprostinil and inhaled iloprost have improved functional capacity in the very small numbers of HIV-infected PH patients that have been reported. In general, the treatment of PH in HIV-infected patients does not appear to differ much from treatment in uninfected patients, except that specific clinical trial data are lacking for HIV patients, and concomitant protease inhibitor therapy introduces the problem of drug-drug interactions. Case reports have described cures of HIV-associated pulmonary arterial hypertension.

Cardiomyopathy and Left Ventricular Abnormalities

The incidence of HIV-associated cardiomyopathy has decreased dramatically from the pre-ART era, from 25.6 cases per 1000 person-years to 3.9 cases, according to one review (**see Chapter 79**).[80] Additionally, in the pre-ART era, HIV-associated cardiomyopathy was defined as symptomatic, systolic dysfunction with left ventricular dilation, and was seen almost exclusively in patients with advanced HIV disease and AIDS; in the post-ART era, the diagnosis often refers to systolic or diastolic dysfunction detected by echocardiography in asymptomatic HIV patients.

The pathophysiology of HIV-associated cardiomyopathy is likely multifactorial, with proposed causes including direct HIV infection of the myocardium with or without myocarditis, coinfection with other viruses such as coxsackievirus B3 and cytomegalovirus, toxicity from ART, autoimmune factors, opportunistic infections, and nutritional disorders. When HIV-associated cardiomyopathy consisted of severe, dilated cardiomyopathy, the cause was believed to be opportunistic infections or myocarditis. Now that the disease has changed to more nuanced myocardial dysfunction, the understanding of mechanisms has become more nuanced as well.

Infection of the heart with the HIV virus is thought to cause impaired systolic function. HIV gene products, such as tat (transactivator of transcription, can also contribute. Proinflammatory cytokines such as interleukin-1β and tumor necrosis factor have also been shown to depress systolic function.[80] Some types of ART cause mitochondrial toxicity, which may impair ventricular function. In sub-Saharan Africa and other poor areas, nutritional deficiencies may contribute to HIV-associated cardiomyopathy. HIV-associated heart failure has been reported in low- and middle-income countries.[81] Most studies of HIV patients have been performed in developed countries with readily available access to ART, so a different spectrum of CV diseases may be observed in developing countries.

Left ventricular hypertrophy is more common in HIV-infected patients than in controls). In one study, HIV-infected participants had a left ventricular mass index that was 8 g/m^2 (the mean) larger than the mass index in controls ($P = 0.001$).[82] The higher left ventricular mass index was independently associated with a lower nadir CD4 T-cell count, suggesting that immunodeficiency may play a role in this process. After adjustment for age and traditional risk factors, HIV patients were 2.4 times more likely to have diastolic dysfunction than controls. Another study compared left ventricular mass in patients with and without HIV infection and with and without hypertension.[83] In both hypertensive and normotensive persons, HIV patients had a greater left ventricular mass and more diastolic dysfunction than uninfected controls.

Treatment recommendations for HIV-related cardiomyopathy are based on trials done in uninfected cardiomyopathy patients, and on guidelines based on these trials.[80] Thus, ACE inhibitors, beta blockers, and aldosterone antagonists should be used, even though trials of these drugs have not been done in HIV-infected patients with cardiomyopathy.

ART is not a therapy specifically used for cardiomyopathy; however, the incidence of cardiomyopathy

has declined dramatically since the introduction of ART. Whether ART can reverse established cardiomyopathy is not known. On the other hand, ART drugs such as zidovudine have direct myocardial toxicity, and ART may accelerate coronary atherosclerosis, ultimately leading to left ventricular dysfunction. The role of inflammation and the immune response in HIV-associated cardiomyopathy is highlighted by a study in HIV-infected children with left ventricular dilation; better left ventricular contractility was seen in those with higher endogenous IgG levels and those treated with intravenous immunoglobulin. Of note, among individuals perinatally infected with HIV, ART appears to have a protective effect on cardiac structure, as well as a deterrent effect on the development of heart failure, suggesting that ART has a protective effect.[84]

Heart transplantation with excellent long-term survival rates has been reported in small numbers of HIV-infected patients. The fear that immunosuppression in such patients might lead to AIDS has proved unfounded, and the notion that HIV infection should be a contraindication to cardiac transplantation is no longer tenable.

HIV-associated cardiomyopathy in the pre-ART era carried a grim prognosis. In one study, the median survival time in patients with AIDS and cardiomyopathy was 101 days, compared with 472 days in patients with AIDS alone. In another study, the adjusted hazard ratio for death for patients with cardiomyopathy associated with AIDS was 5.86, compared with that for idiopathic cardiomyopathy.

Since the advent of ART, the epidemiology and prognosis of HIV-associated cardiomyopathy have improved dramatically. Symptoms of heart failure or echocardiographic evidence of cardiomyopathy greatly increase the risk of death.[80] Sudden cardiac death in HIV patients occurs at 4.5 times the expected rate, and systolic and diastolic dysfunction are known to be present in more than half of such cases.[85] The presence of contractile reserve as assessed by dobutamine stress echocardiography has been reported to be a marker for improved survival rates in HIV patients with cardiomyopathy. Patients with a contractile reserve were also more likely to experience an improvement in the ejection fraction.

Arrhythmias and Sudden Cardiac Death

Cardiac arrhythmias are more common in HIV patients compared with uninfected controls (**see Chapter 32**). In the Veterans Affairs HIV Clinical Case Registry of 30,533 HIV-infected veterans, the prevalence of atrial fibrillation (**see Chapter 38**) was increased and was associated with lower CD4 counts and higher viral loads, as well as the usual clinical factors related to atrial fibrillation.[86] Whether atrial fibrillation should be treated differently in an HIV patient is unknown, because the risks for complications of atrial fibrillation, such as embolic stroke, have not been defined in these patients. Thus the thromboembolic predictive value of calculators such as CHADS2 and CHADS2Vasc remain unknown in the setting of HIV.

HIV patients appear to be more susceptible to sudden cardiac death than uninfected persons (**see Chapter 42**). In a consecutive series of 2860 HIV patients followed for a mean of 3.7 years, the mean sudden cardiac death rate was 2.6 per 1000 person-years (95% CI, 1.8 to 3.8), or 4.5-fold higher than expected.[85] Patients who succumbed to sudden cardiac death had a higher prevalence of previous MI, cardiomyopathy, heart failure, and arrhythmias. Left ventricular systolic dysfunction and diastolic dysfunction, especially in the setting of detectable HIV RNA levels, were predictive of sudden cardiac death in HIV.[87] Additional studies are needed to determine the role of the implantable cardioverter defibrillator (ICD) in prevention of sudden cardiac death in HIV.

Cerebrovascular Disease

In the Veterans Aging Cohort Study the risk of ischemic stroke was increased in HIV-infected men compared with uninfected persons (IRR, 1.25; 95% CI, 1.09 to 1.43; $P < 0.01$) (**see Chapter 65**).[47] After adjusting for demographic factors, ischemic stroke risk factors, comorbid diseases, and substance abuse, the risk of ischemic stroke was attenuated but still higher among HIV-infected men (HR, 1.17; 95% CI, 1.01 to 1.36; $P = 0.04$). In a large series from the U.S. Nationwide Inpatient Sample, the in-hospital mortality rate was higher in HIV-infected than uninfected stroke patients (7.6% vs. 5.2%).[88] Some evidence suggests that the rate of stroke may be higher in women infected with HIV than in men with infection.[89]

The risk of hemorrhagic stroke also appears to be elevated in HIV-infected patients. In a database study covering all residents in Quebec from 1985 to 2007, the incidence of intracerebral and subarachnoid hemorrhage was higher in HIV-infected individuals than uninfected age-matched controls (HR, 3.28; 95% CI, 1.75 to 6.12). The risk among HIV-infected individuals with an AIDS-defining condition was particularly high (HR, 7.64; 95% CI, 3.78 to 15.43). Among those without an AIDS-defining condition, the hazard ratio was nearly doubled but was not statistically significant.[89] Other studies have also demonstrated increased rates of intracerebral hemorrhage in the setting of HIV.[90]

The mechanisms accounting for the increase in stroke risk in HIV patients are in general similar to the mechanisms accounting for the increased risk of MI: HIV-associated immune activation and inflammation, adverse effects of long-standing ART use, and the usual stroke risk factors, including hypertension and smoking. In a case control study, achievement of viral suppression was associated with a reduced risk of ischemic stroke, suggesting that treated and suppressed HIV disease reduced the risk for stroke.[91] Carotid IMT is a strong independent marker of stroke risk; the age-adjusted carotid IMT is increased in HIV patients compared with controls. Impaired fibrinolysis resulting in a hypercoagulable state has been described in HIV patients with hyperinsulinemia and fat redistribution who are receiving protease inhibitors.

In the pre-ART era, severely immunocompromised HIV-infected individuals with and without strokes often exhibited an intracranial vasculopathy with aneurysmal arteriopathy and, at times, concomitant infections, including varicella zoster virus and cytomegalovirus infections.[89] Pathologic examination of affected vessels revealed subintimal fibrosis, disruption of the internal elastic lamina, and thinning of the media layer. All abnormalities improved with initiation of ART; this finding suggests that this entity is unlikely to be clinically relevant in virally suppressed contemporary patients.

The data linking ART to an increased risk of stroke are less compelling than the data for MI, possibly because of the lower incidence of stroke. A high viral load and a low CD4 count increase the risk of stroke. Yet even treated individuals with well-controlled infection show evidence of inflammation and immune activation, and probably are at increased risk for stroke.

Scant data are available comparing the prognosis of stroke in HIV patients with their uninfected counterparts. Similarly, the acute and long-term treatment of stroke in HIV patients has not been differentiated from stroke treatment in uninfected individuals. Primary and secondary prevention of stroke in HIV patients is of great importance because of the increased risk in these patients, and because of their high prevalence of modifiable risk factors, specifically smoking, dyslipidemia, and hypertension. Several studies have reported that aspirin and statins are underused in HIV patients. The benefit of aspirin may extend beyond its antithrombotic properties because it reduces markers of T-cell and monocyte activation in virologically suppressed HIV-infected patients.

Future Perspectives

ART has transformed HIV infection into a chronic disease. CV disease is therefore a growing health concern in the aging HIV population. Coronary artery disease, along with other emerging CV conditions, including heart failure, diastolic dysfunction, PH, stroke, and arrhythmias, is more common in HIV-infected individuals even once the HIV disease has been treated and suppressed. The underlying mechanism for the increased risk in HIV patients, as well as the optimal methods for treating CV disease in HIV-infected individuals, remains largely unknown. How to best identify and treat individuals at risk is also undefined. Treatment and risk prediction will likely be combined in some manner, with both targeting traditional risk factors along with HIV-specific issues. HIV infection and ART may lead to CV disease resulting from chronic persistent inflammation, because of the fact that although medication controls HIV disease, it does not cure it. By the year 2030, more than 70% of people living with HIV are projected to be age 50 years or older. Thus, because CV disease is prevalent among older individuals (**see Chapter 88**), it will likely continue to be a significant health concern among individuals living with HIV, both now and in the future. Cardiologists and caregivers of people living with HIV should be aware of HIV-related CV issues and their treatment.

Pericardial Diseases

Martin M. Lewinter, Massimo Imazio

The pericardium is the site of a wide variety of diseases that result in some of the classic physical, imaging, and hemodynamic findings in cardiology, including acute pericarditis, pericardial effusion and tamponade, constrictive and subacute effusive-constrictive pericarditis, and selected specific pericardial disease etiologies. For more detailed treatments of pericardial anatomy, physiology, and disease, see the classic monograph by Shabetai,[1] the 2015 European Society of Cardiology (ESC) guidelines for diagnosis and management,[2] and two recent consensus statements on multimodality imaging in pericardial disease.[3,4]

Anatomy and Physiology of the Pericardium

The pericardium is composed of two layers, the *visceral pericardium*, a monolayer of mesothelial cells and collagen and elastin fibers adherent to the epicardial surface of the heart, and the fibrous *parietal layer*, which is normally about 2 mm thick and surrounds most of the heart (**Fig. 83.1**).[1] The parietal pericardium is largely acellular and contains collagen and elastin fibers. The visceral pericardium reflects back near the origins of the great vessels and is continuous with and forms the inner layer of the parietal pericardium. The pericardial space or sac is contained within these two layers, and normally contains up to 50 mL of serous fluid. The reflection is a few centimeters proximal to the junctions of the caval vessels with the right atrium; thus, portions of the caval vessels lie within the pericardial sac. Posterior to the left atrium, the reflection occurs at the oblique sinus of the pericardium. The left atrium is largely extrapericardial. The parietal pericardium has ligamentous attachments to the diaphragm, sternum, and other structures.

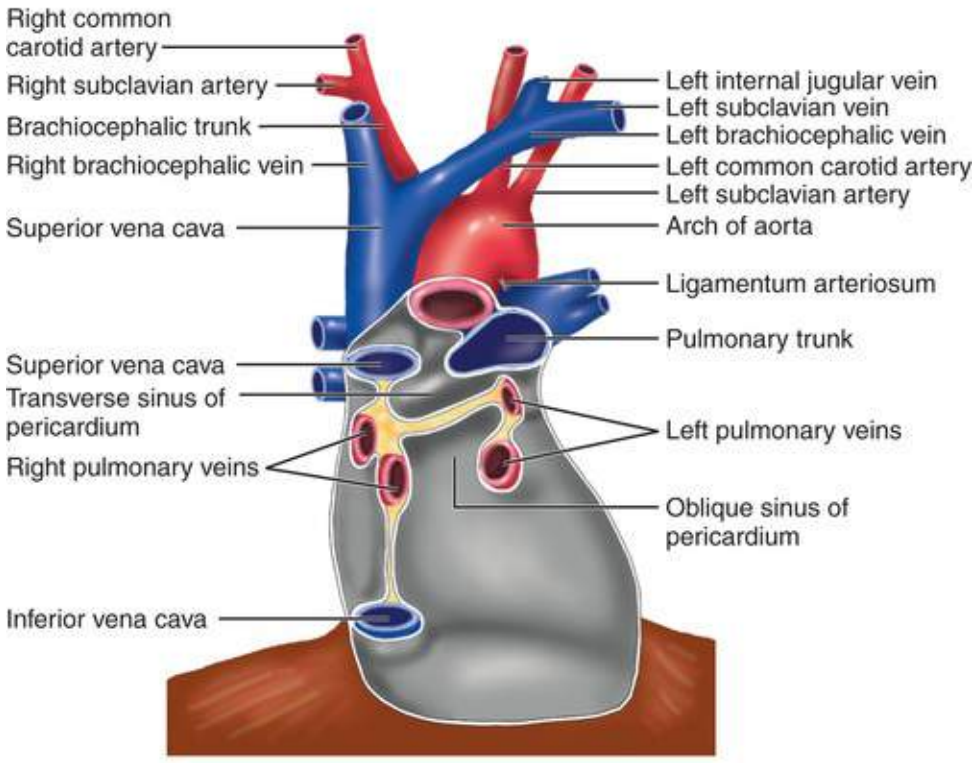

FIGURE 83.1 The pericardial reflections near the origins of the great vessels shown after removal of the heart. Note that portions of the caval vessels are within the pericardial space. (From Johnson D: The pericardium. In Standring S [editor]: Gray's anatomy. St. Louis, Mosby, 2005, pp 995-6.)

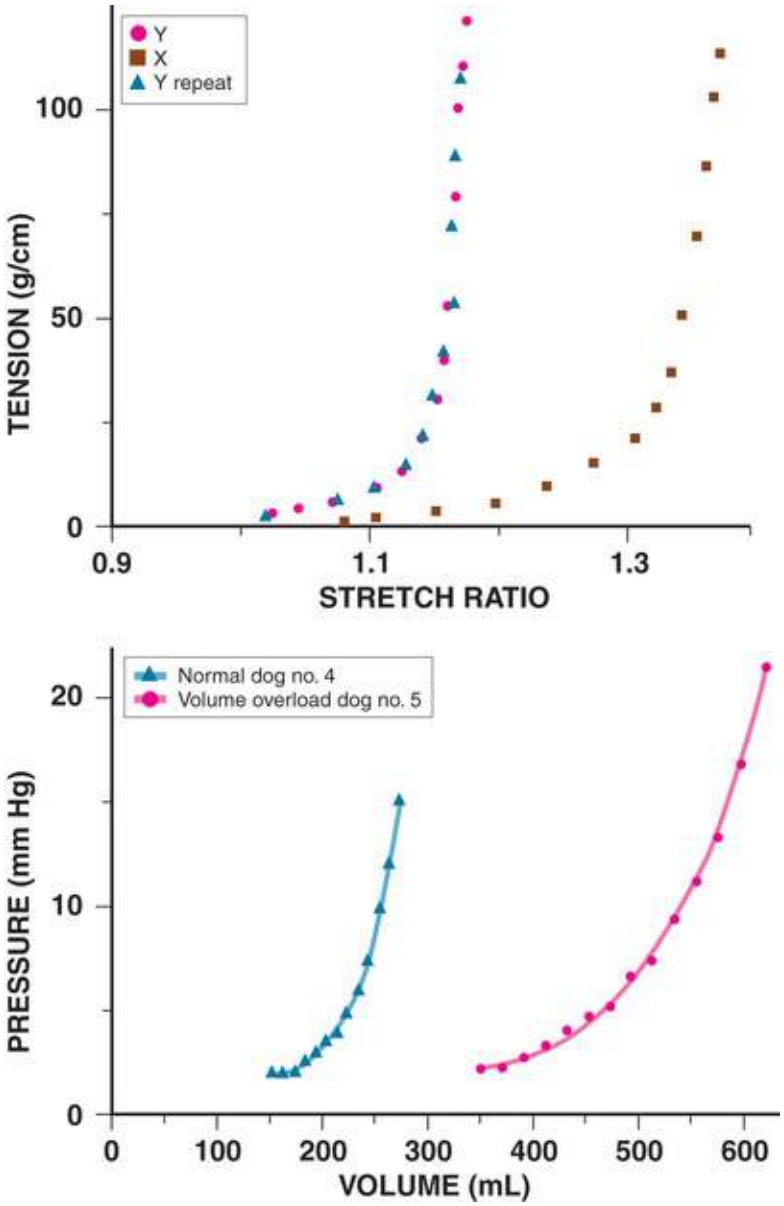
Although its removal has no obvious negative consequences, the pericardium does have functions.[1] Its attachments maintain the heart at a relatively constant position within the thorax, and it provides a barrier to infection. The pericardium is well innervated with mechanoreceptors, chemoreceptors, and phrenic afferent receptors that participate in reflexes arising from the pericardium and/or epicardium (e.g., the Bezold-Jarisch reflex) and transmission of pericardial pain. The pericardium also secretes prostaglandins and related substances that may modulate neural traffic and coronary tone.

The best-characterized mechanical function of the pericardium is its *restraining* effect on cardiac volume.[1] This reflects the mechanical properties of the parietal pericardial tissue. At low stresses, the tissue is very elastic (**eFig. 83.1, top**). With further stretch, it abruptly becomes stiff and resistant to even more stretch. The point on the stress-strain relation (**see eFig. 83.1, top**) where this transition occurs is near the upper range of physiologic cardiac volumes. The *pressure-volume relation* (PVR) of the pericardial sac reflects the properties of the tissue (**see eFig. 83.1, bottom**, left curve) (i.e., a flat, compliant segment transitioning relatively abruptly to a noncompliant segment around the upper limit of normal total cardiac volume).[1] Thus, the sac has a relatively small reserve volume. When exceeded, the pressure within the sac operating on the surface of the heart increases rapidly and is transmitted into the cardiac chambers. The shape of the pericardial PVR dictates that once a critical level of effusion is reached, relatively small amounts of additional fluid will cause large increases in intrapericardial pressure and have marked effects on cardiac function. Conversely, removal of small amounts of fluid can result in striking benefit. The shape of the pericardial PVR also suggests that it *normally* restrains the cardiac volume (i.e., the force it exerts on the surface of the heart limits filling, with a component of *intracavitary pressure* reflecting the surface pressure). Studies with specially designed balloons demonstrate a substantial surface pressure, especially when the upper limit of normal cardiac volume is

exceeded.[1]



EFIGURE 83.1 **Top,** relationship between stretch and tension in vitro in normal human pericardial tissue. The tissue has been stretched in two, mutually orthogonal directions (X, Y). Note relatively abrupt transition from relatively flat to steep, inelastic relationship. In addition, the tissue is anisotropic (i.e., the relation between tension and stretch depends on the direction of stretch). **Bottom,** pressure-volume relationship of the normal canine pericardium (left) and after 4 weeks of cardiac dilation because of volume overload (right). Note relatively abrupt transition to a steep relationship in normal pericardium and marked shift to the right and flattening after chronic volume overload. (**Top,** from Lee MC, Fung YC, Shabetai R, LeWinter MM: Biaxial mechanical properties of the human pericardium and canine comparisons. Am J Physiol 1987;22:H75. **Bottom,** from Freeman G, LeWinter M: Pericardial adaptations during chronic cardiac dilation in dogs. Circ Res 1984;54:294.)

Pericardial contact pressure has also been estimated by quantifying the shift in the right and left heart diastolic PVR before and after pericardiectomy.[1] A decrease in pressure at a given volume is the *effective* pericardial pressure at that volume. Studies in normal canine hearts indicate negligible pressure at low normal filling volumes, with pressures in the range of 2 to 4 mm Hg at the upper range of normal. At filling volumes above normal the pressure rapidly increases. Thus, at a left-sided filling pressure of approximately 25 mm Hg, the contact pressure is approximately 10 mm Hg. Patients undergoing pericardiotomy during heart surgery develop mild postoperative increases in cardiac volume, consistent with relief of the underlying, normal pericardial restraint to filling.

The normal pericardium also contributes to diastolic interaction, defined here as transmission of intracavitary filling pressure to adjoining chambers.[1] Thus, for example, a portion of the right ventricular (RV) diastolic pressure is transmitted to the left ventricle across the interventricular septum and contributes to the left ventricular (LV) diastolic pressure. Because its presence increases the RV intracavitary pressure, the pericardium amplifies diastolic interaction. As cardiac volume increases, the pericardium contributes increasingly to intracavitary filling pressures owing both to external contact pressure and increased diastolic interaction. When the cardiac chambers dilate rapidly, the restraining effect of the pericardium and its contribution to diastolic interaction are augmented, resulting in a hemodynamic picture with features of both cardiac tamponade and constrictive pericarditis. An example is RV myocardial infarction (MI).[1] Here, the right heart dilates rapidly such that the total heart volume exceeds the pericardial reserve volume. As a result, left- and right-sided filling pressures equilibrate at elevated levels and a paradoxic pulse and inspiratory increase in systemic venous pressure (Kussmaul sign) may occur. Other conditions with similar effects include acute pulmonary embolus and subacute mitral regurgitation.[1]

Chronic cardiac dilatation (e.g., in dilated cardiomyopathy or regurgitant valvular disease) can result in cardiac volumes well in excess of the pericardial reserve volume, yet exaggerated restraining effects are not observed. Thus, the pericardium adapts to accommodate chronic increases in cardiac volume. In experimental chronic volume overload, the pericardial PVR shifts to the right and its slope decreases (**see eFig. 83.1, bottom**, right curve) (i.e., it becomes more compliant, along with an increase in area and mass and a decreased effect on the diastolic PVR).[1] Presumably, a similar effect occurs with large, slowly accumulating effusions.

Acute Pericarditis

Definition, Causes, Epidemiology, and Pathophysiology

Acute pericarditis is an inflammatory syndrome with or without pericardial effusion with a wide variety of causes (**Table 83.1**).[1,2,5-7] The background prevalence of tuberculosis (TB) is a key element in the assessment of a suspected case of pericarditis. In developing regions where TB is endemic, it is the most common cause of pericarditis and effusion. TB is infrequent in developing countries and therefore a much less important consideration.[2,6,7]

TABLE 83.1

Categories of Diseases That Can Involve the Pericardium and Selected Specific Etiologies

Idiopathic*
Infectious
Viral* (echovirus, coxsackievirus, adenovirus, cytomegalovirus, hepatitis B virus, infectious mononucleosis, HIV/AIDS
Bacterial* (*M. tuberculosis*, *M. avium-intracellulare*, pneumococcus, staphylococcus, streptococcus, *Mycoplasma*, Lyme disease, *H. influenzae*, *Neisseria meningitides*, and many others)
HIV-associated*
Fungal (histoplasmosis, coccidioidomycosis)
Protozoal
Inflammatory
Connective tissue disease* (systemic lupus erythematosus, rheumatoid arthritis, scleroderma, dermatomyositis, Sjögren syndrome, mixed)
Drug-induced* (e.g., procainamide, hydralazine, isoniazid, cyclosporine)
Arteritis (polyarteritis nodosa, temporal arteritis)
Inflammatory bowel disease
Postcardiotomy, postthoracotomy,* post–cardiac injury syndrome*
Genetic immune system diseases* (tumor necrosis factor receptor-1–associated periodic syndrome [TRAPS], familial Mediterranean fever)
Miscellaneous: sarcoidosis, Erdheim-Chester disease, Churg-Strauss disease, immunoglobulin G4–related disease
Post–Myocardial Infarction
Early
Late (Dressler syndrome)*
Cancer
Primary: mesothelioma, fibrosarcoma, lipoma, and others
Secondary*: breast and lung carcinomas, lymphomas, Kaposi sarcoma
Radiation-Induced Disorders*
Early Post–Cardiac Surgery and Post–Orthotopic Heart Transplantation
Hemopericardium
Trauma
Post–myocardial infarction free wall rupture
Endomyocardial biopsy
Dissecting aortic aneurysm
Device- and procedure-related: percutaneous coronary procedures, implantable defibrillators, pacemakers, post–arrhythmia ablation, post–atrial septal defect closure, post–left atrial appendage isolation, post–percutaneous valve repair/replacement, laparoscopic hiatal hernia repair
Oral anticoagulants
Congenital
Cysts, congenital absence
Miscellaneous
Stress cardiomyopathy
Cholesterol (“gold paint” pericarditis)
Chronic renal failure, dialysis-associated*
Chylopericardium
Hypothyroidism and hyperthyroidism
Amyloidosis
Pneumopericardium
Polycystic kidney disease
Pulmonary arterial hypertension

*Etiologies that can present as the syndrome of acute pericarditis.

There are limited epidemiologic data documenting the incidence and prevalence of acute pericarditis. The incidence is difficult to quantify because many cases are likely undiagnosed. At autopsy, the frequency is approximately 1%.[2,7] Pericarditis is commonly seen in the emergency department, where it accounts for up to 5% of patients with nonischemic chest pain.[5,7] A review of causes in published series is presented in **Table 83.2**.[2,5-7] Presumed viral and idiopathic forms are most common in developed countries. We use *idiopathic* to denote acute pericarditis for which no specific cause is found with routine

diagnostic testing as outlined below. Most idiopathic cases are presumed to be viral. Testing for specific viruses is costly and has a low yield and little impact on management.[8] Such a term, although an admission of ignorance, is clinically meaningful if nonviral causes of pericarditis have been excluded, because treatment with antiinflammatory therapy is similar for all cases and the prognosis is good.[2,5-7]

TABLE 83.2

Etiology of Pericarditis in Major Series

ETIOLOGY	REPORTED FREQUENCY (%)
Idiopathic	15% (Africa) to 80% to 90% (Europe)
Infectious pericarditis	
Viral	Largely unknown
Bacterial	
Tuberculosis	1% to 4% in developed countries; up to 70% in Africa
Purulent	<1% in developed countries; 2% to 3% in Africa
Other infectious causes	Rare, largely unknown
Noninfectious pericarditis	
Neoplastic	5% to 9% to 35% (in tertiary referral centers)
Autoimmune	2% to 24%
Other noninfectious causes	Rare (largely unknown)

In a contemporary series of acute pericardial syndromes from Northern Italy, the incidence of acute pericarditis was 27.7 cases/100,000 population/year with concomitant myocarditis in about 15%.[9] In a series of hospitalized patients with acute pericarditis from Finland, the standardized incidence rate of hospitalization was 3.32/100,000 population/year.[10] Men age 16 to 65 years were at higher risk (relative risk [RR], 2.02), with the highest risk difference among young adults compared with the overall population. Acute pericarditis was the cause of 0.20% of all cardiovascular admissions. The proportion of admissions declined in younger patients. The in-hospital mortality rate was 1.1%; it increased with age and in persons with severe infections such as pneumonia or septicemia.

Most of the various causes of pericardial inflammation result in a response characterized by edema, thickening of the parietal layer, production of exudative pericardial fluid, and increased friction between the layers.[1] Acute pericarditis and myocarditis share common causes, and, as noted, as many as 15% of pericarditis cases are associated with myocarditis.[2,7,9,11] Coexistent myocarditis is usually manifested by a modest release of biomarkers such as troponin I (**see Chapter 79**). LV dysfunction is rare, and the long-term prognosis of pericarditis complicated by myocarditis is excellent.[11] When ventricular function is normal, the term *myopericarditis* is used. Cases with impaired function are labeled *perimyocarditis*.

History and Differential Diagnosis

In more than 90% of cases, the main symptom of acute pericarditis is chest pain, often quite severe.[2,5-7] It is usually retrosternal but may be localized to the left anterior chest and radiate to the neck, shoulders, and arms. The trapezius ridge is a classic radiation. Pericardial pain is pleuritic and worsened by lying down. Associated symptoms include dyspnea, cough, and occasionally hiccups. An antecedent history suggesting a viral illness is common. The history may provide clues to specific causative diagnoses. Thus, for example, a known cancer or autoimmune disorder, high fevers with shaking chills, or weight loss suggests a specific (i.e., nonidiopathic) cause.

The differential diagnosis of chest pain is lengthy (**see Chapters 10 and 56**). Diagnoses most easily confused with pericarditis include myocardial ischemia/infarction, pneumonia with pleurisy, pulmonary embolism/infarction, costochondritis, and gastroesophageal reflux. Acute pericarditis is usually easily distinguished from myocardial ischemia, but further testing may be required to resolve the issue. Other

considerations include aortic dissection, intraabdominal processes, pneumothorax, and herpes zoster pain before skin lesions appear. Rarely, pericarditis can signal a preceding, silent MI.

Physical Examination

Patients with *uncomplicated* acute pericarditis often appear uncomfortable and anxious, with low-grade fever (<38°C) and sinus tachycardia. Arrhythmias are rare. Thus, atrial fibrillation or flutter is reported in less than 5% of cases.[12] The pathognomonic physical sign of acute pericarditis is the friction rub. A rub is reported in about one third of cases at presentation. Rubs are typically evanescent and may require repeated auscultation for detection.[5-7] The rub is ascribed to friction between the pericardial layers. The classic rub consists of three components corresponding to ventricular systole, early diastole, and atrial contraction, and can be likened to the sound made when walking on crunchy snow. The rub is usually loudest at the lower left sternal border and best heard with the patient leaning forward. It is important to perform a thorough physical examination to look for clues to specific causative diagnoses as well as findings suggesting significant pericardial effusion.

Laboratory Testing

The electrocardiogram (ECG) is a key test for diagnosing acute pericarditis (**see Chapter 12**). The classic finding is "diffuse" ST-segment elevation (**Fig. 83.2**).[2,5-7] The ST-segment vector points leftward, anteriorly, and inferiorly, with ST-segment elevation in all leads except aVR and often V_1. Usually, the ST segment is coved upward and resembles the current of injury of transmural ischemia. The distinction between acute pericarditis and transmural ischemia is usually not difficult because of more extensive lead involvement and lack of evolution to pathologic Q waves in pericarditis, and more prominent reciprocal ST depression in ischemia. However, ST elevation in pericarditis can at times involve a smaller number of leads and in some cases the ST segment more closely resembles early repolarization. As with the rub, ECG changes can be dynamic. Frequent recordings can yield a diagnosis in patients who initially have neither rub nor ST elevation. PR-segment depression is also common and considered the earliest ECG sign of acute pericarditis, reflecting pericardial involvement overlying the atria (**see Fig. 83.2**). PR depression can occur without ST elevation and be the initial or sole ECG manifestation. The typical ECG evolution follows four stages: (1) PR depression and/or diffuse ST-segment elevation, (2) normalization of the ST segment, (3) T-wave inversion with or without ST-segment depression, and (4) normalization. The ECG often evolves without all four stages.

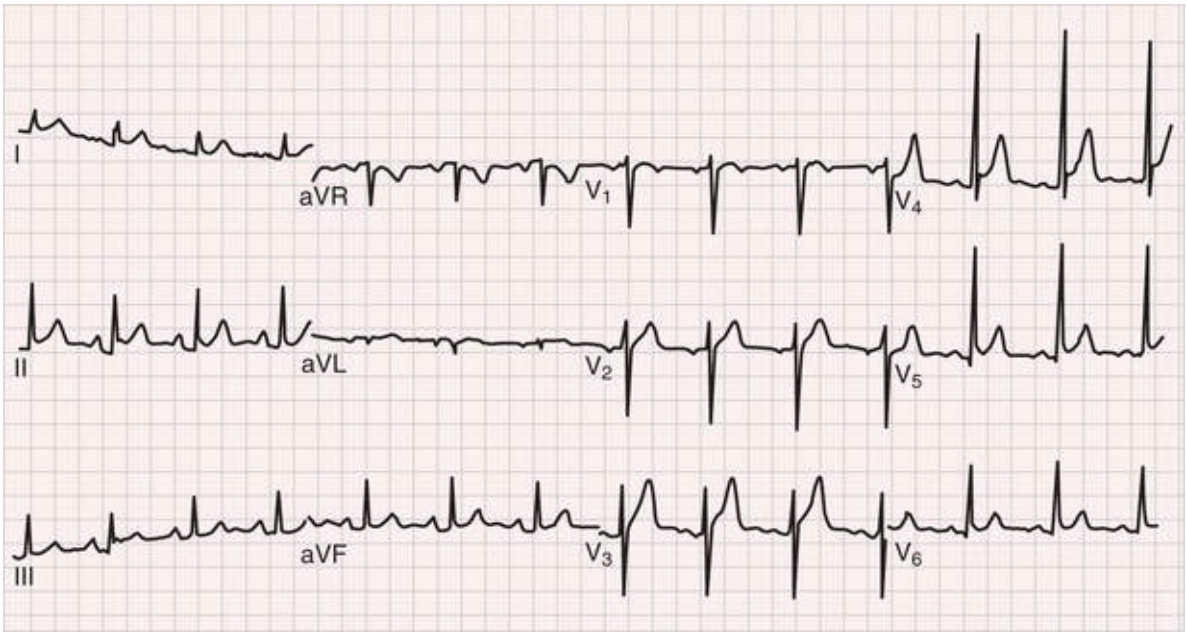


FIGURE 83.2 The electrocardiogram in acute pericarditis. Note the presence of both diffuse ST-segment elevation and PR-segment depression.

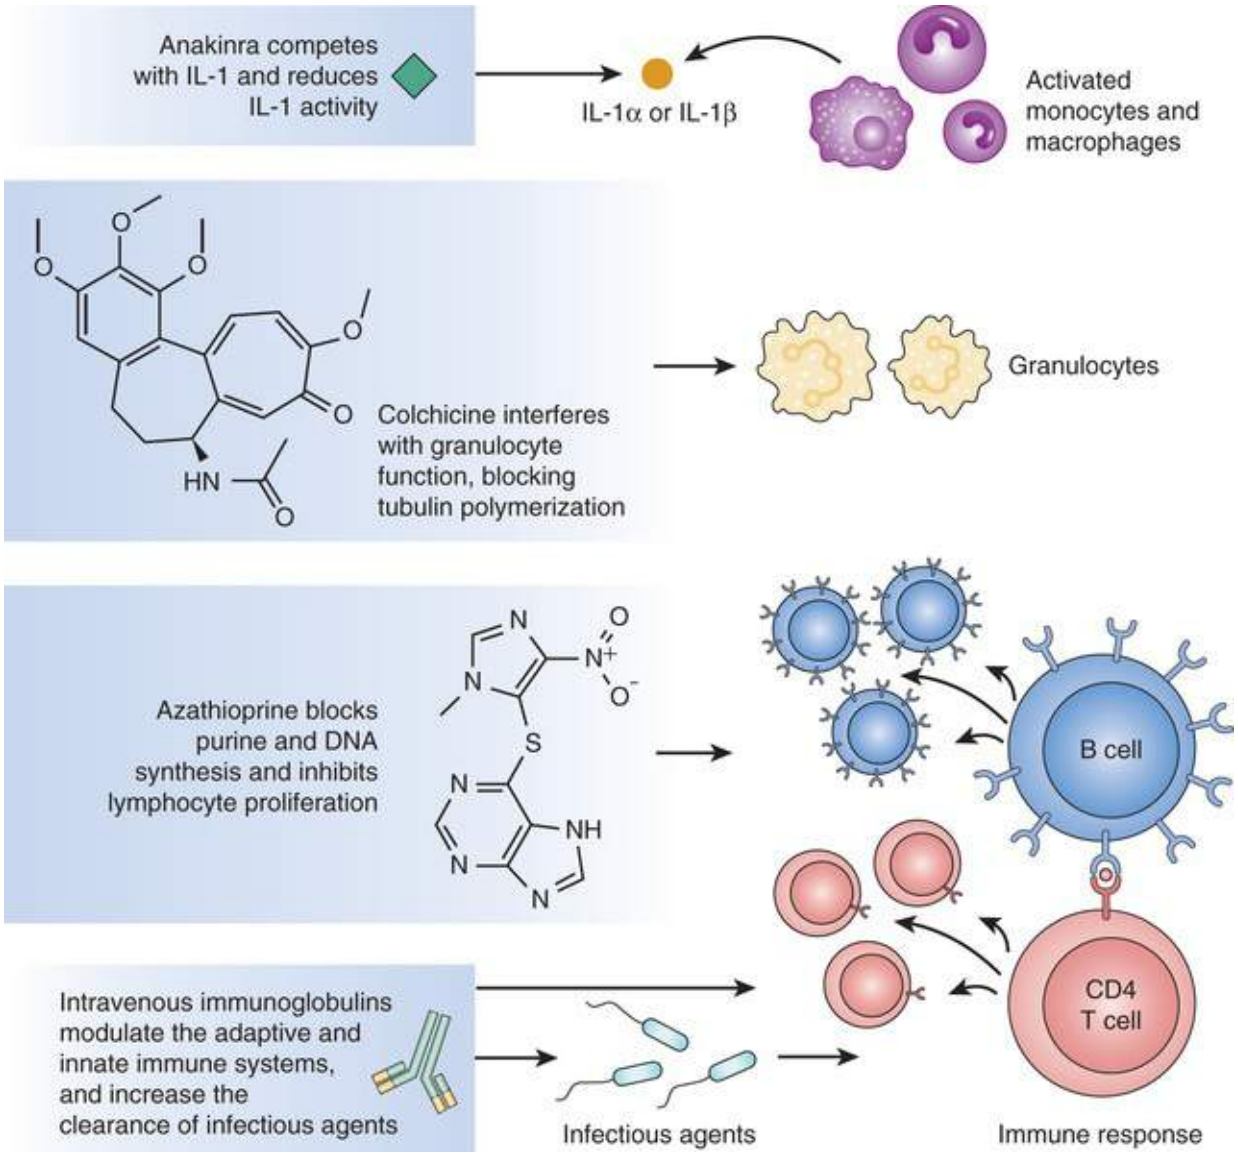
Although usually considered a hallmark of pericarditis, typical ECG changes reflect concomitant involvement of the myocardium, because the pericardium is electrically silent. For that reason, ECG changes are reported in no more than 60% of cases and are more common (>90%) with concomitant myocarditis.[9,11] Additional ECG changes that may constitute clues to the cause of pericarditis or associated findings include atrioventricular block in Lyme disease, pathologic Q waves signifying a previous, silent MI, and low-voltage or electrical alternans pointing toward significant effusion.

Many patients with acute pericarditis have a modestly elevated white blood cell (WBC) count.[2,5-7] WBCs in excess of 13,000 to 14,000/mm^3 suggest a specific etiology. As noted earlier, as many as 15% of patients with acute pericarditis have coexistent myocarditis based on elevations in biomarkers such as troponin I (**see Chapter 67**). Patients with myocarditis almost always have ST-segment elevation.[9,11] In almost all cases the LV ejection fraction (EF) is normal. Another concern in patients with elevated injury biomarkers is a prior silent MI followed by subsequent pericarditis. The latter usually occurs after large MIs with transmural ECG changes.[13]

Serum high-sensitivity C-reactive protein (hsCRP) is elevated in approximately three fourths of patients with acute pericarditis.[14] Normal values generally occur in patients seen early or who have previously received antiinflammatory therapy. hsCRP usually normalizes within 1 week and in almost all cases by 4 weeks after the initial evaluation. Increased hsCRP is independently associated with recurrent symptoms. It has been suggested that serial hsCRPs be used to help confirm the diagnosis of pericarditis and monitor disease activity in order to individualize the duration of therapy.[2,14] Although the utility of hsCRP for this purpose has not been prospectively shown, the association of elevated values with recurrences provides a rationale for measurement at the initial encounter and when it is uncertain how long treatment should be maintained.

Chest radiograms are normal in uncomplicated acute pericarditis.[1,5,7] Occasionally, small pulmonary infiltrates or pleural effusions are present, presumably caused by the underlying causative infection. Mass lesions and enlarged lymph nodes suggestive of neoplastic disease have great significance. Because small to moderate effusions may not cause an abnormal cardiac silhouette, even modest cardiac enlargement is of concern and generally associated with an effusion of more than 300 mL (**eFig. 83.2**).



EFIGURE 83.2 Mechanisms of action of newer antiinflammatory drugs used to treat pericarditis. (From Imazio M, Lazaros G, Brucato A, Gaita F: Recurrent pericarditis: new and emerging therapeutic options. Nat Rev Cardiol 2016;13:99.)

The echocardiographic-Doppler examination (**see Chapter 14**) is completely normal in approximately 40% of patients with acute pericarditis.[5-7] It is performed mainly to determine if an effusion is present and recommended in all patients with suspected pericarditis.[2] Pericardial effusion is reported in about 60% of cases of acute pericarditis and is usually mild (< 10 mm on semiquantitative echocardiographic assessment). Moderate or larger effusions (> 20 mm) are unusual and may signal a diagnosis other than *idiopathic* pericarditis. An effusion in a patient with a history consistent with acute pericarditis can be considered confirmatory of the diagnosis.

Echocardiography is also useful in unusual cases where associated myocarditis is severe enough to alter ventricular function and to detect a previously silent MI. It is rarely necessary to use imaging modalities other than echocardiography in uncomplicated acute pericarditis. However, as discussed below, in difficult cases computed tomography (CT) and/or cardiac magnetic resonance imaging (MRI) can help to detect pericardial thickening and/or active inflammation.[2]

Diagnosis, Natural History, and Management

ESC guidelines include the results of the first randomized clinical trials in pericarditis as well as more recent observational studies. However, objective data to support recommendations for management of

acute pericarditis as well as other pericardial diseases remain limited. Most are based on expert opinion and consensus. According to the guidelines, the clinical diagnosis of acute pericarditis can be made based on two of the following criteria: (1) chest pain, (2) pericardial friction rub, (3) ECG changes consisting of typical ST elevation and/or PR depression, and (4) pericardial effusion.[2]

In cases with atypical presentations, imaging to detect pericardial thickening and inflammation can be helpful in establishing the diagnosis. This may be provided by CT based on thickening and enhanced imaging after contrast injection, and/or MRI based on edema on T2-weighted dark blood images and late pericardial enhancement indicating active inflammation and/or fibrosis after injection of gadolinium (**see Chapters 17 and 18**).[2,7] Elevation of biomarkers of inflammation (e.g., hsCRP) is supportive of the diagnosis but not definitive.

Initial management is focused on confirming the diagnosis, screening for specific causes that would alter management, detection of effusion and other echocardiographic abnormalities, alleviation of symptoms, and appropriate treatment if a specific cause is discovered (**Table 83.3**). Certain features are associated with both an increased risk of complications and nonviral etiologies that may warrant targeted therapies (**Fig. 83.3**). On this basis, triage of patients is possible after initial evaluation (**see Fig. 83.3**).[2,5,7,15] We recommend the following routine laboratory evaluation: ECG, complete blood count, serum creatinine, hsCRP and troponin I, chest radiograph, and echocardiogram. Additional testing should be guided by suspicion of a specific cause. Thus, for example, in young women, obtaining antinuclear antibody (ANA) titers to test for systemic lupus erythematosus is reasonable because acute pericarditis can occasionally be its initial presentation. However, low ANA titers are common in patients with *recurrent* idiopathic pericarditis without other systemic lupus erythematosus criteria.[16] Thus, in this setting, low ANA titers appear to be nonspecific, possibly reflecting an immune-mediated pathogenesis. **Fig. 83.3 and Table 83.3** summarize our recommendations for triage and initial management of patients with definite or suspected acute pericarditis.

TABLE 83.3

Initial Approach to the Patient with Definite or Suspected Acute Pericarditis

1. If the diagnosis is suspected but not certain, listen often for pericardial rub and obtain ECGs frequently to check for diagnostic findings.
2. If the diagnosis is suspected or certain, obtain the following tests to help confirm the diagnosis (if necessary) and determine whether a specific causative diagnosis and/or significant associated conditions and/or complications are present: Hemogram hsCRP Troponin I Chest radiograph Echocardiogram Consider additional testing on the basis of clinical suspicion of a specific etiology
3. If the diagnosis is likely or certain, initiate therapy with an NSAID plus colchicine

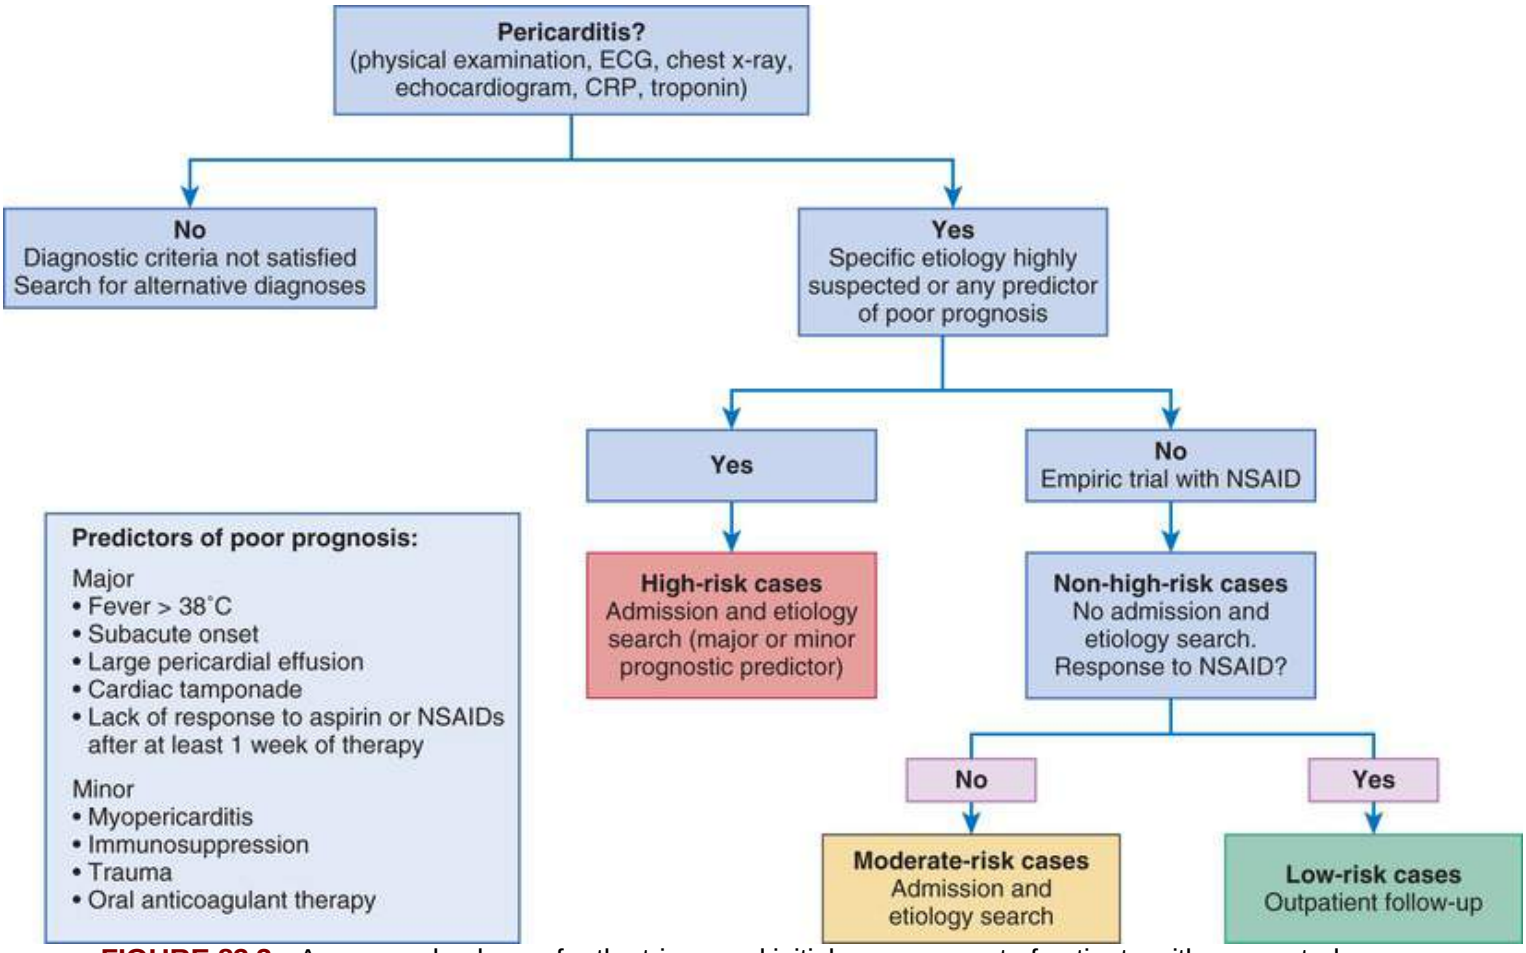


FIGURE 83.3 A proposed scheme for the triage and initial management of patients with suspected pericarditis, including markers of elevated risk (*inset*). *CRP*, C-reactive protein; *ECG*, electrocardiogram. See also references 2, 5, 7, and 15. (From Adler Y, Charron P, Imazio M, et al: 2015 ESC Guidelines for the diagnosis and management of pericardial diseases: the task force for the diagnosis and management of pericardial diseases of the European Society of Cardiology (ESC). Eur Heart J 2015;36:2921.)

Acute idiopathic pericarditis is a self-limited disease without significant complications or recurrence in 70% to 90% of patients.[5-7,17] If laboratory data do not contradict the diagnosis of *idiopathic* pericarditis, symptomatic treatment with nonsteroidal antiinflammatory drugs (NSAIDs) is recommended.[2,5-7,18-20] Other recommendations include restriction of physical activity beyond a sedentary level until resolution of symptoms and normalization of hsCRP for patients not involved in competitive sports. For athletes, a return to sports is recommended after an arbitrary term of 3 months and only after symptoms have fully resolved and hsCRP levels, ECG findings, and echocardiographic findings have normalized.[2]

The choice of a specific antiinflammatory regimen is based on concomitant therapies (e.g., favoring aspirin [ASA] if antiplatelet therapy is required), patient preferences, and the medical history (allergies, intolerances, proven efficacy).[2,5-7,21] Two alternative regimens with an excellent safety profile are recommended (**Table 83.4**): ibuprofen 600 to 800 mg orally three times daily, or ASA 750 to 1000 mg orally three times daily.[2] Gastric protection in the form of a proton pump inhibitor should be provided. Many patients have gratifying responses to the first few doses of an NSAID. Most respond fully after 10 to 14 days and need no additional treatment. As noted, using normalization of hsCRP to guide the duration of therapy is a reasonable alternative to a predetermined time course.[2,14] Once the patient is asymptomatic and the hsCRP has normalized, tapering rather than abrupt cessation of antiinflammatory drugs should be considered in an attempt to reduce recurrences (**see Table 83.4**).[2]

TABLE 83.4

Empirical Antiinflammatory Therapy for Acute Idiopathic Pericarditis

DRUG	USUAL DOSAGES	INITIAL DURATION	TAPERING*
Aspirin	750-1000 mg every 8h	1-2 weeks	Decrease doses every week for 2-3 weeks, then discontinue
Ibuprofen	600-800 mg every 8h	1-2 weeks	Decrease doses every week for 2-3 weeks, then discontinue
Colchicine	0.5-0.6 mg once (<70 kg) or 0.5-0.6 mg BID (≥70 kg)	3 months	Optional, over 2-3 weeks

*Therapy duration is individualized and guided by symptoms and hsCRP. Maintain initial dose and taper only if patient is asymptomatic and hsCRP is normalized.

Colchicine is recommended for 3 months as an adjunct to NSAIDs. Colchicine added to standard antiinflammatory therapy improves the response and reduces recurrences by approximately half during follow-up.[2,22-24] The drug is thought to exert an antiinflammatory effect by blocking microtubule assembly in WBCs. Weight-adjusted doses (0.5 to 0.6 mg orally every 12 hours or 0.5 to 0.6 mg once daily for patients < 70 kg) are recommended.[2,22]

Reliable patients with no more than small effusions who respond well to initial therapy need not be admitted to the hospital. Those who do not respond well initially, who have larger effusions, in whom a cause other than idiopathic pericarditis is suspected, or who meet any high-risk criteria (**see Fig. 83.3**) should be hospitalized for observation, diagnostic testing, and treatment.[2,5-7] In those who respond slowly to an NSAID and colchicine, analgesics may allow time for a more complete response. Initial use of the intravenous (IV) route of administration for NSAIDs can be considered to more quickly alleviate symptoms.[2,21]

Corticosteroid use should be minimized in patients with acute pericarditis because it may impair the clearance of infectious agents.[2,5-7] However, there are selected indications for corticosteroid use: (1) contraindications to or failure of an NSAID and colchicine, (2) underlying conditions (e.g., autoimmune diseases) whose primary treatment is corticosteroids, (3) concomitant diseases (e.g., renal failure), (4) pregnancy, and (5) concomitant therapies constituting relative contraindications to NSAIDs and/or colchicine (e.g., oral anticoagulants). Relatively low doses of corticosteroids are recommended (e.g., prednisone 0.2 to 0.5 mg/kg daily) to minimize complications.[2] Recent data on recurrence show that high doses of corticosteroids (e.g., prednisone 1.0 to 1.5 mg/kg/day) are associated with major side effects in about one quarter of patients, leading to drug withdrawal, more hospitalizations, and more recurrences.[2,25] Tapering should be gradual, typically over 6 to 12 weeks, and guided by the symptomatic response and hsCRP levels.[2,25] High-dose corticosteroids, especially with rapid tapering, appear to particularly increase recurrences. Concurrent colchicine should be administrated during corticosteroid therapy.

Complications of acute pericarditis include effusion, tamponade, and constriction. As noted earlier, small effusions are common. Relatively little is known about the incidence of more significant complications. In the largest modern report, a specific cause was identified in 17% of patients.[26] Over an average 31-month follow-up, tamponade developed in 3.1% and constriction in 1.5%. Most complications occurred in patients with identified specific causes. Constrictive pericarditis was addressed in more detail in a recent analysis of 500 patients.[17] Overall, constriction developed in 1.8% over a median 72-month follow-up. In the 83% of patients with idiopathic pericarditis, constriction developed in only 0.48%.[17] Thus, patients with idiopathic pericarditis can be reassured that the chance of developing constriction is exceedingly low.

Recurrent Pericarditis

Recurrences occur in 15% to 30% of patients with idiopathic acute pericarditis,[5-7,27,28] Recurrences are

the most common complication and may seriously affect the quality of life. They have never been associated with evolution to constrictive pericarditis. The risk of constriction is associated with the etiology, not the number of recurrences.[17] A diagnosis of recurrent pericarditis requires new symptoms and signs of disease activity (friction rub, ECG changes, new or worsening pericardial effusion, elevation of hsCRP) after a symptom-free interval of at least 4 to 6 weeks to allow completion of antiinflammatory therapy for a previous episode.[2,5-7] It is not unusual for patients to have recurrent pain without objective evidence of disease activity. These patients may respond to repeated treatment, but should not be classified as having a definite recurrence.

For recurrences we recommend therapy with an NSAID plus colchicine and a proton pump inhibitor at the same doses outlined for an initial episode. Therapy should be continued until complete resolution of symptoms, signs, and laboratory findings, including hsCRP if elevated. At this point the NSAID should be gradually tapered. If this therapy fails, corticosteroids may replace the NSAID or may be added as "triple therapy." As for an initial episode, doses of 0.2 to 0.5 mg/kg/day of prednisone or its equivalent are recommended for at least 2 to 4 weeks until symptoms and signs resolve and hsCRP normalizes, followed by gradual tapering every 2 to 4 weeks.[2] Colchicine in doses discussed earlier should always be included for at least 6 months. The duration of therapy may be prolonged to 12 months in more difficult cases.[2] For recurrence during corticosteroid tapering, we recommend maintaining the same dose if possible and controlling the recurrence by adding an NSAID, increasing the dosage of the NSAID, and/or starting colchicine if this has not been done. Some patients have recurrences that are mild and easily managed with reinstitution of an NSAID for a brief period of time. In our experience, these patients often do not have objective evidence of inflammation. There is no need to employ more intensive antiinflammatory regimens in these patients.

For patients with recurrences who are resistant to colchicine and corticosteroids (i.e., who cannot withdraw from corticosteroids and still have recurrences while taking colchicine), additional therapies are available.[2] All are off-label indications and supported by case reports and/or small series. These patients are relatively rare, representing no more than 5% to 10% of recurrent pericarditis cases.[29,30] Therapies include azathioprine (2 mg/kg/day orally for several months with gradual dose increases and monitoring of WBCs, transaminases, and amylases), which may allow discontinuation or reduction of corticosteroid doses,[2] human intravenous immunoglobulin (400 to 500 mg/kg/day for 5 days with a possible repeat course after 1 month),[31] or anakinra, an interleukin 1 antagonist (1 to 2 mg/kg/day up to 100 mg daily subcutaneously for several months).[32] The optimal duration of therapy for these treatments is not established. Their mechanisms of action (including colchicine) in recurrent pericarditis are summarized in **eFig. 83.2**. For physicians who do not ordinarily prescribe these drugs it is prudent to enlist the help of colleagues experienced in their use. As a last resort for cases refractory to all medical therapies, pericardiectomy may be considered.[2,29,33]

Pericardial Effusion and Cardiac Tamponade

Etiology

Virtually any disease that can cause pericarditis can cause an effusion (**see Table 83.1**).[1,2,8,34] Effusions are common early after cardiac surgery and orthotopic heart transplantation, but tamponade is unusual.[2] They usually resolve within several weeks to a few months. Various miscellaneous, noninflammatory diseases can cause effusion (**see Table 83.1**). Patients with severe circulatory congestion may have small to moderate transudative effusions. Bleeding into the pericardial sac occurs after blunt and penetrating

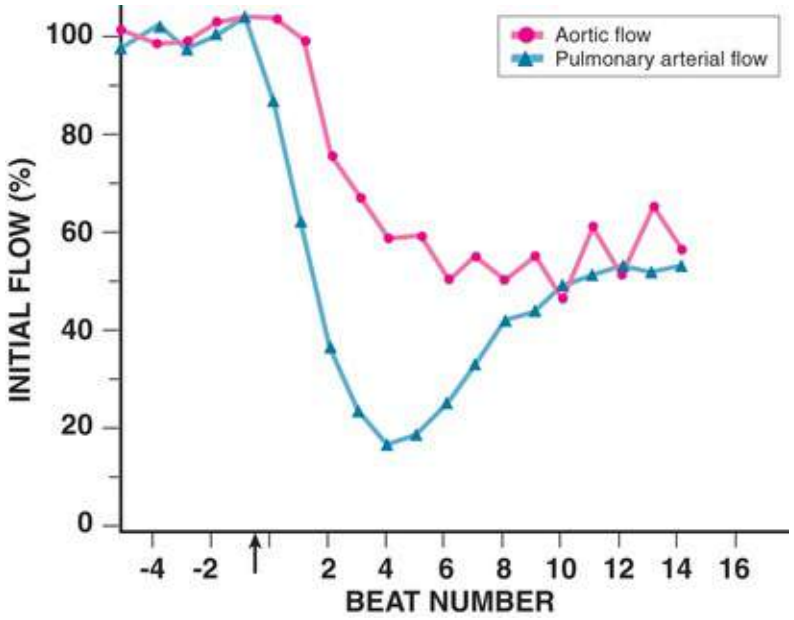
trauma, following post-MI rupture of the LV free wall, and, increasingly, as a complication of cardiac procedures. Retrograde bleeding is a major cause of death due to aortic dissection (**see Chapter 63**). Pericardial effusions are also common in patients with pulmonary hypertension.[35] Asymptomatic pericardial effusions are often discovered when a chest x-ray or echocardiogram is performed for unrelated indications. Last, otherwise healthy patients are occasionally encountered with large, asymptomatic pericardial effusions with no clear etiology.[2]

Those causes of effusion with a high incidence of progression to tamponade include bacterial, fungal, and HIV-associated infections (**see Chapter 82**); bleeding; and neoplastic involvement. Although large effusions due to acute idiopathic pericarditis are unusual, because this type of pericarditis is so common it accounts for a significant percentage of tamponade cases. About 20% of large, symptomatic effusions without an obvious etiology following routine evaluation constitute the initial presentation of a cancer.[2,8] Details of pericardial effusion pertinent to selected, specific disease entities are discussed in the sections at the end of this chapter.

Pathophysiology and Hemodynamics

Formation of an effusion is a generic response to inflammatory, infectious, or neoplastic diseases involving the pericardium. Lymphomas occasionally cause effusion in association with enlarged mediastinal lymph nodes by obstructing lymph drainage.[1] The pathophysiology of effusions when there is no obvious inflammation or bleeding (e.g., with uremia or idiopathic disease) is very poorly understood.

When an effusion accumulates, the pressure in the pericardial sac depends on the amount of fluid and the pericardial PVR.[1] The mechanical consequences of high pressure acting on the surface of the heart mainly result from compression and collapse of the right heart and caval vessels. Underfilling of the left heart then ensues from reduced right heart output. **eFig. 83.3** depicts an experiment illustrating these principles. Clinically, cardiac tamponade has a continuum from an effusion causing minimal effects to full-blown circulatory collapse. The most critical point occurs when an effusion reduces the diastolic volume of the cardiac chambers such that cardiac output declines. As discussed earlier, the limited pericardial reserve volume dictates that modest amounts of rapidly accumulating fluid (as little as 150 to 200 mL) can impair cardiac function. In contrast, large, slowly accumulating effusions are often well tolerated. The compensatory response to a hemodynamically significant effusion includes increased adrenergic tone and parasympathetic withdrawal. The resultant tachycardia and increased contractility maintain the cardiac output and blood pressure for a period of time.[1] Eventually, however, both decline. Patients who cannot mount a normal adrenergic response (e.g., those receiving beta blockers) are more susceptible to the effects of an effusion. In terminal tamponade, a depressor reflex with paradoxic bradycardia may supervene.



EFIGURE 83.3 Non–steady state responses to an abrupt increase in pericardial pressure provide insights into the pathophysiology of cardiac tamponade. The figure shows an experiment in a dog in which aortic and pulmonary arterial stroke volumes (SVs) were measured beat to beat before and after fluid was abruptly introduced into the pericardial sac (arrow). This causes an immediate decrease in pulmonary SV but no change in aortic SV. Two beats later aortic SV decreases and a new steady state is then achieved with equivalent decreases in aortic and pulmonary SV. During the time required to reach a new steady state, pulmonary SV is less than aortic SV. This transient inequality results in transfer of blood from the pulmonary into the systemic circulation and may explain the decrease in pulmonary vascularity on chest radiograph in tamponade. Thus, the primary, direct effect of increased pericardial pressure is to impede right heart filling, with effects on the left heart largely secondary to underfilling. (From Ditchey R, Engler R, LeWinter M, et al: The role of the right heart in acute cardiac tamponade in dogs. Circ Res 1981;48:701.)

As fluid accumulates, left- and right-sided atrial and ventricular diastolic pressures rise, and in severe tamponade they equalize at a pressure similar to that in the pericardial sac, typically 20 to 25 mm Hg (**Fig. 83.4**). Equalization is closest during inspiration. Thus, the pericardial pressure dictates intracavitary pressure and *transmural* filling pressures of the cardiac chambers are near zero. Correspondingly, cardiac volumes progressively decline. The small end-diastolic ventricular volume (decreased preload) mainly accounts for the reduced stroke volume (SV). Because of compensatory increases in contractility, the end-systolic volume also decreases, but not enough to maintain the SV. Because the right heart filling pressure is normally lower than the left heart filling pressure, as fluid accumulates pressures increase more rapidly in the right heart than the left heart.

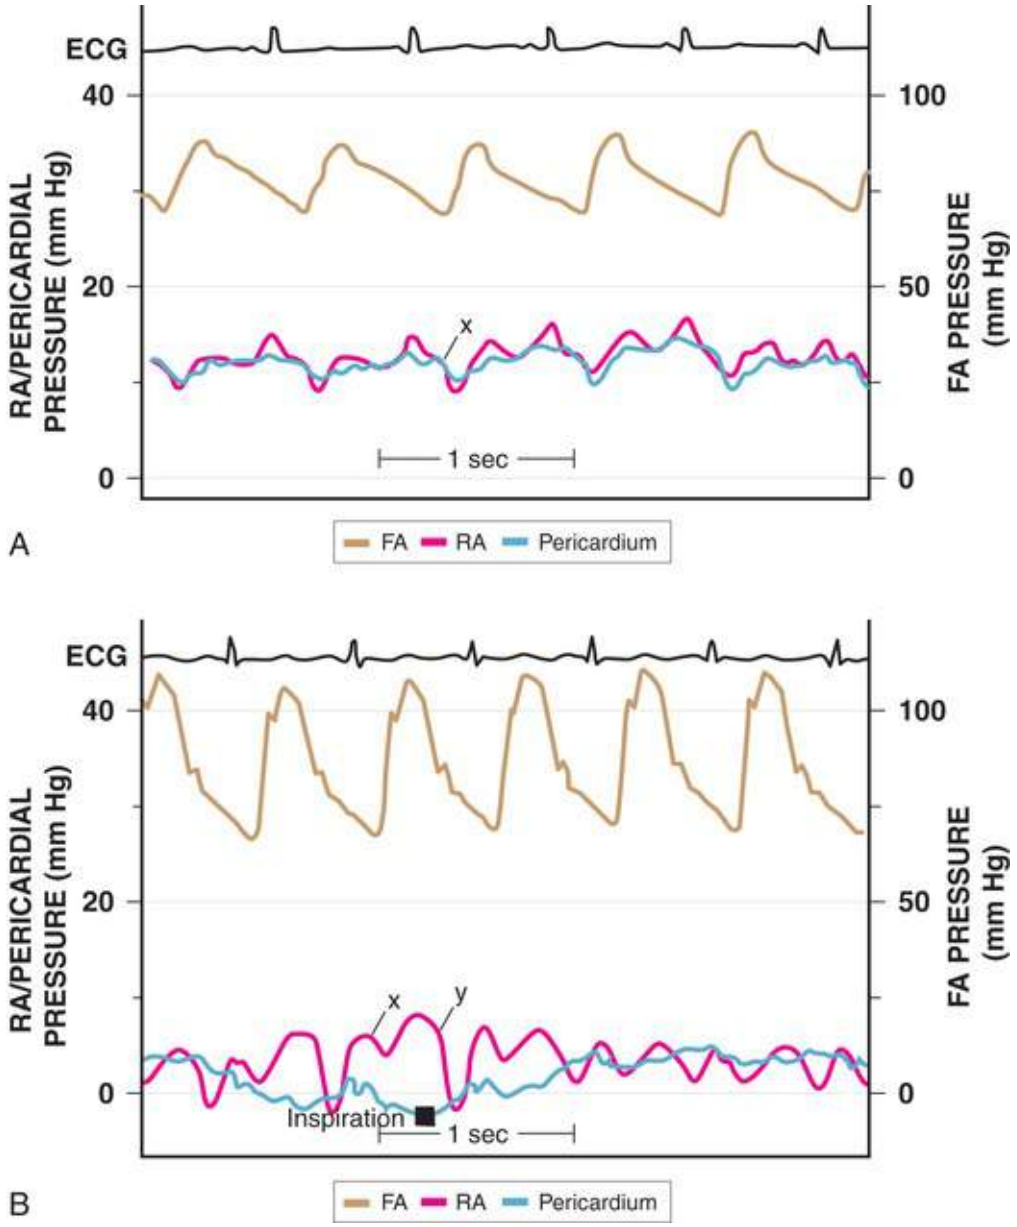


FIGURE 83.4 Femoral arterial (FA), right atrial (RA), and pericardial pressure before **(top)** and after **(bottom)** pericardiocentesis in a patient with cardiac tamponade. Both RA and pericardial pressure are about 15 mm Hg before pericardiocentesis. In this case there was a negligible paradoxic pulse. Note presence of x descent but absence of y descent before pericardiocentesis. Pericardiocentesis results in marked increase in FA pressure and marked decrease in RA pressure. During inspiration, pericardial pressure becomes negative, there is clear separation between RA and pericardial pressure, and y descent is now evident and prominent, suggesting the possibility of an effusive-constrictive picture.
(Modified from Lorell BH, Grossman W: Profiles in constrictive pericarditis, restrictive cardiomyopathy and cardiac tamponade. In Baim DS, Grossman W [editors]: Grossman's cardiac catheterization, angiography, and intervention. Philadelphia, Lippincott Williams & Wilkins, 2000, p 840.)

In addition to elevated and equal intracavitary filling pressures, low transmural filling pressures, and small cardiac volumes, two other hemodynamic abnormalities are characteristic of tamponade. One is loss of the y descent of the RA or systemic venous pressure wave (**see Fig. 83.4**). The x and y *descents* correspond to periods when venous inflow is increasing. Loss of the y descent has been explained based on the concept that the total heart volume is fixed in severe tamponade.[1] Thus, blood can enter the heart only when blood is simultaneously leaving. The normal y descent begins when the tricuspid valve opens (i.e., when blood is not leaving). In tamponade, inflow cannot increase and the descent is lost. The x descent occurs during ventricular ejection. Because blood is leaving the heart, inflow can increase and the x descent is retained. Loss of the y descent is appreciated in systemic venous or RA pressure recordings and is a useful clue to the presence of tamponade. Although absence of the y descent and loss

of diastolic venous inflow have been considered classic signs, in many cases of tamponade in the modern era pulsed-wave Doppler recordings do reveal venous inflow into the right heart during ventricular diastole.[1,3,4,36] These patients can have effusive-constrictive pericarditis, with a mixed hemodynamic picture.

The second characteristic finding is the paradoxic pulse (**Fig. 83.5**), an abnormally large decline in systemic arterial pressure during inspiration (defined as a drop of > 10 mm Hg in systolic pressure). Other causes of *pulsus paradoxus* include constrictive pericarditis, pulmonary embolus, and pulmonary disease with large variations in intrathoracic pressure. In severe tamponade, the arterial pulse may be impalpable during inspiration. The mechanism of the paradoxic pulse is multifactorial, but respiratory changes in systemic venous return are certainly important.[1] In tamponade, in contrast to constriction, the normal inspiratory *increase* in systemic venous return is present and the normal inspiratory *decline* in systemic venous pressure is retained (Kussmaul sign is *absent*). The increase in right heart filling occurs, once again, under conditions where total heart volume is fixed and left heart volume markedly reduced. The interventricular septum shifts to the left in exaggerated fashion on inspiration, encroaching on the left ventricle such that the SV and pressure generation are further reduced (**see Fig. 83.5**). This is termed *exaggerated ventricular interaction* (in distinction from the previous definition of ventricular interaction).[3,4] Although the inspiratory increase in right heart volume (preload) increases the RV SV, a few cardiac cycles are required to increase the LV filling and SV and counteract the septal shift. Other factors that may contribute include increased afterload caused by transmission of negative intrathoracic pressure to the aorta and traction on the pericardium caused by descent of the diaphragm. Associated with these mechanisms, left and right heart pressure and stroke volume variations are exaggerated and 180 degrees out of phase (**see Fig. 83.5**). **Table 83.5** lists the hemodynamic findings in tamponade compared with constrictive pericarditis. When there are preexisting elevations in diastolic pressures and/or volume, tamponade can occur without a paradoxic pulse.[1] Examples include chronic LV dysfunction, aortic regurgitation, and atrial septal defect. In patients with retrograde bleeding into the pericardial sac due to aortic dissection, tamponade may occur without a paradoxic pulse because of aortic valve disruption and regurgitation.

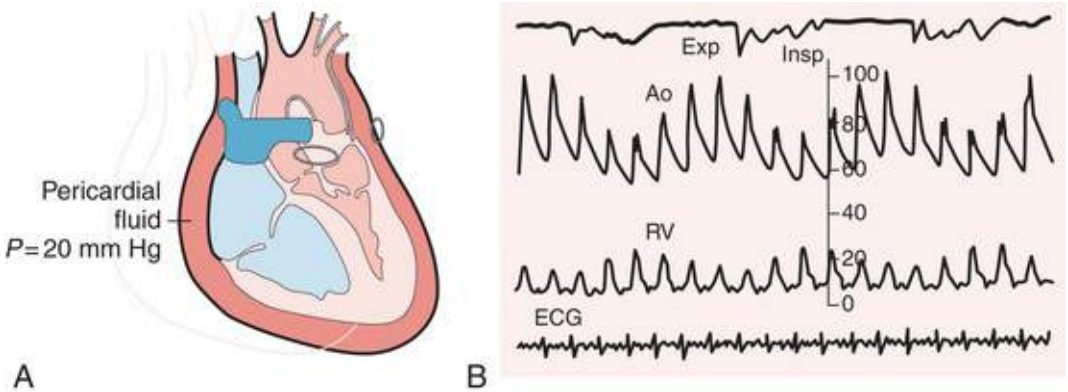

FIGURE 83.5 **Left,** schematic illustration of leftward septal shift with encroachment of left ventricular volume during inspiration in cardiac tamponade. **Right,** respiration marker and aortic and right ventricular pressure tracings in cardiac tamponade. Note paradoxic pulse and marked respiratory variation that is out of phase by 180 degrees in right- and left-sided pressures. (From Shabetai R: The pericardium. New York, Grune & Stratton, 1981, p 266.)

TABLE 83.5

Hemodynamics in Cardiac Tamponade and Constrictive Pericarditis

	TAMPONADE	CONSTRICTION
Paradoxic pulse	Usually present	Present in ~1/3
Equal left/right filling pressures	Present	Present
Systemic venous wave morphology	Absent y descent	Prominent y descent (M or W shape)
Inspiratory change in systemic venous pressure	Decrease (normal)	Increase or no change (Kussmaul sign)
Square root sign in ventricular pressure	Absent	Present

Although mean left- and right-sided filling pressures are typically 20 to 25 mm Hg, tamponade can occur at lower filling pressures, termed *low-pressure tamponade*.[1,2,37] Low-pressure tamponade often occurs when there is a decrease in blood volume in the setting of a preexisting effusion that would not otherwise cause hemodynamic consequences. A modestly elevated pericardial pressure can then lower the transmural filling pressure to levels where the SV is compromised. Because venous pressure is only modestly elevated or even normal, the diagnosis may be missed. Low-pressure tamponade may be observed during hemodialysis, in patients with blood loss and volume depletion, and when diuretics are administered to patients with effusions. In the only sizeable report, about 20% of patients undergoing closed pericardiocentesis met the criteria for low-pressure tamponade.[37] Compared with high-pressure tamponade, low-pressure patients were less often critically ill and signs of tamponade were less prominent. Echocardiographic findings were similar and benefit was derived from pericardiocentesis.

Pericardial effusions can be loculated or localized, resulting in regional tamponade, most commonly after cardiac surgery.[1,2] Although reports are scarce, regional tamponade can cause atypical hemodynamic findings (e.g., reduced cardiac output with unilateral filling pressure elevation). Regional tamponade should be considered whenever there is hypotension in a setting where a loculated effusion is present or suspected. Rarely, large pleural effusions and pneumopericardium can compress the heart and cause tamponade.[1,2,38]

Clinical Presentation

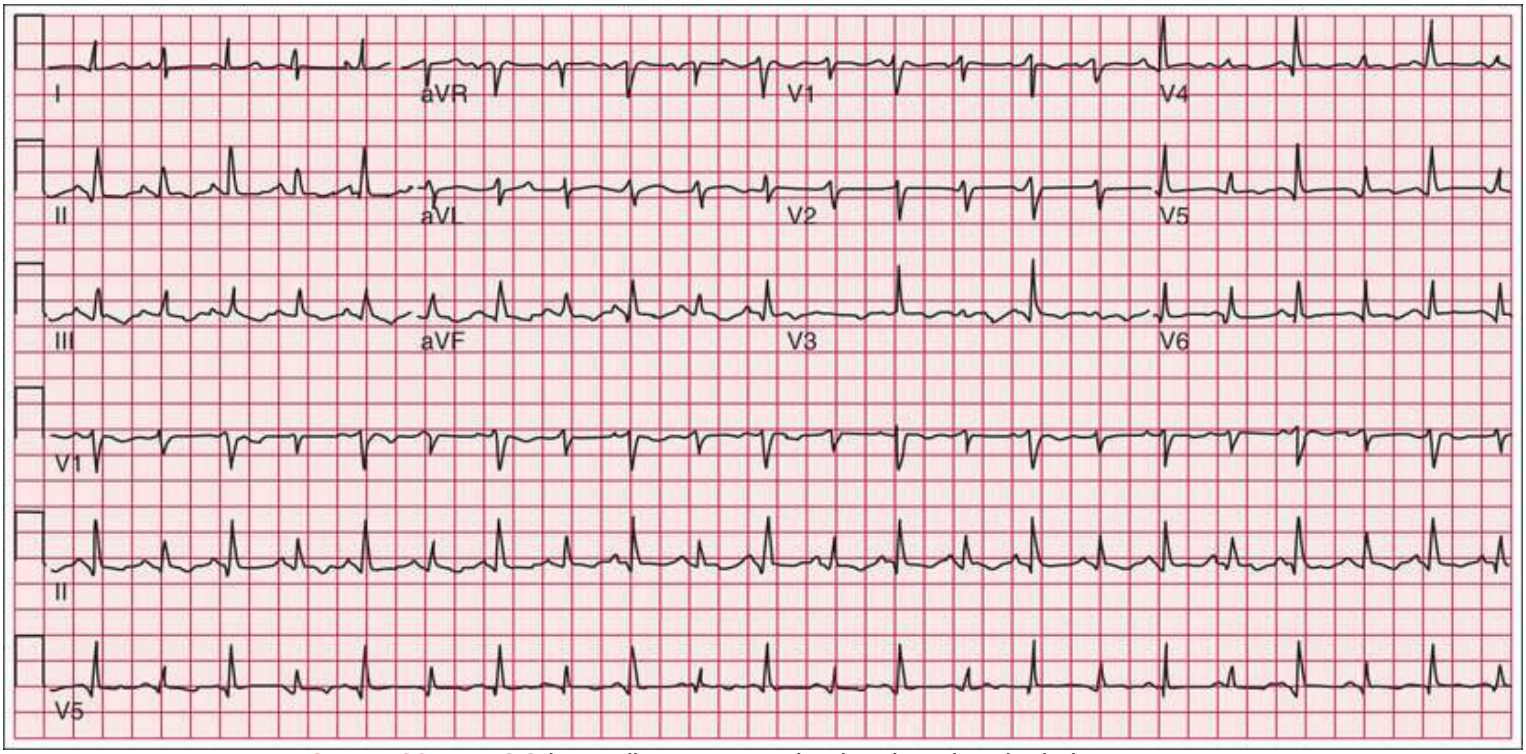
A history pertinent to a specific pericardial disease etiology may be elicited. As noted earlier, asymptomatic effusions may be discovered in otherwise healthy patients when chest imaging is performed for an unrelated reason.[2] Specific etiologies are rarely found in these cases. Effusions do not cause symptoms in and of themselves without tamponade, although patients may have pain due to pericarditis. Patients with tamponade may complain of dyspnea, the mechanism of which is uncertain because there is no pulmonary congestion, and they are more comfortable sitting forward. Other symptoms reflect the severity of cardiac output and blood pressure reduction.

A complete physical examination in patients with pericardial effusion can provide clues to a specific cause. In pericardial effusion without tamponade, the cardiovascular examination is normal unless the effusion is large, the cardiac impulse is difficult to palpate, and the heart sounds are muffled. A friction rub may of course be present. Tubular breath sounds may be heard in the left axilla or base due to bronchial compression. The presence of *Beck's triad* of hypotension, muffled heart sounds, and elevated jugular venous pressure suggests severe tamponade. Patients with tamponade appear uncomfortable and display varying signs of reduced cardiac output and shock, including tachypnea, diaphoresis, cool extremities, peripheral cyanosis, depressed sensorium, and, rarely, yawning.[1,2] Hypotension is usually present, although in early stages compensatory mechanisms maintain the blood pressure. Some patients with subacute tamponade are *hypertensive* on presentation, with a decline in blood pressure following

pericardial drainage.[39] A paradoxic pulse is the rule, but it is important to be alert to situations where it may be absent. The paradox is quantified by cuff sphygmomanometry as the difference between the pressure at which Korotkoff sounds first appear and that at which they are present with each contraction. Tachycardia is also the rule unless heart rate–lowering drugs have been administered, conduction system disease coexists, or a preterminal bradycardic reflex has supervened. The jugular venous pressure is markedly elevated except in low-pressure tamponade, and the y descent is usually absent (**see Fig. 83.4**). The normal decrease in venous pressure on inspiration is retained. Examination of the heart itself is consistent with an effusion, as outlined above. Tamponade can be confused with anything that causes hypotension, shock, and elevated jugular venous pressure, including decompensated heart failure, pulmonary embolus or other causes of pulmonary hypertension, and RV MI.

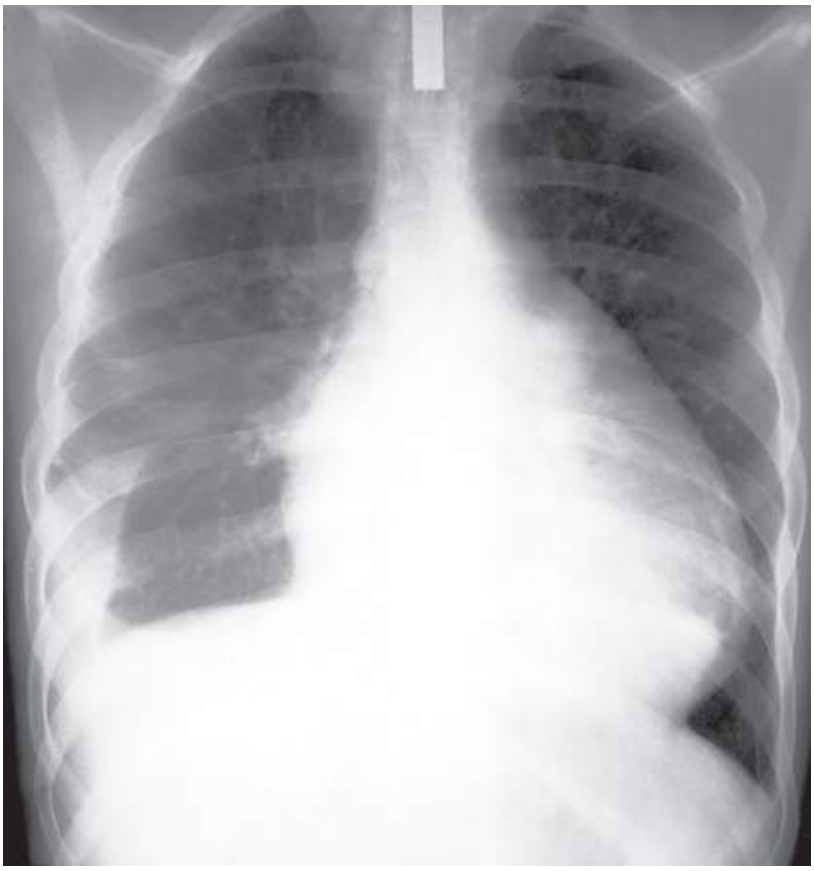
Laboratory Testing

ECG abnormalities include reduced voltage and electrical alternans (**eFig. 83.4**).[1,2] Reduced voltage is nonspecific and can be caused by conditions such as emphysema, infiltrative myocardial disease, and pneumothorax. Electrical alternans is specific but relatively insensitive and caused by anteroposterior swinging of the heart with each contraction. When pericarditis coexists, the usual ECG findings may be present.



EFIGURE 83.4 ECG in cardiac tamponade showing electrical alternans.

The chest radiograph reveals a normal cardiac silhouette until effusions are at least moderate in size. With larger effusions the anteroposterior cardiac silhouette assumes a rounded, flask-like appearance (**eFig. 83.5**). Lateral views may reveal the fat pad sign, a linear lucency between the chest wall and anterior surface of the heart resulting from separation of parietal pericardial fat from epicardium. The lungs are oligemic.



EFIGURE 83.5 Anteroposterior chest radiograph in a patient with a large pericardial effusion (see text). (From Kabbani SS, LeWinter M: Cardiac constriction and restriction. In Crawford MH, DiMarco JP [editors]: Cardiology. St. Louis, Mosby, 2001, p 5,15.5.)

M-mode and two-dimensional Doppler echocardiography are the standard noninvasive methods for detection of pericardial effusion and tamponade.[3,4] A significant effusion appears as a lucent separation between the parietal and visceral pericardium for the entire cardiac cycle (**Fig. 83.6** and Video 83.1). Small effusions are usually first evident over the posterobasal left ventricle. Fluid then spreads anteriorly, laterally, and behind the left atrium, where it is limited by the visceral pericardial reflection. Ultimately, the separation becomes circumferential. Circumferential effusions are graded as small (echo-free space in diastole < 10 mm), moderate (10 to 20 mm), or large (> 20 mm).[3,4] Because the rapidity of accumulation is critical, the hemodynamic significance of an effusion may not be closely correlated with its size. However, it is unusual for tamponade to occur without a circumferential effusion. Frond-like or shaggy-appearing structures in the pericardial space detected by echocardiography suggest clots, chronic inflammation, or neoplastic pericardial processes. As discussed below, CT and MRI are more precise than transthoracic echocardiography for estimating pericardial thickness. *Transesophageal echocardiography* (TEE), however, is comparable to CT and MRI for this purpose.[3,4]

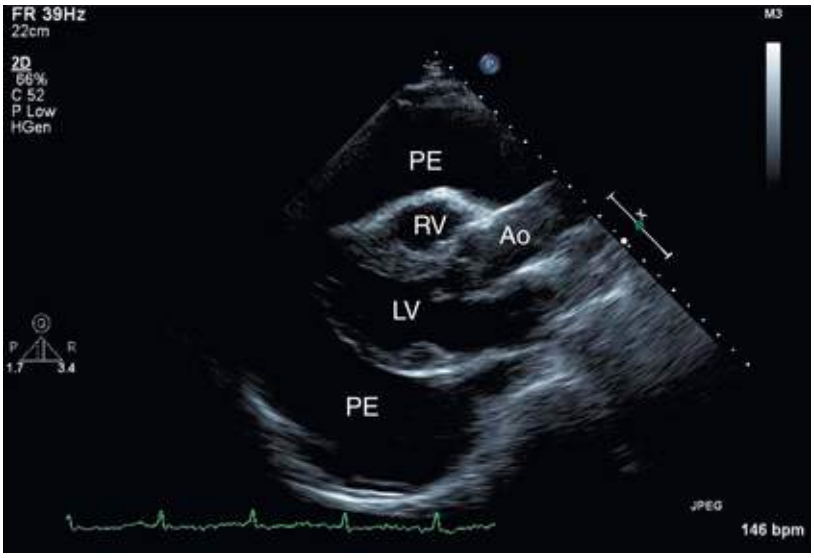


FIGURE 83.6 Two-dimensional echocardiogram of a large, circumferential pericardial effusion (PE). *Ao*, aorta; *LV*, left ventricle; *RV*, right ventricle. (From Kabbani SS, LeWinter M: Cardiac constriction and restriction. In Crawford MH, DiMarco JP [editors]: Cardiology. St. Louis, Mosby, 2001.)

Several echocardiographic findings indicate that tamponade is severe enough to cause hemodynamic compromise.[3,4,36] These include early diastolic collapse of the right ventricle, late diastolic indentation or collapse of the right atrium, and exaggerated respiratory variation in RV and LV size and interventricular septal shifting during inspiration causing a bulge or "bounce." Early diastolic RV collapse (**Fig. 83.7** and see Video 83.1) and late diastolic RA collapse (**eFig. 83.6** and see Video 83.1) are signs that usually first appear relatively early during tamponade, when pericardial pressure transiently exceeds intracavitary pressure.[3,4,36] Rarely, a large *pleural* effusion can cause right-sided chamber collapse, and isolated LV and LA chamber collapse can occur with pericardial hematomas after cardiac surgery.[3,4] The cardiac chambers are small in tamponade and, as noted, the heart may swing anteroposteriorly (see Video 83.1). Distention of the inferior vena cava that does not diminish with inspiration is an important confirmatory finding. Doppler velocity recordings demonstrate exaggerated respiratory variation in right- and left-sided venous and valvular flow, with inspiratory increases on the right and decreases on the left.[3,4,36] Caval inflow occurs largely during ventricular systole. These flow patterns are at least as sensitive for tamponade as M-mode and two-dimensional echocardiographic features.

EFIGURE 83.6 Two-dimensional echocardiogram illustrating right atrial collapse or indentation in cardiac tamponade. (From Gilliam LD: Hemodynamic compression of the right atrium: a new echocardiographic sign of cardiac tamponade. Circulation 1983;68:294.)

With most effusions, transthoracic echocardiography provides sufficient diagnostic information to make management decisions. TEE studies provide better-quality images, but are usually impractical in sick patients unless they are intubated. Fluoroscopy is useful in the cardiac catheterization laboratory for detection of procedure-related effusions when they cause damping or abolition of cardiac pulsation. CT (**see Chapter 18**) and MRI (**see Chapter 17**) are useful adjuncts to echocardiography in the characterization of effusion and tamponade, but neither is ordinarily required and/or advisable in sick patients who require urgent management and treatment decisions.[40,41] They have a role when hemodynamics are atypical, other conditions complicate interpretation, the severity of tamponade is uncertain, or echocardiography is technically inadequate. Video 83.2 is a magnetic resonance cine image of a large, circumferential effusion and a small, underfilled left ventricle. The right ventricle is not compressed because of long-standing pulmonary hypertension, evidenced by RV enlargement. Here, coexistent pulmonary hypertension reduces the accuracy of echocardiographic signs of tamponade.

CT and MRI provide more detailed quantitation and regional localization of effusions than echocardiography and are useful with loculated effusions and coexistent pleural effusions. In Video 83.3 , the wide field of view afforded by MRI demonstrates both a large pericardial effusion and a pleural effusion in a patient with polyserositis. Pericardial thickness can be measured with both methods, allowing indirect assessment of the severity and chronicity of inflammation; as discussed earlier, MRI with gadolinium directly identifies inflammation. Clues to the nature of pericardial fluid can be gained from CT attenuation coefficients.[3,4] Attenuation similar to water suggests a transudative effusion; attenuation denser than water, a malignant effusion or bloody or purulent fluid; and attenuation less dense than water, a chylous effusion. Malignant effusions are associated with a thicker pericardium than benign effusions.[40] A thickness of more than 4.1 mm on CT points to metastatic involvement. Finally, cine CT or MRI provides information similar to echocardiography for the assessment of tamponade (e.g., septal shifting, chamber collapse).

Management

Management is dictated first and foremost by whether tamponade is already present or has a high chance of developing (**Table 83.6**).[1,2,41] Situations where tamponade is a near term threat include suspected bacterial (including tuberculous) pericarditis, hemopericardium, and any moderate to large effusion that is not thought to be chronic and/or is increasing in size. When tamponade is present or threatened, decision making requires urgency and a low threshold for pericardiocentesis (**see Table 83.6**). *In the absence of actual or threatened tamponade,* management can be more deliberative. This includes several categories of patients. Some have acute pericarditis with a small to moderate effusion detected as part of routine evaluation. Others do not have symptoms or signs of pericarditis or effusion but undergo echocardiography because of the presence of diseases known to involve the pericardium. The rest are asymptomatic and have effusions detected when tests are performed for reasons other than suspected pericardial disease (e.g., evaluation of an enlarged cardiac silhouette or investigation of thoracic pathology).

TABLE 83.6

Initial Approach to the Patient with Pericardial Effusion

1. Determine if tamponade is present or threatened based on history, physical examination, echocardiogram.
2. If tamponade is not present or threatened: If etiology is not apparent, consider diagnostic tests as for acute pericarditis. If effusion is large, consider a course of an NSAID plus colchicine or corticosteroid; if no response, consider closed pericardiocentesis.
3. If tamponade is present or threatened: Urgent or emergent closed pericardiocentesis or careful monitoring if trial of medical treatment to reduce effusion is considered appropriate.

In many cases of effusion where tamponade is neither present nor threatened, a cause will be evident or suggested based on the history and/or previous diagnostic tests. When a diagnosis is not clear, an assessment of specific causes should be undertaken, including the diagnostic tests recommended for acute pericarditis and anything else dictated by the clinical picture (e.g., screening for neoplastic or autoimmune diseases, infections, and hypothyroidism). Careful judgement should be exercised in testing. Thus, a patient with severe heart failure and circulatory congestion with a small effusion does not need such testing, but patients with evidence of a systemic disease deserve very careful attention.

In patients without actual or imminent tamponade, pericardiocentesis (closed or open with biopsy) can be undertaken for diagnostic purposes but is not always required. As discussed above, in many cases a diagnosis will either be obvious when the effusion is first noted or become evident as part of the initial investigations. Moreover, in this setting routine analysis of pericardial fluid has a low diagnostic yield.[2,8,41] In situations where pericardiocentesis is felt to be necessary for diagnostic purposes, consideration should be given to open drainage with biopsy.

Otherwise healthy patients with large, asymptomatic effusions and no evidence of tamponade or a specific cause are a special category.[2,41] The effusions are by definition chronic and in general stable, but a minority (perhaps 20% to 30%) develop tamponade unpredictably. Moreover, after closed pericardiocentesis the effusions may not reaccumulate.[2,41] Thus, there is a rationale for pericardiocentesis following routine evaluation for specific etiologies as outlined above. Before undertaking pericardiocentesis, a course of an NSAID or corticosteroids combined with colchicine may be considered, because this has a low risk. In the absence of evidence of inflammation (e.g., increased CRP, gadolinium uptake on MRI), however, antiinflammatory regimens are not likely to be efficacious. Recurrence of this type of effusion after closed pericardiocentesis is considered an indication for pericardiectomy or a pericardial window.[2,41]

Patients with actual or threatened tamponade constitute a medical emergency. With the exception of those who do not wish prolongation of life (mainly those with metastatic cancer), hospital admission and careful hemodynamic and echocardiographic monitoring are mandatory. The great majority of patients require pericardiocentesis to treat or prevent tamponade, but there are some exceptions. Patients with acute, apparently idiopathic pericarditis with no more than mild tamponade can be treated for a brief period of time under careful monitoring with an NSAID and/or prednisone combined with colchicine in an attempt to rapidly shrink the effusion. Patients with known inflammatory/autoimmune diseases can be treated similarly (there is no evidence that corticosteroids increase recurrence in these patients). Patients with *suspected* bacterial infections or hemopericardium *with small effusions (< 10 mm)* should be considered to have threatened tamponade because of the cause. These patients may be suitable for initial conservative management and careful monitoring because the risk of closed pericardiocentesis is increased with smaller effusions.

Hemodynamic monitoring with a central venous or pulmonary artery catheter is often useful, especially in patients with threatened or mild tamponade in whom a decision is made to defer pericardiocentesis.

Monitoring is also helpful *after* pericardiocentesis to assess reaccumulation and the presence of underlying constriction (**see Fig. 83.4**), as discussed subsequently. Insertion of a catheter in the central circulation should not be allowed to delay definitive therapy in critically ill patients.

For the majority of patients in this category, urgent or emergent pericardiocentesis is indicated. Once actual or threatened tamponade is diagnosed, IV hydration with normal saline should be instituted.[2,41,42] Positive inotropes are of little value. Volume expansion and positive inotropes are temporizing measures and should not be allowed to substitute for or delay pericardiocentesis. In the vast majority of cases, *closed pericardiocentesis* is the treatment of choice. Before proceeding, it is important to be sure that there is indeed an effusion large enough to cause tamponade that is amenable to a closed approach, especially if the hemodynamic findings are atypical. Loculated effusions or effusions containing clots or fibrinous material increase the risk and difficulty of closed pericardiocentesis. An open approach should be considered for safety and to obtain pericardial tissue and create a window.

Whether to perform closed versus open pericardiocentesis in patients with hemopericardium can be a difficult decision.[2,41] The danger of a closed approach is that lowering intrapericardial pressure will allow more bleeding without affording an opportunity to correct its source. In cases of trauma or post-MI LV rupture, closed pericardiocentesis should usually be avoided. If bleeding is slower (e.g., due to a procedural coronary perforation or puncture of a cardiac chamber), closed pericardiocentesis is often indicated because bleeding may stop spontaneously and/or the procedure can provide temporary relief before definitive repair. Closed pericardiocentesis in patients with hemopericardium due to type A aortic dissection has been considered relatively contraindicated. However, in a small series of patients, preoperative pericardiocentesis using intermittent cycles of drainage dictated by systolic blood pressure levels appeared to be safe and effective for stabilization.[43]

The most common approach to closed pericardiocentesis is subxiphoid needle insertion with echocardiographic guidance to minimize the risk of myocardial puncture and assess the completeness of fluid removal.[2] Once the needle has entered the pericardial space, a modest amount of fluid is immediately removed (perhaps 50 to 100 mL) in an effort to produce rapid improvement. A guidewire is then inserted and the needle replaced with a pigtail catheter. The catheter is manipulated to maximize fluid removal. When possible, the procedure should be performed in the cardiac catheterization laboratory with experienced personnel in attendance. If echocardiographic guidance is unavailable, the needle should be directed toward the left shoulder. Echocardiographically guided pericardiocentesis has a success rate of more than 95% and a rate of serious complications of less than 2%.[44,45] Rarely, patients suffer *pericardial decompression syndrome* following either closed or open drainage.[46] This is a poorly understood but life-threatening syndrome characterized by combinations of cardiogenic pulmonary edema and shock.

If a pulmonary artery catheter has been inserted, the RA and pulmonary capillary wedge pressure and cardiac output should be monitored before, during, and after the procedure. Ideally, the pericardial fluid pressure should also be measured. Hemodynamic monitoring is useful for several reasons. Initial measurements confirm and document the severity of tamponade. Measurements after completion establish a baseline to assess reaccumulation. As discussed below, some patients with tamponade have coexisting constriction (i.e., effusive-constrictive pericarditis), which is difficult to detect when an effusion dominates but becomes apparent after pericardiocentesis.[47] Following pericardiocentesis, repeat echocardiography and in many cases continued hemodynamic monitoring should be employed to assess reaccumulation. Intrapericardial catheters should be left in place for several days to allow continued drainage. This minimizes recurrence and facilitates the delivery of intrapericardial drugs if appropriate.[2,48,49]

Open pericardiocentesis is occasionally preferred for the initial removal of fluid. Bleeding due to trauma and rupture of the LV free wall have been mentioned previously in this regard. Loculated effusions and/or effusions that are borderline in size are drained more safely in the operating room. Recurring effusions, especially those causing tamponade, can initially be drained using a closed approach because of logistical considerations. However, open pericardiocentesis with biopsy and creation of a pericardial window are preferred for recurrences severe enough to cause tamponade.[2]

Percutaneous balloon pericardiotomy and pericardioscopy have been employed to drain fluid, create pericardial windows, and perform pericardial biopsy.[50,51] Balloon pericardiotomy may be particularly useful for malignant effusions and other situations where recurrence is common and a definitive approach without a surgical procedure is desirable. These methods appear safe and effective, but experience is limited and confined to centers with a special interest in pericardial disease.

Analysis of Pericardial Fluid

Normal pericardial fluid has the features of a plasma ultrafiltrate.[1] Lymphocytes are the predominant cell type. Although routine analysis of fluid does not have a very high yield for disease etiology, analysis is rewarding with bacterial infections and malignant effusions. Measurements should include WBCs and differential, hematocrit, and protein content.[2] Although most effusions are exudates, detection of a transudate reduces diagnostic possibilities. Sanguineous fluid is nonspecific and does not necessarily indicate active bleeding. Chylous effusions can occur after traumatic or surgical injury to the thoracic duct or obstruction by neoplasms. Cholesterol-rich (“gold paint”) effusions occur in hypothyroidism. Pericardial fluid should routinely be stained and cultured for bacteria, including *Mycobacterium tuberculosis*, and fungi and as much fluid as possible submitted for detection of malignant cells.

In suspected tuberculous pericardial disease, several other tests are useful. including unstimulated interferon-gamma (uIFN-γ), adenosine deaminase (ADA), lysozyme levels, and the polymerase chain reaction (PCR).[1,2,8,18] If there is a suspicion of tuberculous pericarditis, at least one of these tests should be routine because of the difficulty in diagnosing this disorder and delays in making a diagnosis by culture.

New and novel approaches for the analysis of pericardial fluid have been the subject of active investigation. As discussed below, there may be a role for measurement of tumor markers as a screen for malignant effusion.[2,52] Selected cytokine and related biomarkers measured in both pericardial fluid and serum have shown promise in distinguishing various types of inflammatory effusions, but their precise roles have not been elucidated.[53,54] Identification of genomic material by PCR may be helpful in identifying a viral etiology in patients with effusions of uncertain etiology.[55]

Pericardioscopy and Percutaneous Biopsy

Pericardioscopic-guided drainage of pericardial effusions was discussed earlier. When standard noninvasive methods of evaluating the cause of pericardial effusions are unsuccessful, extended pericardioscopically guided biopsies combined with a battery of immunologic and molecular methods applied to both fluid and tissue (e.g., PCR) have been advocated to improve the diagnostic yield and management.[50] This is a promising approach that appears safe in experienced hands. However, experience is limited and it is not known whether such an approach will in fact improve long-term outcomes.

Constrictive Pericarditis

Etiology

Constrictive pericarditis is the end stage of an inflammatory process involving the pericardium. Most diseases listed in **Table 83.1** can cause constriction. In the developed world the disorder is most commonly idiopathic or due to surgical complications or radiation injury.[1,2,56,57] TB was a very common cause before the advent of effective drug therapy and remains important in developing countries.[58] Constriction can follow an initial insult by as little as several months and occasionally less, but typically takes years to develop. The end result is fibrosis, often calcification, and adhesions of the parietal and visceral pericardium. Scarring is usually more or less symmetric and impedes filling of all heart chambers. Most patients have a thickened pericardium, but 18% are reported to have normal thickness on direct histopathologic examination and 28% on CT scanning.[2-4] In a subset of patients, constriction is transient and/or reversible by antiinflammatory drugs. This is observed early after cardiac surgery and in other patients with intense pericardial inflammation (discussed below).[1,59-62]

Pathophysiology

The consequence of pericardial scarring is markedly restricted filling of the heart.[1,2] This results in elevated and equal filling pressures in all chambers and systemic and pulmonary veins. In early diastole the ventricles fill rapidly because of markedly elevated atrial pressures and accentuated early diastolic ventricular suction related to small end-systolic volumes. During early to mid-diastole, ventricular filling abruptly ceases when the cardiac volume reaches the limit set by the pericardium. Thus, almost all filling occurs early in diastole. Systemic venous congestion results in hepatic congestion, peripheral edema, ascites, anasarca, and cardiac cirrhosis. Reduced cardiac output also results from impaired filling and causes fatigue, muscle wasting, and weight loss. In “pure” constriction, ventricular contractile function is preserved, although the EF can be reduced because of a small end-diastolic volume. The myocardium is occasionally involved in inflammation and fibrosis, leading to contractile dysfunction, which predicts a poor result after pericardiectomy.[63]

Failure of transmission of intrathoracic respiratory pressure changes to the cardiac chambers through the thickened pericardium is an important contributor to the pathophysiology of constrictive pericarditis (**Fig. 83.8**). On inspiration, the drop in intrathoracic pressure is transmitted to the pulmonary veins but not the left heart.[1] Consequently, the small pulmonary venous to LA pressure gradient that normally drives left heart filling is reduced, resulting in decreased transmitral inflow. The inspiratory decrease in LV filling allows an increase in RV filling and a leftward interventricular septal shift. The opposite occurs with expiration. As in tamponade, these changes result in exaggerated respiratory variation in mitral and tricuspid inflow and LV and RV systolic and diastolic pressure and volumes. High systemic venous pressure and reduced cardiac output induce retention of sodium and water by the kidneys. Inhibition of natriuretic peptides may exacerbate increased filling pressures.[64]

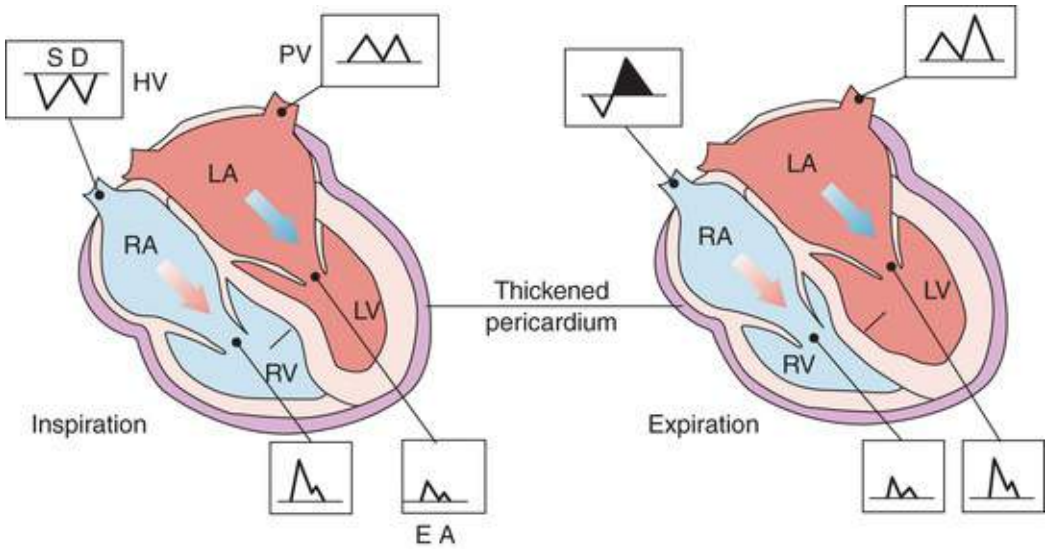

FIGURE 83.8 Schematic representation of transvalvular and central venous flow velocities in constrictive pericarditis. During inspiration the decrease in left ventricular filling results in a leftward septal shift, allowing augmented flow into the right ventricle. The opposite occurs during expiration. *D*, diastole; *EA*, mitral inflow; *HV*, hepatic vein; *LA*, left atrium; *LV*, left ventricle; *PV*, pulmonary venous flow; *RA*, right atrium; *RV*, right ventricle; *S*, systole.

Clinical Presentation

The usual presentation consists of signs and symptoms of right heart failure, including lower extremity edema, vague abdominal complaints, and passive hepatic congestion. With progression, hepatic congestion worsens and can progress to ascites, anasarca, and jaundice due to cardiac cirrhosis. Signs and symptoms of left heart failure, dyspnea, cough, and orthopnea may also appear. Atrial fibrillation and tricuspid regurgitation, which further exacerbate venous pressure elevation, are common at this stage. At the end stage, effects of a chronically low cardiac output are prominent, including fatigue, muscle wasting, and cachexia. Other findings include recurrent pleural effusions and syncope. Constrictive pericarditis can be mistaken for any cause of right heart failure, as well as end-stage liver disease.

Physical Examination

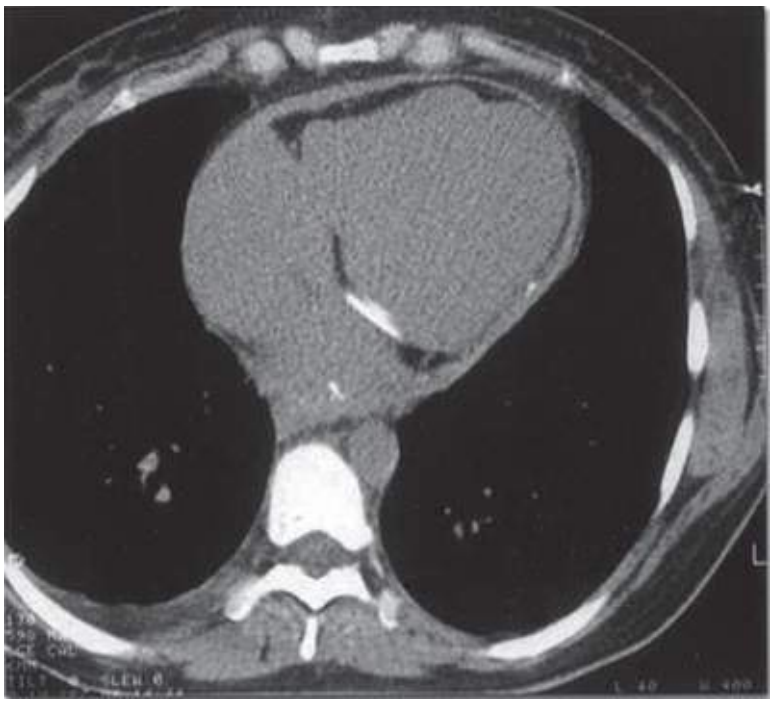
Physical findings include markedly elevated jugular venous pressure with a prominent, rapidly collapsing y descent. This, combined with a normal x descent, results in an M- or W-shaped venous pressure contour. In patients with atrial fibrillation, the x descent is lost, leaving only the prominent y descent. The latter can be difficult to distinguish from tricuspid regurgitation, which, as noted above, may also be present. The *Kussmaul sign*, an inspiratory increase in mean venous pressure, is usually present,[1] or the pressure may simply fail to decrease on inspiration. The Kussmaul sign reflects loss of the normal increase in right heart venous return on inspiration, even though tricuspid flow increases. These venous pressure abnormalities contrast with tamponade, where the y descent is lost. A paradoxic pulse occurs in perhaps one third of patients, especially with an effusive-constrictive picture. It is probably best explained by the aforementioned lack of transmission of decreased intrathoracic pressure to the left heart. **Table 83.5** reviews hemodynamic findings in tamponade versus constriction.

The most notable cardiac physical finding is the pericardial knock, an early diastolic sound best heard at the left sternal border and/or the cardiac apex. It occurs slightly earlier and has a higher frequency content than a third heart sound and corresponds to early, abrupt cessation of ventricular filling. Widening of second sound splitting may also be present, as well as a tricuspid regurgitant murmur. Abdominal

examination reveals hepatomegaly, often with palpable venous pulsations, with or without ascites. Other signs of hepatic congestion/cirrhosis include jaundice, spider angiomas, and palmar erythema. Lower extremity edema is the rule. Muscle wasting, cachexia, and massive ascites and anasarca occur with end-stage constriction.

Laboratory Testing

There are no specific ECG findings. Nonspecific T-wave abnormalities, reduced voltage, and LA enlargement may be present. Atrial fibrillation is very common. On chest radiography, the cardiac silhouette can be enlarged due to a coexisting pericardial effusion. Pericardial calcification is seen in a minority of patients and suggests TB (**eFig. 83.7**), but is not diagnostic of constrictive physiology. Pleural effusions are common and can be a presenting sign. If left heart filling pressures are markedly elevated, pulmonary vascular congestion and redistribution may be present.



EFIGURE 83.7 CT scan showing increased pericardial thickness and mild calcification in a patient with constrictive pericarditis.

Echocardiography and Doppler Echocardiography Examination

M-mode and two-dimensional transthoracic and Doppler echocardiography are primary imaging modalities in the evaluation of constrictive pericarditis (**see Chapter 14**). Major findings include pericardial thickening and calcification (best appreciated with transesophageal echocardiography), abrupt displacement of the interventricular septum during early diastole (septal bounce), and signs of systemic venous congestion (dilation of hepatic veins, inferior vena caval distention with blunted respiratory variation).[3,4,36] Premature pulmonic valve opening resulting from elevated RV early diastolic pressure and exaggerated septal shifting during respiration are common. As discussed above, the LV EF is usually normal. Mild to moderate (but not severe) biatrial enlargement is common.

Lack of transmission of intrathoracic pressure to the cardiac chambers and the resulting mitral/tricuspid inflow patterns have been discussed earlier. In accordance with these patterns, Doppler measurements usually reveal exaggerated respiratory variation in both mitral and tricuspid inflow velocity and tricuspid-mitral inflow velocity differences, with the latter 180 degrees out of phase (**see Fig. 83.8**). Although there is some overlap with tamponade, these inflow patterns have good sensitivity and specificity for diagnosing constriction and also help in differentiation from restrictive cardiomyopathy.[3,4,36] Typically, patients with constriction demonstrate an increase of 25% or more in mitral E velocity during expiration compared with inspiration and increased diastolic flow reversal with expiration in the hepatic veins. The mitral E-wave deceleration time is usually less than 160 ms. However, up to 20% of patients with constriction do not exhibit typical respiratory changes, most likely because of markedly increased LA pressure or possibly a mixed constrictive-restrictive pattern due to myocardial involvement. In patients without typical respiratory mitral-tricuspid flow findings, examination after maneuvers that decrease the preload (head-up tilt, sitting) can unmask characteristic respiratory variations.

Respiratory variations in mitral inflow velocity similar to those observed in constrictive pericarditis can be observed in chronic obstructive pulmonary disease (COPD), RV MI, pulmonary embolism, and pleural effusion.[3,4,36] These conditions have clinical and echocardiographic features that differentiate them from constrictive pericarditis. Superior vena caval flow velocities are particularly helpful in distinguishing constriction from COPD. Patients with COPD display a marked increase in inspiratory superior vena cava systolic forward flow velocity not seen in constriction. As discussed earlier, TEE is superior to transthoracic echocardiography for estimating the pericardial thickness and correlates well with CT.[3,4,36] When mitral inflow velocities by transthoracic echocardiography are technically inadequate or equivocal, measurement of the transesophageal pulmonary venous Doppler velocity demonstrates pronounced respiratory variation, larger than that observed across the mitral valve.

Tissue Doppler and strain (deformation) imaging are useful adjuncts for diagnosing constriction and distinguishing it from restrictive cardiomyopathy (see below).[3,4,36] Tissue Doppler reveals increased e′ velocity of the medial mitral annulus and septal abnormalities corresponding to the “bounce.” The lateral mitral annular e′ is lower than the medial annular e′, an abnormality termed *annulus reversus*. In restrictive cardiomyopathy, the characteristic tall and narrow transmitral E is present, but the e′ is reduced. Regional variations in deformation and strain include reduced LV circumferential strain, torsion, and early diastolic untwisting with preserved longitudinal strain and deformation. In contrast, in restriction, circumferential strain and untwisting are preserved but these parameters are reduced in the longitudinal direction.

Cardiac Catheterization and Angiography

Cardiac catheterization in patients with suspected constriction provides documentation of hemodynamics and assists in discriminating between constriction and restrictive cardiomyopathy (**see Chapter 19**).[1,2] Coronary angiography should ordinarily be performed in patients being considered for pericardiectomy. Rarely, external pinching or compression of a coronary artery by the constricting pericardium is detected.

The RA and RV diastolic pressure, pulmonary capillary wedge pressure, and pre–a wave LV diastolic pressure are elevated and equal, or nearly so, at around 20 mm Hg. Differences of more than 3 to 5 mm Hg between the left and right heart filling pressures are rare. The RA pressure tracing shows a preserved x descent, a prominent y descent, and roughly equal a-wave and v-wave heights, with a resultant M or W configuration. RV and LV pressures reveal an early, marked diastolic dip followed by a plateau (dip-and

plateau, or square root sign) (**Fig. 83.9**). Respiratory variation in the LV and RV systolic and diastolic pressures is increased. This has been quantified using the *systolic area index*, or the ratio of RV to LV systolic pressures × time area in inspiration versus expiration.[2,65] A ratio higher than 1.1 strongly suggests constriction. Pulmonary artery and RV systolic pressures are often modestly elevated to 35 to 45 mm Hg. Greater elevation is not a feature of constriction and casts doubt on the diagnosis. Hypovolemia (e.g., due to diuretic therapy) can mask hemodynamic findings. Rapid infusion of 1 L of normal saline over 6 to 8 minutes may reveal typical features. The SV is reduced, but cardiac output can be preserved because of tachycardia.

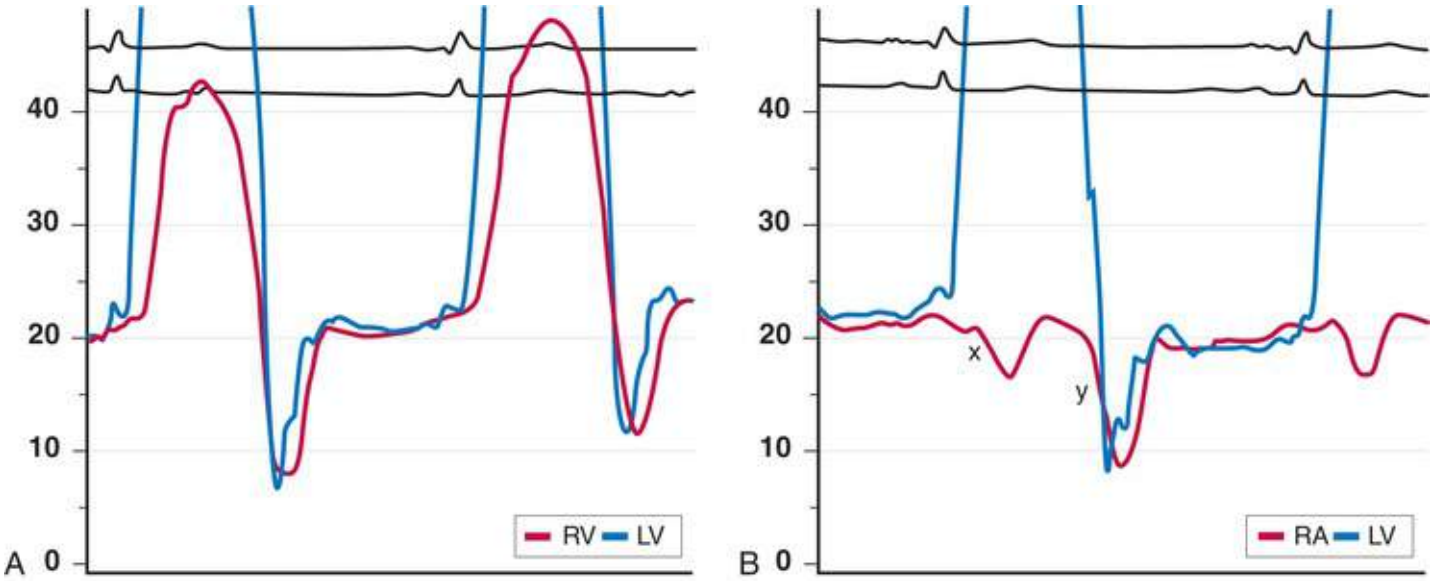


FIGURE 83.9 Pressure recordings in a patient with constrictive pericarditis. **A,** Simultaneous right ventricular (RV) and left ventricular (LV) pressure tracings with equalization of diastolic pressure as well as "dip-and-plateau" morphology; **B,** Simultaneous right atrial (RA) and LV pressure with equalization of RA and LV diastolic pressure. Note the prominent *y* descent. (From Vaitkus PT, Cooper KA, Shuman WP, Hardin NJ: Images in cardiovascular medicine: constrictive pericarditis. Circulation 1996;93:834.)

Computed Tomography and Magnetic Resonance Imaging

ECG-synchronized CT (**see Chapter 18**) and MRI (**see Chapter 17**) are important adjuncts to echocardiography-Doppler examinations in evaluating suspected constrictive pericarditis. CT is helpful in detecting even minute amounts of pericardial calcification and is the most accurate method for measuring thickness (normal < 2 mm) (**see eFig. 83.3**).[3,4,66,67] These features make CT particularly well suited for preoperative planning. CT can also obviate the need for invasive coronary angiography in some patients with normal-appearing vessels. Its major disadvantage is the frequent need for iodinated contrast medium to best display pericardial pathology. MRI provides a detailed examination of the pericardium without the need for contrast or ionizing radiation. It is less sensitive for detecting calcification than CT and less accurate for measuring thickness. The "normal" pericardium visualized by MRI is up to 3 to 4 mm in thickness. This most likely reflects the entire pericardial "complex," with physiologic fluid representing a component of the measured thickness. Cine acquisition MRI or CT is useful for detecting common findings of constriction (septal bounce, ventricular interaction) when echocardiography is technically inadequate (Video 83.4). Additional CT/MRI findings include distorted ventricular contours, hepatic venous congestion, ascites, and pleural effusions.

A thickened pericardium indicates acute and/or chronic pericarditis. Late gadolinium enhancement on MRI is more specific for active inflammation and may be useful in identifying patients who are candidates for medical management with antiinflammatory drugs (**Fig. 83.10** and see below).[59-62] If there is evidence of impaired diastolic filling, pericardial thickening, especially with calcification, is virtually diagnostic of constriction. Absence of thickening argues against the diagnosis but, as noted earlier, does not exclude it. Most patients with constriction and normal thickness have calcification and distorted ventricular contours, providing clues to the diagnosis. Localized constriction caused by focal thickening is reported. In patients being considered for pericardiectomy, delineation of the location and severity of thickening and calcification by CT or MRI aids in risk stratification and surgical planning.

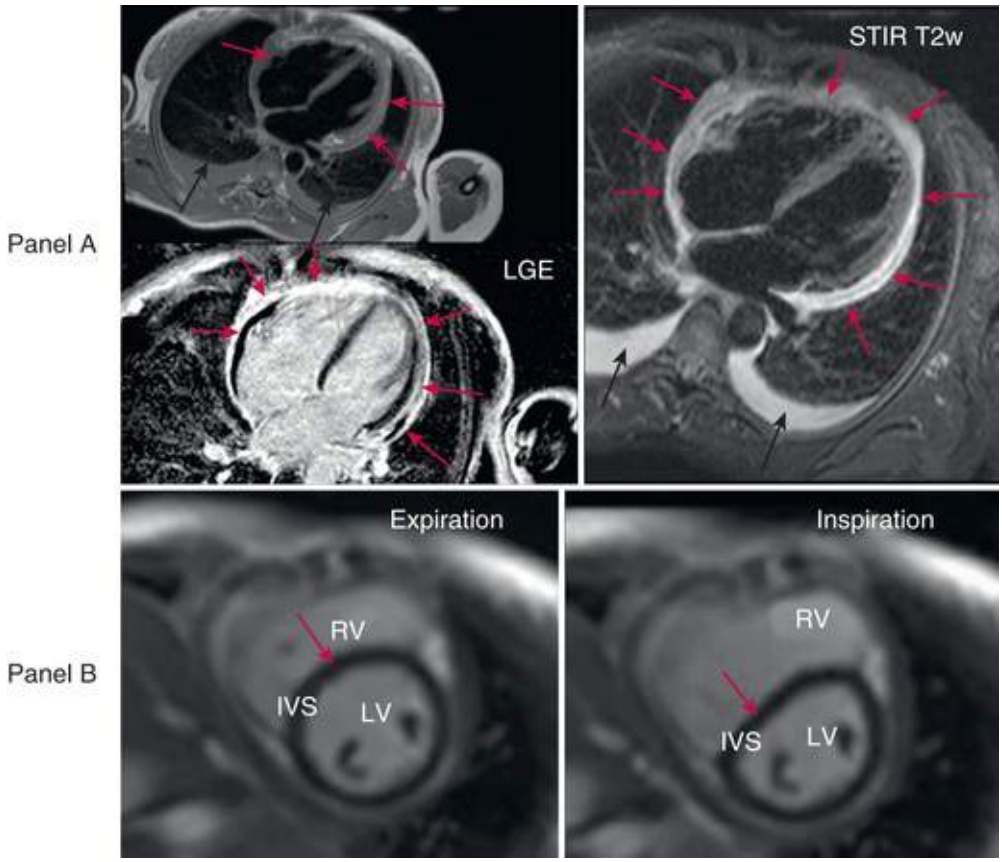

FIGURE 83.10 MRI of a patient with active pericarditis and constrictive physiology at presentation. In panel **A,** pericardial thickening and inflammation are present (*red arrows* indicate late gadolinium enhancement on the left and edema on STIR T2w image on the right). In panel **B,** real-time MRI reveals septal flattening or a "bounce" (*red arrows*) on inspiration owing to exaggerated ventricular interdependence. *IVS*, interventricular septum; *LGE*, late gadolinium enhancement; *LV*, left ventricle; *RV*, right ventricle. (Modified from Imazio M, Gaita F, LeWinter M: Evaluation and treatment of pericarditis: a systematic review. JAMA 2016;314:1498.)

Differentiating Constrictive Pericarditis from Restrictive Cardiomyopathy

Because of their treatment differences, distinguishing constrictive pericarditis from restrictive cardiomyopathy is important (**Table 83.7**). Restrictive cardiomyopathy used to be unusual and most commonly caused by amyloidosis, but it has become more prevalent because of its occurrence in a subgroup of patients with heart failure with a preserved EF who are obese and have features of the

metabolic syndrome.[69] The presentation and course of constriction and restriction overlap in many respects. A pericardial knock points to constriction, but third heart sounds in restrictive disease can be confusing. ECG and chest radiographic findings are mostly nonspecific. However, a calcified pericardium indicates constriction, while a low QRS voltage suggests amyloidosis. Echocardiographic distinctions are very helpful. Patients with restriction usually have thick-walled ventricles resulting from infiltrative processes or hypertrophy, but this is not invariably present.[68] Marked biatrial enlargement is typical of restriction but not constriction. In constriction, the most distinctive finding is the septal bounce. As discussed above, the pericardium is usually but not invariably thickened in constriction.

TABLE 83.7

Hemodynamic and Echocardiographic Features of Constrictive Pericarditis Compared with Restrictive Cardiomyopathy

	CONSTRICTION	RESTRICTION
Prominent y descent in venous pressure	Present	Variable
Paradoxic pulse	~1/3 cases	Absent
Pericardial knock	Present	Absent
Equal right- and left-sided filling pressures	Present	Left at least 3-5 mm Hg higher than right
Filling pressures > 25 mm Hg	Rare	Common
Pulmonary artery systolic pressure > 60 mm Hg	No	Common
Square root sign	Present	Variable
Respiratory variation in left-sided and-right-sided pressures/flows	Exaggerated	Normal
Ventricular wall thickness	Normal	Usually increased
Pericardial thickness	Increased	Normal
Atrial size	Possible LA enlargement	Biatrial enlargement
Septal bounce	Present	Absent
Tissue Doppler E′ velocity	Increased	Reduced
Speckle tracking	Normal longitudinal, decreased circumferential restoration	Decreased longitudinal, normal circumferential restoration

Doppler flow measurements are also useful in differentiating constrictive from restrictive physiology.[3,4,36] Enhanced respiratory variation in mitral inflow velocity (>25%) is seen in constriction, but varies by less than 10% in restriction (**see Fig. 83.8**). In restriction, pulmonary venous systolic flow is blunted and diastolic flow is increased; this is not observed in constriction. Hepatic veins demonstrate enhanced expiratory flow reversal with constriction, in contrast to increased inspiratory flow reversal in restriction. As discussed above, tissue Doppler and strain imaging can aid in differentiation.[3,4,36]

Hemodynamic differentiation between constrictive pericarditis and restrictive cardiomyopathy can be difficult. However, careful attention to the hemodynamic profile usually allows for their distinction (**see Table 83.7**). In both conditions, RV and LV diastolic pressures are markedly elevated. In restriction, diastolic pressure in the left ventricle is usually higher than in the right ventricle by at least 3 to 5 mm Hg, whereas in constriction, LV and RV diastolic pressures track closely and rarely differ by more than 3 to 5 mm Hg. Severe pulmonary hypertension is observed in restriction but virtually never in constriction. Extremely high diastolic pressure elevations (> 25 mm Hg) are much more common in restriction.[1,2,36,68] Finally, the *systolic area index* is greater in constriction than restriction and reported to have high sensitivity and specificity for distinguishing between them.[65]

CT or MRI is very useful in differentiating constriction from restriction because each has the ability to assess pericardial thickness and calcification, although once again, some patients with constriction have normal thickness.[3,4,66,67] Endomyocardial or abdominal fat pad biopsy is used to diagnose amyloidosis. Brain natriuretic peptide (BNP) levels are elevated in restrictive cardiomyopathy but not in constriction.[64]

Management

Constrictive pericarditis has a progressive but variable course. For most patients, surgical pericardiectomy is the definitive treatment. Pericardiectomy for constriction has a relatively high perioperative mortality rate, ranging from 2% to nearly 20% in modern series.[56-58,69-72] Risk factors for poor outcomes include radiation-induced disease; comorbidities, especially COPD and renal insufficiency; coronary artery disease and prior cardiac surgery; reduced LV EF; cardiopulmonary bypass; and New York Heart Association (NYHA) stage IV symptoms. Severely debilitated patients with stage IV symptoms in general have a prohibitively high risk. Radiation-induced disease is also considered a relative contraindication**.** Relatively healthy older patients with mild constriction can be managed nonsurgically, with pericardiectomy held in reserve until the disease progresses. Otherwise, surgery should not be delayed once the diagnosis is made. Diuretics and salt restriction are used to relieve the volume overload, but patients ultimately become refractory. Because sinus tachycardia is compensatory, beta-adrenergic blockers and calcium antagonists that slow the heart rate should be avoided. In patients with atrial fibrillation and a rapid ventricular response, digoxin is recommended for rate control.

Pericardiectomy can be performed through a median sternotomy or a left fifth interspace thoracotomy and involves radical excision of as much parietal pericardium as possible.[1,2,73] The visceral pericardium is inspected and resection considered if it is involved. Most surgeons attempt pericardiectomy without cardiopulmonary bypass. The latter is available as a backup measure and is frequently required to facilitate access to the lateral and diaphragmatic surfaces of the heart and allow removal of a maximal amount of tissue. Ultrasonic or laser debridement is an adjunct to conventional debridement or as the sole technique in patients with extensive, calcified adhesions.[2] The “waffle” procedure, in which multiple transverse and longitudinal incisions are made in the epicardial layer, is an alternative in patients with extensive epicardial involvement; it can be performed without cardiopulmonary bypass.[74]

Hemodynamic and symptomatic improvement following pericardiectomy is achieved in some patients very soon after surgery. In others improvement may be delayed for weeks to months. Videos 83.5 and 83.6 are cine MR images before and after successful pericardial stripping demonstrating relief of exaggerated respiratory variation in the right and left heart volume. There have been a number of reports of long-term results of pericardiectomy for constriction.[56,69-71,75] One-year survival rates range from 81% to 91%; 5-year rates from 64% to 85%; and 10-year rates from 49% to 81%. Most survivors are largely free of adverse cardiovascular outcomes. Long-term results are worst in patients with radiation-induced disease, impaired renal function, a reduced LV EF, moderate or severe tricuspid regurgitation, low serum sodium levels, and advanced age. LV diastolic function returns to normal in about 40% of patients early and about 60% late after surgery.[75] Persistence of abnormal filling is correlated with symptoms. Poor responses to pericardiectomy have been attributed to myocardial atrophy or fibrosis, incomplete resection, and development of recurrent cardiac compression by mediastinal inflammation and fibrosis. Tricuspid regurgitation usually does not improve and can cause hemodynamic deterioration.

There have been several reports of transient or reversible constrictive pericarditis.[2,61,62] Patients presenting early after cardiac surgery appear to be most common. Many patients have coexistent effusions and can be classified as having effusive-constrictive pericarditis (see below). Because reported patients have been treated with various antiinflammatory regimens, it is unknown if the disease would have improved spontaneously. Reversible constriction typically resolves in 2 to 3 months. MRI late gadolinium enhancement has been correlated with severity of fibrosis and inflammation in operative specimens from patients with constriction.[60] Intensity of enhancement as well as a pericardial thickness of 3 mm or more on late enhancement images is predictive of resolution of constriction with antiinflammatory drug treatment (**see Fig. 83.10**).[1,61,62] Responders also have higher hsCRP levels. Although it is attractive to identify patients with constriction in whom surgery can be avoided, it is not clear how common they are,

because reported series are small and highly selected.[59,60,62,63] Nonetheless, patients with intense late gadolinium enhancement on MRI, especially those with a pericardial thickness of more than 3 mm, should be considered for a trial of antiinflammatory therapy, especially if they have had recent cardiac surgery, symptoms have appeared relatively rapidly, the hsCRP is elevated, and there is not extensive calcification. NSAIDs, colchicine, and corticosteroids have been used in various combinations; there is no obvious preferred agent or combination. Thus, it is impossible to make informed recommendations in regard to treatment strategies. As a practical matter, an antiinflammatory regimen should be administered for perhaps 2 to 3 months to allow time for it to work, but surgery should not be excessively delayed if the benefit is not apparent. Although there is no specific evidence to support it, we suggest combined corticosteroids and colchicine in dosages similar to those recommended for recurrent pericarditis.

Effusive-Constrictive Pericarditis

Effusive-constrictive pericarditis combines elements of effusion/tamponade and constriction. Constrictive features usually are detected after pericardiocentesis.[2,47] A proposed definition of underlying constriction is the failure of RA pressure to decline by at least 50% to a level below 10 mm Hg when pericardial pressure is reduced to almost 0 mm Hg by pericardiocentesis and/or all detectable fluid is removed. Many cases of “transient” or medically treatable constrictive pericarditis may represent effusive-constrictive pericarditis. The course can be quite variable, but is usually subacute, ranging from 1 to 2 to several months. An inflammatory effusion typically dominates early, with constriction becoming more prominent later, but there are many variations. The visceral pericardium is usually prominently involved. The reported incidence of effusive-constrictive pericarditis in patients with pericardial effusion varies from 1% to 15% in different series and may be especially high in patients with TB.[47]

The most common causes of effusive-constrictive pericarditis are cancer, irradiation, TB, complications following pericardiotomy, and connective tissue diseases; the condition may be idiopathic, as well. TB is by far the leading cause in sub-Saharan Africa.[2,47] Physical, hemodynamic, and echocardiographic findings are mixtures of those associated with effusion and constriction and may vary with time as the syndrome progresses. The diagnosis may require acquisition of pericardial fluid and biopsy specimens if the cause is not obvious and tamponade does not mandate pericardiocentesis. Management is tailored to the specific cause, if known. In idiopathic and postpericardiotomy cases, antiinflammatory treatment as described above for noneffusive constrictive pericarditis may be used in an attempt to avoid pericardiectomy, but no guidance is available in regard to a preferred approach. MRI with gadolinium uptake and measurement of hsCRP may be useful to identify patients with active inflammation who are more likely to respond to an antiinflammatory regimen. Pericardiectomy is ultimately required in many patients.

Specific Etiologies of Pericardial Disease

The pericardium is involved in a wide variety of diseases (**see Table 83.1**). The following sections discuss the most significant specific diseases affecting the pericardium.

Infectious Diseases

Viral Pericarditis

Viral pericarditis is presumed to be the most common pericardial infection in countries with a low prevalence of TB.[1,2] Numerous viruses have been implicated (**see Table 83.1**). The definitive diagnosis requires identification of viral particles or genomic material in pericardial fluid or tissue or a rise in serum antibodies. This is impractical and/or unnecessary in the vast majority of cases of acute pericarditis because management of immunocompetent patients is not affected by a specific viral diagnosis.

Bacterial Pericarditis

In sub-Saharan Africa the most common bacterial cause of pericardial disease is TB. In the developed world, TB and other forms of bacterial (purulent) pericarditis are unusual in immunocompetent patients. We first discuss TB and then other forms of bacterial pericarditis.

Tuberculous Pericarditis

Tuberculous pericarditis represents a secondary localization with a primary infection in a different organ (most commonly, pleural-pulmonary infection).[2,76] The primary infection site may not be obvious. The clinical presentation may be acute pericarditis with effusion, apparent isolated effusion, effusive-constrictive pericarditis, or constrictive pericarditis. Acute pericarditis without an effusion is very uncommon. Making the correct diagnosis is critical because the death rate is high (20% to 40% within 6 months of diagnosis) in the absence of effective anti-TB treatment.

A *definitive* diagnosis requires demonstration of tubercle bacilli in pericardial fluid or tissue.[2,76] A *probable* diagnosis is achieved with evidence of the disease elsewhere and/or a lymphocytic pericardial exudate with elevated uIFN-γ, ADA, or lysozyme levels. A presumptive diagnosis without evidence as outlined above is appropriate only in countries with a high prevalence of TB followed by a positive response to empirical anti-TB therapy.[2,76]

Rifampicin, isoniazid, pyrazinamide, and ethambutol for at least 2 months, followed by isoniazid and rifampicin for a total of 6 months, is recommended. Treatment for 9 months or longer gives no better results, and has disadvantages of increased cost and risk of poor compliance.[2,76,77]

In addition to its high mortality rate if untreated, tuberculous pericarditis has a high risk (20% to 40%) of evolving to constriction, often within 6 months.[2,76,77] Prompt antibiotic therapy is essential to prevent this. Additional treatments that may be useful to prevent constriction include intrapericardial urokinase and adjunctive prednisolone for 6 weeks.[2,78] The latter may halve the frequency of this complication but should be avoided in HIV patients. Pericardiectomy is recommended if the patient's condition is not improving or is deteriorating after 4 to 8 weeks of therapy.[2]

Nontuberculous Bacterial Pericarditis

In developed countries, nontuberculous bacterial pericarditis is rare, amounting to less than 1% of pericarditis cases, and generally manifests as part of a serious febrile illness (fever > 38°C) with a moderate to large pericardial effusion.[2,18] If bacterial pericarditis is suspected, urgent pericardiocentesis is mandatory for the diagnosis, providing effusions are of sufficient size. Blood cultures should be obtained in any patient with pericarditis and fever higher than 38°C.[2,18]

The pericardial fluid is usually purulent, with a low glucose concentration and high WBC count with a large proportion of neutrophils. The diagnosis is made by microscopic detection of bacteria and/or positive cultures of fluid.[2]

Intravenous antimicrobial therapy should be started empirically until microbiologic results are

available. Prolonged drainage is crucial. Purulent effusions are often heavily loculated and likely to reaccumulate. Intrapericardial thrombolysis may help to achieve adequate drainage before one must resort to surgery. Subxiphoid pericardiostomy and rinsing of the pericardial sac should be considered.[2,18]

Bacterial pericarditis has a very high mortality rate if untreated. Purulent pericarditis has a high risk of evolving to constrictive pericarditis.[17]

Pericardial Disease and Human Immunodeficiency Virus

Various pericardial diseases have been reported in HIV patients (**see Chapter 82**). The epidemiology has been greatly altered by highly active antiretroviral therapy (HAART), which has markedly reduced the incidence of all forms of cardiac involvement.[76,79] In a recent large cohort of HIV patients,[79] 85% of whom received HAART, a pericardial effusion was detected in less than 1%. In general, patients receiving HAART have pericardial disease etiologies and prognoses similar to those of patients without HIV. In contrast, pericardial diseases are more complex and have a negative prognostic significance in the setting of untreated HIV and AIDS.[80] Small, asymptomatic pericardial effusions of uncertain etiology are common in untreated HIV and are associated with a poor prognosis.[76] TB is the most common cause of pericardial effusion in African HIV patients.[76,79] Other, less common forms of pericardial disease include involvement by various neoplasms, typical acute pericarditis, and myopericarditis. Constriction is rare.

Pericarditis in Patients with Renal Disease

Pericardial disease in patients with renal failure is now uncommon, but should always be considered in patients with appropriate signs and symptoms. There are three main presentations: (1) uremic pericarditis, often with moderate to large effusions, occurring before dialysis or within 8 weeks from its initiation and related to retention of toxic metabolites; (2) “dialysis pericarditis,” occurring 8 weeks or more after initiation of dialysis; and (3) constrictive pericarditis, which is rare.[2,80] Some features of pericardial disease in patients with renal disease are distinctive. Chest pain is relatively infrequent (one third of patients are asymptomatic), ECG changes are usually absent because the myocardium is not involved, and pericardial effusions are often bloody because of uremic coagulopathy. Tamponade is uncommon because effusions usually develop gradually.

Intensive dialysis is effective in uremic pericarditis naïve to dialysis; when patients already receiving dialysis develop pericarditis, intensifying dialysis may be effective. Pericardiocentesis should be considered in patients not responding to dialysis and of course in those with tamponade. The role of antiinflammatory regimens is unknown, but there does not appear to be a major component of inflammation in these patients.

Pericardial Involvement in Systemic Autoimmune and Autoinflammatory Diseases

Systemic inflammatory diseases (systemic lupus erythematosus, rheumatoid arthritis, scleroderma, systemic vasculitides, sarcoidosis, inflammatory bowel disease) are common causes of pericarditis and/or pericardial effusion.[2,81] As many as 10% of patients with pericarditis (often recurrent) have a known systemic inflammatory disease. Rarely, pericardial disease is the first manifestation. The degree of pericardial involvement is usually related to the activity of the underlying disease. Concomitant myocarditis may be present, because these diseases also cause myocardial inflammation. Constrictive

pericarditis rarely occurs, especially in rheumatoid arthritis patients.[2,81]

A subgroup of these patients, especially children, may be affected by rare, autoinflammatory periodic fevers.[2,77] Periodic fevers are genetic disorders characterized by mutations of genes involved in the regulation of the inflammatory response, without involvement of specific T cells or autoantibodies. The most common are *familial Mediterranean fever* (FMF), in which serositis episodes last 1 to 3 days, and *tumor necrosis factor receptor–associated periodic syndrome* (TRAPS), in which episodes last weeks. Mutations associated with these disorders are encountered rarely in patients presenting with recurrent pericarditis. A positive family history for pericarditis or periodic fevers and the need for immunosuppressive agents are clues to the presence of these diseases. Genetic testing is required for diagnosis.

Various antiinflammatory regimens have been employed. They are dictated by the specific disease and may include corticosteroids and/or combinations of additional drugs. For periodic fevers, anti-IL1 (e.g., anakinra) or anti-TNF agents should be considered.[4] Colchicine is highly effective in FMF, especially for prophylaxis, but not for TRAPS. Management requires a multidisciplinary approach, including cardiologists, rheumatologists/clinical immunologists, and other specialists as needed.

Post–Cardiac Injury Syndromes

The term post–cardiac injury syndrome (PCIS) is applied to a group of inflammatory pleuropericardial syndromes, including post-MI pericarditis, postpericardiotomy syndrome (PPS), and posttraumatic pericarditis.[2,82] With the exception of *early* post-MI pericarditis, all are presumed to have an autoimmune pathogenesis triggered by initial damage to pericardial tissue associated with myocardial necrosis (late post-MI pericarditis), surgical trauma (PPS), accidental thoracic trauma (traumatic pericarditis), or iatrogenic trauma (pericarditis after cardiac procedures, including perforation during percutaneous coronary intervention [PCI] and valve procedures, various arrhythmia ablation procedures, device implantations, and LA isolation procedures).

An immune-mediated pathogenesis is supported by a latent period, generally a few weeks, before the appearance of the first manifestations, a response to antiinflammatory drugs, and possible recurrences. PCIS is an emerging cause of pericarditis in developed countries because of an aging population and expansion of cardiac procedures.

According to proposed criteria, the diagnosis of PCIS after a cardiac injury requires at least two of the following: (1) fever without an alternative cause, (2) pleuritic chest pain, (3) pericardial or pleural rubs, (4) pericardial and/or pleural effusion, and (5) elevated hsCRP.[2,82]

Specific definitions and considerations apply to post-MI pericarditis (**see also Chapter 5**). Two forms are recognized.[83] *Early post-MI pericarditis* occurs soon after the MI. It is rare in the primary PCI era and occurs in association with large, transmural MIs because of absent or late/failed reperfusion. *Late post-MI pericarditis (Dressler syndrome)* is also rare (< 1% of MIs in the primary PCI era) and most common after large MIs.

Early post-MI pericarditis is usually asymptomatic and diagnosed by auscultation of a rub generally 1 to 3 days after the index event. It rarely causes an effusion large enough to produce tamponade. However, tamponade does occur with LV free wall rupture. Because of its association with large MIs, early post-MI pericarditis should alert the clinician to this possibility, especially if an effusion is present. In the occasional symptomatic patient, pleuritic chest pain appears within the above time frame. It is important to distinguish pericardial pain from recurrent ischemic discomfort. Ordinarily, this is not difficult on clinical grounds. Typical ECG changes of acute pericarditis are uncommon. Pericardial inflammation is

localized to the infarcted area; hence, ECG changes usually involve subtle reelevation of the ST segment in the originally involved leads. An atypical T-wave evolution consisting of persistent upright T waves or early normalization of inverted T waves appears to be highly sensitive for early post-MI pericarditis.[2,83] Late post-MI pericarditis occurs from 1 week to a few months after MI. Symptoms include fever and pleuritic chest pain. Physical examination may reveal pleural and/or pericardial rubs. The chest radiograph may show a pleural effusion and/or enlargement of the cardiac silhouette. The ECG often demonstrates changes typical of acute pericarditis. Effusions are common, but tamponade is unusual.

Treatment of PCIS is based on empirical antiinflammatory therapy plus colchicine as outlined for viral/idiopathic pericarditis.[2,82,83] Asymptomatic early post-MI pericarditis does not require treatment. Acetaminophen or aspirin as needed is preferred for occasional symptomatic patients.

The prognosis of PCIS is generally good. Long-term follow-up is warranted because constrictive pericarditis has been reported in about 3% of cases.[17]

Metastatic Pericardial Disease

Metastatic pericardial disease may present as acute pericarditis, effusion, effusive-constrictive pericarditis, or constriction.[2,19,77,84] Effusions are often moderate to large and frequently cause tamponade. They are usually caused by direct pericardial implants resulting from hematogenous spread and less commonly by metastatic lymphatic involvement. Virtually any metastatic tumor can involve the pericardium. Lung and breast cancers are most common, with lymphomas, leukemias, melanomas, and cancers of contiguous organs (e.g., the esophagus) making up most of the rest.

The definitive diagnosis is based on confirmation of malignant infiltration of the pericardium by pericardial fluid cytology or biopsy.[2,19,77,84] A probable diagnosis may be achieved by detection of tumor markers in pericardial fluid (CEA, GATA3, VEGF, and various others), although none has proven accurate enough to definitively distinguish malignant from benign effusions.[2,52] Evidence of malignant disease elsewhere with concomitant pericarditis or pericardial effusion is very suggestive. In almost two thirds of patients with documented malignancy, pericardial effusion is due to nonmalignant causes (e.g., radiation, other therapies, or opportunistic infections).[77,84]

Management of these patients requires a multidisciplinary approach, including oncologists, radiotherapists, and other subspecialists as needed.[2,19,77,84]

General principles include (1) using appropriate systemic antineoplastic treatment;(2) performing therapeutic and diagnostic pericardiocentesis for cardiac tamponade and as a diagnostic tool for moderate to large pericardial effusions that are suspected to be neoplastic (prolonged drainage is recommended to reduce the high recurrence rate [> 40% to 50%]; additional interventions for recurrent effusions include surgical pericardial window creation and percutaneous balloon pericardiotomy);(3) performing intrapericardial instillation of cytostatic/sclerosing agents is an option to prevent recurrences, and can be surprisingly effective (the agent used should be tailored to the type of cancer [e.g., cisplatin in lung cancer, thiotepa in breast cancer]); and (4) irradiation for controlling malignant effusions in patients with radiosensitive tumors such as lymphomas and leukemias.

In practice, management is usually palliative in patients with advanced disease, and aimed at relief of symptoms rather than treatment of the underlying disease, taking into account the prognosis and the overall quality of life of the patient.

Radiation-Induced Pericarditis

Chest radiation is an important cause of pericardial disease.[2,85] Radiation therapy can also affect the myocardium, valves, coronary arteries, and all mediastinal structures, inducing fibrosis. Most cases are secondary to therapy for Hodgkin lymphoma or breast or lung cancer. Modern treatment with lower doses and better shielding and dose calculation has reduced this complication, with a drop in incidence from 20% to about 2.5%.[2,85]

Radiation can induce an early, transient, often subclinical acute or subacute pericarditis with or without effusion. Constrictive pericarditis may appear 2 to 20 years later and is not *necessarily* preceded by clinically diagnosed early pericarditis. Late constriction affects a very variable number of patients and appears to be dose dependent and often related to a late effusion in the acute phase. The latter may be serous or hemorrhagic and has a high probability of leading to fibrous adhesions. Therapy for symptomatic pericarditis with or without effusion during the acute phase is similar to that for idiopathic pericarditis.[2,77] Concomitant myocardial damage contributes to poor outcomes after pericardiectomy for constriction.[2]

Thyroid-Associated Pericardial Disease

Pericardial effusions develop in 25% to 35% of patients with severe hypothyroidism (**see Chapter 92**).[2] These effusions can be large but rarely if ever cause tamponade. Hypothyroid effusions often have high concentrations of cholesterol. They gradually resolve with thyroid replacement. Rarely, effusion can occur in hyperthyroidism.

Pericardial Diseases in Pregnancy and During Lactation

Small, insignificant pericardial effusions are observed in approximately 40% of healthy pregnant women (**see Chapter 90**).[2,86] Pregnancy per se does not influence the incidence, cause, or course of pericardial disease but it does impact its management. Pericarditis is usually viral or idiopathic and has a good prognosis, with outcomes similar to those in the general population. For medical therapy, NSAIDs may be prescribed during the first trimester and early second trimester. After gestational week 20, all NSAIDs (except aspirin ≤100 mg/day) can cause constriction of the ductus arteriosus and impair fetal renal function and should either not be started or should be withdrawn. Low-dose corticosteroids (e.g., prednisone 0.2 to 0.5 mg/kg/day) are a viable option that can be adopted for the entire duration of pregnancy if necessary. Absent a specific indication (e.g., FMF), colchicine is contraindicated during pregnancy.[2,86] Paracetamol is allowed throughout pregnancy and breastfeeding, as are proton pump inhibitors. Normal vaginal delivery should be encouraged in the absence of contraindications. During lactation, ibuprofen, indomethacin, naproxen, and prednisone are allowable. Colchicine is considered contraindicated, although in women with FMF no adverse events affecting fertility, pregnancy, or fetal or child development have been reported, even after prolonged exposure.[2,77]

Pericardial Diseases in Children

Pericarditis is an important cause of chest pain in children, accounting for about 5% of patients in pediatric emergency departments. The etiologic spectrum differs from adults, with specific causes more common, including bacterial infections, autoimmune diseases, and PCIS following surgical repair of congenital defects.[2,77] Children often have a more marked systemic inflammatory response compared with adults. Fever and pleuropulmonary involvement and elevation of inflammatory markers are more common

than in adults.

At present, there are no randomized clinical trials in pediatric settings, and thus the management of pericardial syndromes in children follows the general scheme for adults, with appropriate dose adjustments.[2] Aspirin should generally be avoided because of the risk of Reye syndrome. Colchicine can be used, but corticosteroids should be restricted even more than in adults given the possibility of side effects that are particularly deleterious in children (e.g., striae rubra, growth impairment). Corticosteroid dependence is particularly difficult and biologic agents such as anakinra have been used as an alternative to allow corticosteroid withdrawal.[32] Exercise restriction can be particularly bothersome for children, especially in recurrent cases. The long-term prognosis is generally good, albeit related to the etiology of pericardial syndromes.[4,77]

Stress Cardiomyopathy

Stress cardiomyopathy (takotsubo syndrome) has become increasingly recognized over the past decade. Reversible ballooning of the apical portion of the left ventricle was originally described, but variants are common. Pericarditis and pericardial effusion are detected in an uncertain but significant percentage of patients, and there is at least one report of cardiac tamponade.[87] The mechanism of pericardial involvement is likely epicardial inflammation, but there is no definite proof of this.[87]

Hemopericardium

Any form of chest trauma can cause hemopericardium.[1,2] Post-MI free wall rupture occurs within several days of transmural MI (**see Chapter 5**). Hemopericardium due to retrograde bleeding into the pericardial sac is an important complication of type I dissecting aortic aneurysm (**see Chapter 57**). These patients can have combined aortic regurgitation due to disruption of the aortic valve and tamponade without a paradoxic pulse. The role of pericardiocentesis has been discussed above.

A variety of invasive cardiology procedures can be complicated by hemopericardium.[2] Puncture of atrial or ventricular walls can occur during mitral valvuloplasty and newer percutaneous mitral procedures.[2,88] Tamponade can occur rapidly or with a delayed course and can usually be managed with percutaneous drainage. Small pericardial effusions are occasionally observed after device closure of atrial septal defects, but tamponade is rare.[2] Insertion of the Watchman LA appendage device and other LA isolation procedures is complicated by a significant incidence of perforation and effusions. which not infrequently cause tamponade.[89,90] Transcutaneous aortic valve implantation is complicated by about a 1% incidence of tamponade.[91]

Pericardial effusion and tamponade due to coronary perforation is a rare complication of PCI (**see Chapter 62**), with an incidence of 0.1% to 0.6%.[2,92] The clinical presentation is usually rapidly progressive cardiac decompensation, although occasionally it can be more delayed. The diagnosis is usually made by extravasation of dye from a coronary vessel. Loss of cardiac pulsation on fluoroscopy indicates a significant effusion. Management requires sealing the perforation, pericardiocentesis, and reversal of anticoagulation.[2,92] If a perforation cannot be managed, percutaneous emergency surgery is indicated. Endomyocardial biopsy is occasionally complicated by perforation, but tamponade is unusual.[2,93]

Pericardial effusion and tamponade can occur as complications of various catheter-based arrhythmia procedures, including atrial fibrillation ablations. The incidence of effusion following atrial fibrillation ablation has been under 1%.[94,95] Many patients can be managed conservatively, and closed drainage is

usually sufficient. Epicardial ventricular tachycardia ablations can also cause hemopericardium.[96] RV perforation occasionally complicates pacemaker and implantable defibrillator lead insertion, as well as acute lead dislodgement, but rarely causes tamponade.[97] Finally, cardiac tamponade is a rare complication of laparoscopic gastroesophageal surgery.[98]

Congenital Anomalies of the Pericardium

Pericardial cysts are rare, benign congenital malformations typically located at the right or left cardiophrenic angle and rarely in other mediastinal locations.[2,8,99] Cysts are typically round or elliptical, with a size from a few centimeters to more than 20 cm. They do not communicate with the pericardial sac. Histologically, cysts are lined with a single layer of mesothelial cells, with the remainder of the wall composed of collagen and elastic fibers. Cysts are usually discovered as an incidental finding on imaging studies, but may occasionally become symptomatic due to hemorrhage or infection, increasing in size and causing symptoms due to compression of adjacent structures.[99] On CT imaging, cysts appear as round or elliptical masses with the same density as water. Absent complications, pericardial cysts do not show contrast enhancement or delayed gadolinium uptake.[100]

Surgery is not ordinarily recommended for pericardial cysts unless they become symptomatic. However, approximately 10% of apparent cysts actually represent a pericardial diverticulum with a persistent connection to the pericardial sac. This may not be apparent on imaging studies and only identified at surgery.[101] These lesions may cause atypical symptoms that are relieved only after surgery. Minimally invasive thoracoscopic resection or percutaneous aspiration is a less invasive alternative.[101]

Congenital absence of the pericardium is also very rare (**see Chapter 75**). Usually, part or all of the left parietal pericardium is absent, but partial absence of the right side has also been reported.[2] Partial absence of the left pericardium is associated with other anomalies, including atrial septal defect, bicuspid aortic valve, and pulmonary malformations. Although often asymptomatic, herniation of portions of the heart through the defect and/or torsion of the great vessels can occur, with life-threatening consequences. Patients can have chest pain or syncope, or may succumb to sudden death. The ECG typically reveals an incomplete right bundle branch block. Absence of all or most of the left pericardium results in a chest radiograph with a leftward shift of the cardiac silhouette and an elongated left heart border. Echocardiography reveals paradoxic septal motion and RV enlargement. CT or MRI establishes a definitive diagnosis. Pericardiectomy ameliorates symptoms and prevents herniation.

Primary Pericardial Tumors

Various, rare primary pericardial neoplasms have been reported, including mesotheliomas, fibrosarcomas, lymphangiomas, hemangiomas, teratomas, neurofibromas, and lipomas.[1,2] It is difficult to generalize about presentation and course. Many are locally invasive and/or compress cardiac structures or are detected because of an abnormal cardiac silhouette on chest radiograph. Mesotheliomas and fibrosarcomas are lethal. Others such as lipomas are benign. CT and MRI are helpful in delineating the anatomy of these tumors, but surgery is required for diagnosis and treatment.

Pulmonary Embolism

Samuel Z. Goldhaber

State-of-the-Art Findings in Pulmonary Embolism

Pulmonary embolism (PE) and deep vein thrombosis (DVT) together constitute one of the “big three” cardiovascular diseases, the other two being myocardial infarction (MI) and stroke. *Venous thromboembolism* (VTE) encompasses PE and DVT. Estimates of the global incidence of VTE range from 1.2 to 2.7 per 1000 per year.[1] There is seasonality in hospitalizations for PE. The highest number of admissions is in the winter, and the lowest number is in the summer.[2]

In the United States, PE causes more than 100,000 deaths annually. Most deaths in hospitalized patients with PE result from right heart failure due to the initial PE or from recurrent PE despite anticoagulation. PE has an approximately 4% in-hospital case fatality rate in adults 65 years of age or older in the United

States. However, the 30-day readmission rate is 15%, and the 6-month mortality rate jumps to 20% in this population.[3] Patients residing in zip (postal) codes with lower socioeconomic status have increased in-hospital mortality rates and less frequently receive thrombolysis compared with patients residing in zip codes with higher socioeconomic status.[4]

Major long-term complications of VTE include recurrent VTE, chronic thromboembolic pulmonary hypertension (CTEPH),[5] and postthrombotic syndrome (also called chronic venous insufficiency) of the legs.[6] Postthrombotic syndrome patients report worse long-term physical health, mental health, and quality of life than controls.[7] Newly diagnosed VTE patients cost the U.S. health care system $7 to $10 billion annually.[8] The estimated cost of VTE for the European Union ranges from 1.5 billion to 13.2 billion Euros annually.[9]

In a European Registry of PE, the 30-day case fatality rate was 5%.[10] Over a 13-year period in Europe, thrombolytic therapy use increased from 0.7% to 1.0%, and surgical embolectomy procedures doubled from 0.3% to 0.6%. The United States and Europe share common trends over the past decade: (1) an increase in the incidence of PE, (2) a decrease in the hospital length of stay, and (3) a decrease in the case fatality rate.[11] Increased age[12] and concomitant DVT[13] are associated with a higher 30-day mortality rate.

Cancer patients have a fourfold increased risk of VTE compared with the general population.[14] When unprovoked VTE occurs, there is an increased likelihood that occult cancer will subsequently be detected, especially during the first 6 months after the diagnosis of VTE.[15] Age, prior provoked VTE, and cigarette smoking may help predict the presence of occult cancer in patients with a first unprovoked episode of VTE.[16] Nevertheless, it remains controversial whether to order abdominopelvic CT scans to try to diagnose occult cancer in patients with a first unprovoked episode of VTE.[17] VTE is also a women's health disease. PE is the leading cause of maternal death in the United States. Overall, pregnancy increases the risk of VTE fivefold,[18] and this risk persists for at least 12 weeks into the postpartum period.[19]

There is increasing recognition that VTE and atherothrombosis have similarities in epidemiology and pathophysiology. Inflammation, with its underlying prothrombotic state, is a pivotal factor in the pathophysiology of PE and links VTE and arterial thrombosis.[20] This realization has uncovered a wide range of unconventional risk factors for PE related to inflammation. For example, patients with the inflammatory state of severe sepsis and septic shock have a high incidence of VTE despite the use of thromboprophylaxis. In a multicenter prospective study of these intensive care unit (ICU) patients, the rate of VTE was 37% and associated with an increased length of stay and a trend toward higher death rates due to PE.[21] Chronic kidney disease is also associated with VTE,[22] probably because impaired kidney function heightens oxidative stress and inflammation. Other inflammation-based risk factors for VTE include inflammatory bowel disease, rheumatoid arthritis, psoriasis, pneumonia, urinary tract infections, influenza, diabetes mellitus, or other potential triggers such as transfused blood or erythropoietin-stimulating factors.

The risk of subsequent arterial cardiovascular events doubles in VTE patients compared with controls.[23] Among 1023 Australian patients initially hospitalized with PE, the cumulative mortality rate was 32% over 5 years, with 40% of the deaths attributed to cardiovascular causes. The mortality rate following discharge was 2.5 times higher than in an age-matched and sex-matched population.[24] In a Danish observational study with a median follow-up of 16 years, 1853 participants suffered MI, and 699 were diagnosed with VTE. MI was associated with a 72% increased risk of PE.[25] Heart failure and chronic obstructive pulmonary disease (COPD) also potently increase the risk for in-hospital death among patients with VTE.

PE impairs the quality of life.[7] Young adults diagnosed with VTE have a doubling of prescriptions of

psychotropic drugs compared with age- and gender-matched controls. Antidepressants were most frequently prescribed (53%), followed by sedatives (22%), anxiolytics (20%), and antipsychotics (5%).[26] PE and DVT increase in frequency with age but also afflict infants, children, and teenagers.[27] Recurrence after completion of a time-limited course of anticoagulation occurs often, especially when surgery, trauma, or estrogens do not precipitate the initial event. VTE exacts a psychological toll on patients, who wonder whether they will suffer a recurrent event and worry about the potential burden on their families, diminished quality of life, and shortened life span.

Advances in diagnostic, therapeutic, and preventive strategies, coupled with novel perspectives on VTE pathophysiology, have emerged at an unprecedented pace. Clinical and electronic decision tools facilitate early VTE detection and improve prevention strategies. Novel oral anticoagulants (NOACs) such as dabigatran, rivaroxaban, apixaban, and edoxaban allow the management of PE and DVT with fewer bleeding complications than with warfarin. Fixed dosing, the absence of drug-food interactions, the minimal number of drug-drug interactions, and no need for testing blood coagulation levels simplify NOAC therapy and enhance the safety of anticoagulation.[28]

With recognition of the critical role of the activated platelet in VTE pathogenesis, low-dose aspirin provides additional prophylactic and therapeutic options. For patients requiring advanced therapy beyond anticoagulation alone, invasive tools such as ultrasound-facilitated and catheter-assisted thrombolysis with low-dose tissue plasminogen activator therapy promise a lower rate of hemorrhagic complications than that associated with traditional, systemically administered high-dose thrombolysis. Reduced-dose systemic thrombolysis with tissue plasminogen activator is also gaining a foothold in the advanced therapy armamentarium because of its low rate of major bleeding.[29]

Our knowledge of the genetics of VTE is expanding rapidly.[30] To date, at least 17 genes have been demonstrated to harbor genetic variation associated with VTE risk. Common polymorphisms account for only about 5% of VTE heritability. The translational application of our advances in genetics remains elusive (**see also Chapter 6**).

Molecular Pathophysiology

VTE and atherothrombosis have intertwining risk factors and pathophysiology. Dichotomizing PE as a “red clot” disease and atherothrombosis as a “white clot” disease is no longer tenable. VTE is part of a pan–cardiovascular syndrome that includes coronary artery disease, peripheral artery disease, and cerebrovascular disease. The Virchow triad of stasis, hypercoagulability, and endothelial injury often activates the pathophysiologic cascade leading to VTE. Inflammation is not included in the Virchow triad, but it is a key precipitant. Infection and its associated inflammation lead to the recruitment of platelets—one of the first steps necessary for thrombus initiation. Activated platelets release polyphosphates, procoagulant microparticles, and proinflammatory mediators. These activated platelets bind neutrophils and stimulate them to release their nuclear material and to form weblike extracellular networks containing DNA, histones, and neutrophil granule constituents. These networks are called *neutrophil extracellular traps* (NETs) and consist of DNA extruded from leukocytes. NETs are prothrombotic and procoagulant. Histones stimulate platelet aggregation and promote platelet-dependent thrombin generation. As venous thrombi start to organize, neutrophils infiltrate the NETs. As thrombi mature, NETs provide the scaffold that binds red blood cells and promotes further platelet aggregation.[31]

Venous thrombi contain fibrin, red blood cells, platelets, and neutrophils (**Fig. 84.1**). These thrombi flourish in an environment of stasis, low oxygen tension, oxidative stress, increased expression of

proinflammatory gene products, and impaired endothelial cell regulatory capacity. Inflammation resulting from infection, transfusion, or erythropoiesis-stimulating factor[32] activates a cascade of biochemical reactions in the vein endothelium that promotes thrombosis.[33]

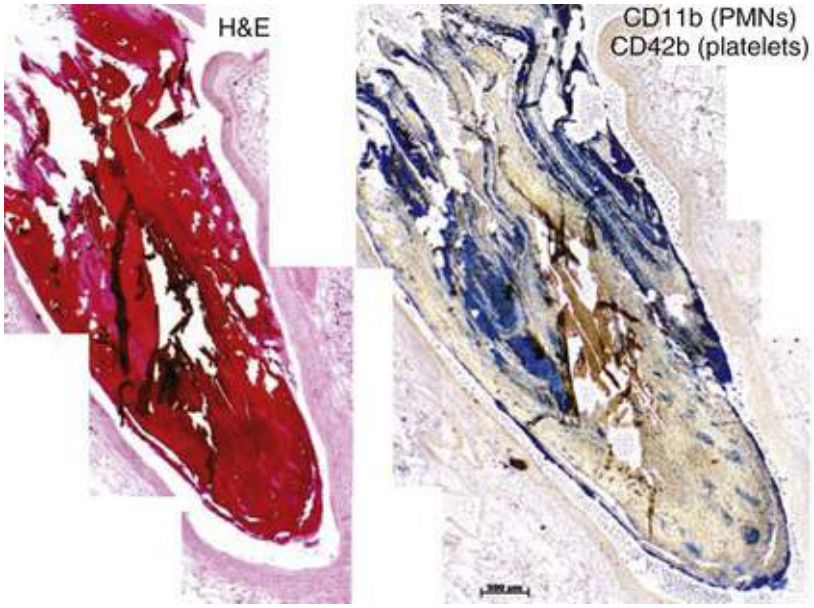

FIGURE 84.1 Micrographs of a fatal PE examined at autopsy. **Left,** Conventional hematoxylin-eosin (H&E)–stained preparation. **Right,** Two special stains were used for this preparation: a CD11b stain for polymorphonuclear leukocytes (*PMNs*, polymorphonuclear monocytes) (*light brown*) and a CD42b stain for platelets (*blue*). The special staining shows that this fatal thromboembolus is composed mostly of platelets (*blue*). (Courtesy Alexander S. Savchenko, PhD, and Denisa D. Wagner, PhD.)

The high recurrence rate of VTE in the absence of anticoagulation supports the hypothesis that venous thrombosis can persist as a subclinical, perhaps chronic, inflammatory state that becomes clinically apparent intermittently, when activated platelets degranulate and release preformed proinflammatory mediators. The JUPITER (Justification for the Use of Statin in Prevention: An Intervention Trial Evaluating Rosuvastatin) study found a 43% reduction in symptomatic VTE among an initially healthy cohort of 17,802 subjects with asymptomatic elevation of baseline hsCRP levels who were treated with rosuvastatin 20 mg daily.[34] The principal postulated mechanism of action was rosuvastatin's antiinflammatory effect, evidenced by its reduction of hsCRP levels.

Cardiopulmonary Dynamics

PE can elicit a complex cardiopulmonary response that includes increased pulmonary vascular resistance due to vascular obstruction, neurohumoral agents, or pulmonary artery baroreceptors; impaired gas exchange caused by increased alveolar dead space from vascular obstruction and hypoxemia from alveolar hypoventilation and right-to-left shunting, as well as impaired carbon monoxide transfer caused by loss of gas exchange surface; alveolar hyperventilation caused by reflex stimulation of irritant receptors; increased airway resistance due to bronchoconstriction; and decreased pulmonary compliance due to lung edema, lung hemorrhage, and loss of surfactant.

The extent of pulmonary vascular obstruction, the presence of underlying cardiopulmonary disease, and the neurohumoral response determine whether right ventricular dysfunction ensues. As obstruction increases, pulmonary artery pressure rises. Further increases in pulmonary vascular resistance and

pulmonary hypertension result from secretion of vasoconstricting compounds such as serotonin, reflex pulmonary artery vasoconstriction, and hypoxemia. The overloaded right ventricle releases cardiac biomarkers such as pro–B type natriuretic peptide (pro-BNP), brain natriuretic peptide (BNP), and troponin, all of which portend an increased likelihood of adverse clinical outcomes.

The sudden rise in pulmonary artery pressure abruptly increases right ventricular afterload, with consequent elevation of right ventricular wall tension followed by right ventricular dilation and dysfunction (**Fig. 84.2**). As the right ventricle dilates, the interventricular septum shifts toward the left, leading to underfilling and decreased left ventricular diastolic distensibility. With hampered filling of the left ventricle, systemic cardiac output and systolic arterial pressure both decline, impairing coronary perfusion and causing myocardial ischemia. Elevated right ventricular wall tension after massive PE reduces right coronary artery flow and increases right ventricular myocardial oxygen demand, causing ischemia. Perpetuation of this cycle can lead to right ventricular infarction, circulatory collapse, and death.

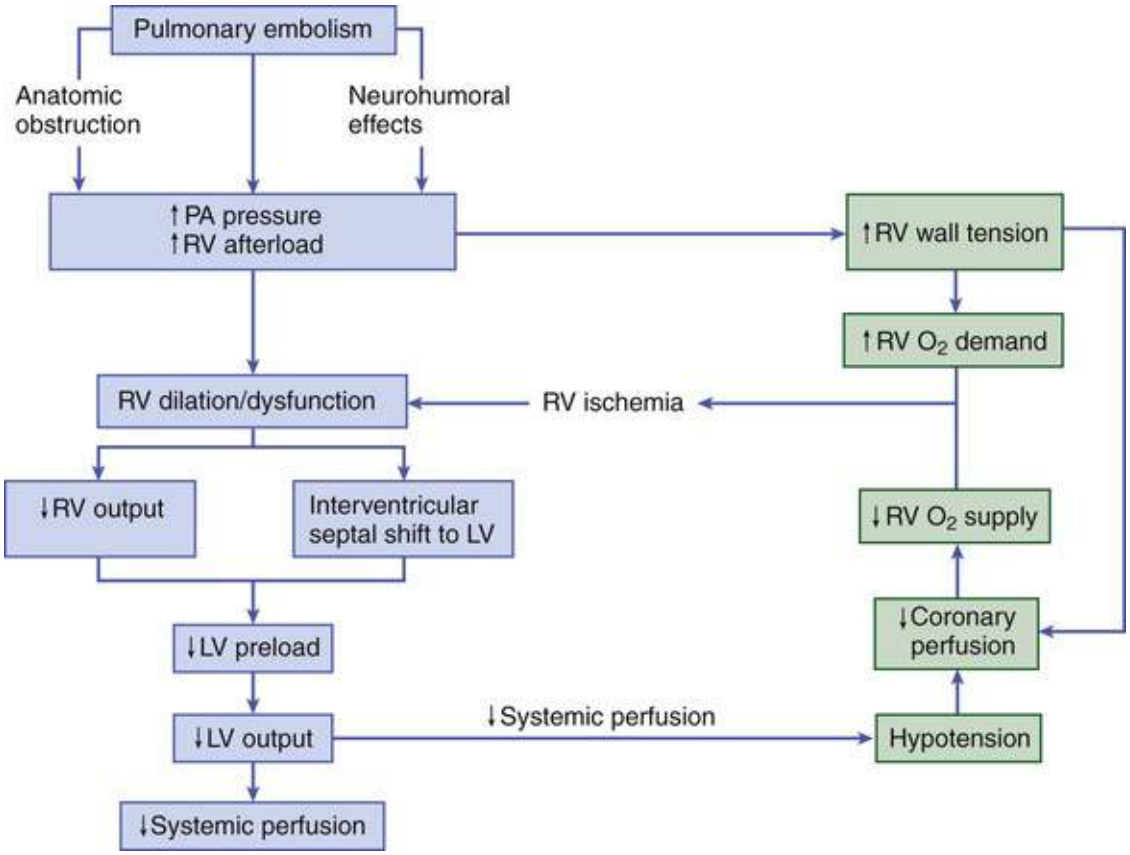

FIGURE 84.2 Pathophysiology of right ventricular dysfunction and its deleterious effects of causing decreased systemic arterial pressure, decreased coronary perfusion, and deteriorating ventricular function. *LV*, left ventricle/ventricular; *PA*, pulmonary artery; *RV*, right ventricle/ventricular.

Classification of Pulmonary Embolism

Classification of acute PE (**Table 84.1**) can assist with prognostication and clinical management. Massive PE accounts for 5% to 10% of cases. Submassive PE is more common, occurring in approximately 20% to 25% of patients. Low-risk PE constitutes the majority of PE cases, approximately 65% to 70%.

TABLE 84.1

Classification of Acute Pulmonary Embolism

CATEGORY (FREQUENCY)	PRESENTATION	THERAPY
Massive PE (5% to 10%)	Systolic blood pressure < 90 mm Hg or poor tissue perfusion or multisystem organ failure plus extensive thrombosis, such as "saddle" PE or right or left main pulmonary artery thrombus	Anticoagulation (usually with high-dose intravenous UFH), plus advanced therapy: systemic thrombolysis, pharmacomechanical catheter–directed therapy, surgical embolectomy, and/or inferior vena cava (IVC) filter
Submassive PE, high risk (15%)	Hemodynamically stable but moderate or severe RV dysfunction or enlargement, coupled with biomarker elevation indicative of RV microinfarction and/or RV pressure overload	Anticoagulation until decision made regarding implementation of advanced therapy; controversy centers on this group. For systemic thrombolysis, reducing the rate of cardiovascular collapse and death must be balanced against the increased rate of hemorrhagic stroke.
Submassive PE, low risk (5% to 10%)	Hemodynamically stable with RV dysfunction or biomarker elevation, but not both	Anticoagulation followed by "watch and wait." Implement advanced therapy if there is clinical deterioration.
Small to moderate PE (70%)	Normal hemodynamics and normal RV size and function	Anticoagulation and consider brief hospital stay or entirely home therapy.

RV, right ventricular; *UFH*, unfractionated heparin.

Massive Pulmonary Embolism

Patients with massive PE can develop cardiogenic shock and multisystem organ failure. Renal insufficiency, hepatic dysfunction, and altered mentation occur commonly. Massive PE has a high mortality rate. Thrombosis is widespread, affecting at least half of the pulmonary arterial vasculature. Clot typically is present bilaterally, sometimes as a "saddle" PE in the main pulmonary artery. Dyspnea usually is the most prominent symptom; chest pain is unusual; transient cyanosis is common; and systemic arterial hypotension requiring pressor support occurs frequently. Excessive fluid boluses may worsen right-sided heart failure, rendering therapy more difficult. These patients may require heroic efforts to enable survival, such as extracorporeal membrane oxygenation.[35]

Submassive Pulmonary Embolism

Submassive PE patients present with normal systemic arterial pressure. The European Society of Cardiology PE Guidelines now subdivide submassive PE into high-risk and low-risk entities.[36] Patients with submassive PE, high risk, present with both right ventricular hypokinesis and elevated cardiac biomarkers such as troponin, pro-BNP, or BNP. Those with submassive PE, low risk, present either with right ventricular dysfunction or elevated cardiac biomarkers, but not both. Usually, one third or more of the pulmonary artery vasculature is obstructed in submassive PE patients. Sudden onset of moderate pulmonary arterial hypertension (**Fig. 84.3**) and right ventricular enlargement occur commonly. If patients have no previous history of cardiopulmonary disease, they may appear clinically well, but this initial impression may be misleading. They are at risk for recurrent PE, even with adequate anticoagulation. Most survive, but some will deteriorate clinically and require escalation of therapy with pressor support or thrombolysis.[37]

FIGURE 84.3 Doppler echocardiographic tracing obtained in a patient with submassive PE. The estimated pulmonary artery systolic pressure is 54 mm Hg, with an additional contribution of right atrial pressure, resulting in moderately severe acute pulmonary hypertension.

Low-Risk Pulmonary Embolism

Patients with low-risk PE exhibit no markers of an adverse prognosis. They present with normal systemic arterial pressure, no cardiac biomarker release, and normal right ventricular function. They often prove to have an anatomically small PE and appear clinically stable. Adequate anticoagulation usually leads to an excellent clinical outcome. They may be good candidates for home therapy.[38]

Pulmonary Infarction

Pulmonary infarction is characterized by pleuritic chest pain that may be unremitting or may wax and wane. Hemoptysis occasionally accompanies the pleurisy. The embolus typically lodges in the peripheral pulmonary arterial tree, near the pleura (**Fig. 84.4**). Tissue infarction usually occurs 3 to 7 days after embolism. Signs and symptoms often include fever, leukocytosis, elevated erythrocyte sedimentation rate, and radiologic evidence of infarction.

FIGURE 84.4 Chest computed tomography (CT) image showing a large, wedge-shaped (*outline*), right-sided pulmonary infarction.

Paradoxical Embolism

Paradoxical embolism may manifest with a sudden stroke, which may be misdiagnosed as "cryptogenic." The cause is a DVT that embolizes to the arterial system, usually through a patent foramen ovale. The DVT can be small and break away completely from a tiny leg vein, leaving no residual evidence of thrombosis that can be imaged on venous ultrasound examination.[39]

Nonthrombotic Pulmonary Embolism

Sources of embolism other than thrombus are uncommon. They include fat, tumor, air, and amniotic fluid. Fat embolism most often occurs after blunt trauma complicated by long bone fractures.[40] Air embolus can occur during placement or removal of a central venous catheter. Amniotic fluid embolism may be catastrophic and is characterized by respiratory failure, cardiogenic shock, and disseminated intravascular coagulation. Intravenous drug abusers sometimes self-inject hair, talc, and cotton as contaminants of the drug of abuse; these patients also are susceptible to septic PE, which can cause endocarditis of the tricuspid or pulmonic valve.

Classification of Deep Vein Thrombosis

Lower Extremity Deep Vein Thrombosis and the Relationship Between Deep Vein Thrombosis and Pulmonary Embolism

Patients present with DVT symptoms about twice as frequently as with symptoms of PE. Leg DVT occurs approximately 10 times more often than upper extremity DVT. The more proximal the thrombus is within the deep leg veins, the more likely it is to embolize and cause acute PE. When venous thrombi detach from their sites of formation, they travel through the venous system toward the vena cava. They pass through the right atrium and right ventricle and then enter the pulmonary arterial circulation. An extremely

large embolus may lodge at the bifurcation of the pulmonary artery, forming a saddle embolus (**Fig. 84.5**). Many patients with large PEs lack ultrasonographic evidence of DVT, probably because the clot has already embolized to the lungs.

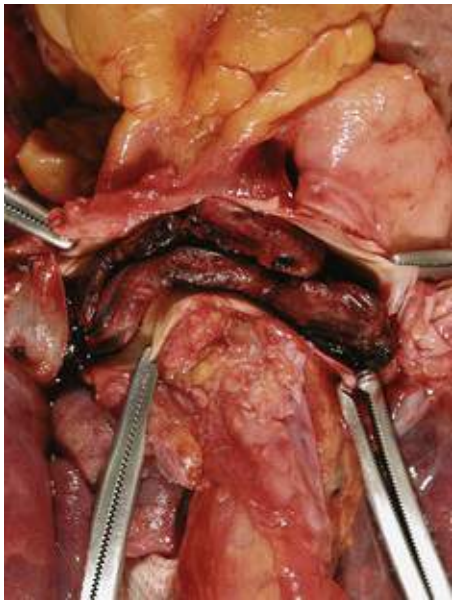

FIGURE 84.5 Surgical specimen from a 41-year-old woman with poorly controlled hypertension who suffered an intracerebral hemorrhage, complicated 6 days later by acute PE. Emergency catheter embolectomy was unsuccessful, and she suffered cardiac arrest. At autopsy, a large saddle embolus extended from the root of the pulmonary artery into the left and right lungs.

Upper Extremity Deep Vein Thrombosis

Upper extremity DVT is an increasingly important clinical entity because of the more frequent placement of pacemakers and implantable cardioverter-defibrillators, as well as more frequent use of chronic indwelling catheters for chemotherapy and nutrition. The likelihood of upper extremity DVT increases as the size of a peripherally inserted central catheter increases.[41]

A hospital initiative to use smaller-diameter catheters and to minimize the number of lumens can markedly reduce the frequency of catheter-associated DVT.[42] Patients with upper extremity DVT are at risk for PE, superior vena cava syndrome, and loss of vascular access. In a study of 3790 patients receiving peripherally inserted central catheters during hospitalization, central catheter use tripled the likelihood of upper-extremity DVT and increased by about 50% the likelihood of leg DVT.[43]

Postthrombotic Syndrome and Chronic Venous Insufficiency

Dysfunction of the valves of the deep venous system often results from damage due to DVT. Obstruction of the deep veins may limit the outflow of blood, causing increased venous pressure with leg muscle contraction. Abnormal hemodynamics in the large veins of the leg are transmitted to the microcirculation, causing venous microangiopathy.[6] Patients with DVT who develop postthrombotic syndrome have higher levels of inflammatory markers compared with those who do not.[44] Physical findings may include varicose veins, abnormal pigmentation of the medial malleolus, and skin ulceration (**Fig. 84.6**). Postthrombotic syndrome has high economic impact[45] because of time lost from work and the expense of medical diagnosis and treatment. Chronic venous disease is associated with a reduced quality of life as a

consequence of pain, decreased physical function, and decreased mobility. Vascular compression stockings (below-knee, 30 to 40 mm Hg) do not prevent the development of postthrombotic syndrome after an acute proximal DVT.[46] However, for patients with venous insufficiency, vascular compression stockings are a mainstay of therapy, improving venous hemodynamics, reducing edema, alleviating calf discomfort, and minimizing skin discoloration.

FIGURE 84.6 Left medial malleolus venous ulcer due to postthrombotic syndrome in a 57-year-old man with a history of left iliofemoral DVT and extensive tobacco use. Note the erythema and thickening of the skin of the left lower calf. (Courtesy Suresh Vedantham, MD.)

Superficial Venous Thrombosis

In a large Danish population-based case-control study, the risk of VTE was 3.4% in the 3 months following diagnosis of superficial venous thrombosis. The risk of VTE remained elevated fivefold for more than 5 years after the initial superficial venous thrombosis.[47] Short-term use of fondaparinux (2.5 mg once daily for 45 days) is the best validated anticoagulant therapy.[48]

Epidemiology

General Considerations

The incidence of VTE in North America and Europe is approximately 1.5 cases per 1000 person-years.

About two thirds of cases are DVT, and the rest are PE with or without DVT. The incidence increases with age in both men and women. Approximately half of VTE cases occur without antecedent trauma, surgery, immobilization, or cancer. Cardiovascular risk factors are associated with VTE. A metaanalysis of data for 63,552 patients with VTE and control subjects found that the relative risk for VTE was 2.3 for obesity, 1.5 for hypertension, 1.4 for diabetes mellitus, 1.2 for cigarette smoking, and 1.2 for hypercholesterolemia.[49] The overlap between venous and arterial thrombosis risk factors means that clinicians can counsel patients on steps to reduce VTE and coronary heart disease risk simultaneously.

Clinical Risk Factors

Risk factors for VTE in the community include advancing age, frailty, and immobility; the presence of cancer or venous insufficiency; previous VTE; or traumatic injury. Pregnant women also are at risk. Of those suffering VTE in the Worcester Venous Thromboembolism Study, 23% had undergone surgery and 36% had been hospitalized within the preceding 3 months. Among those patients, fewer than half had received anticoagulant prophylaxis.[50]

Obesity increases the risk of VTE. In a study of more than 1 million women with a mean age of 56 years in the United Kingdom, VTE risk increased with increasing body mass index (BMI). Women with a BMI 35 kg/m^2 or greater, for example, were three to four times more likely to develop VTE than women with a BMI between 22 and 25 kg/m^2.[51] A Spanish VTE registry called RIETE (Registro Informatizado de Enfermedad TromboEmbólica) included 18,023 patients with PE. Immobilized patients had a more than twofold increased risk of fatal PE. Of RIETE patients dying from PE, 43% had a history of recent immobilization for 4 days or longer.[52]

Some risk factors for VTE are not readily modifiable (**Table 84.2**). As VTE patients with cancer survive longer due to advances in oncologic therapy, the frequency of VTE is increasing, because cancer patients have a marked increased incidence of VTE (**see Chapter 81**). Cancer chemotherapy–associated VTE is common. Increased VTE risk is associated with solid tumors, especially adenocarcinomas of the pancreas, stomach, lung, esophagus, prostate, and colon. Less well known is that VTE risk also increases with “liquid tumors,” such as myeloproliferative disorders, lymphoma, and leukemia.

TABLE 84.2

Major Risk Factors for Venous Thromboembolism That Are Not Readily Modifiable

Advanced age
Arterial disease, including carotid and coronary disease
Personal or family history of venous thromboembolism
Recent surgery, trauma, or immobility, including stroke
Congestive heart failure
Chronic obstructive pulmonary disease
Acute infection
Blood transfusion
Erythropoietin-stimulating factor
Chronic inflammation (e.g., inflammatory bowel disease)
Chronic kidney disease
Air pollution
Long-haul air travel
Pregnancy, oral contraceptive pills, or postmenopausal hormone replacement therapy
Pacemaker, implantable cardioverter-defibrillator leads, or indwelling central venous catheter
Hypercoagulable states
Factor V Leiden resulting in activated protein C resistance
Prothrombin gene mutation 20210
Antithrombin deficiency
Protein C deficiency
Protein S deficiency
Antiphospholipid antibody syndrome (acquired, not inherited)

Pregnancy, hormonal contraception, and postmenopausal hormonal therapy each contribute to increased risk. Use of progesterone-only birth control pills is not associated with increased VTE risk. Long-haul air travel is among the most frequently discussed acquired risk factors, although the associated risk of fatal PE is less than one in one million. When death occurs, however, it is dramatic and especially tragic because the victim is often an otherwise healthy young person.

Hypercoagulable States

The two most common identified genetic causes of thrombophilia are factor V Leiden and the prothrombin gene mutation (**see Chapter 93**). Normally, a specified amount of activated protein C (aPC) can be added to plasma to prolong the activated partial thromboplastin time (aPTT). Patients with “aPC resistance” exhibit blunted aPTT prolongation and are predisposed to the development of PE and DVT. A single-point mutation, designated factor V Leiden, in the factor V gene causes aPC resistance. Factor V Leiden triples the risk of VTE and is associated with recurrent pregnancy loss, probably as a consequence of placental vein thrombosis. Use of oral estrogen-containing contraceptives by patients with factor V Leiden increases the VTE risk by at least 10-fold. A single-point mutation in the 3′ untranslated region of the prothrombin gene (G-to-A transition at nucleotide position 20210) increases levels of prothrombin. The prothrombin gene mutation doubles the risk of VTE.

The antiphospholipid syndrome, the most common acquired thrombophilia, can cause venous or arterial thrombosis, thrombocytopenia, recurrent fetal loss, or acute ischemic encephalopathy. The presence of specific autoantibodies is an essential component of the diagnosis. The persistence for at least 12 weeks of one of the following antiphospholipid antibodies is required: IgG or IgM anticardiolipin antibodies, anti-beta2-glycoprotein I, antiprothrombin, or lupus anticoagulant. Presence of the antiphospholipid syndrome means heightened susceptibility to recurrent venous or arterial thrombosis if anticoagulation is

discontinued.[53]

Obtaining a family history remains the fastest and most cost-effective method of identifying a predisposition to venous thrombosis. Investigation with blood tests to detect known causes of hypercoagulability can be misleading. Consumption coagulopathy caused by venous thrombosis, for example, may be misdiagnosed as deficiency of antithrombin, protein C, or protein S. Heparin administration can depress antithrombin levels. Use of warfarin ordinarily causes a mild deficiency of protein C or protein S. Oral contraceptives and pregnancy also depress protein S levels.

Diagnosis

PE notoriously masquerades as other illnesses, such as asthma, pneumonia, pleurisy, acute coronary syndrome, and congestive heart failure. PE often occurs concomitantly with other illnesses, especially pneumonia and heart failure, thereby confounding the diagnostic workup. The most useful approach is a clinical assessment of likelihood, based on presenting symptoms and signs, in conjunction with judicious diagnostic testing. When PE is not among the most likely diagnoses, a normal plasma D-dimer enzyme-linked immunosorbent assay (ELISA) usually can rule out this condition. When PE is strongly suspected, a D-dimer ELISA need not be obtained, and one can proceed directly to chest computed tomography (CT) imaging.[54] Although the traditional upper limit of normal for a D-dimer screening test is 500 ng/mL, the upper limit of normal should be increased for patients older than 50 years. For these older patients, the age-adjusted D-dimer cutoff level is defined as age multiplied by 10.[55]

Clinical Presentation

PE causes nonspecific symptoms and signs. Hence, clinical suspicion for PE is of paramount importance in guiding diagnostic testing. Dyspnea is the most frequent symptom, and tachypnea is the most frequent sign (**Table 84.3**). Severe dyspnea, syncope, or cyanosis portends a major life-threatening PE, in which the patient often lacks chest pain. Paradoxically, severe pleuritic pain often signifies that the embolism is small, not life-threatening, and located in the distal pulmonary arterial system, near the pleural lining.

TABLE 84.3

Most Common Symptoms and Signs of Pulmonary Embolism

Symptoms
Unexplained dyspnea
Chest pain, especially pleuritic or “positional”
Anxiety
Cough
Signs
Tachypnea
Tachycardia
Low-grade fever
Left parasternal lift
Jugular venous distention
Tricuspid regurgitant murmur
Accentuated P_2
Hemoptysis
Leg edema, erythema, tenderness

PE should be suspected in hypotensive patients who have evidence of (1) venous thrombosis or predisposing VTE risk factors, (2) acute cor pulmonale (acute right ventricular failure), with features such as distended neck veins, right-sided S_3 gallop, right ventricular heave, tachycardia, or tachypnea, especially if (3) there are echocardiographic findings of right ventricular dilation and hypokinesis or electrocardiographic evidence of acute cor pulmonale manifested by a new $S_1Q_3T_3$ pattern (**Fig. 84.7**), new right bundle branch block, or right ventricular ischemia with inferior T wave inversion, or T wave inversion in leads V_1 through V_4. Clinical decision rules can stratify patients into groups with a high clinical likelihood of PE or without a high clinical likelihood of PE, using a set of seven bedside assessment questions known as the Wells criteria (**Table 84.4**).

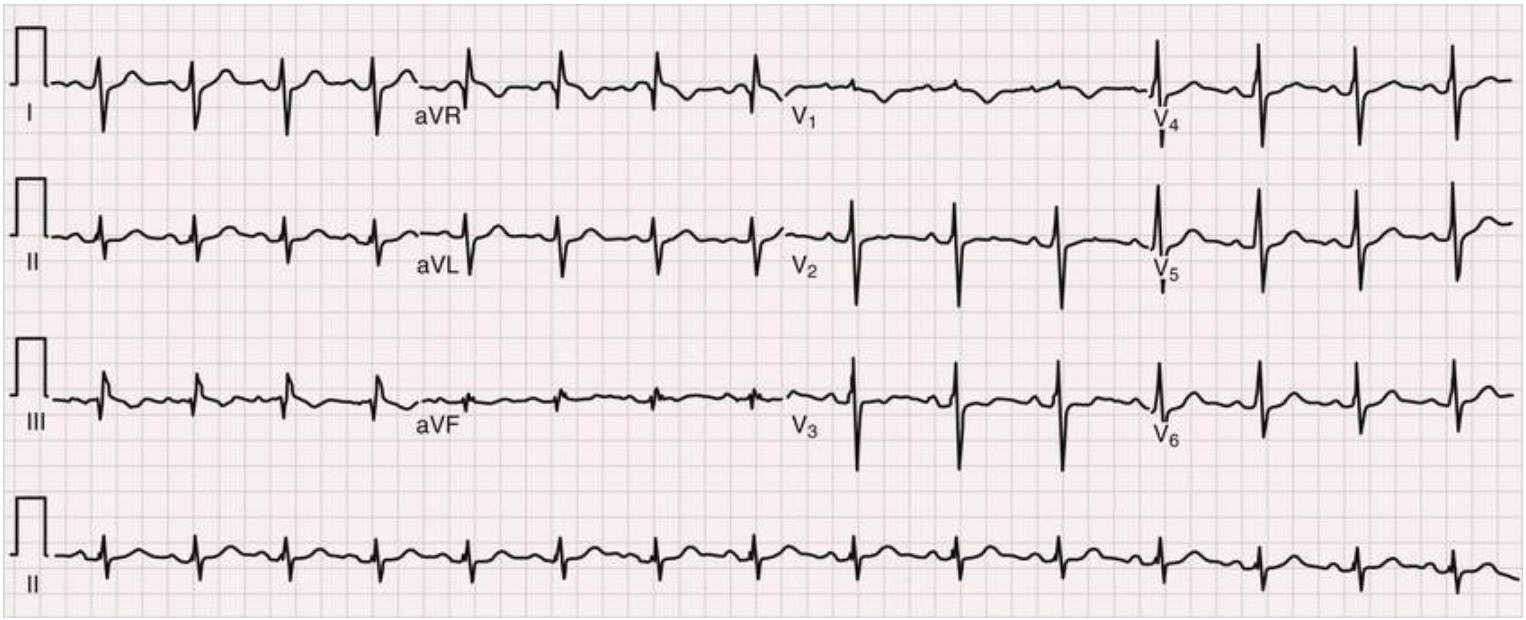

FIGURE 84.7 Electrocardiogram (ECG) from a 33-year-old man who presented with a left main pulmonary artery embolism on chest CT scan. He was hemodynamically stable, with normal right ventricular function on echocardiography. His troponin and BNP levels were normal. He was managed with anticoagulation alone. The initial ECG tracing shows $S_1Q_3T_3$ (leads I and III) with an S wave in lead I, Q wave in lead III, and inverted T wave in lead III, and incomplete right bundle branch block, with inverted or low amplitude T waves in leads V_1 through V_4.

TABLE 84.4

Classic Wells Criteria for Assessing Clinical Likelihood of Pulmonary Embolism

CRITERION	SCORING*
DVT symptoms or signs	3
An alternative diagnosis is less likely than PE	3
Heart rate > 100 beats/min	1.5
Immobilization or surgery within 4 weeks	1.5
Previous DVT or PE	1.5
Hemoptysis	1
Cancer treated within 6 months or metastatic	1

*More than 4 score points indicates high probability; 4 score points or fewer indicates probability that is not high.

Differential Diagnosis

PE has a broad differential diagnosis, covering a wide spectrum from life-threatening conditions such as

acute MI to anxiety states (**Table 84.5**). Concomitant illnesses should be taken into account. For example, if pneumonia or heart failure does not respond to appropriate therapy, the possibility of coexisting PE should be considered. Idiopathic pulmonary hypertension may manifest with sudden exacerbations that mimic acute PE.

TABLE 84.5

Differential Diagnosis of Pulmonary Embolism

Anxiety, pleurisy, costochondritis
Pneumonia, bronchitis
Acute coronary syndrome
Pericarditis
Congestive heart failure
Aortic dissection
Idiopathic pulmonary hypertension

Diagnostic Methods Other Than Imaging

Plasma D-Dimer Assay

The plasma D-dimer assay, a blood screening test, relies on the following principle: Most patients with PE have ongoing endogenous fibrinolysis that is not effective enough to prevent PE but breaks down some of the fibrin clot to D-dimers. Although elevated plasma concentrations of D-dimers are sensitive for the diagnosis of PE, they are not specific. Even in the absence of PE, levels are elevated for at least 1 week postoperatively and also are abnormally high in patients with MI, sepsis, cancer, or almost any other systemic illness. The plasma D-dimer assay therefore is ideally suited for screening outpatients or emergency department patients who have suspected PE but no coexisting acute systemic illness. This test generally is not useful for screening acutely ill hospitalized inpatients, because they usually have elevated D-dimer levels. In addition to being a screening test for PE, an elevated D-dimer independently correlates with increased rates of mortality and subsequent VTE across a broad variety of disease states.[56]

Electrocardiogram

The electrocardiogram (ECG) helps exclude acute MI and acute pericarditis. This test may lead the clinician toward the diagnosis of PE among patients with electrocardiographic manifestations of right-sided heart strain. The most famous sign of right heart strain is $S_1Q_3T_3$, but I have found that the most common sign is T wave inversion in leads V_1 to V_4. Keep in mind that right-sided heart strain is not specific for PE and may be observed in patients with asthma, COPD, or idiopathic pulmonary hypertension. In patients with massive PE, the ECG may not be especially remarkable and may exhibit sinus tachycardia or slight ST-segment and T-wave abnormalities, or may even have an entirely normal appearance.

Imaging Methods

Chest Radiography

A near-normal radiographic appearance in the setting of severe respiratory compromise is highly suggestive of massive PE. Major chest radiographic abnormalities are uncommon. Focal oligemia

(Westermark sign) indicates massive central embolic occlusion. A peripheral wedge-shaped density above the diaphragm (Hampton hump) usually indicates pulmonary infarction (**see Fig. 84.4**). A subtle abnormality suggestive of PE is enlargement of the descending right pulmonary artery. The chest radiograph also can help identify patients with diseases that mimic PE, such as lobar pneumonia and pneumothorax, but patients with these illnesses also can have concomitant PE.

Lung Scanning

Pulmonary radionuclide perfusion scintigraphy (lung scanning) uses radiolabeled aggregates of albumin or microspheres that lodge in the pulmonary microvasculature. Patients with large PE often have multiple perfusion defects. If ventilation scanning is performed on a patient with PE but no intrinsic lung disease, a normal ventilation study result is expected, yielding ventilation-perfusion mismatch interpreted as a high probability of PE. However, many patients with low-probability scans but with clinical findings strongly suggestive of PE do, in fact, have PE proven by invasive pulmonary angiography. Thus, a clinical probability assessment helps in correct interpretation of the scan results.

Most lung scans are nondiagnostic. An unequivocal normal or high-probability scan is the exception, not the rule. Interobserver variability is common, even among experts. Three principal indications for obtaining a lung scan are renal insufficiency, anaphylaxis occurring in reaction to an intravenous contrast agent that cannot be suppressed with high-dose corticosteroids, and pregnancy (lower radiation exposure to the fetus than CT scanning).

Chest Computed Tomography

Chest CT has supplanted pulmonary radionuclide perfusion scintigraphy as the initial imaging test in most patients with suspected PE.[57] Multidetector-row CT scanners can rapidly image the entire chest with submillimeter resolution. Three-dimensional images can be reconstructed, and color can be added electronically to enhance details of thrombus localization. The CT scan helps determine surgical or catheter accessibility to the thrombus. One cautionary note is that the CT scan may lead to overdiagnosis of PE due to breathing motion artifact or beam-hardening artifact.[58]

The latest generation of scanners can image thrombus in sixth-order vessels. These thrombi are so tiny that their clinical significance is uncertain (**Fig. 84.8**). The chest CT scan also can detect other pulmonary diseases that manifest in conjunction with PE or explain a clinical presentation that mimics PE. These diseases include pneumonia, atelectasis, pneumothorax, and pleural effusion, which may not be well visualized on the chest radiograph. A chest CT scan sometimes detects an incidental but critical finding, such as a small lung carcinoma.

FIGURE 84.8 Small peripheral pulmonary embolism in the left lower lobe (*arrow*). (Courtesy U. Joseph Schoepf, MD.)

For patients with PE, the CT scan serves as a prognostic and diagnostic test. It shows a four-chamber view of the heart and images the pulmonary arteries. Careful evaluation of the CT scan can detect signs of right ventricular dysfunction by analyzing (1) the right ventricular–to–left ventricular diameter ratio (**Fig. 84.9**), (2) right ventricular–to–left ventricular volume ratio, (3) interventricular septal bowing, and (4) reflux of contrast medium into the inferior vena cava.[59] Right ventricular enlargement on CT correlates with right ventricular dysfunction and portends a complicated hospital course often marked by clinical deterioration. A right-to-left ventricular dimensional ratio of 0.9 or greater on a chest CT scan is abnormal, indicates right ventricular enlargement, and correlates with right ventricular dysfunction on echocardiography.

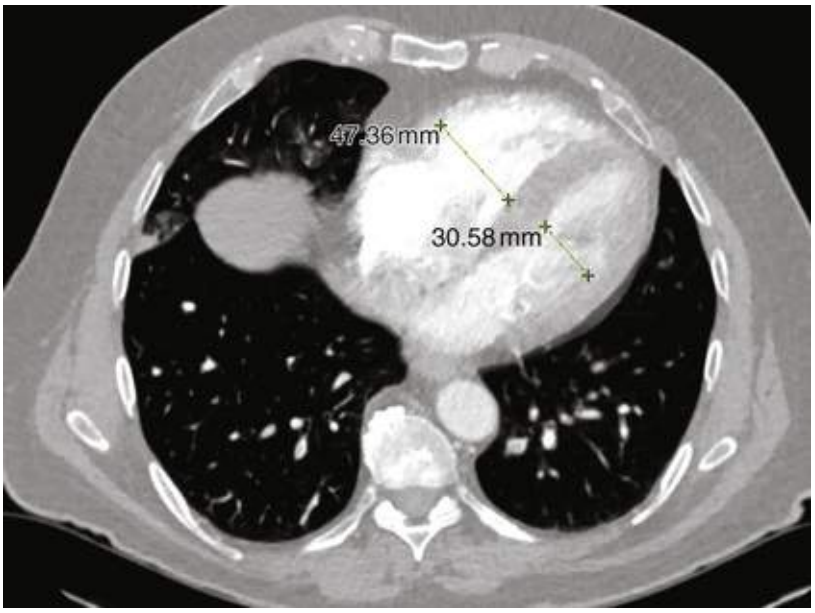

FIGURE 84.9 Enlarged right ventricle on chest CT in a patient with PE. Normally, the ratio of the diameters of the right ventricle and the left ventricle is less than 0.9. This patient has an RV diameter of 47 mm and an LV diameter of 31 mm. The RV/LV diameter ratio of 1.5 is abnormally high. *LV*, left ventricular; *RV*, right ventricular.

Echocardiography

About one half of unselected patients with acute PE have normal echocardiographic findings, so this modality is not recommended as a routine diagnostic test for PE. Echocardiography is, however, a rapid, practical, and sensitive technique for detection of right ventricular overload among patients with established PE. Moderate or severe right ventricular hypokinesis, persistent pulmonary hypertension, patent foramen ovale, and free-floating thrombus in the right atrium or right ventricle are associated with a high risk of death or recurrent thromboembolism.[60] Echocardiography also can help identify illnesses that may mimic PE, such as MI and pericardial disease.

Venous Ultrasonography

The primary diagnostic criterion for DVT on ultrasound imaging is loss of vein compressibility (**Fig. 84.10**). Normally, the vein collapses completely when gentle pressure is applied to the skin overlying it. Upper extremity DVT can be more difficult to diagnose than leg DVT because the clavicle can hinder attempts to compress the subclavian vein. At least one half of the patients with PE have no imaging evidence of DVT, probably because the entire DVT embolized to the pulmonary arteries. Therefore, if the level of clinical suspicion of PE is moderate or high, patients without evidence of DVT should undergo further investigation for PE.

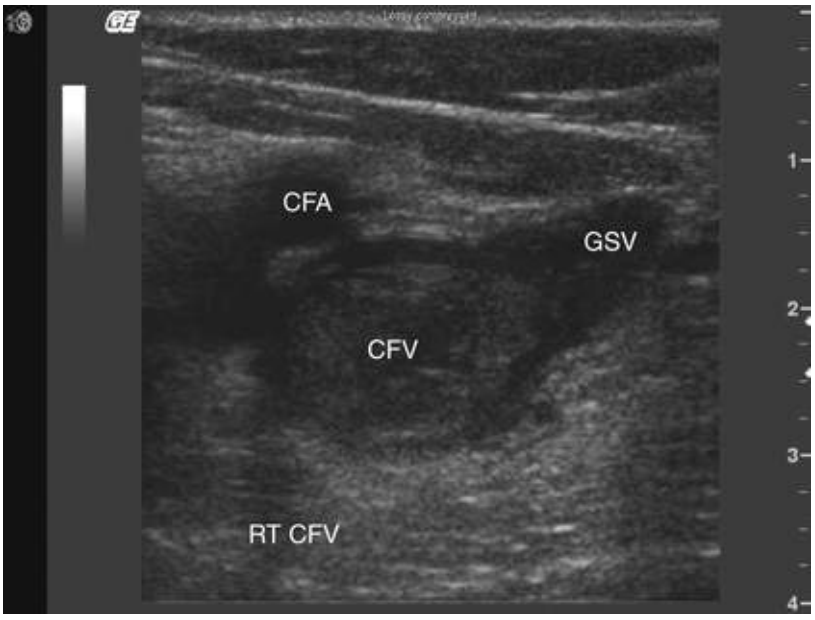

FIGURE 84.10 DVT involving the right common femoral vein (*RT CFV*) seen on venous ultrasound examination. The common femoral vein (*CFV*) does not compress and is dilated. Thrombotic material can be visualized within the vein. *CFA*, common femoral artery; *GSV*, greater saphenous vein. (Courtesy Samuel Z. Goldhaber, MD, and Gregory Piazza, MD, MS.)

Magnetic Resonance Imaging

Gadolinium-enhanced magnetic resonance angiography (MRA) is far less sensitive than CT for the detection of PE, but unlike chest CT or catheter-based pulmonary angiography, MRA does not require ionizing radiation or injection of an iodinated contrast agent. Pulmonary MRA also can assess right ventricular size and function. Three-dimensional MRA can be performed during a single breath-hold and may provide high resolution from the main pulmonary artery through the segmental pulmonary artery branches. MRA has limited sensitivity for detection of distal PE and cannot be used as a stand-alone test to exclude PE.[61]

Pulmonary Angiography

Invasive pulmonary angiography formerly was the reference standard for the diagnosis of PE, but it is now rarely performed as a diagnostic test. Use of this modality is routine, however, to plan interventions such as pharmacomechanical catheter–assisted therapy. New thrombus usually has a concave edge. Chronic thrombus leads to bandlike defects called webs, in addition to intimal irregularities and abrupt narrowing or occlusion of lobar vessels.

Contrast Phlebography

Although contrast phlebography was once the reference standard for DVT diagnosis, this study is now rarely obtained for diagnostic purposes. Venography is the first step, however, for evaluation of patients with large femoral or iliofemoral DVT who will undergo invasive pharmacomechanical catheter–directed therapy.

Overall Strategy: An Integrated Diagnostic Approach

A wide array of diagnostic tests can investigate suspected PE. The first step in an integrated diagnostic strategy (**Fig. 84.11**) is a directed history and physical examination to assess the clinical likelihood of

acute PE. The finding of a clinical probability that is not high is followed by D-dimer testing; a normal D-dimer assay usually rules out PE. If the D-dimer is elevated, chest CT usually provides the definitive diagnosis or exclusion of PE.

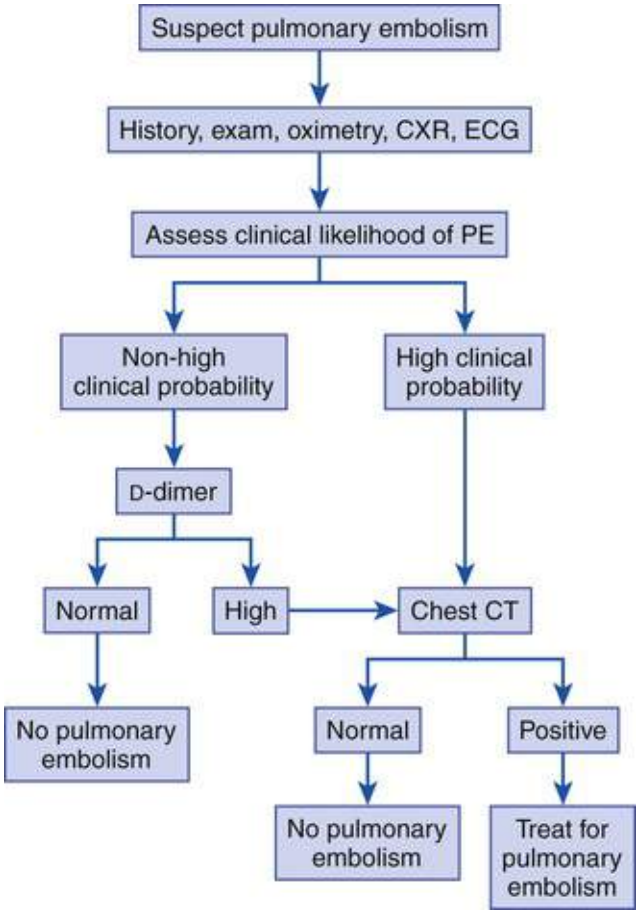

FIGURE 84.11 Integrated diagnostic approach. *CXR*, chest x-ray [examination].

Diagnostic Electronic Decision Support

It is essential to bring runaway technology under control and to slow down the overuse of CT scanning. Too little attention is paid to history taking, physical examination, clinical likelihood scoring systems, and D-dimer screening. Undue reliance on advanced imaging technology has adverse consequences aside from the increased cost, including unnecessary exposure to radiation and intravenous contrast agents, with potential complications of renal dysfunction or anaphylaxis. Electronic decision support at the time of ordering chest CT scans can reduce unwarranted imaging and increase the proportion of test results that are positive for PE.[62]

Anticoagulation Therapy for Acute Pulmonary Embolism

Risk Stratification

PE manifests with a wide spectrum of acuity, ranging from mild to severe. Therefore, rapid and accurate

risk stratification assumes paramount importance. Low-risk patients have an excellent prognosis with anticoagulation alone (**see also Chapter 93**). High-risk patients may require intensive hemodynamic and respiratory support with pressors, mechanical ventilation, or extracorporeal membrane oxygenation.[63] In addition to anticoagulation, advanced management[64] options include systemic thrombolysis, pharmacomechanical catheter–assisted therapy, vena cava filter placement, or surgical embolectomy[65] (**Fig. 84.12**). The three key components for risk stratification are (1) clinical evaluation, (2) assessment of right ventricular size and function, and (3) analysis of cardiac biomarkers to determine whether there is right ventricular microinfarction.

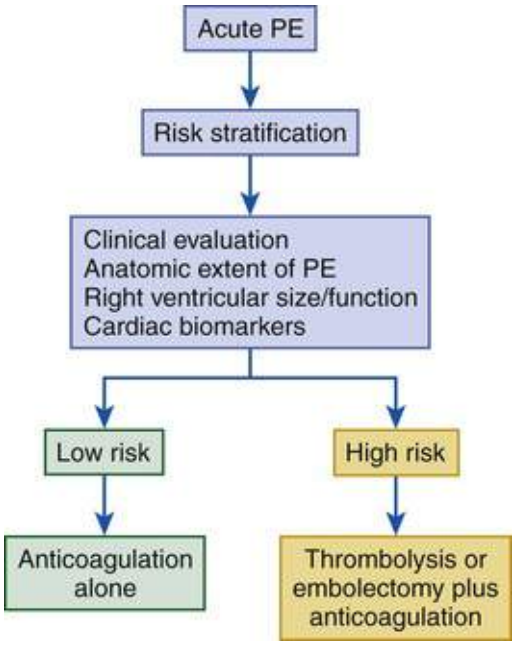

FIGURE 84.12 Management strategy for acute PE, based on risk stratification.

Clinical evaluation is straightforward if the patient looks and feels well and has no evidence of right ventricular dysfunction. The Pulmonary Embolism Severity Index (PESI) identifies 11 features from demographics, history, and clinical findings that can be weighted and scored to identify low-risk and high-risk patients[66] (**Table 84.6**).

TABLE 84.6

Pulmonary Embolism Severity Index (PESI) and Simplified PESI: Predictors of Prognostic Risk

PESI Criteria*	
Age > 80 years	Age in years
Male sex	+10
History of cancer	+30
History of heart failure	+10
History of chronic lung disease	+10
Heart rate ≥ 110 beats/min	+20
Systolic blood pressure < 100 mm Hg	+30
Respiratory rate ≥ 30 breaths/min	+20
Temperature <36°C	+20
Altered mental status	+60
Arterial oxygen saturation <90%	+20
Simplified PESI† Criteria	
Age > 80 years	+1
History of cancer	+1
History of heart failure or chronic lung disease	+1
Heart rate ≥ 110 beats/min	+1
Systolic blood pressure < 100 mm Hg	+1
Arterial oxygen saturation <90%	+1

*Class 1, ≤65; class 2, 66 to 85; class 3, 86 to 105; class 4, 106 to 125; class 5, 126 or more. In the PESI score, classes 1 and 2 are considered low risk, and classes 3 to 5 are considered high risk.

†Patients with a score of 0 are considered to be at low risk for PE; those with scores of 1 or higher are considered at high risk.

Clinicians should try to detect right ventricular dysfunction on physical examination by looking for distended jugular veins, a systolic murmur of tricuspid regurgitation, or an accentuated P_2. Clinical evaluation should integrate the results of electrocardiography that might show a right ventricular strain pattern (right bundle branch block, $S_1Q_3T_3$, negative T waves in leads V_1 through V_4), chest CT, echocardiography, and cardiac biomarkers of right ventricular injury.

Parenteral Anticoagulation

Unfractionated Heparin

Anticoagulation is the cornerstone of treatment for acute PE. Unfractionated heparin (UFH) is a highly sulfated glycosaminoglycan that is partially purified, most often from pig intestinal mucosa. The short half-life of UFH is advantageous for patients who may require subsequent insertion of an inferior vena cava filter, systemic thrombolysis, catheter-directed pharmacomechanical therapy, or surgical embolectomy.

Heparin acts primarily by binding to antithrombin, a protein that inhibits the coagulation factors thrombin (factor IIa) and factors Xa, IXa, XIa, and XIIa. Heparin subsequently promotes a conformational change in antithrombin that accelerates its activity approximately 100- to 1000-fold. This action prevents additional thrombus formation and permits endogenous fibrinolytic mechanisms to lyse at least some of the clot that has already formed. Heparin does *not* directly dissolve thrombus. Beyond its anticoagulant activity, heparin also exerts pleiotropic effects, including antiinflammatory[67] and vasodilatory properties.[68]

For patients with average bleeding risk, UFH should be started with an intravenous bolus of 80 units/kg, followed by a continuous infusion at 18 units/kg/hr. The aPTT should be targeted between 1.5 and 2.5 times the control value. The therapeutic range commonly is 60 to 80 seconds. Monitoring continuous intravenous UFH infusions using anti-Xa assays (instead of aPTT) is gaining popularity,

because this approach measures heparin's effect directly. This assay has special utility for patients with a baseline elevation in aPTT, such as those with lupus anticoagulant. The target level for therapeutic dosing is 0.3 to 0.7 units/mL.

Low-Molecular-Weight Heparin

Low-molecular-weight heparin (LMWH) consists of fragments of UFH that exhibit less binding to plasma proteins and endothelial cells. It therefore has greater bioavailability, with a more predictable dose response, and a longer half-life compared with UFH. These features permit weight-based LMWH dosing without laboratory tests, because no dose adjustment is needed in most instances. The kidneys metabolize LMWH, and patients with renal impairment require downward adjustment of LMWH dosing. If a quantitative assay is desired, an anti-Xa level can be obtained. Whether use of anti-Xa levels improves efficacy and safety remains controversial.

LMWH is recommended as monotherapy without anticoagulation for cancer patients with VTE. In one randomized trial, dalteparin monotherapy reduced by about half the recurrent VTE rate compared with warfarin.[69] In a subsequent trial of tinzaparin monotherapy versus warfarin in cancer patients, patients treated with tinzaparin had a rate of bleeding about 40% lower than those treated with warfarin.[70] A randomized trial of edoxaban versus LMWH for treatment of VTE in cancer patients is ongoing.[71]

Fondaparinux

Fondaparinux is an anticoagulant pentasaccharide that specifically inhibits activated factor X. It can be thought of as an ultra–low-molecular-weight heparin. Fondaparinux's predictable and sustained pharmacokinetic properties allow a fixed-dose, once-daily subcutaneous injection, without the need for coagulation laboratory monitoring or dose adjustment. Fondaparinux has a 17-hour half-life, and its elimination is prolonged in patients with renal impairment. Fondaparinux is licensed for the initial treatment of acute PE and acute DVT. It is often used off label for the management of suspected or proven heparin-induced thrombocytopenia, because it does not cross-react with heparin-induced antibodies.[72]

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is a serious immune-mediated complication of heparin.[73,84] It occurs approximately 10 times more often with UFH than with LMWH. Immunoglobulin G antibodies bind to a heparin–platelet factor 4 complex to activate platelets, causing the release of prothrombotic microparticles. The microparticles promote excessive thrombin generation, which can result in paradoxical thrombosis despite thrombocytopenia. The thrombosis usually manifests as extensive and often bilateral DVT (sometimes affecting one upper extremity and one lower extremity) or PE, but presentations of MI, stroke, and unusual types of arterial thrombosis (such as mesenteric arterial thrombosis) also have been described.

The 4T point score is a semiquantitative clinical screening test for HIT.[74] The four components are (1) *t*hrombocytopenia, (2) *t*iming of decrease in platelet count, (3) *t*hrombosis or other sequelae such as skin necrosis, and (4) absence of o*t*her explanation. Heparin-induced thrombocytopenia should be suspected when the platelet count decreases to less than 100,000 or to less than 50% of baseline. The thrombocytopenia is usually mild, in the range of 40,000 to 70,000. Typically, heparin-induced thrombocytopenia occurs after 5 to 10 days of heparin exposure, most often in cardiac surgical ICUs.

ELISA testing quantifies anti–platelet factor 4 (PF4)/heparin antibody levels, which are measured in

optical density (OD) units. The higher the OD value, the more likely the diagnosis of HIT with thrombosis and of acute PE.[75] The serotonin release assay is the reference standard laboratory test for HIT. When HIT is diagnosed, UFH or LMWH should be discontinued immediately, and patients should not receive platelet transfusions. For HIT with thrombosis, a parenteral direct thrombin inhibitor such as argatroban or bivalirudin should be used. In a single-hospital initiative to substitute LMWH for UFH, HIT cases decreased by 79% and hospital HIT-related expenditures decreased by more than $250,000 annually.[76]

Warfarin Anticoagulation

Warfarin is a vitamin K antagonist, first approved for clinical use in 1954. It prevents gamma-carboxylation activation of coagulation factors II, VII, IX, and X. The full anticoagulant effect of warfarin becomes evident after 5 to 7 days, even if the prothrombin time, used to monitor warfarin's effect, becomes elevated more rapidly. For patients with VTE, the usual target international normalized ratio (INR) range is between 2.0 and 3.0. Self-monitoring of INRs improves patient satisfaction and quality of life and may reduce the rate of thromboembolic events.

Warfarin Overlap with Heparin

Initiation of warfarin as monotherapy to treat acute VTE without UFH, LMWH, or fondaparinux may paradoxically exacerbate hypercoagulability, increasing the likelihood of recurrent thrombosis. Warfarin monotherapy decreases the levels of two endogenous anticoagulants, proteins C and S—thus increasing thrombogenic potential. Overlapping warfarin for at least 5 days with an immediately effective parenteral anticoagulant counteracts the procoagulant effect of unopposed warfarin.

Dosing and Monitoring of Warfarin

Dosing warfarin is both an art and a science. Warfarin traditionally is dosed using an “educated guess” coupled with trial and error. Most practitioners begin with 5 mg daily. Debilitated or elderly patients require a reduced dose. Monitoring warfarin requires walking a tightrope—high INRs predispose to bleeding complications and constitute the most common reason for emergency hospitalization for adverse drug events in older Americans. In contrast, subtherapeutic dosing makes patients vulnerable to recurrent VTE. All patients taking warfarin should wear a medical alert bracelet or necklace in case they require rapid reversal of warfarin. Warfarin can have side effects other than hemorrhage, such as hair loss and increased levels of arterial calcification.[77] Some patients complain of “feeling cold” and fatigue.

Warfarin use is plagued by multiple drug-drug and drug-food interactions. Most antibiotics increase the INR, but some, like rifampin, lower the INR. Even seemingly benign drugs such as acetaminophen increase the INR in a dose-dependent manner. On the other hand, green leafy vegetables contain vitamin K, which lowers the INR. Concomitant medications with antiplatelet effects may increase the bleeding risk without increasing the INR. These include fish oil supplements, vitamin E, and alcohol. Centralized anticoagulation clinics, staffed by nurses or pharmacists, have eased the administrative burden of prescribing warfarin and have facilitated safer and more effective anticoagulation.

Warfarin Pharmacogenomics

Genetic determinants of warfarin dose response include CYP2C9-variant alleles—which impair the hydroxylation of S-warfarin, resulting in extremely low warfarin dose requirements—and variants in the gene encoding vitamin K epoxide reductase complex 1 (VKORC1). Pharmacogenetic testing has marginal

usefulness at best, however, and is not used in routine clinical practice.

Warfarin "Bridging"

When patients undergo elective surgery or procedures such as colonoscopy, warfarin is temporarily discontinued. To ensure continued anticoagulation perioperatively, "bridging" with LMWH used to be prescribed preoperatively while the warfarin activity washed out. Yet, the BRIDGE Trial of atrial fibrillation patients showed that forgoing bridging anticoagulation was noninferior to bridging with LMWH. The group that was not bridged had a 59% reduction in major bleeding complications.[78] Subsequently, the practice of routine bridging for VTE patients has fallen out of favor. Now, with only a few exceptions, such as patients with extreme thrombophilia or patients who have mechanical heart valves, we forgo bridging and simply hold warfarin preoperatively (usually for 4 days) and on the day of surgery.

Novel Oral Anticoagulants

Non–vitamin K antagonist oral anticoagulants (NOACs) (**see also Chapter 93**) have a rapid onset of action and provide full anticoagulation within several hours of ingestion. They are prescribed in fixed doses without laboratory coagulation monitoring and have minimal drug-drug or drug-food interactions. These agents have a short half-life, so do not require bridging when they are stopped for an invasive diagnostic or surgical procedure. For VTE treatment, they are noninferior to warfarin for efficacy and are superior to warfarin for safety.[79]

Evolution of Oral Anticoagulants for Pulmonary Embolism and Deep Vein Thrombosis Treatment

The limitations of warfarin prompted the development of NOACs. Four NOACs are licensed for VTE treatment: dabigatran (an oral thrombin inhibitor),[80,81] and three factor Xa inhibitors[82]: rivaroxaban,[83,84] apixaban,[85] and edoxaban[86] (**Table 84.7**). For extended therapy after an initial 6-month course of anticoagulation, dabigatran was compared with warfarin and with placebo.[87] Extended therapy studies against placebo were also carried out with rivaroxaban[83] and with apixaban.[88]

TABLE 84.7

Novel Oral Anticoagulants (NOACs) for Venous Thromboembolism—Acute and Extended Therapy

DRUG AND STUDY NAME	NOAC	WARFARIN
Acute Therapy		
Dabigatran/ RE-COVER	(*N* = 1274)	(*N* = 1265)
	2.4% recurrence	2.1% recurrence
Dabigatran/ RE-MEDY	(*N* = 1430)	(*N* = 1426)
	1.8% recurrence	1.3% recurrence
Dabigatran/ RE-COVER II	(*N* = 1279)	(*N* = 1289)
	2.3% recurrence	2.2% recurrence
Rivaroxaban/ EINSTEIN Acute DVT	(*N* = 1841)	(*N* = 1718)
	2.1% recurrence	3.0% recurrence
Rivaroxaban/ EINSTEIN-PE	(*N* = 2420)	(*N* = 2413)
	2.1% recurrence	1.8% recurrence
	1.1% major bleeding	2.2% major bleeding
Apixaban AMPLIFY	(*N* = 2691)	(*N* = 2704)
	2.3% recurrence	2.7% recurrence
	0.6% major bleeding	1.8% major bleeding
Edoxaban/HOKUSAI—VTE	(*N* = 4143)	(*N* = 4149)
	3.2% recurrence	3.5% recurrence
	8.5% clinically relevant bleeding	10.3% clinically relevant bleeding
Extended Therapy		
Dabigatran/RE-SONATE	(*N* = 681)	(*N* = 662)
	0.4% recurrence	5.6% recurrence
Rivaroxaban/EINSTEIN DVT Continued Treatment	(*N* = 602)	(*N* = 594)
	1.3% recurrence	7.1% recurrence
Apixaban Extension VTE	(*N* = 829)	(*N* = 840)
	1.7% recurrence	8.8% recurrence

2016 American College of Chest Physicians Guidelines

The American College of Chest Physicians (ACCP) 2016 Guidelines recommend NOACs rather than warfarin to treat acute VTE patients (without cancer), regardless of whether short-term (3 to 6 months) anticoagulation is planned or extended anticoagulation without a stop date is planned. The 2016 Guidelines are based upon the pivotal trials used to obtain Food and Drug Administration (FDA) approval for dabigatran, rivaroxaban, apixaban, and edoxaban and characterize the evidence favoring NOACs over warfarin as “moderate or high quality.” The Guidelines add: “Based on less bleeding with NOACs and greater convenience for patients and health-care providers, we now suggest that a NOAC is used in preference to vitamin K antagonists for the initial and long-term treatment of VTE in patients without cancer.”[89]

Managing Bleeding Complications from Anticoagulants

Protamine sulfate can be given for life-threatening bleeding caused by UFH or LMWH. Life-threatening bleeding caused by warfarin can be managed with prothrombin complex concentrates to achieve immediate hemostasis.[90] For acute management of bleeding in patients taking NOACs, the initial assessment should focus on ensuring hemodynamic stability, detecting the source of bleeding, estimating the time that has elapsed since the last dose of NOAC, and determining renal function. Patients can then be risk stratified. Those with minor bleeding will respond to local hemostatic measures. Those with moderate bleeding may require aggressive volume replacement and definitive surgical intervention. With severe or life-threatening bleeding, hemodynamic support in an intensive care setting plus replacement agents such as prothrombin complex concentrate may be warranted.[91] Prothrombin complex concentrate is licensed to manage bleeding from warfarin. For major bleeding due to NOACs, consider using antidotes

such as idarucizumab to reverse dabigatran[92] or andexanet to reverse rivaroxaban; apixaban, or edoxaban[93] (available in ongoing clinical trials). The International Society of Thrombosis and Haemostasis has issued guidelines on when and how to use antidotes for NOACs.[94] The principal indications are life-threatening bleeding or required emergency surgery or procedural intervention in patients at high risk for bleeding.

Optimal Duration of Anticoagulation Therapy and Selection of an Optimal Anticoagulant

Risk of Recurrent Venous Thromboembolism After Discontinuation of Anticoagulation

There is a high risk of recurrence of VTE after the discontinuation of anticoagulation. Cardiovascular inflammation may explain the recurrent nature of VTE.[95] In a 10-year cohort study of 1626 Italian patients with VTE who received full anticoagulation for a minimum of 3 months, the overall cumulative incidence of recurrence was 11% at 1 year, 20% at 3 years, 29% at 5 years, and 40% at 10 years. Patients with idiopathic or unprovoked VTE have even higher recurrence rates: 15% at 1 year, 26% at 3 years, 41% at 5 years, and 53% at 10 years.[96]

Men suffer recurrent VTE more often than women. In a patient-level metaanalysis of multiple cohort studies, recurrence rates for those with unprovoked VTE after discontinuation of anticoagulation were as follows: 10% for men versus 5% for women at 1 year; 16% for men versus 8% for women at 2 years; 22% for men versus 9% for women at 3 years; and 43% for men versus 11% for women at 5 years.[97] The Vienna Prediction Model uses a nomogram to predict the likelihood of recurrence. Key components that increase the likelihood are male sex, PE (rather than DVT) symptoms at initial presentation, and the magnitude of quantitative D-dimer elevation.[98] Persistent thrombus imaged on chest CT does not predict recurrent PE. Approximately one half of patients with PE will have persistent thrombus on chest CT 6 months after the initial event.

Abnormally elevated D-dimer levels after withdrawal of anticoagulation may signify ongoing hypercoagulability. Yet, the risk for recurrence in patients with a first unprovoked episode of VTE who have a subsequent negative D-dimer result is not low enough to justify stopping anticoagulant therapy. In 319 patients with a negative D-dimer after completing 3 to 7 months of anticoagulation, the rate of recurrent VTE was 6.7% per patient-year.[99]

How to Determine the Optimal Duration of Anticoagulation

Classifying a patient's VTE as provoked or unprovoked helps determine the optimal duration of anticoagulation. Those patients with unprovoked VTE have a higher rate of recurrence than those with provoked VTE after anticoagulation is discontinued. Whether a VTE event is provoked or unprovoked is sometimes uncertain. These circumstances require an individualized duration of therapy. Decisions about continuing or stopping anticoagulation should take patient and family preferences into account. Overall, long-term treatment with warfarin reduces the risk of recurrent VTE but increases the risk of major bleeding.[100] In a double-blind randomized trial of 24 months versus 6 months of warfarin anticoagulation in 371 patients with idiopathic PE, the additional 18 months of anticoagulation reduced the composite outcome of recurrent VTE and major bleeding by 78%. The benefit, however, was not maintained after

discontinuation of anticoagulation.[101]

The EINSTEIN CHOICE study is investigating the optimal medication regimen for extended-duration therapy in patients who have completed 6 to 12 months of anticoagulation for the index acute VTE event. Patients enrolled in this trial are randomized to one of three groups: rivaroxaban 20 mg daily versus rivaroxaban 10 mg daily versus aspirin 100 mg daily. Both doses of rivaroxaban were superior to aspirin for preventing recurrent VTE. The three groups were equivalent with respect to major bleeding complications.[102]

For patients with cancer who require treatment for VTE, an extended duration of anticoagulation is recommended until the cancer is considered cured. LMWH as monotherapy is the standard anticoagulant used under these circumstances.

Aspirin for Extended-Duration Anticoagulation

Two pivotal studies tested low-dose aspirin versus placebo in patients with unprovoked VTE who had completed 6 to 12 months of standard anticoagulation. The studies were similar in patient inclusion and exclusion criteria, and the dose of aspirin was the same (100 mg) in both trials. In a metaanalysis of the results, data for 1224 patients were analyzed, showing a 32% reduction in the rate of recurrence of VTE and a 34% reduction in the rate of major vascular events.[103] Thus, aspirin confers an evidence-based therapeutic benefit for patients who do not wish to restrict the lifestyle with the burdens of indefinite-duration anticoagulation.

Selection of an Optimal Oral Anticoagulant for Extended-Duration Anticoagulation

Standard-intensity extended-duration anticoagulation with warfarin has been the conventional approach, with a target INR range of 2.0 to 3.0. Low-intensity warfarin, with a target INR range of 1.5 to 2.0, is also well validated in the PREVENT (Prevention of Recurrent Venous Thromboembolism) trial.[104] Rivaroxaban, dabigatran, and apixaban are markedly superior to placebo for the prevention of recurrent VTE after a standard 6- to 12-month initial course of anticoagulation (**see Table 84.7**). Dabigatran is noninferior to warfarin for extended-duration anticoagulation.[80]

Advanced Therapy (in Addition to Anticoagulation) for Acute Pulmonary Embolism

Patients with massive PE or high-risk submassive PE (with both right ventricular dysfunction and troponin elevation due to right ventricular injury) generally warrant advanced therapy. Options include full-dose systemic thrombolysis, half-dose systemic thrombolysis, pharmacomechanical catheter–directed therapy (usually with low-dose thrombolysis), surgical embolectomy, and inferior vena cava filter placement.

Massive Pulmonary Embolism

Multidisciplinary Pulmonary Embolism Response Teams (PERTs) are being set up throughout the United States to evaluate immediately those patients who present with massive or high-risk submassive PE. Team

members have subspecialized cognitive and technical skills in PE, and the team approach promotes consensus and a unified, reasoned plan for the individual patient.[105] PERTs are becoming especially important as our emphasis on advanced management is shifting toward an interventional approach.[106]

Systemic Thrombolysis Administered Through a Peripheral Vein

Thrombolysis reverses right-sided heart failure by physical dissolution of anatomically obstructing pulmonary arterial thrombus. The hallmarks of successful therapy are reduction of right ventricular pressure overload and prevention of continued release of serotonin and other neurohumoral factors that exacerbate pulmonary hypertension. Dissolution of thrombus in the pelvic or deep leg veins theoretically decreases the likelihood of recurrent PE. Thrombolysis may also improve pulmonary capillary blood flow and reduce the likelihood of developing CTEPH.

When prescribing thrombolysis, there are three intensities of dosing: (1) full-dose systemic thrombolysis (licensed), (2) half-dose systemic thrombolysis (prescribed off label), or (3) low-dose thrombolysis as part of a strategy of using catheter-directed pharmacomechanical therapy in the cardiac catheterization or Interventional Radiology laboratory.[64] The FDA has approved alteplase for massive PE, in a dose of 100 mg delivered through a peripheral vein as a continuous infusion over 2 hours, without concomitant heparin. Patients who receive thrombolysis up to 14 days after onset of new symptoms or signs can derive benefit, probably because of the effects on the bronchial collateral circulation. Intracranial hemorrhage is the most feared and severe complication.

A metaanalysis examined patients randomized to thrombolytic therapy versus anticoagulation alone, with most patients classified as submassive PE (1775 out of a total of 2115) because they had hemodynamic stability despite right ventricular dysfunction. Thrombolysis resulted in a 47% reduction in the all-cause mortality rate, a 60% decrease in recurrent PE, a 2.7-fold increased risk of major bleeding, and a 4.6-fold increased risk of intracranial hemorrhage.[107]

Advances in Pharmacomechanical Catheter–Directed Therapy, Including Thrombolysis

The 1% to 3% rate of intracranial hemorrhage in patients with PE receiving full-dose systemic thrombolysis has dampened enthusiasm for this potentially life-saving therapy. Pharmacomechanical catheter–directed reperfusion, however, holds the promise of good efficacy, with lower rates of major bleeding owing to lower doses of thrombolytic agent. The typical dose of tissue plasminogen activator in a pharmacomechanical catheter–based procedure, for example, is 24 mg or less—compared with 100 mg for systemic administration.

Interventional mechanical techniques usually performed in conjunction with low-dose thrombolysis include mechanical fragmentation and aspiration of thrombus through a standard pulmonary artery catheter, clot pulverization with a rotating basket catheter, rheolytic thrombectomy, and pigtail rotational catheter embolectomy. After reduction of thrombus burden, pulmonary artery balloon dilation and stenting can be undertaken to treat residual vessel stenoses. Successful catheter embolectomy rapidly restores normal blood pressure and decreases hypoxemia.

Low-intensity ultrasound–facilitated fibrinolysis (**Fig. 84.13**) is a novel approach. Ultrasound disaggregates fibrin strands, increases clot permeability, and disperses infused fibrinolytic drug into the clot through acoustic microstreaming effects. The SEATTLE II Trial studied 150 patients with massive or submassive PE to evaluate the safety and efficacy of ultrasound-facilitated, catheter-directed fibrinolysis using 24 mg of tissue plasminogen activator. No patient suffered intracranial hemorrhage. This procedure

decreased right ventricular dilation, reduced pulmonary hypertension, and decreased the anatomic thrombus burden.[108]

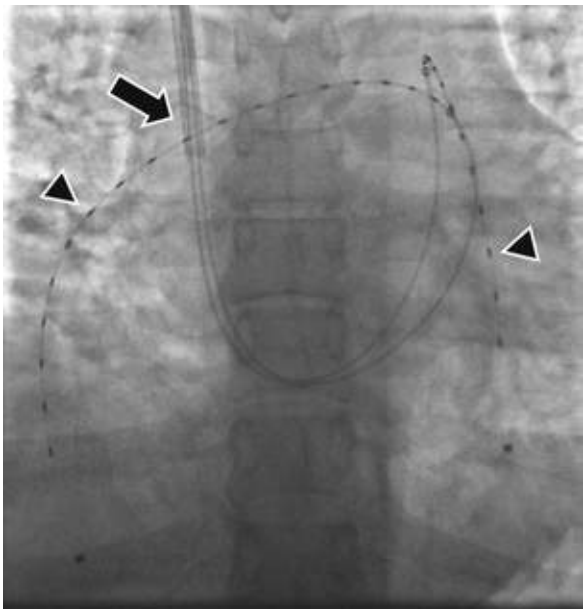

FIGURE 84.13 Bilateral low-power ultrasound–facilitated catheter-directed thrombolysis in a 20-year-old woman with massive PE. In the dual-catheter (*arrow*) system shown, the outer catheter has side holes to permit administration of fluids and medications such as alteplase. The inner sheath contains catheters with ultrasound transducers (*arrowheads*).

Surgical Embolectomy

Emergency surgical embolectomy has reemerged for the management of patients with massive PE and systemic arterial hypotension or submassive PE with severe right ventricular dysfunction, in whom contraindications preclude thrombolysis (**Fig. 84.14**). This procedure also is suitable for patients with acute PE who require surgical excision of a right atrial thrombus or closure of a patent foramen ovale. Surgical embolectomy also can be used as rescue therapy for patients in whom PE is refractory to thrombolysis. Results are best when patients undergo surgery before they become pressor-dependent and before the onset of cardiogenic shock and multisystem organ failure.[109] Avoidance of blind instrumentation of the fragile pulmonary arteries is imperative. Extraction is limited to directly visible clots. In the largest single-center case series, 115 patients underwent surgical pulmonary embolectomy. The overall 30-day mortality rate was 6.6%. In the subgroup of 56 patients with submassive PE, the operative mortality rate was 3.6%.[110]

FIGURE 84.14 Surgical pulmonary embolectomy specimen in a 72-year-old woman who presented with presyncope, hypotension, and hypoxia. She was diagnosed with massive PE by chest CT scan and underwent emergency pulmonary embolectomy. This patient survived despite the marked extent of the lesion.

Inferior Vena Cava Filters

Appropriate use of inferior vena cava (IVC) filters is a hot topic. On the plus side, filters hold the promise of reducing PE rates by trapping DVTs that have detached from pelvic and leg veins and are hurtling toward the heart. The negative side is that filters can cause complications, can add expense, and have not been rigorously studied in critically ill patients.[111,112]
