Use of IVC filters in the United States has increased about 25-fold in the past 20 years. Among Medicare patients with acute PE, about 17% undergo IVC filter placement. In these patients with IVC filters, the in-hospital mortality rate has fallen in the past decade from about 8% to 4%. These patients with filters had a greater frequency of comorbidities such as cancer, heart failure, atherosclerosis, and vascular disease. Filter use appears especially high in blacks, men, and octogenarians. Overall use in the United States varies markedly by region, with highest insertion rates in the South Atlantic states and lowest rates in the mountain states.[113]

Patients with massive PE benefit most from IVC filter insertion. In the International Cooperative PE Registry (ICOPER), 108 of 2392 patients presented with massive PE. Their mortality rate was 52% at 90 days. However, 10 of the 11 patients who received IVC filters survived for 90 days.[114] Among massive PE patients in the Nationwide Inpatient Sample, those receiving filters had a lower mortality rate compared with other massive PE patients, regardless of whether thrombolytic therapy was used in the patients without filters (**Fig. 84.15**).[115] In a nested case-control study within a large European VTE registry, VTE patients with a high risk of bleeding who received filters showed a trend toward lower rates of all-cause deaths compared with patients with high-risk bleeding who did not have filters.[116] In a registry of California hospitals, IVC filter insertion reduced the short-term risk of death only among patients with acute VTE who had a contraindication to anticoagulation because of active bleeding.[117] Filters are rarely advisable in VTE patients who are good candidates for long-term full-intensity anticoagulation. In the PREPIC2 trial of filter insertion plus anticoagulation versus anticoagulation alone, IVC filter insertion did not reduce the risk of symptomatic recurrent PE at 3 months.[118]

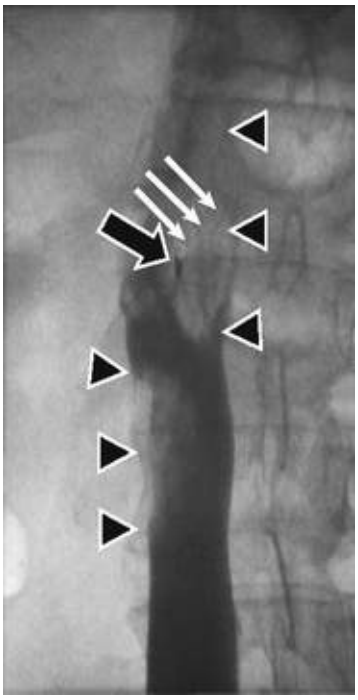

FIGURE 84.15 Large PE-in-transit, with thrombus (*arrowheads*) trapped below and visualized above the Bard Eclipse inferior vena cava filter. The force of the embolizing DVT displaced one of the filter struts (*white arrows*). The "hook" to retrieve the filter is marked with the *black arrow*.

Generally accepted consensus recommendations for IVC filter insertion include (1) major bleeding even with full-dose anticoagulation, (2) major contraindications to full-dose anticoagulation, and (3) recurrent PE despite well-documented full-dose anticoagulation for an existing VTE. There remain outside these consensus recommendations special populations in whom benefits of IVC filter insertion may outweigh risks: (1) patients with massive PE or high-risk submassive PE, (2) patients undergoing surgical pulmonary embolectomy, and (3) surgical patients during preoperative evaluation who are at high risk of VTE with a concomitant high risk of bleeding if anticoagulated.[112]

The Angel catheter is a temporary device that combines the function of an IVC filter with that of a triple-lumen central venous catheter. It is intended for bedside placement without fluoroscopy, using standard venous access techniques. This device is designed to prevent clinically significant PE in patients with recognized contraindications to standard pharmacologic thromboprophylaxis. In a European Angel Catheter Registry that had enrolled 60 patients, only one developed a PE.[119]

Chronic Thromboembolic Pulmonary Hypertension

Chronic thromboembolic pulmonary hypertension (**see also Chapter 85**) occurs in 2% to 4% of patients with acute PE.[120] CTEPH results from persistent obstruction of pulmonary arteries and progressive vascular remodeling. Not all patients presenting with CTEPH have a history of clinically overt PE. The diagnostic workup should include ventilation-perfusion scintigraphy, which has high sensitivity for detecting CTEPH and a negative predictive value of nearly 100%. CT angiography usually reveals mosaic perfusion, part or complete occlusion of pulmonary arteries, and intraluminal bands and webs. Patients with suspected CTEPH should be referred to a specialized center for right-heart catheterization and pulmonary angiography.[121]

Primary therapy for CTEPH is surgical pulmonary thromboendarterectomy, which confers mostly excellent long-term results that are often curative. The operation entails a median sternotomy, cardiopulmonary bypass, and deep hypothermia with circulatory arrest periods. Some patients are not surgical candidates or have residual pulmonary arterial vasoconstriction that may respond to sildenafil or

bosentan. Percutaneous pulmonary artery balloon dilation shows promise in patients who are not deemed eligible candidates for surgery. Riociguat, which stimulates soluble guanylate activity, is approved for patients with inoperable CTEPH or those who have not had resolution of pulmonary hypertension despite pulmonary thromboendarterectomy.

Deep Vein Thrombosis Interventions

Indications for catheter-directed DVT thrombolysis remain uncertain but usually include extensive iliofemoral and upper extremity venous thrombosis. In Norway, the CaVenT Study Group randomly assigned 209 patients with iliofemoral DVT to receive catheter-directed thrombolysis versus conventional therapy with LMWH bridging to warfarin. At 24 months, the frequency of postthrombotic syndrome was 56% in the conventionally treated group, compared with 41% in the intervention group ($P = 0.047$). Iliofemoral patency was present in 66% of the intervention group, compared with 47% of the group receiving conventional anticoagulation.[122] The U.S. National Heart, Lung, and Blood Institute (NHLBI) sponsored the ATTRACT study, a randomized trial of pharmacomechanical catheter–directed thrombolysis versus conventional anticoagulation in 692 patients with iliac or femoral vein DVT. The primary endpoint is the incidence of postthrombotic syndrome. ATTRACT will provide high-quality data regarding the routine use of pharmacomechanical catheter–directed thrombolysis to prevent postthrombotic syndrome in patients with symptomatic proximal DVT.[123]

Emotional Support

Patients find PE to be emotionally draining. They and their families seek reassurance that most patients have good outcomes once the diagnosis has been established. They must confront PE-related issues such as genetic predisposition, potential long-term disability, changes in lifestyle related to anticoagulation, and the possibility of suffering a recurrent event. Clinicians can help allay this emotional burden by discussing the implications of PE with patients and their families. I find that a good way to introduce this topic is to ask: “How are you coping with your PE emotionally and psychologically?” My nurse and I started a PE support group 25 years ago to facilitate these discussions. We usually meet once a month in the evening. The conversation focuses on patient and family anxiety, coupled with the day-to-day difficulties that arise in the aftermath of PE.

Prevention

Rationale for In-Hospital Prophylaxis

PE is the most preventable cause of in-hospital death, but once PE occurs, it is difficult to diagnose, expensive to treat, and potentially lethal despite therapy. VTE prevention is of paramount importance because it is preferable to diagnosis and treatment. Fortunately, low fixed-dose anticoagulant prophylaxis is effective and safe during hospitalization (**Table 84.8**). Commonly used regimens include minidose unfractionated heparin 5000 units twice or three times daily, enoxaparin 40 mg daily, and dalteparin 5000 units daily. A multifaceted approach of electronic alerts, sharing comparative practitioner metrics, and continuing medical education can increase the frequency of appropriate VTE prophylaxis and reduce the incidence of 90-day symptomatic VTEs.[124]

TABLE 84.8

Common Regimens for Venous Thromboembolism Prevention

CONDITION	PROPHYLAXIS
Hospitalization with medical illness	Unfractionated heparin 5000 units SC bid or tid *or* Enoxaparin 40 mg SC qd *or* Dalteparin 2500 units or 5000 units SC qd *or* Fondaparinux 2.5 mg SC qd with normal renal function (in patients with a heparin allergy such as heparin-induced thrombocytopenia) *or* Graduated compression stockings or intermittent pneumatic compression for patients with contraindications to anticoagulation Consider combination pharmacologic and mechanical prophylaxis for high-risk patients
General surgery	Unfractionated heparin 5000 units SC bid or tid *or* Enoxaparin 40 mg SC qd *or* Dalteparin 2500 or 5000 units SC qd
Major orthopedic surgery	Warfarin (target INR 2 to 3) *or* Enoxaparin 30 mg SC bid *or* Enoxaparin 40 mg SC qd *or* Dalteparin 2500 or 5000 units SC qd *or* Fondaparinux 2.5 mg SC qd *or* Rivaroxaban 10 mg qd *or* Aspirin 81 mg qd *or* Dabigatran 220 mg qd *or* Apixaban 2.5 mg twice daily *or* Intermittent pneumatic compression (with or without pharmacologic prophylaxis)

SC, subcutaneous.

In the United States, about 7 million acutely ill medical patients at increased risk for VTE are hospitalized annually with conditions such as pneumonia, heart failure, and COPD. They have a high risk for development of VTE and account for more than 20% of the attributable risks for VTE. Thromboprophylaxis can halve the rate of VTE while patients are hospitalized. The stasis and immobilization associated with postoperative venous thrombosis may actually increase paradoxically after hospital discharge, because following short hospital stays, patients are often too weak and debilitated to walk at home. After hospital discharge, prophylactic anticoagulation is not routinely prescribed. The peak incidence of VTE occurs within the first month after hospital discharge.[125]

To determine whether extended-duration administration of anticoagulation is superior to a standard short course of prophylaxis with enoxaparin, the APEX Trial compared the anti-Xa NOAC, betrixaban, administered for 35 to 42 days, with enoxaparin, administered for 6 to 14 days, in 7513 hospitalized medically ill patients at risk for VTE. Betrixaban has a longer half-life (23 hours) and undergoes less renal clearance than other NOACs. There was a 24% reduction in VTEs among the extended-duration betrixaban patients compared with those assigned to enoxaparin. There was no difference in major bleeding episodes between the two groups.[126] The ongoing MARINER trial is also examining postdischarge medical patients at risk for VTE who will randomly receive rivaroxaban versus placebo.[127]

In-Hospital Risk Factors for Venous Thromboembolism and Bleeding

The most widely used risk assessment tool to decide whether to administer VTE prophylaxis to hospitalized medical patients is the Padua Prediction Score, which has a point scoring system based on 11 variables (**Table 84.9**). A score of 4 or more points indicates a high risk for developing VTE. A simpler validated model to identify VTE risk in hospitalized medical patients, developed at the Intermountain Medical Center in Utah, may help facilitate risk assessment. The model predicts a high risk if a patient has at least one of the following four risk factors: (1) previous VTE, (2) a medical indication for bed rest, (3) a peripherally inserted central venous catheter, or (4) cancer.[128] Pharmacologic thromboprophylaxis is generally withheld if the bleeding risk is excessively high due to threatened, active, or recent major

bleeding or thrombocytopenia.

TABLE 84.9

Padua Prediction Score for Identification of Hospitalized Patients at Risk for Venous Thromboembolism*

RISK FACTOR	SCORING
Cancer	3
Previous VTE	3
Immobility	3
Thrombophilia	3
Trauma/surgery	2
Age ≥ 70 years	1
Heart/respiratory failure	1
Acute MI or stroke	1
Infection/rheumatologic disorder	1
Obesity	1
Hormonal treatment	1

*High risk for developing PE is defined as 4 score points or greater.

Mechanical Prophylaxis in Medically Ill Patients

Mechanical measures consist of intermittent pneumatic compression devices, which enhance endogenous fibrinolysis and increase venous blood flow, and graduated compression stockings. Pharmacologic thromboprophylaxis is more effective than mechanical prophylaxis. Therefore, mechanical measures are prescribed primarily when there is a contraindication to anticoagulation.

Advances in Venous Thromboembolism Prophylaxis in Major Orthopedic Surgery

Extended prophylaxis after hospital discharge decreases the risk of PE and DVT among patients undergoing major orthopedic surgery, particularly total hip or knee replacement, without increasing the frequency of major bleeding events. There is evidence to support the use of virtually any prophylactic measure in patients undergoing major orthopedic surgery. Approved approaches include LMWH, warfarin, NOACs, aspirin, and mechanical measures. The PEPPER Trial [NCT02810704], which is just getting under way, will randomize about 25,000 patients undergoing total knee or hip replacement to warfarin (target INR 1.7 to 2.2) versus rivaroxaban 10 mg daily versus low-dose aspirin 81 mg daily.

Future Perspectives

Breakthroughs in understanding PE are advancing at a rapid pace. Inflammation activates platelets, which play a central role in releasing microparticles that accelerate the thrombotic process. VTE and atherothrombosis have overlapping risk factors and pathophysiologic findings. Risk stratification is more critical than ever before. Not only must we decide which patients are too unstable for anticoagulation alone, but we also need to identify those low-risk patients with PE who can be managed as outpatients.

For patients who have massive or submassive PE, data suggest that thrombolysis reduces mortality rates among patients who initially are hemodynamically unstable or who have stable blood pressure with right ventricular dysfunction and elevated cardiac markers. Pharmacomechanical catheter–directed therapy is an innovative technology that may reduce the thrombus burden by means of a lower dose of

thrombolysis than with peripheral intravenous administration. Registry data also suggest that vena cava filter placement may reduce mortality rates in hemodynamically unstable patients with PE. Inpatient pharmacologic prophylaxis is effective, safe, and standard practice for VTE prevention in patients at moderate or high risk. We continue to investigate which drugs, dosages, and criteria are optimal for extended out-of-hospital VTE prophylaxis among high-risk medical patients. Consortia of clinicians, patients, and the public are working together to improve VTE awareness and to advocate for implementing the cutting-edge technologies, drugs, and best practices that we have discovered.

Pulmonary Hypertension

Vallerie V. Mclaughlin, Marc Humbert

Definition

Pulmonary hypertension (PH) is defined as an increase in mean pulmonary arterial pressure (mPAP) of 25 mm Hg or greater at rest, as assessed by right heart catheterization (RHC). PH was previously known as an orphan disease, that is, a condition that affects few individuals and is overlooked by the medical profession, health care systems, and pharmaceutical companies. Although PH is indeed rare, one can no longer say that it is being overlooked. Indeed, a number of recent important discoveries have improved our understanding of the disease, helped guide patient management, and laid foundations for future research. Since the mid-20th century, major achievements have been made in the field, from the development of RHC techniques to the first description of so-called primary PH and the progress achieved thanks to the National Institutes of Health (NIH) Primary Pulmonary Hypertension Registry and the World Pulmonary Hypertension conferences that have taken place five times in 40 years: 1973

(Geneva, Switzerland), 1998 (Evian, France), 2003 (Venice, Italy), 2008 (Dana Point, California, United States), and 2013 (Nice, France). The most recent guidelines provide a clear classification of the major clinical subcategories of PH (**Table 85.1**), among which pulmonary arterial hypertension (PAH) and chronic thromboembolic pulmonary hypertension (CTEPH) have been subject to the most rapid advancements in terms of knowledge and treatment options in past decades.[1]

TABLE 85.1

Comprehensive Clinical Classification of Pulmonary Hypertension

1. Pulmonary arterial hypertension
1.1. Idiopathic
1.2. Heritable
1.2.1. *BMPR2* mutation
1.2.2. Other mutations
1.3. Drug- and toxin-induced
1.4. Associated with:
A.4.1. Connective tissue disease
1.4.2. Human immunodeficiency virus (HIV) infection
1.4.3. Portal hypertension
1.4.4. Congenital heart diseases
1.4.5. Schistosomiasis
1′. Pulmonary venoocclusive disease and/or pulmonary capillary hemangiomatosis
1′.1. Idiopathic
1′.2. Heritable
1′.2.1. *EIF2AK4* mutation
1′.2.2. Other mutations
1′.3. Drug-, toxin-, and radiation-induced
1′.4. Associated with:
1′.4.1. Connective tissue disease
1′.4.2. HIV infection
1″. Persistent pulmonary hypertension of the newborn
2. Pulmonary hypertension due to left heart disease
2.1. Left ventricular systolic dysfunction
2.2. Left ventricular diastolic dysfunction
2.3. Valvular disease
2.4. Congenital or acquired left heart inflow or outflow tract obstruction and congenital cardiomyopathies
2.5. Congenital or acquired pulmonary vein stenosis
3. Pulmonary hypertension due to lung diseases and/or hypoxia
3.1. Chronic obstructive pulmonary disease
3.2. Interstitial lung disease
3.3. Other pulmonary diseases with mixed restrictive and obstructive pattern
3.4. Sleep-disordered breathing
3.5. Alveolar hypoventilation disorders
3.6. Chronic exposure to high altitude
3.7. Developmental lung diseases
4. Chronic thromboembolic pulmonary hypertension and other pulmonary artery obstructions
4.1. Chronic thromboembolic pulmonary hypertension
4.2. Other pulmonary artery obstructions
4.2.1. Angiosarcoma
4.2.2. Other intravascular tumors
4.2.3. Arteritis
4.2.4. Congenital pulmonary artery stenosis
4.2.5. Parasites (hydatidosis)
5. Pulmonary hypertension with unclear and/or multifactorial mechanisms
5.1. Hematologic disorders: chronic hemolytic anemias, myeloproliferative disorders, splenectomy
5.2. Systemic disorders: sarcoidosis, pulmonary histiocytosis, lymphangioleiomyomatosis, neurofibromatosis
5.3. Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
5.4. Others: pulmonary tumoral thrombotic microangiopathy, fibrosing mediastinitis, chronic renal failure (with or without dialysis), segmental pulmonary hypertension

BMPR2, bone morphogenetic protein receptor type 2; *EIF2AK4*, eukaryotic translation initiation factor 2 alpha kinase 4.

From Galie N, Humbert M, Vachiery J-L, et al: 2015 ESC/ERS Guidelines for the diagnosis and treatment of pulmonary hypertension. Eur Heart J 2016;37:67.

PH is a complex, multidisciplinary disorder. The term *pulmonary hypertension* refers to the presence of high pulmonary vascular pressure, which can be the end result of a variety of different underlying disorders. By definition, PH is an mPAP of 25 mm Hg or greater.[1] The definition of normal versus abnormal is based on several factors: (1) the population resting mPAP is approximately 14 mm Hg, and a value of 20 mm Hg encompasses two standard deviations above the mean; (2) a value of 25 mm Hg is therefore definitively above the normal distribution of values; and (3) the value of 25 mm Hg has, by

consensus, been used to identify candidates for participation in clinical trials and registries. *Precapillary PH* is defined as an mPAP of 25 mm Hg or more; a pulmonary capillary wedge pressure (PCWP) of 15 mm Hg or less; and a pulmonary vascular resistance (PVR) of more than 3 Wood units. Precapillary PH may be group 1 (pulmonary arterial hypertension [PAH]), group 3 (PH due to lung disease), group 4 (CTEPH), or group 5 (PH due to unclear or multifactorial mechanisms) in origin. *Postcapillary PH* is present when the mPAP is 25 mm Hg or more and the PCWP is 15 mm Hg or more. Postcapillary PH is most common in group 2 patients, or those with PH due to left heart disease; it can also occur in group 5 patients, or those with PH with unclear or multifactorial mechanisms. Recent guidelines have updated the characterization of postcapillary PH and now rely on the DPG (diastolic PAP–mean PCWP) gradient to determine the presence of pulmonary vascular disease as opposed to passive congestion. A DPG of less than 7 mm Hg and/or a PVR of less than 3 Wood units reflects isolated postcapillary PH, whereas a DPG of more than 7 mm Hg and /or a PVR of more than 3 Wood units is considered *combined postcapillary and precapillary PH.*[1]

Anatomy

The lung has a unique double arterial blood supply from the pulmonary and bronchial arteries, as well as double venous drainage into the pulmonary and azygos veins. Each pulmonary artery accompanies the appropriate generation of bronchus and divides with it down to the level of the respiratory bronchiole. Pulmonary arteries are classified as elastic or muscular. Elastic arteries are conducting vessels that are highly distensible at a low transmural pressure. As the arteries decrease in size, the number of elastic laminae decreases and the amount of smooth muscle increases. Eventually, in vessels between 100 and 500 µm, elastic tissue is lost from the media and the arteries become muscular. The intima of the pulmonary arteries consists of a single layer of endothelial cells and their basement membrane. The adventitia is composed of dense connective tissue in direct continuity with the peribronchial connective tissue sheath. The muscular arteries are 500 µm or smaller in diameter and are characterized by a muscular media bounded by internal and external elastic laminae. Arterioles are precapillary arteries smaller than 100 µm in outer diameter and composed solely of a thin intima and single elastic lamina. The alveolar capillaries are lined with a continuous layer of endothelium resting on a continuous basement membrane and focally connected to scattered pericytes located beneath the basement membrane. Within the respiratory units, the pulmonary arteries and arterioles are centrally located and give rise to precapillary arterioles, from which a network of capillaries radiates into the alveolar walls. The alveolar capillaries collect at the periphery of the acini and then drain into venules located in the interlobular and interlobar septa.

The bronchial circulation provides nutrition to the airways. The bronchial arteries ramify into a capillary network drained by bronchial veins; some empty into the pulmonary veins and the remainder into the systemic venous bed. The bronchial circulation therefore constitutes a physiologic right-to-left shunt. Normally, blood flow through this system amounts to approximately 1% of the cardiac output (CO), and the resulting desaturation of left atrial blood is usually trivial.

Pathology

Different pathologic features characterize the diverse clinical PH groups. In PAH the pathologic lesions involve mainly the distal pulmonary arteries (< 500 µm in diameter) and are characterized by medial hypertrophy, intimal proliferative and fibrotic changes (concentric, eccentric), adventitial thickening with

moderate perivascular inflammatory infiltrates, complex lesions (plexiform, dilated lesions), and thrombotic lesions (**Fig. 85.1**). PAH patients may show significant bronchial arterial remodeling. Such changes in the systemic vasculature may cause episodes of hemoptysis and are more often observed in PAH patients harboring a *BMPR2* mutation.[2]

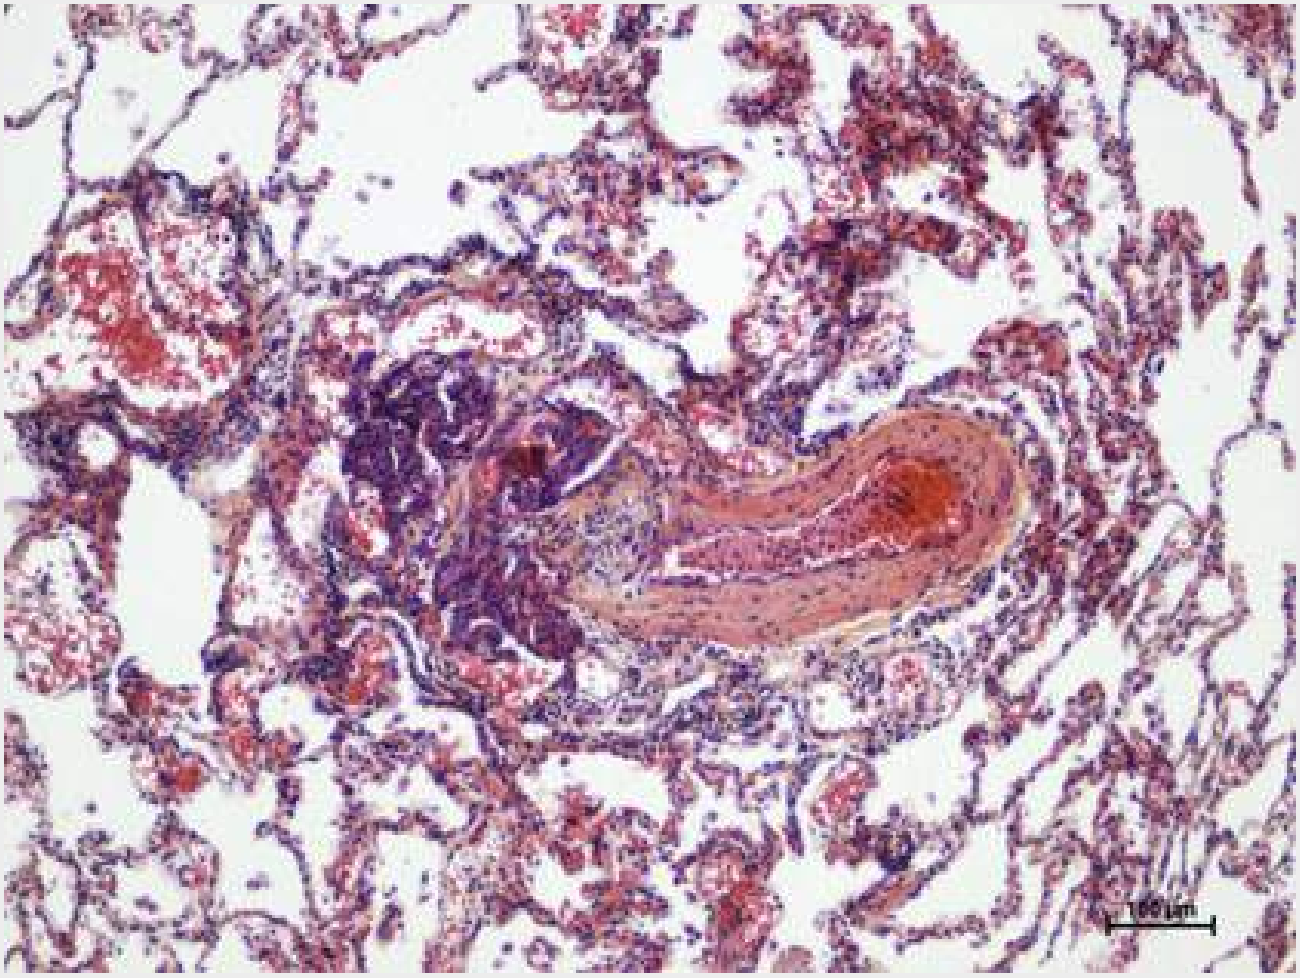

FIGURE 85.1 Plexiform lesion in a patient with PAH.

The pulmonary veins are classically unaffected in PAH, whereas in pulmonary veno-occlusive disease (PVOD), the septal veins and preseptal venules are involved and exhibit occlusive fibrotic lesions, venous muscularization, patchy capillary proliferation, pulmonary edema, occult alveolar hemorrhage, lymphatic dilation with lymph node enlargement (vascular transformation of the sinus), and inflammatory infiltrates. In PVOD the distal pulmonary arteries are affected by medial hypertrophy, intimal fibrosis, and uncommon complex lesions**.** Alveolar capillaries in PVOD are typically dilated and engorged due to downstream obstruction, and frank angioproliferation may even occur to produce lesions of pulmonary capillary hemangiomatosis (PCH). Previously regarded as different entities, current data support the concept that PVOD and PCH are in fact varied expressions of the same disorder. Indeed, clinicopathologic studies indicate marked overlap in the histologic findings of PVOD and PCH, and their clinical and radiographic findings are virtually indistinguishable. The notion of a common disorder is further emphasized by the recent discovery that mutations in the *EIF2AK4* gene are responsible for heritable cases of both PVOD and PCH.[3]

In PH caused by left-sided heart disease, the pathologic changes are characterized by enlarged and thickened pulmonary veins, pulmonary capillary dilation, interstitial edema, alveolar hemorrhage, and lymphatic vessel and lymph node enlargement. The distal pulmonary arteries may be affected by medial

hypertrophy and intimal fibrosis. In PH caused by lung diseases and/or hypoxia, pathologic changes include medial hypertrophy and intimal obstructive proliferation of the distal pulmonary arteries. A variable degree of destruction of the vascular bed in emphysematous or fibrotic areas may also be present.

In CTEPH, organized thrombi are tightly attached to the pulmonary arterial medial layer in the elastic pulmonary arteries and replace the normal intima. These thrombi may completely occlude the lumen or form different grades of stenosis, webs, and bands. In nonoccluded areas, a pulmonary arteriopathy indistinguishable from that of PAH (including plexiform lesions) may develop. Collateral vessels from the systemic circulation (from bronchial, costal, diaphragmatic, and coronary arteries) can grow and at least partially perfuse the areas distal to complete obstructions.[4] In group 5 PH (**see Table 85.1**), one can identify heterogeneous conditions with different pathologic bases for which the cause is unclear or multifactorial.

Pathobiology

PH has a multifactorial pathobiology in which an imbalance in vasoconstriction and vasodilation, thrombosis, and cell proliferation and remodeling of the walls of the pulmonary arteries contribute to increased PVR.[5] As discussed earlier, pulmonary vascular remodeling involves the intima, media, and adventitia of small pulmonary arteries (diameter < 500 μm); all cell types (endothelial, smooth muscle, and fibroblastic), as well as inflammatory cells and platelets, may play a significant role in the condition. Pulmonary vasoconstriction has been regarded as an early component of the PH process, and excessive vasoconstriction has been related to abnormal function or expression of potassium channels and to endothelial dysfunction. Endothelial dysfunction is characterized by impaired production of vasodilators such as nitric oxide (NO) and prostacyclin, along with overexpression of vasoconstrictors such as endothelin-1.[6] Many of these abnormalities both elevate vascular tone and promote vascular remodeling and therefore represent logical pharmacologic targets. Recent genetic and pathophysiologic studies of PH have emphasized the relevance of several other mediators, such as angiopoietins, serotonin, bone morphogenetic proteins (BMPs), and growth factors (platelet-derived growth factor [PDGF], fibroblast growth factor [FGF], epidermal growth factor [EGF], and the transforming growth factor-beta [TGF-β] superfamily). Abnormal proteolysis of the extracellular matrix, autoimmunity, and inflammation are also likely to contribute to the pathobiology of PH, and there is a growing body of literature on the role of cytokines and chemokines in pulmonary vascular remodeling.[7]

Genetics

Idiopathic pulmonary arterial hypertension (IPAH) corresponds to sporadic disease without any family history of PAH or known triggering factor. In 1954, Dresdale and colleagues described the first case of familial PAH and demonstrated the existence of a heritable form of the disease. Since then, many cases of familial PAH have been described, and it was recognized that heritable/familial PAH is inherited as an autosomal dominant trait with incomplete penetrance (the disease will in turn develop in ≈ 20% of mutation carriers). A possible genetic anticipation phenomenon, characterized by the age at onset of the disease being significantly lower in each succeeding generation, has been refuted for heritable/familial PAH.[8] In 2000, *BMPR2* (BMP receptor type 2) was identified as the first PAH-predisposing gene. This gene is located on the long arm of chromosome 2 (2q31-32) and encodes a type II receptor (BMPRII) belonging to the TGF-β receptor superfamily. The BMPRII receptor is involved in the regulation of growth, differentiation, and apoptosis of pulmonary artery endothelial and smooth muscle cells. When

PAH occurs in a familial context, germline mutations in the *BMPR2* gene are detected in more than 75% of cases.[9] *BMPR2* mutations can also be detected in approximately 15% to 20% of apparently sporadic cases. The observation of a personal or familial history of hereditary hemorrhagic telangiectasia in patients with PAH allowed identification of other genes involved in the development of PAH, namely, activin A receptor type II–like kinase 1 (*ACVRL1* or *ALK1*) and endoglin (*ENG*). Furthermore, mutations in other genes (i.e., *BMPR1B*, *CAV1*, and *SMAD9*) have been identified but are considerably less common. Of note, ALK1, ENG, and Smads proteins are all involved in the TGF-β signaling pathway. A channelopathy caused by a mutation in the *KCNK3* gene has been identified in familial and idiopathic cases of PAH, thus indicating for the first time that heritable disease may involve factors apparently independent of the TGF-β signaling pathway.[10,11] Like IPAH, heritable/familial PAH affects twice as many females as males. It must be emphasized that *BMPR2* mutation carriers are younger at the time of diagnosis of PAH and have a more severe hemodynamic compromise (a higher mPAP, lower CO, lower PVR, and lower likelihood of having an acute vasodilator component). Therefore, *BMPR2* mutation carriers are likely to die sooner than their IPAH counterparts and are also more likely to undergo transplantation.[12] It is currently recommended that genetic counseling be offered to family members of patients with heritable/familial PAH.[13] These family members can be tested for the causal mutation (if any); current research is attempting to identify the best PAH screening tool for asymptomatic mutation carriers.[14] Individuals who test positive for PAH-causing mutations and first-degree relatives of heritable PAH patients may be considered for an annual echocardiogram.[1]

Other heritable forms of PH with a recessive mode of transmission have been described in patients with PVOD/ PCH. By using whole-exome sequencing it was found that recessive mutations in *EIF2AK4* (also called *GCN2*) were cosegregated with PVOD/PCH in all families studied in the French National Registry. Bi-allelic *EIF2AK4* mutations were also detected in 5 of 20 histologically confirmed sporadic cases of PVOD/PCH. All mutations, either in a homozygous or compound-heterozygous state, disrupted function of the gene.[15] *EIF2AK4* encodes a serine-threonine kinase present in all eukaryotes that can induce changes in gene expression in response to amino acid deprivation. The pathophysiologic link between bi-allelic *EIF2AK4* loss-of-function mutations and vascular cell proliferation and remodeling of lung vessels remains elusive.[3]

Hemodynamics

The pulmonary circulation is characterized by high flow, low pressure, and low resistance. The normal mPAP at rest is 14.0 ± 3.3 mm Hg, and this value is independent of sex and ethnicity. The resting mPAP is just slightly influenced by age (< 30 years, 12.8 ± 3.1 mm Hg; between 30 and 50 years, 12.9 ± 3.0 mm Hg; > 50 years, 14.7 ± 4.0 mm Hg). Thus, the normal mPAP at rest is virtually independent of age and rarely exceeds 20 mm Hg. According to current guidelines, PH is defined as an mPAP of 25 mm Hg or higher at rest, but more work is needed to better describe the natural history of patients with an mPAP ranging from 21 to 24 mm Hg. PH can be classified as precapillary if the pulmonary arterial wedge pressure (PAWP) is 15 mm Hg or lower; as postcapillary if the PAWP is higher than 15 mm Hg; or as combined precapillary and postcapillary as described earlier.

During exercise, the mPAP is dependent on the exercise level and age. With mild exercise, the mPAP is 19.4 ± 4.8 mm Hg in persons younger than 50 years versus 29.4 ± 8.4 mm Hg in persons 50 years or older. The exercise mPAP is related to age and frequently exceeds 30 mm Hg, especially in elderly individuals; this makes it difficult to define normal mPAP values during exercise. Given these

circumstances, the diagnosis of exercise-induced PH was abandoned in 2008 because of insufficient evidence. Data have since shown that the upper limit of normal of mPAP flow relationships is 3 mm Hg/liter/min with a resistive vessel distensibility on the order of 1% to 2% change in diameter per mm Hg pressure and that higher pressure is associated with decreased exercise capacity. Exercise-induced PH is thus reemerging as a possible clinical entity with a physiologic substrate but remains a research topic until more is known about the natural history of this condition.

The normal pulmonary vascular bed offers less than 10% of the resistance to flow than does the systemic bed and can be approximated as the ratio of the drop in pressure (in mm Hg) to mean flow (in liter/min). The PVR can be calculated as the ratio (mPAP − PAWP)/CO, whereas the total pulmonary resistance (TPR) corresponds to the ratio mPAP/CO. The ratio can be multiplied by 80 to express the results in dyne-sec • cm^{-5} or be expressed in mm Hg/liter/min, which is referred to as a Wood unit. The calculated PVR in normal adults is 67 ± 23 dyne-sec • cm^{-5} (or 1 Wood unit). The physiologic range of the PVR and TPR and the impact of exercise, age, and posture have been a matter of debate for many years. The supine resting PVR in persons younger than 24, 24 to 50, 51 to 69, and 70 years or older is 61 ± 23, 69 ± 28, 86 ± 15, and 90 ± 39 dyne-sec • cm^{-5}, respectively. The corresponding TPR is 165 ± 50, 164 ± 46, 226 ± 64, and 223 ± 45 dyne-sec • cm^{-5}, respectively. During moderate exercise in persons 50 years or younger, an 85% increase in CO is associated with a 25% decrease in TPR and a 12% decrease in PVR. At 51 to 69 years of age, there is no significant decrease in TPR and PVR during exercise. In individuals 70 years or older, the TPR may even increase by 17%, whereas the PVR does not change significantly. At higher exercise levels, the TPR decreases in all age-groups.

Classification of Pulmonary Hypertension

The clinical classification of PH was most recently revised by the 2015 ESC/ERS Guidelines and is depicted in **Table 85.1**.[1]

Group 1 Pulmonary Arterial Hypertension

Changes in classification have been made to reflect the evolving understanding of the clinical and pathologic manifestations of PAH. PAH should not be considered a disease itself but as one measurable sign (elevated pulmonary arterial blood pressure) of an underlying pulmonary vasculopathy for which the clinical context must be appropriately diagnosed. Clinical experience and formal disease registry databases make it increasingly clear that the diseases in group 1 PAH, such as congenital heart disease (CHD) and connective tissue disease, have very different demographics, manifestations, and outcomes. The prevalence of group 1 PAH is in the range of 15 to 50 cases per million.

Causes

Idiopathic Pulmonary Arterial Hypertension

Formerly referred to as primary pulmonary hypertension (PPH), IPAH is a rare disease of unknown cause and is the most common type of group 1 PAH in current-day registries. IPAH is a sporadic disease for which there is neither a family history of PAH nor an identified risk factor. It has a female preponderance (2 : 1 in the NIH registry, 4 : 1 in the current-day REVEAL registry). Even though the mean age at diagnosis was 37 years in the NIH registry and approximately 50 years in the more recent registries,

IPAH can affect children and adults into their 70s.

Heritable Pulmonary Arterial Hypertension

Hereditary transmission of PAH has been reported in approximately 6% to 10% of patients with PAH. The genetic details of heritable PAH are discussed earlier.

Drug- and Toxin-Induced Pulmonary Arterial Hypertension

An association between anorexigens (appetite-suppressant drugs that increase, release, and block the reuptake of serotonin) and PAH was initially observed in the 1960s, when an epidemic of IPAH (then termed PPH) was noted in Europe after the introduction of aminorex fumarate. Structurally related compounds such as fenfluramine, dexfenfluramine, and benfluorex were also demonstrated to be associated with the development of PAH in the 1980s, 1990s, and 2000s, and have since been withdrawn from the market.[16] Epidemiologic studies have also linked the development of PAH to rapeseed oil, L-tryptophan, interferon alpha and beta, and illicit drugs such as methamphetamines. More recently, the tyrosine kinase inhibitor dasatinib has been associated with the development of PAH.[17] From the approval of dasatinib in November 2006 to September 30, 2010, nine incident cases of PAH in patients treated with dasatinib were identified in the French National Registry, which corresponds to an estimated incidence of 0.45% in patients exposed to dasatinib in France. Improvement is usually observed after cessation of the use of dasatinib. Recent experimental data have shown that dasatinib induces lung vascular toxicity and predisposes a person to PH.[18]

Pulmonary Arterial Hypertension Associated With Connective Tissue Diseases.
The prevalence of PAH is greatest in those with the scleroderma spectrum of diseases, although PAH can occur in the setting of any of the connective tissue diseases. Two prospective studies using echocardiography as a screening tool but requiring hemodynamic confirmation with RHC found the prevalence of PAH in the scleroderma population to be 8% to 12%. Because PAH has a high prevalence in patients with scleroderma, scleroderma patients constitute a high-risk group in whom screening can be done; early therapy can be instituted if a diagnosis of PAH is then made in a patient. A reduction in the diffusion capacity of carbon monoxide may precede the clinical or echocardiographic abnormalities. Currently, echocardiography is the most common screening tool (**see Chapter 14**), although studies to refine the screening process in this high-risk group are under way. Recently, a novel screening approach that involves a two-step algorithm, including clinical, pulmonary function test, and echocardiographic variables, was developed.[19] Six simple screening tests in step 1 of the algorithm are used to determine whether referral for echocardiography is appropriate. In step 2, the step 1 prediction score and two echocardiographic variables are used to determine whether referral for RHC is appropriate. The sensitivity of this algorithm is 96%, with a specificity of 48% and positive and negative predictive values of 35% and 98%, respectively.

Unfortunately, the prognosis for patients with scleroderma-associated PAH is poor, even in the current treatment era. In the PAH Quality Enhancement Research Initiative, the 3-year survival rate of patients with scleroderma-associated PAH was 60% as compared with 77% in patients with IPAH; the 3-year survival rate of patients with scleroderma-associated PAH in the French National Registry was only 56%.[20,21] Patients with the scleroderma spectrum of disease may also be at higher risk for other types of PH, including diastolic dysfunction and hypoxemic lung disease.

Pulmonary Arterial Hypertension Associated With Human Immunodeficiency Virus Infection.

PAH is a rare, but well-established, complication of human immunodeficiency virus (HIV) infection. Population studies of individuals infected with HIV suggest that the incidence of PAH is approximately 0.5% and is independent of the $CD4^+$ cell count or previous opportunistic infections. The prevalence of HIV-associated PAH has not changed with the widespread use of highly active antiretroviral therapy. The mechanism is unknown, but the hemodynamics and clinical course are similar to those of IPAH. The prognosis of HIV-associated PAH has improved in recent years. In a recent single-center observation, the survival rate was 88% at 1 year and 72% at 3 years, with a cardiac index higher than 2.8 liters/min/m^2 and a $CD4^+$ lymphocyte count greater than 200 cells/μL, both having been demonstrated to be independent predictors of survival.[22] Routine screening for PAH in HIV-infected patients is not recommended, because of the relatively low prevalence of the disorder in these patients, although PAH should be considered in HIV-infected patients with symptoms of dyspnea in whom another cause cannot be found.

Pulmonary Arterial Hypertension Associated With Portal Hypertension.

The development of PAH in association with elevated pressure in the portal circulation is known as portopulmonary hypertension. Portal hypertension, as opposed to the underlying liver disease, is the risk factor. Neither the severity of the liver disease nor the degree of portal hypertension predicts the presence or severity of portopulmonary hypertension. Epidemiologic studies have estimated the prevalence of PAH in these individuals to be 2% to 6%, but it may be higher in those referred for liver transplantation. Although echocardiography serves as a good screening tool in this population, hemodynamic confirmation is required. The high-flow state of the underlying disease or the high-output cardiac failure with elevated left-sided cardiac filling pressure must be differentiated from true portopulmonary hypertension.

The presence of PAH increases the risk associated with liver transplantation. The recent International Liver Transplant Society Practice Guidelines make recommendations for screening, diagnosis, treatment, and implications for liver transplantation in the setting of portopulmonary hypertension.[23] Based on observational cohorts, a pre–liver transplantation mPAP of 35 mm Hg or greater and an increased PVR are associated with increased morbidity and mortality rates; an mPAP of 45 to 50 mm Hg or greater should be considered an absolute contraindication to liver transplantation.

Pulmonary Arterial Hypertension Associated With Congenital Heart Disease.

PAH is a well-recognized complication of uncorrected increased pulmonary blood flow associated with congenital systemic-to-pulmonary shunts (**see Chapter 75**). PAH associated with CHD represents a very heterogeneous patient population. **Table 85.2** summarizes the clinical classification of PAH associated with CHD. Eisenmenger syndrome is defined as CHD with an initial large systemic-to-pulmonary shunt that induces progressive pulmonary vasculopathy with PAH and subsequent reversal of the shunt and central cyanosis. Eisenmenger syndrome occurs more frequently when blood flow is extremely high and the shunt exposes the pulmonary vasculature to systemic-level pressure, as occurs with a ventricular septal defect, patent ductus arteriosus, or truncus arteriosus. At this point, surgical correction of the defect is contraindicated. PAH may also be present when the shunt is predominantly systemic to pulmonary. It is important to determine in such cases if the shunt is correctable or not. Occasionally a marked elevation of PVR may be present with small cardiac defects, and these patients are considered to have PAH with small or coincidental defects. It is unlikely that these small defects account for the high PVR. Patients have a clinical picture similar to that of IPAH, and closing the defect is contraindicated. Lastly, patients may have PAH after the correction of an intracardiac shunt, particularly if closure took

place late.

TABLE 85.2

Clinical Classification of Pulmonary Arterial Hypertension Associated With Congenital Heart Disease

1. Eisenmenger syndrome Includes all large intracardiac and extracardiac defects that begin as systemic-to-pulmonary shunts and progress with time to severe elevation of PVR and to reversal (pulmonary-to-systemic) or bidirectional shunting; cyanosis, secondary erythrocytosis, and multiple organ involvement are usually present
2. PAH associated with prevalent systemic-to-pulmonary shunts Correctable* Noncorrectable Includes moderate to large defects; PVR is mildly to moderately increased; systemic-to-pulmonary shunting is still prevalent, whereas cyanosis at rest is not a feature
3. PAH with small or coincidental defects† Marked elevation in PVR in the presence of small cardiac defects (usually ventricular septal defects < 1 cm and atrial septal defects < 2 cm of effective diameter as assessed by echocardiography), which themselves do not account for the development of elevated PVR; the clinical picture is very similar to idiopathic PAH; closing the defects is contraindicated
4. PAH after defect correction Congenital heart disease is repaired but PAH either persists immediately after correction or recurs or develops months or years after correction in the absence of significant postoperative haemodynamic lesions

*With surgery or intravascular percutaneous procedure.

†The size applies to adult patients. In adults the simple diameter may not be sufficient for defining the hemodynamic relevance of the defect, and also the pressure gradient, shunt size and direction, and pulmonary-to-systemic flow ratio should be considered.

PAH, pulmonary arterial hypertension; *PVR*, pulmonary vascular resistance.

From Galie N, Humbert M, Vachiery J-L, et al: 2015 ESC/ERS Guidelines for the diagnosis and treatment of pulmonary hypertension. Eur Heart J 2016;37:67.

An important feature of PAH in patients with CHD is the right ventricular adaptive response to elevated PAH. With onset early in life, marked hypertrophy and preservation of a fetal-like phenotype occur. As a result, these patients can sustain an increased afterload with better right ventricular function for many years or decades than can those in whom PAH develops later in life. Survival times for patients with Eisenmenger syndrome is better than for those with IPAH. Currently approved PAH-specific therapies have demonstrated benefit in patients with Eisenmenger syndrome.

Pulmonary Arterial Hypertension Associated With Schistosomiasis.

Diagnosed most commonly in endemic areas of South America and sub-Saharan Africa, recent publications suggest that PH associated with schistosomiasis has clinical and histologic features similar to those of IPAH. PAH develops in approximately 5% of patients with hepatosplenic schistosomiasis, making it one of the most prevalent causes of PAH worldwide.[24]

Pulmonary Veno-Occlusive Disease and/or Pulmonary Capillary Hemangiomatosis

PVOD and/or pulmonary capillary hemangiomatosis (PCH) is a rare pulmonary microvasculopathy affecting primarily the septal veins and preseptal venules, characterized by occlusive fibrotic lesions, venous muscularization, and patchy capillary proliferation. PVOD/PCH also exhibits the findings of pulmonary venous hypertension, including pulmonary hemosiderosis, interstitial edema, and lymphatic dilation with lymph node enlargement (vascular transformation of the sinus). In theory, histologic proof would be required for definitive diagnosis of PVOD/PCH, but surgical lung biopsy is a high-risk procedure in these patients and is therefore contraindicated. Although the risk factors and clinical features may be indistinguishable from those of PAH, patients with PVOD/PCH may have a familial history of consanguinity, or a personal history of exposure to alkylating agents (mitomycin-C, cyclophosphamide), occupational exposure to organic solvents, or a connective tissue disease such as systemic sclerosis.[25,26] These patients usually present with a markedly reduced diffusing capacity of carbon monoxide and oxygen saturation at rest.[27] High-resolution computed tomography (CT) of the chest

in patients with PVOD/PCH is characterized by a higher frequency of centrilobular ground-glass opacities, septal lines, and mediastinal lymph node enlargement than in those with PAH. The rapid development of pulmonary edema after the administration of PAH therapy is sometimes the first clue to the appropriate diagnosis and can be life-threatening. Familial cases of PVOD/PCH have been described, often in consanguineous families. Recessive mutations in *EIF2AK4* (also called *GCN2*) cosegregated with PVOD/PCH are found in 100% of familial cases and 25% of sporadic cases of histologically confirmed PVOD/PCH. These findings point to *EIF2AK4* as the major gene linked to the development of PVOD/PCH and may be considered a diagnostic tool in this rare condition.[15] Heritable PVOD/PCH due to bi-allelic *EIF2AK4* mutations is characterized by a younger age at diagnosis, but the severity of disease is similar to that in noncarriers of *EIF2AK4* mutations. Survival rates of patients with PVOD are poor, and lung transplantation is the treatment of choice for eligible patients.

Clinical Diagnosis

Given the multiple potential causes and factors contributing to the presence of PH, a methodical and extensive evaluation is warranted in most patients with common symptoms in whom the diagnosis is being considered (**Fig. 85.2**).

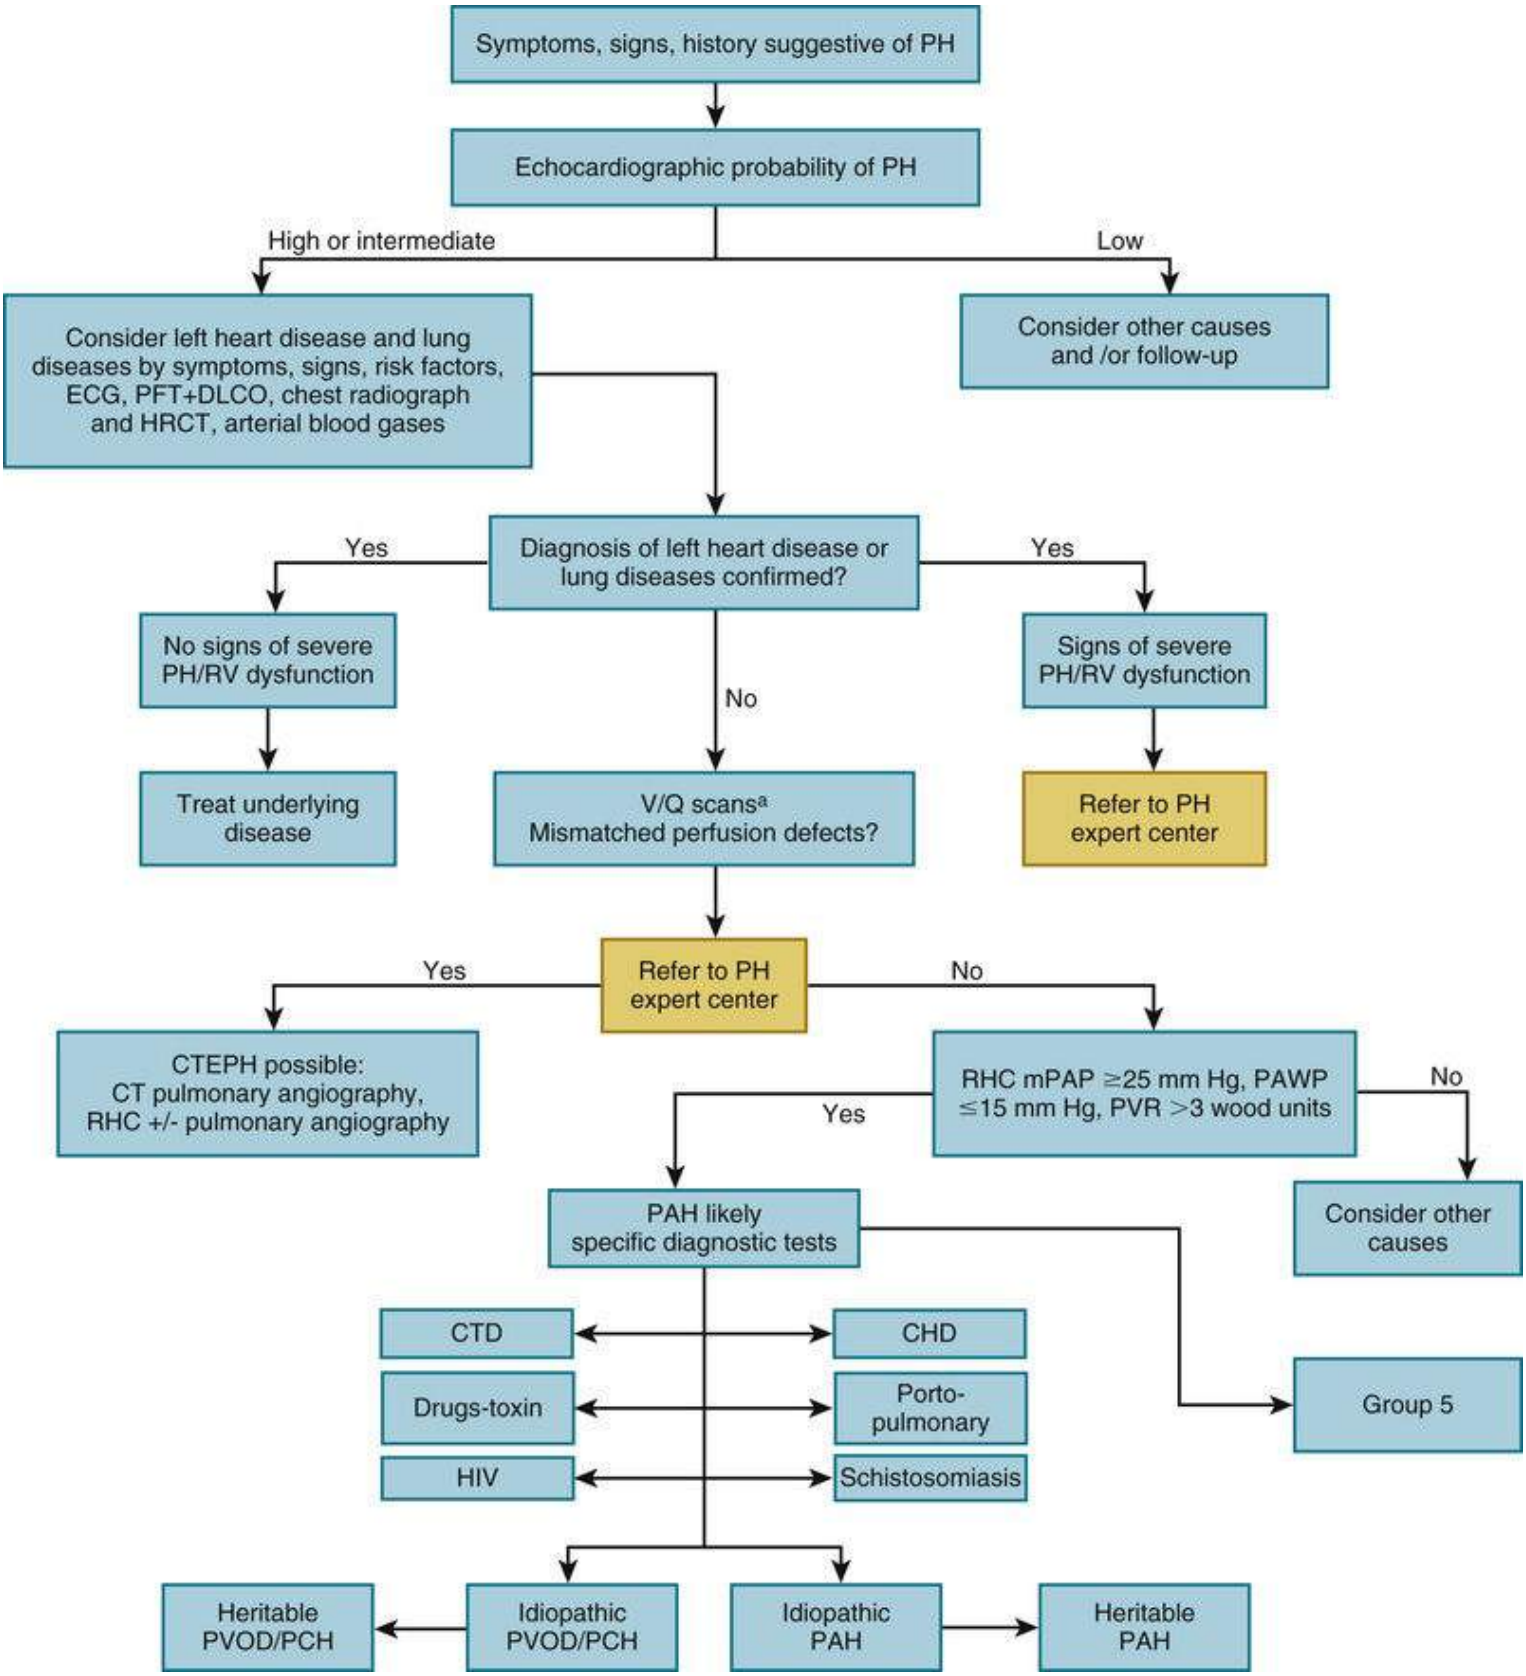

FIGURE 85.2 Evidence-based diagnostic algorithm for PAH patients (group 1 patients only). (Modified from Galie N, Humbert M, Vachiery J-L, et al: 2015 ESC/ERS Guidelines for the diagnosis and treatment of pulmonary hypertension. Eur Heart J 2016;37:67.)

Symptoms

The most common initial symptoms of PH include exertional dyspnea or reduced exercise tolerance, chest pain, fatigue, and light-headedness. Manifestations of more advanced disease include syncope, abdominal distention, and lower extremity edema attributable to right ventricular failure. Of course, the presence of

risk factors for the development of PAH (e.g., connective tissue disease, family history, CHD, use of appetite suppressants) should heighten awareness of the disorder. In the NIH registry, the average time from the onset of symptoms to diagnosis was 2 years (see Classic References). Sadly, current-day registries suggest that a delay in diagnosis persists. In the REVEAL registry, 21.1% of patients experienced symptoms for more than 2 years before PAH was recognized.[28] A delay in diagnosis was most frequently observed in patients whose symptoms occurred at a younger age (< 36 years) and in those with chronic obstructive pulmonary disease (COPD) or obstructive sleep apnea. It appears that young people in whom cardiopulmonary disease is considered less likely to be present or patients thought to have an alternative explanation for the symptoms are most at risk for a delayed diagnosis.

Physical Examination

The physical examination can be subtle or nonspecific, but certain findings should raise suspicion for PAH (**see also Chapter 10**). Features of the physical examination pertinent to the evaluation of PH are listed in **Table 85.3**.

TABLE 85.3

Features of the Physical Examination Pertinent to the Evaluation of Pulmonary Hypertension

Sign	Implication
PHYSICAL SIGNS THAT REFLECT THE SEVERITY OF PULMONARY HYPERTENSION	
Accentuated pulmonary component of S_2 (audible at the apex in > 90%)	High pulmonary pressure that increases force of pulmonic valve closure
Early systolic click	Sudden interruption of opening of the pulmonary valve into a high-pressure artery
Midsystolic ejection murmur	Turbulent transvalvular pulmonary outflow
Left parasternal lift	High right ventricular pressure and hypertrophy present
Right ventricular S_4 (in 38%)	High right ventricular pressure and hypertrophy present
Increased jugular A wave	Poor right ventricular compliance
PHYSICAL SIGNS THAT SUGGEST MODERATE TO SEVERE PULMONARY HYPERTENSION	
Moderate to severe pulmonary hypertension	
Holosystolic murmur that increases with inspiration	Tricuspid regurgitation
Increased jugular V waves	
Pulsatile liver	
Diastolic murmur	Pulmonary regurgitation
Hepatojugular reflux	High central venous pressure
Advanced pulmonary hypertension with right ventricular failure	
Right ventricular S_3 (in 23%)	Right ventricular dysfunction
Distention of jugular veins	Right ventricular dysfunction or tricuspid regurgitation, or both
Hepatomegaly	Right ventricular dysfunction or tricuspid regurgitation, or both
Peripheral edema (in 32%)	
Ascites	
Low blood pressure, diminished pulse pressure, cool extremities	Reduced cardiac output, peripheral vasoconstriction
PHYSICAL SIGNS THAT SUGGEST A POSSIBLE UNDERLYING CAUSE FOR OR ASSOCIATIONS WITH PULMONARY HYPERTENSION	
Central cyanosis	Abnormal ventilation-perfusion ratio, intrapulmonary shunt, hypoxemia, pulmonary-to-systemic shunt
Clubbing	Congenital heart disease, pulmonary venopathy
Cardiac auscultatory findings, including systolic murmurs, diastolic murmurs, opening snap, and gallop	Congenital or acquired heart or valvular disease
Rales, dullness, or decreased breath sounds	Pulmonary congestion or effusion, or both
Fine rales, accessory muscle use, wheezing, protracted expiration, productive cough	Pulmonary parenchymal disease
Obesity, kyphoscoliosis, enlarged tonsils	Possible substrate for disordered ventilation
Sclerodactyly, arthritis, telangiectasia, Raynaud phenomenon, rash	Connective tissue disorder
Peripheral venous insufficiency or obstruction	Possible venous thrombosis
Venous stasis ulcers	Possible sickle cell disease
Pulmonary vascular bruits	Chronic thromboembolic pulmonary hypertension
Splenomegaly, spider angiomas, palmar erythema, icterus, caput medusae, ascites	Portal hypertension

From McLaughlin VV, Archer SL, Badesch DB, et al: ACCF/AHA 2009 expert consensus document on pulmonary hypertension: a report of the American College of Cardiology Foundation Task Force on Expert Consensus Documents and the American Heart Association developed in collaboration with the American College of Chest Physicians; American Thoracic Society, Inc., and the Pulmonary Hypertension Association. J Am Coll Cardiol 2009;53:1573.

An accentuated pulmonic component of the second heart sound is present in most patients with PAH because of the high pulmonary pressure, which results in more forceful closure of the pulmonic valve. If a split S_2 is audible at the apex, P_2 may be accentuated and the possibility of PAH should be further investigated. The findings on physical examination are helpful to gauge the severity of PAH and to detect associated disorders as summarized in **Table 85.3**.

Electrocardiogram

Although the electrocardiogram is neither sensitive nor specific for PAH, it is an inexpensive, noninvasive test that can provide valuable information (**see also Chapter 12**). Common electrocardiographic findings include right atrial enlargement, right axis deviation, and right ventricular enlargement, often with a strain pattern (**Fig. 85.3A**).

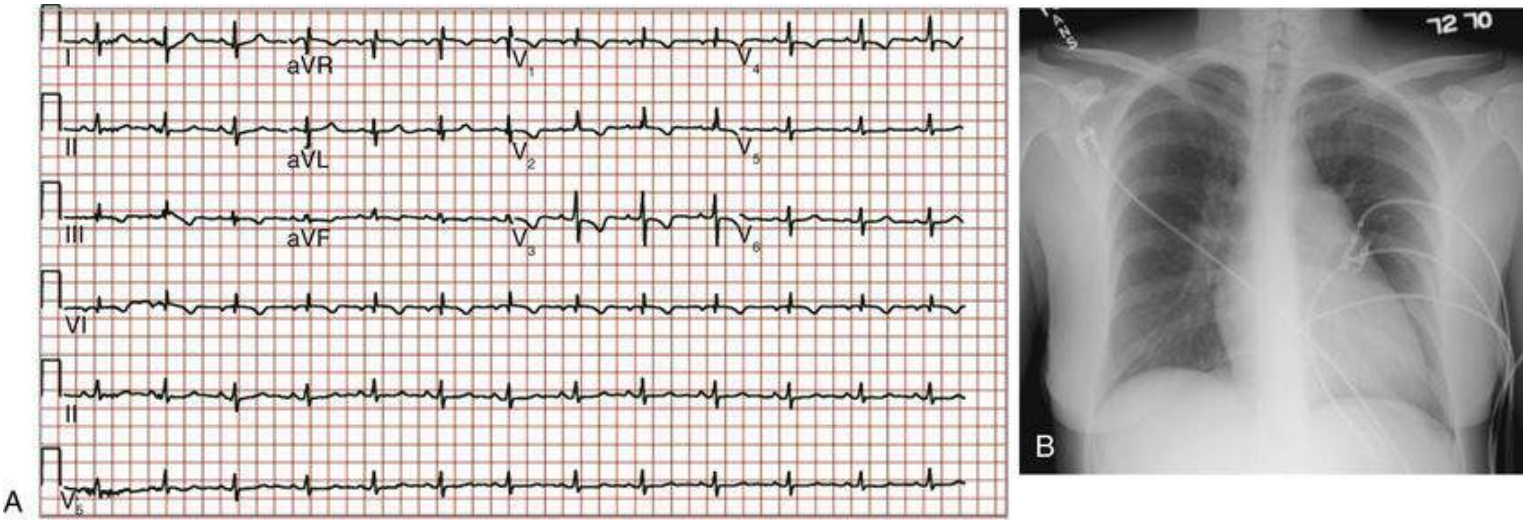

FIGURE 85.3 Clinical assessment of PAH. **A,** Electrocardiogram of a patient with PAH. **B,** Chest radiograph of a patient with PAH.

Chest Radiograph

Findings on the chest radiograph that suggest the presence of PH includes enlarged main and hilar pulmonary artery shadows with "pruning" or attenuation of the peripheral vasculature (**see Fig. 85.3B**) and right ventricular enlargement, which is best appreciated on the lateral view. Other findings on the chest radiograph may point to an associated diagnosis, such as hyperinflation with flat diaphragms (COPD) or pulmonary venous congestion (left-sided heart disease) (**see also Chapter 15**).

Echocardiogram

If PH is suspected from the history, assessment of risk factors, and physical examination, an echocardiogram is the next appropriate study (**see also Chapter 14**). Echocardiography also serves as a useful noninvasive screening test for PH in at-risk populations (e.g., scleroderma or CHD patients). Doppler echocardiography can simultaneously provide an estimate of the right ventricular systolic pressure and functional and morphologic sequelae of PH and give clues to other potential cardiac causes of PH. Common echocardiographic features of PAH include right atrial enlargement, right ventricular enlargement and dysfunction, small underfilled left-sided heart chambers, interventricular septal flattening, tricuspid regurgitation with elevated velocity, and reduced tricuspid annular plane systolic

excursion (TAPSE). A saline contrast injection can be used to detect an intracardiac shunt. One must acknowledge the limitations of the estimated right ventricular systolic pressure because of multiple potential sources of error in this measurement. In any given patient, the estimated right ventricular systolic pressure must be put into context with the patient's symptoms, previous medical history, and other findings on the two-dimensional echocardiogram. In the absence of other potential causes of PH, such as left-sided heart disease or hypoxemic lung disease, an estimated right ventricular systolic pressure greater than 40 mm Hg generally warrants further evaluation in a patient with unexplained dyspnea. Other echocardiographic findings that warrant further evaluation include right atrial and right ventricular enlargement and abnormal interventricular septal motion. Guidelines for echocardiographic assessment of the right heart in adults have recently been published.[29] A checklist for the echocardiographic evaluation of PH is reviewed in **eTable 85.1**.[30]

ETABLE 85.1

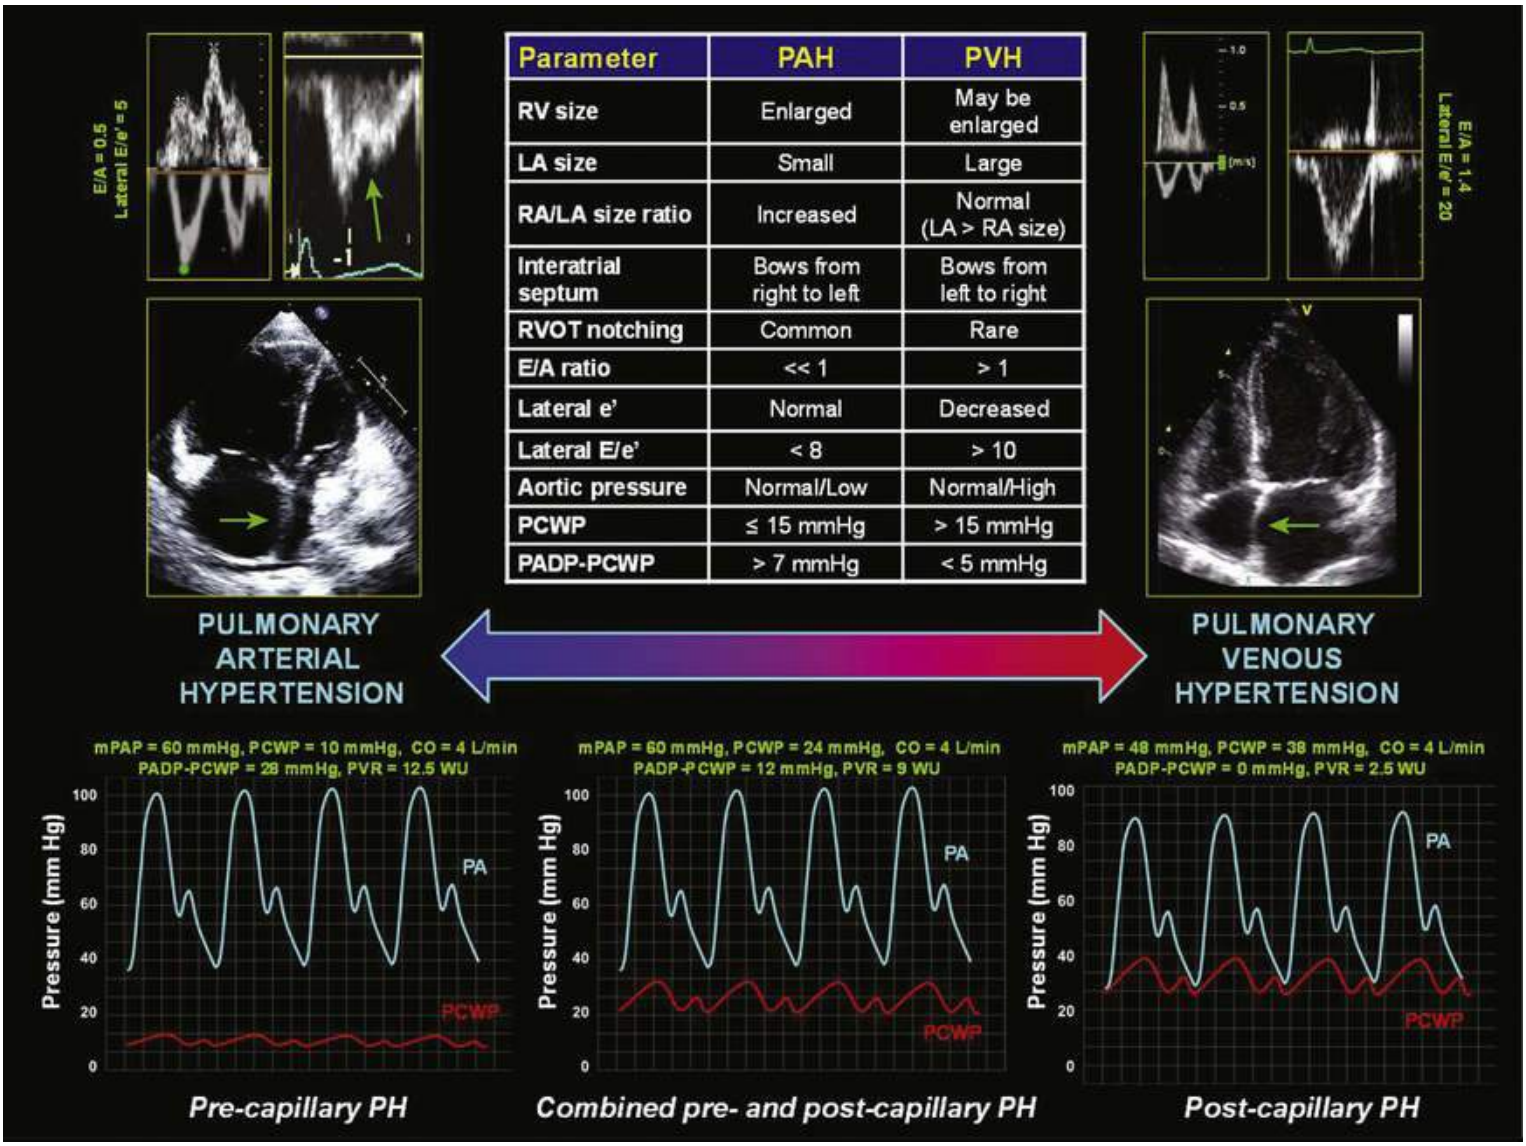
Checklist for the Echocardiographic Evaluation of Pulmonary Hypertension

COMPLETED?	ACTION ITEM	NOTES
☐	Record estimated PASP	Underestimated when Doppler beam alignment is poor or when TR jet is minimal Overestimated in patients with significant anemia or in some cases of agitated saline-enhanced TR jet on continuous-wave Doppler (due to feathering) Assumes absence of pulmonic stenosis Echocardiographic PASP does not equal mean PA pressure (definition of PH per guidelines is based on invasive hemodynamics = mean PA pressure ≥ 25 mm Hg)
☐	Evaluate RV size and function	Signs of RV enlargement (apical 4-chamber view): RV shares apex with LV; RV bigger than LV; RV basal diameter > 4.2 cm RV hypertrophy (subcostal view): RV end-diastolic wall thickness > 5 mm RV systolic dysfunction: RV fractional area change < 35%; TAPSE < 1.6 cm; RV tissue Doppler s′ velocity < 10 cm/s at base of RV free wall (tricuspid annulus) Septal flattening: in systole = RV pressure overload and in diastole = RV volume overload
☐	Evaluate for signs of elevated PVR	RVOT notching on pulse-wave Doppler profile is sign of elevated PVR Peak TR velocity (units = m/s)/RVOT VTI (units = cm) < 0.18: unlikely PVR is elevated
☐	Estimate volume status	Use size and collapsibility of inferior vena cava (during sniff maneuver) to determine RA pressure Hepatic vein flow: systolic flow reversal can be sign of severe TR, RV overload, and/or increased RV stiffness Signs of RA overload/enlargement: RA area > 18 cm^2; interatrial septum bows from right to left
☐	Evaluate severity of tricuspid regurgitation	Features suggestive of severe TR include dense TR jet on continuous-wave Doppler, V-wave cut-off sign; and systolic flow reversal on hepatic vein pulse-wave Doppler imaging
☐	Evaluate for pericardial effusion	In patients with PAH, the presence of pericardial effusion is poor prognostic sign
☐	Evaluate for causes of PH (left heart disease, shunt lesions)	Left heart disease: look for overt LV systolic dysfunction, grade 2 or worse diastolic dysfunction, severe aortic or mitral valve disease, and less common abnormalities of left heart (e.g., hypertrophic cardiomyopathy, cor triatriatum) Shunt lesions: perform agitated saline bubble study
☐	Differentiate PAH from pulmonary venous hypertension	Signs that favor pulmonary venous hypertension: LA enlargement (LA size > RA size); interatrial septum bows from left to right; E/A ratio > 1.2; E/e′ (lateral) > 11; lateral e′ < 8 cm/s In patients with significantly elevated PASP at rest: grade 1 diastolic dysfunction pattern (E/A ratio < 0.8) favors PAH diagnosis because of underfilled LA and decreased LV compliance due to RV/LV interaction (extrinsic compression of LV by RV) See also Fig. 1

LV, left ventricular; *PA*, pulmonary artery; *PAH*, pulmonary arterial hypertension; *PASP*, pulmonary artery systolic pressure; *PH*, pulmonary hypertension; *PVR*, pulmonary vascular resistance; RA, right atrial; *RV*, right ventricular; *RVOT*, right ventricular outflow tract; *TAPSE*, tricuspid annular plane systolic excursion; *TR*, tricuspid regurgitation; *VTI*, velocity-time integral.

From McLaughlin VV, Shah SJ, Souza R, et al.: Management of pulmonary arterial hypertension. J Am Coll Cardiol. 2015;183:1976.

The echocardiogram often provides information on the possibility of group 2 PH, or PH caused by left-sided heart disease. Left ventricular systolic or diastolic dysfunction and aortic and mitral valvular heart disease are easily assessed on an echocardiogram. The presence of left atrial enlargement suggests a chronically elevated left-sided filling pressure. The spectrum of echocardiographic and hemodynamic findings in PH is summarized in **eFig. 85.1**. In some instances, particularly in the assessment of CHD, a transesophageal echocardiogram provides additional information. The role of exercise echocardiography is controversial at this time.



Parameter	PAH	PVH
RV size	Enlarged	May be enlarged
LA size	Small	Large
RA/LA size ratio	Increased	Normal (LA > RA size)
Interatrial septum	Bows from right to left	Bows from left to right
RVOT notching	Common	Rare
E/A ratio	<< 1	> 1
Lateral e'	Normal	Decreased
Lateral E/e'	< 8	> 10
Aortic pressure	Normal/Low	Normal/High
PCWP	≤ 15 mmHg	> 15 mmHg
PADP-PCWP	> 7 mmHg	< 5 mmHg

EFIGURE 85.1 Pulmonary arterial hypertension versus pulmonary venous hypertension: echocardiographic and invasive hemodynamic differentiation. The **left panel** demonstrates prototypical echocardiographic and invasive hemodynamic findings from a patient with PAH. The right atrium and right ventricle are severely enlarged, and the left ventricle and left atrium are small and underfilled. The interatrial septum bows from right to left. On mitral inflow, the E/A ratio is less than 1 because of underfilling of the left atrium and decreased compliance of the left ventricle due to extrinsic compression from the enlarged right ventricle. The lateral e′ velocity and lateral E/e′ ratio are normal (<8), suggesting normal left ventricular relaxation and filling pressures. There is notching in the right ventricular outflow tract profile on pulse-wave Doppler imaging due to increased PA stiffness. PCWP is normal and the PADP-PCWP gradient is severely increased. The **right panel** demonstrates prototypical echocardiographic and invasive hemodynamic findings from a patient with pulmonary venous hypertension. The left atrium is enlarged and the interatrial septum bows from left to right. On mitral inflow, the E/A ratio is more than 1, lateral e′ velocity is reduced, and lateral E/e′ ratio is increased, suggestive of grade 2 diastolic dysfunction with impaired left ventricular relaxation and elevated left ventricular filling pressures. There is no notching in the right ventricular outflow tract profile. PCWP is elevated and there is no gradient between the PADP and PCWP. Note that although the right ventricle in the right panel is not enlarged, right ventricular enlargement and dysfunction can be present in patients with isolated pulmonary venous hypertension. The **middle panel** includes a table listing parameters for echocardiography and invasive hemodynamic testing that are helpful for differentiating PAH from pulmonary venous hypertension. The **lower middle panel** demonstrates invasive hemodynamic findings in a patient with combined precapillary and postcapillary PH (elevated PCWP and PADP-PCWP gradient). It should be noted that the most challenging patients are in this middle zone (combined precapillary and postcapillary PH), with echocardiographic findings that lie in the middle of the prototypical examples of PAH and pulmonary venous hypertension shown here. In these patients, careful evaluation of the echocardiogram and invasive hemodynamics will be necessary for an accurate diagnosis. CO, cardiac output; E/A, ratio of early to late (atrial) mitral inflow velocities; E/e′, ratio of early mitral inflow velocity to early diastolic mitral annular tissue velocity; LA, left atrial; mPAP, mean pulmonary arterial pressure; PADP, pulmonary artery diastolic pressure; PAH, pulmonary arterial hypertension; PCWP, pulmonary capillary wedge pressure; PH, pulmonary hypertension; PVH, pulmonary

venous hypertension; PVR, pulmonary vascular resistance; RA, right atrial; RV, right ventricular; RVOT, right ventricular outflow tract.

The most important echocardiographic prognostic indicators for PAH include the presence of pericardial effusion and the severity of right ventricular dysfunction. The estimated right ventricular systolic pressure is less meaningful prognostically, and in fact this value may fall as the disease progresses and the right ventricle becomes more dysfunctional.

Ventilation-Perfusion Lung Scintigraphy.

Patients with unexplained dyspnea and PH should be evaluated for CTEPH. Ventilation-perfusion lung scintigraphy is considered the most sensitive study for this purpose.[31] If one has a normal- or very low–probability ventilation-perfusion scan, CTEPH can be excluded. Many patients with PAH have a slightly heterogeneous perfusion picture, but not segmental or larger defects. Although spiral CT is an excellent means of evaluating a patient for acute pulmonary embolism, it may miss surgically accessible CTEPH. If CTEPH is still a concern after noninvasive imaging, one should proceed to pulmonary angiography. Pulmonary angiography must be done with caution in patients with advanced hemodynamics. The use of nonionic and low-osmotic contrast material at the slowest flow rate and smallest volume possible is essential. Findings of CTEPH on pulmonary angiography include irregular outlines of contrast-filled arterial contours, pouches, webs, bands, and complete vascular occlusion.

Pulmonary Function Tests.

Pulmonary function tests are useful to assess for obstructive or restrictive lung disease. If these disorders need further evaluation, an arterial blood gas or high-resolution CT study may be appropriate. Patients with group 1 PAH may have modest restriction of and a mildly reduced diffusion capacity of carbon monoxide. A declining diffusion capacity of carbon monoxide in a patient with scleroderma may precede the development of PAH.

Cardiac Magnetic Resonance Imaging.

Although not required for the diagnosis of PAH, cardiac magnetic resonance (CMR) provides an excellent assessment of right ventricular function and may be helpful in assessing for CHD. In response to chronic PH, the right ventricle dilates and there is a reduction in systolic function and stroke volume. The interventricular septum bows into the left ventricle in diastole and systole. Commensurate with this, a right ventricular end-diastolic volume index lower than 84 mL/m^2, a left ventricular end-diastolic volume index higher than 40 mL/m^2, and a stroke volume index higher than 25 mL/m^2 are associated with better survival rates in patients with IPAH. A right ventricular ejection fraction lower than 35% noted on CMR is predictive of death.[32]

Overnight Oximetry.

In addition to the history, overnight oximetry may help identify patients with obstructive sleep apnea. Formal polysomnography may be indicated in patients with significant nocturnal desaturation. Obstructive sleep apnea may cause modest PH, mediated in part by hypoxic vasoconstriction.

Significant PAH (mPAP ≥ 35 mm Hg) can rarely be attributable to sleep-related disordered breathing; however, untreated obstructive sleep apnea will limit the effectiveness of other treatment approaches and should therefore be conscientiously evaluated and managed in all patients with PAH.

Laboratory Studies.

Given the epidemiologic associations, laboratory studies to screen for connective tissue diseases, HIV

disease, and liver disease are included in the diagnostic evaluation. Natriuretic peptides may also be measured to assess the prognosis and response to treatment.

Functional Assessment.

The 6-minute hall walk (6MW) is an important functional test for quantifying exercise ability. Despite its technical inelegance and limitations, the 6MW (when performed appropriately in a standardized fashion) has proved to be a useful prognostic predictor and an important parameter to include in the clinical assessment of disease progression and treatment effect.

The 6MW has been the primary endpoint of almost every clinical trial involving PAH to date. A recent analysis of patients enrolled in a 16-week clinical trial of tadalafil versus placebo attempted to delineate the minimal important difference of the 6MW.[33] Using a distributional and anchor-based methodology, the authors assessed the correlation between change in 6MW distance and change in the physical component summary score of the 36-item Short-Form Health Survey (SF-36). They found the minimal important difference of the 6MW to be approximately 33 meters. Two other metaanalyses have assessed the correlation of change in 6MW distance with clinical events over short-term clinical trials and found either a modest correlation or no correlation.[34,35] Although still useful in longitudinally assessing an individual patient, the role of 6MW distance as a primary endpoint in future clinical trials is a topic of ongoing debate.

Cardiopulmonary exercise testing offers a more sophisticated means of assessing exercise capacity and gas exchange. Poor prognostic indicators during cardiopulmonary exercise testing include a peak systolic blood pressure lower than 120 mm Hg and a peak oxygen uptake of less than 10.4 mL/kg/min.

Right Heart Catheterization

Invasive hemodynamic assessment by RHC is pivotal in the evaluation of any patient with suspected PAH. RHC is typically performed after the noninvasive testing for PH described earlier. Some patients initially suspected of having PAH will not require RHC because they have had an alternative diagnosis established by noninvasive testing. However, all patients who are still suspected of having PAH after noninvasive evaluation should undergo RHC before the initiation of therapy. The usefulness of RHC is dependent on the accuracy and completeness of the data obtained. Essential measurements during RHC include the following:

- Oxygen saturation (superior and inferior vena cavas, pulmonary and systemic arteries)
- Right atrial pressure
- Right ventricular pressure
- Pulmonary artery pressure
- Left-sided filling pressure (PAWP, left atrial pressure, or left ventricular end-diastolic pressure [LVEDP])
- CO/cardiac index
- PVR
- Systemic blood pressure

- Heart rate
- Response to acute vasodilators

Misinterpretation of PAWP is a common pitfall in the invasive diagnosis of PH. PAWP should be measured at end-expiration and in several different segments of the pulmonary vasculature. LVEDP should be determined if there is any doubt about the accuracy of the PAWP tracing or if the results are unexpected in a given patient. A fluid challenge may be necessary to elicit the presence of diastolic dysfunction.

Acute vasodilator testing should be performed in most patients with IPAH, HPAH, and drug-induced PAH. Exceptions include patients who would not be candidates for long-term therapy with a calcium channel–blocking agent, such as those with hemodynamic instability or overt right-sided heart failure. Responders are rare among patients with associated PAH. The most common agents used for acute vasodilator testing are inhaled NO, intravenous epoprostenol, and intravenous adenosine. An acute response is defined as a decrease in mPAP by at least 10 mm Hg to an absolute mPAP value lower than 40 mm Hg in the setting of unchanged or increased CO.[36]

Compliance With Guidelines

Despite publication of the diagnostic algorithmic recommendations in multiple sources, many patients are treated with PAH-specific therapies without having completed the required diagnostic studies. A recent initiative studied compliance with the American College of Chest Physicians diagnostic algorithm.[37] This initiative demonstrated that compliance with the guidelines was poor and that the studies that were *not* performed most frequently included the ventilation-perfusion scan (57%), HIV serology (29%), and connective tissue disease serology (50%). Ten percent of patients were assigned the diagnosis of PAH without RHC. Only 7% of patients being treated with calcium channel–blocking agents fulfilled the criteria for an acute responder. Tools to improve compliance with the guidelines may improve care and outcomes in patients with PAH. Establishing a correct diagnosis is critical before the commencement of PAH-specific therapy.

Treatment

Treatment of PAH has evolved considerably over the past decade, in part because of advances in knowledge of the disease and the availability of agents that target known derangements in the pathobiologic process. Multiple treatment algorithms have been published over recent years. The algorithm from the 2015 ESC/ERS Guidelines[1] is reproduced in **Fig. 85.4.** Treatment decisions are often made with the severity of illness in mind. **Table 85.4** reviews factors that are known to influence the prognosis of patients with PAH. Current treatment goals include palliating the symptoms and improving the exercise tolerance, right ventricular function, and hemodynamics. Even though we strive to improve survival rates, clinical trials of PAH are often of insufficient size and duration to demonstrate a survival benefit, but a recent metaanalysis of currently approved therapies has suggested durable effects on outcomes.[38]

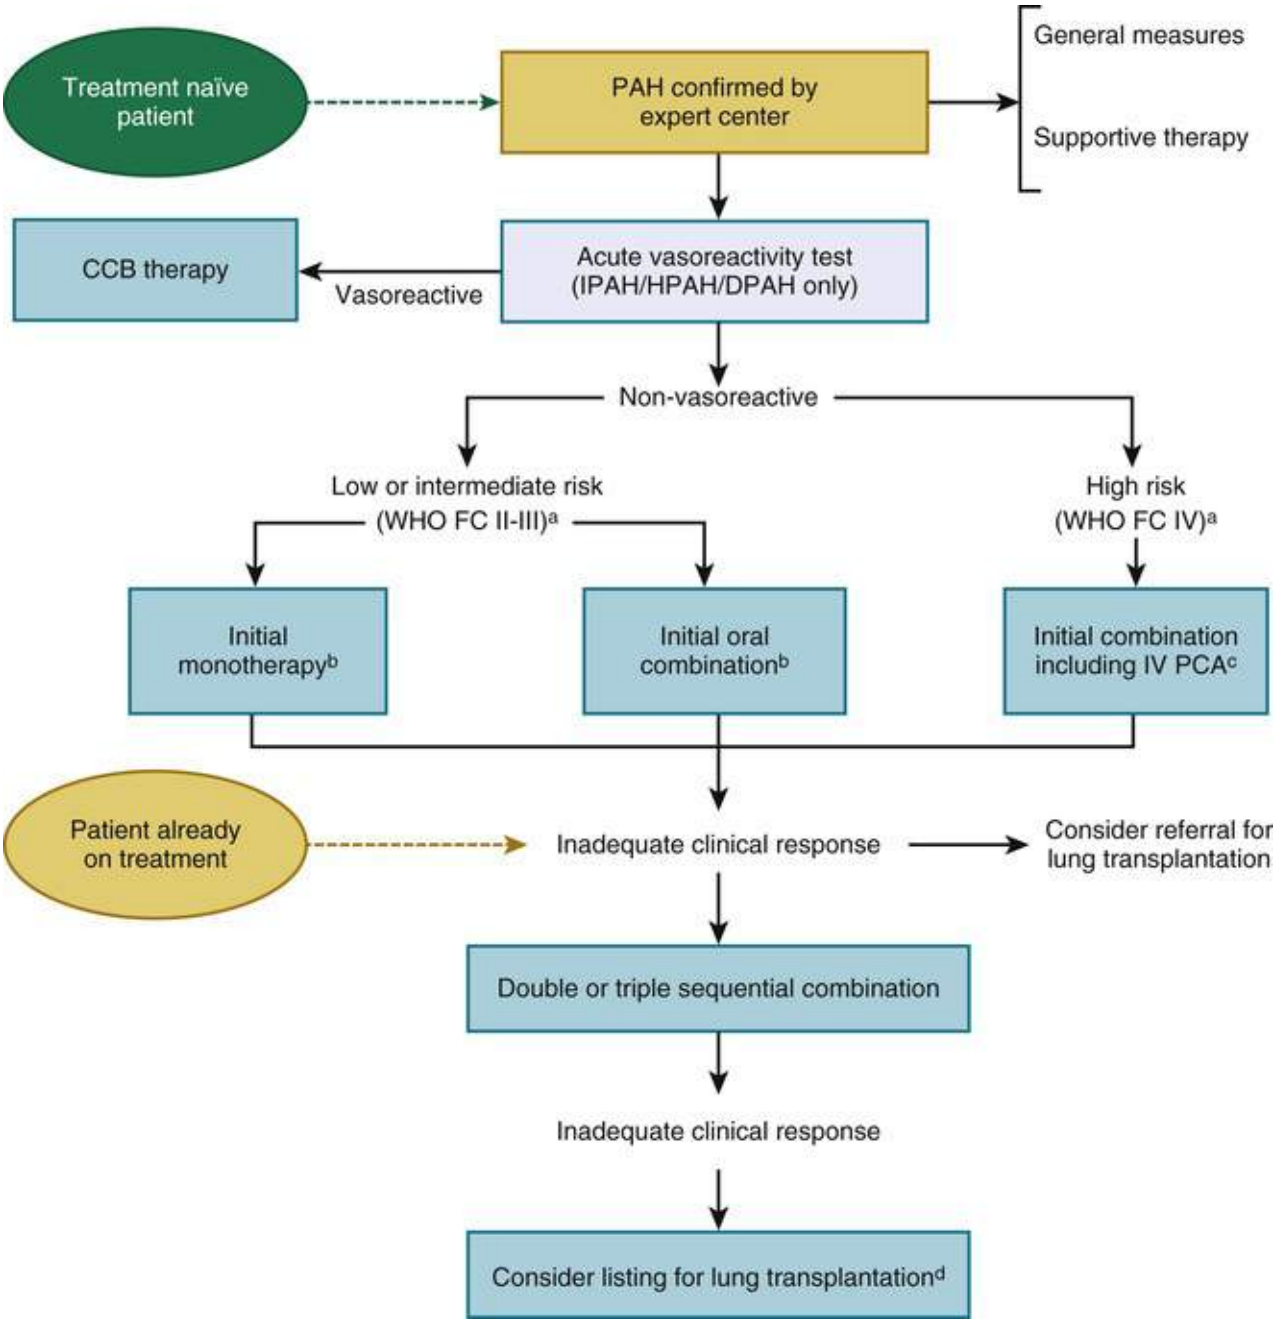


FIGURE 85.4 Evidence-based treatment algorithm for pulmonary arterial hypertension patients (group 1 patients only). (Modified from Galie N, Humbert M, Vachiery J-L, et al: 2015 ESC/ERS Guidelines for the diagnosis and treatment of pulmonary hypertension. Eur Heart J 2016;37:67.)

TABLE 85.4

Risk Assessment in Pulmonary Arterial Hypertension

DETERMINANTS OF PROGNOSIS* (estimated 1-year mortality rate)	LOW RISK (<5%)	INTERMEDIATE RISK (5% to 10%)	HIGH RISK (>10%)
Clinical signs of right heart failure	Absent	Absent	Present
Progression of symptoms	No	Slow	Rapid
Syncope	No	Occasional syncope†	Repeated syncope‡
WHO functional class	I, II	III	IV
6MWD	> 440 m	164-440 m	< 165 m
Cardiopulmonary exercise testing	Peak V_{O2} > 15 mL/min/kg	Peak V_{O2}	Peak V_{O2} < 11 mL/min/kg
	(> 65% pred.)	11-15 mL/min/kg (35% to 65% pred.)	(<35% pred.)
	VE/V_{CO2} slope < 36	VE/V_{CO2} slope 36-44.9	VE/V_{CO2} slope ≥ 45
NT-proBNP plasma levels	BNP < 50 ng/L	BPN 50-300 ng/L	BNP > 300 ng/L
	NT-proBNP < 300 ng/L	NT-proBNP 300-1400 ng/L	NT-proBNP > 1400 ng/L
Imaging (echocardiography, CMR imaging)	RA area < 18 cm^2	RA area 18-26 cm^2	RA area > 26 cm^2
	No pericardial effusion	No, or minimal, pericardial effusion	Pericardial effusion
Hemodynamics	RAP < 8 mm Hg	RAP 8-14 mm Hg	RAP > 14 mm Hg
	CI ≥ 2.5 L/min/m^2	CI 2.0-2.4 L/min/m^2	CI <2.0 L/min/m^2
	Sv_{O2} > 65%	Sv_{O2} 60% to 65%	Sv_{O2} < 60%

*Most of the proposed variables and cut-off values are based on expert opinion. They may provide prognostic information and may be used to guide therapeutic decisions, but application to individual patients must be done carefully. One must also note that most of these variables have been validated mostly for IPAH and the cut-off levels used above may not necessarily apply to other forms of PAH. Furthermore, the use of approved therapies and their influence on the variables should be considered in the evaluation of the risk.

†Occasional syncope during brisk or heavy exercise, or occasional orthostatic syncope in an otherwise stable patient.

‡Repeated episodes of syncope, even with little or regular physical activity.

6MWD, 6-minute walking distance; *BNP*, brain natriuretic peptide; *CI*, cardiac index; *CMR*, cardiac magnetic resonance; *NT-proBNP*, N-terminal pro–brain natriuretic peptide; *pred.*, predicted; *RA*, right atrium; *RAP*, right atrial pressure; Sv_{02},mixed venous oxygen saturation; V_{O2}, oxygen consumption; VE/V_{CO2}, ventilator equivalents for carbon dioxide; *WHO*, World Health Organization.

General Measures.

Basic counseling and education about the disease state are important components in the care of patients with PAH. Low-level graded aerobic exercise such as walking is recommended. The benefits of intensive pulmonary rehabilitation have been demonstrated. Patients are advised against heavy physical exertion and isometric exercise because this may evoke exertional syncope. Oxygen supplementation to keep the saturation higher than 92% at rest and with exertion, sleep, or altitude is advisable. This may not be possible in patients with intracardiac shunting (including a patent foramen ovale). A sodium-restricted diet (<2400 mg/day) is advised and is particularly important for management of the volume status in those with right ventricular failure. Routine immunizations, such as those against influenza and pneumococcal pneumonia, are advised.

The hemodynamic fluctuations of pregnancy, labor, delivery, and the postpartum period are potentially life-threatening in patients with PAH, with a maternal mortality rate of 30% to 50%. Current guidelines recommend that pregnancy be avoided or be terminated early in women with PAH.[1] A contemporary account of pregnancies in patients with PAH described 26 pregnancies at 13 PAH centers.[39] Three deaths (12%) occurred, and refractory right-sided heart failure developed in one patient, who underwent heart-lung transplantation following delivery. There were two spontaneous and six induced abortions. Overall,

62% of the pregnancies resulted in a healthy baby without maternal complications. These women had well-controlled PAH (mean PVR of 500 ± 352 dyne-sec · cm^{-5}). Half of them were long-term responders to calcium channel–blocking agents. A retrospective five-center observation of 18 pregnancies from 1999 to 2009 resulted in 3 deaths (17% mortality rate).[40] It is important to discuss effective methods of birth control with women of childbearing potential in whom PAH is diagnosed.

Background Therapy.

Although there is a pathobiologic rationale for the use of anticoagulants in PAH, current observational registry data are heterogeneous and inconclusive. In a European registry, a survival benefit was noted in IPAH patients treated with anticoagulation; however, a survival benefit was not noted in the U.S. REVEAL Registry.[41,42] Neither registry demonstrated a benefit in associated PAH patients. Diuretics are indicated to manage right ventricular volume overload. Occasionally, intravenous diuretics are required. Serum electrolytes and renal function should be monitored closely. There are few data pertaining to digoxin, although it is sometimes used in patients with right-sided heart failure and a low CO and in those with atrial arrhythmias.

Calcium Channel–Blocking Agents

Calcium channel–blocking agents can be effective therapies for the few patients with a very robust response to acute vasodilator testing, as discussed previously. The current consensus definition of a positive response is defined as a fall in mPAP of at least 10 mm Hg to an mPAP of 40 mm Hg or less with unchanged or increased CO. Patients who meet these criteria may be treated with a calcium channel–blocking agent and should be monitored closely for both the safety and efficacy of therapy. If patients who meet the definition of an acute response do not improve to functional class I or II while taking calcium channel–blocking agents, they should not be considered chronic responders, and an alternative PAH-specific therapy should be prescribed. Very few patients (<7%) with IPAH do well over the long term with calcium channel–blocking drugs (see Classic References). Long-acting nifedipine, diltiazem, and amlodipine are the most commonly used agents. Because of its potential for negative inotropic effects, verapamil should be avoided.

Prostanoids

The reduced prostacyclin synthase level in patients with PAH results in inadequate production of prostacyclin I_2, a vasodilator with antiproliferative effects. Administration of prostanoids has been a mainstay of PAH therapy for almost two decades. Currently, multiple prostanoids are commercially available: epoprostenol (continuous intravenous), treprostinil (continuous subcutaneous, continuous intravenous, intermittent inhaled and oral), and iloprost (intermittent inhaled). Prostanoids are complex therapies that are best administered at centers with expertise in the complicated delivery systems and chronic management of their side effects and dosage regimens.

Epoprostenol was the first therapy approved by the U.S. Food and Drug Administration (FDA) for the indication of what was then called PPH in 1995. Randomized controlled clinical trials in patients with PPH (now called IPAH) demonstrated improvements in exercise tolerance as measured by 6MW distance, hemodynamics, quality of life, and survival over a 12-week period (see Classic References). Long-term observational series have also suggested improved survival rates with intravenous epoprostenol. In addition, intravenous epoprostenol has been evaluated for PAH related to the scleroderma spectrum of diseases. A 12-week randomized controlled clinical trial in this population demonstrated improvements in 6MW distance and hemodynamics. Observational series have also

reported favorable effects of intravenous epoprostenol in patients with numerous forms of associated PAH.

Epoprostenol must be delivered by continuous intravenous infusion. Each patient must learn the techniques of sterile preparation of the medication, operation of the ambulatory infusion pump, and care of the central venous catheter. A thermostable formulation of epoprostenol that does not require ice packs and can be mixed less frequently has more recently been approved. Intravenous epoprostenol is commonly started in the hospital at a dosage of 2 ng/kg/min and titrated upward, depending on the symptoms of PAH and the adverse effects of the therapy. Even though the dosage regimens are highly individualized, the optimal dosage for most adult patients tends to be in the range of 25 to 40 ng/kg/min. A high-CO state has been reported in a series of patients with IPAH treated with chronic epoprostenol therapy and is consistent with the drug having positive inotropic effects. The development of a chronic high-output state could have long-term detrimental effects on underlying cardiac function and should be avoided. Common side effects include jaw pain, flushing, nausea, diarrhea, rash, and musculoskeletal pain. Infections and interruptions in infusion can be life-threatening.

Treprostinil is a stable prostacyclin analogue that has pharmacologic actions similar to those of epoprostenol, but it differs in that it is chemically stable at room temperature and has a longer half-life (4 hours). Treprostinil is currently approved to be administered as a continuous subcutaneous infusion, a continuous intravenous infusion, an intermittent inhaled treatment, and orally. It was first studied as a subcutaneous infusion in a placebo-controlled, multicenter randomized trial of 470 patients over a 12-week period. The 6MW distance improved by 16 meters, although this improvement was noted to be dose related. The optimal dose of treprostinil has not been determined, but dosages of 75 to 150 ng/kg/min are typical. Adverse effects have included pain and erythema at the site of the subcutaneous infusion (85% of patients). Other common side effects included headache, diarrhea, rash, and nausea. Based on bioequivalence data, treprostinil has also been approved by the FDA to be delivered on a continuous intravenous basis. It has been reported that intravenous treprostinil is associated with a higher incidence of gram-negative sepsis than is intravenous epoprostenol. Recently a 60-patient study demonstrated the feasibility of delivering treprostinil via a fully implantable, programmable intravascular delivery system.[43] Patients were followed for approximately 1 year, and no catheter infections or occlusions were reported. This system is currently under FDA review.

A key element of the long-term efficacy of the parenteral prostacyclins appears to be related to the strategy of upward dosage titration of the drug over time. It is important to increase the dosage to the point that the side effects can be tolerated in patients who remain symptomatic because of a direct relationship between the dosage of drug and improvement in exercise testing and hemodynamics. Once an optimal dosage has been achieved, the dosage is kept constant thereafter. Patients who deteriorate after a long period of stability do not usually respond to further increases in the dosage.

Treprostinil is also approved for intermittent inhaled use. In a multicenter, randomized, placebo-controlled study of 235 patients with PAH who were still symptomatic despite therapy with either oral bosentan or sildenafil, the addition of inhaled treprostinil resulted in an improvement in the primary endpoint of 6MW distance.[44] Common side effects included cough, headache, nausea, dizziness, and flushing. Treprostinil diethanolamine is a salt form of treprostinil designed to release the drug in a sustained-release osmotic tablet for twice-daily dosing. Oral treprostinil has been studied as monotherapy in 349 patients with PAH over a 12-week period. An improvement of 23 meters ($P = 0.0125$) in the primary endpoint of 6MW distance was observed.[45] No improvements in the secondary endpoints of time to clinical worsening or functional class were observed. The most common adverse events were headache, nausea, diarrhea, and jaw pain. Oral treprostinil has also been studied in 350 patients with

PAH as add-on therapy to endothelin receptor antagonists and/or phosphodiesterase (PDE) inhibitors.[46] In this 16-week study, the placebo-corrected median difference in 6MW distance was 11 meters ($P = 0.07$). No improvements were observed in the secondary endpoints of time to clinical worsening or functional class, and the adverse event profile was similar to that in the monotherapy trial. Oral treprostinil was FDA approved in December of 2013.

Iloprost is an inhaled prostanoid that was studied in a 12-week multicenter, randomized, placebo-controlled trial of 207 patients. This study demonstrated improvement in a novel composite endpoint, which included improvement by at least one level of functional class, improvement in 6MW distance by at least 10%, and absence of clinical deterioration. Inhaled iloprost has also been studied in combination with bosentan in a multicenter, randomized, placebo-controlled trial. After 12 weeks, improvements were seen in functional class and time to clinical worsening. The combination appeared to be safe. Common side effects of inhaled iloprost included cough, headache, flushing, and jaw pain.

Selexipag is an oral, selective prostacyclin receptor agonist that is chemically distinct from prostacyclin analogs. A phase 2 study demonstrated a statistically significant reduction in PVR in patients with PAH.[47] A placebo-controlled, event-driven, study of selexipag in 1156 patients with PAH demonstrated a 40% reduction ($P < 0.001$) in the composite endpoint of death, hospitalization for PAH, worsening of PAH resulting in the need for lung transplantation or atrial septostomy, initiation of parenteral prostanoids or chronic oxygen for worsening of PAH, and disease progression.[48] Notably, the effect of selexipag was consistent across subgroups, including types of treatment (no background therapy vs monotherapy or dual oral background therapy), disease cause, sex, age, and functional status. The most common adverse effects in the selexipag group were consistent with the known side effects of prostacyclin, including headache, diarrhea, nausea, and jaw pain.

Endothelin Receptor Antagonists

Endothelin-1 is a potent vasoconstrictor and smooth muscle mitogen that contributes to the pathogenesis of PAH. Three endothelin receptor antagonists, bosentan, ambrisentan, and macitentan, are currently commercially available for the treatment of PAH.

Bosentan has been studied in multiple placebo-controlled trials of PAH. The initial multicenter, randomized, placebo-controlled trial involving 32 patients with functional class III or IV PAH demonstrated improvements in 6MW distance and hemodynamics over a 12-week period. The BREATHE-1 study, a multicenter, randomized, placebo-controlled trial of 213 functional class III and IV patients with PAH demonstrated an improvement in 6MW distance and the composite endpoint of time to clinical worsening over a period of 16 weeks (see Classic References). Bosentan has also been evaluated in functional class II patients in a 6-month multicenter, randomized, placebo-controlled trial. This study demonstrated an improvement in PVR and time to clinical worsening. The improvement in 6MW distance was not statistically significant. Bosentan has been studied specifically in patients with congenital systemic-to-pulmonary shunts and Eisenmenger physiology. In this population, improvements in PVR, mPAP, and 6MW distance were noted and bosentan did not worsen oxygen saturation. Bosentan is currently used widely in patients with PAH. Close follow-up of both efficacy and safety is encouraged. The FDA requires that liver function tests be done on a monthly basis, and an algorithm for managing elevated liver function test results is available on the package insert. Other side effects include headache, anemia, and edema.

Ambrisentan has been studied in two phase III multicenter, randomized, 12-week placebo-controlled trials in 394 patients with PAH and demonstrated an improvement in 6MW distance and time to clinical worsening. The FDA no longer requires monthly liver function test monitoring in patients taking

ambrisentan, although many experts continue to perform liver function tests periodically. Other side effects of ambrisentan include headache and lower extremity edema, which is more common in the population older than 65 years.

Macitentan has been studied in a phase III long-term morbidity and mortality trial in which the primary endpoint was time from initiation of treatment to first occurrence of a composite endpoint of death, atrial septostomy, lung transplantation, initiation of treatment with parenteral prostanoids, or worsening PAH.[49] Seven hundred forty-two patients were randomly assigned to either placebo; macitentan, 3 mg; or macitentan, 10 mg daily. There was a 30% and 45% risk reduction in the primary endpoint with the 3-mg and 10-mg doses, respectively. The most frequent adverse events were headache, nasopharyngitis, and anemia. The incidence of edema and elevated liver function test results was similar in the placebo and macitentan groups.

Phosphodiesterase Inhibitors

The reduction in NO synthase in patients with PAH results in derangements of the cyclic guanosine monophosphate (GMP) pathway. PDE5 inhibition has the potential to inhibit the hydrolysis of cyclic GMP and has proved to be an effective therapy for PAH.

Sildenafil was studied in a 12-week multicenter, randomized, placebo-controlled trial and was found to improve 6MW distance and hemodynamics, but not the secondary endpoint of time to clinical worsening. The improvement in 6MW distance was not dose related, and sildenafil is currently approved at a dosage of 20 mg three times daily. More impressive hemodynamic improvements were achieved with higher dosages, and some patients were treated with dosages of up to 80 mg three times daily. Tadalafil was studied in a 16-week multicenter, randomized, placebo-controlled trial and demonstrated an improvement in the primary endpoint of 6MW distance. The highest dosage studied (40 mg) also resulted in an improvement in the secondary endpoint of time to clinical worsening. Tadalafil is approved at a dosage of 40 mg once daily. The most common side effects of the PDE5 inhibitors include headache, flushing, dyspepsia, myalgia, and epistaxis. Rare episodes of sudden vision or hearing loss have been reported.

Soluble Guanylate Cyclase Stimulators

Riociguat is a first-in-class agent that directly stimulates soluble guanylate cyclase independent of NO and increases the sensitivity of soluble guanylate cyclase to NO. In a 12-week, multicenter, open-label, uncontrolled phase II trial in patients with PAH and CTEPH, riociguat improved the 6MW distance and hemodynamics.[50] More recently, a randomized controlled trial of 261 patients with either inoperable CTEPH or persistent PH after pulmonary endarterectomy demonstrated an improvement in the primary endpoint of 6MW distance and the secondary endpoints of PVR, NT-pro-brain natriuretic peptide (BNP), and functional class with riociguat.[51] A randomized controlled trial of 443 patients with PAH (some previously treated with endothelin receptor antagonists or nonparenteral prostanoids) also demonstrated an improvement in the primary endpoint of 6MW distance, as well as multiple secondary endpoints, including PVR, NT-pro-BNP, functional class, and time to clinical worsening with riociguat.[52] The most common adverse events included headache, dyspepsia, peripheral edema, and hypotension. Riociguat should not be used concurrently with PDE5 inhibitors.

Up-Front Combination Therapy

Using multiple agents to target distinct pathobiologic pathways has been successful in other

cardiovascular diseases, including systemic hypertension (**see Chapter 46**) and heart failure (**see Chapter 25**). Given the multiple agents that target distinct pathways in PAH, the use of combination therapy has been explored. Sequential combination therapy has been used in practice and in some clinical trials. More recently, up-front combination therapy has been studied in both a randomized control trial and an observational series. The AMBITION study evaluated 500 treatment-naïve, functional class II or III PAH patients who were randomized to first-line monotherapy with tadalafil or monotherapy with ambrisentan versus up-front combination therapy with tadalafil and ambrisentan.[53] The primary endpoint was a composite of clinical failure events (including death, hospitalization, PAH progression, and an unsatisfactory clinical status). The study was positive, with a 50% reduction in events in the combination group. In addition, improvements were observed in exercise capacity, rate of satisfactory clinical response, and NT-proBNP plasma levels. A single-center observational pilot study on an initial triple combination in 19 World Health Organization functional class (WHO-FC) III and IV patients has provided preliminary evidence of the benefits of up-front triple-combination therapy in patients with severe PAH.[54] Given the high mortality rate of the disease and these encouraging results, the treatment paradigm in PAH is shifting to earlier and more aggressive combination therapy.

Investigational Therapies.

Although three pathways are currently targeted, outcomes are still suboptimal in patients with PAH, and active research on potential therapies for this disease continues. After initial enthusiasm, clinical trial results with kinase inhibitors, including imatinib and nilotinib, and the apoptosis-signal–regulating kinase 1 selonsertib have failed to demonstrate efficacy. Ubenimex is a small-molecule, dual-inhibitor of aminopeptidase and leukotriene A4 hydrolase (LTA4H) currently being evaluated in a phase II trial in PAH patients receiving background therapy. Bardoxolone methyl is a once-daily Nrf2 activator and NF-kB suppressor that promotes mitochondrial respiration and reduces reactive oxidative stress and inflammation. It is currently being studied in phase 2 and 3 trials in PAH. FK506 (tacrolimus) is an activator of BMP signaling that has been recently tested in PAH patients. Targeting the serotonin pathway is another novel approach in development. Last, components of the immune system involved in the development of PAH also offer a potential new area of treatment. Targeting of the IL-6 pathway (tocilizumab) or B cells (rituximab) is currently being studied in phase II PAH trials.

Interventional Therapies.

Atrial septostomy creates a right-to-left interatrial shunt, decreases the right-sided heart filling pressure, improves right ventricular function, and improves left-sided heart filling. Several case series have reported hemodynamic and clinical improvements following this procedure. Although the shunt created decreases systemic arterial oxygen saturation, the goal is an improvement in systemic oxygen delivery based on the improved CO. However, the procedural mortality rate is high, in the range of 9% to 22%, and it is driven by the severity of PAH and right-sided heart failure in patients undergoing this procedure. The recommended technique is graded balloon dilation of the fossa ovalis, which can be achieved in stages over a period of several weeks in unstable patients. It should not be performed in patients with impending death and severe right ventricular failure. Predictors of procedure-related failure or death include a mean right atrial pressure higher than 20 mm Hg, a PVR index higher than 55 units/m^2, or a predicted 1-year survival rate of less than 40%. Currently, atrial septostomy is recommended for patients with severe PAH and intractable right-sided heart failure despite maximal medical therapy. The goals of this procedure are palliation and restoration and maintenance of clinical stability until transplantation can

be performed. Atrial septostomy should be performed only by experienced operators in centers with the resources to care for such critically ill patients. Expert-based consensus guidelines define the following as contraindications to atrial septostomy: mean right atrial pressure higher than 20 mm Hg, resting arterial oxygen saturation lower than 90% on room air, or LVEDP higher than 18 mm Hg.

The advent of disease-targeted therapy for severe PAH has reduced and delayed patient referral for lung transplant programs. The long-term outcomes of medically treated patients remains uncertain, and transplantation should continue to be an important option for those who fail on such therapy and remain in WHO-FC III or IV. Delayed referral in combination with the length of the waiting time, due to the shortage of organ donors, may increase the chances of death for patients on the waiting list and the severity of their clinical status at the time of transplantation.

The overall survival rate following transplantation for PAH has increased to 52% to 75% at 5 years and to 45% to 66% at 10 years. Considering all of the above information, it seems reasonable to consider eligibility for lung transplantation after an inadequate clinical response to the initial monotherapy, and to refer the patient soon after an inadequate clinical response is confirmed with maximal combination therapy. Both heart-lung and double-lung transplantation have been performed for PAH, although the threshold for unrecoverable right ventricular systolic dysfunction and/or left ventricular diastolic dysfunction is unknown. Currently, the vast majority of patients worldwide receive bilateral lungs. Patients with Eisenmenger syndrome due to simple shunts have been treated by isolated lung transplantation and repair of the cardiac defect or by heart-lung transplantation. Recent reports indicate that venoarterial extracorporeal membrane oxygenation (ECMO) may be employed in awake end-stage PH patients for bridging to lung transplantation.

Prognosis

Recently, two large registries have shed light on the prognosis of patients with PAH in the era of PAH-specific therapies. The French registry demonstrated that the survival rate of patients with PAH has improved over the predicted survival rate based on the NIH registry, although it still remains suboptimal, with 1-, 2-, and 3-year survival rates of 85.7%, 69.5%, and 54.9%, respectively, for incident cases.[55] Important predictors of survival times included sex (males fare worse), functional class, exercise tolerance as measured by 6MW distance, and hemodynamics, specifically right atrial pressure and CO. Similarly, in the large U.S.-based REVEAL registry, important prognostic variables were described.[56] Key predictors of outcome in this study included the cause of PAH, functional class, sex, exercise tolerance, and hemodynamics that reflect right ventricular function.

Longitudinal Assessment

Several investigators have proposed scores and parameters indicative of future risk in patients with PAH.[1,57] They were mostly based on the meticulous analysis of data derived from randomized controlled trials and large registries. Although several approaches aiming at predicting the future risk are still based mostly on expert opinion and require independent validation, consensus recommendations on reassessment have been made. The 2009 American College of Cardiology Foundation/American Heart Association (ACCF/AHA) expert consensus document on PH relies on routine assessment of several prognostic indicators, such as WHO functional class, 6MW distance, and echocardiographic and hemodynamic parameters (**Table 85.5**).[36] Patients who achieve WHO-FC I or II with a 6MW distance greater than 400 meters and have normal right ventricular function on echocardiography and normal

hemodynamic measurements of right ventricular function (right atrial pressure and cardiac index) can be assessed on a 3- to 6-month basis by either the referring physician or a PH specialty center. High-risk patients (i.e., those who remain in WHO-FC III or IV with a 6MW distance < 300 meters and have imaging evidence of right ventricular dysfunction and abnormal hemodynamics) should be evaluated at 1- to 3-month intervals. Every assessment should include reevaluation of the WHO functional class and 6MW distance, with echocardiography performed approximately every 12 months or every 6 to 12 months depending on the clinical course. In stable patients, RHC should be performed to assess the response to therapy and signs of clinical worsening; in unstable patients, hemodynamic data should be obtained more frequently. Following the same approach, the 2015 ESC/ERS PH guidelines state that the overall treatment goal in patients with PAH is achieving a “low-risk” status (**see Table 85.5**), which is usually associated with good exercise capacity, good quality of life, good right ventricular function, and a low mortality risk.[1] Specifically, this means bringing and/or keeping the patient in WHO-FC II whenever possible. In most patients, this will be accompanied by a near-normal or normal 6MW distance of more than 440 meters because this number has been derived from the largest cohort investigated so far. Nevertheless, individual factors must be considered, and lower values may be acceptable in elderly patients or patients with comorbidities; values of more than 440 meters may not be sufficient in younger, otherwise healthy patients. Especially in those patients, cardiopulmonary exercise testing should be regularly used because it provides more objective information on exercise capacity and right ventricular performance. It should be noted that these treatment goals are not always realistic and may not be achievable in patients with advanced disease, patients with severe comorbidities, or very old patients.

TABLE 85.5

Longitudinal Evaluation of Patients With Pulmonary Arterial Hypertension*

	LOW RISK	HIGH RISK
Clinical course	Stable; no increase in symptoms and/or decompensation	Unstable; increase in symptoms and/or decompensation
Physical examination	No evidence of right-sided heart failure	Signs of right-sided heart failure
Functional class†	I/II	IV
6MW distance†	> 400 meters	< 300 meters
Echocardiogram	Right ventricular size and function normal	Right ventricular enlargement or dysfunction
Hemodynamics	Right atrial pressure normal	Right atrial pressure high
	Cardiac index normal	Cardiac index low
Brain natriuretic peptide	Nearly normal or remaining stable or decreasing	Elevated or increasing
Treatment	Oral therapy	Intravenous prostacyclin and/or combination treatment
Frequency of evaluation	Every 3-6 months‡	Every 1-3 months
Functional class assessment	Every clinic visit	Every clinic visit
6MW distance	Every clinic visit	Every clinic visit
Echocardiogram§	Yearly or center dependent	Every 6-12 months or center dependent
Brain natriuretic peptide¶	Center dependent	Center dependent
Right heart catheterization	Clinical deterioration and center dependent	Every 6-12 months or clinical deterioration

*For patients in the high-risk category, consider referral to a pulmonary hypertension specialty center for contemplation of advanced therapies, clinical trials, and/or lung transplantation.

†The frequency of follow-up evaluation for patients in functional class III and/or having a 6MW distance of between 300 and 400 meters would depend on a composite of detailed assessments of the other clinical and objective characteristics listed.

‡For patients who remain stable with established therapy, follow-up assessments can be performed by referring physicians or pulmonary hypertension specialty centers.

§Echocardiographic measurement of pulmonary artery systolic pressure is an estimation only, and it is strongly advised that its evaluation not be relied on as the sole parameter for making therapeutic decisions.

¶The usefulness of serial brain natriuretic peptide levels to guide management in individual patients has not been established.

6MW, 6-minute walk.

J Am Coll Cardiol 2009;53:1573.

Goal-Oriented Strategy.

This recommended approach relies on improving clinical markers that have prognostic significance and systematically escalating treatment until a specific goal is attained. This requires that certain parameters be identified early and followed over time and that a threshold value for each parameter be defined before starting therapy.

Although the primarily observational studies mentioned earlier do not allow definitive conclusions, reasonable goals of therapy include the following[30]:

- WHO-FC: I or II
- Echocardiography/CMR: normal or near-normal right ventricular size and function
- Hemodynamics: normal right ventricular function (right atrial pressure < 8 mm Hg and cardiac index > 2.5 to 3.0 liters/min/m^2
- 6MW distance: more than 380 to 440 meters (may not be aggressive enough)
- Cardiopulmonary exercise testing: peak V_{O_2} higher than 15 mL/min/kg and V_E/V_{CO_2} (minute ventilation–carbon dioxide production slope; Eq_{CO_2}) lower than 45 liters/min

• BNP level: “normal”

Patients who achieve these parameters, no matter which specific therapy or approach is used, seem to have a better prognosis than do those who do not achieve these goals. A more aggressive approach to goal-oriented therapy may help us improve survival rates. Despite the many observations that support attainment of such goals, many patients today fall far short of them. For example, approximately 60% of functional class III patients and 50% of functional class IV patients in the REVEAL registry are not being treated with a prostacyclin despite not being at the goal functional class of I or II.[58] Both patient unwillingness and physician reluctance to proceed to the most aggressive therapy are contributing factors.

Consensus recommendations on reassessment are provided in the 2009 ACCF/AHA expert consensus document on PH and in the 2015 ESC/ERS PH guidelines. They rely on routine evaluation of important prognostic indicators such as WHO functional class, 6MW distance, and echocardiographic and hemodynamic parameters (**see Tables 85.4 and 85.5**). In most cases, goals of therapy include improvement to functional class I or II status, 6MW distance greater than 400 meters (considering demographic factors), and normal or near-normal right ventricular function as assessed by echocardiography or invasive hemodynamics.

Perioperative and Intensive Care Unit Management.

Patients with significant PAH are at high risk for general anesthesia. The perioperative risk was studied in an international, prospective 3-year questionnaire–based survey among 11 PH centers.[59] Major complications occurred in about 6% of their patients, and the overall perioperative mortality rate was about 3.5%. The factor that increased complications and mortality rates was more advanced disease as manifested by a higher right atrial pressure and a lower 6MWD. The need for emergency surgery and the use of perioperative vasopressors also increased the risk.

PAH can be considered a fixed obstructive cardiopulmonary lesion with an intraoperative physiology similar to that of severe aortic or mitral stenosis. During induction of anesthesia, systemic vasodilation is common and the systemic blood pressure can decrease. Systemic hypotension can exacerbate right ventricular ischemia by decreasing the right coronary artery perfusion pressure during systole, resulting in decreased CO due to worsening right ventricular function. The reduction in pulmonary blood flow results in more underfilling of the left atrium and left ventricle, worsening the systemic hypotension. Furthermore, as underfilling of the left ventricle becomes more pronounced and overloading of the right ventricle increases, increased interventricular septal flattening ensues, thereby further decreasing the ability of the left ventricle to fill. These abnormalities can quickly result in acute decompensation and potential death in a patient with PAH.

Given the risk of general anesthesia in a patient with PAH, the following strategies can help to ensure the best outcome perioperatively: (1) try to avoid general anesthesia if possible (e.g., use a nerve block); (2) evaluate and treat for decompensated right heart failure; (3) in patients with severe PAH (such as those with functional class III or IV symptoms, or those who are receiving intravenous or subcutaneous prostacyclins), perform preoperative RHC and optimize the hemodynamics prior to elective surgery; and (4) in the operating room, have available PA catheter monitoring, transesophageal echocardiography, and inhaled NO. All PAH patients should continue vasodilator medications perioperatively. A PAH specialist should be involved in perioperative management, especially in the management of high-risk PAH patients who are taking advanced prostanoid therapies.

With advances in pharmacologic therapy for PAH, many patients can now survive with a good

functional status. However, despite these improvements in treatment, the right ventricle remains vulnerable, and patients can quickly spiral downward in the setting of stressors such as infection and/or medication and/or dietary noncompliance, becoming critically ill. Unfortunately, there is scant evidence for the appropriate management of PAH patients in the intensive care unit, and treatment guidelines are based primarily on expert consensus.[60]

Management of the right ventricle is central to successfully treating PAH patients who are critically ill. Often, clinicians give fluids to patients with sepsis or hypotension, a management strategy that can have dire consequences in the setting of PAH. For example, in a patient with PAH who is septic or has a severe infection, systemic vasodilation occurs. As outlined earlier when describing the hemodynamic reaction to general anesthesia, the right ventricle can become more ischemic because of decreased right ventricular perfusion, resulting in further exacerbation of systemic hypotension due to decreased CO. The right ventricle enlarges and compresses the left ventricle further, decreasing left ventricular filling. In this setting, administration of intravenous fluids will only compound the problem as the right ventricular diastolic pressure rises (further impeding the right coronary blood flow) and interventricular septal flattening will worsen.

It is also important to note that acute-on-chronic right ventricular failure in PAH is physiologically different than acute right ventricular failure (e.g., right ventricular myocardial infarction). Most PAH patients are not preload dependent in the setting of right ventricular failure, and even small boluses of intravenous fluid can be harmful. Finally, renal venous congestion often occurs in patients with PAH who are critically ill with right ventricular failure. The right atrial pressure (and therefore central venous pressure) is high in decompensated PAH, resulting in increased renal venous pressure, and systemic hypotension decreases renal perfusion. These hemodynamic changes decrease the renal blood flow and result in increased fluid retention.

Because of these hemodynamic abnormalities, we advocate the following steps for the management of critically ill PAH patients: (1) consider invasive hemodynamic monitoring (e.g., pulmonary artery catheter) for diagnostic purposes to determine the hemodynamic abnormality and filling pressures present; (2) increase the systemic blood pressure with drugs such as dobutamine and/or phenylephrine to achieve a systolic blood pressure of more than 90 mm Hg; (3) optimize the central venous pressure to 8 to 10 mm Hg (use intravenous diuretics or ultrafiltration or continuous venovenous hemofiltration if necessary); (4) transfuse packed red blood cells to maintain the hemoglobin at more than 10 g/dL; (5) continue pulmonary vasodilator drugs that the patient was taking previously as an outpatient; and (6) consider prescribing inhaled NO (typical dosage, 20 ppm), especially if the patient is on a ventilator, remembering to wean off slowly to avoid rebound elevations in PA pressure. If these measures fail to work, adding an inotropic agent to increase the right ventricular contractility can be considered. In addition, the use of short-term, percutaneous, partial ventricular support devices, such as a Tandem Heart (inflow cannula in the right atrium and outflow cannula in the pulmonary artery) or a right ventricular Impella catheter has been described in the setting of right ventricular failure.[61,62] In severe cases, where there is a clearly reversible cause of right ventricular decompensation, extracorporeal life support (e.g., VA-ECMO) can be administered and can be life-saving; bilateral lung transplantation should also be considered in these cases.

Collaborative Care of the Pulmonary Arterial Hypertension Patient.

The management of the PAH patient requires a multidisciplinary approach and collaboration between local care and the PH specialty center. Additional content on this topic is presented in an online supplement entitled Collaborative Care of the Pulmonary Arterial Hypertension Patient.

Group 2 Pulmonary Hypertension Caused by Left-Sided Heart Disease

Definition

Left-sided heart disease is probably the most frequent cause of PH. The key hemodynamic factor that differentiates group 2 PH from others is the elevation in the left-sided heart filling pressure, PAWP. Left-sided ventricular or valvular dysfunction may result in chronic left atrial hypertension, with passive backward transmission of this pressure to the pulmonary vasculature leading to PH. Most commonly, the transpulmonary gradient is normal (< 12 mm Hg) and the PVR is normal or nearly normal (< 3 Wood units). Pulmonary venous hypertension can be a consequence of left ventricular dysfunction, mitral or aortic valve disease, cardiomyopathy, cor triatriatum, or pericardial disease. Although mitral stenosis was a common cause of pulmonary venous hypertension decades ago, heart failure with a preserved ejection fraction (HFpEF) is a common cause of pulmonary venous hypertension currently (**see Chapter 26**). It is presumed that the mechanism of both is similar. Specifically, a chronic elevation in left-sided diastolic filling pressure causes backward transmission of the pressure to the pulmonary venous system. In most cases this results in a passive increase in pulmonary artery pressure. In a subset of patients, a reactive vasoconstriction in the pulmonary arterial bed increases the pulmonary arterial pressure beyond what is expected from the elevated left atrial pressure alone; criteria for combined precapillary and postcapillary PH are reviewed earlier. The presence of PH in the setting of both left ventricular systolic dysfunction and HFpEF portends a poor prognosis.

Pathobiology and Pathophysiology.

Primary or pathognomonic vascular changes in the arterial wall may be absent in group 2 PH. Capillary and arterial remodeling develop as a result of backward transmission of increased pulmonary venous pressure. The pathologic changes are characterized by enlarged and thickened pulmonary veins, pulmonary capillary dilation, interstitial edema, alveolar hemorrhage, and lymphatic vessel and lymph node enlargement. The distal pulmonary arteries may be affected by medial hypertrophy and intimal fibrosis.

The severity of the PH depends, in part, on the contractility of the right ventricle. In the presence of a normal right ventricle, an increase in left atrial pressure initially results in a decrease in the PVR and the pressure gradient across the lungs because of distention of compliant small vessels or recruitment of additional vascular channels, or both. With further increases in left atrial pressure, the pulmonary arterial pressure rises along with the pulmonary venous pressure such that at a constant pulmonary blood flow, the pressure gradient between the pulmonary artery and veins and PVR remain constant. When the pulmonary venous pressure approaches or exceeds 25 mm Hg on a chronic basis, a disproportionate elevation in pulmonary artery pressure may occur, with the pressure gradient between the pulmonary artery and veins rising while the pulmonary blood flow remains constant or falls. This is indicative of an elevation in PVR caused in part by pulmonary arterial vasoconstriction. Some patients may have a genetic predisposition in which the chronically elevated pulmonary venous pressure serves as a trigger for the development of structural changes similar to those found in IPAH. Marked reactive PH with a pulmonary artery systolic pressure in excess of 80 mm Hg occurs in less than a third of patients whose pulmonary venous pressure is elevated more than 25 mm Hg; this finding suggests a broad spectrum of pulmonary vascular reactivity to chronic increases in pulmonary venous pressure. The molecular

mechanisms involved in elevating the PVR are unclear.

Although the right ventricle may initially adapt to the elevated afterload with hypertrophy, it might ultimately progress to chamber dilation, functional tricuspid incompetence, and right ventricular dysfunction. The right ventricle is the ultimate victim of these pulmonary vascular changes, and a common phenotype of end-stage pulmonary venous hypertension is right ventricular failure with systemic venous congestion, renal dysfunction, and ascites. Eventually, reductions in right ventricular output may lead to underfilling of the left ventricle and, at times, a paradoxical decrease in PAWP.

Diagnosis.

PH as a consequence of left ventricular systolic dysfunction, aortic and mitral valve disease, and cor triatriatum is often recognized because of the distinct clinical and echocardiographic patterns of these phenotypes. Recognition of PH resulting from HFpEF is more challenging, and HFpEF is commonly mistaken for IPAH. **Table 85.6** highlights some of the features that can help distinguish PH caused by HFpEF from group 1 PAH. Patients with PH caused by HFpEF tend to be older than group 1 PAH patients and often have more comorbid conditions, such as systemic hypertension, diabetes, coronary artery disease, and obesity. Although exertional dyspnea is often the chief complaint in both groups, orthopnea and paroxysmal nocturnal dyspnea are more specific for HFpEF. Chest imaging may provide evidence of an elevated left-sided heart filling pressure. Pulmonary vascular congestion or interstitial edema may be present on radiography. Chest CT will often reveal a mosaic perfusion pattern and ground-glass opacities consistent with chronic interstitial edema. Electrocardiographic clues favoring HFpEF include left ventricular enlargement, left atrial enlargement, and atrial fibrillation. Frequently, electrocardiographic findings of right ventricular enlargement are absent. Echocardiographic findings suggestive of HFpEF include left atrial enlargement, left ventricular hypertrophy, and Doppler indices of diastolic dysfunction, although grade 1 diastolic dysfunction is common in group 1 PAH. In general, right atrial and right ventricular dilation and intraventricular septal motion consistent with right ventricular pressure and volume overload are much more impressive in group 1 PAH.

TABLE 85.6

Distinguishing Pulmonary Arterial Hypertension From Heart Failure With Preserved Ejection Fraction

CHARACTERISTIC	PULMONARY ARTERIAL HYPERTENSION MORE LIKELY	HFPEF MORE LIKELY
Age	Younger	Older
Comorbid conditions: diabetes mellitus, hypertension, coronary artery disease, obesity (metabolic syndrome)	Often absent	Often present and multiple
Symptoms: paroxysmal nocturnal dyspnea, orthopnea	Often absent	Often present
Cardiac examination	Right ventricular heave, loud P_2, tricuspid regurgitation murmur	Sustained left ventricular impulse, S_4
Chest x-ray	Clear lung fields	Pulmonary vascular congestion, pleural effusions, pulmonary edema
Chest CT	Often clear lungs	Mosaic perfusion pattern, ground-glass opacities consistent with chronic interstitial edema
ECG	Right axis deviation, right ventricular enlargement	Left atrial enlargement, left ventricular enlargement atrial fibrillation, no right axis deviation
Natriuretic peptides	Often elevated	Often elevated
Echocardiography showing left atrial enlargement, left ventricular hypertrophy	Absent	Often present
Echocardiography showing diastolic dysfunction	Grade 1 common	Grade 2, 3 common
Echocardiography of right ventricle	Often enlarged, may share the apex	Often normal, mildly enlarged
Echocardiography showing pericardial effusion	Sometimes	Rare

HFpEF, heart failure with a preserved ejection fraction.

Even though the clinical factors listed earlier provide useful information for differentiating PH in the setting of HFpEF from group 1 PAH, invasive hemodynamic testing is required for a definitive diagnosis.

To make the diagnosis of PAH, the PAWP or LVEDP must be less than 16 mm Hg. If an ideal PAWP tracing cannot be obtained, the LVEDP should be measured directly. If a patient with many characteristics of HFpEF has a PAWP or LVEDP lower than 16 mm Hg, provocative maneuvers should be considered. Exercise is commonly used. Patients often report symptoms of dyspnea with exercise, during which an increase in the heart rate and a reduction in the diastolic filling time may increase the left-sided filling pressure and, as a result, pulmonary artery pressure. Saline loading is frequently used in laboratories without the ability to perform exercise studies. An increase in PAWP in a patient undergoing vasodilator testing with the typical agents used in group 1 PAH should raise suspicion for HFpEF.

Treatment

Treatment of group 2 patients, or those with pulmonary venous hypertension, should always be targeted at the underlying cause. In many patients, a reduction in the left-sided filling pressure will result in a reduction in pulmonary artery pressure. Emphasis should be placed on blood pressure control, volume management, and sodium restriction. Comorbid diseases such as obesity, diabetes, and obstructive sleep apnea must be addressed. Atrial fibrillation is not well tolerated in these patients, and every attempt to maintain the sinus rhythm should be made. No PAH-specific therapy is currently approved for the treatment of pulmonary venous hypertension. In the setting of left ventricular systolic dysfunction, both prostanoids and endothelin receptor antagonists have been studied and have failed to demonstrate a treatment benefit and may even be harmful.

There has been enthusiasm for the use of PDE5 inhibitors for HFpEF. A single-center, randomized controlled study of sildenafil in 54 patients with HFpEF and PH (pulmonary artery systolic pressure > 40 mm Hg) demonstrated that chronic (1 year) treatment was associated with a reduction in right ventricular dilation, enhanced right ventricular contractile function, and improvements in measures of alveolar-capillary gas exchange.[63] However, a multicenter randomized controlled trial of 216 stable patients with HFpEF found no difference in the primary endpoint of change in peak oxygen consumption in those treated with sildenafil versus placebo.[64] There were also no differences in the secondary clinical endpoints. This study did not enrich for patients with HFpEF and more severe PH, and further study in this subgroup may be warranted. More recently a phase II trial of macitentan in patients with combined precapillary and postcapillary pulmonary hypertension has been completed.

Group 3 Pulmonary Hypertension Caused by Chronic Respiratory Diseases

PH is a frequent complication of chronic respiratory diseases such as COPD[65] and interstitial pulmonary fibrosis (IPF).[66] Even though frequently moderate, PH has an impact on the functional capacity and survival rate in these patients. PH should be suspected when patients have signs of right-sided heart failure and when dyspnea and/or severe hypoxemia cannot be explained by the severity of the impairment in lung function. Patients with PH who are hypoxemic should be treated according to guidelines for the management of these respiratory diseases, including long-term oxygen therapy and lung transplantation when appropriate. The impact of PH on exercise capacity and outcomes is more significant in the minority of patients with mPAP higher than 40 mm Hg. Such patients with severe PH have the worst survival rates and should be referred to an expert PH center for complete evaluation and management.

Epidemiology and Natural History of Pulmonary Hypertension in Chronic

Obstructive Pulmonary Disease

A better understanding of the consequences of chronic lung diseases on the pulmonary circulation has been possible since the late 1940s with the demonstration of hypoxic pulmonary vasoconstriction and the first hemodynamic measurements in diseased humans. Severe chronic respiratory diseases cause alveolar hypoxia, which in turn causes PH as a result of ongoing pulmonary vasoconstriction and remodeling. PH increases the work of the right ventricle, thereby leading to right ventricular enlargement (hypertrophy and dilation) and possibly resulting in right-sided heart dysfunction and failure. Because alveolar hypoxia is a prominent cause of PH in patients with severe chronic hypoxemia (Pa_{O_2} < 55 to 60 mm Hg), long-term oxygen therapy is recommended for these patients.

A study of the natural history of PH in patients with COPD shows that its progression is slow and the mPAP may remain stable over long periods. In a study in which 93 patients were observed for 5 to 12 years, the changes in mPAP were rather small (+0.5 mm Hg/yr, with similar evolution of mPAP in patients with or without initial PH). In another study on the natural history of PH in 131 patients with stable COPD, the evolution of pulmonary hemodynamics was evaluated by performing two RHCs at a mean time interval of 6.8 ± 2.9 years. At inclusion all patients had an mPAP at rest lower than 20 mm Hg. At the second RHC, 33 patients had a resting mPAP higher than 20 mm Hg, but this elevation was generally mild. Patients in whom an mPAP higher than 20 mm Hg developed at the second RHC had a higher resting mPAP and a significantly lower resting Pa_{O_2} at inclusion. Logistic regression analysis showed that the resting mPAP was an independent predictor at inclusion for the subsequent development of mPAP higher than 20 mm Hg. In addition, patients with COPD in whom an elevated mPAP (> 20 mm Hg) developed had significant worsening of Pa_{O_2}, whereas the mean Pa_{O_2} was stable in the remainder. Thus, progression of the mPAP over time in patients with COPD and mild to moderate hypoxemia is usually slow.

Robust data on the prevalence of PH in large populations of patients with COPD of all levels of severity have been difficult to produce because of the poor sensitivity of echocardiographic screening in COPD, the lack of systematic RHC analysis in large cohorts of patients, and the usual focus on particular subsets of patients. However, it is clear that severe PH (defined as mPAP > 40 mm Hg) is rare in patients with COPD. Conversely, moderate elevations in mPAP in patients with COPD are more common. In the modern management era (when long-term oxygen therapy was widely available), the National Emphysema Treatment Trial reported an mPAP of 26.3 ± 5.2 mm Hg in a series of 120 patients with severe emphysema. Another analysis of patients with severe COPD who were candidates for lung volume reduction surgery or lung transplantation showed that 36.7%, 9.8%, and 3.7% of patients had an mPAP of 26 to 35 mm Hg, 36 to 45 mm Hg, and more than 45 mm Hg, respectively. In this study, the mPAP was inversely correlated with the Pa_{O_2}. Cluster analysis suggested the existence of four groups of patients: (1) patients with a moderately lowered forced expiratory volume in 1 second (FEV_1) and Pa_{O_2} and a normal mPAP level; (2) patients with severe airflow obstruction, moderate hypoxemia, and PH; (3) patients with severe airflow obstruction, severe hypoxemia, and a high mPAP; and (4) patients with moderate airflow obstruction contrasting with moderate to severe PH and severe hypoxemia. When compared with the other groups, the last group of patients was characterized by a higher FEV_1, a lower Pa_{O_2}, and a higher level of mPAP. Moreover, the Pa_{CO_2} was significantly lower than in the other groups, suggesting a more pronounced pulmonary vascular component. Consistent with these data, only 27 of a series of 998 patients with COPD had severe PH as defined by an mPAP of more than 40 mm Hg.

Interestingly, 16 of these 27 patients had another cause of PH. Indeed, patients with COPD may have severe comorbid conditions that may favor precapillary or postcapillary PH, including systolic and diastolic left-sided heart diseases, CTEPH, portal hypertension, sleep-related disordered breathing, and exposure to drugs that may induce PAH. The remaining 11 patients (1.1%) had COPD as the only cause of PH, with a median mPAP of 48 mm Hg. These patients with severe PH had an unusual pattern of cardiopulmonary abnormalities consisting of mild to moderate airway obstruction, severe hypoxemia, hypocapnia, and a decreased diffusion capacity for carbon monoxide (D_{LCO}). In these patients, exertional dyspnea was more severe and survival times were shorter than in control COPD patients.

In some situations, such as during exercise, during sleep, and with exacerbations, the PH may be more troublesome. First, the mPAP may increase with exercise in patients with advanced COPD. Indeed, the PVR does not decrease with exercise in patients with severe COPD (as opposed to healthy individuals). Thus an increase in CO with exercise will induce increases in the mPAP and may contribute to the limitation of exercise. Second, some data show episodes of alveolar hypoventilation and subsequent hypoxia in patients with COPD; such events may contribute to the pathophysiology of PH. Third, exacerbations of COPD may be the cause of marked increases in mPAP during episodes of acute respiratory failure. These acute changes in mPAP are reversible and correlate with the Pa_{O_2}. However, the exact link between exacerbations and PH in COPD is currently unknown, although patients with COPD and PH have more severe COPD exacerbations than do those without PH. Altogether, PH is a strong prognostic factor in patients with COPD who are being treated with long-term oxygen therapy, even in the modern management era.

Pathology and Pathophysiology of Pulmonary Hypertension in Chronic Obstructive Pulmonary Disease.

Chronic inflammation and alveolar hypoxia, loss of pulmonary capillaries because of emphysema, and possibly mechanical injury as a result of hyperinflation are likely to contribute to PH secondary to COPD. Pathologic studies support the concept that pulmonary arterial remodeling, reduction of the number of pulmonary vessels because of emphysema-related loss of such vessels, and pulmonary thrombosis contribute to chronic PH in patients with COPD. Postmortem studies have shown muscularization of the small resistance pulmonary arteries, which can extend to the periphery in normally nonmuscularized vessels. Thickened media and intimal changes are common in COPD, but no complex plexiform lesions described in PAH have been found in these studies. In addition, inflammatory processes have been detected in the pulmonary arteries and distal airways of these patients, as well as in smokers without PH. Pulmonary vascular inflammation is currently considered a key player in other pulmonary vascular diseases such as PAH and CTEPH and could also play a role in PH complicating the course of COPD.

Diagnosis of Pulmonary Hypertension in Patients With Chronic Obstructive Pulmonary Disease.

Diagnosis of PH in patients with COPD is difficult because it is challenging to differentiate signs of PH from the comorbid lung disease and possibly other cardiovascular complications such as systolic or diastolic left-sided heart disease. Symptoms such as shortness of breath and fatigue are nonspecific. In the era of long-term oxygen therapy, signs of right-sided heart failure are rare in COPD except during severe acute exacerbations or in the most severe cases. Peripheral edema may also have other causes than right-sided heart failure. Simple tests such as chest radiography, electrocardiography, spirometry,

plethysmography, D_{LCO}, and arterial blood gases are important to perform but do not allow an accurate prediction of PH. However, they are useful in raising suspicion for PH. Indeed, when severe dyspnea on exertion and/or severe hypoxemia is not explained by the severity of COPD, it is of major importance to investigate whether the symptoms could be due to a comorbid condition such as PH. Along the same line, an unexpectedly low 6MW distance and severe desaturation should raise suspicion for PH. In patients with COPD and severe PH, the incremental maximal cardiopulmonary exercise test displays a pattern, also observed in chronic heart failure, characterized by very low maximal work, larger ventilatory reserve at peak exercise, and lower end-tidal Pa_{CO_2} than in patients with COPD and no or mild to moderate PH. Biomarkers such as BNP, when elevated, do not distinguish left-sided from right-sided heart failure and can be normal in patients with mild to moderate PH. Doppler echocardiography is an interesting noninvasive tool for screening for PH and evaluating left-sided heart function. However, its sensitivity and specificity are suboptimal in patients with COPD. Thus normal findings on Doppler echocardiography may not be sufficient to exclude PH if it is clinically suspected. Importantly, PH cannot be diagnosed on the basis of Doppler echocardiography. Indeed, the “gold standard” diagnostic procedure for diagnosis of PH is RHC. As discussed previously, RHC will not only allow the diagnosis of precapillary PH but will also evaluate its hemodynamic severity and exclude a postcapillary component. At this stage it is essential to emphasize the importance of screening for comorbid conditions such as left-sided heart disease, sleep-related disordered breathing, pulmonary embolism, and interstitial lung disease, which may contribute to the clinical findings.

Treatment of Pulmonary Hypertension in Patients With Chronic Obstructive Pulmonary Disease

Optimizing COPD care, including of course smoking cessation, is the first step in management. Besides this, long-term oxygen therapy is the cornerstone for prevention and management of PH in COPD, and it should be prescribed for patients with COPD and a Pa_{O_2} lower than 60 mm Hg. Long-term oxygen therapy resulted in a slight decrease in mPAP in patients treated for more than 18 hr/day in the NOTT study, but nocturnal oxygen therapy (10 to 12 hr/day) did not improve the mPAP. Thus long-term oxygen therapy may stabilize, attenuate, and sometimes reverse PH in patients with COPD.

Attempts to treat patients with COPD and comorbid PH with vasodilators such as calcium channel–blocking agents have proved disappointing inasmuch as inhibition of hypoxic vasoconstriction leads to deleterious effects on gas exchange. The efficacy of sildenafil in improving exercise tolerance in a group of patients with COPD and moderately increased PAP has been tested.[67] This was a double-blind, randomized controlled trial of 60 patients receiving 20 mg sildenafil (29 patients) or placebo (31 patients) three times daily and undergoing pulmonary rehabilitation for 3 months. The primary endpoint was the gain in cycle endurance time at a constant work-rate. Secondary endpoints included performance in the incremental exercise test, 6MW distance, and quality of life. None of the endpoints was reached; therefore the authors concluded that in patients with severe COPD and moderately increased PAP, concomitant treatment with sildenafil does not improve the results of pulmonary rehabilitation in exercise tolerance. Similar disappointing results were obtained in a study of 120 patients with COPD and mild PH randomized to tadalafil (10 mg daily) or placebo for 12 weeks, the primary endpoints being exercise tolerance and stress test within a respiratory rehabilitation program.[68] Based on consistent observations that pulmonary vasodilators offer no clinical benefit to patients with COPD and PH, guidelines do not recommend such therapies and emphasize the need for more randomized controlled studies in this area.

If patients with COPD and PH are eligible, lung transplantation should be considered. In a

retrospective analysis of 409 patients with end-stage COPD (mean FEV_1 of 23 ± 7%) who underwent evaluation for lung transplantation, Andersen and colleagues[69] showed that precapillary PH was present in 36% of the patients (13% had postcapillary PH). As reported by many other groups, precapillary PH was mild to moderate in most patients, and only 1.5% had an mPAP higher than 40 mm Hg. Interestingly PH was associated with worse survival rates in patients with COPD, but it did not influence survival rates after lung transplantation, thus highlighting the fact that PH should be considered an important parameter in patients with COPD who are candidates for lung transplantation.

Pulmonary Hypertension in Other Chronic Respiratory Diseases

PH is a frequent and severe complication of interstitial lung diseases such as IPF and the syndrome of combined pulmonary fibrosis and emphysema.[70] Of note, PH occurring in other respiratory conditions such as sarcoidosis,[71] pulmonary Langerhans cell histiocytosis,[72] and lymphangioleiomyomatosis[73] are classified in the group of PH with multiple or unknown causes. When present, PH has a dramatic impact on the morbidity and survival rates of patients with IPF. Despite recent therapeutic progress (including pirfenidone and nintedanib, which reduce the rate of decline in lung function in patients with mild to moderate disease), management of IPF remains largely supportive because of a relentless progression to respiratory failure and death after a median of only 3 years from the time of diagnosis. Precapillary PH is common in patients with advanced IPF, with a prevalence of 32% to 46% at RHC during evaluation for lung transplantation. The hemodynamic severity of PH in this context is usually mild (mPAP < 35 mm Hg), although 2% to 10% of patients have mPAP values higher than 35 mm Hg. In these patients PH is associated with marked dyspnea, decreased exercise capacity (as measured by 6MW distance and peak oxygen uptake during cardiopulmonary exercise testing), lower D_{LCO}, greater oxygen requirements, and reduced survival rates. In patients with moderate functional impairment, the prevalence of PH is lower. In a recent series of patients who underwent systematic RHC at the initial evaluation of IPF, PH was present in 14.9%, and an mPAP higher than 35 mm Hg was found in 5%, thus demonstrating that PH may develop earlier in some patients. As in COPD, the frequency of PH increases in the presence of comorbid conditions, including obstructive sleep apnea, venous thromboembolic disease, and left ventricular dysfunction, or in the setting of the syndrome of combined pulmonary fibrosis and emphysema. The primary treatment approach is to correct the hypoxemia with supplemental oxygen whenever appropriate and to consider lung transplantation when not contraindicated by age or comorbid conditions.

As in COPD, the pathogenesis of PH in patients with IPF is not limited to hypoxic pulmonary vasoconstriction. Indeed, pulmonary hemodynamics do not correlate with impairment in pulmonary function in this setting, and oxygen supplementation rarely reverses PH in patients with interstitial lung diseases and especially IPF. Together with hypoxia, parenchymal lung destruction, intrinsic pulmonary vascular abnormalities, alteration in cytokines and other mediators, microvascular injuries, and possibly autoimmunity may collectively contribute to the pulmonary vascular remodeling in IPF.

Overall, it has become clear that conventional management of underlying IPF, including supplemental oxygen, does not address the issue of associated PH. PAH therapies have been tested to improve clinical outcomes and hemodynamics in PH secondary to IPF. Currently available studies have been rather disappointing because of the low number of patients studied, the poor clinical and hemodynamic characterization of the patients, and the concern that vasodilators may contribute to worsening gas exchange via inhibition of hypoxic pulmonary vasoconstriction. The NIH IPF network study of sildenafil has evaluated patients with IPF and D_{LCO} lower than 35% of predicted (and therefore included some patients with associated PH, although there was no confirmation by RHC). This study was negative for the

primary endpoint of a 20% change in 6MW distance. In an exploratory post hoc analysis, the small group of patients with echocardiographic evidence of right ventricular dysfunction had a stronger trend toward a treatment benefit consisting of greater improvement in exercise capacity and quality of life. However, post hoc analysis of a negative trial cannot be considered convincing evidence. In addition, hypoxemia observed has confirmed that vasodilator therapy can have deleterious effects on gas exchange in IPF. Studies of oral endothelin receptor antagonists in IPF with PH have been negative.[74-76] Raghu and colleagues have reported negative results of a trial on the treatment of IPF with ambrisentan and issued a detailed analysis of patients with PH randomized in this trial. Of the initial 488 patients randomized in the global trial, PH was found in 68 individuals (defined as having an mPAP > 22 mm Hg and a PAWP ≤ 15 mm Hg), but the follow-up hemodynamic data were available in only 19 of them (12 in the ambrisentan-treated arm and 7 in the placebo-treated arm) and did not reveal any major differences. A lack of efficacy in the entire study group and the higher incidence of IPF progression events in the ambrisentan-treated arm argue against the use of ambrisentan in patients with IPF.

A small nonrandomized pilot study that evaluated 12 weeks of treatment with riociguat in 15 patients with different forms of interstitial disorders showed that the drug might improve the cardiac index, PVR, and 6MW distance, but no changes were recorded in the mPAP.[77] Of note, the arterial oxygen saturation decreased in treated patients. To what extent these data actually translate into clinical improvement was unclear, and the authors concluded that further studies were necessary to evaluate the safety and efficacy of riociguat in these patients. Therefore, riociguat was tested in a randomized controlled trial versus placebo in patients with PH due to idiopathic interstitial pneumonia. This trial was prematurely terminated because of an increased risk of death and other serious adverse events in the active treatment arm.[78]

Group 4 Chronic Thromboembolic Pulmonary Hypertension

CTEPH is a common subset of PH that is curable by surgery.[79] The definition of CTEPH is based on findings described after at least 3 months of effective anticoagulation (to discriminate chronic from acute disease). Such findings include precapillary PH and at least one segmental perfusion defect detected by lung scanning, multidetector CT angiography, and/or pulmonary angiography. CTEPH is caused by chronic obstruction of major pulmonary arteries following pulmonary embolism. CTEPH occurs in 3 to 30 individuals per million general population per year and has been shown to be a long-term complication of pulmonary embolism with a cumulative incidence of 0.1% to 9.1% within 2 years after a symptomatic event. These large margins of error result from referral bias, the paucity of early symptoms, and the difficulty in properly distinguishing an acute pulmonary embolism revealing preexisting CTEPH from a truly causal initial venous thromboembolic event. In the international CTEPH registry, a clinical history of acute venous thromboembolism was observed in three quarters of patients with CTEPH and was an independent risk factor for CTEPH when compared with IPAH. However, a number of cases may still originate from asymptomatic venous thromboembolism. CTEPH appears to be caused primarily by venous pulmonary thromboembolism, as opposed to primary pulmonary vascular in situ thrombosis. Prothrombotic factors such as inadequate anticoagulation, a large thrombus mass and residual thrombus, and recurrences may contribute to development of the disease. However, CTEPH does not show the classic risk profile of venous thromboembolism, and only some specific thrombophilic factors such as lupus anticoagulant/antiphospholipid antibodies and the coagulation factor VIII have been found to be associated with it. Thus a purely mechanistic view of CTEPH as a disease caused by obliteration of central pulmonary arteries by pulmonary emboli is too simplistic, and it has been proposed that the

pulmonary embolism may be followed by a pulmonary vascular remodeling process modified by infection, immune phenomena, inflammation, circulating and vascular-resident progenitor cells, thyroid hormone replacement, and malignancy. Hypercoagulation, “sticky” red blood cells, high platelet counts, and uncleavable fibrinogens contribute to major vessel obliteration in CTEPH. Nonplasmatic risk factors include splenectomy, ventriculoatrial shunt for hydrocephalus therapy, and inflammatory bowel disease. Associated with major pulmonary vascular obstruction, CTEPH consists of small pulmonary vessel disease (pulmonary arteriopathy),[4] which may originate from a high-flow or high-pressure state in previously unaffected vessels or be driven by hypoxia, infection, and inflammation from associated conditions.

CTEPH occurs equally in both sexes, and all age-groups can be affected, yet the median age of patients is 63 years. Physical signs in early CTEPH are generally absent. Only in later disease stages are nonspecific signs of right-sided heart dysfunction detected. Clinical symptoms of CTEPH resemble those of IPAH, with edema and hemoptysis occurring more often in CTEPH and syncope being more common in IPAH. Clinical suspicion is based on risk factors and symptoms. Although CT is the tool for diagnosis of acute pulmonary embolism, the ventilation-perfusion lung scan is the main imaging modality for CTEPH detection. Criteria for diagnosing CTEPH on a ventilation-perfusion scan are at least one defect encompassing at least half a segment. Potential pitfalls are small matched defects or nonsegmental perfusion abnormalities as occur in PAH and PVOD. In patients with large central thrombi and PAH associated with CHD or in those with pulmonary arterial aneurysms, the perfusion defects typically remain nonsegmental. RHC will demonstrate precapillary PH. PVR is a predictor of prognosis for surgical candidates. Concomitant small pulmonary vascular disease is a predictor of an adverse surgical outcome in CTEPH. Contrast-enhanced CT angiography, including three-dimensional rendering techniques, depicts pulmonary artery webs and bands, wall irregularities, stenoses, and complete vascular obstructions, as well as bronchial collaterals. High-resolution CT of the chest screens for comorbid parenchymal disease (such as emphysema, bronchitis, or interstitial lung disease), as well as pulmonary infarcts. Perfusion inequalities manifested as a mosaic parenchymal pattern can be detected. The final step in the diagnostic pathway is the classic side-selective pulmonary angiography in the anteroposterior and lateral projections for the purpose of confirming the diagnosis, assessing the most proximal involvement, and evaluating for surgical complexity and accessibility.

Surgery is the treatment of choice for CTEPH. In contrast to embolectomy, pulmonary endarterectomy creates a surgical plane through the medial layer of the pulmonary artery with the patient under deep hypothermia and circulatory arrest. According to the surgical specimen, four anatomic types of CTEPH are distinguished: type 1 disease (≈ 25% of cases) involving the main and lobar pulmonary arteries with fresh red thrombus superimposed on white obstructions; type 2 disease (≈ 40% of cases) consisting of intimal thickening and fibrosis proximal to segmental arteries; type 3 disease (≈ 30% of cases) with fibrosis, intimal webbing, and thickening confined to distal segmental and subsegmental arteries; and type 4 disease (< 5% of cases) defined by microscopic distal arteriolar vasculopathy without visible thrombus. Type 4 is not operable. General operability criteria include NYHA functional class II, III, or IV; surgical accessibility of thrombi in the main, lobar, or segmental pulmonary arteries, with a reasonable relationship to hemodynamic severity; absence of severe comorbid diseases; and patient consent. Advanced age per se is not a contraindication to surgery. A difficult issue in the preoperative assessment of patients with CTEPH is definition of the extent of small-vessel disease. Patients with CTEPH and defects in the main, lobar, or proximal segmental level have proximal disease and are best suited for surgery. In contrast, patients with significant PH but little or no obstruction are considered poor candidates for surgery. This latter group is believed to display significant pulmonary arteriopathy. The

contemporary in-hospital mortality rate due to perioperative complications is as low as 4.7% or less. After surgery, most patients exhibit hemodynamics that are almost normal and experience substantial relief from their symptoms. The International CTEPH registry has reported survival data in a cohort of 679 patients newly diagnosed with CTEPH who were prospectively included over a 24-month period. The estimated survival rates at 1, 2, and 3 years were 93%, 91%, and 89%, respectively, in the 404 operated patients, and only 88%, 79%, and 70%, respectively, in the 205 patients who did not undergo operation.[80] Thus patients who do not undergo surgery or who suffer from persistent or residual PH after surgery face a poor prognosis.

Optimal medical treatment for CTEPH consists of anticoagulants and diuretics, and oxygen in cases of heart failure or hypoxemia. Lifelong anticoagulation is recommended, even after pulmonary endarterectomy; no data exist on the efficacy and safety of new oral anticoagulants. Although there is no consensus, routine cava filter placement is not justified by the available evidence. Pulmonary microvascular disease in CTEPH has provided the rationale for the off-label use of drugs approved for PAH. Some nonrandomized studies have provided evidence for an improvement in exercise capacity and hemodynamics. Medical treatment of CTEPH with targeted therapy may be justified in technically nonoperable patients or in the presence of an unacceptable surgical risk-benefit ratio (**Fig. 85.5**).

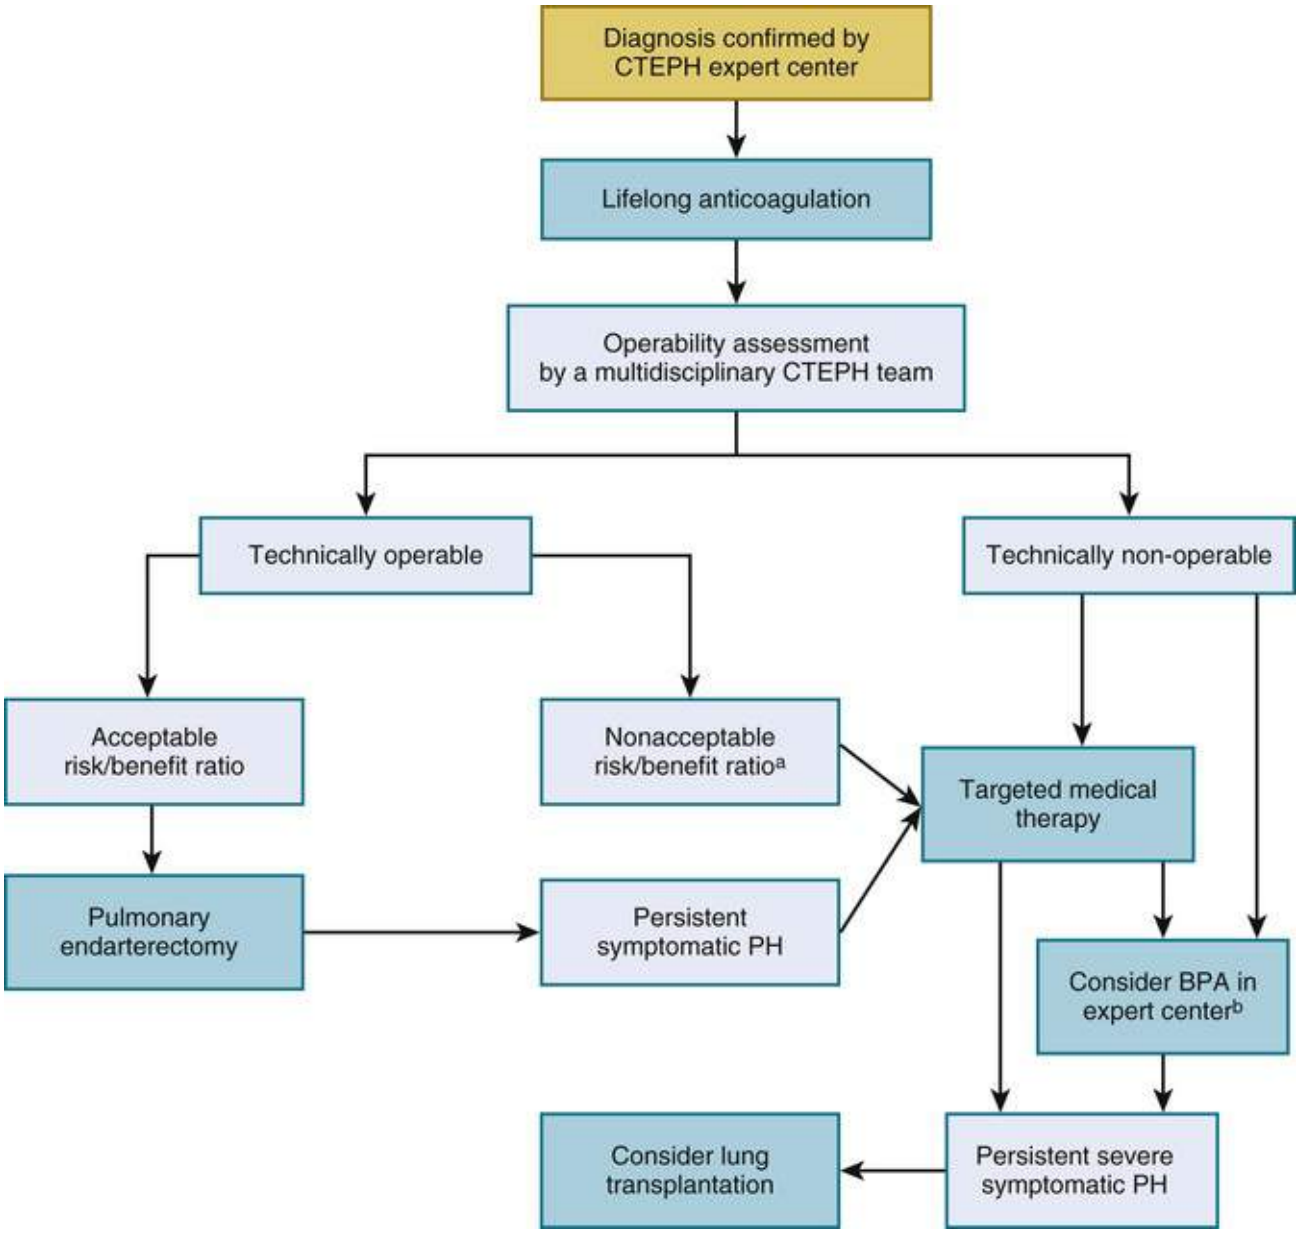

FIGURE 85.5 Treatment algorithm for chronic thromboembolic pulmonary hypertension. (Modified from Galie N, Humbert M, Vachiery J-L, et al: 2015 ESC/ERS Guidelines for the diagnosis and treatment of pulmonary hypertension. Eur Heart J 2016;37:67.)

Patients with persistent or recurrent PH after pulmonary endarterectomy may also be candidates for targeted medical therapy. Additional content on this topic is presented in an online supplement entitled Targeted Medical Therapy After Pulmonary Endarterectomy.

Other pulmonary artery obstructions may be due to angiosarcoma (and other intravascular tumors), pulmonary arteritis (such as Takayasu arteritis), congenital pulmonary artery stenoses, or parasitic infection (hydatidosis). The most common differential diagnosis of CTEPH in expert centers remains progressive tumoral occlusion of proximal pulmonary arteries (with additional thrombosis). Such cases are due principally to pulmonary artery sarcomas. Differentiation from CTEPH can be difficult, and findings on CT or magnetic resonance angiography, as well as ^{18}F-fluorodeoxyglucose positron emission tomography, may be useful in distinguishing an obstruction by tumor from thrombotic material.

Pulmonary Hypertension With Unclear or Multifactorial Causes

Hematologic Disorders.

PH can complicate the course of chronic myeloproliferative disorders, including polycythemia vera, essential thrombocythemia, and chronic myelogenous leukemia. Several mechanisms may contribute to the development of PH, including congestive heart failure secondary to a high CO and fluid overload, CTEPH, direct obstruction of pulmonary arteries because of intrapulmonary hematopoiesis, portopulmonary PH, drug-induced PAH (as from dasatinib or interferon), and splenectomy.

Splenectomy as a result of trauma or as a consequence of hematologic disorders may increase the risk for development of IPAH or CTEPH, which is more likely to be distal.

Chronic hemolytic anemia, including sickle cell disease (SCD) and beta-thalassemia, may cause PH through multiple mechanisms ranging from postcapillary PH because of high-output heart failure to precapillary PH caused by pulmonary vascular remodeling and thrombosis, proximal and distal CTEPH, and portopulmonary hypertension. Of the chronic hemolytic anemias, PH has been described most frequently in association with SCD. In a prospective study of 398 patients with SCD, a tricuspid regurgitant velocity higher than 2.5 meters/sec was measured in 27%, who then underwent RHC. The prevalence of PH was 6%, with approximately half meeting the criteria for group 1 PAH and the other half being categorized as having postcapillary PH.[81] The positive predictive value of echocardiography for the detection of PH was 25%. The role of PAH-specific therapy for PAH associated with SCD is unclear because no PAH-specific therapy has been adequately studied in patients with SCD. A double-blind placebo-controlled trial of sildenafil in patients with SCD and a tricuspid regurgitant velocity of 2.7 meters/sec or higher was stopped early because of a higher percentage of patients experiencing adverse events, particularly hospitalization for a pain crisis, in the sildenafil arm.[82]

Systemic Disorders.

Sarcoidosis is a common systemic granulomatous disease of unknown origin. PH is an increasingly recognized complication of sarcoidosis, with a reported prevalence of 1% to 28%. PH is most often due to destruction of the capillary bed by the pulmonary fibrotic process in type IV disease and/or to the resultant chronic hypoxia. However, the severity of PH may be more severe than expected when considering the degree of parenchymal lung disease, which can be modest or even absent, and to the blood gas abnormalities, thus suggesting that other mechanisms could contribute to the development of PH. Among these mechanisms, one can consider extrinsic compression of large pulmonary vessels by lymph node enlargement or mediastinal fibrosis; granulomatous infiltration of the pulmonary vasculature, especially that affecting the pulmonary veins; cardiac sarcoidosis, which may cause heart failure and postcapillary PH; and hepatic sarcoidosis, which may cause portopulmonary PH. Management, including corticosteroid therapy, lung or heart-lung transplantation, and off-label use of PAH drugs, will depend on the dominant pathomechanism at play.

Pulmonary Langerhans cell histiocytosis (also known as *pulmonary histiocytosis X*) is a rare lung disease that predominantly affects young adults and develops almost exclusively in those with a history of current or previous cigarette smoking. Precapillary PH is frequently detected in patients with advanced lung destruction, although no clear relationship exists between PH and the extent of parenchymal lung disease and/or hypoxia, thus suggesting that alternative or additional pathomechanisms might contribute to an intrinsic pulmonary vasculopathy that involves both the precapillary arterioles and postcapillary venous compartment (with frequent PVOD-like lesions). Patients with pulmonary Langerhans cell histiocytosis in whom PH develops have a particularly poor prognosis, and early referral for lung transplantation assessment is recommended. Encouraging recent data suggest that agents licensed for use in patients with PAH confer improvements in pulmonary hemodynamics and are generally well tolerated. Further investigation of the use of PAH medical therapy in this population is warranted. Additional content on the causes of type 5 PAH, including lymphangioleiomyomatosis,

metabolic causes, and tumor metastasis, is presented in an online supplement entitled Systemic Disorders Causing Type 5 Pulmonary Arterial Hypertension.

Fibrosing mediastinitis may be associated with severe PH secondary to compression of the large pulmonary arteries and veins. Ventilation-perfusion lung scan, CT of the chest, and pulmonary angiography are useful for accurate diagnosis. However, the findings can mimic those of proximal thrombotic obstruction. The major causes are histoplasmosis, tuberculosis, and sarcoidosis.

PH has been reported in patients with *end-stage renal disease maintained on long-term hemodialysis*. There are several potential explanations for the development of PH in these patients: the mPAP may be increased by a high CO (resulting from the arteriovenous access and anemia), as well as by fluid overload. In addition, diastolic and systolic left-sided heart dysfunction is also common and leads to postcapillary PH. Furthermore, the hormonal and metabolic derangement associated with end-stage renal disease might promote dysfunction of the pulmonary vascular tone.

Pulmonary Hypertension Registries

Guidelines recommend that the management of PAH and CTEPH be performed in specialized centers with multidisciplinary teams working in a shared care approach. Such centers should be part of larger national or international networks, which should be able to capture valuable information in registries and patient cohorts to better understand the epidemiologic trends of these severe and uncommon conditions. The first registry to evaluate the characteristics and survival statistics of patients with PH and later develop a prognostic model was the NIH primary PH registry in the 1980s. A prognostic equation was developed from data collected before the availability of PAH-targeted therapies. This equation describes the natural history of IPAH but cannot be used to predict survival rates for treated patients in the modern management era. In the modern management era, several registries of PAH and CTEPH have been developed that compensate for the NIH equation's shortcomings. Among others, these include the French National Registry,[55] the United Kingdom and Ireland registry,[83] the U.S. registry to evaluate early and long-term PAH disease management (REVEAL),[56,58] the COMPERA Registry,[84] and the international CTEPH registry.[79] Although similar in many respects, PAH registries vary in patient populations, including the number of patients with newly and previously diagnosed PAH, as well as the era of observation, period of survival, and timing of assessment of potential predictive factors. Nonetheless, the predictive factors identified in each registry share an important homology in that the cause of the disease, patient sex, and markers of right-sided heart dysfunction are integral in depicting survival possibilities. Interestingly, the PAH risk score and equations have been generated from these registries and have been validated in independent contemporary cohorts. In the most recent period of PAH registries, changes in patients' phenotypes have been demonstrated, with a higher proportion of patients being older than 60 years and having an increased frequency of cardiovascular risk factors such as obesity and diabetes.

In recent registries, approximately half the patients with PAH display idiopathic, heritable, and drug-induced disease, whereas the remaining patients have PAH associated with connective tissue diseases, CHD, portal hypertension, and HIV infection. In the Western world, scleroderma is the most common associated condition, but CHD still predominates in developing countries. In endemic regions of Brazil, PAH caused by hepatosplenic schistosomiasis is an ongoing problem. At diagnosis, approximately three quarters of patients with PAH are in NYHA functional class III or IV, thus emphasizing that the diagnosis still occurs late in the course of the disease in patients with marked exercise limitation and hemodynamic compromise. The delay between the symptom onset (mainly dyspnea on exercise) and the diagnosis of

PAH is still 2 years or more in most modern management registries, similar to that observed in the NIH registry, which emphasizes the need for better awareness of PAH and diagnostic strategy. The low estimates of the prevalence and incidence of PAH in Western countries are 15 and 2 cases per million adult inhabitants per year, respectively (6 cases and 1 case per million of adult inhabitants per year, respectively, for IPAH). Survival rates of patients with PAH remain poor—and even more so in patients with scleroderma or familial PAH. In IPAH, 1-, 2-, and 3-year survival rate estimates are in the range of 85% to 90%, 75% to 85%, and 55% to 75%, respectively, thus indicating that PAH remains a dramatic condition in the modern management era. Multivariate analysis indicates that being female, having a better 6MW distance/NYHA functional class, and exhibiting better right ventricular hemodynamic function are jointly associated with better survival prognoses.[55] Refining prognostic factors is currently the main focus of the REVEAL study group, which has produced and validated a PAH risk score calculator that may be useful in predicting outcomes of patients with PAH.

Future Perspectives

Even though our understanding of the pathogenesis and treatment of PAH has advanced substantially over recent decades, we still have a long way to go. A basic understanding of the pathobiology of PAH often relies on animal models, which do not accurately reflect human disease.[85] In the hope of advancing translational science, the Pulmonary Hypertension Breakthrough Initiative is a project that harvests explanted lungs from patients with PAH at the time of lung transplantation. Similarly, national and international consortia have been launched in recent years allowing major international partnerships in the field of pulmonary vascular medicine.[12] Making human tissue available for study has the potential to accelerate advances in the basic and translational sciences.[85] Patients with PAH currently have a better quality of life and survival than they did a decade or two ago, but their survival is still suboptimal, and more advances in medical therapies are needed.[86] Fortunately, numerous therapies, including some with novel mechanisms of action, are currently being investigated.[87] Data from important current-day registries continue to shed light on important prognostic variables and may help guide us in appropriate treatment strategies.[86] The importance of the right ventricle cannot be overstated. Imaging modalities for the right ventricle are being refined, and it is likely that CMR will play a crucial role. Patients do not die of high pulmonary artery pressure. They die of right ventricular failure. A better grasp on treating the failing right ventricle is a priority for the future.

Although we have made considerable inroads in the treatment of group 1 PAH, clinical trial data for the more common disorders of group 2 and 3 PH are lacking. Off-label use of PAH-specific therapy in these populations is common, but there is little in the way of efficacy and safety data. Trials of populations disproportionately enriched in patients with PH in the setting of left-sided heart disease or parenchymal lung disease may be a good starting point.

Acknowledgments

The authors wish to acknowledge the previous contributions of Dr. Stuart Rich, which have laid the foundation for this chapter, and Kristin Kalasho, for her administrative support.

Collaborative Care of the Pulmonary Arterial Hypertension Patient

Because of the delay from the onset of symptoms to the diagnosis of pulmonary arterial hypertension (PAH), greater awareness in the community is required to achieve an earlier diagnosis. Some community settings may be equipped to perform a thorough diagnostic evaluation, including right heart catheterization with vasodilator testing, but others may not. An open dialogue with a pulmonary hypertension (PH) center will help facilitate a correct and timely diagnosis in instances where local expertise is not available.

Given the complexities of the diagnosis, and the cost and side effect profile of the therapies, referral to a PH center for confirmation of the diagnosis and comanagement of the patient should be considered. A series describing new referrals to three PH specialty centers demonstrated that patients are referred late and have functional class 3 and 4 symptoms more than half of the time; the diagnosis is often incorrect (nearly half of patients receive a different diagnosis after evaluation at the referral center); and PAH-specific therapy is commonly started inappropriately.[1] In fact, 30% of patients received PAH-specific therapies before referral, and 57% of the time the use of PAH-specific therapy was not in accordance with PH guidelines.

The PH center often can provide specialized care that is not available in the community. PH nurse clinicians are critical in the management of PAH patients. They provide vital education regarding the disease and its therapies, and maintain an active role in case management to titrate medications, monitor side effects, and recognize complications. Access to clinical research trials and advanced treatment options, such as parenteral prostacyclins and lung or heart-lung transplantation, is an important aspect of the level of care available at PH centers.

Collaboration is key, and it is incumbent upon the PH center to maintain an open dialogue with the local health care providers. The primary care physician, local cardiologist, or pulmonologist must be kept up to date on the patient's status and their therapies because he or she may be the first physician to encounter a complication of PAH therapy (e.g., a line infection), recognize disease progression (e.g., fluid retention and right heart failure), or diagnose a new problem (e.g., pneumonia). Because many patients live far from a PH center, comanagement of such issues is in the best interests of the patient.

Targeted Medical Therapy After Pulmonary Endarterectomy

The use of targeted therapy in operable patients with severe hemodynamic compromise as a bridge to pulmonary endarterectomy has not yet been supported by scientific evidence. The dual endothelin antagonist bosentan was evaluated in 157 patients with inoperable chronic thromboembolic pulmonary hypertension (CTEPH), or persistent/recurrent PH after pulmonary endarterectomy, over 16 weeks. This study demonstrated a positive treatment effect of bosentan on hemodynamics, but no improvement was observed in exercise capacity in CTEPH.[1] Thus it was decided to propose further clinical trials to better define the role of medical therapy in patients with CTEPH. In the CHEST-1 study, riociguat was administered to 261 of 446 screened patients with inoperable CTEPH, or persistent/recurrent PH after pulmonary endarterectomy, for 16 weeks, and its use led to a mean increase of 39 meters in the 6MW distance ($P < 0.001$; primary endpoint) and to a least-squares mean difference of 246 dynes.cm.s^{-5} in the pulmonary vascular resistance (PVR; $P < 0.001$, secondary endpoint); the time to clinical worsening remained unchanged.[2] Eligible patients (n = 237) from the CHEST-1 study entered the CHEST-2 open-label extension study, in which all patients received riociguat individually adjusted to a maximum dosage of 2·5 mg three times per day. At 2 years, the overall survival rate was 93%.[3] Preoperative medical treatment is uncertain because the magnitude of effects was small in one RCT.[4] Prospective randomized controlled trials are needed in patients with potential treatment benefit, for example, patients with a high PVR and technically challenging anatomy.

In 2001 Feinstein and Landzberg published a report of 18 patients with nonoperable CTEPH who they subjected to balloon dilation of the pulmonary arteries. Despite a significant decrease of mPAP, 11 patients developed reperfusion pulmonary edema and 3 required mechanical ventilation. Recently, Japanese investigators have refined balloon pulmonary angioplasty (BPA) by using smaller balloons, by cautiously limiting the number of balloon inflations per session to one or two pulmonary vascular segments, and by the use of intravascular imaging.[5] An average number of 4.8 sessions is needed per patient to improve parameters of right ventricular function. Several complications, such as hemoptysis, hemorrhage, and reperfusion edema, have been reported after BPA. A high mPAP, a first BPA session, and severe hemodynamics are the main risk factors for pulmonary edema. Prevention and management of complications are important, including a careful stepwise approach to reduce the risk of reperfusion edema. Limiting the blood flow by using undersized balloons for pulmonary artery dilation may reduce the reperfusion vascular insults at initial sessions. At subsequent sessions, when the hemodynamic conditions are less severe, a balloon of the proper size can be used for dilation of the vessels. Such a careful approach, with targeting of only one lobe during each session and cautious balloon sizing, has reduced the incidence of complications such as hemoptysis and reperfusion pulmonary edema to 2% in individual centers. Further studies should evaluate the benefits of medical treatment before BPA. Nasal continuous positive airway pressure or nasal high-flow oxygen therapy is used to treat mild to moderate hypoxemia in reperfusion edema. A critical complication in BPA is pulmonary artery perforation, which may lead to severe lung hemorrhage and death. Proper wire positioning and knuckle wire techniques may be helpful to reduce pulmonary perforation. Using a balloon of disproportionate size to the vessel could be a risk for pulmonary artery rupture. Stent implantation to prevent restenosis in BPA for CTEPH is not necessary, and no obvious restenosis or recurrence has been reported after BPA to date.[6]

BPA is not currently extensively used, but it is rapidly gaining attention worldwide. This investigational procedure should be performed only by experienced persons in centers that treat many

CTEPH patients. Independent evaluations are needed to define its short- and long-term efficacy and safety.

Systemic Disorders Causing Type 5 Pulmonary Arterial Hypertension

Lymphangioleiomyomatosis

Lymphangioleiomyomatosis is a rare multisystem disorder affecting women that is characterized by cystic lung destruction, lymphatic abnormalities, and abdominal tumors (angiomyolipoma). Pulmonary hypertension (PH) of mild hemodynamic severity may occur in these patients, even with mild impairment in pulmonary function. *Neurofibromatosis type 1* (also known as *von Recklinghausen disease*) is an autosomal dominant disease that can be recognized by characteristic café au lait skin lesions and cutaneous fibromas. Cases of PH have been reported that may be due to *chronic thromboembolic pulmonary hypertension* (CTEPH), as well as to *comorbid lung disease*. In rare cases, histologic examination has found pulmonary vascular disease involving arteries and veins. Very rare cases of PH have been observed in patients with *antineutrophil cytoplasmic antibody (ANCA)–associated vasculitis*, with the clinical features being similar to those of PAH.

Metabolic Disorders

PH may occur in *type Ia glycogen storage disease*, a rare autosomal recessive disorder caused by a deficiency of glucose-6-phosphatase. The mechanisms of PH are uncertain; portacaval shunts, atrial septal defects, severe restrictive pulmonary disease, and thromboembolic disease are thought to play a role. Plexiform lesions have been reported in a postmortem study of a single patient.

Gaucher disease, a rare disorder attributable to a deficiency of lysosomal B glucosidase, causes an accumulation of glucocerebroside in reticuloendothelial cells. PH has been reported in these patients; several potential mechanisms are thought to be involved (interstitial lung disease, chronic hypoxia, capillary plugging by Gaucher cells, and splenectomy).

The association of *thyroid diseases* and PH has been reported in a number of studies. The high prevalence of autoimmune hypothyroidism and hyperthyroidism suggest that these conditions may share a common (auto)immune susceptibility.

Metastatic Tumor Emboli

Occlusion of the microvasculature by metastatic tumor emboli represents another cause of rapidly progressive PH. Severe hypoxemia is often observed in such cases. High-resolution CT of the chest frequently shows thickening of septa. In contrast, a ventilation-perfusion lung scan may show multiple subsegmental perfusion defects. Pulmonary microvascular cytologic sampling through a pulmonary artery catheter in the wedge position is an important diagnostic tool. Most reported cases occur in association with breast, lung, or gastric cancer.

Chronic Lung Diseases and Cardiovascular Disease

Surya P. Bhatt, Mark T. Dransfield

Chronic lung diseases (CLDs) encompass the spectrum of obstructive and restrictive lung disorders. Both major categories are highly prevalent in the population and are associated with substantial rates of morbidity and mortality. Although each pulmonary disease has a specific etiopathogenic pathway, there is substantial overlap in these pathways, as well as increasing recognition that the inflammatory state associated with these disorders is not confined to the lungs but extends to the systemic circulation, with effects on extrapulmonary organs, especially the cardiovascular system. The natural history of these CLDs is punctuated by acute exacerbations during which the inflammatory state is heightened. Although the mortality rate of cardiovascular disease is declining, that is not the case for CLD; CLD is now the third leading cause of death in the United States and the only chronic disease category for which the mortality rate continues to rise.[1,2] The most important risk factors for CLD are cigarette smoking, age, and environmental exposure to pollutants (**see also Chapter 52**). Although these risk factors are also the most common ones for cardiovascular disease, multiple recent studies have shown that cardiovascular disease

is more frequent in CLD independent of these shared risk factors.[3,4] There is also an overlap in disease presentation, symptoms, clinical examination findings, and diagnostic test results as well as a number of important medication interactions, adding significant complexity to the care of these patients. In addition, cardiovascular disease frequently contributes to exacerbations and hospitalizations in patients with CLD. Approximately half the patients with CLD remain undiagnosed, and it is probable that greater awareness of the overlapping manifestations of CLD and cardiovascular disease can help identify both disorders earlier and perhaps reduce the associated morbidity. Most of the current published evidence regarding the prevalence, impact, diagnosis, and treatment of cardiovascular disease in patients with CLD is for chronic obstructive pulmonary disease (COPD), though recent reports suggest that cardiac disease is an important comorbidity in patients with other CLDs as well.

Chronic Obstructive Pulmonary Disease

Epidemiology of COPD and Associated Cardiovascular Disease

COPD is a chronic inflammatory disease of the lungs characterized by partially reversible airflow obstruction. Approximately 8% of people in the United States have COPD.[2] The age-adjusted prevalence of coronary artery disease (CAD) in the United States is 6%, and about 1.7% of the population has congestive heart failure (CHF). Given the aging population and greater longevity, it is expected that many of these chronic diseases coexist; however, a number of cardiovascular diseases occur at a greater frequency in patients with COPD than in the general population.[1]

Coronary Artery Disease (see Chapters 59 to 61)

COPD and CAD share multiple risk factors, including older age and cigarette smoking; however, these do not fully account for the increased risk of CAD in COPD. There is a dose-response relationship between a low forced expiratory volume in the first second (FEV_1) and cardiovascular mortality rates. Results from the Lung Health Study showed that the adjusted cardiovascular mortality rate increases by 28% for every 10% reduction in FEV_1. Although FEV_1 is not part of the traditional Framingham Study risk factors for CAD, the Renfrew and Paisley prospective population study reported that approximately one fourth of the attributable risk for death due to CAD is due to a low FEV_1, placing reduced lung function very high on the list of cardiovascular risk factors. Epidemiologic studies have shown that CAD occurs 2 to 5 times more frequently in COPD patients than in controls, and this relationship holds even after adjusting for shared risk factors. As is the case in the general population, COPD is underrecognized in patients with CAD, with approximately half of the patients remaining undiagnosed. There are no population-level data for the prevalence of COPD in patients with CAD, but data from clinical studies suggest that this ranges from 7% to 34%.[1]

Congestive Heart Failure (see Chapter 24)

Poor lung function is also a risk factor for CHF; a low FEV_1 is associated with incident heart failure and an increased risk of hospitalization due to heart failure. Cross-sectional studies have shown that up to one fifth of COPD patients have undiagnosed heart failure. Heart failure with preserved left ventricular ejection fraction (HFpEF) occurs in approximately 5% of COPD patients, with a higher prevalence in

older patients, and subclinical diastolic dysfunction has been reported in up to 75% of COPD patients. The prevalence of COPD in patients with heart failure is also high, with estimates ranging from 11% to 55%.[5]

Cerebrovascular and Peripheral Arterial Disease (see also Chapters 64 and 65)

Multiple epidemiologic studies have demonstrated an inverse relationship between FEV_1 and ischemic stroke. Data from the Copenhagen City Heart Study show that the risk of ischemic stroke increases by 5% for every 10% decrease in FEV_1, after adjustment for cardiovascular risk factors. The relationship between COPD with demonstrated airflow obstruction and ischemic stroke is weaker, though current evidence suggests there is a higher risk than in the general population. Peripheral arterial disease and aortic aneurysms are also common in COPD, with small studies demonstrating that up to one third of patients with COPD have peripheral arterial disease.[1]

Cardiac Arrhythmias (see also Chapters 37 to 39)

Supraventricular and ventricular arrhythmias are common in COPD and are more frequent than in matched controls.[6] Multifocal atrial tachycardia is almost exclusively seen in patients with COPD. Twenty-four-hour monitoring of stable but hypoxemic COPD patients shows a high frequency of various electrocardiographic abnormalities, including supraventricular tachycardia (69%), ventricular premature beats (83%), ventricular bigeminy (68%), and nonsustained ventricular tachycardia (22%). Low FEV_1 is also associated with incident atrial fibrillation.[6]

Pathophysiology of Cardiovascular Disease in COPD

Although COPD and cardiovascular disease share multiple risk factors, these do not fully account for the increased occurrence of CAD in COPD. Multiple overlapping pathobiologic pathways are likely involved in the development of both COPD and CAD (**Table 86.1**). These same mechanisms are important in the pathogenesis of other cardiovascular morbidities seen in COPD, including cerebrovascular and peripheral arterial disease.

TABLE 86.1

Cardiovascular Risk Factors in Chronic Lung Disease

TRADITIONAL OR SHARED RISK FACTORS	OVERLAPPING PATHWAYS
Cigarette smoking	Systemic inflammation
Aging and senescence	Oxidative stress
Environmental pollutants	Prothrombotic state
Sex	Activated renin-angiotensin system
Diet	Genetics
	Sedentarism

Coronary Artery Disease

The major pathogenetic mechanism for CAD is atherosclerosis. Multiple studies have shown an inverse relationship between the age-adjusted FEV_1 and carotid intima-media thickness. Carotid plaques, especially vulnerable lipid-rich ones, are more frequently seen in COPD patients than in smokers without

airflow obstruction and nonsmokers.[7] Patients with COPD have greater arterial stiffness as measured by aortic pulse wave velocity, after adjustment for age and smoking. The degree of emphysema seen on computed tomography is independently associated with thoracic aortic as well as coronary artery calcification. Indeed, COPD can be considered a proatherosclerotic condition, much like some autoimmune diseases such as rheumatoid arthritis and systemic lupus erythematosus, with a magnitude of risk equivalent to or greater than other proinflammatory conditions such as diabetes mellitus and chronic kidney disease.[8] Although the mechanistic pathways for accelerated atherosclerosis in COPD remain unclear, a number of overlapping mechanisms have been implicated (**Fig. 86.1 and see Table 86.1**).

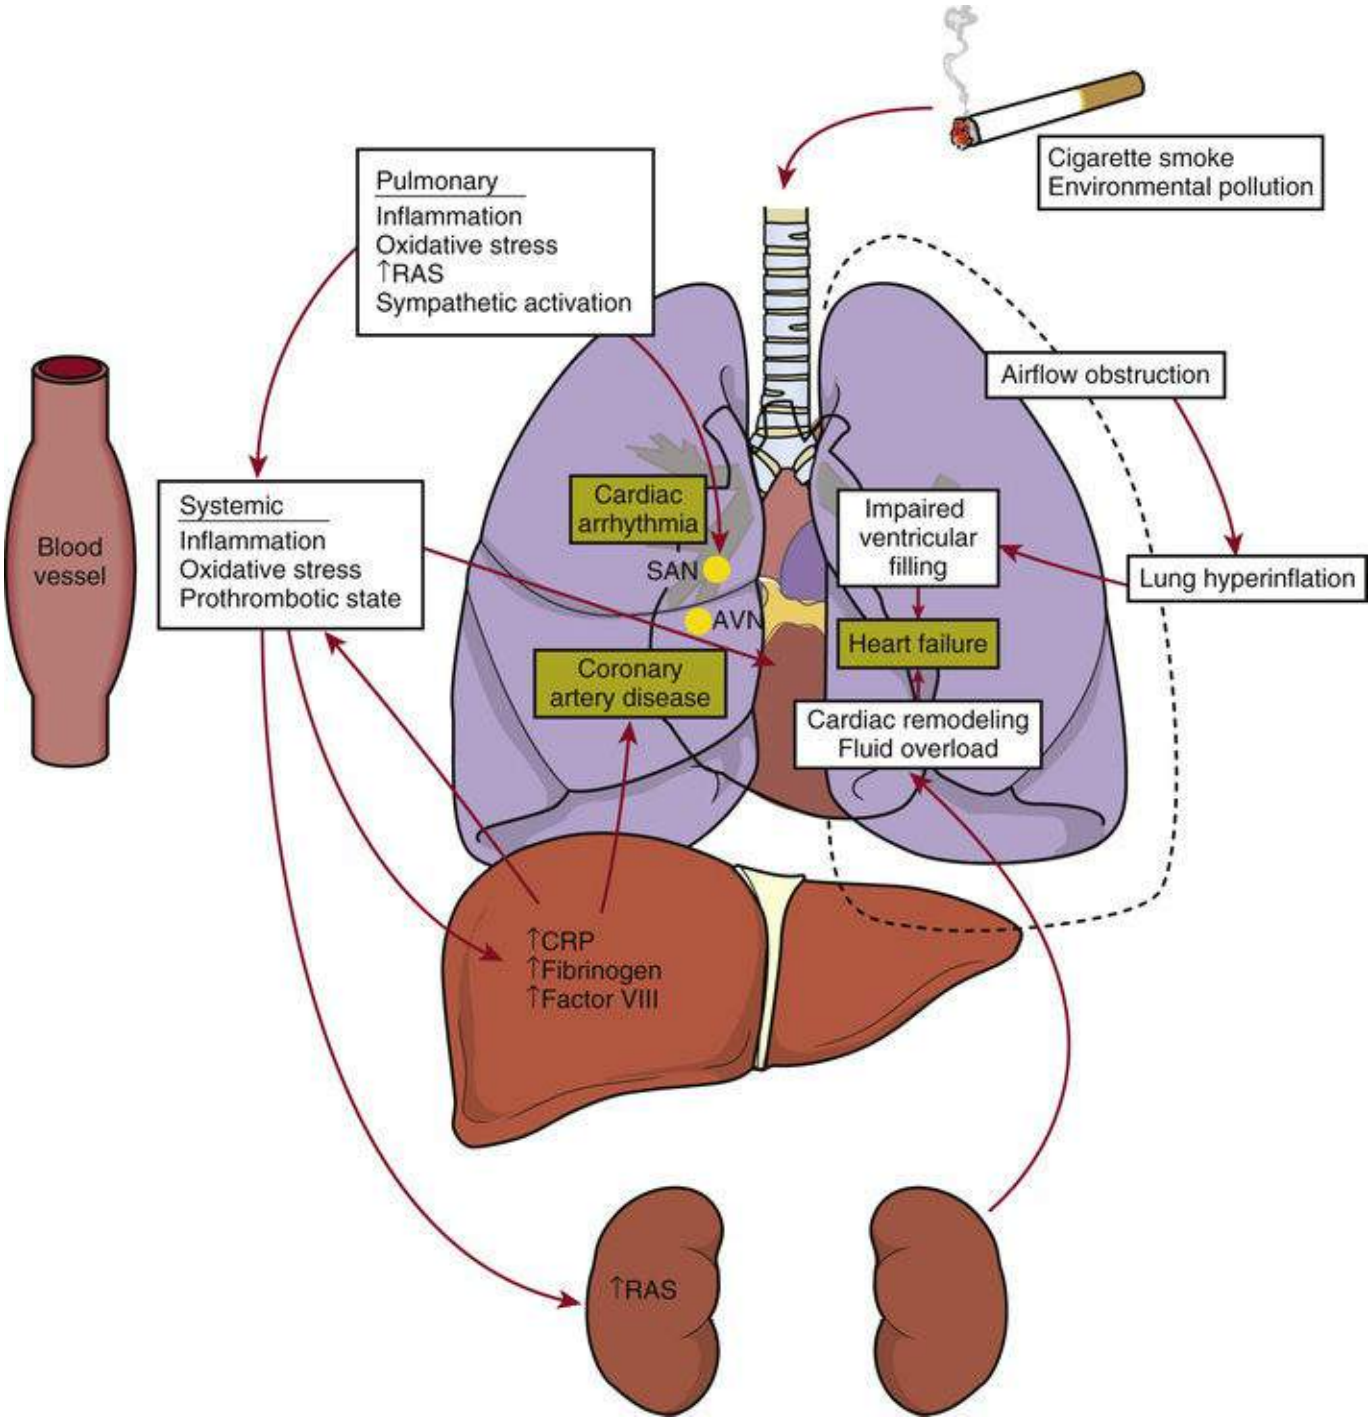

FIGURE 86.1 Possible overlapping pathways of cardiovascular disease in chronic lung disease. *Coronary artery disease*: Cigarette smoke and environmental agents induce inflammation as well as oxidative stress in the lungs, which translocates into the systemic circulation. Cytokines such as interleukins, tumor necrosis factor, and granulocyte macrophage colony–stimulating factor, as well as reactive oxygen species, can stimulate the liver to produce acute-phase reactants such as C-reactive protein and procoagulants such as fibrinogen and factor VIII. They can also induce the bone marrow to release inflammatory cells such as leukocytes and monocytes, as well as platelets. In addition, chronic hypoxia induces activation of the renin-angiotensin system and upregulation of the sympathetic nervous system, both of which can contribute to endothelial dysfunction. These multiple factors can result in increased expression of adhesion molecules on the vascular endothelium (intercellular adhesion molecule [ICAM] and vascular cell adhesion molecule [VCAM]), which in turn stimulate chemotaxis of monocytes and macrophages into the vascular intima, platelet aggregation and greater uptake of oxidized low-density lipoprotein (ox-LDL) and formation of lipid-rich plaques. *Heart failure*: Air trapping and lung hyperinflation can cause diastolic dysfunction and impaired ventricular filling. Coronary artery disease and activation of the renin-angiotensin system can result in cardiac remodeling and congestive heart failure. *Cardiac arrhythmias*: Sympathetic activation, either resulting from chronic hypoxemia or due to medication effects, can result in supraventricular and ventricular arrhythmias.

Shared Risk Factors

Aging and Senescence.

The prevalence of both COPD and CAD increases with age. COPD is about 6 times more frequent in persons older than 70 years as in those age 40 to 49 years; CAD is seen 17 times more frequently in those older than 65 years than in those age 18 to 44 years. Advancing age is associated with chronic inflammation, oxidative stress, progressive telomeric shortening, and impaired capacity of tissues to repair damage, factors associated with cellular senescence and implicated in vascular aging as well as emphysema. This process is accelerated by environmental agents, including cigarette smoking.[1]

Cigarette Smoking.

The strongest risk factor for COPD is cigarette smoking, which is also a major risk factor for CAD. Cigarette smokers have a 15% to 50% lifetime risk of developing COPD, and the population-attributable risk is 50% to 70%. It should be noted that approximately a third to half of the COPD cases worldwide occur in lifetime never smokers.[9] Second-hand smoke exposure also increases the risk of developing airflow obstruction 1.5 fold. In developing countries, biomass fuel exposure is associated with a 2.5 times greater risk of COPD than in matched controls. Both these types of non–active smoking–related exposures are also risk factors for CAD.

Environmental Pollutants.

Exposure to particulate matter (PM) and gaseous pollutants increases the risk of developing COPD,[10] and the population-attributable risk for COPD from occupational exposure to dusts is approximately 19%, and up to 30% in never smokers. These exposures are also associated with an increase in acute coronary events, as well as progressive atherosclerotic heart disease. Chronic residence in areas with high levels of PM is associated with a higher mortality rate resulting from COPD (hazard ratio, 1.22 per 10 $\mu g/m^3$ increase in PM10); a similar increase in mortality rates has also been observed for CAD.

Sex.

Although COPD is generally considered to be a disease of older men, recent data suggest there may be greater susceptibility to cigarette smoke in women. For an equivalent smoking exposure burden, more women develop COPD than men; this difference could also be the result of the smaller airways in women. Similarly, although men have a higher incidence of CAD than women, recent data suggest that women may be more susceptible to the harmful vascular effects of cigarette smoking than men.[11]

Diet.

Multiple studies have suggested a weak link between the intake of various dietary factors and the loss of lung function. In population-based studies, a higher intake of vitamins C, D, and E, carotenoids, flavonoids, and fruits rich in antioxidants have all been reported to slow the rate of age-related lung function decline; however, supplementation of these dietary factors has not been demonstrated to improve lung function.[12] Similarly, antioxidant supplementation, vitamins C and E, beta carotene, and omega-3 fatty acids have all been reported to decrease the occurrence of CAD in nonrandomized trials.

Overlapping Pathobiologic Pathways (see Fig. 86.1)

Atherosclerosis and Inflammation

Multiple studies have documented heightened systemic inflammation in COPD, and systemic inflammation is well established as a major factor in the development and progression of atherosclerosis. COPD is associated with chronic low-grade systemic inflammation that likely stems from ongoing pulmonary inflammation. In vivo experiments in rabbits exposed to particulate matter have shown that there is a marked increase in vulnerable plaques even in the absence of dyslipidemia, and this is associated with pulmonary and systemic inflammation. These effects are mediated by airway epithelial cells and macrophages that release proinflammatory mediators, such as interleukin-1, interleukin-6, tumor necrosis factor-α, interleukin-8, and granulocyte macrophage–colony stimulating factor. The resultant pulmonary inflammation translocates into the systemic circulation, stimulating the liver to produce acute phase reactants such as C-reactive protein and procoagulants, including factor VIII and fibrinogen, and leading to a chronic, low-grade systemic inflammatory state. The lungs are constantly exposed to environmental agents, including cigarette smoke, air pollutants, and infectious agents, all of which can cause a chronic inflammatory condition.[13] The data for direct associations between markers of systemic inflammation and measures of atherosclerosis in COPD are, however, sparse and with weak correlations.

Oxidative Stress

A close relationship exists between inflammation and oxidative stress. Inflammation in the lungs is associated with a disturbance in the oxidant-antioxidant balance, with a rise in oxidative stress.[13] Reactive oxygen species cause oxidative injury to cells, resulting in up-regulation of proinflammatory mediators both in the lungs and systemically. Oxidative stress also causes lipid peroxidation, and the resulting oxidized low-density lipoprotein is an important mediator of atherosclerosis.

Prothrombotic State

The low-grade systemic inflammation seen in COPD can also result in a prothrombotic state. COPD patients have decreased platelet volume and higher platelet counts compared with matched controls, and these are associated with a lower response to antiplatelet agents. COPD is also associated with increased levels of prothrombin and coagulation factors II, V, VII, VIII and IX, and with lower levels of tissue factor pathway inhibitor. These changes are associated with a greater predisposition to thrombin generation.[14]

Genetics

Multiple genetic associations exist for pathways of inflammation and oxidative stress common to COPD and CVD.[15] Both conditions are characterized by accelerated aging, the result of accumulated DNA damage and telomere shortening. A number of other mechanisms are likely involved with shared genetic associations. For instance, glutathione-S-transferase, an important mediator of oxidative stress in COPD, has also been implicated in atherosclerosis; matrix metalloproteinases cause proteolysis and damage to the alveolar wall, and are also involved in early atherosclerosis and plaque rupture.

Renin-Angiotensin System

The lungs have high concentrations of angiotensin-converting enzyme, and chronic hypoxia can activate the renin-angiotensin system, which has potent proinflammatory and profibrotic effects.[1] Up-regulation of the renin-angiotensin system also causes endothelial dysfunction and may lead to vasoconstriction and thrombosis. Renin-angiotensin system activation has also been implicated in atherosclerosis.

Sedentarism

Physical activity is a modifiable behavior associated with COPD outcomes. Physical activity progressively declines with worsening disease severity and is a strong predictor of all-cause mortality rates in COPD, as well as in patients with CAD. Sedentary habits are strongly associated with CAD, and it remains to be investigated if low physical activity is just a consequence of disease severity in COPD or if physical activity alters disease progression.[16]

Heart Failure

CAD is the most important risk factor for systolic heart failure; with the accelerated atherosclerosis frequently observed in COPD, coronary ischemia is the most likely pathogenetic mechanism for the greater frequency of heart failure reported in COPD. Coronary ischemia also likely results in diastolic dysfunction, and activation of the renin angiotensin system also has a role in cardiac dysfunction and remodeling. A substantial proportion of patients with COPD have static and dynamic hyperinflation. Static hyperinflation is characterized by a reduced inspiratory capacity to total lung capacity at rest, and is associated with a reduced cardiac chamber size and impaired left ventricular diastolic filling.[17] Dynamic hyperinflation is reflective of air trapping during exertion, and this has a strong inverse correlation with the oxygen pulse, an estimate of stroke volume, on cardiopulmonary exercise testing, suggesting a lower stroke volume as the thoracic lung volume increases. The mechanisms underlying the effects of lung hyperinflation on cardiac performance are likely related to the effect on ventricular filling, reduced venous return, or associated dyspnea, resulting in activation of the renin-angiotensin system, salt and fluid retention by the kidneys, and relative volume overload. Severe COPD is also associated with right heart dysfunction, which when severe can result in a septal bulge toward the left ventricle and impair left ventricular filling. Pulmonary hypertension is frequently seen (**see Chapter 85**) but is rarely severe, and can cause impaired left ventricular filling even in patients with only mildly elevated pulmonary arterial pressures.[18]

Cardiac Arrhythmias

Patients with COPD frequently have acid-base abnormalities as well as hypoxemia and hypercapnia, all risk factors for supraventricular and ventricular arrhythmias. These abnormalities are more commonly seen in either late stages of the disease or during acute exacerbations. A substantial number of COPD patients, even with milder disease, have autonomic neuropathy; this is associated with a prolonged QTc interval and a greater risk of ventricular arrhythmias. COPD is characterized by an increased sympathetic tone, with a higher resting heart rate compared with age-matched controls. A number of medications, including β-agonists, anticholinergics, and theophylline, may also be proarrhythmogenic. These are discussed further in the section on Medication Interactions.

Clinical Manifestations: Overlap and Diagnosis

COPD is characterized by one or more of the following: chronic cough, sputum production, wheezing, and dyspnea on exertion or at rest. Patients with severe disease can also have paroxysmal nocturnal dyspnea. These symptoms are nonspecific and the diagnosis should always be confirmed by spirometry. Spirometry involves a forced exhalation maneuver from maximal inhalation (total lung capacity) to maximal exhalation (residual volume), with the volume of gas expired defined as the forced vital capacity (FVC). The volume of air exhaled in the first 1 second of this maneuver, or forced expiratory volume (FEV_1),

falls with increasing disease severity and airflow obstruction. The diagnostic hallmark of COPD is the demonstration of a reduced ratio of FEV_1 to FVC of less than 0.70, or less than the lower limit of normal as defined by normative population reference values, in the presence of symptoms.

Patients with COPD and cardiovascular disease are often seen by both cardiologists and pulmonologists, who frequently miss the diagnosis that does not belong to their specialty. This is both due to a lack of awareness as well as the substantial overlap in symptoms. COPD, CAD, and heart failure can all present with exertional dyspnea. In addition to dyspnea, COPD and heart failure share other common symptoms, such as cough and wheezing, and sometimes nocturnal cough and paroxysmal nocturnal dyspnea. These are symptoms common to both systolic heart failure and HFpEF. Peripheral edema is also commonly seen in both heart failure and COPD, particularly when the latter is severe and associated with cor pulmonale. In patients with an established diagnosis of one condition, the symptoms of the other are commonly overlooked and ascribed to the primary condition. In patients with symptoms that are disproportionate to the severity of the underlying disease, coexisting lung and cardiovascular disease should be suspected and investigated.

In the majority of patients, COPD can be differentiated from cardiovascular disease with a thorough history and physical examination, supported by appropriate laboratory and radiographic studies, including chest radiographs, spirometry, two-dimensional (2D) echocardiography, blood biomarkers such as troponins and brain natriuretic protein, and resting and stress electrocardiography. Although the lungs are poor conductors of ultrasound, recent studies have demonstrated that lung ultrasound artifacts can be used to detect pulmonary edema and differentiate CHF from COPD in acute settings.[19] Spirometric confirmation of airflow obstruction is necessary for a definitive diagnosis of COPD, which should not be made on the basis of the smoking history and symptoms alone. Although differentiation of these conditions is frequently possible, physiologic changes associated with heart failure can confound the detection and severity grading of airflow obstruction. Interstitial edema can manifest as a reduction in FVC and thus an artificially elevated FEV_1/FVC ratio (pseudorestrictive pattern). Peribronchial edema can cause bronchial hyperreactivity and bronchoconstriction, resulting in airflow obstruction (cardiac asthma). For these reasons, it is recommended that spirometric evaluation of lung disease be done when the patient is as euvolemic as possible. Lung volumes are often elevated in COPD and reduced with heart failure, and plethysmography estimation of total lung capacity may be useful in differentiating the two conditions, although significant overlap of lung volumes in these conditions reduces specificity. The diffusing capacity of carbon monoxide (DLCO) is a surrogate for oxygen transfer through the blood-alveolar barrier and is more likely to be low in patients with emphysema than in heart failure patients, in whom the DLCO is frequently normal or elevated due to increased intrapulmonary blood volume. In some patients with coexisting severe disease, cardiopulmonary exercise testing may become necessary to understand the relative contributions of each disease to exercise limitation.

Treatment and Medication Interactions

Most guideline documents now agree that the treatment of COPD and cardiovascular disease should follow standard recommendations for each disease. Nonpharmacologic therapy with pulmonary rehabilitation is associated with significant improvement in dyspnea, respiratory quality of life, and exercise capacity, independent of severity of lung disease, and the presence of cardiac comorbidity should not be considered a contraindication for exercise training (**see Chapter 53**); rehabilitation exercises have clear benefits in cardiovascular disease as well. The mainstays of pharmacologic therapy for COPD are inhaled bronchodilators, including β-agonist and anticholinergic medications, and inhaled

corticosteroids in those with more advanced disease and frequent exacerbations. Although these medications alleviate dyspnea and improve exercise capacity and respiratory quality of life, there remains debate about whether some of these medications increase the risk of cardiovascular events.[20] Large population studies, albeit retrospective, have found a 1.5 to 4.5 times increased incidence of arrhythmias with the use of the short-acting β-agonist medications. A similarly increased risk of arrhythmias has also been reported for long-acting β-agonists. The data for the short-acting anticholinergic drug ipratropium are mixed, with some but not all studies showing a slightly greater risk of arrhythmias. Although metaanalyses of safety data for long-acting antimuscarinics such as tiotropium suggested a greater risk of arrhythmias in those with significant underlying cardiac disease, a recent large randomized controlled study to address safety issues found that there is no increased risk of arrhythmias with the use of tiotropium, even in those with established cardiac disease.[21] Post hoc safety studies have also suggested that the risk of cardiac events and mortality is not increased by tiotropium, although clinical studies excluded those with recent cardiac events or with unstable cardiac disease, in whom caution should be exercised.[22]

There are also reports of increased hospitalizations in CHF patients treated with inhaled β-agonist medications. Use of theophylline and oral steroids is also associated with atrial fibrillation (**see also Chapter 38**). Pooled analyses suggest that roflumilast, a selective phosphodiesterase-4 inhibitor, has a safe cardiac profile, but post-approval phase 4 data are not yet available.[23] Azithromycin is used to prevent frequent exacerbations and can cause prolongation of the QT interval (**see also Chapters 32 and 33**). Retrospective data suggesting there might be an increased risk of arrhythmias with the use of azithromycin provoked the issuance of a black box warning from the U.S. Food and Drug Administration. However, multiple large randomized studies did not report adverse cardiac effects; these studies excluded patients with a prolonged QTc interval, and this safety precaution is now recommended in clinical practice.

Multiple cardiac medications are also frequently used in patients with COPD. There is notable concern for worsening airflow obstruction with the use of beta blockers, although clinical trials suggest this is clinically not significant, especially for cardioselective medications. Indeed, the use of cardioselective beta blockers in COPD is associated with improved survival rates, both over the long term and when continued during acute exacerbations. Retrospective data also suggest that their use is associated with a reduction in exacerbation frequency, likely due to their cardioprotective effects, although this remains to be confirmed in randomized trials. Retrospective studies also suggest a beneficial effect on exacerbation frequency with the use of statins, angiotensin-converting enzyme inhibitors, and angiotensin receptor blockers; however, a large randomized study failed to show any benefits of statins on exacerbation rates.[1]

Acute Exacerbations

The natural history of COPD is punctuated by episodes of acute exacerbation of symptoms, which often result in hospitalization, significantly affect the quality of life and accelerate the decline of lung function, and are associated with substantial short- and long-term risks of mortality. These exacerbations are associated with heightened pulmonary and systemic inflammation, increased oxidative stress, increased sympathetic tone, lung hyperinflation, and cardiac arrhythmias. Exaggerated signals along these pathways confer a greater risk of coronary ischemia, rupture of vulnerable plaques, ventricular cardiac arrhythmias, and heart failure. The risk of an acute myocardial infraction 1 to 5 days after an exacerbation is doubled, and subclinical ischemia is likely more common.[24] Indeed, levels of troponin and N-terminal brain natriuretic protein are elevated during exacerbations and are both associated with higher mortality rates.

Diastolic dysfunction is common in stable COPD and can decompensate in the setting of subclinical or clinically detected cardiac arrhythmias. Congestion along the peribronchovascular bundle can increase airway reactivity and cause a decompensation in respiratory status that can be clinically difficult to distinguish from usual acute exacerbations.

Prognosis

The coexistence of cardiac disease and COPD frequently results in poorer outcomes. Approximately half the patients with COPD die of cardiovascular disease. The presence of heart failure approximately doubles the 4-year mortality risk in COPD. Patients with diastolic dysfunction have a greater frequency of COPD exacerbations, and severe exacerbations are associated with diastolic dysfunction in about a third of patients. COPD also has an adverse impact on cardiovascular outcomes, and is associated with a two-fold increased frequency of hospitalizations due to angina and myocardial infarction. COPD is also associated with a considerably greater risk of rehospitalization and death after myocardial infarction.

Interstitial Lung Disease

Interstitial lung diseases (ILDs) are a heterogeneous group of diffuse parenchymal lung disorders that are linked by genetic susceptibility, environmental exposures including cigarette smoking, and aging, and characterized by varying degrees of inflammation and fibrosis of the lung parenchyma, resulting in progressive loss of lung function and death. The major categories of ILD are idiopathic pulmonary fibrosis (IPF) and nonspecific interstitial pneumonitis (NSIP), which is now recognized as a distinct entity. Other rarer ILDs include smoking-related interstitial pneumonitis and acute and subacute interstitial pneumonitis. NSIPs are either idiopathic or seen in association with collagen vascular diseases, hypersensitivity pneumonitis, and drug toxicity. Cardiovascular disease associated with connective tissue diseases is described elsewhere (**see Chapter 94**). This section focuses on IPF, the major type of ILD and that with the worst long-term prognosis.

IPF has a prevalence of 13 to 42 cases per 100,000 in the United States, and although prevalence data are scarce for non-IPF ILDs, these in combination are likely more prevalent.[25] Indeed, in populations at risk for ILD, such as smokers, the rate of interstitial lung abnormalities visualized on computed tomography (CT) scans can be as high as 10%.[26] IPF is associated with the same type of cardiac comorbidities as COPD. Arrhythmias are reported in about one fifth, CHF in 4% to 26%, and CAD in 3% to 68%, depending on the disease severity.[4] Similar to COPD, IPF has been identified as an independent risk factor for developing CAD, and the risk might be greater for IPF for similar levels of smoking exposure. The mechanisms for this association are similar to those reported for COPD, with upregulation of inflammatory and oxidative pathways. Cardiovascular disease is second only to respiratory failure as a cause of death in IPF patients, with 25% dying of cardiac causes, and a diagnosis of ILD prompt a careful evaluation for cardiac disease.[27]

ILDs usually present with symptoms of chronic dry cough and exertional dyspnea. Clinical examination usually reveals Velcro-like crackles at lung bases, which can be mistaken for the basilar crackles heard in heart failure. Pulmonary function tests show a restrictive defect on spirometry ($FEV_1/FVC > 0.70$ and FVC < 80% predicted); restrictive defects should be confirmed with lung volume measurements. CT can usually differentiate IPF from heart failure based on the predominant pleural-based basal interstitial opacities without pleural effusion, although this may not be straightforward when the two diseases

coexist. The definitive diagnostic test for IPF is lung biopsy. There is no known cure for IPF, although two recently approved oral drugs, pirfenidone and nintedanib, can slow disease progression. Nintedanib is a tyrosine kinase inhibitor, and there are reports of QT prolongation, left ventricular dysfunction, hypertension, and arterial thrombosis associated with the use of tyrosine kinase inhibitors, although most of the data were derived from their use in cancer patients.

Bronchial Asthma

Bronchial asthma is a chronic inflammatory disease of the airways characterized by reversible airflow obstruction. Although bronchodilator reversibility is useful to support a diagnosis of asthma, this is not sufficiently specific to differentiate asthma from COPD, which can still be associated with bronchodilator reversibility in approximately 40% of patients. The prevalence of asthma is approximately 8% in the United States. Although asthma is also associated with chronic inflammation and data to support a relationship between chronic asthma and cardiovascular disease are scarce, the CAD risk appears to be slightly greater than in the general population after adjustment for other cardiac risk factors.[28]

Lung function findings in bronchial asthma usually include airflow obstruction that is reversible on administering bronchodilators. Patients with mild asthma may have normal spirometry, and those with severe uncontrolled asthma may have airflow obstruction that does not fully reverse with bronchodilators, similar to COPD. Bronchial asthma is often readily diagnosed by the history, physical examination, and spirometry when it occurs early in life. However, older patients presenting with cough, wheezing, and nocturnal dyspnea should be additionally evaluated for cardiac causes. Congestion along the bronchovascular bundle in patients with left ventricular failure may result in cardiac asthma. Cardiac asthma is diagnosed clinically, although mild or negative bronchoprovocation test results with methacholine support the diagnosis. Although the data to support the use of bronchodilators for cardiac asthma are scant, a trial of bronchodilators is often recommended to determine if bronchial asthma coexists. Treatment of cardiac asthma is primarily directed at improving cardiac function.

Given the high prevalence of asthma, it is important to consider the potential cardiac side effects of inhaled medications, especially long-acting β-agonists such as salmeterol and formoterol. When used alone, these medications are associated with a 1.5 to 4.5 times increased risk of asthma-related mortality, and in some cases cardiac mortality likely due to arrhythmias, prompting the FDA to issue a black box warning against monotherapy with these medications. A combination of long-acting β-agonists with inhaled corticosteroids appears to ameliorate this risk.[29,30]

Cystic Fibrosis

Cystic fibrosis (CF) is an autosomal recessive disorder of mucus and sweat glands and primarily manifests as obstructive airway disease and pancreatic insufficiency. There are approximately 30,000 patients with CF in the United States and about 70,000 worldwide. With advances in diagnosis, therapy, and care, the median survival time has steadily increased from 10 years in the early 1960s to 40 years currently. With increasing longevity, there is growing awareness of the cardiovascular complications of this chronic inflammatory lung disease. The mechanisms for accelerated atherosclerosis are likely similar to those seen in other CLDs; endothelial dysfunction as evidenced by impaired brachial artery flow–mediated dilation has been documented in CF patients as young as 7 to 18 years old.[31] In addition to CLD, these patients are usually deficient in fat-soluble antioxidant vitamins despite supplementation, resulting

from pancreatic insufficiency. Nutritional recommendations are usually to ingest a high-fat diet that provides up to 40% of total calories to compensate for maldigestion, as well as the increased energy expenditure observed in CF. Consistent alterations in levels of polyunsaturated fatty acids have been observed in CF patients; they are likely proatherosclerotic. CF-related diabetes also is a strong risk factor for early CAD.

Lung Transplantation

Approximately 2100 lung transplants were performed in the United States in 2016, most commonly for COPD, IPF, and CF. Within 3 years of lung transplantation, 90% of recipients without preexisting cardiovascular risk factors develop one or more incident cardiac risk factors and 40% develop two or more risk factors.[32] These risks are accentuated by the use of immunosuppressive medications such as cyclosporine and glucocorticosteroids, which are associated with accelerated vasculopathy. Compared with other solid-organ transplants, such as the heart, kidney, and liver, which have 10-year survival rates that approximate 50% to 60%, the 10-year survival rate for lung transplants is only 22%. The main cause of death within 5 years of lung transplantation is bronchiolitis obliterans syndrome, and cardiovascular causes account for 5% of deaths. However, with increasing longevity of these patients, cardiovascular disease is expected to increase, and cardiac assessment should be part of the evaluation of all patients following transplantation.

Future Perspectives

CLDs are associated with a high prevalence of cardiovascular disease compared with matched controls. Many CLDs such as COPD and IPF should be regarded as proatherosclerotic conditions and these patients should be screened accordingly for cardiovascular disease. Accelerated atherosclerosis is likely due to a combination of traditional cardiovascular risk factors as well as systemic inflammation and oxidative stress. In patients with symptoms disproportionate to the severity of their underlying disease, additional causes, including CAD and heart failure, should be actively investigated. Drugs used for COPD and IPF can increase the risk of arrhythmias, and caution should be exercised, with close attention paid to risk-benefit analyses as well as consideration of additional drug interactions. Pulmonary rehabilitation is associated with significant improvement in the functional status of all patients with CLD, and the presence of cardiac comorbidity should not be considered a contraindication. A low index of suspicion for cardiac disease is recommended in all patients with CLD, irrespective of the severity of disease.

Sleep-Disordered Breathing and Cardiac Disease

Susan Redline

Sleep-disordered breathing (SDB) is prevalent in patients with cardiac diseases, contributing to a reduced quality of life, a reduced functional capacity, and poor outcomes. SDB causes acute and chronic physiologic stressors that can exacerbate cardiac ischemia, reduce systolic and diastolic function, cause cardiac structural and electrical remodeling, and increase the risk of cardiac arrhythmias and sudden death. Despite strong evidence linking SDB to cardiovascular disease (CVD), and the vulnerability of the cardiac patient to SDB-related stressors, SDB often goes unrecognized in cardiology practice, so there is potential for improved recognition and initiation of interventions. This chapter reviews aspects of SDB recognition, pathophysiology, and health outcomes relevant to cardiac disease.

Definitions

SDB refers to a spectrum of sleep-related breathing disorders that includes obstructive sleep apnea (OSA), central sleep apnea (CSA), Cheyne-Stokes respiration, and sleep-related hypoventilation. The

mechanisms and risk factors for these disorders have overlapping as well as unique characteristics. Each is associated with impaired ventilation during sleep and sleep disruption, although they differ in regard to their roles and the severity of altered neuromuscular respiratory drive and airway collapsibility that they cause. The constellation of symptoms and diagnostic criteria and their associations with CVD are summarized in **Table 87.1**.

TABLE 87.1

Key Features of Obstructive Sleep Apnea and Central Sleep Apnea

	OBSTRUCTIVE SLEEP APNEA	CENTRAL SLEEP APNEA
Common presenting symptoms	Snoring, observed apneas, gasping or snorting during sleep, daytime sleepiness	Observed apneas, gasping or snorting during sleep, frequent awakenings, unrefreshed sleep, fatigue
Diagnosis	Home sleep apnea test or polysomnography showing AHI > 5 with a predominance of obstructive apneas or hypopneas (>50%)	Polysomnography showing a predominance of central apneas or hypopneas (>50%) with a central apnea hypopnea index > 5 Cheyne-Stokes respiration: ≥ 3 consecutive central apneas/central hypopneas separated by crescendo and decrescendo change in breathing amplitude with a cycle length ≥ 40 sec associated with a central AHI > 5
Associated risk factors	Obesity, male, middle to older age	Male, older age
Associated cardiovascular disease*	Resistant hypertension, stroke, heart failure (preserved and reduced ejection fraction), atrial fibrillation, coronary artery disease	Atrial fibrillation, heart failure (reduced and preserved ejection fraction), stroke, pulmonary hypertension, coronary artery disease

*Order shown indicating approximate relative strength of association.

Obstructive sleep apnea (OSA), characterized by recurrent episodes of complete (apnea) or partial (hypopnea) upper airway occlusion, affects 34% of middle-aged males and 17% of middle-aged females.[1] OSA and CVD are commonly aggregated because of their shared risk factors (e.g., central obesity) and causal relationships; therefore, the prevalence of OSA is as high as 40% to 80% in patients with hypertension, heart failure (HF), coronary heart disease (CHD), and cerebrovascular disease.[2] Patients with OSA typically report loud or disruptive snoring, poor sleep quality, and unrefreshed sleep. Excessive daytime sleepiness is a cardinal symptom, and its presence marks severe disease that is associated with an increased risk of adverse CVD outcomes, as well as better adherence with OSA treatment.[3] People with OSA commonly have an impaired quality of life and a depressed mood; in patients with concomitant CVD, these important patient-centered outcomes can improve with OSA treatment.[4]

The diagnosis of OSA is based on (1) symptoms of breathing disturbances during sleep (snoring, snorting, gasping, or breathing pauses) *or* daytime sleepiness or fatigue, despite sufficient opportunities to sleep and unexplained by other medical problems; *and* (2) five or more obstructive apneas or hypopneas per hour of sleep (Apnea-Hypopnea Index [AHI]) documented in a sleep study. OSA may be diagnosed in the absence of symptoms if the AHI is greater than 15.[5] Each apnea or hypopnea represents a reduction in breathing for at least 10 seconds, associated with a drop in oxygen saturation and/or a brain cortical arousal (**Fig. 87.1**).[6] Apneas indicate a near absence of airflow during the period of obstruction, but hypopneas are recorded when the airflow is reduced by 30% to 50%. OSA severity is judged based on the frequency of breathing disturbances (AHI level), degree of hypoxemia and sleep disruption, and level of daytime impairment, such as sleepiness and cognitive impairment.

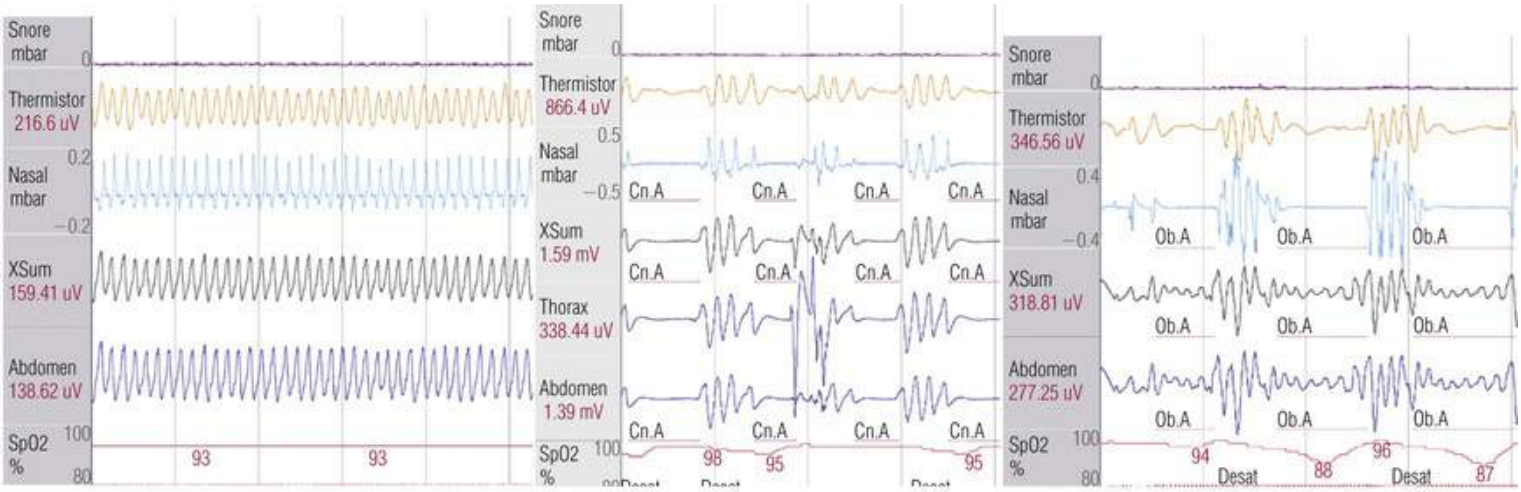

FIGURE 87.1 Examples from an overnight sleep study, displaying respiratory channels. The first panel shows normal breathing with stable oxygen saturation values. The second panel shows repetitive central apneas, characterized by 15- to 40-second periods of absent airflow (shown on the nasal and thermistor channels), with no associated respiratory effort of snoring, and oxyhemoglobin desaturation of 3% with each event. The third panel shows obstructive apneas, characterized by absent airflow with persistent effort on the thorax and abdominal channels, with deep desaturations (each panel is ≈ 3 minutes long).

The AHI and other indices of sleep are measured with multichannel overnight recordings that minimally quantify changes in airflow, breathing effort, and oxygen saturation. Home-based sleep apnea tests typically collect these core features, needed for diagnosing SDB, but not additional information required to characterize the sleep quality. In contrast, polysomnography performed in the sleep laboratory records respiratory data as well as data from the electroencephalogram, electrocardiogram, and leg muscles, providing the ability to specifically stage sleep, quantify sleep fragmentation, and identify other sleep-related phenomena such as periodic leg movements. Although home sleep apnea tests are increasingly used due to their lower cost, in-laboratory polysomnography still serves to evaluate patients with complex comorbidities, such as HF. When interpreting the results of home sleep apnea tests, it is important to note that they can underestimate the AHI by approximately 12%,[7] and larger misclassifications are likely in patients with poor sleep quality, such as those with HF.

Pathophysiology

Pathophysiology of Obstructive Sleep Apnea

The pharyngeal airway has no bony or cartilaginous support, and its size and shape dynamically change with each expiration and inspiration (when negative intraluminal pressure causes the airway to be “sucked' inward). Its patency therefore depends on the activation of pharyngeal dilator muscles, which decreases with sleep onset. Whether an apnea occurs depends on whether the level of neuromuscular activation of the upper airway muscles is adequate to overcome forces that promote airway collapse during sleep.[8]

The presence of an anatomically small airway (e.g., micrognathia, fat deposition in the lateral pharyngeal walls) and lying in the supine position (when gravitational and positional factors alter the position of the tongue and other soft tissues) increase the level of neuromuscular drive needed to maintain airway patency. Therefore, patients with small oropharyngeal airways due to craniofacial factors or excessive airway soft tissue have an increased risk for OSA. When a person is in the recumbent position, there can be a rostral redistribution of peripheral fluid from the lower extremities to the neck area, contributing to airway narrowing during sleep, and this factor can predispose patients with HF and even

mild peripheral edema or venous stasis to OSA.[9] The lung volume influences the pharyngeal wall stiffness through tractional forces; therefore, reduced lung volumes, as may occur in obesity or with pulmonary congestion, can exacerbate the propensity for OSA.[10] Conversely, high lung volumes, as in chronic obstructive lung disease, may modestly protect against OSA.[11] Increased nasal resistance (e.g., due to nasal septal deviation, polyps) promotes airway collapse by increasing the negative intraluminal suction pressure, and is a risk factor for OSA in conditions such as pregnancy or allergy associated with nasal swelling.[12]

Pharyngeal muscle activation depends both on the sensitivity of central and peripheral respiratory chemoreceptors and on neuromuscular responsiveness to CO_2 (**Fig. 87.2**).[10] During sleep, the blood CO_2 typically mildly increases, and this helps to activate respiratory muscles and stiffen airway dilators, protecting the upper airway. Depressed chemosensitivity and arousal response may prevent appropriate termination of apneas, prolonging the duration of the apnea and the severity of oxyhemoglobin desaturation. This ventilatory control problem can cause pathologic CO_2 retention and acidosis during sleep, a phenomenon common in obesity-hypoventilation and sleep-hypoventilation syndromes.[13] Conversely, an overly sensitive response to CO_2 can cause wide fluctuations in the ventilatory drive, resulting in central nervous system arousal and sleep fragmentation. Episodic hyperventilation can drive CO_2 levels to below the apneic threshold, precipitating cycles of apneas. This mechanism also occurs in CSA, and in its most extreme form, is manifested as Cheyne-Stokes respiration.[2]

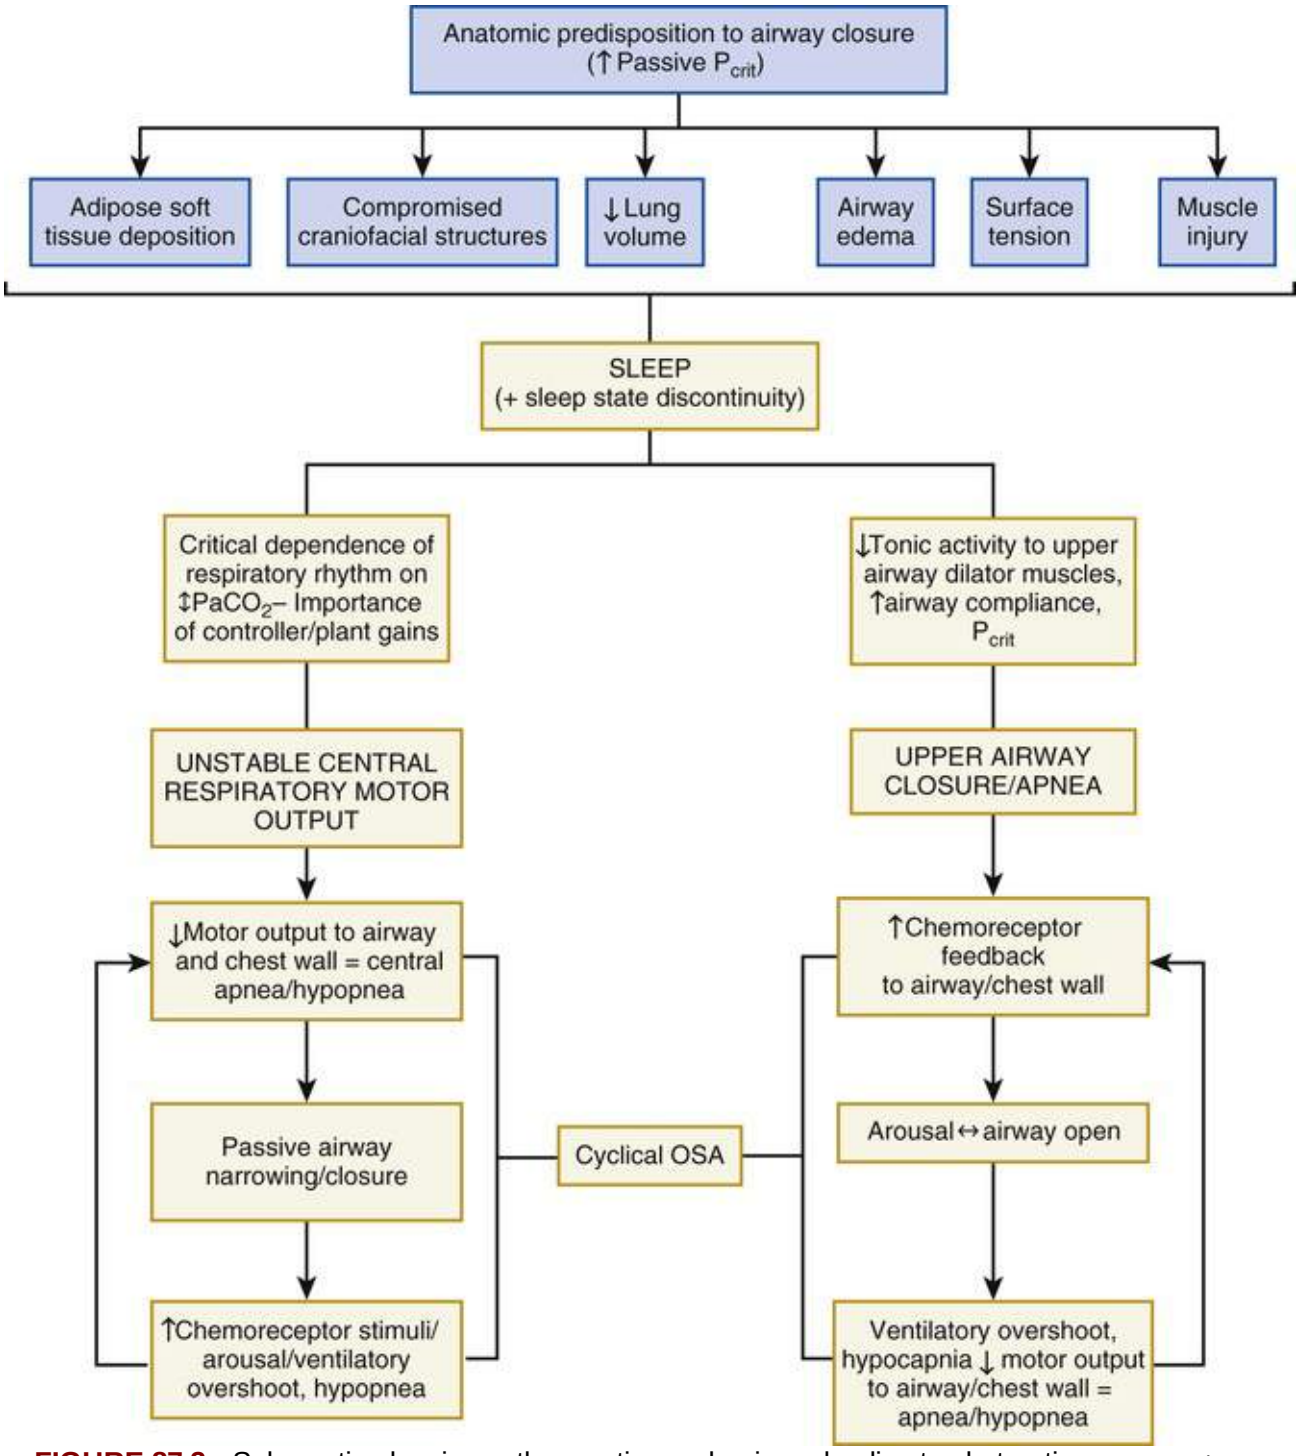

FIGURE 87.2 Schematic showing pathogenetic mechanisms leading to obstructive apneas. (From Dempsey JA, Veasey SC, Morgan BJ, O'Donnell CP: Pathophysiology of sleep apnea. Physiol Rev 2010;90:47-112.)

The severity of OSA can vary by sleep stage and position. During REM (rapid eye movement) sleep, the neuromuscular drive is low and fluctuating; it is the stage when OSA is commonly most severe. Women appear predisposed to "REM-dependent" OSA, referring to a predominance of apneas in REM sleep.[14] OSA also can worsen following acute ingestion of alcohol, which reduces neuromuscular activation, and when a person is in the supine position.[15]

Pathophysiology of Central Sleep Apnea

Variants of CSA occur secondary to genetic syndromes, neuromuscular disease, and opioid use, reflecting abnormalities of the central and peripheral ventilatory control systems.[16] In adults, CSA often occurs in association with cardiac or cerebrovascular disease. Its pathogenesis relates to a heightened sensitivity to

CO_2 and a prolonged circulation delay between the pulmonary capillaries and carotid chemoreceptors, causing instability in breathing.[17] Periods of hyperventilation cause CO_2 levels to fall below the apneic threshold, precipitating apneas and hypopneas. The occurrence of cycles of crescendo-decrescendo breathing is recognized as Cheyne-Stokes respiration.

Risk Factors for and Recognition of Sleep-Disordered Breathing

Male sex, older age, and obesity are well-recognized OSA risk factors.[18] OSA is 2- to 4-fold more prevalent in men than in women.[19] Factors that predispose men to OSA include android patterns of adiposity (associated with upper airway fat deposition) and relatively long pharyngeal length, which predisposes to collapsibility.[20] The OSA prevalence increases in women following menopause, and hormone replacement therapy is associated with reduced AHI levels, consistent with a role for sex hormones in modulating risk.[21] Although the precise role of sex hormones on OSA is not well understood, estrogens and progesterone influence ventilation, including responses to hypoxia and CO_2.[22] However, OSA severity increases not only in older women but also in older men, reflecting age-related comorbidities (e.g., cardiac diseases, neurologic diseases) and other age-related effects on airway stiffness and ventilation.[18] OSA in elderly persons may differ from that in middle-aged individuals, with less prominent associations with snoring, obesity, autonomic system dysregulation, and CVD reported.[23] It is not known whether differences in studies of middle-aged populations compared with older populations result from study biases or are true differences in OSA effects across the population.

Being overweight or obese accounts for approximately 40% to 60% of cases of OSA. Obese middle-aged individuals are 4-fold or more likely to have OSA as compared with normal-weight individuals.[1] Obesity contributes to OSA through effects on airway narrowing caused by fat deposition in the tongue and parapharyngeal tissues and by reducing chest wall compliance and lung volumes. Obesity-associated cytokine levels also may influence ventilatory control and promote daytime sleepiness. Even a modest weight loss or weight gain can have an impact on the severity of OSA. For example, a 1% increase in the body mass index (BMI, kg/m^2) is estimated to increase the AHI by 3%; this finding emphasizes the importance of weight management in OSA.[1] Approximately 20% of OSA patients are *not* obese, however, and the absence of obesity should not preclude an appropriate evaluation of patients with OSA symptoms. Other risk factors for OSA are craniofacial features that narrow the oropharyngeal airway, upper airway dilator muscle dysfunction, heightened ventilatory chemosensitivity, and a low respiratory arousal threshold.[18]

A first-degree relative of a patient with OSA has an approximately 2-fold increased risk of OSA compared with someone without an affected relative.[24] Over 60% of the genetic variance explaining OSA is not associated with obesity, indicating the importance of multiple etiologic factors.[25] Several genetic variants associated with OSA may also be associated with cardiac disease and abnormal lipid and glucose levels, suggesting overlapping genetic mechanisms (“pleiotropy”) for OSA and cardiac disease.[26,27] Sexual dimorphisms in genetic variants for OSA have been identified, similar to reports of sex-based differences in genetic variants for adiposity and cardiac disease.[26]

Population studies have demonstrated that clinically significant OSA often goes unrecognized and untreated.[28] Despite improved public awareness of OSA, it is estimated that more than 80% of individuals with moderate or severe OSA are undiagnosed.[28,29] Even among those diagnosed, more than 30% of patients report that the period between onset of symptoms and diagnosis exceeded 10 years.[30]

Underrecognition is high among ethnic and minority groups and elderly individuals, particularly African Americans and older Chinese Americans,[29] groups also at risk for cardiometabolic diseases. Underrecognition in women may result from the preferential reporting of symptoms of fatigue rather than sleepiness, and the frequency of comorbid insomnia that can confound the diagnosis and reduce the sensitivity of screening questionnaires.[21] Women often display REM-predominant OSA and may experience apneas that result in arousal without desaturation, findings that home sleep tests may miss.

Risk factors for CSA are male sex, hypocapnia during wakefulness, and older age, as well as HF, CVD, and atrial fibrillation.[17] Due to elevations in sympathetic drive, patients with CSA may not report sleepiness, and rather report symptoms of insomnia, such as difficulty falling asleep and frequent awakenings.

The role of routine screening for sleep apnea is not established. In 2017, The U.S. Preventive Services Task Force concluded that there was insufficient evidence to recommend routine screening for sleep apnea in primary care settings.[31] However, patients with diagnosed sleep apnea frequently report prolonged delays between the onset of symptoms and diagnosis and treatment, indicating a need to improve recognition.[30] Screening questions (**eFig. 87.1**) or web-based algorithms that combine information on snoring frequency, age, BMI, and sex for calculating OSA risk,[32] should be considered in cardiology practices,[33] settings where sleep apnea prevalence is high, to improve identification and expedite treatment of this disorder.

Pathophysiologic Mechanisms That Link Sleep-Disordered Breathing to Cardiovascular Diseases

During healthy sleep, individuals experience a decrease in sympathetic nervous system activity and an increase in parasympathetic activity, with associated decreased levels of blood pressure (BP) and heart rate. Repetitive collapse of the upper airway that disrupts sleep continuity and causes arousal disturbs

these patterns, resulting in surges in sympathetic activity and acute BP elevations.[17,34] Impaired gas exchange with intermittent hypoxia further affects the autonomic nervous system, as well as triggers release of acute-phase proteins and reactive oxygen species. The release of these mediators may favor an augmented inflammatory and hypercoagulable state, exacerbating insulin resistance and lipolysis.[35] Hypoxia and autonomic nervous system alterations can contribute to electrical remodeling of the heart and myocyte injury. Oxyhemoglobin desaturation resulting from apneas and hypopneas further compromises oxygenation of myocardial tissue. Inspiratory efforts against a closed glottis (with OSA) additionally cause wide swings in intrathoracic pressure, negatively affecting preload and afterload and left ventricular (LV) transmural pressure, increasing myocardial oxygen consumption and impeding stroke volume. The pathophysiologic consequences of OSA are shown schematically in **Fig. 87.3** and further summarized later in this chapter.

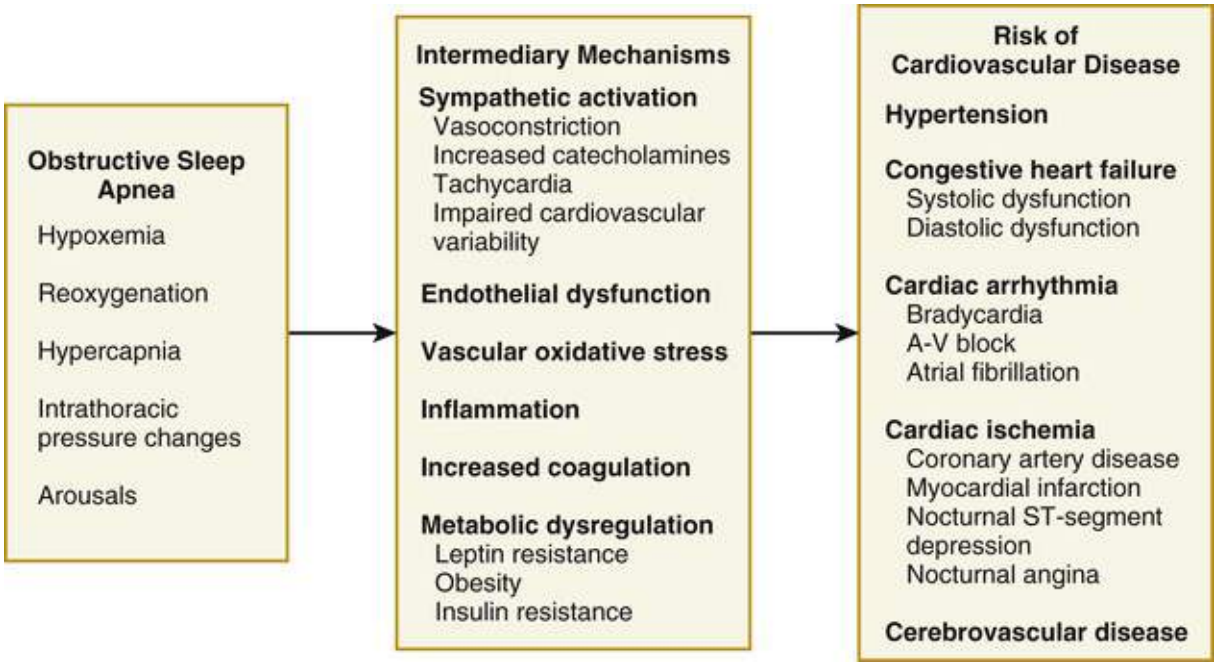

FIGURE 87.3 Schematic showing links among apnea-related physiologic stressors, intermediate mechanisms, and cardiovascular outcomes. (From Shamsuzzaman ASM, Gersh BJ, Somers VK, et al: Obstructive sleep apnea: implications for cardiac and vascular disease. JAMA 2003;290(14):1906-14.)

Sleep-Disordered Breathing and Hypertension

Approximately 30% of patients with essential hypertension (**see also Chapter 46**) and 80% of patients with resistant hypertension have OSA.[36] Conversely, more than 50% of patients with OSA have hypertension.[37] Patients with severe untreated OSA who are prescribed intensive antihypertensive therapy are at a 4-fold increased risk of elevated BP compared with patients with less severe OSA.[38] Although the aggregation of hypertension and OSA partially reflects common risk factors, experimental animal and human data indicate that OSA is causally associated with hypertension. The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) identified OSA as a treatable cause of hypertension.[39]

OSA has both acute and chronic effects on BP.[40] Acutely, the BP and heart rate increase within 10 seconds of the termination of an apnea or hypopnea, corresponding to peak times of the arousal,

ventilation, and oxygen saturation nadir.[41] Frequent arousals trigger chemoreflexes and sympathetic output to the peripheral blood vessels, with consequent vasoconstriction, and altered renin-angiotensin-aldosterone system activity. Transient increases in BP can persist into the daytime. Chronic intermittent surges in BP also cause vascular remodeling.

OSA is associated with a nondipping overnight BP pattern, increases in daytime BP to prehypertensive and hypertensive ranges, and an increased risk of resistant hypertension.[42] "Dose-response" associations are reported. Specifically, a 1-unit increase in the AHI is estimated to increase the odds of nondipping systolic BP by 4%.[38] The Wisconsin Cohort Study, a prospective study of state employees, reported that the odds ratio, adjusted for obesity and other confounders, for the presence of hypertension after 4 years of follow-up was 2.9 for moderate or severe OSA.[43] Recent data indicate that it is the apneas and hypopneas occurring in REM sleep, rather than the AHI occurring across all sleep stages, that is associated most strongly with hypertension incidence.[44] During REM sleep, the sympathetic drive is highest, the muscular tone is lowest, and the respiratory events tend to last the longest and be associated with the most severe hypoxemia.

Over 30 randomized controlled trials have examined BP responses to continuous positive airway pressure (CPAP), the mainstay therapy for OSA.[45] Metaanalyses estimate that CPAP treatment reduces the systolic and diastolic BP by an average of 2 to 3 mm Hg and 1.5 to 2 mm Hg, respectively. Generally, studies reported larger effects for nocturnal BP than daytime BP, and in individuals who have high CPAP adherence or more severe OSA, or are younger, sleepier, or have resistant hypertension (with average BP improvements of 4 to 9 mm Hg). CPAP also can improve nondipping patterns, a well-established risk factor for all-cause mortality rates. The Heart Biomarker Evaluation in Apnea Treatment (HeartBEAT) study compared CPAP with supplemental oxygen therapy and usual care in patients with OSA at increased CVD risk, most of whom were under care by cardiologists and were using an average of 2.4 antihypertensive medications.[46] Relative to the usual care group, which included guideline-based management of CVD, the CPAP group experienced significant lowering of the 24-hour BP (by 2.4 mm Hg), with larger changes for the nocturnal BP (by 3.5 mm Hg). A metaanalysis of six studies that evaluated the influence of CPAP on resistant hypertension estimated that CPAP reduced the ambulatory 24-hour systolic and diastolic BP by 7.2 mm Hg and 5.0 mm Hg, respectively.[47] CPAP use in resistant hypertension also improved the nocturnal BP and nondipping patterns. To address the role of CPAP in reducing the incidence of hypertension, a multicenter trial conducted in Spain randomized 723 patients with moderate OSA but without significant sleepiness to CPAP or usual care.[48] Over a median of 4 years of follow-up, an intention-to-treat analysis showed no reduction in the incidence of hypertension or CVD events with CPAP. However, in an analysis of patients who used CPAP for 4 hours or more per night, a significant 31% reduction in incident hypertension or CVD was observed and the magnitude of the 24-hour BP improvement was related directly to the hours of CPAP use (each additional hour of CPAP use resulted in a decrease in the average systolic BP of 1.3 mm Hg).

The existing clinical trials highlight the importance of treatment adherence in achieving BP improvement. Other sources of variability in responses to OSA treatment include differences in residual apneic activity with treatment, severity of OSA, age, and cause of hypertension. The level of CPAP adherence needed to obtain a significant BP reduction is unknown. Although a minimum threshold of 4 hours of CPAP use per night is commonly targeted, more than 6 hours of CPAP use per night, including use during the late-night hours in REM sleep, is likely more effective. A variety of pathophysiologic processes contribute to hypertension, including insulin resistance, obesity, autonomic nervous system dysfunction, and variations in salt and fluid balance. OSA likely affects these mechanisms differently, and is likely to be more effective in certain subgroups. Different treatment responses also may reflect

variations in the duration of OSA prior to the initiation of treatment. Individuals who have had untreated OSA for years may undergo chronic remodeling of the vascular bed and changes in BP regulatory mechanisms that are not readily reversed with CPAP. Earlier treatment or a longer duration of treatment interventions than is commonly evaluated in clinical trials may be needed to observe larger BP improvements. A recent study showed that three microribonucleic acids predicted BP responses in patients with OSA and resistant hypertension, suggesting the potential usefulness of biomarkers for predicting responsive subgroups.[49]

Combining CPAP with other modalities, such as medications or weight loss, may have greater effects than single-modality therapy and also may be considered as a form of adjunctive therapy. Patients with hypertension and OSA have less improvement in the 24-hour BP than hypertensive patients without OSA. The addition of CPAP, when used for 4 hours or more per night, enhances the effects of pharmacotherapy in improving the BP.[50] Among obese patients with moderate OSA and elevations of C-reactive protein (CRP), a combination of weight loss plus CPAP proved more effective in lowering the BP than CPAP alone, suggesting the importance of concomitant lifestyle interventions in high-risk groups.[51]

Based on the existing evidence, hypertension guidelines identify OSA as a prevalent and modifiable cause of systemic hypertension.[39] Although average treatment effects are modest, long-term improvements of systolic BP by 2 to 3 mm Hg may reduce the risk of stroke and CHD by as much as 10%. Therefore, OSA treatment, especially when high levels of adherence are achieved and efficacy is greater, should have a beneficial population-level effect on adverse cardiovascular outcomes.

Sleep-Disordered Breathing and Coronary Heart Disease

SDB exacerbates atherosclerosis by triggering sympathetic nervous system activity, augmenting the release of proinflammatory proteins and contributing to dyslipidemia, insulin resistance, and endothelial dysfunction.[52-56] SDB-related episodes of recurrent hypoxemia activate leukocytes and endothelial cells, increase the expression of adhesion molecules, and lead to the release of oxygen free radicals.[57] Patients with SDB have elevations of proinflammatory mediators that are also implicated in atherogenesis, including transcription factor nuclear factor-kappa B, leukotriene B4, intercellular adhesion molecules, tumor necrosis factor-alpha (TNF-α), CRP, and interleukin-6 (IL-6). Prothrombotic markers (including fibrinogen, plasminogen-activating inhibitor-1, activated coagulation factors XIIa and VIIa, thrombin/antithrombin III complexes, and soluble P selectin) and markers of oxidative stress (overnight urinary 8-isoprostane levels, oxidized DNA, and neutrophil superoxide generation) also rise.[57] Many of these biomarkers vary in direct proportion to the severity of SDB-related hypoxemia. Although the extent to which biomarker elevations are independent of obesity or other confounders is not clear, several studies have demonstrated that SDB treatment with CPAP, even for as short a time as 2 weeks, reduces sympathetic activation, inflammation, oxidative stress, and endothelial dysfunction.[58]

Cardiac imaging provides insights into the association between OSA and subclinical CVD. The Multi-Ethnic Study of Atherosclerosis showed that after adjusting for multiple confounders, the coronary artery calcium burden (CAC > 400) was 40% more common in individuals with a physician diagnosis of sleep apnea than in controls. Furthermore, over 8 years, the CAC was more likely to progress in those with OSA than in those without SDB.[59] Polysomnography can characterize patterns of association between sleep-related stressors and the CAC. Higher CAC scores are associated with increases in the overnight arousal frequency and decreased time in state N3 sleep (slow-wave sleep, when sympathetic activity is

lowest and parasympathetic tone is lowest).[60]

In addition to contributing to the chronic atherosclerotic burden, OSA may cause acute ischemia because of both decreased oxygen delivery (secondary to obstructed breathing and hypoxemia) and increased oxygen consumption (associated with elevated diastolic and transmural pressures and cardiac hypertrophy).[61,62] Ischemic stressors may be most notable during the rebreathing phase of obstructive apneas, when large hemodynamic changes occur.[2] The fractional flow reserve, a quantitative measurement of coronary artery stenosis, can dynamically vary with obstructive apneas because of fluctuations in the intrathoracic pressure that affect the venous and aortic pressures and coronary perfusion.[63] Patients with intermediate coronary lesions may experience intermittent myocardial ischemia as a result of cyclical changes in the coronary blood flow. Endothelial damage and compromised coronary vascular conductance may ensue due to surges in the BP and heart rate associated with sympathetic activation and reduced endothelial production of nitric oxide.[64] Subclinical ischemia can be manifested on overnight electrocardiograms of patients with OSA, showing ST segment depression, which indicates nocturnal myocardial ischemia, and changes in QT dispersion, as well as paroxysms of ventricular tachycardia or atrial fibrillation that are associated temporally with the occurrence of apneas.[65-67] Women with OSA have elevated levels of high-sensitivity troponin, a marker of subclinical myocardial injury; the level of troponin is one factor in the risk for HF or death in untreated OSA.[68] In a prospective analysis of more than 10,000 individuals, patients with significant nocturnal hypoxemia had a nearly 2-fold increase in the risk of sudden cardiac death after potential confounders had been considered.[69] Individuals with OSA compared with those without OSA were more likely to experience a morning-peak onset of myocardial infarction[70] and die suddenly between midnight and 6:00 AM, the hours when apneas and hypopneas occur.[71]

More than 75% of patients presenting with acute coronary artery syndrome reportedly have SDB.[72] The contribution of SDB to ischemia in this setting is uncertain. Some research findings suggest that patients with SDB may develop a collateral coronary blood flow from periods of intermittent hypoxemia, with resultant angiogenesis,[73] which may reduce the extent of myocardial injury immediately following an ischemic event. In contrast, infarct sizes are reportedly higher 3 months after myocardial infarction salvage procedures in patients with OSA than in patients without OSA.[61]

Recent epidemiologic studies from across the world provide evidence that SDB is an independent risk factor for CHD. In the prospective Sleep Heart Health Study cohort, moderate to severe SDB was associated with a 35% increased incidence of CHD over 8 years; among men younger than age 70 years, this risk was 70%.[74] In over 5000 participants in the Multi-Ethnic Study of Atherosclerosis who were free of known CVD at baseline and followed for 7.5 years, a physician-diagnosis of sleep apnea was associated with a 1.9 increased adjusted hazard ratio for incident cardiovascular events and a 2.4-fold higher mortality rate.[75] Several studies from Spain followed patients referred to sleep laboratories for periods of 5 to 10 years. Among men, untreated severe OSA was associated with a 2.9-fold increased risk of fatal cardiovascular events and a 3.2-fold increased risk of nonfatal cardiovascular events compared with a control group. A prospective study of over 1000 women followed for a median time of 72 months showed that women with untreated mild to moderate or severe OSA also had significantly increased CVD mortality rates over those of controls; after adjusting for confounders, the mortality rate was 3.5-fold higher in women with severe OSA than in controls.[76] Patients with CHD who have OSA experience higher rates of major acute cardiovascular events than patients without OSA.[77,78] Untreated OSA is also associated with an increased need for a revascularization procedure as compared with rates in patients without OSA.[79,80]

Several large observational studies demonstrate that patients with severe OSA treated with CPAP have

significantly reduced rates of fatal and nonfatal CVD compared with untreated patients.[2] Patients with CHD treated with CPAP reportedly have lower rates of nocturnal ischemia, acute coronary syndrome, need for coronary revascularization, and death from CVD compared with untreated patients with OSA. Only three large randomized controlled trials have examined the role of CPAP in secondary prevention of CVD in patients with moderate to severe OSA. All studies excluded patients with significant sleepiness, and one also excluded those with severe overnight hypoxemia. Interventions were CPAP (or autotitrating PAP) or conservative therapy. Modest CPAP adherence limited all studies, and two were underpowered to detect moderate improvements. The first study, following 725 patients without CVD for a median of 4 years, did not find a benefit for the CPAP group. However, patients who used CPAP for 4 hours or more per night experienced a significant improvement in the composite study outcome (incidence density ratio, 0.72; 95% confidence interval [CI], 0.52 to 0.98) compared with controls and nonadherent patients.[81] The Randomized Intervention with Continuous Positive Airway Pressure in Coronary Artery Disease and OSA (RICCADSA), randomized 244 nonsleepy patients with established CHD and moderate or severe OSA to CPAP or usual care in a single European center.[82] At a median follow-up time of 57 months, the CPAP group compared with the usual-care group had a 20% nonstatistically significant reduction in the primary composite endpoint. When restricted to patients using CPAP for 4 hours or more per night, a significant 80% decrease in event rates was observed (HR, 0.29; 0.10 to 0.86). The multicenter international Sleep Apnea Cardiovascular Endpoints (SAvE) trial followed 2717 patients with a history of coronary artery or cerebrovascular disease for a mean of 3.7 years.[4] This study did not observe a difference in the primary composite endpoint. A subanalysis showed that individuals adherent to CPAP had a 40% significant reduction in cerebrovascular events compared with a propensity-matched subgroup from the usual-care group. The better effect for cerebrovascular disease than for the composite endpoint or CHD is in agreement with observational data showing stronger associations between OSA and cerebrovascular disease compared with CHD.[83]

The existing data suggest that CPAP is unlikely to improve CVD outcomes unless it is used for at least 4 hours per night. However, even if CPAP were used for shorter times, the SAvE study demonstrated that CPAP significantly improved the patient's quality of life and mood and resulted in fewer days of missed work, indicating that the effects of CPAP are beneficial in patients with CVD.[4] The results of these studies also emphasize the need to provide adherence support for patients prescribed CPAP. In patients with CVD, adjunctive behavioral therapies (e.g., motivational education) have demonstrated improvements of CPAP use by an average of 90 minutes per night.[84] The existing trials also indicate a need to further develop and evaluate alternatives to CPAP.

Sleep-Disordered Breathing, Cardiac Function, and Heart Failure

Both CSA and OSA are common in HF, present in up to 60% of HF patients.[17,85] CSA is the most common SDB variant associated with HF with a reduced ejection fraction (HFrEF), but OSA is predominant in HF with a preserved ejection fraction (HFpEF). Both conditions commonly occur in the same individual. Patients with a reduced ejection fraction without clinically significant HF also have a higher prevalence of SDB than age-matched individuals with normal cardiac function.[86]

There is a bidirectional relationship between HF and SDB (**Fig. 87.4**). In patients with HF, pulmonary vascular congestion, elevated peripheral and central chemosensitivities, and a prolonged circulation time can cause hyperventilation, with instability in ventilation leading to apneas.[9,17,87] Conversely, SDB may

adversely affect cardiac function by contributing to systemic and pulmonary hypertension, nondipping BP, atherosclerosis and ischemic injury, hypoxemia- and catecholamine-related myocyte injury, and cardiac remodeling. Hypoxia can trigger pulmonary vasoconstriction, which may increase the right ventricular afterload, cause right ventricular distention and leftward shift of the ventricular septum during diastole, impair left ventricular (LV) filling, and reduce the stroke volume and cardiac output.[88] SDB is increasingly recognized as a common cause of diastolic dysfunction, with effects attributable to chronic pressure overload, impaired coronary flow reserve, and inflammation leading to cardiac interstitial fibrosis.[89] Population studies show that the LV mass and LV mass volume ratio (concentric remodeling) increase in proportion to the severity of SDB, with associations stronger in adults younger than 65 years of age.[90] Indices of diastolic dysfunction, including an increased E/A ratio, reduced mitral deceleration, and isovolumic relaxation, are higher in patients with SDB compared with controls.[91-93]

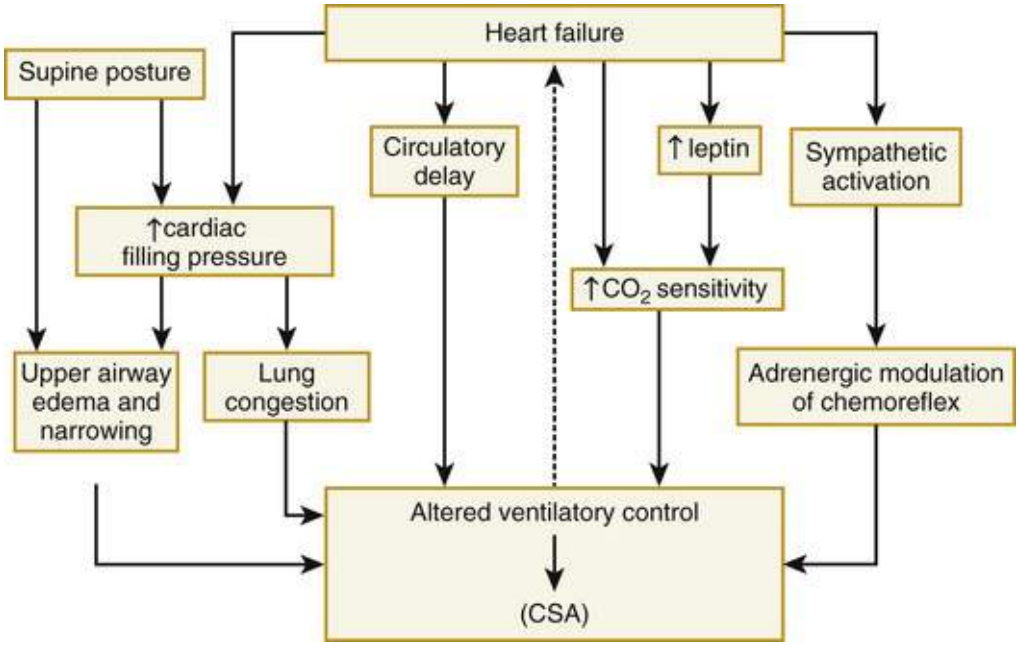

FIGURE 87.4 Schematic outlining possible mechanisms underlying development of central sleep apnea and the possible feedback from central sleep apnea resulting in exacerbation of heart failure. (From Somers VK, White DP, Amin R, et al: Sleep apnea and cardiovascular disease: an American Heart Association/American College of Cardiology Foundation Scientific Statement from the American Heart Association Council for High Blood Pressure Research Professional Education Committee, Council on Clinical Cardiology, Stroke Council, and Council on Cardiovascular Nursing. In collaboration with the National Heart, Lung, and Blood Institute National Center on Sleep Disorders Research [National Institutes of Health].Circulation 2008;118(10):1080-111.)

Prospective studies have shown that SDB independently predicts new-onset HF. Middle-aged men with severe SDB (predominantly OSA) have an estimated 60% increased 8-year incidence of HF compared with men without SDB. A 14-year prospective analysis of data from the Atherosclerosis Risk in Communities Study (ARIC) demonstrated that women with SDB have an approximately 30% increased incidence of HF or death compared with women without SDB, and also have an increased risk for developing LV hypertrophy. In older men, the Outcomes of Sleep Disorders in Older Men Study (MrOS) demonstrated that the presence of SDB predicted a nearly 2-fold increased incidence of HF.[94] However, in this study, the risk was related to the presence of CSA or Cheyne-Stokes respiration rather than OSA.

In patients with HF, SDB predicts HF exacerbations and progression, including an impaired quality of life, increased fatigue, a reduced functional status, more frequent hospitalizations, arrhythmias, and death.[95,96] CPAP treatment, by reducing the BP and improving oxygenation, subendocardial ischemia, the

preload and afterload, sympathetic activation, and inflammatory and oxidative stress, could improve cardiac function. Short-term studies demonstrate that PAP can reduce HF symptoms and improve the quality of life and functional status. A retrospective analysis of approximately 30,000 Medicare beneficiaries with newly diagnosed HF showed that treatment of SDB decreased rates of readmission, costs of health care, rates of mortality.[97] Small randomized controlled studies in HF also demonstrated that CPAP improved the vascular and myocardial sympathetic nerve function, myocardial energetics, and diastolic dysfunction.[2] A metaanalysis estimated that CPAP treatment in OSA and HF was associated with a 5.2% improvement in the LV ejection fraction.[98]

Given this evidence and the strong observational data and known physiologic effects of SDB on cardiac function, the American Heart Association published an HF guideline in 2013 that recommended screening patients with HF for SDB and treating those who test positive. Current treatment strategies include optimization of cardiac function, with a particular focus on minimizing the fluid overload, and weight loss as appropriate. Exercise and elastic stockings can help prevent rostral redistribution of fluid. Although PAP is indicated for OSA, there is uncertainty on how to treat CSA/Cheyne-Stokes respiration in patients with HFrEF. The CSA may improve after intensive HF treatment with pharmacotherapy and cardiac resynchronization therapy.[99] The Canadian Positive Airway Pressure (CANPAP) study demonstrated that CPAP improved several intermediate endpoints in patients with CSA and HFrEF (ejection fraction, catecholamines), but did not improve mortality rates. A post hoc analysis suggested improved heart transplant-free survival in patients in whom CSA was suppressed.[100] Based on this observation, two multinational studies evaluated the role of adaptive servoventilation (ASV), a pressure device that delivers autoadjusting pressure support on a breath-by-breath basis and can suppress both obstructive and central apneas (which are more difficult to suppress with CPAP).[101] The first trial (SERVE-HF trial), conducted in 1345 patients with symptomatic HF, an LV ejection fraction of less than 45%, and moderate or severe CSA, unexpectedly showed a 34% increase in CVD mortality rates.[102] In 2015, an advisory was issued against the use of PAP for treatment of patients in whom CSA predominates in the setting of HFrEF with an ejection fraction of less than 35%. A second ongoing trial, Effect of ASV on Survival and Hospitalizations (ADVENT-HF), is testing an alternative ASV device in patients with OSA or CSA. Other therapies under investigation are transvenous phrenic nerve stimulation (PNS) and nocturnal oxygen supplementation (NOS). The results of a 6-month efficacy study of PNS are promising, with improved indices of SDB.[103] NOS therapy can stabilize breathing in patients with CSA and improve intermediate markers of cardiac function and quality of life[104]; ongoing larger trials are being planned.

Sleep-Disordered Breathing and Cardiac Arrhythmias

Patients with SDB are predisposed to ventricular and atrial arrhythmias because of underlying cardiac risk factors and cardiac disease, as well as to the specific SDB-related stressors of intermittent hypoxemia, acidosis, surges of sympathetic nervous system activation, and swings in intrathoracic pressures.[105-107] Susceptibility to atrial arrhythmias also reflects the vulnerability of the atrial walls to swings in intrathoracic pressure and mechanoreceptor activation, as well as sensitivity of the pulmonary vein ganglia to autonomic stimulation.[106] Bradycardia and atrioventricular block may occur secondary to vagal stimulation accompanying apneas and hypoxemia.

Abnormalities of P wave morphology and QT dispersion, indicative of underlying electrical conduction problems, have been observed in the overnight recordings of patients with SDB.[108,109] Moreover, apneas and hypopneas appear to be direct triggers of paroxysms of ventricular tachycardia and

atrial fibrillation. Analysis of the temporal patterns of overnight arrhythmias demonstrated a 17-fold increased rate of arrhythmias occurring after an episode of apnea compared with a period of normal breathing.[67] Based on this analysis, a patient with moderate OSA (AHI 25) is estimated to experience one episode of a significant arrhythmia every 6 months attributable to apneic activity. In community studies, moderate or severe OSA was associated with a 2- to 4-fold increased risk of nocturnal arrhythmias; this finding suggested a basis for the observed increase in nocturnal sudden cardiac death in SDB.[105] The Outcomes Registry for Better Informed Treatment of Atrial Fibrillation (ORBIT-AF) showed that 18% of 10,132 patients in the registry with atrial fibrillation had an OSA diagnosis.[110] Patients with OSA had a higher rate of severe or disabling symptoms, a history of more aggressive atrial fibrillation therapies, and higher hospitalization rates. Among patients referred to cardiology clinics for atrial fibrillation, patients with SDB experience increased rates of recurrent atrial fibrillation; with CPAP treatment, rates decrease to the levels observed in patients without SDB.[111] Patients with SDB compared with those without SDB have an increased occurrence of atrial fibrillation following pulmonary vein ablation procedures or coronary artery bypass graft surgery, suggesting that untreated SDB is an important prognostic factor.[106,112-117] The degree of hypoxemia appears to be a potent stimulus for ventricular arrhythmias,[118] sudden cardiac death,[69] and recurrence of atrial fibrillation following cardioversion.[111]

A metaanalysis estimated that CPAP use in patients with OSA reduces the atrial fibrillation risk by 44%.[117] Uncontrolled studies indicate that CPAP treatment is associated with a significantly decreased recurrence rate of AF after electrical cardioversion or ablative therapies and reduces the likelihood of progression to more permanent forms of atrial fibrillation. A high frequency of central apneas predicts nocturnal atrial fibrillation and incident atrial fibrillation in individuals without clinically apparent cardiac disease.[119] These findings have influenced a consensus panel to identify OSA as an atrial fibrillation risk factor,[120] and they support the growing interest in screening patients undergoing evaluation for pulmonary vein isolation for SDB. The high rate of atrial fibrillation recurrence in untreated patients has discouraged the use of ablation procedures until OSA is treated with CPAP.

Future Perspectives

SDB is highly prevalent in patients with hypertension, coronary artery disease, HF (with or without a reduced ejection fraction), atrial and ventricular arrhythmias, and stroke. The profound nightly disturbances that occur with SDB cause a range of physiologic disturbances that adversely affect the cardiac structure and function, and likely exacerbate the incidence and progression of these diseases. Treatment of OSA can improve the BP, ejection fraction, ventricular ectopy, and recurrence rate of atrial fibrillation and can also improve the quality of life and mood in patients with CVD. The existing data indicate that patients with OSA who successfully use CPAP have reduced rates of resistant hypertension and experience improved outcomes, including fewer cardiac and cerebrovascular events and lower mortality rates. Although the impact of directly treating CSA on cardiovascular outcomes remains uncertain, the presence of CSA potently predicts increased mortality rates, and patients with CSA and HF may benefit from intensive HF therapy. Cardiologists may be increasingly involved in recognizing SDB and can use information on its pathophysiologic effects to tailor interventions and inform chronic disease management strategies.

PART X
Cardiovascular Disease in Special Populations

OUTLINE

88

Cardiovascular Disease in the Elderly

*Daniel E. Forman, Jerome L. Fleg *, Nanette Kass Wenger*

Aging predisposes people to cardiovascular disease (CVD), as well as to multiple comorbidities that intertwine and fundamentally alter the management of CVD.[1] Geriatric cardiology is a subdiscipline of cardiology that is oriented to the distinctive complexities and needs of older cardiovascular (CV) patients.[2] On average, patients with CVD are living longer than in previous eras, and the principles of geriatric cardiology are therefore increasingly relevant for all CV providers (**see also Chapter 45**).

Successes in medical care as well as advances in prevention and public health have contributed to sizable increases in longevity. In 1900 in various countries, the usual lifespan was 25 to 50 years,[3] but it has now increased throughout the world.[4] In the United States, the number of people 65 years of age or older was barely 3 million in 1900, but it is now about 46 million, and it is expected to be almost 84 million by the year 2050.[5] The subgroup of persons who are 85 years of age or older is the most rapidly increasing demographic group in the world. In the United States, this very old subgroup was only about 0.2% of the total population in 1900, but it is anticipated to reach 5% to 6% by 2050.

Older adults, even those with no prior CVD or CVD risk factors, are likely to develop CVD as a progression of the physiologic and pathologic changes in old age.[6] The prevalence of coronary heart disease (CHD), heart failure (HF), atrial fibrillation (AF), peripheral arterial disease (PAD), and most other types of CVD escalates in relation to age, reflecting distinctive physiologic vulnerabilities. Some types of CVD (e.g., aortic stenosis and sick sinus syndrome) arise almost exclusively in old age. Age-related vulnerability to CVD is compounded by cumulative CVD risk factors over a lifetime.[7]

Approximately 70% of those age 65 years or older in the United States have CVD, including 85% of those 80 years of age or older.[8] This means that there are a disproportionate number of hospitalizations, procedures, and costs, as well as more use of health care resources, among the elderly.[9] The mortality rates associated with CVD also escalate; adults 75 years of age or older make up only about 6% of the current U.S. population but account for over 50% of CVD deaths. Even when treatments go well, detrimental consequences are more likely to occur. CVD is a common precursor to functional decline, frailty, diminished independence, and disability[10]; many older patients who are ostensibly “successfully treated” by standard metrics still end up living in long-term care facilities for the rest of their lives. Subclinical CVD manifestations may also occur that predispose elderly people to an insidious decline in physical and cognitive function, frailty, and other detrimental clinical sequelae.[11]

What Is Aging?

Aging is customarily measured in chronological years, but the broad concept of aging is significantly more complex than years alone would indicate.[1] Fundamental aspects of aging are determined by the mounting toll of biologic stresses over time (e.g., oxidative stress, inflammation) in juxtaposition to diminishing homeostatic capacities (contingent on telomere length, gene expression, and other biologic factors). The progression of aging is moderated by each person's lifelong health habits (e.g., nutrition, physical activity, sleep, alcohol), CVD risk factors (e.g., blood pressure, cholesterol, tobacco, weight), comorbidities (e.g., infections, metabolic diseases, chronic kidney disease [CKD], chronic obstructive pulmonary disease [COPD]), psychological status (e.g., depression, anxiety), social structure (e.g., spouse, children), and functional capacity (e.g., physical, cognitive). Although chronological years are immutable, other aspects of aging can often be modified. Habitual exercise, for example, fundamentally reduces the trajectory of aging[12] and the susceptibility to age-related CVD.

Age-Associated Changes in Cardiovascular Structure and Function

To better understand the distinctions of CVD in old age, it is important to clarify basic physiologic principles that modify the baseline health and affect disease. Although age-associated changes in CV structure and function are commonly characterized as “normal,” there are intrinsic changes that resemble early disease (e.g., stage 1 hypertension and early atherosclerosis). Essentially, CV aging and CVD interconnect as parts of a continuum, with underlying molecular links.[6] Lakatta describes a progression of abnormal molecular signaling within the DNA environment of aging vascular cells to a compensatory physiology that progressively morphs toward disease. The abnormal molecular signals, sensing, and responses result in abnormal transcription, cell renewal, and proteostasis. Renin-angiotensin-aldosterone signaling and proinflammatory cytokines are homeostatic responses that help to limit molecular abnormalities, but they also increase the allostatic load on the CV system and gradually predispose a person to CVD (**Fig. 88.1**).[6]

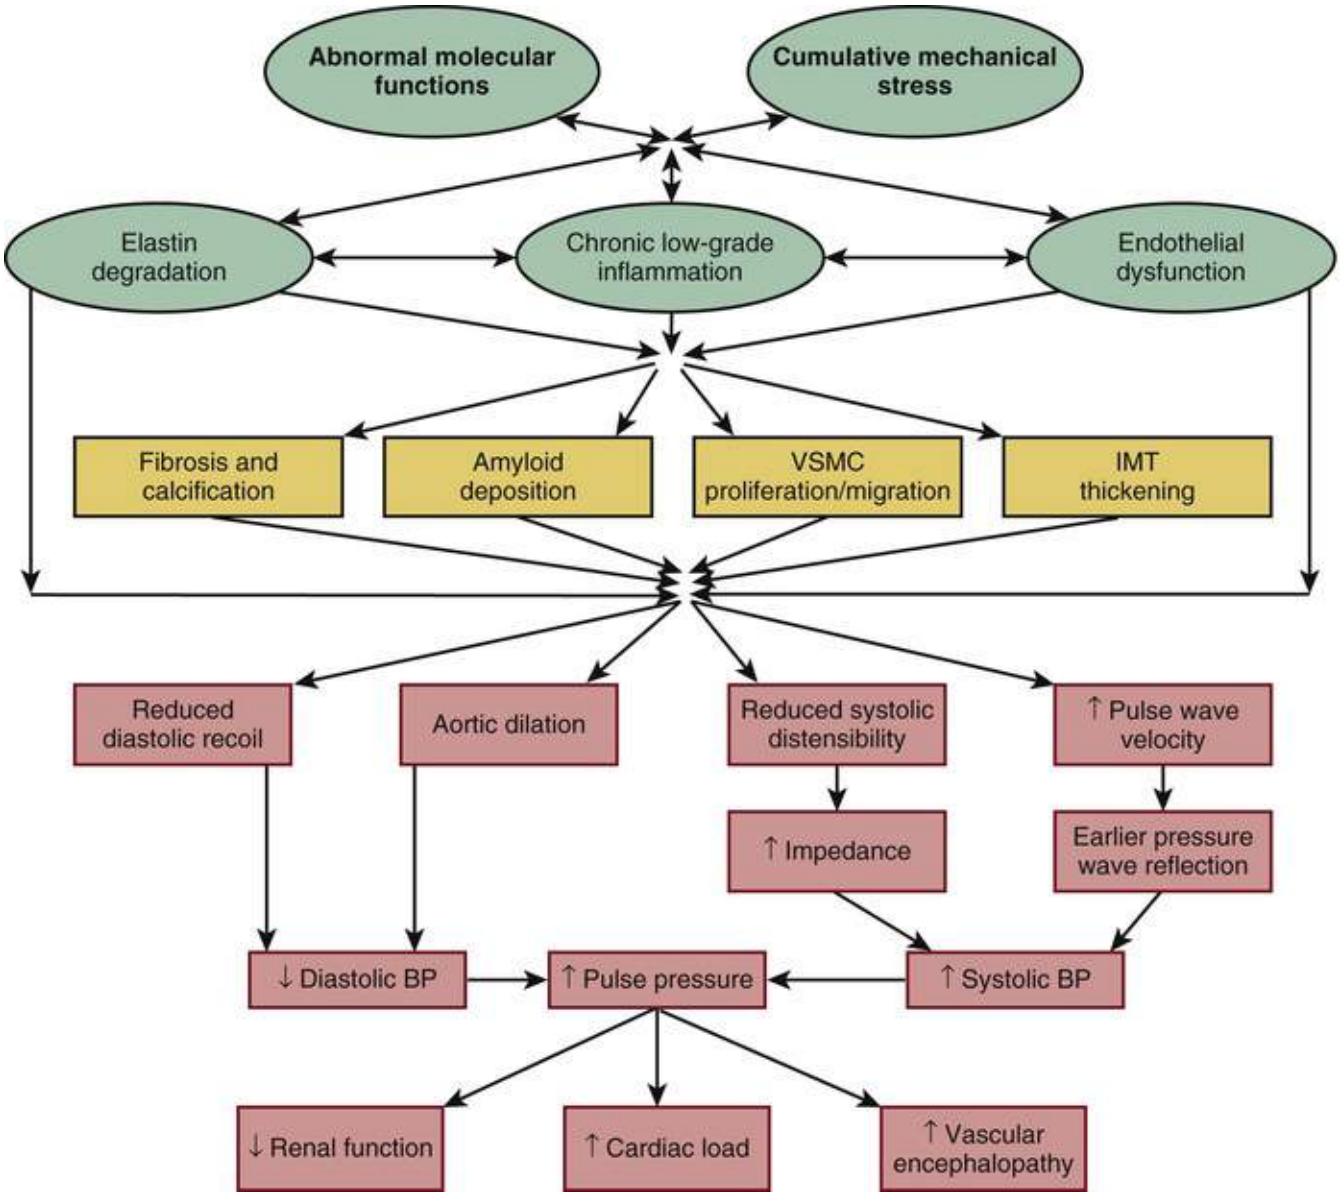

FIGURE 88.1 Conceptual model of arterial aging and arterial decline. Age-associated molecular disorders and cumulative mechanical stress lead to a state of chronic inflammation, elastin degradation, and endothelial and VSMC dysfunction. Downstream effects result in arterial wall calcification, fibrosis, amyloid deposition, VSMC proliferation, and intimal-medial thickening. These structural changes lead to functional alterations that result in widened pulse pressure. The increase in pulsatility leads to increased left ventricular load, chronic kidney disease, and vascular dementia. (Modified from Lakatta EG. So! What's aging? Is cardiovascular aging a disease? J Mol Cell Cardiol 2015;83:1-13.)

Vasculature

Prominent structural and functional changes affect the arterial system in older adults, even those with no apparent CVD. The arterial wall media thickens because of smooth muscle cell hypertrophy, extracellular matrix accumulation, and calcium deposition. Intimal-medial thickness (IMT) increases nearly 3-fold between the ages of 20 and 90 years in normotensive individuals.[13] The range of IMT also increases with age, suggesting a variable response to aging, likely due to different genetic and lifestyle factors.

Along with increased IMT, advancing age leads to fraying of elastic fibers, as well as increases in collagen content and enzymatic cross-linking in the media that reduces arterial distensibility and increases stiffness.[14] Irreversible nonenzymatic glycation-based cross-linking of collagen forms advanced glycation end products (AGEs) that exacerbate the stiffening.

Changes in both vasodilating nitric oxide (NO) and vasoconstricting angiotensin II also contribute to

vascular aging. Age-dependent reductions in endothelium-dependent vasodilation have been attributed to reduced NO production.[14] Animal studies show both lower NO levels and reduced NO, consistent with reduced endothelial NO synthesis. Conversely, angiotensin II in the vessel wall increases 1000-fold with substantially increased angiotensin II signaling.

Both oxidative stress and chronic low-grade inflammation are key mediators of the structural and functional changes in the arterial wall with aging (**see also Chapter 44**). Oxidative stress results from excessive generation of reactive oxygen species by enzymes such as NADPH oxidase, uncoupled NO synthase, and xanthine oxidase by the mitochondrial transport chain and from reduced antioxidant capacity.[15] Increased reactive oxygen species and dysfunctional endothelial NO synthase contribute to age-associated decrements in endothelium-mediated vasodilation. Elevated oxidative stress also leads to enhanced protein oxidation, activation of inflammatory and endoplasmic reticulum stress responses, and apoptosis.

As a result of structural and functional changes in the arterial walls, stiffening of large and medium-sized arteries occurs with aging, independent of disease. Even when pressures are within the normotensive range, the systolic blood pressure (SBP) generally rises. However, in the majority of older adults, the SBP progresses into the hypertensive range (**see also Chapter 46**). In contrast, the diastolic blood pressure (DBP) tends to rise until the sixth decade and declines thereafter because of the reduced elastic recoil from the stiffer large arteries (**Fig. 88.2**).[14] High blood pressure in older adults is therefore typically manifested as isolated or predominant SBP elevation. The pulse pressure, the difference between SBP and DBP, also increases, augmenting the pulsatile load on the heart and vasculature. Several studies suggest that pulse pressure is a more potent predictor of CV events in middle-aged and older adults than either SBP or DBP.[13]

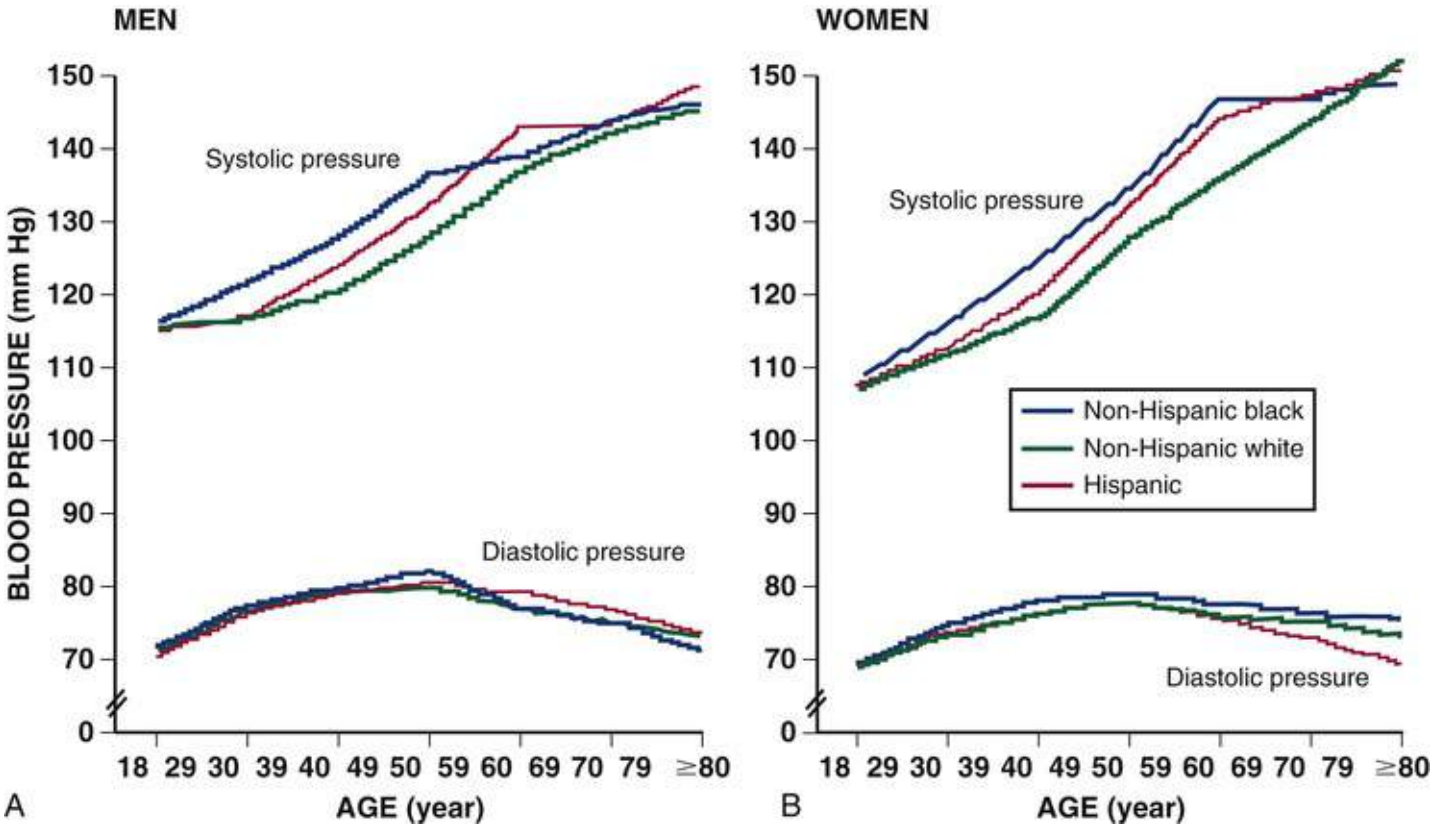

FIGURE 88.2 Age-associated changes in blood pressure in men and women by race and ethnicity. (From Aronow WS, Fleg JL, Pepine CJ, et al. ACCF/AHA 2011 expert consensus document on hypertension in the elderly: a report of the American College of Cardiology Foundation Task Force on Clinical Expert Consensus Documents. Circulation 2011;123(21):2434-2506.)

The pulse wave velocity (PWV), the speed with which an arterial pulse wave traverses the arterial tree, is another index of arterial stiffness that provides insights regarding aging changes in the arterial system; PWV is typically measured between the carotid and femoral arteries. Aortofemoral PWV increases 2- to 3-fold across the adult lifespan in normotensive populations. Studies in both healthy cohorts and those with CVD have shown that a higher PWV predicts future CV events, independent of the blood pressure.[14]

Left Ventricular Composition and Mass

In younger adults, the heart is composed of approximately 25% cardiomyocytes and a complex structure of connective tissue. With aging there is a decrease in the total number of cardiomyocytes, likely due to apoptosis, as well as an increase in their individual sizes (i.e., hypertrophy).[13] In both animal and human studies, apoptotic myocytes were more prevalent in the hearts of older males compared with females, paralleling an age-related decline of left ventricular (LV) mass in men but not in women. Within the connective tissue, the collagen content, fibrosis, and deposition of cardiac amyloid and lipofuscin all increase. The heart therefore becomes more fibrotic and stiffer with age (i.e., greater passive and active tension).[13]

Left Ventricular Wall Thickness, Cavity Size, and Shape

Despite the absence of an increase in cardiac mass with aging, there is a significant increase in myocardial thickness,[13] particularly due to increased cardiomyocyte size. Although concentric LV hypertrophy occurs, the interventricular septum increases in thickness more than the free wall, and there is

a change in LV shape. A magnetic resonance imaging (MRI) study in healthy volunteers demonstrated shortening of the left ventricle along its long axis and a shift from an elongated prolate ellipsoid geometry to a more spherical left ventricle with age.[13] Because a more spherical ventricle is exposed to higher wall stress, the age-associated change in cardiac shape has important implications for contractile efficiency. Greater LV sphericity is associated with a higher incidence of LV dysfunction and HF (**see also Chapter 23**) A large cardiac MRI study shows age-related declines in both LV diastolic and systolic volumes and an increased LV mass/volume ratio in both sexes.[13]

Resting Cardiac Function

In healthy normotensive adults, the resting echocardiographic LV shortening fraction and radionuclide LV ejection fraction (LVEF), the two most commonly used measures of global LV systolic performance, are not age related.[13] Prolonged contractile activation of the thickened LV wall maintains a normal ejection time, and compensates for the late systolic augmentation of the blood pressure, preserving the systolic LV pump function despite increased arterial stiffness. In contrast, LV diastolic performance is prominently altered by aging. Whereas LV diastolic filling occurs primarily in early diastole in younger adults, the transmitral early diastolic peak-filling rate declines by 30% to 50% between ages 20 and 80 years.[13] Conversely, there is an age-associated increase in peak A-wave velocity, which represents late LV filling facilitated by atrial contraction. The increase in late LV filling is mediated via a modest age-associated increase in left atrial size.[13]

Although age-related delays in the early diastolic filling rate do not usually compromise the end-diastolic volume and stroke volume at rest, stress-induced tachycardia (e.g., with exercise, fever, or other physiologic stress) is likely to exacerbate diastolic filling abnormalities. Tachycardia not only disproportionately shortens the time available for diastolic filling, but also exacerbates the impaired energy-dependent uptake of calcium into the sarcoplasmic reticulum. Therefore, fast heart rates are commonly associated with diastolic filling abnormalities, and the higher LV diastolic pressure is transmitted into the lungs despite a normal resting LV systolic function. These findings are commonly manifested as HF with a preserved ejection fraction (HFpEF), especially when superimposed on other common age-associated comorbidities such as hypertension, diabetes, CHD, and AF (**see also Chapter 26**).

The enlargement of the left atrium that occurs as a function of age and diastolic dysfunction occurs primarily after age 70 years[13] and increases the susceptibility of older adults to AF. Whereas AF is often well tolerated in many younger adults, it is more likely to provoke symptoms and clinical events among the elderly. Not only is AF commonly associated with poorly tolerated fast ventricular rates, but the AF-induced loss of the atrial boost to diastolic filling aggravates age-related diastolic filling impairment. Thus, older patients with AF are more likely to have a reduced cardiac output and resultant dyspnea and fatigue than younger individuals (**see also Chapter 38**).

Age-associated myocardial changes also predispose some older adults to myocardial ischemia and HF. A thicker left ventricle predisposes to subendocardial ischemia by increasing the distance between the epicardial coronary arteries and the subendocardial myocytes. In addition, capillary growth and flow regulation in older hearts may not match the oxygen demands of the hypertrophied myocytes (in contrast to cardiac hypertrophy in young athletes). These intramyocardial changes in capillarity and flow dynamics are compounded by peripheral arterial stiffening and an accelerated PWV (i.e., faster reflected pressure waves now arriving in systole, such that subendocardial perfusion is no longer bolstered by augmented pressures in diastole).[14]

Amidst aforementioned age-associated changes in the vasculature and heart, especially when compounded by prolonged exposure to other CVD risk factors, the occurrence of CVD increases dramatically in older adults (**Table 88.1**).[13] Intrinsic vulnerability to atherosclerosis in the vasculature predisposes to myocardial ischemia, myocardial infarction (MI), stroke, and PAD. Heart failure with a reduced ejection fraction (HFrEF) may develop as the result of ischemic coronary events or prolonged hypertension, either of which can impair LV systolic function. However, HFpEF is more likely to develop in the setting of ventricular stiffening, especially in association with hypertension, AF, and diabetes, all of which increase in frequency with age. Furthermore, CV aging occurs in a context of other age-related changes that compound the effects of CVD (**Table 88.2**)[13] (**see also Chapter 26**). Risks of myocardial ischemia and HF are, for example, considerably worsened in the presence of concomitant renal, metabolic, hematologic, pulmonary, and other noncardiac physiologic changes.

TABLE 88.1

Relationship of Cardiovascular Aging in Healthy Humans to Cardiovascular Disease

AGE-ASSOCIATED CHANGES	PLAUSIBLE MECHANISMS	POSSIBLE RELATIONSHIP TO DISEASE
CV Structural Remodeling		
↑ Intimal-medial thickness	↑ VSMC migration and matrix production	Early stages of atherosclerosis
↑ Vascular stiffness	Elastin fragmentation ↑ Elastase activity	Systolic hypertension
	↑ Collagen production and cross-linking	
	Altered growth factor regulation and tissue repair	Atherosclerosis
↑ LV wall thickness	↑ LV myocyte size	↓ Early LV diastolic filling
	↓ Myocyte number Focal collagen deposition	↑ LV filling pressure/dyspnea
↑ Left atrial size	↑ Left atrial volume/pressure	↑ Risk of atrial fibrillation
Calcium deposits in valves and conduction system	Mechanical stress	Aortic stenosis Atrioventricular block
CV Functional Changes		
Altered vascular tone	↓ NO production/effects	Vascular stiffening/hypertension
	↓ βAR responses	
↓ CV reserve	↑ Vascular load	Lower threshold for heart failure

βAR, beta-adrenergic receptor; CV, cardiovascular; LV, left ventricular; VSMC, vascular smooth muscle cell.

TABLE 88.2

Common Age-Related Changes That Compound Cardiovascular Disease Risks

Kidneys	↓ Glomerular filtration rate ↓ Renal metabolism
Lungs	↓ Ventilatory capacity ↑ Ventilation/perfusion mismatching
Musculoskeletal	↓ Skeletal muscle mass and function (sarcopenia) ↓ Protein reserves ↓ Bone mass
Immune function	↑ Susceptibility to infections
Hematopoietic	↑ Levels of coagulation factors ↑ Platelet aggregability ↑ Inhibitors of fibrinolysis ↑ Anemia
Neurohormonal	↓ Cerebral autoregulatory
Liver	↓ Hepatic metabolism
Mood	↑ Depression ↑ Anxiety
Sleep	↑ Obstructive sleep apnea

Cardiovascular Response to Exercise

The ability to perform physical exercise is highly relevant in clinical evaluation, especially in older

adults. The CV response to exercise is a well-established metric for diagnosis, prognostication, and monitoring of patients with CVD. It is also strongly predictive of the ability of older individuals to withstand major procedures or aggressive therapies (**see also Chapter 13**).

Aerobic Exercise Capacity

Numerous studies have demonstrated that cardiorespiratory fitness (oxygen consumption [VO_2] max per kg weight at peak exercise) declines markedly with age. In cross-sectional studies, the decline is approximately 50% from the third to ninth decade. In longitudinal studies, a more pronounced age-associated VO_2max decline is evident, regardless of habitual physical activity levels (**Fig. 88.3**).[13] The decline is only partially explained by changes in maximal heart rate and other CV parameters. Sarcopenia, the age-related atrophy and weakening of skeletal muscle, contributes significantly to the age-associated decrease in VO_2max. Age-related sarcopenia involves a reduced number, size, and function of muscle fibers. By age 75 years, muscle mass typically represents approximately 15% of body weight compared with 30% in young adults. Fast-twitch fibers atrophy to a greater extent than slow-twitch fibers, which likely contributes to decrements in strength that are proportionally greater than the loss of muscle mass. Increased intramuscular fat and decreased mitochondrial bioenergetics contribute to reduced muscle function.[16] Effects of CVD (most notably HF) on skeletal muscle compound the effects of sarcopenia.[17]

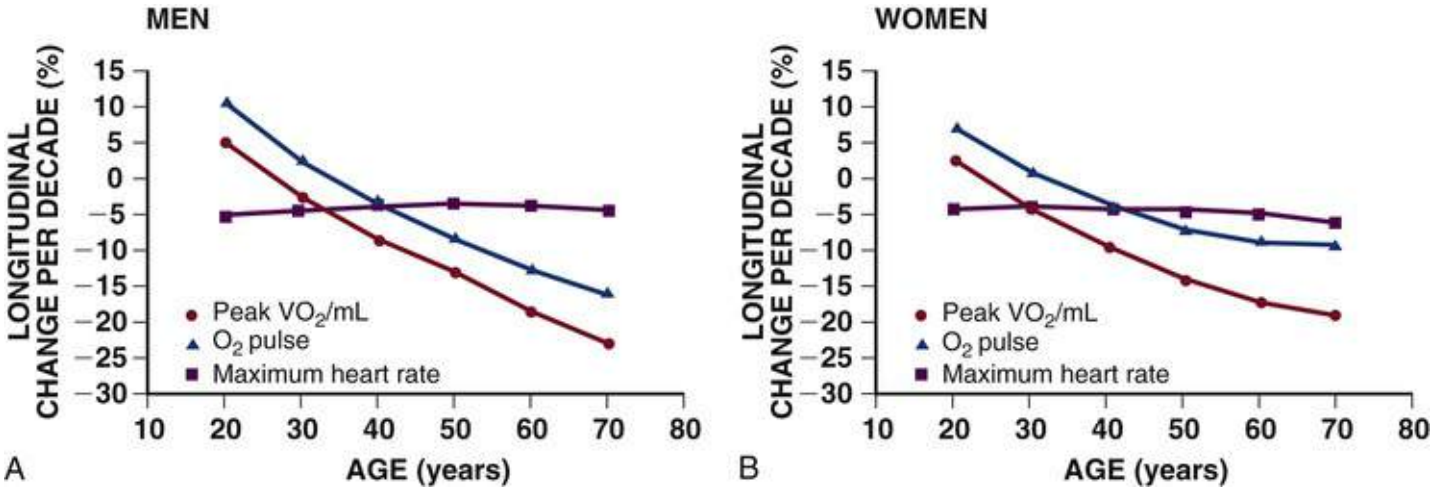

FIGURE 88.3 Longitudinal changes in peak oxygen consumption and its components, maximal heart rate, and oxygen pulse in healthy volunteers. Although the decrease in heart rate remained relatively constant over time, at approximately 5% per decade, an accelerated age-associated decline occurred in oxygen pulse that parallels that seen for peak oxygen consumption. (From Fleg JL, Strait J. Age-associated changes in cardiovascular structure and function: a fertile milieu for future disease. Heart Fail Rev. 2012;17(4-5):545-54.)

The accelerated decline of aerobic capacity with age has important implications regarding functional independence and quality of life (QOL). Because many of the activities of daily living require fixed aerobic expenditures, they require a significantly larger percent of VO_2max in older than younger adults. When the energy required for an activity approaches or exceeds the aerobic capacity of an elderly individual, he or she will be less likely to perform it.

Cardiac Function During Exercise

A decline of approximately 50% in the peak VO_2 between the ages of 20 and 80 years was accompanied

by a decline of approximately 30% in cardiac output and approximately 20% in arteriovenous uptake. The decrease in cardiac index with age at maximal effort was due primarily to a reduced heart rate because the LV stroke volume is preserved in men and women.[13] Although older individuals have a blunted capacity to reduce LV end-systolic volume and to increase LVEF with exercise, this deficit is offset by a larger end-diastolic volume[13] (i.e., a slower heart rate allows more time for LV filling, and thus a greater amount of blood remains in the heart at end diastole). Although slower LV diastolic filling is a normal aspect of aging, inability to increase the LV end-diastolic volume during exercise is suggestive of cardiac pathology. Mechanisms for the age-associated reduction in maximal LVEF include reduced intrinsic myocardial contractility, increased arterial afterload, arterial-ventricular load mismatching, and blunted sympathetic modulation of LV contractility and arterial afterload.[13,14] These changes contribute to susceptibility to CVD, and adversely affect its prognosis.

Geriatric Domains Pertinent to Cardiovascular CARE

Just as physiologic changes that occur with age determine distinctive CVD vulnerabilities and complexities, geriatric syndromes can play a determinative role that affects disease physiology, presentation, and management. Multimorbidity, polypharmacy, frailty, disability, delirium, and the presence of other geriatric syndromes fundamentally affect CVD, cause differences in CVD in older adults and younger adults, and even cause differences from one older CVD patient to another. Precepts of evidence-based CVD therapeutic strategies often lose applicability as geriatric syndromes transform prototypical CVD concerns (**Table 88.3**).

TABLE 88.3

Geriatric Syndromes and Clinical Implications

GERIATRIC SYNDROME	DIAGNOSIS	PROGNOSIS	DISEASE MANAGEMENT	PROCESS OF CARE
Multimorbidity: Chronic diseases (diabetes mellitus, arthritis, COPD), as well as geriatric syndromes (falls, incontinence, sarcopenia)	Affects or complicates disease presentation	Confounds CVD risk assessment ↓ Short- and long-term disease prognosis	Primary management of CVD may exacerbate comorbid conditions Coexisting diseases may preclude guideline-directed therapies	Multiple providers Conflicting medical priorities Care for CVD may exacerbate another problem Requires working across specialties
Polypharmacy: ≥4 chronic medications	Drug-drug or drug-disease interactions	↑ Adverse events, hospitalizations, deaths	Overtreatment and poor adherence are likely Impacted by age-related changes in pharmacodynamics and/or pharmacokinetics	Drug complexities Across transitions Between providers Over different systems and types of care
Frailty	Multiple frailty metrics with different rationales: Fried frailty phenotype: ↓ Weight, ↓ energy, ↓ physical activity, ↓ speed, ↓ strength Parsimonious measures that incorporate Fried precepts: gait speed, short physical performance battery Frailty Index based on cumulative deficits	Increased vulnerability to adverse outcomes (from disease or therapy) ↑ Risk of procedural and therapeutic complications ↑ Risk of disability, falls, hospitalization, death	Crucial to recognize as part of shared decision making Potentially modifiable with exercise and diet	Frailty affects all aspects of CVD care Decision making Risk assessment Recovery ↑ Value of rehabilitation
Disability	Inability to care for oneself or to manage one's own home Diagnostic tools: Katz Index of Independence in Activities of Daily Living (ADL); Bristol ADL Scale Lawton Instrumental Activities of Daily Living (IADL) Scale; Barthel IADL Index	↑ Risk of adverse outcomes, complications, death	↓ Functional status leads to reduced capacity for self-care (e.g., difficulties with medication administration and/or self-monitoring)	Acute CVD event may precipitate worsening in functional status Poor health care transitions
Delirium	Disturbed attention Predisposing risks include cognitive deficit, sensory limitations, disorienting medications Confusion Assessment Method (CAM)	↑ Length of stay ↑ Death ↓ Shared decision making	Optimize environment to increase orientation, avoid sedation, reduce medications, reduce pain Optimize safety	Can manifest as agitated state or quiet and withdrawn state

COPD, chronic obstructive pulmonary disease; *CVD*, cardiovascular disease.

Multimorbidity

Multimorbidity, or the presence of “multiple chronic conditions,” implies a situation in which two or more chronic conditions are active. For therapies to achieve outcomes that are perceived by a patient with multimorbidity as having value, they must usually address all of the many conditions.[18] Thus, multimorbidity fundamentally transforms the CVD therapeutic paradigm, which would be oriented primarily to CVD-specific care and which may fail to address comorbid conditions or even make them worse.

Multimorbidity increases with age and is prevalent in more than 70% of adults age 75 years or older[19]; in up to 90% of older HF patients,[20] it challenges the basic principles underlying conventional CV management. “Evidence-based” CVD guidelines often rely on investigations that in the past chose study populations with few, if any, comorbidities. Such rigorous selection of study populations allowed delineation of therapies for specific diseases free from the confounding effects of comorbid states. Such evidence-based therapy guidelines are less meaningful when they are applied to clinical circumstances in which multiple diseases and medications are present in older patients (as is commonly the case). In these

groups, they are likely to engender interactions and complexities that were never studied originally. In a study of Medicare patients,[21] the dyad of hypertension and hyperlipidemia was present in 53%; among patients with HF, stroke, or AF, 50% had five or more comorbidities (**Fig. 88.4**).[18,21]

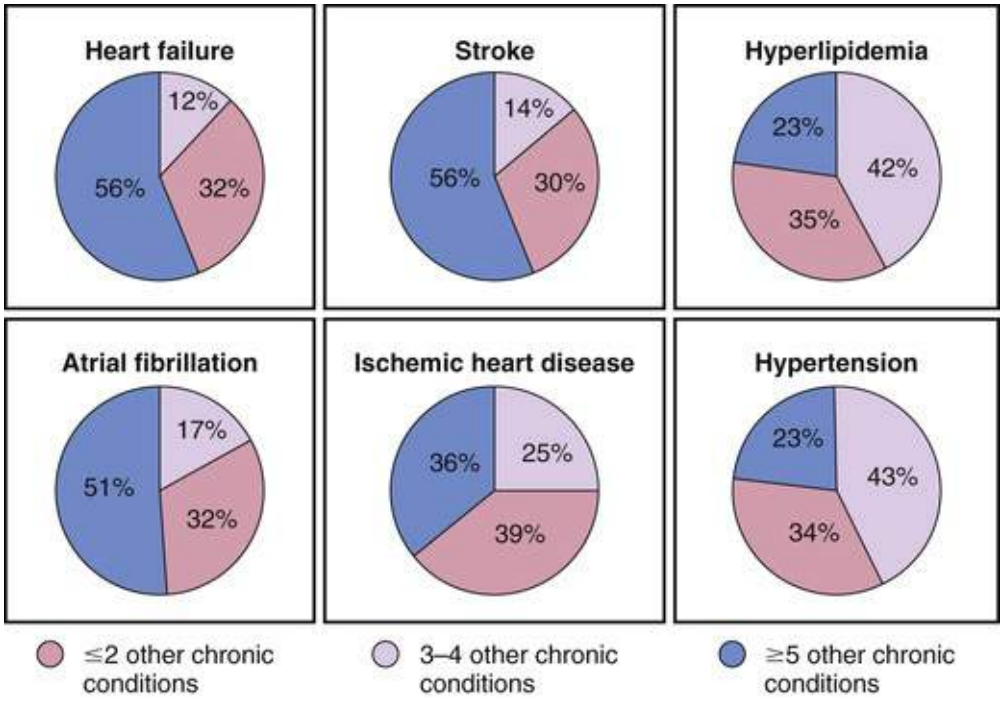

FIGURE 88.4 Number of coexisting chronic conditions among Medicare fee-for-service beneficiaries with common cardiovascular diagnoses. (From Fleg JL, Aronow WS, Frishman WH. Cardiovascular drug therapy in the elderly: benefits and challenges. Nat Rev Cardiol. 2011;8(1):13-28; Arnett DK, Goodman RA, Halperin JL, et al. AHA/ACC/HHS strategies to enhance application of clinical practice guidelines in patients with cardiovascular disease and comorbid conditions: from the American Heart Association, American College of Cardiology, and U.S. Department of Health and Human Services. J Am Coll Cardiol. 2014;64(17):1851-56.)

Management of CVD must be considered with added precautions because conventional therapies more often induce untoward outcomes when multiple comorbidities are present (e.g., angiotensin-converting enzyme [ACE] inhibitors are more likely to provoke a fall in an older patient with sarcopenia and Parkinson disease). Furthermore, outcomes of older patients with CVD are often more likely to be determined by noncardiac comorbidities. For example, short-term rehospitalization for HF is frequently determined by comorbidities other than CVD. Despite contributing to only 14% of the Medicare population, patients with six or more chronic conditions account for 25% of readmissions.[19] Such patients usually see on average two primary care providers and five specialists a year, each prioritizing his or her own disease orientation and thereby contributing to fragmented care and increased risk.[22]

Polypharmacy

Polypharmacy is common among older adults with multimorbidity because clinicians prescribe a group of evidence-based medications oriented to each disease; this often results in a risky accumulation. Each guideline is supported by evidence, but there is no guideline that addresses medication regimens for multiple concurrent diseases and their aggregated effects.[23] “Quality indicators,” which are frequently used to assess the quality of care, are often based on clinical guidelines; they may implicitly reinforce incentives for clinicians to prescribe guideline-based medications irrespective of the total number of medications the patient is taking. Although most CVD guidelines acknowledge that clinical judgment is

needed to integrate evidence-based standards with each patient's idiosyncrasies and complexities, they do not provide a refined strategy to achieve or access such tailored care.[1] Consequently, the concept of individualizing guideline-based CVD care is often more theoretical than real, especially because a divergence from guideline recommendations may be (mis)interpreted (e.g., by insurers) as substandard care (and potentially vulnerable to punitive repercussions, such as nonremuneration or insinuations of negligence) rather than appropriate care. Similarly, CV adherence initiatives such as “get with the guidelines”[24] implicitly encourage cardiologists to prioritize full regimens of CV medications without explicit modifications that adjust for comorbidities and patient complexity.

The Sloan survey shows that 44% of older men and 57% of older women received five or more prescription medications,[25] a finding typical among those with CVD. Consequences are often dangerous. Common scenarios include patients who might receive multiple medications for hypertension despite a context of poor gait, poor nutrition, sarcopenia, and falls. Similarly, many patients with CHD and AF may be prescribed aspirin, P2Y12 inhibitors, and warfarin despite a history of epistaxis or other bleeding pathologies. Most CVD patients are also taking medications to control cholesterol levels or diabetes, enhance memory, relieve the pain of arthritis, help prostate disorders, provide bladder control, relieve anxiety or insomnia, and benefit many other typical comorbidities, compounding the risks for adverse drug reactions, poor adherence, and exorbitant costs.[25]

The safety risks associated with mounting numbers of medications in old age are compounded by age-related changes in pharmacokinetics and pharmacokinetics (**see also Chapter 8**). Pharmacokinetics refers to the processing of a drug by the body, which encompasses absorption, distribution, metabolism, and excretion.[25] Pharmacodynamics relates to the actions of drugs on the body.[25] Both are significantly affected by aging effects on body composition, metabolism, and vulnerability to adverse sequelae. Because most cardiac medications are absorbed by passive diffusion, gastrointestinal aging has only minor effects on absorption. Distribution is more affected by age. Medications that are distributed predominantly in skeletal muscle (e.g., digoxin) must be adjusted for age-related lean tissue atrophy, particularly among women, in whom lean mass is usually less than men. Weight is also usually lower in older adults, and weight-based dosage adjustments are indicated for many medications (e.g., low-molecular weight heparin (LMWH]). The most significant age changes of pharmacokinetics are related to metabolism and excretion. Changes in renal metabolism are especially significant. In general, the glomerular filtration rate (GFR) is lower in older women than men, and decreases about 10% per decade in both sexes.[26] By age 80 years, the GFR is typically one half to two thirds of that in younger adults. This reduction can be masked by overestimation of the GFR using the Modified Diet in Renal Disease formula and the Chronic Kidney Disease Epidemiology Collaboration. The Cockroft-Gault is the preferred GFR equation; it accounts for age, sex, and weight, and characterizes a linear decrease of renal function. The dosage of many medications cleared by the kidney must be reduced in old age, such as digoxin, LMWH, glycoprotein IIb or IIIa inhibitors, and direct oral anticoagulants (DOACs) (**see also Chapter 98**).

Hepatic metabolism is affected by multiple processes pertaining to drug delivery, enzymatic transport into liver cells, and enzymatic transformation and/or excretion via efflux transporter enzymes into bile. These processes can be influenced by heterogeneous factors such that there is no validated algorithm to estimate age-related changes in hepatic and extrahepatic drug clearance. The most notable age-related changes are evident in oxidative biotransformation by membrane-bound cytochrome P (CYP)-450. Clearance of beta blockers (e.g., metoprolol), calcium channel blockers (e.g., verapamil, diltiazem, and dihydropyridines), and many statins (e.g., atorvastatin and fluvastatin) depends on this pathway and usually diminishes with age.

Pharmacodynamic alterations are especially common amidst age-related constitutional changes.

Changes in thirst, temperature regulation, autonomic reflexes, sympathetic and cholinergic receptors, and cell signaling all have an impact on the effects of medications, with greater susceptibility to orthostasis, syncope, and other clinical sequelae. Changes in vascular stiffness and endothelial responses are also coupled to neurohormonal changes and cognitive declines, with greater susceptibilities to hemodynamic instability, delirium, and other consequences.

The context of multimorbidity, polypharmacy, altered pharmacokinetics and pharmacodynamics, and other age-related factors contributes to higher risks of adverse drug events. Studies show rates as high as 10.7%, and CV drugs account for about half of the reported events.[27] Budnitz and colleagues demonstrated four leading "culprit" medications: warfarin (33.3%), insulin (13.9%), oral antiplatelet medications (13.3%), and oral hypoglycemics (10.7%).[27] Although the Beers criteria[28] includes medications typically problematic for older adults (and which should generally be avoided), this study highlights the fact that standard cardiac medications may also become harmful as patients grow older. Because the number of medications prescribed is the most significant risk factor for adverse drug interactions, this risk increases markedly with age. Advancing age also increases the risks of medication errors, with many detrimental consequences, including causation of approximately 20% of hospital readmissions.

Drug-drug interactions are typical in patients taking several medications, particularly when medications are metabolized by the same pathway (**Table 88.4**).[29] Amiodarone, for example, inhibits CYP oxidative enzymes and increases drug levels of those medications that would normally be metabolized (**see also Chapter 36**). Effects may also occur if clinical actions of medications are additive (e.g., administering aspirin, clopidogrel, and apixaban together will exacerbate bleeding risks) or competing (e.g., administering liraglutide and steroids together will decrease glucose control).

TABLE 88.4

Common Iatrogenic Effects of Secondary Prevention Medications in Older Patients with Cardiovascular Disease

MEDICATION CLASS	MEDICATION	GENERAL SIDE EFFECTS	DRUG-DRUG INTERACTIONS	DRUG–COMORBID DISEASE INTERACTIONS
Antiischemics and antihypertensives	Beta blockers	Confusion, fatigue, dizziness, bronchospasm, conduction block, chronotropic incompetence, claudication, depression, cold sensitivity, incontinence Hypoglycemia Increased system absorption in body fat, with delayed metabolism	Calcium channel blockers: conduction disease and chronotropic incompetence Sulfonylureas: hypoglycemia	COPD: ↑ bronchospasm Depression or anxiety: ↑ fatigue and depression PAD: ↑ claudication Raynaud syndrome: ↑ symptoms HF: ↑ decompensation Conduction disease: bradycardia, heart block
	ACE inhibitors	Falls, dizziness, hypotension (orthostatic, postprandial), hyperkalemia, fatigue, azotemia, cough	Diuretics (and other antihypertensives): hypotension NSAIDs: renal failure	CKD : hyperkalemia and renal failure
	Nitrates	Dizziness, hypotension, syncope, headache	Diuretics: hypotension and ↓ cardiac output) Phosphodiesterase inhibitors: severe hypotension Alcohol: hypotension	Aortic stenosis: hypotension
	Diuretics	Urinary frequency and incontinence, electrolyte abnormalities (e.g., hypokalemia, hyponatremia, hypomagnesemia), hyperglycemia, hyperuricemia, dehydration, muscle cramps	ACE inhibitors and other diuretics: hypotension	CKD: worsened renal failure Diabetes: ↑ hyperglycemia Incontinence: ↑ incontinence
	Calcium channel blockers	Dizziness, flushing, peripheral edema (dihydropyridines), constipation (verapamil)	Beta blockers: conduction disease and chronotropic incompetence	HF: decompensation Conduction disease: bradycardia, heart block GI: ↑ constipation
Antiplatelet	Aspirin	GI bleeding, dyspepsia, tinnitus, skin reactions	Warfarin, DOACs, or thienopyridine: ↑ bleeding	History of GI bleeding: ↑ bleeding risks
	Thienopyridines	GI bleeding, bruising, rash	Warfarin, DOACs, and/or aspirin: ↑ bleeding.	History of GI bleeding: ↑ bleeding risks
Cholesterol reduction	Statins	Myalgias, confusion, renal insufficiency, liver toxicity	Medications metabolized by cytochrome P450 system (fibrates, amiodarone, erythromycin, diltiazem, azole antifungals): ↑ statin levels and ↑ levels of the other medications Fibric acids: myopathy (gemfibrozil > fenofibrate) Grapefruit juice: ↑ statin levels (via cytochrome P450 mechanism)	Hypothyroidism, CKD, diabetes: ↑ susceptibility to statin-induced myopathy

ACE, angiotensin-converting enzyme; *CKD*, chronic kidney disease; *COPD*, chronic obstructive pulmonary disease; *DOAC*, direct oral anticoagulant; *GI*, gastrointestinal; *HF*, heart failure; *NSAID*, nonsteroidal antiinflammatory drug; *PAD*, peripheral artery disease.

Drug-disease interactions occur as medications that benefit one chronic disease adversely exacerbate another disease or syndrome. Beta blockers for cardiac ischemia may, for example, trigger bronchospasm or claudication in patients with concomitant COPD or PAD. Calcium channel blockers can exacerbate chronic constipation, which is usually further compounded by sedentariness. Diuretics can aggravate incontinence and related social isolation and depression. In general, almost every medication brings risks of unintended consequences, reinforcing the geriatric precept to consider removing therapies if their value is not clear. A related principle of “deprescribing” medications is a growing focus in clinical care and research.[30]

Nonadherence is another concern for older CVD patients. Given the high risk associated with CVD

among older adults, the same population that is vulnerable to ill effects from over prescription is also highly susceptible to poor outcomes if certain medications are omitted. Thus, in a context of pervasive polypharmacy it is still critical to emphasize adherence to CV medications.[23,31] The challenge is to prescribe medications that are predominantly beneficial. Adding pharmacists to transcatheter aortic valve replacement (TAVR), HF, and other CVD care teams can often help achieve this goal.

Frailty

Frailty generally implies a state of vulnerability to stressors and limited reserves to stabilize declines across multiple physiologic systems.[32] Adults who are frail are prone to developing disease, and have worse disease outcomes and greater risks for harmful sequelae from standard therapies. With the advent of TAVR, the interest in frailty became accelerated among cardiology proceduralists because frailty serves as a key selection criterion when TAVR is being considered.[33] However, the interest in frailty quickly expanded to also better conceptualize personalized management with respect to acute coronary syndromes (ACSs), CHD, and many other types of CV care.[34] The prevalence of frailty ranges from 20% to 70% in different populations of CVD patients.

A single frailty assessment tool has not become dominant, and two prevailing approaches to identify frailty have evolved[35]: frailty conceptualized as an observable phenotype versus frailty conceptualized as a numerical index. The “eyeball test” is one of the earliest examples of frailty as a phenotype, but it is inherently inexact. Fried et al.[32] advanced the premise of a “frailty phenotype” by identifying five specific physical characteristics by which it could be standardized: weakness, low energy, slowed walking speed, decreased physical activity, and weight loss. Those with one or two domains are classified as prefrail, and those with three to five domains are considered frail.

Fried et al.[32] also explained frailty as a biologic manifestation of inflammation; circulating inflammatory biomarkers (high-sensitivity C-reactive protein and interleukin-6), as well as inflammatory cells (neutrophils and monocytes), are increased in frailty.[32] Thus, frailty interacts with CVD, such that adults who are frail by Fried criteria are more likely to have CVD, and older adults with CVD are more likely to be frail. Fried's conceptualization of frailty as a biologic phenomenon also explicitly differentiates frailty from multimorbidity and disability.[32]

In contrast, Mitnitski and Rockwood[36] describe frailty as an index of deficits of candidate variables (i.e., a ratio of physical deficits as well as morbidities, disability, and other clinical variables that accumulate and progressively burden an individual). The magnitude and speed at which deficits accumulate can be used to gauge vulnerability and risk. Although, Mitnitski and Rockwood originally identified 92 candidate domains for the frailty index, in subsequent studies as few as 30 were determined to be effective for assessment.

Despite their methodologic and conceptual differences, the Fried index, Mitnitski and Rockwood index and many other frailty indices are concordant in defining frailty as a state of increased vulnerability that predicts greater clinical risk. Moreover, the different frailty tools all tend to regard frailty as a dynamic state such that measurements can be repeated to distinguish changes in clinical status. Still, the inconsistencies regarding frailty assessments have contributed to confusion, inconsistency, and controversy in this field.[35]

In general, a “frailty phenotype” is easier to recognize in a clinical setting as part of a physical examination. Alternatively, the “frailty index” is more easily determined using criteria coded in electronic clinical and administrative datasets. Variations on the Mitnitski and Rockwood index have been used to track trajectories of frailty across health systems.[37] Many groups are now studying variations in CVD

therapy relative to the degree of frailty.

Alternatives to Fried's composite of physical phenotypic features include single-measure performance assessments,[38] including gait speed, handgrip strength, balance, or chair rise as demonstrated by Afilalo in a video tutorial.[39] Any one of these parsimonious assessments provides relatively efficient screening and assessment by a clinician as part of a routine evaluation and/or before an anticipated procedure. The prognostic utility of gait speed in community populations provides compelling validation as a single assessment of physical frailty.[40] The continuous nature of gait speed also enables detection of small changes (0.1 m/sec) where ordinal scales might not be as sensitive. The Timed Up and Go (TUG) and Short Physical Performance Battery (SPPB)[38] are also easy to implement and expand upon gait speed to better quantify strength, balance, and other pertinent clinical perspectives.

Disability

Disability refers to a physical or mental condition that limits a person's movements, senses, or activities. Whereas younger adults with CVD are usually able to rebound after a successful CVD hospitalization or therapy, recovery is less certain among older adults with similar disease. Disability is greater among women than men. Multimorbidity, frailty, polypharmacy, and other geriatric syndromes predispose to disability in the hospitalized elderly person, especially in the context of acute illness, deconditioning, cognitive impairment, poor sleep quality, and other burdens that tend to occur in older adults. Frailty is particularly conducive to disability, with disability often arising when physiologic reserve and compensation are depleted. The impact of hospital-related disability[41] is common and in some respects paradoxical because older adults are vulnerable to morbid effects from the hospitalizations that are used to deliver care. Thus, even patients who receive optimal care are less likely to recover to their prehospital capacity.[42] Recurrent hospitalizations tend to contribute to a cycle of progressive disability, with inability to recover from illness that progresses and induces a worsening QOL and an escalation of mortality risks (**Fig. 88.5**).[43] Sarcopenia, increased fat mass, poor nutrition, cognitive decline, and inflammation all contribute to disability risk.

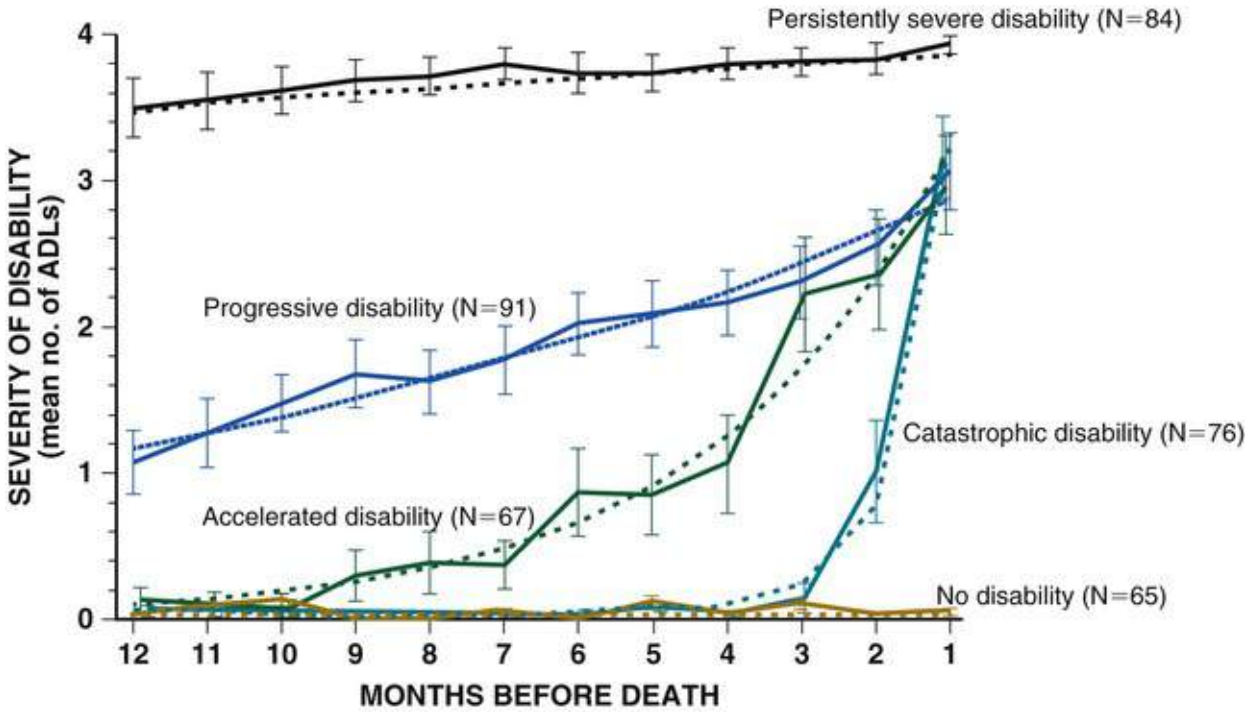

FIGURE 88.5 Trajectories of disability in the last year of life. Most decedents had high levels of disability in the last month of life, yet more than half were not disabled 12 months before death. The severity of disability is indicated by the mean number of activities of daily living (ADLs) in which the subjects had disability. The *solid lines* indicate the observed trajectories, and the *dashed lines* indicate the predicted trajectories. The *I bars* indicate 95% confidence intervals for the observed severity of disability. (From Gill TM, Gahbauer EA, Han L, Allore HG. Trajectories of disability in the last year of life. *N Engl J Med.* 2010;362(13):1173-80.)

The utility of CVD therapy to mitigate age-related disability has not been a primary focus of most research initiatives. Therapies prioritized to treat CVD may inadvertently also increase vulnerabilities to disability (e.g., myalgias with statins and/or fatigue with beta blockers). However, endpoints in some recent CV trials reflect recognition of this possibility: Instead of focusing on thromboembolic events, bleeding, and such customary disease metrics in an aspirin trial, the ASPirin in Reducing Events in the Elderly (ASPREE)[44] trial is focused on “disability-free life,” including freedom from dementia.

Delirium

Delirium is a disorder of disturbed attention that can be manifested as agitated disruptive behavior or as quiet and withdrawn behavior that is less likely to elicit attention and a corrective response. Although delirium is not directly related to CVD pathophysiology, it has a direct bearing on CVD management and outcomes. Among hospitalized elderly persons, 15% to 55% are affected, predisposing to high mortality rates as well as to frailty and disability. Presentation usually entails a rapid decline in consciousness with difficulty focusing or sustaining attention.

The strongest risk factor for delirium is baseline cognitive dysfunction. Dementia affects 14% of adults age 70 years or older in the United States, increasing to 37% in those over 90 years.[45] Moreover, dementia rates are higher in those with CVD, including reports of 35% of those undergoing coronary artery bypass graft (CABG)[46] surgery and 47% of those hospitalized with HF.[47]

Multiple factors of hospitalization are likely to trigger delirium, including the stress of a new environment, poor sleep, new medications, withdrawal from home medications, pain, dehydration, hypoxia, and metabolic shifts. Anticipatory screening by the Confusion Assessment Method (CAM) is a validated tool for screening in a hospital setting[48] and can prompt modification of precipitating factors (e.g., environmental modifications, medication adjustments, electrolyte and nutritional enhancements).

Relevance of Geriatric Syndromes to Cardiovascular Disease

An overriding principle of geriatrics is that the presence of CVD and its management often have the inadvertent effects of destabilizing a tenuous equilibrium in older adults. Incontinence, for example, may not seem to be a CV problem, but it can be induced or aggravated by diuresis or CV medications that affect sphincter or bladder control and may profoundly affect a patient's fundamental confidence, self-efficacy, and lifestyle. Likewise, falls may be provoked by routine CV medications, especially in the common contexts of frailty, polypharmacy, poor hydration, delirium, and other geriatric risks. In general, geriatric syndromes are usually relevant to CVD management because they confound therapy, transitions, health literacy, decision making, adherence, and resiliency to recover (**Fig. 88.6**). Although greater morbidity and mortality risks of CVD usually imply greater absolute risk-lowering benefits of therapy, there is also the potential for greater complications. Iatrogenesis, delirium, and disability are all more likely. Clinical guidelines are relevant, but their application to older adults requires added attention to the broader clinical context.

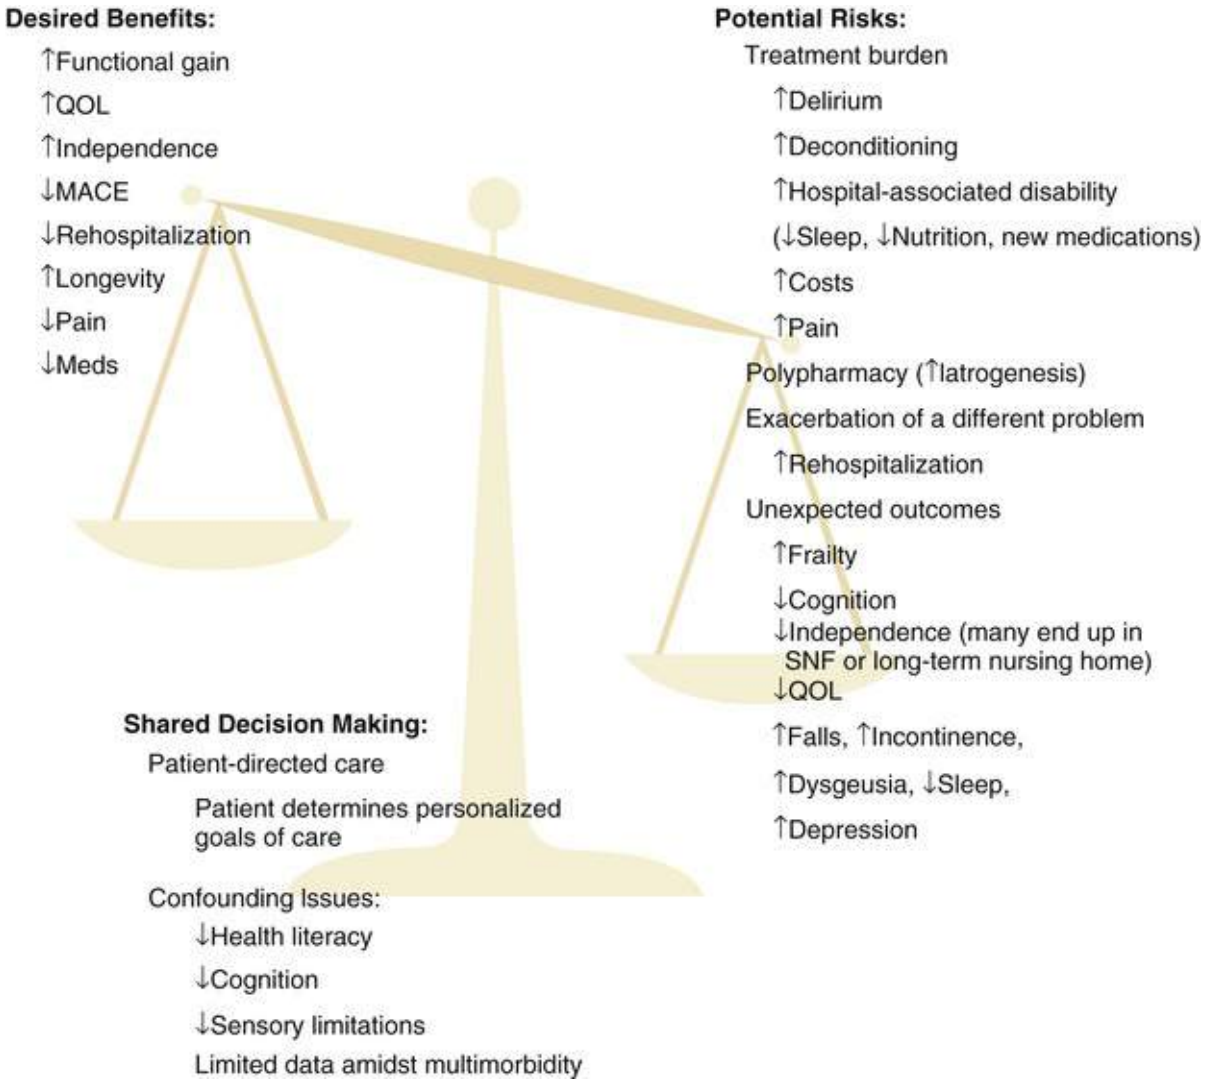

FIGURE 88.6 Shared decision making. Among older adults with CVD, clinical goals are more typically oriented to functional gains, independence, and quality of life (QOL), often with less priority ascribed to traditional CVD endpoints of major adverse cardiovascular events (MACE) and survival that are emphasized in most major trials. Therapeutic risks are also relatively greater for older adults, particularly as geriatric syndromes compound the potential for harm. Shared decision making is an important goal, but it is fundamentally challenged by common limitations of health literacy, cognition, elucidating data, and other vital elements. SNF, Skilled nursing facilities.

Aging and Specific Cardiovascular Conditions

Ischemic Heart Disease

Age is a strong and independent risk factor for the development of coronary atherosclerosis, and older adults constitute the majority of U.S. patients with new-onset angina pectoris. The AHA reports that 20% of men and 10% of women age 60 to 79 years have ischemic heart disease (IHD), with the prevalence increasing to 32% and 19% in men and women over 80 years of age (**see also Chapter 58**).[8] Atherosclerosis is more severe and diffuse in older adults, with a higher prevalence of left main stenosis, multivessel disease, and impaired LV function. Although obstructive epicardial atherosclerotic plaque is the dominant cause of myocardial ischemia in older adults, other pathophysiologic mechanisms include microvascular dysfunction, endothelial dysfunction, vascular spasm, and microembolism; LV hypertrophy with associated microvascular deficiency or other factors may lead to supply-demand imbalance.[49]

Presentation

Only a minority of older adults describe typical angina, with ischemic presentations more often characterized by exertional fatigue and dyspnea, lack of energy, and epigastric or back discomfort (**see also Chapter 56**). Postprandial or emotional stress symptoms are common. Many of these symptoms are difficult to differentiate from comorbidities. The history may be further challenged by a declining activity level, comorbid conditions, and cognitive impairment. Silent myocardial ischemia is also common. Baseline electrocardiogram (ECG) abnormalities are more prevalent than at a younger age and further confound assessments.

Risk Stratification

Most risk assessment models pertain to younger populations, with uncertain specificity and sensitivity for older adults, who often have differing social demographics, symptoms and signs, risk factors, comorbidities, and laboratory and ECG features.[50] Ischemic evaluation, as in younger age-groups, is based on the pretest likelihood of IHD, such that a low-risk patient may not warrant additional testing and a high-risk older adult is a candidate for invasive angiography; those with an intermediate pretest probability benefit most from risk stratification (**see also Chapter 3**). Exercise tolerance testing (ETT) is less feasible in older adults due to the lower exercise capacity associated with aging and comorbidities, as well as baseline ECG abnormalities that limit ischemic assessments (**see also Chapter 13**). However, ETT with modified exercise protocols (e.g., beginning at lower intensities of exercise and smaller workload increments) often enables adequate exercise stress provocation in older patients. Imaging (i.e., myocardial perfusion imaging or echocardiography) increases the sensitivity and specificity for the diagnosis of ischemia. In a metaanalysis of the optimal noninvasive strategy for risk assessment for patients over 65 years of age with known or suspected IHD, stress imaging with nuclear myocardial perfusion or echocardiography effectively stratified the risk, whereas ETT alone did not.[50] For older patients unable to exercise, pharmacologic stress testing can facilitate risk stratification, but the added utility of exercise to delineate physical function, hemodynamics, arrhythmia, and other pertinent clinical parameters remains an important consideration.

Although older adults have a high prevalence of coronary artery calcium, the value of the coronary artery calcium score in elderly patients is limited. Coronary CT angiography is less accurate in assessing

lesion severity in older patients due to their high prevalence of coronary artery calcium.[51] Invasive coronary angiography, a prerequisite for ascertaining the feasibility and selection of revascularization procedures, is recommended for older adults whose clinical characteristics and results of noninvasive testing indicate a high likelihood of significant CHD. It is also recommended with a moderate clinical risk profile with decreased LV systolic function. Despite risks of bleeding, stroke, contrast-induced kidney injury, arterial tortuosity, CKD, and reduced tolerance for sedatives and narcotics, older adults still benefit from coronary angiography and subsequent revascularization, due to the high prevalence of multivessel and left main disease.

Management (see also Chapter 62)

The 2012 ACCF/AHA/ACC/AATS/PCNA/SCAI/STS Guideline for the Management of Patients with stable (S) IHD[52] includes a specific focus on older adults. More than one third of patients with SIHD are over age 75 years. Pharmacologic agents to control angina symptoms are comparable to those prescribed at a younger age, but with added attention to adverse effects (e.g., aspirin increases the risk of bleeding; beta blockers may exacerbate adrenergic dysfunction, bradycardia, and hypotension; calcium channel blockers may also induce bradycardia and hypotension, as well as pedal edema, constipation, and incontinence; ACE inhibitor and angiotensin receptor blocker (ARB) therapy may impair renal function due to the high prevalence of renal artery stenosis; and nitrates can exacerbate postural hypotension).

Invasive coronary angiography and optimal revascularization are recommended for older adults with refractory symptoms, particularly those with significant ischemia shown on noninvasive diagnostic tests.[53] In the 4-year follow-up of the Trial of Invasive versus Medical Therapy in Elderly patients (TIME) study, better symptom relief and exercise capacity were achieved by revascularization than by an optimized medical strategy in elderly SIHD patients.[54]

In decisions for revascularization therapy, physiologic status has greater bearing than chronological age. The Euro SCORE and the Society of Thoracic Surgery risk scores not only integrate surgical parameters and comorbidities, but also now include metrics of mobility and frailty (gait speed), respectively, as added perspectives to help gauge the short-term procedural outcomes and the longer-term QOL and ability to live independently.[55]

In older adults, percutaneous coronary intervention (PCI) has a greater rate of procedural complications than in younger adults, including bleeding, stroke, contrast-induced kidney injury, and postprocedural MI. Dual antiplatelet therapy, a requisite concomitant for optimal performance of drug-eluting stents, is associated with increased bleeding and transfusion risk in elderly adults. Bleeding risks can be minimized by using weight and renal dose-adjustments of anticoagulant and antiplatelet agents.

The choice of PCI over CABG involves consideration of the anatomy, comorbidities, functional capacity, and patient preferences. In U.S. patients over 65 years of age but without acute MI, there is no difference in the mortality rates with CABG or PCI at 1 year following the procedure, but the mortality rate is lower with CABG than with PCI at 4 years. The higher rate of complete revascularization with CABG decreases the recurrence of symptoms and the need for repeat revascularization and improves the mortality rate.[56] However, CABG requires a longer recovery time, has a higher risk of stroke, and carries procedure-related neurologic complications. Notably, some reports show that more than 50% of post-CABG patients experience short-term cognitive impairment and approximately 20% experience long-term cognitive impairment, although reviews suggest that postoperative cognitive changes may correspond primarily to baseline cognitive deficiencies.[46,57]

Acute Coronary Syndromes

In the United States, the average age of the first episode of an acute coronary syndrome (ACS) is 65 years in men and 72 years in women (**see also Chapters 59 and 60**). Age is the strongest risk factor for poor outcomes following an ACS. The importance of age as a prognostic marker is reflected in the majority of ACS risk scores, including the Evaluation of the Methods and Management of Acute Coronary Events (EMMACE) and the Global Registry of Acute Coronary Events (GRACE).[58] About 60% of hospitalizations for ACS are for patients over 65 years of age, with approximately 85% of deaths due to ACS occurring in this age-group; 32% to 43% of non–ST elevation (NSTE)–ACS admissions and 24% to 28% of ST-elevation MI (STEMI) hospital admissions were for patients older than 75 years.[59]

Presentation

Although ACS involves predominantly men in their middle years, the numbers and proportion of women with ACS increase in old age. Among adults 75 to 84 years old, the numbers of men and women with ACS are similar, and in the population over 80 years of age, the majority of ACSs occur in women. Mortality rates are generally higher in older women than men with ACS. NSTE-ACS is far more prevalent than STEMI in the older population.

Elderly ACS patients are less likely to present with typical ischemic chest pain, but rather to develop autonomic symptoms, including dyspnea, diaphoresis, nausea and vomiting, presyncope or syncope, weakness, altered mental status, or confusion,[58] even when chest discomfort is present. Chest pain is reported in only approximately 40% of those older than 85 years compared with nearly 80% in those younger than 65 years; consequently, there is a reduced probability of the prompt and correct diagnosis of ACS in the elderly, leading to delays in therapy.

Because of a lower activity level, symptoms in older adults are less likely to be induced by physical exertion, but rather to be precipitated by hemodynamic stresses with comorbidities, particularly infection or dehydration. Heart failure classified as Killip class 2 or higher is 45% more likely at presentation at age 85 years or older. Type 2 MI is also more common in older adults due to other comorbid conditions such as tachycardia, hypoxemia from pneumonia, chronic lung disease, and bleeding episodes. A high index of suspicion is important in elderly patients to achieve a timely diagnosis.

Diagnosis

Because elderly patients are more likely to present with NSTE-ACS than STEMI, dynamic ST segment–T wave changes are important for detecting ischemia, although interpretation for ischemia is also commonly confounded by baseline ECG abnormalities. Initial and serial assessments of cardiac biomarkers are important, with the caveat that elderly individuals have higher baseline levels of troponin (cTn); 20% of community-dwelling adults over 70 years of age have levels above the 99th percentile at baseline. A key priority is to differentiate ACS from a multiplicity of acute and chronic conditions that also lead to low-level myocardial necrosis (type 2 MI). Further, a larger portion of elderly patients with ACS have elevated BNP, which predicts a worse outcome.

Management

ACS guidelines stress that older patients present complex challenges because of atypical symptoms, confounded by a high prevalence of cardiac and noncardiac comorbidities, age-related alterations in CV anatomy and physiology, and an increased risk for adverse drug events and interactions caused by

polypharmacy. Although the pharmacologic standards of care for ACS do not differ with age, medication side effects are more common in elderly ACS patients. Antianginal agents, oxygen for hypoxemic patients, and antiplatelet and/or anticoagulant therapy are indicated; bivalirudin may reduce bleeding compared with unfractionated heparin plus GPIIb/IIIa inhibitors.

Revascularization for STEMI

Timely reperfusion is the cornerstone of care of older patients with STEMI, who have reasonable post-MI outcomes when treated aggressively. Elderly STEMI patients have more contraindications to reperfusion, but even if eligible, they are less likely to receive it. Primary PCI with stent placement is preferred over thrombolysis in older adults because it results in greater survival benefit, reduced reinfarction and need for repeat revascularization, and less intracranial hemorrhage. Although, compared with placebo, fibrinolytic therapy reduced STEMI mortality rates in elders, few older adults were studied in seminal trials. Moreover, compared with PCI, fibrinolytic therapy has been associated with a significantly increased risk of myocardial rupture after age 75.[60] In most cases, fibrinolytics are used in STEMI presenting 12 hours or sooner after symptom onset and expected to have a system delay (≥ 120 min) before a possible PCI.

Revascularization for NSTE-ACS

Because older adults with NSTE-ACS are at generally greater risk than their younger counterparts, an early invasive strategy has more benefit in elderly than in younger patients in the absence of prohibitive comorbidities. PCI is safe even for NSTE-ACS patients who are 90 years of age or older, with high success rates and a low major bleeding risk, especially with the radial artery approach. In older adults with NSTE-ACS and diabetes, there is a greater survival advantage with CABG as a revascularization strategy. However, the operative mortality rates and risks of major complications are substantial, up to 8% at 80 years of age or older.[59] Both prolonged hospitalization and postsurgery recovery are also significant. In the After Eighty study, an invasive strategy was superior to a conservative strategy in the reduction of composite events (i.e., MI, need for urgent revascularization, stroke, and death) for patients 80 years of age or older.[61] The small number of nonagenarians had no significant benefit. The two strategies did not differ in bleeding complications, likely related to the predominant use of a radial access approach.[61]

Care Following an Acute Coronary Syndrome; Discharge Planning

Patients over 80 years of age have longer lengths of stay following ACS (8 days for those older than 80 years vs. 5 days for those younger than 65 years); frail individuals have longer hospital stays and increased rates of discharge to institutional care. Elderly patients have a high risk of rehospitalization and death, with a 50% increased mortality risk per 10 years of increasing age starting at age 65. Commonly encountered complications of ACS in older adults relate to cardiac vulnerabilities (e.g., HF, pericarditis, atrial and ventricular arrhythmias, and conduction system abnormalities) but also to the added vulnerabilities associated with physiologic aging in the heart, lungs, kidneys, neuroautonomic system, and metabolic system. Heart failure is a particularly common manifestation in ACS in older patients. Similarly, bleeding, procedural complications, medication side effects, delirium, and other age-related vulnerabilities are common.

In-hospital mortality and complication rates increase with advancing age, but lower mortality rates have been reported in patients receiving more recommended therapies. Beta blockers have greater benefit

in elderly patients in preventing subsequent MI and death than in younger groups. ACE inhibitors and ARB therapies are beneficial in the elderly, particularly those with HF or reduced LV systolic function. Benefits of statins are established in older adults through their early 80s.[59] Dual antiplatelet therapy after PCI/stenting presents a challenge in older adults who also require antithrombotic therapy (e.g., warfarin or DOACs) for AF, deep vein thrombosis (DVT), a mechanical heart valve, or other reasons. Recent trials suggest that therapy with a P2Y12 inhibitor plus an oral anticoagulant, and omitting of aspirin, may be as effective as triple therapy in preventing MI, CV death, and ischemic stroke, with decreased bleeding.[62]

Comprehensive discharge planning includes the patient and family, and must address comorbidity, polypharmacy, frailty, and often impaired communication and cognition. Failure to understand and comply with the plan of care contributes to the high rate of ACS readmission and poor outcomes. The incidence of death among elderly patients in the first year after NSTEMI increased markedly with age, from 13.3% at 65 to 79 years to 45.5% at age 90 years or more. Rehospitalizations are due to nearly as many non–CV-related conditions as CV-related conditions. At 1 year, nonagenarians had substantially higher rates of death with or without a preceding rehospitalization and twice the adjusted mortality rate as the 65- to 79-year age group.[63]

Cardiac Rehabilitation

Comprehensive cardiac rehabilitation (see Prevention of Cardiovascular Disease in Older Persons, later) has great value for older ACS and SIHD patients.[64] It can help achieve reduced mortality rates, decreased hospitalization rates, and an improved QOL. Despite a class IA recommendation in all clinical practice guidelines, referrals decrease in relation to age, especially for older women.

Heart Failure

Heart failure epitomizes a convergence of CVD and geriatrics (**see also Chapter 21**). (1) The incidence and prevalence of HF rise exponentially with age, and entail the predisposing aspects of CV physiologic aging, mounting CVD risk factors over a lifetime, and geriatric syndromes. (2) The HF pathophysiology affects multiple systems (i.e., encompassing the heart as well as the vasculature, lungs, kidneys, and skeletal muscle).

Epidemiology

In the United States, the number of HF patients is projected to increase from about 5.7 million persons currently to nearly 8 million persons by 2030.[65] In the 2011 to 2014 National Health and Nutrition Survey (NHANES), the HF prevalence rose from 1.4% in men and 1.9% in women 40 to 59 years to 14.1% and 13.4% in men and women, respectively, 80 years of age or older.[8] The incidence of HF also increases markedly with age, rising from approximately 0.1% in persons 45 to 54 years old to approximately 3% in those 85 years of age or older.[66] The incidence of HFpEF increases particularly rapidly among the very old; underlying diastolic LV filling changes as well as a high prevalence of hypertension, diabetes, AF, and other predisposing comorbid risks are all pervasive in the older adult demographic, intensifying the susceptibility to HFpEF.[67] Hospital discharges for HF approximate 1.1 million per year in the United States, the majority in older adults. National Center for Health Statistics data show HF hospitalizations were 85.7 per 10,000 in adults age 65 to 74; 214.6 per 10,000 in adults age 75 to 84; and 430.7 per 10,000 in adults age 85 and older (**Table 88.5**).[8]

TABLE 88.5

Heart Failure in Older Adults Versus Middle-Aged Adults

CHARACTERISTIC	OLDER ADULTS	MIDDLE-AGED ADULTS
Prevalence	6% to 18%	<1%
Gender	Predominantly women	Predominantly men
Cause	Hypertension	Coronary heart disease
Left ventricular systolic function	Normal	Impaired
Left ventricular diastolic function	Impaired	Normal or mildly impaired
Comorbidities	Multiple	Few

Mortality rates from HF also increase exponentially with aging; annual mortality rates are less than 10 per 100,000 in adults age 45 to 49 years, rising to 150 per 100,000 in octogenarians.[66] The median survival time was only 20 months for 825 patients 85 years or older versus 50 months for those younger than 85 years in a Danish study of 8507 hospitalized HF patients.[68] Atrial fibrillation, a lower LVEF, and renal insufficiency were associated with greater long-term mortality rates. Comorbid risks for HF overlap in older and younger adults, but the higher prevalence of comorbidities in older adults results in a higher attributable risk (defined by the prevalence times the relative risk) for developing HF despite a lower relative risk. Cardiovascular comorbidities were greater in those younger than 85 years than in those older than 85 years, reflecting differences in the risk factors predisposing to HFrEF or HFpEF, and the somewhat accelerating incidence of HFpEF in very old age.

In the Cardiovascular Health Study (CHS), a community-based sample of individuals age 65 years or older at baseline, hypertension and CHD were the most common HF antecedents, each accounting for approximately 13% of incident HF cases. Other common risk factors for HF in CHS were diabetes, PAD, valvular disease, AF, and reduced renal function. The relationship between multimorbidity and HF is explained in part by the stresses induced by conditions superimposed upon age-related reductions in CV reserve.[69] Inflammation associated with mounting comorbidity also exacerbates HF risks, particularly HFpEF.[67] Lifestyle factors (e.g., smoking, obesity, and low physical activity) increase HF risk in older and younger populations.

Pathophysiology

Numerous population-based observational studies have demonstrated important age-related differences in the clinical profile and pathophysiology of HF (**Table 88.5** and see also **Chapter 23**).[70] Whereas HF is more frequent in men than women at younger ages and through the 70s, women predominate by age 80 and beyond. More than half of older HF patients have a normal or near normal LVEF (i.e., HFpEF); in contrast, HFrEF is the dominant form of HF in younger patients. Although mortality rates from HFpEF are somewhat lower than for HFrEF, hospitalization rates are similar.[71]

Diagnosis

Because HF affects multiple organ systems, no single test or procedure can definitively diagnose HF or exclude it (**see also Chapter 24**). The specificity of the major Framingham diagnostic criteria for HF, orthopnea, and paroxysmal nocturnal dyspnea in older adults is low because these classic manifestations of HF can also be found in non-HF disorders such as pulmonary disease, deconditioning, and depression. The low physical activity levels of many older adults may mask the development of dyspnea or fatigue.

Among 5771 community-dwelling adults 65 years old or older in CHS, 7% had both orthopnea and paroxysmal nocturnal dyspnea (PND), but only 20% of these had centrally adjudicated HF.[72] Elevated jugular venous pressure is the most specific sign of fluid retention in HF and is useful for the diagnosis of

HFrEF or HFpEF. Nonetheless, many patients with chronic HF may be euvolemic and may not have classic HF symptoms and signs. Peripheral edema is also common but is not specific because it also may occur secondary to venous insufficiency, obesity, or low serum albumin. Similarly, symptoms of fatigue at rest may prompt concerns regarding depression rather than HF. Many older adults may attribute their HF symptoms to aging, thus delaying presentation until symptoms are more severe. Cognitive or sensory impairments may delay the diagnosis of HF in older adults.

When symptoms and signs of HF are insufficient or equivocal, objective laboratory criteria are helpful in establishing the diagnosis. A chest x-ray showing pulmonary venous hypertension and/or interstitial pulmonary edema is diagnostic. Both B-type natriuretic peptide (BNP) and N-terminal pro-BNP (NT-pro-BNP) are neurohormones secreted by the failing ventricle in HF in response to increased myocardial wall stress. Because modest increases of these hormones occur with advanced age, higher cutpoints to diagnose HF are needed in older patients.[73] BNP levels are generally lower in HFpEF than HFrEF, making them less reliable as a diagnostic index for a population in which HFpEF predominates. BNP has never been demonstrated to improve the accuracy of diagnosing HF or the efficacy of its treatment in real-world settings.[74]

After establishing a clinical diagnosis of HF, the next step is to determine its cause. In older adults, the cause may be multifactorial, with hypertension, IHD, valvular disease, and diabetes the most common antecedents. Treatable conditions such as hypertension, AF, myocardial ischemia, and significant aortic or mitral valvular lesions are important priorities. Age itself is not a cause of HF; LVEF is well maintained through the mid-80s, although early diastolic performance declines gradually as adults age.

Cardiac imaging remains an important part of the HF workup in older as in younger adults, both in establishing the cause and in guiding therapy. Given its wide availability, modest cost, noninvasiveness, and ability to measure both cardiac anatomy and function, echocardiography is the most attractive initial imaging test. Findings of AS, pericardial effusion, or LV wall motion abnormalities suggestive of CHD are all common among older adults, and have important diagnostic and therapeutic implications, as does the determination of LVEF. Reduced LVEF occurs in less than half of octogenarians with HF.

For older adults not adequately imaged by transthoracic echocardiography, cardiac magnetic resonance (CMR) imaging provides an alternate method to determine both cardiac structure and function. If renal function is adequate, the intravenous contrast agent gadolinium may be useful as part of the CMR examination to determine the presence and severity of myocardial scarring. Computed coronary tomographic angiography may be useful if CHD is strongly suspected from clinical or echocardiographic data, although its accuracy in older adults may be diminished by coronary artery calcifications. Invasive coronary angiography is generally reserved for individuals in whom CHD is suspected and who are candidates for coronary revascularization. Technetium pyrophosphate imaging is highly sensitive and specific for diagnosing transthyretin amyloidosis, an infiltrative cardiomyopathy that predominantly affects the elderly.[75] This disorder typically presents as HFpEF and has an especially adverse prognosis.

Lifestyle Management in Heart Failure

Although major advances have occurred in drug and device treatment of chronic HF in recent decades, lifestyle factors such as diet, physical activity, and patient/caregiver education retain an important role. Recent studies suggest that strict sodium and fluid restriction may not be necessary or optimal in HF patients, especially older adults. Rigid sodium and fluid restriction in elders may reduce an already low caloric intake and exacerbate malnutrition and sarcopenia, both common in older HF patients and associated with adverse outcomes. In one trial, a sodium intake of 2.7 g/day reduced the rate of death or hospitalization by 25% compared with an intake of 1.8 g/day.[76]

Numerous trials have shown that exercise training in older patients with HFrEF improves the functional capacity to a similar relative degree as in younger patients without increased safety concerns. Although earlier exercise training studies were too small to reliably examine the effect of exercise training on rates of mortality or hospital admissions in HFrEF patients, the HF: A Controlled Trial Investigating Outcomes of Exercise Training (HF-ACTION) trial studied 2331 patients. It reported a similar modest improvement in a combined endpoint of all-cause mortality and hospitalizations, as well as in combined CV deaths and HF hospitalizations, in the 435 patients age 70 years or older compared with younger patients in a program of 36 supervised exercise sessions followed by home training for up to 4 years.[77] Based on the HF-ACTION results, Medicare approved outpatient-supervised CR for stable HFrEF patients. Incorporating resistance exercises as well as flexibility and balance training is especially useful to counter age- and disease-associated deficits in these domains. In the absence of a formal training program, regular walking or other moderate-intensity exercise is encouraged. Although an equivalent CV event–driven rationale for exercise training in HFpEF is not available, many smaller trials suggest benefits, which may relate principally to improvements in peripheral mechanisms of disease (e.g., skeletal muscle and peripheral perfusion). Studies of exercise training for more frail HF patients (HFrEF and HFpEF) are ongoing.[64,78]

Education of older HF patients and their caregivers regarding HF manifestations and treatment helps ensure optimal adherence, improve the QOL, and reduce hospitalizations. Because HF exacerbations are usually preceded by fluid retention, it is helpful if patients weigh themselves daily, preferably in the early morning after urinating. If weight gain of 5 or more pounds or signs of decompensation (e.g., increased edema, paroxysmal nocturnal dyspnea, orthopnea, exertional dyspnea, and/or fatigue) occur, patients or their caregivers should be instructed to increase the diuretic dose temporarily and/or to contact their health care provider. In older patients with NYHA class III HF, an implanted pulmonary artery pressure sensor resulted in more medication changes, a 58% decrease in 30-day all-cause readmissions, and a 49% decrease in HF hospitalizations over 515 days of mean follow-up.[79]

Because of the high hospitalization rates and their associated costs in older HF patients, much attention has been directed toward developing disease management programs to optimize HF patient care and improve outcomes. Although not all HF disease management trials have shown benefit, a metaanalysis of 25 trials including 5942 patients recently hospitalized for HF found that interventions, typically involving home visits and/or telephone follow-up, reduced HF readmissions at both 6 and 12 months postbaseline.[80] Multiple trials have also confirmed an improved QOL from such programs. However, the inclusion of more HF patients who are 80 years of age or older is needed to determine the utility of such programs in this high-risk subset.

Pharmacotherapy for Chronic HFrEF

Although ACE inhibitors, ARBs, and beta blockers reduce CV events and improve survival rates in patients with HFrEF, this evidence base is derived from randomized clinical trials (RCTs) that enrolled only modest numbers of patients over age 65 years, and very few age 80 years of age or older (**see also Chapter 25**). Thus, clinicians must exercise caution in implementing these guideline-based recommendations in aged HF patients with multiple comorbidities. For example, in the Studies of Left Ventricular Dysfunction (SOLVD) Treatment trial, the largest trial of ACE inhibitors, although 36% of patients were age 65 years or older, none were 81 years or older. The proportion of patients over 80 years old in RCTs of beta blockers is similarly very small. In the Metoprolol CR/XL Randomized Intervention Trial in Congestive Heart Failure (MERIT-HF), a subgroup analysis showed that metoprolol had similar efficacy for reducing CV events in HFrEF patients 65 years of age or older as in younger

patients, but none were 81 years old or more. The Randomized Aldactone Evaluation Study (RALES) showed a 30% reduction in all-cause mortality rates with the aldosterone blocker spironolactone in patients with NYHA class III to IV HFrEF, including 9% who were 80 to 90 years old, though none were over 90 years. Despite this high proportion of older patients in RALES, the selection was limited to relatively healthy elderly persons, and only about 20% of real-world very old HFrEF patients would have been eligible to enroll.[70] Finally, although nearly half of the Digoxin Investigative Group (DIG) participants were 65 years of age or older, only about 5% were 80 years or older.[66] Regardless of the drug regimen in older HFrEF patients, frequent follow-up for adverse effects and need for medication adjustment is essential.

Diuretics

Diuretics remain the cornerstone for treatment of congestive signs and symptoms in chronic HFrEF despite the absence of RCT data that they reduce CV mortality rates. Observational studies suggest that chronic use may be associated with adverse outcomes, likely mediated by activation of neurohormones and electrolyte imbalances. Any of the three commonly used loop diuretics, furosemide, torsemide, and bumetanide, may be considered for older adults. Each should be started at a low dosage and slowly up-titrated to achieve euvolemia; after euvolemia is achieved, lower doses can be tried. Serum electrolytes and renal function require more careful monitoring in the elderly to reduce the risk for hypokalemia, hyponatremia, and prerenal azotemia. Concerns regarding incontinence and/or disproportionate concerns regarding voiding are also pertinent because such concerns may ultimately overwhelm an older patient's treatment experience.

ACE Inhibitors or ARBs

Based on strong clinical trial evidence, older HFrEF patients who have no history of allergy or intolerance to ACE inhibitors should be prescribed these drugs, starting at low doses. ARBs should be considered for patients who cannot tolerate an ACE inhibitor. Close monitoring is required to avoid hypotension, hyperkalemia, or azotemia, especially in the first few weeks after initiating or up-titrating therapy. In RCTs, the average daily dose of an ACE inhibitor or ARB was lower in older than younger patients.

Sacubitril-Valsartan Combination

The 2014 PARADIGM-HF study showed that the combination of the neprilysin inhibitor sacubitril and the ARB valsartan reduced total mortality rates by 16%, CV death rates by 20%, and HF hospitalization risks by 21% compared with the ACE inhibitor enalapril in 8442 patients with NYHA class II to IV HFrEF. These benefits were similar in the 1563 patients over 75 years of age and in younger groups.[81] Although hypotension, renal impairment, and hyperkalemia increased with age in both treatment arms, findings of more hypotension but less renal impairment or hyperkalemia with sacubitril-candesartan were consistent across age-groups. The high current cost of this novel therapy has limited its use.

Beta Blockers

Unlike ACE inhibitors and ARBs, a class effect is not evident for beta blockers in HFrEF. Clinical trial data support only carvedilol, metoprolol succinate extended release, bisoprolol, nebivolol, and bucindolol, but the latter two drugs are not approved for use in the United States. Although major RCTs of beta blockers included few patients older than 80 years, benefits appear similar across ages. In

hypertensive older patients with HFrEF, carvedilol may be a better beta blocker choice than metoprolol succinate or bisoprolol because of its vasodilating properties and tendency to lower blood pressure more effectively. In registry data analyses, only about one third of older HFrEF patients reached target doses used in prior RCTs (carvedilol 25 mg twice/day or bisoprolol 10 mg/day).[82] Side effects such as fatigue and/or chronotropic insufficiency are more common in older patients, limiting maximal tolerated doses.

Aldosterone Antagonists

Despite powerful RCT evidence for the efficacy of aldosterone antagonists in HFrEF, their effectiveness and tolerability in real-world patients has been questioned.[83] These drugs should be used with caution in older adults, with careful monitoring of renal function and serum potassium. Generally, patients should be started and maintained on spironolactone 12.5 mg daily or eplerenone 25 mg daily (or every other day if renal insufficiency is evident). Because aldosterone antagonists are administered for their neurohormonal benefits rather than modest diuretic effects, the dose should not be titrated up based on the volume status. Although hyperkalemia has been a major limiting factor in older adults, the recent approval of the oral potassium-binding drug patiromer may enable more such individuals to benefit from aldosterone antagonists.

Digoxin

Even after over two centuries, use of digitalis in HF patients remains controversial. The drug has a narrow therapeutic window and lack of life-prolonging benefits; nonetheless, the large DIG trial showed that digoxin reduced HF hospitalizations in HFrEF patients in sinus rhythm, including those up to 80 years. This trial antedated the widespread use of beta blockers and aldosterone antagonists, so its benefit in the current era is unclear. Recommended digoxin doses in older HFrEF patients are 0.125 mg a day or lower. Digoxin in these doses generally achieves a serum digoxin concentration of 0.5 to 0.9 ng/mL, which is likely to provide maximum clinical benefit with low risk of toxicity.[84] Routine checking of the serum digoxin concentration is not necessary but should be considered when symptoms or signs of digoxin toxicity are suspected.

Other Pharmacologic Therapies

Although an RCT demonstrated a reduction of CV events with the combination of hydralazine and isosorbide dinitrate in younger (mean age 57 years) African Americans with HFrEF, adequate data in older patients are lacking. However, the combination might be considered in patients unable to tolerate ACE inhibitors, ARBs, and/or beta blockers. There is no evidence of a long-term survival benefit from oral phosphodiesterase inhibitors, such as amrinone, milrinone, and vesnarinone or a calcium-sensitizing phosphodiesterase inhibitor such as levosimendan in HFrEF. Conversely, these drugs have been associated with increased mortality rates in RCTs. Although not usually considered for older HFrEF patients, in such individuals with refractory symptoms despite optimal evidence-based therapy, they may provide greater improvement in function and QOL than traditional therapies. The recently approved drug ivabradine acts by lowering the heart rate via inhibition of the I_f current without affecting the contractility. In the Systolic Heart Failure Treatment with the I_f Inhibitor Ivabradine Trial (SHIFT), ivabradine reduced HF hospitalization rates but not mortality rates in HFrEF patients with a resting heart rate of more than 70 beats/min despite maximally tolerated doses of beta blockers.[85] Although significant benefit was seen across age-groups, the risk reduction was greater in patients younger than 53 years (hazard ratio [HR], 0.62) than over 69 years (HR, 0.84).

Nonmedical Options for Chronic HFrEF

The high rates of mortality and morbidity in patients with HFrEF despite guideline-based medical therapy have led to development of nonmedical options, including devices and surgical procedures. Device therapy is discussed in the section on Aging and Cardiac Rhythm Abnormalities in this chapter. Given the chronic shortage of donor hearts for transplantation, patients in their eighth decade and beyond are not likely to be cardiac transplant recipients. Fortunately, the development of long-term or permanent LV assist devices (LVADs) has been shown to improve survival rates and the QOL in such patients with end-stage HF. Risks of bleeding, infection, and thrombosis have been reduced with the advent of continuous-flow LVADs. An analysis of 1149 continuous-flow LVAD recipients showed similar 1-year mortality rates in the 163 patients 70 years of age or older compared with younger patients, although the risk of gastrointestinal bleeding was higher in the older group.[86] The health-related QOL improved to a similar extent in 493 LVAD recipients age 70 years or older as in 977 younger recipients. However, appropriate patient selection in experienced centers is critical for favorable outcomes.

Functionally active older HFrEF patients may benefit from cardiac surgical procedures. Although CABG surgery has not been shown to improve overall survival rates in persons with a reduced LVEF,[87] it is generally considered for functionally independent older HFrEF patients with multivessel CHD and evidence of ongoing myocardial ischemia and symptoms despite optimal medical therapy. Similarly, surgery or TAVR in elders with severe AS is accompanied by a markedly improved survival rate and functional status, although with a higher risk for bleeding and stroke and a greater need for pacemaker implantation. Cardiac transplantation has been employed successfully in highly selected patients in their 60s and early 70s, although with slightly higher rates of surgical complications and mortality but fewer rejection episodes than in younger patients.

Pharmacotherapy for Chronic HFpEF

Symptoms are similar in patients with HFrEF and HFpEF, and symptomatic management of HFpEF is also similar to that described above for HFrEF (**see also Chapters 25 and 26**). Diuretics play a major role in controlling fluid retention and dyspnea. However, unlike HFrEF, there is no evidence of symptomatic benefit or reduction of CV events from ACE inhibitors, ARBs, or beta blockers.[88] Still, beta blockers, rate-slowing calcium channel blockers, and digoxin may reduce symptoms by controlling the heart rate in patients with concomitant AF. Although digoxin tended to reduce HF hospitalizations in HFpEF patients with a normal sinus rhythm in the ancillary DIG trial, this benefit was offset by higher hospitalization rates due to angina pectoris.[66] Spironolactone failed to significantly reduce the composite endpoint of CV death, aborted cardiac arrest, or HF hospitalization in the 3445 HFpEF patients in the TOPCAT trial, but reduced HF hospitalization rates by a significant 17%.[89] Marked geographic heterogeneity in patient characteristics was noted, with patients in the placebo group from Russia and Soviet Georgia having mortality rates approximately 80% lower than in the Americas. In the latter subset, spironolactone reduced the primary outcome by a significant 18%. Thus, spironolactone remains a consideration for older HFpEF patients who are symptomatic despite diuretics and after control of blood pressure and/or ischemia.

Pulmonary Hypertension

Pulmonary hypertension (PH) is increasingly recognized among older adults and is usually secondary to LV dysfunction (**see also Chapter 85**). Differentiation of PH from HF or pulmonary disease is a key challenge, and specialized centers have evolved that focus on this differential effort.[90] HFpEF

accompanied by pulmonary venous hypertension is associated with increased mortality rates, as well as worse symptoms and a diminished QOL.[91]

Pulmonary arterial hypertension was once considered a disease that primarily affected young women, but it is increasingly recognized in the geriatric population. Recent registry data show an increase in the proportion of elderly patients with pulmonary arterial hypertension, particularly elderly males.[92] Because fewer than 20% of elderly patients were enrolled in the clinical trials of the newer oral and parenteral therapies, extrapolation of these data to older adults is uncertain. Rather than subcutaneous or intravenous treprostinil or epoprostenol, the oral medications bosentan, ambrisentan, and sildenafil or inhaled iloprost may be more appropriate for initial therapy.[93]

Valvular Heart Disease (see also Chapter 67)

Just as other age-associated changes in CV structure may predispose a person to developing overt CVD, the cardiac valves undergo myxomatous degeneration and collagen infiltration, especially in the left heart. In the aortic valve, these processes are manifested as valvular sclerosis, detected on physical examination by a short ejection murmur, and confirmed on echocardiography by leaflet thickening without calcification or orifice narrowing. Echocardiographic aortic sclerosis was observed in about half of individuals 85 years of age or older in the CHS and was associated with atherosclerotic risk factors, including hypertension, hyperlipidemia, smoking, and diabetes. In approximately 2% of older adults, progressive calcification of the aortic leaflets results in valvular narrowing (i.e., aortic stenosis). Aortic valvular regurgitation, found in over a quarter of octogenarians, is usually due to annular dilation caused by chronic hypertension or leaflet calcification.

In the mitral valve, myxomatous degeneration usually is manifested as mitral regurgitation (MR) and is the primary mechanism for MR in older persons. Calcific deposits may also occur in the mitral valve leaflets, but more often are found in the mitral annulus, particularly in older women. Functional (i.e., secondary) MR is also common in seniors, usually due to ischemia-related papillary muscle dysfunction or to mitral annular dilation resulting from LV enlargement. Less common causes of mitral or aortic valvular regurgitation are endocarditis, rheumatic heart disease, mitral chordal rupture, aortic dissection, and trauma.

Aortic Stenosis

Aortic stenosis is the prototypical valvular lesion in older adults, present in approximately 15% of those 65 years or older, and is severe, as defined by a valve area of less than 1 cm^2 or 0.6 cm^2/m^2 body surface area, in approximately 2% (**see also Chapter 68**). In the majority, aortic stenosis is secondary to calcification of a trileaflet aortic valve; patients with congenital bicuspid valves generally present 1 to 2 decades earlier. Patients are generally asymptomatic on initial presentation, with a harsh late-peaking systolic ejection murmur. In older sedentary individuals, the cardinal symptoms of angina, exercise intolerance, or syncope may not be reported because exertion sufficient to precipitate them occurs infrequently. The second heart sound is usually diminished and may be absent if calcification is extensive. In contrast to younger adults, the carotid artery upstroke is often not delayed because of large artery stiffening. The diagnosis is confirmed by Doppler echocardiography, which demonstrates the stenotic, calcified aortic valve with a high transvalvular Doppler flow velocity, and a calculated aortic valve area of less than 1.0 cm^2. LV hypertrophy is generally present, as well as a reduced early diastolic LV filling rate; however, these findings are nonspecific because they are often present in older adults due to aging changes and hypertension; the LVEF is usually preserved until late in the disease course.

The classic findings of severe aortic stenosis on Doppler echocardiography are a stenotic, heavily calcified valve with restricted leaflet motion. A mean gradient across the aortic valve of 40 mm Hg or more and a peak flow velocity of more than 4 m/sec with an LV stroke volume index of 35 mL/m^2 or more signifies the most common hemodynamic pattern (high flow, high gradient). However, more than 40% of older patients have lower mean transvalvular gradients and/or peak velocities (i.e., low-gradient aortic stenosis). About half of this latter group also have LV stroke volume indices of less than 35 mL/m^2, or so-called low-flow, low-gradient aortic stenosis. This hemodynamic pattern is more common in women with small LV cavities and in patients with AF.[94] All-cause mortality rates over long-term follow-up are similar in medically treated patients with low-flow, low-gradient aortic stenosis to rates in patients with the more typical high-flow, high-gradient pattern; both groups experience a significant mortality rate reduction from aortic valve replacement (AVR). However, the subset with the high-flow, low-gradient pattern did not generally have a mortality benefit from AVR.[94]

More robust older adults can generally undergo surgical AVR with acceptable morbidity and mortality rates. A tissue valve is generally preferred over a mechanical valve in older individuals to avoid the need for anticoagulation, unless AF is present. Deterioration of bioprosthetic valves generally occurs more slowly in older than younger patients, increasing the likelihood that the prosthetic valve will not need to be replaced during the patient's limited lifespan. In the large Society of Thoracic Surgery national database, patients 65 to 80 years old who underwent surgical AVR experienced similar long-term survival rates with mechanical and bioprosthetic valves but had higher rates of bleeding and stroke with lesser rates of reoperation and endocarditis with mechanical valves.[95]

Until the last several years, the only option for AVR was open heart surgery. In patients with a relatively low risk who were over 80 years of age, typical of those undergoing surgical AVR, the 30-day mortality rate averages approximately 5% and the 1-year mortality rate is approximately 10%. Mortality and morbidity rates from surgical AVR are substantially increased in seniors with major comorbidities and with concomitant CABG. A large proportion of such high-risk patients who are 80 years or older are not referred or accepted for surgical AVR because of their excessive risk.

Transcatheter AVR (TAVR) has been transformative as an alternative for this sizeable high-risk older patient subset with severe aortic stenosis. In the initial PARTNER trial, the 1-year mortality rate in otherwise inoperable patients with severe aortic stenosis randomized to TAVR was 30% compared with 50% in the medically treated group. Subsequent trials in patients at high surgical risk showed similar 30-day and 1-year survival rates in patients randomized to TAVR versus surgical AVR. The risks of stroke, vascular complications, permanent pacemaker implantation, and paravalvular leakage are generally higher with TAVR, although rates of stroke and vascular complications decreased in more recent trials. In the very large Transcatheter Valve Therapy Registry, the 30-day mortality rate after TAVR declined from 4% to 3% between 2013 and 2015 and the 1-year mortality rate declined from 26% to 22% during that time.[96] After TAVR, substantial improvement is seen in functional capacity, NYHA class, and QOL, as in surgical AVR. Excellent durability of TAVR, as defined by stability of the aortic valve gradient and valve area, has been demonstrated to 5 years. TAVR should be considered in high-risk older patients whose life expectancy exceeds 1 to 2 years. As experience with TAVR increases, it may become an attractive alternative to surgical AVR in intermediate-risk and even low-risk older patients with severe aortic stenosis. As with other bioprosthetic valves, daily aspirin 75 to 100 mg is recommended as antithrombotic therapy.

Aortic Regurgitation

The prevalence of aortic regurgitation (AR) increases with age. Common causes of AR in older adults are

valvular disease (degenerative or infectious) or aortic root dilation due to hypertension, connective tissue disease, aortic dissection, or trauma. Severe AR may be asymptomatic for many years; however, the life expectancy without surgery is about 2 years in older individuals once HF develops. Left ventricular dilation, a reduced ejection fraction (EF), and moderate or greater pulmonary hypertension predict higher mortality rates. In one large series, the 15-year mortality rate was 74% in unoperated patients.[97]

The classic diastolic high-pitched blowing murmur of AR is generally heard best at the lower left sternal border if due to valvular disease and at the upper right sternal border if due to aortic root disease. The presence of a widened pulse pressure is not as helpful an ancillary sign of AR in older adults because they often have a widened pulse pressure due to arterial stiffening. Definitive diagnosis of AR is made by quantifying the regurgitant jet on Doppler echocardiography. Severe AR accompanied by a systolic LV dimension of more than 4.5 cm or an LVEF of less than 50% is an indication for AVR even in the absence of symptoms.[98] Older patients are more likely to develop HF symptoms and LV dysfunction earlier in the disease course and have higher postoperative mortality rates than younger individuals. Operative mortality rates in older patients vary with LV function, increasing from less than 5% with normal function to 14% for LVEF of less than 35%. Although moderate or severe AR has been a contraindication for TAVR to date, recent small series have shown successful treatment of AR by TAVR.[99] TAVR may become a reliable alternative to surgical AVR in high-risk older individuals with severe AR.

Mitral Stenosis

With the dramatic reduction in rheumatic heart disease in developed countries over the past half century, mitral stenosis, the hallmark lesion of this disease, has become uncommon (**see also Chapter 69**). At present, mitral stenosis is most commonly seen in foreign-born older adults, typically women, often with a prior mitral commissurotomy. Congestive symptoms generally indicate significant transmitral obstruction and a valve area of less than 1.0 cm^2. Associated AF is more common in older patients with mitral stenosis due to superimposed age-related left atrial enlargement and electrophysiologic changes. The resultant stasis of blood in the left atrium, especially the appendage, increases the risk for systemic thromboembolism, including stroke.

The pathognomonic low-pitched diastolic murmur of mitral stenosis may be absent or of low intensity in older adults due to an increased anteroposterior chest diameter or low stroke volume. In addition, the first heart sound may not be loud and the opening snap may be absent due to a fibrotic calcified mitral valve. Echocardiography is essential to confirm the diagnosis of MS, determine its severity, and characterize the extent of leaflet calcification and presence of associated MR.

In symptomatic elders with severe mitral stenosis, an intervention to increase the mitral valve area is usually indicated. If the valve leaflets are not heavily calcified and their motion not severely restricted, percutaneous balloon valvulotomy may be attempted. However, success rates are below 50% in older patients, and the rates of procedural complications and mortality are increased; cardiac tamponade occurs in approximately 5% and thromboembolism in approximately 3%; approximately 3% of patients die. Risks from mitral valve replacement are also increased in older adults, with perioperative mortality rates of 10% or more. Thus, the decision to perform balloon valvulotomy rather than surgical mitral valve replacement is individualized, with considerations of valvular anatomy, operative risk, life expectancy, and patient preference.

Mitral Annular Calcification

Mitral annular calcification (MAC) is an age-associated degenerative process that is more common in

older women than men.[100] It has been reported in about approximately 10% of community-dwelling adults age 45 to 84 years and in much higher percentages in those 85 years of age or older. The process parallels that in the aortic valve, including the association with common atherosclerotic risk factors. Older patients with severe CKD have a particularly high rate of MAC. When MAC is extensive, it compromises the sphincter function of the mitral annulus, and may stretch the mitral leaflets during systole, causing MR. Although mitral stenosis may result from severe MAC that protrudes into the valve orifice, the mitral stenosis is rarely severe. Calcific deposits from MAC may extend into the membranous ventricular septum, causing conduction disturbances. MAC increases the risk for endocarditis, especially perivalvular abscesses, because of the avascularity of the annular tissue. Several studies have shown an increased risk of stroke or silent brain infarction in older patients with MAC. Although the net benefit of anticoagulation in patients with MAC is unclear, individuals with associated AF, mitral stenosis, or severe MR are usually considered for such therapy.

Mitral Regurgitation

Mitral regurgitation (MR) is a common valvular lesion in older adults, with more than 10% of individuals age 75 years or older having at least moderate MR. Myxomatous degeneration is the most frequent structural cause, with endocarditis, rheumatic heart disease, and papillary muscle rupture after MI less frequent causes. Functional MR is most often due to chronic LV and annular dilation or to ischemic papillary muscle dysfunction. Whereas myxomatous degeneration in younger populations typically presents as chest pain and mitral valve prolapse and is typically seen in women, in later life MR and congestive symptoms are seen in the most common presentation, with a similar prevalence in men and women. Chronic MR is often asymptomatic in older adults until it becomes severe. Presenting symptoms are initially exercise intolerance and fatigue, progressing to congestive symptoms as systolic LV function declines. Secondary pulmonary hypertension is common in severe MR, and may result in right-sided HF.

Physical findings with significant MR are not generally altered by age; Doppler echocardiography quantifies the size of the regurgitant jet and provides insights regarding the cause of MR based on leaflet and annular morphology and LV size and function.

The prognosis of older patients with MR depends on its severity and cause. Patients with acute MR secondary to papillary muscle rupture after an acute MI are an especially high-risk group due to the underlying myocardial insult and hemodynamic instability. Emergent surgical resection of the damaged papillary muscle and infarct zone is the treatment of choice. Patients with severe chronic MR and LV systolic dysfunction and/or dilation are also at high risk of adverse outcomes. Medical therapy for such patients should include ACE inhibitors or ARBs and beta blockers, diuretics to relieve congestive symptoms, and rate or rhythm control of AF.

The 2014 ACC/AHA Guidelines for Valvular Heart Disease recommend mitral valve repair or replacement for severe MR and an LV end-systolic dimension of 45 mm or larger and/or LVEF of less than 60%, or pulmonary artery systolic pressure higher than 50 mm Hg at rest or higher than 60 mm Hg after acute exercise.[98] Major therapeutic decisions after older patients with severe MR have been stabilized with optimal medical therapy include if and when to repair or replace the mitral valve. Most older patients fulfilling the criteria for mitral valve intervention are candidates for valve repair. Exceptions are those whose mitral valve leaflets are fused, extensively fibrotic, or calcified, and those with chordal shortening or fusion. Several sizeable studies have shown that patients in their 70s and 80s have reasonably low mortality rates (≈5% or less) from mitral valve repair, with 70% to 80% 5-year survival rates; these results are similar to or better than those with mitral valve replacement. Functional status and QOL are also improved to a similar degree after mitral valve repair or replacement.

In parallel to the development of TAVR for treatment of severe aortic stenosis, percutaneous mitral valve repair using the MitraClip now provides a less invasive approach for severe MR. This device reduces the mitral annular size similar to surgical annuloplasty. In the Endovascular Valve Edge-to-Edge Repair Study (EVEREST) II, 351 older patients (mean, 76 years) with a calculated surgical mortality risk of 12% or more underwent MitraClip insertion. At 30 days, cardiac death occurred in 5%, MI in 1%, and stroke in 2.6%. At 12 months following the procedure, the NYHA class and QOL had improved substantially, LV volumes were reduced, and the MR severity was less than 2+ in 84% of patients.[101] A more recent study of 564 patients of mean age 83 years reported a 30-day mortality rate of 6%, strokes in 2%, and bleeding in 3%, with reduction of MR to a grade less than 2 in 93%.[102] Thus, percutaneous repair is an attractive option for a large proportion of high-risk older patients with severe MR.

Endocarditis

Endocarditis in older adults typically occurs as a result of indwelling vascular catheters, genitourinary or gastrointestinal instrumentation, pacemaker or ICD leads, prosthetic implants, or MAC (**see also Chapter 73**). Diabetes and genitourinary and gastrointestinal cancer are major predisposing conditions. The most common pathogens in this age-group are *Staphylococcus aureus*, often methicillin resistant, *Streptococcus bovis*, and enterococci. Morbidity and mortality rates from endocarditis are higher in older persons, due in part to comorbidities such as HF. Fewer vegetations and emboli but more abscesses are found in older adults.[103] Indications for endocarditis prophylaxis are similar regardless of age and include prosthetic valve implants, prior endocarditis, and cardiac transplantation.

Cardiac Rhythm Abnormalities (see Chapter 32)

Cardiac rhythm disorders increase in frequency with aging and become increasingly important contributors to morbidity and mortality. Both age-related changes in the heart and cardiac conduction system and the high prevalence of CVD are the substrates for arrhythmias. Fibrous, fatty, and calcific infiltration of the conduction system, calcification of the cardiac fibrous skeleton, reduction in the number of functioning sinus node pacemaker cells, impaired intracellular calcium handling, and blunted adrenergic responsiveness all increase the susceptibility to arrhythmias.[104] Medications may also increase the incidence of arrhythmias, because sinus node automaticity and conduction disorders may be exacerbated by drugs. Both right and left bundle branch block increase with age. Management of cardiac rhythm disorders at an elderly age is complicated by a reduced life expectancy, multimorbidity, geriatric syndromes such as frailty, cognitive impairment, and polypharmacy, and the increased vulnerability to the adverse effects of therapies.

Though the resting heart rate does not change with aging, the maximal heart rate decreases as a result of sinus node responsivity to beta-adrenergic sympathetic stimulation[104]; comparably, beat-to-beat variability also decreases with age. Atrial ectopy occurs in about 10% of elderly individuals in the absence of known cardiac disease, with ventricular ectopy in 6% to 11% on resting ECG.

Bradyarrhythmias

Bradyarrhythmias are primarily due to sinus node dysfunction and atrioventricular (AV) block and increase with age (**see also Chapter 40**). The number of sinus node pacemaker cells decreases with age, with less than 10% functional by age 75.[104] Medications for comorbidities (e.g., beta blockers for IHD) may also increase the incidence of bradyarrhythmias. Similarly, bradyarrhythmia may be provoked as a

secondary effect of treatment for sick sinus (or tachy-brady) syndrome when pharmacologic management of the tachyarrhythmia provokes bradycardia, even to the point where a pacemaker becomes required. Hemodynamic effects may develop from decreased cardiac output, with dizziness, light-headedness, and syncope common sequelae, although symptoms may also include dyspnea, exercise intolerance, fatigue, or rarely chest pain. The ECG is the first diagnostic study, with a Holter monitor, event monitor, or implantable loop recorder also useful for detecting bradyarrhythmias. Assessing for chronotropic incompetence by exercise testing may be of benefit for patients with activity-related symptoms.

The initial management involves discontinuation of relevant medications (e.g., beta blockers, calcium channel blockers, digoxin, clonidine, and amiodarone). The presence of hypothyroidism and Lyme disease should also be considered. Temporary cardiac pacing may be warranted. For persistent symptomatic bradycardia, permanent cardiac pacing is usually indicated (**see also Chapter 41**). More than 75% of pacemakers are implanted in patients age 65 years or older, with half over 75 years.[105] There is a class I indication for pacemaker implantation for sinus node dysfunction with documented symptomatic bradycardia or chronotropic incompetence, and a class II indication for symptoms at a heart rate of less than 40 beats/min.[106] Pacemaker implantation carries a class I indication for third-degree or advanced second-degree AV block with symptomatic bradycardia; an escape rhythm originating below the AV node; a rate of less than 40 beats/min; pauses of 5 seconds or longer; or after cardiac surgery without expectation for resolution. In the elderly, pacemakers can help mitigate falls and syncope, and increase the exercise capacity and QOL.

Dual-chamber pacing improves the QOL in elderly patents, likely because programmable pacing of both the atrial and ventricular rates improves diastolic flow and cardiac output, which are more dependent on the atrial contribution to ventricular filling in this population. Dual-chamber pacing also reduces the incidence of recurrent AF and decreases the rate of hospitalizations. Cardiac resynchronization therapy (CRT) has benefit for selected patients with symptomatic systolic HF (EF ≤ 35%) and a prolonged QRS (> 150 ms), as well as those with mild systolic dysfunction with an anticipated high pacing frequency (<40%).[107] Class I indications for CRT are similar in older and younger patients.[106] In CRT trials, few patients older than age 75 years were enrolled; subgroup analyses from the Cardiac Resynchronization–Heart Failure (CARE-HF) group, age younger than 66 years versus older than 66 years, and Comparison of Medical Therapy, Pacing, and Defibrillation in Heart Failure (COMPANION) group, age 65 years or younger versus older than 65 years, suggest that older patients derive similar benefit. The U.S. Food and Drug Administration has recently approved the first leadless pacemaker; studies assessing its safety and efficacy are ongoing.[105] Older, frailer patients may derive particular benefit because lead and generator pocket complications can likely be averted.

The 2012 Guideline update supports remote monitoring after the initial 2-week period,[106] which is particularly important for older adults who may have physical limitations that make frequent in-person visits for pacemaker surveillance more challenging. Nevertheless, patients with cognitive impairment may have difficulty performing home-based transmissions, and detailed patient/caregiver education is essential. Remote monitoring may allow earlier detection of clinical deterioration, which may reduce hospital readmission rates.

Supraventricular Arrhythmias

Supraventricular Tachycardia

Episodes of supraventricular tachycardia (SVT; **see also Chapter 37**), in which atrial tachycardia, AV

nodal reentrant tachycardia (AVNRT), and AV reciprocating tachycardia (AVRT) are present, have been observed in up to 50% of the normal elderly population in studies using 24-hour monitoring.[104] Management is similar to younger adults. Multifocal atrial tachycardia (MAT) is especially common in the setting of decompensated pulmonary disease; patients are often quite ill and symptomatic. Management of MAT is often constrained by poor tolerance of beta blockers and amiodarone, and limitation of use of non–dihydropyridine calcium channel blockers when there is LV dysfunction. The best outcome is achieved by control of the underlying pulmonary disease.

Atrial Fibrillation

Atrial fibrillation (AF) occurs in about 12% of patients age 75 years or older and 18% of patients age 85 years or older (**see also Chapter 38**). The high prevalence of AF relates to age-related changes in the atrial tissues, including fibrosis and conduction abnormalities that provide the substrate for electrical disarray. Hypertension and structural heart disease, common at an elderly age, lead to additional maladaptive atrial changes and further predispose a person to AF.

The 2014 AHA/ACC/HRS Guideline for the Management of Patients with Atrial Fibrillation estimates that approximately one third of patients with AF are 80 years of age or older.[108] Because changes in the cardiac structure and function that accompany aging differ from those in younger adults, AF may occur in elderly patients in the absence of underlying heart disease. Nonetheless, elderly patients with AF are a heterogeneous group with multiple comorbidities,[108] which must be considered in management decisions; the most common comorbid chronic conditions are hypertension, IHD, obesity, hyperlipidemia, and HF. Because most AF studies involve cohorts 5 to 10 years younger than the average age of AF patients in the general population, it is uncertain whether findings of these studies can be generalized to patients 75 years of age and older and, especially, those 85 years of age and older.

Common symptoms of AF are palpitations, light-headedness, chest discomfort, shortness of breath, fatigue, and decreased activity tolerance. Acute pulmonary edema may arise with an abrupt loss of the atrial contribution to ventricular filling in a stiff left ventricle. Palpitations are less common than in younger patients, and symptoms are frequently minimal or atypical. Less commonly, AF may be initially manifested as syncope or a fall.

Nonvalvular AF is associated with a 5-fold increase in stroke. Strokes are often severe, and adverse outcomes are likely even after controlling for age and comorbidities. Increasing age is a potent risk factor for stroke, as highlighted in the CHA_2DS_2-VASc score, which assigns 1 point for age 65 to 74 years, 2 points for age 75 years or older, and 1 point for female sex. Thus, all women age 65 years or older and all men age 75 years or older have a CHA_2DS_2-VASc score of 2 or more and are candidates for anticoagulation. In patients with nonvalvular AF, the selection of antithrombotic therapy should be based on the risk of thromboembolism, irrespective of whether the AF is paroxysmal, persistent, or permanent.

Advanced age increases the risk of bleeding. The HAS-BLED[109] score reflects the bleeding risk associated with age. “Old age” within the HAS-BLED score is defined as 65 years or older. Concomitant CHD may contribute to an increased bleeding risk when dual antiplatelet agents are combined with anticoagulation. In the ISAR-Triple study, with a mean patient age of 74 years, 6 weeks of triple therapy (clopidogrel, aspirin, and warfarin) versus 6 months of clopidogrel and warfarin resulted in less bleeding with similar major adverse cardiac events (MACEs).[110] Fall risks are also pertinent when considering anticoagulation in older adults, although anticoagulant benefits generally far outweigh even a high risk of falling.[111] The decision to initiate anticoagulation must incorporate the risks for stroke and for bleeding, because both increase with advanced age, especially in association with comorbidities common to older

adults.

Warfarin has been the traditional anticoagulant, with a target international normalized ratio (INR) of between 2 and 2.5 recommended at an elderly age. The estimated maintenance dose of warfarin is lower in seniors, typically 2 to 5 mg daily, often initiated without a loading dose or with a loading dose of 5 mg. The requirements for regular INR surveillance as well as dietary limitations constitute significant challenges for many older patients. Multiple drug interactions with warfarin pose added problems, as does the increased risk of osteoporosis, particularly in women. Direct-acting oral anticoagulants (DOACs) constitute alternatives to warfarin without the need for dietary restriction or INR monitoring. Among patients 75 years of age or older, DOACs demonstrated similar or better stroke prevention efficacy with similar or less bleeding compared with warfarin. Dose adjustment may be required based on age, body weight, and/or renal function. For patients who are not candidates for anticoagulation, an alternative may be percutaneous left atrial appendage closure with the WATCHMAN device, approved for use in the United States[112] but with sparse data for older patients.

Symptoms of AF may be managed by rate or rhythm control. Because a rate control strategy is safer and usually as effective as rhythm control, it is the recommended first-line treatment in asymptomatic or mildly symptomatic patients of all ages. Class I options for achieving rate control include beta blockers and nondihydropyridine calcium channel blockers. Digoxin can aid in rate control in relatively sedentary individuals. Dronedarone is also useful. However, both nondihydropyridine calcium channel blockers and dronedarone are contraindicated in systolic HF. Given the vulnerability of older adults to medication-induced heart block, particularly with amiodarone and digitalis, the Rate Control Efficacy in Permanent Atrial Fibrillation (RACE) II trial[113] assessed a more lenient rate control strategy. Therapy targeting a heart rate of less than 110 beats/min in elderly adults (class IIb) without significant symptoms, CHD, or HF was comparable to strict rate control (< 80 beats/min), which may help obviate the need for cardiac pacing secondary to bradycardia.

Antiarrhythmic drugs have a higher incidence of adverse events in older adults because of the potential for drug interactions, unpredictable pharmacokinetics and pharmacodynamics, and variable renal function.[114] A rhythm control strategy was associated with increased mortality rates in older adults in the Atrial Fibrillation Follow-up Investigation of Rhythm Management (AFFIRM) trial. Because a rhythm control strategy does not obviate the need for anticoagulation, a rate control strategy is preferable in older adults. Nonetheless, maintenance of the sinus rhythm has also been associated with a better QOL,[115] and many clinicians still try to restore the sinus rhythm in older adults at least once.

Atrioventricular node ablation to create a complete heart block with pacemaker implantation has a class IIa recommendation to achieve a regular rhythm in symptomatic patients in whom pharmacologic therapy has failed. Catheter or surgical AF ablation are also compelling considerations, but older patients are not well represented in the ablation literature, and in particular, data are lacking in the older population following ablation.[108,116] Older adults commonly have large atria and chamber fibrosis that may reduce the likelihood of restoring and maintaining the sinus rhythm.

Ventricular Arrhythmias

Although the incidence of ventricular arrhythmias increases with age, the incidence of sudden cardiac death (SCD) appears to decline after age 80 years, mostly because rates of other causes of death rise (**see also Chapters 39 and 42**). The ACC/AHA/ESC 2006 Guidelines for the Management of Patients with Ventricular Arrhythmias and the Prevention of SCD addresses older adults.[117] Overall, medical therapy for ventricular arrhythmias does not differ by age. In older post-MI patients, beta-blocker therapy of ventricular arrhythmias is associated with reduced rates of SCD.

Although the prevalence of ventricular premature complexes increases with age, no specific treatment is required in the absence of bothersome symptoms. Symptomatic ventricular premature complexes often respond to a low-dose beta blockade. The potentially life-threatening ventricular arrhythmias, sustained ventricular tachycardia and ventricular fibrillation, virtually always occur with structural heart diseases such as ischemic or hypertensive cardiomyopathy.

Implantable Cardioverter-Defibrillators

Both the ACC/AHA/ESC 2006 guidelines for management of patients with ventricular arrhythmias and the prevention of SCD and the ACC/AHA/HRS 2008 guidelines for device therapy of cardiac rhythm abnormalities address older adults.[106,117] The relevance of comorbidities, the limited life expectancy, and QOL issues are emphasized when considering implantable cardioverter-defibrillators (ICDs) for elderly patients (**see also Chapter 41**). The ICD guidelines do not have age-based indications, and acknowledge that few clinical trials of device-based therapy have enrolled enough older patients to reliably estimate the benefits in this age-group.[117] In the Multicenter Automatic Defibrillator Implantation Trial (MADIT) II, patients with an LVEF of 30% or less and prior MI, ICD therapy improved survival rates in those older than 70 years of age by more than 30% compared with conventional therapy. Nonetheless, the potential durability of the ICD benefit is shorter and the risk of procedural complications higher in older patients.[118] The benefit is limited because causes of death other than SCD are a factor and because ventricular tachycardia or ventricular fibrillation is less often a cause of SCD than asystole or pulseless electrical activity in elderly patients. In a metaanalysis of the three major ICD trials (CASH, CIDS, AVID), patients 75 years or older were more likely to die from causes other than arrhythmia.[118]

The guidelines address end-of-life issues, stipulating that ICDs should not be placed in patients with a life expectancy of less than 1 year.[106,119] Implanting physicians are also encouraged to discuss end-of-life issues before implantation, and to encourage patients to complete advance directives and specifically address device management and deactivation if the patient becomes terminally ill. Device deactivation in hospice care prevents multiple potential painful shocks in terminally ill patients and may enable painless sudden death in the highly symptomatic patient with end-stage HF.

Venous Thromboembolic Disease

Epidemiology and Diagnosis

Deep vein thrombosis (DVT) and pulmonary embolism (PE) increase exponentially in occurrence with advancing age; increased blood thrombotic factors, limited mobility, and laxity of the large venous valves contribute to risks. More than half of cases of venous thromboembolism (VTE) follow surgery injury, serious medical illness, or prolonged bed rest (**see also Chapter 84**). Malignancy is also a significant contributor. A sharp increase in risk occurs after age 65 years, with a hazard ratio of 1.7 for every decade after age 65. VTE occurs in 30/100,000 persons at age 40 years versus 260/100,000 at age 80 years or older. Half of all patients with acute VTE are older than 70 years, and one fourth are 80 years of age or older.[120] PE is more common than DVT in elderly patients. There is an increased hospital mortality rate with acute PE in older adults, a 10% to 30% excess compared with younger individuals and a 1-year mortality rate of 39%.

In older adults, DVT has less typical symptoms, such as lower extremity discomfort or difficulty with ambulation, than in younger adults, likely because of the more frequent occurrence of proximal DVT without calf involvement. PE requires a high index of suspicion in any older patient admitted for shortness

of breath. Pleuritic chest pain and hemoptysis are less likely with PE than cough or syncope. Older adults with PEs are more likely to have ECG abnormalities, including $S_1Q_3T_3$, right bundle branch block (RBBB), AF, and anterior T wave abnormalities.

Color-flow imaging, in addition to duplex Doppler ultrasound, is highly accurate for the diagnosis of DVT. D-dimer tests are highly sensitive for thrombus formation and can be used to exclude VTE in patients with a low clinical probability. The application of age-adjusted cutoff values substantially increases the specificity without modifying the sensitivity and seems particularly useful in patients over 50 years of age.[121,122] In the Age-adjusted D-dimer cutoff levels to rule out pulmonary embolism (ADJUST-PE) study, compared with a fixed D-dimer cutoff of 500 µg/L, the combination of a pretest probability assessment with an age-adjusted D-dimer cutoff was associated with a larger number of patients in whom PE could be ruled out with a low likelihood of subsequent clinical VTE.[123]

Management

Aggressive prophylaxis for VTE prevention is the most important intervention, particularly early mobilization for hospitalized patients. The routine use of compression stockings to prevent postthrombotic syndrome in acute VTE is not recommended in the 2016 guidelines (in contrast to prior editions).[124] Thromboprophylaxis with LMWH or low-dose unfractionated heparin is recommended, with extensive studies validating its use in elderly patients. Fondaparinux is also effective. Compression stockings are recommended when the anticoagulant bleeding risk is excessive.

The number of patients 75 years of age or older who require anticoagulation is rising steadily. Managing these patients is challenging because of their high risk of both thrombosis and bleeding. Frailty; chronic comorbid conditions, including renal impairment; polypharmacy; and frequent acute illnesses are all common; anticoagulant drugs must be used carefully. Initial heparin therapy is a requisite factor when warfarin is started. LMWH is preferable to unfractionated heparin because of the simplicity of administration, lower risk of major bleeding events, and lower rate of mortality; LMWH facilitates early hospital discharge and home management. Dose adjustment to body weight and renal function in older adults is essential. Conventional anticoagulation for DVT lasts 3 months, but bleeding risks, particularly in patients older than 75 years and/or with concomitant cognitive impairments, falls, or other complexities often affect the treatment duration. Unprovoked VTE is reasonably treated for a longer duration when the bleeding risk is acceptable.

In an international prospective VTE registry of patients older than 80 years,[125] anticoagulation was associated with an incidence of major bleeding of 3.4%, which exceeded the 2.1% incidence of recurrent VTE. In the same population, a 3.7% incidence of fatal PE exceeded the 0.8% incidence of fatal bleeding. Thus in this vulnerable high-risk population, anticoagulation is favored, but individualization is requisite for those at higher risk of bleeding. VTE has a 30% 10-year recurrence rate in patients not receiving long-term anticoagulation. VTE recurrence and bleeding risks are also greatest in the initial 3 to 6 weeks of therapy; careful surveillance is therefore necessary, particularly in the early phases of therapy.

In acutely ill PE patients with hypotension and hemodynamic instability, systemic thrombolysis is the preferred form of management. Catheter-assisted thrombus removal or catheter-based thrombolysis is also recommended in centers where this specialized care is available. For subsegmental PE and no proximal DVT, clinical surveillance is recommended rather than anticoagulation, with a low risk of recurrent VTE. Anticoagulation is advised over clinical surveillance in patients with a high VTE risk.[124]

Long-term anticoagulation with DOACs or warfarin is appropriate when there is no malignancy, but LMWH is preferable to warfarin in the presence of cancer.[124] In a metaanalysis of randomized trials of

DOACs in elderly adults, DOACs were associated with equal or greater efficacy than warfarin with reduced bleeding. DOACs also had a significantly lower risk of VTE or VTE-related deaths than conventional anticoagulation in elderly adults.[126,127] The DOACs overcome several drawbacks of warfarin therapy, including fewer drug-drug interactions and no requirement for anticoagulation monitoring. DOACs have a rapid onset and offset of action. Dosing must be adjusted for renal function.

Syncope

The prevalence of syncope increases with age, rising to over 20% among adults age 75 years or older (**see also Chapter 43**). More than 80% of patients hospitalized for syncope are 65 years of age or older. The incidence may be underestimated in older adults because syncope is often misclassified as an unexplained fall, collision, or traumatic episode.[128] Amnestic features associated with falls or trauma in older adults add to imprecision because histories are often ambiguous with falls or accidents, and often lead to workups in which syncope is never considered.[129]

Prognosis and Management Complexity

The prognosis of syncope worsens with age, with 2-year mortality rates reported to exceed 25%. Cardiac syncope has the worst mortality prognosis because of the hazards associated with cardiac disease. However, other causes of syncope can be similarly detrimental among older adults because the noncardiac predisposing factors can also be hazardous (e.g., Parkinson disease, DM, amyloid disease, and dementia).[130] Syncope in older adults is often associated with falls, collisions, or traumatic events that compound the prognostic risks. Syncope in older adults often becomes a life-changing event because it catalyzes the progression to institutionalization, depression, and a worsening QOL.[1]

Whereas syncope guidelines are based on a robust literature oriented to CV physiology and technologic advances, syncope in older adults is also fundamentally linked to geriatric domains.[1] Age-related physiologic changes predispose to syncope because they erode homeostasis[128] and fluid conservation.[131] Attenuated baroreceptor and autonomic reflexes, changes in adrenergic responsiveness, and impaired maintenance of intravascular volume are destabilizing when concomitant morbidities and/or pharmacologic stresses overwhelm the weakened equilibrium. Contributing factors include CVDs (e.g., valvular heart disease, AF, pulmonary hypertension, amyloidosis), non–CV diseases (e.g., diabetes, Parkinson disease, dementia, dehydration), and polypharmacy (e.g., alpha blockers; beta blockers; calcium channel blockers; ACE inhibitors, diuretics, and cholinergic medications). Older adults with syncope have an average of 3.5 chronic medical illnesses and are taking three times as many medications as the general population.[132] Frailty exacerbates risks and management challenges.

Orthostatic syncope is particularly common when impaired baroreceptors are compounded by poor hydration and excessive vasodilating medications.[133] Postprandial hypotension and diminished thirst with aging commonly exacerbate these susceptibilities.[132] Age-related orthostatic hypotension can be contributory; although many older adults have asymptomatic orthostatic hypotension, their vulnerability to syncope is increased.[134]

Reflex-mediated causes of syncope are also common, including both vasovagal syncope and carotid sinus syndrome. Vasovagal syncope typically occurs from either unopposed vagal tone (cardioinhibitory) or from peripheral and splanchnic pooling (vasodepressor). Vasodepressor syncope is common with reduced vagal activity, and often occurs without prodromal nausea, pallor, or diaphoresis. Cardioinhibitory vasovagal syncope is often linked to carotid sinus syndrome and underlying carotid sinus hypersensitivity. Age-related stiffening of the carotid vasculature impedes transduction of pressure

to the baroreceptors, and often leads to increased baroreceptor sensitivity. Pressure on the neck can trigger the carotid sinus and provoke decreased sympathetic tone, leading to excessive vasodilation, bradycardia, and diminished cardiac output. Whereas the estimated prevalence of carotid sinus syndrome is as high as 30% among older adults, carotid sinus hypersensitivity can also be asymptomatic.[135]

Bradyarrhythmias and tachyarrhythmias commonly predispose to cardiac syncope.[104] Bradycardias in older adults often result from medications, sick sinus syndrome, and/or AV block, and predispose to syncope through impaired cardiac output. Atrial and ventricular tachycardias are also highly prevalent, and predispose to impaired cardiac output, particularly in combination with ventricular diastolic filling abnormalities.

Structural CV abnormalities with aging that impair cardiac output also predispose to syncope. The most common cause is aortic stenosis, which is associated with effort syncope when cardiac output cannot increase to meet demands. Pulmonary hypertension, atrial myxoma, hypertrophic cardiomyopathy, aortic dissection, PE, and subclavian steal syndrome are less common structural CV abnormalities associated with syncope in older adults.

Diagnosis and Treatment

As in younger adults, a careful history and physical examination and a systematic approach to diagnosis are essential. Postural vital signs are more likely to yield a definitive diagnosis compared with electroencephalograms, head and neck imaging, cardiac enzyme measurements, and telemetry. The diagnostic yield of an echocardiogram varies with the probability of finding significant structural heart disease, which may be determined from a careful history, physical examination, and ECG.

Orthostatic and vasovagal syncope are often delineated by the history and physical examination, with treatment relying on modification of contributing factors. Preventive strategies may include medication adjustments, instructions to rise slowly from supine positions, increasing salt and water intake, and modification of dietary habits for postprandial hypotension.[136] Compression stockings may help mitigate venous pooling. Caffeine intake may reduce splanchnic blood flow and moderate postprandial hypotension. Pharmacologic therapies such as fludrocortisone, salt tablets, and midodrine may also be useful, but iatrogenic risks must also be considered.

Carotid sinus massage has been applied in multiple studies of unexplained syncope in older adults. If a positive result is not obtained, the procedure is repeated on the opposite side. If a cardioinhibitory response is elicited, atropine is usually administered and carotid sinus massage repeated to clarify the relative degree of vasodepression. Transient neurologic complications have been reported (i.e., abnormal sensations or visual symptoms, paresthesia, paresis, or cognitive dysfunction). In most instances these symptoms resolve within a short time.

Tilt-table (TT) testing can enhance diagnostic evaluations. The addition of nitroglycerin (NTG) to TT testing increases its sensitivity. Whereas isoproterenol was originally used to increase the sensitivity of TT, it is associated with significant side effects in older adults (e.g., ischemia, hypertension, and arrhythmia). Isoproterenol during TT can also obscure bradyarrhythmias that may underlie a predisposition to syncope. Compared with isoproterenol, NTG during TT is more easily administered, better tolerated (although associated with significant hypotension and/or headaches), and more effective clinically.

Diagnostic modalities for detecting arrhythmias range from ECGs and in-hospital telemetry to event monitors and implanted loop recorders. The utility of a given diagnostic modality for detecting arrhythmia is highly dependent on the frequency of the arrhythmia, and duration of monitoring is directly related to diagnostic yield. The capacities of older patients are also relevant because event monitors require the

patient to engage with the monitoring device in a manner that can be difficult for many seniors. Implantable loop recorders have the highest diagnostic yield, more commonly revealing bradyarrhythmias than tachyarrhythmias.[137]

Peripheral Arterial Disease, Abdominal Aortic Aneurysm, and Aortic Dissection

Peripheral artery disease (PAD) is atherosclerosis of the noncardiac arteries (**see also Chapter 64**). Lower extremity (LE) and carotid PAD, abdominal aortic aneurysm (AAA), and aortic dissection are all types of PAD. The incidence and prevalence of PAD in all three regions rise steeply with age; about 25% of both men and women over 80 years and over 30% of nonagenarians have PAD.[138] Although LE-PAD is slightly more prevalent in women over 90 years, carotid artery stenosis and AAA are more prevalent in comparably aged men.

Lower Extremity Peripheral Arterial Disease

Epidemiology

In the 2016 AHA/ACC Guideline on the Management of Patients with LE-PAD, patients identified at increased risk included those 65 years of age and older and those 50 to 64 years of age with other risk factors for atherosclerosis, a family history of PAD, or known atherosclerosis in another vascular bed.[139] The prevalence of LE-PAD and its earlier occurrence of symptoms are influenced by several modifiable risk factors, including cigarette smoking, diabetes, hypertension, hypercholesterolemia, and decreased renal function, although the association between age and PAD persisted even after adjustment for baseline demographics and clinical risk factors. The natural history of patients with asymptomatic PAD or with mild or moderate claudication is relatively benign, in contrast to the rapid progression characteristic of patients with ischemic rest pain or limb-threatening ischemia. Elderly PAD patients frequently have concomitant IHD and cerebrovascular disease, contributing to the significant rates of CV morbidity, disability, and mortality.

Diagnosis

The clinical presentation depends on the severity and location of the arterial stenosis and varies from claudication to limb-threatening ischemia. Only 10% of elderly individuals have classic claudication, 40% are asymptomatic, and 50% have atypical leg symptoms. Claudication is characterized by reproducible pain with ambulation relieved with rest. Its typically entails slow symptom progression, with critical limb ischemia occurring in only 1% to 2% over 5 years. By contrast, nonfatal MI or stroke may occur in 20%.

Claudication adversely affects the QOL and is associated with high rates of depression. Patients may describe exertional non–joint-related limb symptoms, rest pain, perceived walking impairment, or a decline in activity over time. Nonhealing lower extremity wounds may be evidence of critical limb ischemia. In the Rotterdam Study, 19% of persons over 55 years and 48% to 55% of those over 80 years had PAD, yet only 6% of older adults had claudication.[140] This likely reflects multiple comorbidities, such as neuropathy, arthritis, spinal stenosis, HF, and COPD, which result in indistinguishable symptoms or limit mobility. At 10-year follow-up, there was a 40% mortality rate, increasing to 70% in high-risk categories.

The presence of PAD increases the risk for CV events and substantially increases the risk for limb-related morbidity. Identification of PAD by screening is important because it detects patients at increased risk of atherosclerosis at other sites: asymptomatic patients identified at screening often benefit from medical therapy such as aspirin and reduction of atherosclerotic risk factors.

Physical examination includes inspection of the skin of the extremities, palpation of all peripheral pulses, auscultation for bruits, examination of the abdomen, and extremity neurologic examination. Patients with significant PAD have pallor of the feet on elevation; ulcerations of the extremities are typically between the digits or at the tips of the toes. Noninvasive vascular testing both confirms the diagnosis of PAD and ascertains the level and extent of disease. An ankle brachial index (ABI) is the initial recommended diagnostic and prognostic test and is indicated in all patients with new PAD with exertional leg symptoms[139,141] and in those over 65 years with nonhealing leg wounds.[142] Guidelines[143] also suggest ABI screening for patients with a family history of AAA and current smokers or those over 50 years who ever smoked, as well as individuals with diabetes. An ABI of less than 0.9 triples the risk for death from CVD. Definitions for normal and abnormal ABI were modified in 2011 based on results of the ABI Collaboration. A normal ABI is 1.00 to 1.40, an abnormal ABI is 0.90 or less, and a borderline ABI is 0.91 to 0.99. However, the ABI may be misleading in older adults with stiff, noncompressible calcified arteries that cause a high ABI; therefore, most consider an ABI of more than 1.30 consistent with PAD in older adults. An alternative measure is the toe brachial index, with values of less than 0.70 considered diagnostic of PAD.[139,144] An exercise ABI may be helpful in patients with borderline resting ABI values and symptoms suggestive of claudication.[139,141] With exercise, patients with claudication typically have ABIs between 0.4 and 0.9, those with rest pain have ABIs between 0.2 and 0.4, and those with critical limb ischemia, defined as ischemic pain at rest or tissue loss including skin alteration or gangrene, have ABIs of 0 to 0.4. Because many older adults are unable to perform a treadmill exercise test, hall walks are also commonly used to assess the functional response to therapy and to provide prognostic information. Duplex ultrasound, computed tomography angiography, or magnetic resonance angiography may be valuable for diagnosing the location of the arterial obstruction, assessing the severity of stenosis, and planning for intervention. Invasive angiography is useful when revascularization is being considered.

Management

The goals of management of LE-PAD are amelioration of symptoms and a decrease in the risk of atherosclerotic CVD progression and PAD complications.[143] Multiple measures are requisite to improve symptoms and prevent limb loss. Lifestyle interventions such as a structured exercise regimen can significantly benefit elderly PAD patients.[141,143,145] Although smoking is the greatest risk factor for PAD in older adults, they are less likely than younger patients to receive a recommendation for smoking cessation or referral for intensive smoking cessation therapy.[146]

Precepts of therapy are consistent with guidelines applied to younger adults with PAD, including blood pressure control and statin therapy, with the latter potentially improving symptoms. Simvastatin therapy significantly increases the walking capacity.[29] High-intensity statins are recommended, with consideration of moderate-intensity statins at age over 75 years. Statins, antiplatelet therapy, and beta blockers decreased the 10-year mortality rate in the Rotterdam Study.[140] There is no evidence that beta blockers used to manage hypertension adversely affect claudication. Decisions to use aspirin plus clopidogrel should be individualized in high-risk patients not at increased bleeding risk.[142] There is no benefit of oral anticoagulation over aspirin in reducing mortality rates, but oral anticoagulation increases major bleeding events. The recent Effects of Ticagrelor and Clopidogrel in Patients with Peripheral Artery Disease

(EUCLID) trial failed to show that ticagrelor was superior to clopidogrel in patients with PAD, at a mean age of 66 years, 28% of whom were women.[147] Cilostazol, a phosphodiesterase inhibitor, is advised to improve claudication symptoms and walking distance but is contraindicated in patients with HF[148]; a comparable response to cilostazol was documented at ages younger and older than 65 years. A metaanalysis showed that 100 mg cilostazol twice daily improved the maximal walking distance by 50% and the pain-free walking distance by 67%. The protease-activated receptor (PAR-1) antagonist vorapaxar has been suggested to reduce the risk of acute limb ischemia due to bypass graft thrombosis and native vessel in-situ thrombosis in patients with symptomatic PAD, but further studies are requisite.[149]

Endovascular therapy (atherectomy, angioplasty, stenting) or surgical bypass is recommended for critical limb ischemia and for lifestyle-limiting claudication in patients with an inadequate response to guideline-directed medical therapy. Patient preferences and goals of care are important considerations in the evaluation for revascularization. Considerations include the extent of the disability as assessed by the patient, the inadequacy of response to medical and structured exercise therapy, the location and extent of disease, the status of comorbid conditions, and the risk-to-benefit ratio. In the Claudication: Exercise Versus Endoluminal Revascularization (CLEVER) trial, both supervised exercise and stent revascularization were superior to optimal medical care alone.[150] Recently there has been an increase in endovascular revascularization, which is associated with lesser hospital mortality rates and decreased major amputations, with results comparable to standard surgical intervention. In the Bypass versus Angioplasty in Severe Ischemia of the Leg (BASIL) trial,[151] patients who had undergone bypass surgery and those who had undergone balloon angioplasty had comparable overall survival and amputation-free survival. However, for those patients who survived for at least 2 years after randomization, a surgical-first revascularization strategy was associated with a significant increase in subsequent overall survival and a trend toward improved amputation-free survival.[139]

Amputation is recommended for tissue loss beyond salvage, with recognition that older adults are less likely to adapt to prosthetic devices; amputation often results in decreased independence and long-term care placement. More than half of all patients who undergo amputation for critical limb ischemia are over age 80 years. The increase in amputation in older adults is likely related in part to the late recognition of PAD.

Abdominal Aortic Aneurysm

Epidemiology

The occurrence of abdominal aortic aneurysm (AAA) increases with aging and is 5 times more common in men than in women, but the gender difference diminishes with age (**see also Chapter 63**). The prevalence rises from 1.3% in men and 0% in women age 45 to 54 years to 12.5% in men and 5.2% in women age 75 to 84 years.[140] Typically, AAA involves the aortic segment between the renal and inferior mesenteric arteries.

Diagnosis and Management

AAAs are typically asymptomatic. Inflammatory changes, abnormal collagen remodeling and cross-linking, and loss of elastin and smooth muscle cells interrupt the integrity of the aortic wall. The diagnosis is made by an abdominal aortic diameter of more than 3 cm. Growth of more than 1.5 cm in diameter per year is a key concern. Aneurysm diameter is the strongest predictor of rupture, with both a larger aneurysm diameter and more rapid increase in aneurysm expansion associated with symptoms and

complications.[152]

Although typically asymptomatic, there may be mesenteric ischemia or acute renal failure, either due to atherosclerotic or atherothrombotic disease. The dreaded complication is aortic rupture, which carries a mortality rate of up to 90%. Rupture occurrence is low for an aortic diameter of less than 4 cm, 20% for a diameter of more than 5 cm, 40% for a diameter of more than 6 cm, and >50% for an AAA diameter of 7 cm or greater. Aortic rupture is characterized by severe acute pain, pulsatile abdominal mass, and hypotension. In general, decisions regarding AAA repair in an older patient are individualized, with considerations of age, risk factors for perioperative morbidity and mortality, anatomic factors, and the experience of the medical center; older patients may benefit more from endovascular repair, provided their anatomy is appropriate.

AAA screening has led to significantly reduced mortality rates in men age 65 to 79 years who undergo duplex ultrasound screening, but similar screening benefits for women are not clear. The U.S. Preventive Services Task Force (USPSTF)[153] recommends one-time screening with abdominal duplex ultrasonography for men age 65 to 75 years who have ever smoked and also recommends consideration of screening if there is a first-degree relative with AAA or a history of CVD, hyperlipidemia, obesity, or hypertension.

A very large AAA, even if it is asymptomatic, warrants rapid evaluation and prompt referral for vascular surgery. No pharmacotherapy has been shown to delay or decrease AAA expansion. No further screening is recommended for an AAA of less than 3 cm. With an AAA diameter of 3 to 4 cm, guidelines recommend annual ultrasound imaging; with an AAA diameter of 4 to 5.4 cm, imaging every 6 months; and with an AAA diameter of more than 5.5 cm or a growth rate of more than 1 cm per year, CT or MRI for confirmation and evaluation for repair. Conservative management is recommended for asymptomatic patients with an AAA of less than 5.5 cm.

The medical therapy of AAA includes tobacco cessation, blood pressure control, and statin therapy. For AAAs of 5.5 cm or more or an increase in the growth rate, endovascular or open surgical repair is recommended.[142] There is no evidence that moderate-intensity physical activity precipitates AAA rupture. The United Kingdom Endovascular Aneurysm Repair (EVAR) trial compared endovascular repair with open repair for AAAs of 5.5 cm or more in patients age 60 years or older (mean age, 74 years).[154] Patients were 90.7% male and had a mean age of 74 years. The perioperative mortality rate with endovascular repair was 1.8%, compared with 4.3 % for open repair; patients included nonagenarians. However, the initial benefit was not sustained over time. Reintervention was required in 5.1% with endografts versus 1.7% who had had open surgery; this finding underscores the need to carefully evaluate stent grafts over time.[142,154]

Aortic Dissection

Pathophysiology and Epidemiology

The pathophysiology of aortic dissection relates to medial degeneration characterized by disruption and loss of the elastic fibers, decreased proteoglycan deposition, and loss of smooth muscle cells. The typical cause in elderly adults is atherosclerotic or iatrogenic in contrast to younger individuals, in whom dissection is more likely to be caused by Marfan syndrome or other genetic diseases. In the International Registry of Acute Aortic Dissection (IRAD), 65% of the patients were men with a mean age of 63 years; women were generally older, with a mean age 67 years; 32% of patients were over age 70 years and were more likely to have atherosclerosis, prior aortic aneurysm, iatrogenic dissection, or intramural

hematoma.[155] Hypertension remains the most important predisposing factor for acute aortic dissection.

Clinical Presentation

Aortic dissection typically presents as an acute catastrophic illness with severe chest pain and acute hemodynamic compromise. The classic presentation is of chest pain (80%), which is far more likely to be anterior (71%) than posterior (32%). Older adults appear less likely to have chest pain and may present with syncope, cerebrovascular accident, or HF. Hypotension is more common at presentation than in younger patients and carries an ominous prognosis. A pulse deficit, although less common in older adults, is associated with increased mortality rates. Based on an IRAD review, the murmur of aortic regurgitation, indicating propagation retrograde to involve the aortic valve, is less common in patients over age 70 years. Computed tomographic angiography is the initial diagnostic procedure of choice due to its widespread availability. The typical finding of a widened mediastinum on chest x-ray in type A dissection has decreased in recent years.[155]

Management

Type A dissection occurs in about 32% of aortic dissections. In octogenarians managed medically, there was a 45% to 62% hospital mortality rate with type A dissection. In a comparable population, surgery was associated with a 63% 1-year survival rate (with an uncomplicated dissection), favoring surgical management. Surgical operative mortality rates have declined over time. In contrast, for complicated type A aortic dissection (i.e., with neurologic defect, mesenteric ischemia, or cardiopulmonary resuscitation), medical management is often preferable. Type B aortic dissection is also usually managed medically; parenteral beta blockade may obtain a heart rate of less than 60 beats/min and an SBP in the range of 100 to 120 mm Hg. There has been increasing use of endovascular repair for type B dissection in the IRAD Registry.[155]

Cerebrovascular Disease and Stroke

Stroke is the second most common cause of death in the United States and the third most common cause of disability (**see also Chapter 65**). Men have a greater occurrence of stroke at a younger age, but stroke is more prominent in women than men over 75 years of age.[156] More women die annually from stroke in the United States (58% of total), primarily because of the larger numbers of elderly women. Approximately 15% of all strokes are heralded by a transient ischemic attack (TIA).

Stroke is a leading cause of long-term disability (in women more than men); among U.S. Medicare stroke patients discharged from the hospital, approximately 45% return home, 24% are discharged to inpatient rehabilitation facilities, and 31% are discharged to skilled nursing facilities (SNFs). Of patients who return home, one third use home health care services. Adults over 85 years comprise 17% of patients and have higher risk-adjusted mortality rates, greater disability rates, longer hospitalizations, and less evidence-based care. Recent ASA/AHA guidelines on cerebrovascular disease and stroke[157] clarify that older patients have increased mortality and morbidity rates and more adverse events, including hemorrhagic transformation and reduced neurologic recovery, plus a high susceptibility to iatrogenic effects of pharmacologic, percutaneous, and surgical stroke therapies.

Primary and Secondary Prevention of Stroke

Stroke risk factors require both primary and secondary preventive interventions, as in a younger

population.[157,158] The AHA/ASA Guideline for Primary Prevention of Stroke[157] emphasizes primary prevention because 76% of strokes are first events. Aspirin 160 to 325 mg is indicated, but an added benefit of clopidogrel is uncertain.

Hypertension is a powerful risk factor for both ischemic stroke and intracranial hemorrhage. Antihypertensive therapy with a reduction of SBP of 10 mm Hg was associated with an average 41% reduction in stroke risk. Although the benefit of hypertension treatment in preventing stroke is clear,[159] optimal blood pressure goals for elderly patients remain controversial.

Diabetes mellitus increases the incidence of ischemic stroke at all ages, but more prominently in the nonelderly population. The reduced survival rate of diabetic stroke patients is more common for women. In the ACCORD study, targeting the SBP to lower than 120 mm Hg in patients with type 2 diabetes did not reduce CV events compared with a target SBP of lower than 140 mm Hg, except for the endpoint of stroke, in which intensive blood pressure reduction was better.[159]

Atrial fibrillation is a powerful risk factor for stroke, independently increasing the risk about 5-fold at all ages, but with the percentage of stroke attributable to AF increasing from 1.5% at age 50 to 59 years to 23.5% at 80 to 89 years. Screening for AF in patients with cryptogenic stroke or TIA is recommended, and anticoagulation with warfarin or a DOAC is a requisite for reducing the stroke risk. Aggressive management of blood pressure plus antithrombotic prophylaxis is recommended for AF patients.[159] Screening women over age 75 years by pulse followed by an ECG when indicated, is recommended.

Carotid ultrasound screening to ascertain stroke risk is reasonable for patients over age 65 years prior to elective CABG surgery and in those with PAD, a history of cigarette smoking, a history of stroke or TIA, or carotid bruits. Because patients over 80 years of age were excluded from the Asymptomatic Carotid Atherosclerosis Study, the benefits of endarterectomy cannot be extrapolated to those patients, however. In patients over age 70 years, carotid endarterectomy may provide an improved outcome compared with carotid artery stenting; the two techniques have equivalent benefits in younger patients.[158]

Ischemic Brain Injury

Brain ischemia results from an inadequate blood supply bringing needed oxygen to the brain. Ischemia from thrombosis or embolism is common.

Thrombosis

Ischemic stroke is the most common type of stroke in the United States, but many uncertainties remain regarding acute therapies at an elderly age. The role of acute intravenous treatment with recombinant tissue plasminogen activator (TPA) is uncertain for patients with one of the following exclusion criteria: age over 80 years, taking oral anticoagulants despite an INR of 1.7 or less, a baseline NIH Stroke Scale score of more than 25 or a history of both stroke and diabetes mellitus.[160] The Third International Stroke Trial (IST-3) suggested a TPA benefit at least as great in patients 80 years of age or older.[161] A time window of 3 to 4.5 hours is critical for intravenous TPA. The risk-to-benefit ratio of acute angiography and thrombus extraction with intraarterial thrombectomy in specialized stroke centers has not been established for an elderly population.

Decompressive surgery for malignant cerebral edema, although potentially lifesaving for stroke patients, must be individualized[162]; the value of decompressive craniectomy is uncertain in patients over age 65 years. In the Decompressive Surgery for the Treatment of Malignant Infarction of the Middle Cerebral Artery (DESTINY) II trial,[163] patients with a median age of 70 years derived a survival benefit from decompressive hemicraniectomy for a large MCA ischemic stroke. However, most were still left

disabled and required assistance with most activities of daily living.

Embolism

Although AF is the dominant cardiac cause of cerebral embolism (see above), valve disorders, cardiac chamber thrombi, and aortic and carotid atherosclerosis are other high-risk sources, identifiable by imaging studies.

Hemorrhage

Brain hemorrhage involves excess blood in the closed cranial cavity; the hemorrhage may be intracerebral or subarachnoid. Intracerebral hemorrhage (ICH) is the most lethal form of stroke, particularly in the elderly.[164] The Surgical Trial in Lobar Intracerebral Hemorrhage II (STICH), with about half of patients over age 70 years, suggested a potential benefit of early surgical intervention specifically for superficial ICHs.[165] The recommendation is for aggressive care for 2 full days following ICH and postponement of a new do-not-resuscitate order to permit appropriate family discussion and decision making.[164,166] Resumption of antithrombotic therapy following ICH related to antithrombotic therapy must be individualized, considering the risk of subsequent thromboembolism or recurrent ICH and the overall patient status. The most common cause of subarachnoid hemorrhage is rupture of an intracranial aneurysm,[167] for which microsurgical clipping and/or endovascular coiling may be beneficial.

Other Stroke-Related Issues

Vascular cognitive impairment[168] is the second most common cause of dementia, with modest evidence that blood pressure control in middle-aged and young-elderly individuals may help prevent late-life dementia; the usefulness of blood pressure lowering for adults over age 80 years is not well established for this purpose.

Prompt and continued comprehensive stroke rehabilitation is requisite for restoring function and maximizing independence. Older adults with chronic pain following a stroke require precise ascertainment of such pain and pharmacologic management with amitriptyline, nortriptyline, or lamotrigine. Patients benefit from a collaborative approach that addresses end-of-life decision making and palliative care, and that includes the patient and family.[169]

Prevention of Cardiovascular Disease in Older Persons

Efforts to prevent new or recurrent CV events in older adults center on control of modifiable factors known to facilitate development or progression of CVD. It is often less clear that controlling these “risk factors” among older adults similarly reduces the risk of CV events. Most landmark clinical trials that established the treatment benefit included few if any individuals older than 70 to 75 years, or only those without the comorbidities typically found in this age-group. Risks for mortality from disorders other than CVD may reduce the likelihood of demonstrating a survival benefit in older adults. Finally, older adults represent selective survivors of their birth cohorts and may be less susceptible than the decedents to the adverse effects of certain risk factors. The following sections review the available evidence regarding common CV risk factors in older individuals.

Hypertension

Prior to the 1980s, the age-associated elevation of SBP in older adults was generally considered a normal finding that did not warrant treatment (**see also Chapter 46**). Numerous observational studies have since documented increased CV morbidity and mortality rates in such individuals.[14] After age 70 years, isolated systolic hypertension (ISH) accounts for more than 90% of all patients with hypertension.[14] Hypertension is the most common CV risk factor among older men and women, with prevalence rates of approximately 70% in those age 75 years and older.[14,170] Hypertension has the greatest population-attributable risk for CHD, cerebrovascular disease, and PAD among older adults. Over 70% of older adults with incident MI, stroke, acute aortic syndromes, or HF have preexisting hypertension. Hypertension is the most prevalent antecedent of HF, especially with a preserved EF, and of CKD.[8] Multiple clinical trials in older cohorts have shown benefits of hypertension treatment.[25] Although only two trials showed significant reductions in total mortality rates, several showed substantial reductions in rates of stroke and HF. The reduction in CV events appeared similar in subgroups older versus younger than the median age in all eight trials reporting this comparison. The landmark HYpertension in the Very Elderly Trial (HYVET) demonstrated a 39% significant decrease in rates of fatal stroke, 21% significant decrease in all-cause mortality rates, and 64% significant decrease in rates of HF over 1.8 years of mean follow-up in 3845 patients 80 years of age or older with SBP of 160 mm Hg or higher treated with the thiazide-like diuretic indapamide to a target blood pressure of 150/80 mm Hg versus placebo.[171] More recently, the Systolic Blood Pressure Intervention Trial (SPRINT) showed a 34% reduction in the rate of CV events and a 33% reduction in mortality rates in 2636 patients age 75 years or older with SBP over 130 mm Hg randomized to a target of 120 mm Hg versus 140 mm Hg.[172]

The Eighth Joint National Committee on Prevention, Evaluation, and Treatment of Hypertension (JNC 8) revised the goal blood pressure from the prior target of less than 140/90 mm Hg to less than 150/90 mm Hg in adults age 60 years or more, which sparked considerable controversy.[173] This target, which antedated the SPRINT findings, will likely be lowered based on the SPRINT results. In older patients with CHD, excessive lowering of the DBP should be avoided to avoid deleterious reductions in coronary blood flow. Some studies have found higher CHD rates when the DBP is reduced below 70 to 75 mm Hg.[14]

Hypertension Management

Nonpharmacologic interventions are recommended as initial therapy to manage mild hypertension (**see also Chapter 47**). Such an approach is especially useful in older adults to avoid or reduce the number and doses of antihypertensive drugs and their potential for adverse effects, biochemical changes, and high costs. For milder hypertension, lifestyle modifications may be the only treatment needed. These include aerobic exercise; reductions in excess body weight, mental stress, and intake of sodium and alcohol; smoking cessation; and adoption of the Dietary Approaches to Stop Hypertension (DASH) eating plan.[14] The declines in blood pressure with both weight reduction and sodium restriction are usually larger in older than in younger adults.[14] However, data are scanty in patients over age 75 years.

Five major classes of antihypertensive drugs, diuretics, beta-adrenergic blockers, ACE inhibitors, ARBs, and calcium channel blockers, have been shown in clinical trials to reduce CV events in older adults.[14] Two or more drugs will be required to achieve target blood pressure levels in approximately two thirds of seniors with hypertension. Combination therapy often allows lower individual drug dosages, minimizing dose-dependent side effects and achieving a longer duration of action and additive target organ protection,[14] although it also contributes to polypharmacy. Initiation of antihypertensive drugs in

older adults should be at the lowest doses, with gradual increments as tolerated, given the age-related changes in absorption, distribution, metabolism, and excretion of pharmacologic agents. The choice of specific agents is dictated by efficacy, tolerability, specific comorbidities, and cost.

Dyslipidemia

Dyslipidemia remains an important CV risk factor in older adults, although the relative risk imparted by lipid disorders may be attenuated compared to younger populations (**see also Chapter 48**). Multiple cohort studies have shown that both the total cholesterol and low-density lipoprotein cholesterol (LDL-C) correlated significantly with fatal CHD in both sexes across a broad age range, including patients older than 65 years.[29] Despite the voluminous literature demonstrating a reduction in CV events in both primary and secondary prevention populations receiving medications, primarily statins, to lower LDL-C, the majority of patients in these trials were younger than age 65 years, and very few were 80 years or older (**Table 88.6**).[174] The benefits of statin therapy to reduce LDL-C were similar or greater in older versus younger patients. In the Study Assessing Goals in Elderly (SAGE) trial, limited to patients 65 to 85 years old with 3 minutes or more of ischemia during 48-hour ambulatory ECG monitoring, 80 mg of atorvastatin reduced all-cause mortality rates by 67% compared with pravastatin 40 mg, although major CV events were reduced to a lesser extent. In the Pravastatin or Atorvastatin Evaluation and Infection Therapy (PROVE-IT) trial, atorvastatin 80 mg reduced major CV events by 16% compared with pravastatin 40 mg in patients hospitalized with ACS; the risk was reduced similarly in the subset age-group over 65 years. In a recent study of over 500,000 veterans of mean age 68.5 years (98% men) with known atherosclerotic CVD, a graded association was observed between the intensity of statin therapy and all-cause mortality rates.[175] Similar benefits of statins were seen in patients 76 to 84 years, in whom the mortality rate was 9% lower with high-intensity versus moderate-intensity statins.

TABLE 88.6

Statin Trials Supporting Secondary Prevention in Older Adults

TRIAL NAME	MEDICATION	N	AGE RANGE (yrs)	PERCENTAGE OF OLDER PATIENTS	FOLLOW-UP (yrs)	OUTCOMES
4S	Simvastatin	4,444	35-70	≥ 65 yrs (23%)	5.4	34% RRR in all-cause mortality 34% RRR in MACE
HPS	Simvastatin	20,536	40-80	≥ 70 yrs (29%)	5	25% RRR in death or MI
CARE	Pravastatin	4,159	21-75	≥ 65 yrs (31%)	5	24% RRR in death or MI
LIPID	Pravastatin	9,014	31-75	≥ 65 yrs (36%)	6.1	24% RRR in all-cause mortality and cardiac mortality 29% RRR in nonfatal MI 20% RRR in coronary revascularization
MIRACL	Atorvastatin	3,086	18-80	Not reported	16 wks	16% RRR in death, nonfatal MI, recurrence of myocardial ischemia, and resuscitated cardiac arrest
TNT	Atorvastatin	10,001	35-75	≥ 65 yrs (38%)	4.9	19% RRR in composite endpoint of MACE, CHD-related death, nonfatal MI, or stroke
SAGE	Pravastatin vs. Atorvastatin	893	65-85	≥ 65 yrs (100%)	1	29% RRR in MACE and 67% RRR in death in atorvastatin group
PROSPER	Pravastatin	2,565	70-82	≥ 70 yrs(100%)	3.2	20% RRR in CHD, nonfatal MI, and stroke

CHD, coronary heart disease; *MACE*, major adverse cardiovascular events; *MI*, myocardial infarction; *RRR*, relative risk reduction.

Although secondary analyses of several primary prevention trials have also shown a risk reduction in older subsets, the benefits of statins for primary prevention in this age-group are less clear than for secondary prevention. In the PROspective Study of Pravastatin in the Elderly at risk (PROSPER) trial, a reduction in CV endpoints was seen only in the subset with known CV disease and only in men. The Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin

(JUPITER) showed that rosuvastatin decreased CV endpoints by 44% in 17,802 clinically healthy persons 60 to 71 years old with elevated serum C-reactive protein levels and LDL-C levels of less than 130 mg/dL. Based on the available data, the 2013 ACC-AHA Prevention Guidelines recommend moderate-intensity statin therapy, designed to lower LDL-C by 30% to 49%, in patients older than 75 years with known CV disease and LDL-C of 70-189 mg/dL.[176] This differs from the recommendation of high-intensity statin therapy (i.e., lowering LDL-C at least 50%, in those 40 to 75 years old). For older adults already receiving high- dose statins and tolerating them well, the guidelines do not recommend lowering the dose. High-intensity statin therapy is recommended for individuals with LDL-C of 190 mg/dL or more regardless of age. Cholesterol-lowering drugs are not recommended in persons over 75 years of age without clinical atherosclerotic CVD unless LDL-C is 190 mg/dL or more. In older individuals with LDL-C of 70 to 189 mg/dL, the potential but unproven benefit of long-term statin therapy must be weighed against the cost, inconvenience, and possible side effects.

The safety of statins in older patients has been amply demonstrated in a metaanalysis of 26 RCTs, including data from 170,000 patients.[177] No dose adjustment is generally needed in elders; the statin dose was titrated to achieve the desired LDL-C goal. The most common side effect observed with statins is myalgia, which occurs in about 5% of patients.[178] Myopathy documented by elevated muscle enzyme levels is much less common, occurring in 0.01% to 0.05%. The most severe adverse effect, rhabdomyolysis, has an incidence of 3.4 per 100,000 person-year. Age is not an independent risk factor for these complications.

In older patients intolerant of statins or who cannot achieve their LDL-C goal while receiving maximal statin doses, ezetimibe may be a useful adjunct. Ezetimibe reduces cholesterol absorption from the gut, generally reducing LDL-C by 15% to 20%. Ezetimibe is generally well tolerated in the elderly, though it reduced CV events by a modest 6% in the Improved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT).[179] Fibrates are sometimes used to raise low HDL-C or reduce elevated triglycerides, but evidence supporting their benefit in reducing CVD events is relatively sparse.[180] The combination of gemfibrozil and statins is associated with an increased risk of rhabdomyolysis (0.12%) and should usually be avoided, especially in older adults. Niacin (nicotinic acid) is the most effective drug available to raise low HDL-C; it also reduces elevated triglycerides and modestly lowers LDL-C. Recent trials in patients treated with statins showed no benefit of high-dose niacin in reducing CV events.[181]

Diabetes

Advancing age is accompanied by reduced insulin sensitivity and secretion, contributing to greater glucose intolerance and higher rates of type 2 diabetes mellitus in older adults (**see also Chapter 51**). Approximately 15% of adults 65 years of age or older have diagnosed diabetes, and in another 7% diabetes is undiagnosed.[29] In older adults, diabetes is often underdiagnosed due to the absence of classic symptoms. An estimated 30% of older adults with diabetes have clinical CHD, double the prevalence in age-matched patients who do not have diabetes. Older adults with diabetes and CVD are at high risk for adverse macrovascular and microvascular outcomes as well as functional disability and geriatric syndromes (e.g., frailty and falls).

The primary treatment goals for older adults with diabetes include managing hyperglycemia and reducing the risk of adverse clinical outcomes. Lifestyle modification is principal. Weight loss can reduce insulin resistance and improve glycemic control. Dietary interventions that optimize macronutrient content as well as calorie count help improve glycemic control, independent of weight change. Regular aerobic and resistance exercise lower HbA1c by 0.5% to 1.0% in older adults, even without changes in body

weight or fat mass.

Despite the benefits of lifestyle interventions, most older diabetic patients require medications to achieve glycemic control. Because several large clinical trials have found either no effect or even increased mortality rates in older patients receiving intensive glycemic therapy, a less-intensive target HbA1c of 7% to 7.9% is recommended for most older adults, especially those with long-standing diabetes and chronic comorbidities, including CVD. Even higher targets may be considered for older patients with frailty or a short life expectancy.[182]

Metformin is favored as a first-line therapy due to its low risk for hypoglycemia and other adverse effects. Additional options include the short-acting sulfonylurea glipizide and the short-acting insulin secretagogue repaglinide.[29] Two new agents worthy of consideration are the sodium-glucose cotransporter 2 inhibitor empagliflozin and the glucagon-like peptide-1 analogue liraglutide, both of which reduced CV events in large RCTs. The reduced CV risk with empagliflozin was especially prominent in patients 65 years old or older.[183] If insulin therapy is needed, ultra–long-acting basal and very short-acting prandial insulins are strongly preferred over intermediate-acting insulin formulations. Although tighter glycemic control in diabetes may help to avoid microvascular complications, a greater reduction in CV risk may be achieved with control of concurrent risk factors, such as hypertension and dyslipidemia.[29]

Tobacco

Although only 9.8% of men and 8.5% of women 65 years old or older in the United States were current smokers in a 2008 survey, 54.3% of men and 28.9% of women over 65 years of age were former smokers.[8] Numerous studies have demonstrated that continued smoking increases the rate for recurrent coronary and vascular events in both younger and older patients; reduced CV event rates are seen among those who quit smoking. Data from the Coronary Artery Surgery Study registry showed a reduction in MI and death in former smokers age 70 years or older, similar to that in younger patients with CHD. A metaanalysis of 17 general population studies in over 1.2 million persons age 60 years or older from seven countries showed a dose-dependent increase in all-cause mortality rates in current smokers, with a mean relative mortality of 1.83 versus never smokers. Among former smokers, the mortality risk was attenuated to 1.34. Risk reduction from smoking cessation was seen even in persons age 80 years or over.[184] In a registry of patients with CHD, the mortality rate was markedly lower in recent quitters than in persistent smokers. Smoking cessation also reduces the risk of new or recurrent stroke and improves claudication symptoms.

Physical Inactivity

Physical inactivity is a well-established risk factor for multiple chronic diseases, including hypertension, type 2 diabetes, CHD, stroke, PAD, depression, osteoporosis, and certain cancers (**see also Chapter 53**). Physical inactivity is also associated with increased CV mortality rates.[29] Because the biologic and clinical repercussions of a sedentary lifestyle exacerbate age-related pathophysiologic changes, the health consequences and societal costs of physical inactivity are especially relevant to older adults. Physical inactivity results in decreased functional capacity, increased risk of falling, worsened psychological status, and reduced cognitive function. In older adults, decreased physical activity constitutes the most common modifiable CV risk factor after hypertension. Only 18% of persons 75 years or older reported regular moderate or vigorous physical activity, and only 14% of men and 8% of women 65 years or older reported aerobic and muscle-strengthening activities that met the 2008 federal physical activity

guidelines. Patel and colleagues reported increased total mortality rates, especially CV mortality rates, over a 14-year follow-up in men and women 50 to 74 years old who sat more than 6 hours per day compared with those who sat only 3 hours per day[185]; similar findings have been reported in other studies.[29]

An extensive literature shows that reducing physical inactivity (i.e., increasing activity) improves the health status regardless of age, gender, race, or ethnicity. Regular physical activity improves CHD risk factors, including body weight, blood pressure, serum lipids, and insulin sensitivity, as well as bone density, muscular strength, functional capacity, and cognitive and psychological functioning, all key elements of health and well-being in older adults.[29] Numerous observational studies and RCTs demonstrate that older adults benefit from initiating an exercise program; benefits include greater functional capacity, less mobility disability, better QOL, reduced recurrent CV events, and an increase in active life expectancy.[29] A lower CV risk has been associated with even modest physical activity in older adults. In the Honolulu Heart Program, relatively healthy men 71 to 93 years old who walked more than 1.5 miles/day experienced half the risk for new CHD than men who walked less than 0.25 miles/day over 2 to 4 years of follow-up; the risk of incident dementia was also reduced.[29]

Physical Activity Prescription

The most important consideration when counseling regarding physical activity is to help shape a program that is pleasurable and achievable, and that avoids injury or exacerbation of comorbid problems. Aerobic activity, strength activity, balance, and flexibility are all vital components. For adults willing to enter a formal exercise program, specific exercises can help improve tolerance of the physical demands of daily living and recreational activities. Generally, work intensities start lower than in younger patients, with smaller increments over time, especially in those with significant comorbidities that limit mobility (e.g., arthritis, pulmonary disease, and PAD). Increasing the frequency and duration of exercise sessions should supersede increases in intensity to reduce the potential for overuse injuries. For adults who are disinclined to exercise in a program, increasing activity as part of daily living is also beneficial. Regular leisure activities such as housekeeping, walking, and gardening are all healthful.

Accumulating evidence suggests that activity benefits may increase in proportion to intensity. Reports in patients with established heart disease, including one study of patients with a mean age of 75 years, suggest that high-intensity aerobic interval training can elicit greater improvement in exercise capacity than continuous exercise at a lower intensity.[29] Despite these encouraging data, such training is more complex than traditional training, necessitating more supervision for implementation and safety. Larger studies are needed to establish the efficacy and safety of high-intensity interval training in older patients.

Cardiac Rehabilitation

Cardiac rehabilitation consists of structured exercise training combined with secondary prevention reinforcement, including an individualized exercise prescription as well as close supervision and support (**see also Chapter 54**).[29] It can be particularly helpful in catalyzing physical activity and wellness in adults who are sedentary amidst illness, deconditioning, and entrenched behavior patterns. Older adults with CHD who participated in supervised cardiac rehabilitation had mortality rates that were 21% to 34% lower than nonparticipants over the subsequent 5 years, independent of other risk factors.[186] Patients also benefit in terms of increased physical capacity, independence, and self-efficacy after a hospitalization and/or CVD exacerbation, mitigating the risks of posthospitalization disability.[64] Unfortunately, the vast majority of older patients do not participate in cardiac rehabilitation due to

multiple factors, including lack of referral, logistical barriers, or socioeconomic barriers. Failure to refer, particular for women, is a major contributor to the low participation of older adults. Participation in cardiac rehabilitation by Medicare-eligible recipients is only approximately 12%.[29]

Obesity

An estimated two thirds of seniors are overweight or obese (i.e., body mass index [BMI] ≥ 30 kg/m^2), closely paralleling rates in the general population. Data from NHANES suggest that 35% of noninstitutionalized women and 40% of men 65 to 74 years old are obese, as well as 27% of women and 26% of men 75 years of age or older.[8] Between 1988 and 1994 and 2007 and 2008, obesity rates increased 30% to 40% in older women and 67% to 100% in older men.

Being overweight or obese is associated with mildly increased mortality rates,[8] but the risk ratio decreases as age advances. Given the higher mortality rates in old age, the mortality risk attributable to obesity is higher in older adults. In obese patients with established CVD, multiple studies have demonstrated an obesity paradox; overweight and obese patients have higher survival rates than patients of normal weight. Similar findings have been observed in older populations with CVD, but most of these studies have not differentiated between fat and lean mass, which likely plays an important role in health effects in old age.

Diet

Undernutrition is more common in older than younger individuals due to a combination of medical and socioeconomic factors: 5% to 10% of community-dwelling persons age 70 years or older are undernourished, and the prevalence increases to 30% to 65% in institutionalized elders. It is useful for cardiologists and primary care providers to assess the dietary intake of older patients, provide general dietary advice, and refer to a nutritionist if a major dietary deficiency or malnutrition is suspected. Vitamin and mineral deficiencies are common in seniors due to inadequate intake, decreased absorption, and the effects of disease and medications. Vitamin D deficiency is particularly common in older adults due to low sunlight exposure and reduced synthesis by the skin, and has been associated with increased CV mortality rates.[29] Trials of vitamin D supplementation have not shown consistent benefit.

The Mediterranean diet (i.e., fruits, vegetables, whole grains, and nuts plus low intake of saturated fat) has been associated with beneficial effects on CV risk factors and outcomes in both older and younger adults. Some of these benefits may emanate from flavonoids, which are abundant in fruits, vegetables, nuts, tea, and wine, and have antiinflammatory and antioxidant effects. Higher flavanoid intake was associated with a lower risk of CV death in a population of 98,000 adults of an initial mean age of 70 years.[187]

Noncardiac Surgery and Perioperative Management Considerations in Older Adults

The number of individuals over 70 years of age undergoing surgical interventions has increased dramatically and continues to expand. Perioperative management in older adults poses distinctive age-related challenges. Advance directives are important and patients should identify a health care proxy. Suspending a do-not-resuscitate designation is common during procedures, but it is important to clarify management plans should an adverse outcome ensue.

The 2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery[188] highlights that 25% to 30% of perioperative deaths are CV related and recommends stratifying by MACE risks. The Revised Cardiac Risk Index (RCRI) determines risk using six criteria: (1) IHD; (2) HF; (3) cerebrovascular disease; (4) diabetes requiring preoperative insulin use; (5) CKD (creatinine > 2 mg/dL); and (6) undergoing suprainguinal vascular, intraperitoneal, or intrathoracic surgery. The risk for cardiac death, MI, HF, cardiac arrest, or heart block with no predictors is 0.4%, with one predictor 0.9%, two predictors 6.6%, and three or more predictors 11% or more. The risk is compounded by geriatric domains (e.g., multimorbidity, frailty, polypharmacy, disability, impaired cognition, and mood). The functional status is often more relevant than the RCRI criteria because it entails issues of sarcopenia, frailty, inflammation, and nutrition and their bearing on the metabolic demands of surgery, as well as risks associated with immobilization. Gait speed, a marker of frailty, has been recognized as an important predictor of adverse outcomes even beyond standard assessments by the Society of Thoracic Surgery scoring system; a slow gait speed (≥0.8 m/sec) adds significantly to risks based on the Society of Thoracic Surgery score.[189]

Age-related changes alter drug pharmacodynamics and pharmacokinetics, rendering older patients more vulnerable to anesthetic and analgesic complications. Although regional (epidural) anesthesia does not generally decrease the mortality risk or risk of postoperative delirium or cognitive dysfunction, it is associated with better peripheral vascular circulation, less blood loss, improved pain control, reduced ileus, attenuation of thromboembolic complications, fewer respiratory complications, reduced postoperative narcotic requirements, and a reduced surgery stress response.

Specific Complications and Their Management

Table 88.7 lists some of the basic management principles that pertain to older adults.[188] Geriatric domains compound risks.[190] Delirium is a frequent complication in older adults, with an incidence of 40% to 52%.[191] Postoperative delirium is associated with persistent cognitive deficits and contributes to short- and long-term mortality risks, as well as increased hospital costs, functional decline, and disability. Delirium is highest following cardiac and aortic surgery and substantially less with hip surgery or minor procedures. Avoidance of restraints, provision of hearing and vision aids, presence of family, early mobilization, a normal sleep/wake cycle, adequate pain management, and hydration are key preventive strategies. Postoperative cognitive dysfunction entails deterioration in memory and executive functions in the days to weeks after surgery, but because patients are not confused, conventional screening tools for delirium are insensitive. The incidence following major surgery has been reported to be more than 50%, and is associated with a protracted hospital stay and diminished QOL. Recent studies suggest that postoperative cognitive dysfunction may correspond primarily to baseline cognitive deficiencies[46,57]; this highlights the strong need for thorough preoperative assessments.

TABLE 88.7

Perioperative Medications and Cardiovascular Management Considerations

MEDICATIONS	CARDIOVASCULAR MANAGEMENT CONSIDERATIONS
Discontinue before surgery • ASA, NSAIDs 5-7 days before surgery to ↓ bleeding • Anticoagulants 1-4 days before surgery; consider bridging when indicated • Anticholinergics to ↓ delirium • Diuretics: hold for 24 hr • Benzodiazepine: taper to ↓ withdrawal • Hypoglycemics typically held **Continue or start before surgery** • Antiepileptics • Cardiovascular and antihypertensive medications • Insulin usually at half normal dose and steroids at stress dose • Beta blockers (if high risk based on ≥ 3 revised cardiac risk index factors) should be started several days before surgery and continued for at least 1 month following surgery (heart rate goal, 55-60 beats/min) **Avoid entirely** • Prophylactic nitroglycerin	**Hypertension:** treat very high blood pressure (>180/110 mm Hg) but avoid overly aggressive therapy that may increase risks of intraoperative hypotension **Myocardial infarction:** pain may be masked by narcotics; ST segments are an independent marker of risk and warrant biomarker evaluation • Postoperative myocardial infarction has similar pathology and management to nonsurgical patient, but needs to be differentiated from demand ischemia **Arrhythmias:** often related to noncardiac causes such as infection, hypotension, hypothermia, hypokalemia or hypomagnesemia, pulmonary embolism, ischemia, volume overload, pain, and hypoxemia • Supraventricular tachycardia; ↑ perioperative stroke; ↑ length of stay; ↑ cost • Postoperative atrial fibrillation occurs in about 4% of patients < age 50 but in up to 25% of patients > age 70; ventricular ectopic activity occurs in as many as one third of high-risk patients • Atrial fibrillation occurs in 3% to 5% of major nonthoracic, noncardiac surgical procedures, and 10% to 15% of intrathoracic procedures. Stable patients should be treated with heart rate control and anticoagulation with unfractionated or low-molecular-weight heparin. **Heart failure (volume overload):** common amidst volume overload of surgery (particularly due to reduced cardiovascular reserves that occur with aging) **Deep vein thrombosis:** The risk range is 4% to 8% in older patients not receiving prophylaxis, and doubles in high-risk settings. Predisposing factors include older age, venous stasis, hypercoagulable state. Preventive strategies include early ambulation, mechanical prophylactic measures such as graded pneumatic compression boots or compression stockings, and anticoagulation.

Decubitus ulcers are also common in older surgical patients. Risks include loss of subcutaneous tissue and decreased elasticity of the aged skin, which predisposes to damaged superficial tissues when the skin is compressed for prolonged periods. There may be secondary infection, delayed recovery, and prolonged hospitalization, typically with discharge to a transitional care facility. Preventive measures include routine postoperative skin examination, frequent repositioning, use of support surfaces that redistribute pressure, pressure-relieving overlays in the operating room, and use of foam alternatives and heel protectors.

Older adults are also susceptible to hypothermia due to impaired central and peripheral thermoregulatory function and the effects of anesthesia. It is particularly common among underweight or frail older adults, and may contribute to electrolyte abnormalities, platelet dysfunction, an increased risk for wound infection, and impaired drug metabolism. Warming to a core temperature of about 36°C is recommended, with correction of electrolyte abnormalities.

Respiratory complications are more common with age and include pneumonia, prolonged ventilation, and the requirement for intubation. Postoperative aspiration pneumonia is also common, with risks compounded by cognitive decline, delirium, and sedation. Urinary tract infections and acute or progressive renal failure are also common. Minimizing nephrotoxins and urinary catheters and maintaining hydration are important considerations.

Postoperative Priorities

Early mobilization is vital to perioperative care; it can minimize DVT, deconditioning, frailty, and sarcopenia. Early mobilization has also been associated with improved cardiac output and hemodynamics, and it may reduce bone loss, hypocalcemia, joint contractures, constipation, incontinence, pressure ulcers, sensory deprivation, atelectasis, hypoxemia, pneumonia, depression, delirium, anxiety, and insomnia. To mitigate delirium and cognitive perturbations, it is important to minimize sedation and opiates, provide early extubation, and place an emphasis on recovery. Risk assessment at discharge must include consideration of hospitalization-associated disability, frailty, sarcopenia, deconditioning, and malnutrition, as well as altered cognition; all may provoke dependency and loss of independence, as well as rehospitalization. The use of rehabilitation is critical whether delivered by a home health worker or physical therapist or in an SNF or rehabilitation facility.

Distinctive Precepts of Patient-Centered CARE in Relation to Old Age

In younger adults, CVD typically entails an identifiable pathophysiologic perturbation that disrupts a baseline of health that is generally similar from one patient to another. However, in older adults, CVD pathophysiology more likely occurs in a more heterogeneous baseline physiology. Each senior has idiosyncratic physiology, metabolism, body composition, comorbidity, and lifestyle contexts such that CVD affects the person in ways that are relatively distinctive. Thus, while guidelines-based care provides an important therapeutic standard among younger CVD patients, in older adults, individualized management becomes relatively more imperative.[192] Whereas standard CVD therapeutics are oriented primarily to prolonging survival rates and/or preventing MACE, each older adult is more likely to have distinctive goals. Many place greater value on enhancing their functional capacity, independence, QOL, and/or other dimensions of health and well-being, factors that are jeopardized by CVD[2] in old age.

Diagnosis

Prototypical CV symptoms of pain, dyspnea, dizziness, exercise intolerance, and other complaints are less sensitive and specific in the context of age-related clinical and physiologic changes. Clinical signs (e.g., rales, edema) have many similar limitations. Diagnostic delays often result in CVD being recognized only after it has progressed to an advanced stage and often too late to implement time-sensitive revascularization or other therapeutic options.[193] Ironically, at other times, CVD is more likely to be overdiagnosed in many older adults, particularly in relation to diagnostic imaging techniques (e.g., perfusion imaging or CT scanning for CHD) or biomarkers (e.g., BNP for HF)[194] that can be more reflective of age-related physiologic changes than disease.

Risk Assessment

Prognostic risks in older adults are commonly compounded by risks associated with aging physiology (e.g., more aggressive CHD) or comorbid disease (e.g., multiple types of concurrent CVD as well as COPD, CKD, cancer, and other noncardiac diseases), as well as geriatric domains (e.g., multimorbidity, polypharmacy, delirium, falls, and even lack of family support for someone frail and disabled). In almost every risk prediction model, age stands out as the highest predictor of poor outcome.[6] Yet the basic application of prognosis is also blurred by the way prognosis is conceptualized and measured. Prognosis connotes “disease outcomes,” and in younger populations refers primarily to death and morbidity. In older CVD patients, prognosis is usually applied more broadly, with reference to functional capacity, QOL, and other concerns that are more pertinent with age but are usually less well delineated and measured. Therefore, related risk-to-benefit concepts often become ambiguous for elderly CVD patients struggling with multiple personal issues.

Disease Management and Care Coordination

The fact that there are high risks associated with CVD in old age implies that the potential for risk reduction is increased with effective therapies. However, risks for harm from therapies are also increased. Older adults not only have a reduced capacity to tolerate medications, devices, and procedures, but the therapeutic effects of these interventions are usually more variable**.** Even when acute

therapy seems to go well, progression to frailty and disability may occur. Therefore, guidelines and precepts cannot be immediately applied to typical geriatric patients, but must be weighted in terms of risks and benefits relative to each patient's circumstances and the continuum of aging changes. Caregiving becomes as much an art as a science. CVD therapies elemental for younger adults require greater individualization in older patients.[195] Although this has value in its potential to engender personalized care, it also raises the countervailing tension that less standardized care may lead to variable quality and outcomes.

Shared decision making seems a relatively logical way to facilitate CVD management that meets the personal needs and circumstances of each patient, but it assumes that older adults understand their diseases and aggregate health circumstances, as well as the value and limitations of each therapy.[22] Limitations in health literacy are common in any age, but are especially relevant for older adults with CVD. Vascular and myocardial disease, frailty, multimorbidity, dementia, and depression are among the age-sensitive dynamics that detract from cognitive capacities that enable health literacy. Improved decision-making tools for patients and caregivers remain an important aspect of care.

Each older patient's values are also pertinent. Some may experience aggressive therapies as burdensome and eschew options that seem likely to yield important benefits (e.g., treating hypertension in an asymptomatic senior). Others may feel devalued or even maltreated unless a full medical armamentarium is employed, even if no meaningful benefits are likely (e.g., insisting on a TAVR despite advanced Parkinson disease). Complicated family dynamics are also common, ranging from a spouse or child demanding a therapy with uncertain utility, to those who fail to provide any support or help.

Most older patients also have multiple providers, including multiple physicians as well as advanced practice nurses, physician assistants, pharmacists, nutritionists, speech pathologists, physical and occupational therapists, and social workers, as well as possible palliative care and hospice consultants. Having multiple providers provides complementary expertise but it also may predispose the patient to fragmented care. The potential for mixed messaging, counterproductive therapeutic plans, confusion, and nonadherence is high. The conceptual value of having a medical “quarterback” to integrate care of older adults across multiple providers has been emphasized. Although this is often assumed to be the domain of the primary care provider, decisions regarding medications, devices, procedures, and ongoing monitoring increasingly require CV expertise. Thus, CV clinicians must increasingly be skilled to work within such complex team relationships. Effective interpersonal skills and organization are increasingly requisite for successful CV care.

The impact of transitions is also greater in older than younger CVD patients. Transitions between floors and services within hospitals, from hospital to home, and from hospitals to SNFs to home all entail complex management issues, multiple systems of care, and a high potential for confusion. At each point of transition the older adult is vulnerable to adverse events. A critical part of CVD care is reconciliation of medications and management at each stage of treatment and emphasis on the broader priorities of physical and cognitive function that help to mitigate susceptibility to frailty, disability, delirium, and decline.

Adherence

Adherence is a significant challenge among older adults. Reasons include poor coordination of recommendations from multiple clinicians, limited health literacy (typically exacerbated by cognitive declines), and/or limited financial and social resources. Poor adherence also can evolve when recommendations are not aligned with a patient's goals and preferences.[196] Multiple tools for improving adherence, including medication lists, electronic reminders, pill organizers and dispensers, and remote

monitoring devices, have been promoted, but suboptimal medication management often persists. Taking steps to ensure that treatment recommendations are consistent with patients' goals and capacities remains an important part of enhanced solutions. Costs are also relevant. Despite introduction of a Medicare prescription program in 2006, 8% of older adults did not fill one or more prescriptions because of costs[25,197] and proportions of those who did not fill prescriptions have continued to rise in older adults with low incomes.

Life Expectancy

Anticipated life expectancy is sometimes used to gauge the utility of care for older patients. Convenient tools to approximate the length of life have been developed and validated.[198] CVD therapies may then be considered in relation to the predicted longevity, with the intention of only using therapies when there is sufficient longevity for a meaningful effect. These decisions must be informed by awareness of each therapy's anticipated lag time to benefit as well as any potential lag time to harm. It is important to clarify which therapies are likely to relieve symptoms and which may extend life. Therapies providing symptom improvement can be useful even if longevity is limited (e.g., balloon aortic valvuloplasty), whereas those that primarily prolong survival times (e.g., statin therapy) might only have value for those with significant life expectancy. This approach is also limited by the fact that many therapies have multiple effects. Whereas statins take about 2 years to yield likely survival benefits for CHD, they can reduce claudication more rapidly.[29]

Opportunities for Telehealth

The burgeoning field of telehealth has generated much excitement about potential applications in older adults with CVD, particularly in response to the logistic limitations of many infirm elderly. The utility of telehealth in diabetes management is often shown as a model of potential benefit for broader applications,[199] including monitoring (e.g., blood pressure, pulse), adherence, and physical activity. However, the utility of telehealth has been most successful in younger populations of tech-savvy adults. Its application to older, frailer, and cognitively impaired elderly remains challenged by the skills required to manipulate smart phone applications and/or other telehealth devices, as well as concerns regarding adherence, safety, and value.[200]

Postacute Care: Skilled Nursing Facilities and Long-Term Care

The role of postacute care for CVD patients is changing. Older and sicker patients were once routinely hospitalized for long lengths of stay and were more stable upon discharge to postacute care. As contemporary incentives encourage more rapid discharges from acute hospitalizations, increased numbers of older CVD patients are being discharged to SNFs. Of the more than one million hospital discharges for HF each year in the United States, approximately 20% are discharged to SNFs.[201] Patients are more likely to be unstable, and left to the care of a staff that often lacks advanced CVD sophistication and/or systematized communication with CVD clinicians. Medicare is increasingly demanding that SNFs improve quality metrics and reduce hospital readmissions.[202] SNFs that achieve high performance measures by October 1, 2018, will receive incentive payments; SNFs that lag behind will be subject to penalties.

Palliative Care and End-of-Life Decisions

Palliative care is a holistic approach for patients facing a life-threatening illness (**see also Chapter 31**).

It focuses on symptoms as well as psychosocial and spiritual needs. It provides an extra layer of support, often in association with standard care. Palliative care has been demonstrated to improve the quality of care and even overall survival times,[203] and it is distinct from hospice care, which is oriented to patients with a prognosis of less than 6 months of expected survival, and who have agreed to forgo more aggressive treatment.

In some respects, geriatric cardiology and palliative care overlap. Many palliative care patients are older, and struggle with frailty, disability, and other complexities of care that prompt tailored approaches to CV management. Geriatric cardiology and palliative care are also quite distinct, however.[2] Cardiologists are oriented to the crossroads of management, and must determine which older, frail patients with complex medical needs may still benefit from prevention and intervention strategies that may forestall or reverse a decline (e.g., TAVR may mitigate disease that had initially seemed at the end stage), whereas palliative care is more oriented to management in a context of predominant decline.

Collectively, both cardiologists and palliative care experts have a formidable potential to work synergistically. Cardiologists have particular skills to optimize function, QOL, and other symptomatic improvements for older CVD patients with limited life expectancy, and to provide illuminating insights amidst predictable complexity (e.g., multimorbidity, comorbidity, delirium). Similarly, cardiology care of older adults entails skills to inform end-of-life decision making, including decisions about resuscitation, thresholds of futility, and critical insights to help families and surrogate caregivers if patients lose the capacity to make their own decisions.

Geroscience: Stopping the Aging Clock

Geroscience is an interdisciplinary field that aims to understand the relationship between aging and age-related diseases. Whereas research on CVD and aging has focused primarily on elements of disease and/or the complexity of applying CVD precepts to older adults with multimorbidity and complexity, geroscience is oriented to mechanisms determinant of aging. If constitutive mechanisms of aging can be eliminated or sufficiently forestalled, many age-related diseases may no longer develop. Candidate mechanisms include macromolecular damage, mitochondrial oxidative stress, malformed proteostasis, deficient autophagy and ubiquitin-mediated proteolysis, stem cell dysfunction, diminished bioavailability of nitric oxide, up-regulated renin-angiotensin-aldosterone physiology, and low-grade inflammation.[204]

Caloric restriction and low-molecular-weight pharmaceutical compounds (e.g., rapamycin, resveratrol, and metformin) have received increasing attention as innovative approaches to retard aging. Although caloric restriction may seem counterintuitive for older adults often coping with sarcopenia, frailty, depression, and other aspects of health for which diet is critical, nutritionally balanced modest caloric restriction induces many favorable physiologic benefits. Caloric restriction down-regulates mTor signaling. mTor becomes relatively dysregulated with age, and in animals, mTor inhibition has been demonstrated to preserve CV function and induce other CV benefits.[205] Rapamycin provides similar mTor down-regulating effects. Caloric restriction research has catalyzed a robust area of human investigation wherein drugs triggering similar mechanical benefits are being investigated. Many other signaling pathways and related pharmaceuticals remain in consideration as potential aging modifiers. Metformin increases AMP-kinase, has antiinflammatory benefits, and is easily studied for antiaging effects in humans because it is already approved for treatment of diabetes. The ongoing Targeting Aging with Metformin (TAME) trial is specifically studying the effect of metformin to prevent or delay the onset of age-related diseases and conditions, including CVD.[206]

Although geroscience is an emerging field to prevent age-related diseases, it is important to emphasize the prominence that geriatric perspectives have attained in prevention and treatment of established CVD. Studies of revascularization, HF, arrhythmia, imaging, valvular heart disease, and other foundations of CV care are increasingly inclusive of age-related perspectives regarding pathophysiology, diagnosis, and management. Future studies focusing on the oldest old will provide requisite data for the care of a rapidly growing subset, especially women, with CVD and the need to guide beneficial interventions.

Cardiovascular Disease in Women

Martha Gulati, C. Noel Bairey Merz

Cardiovascular disease (CVD) remains the leading cause of death in women. Coronary heart disease (CHD) accounted for 399,028 deaths in women in 2014 and accounts for 1 in every 4 female deaths in the United States.[1] Approximately 47.8 million women are living with some form of CVD. The lifetime risk of developing CVD for a 40-year-old woman is estimated to be 1 in 2, with 1 in 3 at risk of developing CHD, 1 in 5 of developing heart failure (HF), and 1 in 5 having a stroke in their lifetime.[1] Since 2001, there has been a continuous decline in mortality rates from heart disease in women,[1] but in younger women (< 55 years of age) in the last 2 decades, there has been no significant improvement in the mortality rate from heart disease.[2]

There are both sex (biologic) and gender (sociocultural) differences in CVD and its outcomes. A number of variables are found to differ in women and men, including several specific CVD risk factors, treatment and management strategies for both primary and secondary prevention of CVD, and pathophysiologic mechanisms of CVD.

Prevention of CVD in women is influenced by an awareness of sex and gender differences. Although more women had been dying from CVD than men in the United States, it was not until 1991 that the National Institutes of Health (NIH) established a policy that all NIH-funded trials studying conditions that

affect both sexes must include both women and men. In 2016, the NIH made it mandatory to include both sexes in cell and animal studies.[3] Although awareness of CVD as the leading cause of death in women increased from 1997 to 2012 (30% vs. 56%; $P < 0.001$), it remains suboptimal and relatively unchanged since 2006, particularly in racial and ethnic minorities.[4] A nationally representative survey done by the Women's Health Alliance showed that even though 74% of women had one or more CVD risk factor, only 16% of women had been informed that they were at risk for heart disease.[5] Physician awareness, education, and assessment of a woman's CVD risk are also far from expected. In a 2014 survey of physicians, only 22% of primary care physicians and 42% of cardiologists felt well equipped to assess the CVD risk in women, and less than 50% of physicians were using the recommended Atherosclerotic Cardiovascular Disease (ASCVD) risk assessment calculator for their women patients.[6]

Sex, Gender, and Genetic Differences in Cardiovascular Disease

The Institute of Medicine has defined *sex* as "the classification of living things, generally as male or female according to their reproductive organs and functions assigned by the chromosomal complement."[7] Sex differences result from true biologic differences in the structure and function of the cardiovascular systems of men and women, in contrast to gender differences, which stem from a person's self-representation and result in psychosocial roles and behaviors imposed by society. Certainly gender differences play a role in the treatment of CVD and, hence, the impact outcomes, but they are very different from sex differences, which arise from the genetic differences between men and women. Sex differences arise from the chromosomal differences between men (XY) and women (XX).

Genetic markers predictive of CVD remain undefined to date in women. The Women's Health Genome Study followed 19,313 white women prospectively for a median of 12.3 years to assess whether a genetic risk score could improve the predictive risk assessment of women beyond traditional risk factors.[8] The prediction of CVD risk in women by means of the comprehensive literature-based genetic risk score has not improved; thus, no genetic marker is known that can be used to improve the risk assessment in women, beyond traditional methods.

Risk Factors for Cardiovascular Disease in Women (See also Chapter 45)

Established Risk Factors

Age

Age powerfully predicts the risk for CVD, and specifically CHD. The prevalence of CVD increases with age in both men and women, but CHD events lag at least 10 years in women compared with men.[1] CHD increases in women after the age of 60 years, with 1 in 3 women having evidence of CHD after the age of 65 years, in contrast with 1 in 8 in women age 45 to 64 years. The ASCVD risk score increases with increasing age.[9] The largest sex difference in CHD mortality rates occurs in relatively young and middle-aged women, with relative stagnation in rates, in contrast with continued declines seen in men and elderly women.[2]

Family History

A history of CHD in a first-degree relative imparts a risk for an individual. The ASCVD risk assessment tool and the AHA Guidelines for the Prevention of Cardiovascular Disease in Women define a family history of premature CHD as a first-degree relative with CHD before the age of 65 years for women and age 55 years for men.[9,10] Premature CHD in first-degree female relatives is a relatively more potent family history risk factor than in male relatives.[11] In addition, women classified as low risk for CHD (using the Framingham Risk Score) but with a sister with premature CHD more likely have evidence of subclinical CHD as shown by the amount of coronary artery calcium, based on a study of 102 asymptomatic women.[12] The 2013 American College of Cardiology/American Heart Association (ACC/AHA) guidelines on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults recommends consideration of a premature family history of CVD when assessing risk in asymptomatic adults.[9]

Hypertension (See also Chapters 46 and 47)

Women have a higher overall prevalence of hypertension compared with men, depending on age. Based on the National Health and Nutrition Examination Survey (NHANES), before the age of 60, more men than women have hypertension, but after age 60, the prevalence of hypertension is higher in women.[13] Hypertension rises twofold to threefold in women taking oral contraceptives, which raise the blood pressure by 7 to 8 mm Hg on average.[14]

The NHANES from 2011 to 2014 demonstrated that hypertensive women more likely received treatment than men (56.3% vs. 50.6%).[13] Younger women (≤ 59 years) were more likely to have controlled blood pressure compared with men. Women over the age of 60 not only had a higher prevalence of hypertension but had poorer blood pressure control than men.[13]

Hypertension is associated with an increased risk of the development of congestive heart failure, and this risk appears to be greater in women.[15] Women who present with strokes more likely have a history of hypertension than men.[16] Indeed, the lifetime risk of stroke is greater in women compared with men, related to their greater life expectancy and the rise in stroke rates with age.

Diabetes (See also Chapter 51)

Diabetes increased the risk of CHD and confers a greater risk for CHD in women than men, increasing a woman's risk of CHD by threefold to sevenfold, with only a twofold to threefold increase in diabetic men. In addition, the risk of fatal CHD in a diabetic woman is 3.5 times that in a nondiabetic woman, and is higher than in diabetic men (relative risk [RR] of fatal CHD is 2.0 that of a nondiabetic man).[17] In addition, women with type 1 diabetes have twice the risk of fatal and nonfatal cardiovascular events, and a 40% greater risk of all-cause deaths compared with men.[18]

The American Diabetes Association suggests consideration of diabetes screening for women and men over the age of 45 years, and then every 3 years if the results are normal. For women with a history of gestational diabetes, screening for diabetes should occur 6 to 12 weeks postpartum and every 1 to 2 years thereafter.[19]

Dyslipidemia (See also Chapter 48)

Dyslipidemia is common in women; more than half of American women have a total cholesterol level greater than 200 mg/dL and 36% have a low-density lipoprotein cholesterol (LDL-C) level greater than 130 mg/dL. Notably in women, adverse changes in the lipid profile accompany menopause and include increased levels of total cholesterol, LDL-C, and triglycerides and decreased levels of high-density lipoprotein cholesterol (HDL-C), although it remains unclear how much risk factor worsening is related to aging as opposed to menopause-related hormonal changes.[20]

The ASCVD risk assessment focuses on LDL-C as the primary target of lipid-lowering therapy to reduce the risk of CVD.[9] The use of nuclear magnetic resonance spectroscopy for lipoprofiles, apolipoproteins, particle size, and density has not demonstrated superiority over a standard fasting lipid profile for cardiovascular risk assessment in asymptomatic women.[21]

HDL-C levels in women average around 10 mg/dL higher than in men throughout their lives. HDL is inversely associated with ASCVR events.[22] Nonetheless, HDL as a target of therapy has, to date, never improved outcomes and is not the target of the ASCVD risk assessment.

Smoking

In 2014, 18.8% of men and 14.8% of women reported tobacco use, putting them at increased risk of CVD.[23] Although women smoke less than men, smoking may be more detrimental in women than men. Female smokers die 14.5 years earlier than female nonsmokers, and male smokers die 13.2 years earlier than male nonsmokers.[24] Cessation of smoking substantially reduces the risk in women; the mortality risk among former smokers decreases nearly to that of never smokers.[25]

The use of oral contraceptives and smoking imparts an even greater risk of myocardial infarction (MI) than smoking alone, likely related to prothrombotic effects. Smoking 25 or more cigarettes a day increases a women's risk by 12-fold, but smoking 25 or more cigarettes a day and taking oral contraception increases one's risk by 32-fold.[26] Third-generation hormonal contraceptives appear to pose less risk than prior- and fourth-generation formulations.[14]

Physical Activity and Physical Fitness (See also Chapter 53)

Sedentary behavior is more common in women than in men (31.7% vs. 29.9%), and inactivity increases with age,[1] although gender bias in physical activity measurement instruments, which do not consider domestic activities such as cooking, cleaning, and childcare, may account for these observed differences. Using the 2008 U.S. federal physical activity guidelines, in every age-group adult women studied in the 2014 National Health Interview Survey reported performing less leisure time physical activity than men.[27]

Physical inactivity is associated with higher blood pressure, worse cholesterol levels, poorer glucose metabolism, poorer mental health, and obesity. Physical inactivity, quantified by a prolonged sitting time, has been shown to be an independent risk factor for CVD in women beyond leisure-time physical activity.[28]

Exercise capacity, also known as physical fitness, strongly and independently predicts all-cause mortality rates in asymptomatic women and can be quantified. In the Women Take Heart Project, asymptomatic women who did not achieve 5 metabolic equivalents (METs) on the Bruce protocol had a threefold increased risk of death compared with women who achieved more than 8 METs.[29] Furthermore, the risk of death among asymptomatic and symptomatic women whose exercise capacity was less than 85% of the predicted value for age was at least twice that of women whose exercise capacity was at least 85% of their age-predicted value.[30] Age-predicted fitness can be estimated using the validated nomogram (**Fig. 89.1**). In the Effectiveness-Based Guidelines for the Prevention of Cardiovascular Disease in Women 2011 Update, physical inactivity or poor physical fitness is a criterion for placing a woman in the "at-risk" group.[10]

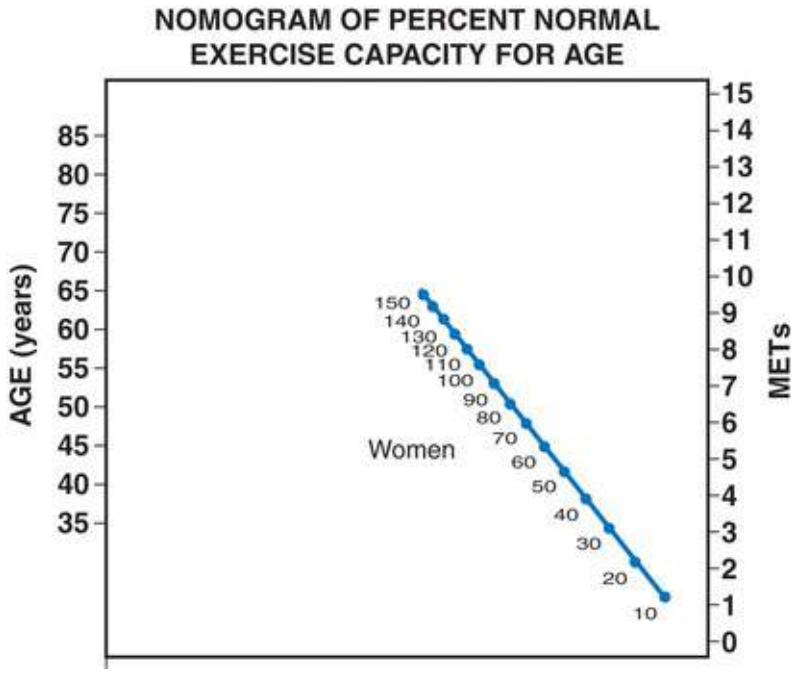

FIGURE 89.1 Nomogram of the percentage or predicated exercise capacity for age in asymptomatic women. A *line* drawn from the patient's age on the left-hand scale to the MET value on the right-hand scale will cross the percentage line corresponding to the patient's percentage of predicted exercise capacity for age. (From Gulati M, Black HR, Shaw LJ, et al: The prognostic value of a nomogram for exercise capacity in women. N Engl J Med 2005;353:468.)

Emerging Risk Factors

Metabolic Syndrome (See also Chapters 45 and 50)

NHANES data from 2003 to 2012 indicate that 35.6% of women met the criteria for having the metabolic syndrome, with higher rates than seen in men (33.3%; $P < 0.01$).[31] In addition, those with the metabolic syndrome have an increased risk of developing CVD, and this association is strongest in women, with a relative risk of CHD of 2.63, compared with a relative risk of 1.98 in men, when compared with their same gender counterparts without the metabolic syndrome.[32]

Obesity (See also Chapter 50)

Obesity, defined as a body mass index (BMI) of more than 30 kg/m^2, is epidemic in the United States, with the 2011 to 2014 NHANES estimation of obesity in women at 38%, higher than the prevalence in men (34.3%).[33] The rising incidence of diabetes is associated closely with obesity. In the Nurses' Health Study, obesity was the most powerful predictor of diabetes, with women with a BMI of 35 kg/m^2 or higher having a relative risk for diabetes almost 40-fold greater than women with a BMI of less than 23 kg/m^2. The pattern of obesity appears to be related to CVD, whereby a waist circumference larger than 35 inches, indicative of visceral obesity, is related to an elevated CVD risk, whereas an elevated BMI alone is not.[34]

Although obesity has also been associated with an increased mortality rate from CVD and shortened life expectancy from CVD,[35] obesity is not an independent risk factor for CVD given that obesity is strongly associated with many of the traditional CHD risk factors. Notably, overweight, defined as a BMI of more than 25 kg/m^2 but less than 30 kg/m^2, is associated with lower mortality rates and CVD death rates compared with a leaner measurement.[36] Obesity may simply be a marker for low physical activity and fitness levels. Prior work in women where both obesity and physical fitness were measured suggests that physically fit obese women are not at an elevated risk, and conversely lean women who are not physically fit have an elevated risk.[37]

High-Sensitivity C-Reactive Protein (See also Chapter 50)

Although high-sensitivity C-reactive protein (hsCRP) is not a causal risk factor for CVD, it may improve risk detection in women.[38] The Women's Health Study demonstrated that a model that included hsCRP improved the cardiovascular risk prediction in women.[38] For women with the metabolic syndrome, hsCRP may add prognostic information regarding the future cardiac risk. In one study of apparently healthy women, women with the metabolic syndrome and hsCRP levels greater than 3.0 mg/L had almost twice the risk of future cardiovascular events as those with the metabolic syndrome and an hsCRP level of less than 3.0 mg/L.[39] Measuring hsCRP is not recommended in the routine risk assessment of women, but rather it is an option in those persons in the intermediate risk range based on the Framingham Risk Score.[40]

Autoimmune Disease (See also Chapter 94)

Systemic inflammation in autoimmune disease may accelerate atherosclerosis and ischemic heart disease, and these diseases occur more frequently in women.[41] Rheumatoid arthritis and systemic lupus erythematosus (SLE) are associated with a significantly increased risk for CVD.[42,43] Cardiovascular events often occur in younger women with SLE, with a risk for acute MI 9-fold to 50-fold greater than in the general population.[44] Traditional risk factors such as smoking, family history of premature CHD, hypertension, and elevated cholesterol levels do not completely account for the increased risk of CHD in patients with SLE. In the Effectiveness-Based Guidelines for the Prevention of Cardiovascular Disease in Women 2011 Update, systemic autoimmune collagen-vascular disease was listed as a criterion for an “at-risk” status.[10]

Polycystic Ovary Syndrome (See also Chapter 92)

Unique to women, polycystic ovary syndrome (PCOS) is associated with the development of many of the features of metabolic syndrome, as well as insulin resistance, although first-degree male relatives also appear to have more insulin resistance.[45] Women with PCOS have an increased prevalence of impaired

glucose tolerance, the metabolic syndrome, and diabetes compared with women without PCOS.[46] PCOS may confer an elevated risk for CVD independent of established risk factors in older postmenopausal women.[47] Furthermore, in the National Heart, Lung, and Blood Institute (NHLBI)–sponsored Women's Ischemia Syndrome Evaluation (WISE) study of postmenopausal women with PCOS, the cumulative 5-year CVD event-free survival rate was 79% for women with PCOS compared with 89% for women without PCOS.[47]

Functional Hypothalamic Amenorrhea (See also Chapter 92)

Up to 10% of premenopausal women have documented ovarian dysfunction, with a larger proportion having subclinical hormonal dysfunction that may increase CVD risk. Functional hypothalamic amenorrhea (FHA) is a cause of a premenopausal ovarian dysfunction and occurs when gonadotropin-releasing hormone increases, thereby increasing luteinizing hormone in a pulse frequency, causing amenorrhea and hypoestrogenemia. Psychological stressors or metabolic insults such as caloric restriction or excessive exercise can induce FHA. In a large cohort study, women with menstrual irregularities had a 50% increased risk of nonfatal and fatal CHD compared with women with regular menstrual cycling. Additional data indicate that FHA is associated with premature coronary atherosclerosis in women undergoing coronary angiography, and that use of oral contraceptive therapy may offer protection.[48] Thus amenorrhea and cycling irregularity may augment CVD risk in women, a topic that requires further work.

Eclampsia, Preeclampsia, and Pregnancy-Associated Hypertension (See also Chapter 90)

Gestational hypertension of any sort is associated with an increased risk of hypertension, chronic kidney disease, diabetes, stroke, and CVD (including HF and MI).[49-51] Women with a history of preeclampsia have approximately double the risk for subsequent ischemic heart disease (IHD), stroke, and venous thromboembolic events over the 5 to 10 years following the pregnancy.[52] The median age for a stroke in these women is 50 years or younger; this indicates that the risk for CVD is accelerated even though these women have a premenopausal status and would be presumed to have a lower risk because they are being screened for and treated for CVD risk factors.[53] Despite the association with elevated CVD events and labeling of pregnancy as a “stress test” for future cardiovascular events, some research suggests that the risk of CVD results from shared prepregnancy risk factors rather than any direct influence of the hypertensive disorder that occurred during pregnancy.[54] The Effectiveness-Based Guidelines for the Prevention of Cardiovascular Disease in Women 2011 Update listed a history of preeclampsia or pregnancy-induced hypertension as a criterion for an “at-risk” status. Additionally, hypertensive disorders of pregnancy are noted in the 2014 Guidelines for Stroke Prevention in Women to be associated with an increased risk of stroke during pregnancy, immediately after pregnancy, and even years after the associated pregnancy.[16]

Gestational Diabetes (See also Chapter 90)

A history of gestational diabetes doubles the risk of diabetes in the 4 months postpartum and remains a lifelong risk factor for diabetes and CVD.[55] Fasting glucose levels of 121 mg/dL or higher during pregnancy increase the risk for diabetes in the early puerperium by 21-fold.[56] The Effectiveness-Based Guidelines for the Prevention of Cardiovascular Disease in Women 2011 Update incorporated a history of gestational diabetes as an “at-risk” criterion, which means that attention to cardiovascular risk factors and

implementation of therapeutic lifestyle changes is required in these women throughout life.

Breast Cancer Therapy (See also Chapter 81)

Recent advancements in breast cancer treatment have led to improved survival rates from that disease but an elevated risk of CVD.[57] Breast cancer therapies are associated with varying degrees of direct cardiovascular injury in conjunction with significant indirect lifestyle changes that also reduce cardiovascular reserves.[58] Although it is uncertain whether breast cancer overall, or specific therapies for breast cancer per se, will emerge as risk factors for CVD, this issue assumes increasing importance in the management of women surviving breast cancer, given that recent work demonstrates an increased risk of CVD just 7 years after the breast cancer diagnosis.[57]

Reproductive Hormones

Oral Contraceptive Therapy

The AHA and the American College of Obstetricians and Gynecologists (ACOG) have published guidelines on medical eligibility for contraceptive use.[16,59] For most women, who are healthy and free of CVD and cardiovascular risk factors, the use of combination estrogen-progestin oral contraceptives is associated with low relative and absolute risks of CVD.[60] Women who are smokers over the age of 35 years and women with uncontrolled hypertension, a history of thromboembolic disease, or a history of IHD have an unacceptable level of CVD risk associated with oral contraceptives.[14,16]

Postmenopausal Hormone Therapy

Most cases of CVD occur after menopause in older women, in association with an increased burden of established CVD risk factors.[61] It is for this reason that postmenopausal hormone therapy is thought to reduce the CVD risk, a theory supported by observational data. Nonetheless, randomized trials, such as the Heart and Estrogen/Progestin Replacement Study (HERS) I, HERS II, Women's Health Initiative (WHI), and Raloxifene Use for The Heart (RUTH), found that neither hormone therapy nor selective estrogen receptor modulators (SERMs) prevent primary or secondary CVD events. The AHA Effectiveness-Based Guidelines for the Prevention of Cardiovascular Disease in Women 2011 Update and the AHA Guidelines for the Prevention of Stroke both state that hormone replacement therapy and SERMS should not be used for the primary or secondary prevention of CVD and are a class III, level of evidence A, intervention.[10,16]

Assessment of Risks for Cardiovascular Disease in Women (See also Chapter 45)

The INTERHEART study examined the association of multiple risk factors with the risk of an MI and compared the relative risks of their association by gender.[62] This study found that nine factors accounted for 94% of the population-attributable risk for acute MI in women and 90% of the risk in men. These risk factors included the apolipoprotein B/apolipoprotein A-1 ratio, cigarette smoking, hypertension, diabetes, abdominal obesity, psychosocial factors (index score based on depression, stress at home or work, financial stress, life events, and a control score), fruit and vegetable intake, exercise, and alcohol intake. For most of the risk factors, the strength of the association was similar amongst both sexes, but diabetes and psychosocial factors had a greater association with the risk of acute MI in women. Lifestyle choices, including exercise, fruit and vegetable consumption, and modest alcohol consumption were associated with a greater level of prevention of acute MI in women compared with men (**Fig. 89.2**).[62]

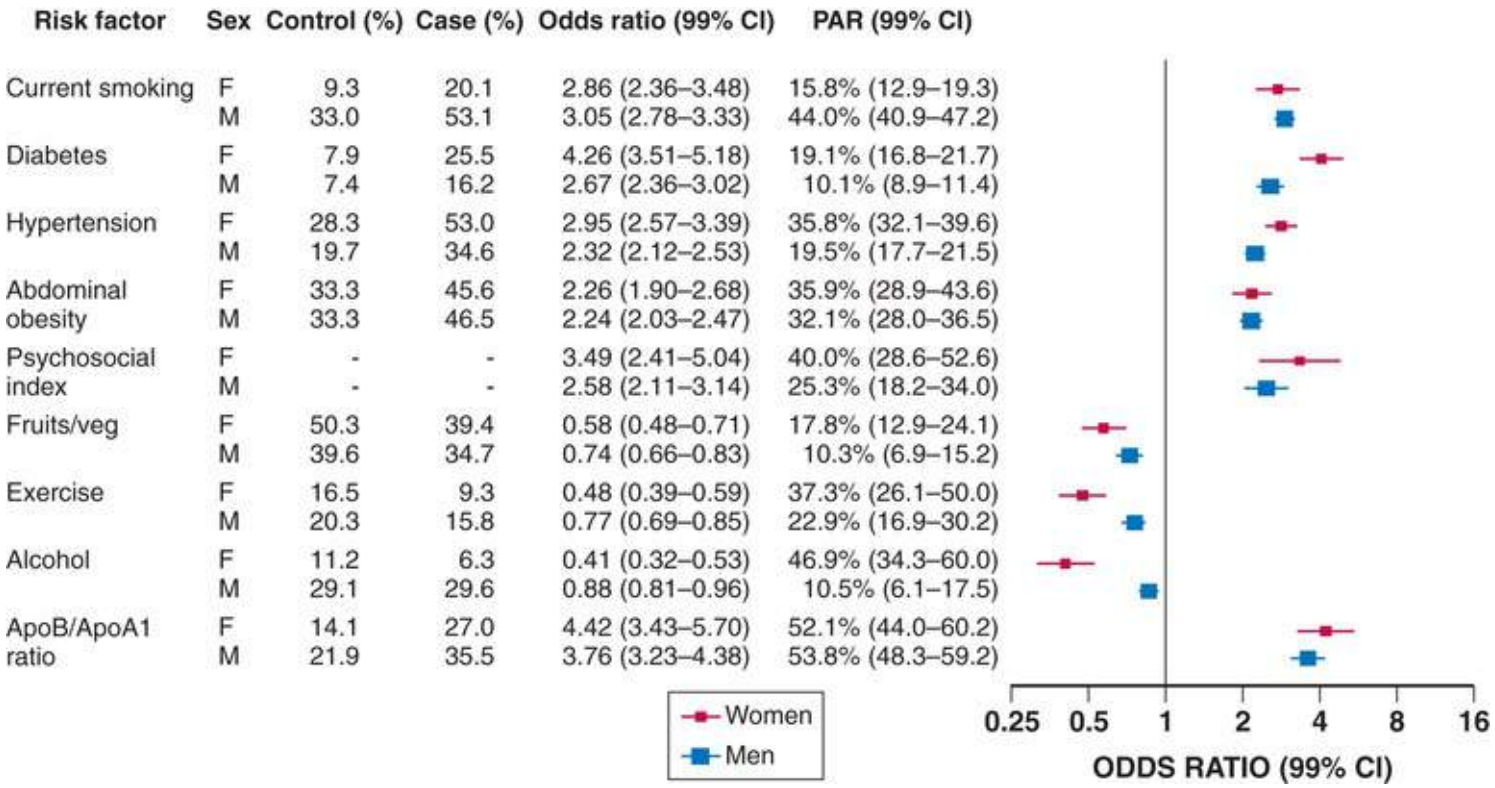

FIGURE 89.2 Relative risk of cardiac risk factors among women and men from the INTERHEART Study. A case-control comparison of the relative risk for a myocardial infarction based on gender. (From Yusuf S, Hawken S, Ounpuu SD, et al: Effect of potentially modifiable risk factors associated with myocardial infarction in 52 countries [the INTERHEART study]: case-control study. Lancet 2004;364:937.)

The Framingham Risk Score has limitations, particularly in nonwhite and female populations.[63] Nonetheless, it was the basis of the 2011 AHA Effectiveness-Based Guidelines for the Prevention of Cardiovascular Disease in Women, which used the Framingham Risk Score to stratify women into three categories: high risk, at risk, and optimal risk, and placed emphasis on the lifetime risk of CVD in women.[10] The Reynolds risk score calculates the risk in women and men. It includes the hsCRP and family history as risk factors and considers cerebrovascular events as an outcome. The European "SCORE" (Systematic Coronary Risk Evaluation) includes geographic variability within European countries as a calibration metric. The 2013 ACC/AHA guidelines on the treatment of blood cholesterol to reduce the

atherosclerotic cardiovascular (ASCVD) risk in adults offer a new risk score that was derived in population studies that included white and black men and women.[9]

Specific Cardiovascular Diseases in WOMEN

Ischemic Heart Disease in Women

Both sexes can experience the typical symptoms of myocardial ischemia, particularly MI (**see also Chapter 56**). Yet there may be a difference in symptom perception based on sex, with more women reporting symptoms that have been labeled as "atypical."[64] In an analysis of 69 studies of symptoms in those presenting with an acute coronary syndrome (ACS), the absence of chest pain or chest discomfort was noted more often in women than in men (37% vs. 27%).[65] Data from the National Registry of Myocardial Infarction show that women were more likely than men to present with an MI without any chest pain at all (42 % vs. 31%' $P < 0.001$), particularly younger women, who have the highest hospital mortality rates.[66] The absence of chest pain and the hospital mortality differences became attenuated with age. For many women, the symptoms may often be more nonspecific or less severe and can include shortness of breath; pain or discomfort in other body locations, such as that localized to the arm(s), shoulder, middle back, jaw, or epigastrium; indigestion; nausea or vomiting; diaphoresis; faintness or dizziness or syncope; fatigue; generalized weakness; or palpitations.[64]

The NIH-NHBLI–sponsored Women's Ischemia Syndrome Evaluation (WISE) collected detailed information on symptoms of women, including ischemic symptoms.[67] This study confirmed more atypical symptoms, with symptoms often occurring at rest, in addition to symptoms that were stress related.[67] This nonspecific clinical presentation makes it difficult to evaluate symptoms and make a precise estimation of the likelihood of CAD in women. Evidence regarding the "typical" presentation of chest pain symptoms and its relationship to the likelihood of IHD and/or obstructive CAD was derived largely from male populations.

Diagnosis of Ischemic Heart Disease

The more atypical presentation of women makes the diagnostic evaluation of symptomatic women challenging and results in more frequent referral for diagnostic testing to improve the precision of the IHD likelihood estimate. The classification of IHD risk in women refers solely to women who present for evaluation of suspected CAD who have chest discomfort or some ischemic equivalent, including excessive dyspnea.[68] Broadly characterized, premenopausal women with symptoms should be considered at low risk. Symptomatic women in the fifth decade of life should be considered at low to intermediate IHD risk, if they are capable of performing routine activities of daily living (ADLs). If performance of routine ADLs is compromised, a woman in her 50s should be elevated to the intermediate IHD risk category. Women in their 60s are also generally considered at intermediate IHD risk, and women 70 years of age and older are considered at high risk for CAD. Based on the 2014 Consensus Statement for Noninvasive Testing in the Clinical Evaluation of Women with Suspected Ischemic Heart Disease, women at low IHD risk are not candidates for a diagnostic evaluation; in the exceptional case, a routine exercise electrocardiogram (ECG) is the recommended test.[68] The woman with a low-intermediate or intermediate risk is a candidate for an exercise ECG if she has a functional capacity estimate of 5 METs or higher. Women at intermediate-high IHD risk with an abnormal 12-lead resting ECG should be referred for CAD noninvasive imaging, including pharmacologic stress myocardial perfusion imaging (MPI), echocardiography, cardiovascular magnetic resonance (CMR) imaging, or coronary computed tomography

angiography (CCTA). Women with a high IHD risk with stable symptoms may be referred for a stress imaging modality for functional assessment of the ischemic burden and guidance of posttest antiischemic therapies (**Fig. 89.3**).[68]

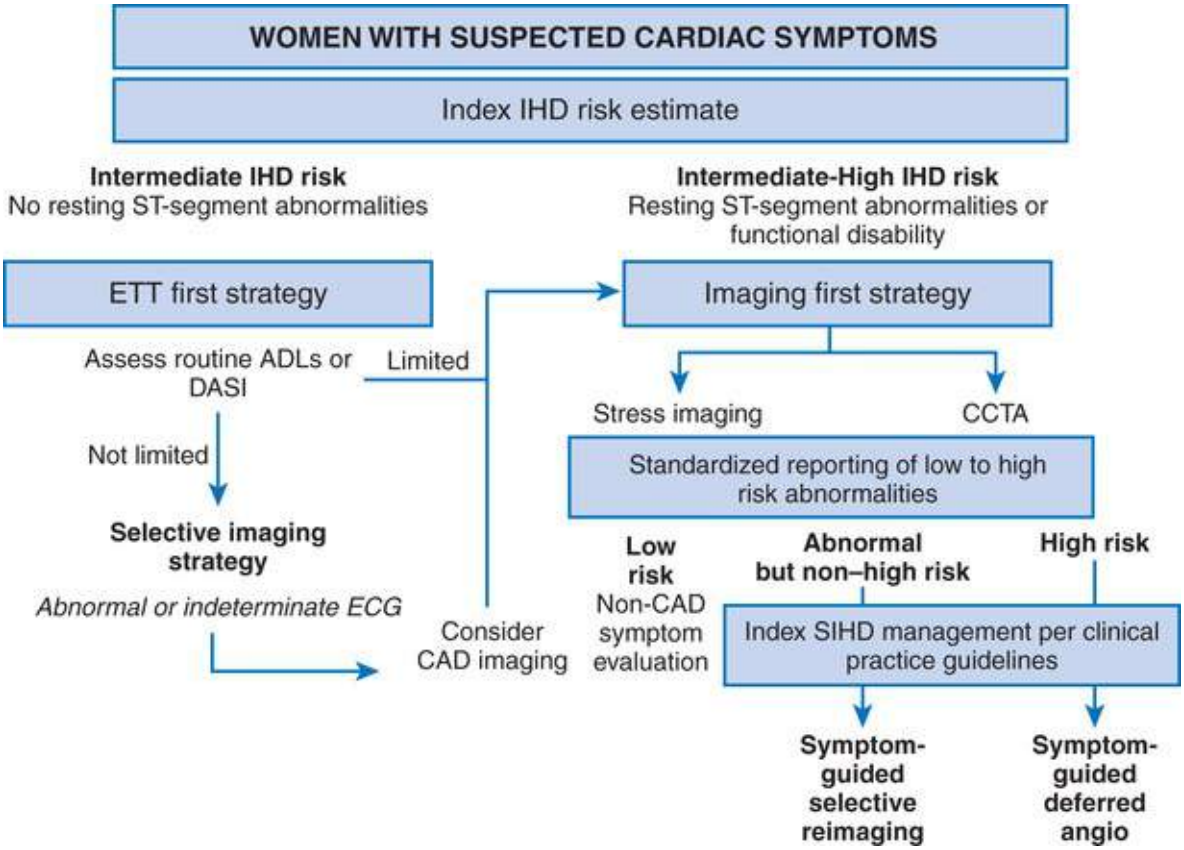

FIGURE 89.3 Diagnostic evaluation of women with suspected ischemic heart disease (IHD) and intermediate-risk and intermediate-high IHD risk. *ADL*, activities of daily living; *angio*, angiography; *CCTA*, coronary computed tomography angiography; *DASI*, Duke Activity Status Index, *ETT*, exercise treadmill testing; *SIHD*, stable ischemic heart disease. (From Mieres J, Gulati M, Bairey Merz N, et al. Role of noninvasive testing in the clinical evaluation of women with suspected ischemic heart disease: a consensus statement from the American Heart Association. Circulation 2014;130(4):350-79.)

These guidelines emphasize the usefulness of the traditional exercise stress test without imaging as the initial test of choice for women with a normal ECG who are able to exercise. The exercise ECG has often been considered less useful in women because of a higher false-positive rate. This diminished accuracy of the ECG response to exercise in women has been attributed to more frequent resting ST-T wave changes, lower ECG voltage, and hormonal factors such as endogenous estrogen in premenopausal women and hormone replacement therapy in postmenopausal women.[69] The sensitivity and specificity for the diagnosis of obstructive CAD in women ranges from 31% to 71% and 66% to 86%, respectively.[70] Although the ST segment depression with exercise may be less diagnostic of obstructive CAD in women given the lower sensitivity of the test, a negative exercise ECG stress test has significant diagnostic value. Although the positive predictive value of ST segment depression with exercise testing in women is significantly lower than in men (47% vs. 77%; $P < 0.05$), the negative predictive value of ST segment depression in symptomatic women was similar to that in men (78% vs. 81%).[71] In addition, a markedly abnormal exercise ECG demonstrating 2 mm or more of ST segment changes, in particular when occurring at low workloads (< 5 METs) or persisting for more than 5 minutes into recovery, is associated with a high likelihood of obstructive CAD for both women and men. A woman with a negative exercise ECG and normal exercise abilities has an excellent event-free survival rate and a low risk of obstructive

CAD.[70] In addition, the What Is the Optimal Method for Ischemia Evaluation in Women (WOMEN) trial showed that the prognostic value of an exercise ECG is no different than an exercise MPI test. This study randomized 824 symptomatic women with an estimated functional capacity of 5 METs or more with suspected CAD to either an exercise ECG or exercise MPI stress test, and measured major adverse CAD outcomes over the following 2 years.[72] The results revealed that functionally capable women presenting for evaluation of chest pain symptoms had similar 2-year outcomes whether randomized to exercise ECG or MPI ($P = 0.59$). This trial showed that an exercise ECG prompted a follow-up evaluation with a stress MPI test in nearly 1 in 5 women; this supported an ECG-first strategy, limiting follow-up stress imaging to women with indeterminate or abnormal ECG findings.

With any imaging modality used in women, considerations must be made regarding the amount of radiation exposure. Many cardiac diagnostic procedures, including stress MPI, CCTA, and coronary angiography, expose women to ionizing radiation. In women for whom the benefit of IHD risk detection far exceeds the small projected cancer risk following exposure, radiation exposure should not be a consideration as a physician makes a decision.[73] For all other women, in particular low-risk premenopausal women, alternative tests without radiation exposure (i.e., exercise ECG) or a no-testing strategy should be applied. The Council for Radiation Protection and Measurement has emphasized several key principles to guide the referral of women to MPI, CCTA, and coronary angiography, including justification of use, dose reduction optimization, and an adequate knowledge base to guide use.[74] Following the guidelines and meeting the ACC's appropriate use criteria can limit radiation exposure in women, lowering cancer risks from imaging in the population.[75,76]

Beyond Obstructive Coronary Artery Disease: The Paradox of Ischemic Heart Disease in Women

Patients with signs and symptoms of IHD have paradoxical sex differences. Women have less anatomic obstructive CAD and relatively more preserved left ventricular function despite higher rates of myocardial ischemia and mortality compared with men, even when controlling for age.[67,77] Data from the WISE and other studies implicate adverse coronary reactivity,[78] microvascular dysfunction,[79] and plaque erosion/distal microembolization[80] as contributory to a female-slanted myocardial ischemia pathophysiology. Thus, knowledge beyond an anatomic description of obstructive CAD may provide important clues to myocardial ischemia detection and treatment for women. For these reasons, the term *ischemic heart disease* is more useful than CAD when discussing women and their forms of CHD.

Treatment of Ischemic Heart Disease

Acute Coronary Syndrome and Angina

Optimal medical therapy for women with IHD does not differ from that for men according to the non–gender-based, ACC/AHA guidelines for ST and non-ST elevation MI and chronic angina.[81,82] Nonetheless, women often receive less intensive medical therapy or lifestyle counseling, which ultimately influences outcomes.[83,84] In addition to the differences in medical therapy, there are sex differences in the use of cardiac catheterization and revascularization and the timing of these procedures, which are associated with poorer outcomes in women after an ACS or MI.[83] Based on the most recent assessment of adhering to guidelines for the treatment of ST-elevation MI, there remains a significant sex difference in the aggressiveness of care, which has an impact on mortality rates in women. In the “Get With the Guidelines” data on 31,555 men and women with ST-elevation MI, younger women (≤ 45 years) and

older women (> 45 years) were less likely to receive angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) at discharge, to receive lipid-lowering therapy, to have a blood pressure of less than 140/90 mm Hg at discharge, or to receive stents, and fewer women received a door-to-balloon time of 90 minutes or less/door-to-thrombolytic time of 30 minutes or less. There were no differences in the use of the intraaortic balloon pump ($P = 0.99$) or left ventricular assist device ($P = 0.36$) between younger women and younger men. All women had significantly increased in-hospital mortality rates and lengths of stay, but older women were less likely to receive ACE inhibitors at discharge, to have LDL levels recorded during hospitalization, to be advised on rehabilitation or weight management, to be treated with beta blockers within 24 hours of presentation, or to be discharged with clopidogrel, aspirin, or beta blockers. There was a significant interaction between age and gender ($P = 0.03$) for in-hospital deaths such that the gender disparity was greater in the younger cohort than the older cohort. A similar interaction was seen for the door-to-thrombolytic time such that the gender delay was greatest in the youngest women (odds ratio [OR] of delay > 30 minutes in women versus men, 1.73; 95% confidence interval [CI] in younger patients, 1.21 to 2.45 versus 1.08; 95% CI in older patients, 1.00 to 1.18; P interaction = 0.003), with significantly fewer women 45 years of age or younger achieving the door-to-thrombolytic goal of 30 minutes or less.[85]

There are also sex differences regarding invasive strategies with ACS based on the presence or absence of biomarkers. In a metaanalysis of eight ACS trials, an invasive strategy resulted in a reduction of the composite endpoint of death, MI, or repeat ACS in both sexes, but it was more beneficial in women with positive biomarkers (33% risk reduction) in contrast with women with negative biomarkers, where an invasive strategy was not associated with a significant reduction in the composite endpoint.[86] Men had no such difference based on biomarkers. Women also have a higher mortality rate than men with percutaneous coronary intervention (PCI) after an ST or a non-ST elevation MI.[87] In contrast, the use of fibrinolysis has demonstrated a lower incidence of mortality or nonfatal MI at 30 days in women, compared with men who received enoxaparin compared with unfractionated heparin, suggesting that specific therapies may beneficially affect outcomes in women.[88]

Studies document an increased bleeding risk in women undergoing PCI who receive glycoprotein IIb/IIIa inhibitors.[89] In a metaanalysis of ACS populations, men benefited from glycoprotein IIb/IIIa inhibitors but women experienced more harm.[90] Nonetheless, high-risk women with troponin elevations did demonstrate a benefit. Prior studies have suggested that the elevated bleeding risk in women is due to body size and renal function, and studies have shown that the sex difference in bleeding resolves when doses are adjusted for age and renal function.[89]

A persistent pattern of higher mortality rates and poorer cardiovascular outcomes in women compared with men with IHD remains.[83] This is mostly attributable to the suboptimal use of guideline therapy in at-risk women, despite evidence that application of guideline therapy following an ACS reduces the mortality disparity in women and that management of ACS and chronic angina with intensive medical therapy benefits both sexes equally.[91,92]

In addition, women with ACS are more likely than men to have “normal” angiograms or demonstrate no obstructive CAD. “Female-pattern” IHD characterized by a relatively lower obstructive CAD burden and preserved left ventricular ejection fraction (LVEF) represents a yentl syndrome, whereby women receive less recognition and treatment than men with IHD.[93] The National Cardiovascular Data Registry showed that the odds of obstructive CAD are 50% lower for women undergoing coronary angiography compared with men.[77] Other ACS registries have demonstrated more frequent nonobstructive CAD in women compared with men (10% to 25% of women compared with 6% to 10% of men).[94] In the setting of an ACS, “normal” coronary arteries do not have a benign prognosis.[94] Given the 1.4 million ACS events per

year, 600,000 of which are in women, this translates to 60,000 to 150,000 women with ACS and nonobstructive CAD. Despite less obstructive CAD, women have a poorer prognosis after an ACS, particularly younger women.[95] Although the worse prognosis in women has been attributed to advanced age and an increase in comorbidities,[67] in addition to an underutilization of life-saving medication and therapies,[96] sex differences persist despite controlling for such variables.[97] Because women have been underrepresented in the randomized controlled trials of ACS and acute MI, we have limited sex-specific treatment knowledge in this cluster of conditions. Nonetheless, the Variation in Recovery: Role of Gender on Outcomes of Young AMI Patients (VIRGO) study showed that 1 in 8 young women (< 55 years) presenting with an acute MI fell in an unclassified category when using the current established classification system for acute MI (**Table 89.1A**), and as a result the researchers proposed a new classification system for acute MI (**Table 89.1B**).[98]

TABLE 89.1A

Taxonomy Development: Classification by the Third Global Definition of Myocardial Infarction

THIRD UNIVERSAL DEFINITION OF MYOCARDIAL INFARCTION	DEFINITION	CLASSIFICATION OF VIRGO PATIENTS (n)
Type I	Plaque rupture, ulceration, fissuring, erosion, dissection with resulting thrombus*	504
Type 2	Condition other than CAD contributes to imbalance between myocardial oxygen supply or demand*	40
Type 3	Cardiac death with symptoms suggesting ischemia	Excluded
Type 4a	Related to percutaneous coronary intervention	Excluded
Type 4b	Stent thrombosis	2
Type 5	Related to coronary artery bypass graft	Excluded
Unclassified		54*

*Of the 54 unclassified patients, 51 were women.

VIRGO, Variation in Recovery: Role of Gender on Outcomes of Young AMI Patients.

From Spatz ES, Curry LA, Masoudi FA, et al: The Variation in Recovery: Role of Gender on Outcomes of Young AMI Patients (VIRGO) Classification System: A Taxonomy for Young Women with Acute Myocardial Infarction. Circulation 2015;132:1710-18.

TABLE 89.1B

VIRGO Classification System in Myocardial Infarction Patients

Class I: Plaque-Mediated Culprit Lesion

Culprit lesions refer to the obstruction (or near obstruction) of a major epicardial vessel, most likely the result of a plaque rupture, fissure, or ulceration. Culprit lesions are usually treated with PCI or CABG, plus or minus thrombectomy, unless there is evidence of spontaneous resolution (e.g., residual haziness, contrast staining). Additionally, some culprit lesions may not be amenable to revascularization due to the size of the vessel or the location of the lesion.

Class IIa: Obstructive CAD With Evidence for Supply-Demand Mismatch*

Maximum stenosis of any one major epicardial vessel is > 50%, though no culprit lesion is identified. An additional "insult" is implicated as causing a mismatch between myocardial oxygen supply and/or demand.

Class IIb: Obstructive CAD *Without* Evidence for Supply-Demand Mismatch*

Maximum stenosis of any one major epicardial vessel is > 50%, though no culprit lesion is identified; no clinical evidence for myocardial oxygen supply-demand mismatch.

Class IIIa: Nonobstructive CAD With Evidence for Supply-Demand Mismatch*

Maximum stenosis of any one major epicardial vessel is < 50%, though no culprit lesion is identified; an additional "insult" is implicated as causing a mismatch between myocardial oxygen supply and/or demand.

Class IIIb: Nonobstructive CAD *Without* Evidence for Supply-Demand Mismatch

Maximum stenosis of any one major epicardial vessel is < 50%, though no culprit lesion is identified; no clinical evidence for myocardial oxygen supply-demand mismatch.

Class IV: Other, Nonatherosclerotic Pathophysiologic Mechanism

Distinct pathophysiologic mechanism identified with probable or definite certainty, including vasospasm, dissection, embolism.

Class V: Indeterminate

Presentation fits into 2 or more of the above classes (e.g., prior angioplasty without obstructive coronary artery disease on presentation); distal pruning of vessels without description of degree of stenosis or certainty regarding whether there is an acute occlusion.

*Clinical evidence supporting a scenario of myocardial oxygen supply-demand mismatch included systolic blood pressure > 180 mm Hg or < 90 mm Hg; diastolic blood pressure > 100 mm Hg; heart rate > 120 beats/min; atrial fibrillation/flutter; ventricular tachycardia/fibrillation; severe illness (pneumonia, exacerbation of chronic obstructive pulmonary disease, trauma, acute renal failure, stroke, severe gastrointestinal bleed, anemia, sepsis, surgical complication, any fracture, hyperosmolar hyperglycemic state, diabetic ketoacidosis); other (surgery, hypoglycemia, seizure, acute liver failure, *Clostridium difficile* colitis, pyelonephritis). *CABG*, coronary artery bypass graft; *CAD*, coronary artery disease; *PCI*, percutaneous coronary intervention; *VIRGO*, Variation in Recovery: Role of Gender on Outcomes of Young AMI Patients.

From Spatz ES, Curry LA, Masoudi FA, et al: The Variation in Recovery: Role of Gender on Outcomes of Young AMI Patients (VIRGO) Classification System: A Taxonomy for Young Women With Acute Myocardial Infarction. Circulation 2015;132:1710-18.

The increasing recognition of MI in those without obstructive CAD is now commonly referred to as myocardial infarction with nonobstructive coronary arteries (MINOCA).[99] MINOCA occurs more frequently in women, particularly younger women. Although hyperlipidemia may be less common, other traditional CVD risk factors are frequently present. All-cause mortality rates appear to be lower in MINOCA compared with MI with obstructive CAD, but they are still substantial (in-hospital mortality rate, 1.1 vs. 3.2%, $P = 0.001$; 12-month mortality rate, 6.7% vs. 3.5%; $P = 0.003$).[99] There are multiple potential causes for MINOCA, including but not limited to subendocardial ischemia (coronary microvascular disease), myocarditis, coronary vasospasm, takotsubo cardiomyopathy, hypertrophic cardiomyopathy, and spontaneous coronary artery dissection. At this time, diagnosis requires additional testing and imaging to determine the cause. The current guidelines that exist for ST and non-ST elevation MI do not differ by sex, and no studies to date support the value of specific therapies for MINOCA; hence efforts to improve the application of guidelines in practice could improve MI and IHD outcomes in women.[81,82,100,101]

Nonobstructive Ischemic Heart Disease

Women with any symptoms suggestive of myocardial ischemia have a probability of obstructive CAD that is lower than that for men. The WISE study demonstrated that 57% of women with symptoms and signs of ischemia had no obstructive CAD by coronary angiography.[102] In women without obstructive CAD, more than half will continue to have signs and symptoms of myocardial ischemia, undergo repeated

hospitalizations, and be studied with coronary angiography.[103] From the WISE data, such women with chest pain and no obstructive CAD have a higher rate of mortality and adverse cardiovascular events when compared with asymptomatic women, underscoring that the prognosis in women with symptoms and signs of ischemia is not benign, even when no obstructive CAD is present and the coronary arteries are "normal" (**Fig. 89.4**).[104]

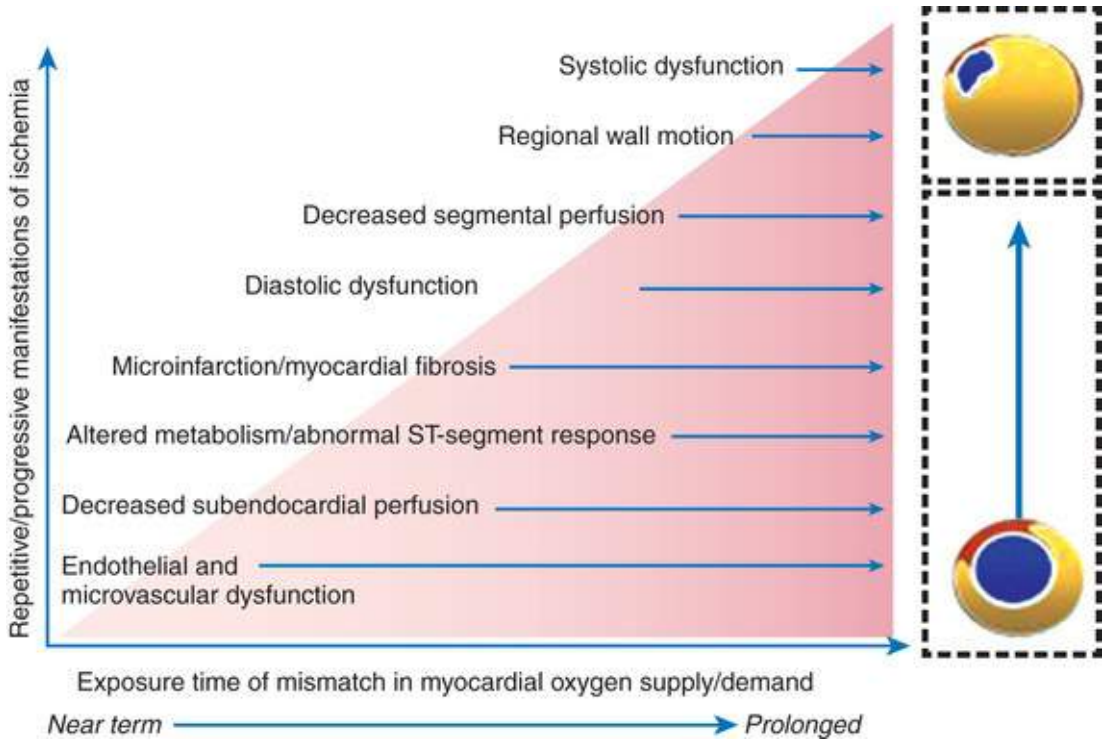

FIGURE 89.4 Cascade of mechanisms and manifestations of ischemia that affect IHD risk in women.

Microvascular Angina (See also Chapter 57)

Microvascular coronary dysfunction may cause IHD with no obstructive CAD. It appears to be more prevalent in women than men, possibly because of risk factor clustering and hormonal alterations, and likely contributes to the observed paradoxical frequent (atypical) symptoms, evidence of ischemia, and adverse outcomes in women (**Fig. 89.5**). Formerly referred to as "cardiac syndrome X," characterized by signs and symptoms of ischemia with no obstructive CAD, it has long been considered more prevalent in women. The WISE study has documented that at least half of the cardiac syndrome X women have microvascular coronary dysfunction, which results in IHD adverse outcomes.[105] A hypothetical model of microvascular angina in women is depicted in **Fig. 89.5**. This model provides a rationale for why current approaches for detection of focal obstructive coronary lesions are less effective in women with a greater prevalence of nonobstructive CAD. Abnormal coronary reactivity occurs in the setting of underlying atheroma vulnerable to clinical instability and more progressive disease states. For this reason, identifying nonobstructive atheroma may provide greater risk information in women. An overarching working model incorporates this proposed female-specific IHD pathophysiology (**see Fig. 89.5**). Although the relationship between microvascular coronary dysfunction and epicardial atherosclerosis is not fully understood, a leading hypothesis is that it is a single disease process, where the response to intimal injury may vary related to sex differences in vascular remodeling and vascular reactivity.

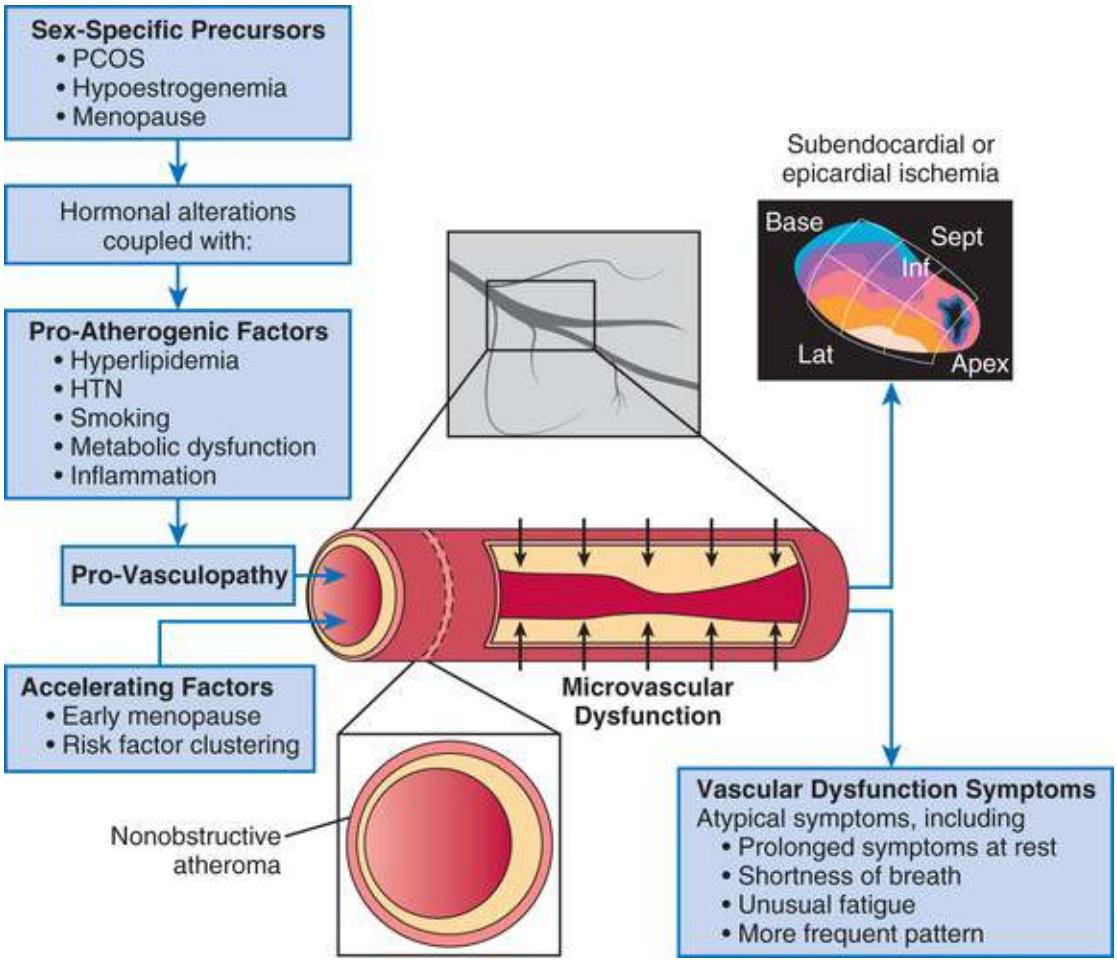

FIGURE 89.5 Model of microvascular angina in women. *HTN*, hypertension; *PCOS*, polycystic ovary syndrome.

Takotsubo Cardiomyopathy (See also Chapters 58 and 59)

Takotsubo cardiomyopathy should be considered in women as part of the differential diagnosis of ACS.[106] Other names for this syndrome include transient ventricular ballooning syndrome, left ventricular apical ballooning syndrome, stress-induced cardiomyopathy, ampulla cardiomyopathy, and broken heart syndrome. Takotsubo cardiomyopathy occurs in an estimated 1% to 2% of ACS patients, with women (particularly postmenopausal women) accounting for over 90% of the cases.[106]

Coronary Artery Bypass Grafting and Valve Surgery

Coronary artery bypass graft (CABG) surgery is a common procedure for the treatment of obstructive CAD for both men and women in the United States. Women undergo approximately 25% of CABG procedures annually.[1] Women have higher perioperative morbidity and mortality rates after CABG than men; this is typically explained by baseline differences in age, risk factors, comorbidities, and left ventricular dysfunction.[107] Women have more postoperative depression and may have a poorer quality of life 1 year after CABG,[108] although this is perhaps attributable to gender-related reporting bias. When off-pump CABG is performed, outcomes are more favorable for women. In a large study of 12,812 consecutive isolated CABG patients from 1997 to 2006, women who underwent off-pump CABG had a lower operative mortality rate than women who underwent traditional CABG (OR, 2.07; $P = 0.005$).[109]

There are no sex-specific guidelines for valvular heart disease and valve surgery, although there are sex-specific outcome data after valve surgery. In a large series of 2255 patients from Canada who underwent surgical aortic valve replacement (AVR), the mean age of women was older than that for men

(68.3 ± 12.3 years vs. 64.3 ± 14.1 years).[110] Women were equally as likely to get a mechanical valve as a bioprosthetic valve in this series. Although women had more late post-AVR strokes, they had fewer reoperations and had better overall long-term survival rates compared with men.[110] Results in the Massachusetts Cardiac Surgery Database from 2000 to 2008 demonstrate that among women and men undergoing AVR (in isolation or with CABG), there were no sex differences in mortality rates at 30 days or 1 year.[111] Postoperative stroke was again more frequent in women (3.0% for women vs. 2.2% for men; P = 0.31); postoperative MI and septicemia occurred more frequently in men (MI, 10.9% in women vs. 13.6% in men; *P* = 0.001; septicemia, 1.2% in women vs. 2.0% in men; *P* = 0.009). In a study of 641 patients from two large centers in Canada, female sex was associated with better short- and long-term survival rates after transcatheter aortic valve intervention (TAVI), although women had more iliac complications (9% in women vs. 2.5% in men; *P* = 0.030).[112] In the PARTNER trial of high-risk and inoperable patients with severe aortic stenosis (1220 women and 1339 men), women had lower rates of renal disease, smoking, hyperlipidemia, and diabetes, yet a higher STS mortality risk compared with men. Despite again noting increased vascular and major bleeding complications in women, women had lower 1-year mortality rates with TAVI compared with men (19.0% vs. 25.6%; *P* < 0.001).[113] For mitral valve replacement surgery, regardless of the type of valve replacement (mechanical or bioprosthetic), women have better long-term survival rates than men.[110] Recent data regarding transcatheter mitral valve repair (TMVR) with the MitraClip have shown no difference by sex in terms of rehospitalization for heart failure but superior long-term survival rates in women compared with men.[114]

Peripheral Arterial Disease in Women

Peripheral arterial disease (PAD) has a high prevalence in women in the United States (**see also Chapter 64**). It increases with age and ranges from 2% at age 40 years to as high as 25% at 80 years or older.[115] The incidence of PAD in patients with chronic kidney disease has been shown to have significant sex differences, with women having a 1.53-fold greater adjusted PAD risk compared with men followed in the Chronic Renal Insufficiency Cohort (*P* < 0.001).[116] Despite the prevalence of PAD, awareness of this issue is the lowest of awareness of CVD risk factors and other forms of CVD, with 3 out of every 4 Americans having no awareness of PAD.[117] Lower extremity PAD is associated with equal morbidity and mortality rates and comparable health costs as IHD and ischemic stroke.[118] PAD can be assessed using the ankle-brachial index (ABI); PAD is diagnosed when the ABI is lower than 0.90.

PAD symptoms show sex differences. Women with PAD can lack the classic symptom of intermittent claudication and may even be asymptomatic. As with other CVDs, there appears to be a long “latent phase” that can progress over time. This was demonstrated in the Women's Health and Aging Study (WHAS) of 933 disabled women 65 years of age or older, where 328 (35%) had an ABI of less than 0.90, and 63% of those with PAD had no exertional leg symptoms.[119] Asymptomatic PAD appears about twice as common in women as in men.[120]

Despite displaying fewer symptoms with PAD, once a diagnosis of PAD is made, women appear to have more functional impairment from PAD than men. In a cohort of 560 people with PAD and intermittent claudication, the treadmill distance to the onset of intermittent claudication symptoms was 33% shorter and the treadmill walking distance was 23% shorter in women than in men.[121]

Although women have more functional capacity impairment, men with critical limb ischemia were twice as likely as women to undergo revascularization, based on one analysis.[122] Nonetheless, the same institution has more recently demonstrated no sex differences in revascularization rates in PAD patients,[123] in contrast with other contemporary registries.[124] Multiple studies have reported similar amputation-free

survival rates after lower extremity revascularization for PAD in men and women, but with diabetic patients with PAD, amputation rates actually appear lower in women compared with men.[125] Sex differences in survival rates after lower extremity PAD revascularization have been inconsistent, but issues of gender are often confounded by morbidity, age, and procedural factors that affect perioperative mortality rates. The 2012 A Call to Action: Women and Peripheral Artery Disease: A Scientific Statement from the American Heart Association addresses the epidemiology, diagnosis, and management of PAD in women.[115]

Other forms of PAD also demonstrate sex differences. Mesenteric arterial disease is far more frequent in women, with 70% of chronic intestinal ischemia events occurring in women and two thirds of acute presentations occurring in elderly women.[115] Renal artery stenosis and abdominal aortic aneurysms are more common in men than women. Because abdominal aortic aneurysms are less frequently associated with deaths in women, screening in asymptomatic women is not recommended, in contrast with men.[126]

Heart Failure in Women (See also Part IV)

Heart failure (HF) affects 6.5 million Americans, including 3.6 million women.[1] In 2014, there were 37,287 deaths in women due to HF and more deaths in women than in men (55.8% vs. 44.2%).[1] The lifetime risk for developing HF (without a prior MI) in a 40-year-old is 1 in 6 for a woman compared with 1 in 9 for a man. The prevalence of HF increases with age, with more women than men having HF after the age of 79 years (**Fig. 89.6**).

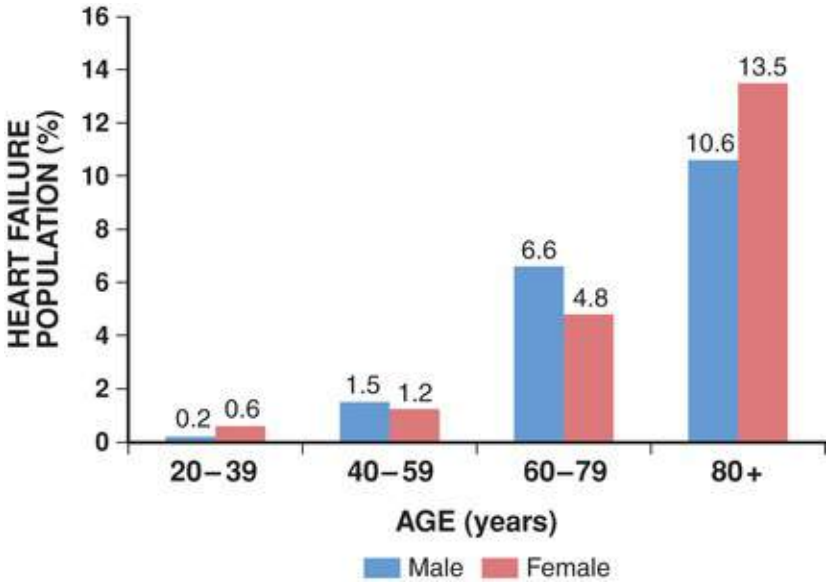

FIGURE 89.6 Prevalence of heart failure by sex and age (National Health and Nutrition Examination Survey: 2009 to 2012). (From Mozaffarian D, Benjamin EJ, Go AS et al: Heart Disease and Stroke Statistics 2016 Update: AReport from the American Heart Association. Circulation 133(4):e38-e60.)

The risk factors associated with HF and its underlying pathophysiology differ by gender. Women with HF have more hypertension, valvular heart disease, and thyroid disorders than men but are less likely to have obstructive CAD. Even though obstructive CAD is less frequent in women, when it is present it is a stronger risk factor for the development of HF than hypertension. Risk factors selective for women include cardiac toxicity from chemotherapeutic drugs used for treatment of breast cancer and peripartum cardiomyopathy. Women who present with acute decompensated HF are twice as likely as men to have preserved left ventricular function or HF with preserved ejection fraction (HFpEF),[127] with obesity being

a significant risk factor for women with HFpEF, particularly African American women.[128] Even those women with an impaired LVEF will have a higher LVEF when compared with men. Notably, women with HF have a lower quality of life, lower functional capacity, more hospitalizations for HF, and more frequent episodes of depression. Nonetheless, the overall survival rate is better for women compared with men with HF. This is not just a result of women having more HFpEF events, because mortality rates from HF do not relate to a preserved or impaired ejection fraction in either sex, although those with ischemic cardiomyopathy have a worse prognosis.[129]

Peripartum Cardiomyopathy (See also Chapter 90)

Peripartum cardiomyopathy causes an impaired LVEF that occurs in the last month of pregnancy or within 5 months postpartum with no preexisting cardiac disease and no identifiable cause. Its incidence is estimated to be 1 in 4000 pregnancies, and is associated with risk factors including advanced maternal age, African descent, high parity, twin pregnancy, usage of tocolytics, and poverty.[130] After the diagnosis, about half recover their LVEF within 6 months; however, 20% deteriorate and either die or require heart transplantation. Recovery appears to be related to a less severe decline in LVEF.[131] The risk during a subsequent pregnancy is not entirely clear, but in a retrospective analysis of 44 patients with peripartum cardiomyopathy in a pregnancy, the LVEF declined in the next pregnancy in both those who had recovered left ventricular dysfunction (from 56 ± 7% to 49 ± 10%; $P = 0.002$) and in those with persistent impairment of LVEF (from 36 ± 9% to 32 ± 11%; $P = 0.08$).[132]

Diagnosis of Heart Failure

In term of diagnosing acute HF, the Studies Of Left Ventricular Dysfunction (SOLVD) study demonstrated that women with an impaired systolic LVEF were more likely than men to have edema, elevated jugular venous pulsation, and an S_3 gallop.[133] In contrast, the Acute Decompensated Heart Failure National Registry (ADHERE) showed no sex differences in presenting signs and symptoms of acute HF, and this study included 54,674 women, accounting for more than half the number in the registry.[134] The difference in this study compared with others may relate to the fact that the ADHERE registry specifically looked for patients with acute decompensated HF rather than those with chronic symptoms. There may be sex differences in the biomarker brain natriuretic peptide (BNP) used to diagnose HF. Women have higher baseline BNP values than men, but BNP values higher than 500 pg/mL predict death more strongly in women with HF than men.[135] Nonetheless, a recent study from Japan showed that in patients with acute decompensated HF, no sex differences were found in the mean BNP levels; an elevated BNP level predicted future cardiovascular events in men but not women.[136] Further studies are needed to delineate and understand the sex differences in these biomarkers.

Treatment of Heart Failure

Treatment for HF may benefit both sexes equally; however, the underrepresentation of women in HF trials and the fact that HFpEF is more prevalent in women contribute to our lack of evidence regarding treatment of HF in women.[127] The CHARM trials, along with others, showed women were more likely to have preserved left ventricular function (50%) than men (35%).[62] Overall evidence-based HF therapies are underused in both sexes, but more so in women. Women less likely receive vasoactive agents, but men and women have equal hospital lengths of stay and age-adjusted in-hospital morality HF rates. At this time, the HF guidelines are not sex specific because sex-specific pathophysiologic mechanisms are not well understood and there is a lack of randomized trials.

Implantable cardioverter-defibrillator (ICD) devices are underused in both sexes with HF, but particularly in women. The Get With the Guidelines–Heart Failure database from 2005 to 2009 examined all potential eligible patients from the Medicare database. Eligible women were less likely than men to get an ICD (42.4% vs. 26.5%; $P < 0.0001$), particularly black women. There was an increase in ICD utilization over time, and the racial disparities disappeared by 2009, but the sex disparities persisted.[137] None of the randomized trials for ICDs enrolled sufficient numbers of women to permit conclusions regarding sex differences. Although studies to date are underpowered for the detection of sex differences, they do indicate that ICDs do not demonstrate a mortality benefit in women. The Sudden Cardiac Death in Heart Failure Trial (SCDHeFT) included 588 women in NYHA functional class II to III with an LVEF of 35% or less (ischemic and nonischemic cardiomyopathy) and did not show a benefit of an ICD in women. The Multicenter Automatic Defibrillator Implantation Trial (MADIT) II included patients with ischemic cardiomyopathy with an LVEF of 30% or less; there was a nonsignificant trend toward lower mortality rates in women with an ICD.[137] This study, like those preceding it, enrolled too few women to draw a strong conclusion, however. In a prospective study from Canada of 6021 patients (20% women) referred for an ICD, 5450 patients underwent ICD placement. Women had similar implantation rates but greater complication rates both at 45 days and at 1 year (OR, 1.78; 95% CI, 1.24 to 2.58; $P = 0.002$ at 45 days; HR, 1.91; 95% CI, 1.48 to 2.47; $P < 0.001$ at 1 year); there was no sex difference in the mortality rate.[138] The early complications were lead repositioning for men and lead replacement for women, and the late complications for both genders included pocket infection and electrical storm often related to a lead. In addition, women were less likely to receive appropriate shocks or appropriate therapy via shock or antitachycardia pacing compared with men (HR, 0.69; 95% CI, 0.51 to 0.93; $P = 0.015$ at 45 days; and HR, 0.73; 95% CI, 0.59 to 0.90; $P = 0.003$ at 1 year). These differences may result in part from sex differences in body size and a delayed presentation in women.

Cardiac resynchronization therapy (CRT) also shows benefit in both women and men with HF and a wide QRS complex, but observational data from the National Cardiovascular Data Registry demonstrated that the mortality benefit is more pronounced in women, confirming earlier randomized trials that compared CRT with medical therapy alone.[139]

Cardiac Transplantation

Heart transplantation occurs far less frequently in women compared with men, with only 29% of heart transplants in the United States in 2015 occurring in women.[1] This disparity may reflect the older age of women with HF and differences in choices related to transplantation. There does appear to be a sex difference in survival rates while awaiting heart transplantation, with more women dying than men (risk of death in women with UNOS status 1A was HR, 1.20; 95% CI, 1.05 to 1.37; $P = 0.01$), a disparity that is not accounted for based on the current UNOS transplant criteria.[140] This finding does suggest a transplant allocation bias, favoring men over women awaiting heart transplantation. Survival data after transplantation also may result from bias in women compared with men, with the survival gap increasing slightly with time (survival rate for women vs. men at 1 year, 86% vs. 88%; at 3 years, 76% vs. 79%; at 5 years, 68% vs. 72%).[131]

Arrhythmias and Sudden Cardiac Death in Women (See also Part V)

Important sex differences in cardiac electrophysiology can affect arrhythmias and sudden cardiac death.[141]

Starting at puberty, women have higher resting heart rates compared with men. Women also have longer QT intervals and a greater risk for drug-induced torsades de pointes. There are sex differences in characteristics of supraventricular tachycardias (SVTs). Atrioventricular (AV) nodal reentrant tachycardia (AVNRT) is twice as common in women as in men, and AV reentrant tachycardia as seen in Wolff-Parkinson-White syndrome is more common in men. Atrial and ventricular fibrillations also occur more frequently in men with Wolff-Parkinson-White syndrome. Compared with men, women with atrial fibrillation tend to be more symptomatic, have higher risks of stroke and death, and are less likely to receive anticoagulation and ablation procedures than men, and yet they fare worse when treated with antiarrhythmic medications.[142] Although women have an overall lower risk of sudden cardiac death, women with cardiac arrest who receive therapeutic hypothermia have significantly better outcomes than men.[143] Other data show that women are less likely than men to get recommended treatment after an out-of-hospital cardiac arrest.[144]

Prevention of Cardiovascular Disease in Women (See also Part VI)

Guidelines for CVD prevention in women were largely based on the Effectiveness-Based Guidelines for the Prevention of Cardiovascular Disease in Women 2011 Update but have been replaced by the 2013 ACC/AHA evidence-based guidelines on the treatment of blood cholesterol to reduce ASCVD in adults.[145] These guidelines apply to both women and men and lack sex-specific recommendations.

An important component of secondary CVD prevention includes cardiac rehabilitation (**see also Chapter 54**).[146] Cardiac rehabilitation improves functional capacity, decreases anginal symptoms, facilitates CVD risk reduction, and improves psychosocial well-being in both sexes. It also improves the quality of life and medication compliance and reduces rates of morbidity and mortality. Both sexes should be referred for cardiac rehabilitation after experiencing angina or any type of MI, undergoing coronary revascularization (either CABG or PCI) or valvular heart surgery, or receiving a diagnosis of chronic HF.[147] Cardiac rehabilitation is remarkably underused in the United States, however, with an estimated participation rate of only 10% to 20% of eligible patients. Women are particularly underreferred and are less likely to complete cardiac rehabilitation even if they enroll.[148]

Pregnancy and Heart Disease

Candice K. Silversides, Carole A. Warnes

Pregnancy is associated with hemodynamic stress on the cardiovascular system, and this can be

associated with increased risks for both mother and baby, particularly in women with preexisting cardiovascular disease. In the current era, the number of pregnancies in women with cardiovascular disease is increasing, in part due to the growing population of women with congenital heart disease, the older age at conception, and the larger number of pregnant women with comorbidities such as obesity, hypertension, and diabetes. Thus, there is an increasing need for the cardiologist to understand pregnancy and its impact on women with heart disease.

Even in otherwise healthy women, pregnancy outcomes are important for the cardiologist to consider. Maternal complications that develop during pregnancy can be predictors of long-term cardiovascular health. For instance, women with placental disorders, hypertensive disorders of pregnancy, or pregnancy-related diabetes mellitus have high rates of cardiovascular disease later in life.[1,2] When encountered in clinical practice, therefore, pregnancy complications may provide an opportunity for early identification of women at increased risk for development of cardiovascular disease later in life,[3] and perhaps such women should be referred to their primary care physician or a cardiologist to monitor cardiovascular risk factors.

Most women with cardiovascular disease are aware of their cardiac condition prior to pregnancy. Less commonly, cardiovascular disease may come to attention for the first time during pregnancy either because it was previously unrecognized or because it developed de novo. Although women with cardiac disease should have preconception counseling, many have not been adequately informed about the risks of pregnancy. For physicians counseling such women with cardiac disease, a comprehensive knowledge of the underlying defect as well as of the hemodynamic changes that pregnancy will impose is imperative. Fortunately, most women with cardiovascular disease can go through pregnancy successfully with proper care, but a careful prepregnancy evaluation is mandatory. For women with low-risk cardiac conditions, preconception assessment provides reassurance and may help to prevent unnecessary therapies during pregnancy. For women with moderate- and high-risk cardiac conditions, preconception counseling regarding pregnancy risks and contraception options is necessary for women to make informed, safe decisions.

Detecting cardiac decompensation during pregnancy can be difficult because the symptoms and signs of a normal pregnancy can mimic those of cardiac disease. Light-headedness, shortness of breath, peripheral edema, and even syncope often occur during a normal pregnancy, leading the less experienced physician to suspect cardiac disease when none is present. An understanding of the normal findings on cardiac examination in a pregnant patient is therefore important. Women with heart disease are at increased risk for maternal cardiac and perinatal complications.[4] Most cardiac complications can be safely treated during pregnancy, but in some women, the hemodynamic stress of pregnancy leads to irreversible cardiac deterioration. Maternal deaths are now rare in Western countries, but cardiac causes of death have increased and are now the most common indirect cause of maternal deaths in many countries[5] (**Fig. 90.1**). Although the most prevalent cardiac diagnosis among pregnant women is congenital heart disease, maternal deaths are often secondary to acquired diseases, such as myocardial infarction, aortic dissection, and cardiomyopathies.

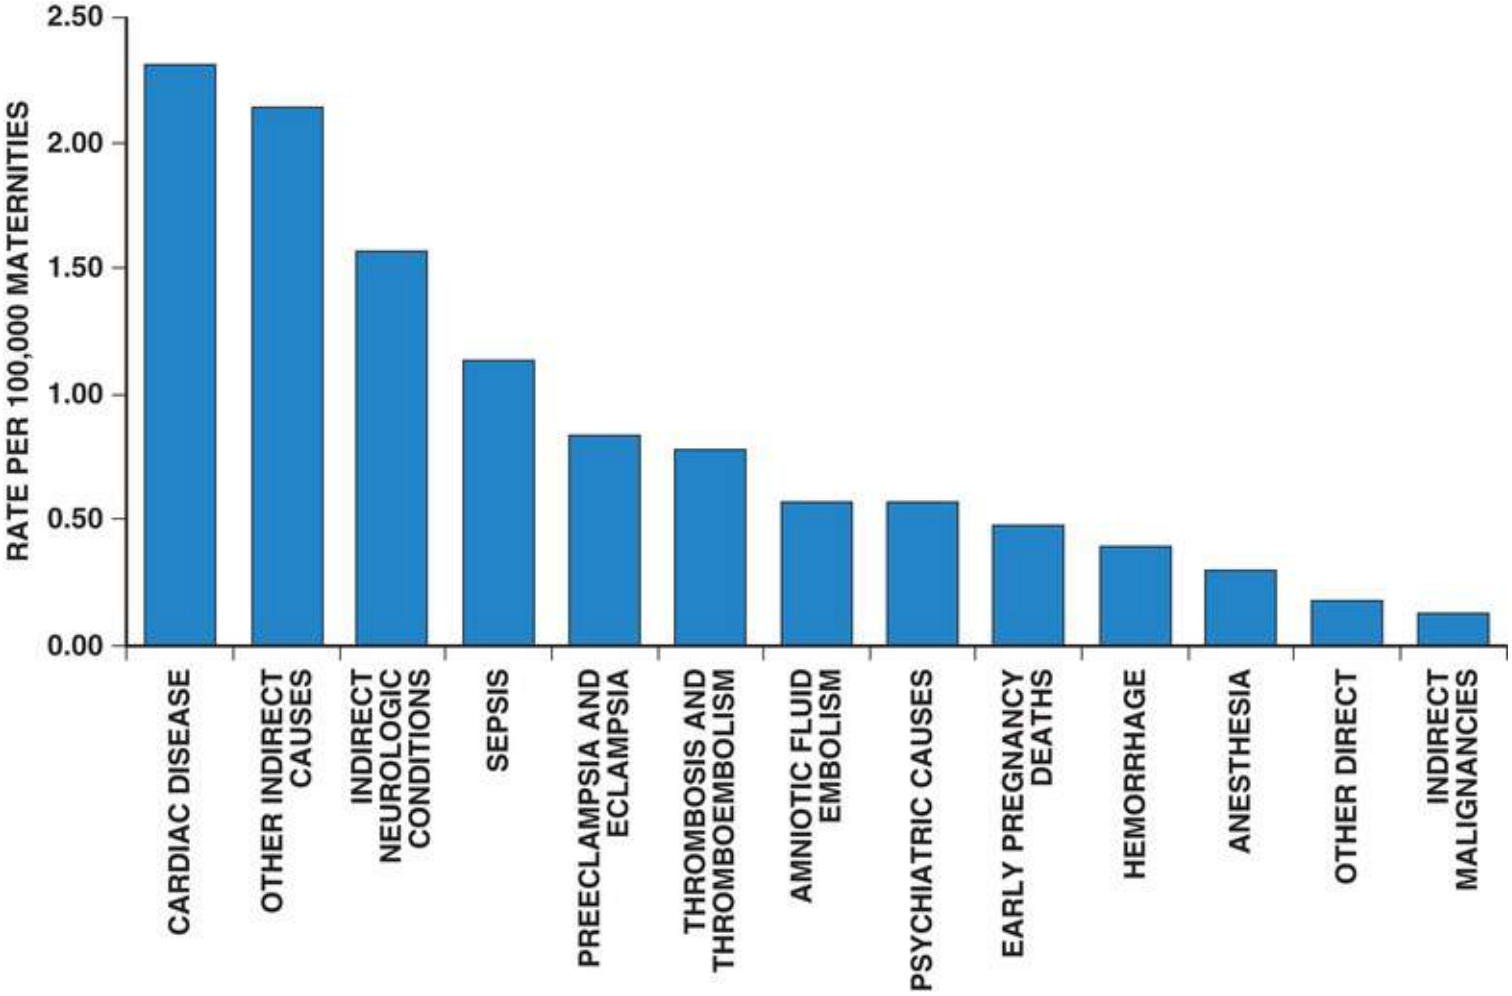

FIGURE 90.1 Leading causes of maternal death in the United Kingdom. Deaths per 100,000 maternities. (From Cantwell R, Clutton-Brock T, Cooper G, et al. Saving mothers' lives: reviewing maternal deaths to make motherhood safer: 2006-2008. The Eighth Report of the Confidential Enquiries into Maternal Deaths in the United Kingdom. *BJOG*. 2011;118[Suppl 1]:1-203.)

Hemodynamic Changes of Pregnancy

The hemodynamic changes of pregnancy begin early in the first trimester (**Fig. 90.2**). The plasma volume begins to increase in the sixth week of pregnancy and by the second trimester approaches 50% above baseline. The plasma volume then tends to plateau until delivery. This increased plasma volume is followed by a slightly lesser rise in red cell mass, which results in the relative anemia of pregnancy. The heart rate begins to increase to approximately 20% above baseline to facilitate the increase in cardiac output. Uterine blood flow increases with placental growth, and an accompanying fall in peripheral resistance may result in a slight fall in blood pressure, which also begins in the first trimester. The venous pressure in the lower extremities rises, causing pedal edema in approximately 80% of healthy pregnant women. The adaptive changes of a normal pregnancy result in an increase in cardiac output, which by the end of the second trimester approaches 30% to 50% above baseline. These hemodynamic changes may be problematic for the mother with cardiac disease. Maternal hemodynamics and perinatal outcomes are interrelated; abnormal uteroplacental flow or an inappropriate drop in the maternal cardiac output during pregnancy is associated with adverse perinatal outcomes.[6,7]

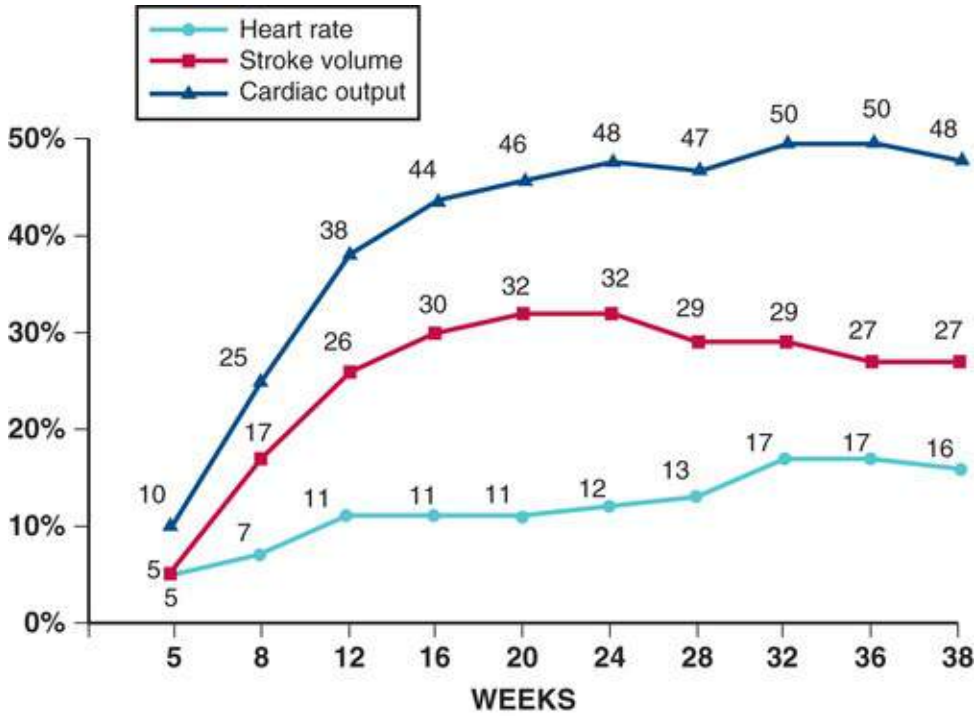

FIGURE 90.2 Hemodynamic changes in pregnancy. Percentage of changes in heart rate, stroke volume, and cardiac output measured in the lateral position throughout pregnancy compared with prepregnancy values. (From Elkayam U, Goland S, Pieper PG, Silverside CK. High-risk cardiac disease in pregnancy: part I. J Am Coll Cardiol 2016;68:396-410.)

The hemodynamic changes during labor and delivery are abrupt. With each uterine contraction, up to 500 mL of blood is released into the circulation, prompting a rapid increase in cardiac output and blood pressure. The cardiac output often is 50% above baseline during the second stage of labor and may be even higher at the time of delivery. During a normal vaginal delivery, approximately 500 mL of blood is lost. By contrast, with a cesarean delivery, approximately 1000 mL of blood often is lost, which may pose a more significant hemodynamic burden to the parturient. After delivery of the baby, an abrupt increase in venous return occurs, in part because of autotransfusion from the uterus but also because the baby no longer compresses the inferior vena cava. In addition, autotransfusion of blood continues in the 24 to 72 hours after delivery, and this is when pulmonary edema may occur.

Preconception Counseling

Risk Stratification

Prepregnancy counseling is important because it gives prospective mothers appropriate information about the advisability of pregnancy and is an opportunity for discussions about the risks to her and the baby. Patients with risks for heart disease should be seen by a physician with experience in pregnancy and heart disease. The initial cardiac evaluation should include a clinical examination, 12-lead electrocardiogram, and transthoracic echocardiogram. In patients with congenital heart disease, the perception of normal activity may be skewed because of long-standing altered exercise expectations, and an exercise test is helpful in delineating the true functional aerobic capacity. Pregnancy outcomes have been associated with an impaired chronotropic response to exercise in women with congenital heart disease.[8] A careful family history is important to assess whether there is any congenital heart disease in the patient's family or that of her partner. Genetic counseling should be offered to women with inherited cardiac conditions. Occasionally, women may consider preimplantation genetic screening, and this requires input from

genetics and fertility specialists.

A careful discussion of the maternal and fetal risks, and of whether or not these risks might change with time or treatment, is indicated. The possibility that pregnancy might cause irreversible hemodynamic deterioration should be considered; this is specifically relevant to women with ventricular dysfunction. The long-term outlook for the mother is a difficult, but important, aspect of counseling. If the woman is going to pursue a pregnancy, a strategy should be outlined regarding the frequency of follow-up evaluation by the cardiologist, and a plan should be put in place for obstetric and cardiovascular management during the pregnancy.

An assessment of maternal cardiac risk incorporates general risk predictors, lesion-specific risks, and individual factors. General predictors of adverse maternal cardiac events in women with heart disease include (1) a prior cardiac event (e.g., heart failure, transient ischemic attack, or stroke before pregnancy) or arrhythmia; (2) a baseline New York Heart Association (NYHA) class higher than class II or cyanosis; (3) a left-sided heart obstruction (mitral valve area < 2 cm^2, aortic valve area < 1.5 cm^2, or peak left ventricular outflow tract gradient > 30 mm Hg as assessed by echocardiography); (4) reduced systemic ventricular systolic function (ejection fraction < 40%); (5) pulmonary regurgitation; (6) mechanical valve prosthesis; or (7) significant atrioventricular valve regurgitation. Risk scores based on these predictors have been developed and can be used as a starting point in risk stratification.[9-11] The use of any of these risk scores carries limitations. The risk indexes are highly population dependent. Some series, for example, include only patients with congenital heart disease; others include patients with acquired heart disease. In all series there are high-risk patient populations, such as those with clinically significant pulmonary hypertension or dilated aortas, who are underrepresented.[9-11] A British working group created a risk stratification tool using a World Health Organization classification that incorporates general and lesion-specific diagnoses.[12,13] All of these risk prediction tools should be used as a guide, along with known lesion-specific risks, other clinical information, and, of course, clinical judgment.

There is a growing population of women conceiving with fertility therapy, including women with heart disease.[14] When fertility therapy is being considered in the cardiac patient, in addition to the cardiac-related risks described earlier, it is important to consider the risks associated with the underlying cause of infertility (i.e., women with infertility or subfertility have higher rates of hypertensive disorders of pregnancy), the risk of fertility medications and therapies (i.e., ovarian hyperstimulation syndrome), and the consequences of multifetal pregnancies (i.e., higher rates of prematurity).

Contraindications to Pregnancy

In some situations, the maternal risk from pregnancy is prohibitively high, and women should be counseled to avoid pregnancy and sometimes even to consider termination of pregnancy if it occurs (**Table 90.1**). No data exist regarding the precise level of pulmonary hypertension that poses a major threat to the mother, but systolic pulmonary artery pressures higher than 60% to 70% of the systemic pressure are likely to be associated with maternal compromise; in these circumstances, pregnancy is best avoided. Women who have a left ventricular ejection fraction of less than 30% from any cause are not likely to withstand the volume load that pregnancy imposes and should be advised not to become pregnant. Patients with Marfan syndrome and a dilated aortic root more than 45 mm in diameter are vulnerable to progressive aortic dilation, dissection, and rupture during pregnancy. A number of other high-risk cardiac conditions, such as complex congenital heart disease, mechanical valves, and severe asymptomatic aortic stenosis, require careful preconception risk stratification.[14a,14b]

TABLE 90.1

High-Risk Cardiac Conditions During Pregnancy

Pregnancy Is Contraindicated
Pulmonary hypertension from any cause
Eisenmenger syndrome
Dilated cardiomyopathy with severe left ventricular systolic dysfunction (subaortic ventricular ejection fraction < 30%)
Peripartum cardiomyopathy with residual left ventricular systolic dysfunction
Symptomatic severe aortic stenosis
Severe mitral stenosis
Marfan syndrome with an aortic root dimension > 45 mm
Inherited aortopathies: Vascular-type (type IV) Ehlers-Danlos syndrome, Loeys-Dietz syndrome with any aortic dilation, Turner syndrome with aortic dilation ≥ 2.7 cm^2
Chronic aortic dissection
Pregnancy Is High Risk
Mechanical prosthetic valves
Dilated cardiomyopathy with moderate left ventricular systolic dysfunction
Severe asymptomatic aortic stenosis
Unrepaired coarctation of the aorta
Cyanotic cardiac heart disease (non–Eisenmenger syndrome)
Fontan circulation
Complete transposition of the great arteries with Mustard or Senning operation
Other complex congenital heart diseases

Evaluation and Testing During Pregnancy

Physical Examination

Evaluation of the pregnant patient begins with a thorough physical examination, including cardiac examination. Because of the altered hemodynamics during pregnancy, the physical examination findings in a healthy pregnant woman reflect such changes and may mimic those in cardiac disease. The heart rate increases and the pulse volume is often bounding. By the middle of the second trimester, the jugular venous pressure may be slightly elevated, with brisk descents, because of the volume overload and reduced peripheral resistance. The apical impulse is more prominent. On auscultation, the first sound may appear loud. The second sound also may appear accentuated, and these combined auscultatory features may suggest an atrial septal defect or pulmonary hypertension. A third sound is very common. An ejection systolic murmur is commonly heard at the left sternal edge, never more than grade 3/6 in intensity, which relates to increased flow through the left or right ventricular outflow tract. Continuous murmurs also may be heard, as either a cervical venous hum or a mammary souffle, and are caused by the hyperdynamic circulation. The venous hum is best heard over the right supraclavicular fossa. The mammary souffle (continuous or systolic) is due to increased flow in the mammary arteries and is heard over the breast late in pregnancy or during lactation. There should be no diastolic murmur. Peripheral edema is common as pregnancy advances.

Laboratory Evaluation

Despite the hemodynamic volume load of pregnancy, most healthy pregnant women have low levels of B-type natriuretic peptide throughout pregnancy and after delivery. By comparison, women with heart disease have higher B-type natriuretic peptide levels throughout pregnancy compared with nonpregnant women, and normal B-type natriuretic peptide levels have a good negative predictive value for predicting adverse cardiac events.[15]

Imaging

Chest Radiography

A chest radiograph is not obtained routinely in any pregnant patient because of concern about radiation exposure to the fetus, but it should not be withheld when the history and clinical findings raise concerns about maternal cardiac status. The chest radiograph in a normal healthy patient may show slight prominence of the pulmonary artery, and as pregnancy advances, elevation of the diaphragm may suggest an increase in the cardiothoracic ratio.

Echocardiography

Transthoracic echocardiography is the cornerstone of cardiac evaluation in pregnancy. In a normal pregnancy, the left ventricular end-diastolic measurement is slightly increased, and there may be similar increases in right ventricular size and the volumes of both atria. There can also be a small increase in the left ventricular wall thickness during pregnancy. Measurement of ejection fraction is determined by changes in preload and afterload, and with the patient in the supine position, preload may be reduced because the fetus may compress the inferior vena cava. The increased cardiac output leads to increases in the velocities across the left and right ventricular outflow tracts. Careful comparison of the two-dimensional anatomic appearances will help differentiate this from a true valvar abnormality. The valve area calculation may be more helpful than a simple measurement of valve gradient; the latter may appear to be increased as pregnancy advances because the circulation becomes more hyperkinetic and cardiac output increases. Transesophageal echocardiography is seldom performed during pregnancy; however, when necessary, it can be performed safely, although careful monitoring of maternal oxygen saturation is necessary if midazolam is used for sedation.

Magnetic Resonance Imaging and Computed Tomography

When necessary, magnetic resonance imaging (MRI), without gadolinium, can be done in pregnancy.[16] Gadolinium is associated with neonatal risk and is usually avoided. MRI may be required in women with high-risk aortopathies who do not have baseline aortic imaging prior to pregnancy or to exclude aortic dissection in women presenting with chest pain. Dural ectasia is diagnosed with MRI; it is an important diagnosis for women with Marfan syndrome who require epidural analgesia. Computed tomography (CT) is not recommended unless necessary because of the risks of radiation exposure to the fetus.

General Management Principles During Pregnancy

During pregnancy, a multidisciplinary team approach is recommended, with close collaboration with the obstetrician, so that the mode, timing, and location of delivery can be planned. The management should be tailored to the specific needs of the patient. There is also a close relationship between maternal health and fetal well-being. The frequency of clinical visits is based on the underlying cardiac condition, with high-risk women being followed more often. Serial echocardiograms during pregnancy are useful in women with mechanical valves who are vulnerable to development of thrombosis during pregnancy, women with ventricular dysfunction, and women at risk for aortic root dilation. Fetal growth should be monitored by the obstetric team, and for the woman with congenital heart disease, a fetal cardiac echocardiogram is offered at approximately 18 to 22 weeks' gestation to determine whether a congenital cardiac anomaly is present.

Medical Therapy

Medical therapy should not be withheld when women develop cardiovascular complications during pregnancy; however, when administration of cardiovascular drugs is being contemplated, the potential fetal adverse effects of the drugs require consideration. For many cardiovascular medications, there are limited data on medication safety during pregnancy, and clinical decisions must be made based on the benefit for the patient versus the potential fetal and neonatal risks. The U.S. Food and Drug Administration (FDA) classification of these drugs has been used for many years, but this categorical system is being replaced by a more narrative structure for pregnancy labeling. The potential side effects of cardiovascular medications are shown in **Table 90.2**. A medication should be given only if the benefits are felt to outweigh the potential risk to the fetus. Principles to be considered include the use of drugs with the longest safety record, the use of the lowest dose and shortest duration necessary, and avoidance of a multidrug regimen, if possible. These issues need to be reviewed carefully with the prospective mother.

TABLE 90.2

Effects of Cardiovascular Drugs on Fetus During Pregnancy and on Infant During Breastfeeding

DRUG	POTENTIAL FETAL SIDE EFFECTS	USE DURING BREASTFEEDING
Adenosine	Likely safe; no known teratogenic effect	Not known if there is transfer to breast milk; likely safe because half-life is short
Amiodarone	Contraindicated; goiter, hypothyroidism and hyperthyroidism, bradycardia, intrauterine growth restriction	Transfer to breast milk; use during breastfeeding not recommended
Aldosterone antagonists	Contraindicated; antiandrogenic effects; oral clefts	Transfer to breast milk; safety of breastfeeding unknown
Angiotensin-converting enzyme inhibitors	Contraindicated; IUGR, oligohydramnios, renal failure, abnormal bone ossification	Transfer to breast milk; use of captopril and enalapril during breastfeeding have been reported
Angiotensin II receptor blockers	Contraindicated; renal malformations, oligohydramnios, abnormal bone ossification	Not known if there is transfer to breast milk; use during breastfeeding not recommended
Aspirin	Safe; low-dose aspirin not harmful; high-dose aspirin associated with premature fetal duct closure	Use with caution during breastfeeding
Antiplatelet drugs: Clopidogrel	Safe	Unknown if there is transfer to breast milk; use during breastfeeding not recommended
Beta blockers	Relatively safe; IUGR, neonatal bradycardia, neonatal hypoglycemia Labetalol frequently used to treat hypertension Atenolol may be associated with lower-birth-weight babies when compared with other beta blockers	Transfer to breast milk; compatible with breastfeeding
Calcium channel blockers	Relatively safe; few data; concern regarding uterine tone at time of delivery Nifedipine frequently used to treat hypertension Diltiazem has been reported to have possible teratogenic effects	Transfer to breast milk; compatible with breastfeeding
Digoxin	Safe; no adverse effects	Transfer to breast milk; compatible with breast feeding
Flecainide	Relatively safe; limited data; used to treat fetal arrhythmias	Transfer to breast milk
Heparin	Safe; does not cross placenta, increased risk of subplacental bleeding	No transfer to breast milk; compatible with breastfeeding
Hydralazine	Safe; no major adverse effects, maternal lupus-like syndrome reported	Transfer to breast milk; compatible with breastfeeding
Furosemide	Safe; caution regarding maternal hypovolemia and reduced placental blood flow	Compatible with breastfeeding
Lidocaine	Safe; high doses may cause neonatal central nervous system depression	Transfer to breast milk; compatible with breastfeeding
Methyldopa	Safe; often used to treat hypertension in pregnancy	Transfer to breast milk; compatible with breastfeeding
Procainamide	Relatively safe; limited data; has been used to treat fetal arrhythmias, no major fetal side effects	Transfer to breast milk; compatible with breastfeeding, but long-term effects are not known
Propafenone	Limited data	Unknown
Sotalol	Safe; often used to treat fetal arrhythmias	Transfer to breast milk; not recommended
Statins	Contraindicated; congenital anomalies	Not known if there is transfer to breast milk; use during breastfeeding not recommended
Warfarin	Warfarin embryopathy when used between 6 and 12 weeks' gestation, placental and fetal hemorrhage, central nervous system abnormalities	Transfer to breast milk; compatible with breastfeeding

Interventions and Surgery

Cardiac catheterization should be performed in women presenting with an acute coronary syndrome. Radiation exposure to the fetus can be minimized by lead screening of the mother's abdomen and pelvis. Balloon valvuloplasty is performed during pregnancy in women with severe mitral, pulmonary, or aortic

stenosis who have symptoms refractory to medical therapy, provided the valve anatomy is favorable. Most valvuloplasties are successful in improving valve gradients, but worsening regurgitation, arrhythmias, tamponade, maternal death, precipitous labor, and fetal death have been reported. The procedure should be performed in centers with extensive experience and surgical back-up; if it is undertaken after 26 weeks of pregnancy, obstetric standby should be available in case of premature labor. Transcatheter aortic valve implantation is not routinely performed in pregnant women, but may be considered in select situations.

Cardiac surgery during pregnancy is seldom necessary and should be avoided whenever possible. A higher risk of fetal malformation and loss has been documented when cardiopulmonary bypass is performed in the first trimester; if it is performed in the last trimester, the likelihood of precipitating premature labor is greater. Later in the third trimester, delivery can be performed prior to cardiac surgery if there is adequate fetal maturity. From a fetal outcome perspective, the optimal time for maternal cardiac surgery during pregnancy is likely between 20 and 28 weeks of gestation. Fetal outcomes may also be improved by use of normothermic rather than hypothermic extracorporeal circulation, higher pump flows, higher pressures, and as short a bypass time as possible. Obstetric monitoring of the fetus during the procedure is recommended so that fetal bradycardia may be dealt with promptly and uterine contractions may be controlled. In the current era, with the interventions outlined above, cardiothoracic surgery of the mother can be performed with relative safety during pregnancy, with a maternal mortality rate similar to that in a nonpregnant woman unless the surgery is emergent. However, fetal complications (prematurity and death) are increased in association with urgent high-risk surgery, maternal comorbidity, and early gestational age.[17] A multidisciplinary approach is important to optimize the outcome for both mother and baby.

Labor and Delivery

The hemodynamic changes that occur at the time of labor and delivery mandate that for the high-risk patient with cardiac disease, a multidisciplinary approach during labor and delivery be used. The cardiologist and the obstetrician should work with the anesthesiologist to determine the safest mode of delivery. For most patients with cardiac disease, a vaginal delivery is feasible and preferable because it is associated with fewer complications.[18] A cesarean delivery is usually reserved for obstetric reasons. An important exception to this rule is that of the patient who is anticoagulated with warfarin, because the baby also is anticoagulated and thus at increased risk for intracranial hemorrhage from the stress of vaginal delivery. Cesarean delivery also may be considered in patients who have a dilated aorta, severe pulmonary hypertension, severe heart failure, or a severe obstructive lesion such as aortic stenosis.[18] For women with high-risk conditions, delivery should take place in a center where expertise is available to monitor the hemodynamic changes of labor and delivery and to intervene when necessary. If vaginal delivery is elected, delivery can be accomplished with the mother in the left lateral position so that the fetus does not compress the inferior vena cava, thereby maintaining venous return. Some women with high-risk cardiac lesions may benefit from an assisted second stage (i.e., with forceps or vacuum extraction) to avoid a long labor. For those women with tenuous hemodynamics, Swan-Ganz catheterization before the onset of active labor facilitates optimization of the hemodynamics and should be continued for at least 24 hours after delivery, when pulmonary edema commonly occurs. No universal consensus has yet emerged regarding the administration of antibiotic prophylaxis at the time of delivery for patients with lesions vulnerable to infective endocarditis. Because bacteremia may occur even during an uncomplicated delivery, antibiotic prophylaxis remains optional for patients most vulnerable to the

deleterious effects of endocarditis—that is, those with prior endocarditis, cyanotic heart disease, and prosthetic valves.[19]

Specific Cardiac Conditions in Pregnancy

Congenital Heart Disease (see also Chapter 75)

Few operations for congenital heart disease are considered curative, and many women have residua and sequelae that must be carefully evaluated at the time of prepregnancy counseling. Maternal cardiac, obstetric, and perinatal adverse outcomes are increased in women with congenital heart disease, although outcomes vary widely depending on the cardiac lesion (**Fig. 90.3**).[20] Perinatal risk includes transmission of heart disease to offspring; the type of maternal cardiac lesion present will affect the propensity of the baby to inherit congenital cardiac disease.

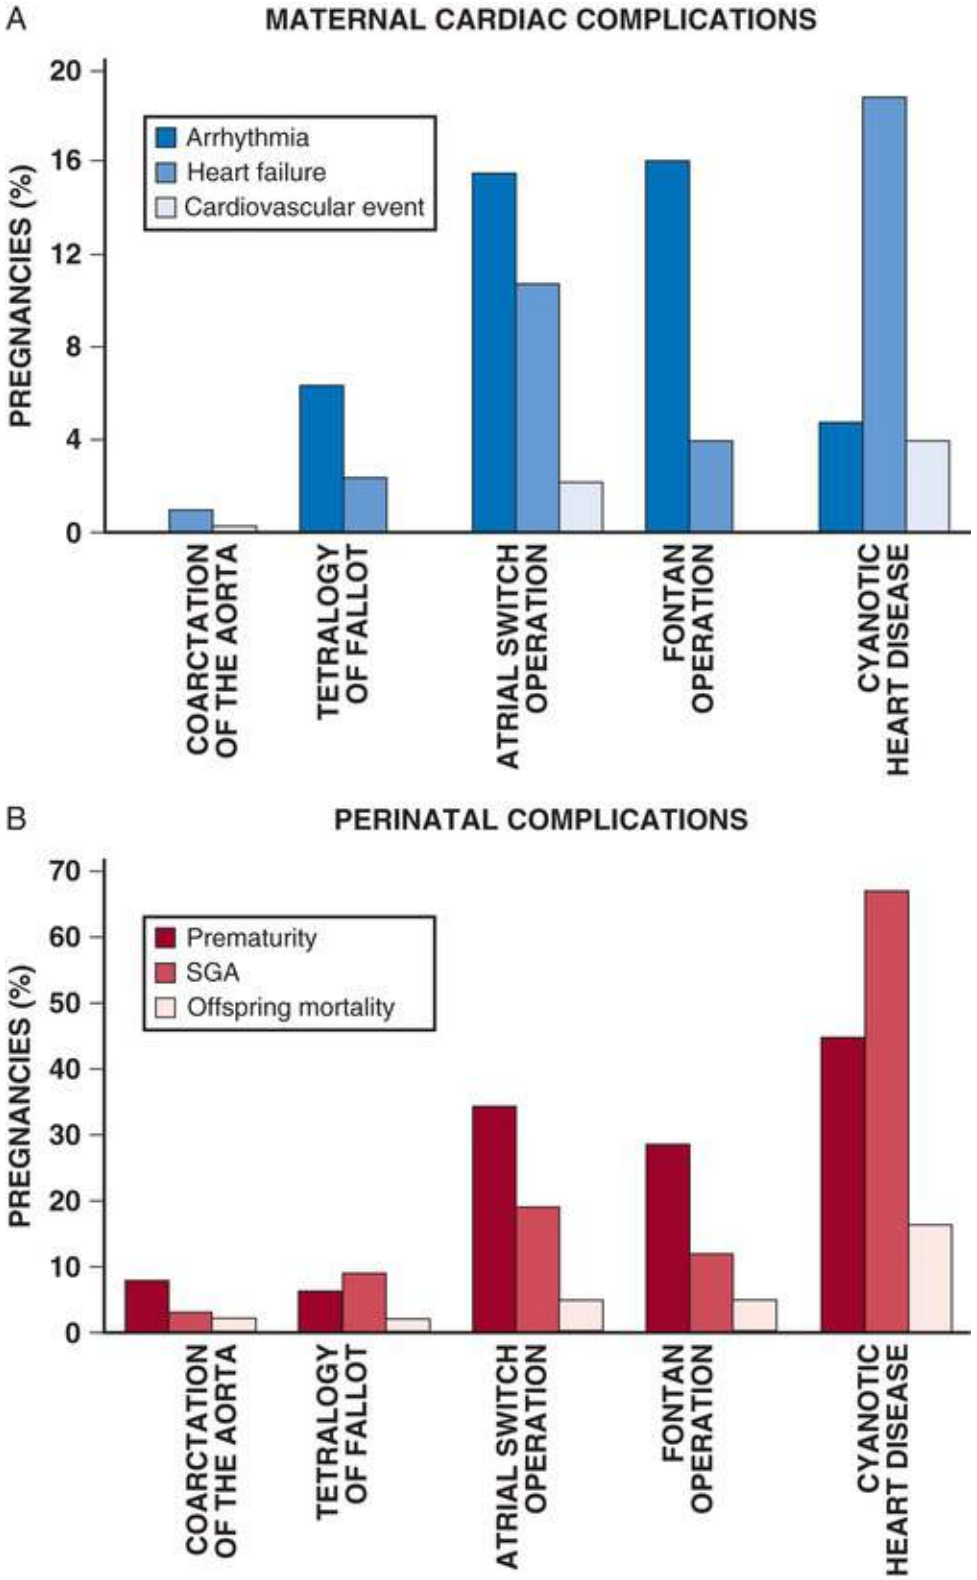

FIGURE 90.3 **A,** Cardiac complications in women with congenital heart disease. *Dark blue bars*, arrhythmias; *light blue bars*, heart failure; *white bars*, other cardiovascular complications (cardiovascular mortality, myocardial infarction, and/or cerebrovascular accidents). **B,** Perinatal complications in women with congenital heart disease. *Dark red bars*, prematurity; *light red bars,* small-for-gestational-age babies; *white bars*, fetal and neonatal mortality. (Data from Drenthen W, Pieper PG, Roos-Hesselink JW, et al. Outcome of pregnancy in women with congenital heart disease: a literature review. J Am Coll Cardiol. 2007;49:2303-11.)

Shunt Lesions

Women with simple shunts often do well during pregnancy. Secundum atrial septal defect is one of the most common congenital heart defects. The volume load on the right ventricle usually is well tolerated, and even women with large unrepaired secundum atrial septal defects usually do not develop cardiac

complications during pregnancy unless concomitant pulmonary hypertension or atrial fibrillation is present. Meticulous attention should be paid to the maternal leg veins, particularly during and after delivery, because deep vein thrombosis could result in a paradoxical embolus and stroke. Women with small ventricular septal defects or patent ductus arteriosus with small ducts with normal or near-normal pressures usually tolerate pregnancy without difficulty. With a large shunt, the added volume load of pregnancy may rarely potentially precipitate left ventricular failure. Women with ventricular septal defects or patent ductus arteriosus and pulmonary hypertension should be counseled that pregnancy is contraindicated.

Coarctation of the Aorta

Most women with coarctation of the aorta will have had a repair prior to pregnancy. When the presence of a coarctation is known, the entire aorta should be imaged at the time of prepregnancy counseling because some women may have residual or recurrent coarctation or aneurysm. Most women will have a successful pregnancy with proper care. The most common maternal complication is systemic hypertension, which may require therapy.[21] A significant coarctation can impair flow to both the uterus and fetus, which may result in small-for-dates babies or even fetal loss. Aggressive antihypertensive therapy should be avoided because of the chance of placental hypoperfusion. Because of the associated aortopathy, the entire aorta is vulnerable to dilation, aneurysm, and dissection.

Tetralogy of Fallot

Most women with tetralogy of Fallot will have had previous surgical repair and should be free of cyanosis. An occasional adult will be seen who has not had previous surgery or in whom palliation was achieved with a surgically created shunt (e.g., Blalock-Taussig shunt). In such cases, pregnancy may pose a risk, depending on the degree of cyanosis, as noted below. For those patients with previous intracardiac repair, a careful assessment of any hemodynamic residua and sequelae should be undertaken before advice is given about the safety of a pregnancy. For those women with an effective surgical repair, good exercise capacity, and minimal residua, pregnancy is well tolerated if they are properly managed. The volume load of pregnancy may not be well tolerated when women have significant right ventricular dilation and dysfunction.[22] Additionally, these women may be at risk for atrial and even ventricular arrhythmias.

Pulmonary Stenosis

Women with isolated valvar pulmonary stenosis almost always tolerate pregnancy well. Some women will have had a pulmonary valvuloplasty and may have residual pulmonary regurgitation. These women also do well if they have good exercise capacity and preserved right ventricular systolic function.

Ebstein Anomaly

The safety of a pregnancy in patients with Ebstein anomaly depends on right ventricular size and function, degree of tricuspid regurgitation, and presence or absence of an atrial communication. The latter is present in approximately 50% of patients, and if the patient is cyanotic at rest, the risk of pregnancy increases considerably. An atrial communication poses the added potential risk of a stroke from a paradoxical embolus, and meticulous attention should be paid to the possibility of maternal deep vein thrombosis. Atrial arrhythmias may not be well tolerated in the pregnant woman with this anomaly, and women are at risk for both atrial fibrillation and atrioventricular reentry tachycardia (**see also Chapter**

37). Accessory bypass tracts causing preexcitation can precipitate rapid tachycardia. Pregnancy risks may be less after successful surgical repair or replacement of the tricuspid valve if there is no other residual disease.

Complete Transposition of the Great Arteries

Women with complete transposition of the great arteries will have had surgery in childhood. Atrial switch operations (Mustard or Senning operation) leave the morphologic right ventricle as the systemic pump, and, over time, the subaortic right ventricle can dilate or weaken. The function of the subaortic ventricle and the degree of systemic atrioventricular valve regurgitation are important determinants of the pregnancy outcome. In a study of 49 completed pregnancies, the most common maternal cardiac complication was arrhythmias, occurring in 22% of the pregnancies.[23] Heart failure and maternal death have been reported. Prematurity is common, and small-for-gestational-age babies are common. Some women have irreversible subaortic ventricular dysfunction or worsening systemic atrioventricular valve regurgitation.[24] Careful preconception evaluation by an expert is important for women with this condition. Dysfunction of the subaortic right ventricle can be a contraindication to pregnancy. Women with atrial switch operations are at risk for arrhythmias and heart failure immediately postpartum and should have monitoring in a cardiac intensive care unit after delivery.

The more contemporary repair for complete transposition is the arterial switch operation (Jatene operation), and these women are now reaching child-bearing age. Women who have undergone this operation may have neoaortic root dilation, aortic regurgitation, pulmonary stenosis, or coronary artery stenosis, and these lesions will affect the pregnancy risk. Preconception assessment by an expert in congenital heart disease is important. Women who have undergone the arterial switch operation who do not have major residual lesions tend to do well.[25] All women with repaired transposition should deliver at a high-risk pregnancy unit.

Fontan Operation

Women who have undergone a Fontan operation will have single-ventricle physiology, typically without a subpulmonic ventricle. Blood flow through the lungs is from passive flow. These women are at increased risk for maternal complications during pregnancy, particularly atrial arrhythmias, which may cause profound hemodynamic deterioration and heart failure.[26,27] They are vulnerable to development of thrombosis in the Fontan circuit because of the low flow through the circuit and prothrombotic state of pregnancy. Function of the single ventricle may deteriorate because of the volume load of pregnancy. Fetal and neonatal complications such as prematurity and low birth weight are major problems in this population.[27,28] This is a complex condition, and preconception counseling by an expert in adult congenital heart disease is crucial. The Fontan circulation is preload dependent, and minimizing pushing at the time of delivery is important to prevent complications. Immediately postpartum, women should have careful monitoring of their rhythm and volume status in a cardiac intensive care unit.

Cyanotic Heart Disease

There are a number of cardiac conditions, such as unrepaired tetralogy of Fallot, where women of child-bearing age may present with cyanosis. Cyanosis poses risks for both mother and fetus.[29] The decrease in peripheral resistance that accompanies pregnancy augments the right-to-left shunt and may exaggerate the maternal cyanosis. Because of the erythrocytosis that accompanies cyanosis and the propensity to thrombosis, women in whom venous thrombosis develops are at risk of paradoxical embolus and stroke.

In addition to the degree of maternal cyanosis, right ventricular function must be assessed before pregnancy by echocardiography or MRI. As for patients with other complex congenital heart diseases, preconception counseling by an expert in adult congenital heart disease is crucial.

Maternal hypoxia imposes a pronounced handicap to fetal growth and survival. In a study of 44 women with 96 pregnancies (excluding women with Eisenmenger syndrome), maternal oxygen saturations of less than 85% were associated with a poor fetal outcome; only 2 of 17 pregnancies (12%) resulted in live-born infants.[29] Conversely, when the maternal oxygen saturation was 90% or higher, 92% of the pregnancies resulted in a live birth. Maternal cardiovascular complications occurred in 14 patients (32%). Eight patients had heart failure, and bacterial endocarditis occurred in two patients, both with surgically palliated tetralogy of Fallot. Two patients had thrombotic complications, one pulmonary and one cerebral.

Pulmonary Hypertension (see also Chapter 85)

In women of childbearing age, pulmonary arterial hypertension may be idiopathic or it may be secondary to congenital cardiac shunts or connective tissue disorders. Pulmonary arterial hypertension, regardless of the cause, carries a high mortality rate when it is associated with pregnancy. The volume load of pregnancy can compromise the poorly functioning right ventricle, precipitating heart failure. The fall in peripheral resistance augments right-to-left shunting, thereby contributing to development of cyanosis. Labor and delivery are particularly dangerous, and the highest incidence of maternal death is during parturition and the puerperium. An abrupt decrease in afterload may occur as the baby is delivered, and hypovolemia from blood loss can cause hypoxia, syncope, and sudden death. Vagal responses to pain also may be life-threatening. A systematic review of pregnancy in 73 women with pulmonary arterial hypertension reported a maternal mortality rate of 25%.[30] Maternal morbidity and mortality are due to right ventricular heart failure, pulmonary hypertensive crises, pulmonary embolism, arrhythmias, and bleeding. Neonatal and fetal deaths are also increased, and premature deliveries occur in many pregnancies. Some recent series have suggested that more successful maternal and neonatal outcomes may be possible.[31,32] Advanced therapies for pulmonary arterial hypertension are being increasingly used in the pregnant population and may, in part, be responsible for improved outcomes. Intravenous and inhaled prostacyclins and phosphodiesterase type 5 inhibitors are the most commonly used pulmonary arterial hypertension medications used during pregnancy. Bosentan is not used during pregnancy because of the potential for teratogenicity.

Termination of pregnancy is the safer option, although in patients with pulmonary hypertension, this too may be a more complex procedure, and cardiac anesthesia is helpful in this regard. For women who continue pregnancy, the mode of delivery needs to be determined after careful consideration by the treating physicians. Cesarean delivery with cardiac anesthesia is an option. If the vaginal route is selected, it should take place in an intensive care unit. Epidural analgesia must be administered with due caution to minimize peripheral vasodilation. A prolonged second stage should be avoided. The use of an anti–deep vein thrombosis device (i.e., Thromboguard) or a compression pump may help prevent peripheral venous thrombosis. In-hospital monitoring should be continued for at least 2 weeks after delivery. Appropriate advice about contraception should be given to all patients.

Marfan Syndrome (see also Chapter 75)

The most common connective tissue disorder is Marfan syndrome, caused by a mutation in the *FBN-1* gene encoding the glycoprotein fibrillin. Marfan syndrome is inherited in an autosomal dominant pattern.

Preconception counseling, including genetic evaluation, is essential and should include advice about the risks of cardiovascular complications for the mother and the risk of transmission to offspring. A careful clinical and cardiovascular imaging evaluation should be performed. Cardiac investigations include a transthoracic echocardiogram and a cardiac MRI or CT to assess the entire aorta for aortic dilation or dissection. It has been suggested that pregnancy usually is contraindicated if the ascending aorta is larger than 4.4 cm in diameter,[33] although the exact dimension is a matter of debate. The European Society of Cardiology guidelines on cardiovascular diseases during pregnancy suggest that women with Marfan syndrome undergo aortic replacement if the aorta is greater than 4.5 cm.[18] It should be emphasized to all women with Marfan syndrome and those with previous aortic dissection that pregnancy is not uniformly safe and the risks are unpredictable. Pregnancy increases the risk of aortic complications in the long term.[33] Aortic complications during pregnancy carry a high maternal mortality rate of up to 11%. Associated cardiovascular problems also need to be evaluated, including the possibility of aortic regurgitation and mitral valve prolapse with associated regurgitation.

Many women are already receiving treatment with beta-adrenergic blockers or angiotensin II receptor antagonists to prevent aortic dilation and dissection. Beta blockers should be continued during pregnancy because they may prevent progressive aortic dilation and dissection. Angiotensin II receptor antagonists should be stopped during pregnancy because of the fetal risk. Periodic echocardiographic surveillance every 6 to 8 weeks is recommended to monitor the mother's aortic root size, with the interval dependent on the initial echocardiographic findings. Any chest pain should be promptly evaluated to rule out dissection. During labor and delivery, pushing should be avoided, with an assisted second stage if necessary. In women with a dilated aorta, delivery should occur in a tertiary care center where experienced cardiothoracic surgical expertise is available.

Valvular Heart Disease (see also Chapter 67)

Aortic Stenosis (see also Chapter 68)

Aortic stenosis in women of childbearing age is usually secondary to a bicuspid aortic valve. In low-income countries, aortic stenosis may be secondary to rheumatic heart disease. A detailed echocardiographic assessment of the valve function should be performed before pregnancy is contemplated. A stress test can be useful to assess functional capacity and blood pressure response to exercise. Women with severe aortic stenosis (a valve area < 1 cm^2 or a mean gradient > 40 mm Hg) need careful preconception risk stratification by a cardiologist with expertise in pregnancy and heart disease. Some women with severe aortic stenosis who have an excellent functional capacity and a normal blood pressure response to exercise will be able to tolerate pregnancy. Others may require valve surgery prior to pregnancy. In addition, a careful examination of the entire thoracic aorta is indicated to look for bicuspid valve associated aortopathy; even with a functionally normal valve, an aortic dilation or ascending aortic aneurysm may be present. Surgical repair prior to pregnancy should be considered if the aorta is larger than 5 cm.

Mild and moderate aortic stenosis is usually well tolerated if the patient has a normal exercise capacity and no symptoms. Pregnancy in women with severe aortic stenosis is characterized by an increased incidence of heart failure, arrhythmias, premature labor, and shorter pregnancy duration. In one study of 96 pregnancies in women with at least moderate aortic stenosis, 21% of women were hospitalized for cardiac reasons during pregnancy.[34] Although maternal mortality rates are very low in contemporary series, death has been reported in this group of women.

Labor and delivery can be particularly problematic in such patients because of the abrupt hemodynamic

changes, including immediately postpartum when there is an abrupt fall in afterload as the baby is delivered. Blood loss at the time of parturition also can precipitate maternal collapse. Epidural analgesia needs to be carefully and slowly administered, and spinal block should be avoided because of the potential for hypotension. Delivery may be facilitated by arterial lines or central venous pressure monitoring, which should be continued for at least 24 hours after delivery. Over the long term, women with moderate or severe aortic stenosis who have been pregnant are more likely to require cardiac interventions when compared with women who have not been pregnant.[35]

Mitral Stenosis (see also Chapter 69)

Mitral stenosis is almost always due to rheumatic heart disease, and cardiac complications during pregnancy are common. Symptoms tend to worsen during pregnancy because of the increased plasma volume coupled with the increase in heart rate, which shortens the diastolic filling time and increases the left atrial pressure. Any decrease in stroke volume causes a further reflex tachycardia, which contributes further to the elevated left atrial pressure. Atrial arrhythmias and pulmonary edema are the most common cardiac complications.[36] The onset of atrial fibrillation may precipitate acute pulmonary edema. Maternal death can occur, particularly in low-income countries where access to pregnancy care is difficult. Perinatal morbidity and mortality rates are also increased.

Women should undergo careful echocardiographic evaluation of the mitral valve and pulmonary pressures before proceeding with pregnancy. Exercise echocardiography also may be helpful in delineating the hemodynamic response to effort in terms of mitral gradient and the presence or absence of pulmonary hypertension. Women with severe mitral stenosis should have a valve intervention prior to pregnancy. During pregnancy, the cornerstone of medical therapy for the symptomatic patient is beta blockade. This pharmacologic mode slows the heart rate, prolongs the diastolic filling time, and can result in marked clinical improvement with control of symptoms. Bed rest also may be helpful to slow the heart rate and to minimize cardiac demands. The use of diuretics is appropriate if pulmonary edema is present. Anticoagulants should be administered in the setting of atrial fibrillation. When the mother fails to respond adequately to medical management, balloon valvuloplasty may be performed if the valve anatomy is favorable and there is no concomitant mitral regurgitation.[37] Surgical valvotomy may be performed but should be reserved for patients with symptoms refractory to medical therapy in whom balloon valvotomy is not feasible.

Mitral and Aortic Regurgitation

Mitral and aortic regurgitation may be tolerated in pregnancy, provided that the regurgitation is of no more than moderate, the mother is asymptomatic before pregnancy, and ventricular function is preserved. Closer monitoring during pregnancy usually is warranted, however, particularly for those with mitral regurgitation, because the left ventricle tends to dilate as pregnancy progresses, and this may exacerbate the degree of mitral regurgitation.

Prosthetic Valves (see also Chapter 71)

Pregnancy for the woman with a prosthetic valve poses risks for mother and baby. The choice of a prosthetic valve for the woman of childbearing age involves a detailed discussion of the relative risks so that she can make an informed decision about whether to select a tissue or mechanical prosthesis. Tissue valves are less thrombogenic than mechanical valves and therefore are less problematic in pregnancy because they do not routinely involve the use of warfarin. The disadvantage is their tendency to

degenerate after an average of 10 to 15 years, necessitating a reoperation, with its attendant risks and potential for death. Mechanical prostheses, by contrast, have a greater longevity but require anticoagulation, and whichever anticoagulant strategy is chosen during pregnancy, there is a higher chance of fetal loss, placental hemorrhage, and prosthetic valve thrombosis.

Tissue Prostheses

The most common types of tissue valves used currently are porcine and pericardial valves. For patients in sinus rhythm, they confer the advantage that warfarin is not required, although most patients take low-dose (81-mg) aspirin. These valves are vulnerable to structural degeneration and calcification, which occurs more rapidly in younger patients. In addition, mitral prostheses tend to degenerate faster than those in the aortic position. Some evidence suggests that pregnancy may accelerate valve degeneration; this potential disadvantage is not universally accepted, however, and other large series have shown no difference in structural valve degeneration in young women who had a pregnancy and those who did not. Nonetheless, all tissue valves will degenerate, necessitating a second operation, with an operative risk that usually is higher than for the first. In some series, the mortality rate for a second valve replacement may be as high as 6%, and it must be recognized that if death occurs after a successful pregnancy, the young child is left without a mother. Thus, at the time of counseling women of childbearing age about valve choice, the surgical results from the individual physician's institution should be reviewed. These findings may vary considerably on the basis of both surgical volume and expertise. Use of homografts poses similar problems of structural deterioration and reoperation. The Ross operation, in which an autograft pulmonary valve is placed in the aortic position and a tissue prosthesis (usually porcine) is implanted in the pulmonary position, is associated with good outcomes during pregnancy when the hemodynamic indices are good. Nonetheless, the Ross procedure eventually requires reintervention.

Mechanical Prostheses

During pregnancy, the maternal blood is highly thrombogenic because of increased concentration of clotting factors, increased platelet adhesiveness, and decreased fibrinolysis. These changes contribute to a significant risk of maternal valve thrombosis and thromboembolism. Although the maternal risk of valve thrombosis is primarily dependent on the anticoagulation regimen chosen and the quality of anticoagulation control, the type of valve, position of the valve (mitral more than aortic), and function of the valve are also determinants of outcome. Women are also at risk of bleeding complications, cerebrovascular events, heart failure, arrhythmias, and endocarditis. Fetal and neonatal complications are increased in this group of women and include fetal loss, stillbirths, intracranial hemorrhage, prematurity, and low-birth-weight babies.

The management of anticoagulation during pregnancy in women with a mechanical valve prosthesis is controversial, and no universal consensus has emerged. Potential anticoagulation options include vitamin K antagonists, low-molecular-weight heparin, unfractionated heparin, or a combination or vitamin K antagonists and heparin. There is no perfect anticoagulation strategy, and each regime is associated with some hazard for the mother or the fetus. In general, the maternal risk is lowest with vitamin K antagonists and the fetal risk is lowest with heparin. A systematic review of pregnancy outcomes in women with mechanical valves (n = 2468 pregnancies), stratified according to the type of anticoagulant used during pregnancy, is shown in **Table 90.3**.[38] All anticoagulant regimens, however carefully managed, carry an increased risk of fetal loss and spontaneous abortion and the potential for hemorrhagic complications, including placental bleeding, miscarriage, and fetal death. Before any approach is adopted, it is

imperative to explain the risks to the patient. With all anticoagulant regimens, the addition of low-dose aspirin, 75 to 162 mg/day, may confer additional maternal benefit. As yet, no data support the use of anti-Xa and direct thrombin inhibitors in patients with prosthetic valves. Mothers with mechanical prostheses are best managed by a multidisciplinary team in a center that provides training and expertise in the management of complex heart disease and pregnancy.

TABLE 90.3

Primary Outcomes of Mothers with Mechanical Valves Taking Anticoagulants During Pregnancy and Their Infants*

ANTICOAGULATION REGIME	MATERNAL MORTALITY RATES ESTIMATED % (95% CI)	MATERNAL THROMBOEMBOLISM RATES ESTIMATED % (95% CI)	LIVE BIRTHS ESTIMATED % (95% CI)	WARFARIN EMBRYOPATHY AND FETOPATHY ESTIMATED % (95% CI)
Vitamin K antagonists (INR target 2.5 to 3.5)	0.9 (0.1, 1.6)	2.7 (1.4, 4.0)	64.5 (48.8, 80.2)†	2.0 (0.3, 3.7)†
Sequential treatment	2.0 (0.8, 3.1)	5.8 (3.8, 7.7)	79.9 (74.3, 85.6)	1.4 (0.3, 2.5)‡
LMWH alone	2.9 (0.2, 5.7)	8.7 (3.9, 13.4)	92.0 (86.1, 98.0)	NA
UFH alone	3.4 (0, 7.7)	11.2 (2.8, 19.6)	69.5 (37.8, 100)	NA§

*Estimates are presented as proportions per 100 affected pregnancies with 95% confidence intervals.

†Of these, 7/407 [0.8% (0.0, 1.7)] represent embryopathy and 5/197 [2.1% (0.1, 4.1)] represent fetopathy.

‡All cases represent fetopathy.

§There were four cases of intracranial bleeding in women using UFH; bleeding was secondary to prematurity and not the anticoagulant effect because UFH does not cross the placenta.

Effects of Pharmacologic Therapy in Valvular Disease

Warfarin.

Fetal exposure to warfarin between 6 and 9 weeks' gestation is associated with *warfarin embryopathy* (stippled epiphyses, nasal hypoplasia). *Warfarin fetopathy* (optic atrophy and central nervous system abnormalities) occurs with exposure later in gestation.[39] The reported risk of embryopathy varies widely but probably averages 2% to 4%. This risk is reduced by initiation of heparin before 6 weeks of gestation. The disadvantage of stopping warfarin is an increased risk of maternal valve thrombosis. The risk of warfarin-related perinatal complications is dose related, but whether warfarin embryopathy, specifically, is dose related continues to be debated.[39] One study suggested that the risk is very low if the maternal warfarin dose is 5 mg/day or less.[40] Warfarin is associated with fewer live births when compared with heparin.[41] Because warfarin carries the lowest risk of maternal valve thrombosis and death, the American College of Cardiology/American Heart Association (ACC/AHA)[42] and the European Society of Cardiology (ESC)[18] have recommended the use of oral anticoagulants in the second and third trimesters until approximately the 36th week of pregnancy with strict control of international normalized ratio values (**Fig. 90.4**). The transition period, when warfarin is discontinued and heparin started, may need to be earlier in women at high risk of preterm birth. Because the fetal risk in the first trimester appears to be dose related, guidelines recommend consideration of continuation of oral anticoagulants in

the first trimester in women whose warfarin dose is less than 5 mg/day. These options must be fully discussed with the patient before she becomes pregnant, not only for the medicolegal implications but to ensure she has complete understanding of all the risks and benefits to mother and baby.

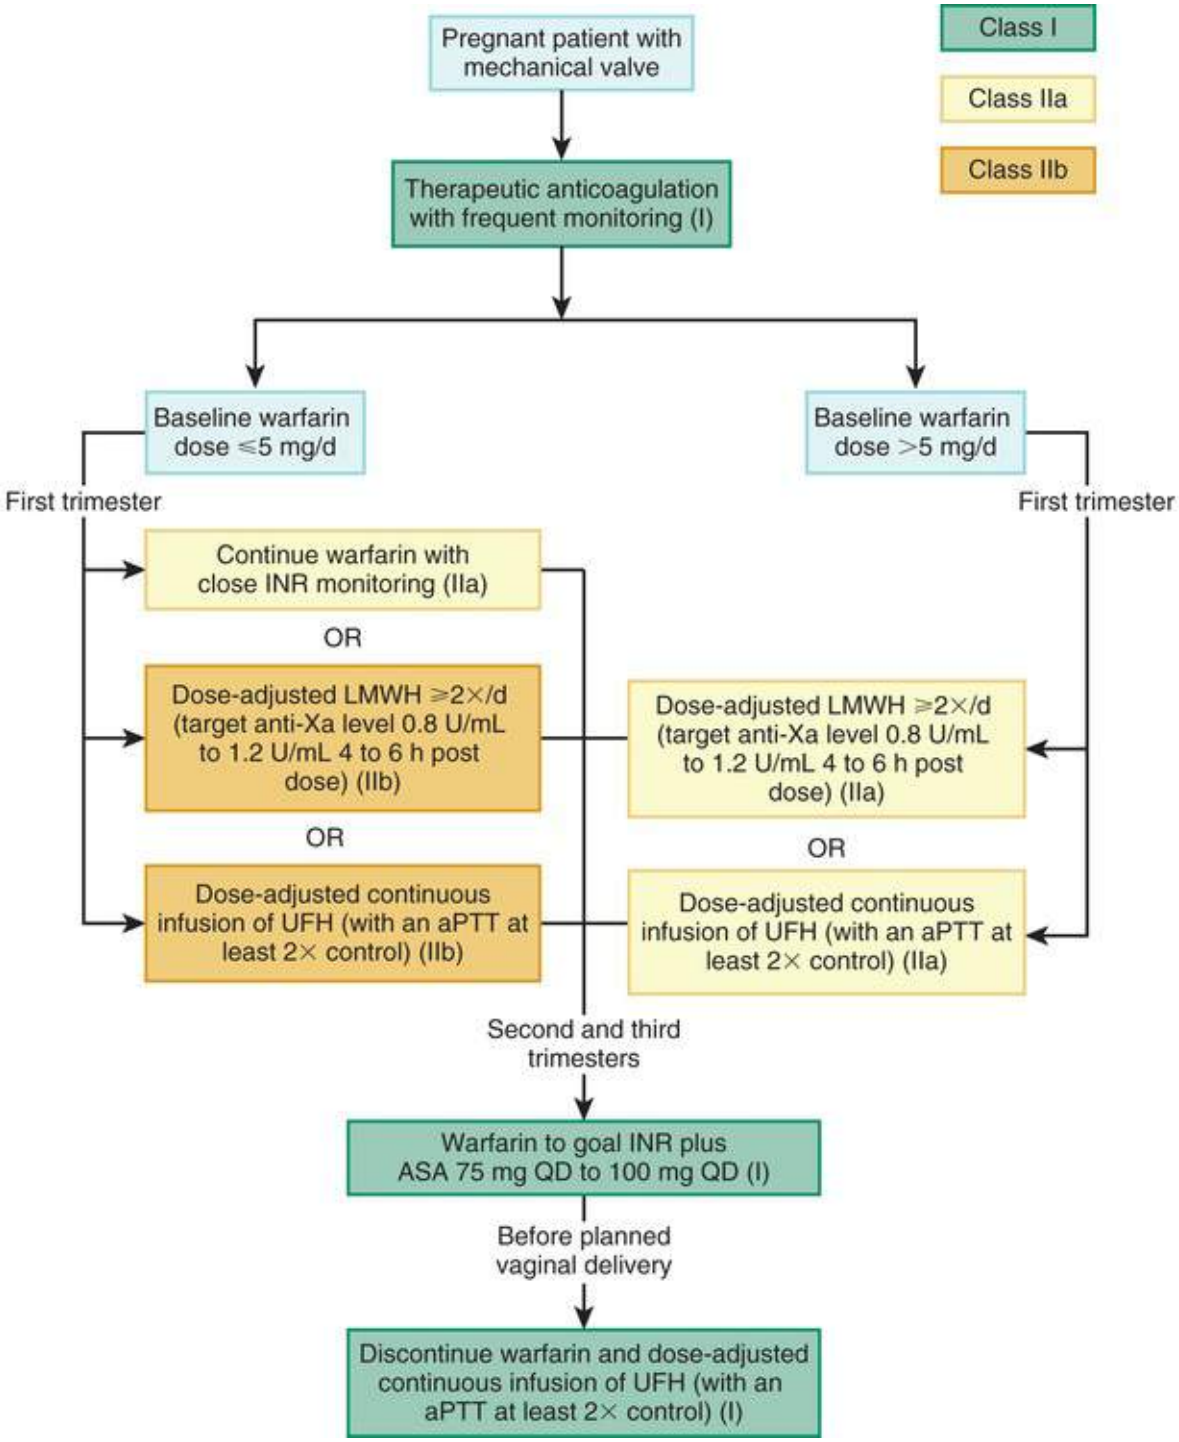

FIGURE 90.4 Anticoagulation of pregnant women with mechanical valves: recommendations from the American College of Cardiology/American Heart Association. *aPTT,* activated partial thromboplastin time; *ASA,* acetylsalicylic acid; *INR,* international normalized ratio; *LMWH,* low molecular weight heparin. (From Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACC guideline for the management of patients with valvular heart disease: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2014;63:2438-88.)

Low-Molecular-Weight Heparin.

Although the use of heparin eliminates the risk of warfarin embryopathy, there is a significant increase in

the risk of maternal thromboembolic complications, including valve thrombosis. Low-molecular-weight heparin is an attractive alternative to unfractionated heparin because of its ease of use and superior bioavailability. It does not cross the placenta, so embryopathy does not occur.

However, no large prospective trials have been conducted to confirm the usefulness of low-molecular-weight heparin in this setting, and reported studies are confined to small series.

Live birth rates are highest with the use of low-molecular-weight heparin, but rates of maternal thromboembolic complications and maternal mortality are increased when compared with warfarin. Thromboembolic complications are usually, but not always, associated with fixed-dose regimes or subtherapeutic anti-Xa levels. The low-molecular-weight heparin dose requirements can change dramatically throughout pregnancy owing to changes in renal clearance and plasma volume. Furthermore, preinjection anti-Xa levels may still be subtherapeutic when the postinjection level is therapeutic. Data remain limited regarding optimal anti-Xa levels, timing of measurement (peak levels versus trough levels, or both), and the frequency of testing. Despite these limitations, the ACC/AHA[42] (**see Fig. 90.4**) and the ESC[18] suggest that low-molecular-weight heparin can be used as an alternative to warfarin for women requiring more than 5 mg/day of warfarin. The American College of Chest Physicians suggests that low-molecular-weight heparin can be used as an alternative to warfarin in any woman, regardless of the warfarin dose.[43] If low-molecular-weight heparin is used, it should be administered subcutaneously every 12 hours and the dose adjusted so that a 4-hour postinjection anti-Xa level is maintained at approximately 1.0 to 1.2 units/mL. Low-molecular-weight heparin should be discontinued at least 36 hours before delivery; at this time a switch to an infusion of unfractionated heparin should be made because it can be started and stopped abruptly. This precaution is especially important if epidural analgesia is to be used, because its prolonged effect increases the risk of spinal hematoma. Unfractionated heparin should be resumed as soon as possible after delivery in the absence of bleeding complications.

Unfractionated Heparin.

Unfractionated heparin is a large molecule that does not cross the placenta and does not cause developmental abnormalities in the fetus. Laboratory control of the activated partial thromboplastin time (aPTT) is difficult, in part because of the variation in response to standard doses and the wide variation in the reagents used to monitor doses. If used during pregnancy, heparin should be given as an infusion and the activated partial thromboplastin time ratio at least 2 control. Subcutaneous unfractionated heparin has been used throughout pregnancy to avoid any fetal exposure to warfarin, but it has been shown to be a poor anticoagulant in pregnancy. The ACC/AHA valve guidelines do not recommend subcutaneous heparin in pregnant women with mechanical valves. [42]

Cardiomyopathies (see also Chapter 77)

Dilated Cardiomyopathy

In young women, dilated cardiomyopathy is often idiopathic, but it may be secondary to the effects of drugs or toxins or to infection. Occasionally, a genetic cause of dilated cardiomyopathy is present, in which case, transmission to offspring should be addressed. Women with dilated cardiomyopathy usually are counseled not to have a pregnancy if the ejection fraction is lower than 30% or if they are in NYHA functional class III or IV.[18] Careful echocardiographic evaluation should be performed before pregnancy. Exercise stress testing may also be helpful, because women with cardiomyopathy may not tolerate pregnancy well if they have a poor aerobic capacity.

Women with dilated cardiomyopathy are at risk for deterioration in left ventricular systolic function,

pulmonary edema, and arrhythmias. Maternal death is rare but has been described. In one study of 36 pregnancies in 32 women with dilated cardiomyopathy, 14 of 36 pregnancies (39%) were complicated by at least one adverse maternal cardiac event.[44] A poor functional class and moderate or severe left ventricular dysfunction were the main determinants of adverse maternal cardiac outcomes. Conversely, women with dilated cardiomyopathy who have only mild left ventricular systolic function, have a good functional class, and have no prior heart failure or arrhythmia often do well in pregnancy.

Women with cardiomyopathies should continue beta-blocker therapy when indicated. Because angiotensin-converting enzyme inhibitors and angiotensin II receptor antagonists are contraindicated in pregnancy, the ventricular function must be assessed without the medications before pregnancy. Symptomatic patients who proceed with a pregnancy may need hydralazine for afterload reduction. Heart failure typically occurs in the third trimester or early postpartum period. Women who develop pulmonary edema should be treated with diuretics and may require hospital admission and bed rest. Early delivery may be necessary in women who decompensate during pregnancy or in those with severe left ventricular systolic dysfunction.

Hypertrophic Cardiomyopathy (see also Chapter 78)

A wide spectrum of anatomic and hemodynamic abnormalities has been documented in hypertrophic cardiomyopathy, including left ventricular outflow tract obstruction, mitral regurgitation, arrhythmias, and diastolic dysfunction. Some patients are asymptomatic, with minimal hemodynamic disturbance; others exhibit profound functional limitation, with marked hemodynamic perturbations. A careful personal history, review of family history, an electrocardiogram, exercise testing, and transthoracic echocardiography should precede counseling about the advisability of a pregnancy. The prospective parents should be informed about the autosomal dominant inheritance pattern, which has variable penetrance. In many patients, a genetic cause can be identified, and genetic counseling and family screening are appropriate before pregnancy is contemplated.

Most studies suggest that women with hypertrophic cardiomyopathy tolerate pregnancy well.[45] The decrease in afterload that might exacerbate the outflow gradient is largely offset by the maternal increase in plasma volume. Patients with significant symptoms before pregnancy (usually related to severe left ventricular outflow tract obstruction) may develop complications. Sudden death in pregnancy is rare but has been reported, and this fact highlights the need for careful preconception evaluation.[45] Heart failure and arrhythmias, both atrial and ventricular, can occur during pregnancy. The reported frequency of arrhythmias and heart failure during pregnancy varies between studies, likely due to differences in patient selection, small numbers, and variable study methods. Maternal cardiac complications at the time of delivery have been reported to occur in as many as 23% of pregnancies.[46] Medications such as beta blockers should be continued throughout pregnancy, but the dose may need to be increased as the pregnancy progresses. Diuretics may be used to treat heart failure in pregnancy, but care must be taken to avoid volume depletion, which exacerbates the left ventricular outflow gradient. Meticulous attention should be paid to hemodynamics at the time of delivery. Hypotension with epidural anesthesia and spinal block should be avoided, specifically in women with obstructive hypertrophic cardiomyopathy. Blood losses should be promptly replaced. Cesarean delivery is indicated for obstetric reasons only. Avoidance of the Valsalva maneuver and a facilitated second stage of labor are advised in women with obstructive hypertrophic cardiomyopathy.

Peripartum Cardiomyopathy

Peripartum cardiomyopathy (PPCM) is a life-threatening condition associated with left ventricular dysfunction occurring during the last months of pregnancy or in the months following delivery in previously healthy women. The incidence of PPCM varies among populations; it is approximately 1 in 3000 in the United States compared with 1 in 300 in Haiti. Known risk factors include black race, older maternal age, multiparity, and preeclampsia. The majority of women present in the first month postpartum. Women may present with heart failure, cardiogenic shock, arrhythmias, or stroke secondary to left ventricular thrombus. Mortality rates in the United States have been reported at between nil and 19%.[47] Uncertainty can exist about whether the cardiomyopathy developed during pregnancy or was a preexisting cardiomyopathy that became apparent during pregnancy.

The cause and pathophysiology are poorly understood, but an angiogenic imbalance is thought to be important, with excess antiangiogenic factors occurring in combination with host susceptibility.[48] Inflammation may play a role, because serum markers of inflammation are elevated in many patients. An unbalanced peripartum oxidative stress may also be important because it leads to the proteolytic cleavage of the nursing hormone prolactin, with the resultant formation of a 16-kDa subform. This subform of prolactin is a potent antiangiogenic, proapoptotic, and proinflammatory agent that affects the endothelium, cardiac vasculature, and cardiac myocyte function. This hypothesis has led to a potential therapeutic strategy with blockade of prolactin by bromocriptine, a dopamine D_2 receptor agonist. This treatment has been shown to prevent the disease in experimental animal models and appeared to be successful in small pilot studies with respect to prevention and treatment in patients.[49] Because prolactin acts as a scavenger for thrombin, its elimination by bromocriptine may increase the risks of thromboembolism, and concomitant heparin anticoagulation has been advised. Randomized trials are necessary to determine safe and effective treatment strategies.

In other respects, the treatment of PPCM is similar to that for other forms of congestive heart failure, except that angiotensin-converting enzyme inhibitors and angiotensin II receptor antagonists should not be used in women who present antenatally.[50] Hydralazine and nitrates can be used for afterload reduction. Beta blockers and digoxin can be used during pregnancy. Diuretics should be used to treat pulmonary edema, and inotropes may be necessary in more severe cases. Aldosterone antagonists may have antiandrogenic effects on the fetus and should be avoided. Left ventricular thrombi are common, and consideration should be given to anticoagulation with heparin in patients with an ejection fraction lower than 35%. Women with severe PPCM should be transferred to a center that can offer mechanical support and transplant services. Temporary circulatory support, with either an intraaortic balloon pump or a left ventricular assist device, or extracorporeal membrane oxygenation may be necessary in those with cardiogenic shock. Cardiac transplantation may be considered in patients refractory to mechanical circulatory support. Early fetal delivery may be necessary in women with refractory heart failure, but the timing and mode of delivery depend on the maternal clinical status. Cesarean delivery is the preferred mode of delivery in hemodynamically unstable patients.

In a study of 100 women with PPCM, normalization of ventricular systolic function occurred in 72%, but recovery was unlikely if the left ventricular ejection fraction was less than 30% or if the left ventricular end-diastolic dimension was greater than 6 cm at the time of diagnosis[51] (**Fig. 90.5**). Left ventricular systolic function usually improves within the first 6 to 12 months postpartum. All women with PPCM are at risk for recurrence in subsequent pregnancies, and this may result in significant clinical deterioration and death. Women who do not have full recovery of left ventricular systolic function are at highest risk and should be advised that pregnancy is contraindicated because of the 20% maternal mortality rate with subsequent pregnancies.

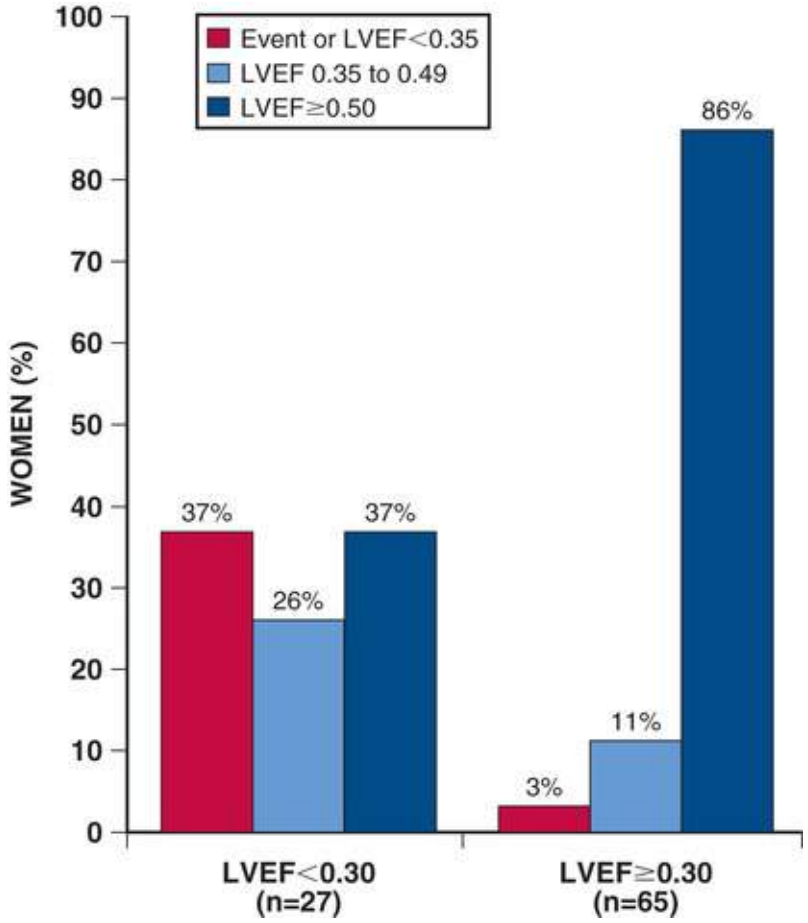

FIGURE 90.5 Recovery of left ventricular systolic function in women with peripartum cardiomyopathy. Comparison of left ventricular systolic function at 1 year postpresentation based on the initial left ventricular ejection fraction. *Red column*, percentage of women with no recovery (event of final ejection fraction < 0.35); *blue column*, percentage of women with partial recovery (final ejection fraction 0.35 to 0.49); *purple column*, percentage of women with complete recovery (final ejection fraction 0.50 to 0.49). (From McNamara DM, Elkayam U, Alharethi R, et al. Clinical outcomes for peripartum cardiomyopathy in North America: results of the IPAC study (Investigations of Pregnancy-Associated Cardiomyopathy). J Am Coll Cardiol 2015;66:905-14.)

Coronary Artery Disease and Pregnancy-Associated Myocardial Infarction (see also Chapter 58)

Coronary disease, of any type, is uncommon in women of childbearing age. Atherosclerotic coronary artery disease may occur with older maternal age, the presence of diabetes, or tobacco abuse. Other coronary lesions such as coronary dissection, coronary thrombus, and coronary artery spasm occur in this young cohort. One study of 50 pregnancies in women with preexisting coronary disease reported a 10% risk of maternal death, acute coronary syndrome, myocardial infarction, or heart failure during pregnancy.[52] This included one maternal death secondary to cardiac arrest. New or progressive angina occurred in 18% of the pregnancies. Ischemic complications were more common in women with coronary atherosclerosis as an underlying diagnosis. High rates of adverse fetal and neonatal complications were also seen.

Pregnancy-associated acute myocardial infarction is rare, but with the rise in maternal age and increasing number of high-risk women who become pregnant, the incidence is increasing. When it occurs, pregnancy increases the maternal mortality rate to an estimated 5% to 10%. The most common cause of pregnancy-associated acute myocardial infarction is coronary artery dissection (**Fig. 90.6**), and the most commonly involved artery is the left anterior descending artery. This tends to occur more commonly in the third trimester or early postpartum period. In a review of 150 cases of pregnancy-associated acute

myocardial infarction, heart failure or cardiogenic shock occurred in 38% of pregnancies, ventricular arrhythmias in 12%, and recurrent angina or infarction in 20%.[53] The most common cause of pregnancy-associated acute myocardial infarction was coronary dissection, found in more than 40% of the women.

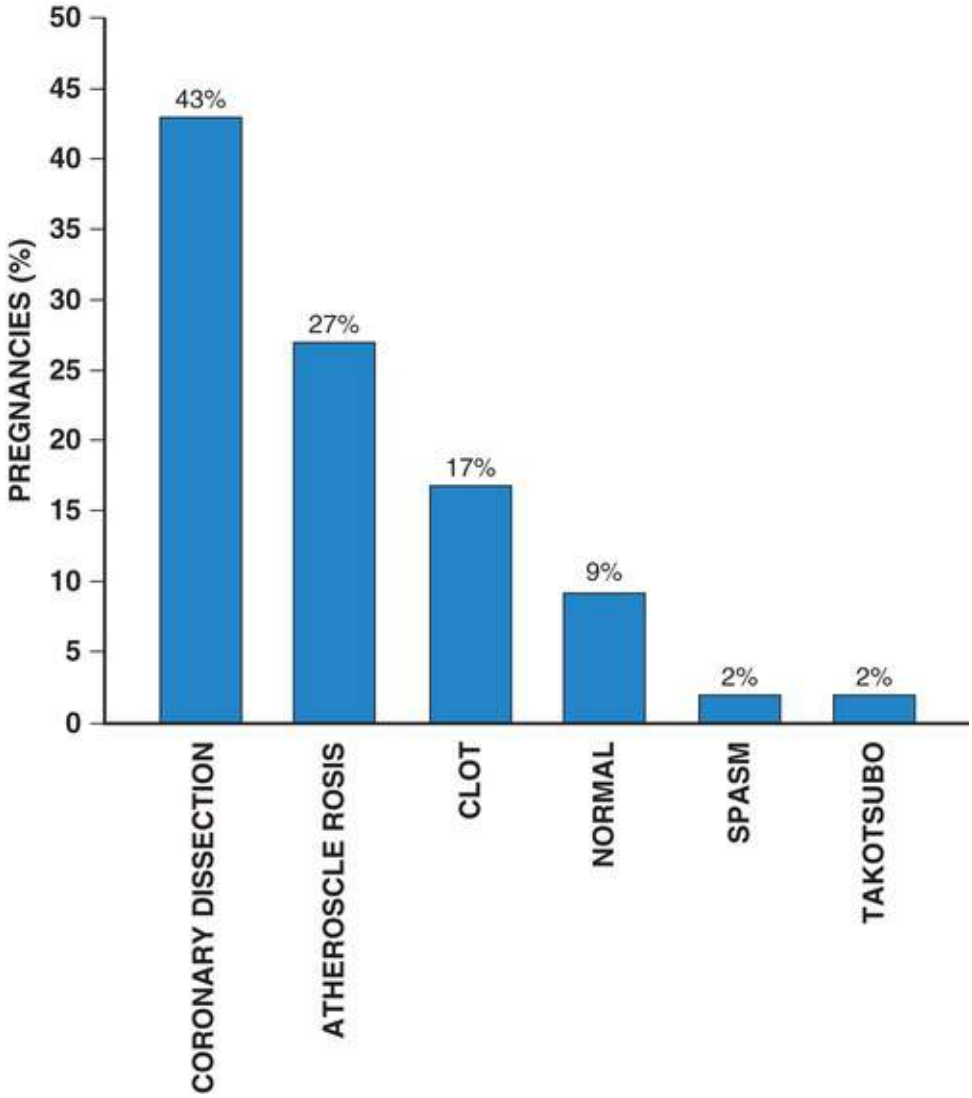

FIGURE 90.6 Causes of acute myocardial infarction in pregnancy. (Data from Elkayam U, Jalnapurkar S, Barakkat MN, et al. Pregnancy-associated acute myocardial infarction: a review of contemporary experience in 150 cases between 2006 and 2011. Circulation 2014;129:1695-1702.)

When an acute coronary syndrome occurs, women should be immediately referred to a skilled intervention center for diagnostic angiography. This management strategy is preferable to thrombolysis, because of the increased likelihood of coronary dissection during pregnancy. Tissue plasminogen activator does not cross the placenta but may cause placental bleeding and should be avoided unless the situation is life-threatening. Many of the standard drug therapies used to treat myocardial infarction, such as morphine, nitroglycerin, aspirin, beta blockers, heparin, and clopidogrel, can be used during pregnancy. Angiotensin-converting enzyme inhibitors and statins are usually avoided because of potential fetal risks. There is limited information on the use of the glycoprotein IIb/IIIa receptor inhibitors prasugrel and ticagrelor in pregnancy. Because of the potential for iatrogenic coronary dissection–related coronary interventions, stenting is reserved for patients with persistent or recurrent ischemia or those who are unstable. Coronary bypass may be considered in women with left main disease or significant proximal coronary artery stenosis.

Hypertension (see also Chapter 46)

Hypertension is the most common medical problem in pregnancy and is a well-recognized contributor to maternal morbidity and mortality rates. The different types of hypertension seen in pregnancy are shown in **Table 90.4**. Gestational hypertension is distinguished from preeclampsia by the lack of proteinuria, maternal organ dysfunction, or uteroplacental abnormalities. Approximately 25% of patients will develop preeclampsia, so close monitoring is warranted. Preeclampsia also develops in approximately 25% of patients with chronic hypertension. The cause of preeclampsia is not entirely clear, but endothelial dysfunction that causes abnormal remodeling of the placental spiral arteries is likely a contributory factor. Hypertension is just one feature of the diffuse endothelial dysfunction, which is associated with vasospasm, reduced end-organ perfusion, and activation of the coagulation cascade. Preeclampsia tends to occur more commonly in nulliparous women; in women with a body mass index of more than 30 kg/m^2; age older than 40 years; preexisting medical conditions (renal disease or pregestational diabetes mellitus, systemic lupus erythematosus, or antiphospholipid antibody syndrome); or a history of preeclampsia, fetal growth restriction, or placental abruption; and in those conceiving after assisted reproductive techniques, with multifetal pregnancies. Hypertension usually does not develop until the second half of gestation, sometimes accompanied by new-onset significant proteinuria (excretion of 3 g of protein over 24 hours) and maternal organ dysfunction or uteroplacental dysfunction.

TABLE 90.4

Classification of Hypertension in Pregnancy*

HYPERTENSION TYPE	DEFINITION AND/OR DESCRIPTION
Chronic hypertension	Hypertension (blood pressure ≥ 140 mm Hg systolic or ≥ 90 mm Hg diastolic) predating pregnancy or diagnosed before 20 weeks of gestation May have associated family history of hypertension or overweight or obesity Secondary causes of hypertension need to be excluded
Gestational hypertension	New hypertension (blood pressure ≥ 140 mm Hg systolic or ≥ 90 mm Hg diastolic) arising after the 20th week of pregnancy and without any of the abnormalities that define preeclampsia (see below) Progresses to preeclampsia in about 25% of cases Blood pressure often normalizes by 12 weeks' postpartum
Preeclampsia (de novo or superimposed on chronic hypertension)	Hypertension developing after 20 weeks' gestation plus one of more of the following variables: Proteinuria Other maternal organ dysfunction: Renal insufficiency Liver involvement (elevated transaminases and/or severe right upper quadrant or epigastric pain) Neurologic complications (eclampsia, altered mental status, blindness, stroke, or more commonly hyperreflexia when accompanied by clonus, severe headaches when accompanied by hyperreflexia, persistent visual scotomata) Hematologic complications (thrombocytopenia, disseminated intravascular coagulation, hemolysis) Uteroplacental dysfunction Fetal growth restriction
White coat hypertension	Diagnosis confirmed by demonstrating normal blood pressure using 24 h ambulatory blood pressure monitoring Occurs in approximately one in four clinic patients

*Based on Tranquilli AL, Dekker G, Magee L, et al. The classification, diagnosis and management of the hypertensive disorders of pregnancy: a revised statement from the ISSHP. *Pregnancy Hypertens*. 2014;4:97-104.

Various professional societies have guidelines on the diagnosis and management of hypertensive disorders in pregnancy, including the American Society of Obstetrics and Gynecology,[54] the Society of Obstetrics and Gynecology of Canada,[55] the Society of Obstetric Medicine of Australia and New Zealand,[56] and the International Committee of the International Society for the Study of Hypertension in Pregnancy.[57] Although antihypertensive medications are effective in treating chronic hypertension that has worsened during pregnancy, they are not effective in preventing the progression of preeclampsia. To reduce the likelihood of preeclampsia, women considered to be at increased risk should be given low-dose aspirin (starting > 16 weeks' gestation), and calcium supplements should be given to calcium-depleted individuals. When preeclampsia develops, women should be admitted to the hospital, with close

monitoring by maternal fetal medicine or obstetric medicine specialists. Hypertension is usually treated with oral antihypertensive agents; commonly used drugs are labetalol, nifedipine, hydralazine, and methyldopa. A blood pressure above 160 to 170 mm Hg systolic and 110 mm Hg diastolic requires urgent treatment. Intravenous labetalol or hydralazine can be used in this setting. Magnesium sulfate often is administered to prevent eclamptic seizures and for fetal neuroprotection if the fetus is premature. Women presenting with preeclampsia after 37 weeks' gestation are delivered. Women with severe forms of preeclampsia and/or HELLP syndrome (*h*emolysis, *e*levated *l*iver enzymes and *l*ow *p*latelet count), regardless of gestational age, are delivered as soon as the mother is stabilized. Women presenting with milder forms of preeclampsia before 37 weeks are often managed conservatively unless the blood pressure cannot be controlled or there is pulmonary edema; new-onset neurologic symptoms; progressive liver, renal, or platelet abnormalities; placental abruption; or nonreassuring cardiotocography and/or ultrasound findings. The blood pressure usually normalizes rapidly after delivery, but it can increase between days 3 and 10 after pregnancy, warranting close monitoring in the postpartum period.

Arrhythmias (see also Chapters 32 and 36)

Because of the physiologic changes of pregnancy, the heart may be more vulnerable to arrhythmias during this time. Potential contributing factors include the increase in preload, causing more myocardial irritability; increased heart rate, which may affect the refractory period; fluid and electrolyte shifts; and changes in catecholamine levels. Worsening of arrhythmias is not a consistent feature, however, and many women with a history of tachycardia may not notice any change in the frequency of symptoms. The presenting symptom complex may be difficult to separate from the normal symptoms of pregnancy, including a sensation of fast heartbeat and skipped beats, which most commonly are supraventricular ectopic complexes. The general approach should include taking a careful history, looking for any precipitating causes, and ruling out any concomitant medical problems (i.e., thyroid disease) by performing appropriate laboratory tests, such as a complete blood count, electrolyte level measurement, and thyroid function determination. A transthoracic echocardiogram will help define whether the arrhythmia occurs in the setting of structural heart disease. In the absence of underlying cardiac disease, pharmacologic treatment should be administered if the patient is symptomatic or if the arrhythmia poses a risk to mother or baby.

Supraventricular Arrhythmias (see also Chapter 37)

Supraventricular arrhythmias are common arrhythmias encountered during pregnancy. They occur in women with structurally normal hearts and in women with preexisting cardiac disease. In general, treatment is the same as for nonpregnant women, but with added concern about medication effects on the fetus (**see Table 90.2**). Maintenance of the sinus rhythm is the preferred strategy for most pregnant women with supraventricular tachycardia. For drug therapy in general, the lowest dose necessary to treat the arrhythmia should be administered, with periodic evaluation of whether it is necessary to continue treatment. Intravenous adenosine usually is the drug of choice for supraventricular reentry tachycardias if vagal maneuvers fail. Atrial fibrillation (**see Chapter 38**) may be an indication of an underlying structural heart disease such as mitral stenosis. In women with structural heart disease and atrial fibrillation, treatment of

the atrial arrhythmia and anticoagulation are both necessary. Oral beta blockers and digoxin have been used in many pregnant women and can be safely used to prevent recurrences. There is less experience with other antiarrhythmic agents (**see Chapter 36**) during pregnancy. If a woman is unstable or if the

arrhythmia is unresponsive to medical therapy, electrical cardioversion can be performed during pregnancy. Some experts recommended use of fetal monitoring at the time of elective cardioversion, in case transient fetal bradycardia occurs. Catheter ablation is almost never necessary, but when it is, catheter ablation without fluoroscopic guidance should be considered if possible.

Ventricular Tachycardia (see also Chapter 39)

Ventricular tachycardia is relatively uncommon during pregnancy. Women with idiopathic or outflow tract ventricular tachycardia may come to attention when they present with symptoms during pregnancy. These women have a structurally normal heart and their outcome is usually good with medical therapy. Ventricular tachycardia, syncope, and sudden death can occur in women with a long QT syndrome, specifically in the postpartum period (**see Chapter 33**). A study of 391 women with a long QT syndrome demonstrated that cardiac events (syncope, aborted cardiac arrest, or sudden cardiac death) were 2.7 times more common in the 9-month postpartum period compared with the pregnancy period.[58] Women with a long QT2 are at higher risk for cardiac complications than women with a long QT1 or QT3. Beta-blocker therapy significantly decreases the risk of serious cardiac events. All women with a long QT syndrome should receive beta blockers during pregnancy and in the postpartum period. Ventricular tachycardia may also occur in women with cardiomyopathies, ischemic heart disease, valvular heart disease, or congenital heart disease.

The treatment of ventricular tachycardia depends on the underlying cardiac condition and the hemodynamic status of the mother. Electrical cardioversion should be performed in women with hemodynamic compromise. Women with idiopathic ventricular tachycardia often respond to beta blockers or calcium channel blockers. Treatment of ventricular tachycardia in pregnant women with structural heart disease should be decided upon in consultation with an electrophysiologist.

Contraception

Addressing contraception options is an important aspect of the care of female patients with cardiac disease. Contraceptive advice should be given before women become sexually active. This is particularly important for adolescents with congenital heart disease or other inherited cardiac conditions, who, like others in this age group, often become sexually active. For some women, pregnancy may carry a high risk of morbidity and even death and detailed advice about various contraceptive methods and their effectiveness is very important. Selecting an optimal form of contraception should be individualized, with consideration of the likelihood of compliance and contraception safety and effectiveness. Emergency oral contraception (the “morning-after” pill) is safe for women with heart disease.

Condoms help protect and are safe for women with heart disease; however, the recognized failure rate is approximately 15 pregnancies/100 woman-years of use. The decision to use a barrier method, therefore, depends on how critical it is for the woman to avoid pregnancy. Intrauterine devices are safe for most women with heart disease and are an effective form of contraception, with low failure rates. A vasovagal response occurring in a patient with pulmonary arterial hypertension, such as Eisenmenger syndrome, could be life-threatening, and many physicians therefore avoid use of IUDs in such patients. Combination estrogen-progesterone oral preparations may not be safe for all women with heart disease. Combined oral contraceptive pills have an extremely low failure rate, and for this reason, as well as their ease of use, these agents are widely taken. For the woman with heart disease, however, an important concern is the associated increased risk of venous thromboembolism, atherosclerosis, hyperlipidemia,

hypertension, and ischemic heart disease, particularly in women who are older than 40 years and those who smoke. In addition, women with congenital heart disease who have cyanosis, atrial fibrillation or flutter, mechanical prosthetic heart valves, or a Fontan circulation probably should avoid estrogen-containing preparations. Patients with significantly impaired ventricular function from any cause or with a history of any previous thromboembolic event should avoid estrogen. Progesterone-only contraceptives are likely safe for most women with heart disease but are less reliable than combined preparations. Other contraceptive modalities include transdermal patches containing estrogen and progesterone and injectable preparations, both of which have similar efficacy rates. Injectable progesterone, given once every 3 months, is a reasonable option for women with heart disease. Subdermal implants, which are inserted into the arm, also are available. Fluid retention and irregular menstruation may be problematic, but cardiovascular contraindications are otherwise the same as those for progesterone. Tubal sterilization can be performed laparoscopically or through a laparotomy approach. For patients with tenuous cardiac hemodynamics, some risk of cardiac instability is likely, and cardiac anesthesia may be preferable. For patients with pulmonary hypertension or Fontan physiology, general anesthesia may be hazardous, and insufflation of the abdomen may elevate the diaphragm, thereby contributing to unstable cardiorespiratory function. Tubal sterilization can be safely accomplished with the use of an intrafallopian plug, which is inserted endoscopically.[59]

Future Perspectives

There have been significant advances in our understanding of pregnancy outcomes and risk stratification over the past two decades. Although pregnancy outcomes remain unknown for some rare cardiac conditions, in newly discovered genetic diseases and in women with new congenital cardiac phenotypes (i.e., those with hypoplastic left heart syndrome), the current assembly of large multicenter cohorts will likely help to define outcomes in these populations in the future. Despite our improved understanding of pregnancy risks, this information continues to be poorly conveyed to women, and tools to improve patient education still need to be developed. Except in the field of hypertensive disorders, randomized trials addressing treatment of heart disease in the pregnant patient are lacking. Although challenging, randomized trials will eventually be needed to define optimal treatment strategies for some conditions in the pregnant population. Finally, maternal mortality rates from cardiac causes have increased worldwide, and many of these deaths can be prevented.[5] In some parts of the world, access to care or to trained medical professionals is not yet available. Developing systems to improve maternal cardiac care on a global scale must be a focus for the future.

Guidelines

Pregnancy and Heart Disease

Candice K. Silversides and Carole A. Warnes

General Management Principles

The European Society of Cardiology (ESC) guidelines on the management of cardiovascular diseases

during pregnancy are a comprehensive set of recommendations pertaining to the care of pregnant women with cardiovascular disease.[1] General recommendation for preconception counseling, antenatal care, and delivery in pregnant women with heart disease are shown in **Table 90.G1**.

TABLE 90.G1

European Society of Cardiology Guidelines on the Management of Cardiovascular Diseases During Pregnancy: General Recommendations for the Care of the Pregnant Women with Heart Disease

CLASS	LEVEL OF EVIDENCE	RECOMMENDATION
Preconception Counseling		
I	C	Prepregnancy risk assessment and counseling is indicated in all women with known or suspected congenital or acquired cardiovascular or aortic disease.
I	C	Genetic counseling should be offered to women with congenital heart disease or congenital arrhythmia, cardiomyopathies, aortic disease, or genetic malformation associated with cardiovascular disease.
Pregnancy Care		
I	C	High-risk patients should be treated in specialized centers by a multidisciplinary team.
I	C	Echocardiography should be performed in any pregnant patient with unexplained or new cardiovascular signs or symptoms.
IIa	C	Magnetic resonance imaging (without gadolinium) should be considered if echocardiography is insufficient for diagnosis.
IIb	C	A chest radiograph with shielding of the fetus may be considered if other methods are not successful in clarifying the cause of dyspnea.
IIb	C	Cardiac catheterization may be considered with very strict indications, timing, and shielding of the fetus.
Labor and Delivery		
I	C	For the prevention of infective endocarditis in pregnancy, the same measures should be used as in the nonpregnant patient.
I	C	Vaginal delivery is recommended as the first choice in most patients.
IIa	C	In patients with severe hypertension, vaginal delivery with epidural analgesia and elective instrumental delivery should be considered.
IIa	C	Cesarean delivery should be considered for obstetric indications or for patients with dilation of the ascending aorta of more than 45 mm, severe aortic stenosis, preterm labor while taking oral anticoagulants, Eisenmenger syndrome, or severe heart failure.
IIb	C	Cesarean delivery may be considered in Marfan patients with an aortic diameter of 40 to 45 mm.
III	C	Prophylactic antibiotic therapy during delivery is not recommended.

Modified from Regitz-Zagrosek V, Blomstrom Lundqvist C, Borghi C, et al. ESC guidelines on the management of cardiovascular diseases during pregnancy: the Task Force on the Management of Cardiovascular Diseases during Pregnancy of the European Society of Cardiology (ESC). Eur Heart J 2011;32:3147-97.

Specific Cardiovascular Conditions

Adult Congenital Heart Disease

Recommendations for the care of pregnant women with congenital heart disease are available in the American College of Cardiologists/American Heart Association (ACC/AHA) guidelines for the management of adults with congenital heart disease,[2] an AHA scientific statement on the management of pregnancy in patients with complex congenital heart disease,[3] the ESC guidelines on the management of cardiovascular diseases during pregnancy,[1] and the Canadian Cardiovascular Society consensus conference on the management of adults with congenital heart disease.[4-6] These guidelines address pregnancy recommendations for women with simple shunt lesions, congenital valve disease, and other complex congenital heart conditions, including Eisenmenger syndrome.

Marfan Syndrome

The ACC/AHA/American Association for Thoracic Surgery (AATS) guidelines for the diagnosis and management of patients with thoracic disease and the ESC guidelines on the management of cardiovascular diseases during pregnancy[1] provide recommendations for the care of pregnant women with Marfan syndrome. In order to determine pregnancy risk, imaging of the entire aorta (CT/MRI) should be performed before pregnancy in patients with Marfan syndrome or any other known aortic disease. Women

with Marfan syndrome and aortic dilatation should deliver in a center where cardiothoracic surgery is available.

Differing thresholds for prophylactic aortic replacement in women with Marfan syndrome have been suggested. The ESC suggests that prophylactic surgery be performed in women with an aortic diameter of 4.5 cm or more.[1] The ACC/AHA/AATS guidelines for the diagnosis and management of patients with thoracic aortic disease suggest that it is reasonable to prophylactically replace the aortic root and ascending aorta if the diameter is more than 4 cm.

Valvular Heart Disease

The ACC/AHA guidelines for the management of patients with valvular heart disease provide recommendations for the care of the pregnant women with native valve disease.[7] Recommendations for pregnant women with stenotic valve lesions are shown in **Table 90.G2,** and indications for valve interventions during pregnancy are shown in **Table 90.G3**. Similar guidelines are available from the ESC.[1]

TABLE 90.G2

ACC/AHA Guidelines for the Management of Patients with Valvular Heart Disease: Pregnancy in Women with Native Valve Stenosis

CLASS OF RECOMMENDATION	LEVEL OF EVIDENCE	RECOMMENDATIONS
I	C	All patients with suspected valve stenosis should undergo a clinical evaluation and transthoracic echocardiography before pregnancy.
I	C	All patients with severe valve stenosis (stages C and D) should undergo prepregnancy counseling by a cardiologist with expertise in managing patients with valvular heart disease during pregnancy.
I	C	All patients referred for a valve operation before pregnancy should receive prepregnancy counseling by a cardiologist with expertise in managing patients with valvular heart disease during pregnancy about the risks and benefits of all options for operative interventions, including a mechanical prosthesis, a bioprosthesis, and valve repair.
I	C	Pregnant patients with severe valve stenosis (stages C and D) should be monitored in a tertiary care center with a dedicated heart valve team of cardiologists, surgeons, anesthesiologists, and obstetricians with expertise in the management of high-risk cardiac patients during pregnancy.
IIa	C	Exercise testing is reasonable in asymptomatic patients with severe aortic stenosis (aortic velocity ≥ 4 m/sec or mean pressure gradient ≥ 40 mm Hg, stage C) before pregnancy.
I	C	Anticoagulation should be given to pregnant patients with mitral stenosis and atrial fibrillation unless contraindicated.
IIa	C	Use of beta blockers as required for rate control is reasonable for pregnant patients with mitral stenosis in the absence of contraindication if tolerated.
IIb	C	Use of diuretics may be reasonable for pregnant patients with mitral stenosis and heart failure symptoms (stage D).
III	B	Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers should not be given to pregnant patients with valve stenosis.

From Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACC Guidelines for the Management of Patients with Valvular Heart Disease: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. Circulation 2014;129:2440-92.

TABLE 90.G3

ACC/AHA Guidelines for the Management of Patients with Valvular Heart Disease: Valve Interventions in Pregnant Women

CLASS OF RECOMMENDATION	LEVEL OF EVIDENCE	RECOMMENDATIONS
I	C	Valve intervention is recommended before pregnancy for symptomatic patients with severe aortic stenosis (aortic velocity ≥ 4.0 m/sec or mean pressure gradient ≥ 40 mm Hg, stage D).
I	C	Valve intervention is recommended before pregnancy for symptomatic patients with severe mitral stenosis (mitral valve area ≤ 1.5 cm^2, stage D).
I	C	Percutaneous mitral balloon commissurotomy is recommended before pregnancy for asymptomatic patients with severe mitral stenosis (mitral valve area ≤ 1.5 cm^2, stage C) who have valve morphology favorable for percutaneous mitral balloon commissurotomy.
IIa	C	Valve intervention is reasonable before pregnancy for asymptomatic patients with severe aortic stenosis (aortic velocity ≥ 4.0/sec or mean pressure gradient ≥ 40 mm Hg, stage C).
IIa	B	Percutaneous mitral balloon commissurotomy is reasonable for pregnant patients with severe mitral stenosis (mitral valve area ≤ 1.5 cm^2, stage D) with valve morphology favorable for percutaneous mitral balloon commissurotomy who remain symptomatic with NYHA class III to IV heart failure symptoms despite medical therapy.
IIa	C	Valve intervention is reasonable for pregnant patients with severe mitral stenosis (mitral valve area ≤ 1.5 cm^2, stage D) and valve morphology not favorable for percutaneous mitral balloon commissurotomy only if there are refractory NYHA class IV heart failure symptoms.
IIa	B	Valve intervention is reasonable for pregnant patients with severe aortic stenosis (mean pressure gradient ≥ 40 mm Hg, stage D) only if there is hemodynamic deterioration or NYHA class III to IV heart failure symptoms.
III	C	Valve operation should not be performed in pregnant patients with valve stenosis in the absence of severe heart failure symptoms.

From Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACC Guideline for the Management of Patients with Valvular Heart Disease: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. Circulation 2014;129:2440-92.

Women with mechanical heart valves are at high risk for complications during pregnancy. An important aspect of care for pregnant women with mechanical valves concerns anticoagulation therapy. There is no universal consensus on the management of anticoagulation for these women; all are associated with a potential risk. Possible anticoagulation options include vitamin K antagonists, low-molecular-weight heparin, unfractionated heparin, or a combination of vitamin K antagonists and heparin. In general, the maternal risk is lowest with vitamin K antagonists and the fetal risk is lowest with heparin. The ACC/AHA guidelines for the management of patients with valvular heart disease,[7] ESC guidelines on the management of cardiovascular diseases during pregnancy,[1] and American College of Chest Physicians guidelines on antithrombotic therapy and prevention of thrombosis[8] all provide recommendations for the management of anticoagulation in women with mechanical valves during pregnancy. The specific recommendations from the ACC/AHA are shown in **Table 90.G4**. All women with mechanical prosthetic heart valves should be cared for at tertiary care centers by a multidisciplinary team with expertise in pregnancy and heart disease.

TABLE 90.G4

ACC/AHA Guideline for the Management of Patients with Valvular Heart Disease: Anticoagulation in Pregnant Women with Mechanical Valves

CLASS OF RECOMMENDATION	LEVEL OF EVIDENCE	RECOMMENDATIONS
I	B	Therapeutic anticoagulation with frequent monitoring is recommended for all pregnant patients with a mechanical prosthesis.
I	B	Warfarin is recommended in pregnant patients with a mechanical prosthesis to achieve a therapeutic international normalized ratio (INR) in the second and third trimesters.
I	C	Discontinuation of warfarin with initiation of intravenous unfractionated heparin (with an activated partial thromboplastin time [aPTT] > 2 times control) is recommended before planned vaginal delivery in pregnant patients with a mechanical prosthesis.
I	C	Low-dose aspirin (75 to 100 mg) once per day is recommended for pregnant patients in the second and third trimesters with either a mechanical prosthesis or bioprosthesis.
IIa	B	Continuation of warfarin during the first trimester is reasonable for pregnant patients with a mechanical prosthesis if the dose of warfarin to achieve a therapeutic INR is 5 mg/day or less after full discussion with the patient about risks and benefits.
IIa	B	Dose-adjusted low-molecular-weight heparin at least 2 times per day (with a target anti-Xa level of 0.8 U/mL to 1.2 U/mL, 4 to 6 hours postdose) during the first trimester is reasonable for pregnant patients with a mechanical prosthesis if the dose of warfarin is greater than 5 mg/day to achieve a therapeutic INR.
IIa	B	Dose-adjusted continuous intravenous unfractionated heparin (with an aPTT at least 2 times control) during the first trimester is reasonable for pregnant patients with a mechanical prosthesis if the dose of warfarin is greater than 5 mg/day to achieve a therapeutic INR.
IIb	B	Dose-adjusted low-molecular-weight heparin at least 2 times per day (with a target anti-Xa level of 0.8 U/mL, 4 to 6 hours postdose) during the first trimester may be reasonable for pregnant patients with a mechanical prosthesis if the dose of warfarin is 5 mg/day or less to achieve a therapeutic INR.
IIb	B	Dose-adjusted continuous infusion of unfractionated heparin (with an aPTT of at least 2 times control) during the first trimester may be reasonable for pregnant patients with a mechanical prosthesis if the dose of warfarin is 5 mg/day or less to achieve a therapeutic INR.
III	B	Low-molecular-weight heparin should not be administered to pregnant patients with mechanical prostheses unless anti-Xa levels are monitored 4 to 6 hours after administration.

From Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACC Guideline for the Management of Patients With Valvular Heart Disease: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. Circulation 2014;129:2440-92.

Cardiomyopathies

Guidelines for the management of pregnant women with cardiomyopathies, including peripartum cardiomyopathy, are available in the ESC guidelines on the management of cardiovascular diseases during pregnancy.[1] Careful preconception assessment is required for all women with cardiomyopathies. Women with severe left ventricular systolic dysfunction are at high risk for complications during pregnancy and should be counseled to avoid pregnancy. Women with clinical heart failure should be treated similarly to standards for nonpregnant patients, with the caveat that some heart failure drugs are contraindicated during pregnancy. Peripartum cardiomyopathy represents a unique condition with potential for full recovery of ventricular function after presentation. The risk of complications in subsequent pregnancies is based on the degree to which the left ventricular systolic function recovers. Pregnancy is not recommended if the left ventricular ejection fraction does not normalize.[1]

Hypertension

Guidelines on the diagnosis and management of hypertensive disorders in pregnancy have been published by a number of professional societies, including the American Society of Obstetrics and Gynecology,[9] Society of Obstetrics and Gynecology of Canada,[10] Society of Obstetric Medicine of Australia and New Zealand,[11] International Committee of the International Society for the Study of Hypertension in Pregnancy,[12] and ESC.[1]

Arrhythmias

In pregnant women who are unstable due to a tachyarrhythmia, direct-current cardioversion or defibrillation is recommended. Antiarrhythmic therapy is typically reserved for symptomatic patients or

those in whom tachycardia causes hemodynamic compromise. The ACC/AHA/Heart Rhythm Society (HRS) guidelines for the management of adult patients with supraventricular tachycardia[13] and the ESC guidelines on the management of cardiovascular diseases during pregnancy[1] provide recommendations for the management of supraventricular tachycardia in pregnant women. Recommendations for management of supraventricular tachycardia in pregnancy are shown in **Table 90.G5.** The 2006 AHA/ACC/ESC guidelines address atrial fibrillation in the pregnant patient.[14] For women who are stable, quinidine or procainamide may be used for pharmacologic cardioversion. Protection against thromboembolism is recommended throughout pregnancy and should be chosen with regard to the stage of pregnancy.

TABLE 90.G5

ACC/AHA Guideline for the Management of Adult Patients with Supraventricular Tachycardia: Recommendations for Treatment in Pregnant Patients

CLASS OF RECOMMENDATION	LEVEL OF EVIDENCE	RECOMMENDATIONS
Recommendations for Acute Treatment of Supraventricular Tachycardia (SVT) in Pregnant Patients		
I	C-LD	Vagal maneuvers are recommended for acute treatment in pregnant patients with SVT.
I	C-LD	Adenosine is recommended for acute treatment in pregnant patients with SVT.
I	C-LD	Synchronized cardioversion is recommended for acute treatment in pregnant patients with hemodynamically unstable SVT when pharmacologic therapy is ineffective or contraindicated.
IIa	C-LD	Intravenous metoprolol or propranolol is reasonable for acute treatment in pregnant patients with SVT when adenosine is ineffective or contraindicated.
IIb	C-LD	Intravenous verapamil may be reasonable for acute treatment in pregnant patients with SVT when adenosine and beta blockers are ineffective or contraindicated.
IIb	C-LD	Intravenous procainamide may be reasonable for acute treatment in pregnant patients with SVT.
IIb	C-LD	Intravenous amiodarone may be considered for acute treatment in pregnant patients with potentially life-threatening SVT when other therapies are ineffective or contraindicated.
Recommendations for Ongoing Management of SVT in Pregnant PatientsPatients		
IIa	C-LD	The following drugs, alone or in combination, can be effective for ongoing management in pregnant patients with highly symptomatic SVT: Digoxin Flecainide Metoprolol Propafenone Propranolol Sotalol Verapamil
IIb	C-LD	Catheter ablation may be reasonable in pregnant patients with highly symptomatic, recurrent, drug-refractory SVT with efforts toward minimizing radiation exposure.
IIb	C-LD	Oral amiodarone may be considered for ongoing management in pregnant patients when treatment of highly symptomatic, recurrent SVT is required and other therapies are ineffective or contraindicated.

Modified from Page RL, Joglar JA, Caldwell MA, et al. 2015 ACC/AHA/HRS Guideline for the Management of Adult Patients with Supraventricular Tachycardia: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines and the Heart Rhythm Society. J Am Coll Cardiol 2016;67:e27-e115.

The AHA/ACC/ESC guidelines for the management of patients with ventricular arrhythmias and prevention of sudden death[15] and the ESC guidelines on the management of cardiovascular diseases during pregnancy[1] provide recommendations for the management of ventricular tachycardia during pregnancy. Pregnant women with ventricular tachycardia or ventricular fibrillation should undergo electrical cardioversion or defibrillation. The AHA guidelines for cardiopulmonary resuscitation and emergency cardiovascular care in special situations[16] address cardiac arrest in pregnancy. There are both maternal and obstetric modifications to consider; however, in general, women should be treated according to the standard basic life support and advanced cardiac life support algorithms. Defibrillation should not be delayed, and typical advanced cardiac life support drugs and dosages should be used. Obstetric and neonatal teams should immediately prepare for possible emergency cesarean delivery. If there is no return of spontaneous circulation after 4 minutes of resuscitative efforts, resuscitation teams must consider performing an immediate emergency cesarean delivery to improve neonatal outcomes.

Cardiovascular Disease in Heterogeneous Populations

Michelle A. Albert, Mercedes R. Carnethon

In an era of unprecedented advances in the detection and management of cardiovascular diseases, disparities in risk and outcome persist, largely defined by race, ethnicity, and socioeconomic status.[1] This chapter provides an overview of the burden of cardiovascular disease, with a focus on hypertension and type 2 diabetes; disease management issues in hypertension, coronary heart disease, and heart failure; and ongoing needs for emerging scientific research to address cardiovascular disparities.

Epidemiology of Cardiovascular Disease in Heterogeneous Populations

Cardiovascular Disease in Racial and Ethnic Groups

According to the 2014 National Health Interview Survey (NHIS), the burden of coronary heart diseases (CHDs) varies only slightly by racial or ethnic group (**Fig. 91.1A**). Rates of CHD incidence are declining twice as quickly in white men (<6.5%/year) as in black men (<3.2%/year); similar patterns are apparent for white women (<5.2%/year) and black women (<4.0%/year).[1] The disparities are most pronounced in

mortality rates; black men were twice as likely to experience fatal CHD as white men (hazard ratio [HR], 2.18; 95% confidence interval [CI], 1.24 to 2.56), and black women were 63% more likely to experience fatal CHD than white women (HR, 1.63; 95% CI, 1.0 to 2.62).[2] Disparities in stroke prevalence and incidence are even more significant (**see Fig. 91.1B**).

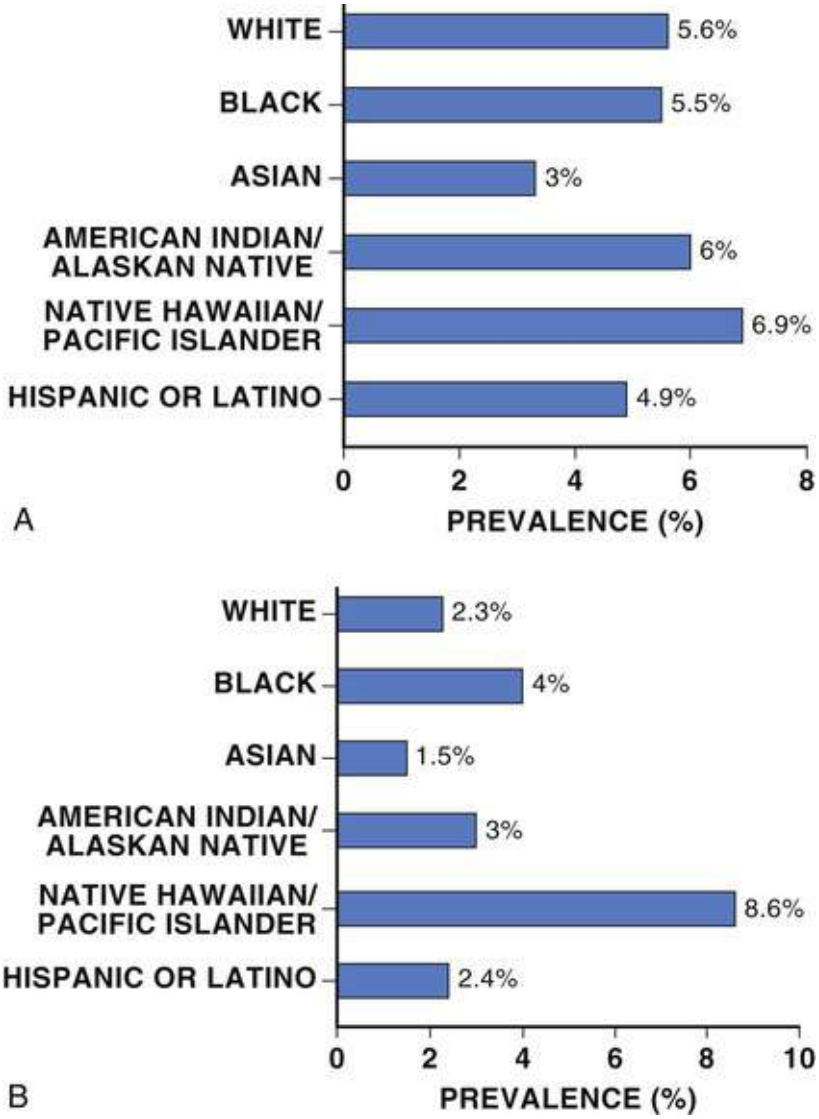

FIGURE 91.1 **A,** Prevalence of coronary heart disease in the United States, 2014. **B,** Prevalence of stroke in the United States, 2014. (From http://ftp.cdc.gov/pub/Health_Statistics/NCHS/NHIS/SHS/2014_SHS_Table_A-1.pdf.)

Hypertension (see also Chapters 46 and 47)

Blacks have higher rates of hypertension than other racial or ethnic groups.[3] Several proposed mechanisms may contribute to an increased incidence in blacks (**Table 91.1**). **Fig. 91.2** presents the epidemiology of hypertension prevalence, awareness, treatment, and control (**see Fig. 91.2A to D**) in the United States and globally. Although rates of awareness in blacks are higher (**see Fig. 91.2C**) than in other groups and blacks use more medications to treat hypertension, blacks have a lower rate of control than other racial or ethnic groups (**see Fig. 91.2D**).[4] American Indian/Alaska Natives (26.4%) also have higher rates of hypertension than Hispanic or Latino adults (22.9%) or Asian adults (19.5%).[5]

TABLE 91.1

Proposed Mechanisms for the Increased Incidence of Hypertension in Blacks

Genetic susceptibility
Socioeconomic status
Renal and cellular salt handling
Dietary Na/K
Alterations in renin-angiotensin-aldosterone system
Vasodilator deficiency
Increased sleep apnea
Low birth weight

Note: Estimates are age-adjusted by the direct method using computed weights based on the subpopulation of persons with hypertension in the 2011–2012. National Health and Nutrition Examination Survey; see reference 7.

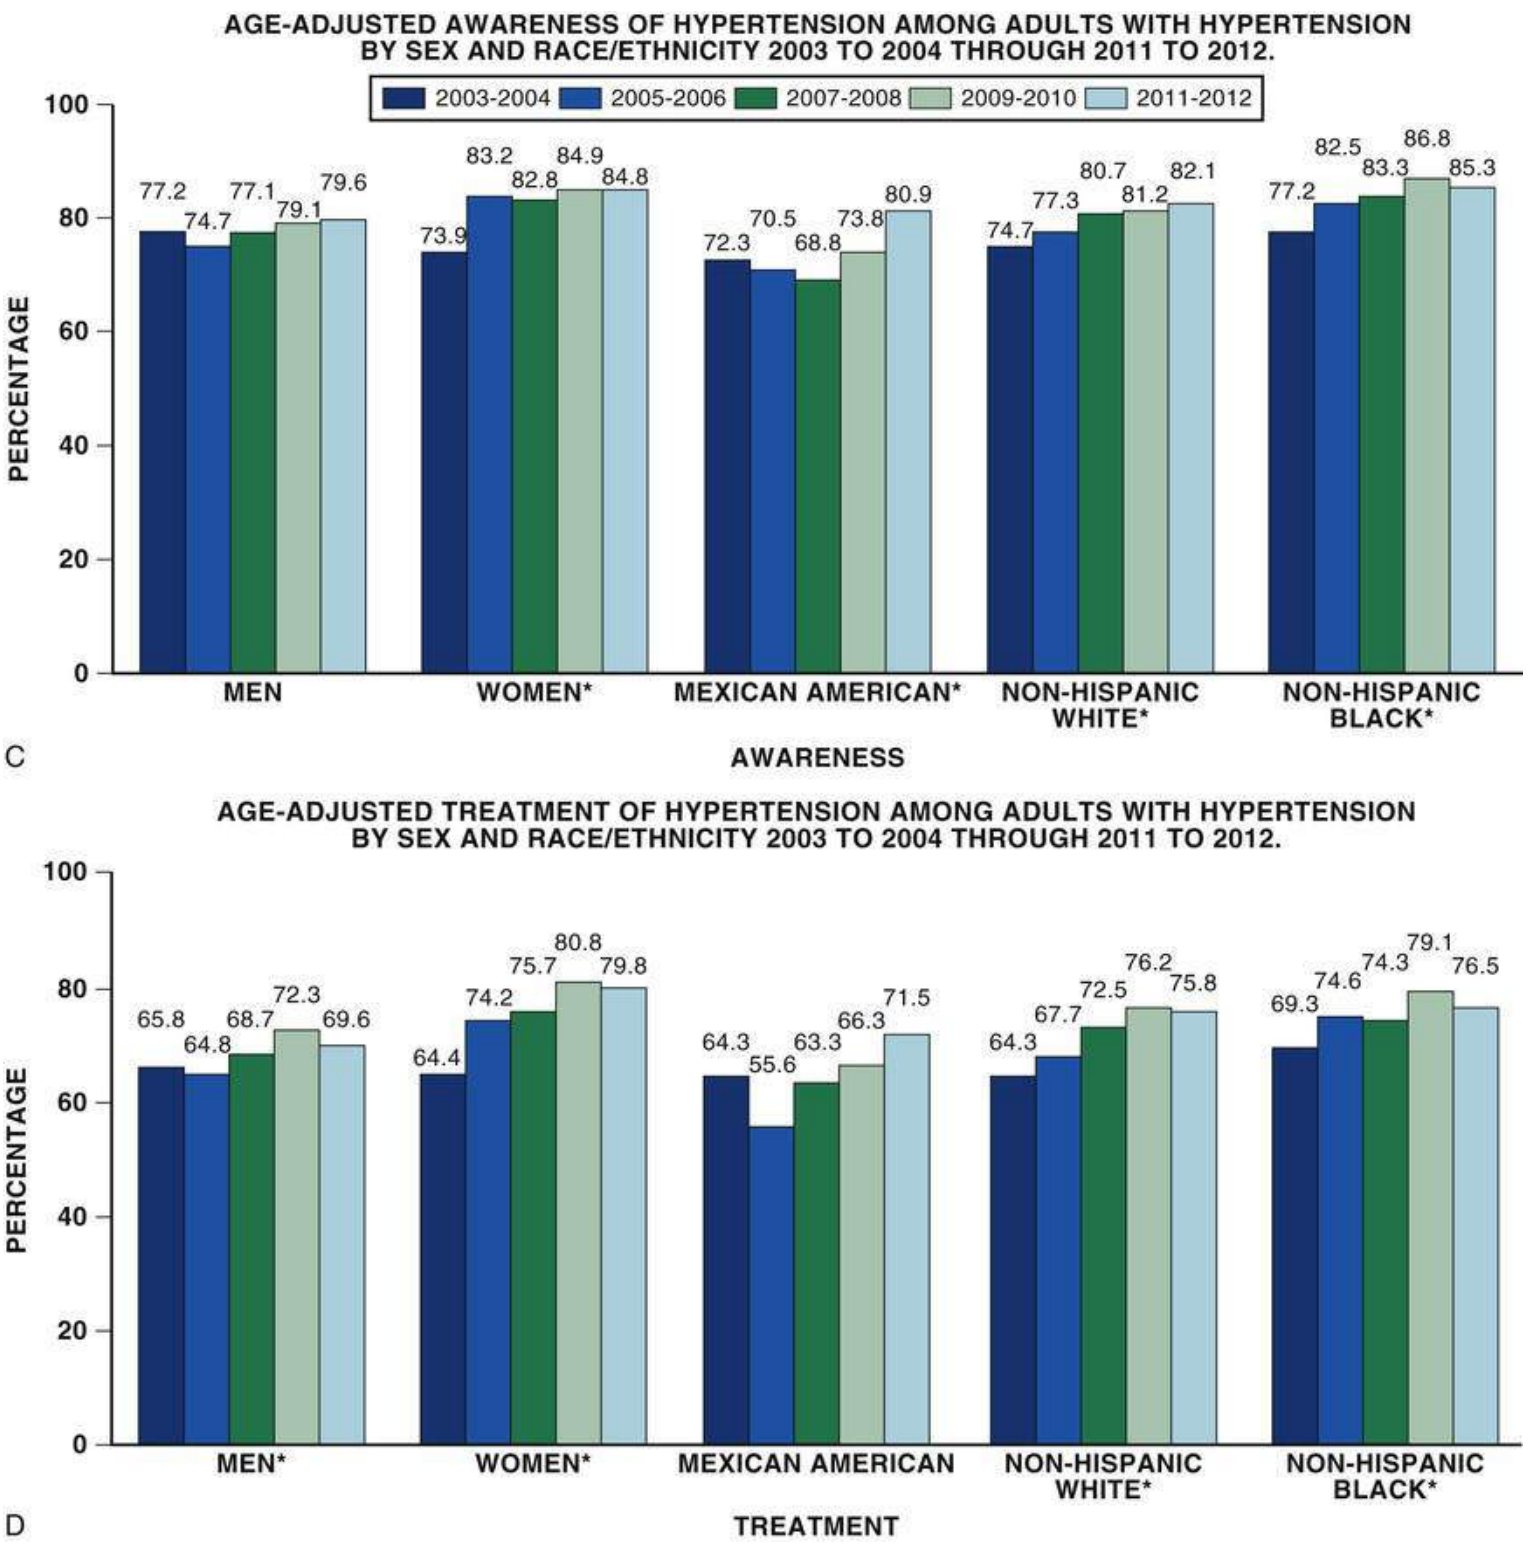

FIGURE 91.2 Epidemiology of adults with hypertension by race/ethnicity, United States. (**A** and **B** adapted from Yoon SS, Carroll MD, Fryar CD. Hypertension prevalence and control among adults, United States, 2011-2014, NCHS Data Brief 2015;220:1-8. **C** and **D** From American Heart Association; adapted from Yoon SS, Gu Q, Nwankwo T, et al. Trends in blood pressure among adults with hypertension: United States, 2003 to 2012, Hypertension 2015;65(1):54-61; and Crim MT, Yoon SS, Ortiz E, et al. National surveillance definitions for hypertension prevalence and control among adults. Circ Cardiovasc Qual Outcomes 2012;5(3):343-51.)

Among Hispanics/Latinos, the hypertension prevalence varies considerably by subgroup. In the Hispanic Community Health Study/Study of Latinos (HCHS/SOL), which measured blood pressure in 16,415 Hispanics/Latinos (but does not include a comparison population of nonHispanics), rates were highest among participants from Cuban, Puerto Rican, and Dominican ethnic backgrounds.[6] Hispanics/Latinos in the HCHS/SOL study were less likely to be aware of their hypertension and less likely to be treated than non-Hispanic whites.[4]

National estimates of hypertension prevalence based on measured blood pressure in Asian Americans are lacking. Amongst the six largest Asian American populations (Asian Indian, Chinese, Filipino, Japanese, Korean, Vietnamese), Filipinos have particularly high rates of hypertension (53.2% to 59.9%), with poor awareness and control rates.[3,7] Filipino patients of older age, those with comorbid medical conditions, and those who did not smoke had improved hypertension treatment, and patients with health insurance had better blood pressure control. These findings suggest that better access to health care and an approach targeted toward multiple risk factors are needed to decrease the hypertension prevalence and risk among Filipinos.[8]

Type 2 Diabetes (see also Chapters 50 and 51)

The overall age-standardized prevalence of diabetes in the U.S. population is 14.3%, but Hispanics/Latinos, blacks, Asians, and American Indian/Alaskan Natives (17.5%) have a higher prevalence than non-Hispanic whites.[9,10]

The diabetes prevalence largely parallels the obesity "epidemic," with evidence of disparities emerging even in childhood.[11] In the Hispanic/Latino community, Dominicans, Puerto Ricans, and Mexicans (17% to 18%) seem to have a higher prevalence than South Americans and Cubans (10% to 13%).[12] This observed variation agrees with genetic research that describes a higher prevalence of diabetes among Hispanics/Latinos with greater African and Native American ancestry.[13] However, emerging research comparing the relative contributions of socioeconomic, environmental, and psychosocial factors, plus ancestry, to diabetes disparities has indicated that socioeconomic factors make up the largest group of mediating factors.[14]

Although the prevalence of diabetes generally parallels the obesity epidemic,[15] that is not the case for Asian Americans. Asian Americans have on average a lower body mass index than other racial or ethnic groups, but, even so, they have evidence of insulin resistance.[15,16,17] Pacific Islanders, South/East Asians, and Filipinos have rates of diabetes at least twofold to threefold higher than whites, and the magnitude of difference is even greater in Chinese, Japanese, Korean, and Vietnamese adults, who had a lower prevalence of diabetes in aggregate than non-Hispanic whites.[7,17] Filipinos and South/East Asians have higher rates of treatment than non-Hispanic whites.[7]

Cardiovascular Disease in Other Population Groups

Persons with psychological conditions and sexual minorities warrant increased attention because of their elevated risks of cardiovascular disease and its effects on health disparities. Psychological conditions including but not limited to anxiety, major depressive disorder, and bipolar disorder affect at least 43.8 million adults, with numerous others who are suffering but are undiagnosed and untreated.[18] This epidemic includes especially vulnerable populations, such as persons of lower socioeconomic status, the homeless, and military veterans.[19] An elevated cardiovascular risk is associated with adverse risk behaviors, isolation, limited contact with the health care system, and downward socioeconomic mobility; medications used to control some forms of mental illness can lead to weight gain and/or sedation, factors that contribute to decreases in motivation for physical activity.[20,21]

Persons whose sexual orientation is lesbian, gay, bisexual, or transgender (LGBT) have not historically been considered "minorities," but they have emerged as a sizeable, distinctive social community. Attention to the unique health needs in the LGBT population have traditionally focused on sexual health and less commonly on cardiovascular disease prevention and management. One exception that reflects the intersection between sexual and cardiovascular health relates to the shift of acquired immunodeficiency

syndrome (AIDS) from an acute illness to a chronic illness, and its associated cardiovascular risks (**see also Chapter 82**). Although the burden of HIV/AIDS is not restricted to sexual minorities, the largest proportion of affected individuals are practicing male homosexuals and nonwhite minority women.[22] Medications used to manage HIV/AIDS have performed well in sparing associated wasting syndromes, but as a result have yielded a higher burden of overweight and obesity and consequent metabolic disorders, including hypertension and diabetes.[23] HIV^+ status (versus HIV− status) is associated with a reduced systolic heart function and an increased prevalence of left ventricular hypertrophy, even after adjustments have been made for metabolic factors. These cardiac changes may predispose individuals with HIV/AIDS to heart failure.[24]

Cardiovascular Disease Management

Hypertension

Lifestyle modification through behavioral intervention that focuses on weight loss, reduced sodium intake, increased physical activity, and reduced alcohol consumption remains the cornerstone of hypertension management. The Systolic Blood Pressure Intervention Trial (SPRINT) studied antihypertensive drug therapy that focused on lowering the systolic blood pressure (SBP) to less than 120 mm Hg rather than to less than 140 mm Hg in 9361 nondiabetic/stroke-free individuals whose SBP was 130 to 180 mm Hg and who had an increased cardiovascular disease risk (≈2%/year). The results showed that there was a 25% lower rate of combined outcomes for myocardial infarction (MI), acute coronary syndrome without MI, stroke, acute decompensated heart failure, or cardiovascular disease death, and a 27% reduced rate of all-cause mortality.[25] Stratified analyses revealed similar results in blacks and nonblacks, with a CI that included 1.0 among blacks. Generalizability of the SPRINT population to the U.S. adult population 50 years old or older using National Health and Nutrition Examination Survey (NHANES) data showed that 4% to 5% of Hispanics and blacks compared with 9% of whites meet eligibility criteria for the study.[26] Nonetheless, approximately 8.5% of blacks and 14.2% of Hispanics with treated hypertension met the blood pressure targets identified in the SPRINT study, a finding that suggests there is substantial room for a hypertension-related cardiovascular disease risk reduction in these groups.

Pharmacotherapy informed by race or ethnicity for black patients favors thiazide diuretics and calcium channel blocker drugs as first-line therapy in a majority of older blacks without contraindications (**Table 91.2**). Yet, data for Hispanics and Asians are limited.[27,28] Ongoing barriers to successful hypertension management in black patients include menthol cigarette smoking, lack of regular health care visits, and insurance issues.[27,28]

Adapted from Still CH, Ferdinand KC, Ogedegbe G, Wright JT Jr. Recognition and management of hypertension in older persons: focus on African Americans. J Am Geriatr Soc 2015;63(10):2130-8.

One of the largest studies to include Hispanic patients (N=8045), the International Verapamil SR/Trandolapril (INVEST; N=8045) trial, demonstrated the effectiveness of both sustained-release verapamil and atenolol in this ethnic group.[29] However, atenolol was associated with increased incident diabetes. Therefore, some argue that because diabetes disproportionately affects the Hispanic population, use of a therapy targeted at the renin-angiotensin-aldosterone system may be more appropriate in Hispanics/Latinos.[30]

The general features of hypertension across the heterogeneous Asian diaspora appear similar. High salt intake, increased salt sensitivity, and more sustained 24-hour blood pressure elevations likely contribute to elevated risks of stroke compared with CHD amongst Asians.[31] The Japanese Society of Hypertension recommends the use of calcium channel blockers, angiotensin-converting enzyme inhibitors, and diuretics as first-line therapy for patients without other compelling indications.[32] Diuretics are recommended for salt-sensitive elderly Japanese patients. Like blacks, South Asian patients develop hypertension at an earlier age and have accelerated end-organ damage compared with whites. Because morbidity and mortality data in South Asians are lacking, management principles resemble those of the general population, including early screening and use of combination therapy.[33]

Coronary Heart Disease

More than 1 million percutaneous coronary interventions (PCIs) are performed annually in the United States for CHD. Blacks and Hispanics have longer wait times and are less likely to undergo PCI than whites, regardless of their insurance status.[34] Data from a large national improvement quality registry,

ACTION Registry-GWTG of STEMI and NSTEMI patients, showed that rates of catheterization were lower for NSTEMI and similar for STEMI in blacks compared with whites.[35] Black patients were also less likely to have coronary artery bypass grafting (CABG). In general, blacks and Hispanics have poorer revascularization outcomes, related to multidimensional influences, including individual, provider, hospital, and societal factors. For example, poorer CABG outcomes among blacks and Hispanics relate in part to hospital quality and socioeconomic factors because poor and racial or ethnic minority patients receive care at lower-performing hospitals, according to standardized quality measures.[36,37] Notably, although little is known about the impact of the United States health care reform on cardiovascular care, racial and ethnic disparities in those who received cardiovascular interventional care persisted after enactment of the Massachusetts health care reform act in 2006.[38]

Use of secondary prevention medications also varies by race and ethnicity: Blacks have 36% lower odds of medication adherence after an acute coronary syndrome.[39] Black and Hispanic women seem to adhere least to medication regimens 1 year following MI, suggesting that there is substantial room for improvement in post-MI care and understanding of treatment barriers in these patients.[40,41] Medication discontinuation is associated with side effects and physician discontinuation advice; higher rates of adherence are related to having private insurance, having assistance with paying for prescriptions, and having an outpatient follow-up appointment scheduled before hospital discharge.

In the context of dual antiplatelet therapy use after drug-eluting stent placement for acute coronary syndrome, there is limited specific data about racial and ethnic groups showing the effectiveness of the drugs and the adverse events that may occur, such as major bleeding. Although genetic and clinical data are sparse, the data that exist show that blacks may have a greater thrombogenic propensity than other groups, as well as a higher prevalence of both arterial and venous thrombosis.[42]

Heart Failure

Blacks have a higher prevalence of heart failure and an earlier onset and presentation than other racial and ethnic groups. Emerging work suggests that there are complex relationships between heart failure with preserved systolic function and race and ethnicity; a study of 13,437 patients (≈86% white, 8% black, and 6% Asian) from four large health systems in the United States demonstrated that although blacks and Asians had a lower risk of death than whites, blacks had more rehospitalizations than other racial and ethnic groups.[43] Data from the Atherosclerosis Risk in Communities (ARIC) study demonstrated that heart failure with systolic dysfunction might be more common in middle-aged blacks, who represented 73% of the heart failure patients in this observational cohort. In contrast with some other databases, in this African American subgroup of ARIC, heart failure with preserved systolic function had an overall better prognosis than heart failure with reduced systolic function. Deaths over a median follow-up period of almost 14 years were 21% for those without heart failure, 31% for those with preserved systolic function heart failure, and 61% for those with reduced systolic dysfunction heart failure.[44]

Impaired vascular function caused by reduced endothelial nitric oxide synthesis and resultant endothelial dysfunction appears to play a key role in the heart failure pathophysiology in blacks.[45] The landmark African-American Heart Failure Trial (A-HeFT) study in 1052 black patients with New York Heart Association class III or IV heart failure showed a 43% reduction in deaths with fixed-dose isosorbide dinitrate and hydralazine treatment compared with placebo against a background of standard heart failure therapy.[45] In a subsequent Genetic Risk Assessment of Heart Failure (GRAHF) substudy of A-HeFT (n=352 patients), the NOS3 Glu298Glu genotype was associated with improvement in the event-

free composite score of survival, hospitalization, and quality of life, in patients treated with isosorbide dinitrate and hydralazine.[46]

Data regarding the prevalence of heart failure and effectiveness of therapeutic options are lacking for Hispanics despite their high prevalence of risk factors and structural heart disease. Among persons of Hispanic/Latino background in the Echocardiographic Study of Latinos (ECHO-SOL), left ventricular systolic and diastolic dysfunction were 3.6% and 50.3%, respectively, with more than 90% of the cardiac dysfunction categorized as subclinical or unrecognized.[47] Central Americans and Cuban Americans had a greater prevalence of diastolic dysfunction than Mexican-Americans. Current American Heart Association/American College of Cardiology (AHA/ACC) guidelines do not propose specific therapy for heart failure based on Hispanic ethnicity.

Information about heart failure in Asians is sparse. **Fig. 91.3** illustrates the potential features of heart failure in Asia. In the United States, data from the GWTG-HF registry showed that Asians with heart failure were more likely to be younger males; to have hypertension, diabetes, and renal disease; and to be uninsured compared with whites.[48]

Potential for Emerging Scientific Research to Address Group Disparities in Cardiovascular Disease

Despite what we have learned about the origin of disparities over the past few decades, disparities appear to be growing rather than shrinking. For areas with available clinical trial data for therapies that effectively treat cardiovascular disease in different racial and ethnic groups, comprehensive delivery and adherence present important challenges. Moreover, efforts to realize the potential of “precision” and “personalized” medicine should also target populations that experience the greatest burden of health disparities, lest unmet needs become more pronounced. Additionally, longitudinal information is needed

on recent immigrant populations, including those from Asia, where the cardiovascular risk varies markedly by country of origin, and those from Africa, where there is a burgeoning epidemic of cardiovascular disease associated with urbanization (**see also Chapter 1**).[49] Specific issues in the near future include scaling, dissemination, and implementation of known effective strategies for prevention and treatment of cardiovascular disease in high-risk heterogeneous populations.

Acknowledgments

The authors thank Anne L. Taylor, Jackson T. Wright, and Ileana L. Piña, coauthors of this chapter from the previous edition of *Heart Disease*, for their contributions.

PART XI
Cardiovascular Disease and Disorders of other Organs

OUTLINE

92

Endocrine Disorders and Cardiovascular Disease

Irwin Klein, Bernadette Biondi

The endocrine system is linked closely with many important cardiovascular diseases. As our understanding of the cellular and molecular effects of various hormones has evolved, we understand better the clinical manifestations that arise from excessive secretion of hormones and from glandular failure and subsequent hormone deficiency states. Recognition of the cardiovascular abnormalities associated with pathologic changes in endocrine glands preceded identification of the specific hormones produced by these glands.

This chapter reviews the spectrum of cardiac disease states that arise from changes in specific endocrine functions. This approach allows us to explore the cellular mechanisms whereby various hormones can alter the cardiovascular system through changes in lipid metabolism and actions on cardiac myocytes, vascular smooth muscle cells, and other target cells and tissues. In addition, this chapter discusses epidemiologic studies and metaanalyses on cardiovascular morbidity and mortality associated with endocrine dysfunction to guide clinicians on the appropriate treatment of affected patients.

Pituitary Hormones and Cardiovascular Disease

The pituitary gland consists of two distinct anatomic portions. The anterior pituitary, or adenohypophysis, contains six different cell types; five of them produce polypeptide or glycoprotein hormones, and one, the sixth, consists of nonsecretory chromophobic cells. Of these cell types, the somatotropic cells, which secrete human growth hormone (hGH), and the corticotropic cells, which produce adrenocorticotropic hormone (ACTH), can contribute to cardiac disease. The posterior pituitary, or neurohypophysis, is the anatomic location of the nerve terminals that secrete vasopressin (antidiuretic hormone), which helps control water balance, and oxytocin, the milk letdown polypeptide.

Growth Hormone

Excessive secretion of hGH and insulin-like growth factor type 1 (IGF-1) by benign pituitary adenomas leads to the clinical syndrome of gigantism in youth, before fusion of the bony epiphysis, and to acromegaly in adults, after maturation of the long bones. hGH exerts its cellular effects through two major pathways. The first is by binding of the hormone to specific hGH receptors on target cells. Such receptors exist in the heart, skeletal muscle, fat, liver, and kidneys, as well as in many additional cell types throughout fetal development.[1] The second growth-promoting effect of hGH results from stimulation of the synthesis of IGF-1. The liver produces most of the IGF-1, but other cell types can produce IGF-1 under the influence of hGH.

Shortly after identification of the IGF family, this second messenger was thought to mediate most actions of hGH. The ability to promote glucose uptake and cellular protein synthesis gave rise to the term “insulin-like.” IGF-1 binds to its cognate IGF-1 receptor, which is localized on almost all cell types. Genetic experiments have demonstrated that the presence of IGF-1 receptors on cell types is linked closely to the ability of these cells to divide. Studies in which the IGF-1 receptor was overexpressed in cardiac myocytes showed that this condition produced an increase in myocyte number and mitotic rate and enhanced the replication of myocytes after differentiation.

Infusion of hGH or IGF-1 acutely changes cardiac function and hemodynamics. The acute increases in cardiac contractility and cardiac output may result, at least in part, from a decrease in systemic vascular

resistance and left ventricular afterload.[2]

Cardiovascular Manifestations of Acromegaly

Acromegaly is a relatively uncommon condition with an annual incidence of 3 to 4 cases per million. Despite its rarity, acromegaly is associated with markedly increased rates of morbidity and mortality; the standardized mortality ratio ranges from 1.3 to 3.[3] About 60% of acromegalic patients develop cardiovascular disease.[4] Hypertension, insulin resistance, diabetes mellitus, and hyperlipidemia are the cardiovascular risk factors associated most frequently with acromegaly.[4-6] Death in acromegalic patients occurs primarily from cardiovascular disease and diabetes, especially in undiagnosed and untreated patients. Only 20% of patients with acromegaly and diabetes will survive 20 years.[7-8] Multiple studies have implicated that increased rates of neoplasia of the gastrointestinal tract, colon polyps, colon cancer, and pulmonary disease are factors in this increased mortality rate[5]; cardiovascular and cerebrovascular events are more frequent contributors to death, however.[7-8] The recently published Endocrine Society Clinical Practice Guidelines recommend that acromegalic patients undergo evaluation for associated comorbidities (hypertension, diabetes mellitus, cardiovascular disease, and sleep apnea).[9]

The cardiovascular and hemodynamic effects of acromegaly vary considerably depending on the patient's age and the disease's severity and duration. A specific acromegalic cardiomyopathy develops in patients with persistently increased secretion of hGH and IGF-1. It can occur even in the absence of cardiovascular risk factors and is manifested as biventricular concentric hypertrophy.[10] As many as two thirds of patients with acromegaly meet echocardiographic criteria for left ventricular hypertrophy (LVH); the right ventricular mass also increases in acromegaly, a finding indicating a more generalized process than systemic hypertension.[10,11] The natural history of this specific cardiomyopathy has three phases.[2] The first phase typically develops in young patients with new-onset acromegaly and involves a hyperkinetic syndrome with increased myocardial contractility and enhanced cardiac output. More evident hypertrophy usually develops during the second phase of cardiomyopathy and is associated with impaired diastolic filling, which reduces the cardiac performance during exercise. Impaired systolic function and low cardiac output progressively develop in the late phase of the disease in patients in whom acromegaly is undiagnosed or undertreated. Heart failure can complicate this late phase of the disease and portends a poor prognosis.[12] Hypertension, type 2 diabetes, and hyperlipidemia may further contribute to impaired contractile function.[13]

The clinical disease activity of patients with an excess of hGH is correlated better with serum levels of IGF-1 than with hGH concentrations. Secondary hypertension accompanies acromegaly and occurs with a mean prevalence of 33% to 46%.[13] The mechanism underlying hypertension in acromegaly remains poorly understood. Administration of hGH promotes sodium retention and volume expansion, and IGF-1 has a potent antinatriuretic effect independent of any effect on aldosterone. Studies of the renin-angiotensin-aldosterone system have shown failure to inhibit release of renin optimally by volume expansion. Both angiotensin-converting enzyme inhibitors and angiotensin receptor blockers can cause a paradoxical increase in blood pressure in patients with acromegaly. Impaired glucose tolerance and diabetes mellitus occur in 15% to 38% of acromegalic patients.[14] The role of hyperinsulinemia in the hypertension associated with acromegaly has been questioned.[14] Although initial reports suggested that accelerated atherosclerosis impairs cardiac function in patients with long-standing acromegaly, a postmortem study revealed significant coronary artery disease in only 11% of patients dying of disease-related causes. Angiography shows normal or dilated coronary arteries in most cases. Fewer than 25% of patients have positive nuclear stress tests, indicating that atherosclerosis and ischemic heart disease do not likely

account for the marked degree of biventricular cardiac hypertrophy, cardiac failure, and cardiovascular death.

Acromegaly increases the prevalence of aortic and mitral valve disease, which persists despite cure of the acromegaly. Progressive mitral regurgitation and increased left ventricular preload and afterload occur in patients with uncontrolled acromegaly. Patients with acromegaly may exhibit dilation of the aortic root.

Abnormalities on the electrocardiogram (ECG), including left axis deviation, septal Q waves, ST-T wave depression, abnormal QT dispersion, and conduction system defects, develop in up to 50% of patients with acromegaly. A variety of dysrhythmias can occur, including atrial and ventricular ectopic beats, sick sinus syndrome, and supraventricular and ventricular tachycardia.[15,16] Monitoring shows a fourfold increase in complex ventricular arrhythmias. Signal-averaged ECGs reveal a parallel rise in late potentials, a finding related to ventricular arrhythmia. Patients with active acromegaly more commonly show these electrophysiologic abnormalities than do treated patients.[16] Patients with newly diagnosed, untreated acromegaly also manifest derangements in cardiac autonomic function, as measured by heart rate recovery and variability.

Diagnosis

In 99% of cases, acromegaly arises from benign adenomas of the anterior pituitary gland. At diagnosis most of these neoplasms are classified as macroadenomas (> 10 mm), and patients have clinical evidence of having had the disease for longer than 10 years. The biochemical diagnosis of acromegaly depends on demonstrating elevated serum IGF-1 levels and the lack of suppression of hGH to less than 1 µg/L following an oral glucose load.[9] Localization of the tumor uses magnetic resonance imaging (MRI) of the pituitary gland or computed tomographic (CT) scanning when MRI is contraindicated or unavailable.

Treatment

Treatment aims to control tumor growth and normalize serum hGH and IGF-1 levels to reduce the risk of premature death and improve the quality of life.[9] Transsphenoidal surgery with resection of the adenoma cures 50% to 70% of patients. Preoperative medical therapy with somatostatin receptor ligands is recommended to reduce the surgical risk in patients with heart failure or severe comorbidities.[9] The cardiovascular complications of acromegaly usually improve with treatment, and survival rates improve significantly in patients achieving disease remission as defined by the normalization of serum IGF-1 and serum hGH levels to less than 1 µg/L.[9] hGH and/or IGF-1 levels that remain elevated after surgery mandate medical therapy.[9] A residual tumor mass following surgery may require radiotherapy if medical therapy is unavailable, unsuccessful, or not tolerated.[9]

Cardiovascular Manifestations of Growth Hormone Deficiency

hGH has an important role in the development of the normal heart and the maintenance of its normal structure and function in adult life.[2] Untreated adult hGH-deficient patients can have cardiac and endothelial dysfunction, insulin resistance, a deranged lipid profile, increased carotid intima-media thickness, elevated inflammatory markers, increased body fat with abdominal obesity, hypercoagulability, and decreased skeletal muscle mass and strength.[17] Patients with hypopituitarism not treated with hGH have a doubled overall mortality rate, principally because of increased cardiovascular mortality rates.[18,19] Early premature atherosclerosis can develop in hypopituitary patients not receiving hGH therapy;

therefore, growth hormone therapy should be continued after a patient with persistent growth hormone deficiency has reached adult height. Growth hormone may have beneficial effects in patients with congestive heart failure due to either ischemic or idiopathic dilated cardiomyopathy.[17-19]

Prolactin Disease

The most common disorder of the anterior pituitary gland is the development of small (< 1 cm), prolactin-producing pituitary adenomas causing amenorrhea and galactorrhea. Prolactin plays an increasingly recognized stimulatory role in inflammation, and prolactin receptors may become localized in human coronary artery plaques, a finding that suggests that prolactin might influence atherogenesis. Because hypothalamic dopamine normally inhibits prolactin secretion, dopamine agonists such as cabergoline and bromocriptine are first-line treatments. Such treatment in prolactin disease has fortunately not been linked with cardiac valvular disease as it has in Parkinson disease.[20] Patients with prolactinoma can have an unfavorable cardiovascular and metabolic risk profile.

Adrenal Hormones and Cardiovascular Disease

Adrenocorticotropic Hormone and Cortisol

The adrenocorticotropic cells in the anterior pituitary synthesize a large protein (proopiomelanocortin), which is processed in the corticotropic cell into a family of smaller proteins that include adrenocorticotropic hormone (ACTH). The adrenal cortex zona glomerulosa produces aldosterone, and the zona fasciculata produces primarily cortisol and some androgenic steroids. The zona reticularis also produces cortisol and androgens. ACTH regulates the synthesis of cortisol in the zona fasciculata and zona reticularis.

Cushing Disease and Cushing Syndrome

Cushing syndrome results from prolonged and inappropriately high exposure of tissues to glucocorticoids.[21] Excessive cortisol secretion and its attendant clinical disease states can arise from excessive release of ACTH by the pituitary (Cushing disease) or through the adenomatous or rarely malignant neoplastic process arising in the adrenal gland itself (Cushing syndrome).[21] Well-characterized conditions of adrenal glucocorticoid and mineralocorticoid excess appear to result from the excessively high levels of (ectopic) ACTH produced by small cell carcinoma of the lung, carcinoid tumors, pancreatic islet cell tumors, medullary thyroid cancer, and other adenocarcinomas and hematologic malignancies.[21] Clinical signs and symptoms of Cushing syndrome often develop in patients treated with exogenous steroids at doses equivalent to 20 mg of prednisone daily for more than 1 month.

Cortisol, a member of the glucocorticoid family of steroid hormones, binds to receptors located within the cytoplasm of many cell types (**Fig. 92.1**). After binding cortisol, these receptors are translocated to the nucleus and function as transcription factors. Several cardiac genes contain glucocorticoid response elements in their promoter regions that confer transcriptional-level glucocorticoid responsiveness. Such genes include those that encode voltage-gated potassium channels, as well as protein kinases, which serve to phosphorylate and regulate the voltage-gated sodium channels. In addition, there are more rapidly acting, nontranscriptional pathways by which cortisol may regulate the activity of voltage-gated potassium channels.

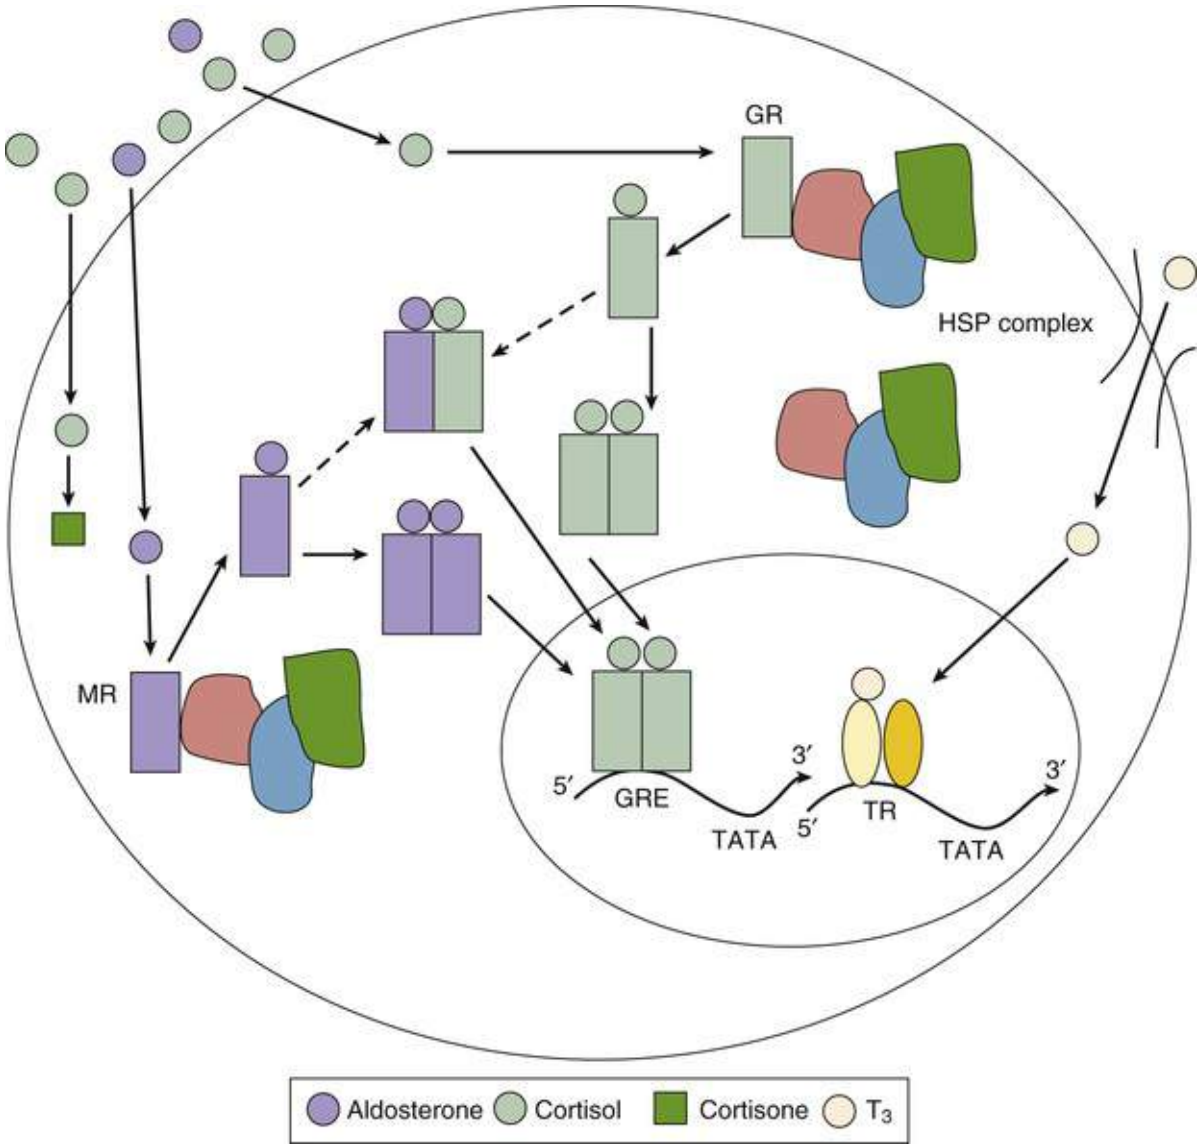

FIGURE 92.1 Schematic representation of a generalized mechanism of action of the nuclear hormone receptor. The mineralocorticoid receptor (MR) has similar affinities for aldosterone and cortisol. Circulating levels of cortisol are 100 to 1000 times greater than those of aldosterone. In MR-responsive cells, the enzyme 11-beta-hydroxysteroid dehydrogenase metabolizes cortisol to cortisone, thereby allowing aldosterone to bind to the MR. The MR and glucocorticoid receptor (GR) are cytoplasmic receptors that after binding ligand, translocate to the nucleus and bind to glucocorticoid response elements (GREs) in the promoter regions of responsive genes. Triiodothyronine (T_3) is transported into the cell via specific membrane proteins and binds to thyroid hormone receptors (TRs), which are bound to thyroid hormone response elements in the promoter regions of T_3-responsive genes. *HSP*, heat shock protein; *TATA*, TATA box promoter region. (Courtesy Dr. S. Danzi.)

The cardiac effects of Cushing syndrome arise from the effects of glucocorticoids on the heart, liver, skeletal muscle, and fat tissue.[22-24] LVH and concentric remodeling can result. Glucocorticoid excess is also associated with left ventricular dysfunction, myocardial fibrosis, and dilated cardiomyopathy.[25] The increased cardiovascular morbidity and mortality rates of Cushing syndrome are largely due to cerebrovascular, peripheral vascular, and coronary artery disease and to chronic congestive heart failure.[22-28] Compared with matched controls, patients with active disease have a hazard ratio (HR) of 6.0 (2.1 to 17.1) for heart failure, 2.1 (0.5 to 8.6) for acute myocardial infarction, and 4.5 (1.8 to 11.1) for stroke.[26-28] Chronic cortisol hypersecretion causes central obesity, hypertension, insulin resistance, dyslipidemia, a prothrombotic state, and the metabolic syndrome. Cortisol-mediated hypertension has multiple mechanisms. The centripetal obesity characteristic of glucocorticoid excess resembles that seen in insulin resistance syndromes. In addition, the marked muscle weakness resulting from corticosteroid-

induced skeletal myopathy contributes to impaired exercise tolerance.

Patients with Cushing disease can exhibit a variety of electrocardiographic changes. The duration of the PR interval appears to be correlated inversely with adrenal cortisol production rates. The mechanism underlying this correlation may be related to expression or regulation of the voltage-gated sodium channel (SCN5A). Changes on the ECG, specifically in the PR and QT intervals, may also arise from the direct (nongenomic) effects of glucocorticoids on the voltage-gated potassium channel (Kv1.5) in excitable tissues.

A particular complex of cardiac and adrenal lesions, referred to as the *Carney complex*, is a combination of Cushing syndrome, cardiac myxoma, and a variety of pigmented dermal lesions (not café au lait spots). This monogenic autosomal dominant trait has been mapped to the q2 region of chromosome 17.[29] Myxomas most commonly occur in the left atrium but can arise throughout the heart, can develop at young ages, and can be multicentric.

Diagnosis

The diagnosis of Cushing disease and Cushing syndrome requires the demonstration of increased cortisol production as reflected by an elevated 24-hour urinary free cortisol level or nocturnal salivary cortisol level.[21] ACTH measurement assesses whether the disease is pituitary, adrenal, or ectopically based; anatomic localization of the suspected lesions with MRI confirms the laboratory findings.

Treatment

Treatment of excessive cortisol production depends on the underlying mechanisms.[30] Initial resection of primary lesion(s) is recommended for underlying Cushing disease (based in the pituitary) and also for Cushing disease related to ectopic and adrenal causes. Transsphenoidal selective adenomectomy with or without postoperative radiation therapy can partially or completely reverse the increased ACTH production by the anterior pituitary. Cushing syndrome requires surgical removal of one adrenal gland (adrenal adenoma, adrenal carcinoma) or both adrenal glands (multiple nodular disease). Immediately after surgery, cortisol and mineralocorticoid (fludrocortisone) need to be replaced to prevent adrenal insufficiency.

Drug therapy before or after surgery can help control persistent cortisol production. Pasireotide can decrease ACTH production from a pituitary tumor. The adrenal enzyme inhibitor ketoconazole may be used alone or in combination with metyrapone to enhance control of severe hypercortisolemia. Mitotane is used primarily to treat adrenal carcinoma. Mifepristone is approved in the United States for people with Cushing syndrome who have type 2 diabetes or glucose intolerance. Mifepristone blocks the direct effect of cortisol on tissues and leads to an improvement in hypertension and/or diabetes in 40% to 60% of patients. Etomidate is useful where immediate parenteral action is required and in seriously ill patients who cannot take oral medications. The goal of therapy is the clinical normalization of cortisol levels.

Primary Hyperaldosteronism (see also Chapter 46)

Aldosterone production by the zona glomerulosa is responsive to the renin-angiotensin system.[30] Renin secretion responds primarily to changes in intravascular volume. Aldosterone synthesis and secretion depend primarily on regulation by angiotensin II, which binds to the angiotensin II type I receptor on cells of the zona glomerulosa.[31] Primary hyperaldosteronism (PA) refers to a group of disorders in which aldosterone production is inappropriately high; production is relatively independent from the major

regulators of secretion (angiotensin II and plasma potassium concentration) and is not suppressible with sodium loading.[32] Common causes of PA include an adrenal adenoma, unilateral or bilateral adrenal hyperplasia, or, in rare cases, an adrenal carcinoma or an inherited condition known as glucocorticoid-remediable aldosteronism.[32]

The mechanism of action of aldosterone on target tissues resembles that reported for glucocorticoids (**see Fig. 92.1**). Aldosterone enters cells and binds to the mineralocorticoid receptor, which then is translocated to the nucleus and promotes the expression of aldosterone-responsive genes. In addition to kidney cells, in which mineralocorticoid receptors control sodium transport, in vitro studies have demonstrated these receptors in rat cardiac myocytes.

In humans, primary aldosteronism causes cardiovascular damage; it can induce development of cardiac hypertrophy, myocardial fibrosis, and diastolic dysfunction.[31-33] Recent prospective studies have reported that more than 10% of hypertensive patients have primary aldosteronism, and that normokalemic hypertension constitutes the most common presentation of the disease.[32] Severe hypokalemia occurs in only a minority of patients (9% to 37%).[32] Primary aldosteronism is associated with higher rates of cardiovascular morbidity and mortality than age- and sex-matched patients with essential hypertension.[32] Primary aldosteronism should be investigated in patients with (1) severe hypertension, (2) treatment-resistant hypertension, (3) hypertension with spontaneous or diuretic-induced hypokalemia, (4) hypertension with adrenal incidentaloma, (5) hypertension and sleep apnea, or (6) a family history of early-onset hypertension or cerebrovascular accident at a young age (< 40 years of age).[32,34,35]

The plasma aldosterone/renin ratio detects possible PA. Patients should have unrestricted dietary salt intake before testing and should be potassium replete.[32-35] Mineralocorticoid receptor antagonists should be withdrawn for at least 4 weeks before testing, especially in patients with mild hypertension. Patients with an abnormal aldosterone/renin ratio undergo one or more confirmatory tests to definitively confirm or exclude the diagnosis.[32,35] After sodium loading, plasma aldosterone levels lower than 5 ng/dL make the diagnosis of PA unlikely. Levels above 10 ng/dL indicate very probable PA.[32] Caution should be used when performing confirmatory tests; patients with spontaneous hypokalemia, plasma renin levels below detection levels, and plasma aldosterone concentrations of more than 20 ng/dL do not require further testing.[32] All patients with suspected disease should undergo adrenal CT to seek adrenocortical carcinoma.[32]

Treatment (see also Chapters 25, 26, 46, and 47)

Patients with primary hyperaldosteronism and hypokalemia should receive slow-release potassium chloride supplementation to maintain plasma potassium. The aldosterone antagonist spironolactone or eplerenone (as a second choice) should be used to control hypertension, hypokalemia, and the deleterious cardiovascular effects of aldosterone hypersecretion.[32] Surgical treatment is practicable in young patients (< age 35 years) with spontaneous hypokalemia, marked aldosterone excess, and unilateral adrenal lesions with evidence of a cortical adenoma on adrenal CT.[32] Adrenal venous sampling before surgery can help to distinguish between unilateral and bilateral adrenal disease. Unilateral laparoscopic adrenalectomy can cure hypokalemia and improve or cure hypertension in such patients.

Patients with bilateral disease and those reluctant to undergo surgery should receive medical treatment with mineralocorticoid receptor antagonists.[32] Genetic testing for familial hyperaldosteronism should be performed in patients with a family history of hypertension and stroke at a young age (< 40 years).[32] Very young patients should be tested for germline mutations in KCNJ5 causing familial hyperaldosteronism type 3.[32]

Addison Disease

Thomas Addison was the first to describe the association of atrophy and loss of function of the adrenal glands with marked changes in the cardiovascular system. Primary adrenal insufficiency occurs when the adrenal cortex cannot produce sufficient glucocorticoids and/or mineralocorticoids.[36] Acute addisonian crisis, one of the most severe endocrine emergencies, is characterized by hypovolemia, hypotension, and acute cardiovascular collapse resulting from renal sodium wasting, hyperkalemia, and loss of vascular tone. Primary adrenal insufficiency arises most commonly from bilateral loss of adrenal function on an autoimmune basis; as a result of infection, hemorrhage, or metastatic malignancy; or in selected cases, from inborn errors of steroid hormone metabolism.[36] Addison disease can occur at any age; it may be associated with other autoimmune disorders (e.g., Hashimoto thyroiditis, type 1 diabetes mellitus, autoimmune gastritis/pernicious anemia, and vitiligo).[36] In contrast, secondary adrenal insufficiency, which results from pituitary-dependent loss of ACTH secretion, leads to a fall in glucocorticoid production; mineralocorticoid production, including aldosterone, remains at relatively normal levels.[36] Studies have addressed the issue of relative hypothalamic-pituitary-adrenal insufficiency in acutely ill patients. Although the actual existence of such an entity and diagnostic criteria for establishing this condition remain to be validated, its possible existence has reopened the question of the need for stress-dose cortisol treatment in the management of patients with critical illness.

The noncardiac symptoms, including increased pigmentation, abdominal pain with nausea and vomiting, hypoglycemia, and weight loss, can be chronic; tachycardia, hypotension, hyponatremia, hyperkalemia, loss of autonomic tone, and cardiovascular collapse and crisis may develop, especially in acutely ill or untreated patients with Addison disease.[36] Delayed treatment of more severe symptoms will increase rates of morbidity and mortality.[37] Blood pressure measurements uniformly show a low diastolic pressure (< 60 mm Hg) along with orthostatic changes that reflect loss of volume and acquired autonomic dysfunction. Laboratory findings (hyponatremia and hyperkalemia) indicate loss of aldosterone production (renin levels are high). Hyperkalemia can alter findings on the ECG by producing low-amplitude P waves and peaked T waves. Patients with newly diagnosed, untreated Addison disease have reduced left ventricular end-systolic and end-diastolic dimensions in comparison with controls. Cardiac atrophy is an unusual condition; it is seen with malnutrition caused by anorexia, in astronauts after prolonged space flight, in populations with sodium-deficient diets, and characteristically with Addison disease (teardrop heart; **Fig. 92.2**). This atrophy reflects a response to decreases in the cardiac workload because restoration of normal plasma volume with mineralocorticoid and glucocorticoid replacement increases ventricular mass.

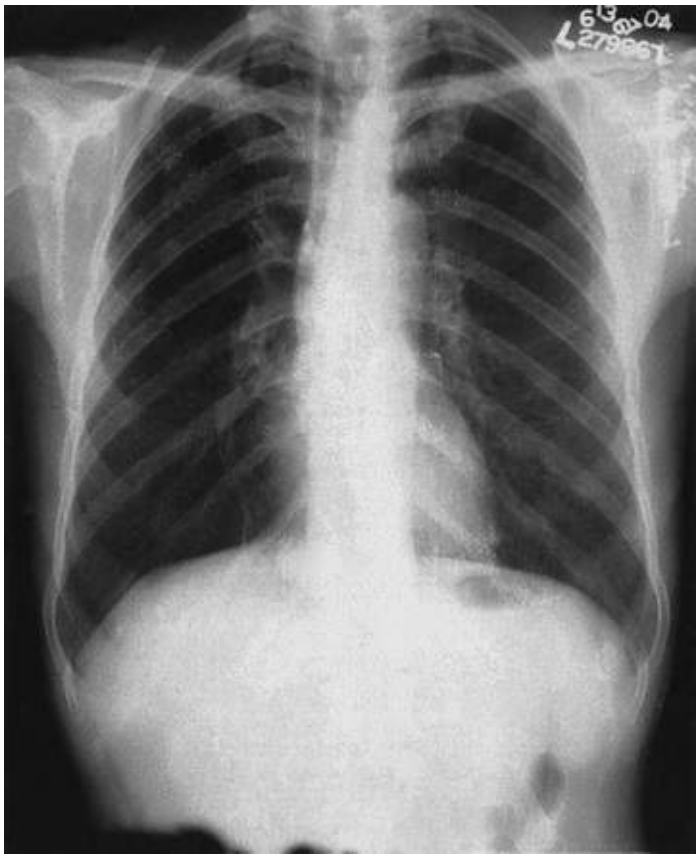

FIGURE 92.2 Routine chest radiograph of a patient with Addison disease related to tuberculosis. In addition to the small cardiac silhouette, calcified lymph nodes are present in the hilum of the right lung. (Courtesy Dr. J.B. Naidich.)

Diagnosis

Acute adrenal insufficiency characteristically occurs in the setting of acute stress, infection, or trauma in a patient with chronic autoimmune adrenal insufficiency or in children with congenital abnormalities in cortisol metabolism. It can also develop as a result of bilateral adrenal hemorrhage in patients with severe systemic infection or diffuse intravascular coagulation.[38] Secondary adrenal insufficiency can occur in the setting of hypopituitarism and is usually chronic, but acute changes caused by pituitary hemorrhage (apoplexy) or pituitary inflammation (lymphocytic hypophysitis) can also occur. Acute adrenal insufficiency can develop in patients treated over a long term with suppressive doses of corticosteroids (> 10 mg of prednisone for > 1 month) if treatment is stopped precipitously or if an acute, severe, non–endocrine-related illness arises.

The diagnostic criteria include low cortisol levels (morning cortisol < 140 nmol/L [< 5 µg/dL]) or cortisol levels that fail to rise above 500 nmol/L (20 µg/dL) 30 or 60 minutes after an intravenous injection of 250 µg of corticotropin.[38] The simultaneous measurement of plasma renin and aldosterone can help to determine whether a mineralocorticoid deficiency is present.

Treatment

Addison disease is a potentially lethal condition.[37,38] Management of acute addisonian crisis requires adequate hydrocortisone replacement therapy (100 mg given as an initial intravenous bolus; then 100 mg every 8 to 12 hours for the first 24 hours, and tapering of the dose over the next 72 to 96 hours).[38] Large volumes of normal saline with 5% dextrose can address the intravascular fluid deficit.[38] Potential underlying precipitating causes (including infection, acute cardiac or cerebral ischemia, or

intraabdominal emergency) require identification and treatment. Long-term treatment of adrenal insufficiency consists of oral corticosteroid therapy (hydrocortisone ≈20 mg in two divided oral doses per day, or prednisone 5 mg administered orally once or twice daily).[38] Patients with confirmed aldosterone deficiency should receive mineralocorticoid replacement with fluorohydrocortisone (starting dose, 50 to 100 µg in adults).[38] Diuretics and aldosterone antagonists, such as spironolactone or eplerenone, should be avoided.[38,39]

Pheochromocytoma

Pheochromocytomas (**see also Chapters 46 and 47**) are primarily benign tumors arising from neuroectodermal chromaffin cells; they usually arise in the adrenal medulla and abdomen, but they may arise anywhere in the plexus of sympathetic adrenergic nerves.[40] Autopsy studies have shown that in 75% of patients the diagnosis was not clinically suspected and that in more than 50% of patients it contributed to death. Most pheochromocytomas are sporadic, but recent data suggest that about 20% are familial.[40,41] Six different familial autosomal dominant diseases can be suspected clinically: neurofibromatosis type 1, multiple endocrine neoplasia type 2 (MEN2), von Hippel-Lindau syndrome, renal cell carcinoma with *SDHB* mutation, *Carney triad* (paragangliomas, gastric stromal tumors, pulmonary chondromas), and *Carney-Stratakis syndrome* (paragangliomas and gastric stromal sarcomas). When pheochromocytoma coexists with medullary thyroid carcinoma or occasionally with hyperparathyroidism, it is designated multiple endocrine neoplasia syndrome type 2A (MEN2A). In patients with MEN2B, pheochromocytomas coexist with medullary thyroid cancer and with mucosal neuromas frequently seen on the lips and tongue.

Clinical manifestations of pheochromocytoma include headache, palpitations, excessive sweating, tremulousness, chest pain, weight loss, and a variety of other constitutional complaints. Hypertension may be episodic but is usually constant and is paradoxically associated with orthostatic hypotension on arising in the morning. The paroxysmal attacks and classic symptoms result from episodic excessive catecholamine secretion.[42,43]

Hypertension caused by pheochromocytoma can first present at the time of elective surgical intervention for an unrelated condition. As a result of release of norepinephrine with an increase in systemic vascular resistance, cardiac output is minimally (if at all) increased despite increases in the heart rate. The ECG can show LVH, as well as repolarization abnormalities, findings suggesting left ventricular strain. Although ventricular and atrial ectopy and episodes of supraventricular tachycardia can occur, little distinguishes the LVH from that of essential hypertension.

Impaired left ventricular function and cardiomyopathy have occurred in patients with pheochromocytoma.[42,43] The mechanism underlying this condition is complex and includes an increased left ventricular work and LVH from associated hypertension; potential adverse effects of excess catecholamines on myocyte structure and contractility; and changes in coronary arteries, including thickening of the media, which presumably impairs blood flow to the myocardium. Postmortem examination of patients with previously diagnosed or undiagnosed disease can show histologic evidence of myocarditis. The possibility of catecholamine-stimulated tachycardia in turn mediating left ventricular dysfunction should be addressed because treatments designed to slow the heart rate may improve left ventricular function. Life-threatening cardiovascular manifestations of pheochromocytoma primarily result from hypertensive emergencies (abnormalities of cardiac rhythm and serious ventricular arrhythmias or conduction disturbances).[42,43] Reversible dilated hypertrophic cardiomyopathy and takotsubo cardiomyopathy are well-established cardiac manifestations of pheochromocytoma.

The primary catecholamine released from adrenal pheochromocytomas is norepinephrine, but

epinephrine can also increase. Demonstration of elevated serum dopamine levels implies malignant transformation, which in turn suggests that the tumor may have arisen in an extraadrenal site and have distinct gene expression profiles. Rarely, pheochromocytoma can arise within the heart, presumably from chromaffin cells, which are part of the adrenergic autonomic paraganglia.

Diagnosis

An increase in norepinephrine, epinephrine, or their metabolites in serum or blood is essential to establish the diagnosis. Quantitative 24-hour urinary fractionated metanephrine levels are the most reliable screening procedures; they provide a sensitivity of 97% and a specificity of 91%.[40] CT is the first-choice imaging modality because of its excellent spatial resolution for the thorax, abdomen, and pelvis.[40] MRI is recommended in patients with metastatic disease and for detection of skull base and neck paragangliomas.[40] ^{131}I-metaiodobenzylguanidine can localize catecholamine-producing lesions, and ^{18}F-fluorodeoxyglucose positron emission tomography scanning can visualize metastatic disease.[40] Genetic testing can aid counseling of patients with established disease and their families.[40]

Treatment

Definitive treatment of pheochromocytoma requires removal of the lesion.[40] Accurate preoperative localization reduces the operative mortality rate and eliminates the need for exploratory laparotomy. Endoscopic procedures are now standard for small tumors, and open resection is indicated for large tumors (e.g., > 6 cm) or invasive pheochromocytomas.[40]

Preoperative pharmacologic treatment should be provided to prevent perioperative cardiovascular complications.[40] It includes 7 to 14 days of alpha-adrenergic blockade (usually with doxazosin, prazosin, or phenoxybenzamine) to normalize the blood pressure. Beta-blocking drugs can normalize the heart rate but should follow the establishment of a sufficient alpha blockade. Before surgical treatment, a high-sodium diet and fluid intake should be started to improve the blood volume contraction and prevent severe hypotension after tumor removal. Operative intervention requires constant blood pressure monitoring, and intravenous phentolamine or sodium nitroprusside may be required to treat episodic hypertension intraoperatively.[40] Gauges of the success of surgery include effective blood pressure and symptom improvement, as well as measurement of urinary catecholamines 4 weeks after the procedure. Lifelong annual biochemical testing to assess for recurrent or metastatic disease is necessary.

Parathyroid Hormones and Cardiovascular Disease

Diseases of the parathyroid glands can produce cardiovascular disease and alter cardiac function through two mechanisms. Parathyroid hormone (PTH) is a protein hormone that can affect the heart, vascular smooth muscle cells, and endothelial cells. PTH-induced changes in serum calcium levels also affect the cardiovascular system.[44]

PTH can bind to its receptor and alter the spontaneous beating rate of neonatal cardiac myocytes through an increase in intracellular cyclic adenosine monophosphate (cAMP). PTH can also alter the calcium influx and cardiac contractility in adult cardiac myocytes and the relaxation of vascular smooth muscle cells. Moreover, a variety of tissues, including cardiac myocytes, produce the structurally related PTH-related peptide (PTHrP). PTHrP can bind to the PTH receptor on cardiac cells and stimulate accumulation of cAMP and contractile activity, as well as regulate L-type calcium currents. Long-term treatment with recombinant human PTH may require monitoring for adverse cardiac effects.

Hyperparathyroidism

In primary hyperparathyroidism, hypercalcemia (or high-normal serum calcium levels) occurs in the presence of inappropriately normal or elevated PTH concentrations because of an overproduction of PTH. Primary hyperparathyroidism producing hypercalcemia most often results from adenomatous enlargement of one of the four parathyroid glands. Cardiovascular actions of hypercalcemia include increased cardiac contractility; shortening of the ventricular action potential duration, primarily through changes in phase 2; and blunting of the T wave and changes in the ST segment, occasionally suggesting cardiac ischemia.[44] The QT interval shortens and occasionally the PR interval decreases. Treatment with digitalis glycosides appears to increase sensitivity of the heart to hypercalcemia.

Hypercalcemia may lead to pathologic changes in the heart, including the myocardial interstitium and conducting system, as well as calcific deposits in the valve cusps, annuli, and possibly coronary arteries. Although initially observed in fairly long-standing and severe hypercalcemia, so-called metastatic calcifications can also occur in secondary parathyroid disease arising from chronic renal failure, in which the serum calcium-phosphorus product constant is exceeded. Patients with primary hyperparathyroidism generally maintain normal left ventricular systolic function, but severe or chronic disease may impair diastolic function. Changes in left ventricular structure and function do not appear to improve by 1 to 2 years after successful parathyroid surgery.[45]

Diagnosis

A simultaneous increase in serum immunoreactive PTH (best represented by the intact PTH assay) with elevation of the serum calcium level establishes the diagnosis of primary hyperparathyroidism. Other causes of hypercalcemia include malignancy with an increased level of PTHrP or hypercalcemia arising directly from bony metastases or neoplastic (lymphoma) or nonneoplastic disease (e.g., sarcoidosis), leading to an increase in the synthesis and release of 1,25-dihydroxyvitamin D_3.

Treatment

Treatment of hyperparathyroidism is with surgical removal of the parathyroid adenoma.[46] Calcimimetic medications (cinacalcet) can lower PTH concentrations and normalize serum calcium levels.[46] Asymptomatic primary hyperparathyroidism, routinely encountered in clinical endocrinology practice, may not require definitive treatment.

Hypocalcemia

Low serum levels of total and ionized calcium directly alter myocyte function. Hypocalcemia prolongs phase 2 of the action potential duration and the QT interval. Severe hypocalcemia can impair cardiac contractility and give rise to a diffuse musculoskeletal syndrome consisting of tetany and rhabdomyolysis. Primary hypoparathyroidism is rare and can develop after surgical removal of the parathyroid glands, as may occur after treatment of thyroid cancer; in the setting of polyglandular dysfunction syndromes, as a result of glandular agenesis (DiGeorge) syndrome; and in the rare heritable disorder pseudohypoparathyroidism. Recombinant human PTH offers a treatment option.

Chronic renal failure is the most common cause of low serum calcium and high PTH levels. In such patients the effects of chronically high levels of PTH (secondary hyperparathyroidism) on the heart and cardiovascular system may be both causative and serve as a biomarker in assessing heart failure treatment strategies.[47,48] In elderly patients with progression of aortic stenosis, a rise in serum PTH and bone

remodeling occurs.[49] The ability of PTH to stimulate G protein–coupled receptors may impair myocyte contractility and contribute to LVH. Cinacalcet can treat the secondary hyperparathyroidism associated with chronic renal failure. A trial to assess its effectiveness on cardiovascular events, however, showed no significant benefit.

Vitamin D Deficiency

Most body tissues and cells express the vitamin D receptor. The active form of vitamin D, 1,25(OH)2D, has a wide range of biologic actions, including inhibiting cellular proliferation and inducing terminal differentiation, inhibiting angiogenesis, stimulating insulin production, and inhibiting renin production.[50] Approximately 30% to 50% of people in the general population have vitamin D deficiency.[50] Observational evidence suggests that lower levels of vitamin D are associated with increased all-cause and cardiovascular morbidity rates.[51,52] Vitamin D deficiency can contribute to coronary risk factors and cardiovascular disease; it predisposes to hypertension, diabetes mellitus and the metabolic syndrome, LVH, congestive heart failure, stroke, peripheral arterial disease, and chronic vascular inflammation. Epidemiologic studies have also recently linked vitamin D deficiency with an increased risk of major adverse cardiovascular events and a twofold risk of myocardial infarction. A recent metaanalysis of 18 randomized controlled trials in which 57,000 individuals were studied showed that a vitamin D intake of more than 500 IU/day improves all-cause mortality rates, in part by decreasing cardiovascular deaths.[53]

Thyroid Hormones and Cardiovascular Disease

The thyroid gland and the heart share a close relationship that arises during embryologic life. During ontogenesis, the thyroid and heart migrate together. Changes in cardiovascular function in all types of thyroid disease illustrate the close physiologic relationship between the heart and the thyroid.[54-56] Cardiovascular complications commonly occur in both subclinical and overt thyroid dysfunction.[54-56]

Cellular Mechanisms of Thyroid Hormone Action on the Heart

Diagnosis and management of thyroid hormone–mediated cardiac disease states require understanding of the cellular mechanisms of thyroid hormone on the heart and vascular smooth muscle cells.[54-56] Under the regulation of thyroid-stimulating hormone (thyrotropin, TSH), the thyroid gland concentrates iodide and, through a series of enzymatic steps, synthesizes predominantly tetraiodothyronine (T_4 ≈ 80%) and a smaller percentage of triiodothyronine (T_3 ≈ 20%) (**Fig. 92.3**). The active thyroid hormone, triiodothyronine, accounts for the vast majority of biologic effects, including stimulation of tissue thermogenesis, alterations in the expression of various cellular proteins, and actions on the heart and vascular smooth muscle cells.[54-57]

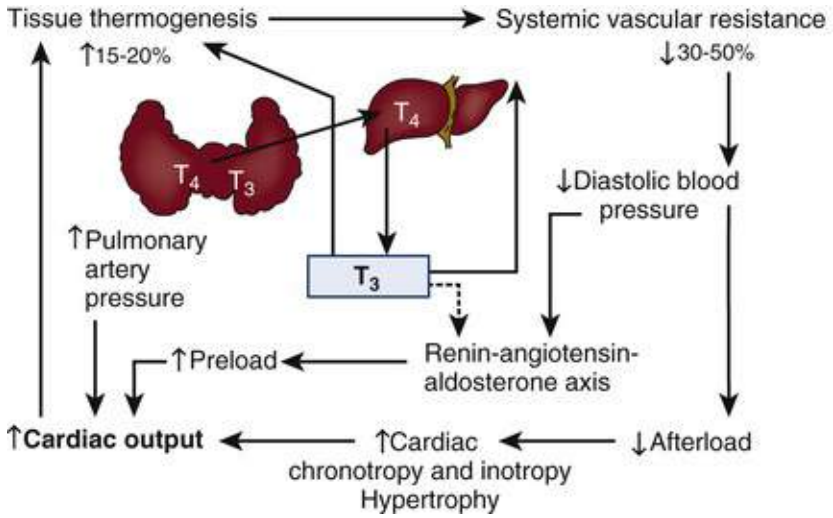

FIGURE 92.3 Changes in cardiovascular hemodynamics associated with thyroid dysfunction. The individual changes for hyperthyroidism are noted for each parameter. The effects of hypothyroidism are diametrically opposite.

Approximately 80% to 90% of the extrathyroidal T_3 is produced by deiodination of T_4 by the type I (D1) and type II (D2) deiodinases.[58] D1 is expressed in the liver and kidney, and D2 is expressed in the central nervous system, bone, skin, pituitary gland, brown adipose tissue, skeletal muscle, and heart. Type 3 deiodinase (D3) can inactivate both T_4 and T_3 and acts primarily during embryonic life; in healthy adults, its expression persists in the heart and can arise in ischemic tissue.[59] Free T_3 enters cells via transport proteins (**Fig. 92.4**) of the monocarboxylate transporter (MCT8, MCT10) and organic anion-transporting polypeptide 1C1 (OATP) family of cell surface transporters.[60] As reported for the steroid and retinoic acid families of receptor proteins, the thyroid hormone receptors bind as homodimers or heterodimers to the thyroid hormone response elements in a promoter region of specific genes. Binding to the promoter regions can activate or repress gene expression.

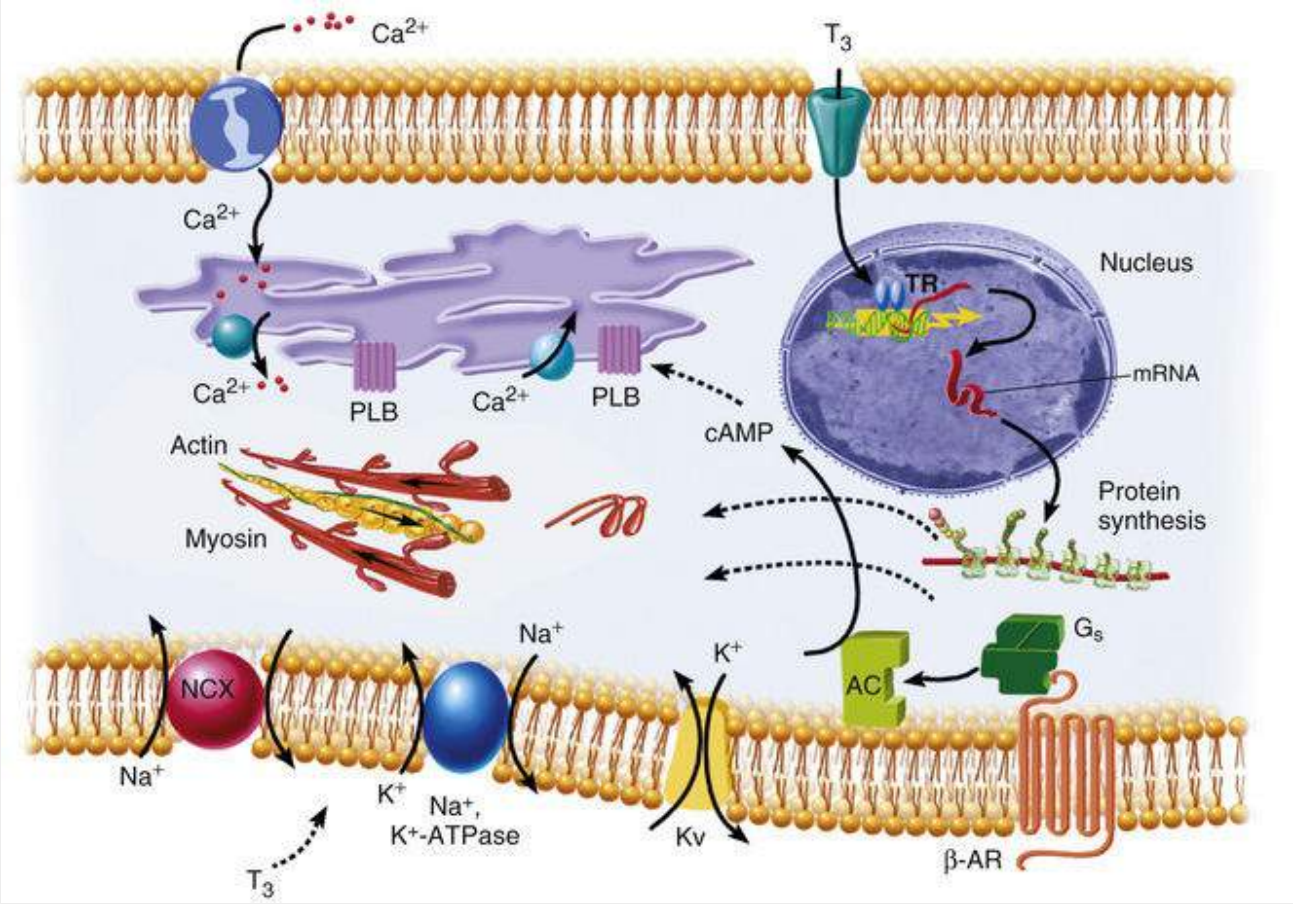

FIGURE 92.4 T_3 enters the cell via specific membrane transporters and binds to nuclear T_3 receptors. The complex binds to thyroid hormone response elements and regulates the transcription of specific genes. Nonnuclear T_3 actions on channels for Na^+, K^+, and Ca^{2+} ions are indicated. *AC*, adenylyl cyclase; *β-AR*, beta-adrenergic receptor; *Gs*, guanine nucleotide–binding protein subunit; *Kv*, voltage-gated potassium channel; *mRNA*, messenger RNA; *NCX*, sodium calcium exchanger; *PLB*, phospholamban; *TR*, T_3 receptor protein.

Thyroid hormone transcriptionally regulates many cardiac proteins (**Table 92.1**), including structural and regulatory proteins, cardiac membrane ion channels, and cell surface receptors, thus providing a molecular mechanism to explain many of the effects of thyroid hormone on the cardiovascular system.[54-56] Major T_3 targets include myosin heavy chain isoforms (alpha and beta). The human ventricle expresses primarily beta-myosin, and limited alterations in isoform expression accompany thyroid disease states. Changes in myosin heavy chain isoform expression occur in the human atria in various diseases, including congestive heart failure and severe hypothyroidism.[54-56,59,61,62]

TABLE 92.1

Thyroid Hormone Regulation of Cardiac Gene Expression

Positively Regulated
Alpha-myosin heavy chain
Sarcoplasmic reticulum Ca^{2+}-ATPase
Na^{+},K^{+}-ATPase
Voltage-gated potassium channels (Kv1.5, Kv4.2, Kv4.3)
Atrial and brain natriuretic peptide
Malic enzyme
Beta-adrenergic receptor
Guanine nucleotide–binding protein Gs
Adenine nucleotide transporter 1
Negatively Regulated
Beta-myosin heavy chain
Phospholamban
Na^{+}-Ca^{2+} exchanger
Thyroid hormone receptor alpha1
Adenylyl cyclase types V, VI
Guanine nucleotide–binding protein Gi
Monocarboxylate transporters 8 and 10

Sarcoplasmic reticulum Ca^{2+}-adenosine triphosphatase (ATPase) (SERCA) is an important ion pump that determines the magnitude of myocyte calcium cycling (**see Chapter 22**). Reuptake of calcium into the sarcoendoplasmic reticulum early in diastole in part determines the rate at which the left ventricle relaxes (isovolumic relaxation time). The polymeric protein phospholamban regulates the activity of SERCA2, and inotropic agents that enhance cardiac contractility through increases in myocyte cAMP act by stimulating the phosphorylation of phospholamban. Thyroid hormone inhibits the expression of phospholamban and increases phospholamban phosphorylation.[54-56] This molecular mechanism can explain why diastolic function varies inversely across the entire spectrum of thyroid disease states, including even mild subclinical hypothyroidism (**Fig. 92.5**),[63-65] and why even mild degrees of hypothyroidism can contribute to heart failure.[66,67] In addition, beta-adrenergic blockade of the heart in hyperthyroidism does not decrease the rapid diastolic relaxation, thus further dissociating thyroid hormone from the adrenergic effects of thyrotoxicosis.[54-56]

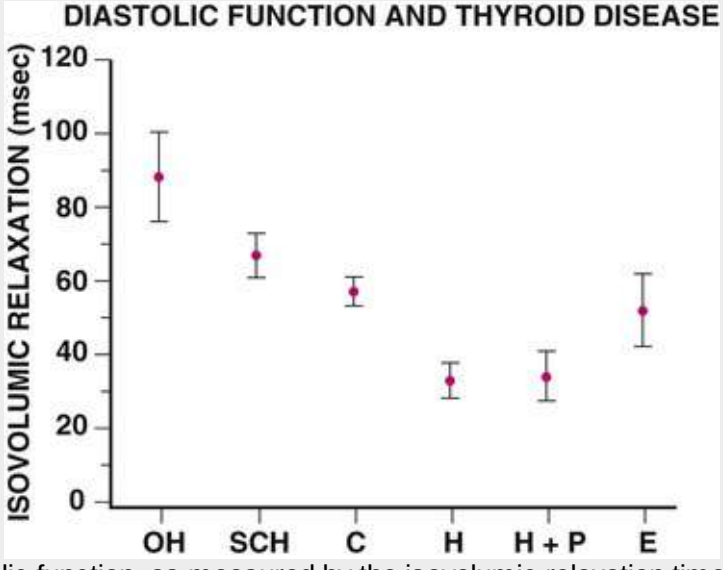

FIGURE 92.5 Diastolic function, as measured by the isovolumic relaxation time, varies over the entire range of thyroid disease, including overt hypothyroidism (OH), subclinical hypothyroidism (SCH), control (C), hyperthyroidism (H), hyperthyroidism after beta-adrenergic blockade (H + P), and hyperthyroidism after treatment to restore normal thyroid function (E).

Changes in other myocyte genes, including Na^+,K^+-ATPase, account for the increase in basal oxygen consumption of the experimental hyperthyroid heart and explain the decrease in digitalis sensitivity of hyperthyroid patients. Thyroid hormone can also regulate the expression of genes that encode its own nuclear receptors and plasma membrane transport proteins (MCT8 and MCT10) within cardiac myocytes (**see Table 92.1**).

In addition to the well-characterized nuclear effects of thyroid hormone, some cardiac responses to thyroid hormone appear to result from nontranscriptional mechanisms,[68,69] as suggested by their relatively rapid onset of action—faster than attributable to changes in gene expression and protein synthesis—and failure to be affected by inhibitors of gene transcription.

Thyroid Hormone–Catecholamine Interaction

Early observations of the heart in hyperthyroidism emphasized that it was functioning similar to the way it might in hyperadrenergic states, and this finding led to the proposal that sensitivity to catecholamines might be enhanced in this setting. This postulate formed the basis for the test described by Emil Goetsch in 1918, in which hyperthyroidism could be diagnosed by demonstrating a marked cardioacceleration and blood pressure response to small subcutaneous doses of epinephrine. The increased $beta_1$-adrenergic receptors on cardiac myocytes observed in experimental hyperthyroidism provide a mechanism for the enhanced catecholamine sensitivity.[70,71] A carefully controlled study of nonhuman primates, however, found no increase in sensitivity of the heart or cardiovascular system to catecholamines in experimental hyperthyroidism.[71] Accompanying the increased levels of $beta_1$-adrenergic receptors and guanosine triphosphate–binding proteins, thyroid hormone decreases the expression of cardiac-specific adenylyl cyclase catalytic subunit isoforms (V, VI) and thereby maintains the cellular response to beta-adrenergic agonists and cAMP generation within normal limits.[71] Cardiac tissue contains both β_1- and β_2-adrenergic receptor subtypes. T_3 causes a rapid fourfold induction of cardiac β_1-receptor mRNA and a threefold increase in the number of cardiac β_1-receptors, which persists for 48 hours. T_3 administration influences β_2-receptor expression only minimally.[71]

Diagnosis of Thyroid Function Disorders

There is a battery of sensitive and specific laboratory tests that can establish a diagnosis of thyroid disease with a high degree of precision. The serum TSH level is the most widely used and sensitive measure for the diagnosis of thyroid dysfunction.[72] Serum TSH levels uniformly increase in patients with primary hypothyroidism (> 4.5 mU/L), and they are low (< 0.1 mU/L) in hyperthyroidism due to the feedback of excessive T_4 and T_3 serum levels on thyrotropin pituitary synthesis and secretion. In the presence of abnormal TSH levels, measurement of free thyroxine (FT_4) and total T_3 (TT_3) or free T_3 (FT_3) can distinguish subclinical from overt thyroid dysfunction.[55,72] Overt and subclinical hyperthyroidism result most commonly from increased thyroid hormone synthesis related to Graves' disease, toxic adenoma, or toxic multinodular goiter.[55,71] Hashimoto disease, prior thyroid surgery, and, in some parts of the world, iodine deficiency are the most common causes of hypothyroidism.[55]

Hemodynamic Alterations in Thyroid Disease

Changes in myocardial contractility and hemodynamics occur across the entire spectrum of thyroid disease (**Table 92.2 and see Fig. 92.5**). Multiple studies, including those in experimental animals, as well

as invasive and noninvasive measurements in humans, indicate that T_3 regulates cardiac inotropy and chronotropy through direct and indirect mechanisms.[54-56,62-65,71] T_3 acts on tissues throughout the body to increase myocardial oxygen consumption and tissue thermogenesis (**see Fig. 92.3**). Echocardiographic data indicate that, in humans, newly diagnosed thyrotoxicosis induces an improvement in left ventricular systolic function and an enhancement in left ventricular relaxation, diastolic flow velocities, and isovolumic relaxation time. T_3 decreases the systemic vascular resistance in arterioles of the peripheral circulation through direct effects on vascular smooth muscle cells. Moreover, thyrotoxicosis may augment the vascular endothelial generation of nitric oxide.[73-75] The drop in systemic vascular resistance results in a smaller left ventricular end-systolic volume. A decrease in mean arterial pressure and activation of the renin-angiotensin-aldosterone system with increased serum angiotensin-converting enzyme activity occurs, as does an increase in renal sodium reabsorption. The increase in plasma volume, coupled with an increase in erythropoietin, increases the blood volume. The combination of expanded blood volume and improvement in diastolic relaxation of the heart contributes to an increased left ventricular end-diastolic volume.[56] Despite the marked reduction in systemic vascular resistance, the pulsatile arterial load undergoes a compensatory change, and increased aortic input sustains the systolic arterial pressure.[56] The systolic arterial pressure almost invariably increases and diastolic arterial pressure decreases in patients with overt hyperthyroidism, so that the pulse pressure characteristically widens and the mean arterial pressure only marginally decreases.[56] Systolic hypertension may develop in up to 30% of hyperthyroid patients and is more pronounced in older patients.[54]

TABLE 92.2

Cardiovascular Changes with Thyroid Disease

PARAMETER	NORMAL	HYPERTHYROID	HYPOTHYROID
Systemic vascular resistance (dyne-cm · sec−5)	1500-1700	700-1200	2100-2700
Heart rate (beats/min)	72-84	88-130	60-80
Cardiac output (liters/min)	5.8	>7.0	<4.5
Blood volume (% of normal)	100	105.5	84.5

The net effect of an increased preload and a decreased afterload yields an increased left ventricular stroke volume in hyperthyroidism.[54-56] In turn, the rise in heart rate and the increased stroke volume combine to cause a twofold to threefold increase in cardiac output. Cardiac output may more than double in hyperthyroidism. Measurements of acetate metabolism by positron emission tomography have demonstrated that the marked increase in cardiac output in hyperthyroidism causes no change in energy efficiency.[54-56] In fact, the hyperthyroid heart increases its performance through the modulation of hemodynamic loads; this positive effect on energy metabolism and oxygen consumption improves the left ventricular mechanical efficiency, optimizing its cardiac mechanical-energetic consumption.[54-56]

Diametrically opposed hemodynamic changes occur in hypothyroidism (**see Table 92.2**). Left ventricular function falls reversibly in hypothyroidism. The cardiac preload decreases because of the impaired diastolic function and the decreased blood volume; the left ventricular ejection fraction at rest, during exercise, and during cardiopulmonary exercise testing declines and tends to improve with restoration of euthyroidism.[54-56] The afterload increases in patients with hypothyroidism as a result of increased systemic vascular resistance, arterial stiffness, and endothelial dysfunction. Systemic vascular resistance may increase as much as 30%, and the mean arterial pressure may rise in up to 20% of patients with diastolic hypertension.[54-56] Even mild hypothyroidism may decrease the endothelial-derived relaxing factors.[73-75] The diastolic hypertension in patients with hypothyroidism is associated with a low renin

level and a decrease in the hepatic synthesis of renin substrate. The cardiac output may decrease by as much as 30% to 40% in hypothyroidism.[54] Despite the decrease in cardiac output and contractility of the hypothyroid myocardium, studies of myocardial metabolism by positron emission tomography have shown that the hypothyroid myocardium is energy-inefficient despite the low level of overall oxygen consumption.[56,75] Indeed, an increased afterload is one of the major factors determining myocardial oxygen consumption.[75]

Hyperthyroidism

Cardiovascular symptoms are an integral clinical feature, and often one of the predominant clinical features, of patients with hyperthyroidism. Most patients experience palpitations resulting from increases in the rate and force of cardiac contractility. The increase in heart rate results from a decrease in parasympathetic stimulation and an increase in sympathetic tone. Heart rates higher than 90 beats/min at rest and during sleep occur commonly, the normal diurnal variation in heart rate is blunted, and the increase during exercise is exaggerated. Many hyperthyroid patients experience exercise intolerance and exertional dyspnea, caused in part by skeletal and respiratory muscle weakness.[71] The low vascular resistance and increased preload compromise the cardiac functional reserve, which cannot rise further to accommodate the demands imposed by submaximal or maximal exercise.[71,75]

A subset of thyrotoxic patients can experience angina-like chest pain. In older hyperthyroid patients with known or suspected coronary artery disease, the increase in cardiac work associated with the increase in cardiac output and cardiac contractility can produce myocardial ischemia, which can respond to beta-adrenergic–blocking agents (beta blockers) or restoration of a euthyroid state. Rare patients, usually younger women, experience a syndrome of chest pain at rest associated with ischemic electrocardiographic changes. Cardiac catheterization has demonstrated that most of these patients have angiographically normal coronary arteries, but coronary vasospasm similar to that found in variant angina can occur (**see also Chapters 61 and 89**). Myocardial infarction develops very rarely, and these patients appear to respond to calcium channel–blocking agents or nitroglycerin.

Hyperthyroidism is associated with a substantial degree of pulmonary hypertension (mean pulmonary artery systolic pressure > 50 mm Hg).[71,76,77] Pulmonary hypertension in turn places a significant degree of stress and afterload on the right ventricle, thus implying that although systemic vascular resistance decreases with thyrotoxicosis, pulmonary vascular resistance does not. Correction of hyperthyroidism usually reduces the pulmonary arterial pressure.[71,77] Severe pulmonary hypertension may also reverse completely after successful treatment of hyperthyroidism. In addition to the reduction in pulmonary blood flow, a specific vasoactive effect of methimazole may explain the improvement in the pulmonary vasculature hemodynamics after treatment of hyperthyroidism.[71,77]

Autoimmune Involvement of the Cardiovascular System in Patients with Graves' Disease and Hashimoto Disease

Hyperthyroidism and hypothyroidism occasionally are linked to autoimmune cardiovascular involvement. Pulmonary arterial hypertension, myxomatous cardiac valve disease, and irreversible dilated cardiomyopathy have been reported in patients with Graves' disease.[71,77] Pulmonary hypertension may result from immune-mediated endothelial damage.[71,77] Takotsubo cardiomyopathy is linked to severe thyrotoxicosis and may be a presenting manifestation of thyroid storm.[77]

Peripartum cardiomyopathy can occur in thyrotoxic African American women.[71,77] Patients with autoimmune thyroid disease may have anticardiolipin antibodies and antiphospholipid syndrome. Recent

reports have documented cerebrovascular ischemic symptoms in young, primarily Asian women with Graves' disease. This syndrome, *moyamoya disease*, is characterized by anatomic occlusion of the terminal portions of the internal carotid arteries and appears to improve both anatomically and symptomatically following treatment.

Atrial Fibrillation in Overt Hyperthyroidism (see also Chapter 38)

The most common rhythm disturbance in patients with hyperthyroidism is sinus tachycardia, but atrial fibrillation causes the most clinical concern. The prevalence of atrial fibrillation in patients with hyperthyroidism ranges from 2% to 20%, in contrast to 2.3% of cases of atrial fibrillation in the control population with normal thyroid function. The ability to restore thyrotoxic patients to a euthyroid state and sinus rhythm justifies TSH testing in most patients with a recent onset of otherwise unexplained atrial fibrillation or other supraventricular arrhythmias. Atrial fibrillation may be the first symptom of thyroid hormone excess in the elderly. Approximately 7% to 8% of middle-aged hyperthyroid patients may develop atrial fibrillation; this prevalence increases stepwise in each decade, with a peak at approximately 15% in patients older than 70 years and a prevalence of 20% to 40% in patients with underlying heart disease, coexistent ischemic heart disease, or heart valve disease.[78] Treatment of atrial fibrillation in the setting of hyperthyroidism includes beta-adrenergic blockade with a $beta_1$-selective or nonselective agent to control the ventricular response (**Table 92.3**).[79-82] Symptomatic relief can occur rapidly. According to the American College of Cardiology/American Heart Association, the first-line treatment of atrial fibrillation and heart failure in patients with thyroid dysfunction should aim primarily to restore a euthyroid state because cardiovascular drugs generally have a reduced efficacy in the face of thyroid hormone excess.[79] Therefore, treatment of hyperthyroidism with beta-adrenergic blockade followed by antithyroid drugs or radioiodine should be the first-line therapy in patients with overt hyperthyroidism and atrial fibrillation to obtain conversion to sinus rhythm and to improve hemodynamics.[81,82] Successful treatment of hyperthyroidism and restoration of normal serum levels of T_4 and T_3 results in reversion to sinus rhythm in two thirds of patients within 2 to 3 months.

TABLE 92.3

Beta-Adrenergic Receptor Blockade for the Treatment of Hyperthyroidism*

DRUG	DOSAGE	FREQUENCY	CONSIDERATIONS
Propranolol	10-40 mg	tid or qid	Nonselective β-AR blockade; longest experience
Atenolol	25-100 mg	bid	Relative beta1 selectivity; increased patient compliance
Metoprolol	25-50 mg	qid	Relative beta1 selectivity
Nadolol	40-160 mg	qd	Nonselective β-AR blockade; once daily; least experience to date
Esmolol	Intravenous pump, 50-100 μg/kg/min		In the ICU setting of severe hyperthyroidism or storm

*Each of these drugs has been approved for the treatment of cardiovascular diseases, but to date none has been approved for the treatment of hyperthyroidism.

β-AR, beta-adrenergic receptor; *ICU*, intensive care unit.

Digitalis may help to control the ventricular response in hyperthyroidism-associated atrial fibrillation, but because of the increased rate of digitalis clearance, the decreased sensitivity of drug action resulting from the high cellular levels of Na^+,K^+-ATPase, and the decreased parasympathetic tone, patients usually require higher doses. Anticoagulation, especially with the new non–vitamin K–dependent agents, in patients with hyperthyroidism and atrial fibrillation is controversial. The potential for systemic or cerebral embolization must be weighed against the risk for bleeding and complications.[80-82] Whether hyperthyroid patients have an increased risk for systemic embolization per se remains uncertain. Thus in

younger patients with hyperthyroidism and atrial fibrillation in the absence of other heart diseases, hypertension, or other independent risk factors for embolization (CHADS VASC score = 0), the benefits of anticoagulation have not been proved and might be outweighed by the risk.

Older patients or those with atrial fibrillation of longer duration have a lower rate of reversion to sinus rhythm.[71,82] In hyperthyroid patients who do not regain normal rhythm spontaneously within 4 months of normalization of thyroid function, pharmacologic or electrical cardioversion should be considered after evaluation of the age of the patient and the underlying cardiac status.[71,81-83] Many such patients will warrant anticoagulant therapy. In patients undergoing ablation to treat atrial fibrillation, the preprocedure reversal of abnormal thyroid function testing increases the short-term and long-term success rates.[81,82]

Heart Failure in Overt Hyperthyroidism

The cardiovascular alterations in hyperthyroidism include increased resting cardiac output and enhanced cardiac contractility (**see Table 92.2**). Nevertheless, a minority of patients have symptoms, including dyspnea on exertion, orthopnea, and paroxysmal nocturnal dyspnea, as well as signs demonstrating peripheral edema, elevated jugular venous pressure, or an S_3. This complex of findings, coupled with failure to increase the left ventricular ejection fraction with exercise, suggests a hyperthyroid cardiomyopathy.[75] The term often used in this setting, *high-output failure*, is not appropriate, because although the resting cardiac output is as much as two to three times normal, the exercise intolerance does not appear to result from cardiac failure but rather from skeletal muscle weakness and perhaps associated pulmonary hypertension.[54-56,66,75,77] High-output states, however, can increase the renal sodium reabsorption and expand the plasma volume. Although the systemic vascular resistance falls with hyperthyroidism, the pulmonary vascular resistance does not, and because of the greater output to the pulmonary circulation, the pulmonary artery pressure increases. This leads to a rise in mean venous pressure, hepatic congestion, and peripheral edema of the type associated with primary pulmonary hypertension or right-sided heart failure.

In patients with long-standing hyperthyroidism and marked sinus tachycardia or atrial fibrillation, a low cardiac output, impaired cardiac contractility with a low ejection fraction, an S_3, and pulmonary congestion can develop; all are consistent with heart failure.[54,56,75] Review of such cases suggests that the impairment in left ventricular function results from the prolonged high heart rate and the development of rate-related heart failure. When the left ventricle becomes dilated, mitral regurgitation may also develop (**see Chapter 69**). Recognition of this phenomenon has importance because treatment aimed at slowing the heart rate or controlling the ventricular response in atrial fibrillation appears to improve left ventricular function, even before initiation of antithyroid therapy. These patients are critically ill and should be managed in an intensive care unit setting. Some patients with hyperthyroidism, similar to the overall congestive heart failure population, do not tolerate initiation of beta blockers in full doses.[54,75]

Treatment of Overt Hyperthyroidism

Treatment of patients with thyrotoxic cardiac disease should include a beta-adrenergic antagonist to lower the heart rate to 10% or 15% above normal. Beta blockers improve the tachycardia-mediated component of ventricular dysfunction, but the direct inotropic effects of thyroid hormone will persist (**see Table 92.3 and see Fig. 92.4**). The rapid onset of action and improvement in many of the signs and symptoms of hyperthyroidism indicate that most patients with overt symptoms should receive beta blockers. Definitive therapy can then be accomplished safely with iodine-131 alone or in combination with an antithyroid drug.[80-82] A recent study affirmed the importance of definitive treatment with iodine-131 by showing that

such treatment is associated with lower cardiovascular mortality rates.[84] Pretreatment with methimazole may be considered before definitive treatment of hyperthyroidism with radioactive iodine or surgery in elderly patients.[80-82]

Thyroid storm, the most severe form of hyperthyroidism, can present with an altered mental status; fever; gastrointestinal symptoms, including pain, nausea, and rarely jaundice; and cardiovascular findings of exaggerated tachycardia, new-onset supraventricular arrhythmias such as atrial fibrillation, or hypotension and cardiovascular collapse. Untreated, the mortality rate from this condition may be as high as 50%, and outcomes vary based on management of the cardiovascular manifestations. These patients require intensive care unit monitoring in addition to the use of antithyroid drugs, potassium iodide, attention to other coexistent medical problems such as infection or trauma, and awareness of drugs they may be taking, such as amiodarone. These patients may tolerate intravenous administration of beta-adrenergic blocking drugs or calcium channel blockers poorly. The development of hypotensive cardiac arrest or worsening heart failure represents the untoward effects of such agents in patients with thyrotoxic heart disease. As noted above, intensive monitoring, judicious use of esmolol, and standard fluid and volume management with simultaneous treatment to lower T_4 and T_3 levels can optimize the therapeutic response (**see Table 92.3**).

Hypothyroidism

The prevalence of hypothyroidism is estimated to be 2% to 4% and increases with advancing age. In contrast to the dramatic clinical signs and symptoms of hyperthyroidism, the cardiovascular findings of hypothyroidism are more subtle.[54,55,63] Mild degrees of bradycardia, diastolic hypertension, a narrow pulse pressure and relatively quiet precordium, and decreased intensity of the apical impulse are all characteristic. Treatment of hypothyroid patients with restoration of a euthyroid state resolves these changes in parallel with the return of systemic vascular resistance to lower levels (**see Table 92.2**).

Hypothyroidism also increases total and low-density lipoprotein (LDL) cholesterol in proportion to the rise in serum TSH levels.[85] Although thyroid hormone can alter cholesterol metabolism through multiple mechanisms, including a decrease in biliary excretion, the primary mechanism involves changes in LDL metabolism caused by decreases in the hepatic LDL receptor number and reduced activity of cholesterol 7α-hydroxylase, an enzyme that lowers cholesterol levels.[85] One study reported that the liver-selective thyroid hormone agonist eprotirome can lower cholesterol levels in statin-treated patients, in support of this concept.[86]

The serum creatine kinase (CK) level rises from 50% to 10-fold in up to 30% of patients with hypothyroidism. Analysis of isoform specificity indicates that more than 96% is CK-MM, consistent with a skeletal muscle origin of the increased enzyme release.[87] The serum level of CK in patients with hypothyroidism after initiation of standard oral thyroid hormone replacement declines slowly with a half-life of approximately 14 days. An interesting issue is whether some patients with statin-induced myopathy have underlying thyroid disease as a contributing factor.[87] Both conditions have similar myopathy or myalgia symptoms (**Table 92.4**), and evaluation of these patients should include thyroid function testing with TSH.

TABLE 92.4

Clinical Characterization of Muscle Disease Syndromes

Hypothyroid Related
Myalgia: nonspecific muscle symptoms, cramping, especially nocturnal; variable creatine kinase (CK) level
Myopathy: impaired endurance, usually with elevation of the CK level; pseudomyotonia
Hoffmann syndrome: impaired function; pseudohypertrophy; often marked elevations in CK level
Statin Induced
Myopathy: any associated disease
Myalgia: muscle aches, weakness without elevation in CK level
Myositis: symptoms plus elevated CK level
Rhabdomyolysis: symptoms plus markedly elevated CK levels

Pericardial effusions can occur, and occasionally, they are large and cause the appearance of cardiomegaly on chest radiographs. Although rare, tamponade with hemodynamic compromise may occur. Echocardiography demonstrates small to moderate effusions in up to 30% of overtly hypothyroid patients; the effusions resolve over a period of weeks to months after initiation of thyroid hormone replacement.

As a result of changes in ion channel expression and parasympathetic tone the ECG in hypothyroidism may show sinus bradycardia, low voltage, and prolongation of the action potential duration and QT interval. The QT prolongation predisposes patients to ventricular arrhythmias, and in some patients with acquired torsades de pointes, the disorder has improved or completely resolved with thyroid hormone replacement.[54]

Increases in risk factors for atherosclerosis, including hypercholesterolemia, hypertension, endothelial dysfunction, and elevated levels of homocysteine, may elevate the risk for atherosclerosis and coronary and systemic vascular disease in patients with hypothyroidism (**see Chapters 45, 46, and 48**).[55,63] Myocardial perfusion scans have demonstrated abnormalities suggestive of myocardial ischemia, but these defects appear to resolve with thyroid hormone treatment. TSH screening can be advised for all adults, particularly patients with hypertension, hypercholesterolemia, hypertriglyceridemia, coronary or peripheral vascular disease, and unexplained pericardial or pleural effusions, as well as for various musculoskeletal syndromes or statin-associated myopathy.[88]

Treatment of Overt Hypothyroidism

Replacement doses of purified preparations of levo-thyroxine sodium (L-T_4) are the treatment of choice in hypothyroid patients.[89,90] The optimal replacement dose of levo-thyroxine should take into account both the age of the patient and the cause of hypothyroidism.[89] Indeed, the levo-thyroxine dosage should be lower in the elderly and higher in patients with more severe disease, particularly those who have undergone thyroidectomy or prior iodine treatment for Graves' disease.[89] In all patients, thyroid hormone replacement should suffice to restore the serum TSH level to normal so that patients are clinically and chemically euthyroid. The known effects of thyroid hormone on the heart and cardiovascular system do not support the concept that these patients benefit from maintenance of mild hypothyroidism.[89-91]

Treatment of hypothyroidism yields predictable responses, especially from a cardiovascular perspective. Stepwise thyroid hormone replacement with levo-thyroxine sodium incrementally decreases the serum TSH, serum cholesterol, and serum CK levels and improves left ventricular performance (**Fig. 92.6**). Patients younger than 50 years with no history of heart disease generally tolerate full replacement doses of levo-thyroxine (1.5 µg/kg/day) without concern for untoward cardiac effects. Patients older than 50 years with known or suspected coronary artery disease have more complicated issues.[89,90] Three major issues arise. The first is whether to perform coronary artery revascularization before initiating thyroid hormone replacement. If patients are not candidates for percutaneous intervention and have unstable

angina, left main coronary artery disease, or three-vessel disease with impaired left ventricular function, even in the setting of overt hypothyroidism, coronary artery bypass grafting can be performed. Rarely, a patient has sufficiently profound hypothyroidism to prolong bleeding times and partial thromboplastin times, a situation that requires preoperative supplementation of clotting factors. Thyroid hormone replacement can be delayed until the postoperative period, when it can be administered in full doses parenterally or orally.[89,90]

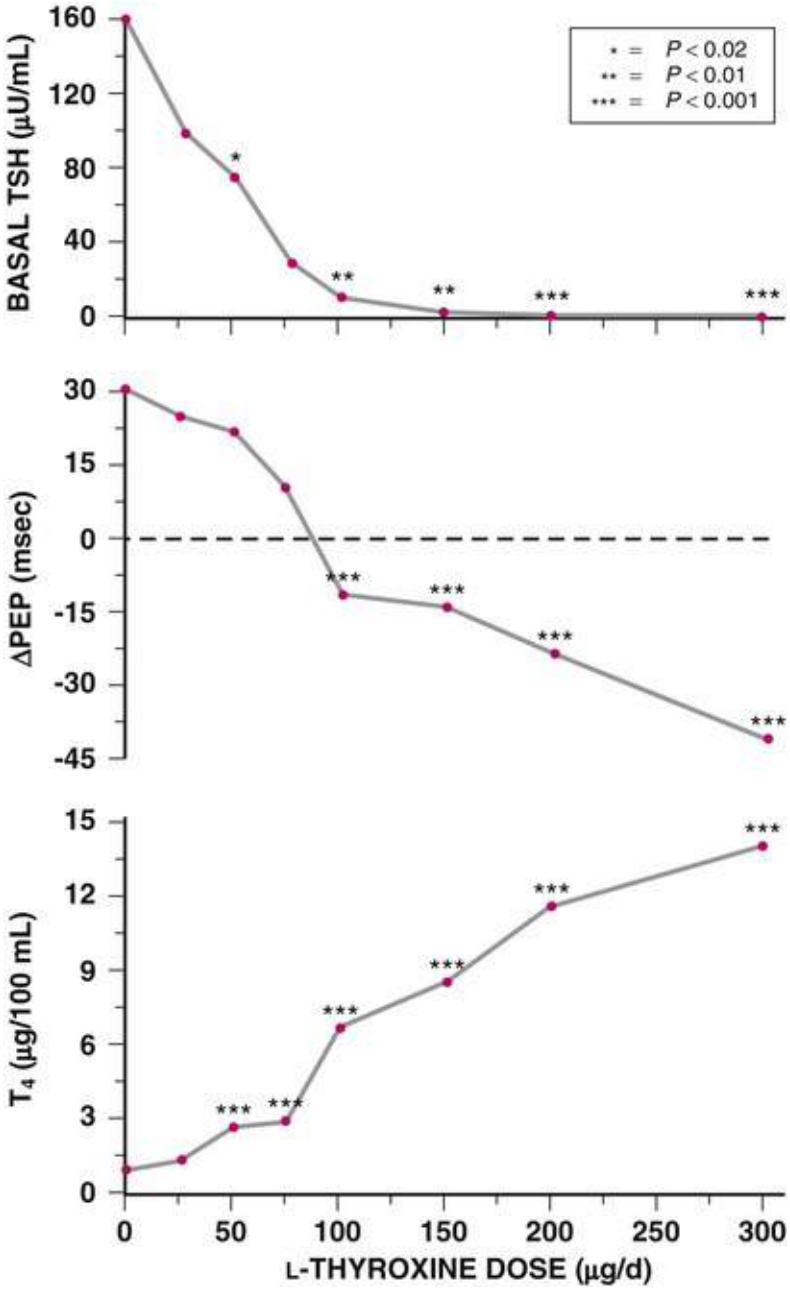

FIGURE 92.6 Response to stepwise levothyroxine sodium treatment of hypothyroid patients as assessed by serum TSH and T_4 levels and by improvement in left ventricular contractility as measured noninvasively by the change in the preejection period (ΔPEP). (From Crowley WF Jr, Ridgway EC, Bough EW, et al: Noninvasive evaluation of cardiac function in hypothyroidism: response to gradual thyroxine replacement. N Engl J Med 296:1, 1977.)

The second issue involves patients with known stable cardiac disease in whom cardiac revascularization is not clinically indicated. Treatment of such patients should begin with low doses (12.5 μg) of levo-thyroxine and then stepwise increases (12.5 to 25 μg) every 6 to 8 weeks until the serum TSH level normalizes.[89,90] Thyroid hormone replacement in this setting and its ability to lower systemic

vascular resistance and decrease afterload, as well as improve myocardial efficiency, can actually decrease clinical signs of myocardial ischemia. Beta blockers are an ideal concomitant therapy to control the heart rate.

The third important issue involves patients who although potentially at risk for coronary artery disease, exhibit no clinical signs or symptoms. In this group, thyroid hormone replacement can start at low doses, generally in the range of 25 to 50 µg/day, and then increase by 25 µg every 6 to 8 weeks until the serum TSH level is normal. If signs or symptoms of ischemic heart disease develop, the same recommendations apply as for patients with known underlying heart disease.[89,90] In the rare condition of *myxedema coma* characterized by the development of hypothermia, altered mental status, hypotension, bradycardia, and hypoventilation in patients with severe and long-standing hypothyroidism, the need for thyroid hormone replacement is more of an emergency.[89] Treatment can be accomplished by intravenous administration of 200 µg of L-T_4 followed by 100 µg of L-T_4 per day to restore vital functions in patients with severe coma. L-T_3 may also be started simultaneously with L-T_4 in a dosage of 10 to 20 µg, followed by 10 µg every 6 hours for 1 or 2 days until the patient's cerebral function improves.[89] Patients with myxedema coma require intensive care unit monitoring with volume repletion, gentle warming, and ventilatory support in the presence of CO_2 retention. Administration of hydrocortisone (50 to 100 mg three times daily) should be undertaken until the results of serum cortisol testing are obtained. When treated in this manner, the hemodynamics, including systemic vascular resistance, cardiac output, and heart rate, will improve within 24 to 48 hours. Severe hyponatremia should be corrected with the judicious administration of hypertonic saline solution (50 to 100 mL of 3% sodium chloride) followed by an intravenous bolus of 40 to 120 mg furosemide.

Subclinical Thyroid Disease

In contrast to overt symptomatic thyroid disease, subclinical thyroid disease implies the absence of classic hyperthyroid- or hypothyroid-related symptoms in patients with thyroid dysfunction. The definition now includes the demonstration of an abnormal TSH level in patients with normal serum levels of total T_4, free T_4, total T_3, and free T_3.[55] With the advent of widespread TSH screening, the magnitude of subclinical thyroid disease may exceed that of overt disease by threefold to fourfold.

Subclinical Hyperthyroidism

Subclinical hyperthyroidism is diagnosed when the serum TSH level is persistently subnormal or undetectable (TSH < 0.1 mU/L) and free thyroid hormone levels are in the mid-to-high range of their reference intervals. The prevalence of endogenous subclinical hyperthyroidism varies greatly depending on the diagnostic criteria, age, sex, and iodine intake of the population.[55] Subclinical hyperthyroidism may increase the left heart rate, ventricular mass, arterial stiffness, and left atrial size and may induce diastolic dysfunction, thereby impairing left ventricular performance.[55] Sinus tachycardia and atrial premature beats frequently occur in young patients, and in older patients (> 60 years), subclinical hyperthyroidism is not associated with symptoms of adrenergic overactivity; there may be associated weight loss, muscle weakness, and most importantly atrial fibrillation.[91-93] Data from all the available metaanalyses demonstrate that subclinical hyperthyroidism is associated with an increased risk of total mortality, coronary heart mortality, incident atrial fibrillation, and heart failure.[67,93] Based on these results, treatment of subclinical hyperthyroidism using methimazole can normalize the serum TSH. In the face of clinical improvement, radioiodine or surgery may be considered as definitive therapy in elderly patients with

persistently undetectable serum TSH levels. Some studies suggest that cardioselective β-blocker treatment may improve the heart rate, left ventricular mass, and diastolic dysfunction in young symptomatic patients.[81,82]

Subclinical hyperthyroidism may develop during L-T_4 therapy in doses that suppress the serum TSH. In some patients receiving thyroid hormone replacement for hypothyroidism, the low TSH level may be the result of unintentional excessive medication, requiring reduction of the L-T_4 dose. Intentional TSH–suppressive doses of levo-thyroxine are only indicated in patients with a previous diagnosis of thyroid cancer with a high risk of recurrences; the risks and -benefits of TSH suppression should be considered in older patients.[94]

Subclinical Hypothyroidism

Subclinical hypothyroidism is diagnosed when the serum TSH is above the upper limit of the normal reference range and free thyroid hormones are within their respective reference range.[55,89] It occurs in up to 4% to 20% of the adult population, and its prevalence increases with advancing age. Although a strong female predilection exists in younger patients, this difference diminishes in older populations. Patients may have mild disease (TSH 4.5 to 9.9 mU/L) or more severe dysfunction (TSH ≥ 10 mU/L). Hashimoto thyroiditis represents the most common cause of acquired subclinical hypothyroidism in the adult. Subclinical hypothyroidism can impair left ventricular diastolic function (**see Fig. 92.5**) and left ventricular systolic and diastolic dysfunction on effort. It can also alter the lipid metabolism, thereby altering the endothelial function and leading to an increased risk of heart failure, atherosclerosis, and coronary heart disease.[55,89]

Two recent metaanalyses assessed individual participant data from the available prospective cohort studies and demonstrated a significant trend of increased risk of heart failure and coronary heart disease events and mortality at higher serum TSH concentrations, particularly in participants with a TSH level of 10 mU/L or greater.[67,95] Therefore, despite the lack of definitive long-term studies on the outcome of mild-to-moderate hypothyroidism with and without replacement therapy, recommendations for treatment of patients with a serum TSH level of 10 mIU/L or higher have fallen on the side of replacement treatment with levo-thyroxine.[90,96] A recent study from the United Kingdom's General Practitioners database showed that treatment of TSH levels between 5 and 10 mIU/mL lowered the incidence of ischemic heart disease events and cardiovascular mortality in patients younger than 70 years.[97] These findings suggest the consideration of treatment of mild disease, particularly in young patients with evidence of atherosclerotic cardiovascular disease, heart failure, or associated risk factors for these diseases.[55]

Amiodarone and Thyroid Function (see also Chapter 36)

Amiodarone is an iodine-rich antiarrhythmic agent used for the treatment of ventricular and atrial tachyarrhythmias. Its 30% iodine content by weight and its structural similarity to levo-thyroxine cause abnormalities in thyroid function test results in as many as 60% of patients treated for short or long periods.[98] The finding that dronedarone, a noniodinated benzofuran antiarrhythmic, does not alter thyroid function reinforces this concept. Similar to other iodinated drugs, amiodarone inhibits the 5′-monodeiodination of T_4 in the liver and pituitary. Inhibition of T_4 metabolism in the liver decreases serum T_3 levels and increases serum T_4 levels, whereas serum TSH levels initially remain normal. With more chronic treatment and as the total iodide content in the body rises, T_4 synthesis and release from the thyroid gland can be inhibited, thereby producing a rise in TSH levels. Patients with underlying goiter,

autoimmune thyroid disease, or enzymatic defects in thyroid hormone biosynthesis and even some patients without any risk factors can progress to overt chemical and clinical hypothyroidism with a marked rise in serum TSH levels. The overall prevalence of hypothyroidism in amiodarone-treated patients is between 15% and 30%. Symptoms of hypothyroidism in this setting can be subtle, and significant hypothyroidism can occur even in their absence.

Thyroid function should be measured every 3 months in all patients receiving amiodarone (**Fig. 92.7**). The effect on thyroid function does not depend on the dose and can occur at any time after initiating treatment; furthermore, because of the high lipid solubility and long half-life of amiodarone, this effect can persist up to 1 year after discontinuing therapy.

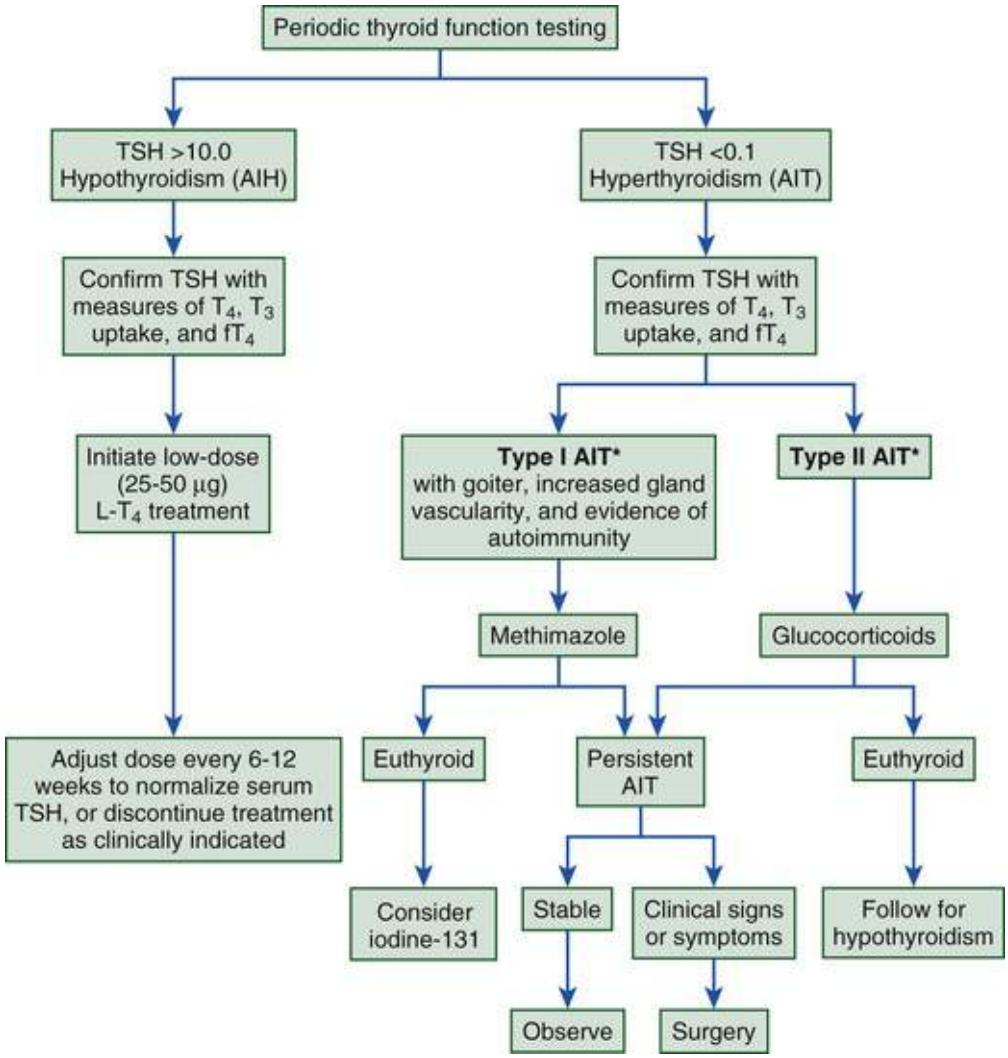

FIGURE 92.7 Amiodarone-induced thyrotoxicosis (AIT) can be diagnosed on the basis of classic signs and symptoms of hypothyroidism or hyperthyroidism or, more commonly, by routine (every 3 to 6 months) thyroid function testing. Any single abnormal TSH level should be confirmed. Clinical hypothyroidism with a TSH level higher than 10 mIU/mL should be treated. AIT management is described and depends on the severity and duration of clinical findings. *Mixed types I and II of AIT may require combination therapy with thionamides and corticosteroids. AIH, amiodarone-induced hypothyroidism; fT_4, free T_4.

Less common but perhaps more challenging is the development of *amiodarone-induced thyrotoxicosis*.[99] Although not initially observed in the iodine-replete American population, the experience from more iodine-deficient populations (as in Italy) suggested that it occurs with a prevalence as high as 10%. The onset was often sudden and could occur shortly after initiation of amiodarone therapy, during chronic treatment, or up to 1 year after stopping therapy. Clinical clues to the development

of this condition include a new onset or recurrence of ventricular irritability (increased firing of an implantable cardioverter-defibrillator), decreased warfarin dose requirements, or return or worsening of the obstructive physiology of hypertrophic cardiomyopathy (**see also Chapter 78**).

Although the pathogenesis is multifactorial, early studies distinguished two forms of amiodarone-induced thyrotoxicosis.[99] Type I occurs primarily in patients with preexisting thyroid disease and most commonly in iodine-deficient areas. These patients may rarely have an increase in 24-hour radioiodine uptake and frequently some measures of thyroid autoimmunity, including antithyroid antibodies. In contrast, a variety of proinflammatory cytokines, including IL-6, presumably mediate type II thyroiditis. It is primarily a destructive process causing release of preformed thyroid hormone, which may continue for weeks or months and most often is associated with low-to-absent radioiodine uptake. Further experience has shown that these two types have substantial overlap in many of the distinguishing features. Amiodarone-induced thyrotoxicosis is associated with a threefold increased risk for major adverse cardiovascular events, underscoring its clinical importance.[100] **Fig. 92.7** proposes a scheme for following thyroid function testing for patients treated with amiodarone.

Because of the increased thyroidal and total-body iodine content, use of iodine-131 is almost always ineffective. Similarly, treatment with antithyroid drugs has marginal effectiveness. Corticosteroids (prednisone 20 to 40 mg/day) provide benefit, perhaps with increased usefulness in patients with type II disease who have high serum levels of IL-6. However, corticosteroids can be instituted in all patients because when effective, the response usually occurs within 2 to 4 weeks of initiating treatment. In patients unresponsive to glucocorticoids with evidence of hyperthyroidism—including weight loss, tachycardia, palpitations, worsening angina, ventricular tachycardia, or other untoward cardiac effects—treatment with antithyroid therapy (methimazole 10 to 30 mg/day) is variably effective and can cause considerable side effects. Total thyroidectomy can be performed safely and can rapidly reverse the hyperthyroidism.[101] Preoperative treatment with beta blockers is indicated, and there have been no reported cases of resulting thyroid storm. Whether amiodarone-mediated thyroid dysfunction should mandate discontinuation of therapy with the drug is an important issue. There is no evidence that stopping treatment with amiodarone hastens the resolution of chemical hyperthyroidism.

Changes in Thyroid Hormone Metabolism That Accompany Cardiac Disease

In addition to the changes in thyroid function that can result from classic thyroid disease, primary alterations in levels of serum total and free T_3 and occasionally in serum T_4 can accompany a variety of acute and chronic illnesses, including sepsis, starvation, and cardiac disease. In the absence of thyroid gland abnormalities, changes in serum T_3 levels result from alterations in thyroid hormone metabolism. Some refer to such cases as nonthyroidal illness. The mechanism for this decrease in serum T_3 levels is multifactorial and in part related to a decrease in 5′-monodeiodination in the liver. Up to 30% of patients with heart failure have a low serum T_3 level, a finding in patients treated with or without amiodarone. In patients with congestive heart failure, the fall in serum T_3 levels is correlated with the severity of heart failure as assessed by the New York Heart Association classification.[102-105] In addition, in patients with heart failure and preserved ejection fraction, the serum level of T_3 was inversely proportional to the level of pro-brain natriuretic peptide. In view of the deleterious effects of hypothyroidism on the myocardium, T_3 replacement may provide benefit. A population-based study of patients with cardiac disease showed that a low serum T_3 level strongly predicts all-cause and cardiovascular mortality rates. These

observations led to studies examining the administration of L-T_4, L-T_3, or thyroid hormone analogs in patients with heart failure to potentially improve their prognosis. L-T_3 infusion in patients with chronic and stable dilated cardiomyopathy and low-T_3 syndrome improved cardiac performance and the neurohumoral milieu without a significant increase in myocardial O_2 consumption.[103,105]

Following uncomplicated acute myocardial infarction, serum T_3 levels fall by about 20% and reach a nadir after approximately 96 hours. Experimental myocardial infarction in animals produces a similar decrease in serum T_3 levels, and replacement of T_3 levels to normal may increase left ventricular contractile function. Children and adults undergoing cardiac surgery with cardiopulmonary bypass demonstrate a predictable fall in serum T_3 levels in the perioperative period.[106] Although treatment strategies involving acute intravenous administration of T_3 to adults after coronary bypass graft surgery have shown improvement in cardiac output and a decrease in systemic vascular resistance, overall mortality rates did not change. In this group of patients, atrial fibrillation decreased by as much as 50% when compared with age-matched controls.[106] Pediatric cardiac patients, especially those undergoing surgery in the neonatal period, demonstrate an even greater decline in serum T_3 levels that can last longer. A low postoperative T_3 level identifies patients at increased risk for morbidity and mortality. A prospective, randomized study has shown that especially in neonates, administration of T_3 in doses sufficient to restore serum T_3 levels to normal decreases the degree of therapeutic intervention and the need for postoperative inotropic agents.[107]

Future Perspectives

The knowledge that a variety of naturally occurring hormones have such profound effects on the heart and cardiovascular system suggests that these actions can be harnessed to treat a variety of cardiovascular diseases. The ability of thyroid hormone to lower cholesterol levels and enhance cardiac contractility (especially diastolic function) via novel transcription-based mechanisms, and at the same time lower the systemic vascular resistance, provides a platform for developing novel therapies. In addition, the recognition that growth hormone and serum T_3 levels are altered in the setting of various forms of cardiac disease and heart failure can provide new biomarkers for assessing novel treatment strategies.

Hemostasis, Thrombosis, Fibrinolysis, and Cardiovascular Disease

Jeffrey I. Weitz

Hemostasis preserves vascular integrity by balancing the physiologic processes that maintain blood fluidity under normal circumstances and prevent excessive bleeding after vascular injury. Preservation of blood fluidity depends on an intact vascular endothelium and a complex series of regulatory pathways that maintain platelets in a quiescent state and keep the coagulation system in check. In contrast, arrest of bleeding requires rapid formation of hemostatic plugs at sites of vascular injury to prevent exsanguination. Perturbation of hemostasis can lead to thrombosis, which can occur in arteries or veins and causes considerable morbidity and mortality. Arterial thrombosis is the most common cause of acute coronary syndrome, ischemic stroke, and limb gangrene, whereas thrombosis in the deep veins of the leg leads to postthrombotic syndrome and pulmonary embolism (**see also Chapter 84**).

Most arterial thrombi form on top of disrupted atherosclerotic plaques because plaque rupture exposes thrombogenic material in the core to blood (**see also Chapter 44**). This material then triggers platelet aggregation and fibrin formation, which results in the generation of a platelet-rich thrombus that temporarily or permanently occludes blood flow.[1] The consequent reduction in blood flow can cause acute coronary syndrome, transient ischemic attack, or ischemic stroke.

In contrast to arterial thrombi, venous thrombi rarely form at sites of obvious vascular disruption.[2] Although venous thrombi can develop after surgical trauma to veins or arise due to indwelling venous catheters, they usually originate in valve cusps of the deep veins of the calf or in muscular sinuses, which can cause stasis. Sluggish blood flow in these veins reduces oxygen supply to the avascular valve cusps. Hypoxemia induces endothelial cells lining the valve cusps to express adhesion molecules, which tether tissue factor–bearing leukocytes and microparticles onto their surface. Tissue factor–bearing leukocytes and microparticles adhere to these activated cells and induce coagulation.[3] In addition, webs of DNA released from activated neutrophils, called neutrophil extracellular traps (NETs), also contribute to thrombosis by providing a scaffold that binds platelets and promotes their activation and aggregation.[4] Impaired blood flow exacerbates local thrombus formation by reducing clearance of activated clotting factors. Thrombi that extend into the proximal veins of the leg can dislodge and travel to the lungs to produce pulmonary embolism.

Arterial and venous thrombi contain platelets and fibrin, but the proportions differ. Arterial thrombi are rich in platelets because of high shear in the injured arteries.[1] In contrast, venous thrombi, which form under low-shear conditions, contain relatively few platelets and consist mostly of fibrin and trapped red cells.[3] Because of the predominance of platelets, arterial thrombi appear white, whereas venous thrombi appear red because of the trapped red cells.

The antithrombotic drugs used for prevention and treatment of thrombosis target components of thrombi and include antiplatelet drugs, which inhibit platelets; anticoagulants, which attenuate coagulation; and fibrinolytic agents, which induce fibrin degradation (**Fig. 93.1**). With the predominance of platelets in arterial thrombi, strategies to inhibit or treat arterial thrombosis focus mainly on antiplatelet agents, although in the acute setting, anticoagulants and fibrinolytic agents may also be used. For occlusive arterial thrombi that require rapid restoration of blood flow, mechanical and/or pharmacologic methods enable thrombus extraction, compression, or degradation. Although rarely used for this indication, warfarin prevents recurrent ischemic events after acute myocardial infarction. The recent observations that the addition of low-dose rivaroxaban, an oral factor Xa inhibitor, to dual-antiplatelet therapy reduces recurrent ischemic events and stent thrombosis in patients with acute coronary syndrome, whereas its addition to aspirin reduces the risk of major adverse coronary and limb events in patients with stable coronary or peripheral artery disease, highlight the potential usefulness of anticoagulants on top of antiplatelet agents for secondary prevention (**see also Chapters 59 and 60**).

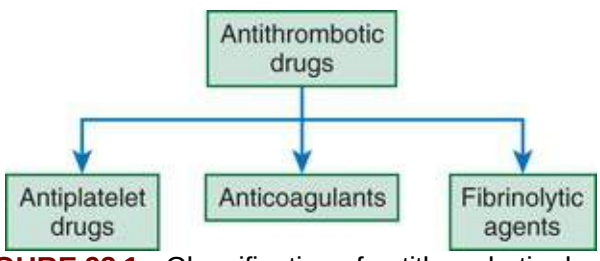

FIGURE 93.1 Classification of antithrombotic drugs.

Anticoagulants are the mainstay for prevention and treatment of venous thromboembolism (VTE), which includes deep vein thrombosis and pulmonary embolism.[3] Antiplatelet drugs are less effective than anticoagulants for prevention of venous thrombosis because of the limited platelet content of venous thrombi. Nonetheless, when given for secondary prevention, aspirin produces about a 30% reduction in risk for recurrent VTE,[5,6] a finding that highlights the overlap between venous and arterial thrombosis. Selected patients with VTE benefit from fibrinolytic therapy[6]; for example, patients with massive pulmonary embolism achieve more rapid restoration of pulmonary blood flow with systemic or catheter-directed fibrinolytic therapy than with anticoagulant therapy alone (**see Chapter 84**). Similarly, some patients with extensive iliac and/or femoral vein thrombosis may have a better outcome with catheter-directed fibrinolytic therapy and/or mechanical thrombus extraction in addition to anticoagulants.

This chapter reviews hemostasis and thrombosis and highlights the processes involved in platelet activation and aggregation, blood coagulation, and fibrinolysis. It reviews the major components of the hemostatic system: the vascular endothelium, platelets, and coagulation and fibrinolytic systems. The chapter then focuses on antiplatelet, anticoagulant, and fibrinolytic drugs in common use. It also provides a brief overview of new antithrombotic drugs in advanced stages of development.

Hemostatic System

Vascular Endothelium (see also Chapter 44)

A monolayer of endothelial cells lines the intimal surface of the circulatory tree and separates blood from the prothrombotic subendothelial components of the vessel wall. Accordingly, the vascular endothelium encompasses about 10^{13} cells and covers a vast surface area. Rather than serving as a static barrier, healthy vascular endothelium dynamically regulates hemostasis by inhibiting platelets, suppressing coagulation, and promoting fibrinolysis.

Platelet Inhibition

Endothelial cells synthesize prostacyclin and nitric oxide and release them into blood. These mediators not only serve to potently vasodilate but also inhibit platelet activation and subsequent aggregation by stimulating adenylate cyclase and increasing intracellular levels of cyclic adenosine monophosphate (cAMP). In addition, endothelial cells express the ecto-adenosine diphosphatase (ecto-ADPase) CD39 on their surface. This membrane-associated enzyme attenuates platelet activation by degrading ADP.[7]

Anticoagulant Activity

Intact endothelial cells actively regulate thrombin generation. Endothelial cells express heparan sulfate proteoglycans on their surface. Like medicinal heparin, heparan sulfate binds circulating antithrombin and enhances its activity. Heparan sulfate proteoglycans also bind tissue factor pathway inhibitor (TFPI), a naturally occurring inhibitor of coagulation.[8] Additional TFPI becomes tethered to the endothelial cell surface via glycosylphosphatidylinositol anchors. Administration of heparin or low-molecular-weight heparin (LMWH) displaces glycosaminoglycan-bound TFPI from the vascular endothelium, and the released TFPI may contribute to the antithrombotic activity of these drugs by inhibiting tissue factor–bound factor VIIa in a factor Xa–dependent fashion.

Endothelial cells are central to the protein C anticoagulant pathway because they express thrombomodulin and endothelial cell protein C receptor (EPCR) on their surfaces.[9] The protein C

pathway is initiated when thrombin binds to thrombomodulin. Once bound, the substrate specificity of thrombin is altered such that it no longer acts as a procoagulant but becomes a potent activator of protein C (**Fig. 93.2**). Activated protein C serves as an anticoagulant by degrading and inactivating activated factor V and factor VIII (factors Va and VIIIa, respectively), key cofactors involved in thrombin generation, a reaction enhanced by protein S. EPCR on the endothelial cell surface promotes this pathway by binding protein C and presenting it to the thrombin-thrombomodulin complex for activation.[9]

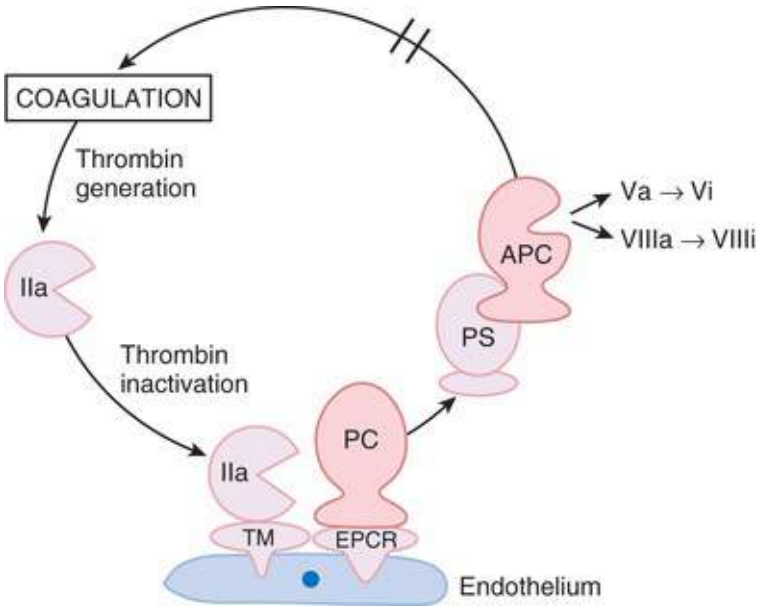

FIGURE 93.2 Protein C pathway. Activation of coagulation triggers thrombin (IIa) generation. Excess thrombin binds to thrombomodulin (TM) on the endothelial cell surface. Once bound, the substrate specificity of thrombin is altered such that it no longer acts as a procoagulant but becomes a potent activator of protein C (PC). The endothelial cell protein C receptor (EPCR) binds protein C and presents it to thrombomodulin-bound thrombin for activation. Activated protein C (APC), together with its cofactor protein S (PS), binds to the activated platelet surface and proteolytically degrades factors Va and VIIIa into inactive fragments (Vi and VIIIi). Degradation of these activated cofactors inhibits thrombin generation *(double bar).*

Fibrinolytic Activity

The vascular endothelium modulates fibrinolysis by synthesizing and releasing tissue and urokinase plasminogen activators (t-PA and u-PA, respectively), which initiate fibrinolysis by converting plasminogen to plasmin.[10] Whereas endothelial cells constitutively express t-PA, they produce u-PA in the settings of inflammation and wound repair. Endothelial cells also produce type 1 plasminogen activator inhibitor (PAI-1), the major regulator of both t-PA and u-PA. Therefore, net fibrinolytic activity depends on the dynamic balance between the release of plasminogen activators and PAI-1. Fibrinolysis localizes to the endothelial cell surface because these cells express annexin II, a coreceptor for plasminogen and t-PA that promotes their interaction. Hence, healthy vessels actively resist thrombosis and help maintain platelets in a quiescent state.[10]

Platelets

Platelets enter the circulation after the fragmentation of bone marrow megakaryocytes. Because they are lack nuclei, platelets have a limited capacity to synthesize proteins. Thrombopoietin, a glycoprotein

synthesized in the liver and kidneys, regulates megakaryocytic proliferation and maturation, as well as platelet production.[11] Once they enter the circulation, platelets have a life span of 7 to 10 days.

Damage to the intimal lining of the vessel exposes the underlying subendothelial matrix. Platelets home to sites of vascular disruption and adhere to the exposed matrix proteins. Adherent platelets undergo activation and not only release substances that recruit additional platelets to the site of injury, but also promote thrombin generation and subsequent fibrin formation (**Fig. 93.3**). A potent platelet agonist, thrombin amplifies platelet recruitment and activation. Activated platelets then aggregate to form a plug that seals the leak in the vasculature. An understanding of the steps in these highly integrated processes helps pinpoint the sites of action of antiplatelet drugs and rationalizes the usefulness of anticoagulants for the treatment of arterial and venous thrombosis.

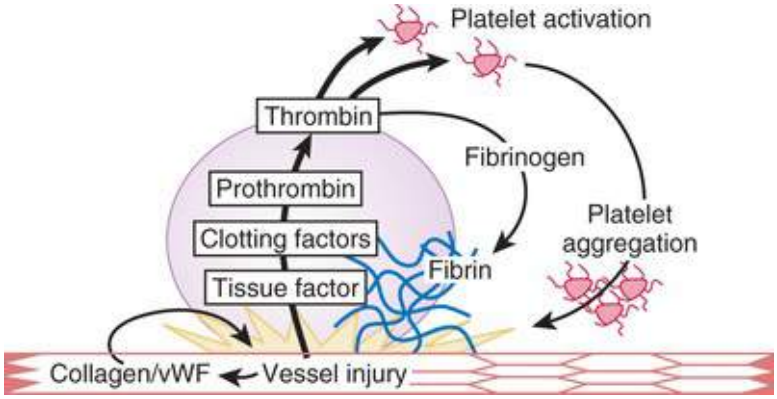

FIGURE 93.3 Central role of thrombin in thrombogenesis. Vascular injury simultaneously triggers platelet adhesion and activation, as well as activation of the coagulation system. Platelet activation is initiated by exposure of subendothelial collagen and von Willebrand factor (vWF), onto which platelets adhere. Adherent platelets become activated and release ADP and thromboxane A_2, platelet agonists that activate ambient platelets and recruit them to the site of injury. Coagulation, which is triggered by tissue factor exposed at the site of injury and enhanced by assembly of clotting factor complexes on the activated platelet surface, results in thrombin generation. Thrombin not only converts fibrinogen to fibrin but also serves as a potent platelet agonist. When platelets are activated, glycoprotein (GP) IIb/IIIa on their surfaces undergoes a conformational change that endows it with the capacity to ligate fibrinogen and mediate platelet aggregation. Fibrin strands then weave the platelet aggregates together to form a platelet/fibrin thrombus.

Adhesion

Platelets adhere to exposed collagen and von Willebrand factor (vWF) and form a monolayer that supports and promotes thrombin generation and subsequent fibrin formation.[12] These events depend on constitutively expressed receptors on the platelet surface, $\alpha_{2\beta1}$ and glycoprotein VI (GP VI), which bind collagen, and GP Ibα and GP IIb/IIIa ($\alpha_{IIb\beta3}$), which bind vWF. Receptors crowd the platelet surface, but those involved in adhesion are the most abundant; every platelet has approximately 80,000 copies of GP IIb/IIIa and 25,000 copies of GP Ibα. Receptors cluster in cholesterol-enriched subdomains, which render them more mobile, thereby increasing the efficiency of platelet adhesion and subsequent activation.[13]

Under low-shear conditions, collagen can capture and activate platelets on its own. The captured platelets undergo cytoskeletal reorganization, which causes them to flatten out and adhere more closely to the damaged vessel wall. Under high-shear conditions, however, collagen and vWF must act in concert to support optimal platelet adhesion and activation. The vWF synthesized by endothelial cells and megakaryocytes assembles into multimers that range in size from 550 kDa to greater than 10,000 kDa.[14]

When released from storage in the Weibel-Palade bodies of endothelial cells or the alpha-granules of platelets, most of the vWF enters the circulation, but the vWF released from the abluminal surface of endothelial cells accumulates in the subendothelial matrix, where it binds collagen via its A3 domain. This surface-immobilized vWF can simultaneously bind platelets via its A1 domain. In contrast, circulating vWF does not react with unstimulated platelets. This difference in reactivity reflects the conformation of vWF; circulating vWF is in a coiled conformation, which prevents access of its platelet-binding domain to vWF receptors on the platelet surface, whereas immobilized vWF assumes an elongated shape, which exposes the platelet-binding A1 domain. In their extended conformation, large vWF multimers act as the molecular glue that tethers platelets to the damaged vessel wall with sufficient strength to withstand a higher shear force. Large vWF multimers provide additional binding sites for collagen and heighten platelet adhesion because platelets have more vWF receptors than collagen receptors.[14,15] Adhesion to collagen or vWF results in platelet activation, the next step in platelet plug formation.

Activation

Adhesion to collagen and vWF initiates signaling pathways that result in platelet activation. These pathways induce cyclooxygenase-1 (COX-1)-dependent synthesis and release of thromboxane A_2 and trigger the release of ADP from storage granules. Thromboxane A_2 is a potent vasoconstrictor and, like ADP, locally activates ambient platelets and recruits them to the site of injury, thereby expanding the platelet plug. To activate platelets, thromboxane A_2 and ADP must bind to their respective receptors on the platelet membrane. The thromboxane receptor (TP) is a G protein–coupled receptor that is found on platelets and the endothelium, which explains why thromboxane A_2 induces vasoconstriction as well as platelet activation.[16] ADP interacts with a family of G protein–coupled receptors on the platelet membrane.[17,18] The most important of these is $P2Y_{12}$, which is the target of the thienopyridines (clopidogrel and prasugrel) and ticagrelor. $P2Y_1$ also contributes to ADP-induced platelet activation such that maximal ADP-induced platelet activation requires activation of both receptors. A third ADP receptor, $P2X_1$, is an adenosine triphosphate (ATP)-gated calcium channel. Platelet storage granules contain ATP, as well as ADP; the ATP released during the platelet activation process may contribute to the platelet recruitment process in a $P2X_1$-dependent fashion.

Although TP and the various ADP receptors signal through different pathways, they all trigger an increase in the intracellular concentration of calcium in platelets. The increase in calcium induces changes in platelet shape via cytoskeletal rearrangement, granule mobilization and release, and subsequent platelet aggregation. Activated platelets promote coagulation by expressing phosphatidylserine on their surface, an anionic phospholipid that supports the assembly of coagulation factor complexes. Once assembled, these clotting factor complexes trigger a burst of thrombin generation and subsequent fibrin formation. In addition to converting fibrinogen to fibrin, thrombin amplifies platelet recruitment and activation and promotes expansion of the platelet plug. Thrombin binds to protease-activated receptor types 1 and 4 (PAR-1 and PAR-4, respectively) on the platelet surface and cleaves their extended amino-terminal tail (**Fig. 93.4**), thereby generating new amino-termini that serve as tethered ligands that bind and activate the receptors.[19] Low concentrations of thrombin cleave PAR-1, whereas PAR-4 cleavage requires higher thrombin concentrations. Cleavage of either receptor triggers platelet activation.

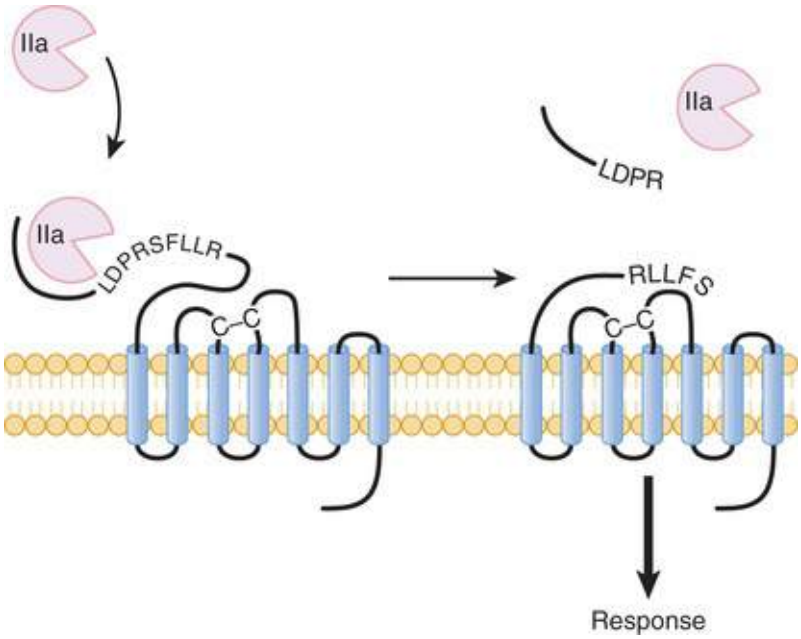

FIGURE 93.4 Activation of PAR-1 by thrombin. Thrombin (IIa) binds to the amino-terminal of the extracellular domain of PAR-1, where it cleaves a specific peptide bond. Cleavage of this bond generates a new amino-terminal sequence that acts as a tethered ligand and binds to the body of the receptor, thereby activating it. Thrombin then dissociates from the receptor. Analogues of the first five or six amino acids of the tethered ligand sequences, known as thrombin receptor agonist peptides, can independently activate PAR-1. *LDPRSFLLR*, Leu-Asp-Pro-Arg-Ser-Phe-Leu-Leu-Arg; *RLLFS*, Arg-Leu-Leu-Phe-Ser.

In addition to providing a surface on which clotting factors assemble, activated platelets also promote fibrin formation and subsequent stabilization by enhancing the factor V, factor VIII, factor XI and factor XIII. Thus, a coordinated activation of platelets and coagulation, and the fibrin network that results from the action of thrombin, help anchor the platelet aggregates at the site of injury. Activated platelets also release adhesive proteins, such as vWF, thrombospondin, and fibronectin, which may augment platelet adhesion at sites of injury, as well as growth factors such as platelet-derived growth factor (PDGF) and transforming growth factor-beta (TGF-β), which promote wound healing.

Platelet Aggregation

Aggregation is the final step in formation of the platelet plug by linking platelets to each other to form clumps. GP IIb/IIIa mediates these platelet-to-platelet linkages. On nonactivated platelets, GP IIb/IIIa exhibits minimal affinity for its ligands. Upon platelet activation, GP IIb/IIIa undergoes a conformational change that reflects transmission of inside-out signals from its cytoplasmic domain to its extracellular domain.[18] This transformation enhances the affinity of GP IIb/IIIa for its ligands, fibrinogen, and, under high-shear conditions, vWF. Arg-Gly-Asp (RGD) sequences located on fibrinogen and vWF, as well as a platelet-binding Lys-Gly-Asp (KGD) sequence on fibrinogen, mediate their interactions with GP IIb/IIIa. When subjected to high shear, circulating vWF elongates and exposes its platelet-binding domain, which enables its interaction with the conformationally activated GP IIb/IIIa.[15] Divalent fibrinogen and multivalent vWF molecules serve as bridges and bind adjacent platelets together. Once bound to GP IIb/IIIa, fibrinogen and vWF induce outside-inside signals that augment platelet activation and result in the activation of additional GP IIb/IIIa receptors, thus creating a positive feedback loop. Because GP IIb/IIIa serves as the final effector in platelet aggregation, it is a logical target for potent antiplatelet drugs. Fibrin, the ultimate product of the coagulation system, tethers the platelet aggregates together and anchors them to the site of injury.

Coagulation

Coagulation results in the generation of thrombin, which converts soluble fibrinogen to fibrin.[20] Coagulation occurs through the action of discrete enzyme complexes composed of a vitamin K–dependent enzyme and a nonenzyme cofactor that assemble on anionic phospholipid membranes in a calcium-dependent fashion. Each enzyme complex activates a vitamin K–dependent substrate that becomes the enzyme component of the subsequent complex (**Fig. 93.5**). Together, these complexes generate a small amount of thrombin that feeds back to amplify its own generation by activating the nonenzyme cofactors and platelets.[20] The phosphatidylserine expressed on the surface of activated platelets provides an anionic surface on which the complexes assemble. The three enzyme complexes involved in thrombin generation are extrinsic tenase, intrinsic tenase, and prothrombinase. Although extrinsic tenase initiates the system under most circumstances, the contact system also plays a role in some situations.

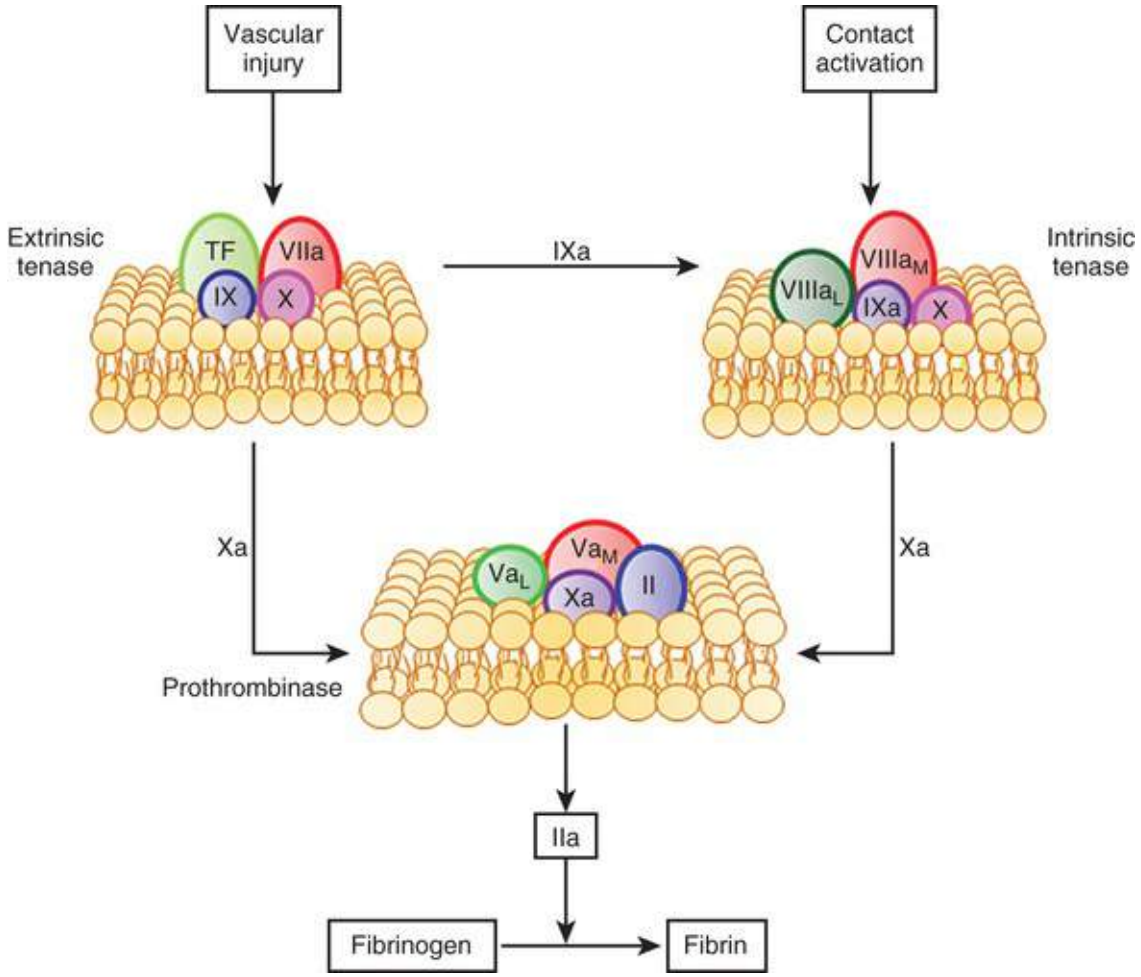

FIGURE 93.5 Coagulation system. Coagulation occurs through the action of discrete enzyme complexes composed of a vitamin K–dependent enzyme and a nonenzyme cofactor. These complexes assemble on anionic phospholipid membranes, such as the surface of activated platelets, in a calcium-dependent fashion. Vascular injury exposes tissue factor (TF), which binds factor VIIa to form extrinsic tenase. Extrinsic tenase activates factors IX and X. Factor IXa binds to factor VIIIa to form intrinsic tenase, which activates factor X. Factor Xa binds to factor Va to form prothrombinase, which converts prothrombin (II) to thrombin (IIa). Thrombin then converts soluble fibrinogen to insoluble fibrin.

Extrinsic Tenase

This complex forms on exposure of tissue factor–expressing cells to blood. Tissue factor exposure occurs

after atherosclerotic plaque rupture because the core of the plaque is rich in cells that express tissue factor. Denuding injury to the vessel wall also exposes the tissue factor constitutively expressed by subendothelial smooth muscle cells. In addition to cells in the vessel wall, circulating monocytes and monocyte-derived microparticles (small membrane vesicles) also provide a source of tissue factor.[21] When tissue factor–bearing monocytes or microparticles bind to platelets or other leukocytes and their plasma membranes fuse, transfer of tissue factor takes place. By binding to the adhesion molecules expressed on activated endothelial cells or to P-selectin on activated platelets, these tissue factor–bearing cells or microparticles can initiate or augment coagulation.[21] This phenomenon probably explains how venous thrombi develop in the absence of obvious vessel wall injury.[2]

An integral membrane protein, tissue factor serves as a receptor for factor VII. Once bound, factor VII undergoes autoactivation,[22] thereby forming the extrinsic tenase complex, which is a potent activator of factors IX and X. Upon activation, factors IXa and Xa serve as the enzyme components of intrinsic tenase and prothrombinase, respectively.

Intrinsic Tenase

Factor IXa binds to factor VIIIa on anionic cell surfaces to form the intrinsic tenase complex. Factor VIII circulates in blood in a complex with vWF. Thrombin cleaves factor VIII and releases it from vWF, thereby converting it to its activated form. Activated platelets express binding sites for factor VIIIa. Once bound, factor VIIIa binds factor IXa in a calcium-dependent fashion to form the intrinsic tenase complex, which then activates factor X. The change in catalytic efficiency of factor IXa–mediated activation of factor X that occurs with deletion of individual components of the intrinsic tenase complex highlights their importance. Absence of the membrane or factor VIIIa almost completely abolishes enzymatic activity, and the catalytic efficiency of the complete complex is 10^9-fold greater than that of factor IXa alone. Because intrinsic tenase activates factor X at a rate 50- to 100-fold faster than extrinsic tenase does, intrinsic tenase plays a critical role in the amplification of factor Xa and thrombin generation. The bleeding that occurs in patients with hemophilia, which is a congenital deficiency of factor VIII or factor IX, highlights the importance of intrinsic tenase in hemostasis.

Prothrombinase

Factor Xa binds to factor Va, its activated cofactor, on anionic phospholipid membrane surfaces to form the prothrombinase complex. Activated platelets release factor V from their alpha granules, and this platelet-derived factor V may play a more important role in hemostasis than its plasma counterpart does. Although plasma factor V requires thrombin activation to exert its cofactor activity, the partially activated factor V released from platelets already exhibits substantial cofactor activity. Activated platelets express specific factor Va binding sites on their surface, and bound factor Va serves as a receptor for factor Xa. The catalytic efficiency of activation of prothrombin by factor Xa increases by 10^9-fold when factor Xa is incorporated into the prothrombinase complex. Prothrombin binds to the prothrombinase complex, where it undergoes conversion to thrombin in a reaction that releases prothrombin fragment 1.2 (F1.2). Plasma levels of F1.2 therefore provide a marker of prothrombin activation.

Fibrin Formation

Thrombin, the final effector in coagulation, converts soluble fibrinogen to insoluble fibrin. Fibrinogen is a dimeric molecule, each half of which is composed of three polypeptide chains. the Aα, Bβ, and γ chains. Numerous disulfide bonds covalently link the chains together and join the two halves of the fibrinogen

molecule (**Fig. 93.6**). Electron micrographic studies of fibrinogen reveal a trinodular structure with a central E domain flanked by two D domains. Crystal structures show symmetry of design with the central E domain, which contains the amino-termini of the fibrinogen chains joined to the lateral D domains by coiled-coil regions.

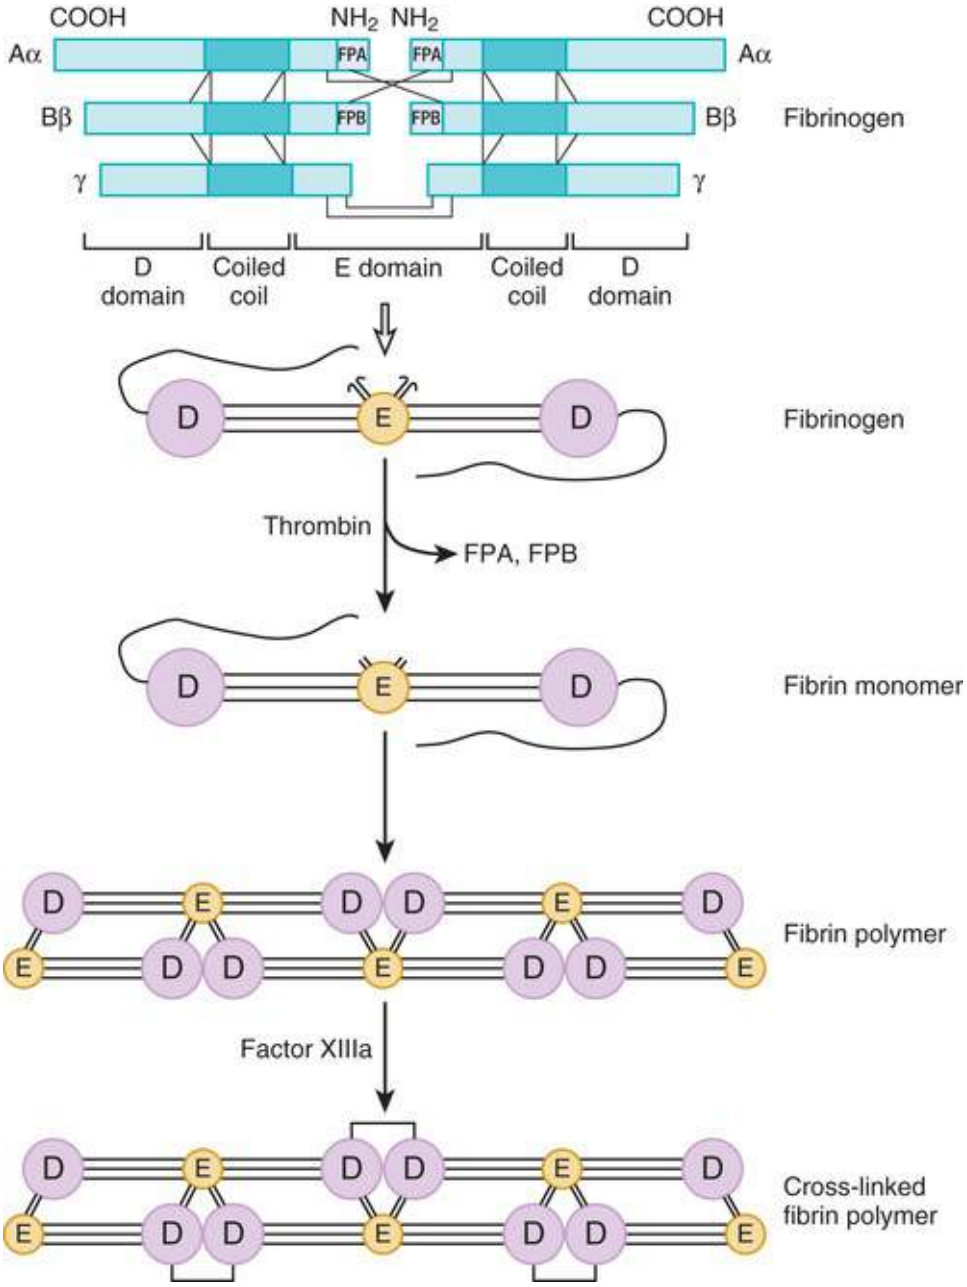

FIGURE 93.6 Fibrinogen structure and conversion of fibrinogen to fibrin. A dimer, each half of the fibrinogen molecule is composed of three polypeptide chains, the Aα, Bβ, and γ chains. Numerous disulfide bonds *(lines)* covalently link the chains together and join the two halves of the fibrinogen molecule to yield a trinodular structure with a central E domain linked via the coiled-coil regions to two lateral D domains. To convert fibrinogen to fibrin, thrombin cleaves specific peptide bonds at the amino (NH_2) terminals of the Aα and Bβ chains of fibrinogen to release fibrinopeptide A (FPA) and fibrinopeptide B (FPB), thereby generating fibrin monomer. Fibrin monomers polymerize to generate protofibrils arranged in a half-staggered overlapping manner. By covalently cross-linking the α and γ chains of adjacent fibrin monomers, factor XIIIa stabilizes the fibrin network and renders it resistant to degradation.

Fibrinogen, the most abundant plasma protein involved in coagulation, circulates in an inactive form. Thrombin binds to the amino-terminals of the Aα and Bβ chains of fibrinogen, where it cleaves specific peptide bonds to release fibrinopeptide A and fibrinopeptide B and generates fibrin monomers (**see Fig.**

93.6). Because they are products of the action of thrombin on fibrinogen, fibrinopeptide plasma levels provide an index of thrombin activity. Release of the fibrinopeptides creates new amino-termini that extend as knobs from the E domain of one fibrin monomer and insert into preformed holes in the D domains of other fibrin monomers. This creates long strands known as protofibrils that consist of fibrin monomers noncovalently linked together in a half-staggered, overlapping fashion.

Noncovalently linked fibrin protofibrils are unstable. By covalently cross-linking α- and γ-chains of adjacent fibrin monomers, factor XIIIa stabilizes the fibrin network in a calcium-dependent fashion and renders it relatively resistant to degradation. Factor XIII circulates in blood as a heterodimer consisting of two A and two B subunits. The active site and calcium binding sites of factor XIII are localized to the A subunit. Platelets contain large amounts of factor XIII in their cytoplasm, but platelet-derived factor XIII consists only of A subunits. Both plasma and platelet factor XIII are activated by thrombin.

Contact Pathway

Current thinking views exposure of tissue factor as the sole pathway for activation of coagulation and regards the contact system—which includes factor XII, prekallikrein, and high-molecular-weight kininogen—as unimportant for hemostasis because patients deficient in these factors do not have bleeding problems. The physiologic role of factor XI is more difficult to assess because the plasma level of factor XI in patients with congenital deficiency of factor XI, so-called hemophilia C, does not predict the propensity for bleeding. Although the capacity of thrombin to feed back upon and activate platelet-bound factor XI may explain this phenomenon, platelet-derived factor XI may be more important than circulating factor XI for hemostasis.

We cannot ignore the contact pathway, however, because coronary catheters and other blood-contacting medical devices, such as stents or mechanical heart valves, probably trigger clotting through this mechanism.[23] Factor XII binds to the surface of catheters or devices, where it undergoes a conformational change that results in its activation. Factor XIIa converts prekallikrein to kallikrein in a reaction accelerated by high-molecular-weight kininogen, and factor XIIa and kallikrein then feed back to activate additional factor XII. Factor XIIa propagates coagulation by activating factor XI (**Fig. 93.7**).

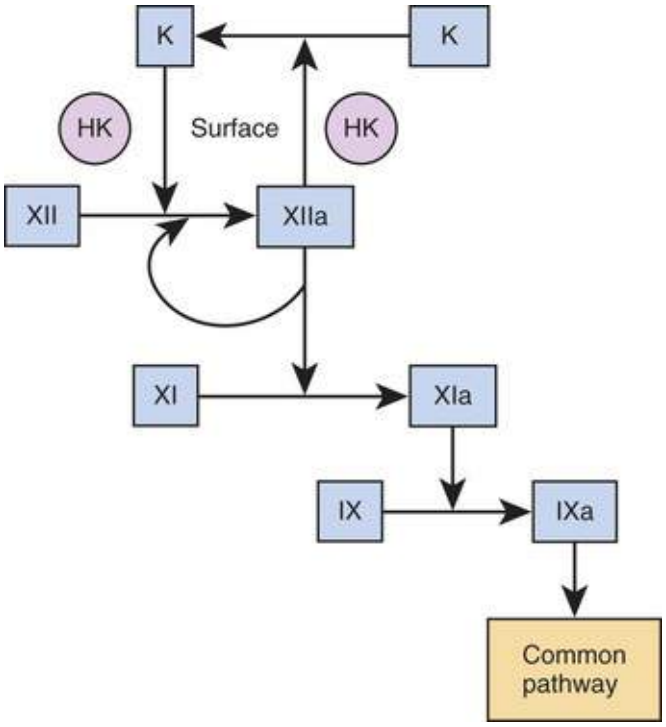

FIGURE 93.7 Contact system. Factor XII is activated by contact with negatively charged surfaces. Factor XIIa converts prekallikrein (PK) to kallikrein (K) and can feed back to activate more factor XII. Similarly, factor XIIa also can feed back to amplify its own generation. Approximately 75% of circulating PK is bound to high-molecular-weight kininogen (HK), which localizes it to anionic surfaces and promotes activation of PK. Factor XIIa propagates clotting by activating factor XI, which then activates factor IX. The resultant factor IXa assembles into the intrinsic tenase complex, which activates factor X to initiate the common pathway of coagulation.

In addition to its role in device-related thrombosis, the contact pathway may also contribute to the stabilization of arterial and venous thrombi. Thus mice deficient in factor XII or factor XI form small unstable thrombi at sites of arterial or venous damage, suggesting that these factors contribute to thrombus stabilization.[24] Potential physiologic activators of the contact pathway include polyphosphates released from activated platelets, DNA or RNA released from damaged or apoptotic cells in atherosclerotic plaque, and the DNA and histone network of NETs extruded from activated neutrophils, which not only promotes platelet adhesion and activation but also triggers activation of factor XII.[24] Support for the role of these activators in thrombosis comes from observations in mice that phosphatases and DNA- or RNA-degrading enzymes attenuate thrombosis at sites of injury. These activators of thrombosis have uncertain roles in humans. Although patients with unstable angina have increased plasma levels of factor XIa,[25] it is unknown whether this reflects activation by factor XIIa or by thrombin. A recent study showed that lowering of factor XI with an antisense oligonucleotide in patients undergoing knee arthroplasty reduced the risk of postoperative VTE to a greater extent than enoxaparin. These findings identify factor XI and factor XII as potential targets for new anticoagulants. Regardless of the extent to which the contact pathway contributes to thrombin generation, the final product of coagulation is fibrin. Hemostasis depends on a dynamic balance between the formation of fibrin and its degradation; the fibrinolytic system mediates fibrin breakdown.

Fibrinolytic System

Fibrinolysis begins when plasminogen activators convert plasminogen to plasmin, which then degrades fibrin into soluble fragments (**Fig. 93.8**). Blood contains two immunologically and functionally distinct plasminogen activators, t-PA and u-PA. t-PA mediates intravascular fibrin degradation, whereas u-PA

binds to a specific u-PA receptor (u-PAR) on the surface of cells, where it activates cell-bound plasminogen.[10] Consequently, pericellular proteolysis during cell migration and tissue remodeling and repair are the major functions of u-PA.

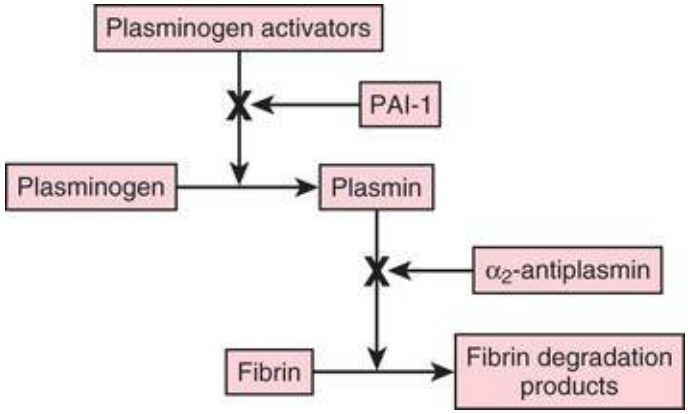

FIGURE 93.8 Fibrinolytic system and its regulation. Plasminogen activators convert plasminogen to plasmin. Plasmin then degrades fibrin into soluble fibrin degradation products. The system is regulated at two levels. Type 1 plasminogen activator inhibitor (PAI-1) inhibits the plasminogen activators, whereas alpha$_2$-antiplasmin serves as the major inhibitor of plasmin.

Regulation of fibrinolysis occurs at two levels. PAI-1 and, to a lesser extent, PAI-2 inhibit the plasminogen activators, whereas alpha$_2$-antiplasmin inhibits plasmin.[10] Endothelial cells synthesize PAI-1, which inhibits both t-PA and u-PA, whereas monocytes and the placenta synthesize PAI-2, which specifically inhibits u-PA. Thrombin-activated fibrinolysis inhibitor (TAFI) also attenuates fibrinolysis and provides a link between fibrinolysis and coagulation.[26] Impaired fibrinolysis promotes thrombus accumulation, whereas its excessive activation leads to bleeding.

Mechanism of Action of Tissue Plasminogen Activator

t-PA, a serine protease, contains five discrete domains: a fibronectin-like finger domain, an epidermal growth factor domain, two kringle domains, and a protease domain. Synthesized as a single-chain polypeptide, plasmin converts single-chain t-PA into a two-chain form. Both forms of t-PA convert plasminogen to plasmin. Native Glu-plasminogen is a single-chain polypeptide with a Glu residue at its amino-terminal. Plasmin cleavage near the amino-terminal generates Lys-plasminogen, a truncated form with a Lys residue at its new amino-terminus. t-PA cleaves a single peptide bond to convert single-chain Glu- or Lys-plasminogen into two-chain plasmin, which is composed of a heavy chain containing five kringle domains and a light chain containing the catalytic domain. Because its open conformation exposes the t-PA cleavage site, Lys-plasminogen is a better substrate for t-PA than Glu-plasminogen is, which assumes a circular conformation that renders this bond less accessible.

t-PA has little enzymatic activity in the absence of fibrin, but its activity increases by at least three orders of magnitude when fibrin is present.[10] This increase in activity reflects the capacity of fibrin to serve as a template that binds t-PA and plasminogen and promotes their interaction. t-PA binds fibrin via its finger and second kringle domains, whereas plasminogen binds fibrin via its kringle domains. Kringle domains are loop-like structures that bind Lys residues on fibrin. Degradation of fibrin exposes more Lys residues, which provides additional binding sites for t-PA and plasminogen. Consequently, degrading fibrin stimulates activation of plasminogen by t-PA more than intact fibrin does.

Alpha$_2$-antiplasmin rapidly inhibits circulating plasmin by docking to its first kringle domain and then

inhibiting the active site.[10] Because plasmin binds to fibrin via its kringle domains, plasmin generated on the fibrin surface resists inhibition by alpha$_2$-antiplasmin. This phenomenon endows fibrin-bound plasmin with the capacity to degrade fibrin. Factor XIIIa cross-links small amounts of alpha$_2$-antiplasmin onto fibrin, which prevents premature fibrinolysis.

Like fibrin, annexin II on endothelial cells binds t-PA and plasminogen and promotes the interaction of these proteins. Cell surface gangliosides and alpha-enolase may also bind plasminogen and promote its activation by altering its conformation into the more readily activated open form. Plasminogen binds to endothelial cells via its kringle domains. Lipoprotein(a), which also possesses kringle domains, impairs cell-based fibrinolysis by competing with plasminogen for cell surface binding (**see also Chapter 48**). This phenomenon may explain the association between elevated levels of lipoprotein(a) and atherosclerosis (**see also Chapters 45 and 48**).[27]

Mechanism of Action of Urokinase Plasminogen Activator

Synthesized as a single-chain polypeptide, single-chain u-PA (scu-PA) has minimal enzymatic activity. Plasmin readily converts scu-PA into an active two-chain form that can bind u-PAR on cell surfaces. Further cleavage at the amino-termini of two-chain u-PA yields a truncated, lower-molecular-weight form that lacks the u-PAR binding domain.[10]

Two-chain forms of u-PA readily convert plasminogen to plasmin in the absence or presence of fibrin. In contrast, scu-PA does not activate plasminogen in the absence of fibrin, but can activate fibrin-bound plasminogen because plasminogen adopts a more open and readily activatable conformation when immobilized on fibrin. Like the higher-molecular-weight form of two-chain u-PA, scu-PA binds cell surface u-PAR, where plasmin can activate it. Many tumor cells elaborate u-PA and express u-PAR on their surface. Plasmin generated on these cells promotes their ability to metastasize.[28]

Mechanism of Action of Thrombin-Activatable Fibrinolysis Inhibitor

Thrombin activatable fibrinolysis inhibitor (TAFI) originates in the liver and circulates in blood in a latent form, where thrombin bound to thrombomodulin can activate it. Unless bound to thrombomodulin, thrombin activates TAFI inefficiently.[26] Activated TAFI (TAFIa) attenuates fibrinolysis by cleaving Lys residues from the carboxy-termini of chains of degrading fibrin, thereby removing binding sites for plasminogen, plasmin, and t-PA. TAFI links fibrinolysis to coagulation in that the thrombin-thrombomodulin complex not only activates TAFI, which attenuates fibrinolysis, but also activates protein C, which mutes thrombin generation (**Fig. 93.2**). TAFIa has a short half-life in plasma because the enzyme is unstable.[26] Genetic polymorphisms can result in the synthesis of more stable forms of TAFIa. Persistent attenuation of fibrinolysis by these variant forms of TAFIa may render patients susceptible to thrombosis.[26]

Thrombosis

A physiologic host defense mechanism, hemostasis focuses on arrest of bleeding by forming hemostatic plugs composed of platelets and fibrin at sites of vessel injury. In contrast, thrombosis reflects a pathologic process associated with intravascular thrombi that fill and occlude the lumens of arteries or veins.

Arterial Thrombosis (see also Chapter 44)

Most arterial thrombi occur on top of disrupted atherosclerotic plaques. Coronary plaques with a thin fibrous cap and a lipid-rich core are most prone to disruption.[1] Rupture of the fibrous cap exposes thrombogenic material in the lipid-rich core to blood and triggers platelet activation and thrombin generation. The extent of plaque disruption and the content of thrombogenic material in the plaque determine the consequences of the event, but host factors also contribute. Breakdown of the regulatory mechanisms that limit platelet activation and inhibit coagulation can augment thrombosis at sites of plaque disruption. Decreased production of nitric oxide and prostacyclin by diseased endothelial cells can trigger vasoconstriction and platelet activation.[29] Proinflammatory cytokines lower expression of thrombomodulin by endothelial cells, which promotes thrombin generation, and stimulate expression of PAI-1, which inhibits fibrinolysis.[30]

Products of blood coagulation contribute to atherogenesis, as well as to its complications. Microscopic erosions in the vessel wall trigger the formation of tiny platelet-rich thrombi. Activated platelets release PDGF and TGF-β, which promote a fibrotic response.[31] Thrombin generated at the site of injury not only activates platelets and converts fibrinogen to fibrin but also activates the thrombin receptor PAR-1 on smooth muscle cells and induces their proliferation, migration, and elaboration of extracellular matrix. Incorporation of microthrombi into plaque promotes their growth, and decreased endothelial cell production of heparan sulfate—which normally limits smooth muscle proliferation—contributes to plaque expansion. The multiple links between atherosclerosis and thrombosis have prompted the term *atherothrombosis*.

Venous Thrombosis (see also Chapter 84)

Venous thrombosis may be caused by genetic or acquired hypercoagulable states or by such factors as advanced age, obesity, or cancer, which are usually acquired and are associated with immobility (**Table 93.1**). Inherited hypercoagulable states and these acquired risk factors combine to establish the intrinsic risk for thrombosis in each individual. Superimposed triggering factors, such as surgery, smoking, pregnancy, or hormonal therapy, modify this risk, and thrombosis occurs when the combination of genetic, acquired, and triggering forces exceeds a critical threshold (**Fig. 93.9**).

TABLE 93.1

Classification of Hypercoagulable States

HEREDITARY	MIXED	ACQUIRED
Loss of Function		
Antithrombin deficiency	Hyperhomocysteinemia	Advanced age
Protein C deficiency		Previous venous thromboembolism
Protein S deficiency		Surgery
Gain of Function		Immobilization
Factor V Leiden		Obesity
Prothrombin gene mutation		Cancer
Elevated factor VIII, IX, or XI levels		Pregnancy, puerperium
		Drug-induced: L-asparaginase, hormonal therapy

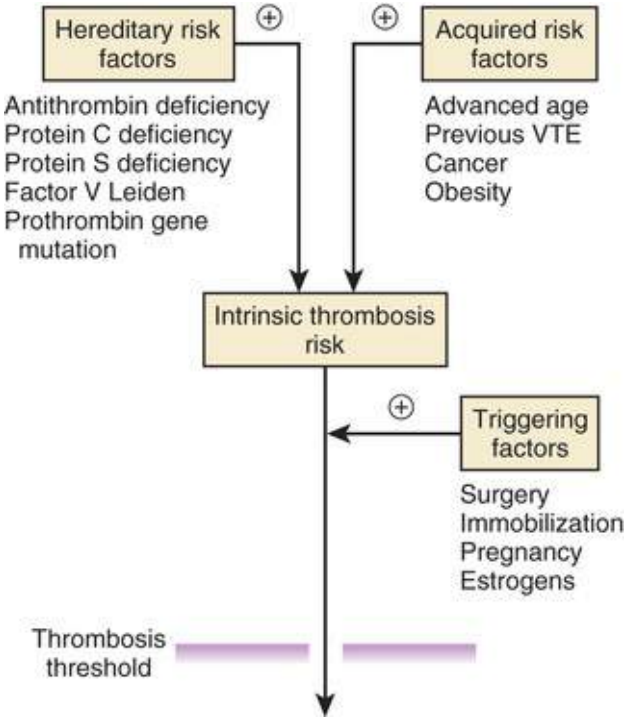

FIGURE 93.9 Thrombosis threshold. Hereditary and acquired risk factors combine to create an intrinsic risk for thrombosis in each individual. This risk is increased by extrinsic triggering factors. If the intrinsic and extrinsic forces exceed a critical threshold at which thrombin generation overwhelms protective mechanisms, thrombosis occurs. VTE, venous thromboembolisn.

Some acquired or triggering factors entail a higher risk than do others. For example, major orthopedic surgery, neurosurgery, multiple traumas, and metastatic cancer (particularly adenocarcinoma) entail the highest risk, whereas prolonged bed rest, the presence of antiphospholipid antibodies, and the puerperium are associated with intermediate risk; pregnancy, obesity, long-distance travel, and the use of oral contraceptives or hormonal replacement therapy are mild risk factors. Up to half of patients with VTE before the age of 45 years have inherited hypercoagulable disorders (so-called thrombophilia), particularly those whose event occurred in the absence of risk factors or with minimal provocation, such as after minor trauma or a long-haul flight or with estrogen use. The following sections describe the inherited and acquired hypercoagulable states.

Inherited Hypercoagulable States

Inherited hypercoagulable states fall into two categories. Some are associated with gain-of-function mutations in procoagulant pathways, such as factor V Leiden, the prothrombin gene mutation, and increased levels of procoagulant proteins; others are associated with loss-of-function mutations of endogenous anticoagulant proteins, such as deficiencies of antithrombin, protein C, and protein S. Although all of these inherited hypercoagulable disorders increase the risk for VTE, only increased levels of procoagulant proteins are clearly associated with an increased risk for arterial thrombosis.

Factor V Leiden

The factor V Leiden mutation, present in about 5% of white individuals, is the most common inherited thrombophilia. Because of a founder effect, the mutation is less common in Hispanics and blacks and rare in Asians. Caused by a point mutation in the factor V gene, the defect results in the synthesis of a factor V molecule with a Gln residue in place of an Arg residue at position 506, one of three sites where activated protein C cleaves factor Va to inactivate it. Consequently, activated factor V Leiden resists rapid

proteolysis and persists 10-fold longer in the presence of activated protein C than its wild-type counterpart does. The mutation is inherited in an autosomal dominant fashion. Individuals heterozygous for the factor V Leiden mutation have a fivefold increased risk for VTE; those homozygous for the mutation have a higher risk. However, the absolute risk for venous thrombosis is low with factor V Leiden, and with a yearly risk of 0.1% to 0.3%, patients with this disorder have a lifetime risk for thrombosis of only 5% to 10%.

An activated protein C resistance assay establishes the diagnosis of factor V Leiden in most cases. This assay involves calculation of the ratio of the activated partial thromboplastin time (APTT) measured after the addition of activated protein C divided by that determined before its addition. Use of factor V–deficient plasma increases the specificity of the test. When the clotting assay results are equivocal, genetic testing using a polymerase chain reaction (PCR)–based assay confirms the diagnosis.

Prothrombin Gene Mutation

The second most common thrombophilic disorder, the prothrombin gene mutation, reflects a G-to-A nucleotide transition at position 20210 in the 3′-untranslated region of the prothrombin gene. This mutation causes elevated levels of prothrombin, which enhance thrombin generation. The prevalence of the prothrombin gene mutation is about 3% in white persons and is lower in Asians and blacks. The mutation increases the risk for venous thrombosis to a similar extent as factor V Leiden does. Laboratory diagnosis depends on genetic screening after PCR amplification of the 3′-untranslated region of the prothrombin gene. Although persons heterozygous for this mutation have 30% higher levels of prothrombin than noncarriers do, the wide range of prothrombin levels in healthy individuals precludes the use of this phenotype for carrier identification.

Elevated Levels of Procoagulant Proteins

Elevated levels of factor VIII and other coagulation factors, including fibrinogen and factors IX and XI, appear to be independent risk factors for venous thrombosis. Increased levels of factor VIII are also associated with an up to threefold increase in the risk for myocardial infarction.[32] Although the molecular bases for the high levels of these coagulation factors have yet to be identified, genetic mechanisms probably contribute because these quantitative abnormalities have high heritability.

Antithrombin Deficiency

Synthesized in the liver, antithrombin regulates coagulation by forming a 1 : 1 covalent complex with thrombin, factor Xa, and other activated clotting factors. Heparan sulfate or heparin accelerates the rate of antithrombin interaction with its target proteases. Inherited antithrombin deficiency is rare; it occurs in approximately 1 in 2000 people and can be due to decreased synthesis of a normal protein or production of a dysfunctional protein. A parallel reduction in the levels of antithrombin antigen and activity identifies deficiencies caused by decreased synthesis, whereas decreased antithrombin activity in the presence of normal antigen levels identifies dysfunctional forms of antithrombin. Comparison of antithrombin activity with or without added heparin identifies variants with impaired heparin-binding capacity.

Acquired antithrombin deficiency results from decreased synthesis, increased consumption, or enhanced clearance. Decreased synthesis can occur in patients with severe hepatic disease, particularly cirrhosis, or in those given L-asparaginase. Increased activation of coagulation can result in antithrombin consumption in disorders such as extensive thrombosis, disseminated intravascular coagulation, severe sepsis, disseminated malignancy, or prolonged extracorporeal circulation. Heparin treatment can also

reduce antithrombin levels up to 20% by enhancing the clearance of antithrombin. Severe antithrombin deficiency can develop in some patients with nephrotic syndrome because of loss of protein in urine.

Protein C Deficiency

Thrombin initiates the protein C pathway when it binds thrombomodulin on the endothelial cell surface (**see Fig. 93.2**). Thrombin bound to thrombomodulin activates protein C approximately 1000-fold more efficiently than free thrombin does.[9] EPCR augments this process 20-fold by binding protein C and presenting it to the thrombin-thrombomodulin complex for activation.[9] Activated protein C then becomes dissociated from the activation complex and decreases thrombin generation by inactivating factors Va and VIIIa on the activated platelet surface. For efficient inactivation of these factors, activated protein C must bind to protein S, its cofactor.

Protein C deficiency can be inherited or acquired. Approximately 1 in 200 adults has heterozygous protein C deficiency inherited in an autosomal dominant fashion, but most have no history of thrombosis. The variable phenotypic expression of hereditary protein C deficiency suggests the existence of other, yet unrecognized, modifying factors. In contrast to antithrombin deficiency, in which the homozygous state is associated with embryonic lethality, homozygous or doubly heterozygous protein C deficiency can occur. Newborns with these disorders often develop purpura fulminans characterized by widespread thrombosis.

Inherited protein C deficiency can result from decreased synthesis of normal protein or from synthesis of dysfunctional forms of protein C. Identification of the type of deficiency requires simultaneous measurement of protein C antigen and activity; reduced synthesis of a normal protein results in a parallel reduction in protein C antigen and activity, whereas synthesis of a dysfunctional protein results in normal antigen with reduced activity.

Acquired protein C deficiency can be due to decreased synthesis or increased consumption. Decreased synthesis can occur in patients with severe liver disease or in those given warfarin. Protein C consumption can occur with severe sepsis, with disseminated intravascular coagulation, and after surgery. Although antithrombin levels can be low in patients with nephrotic syndrome, protein C levels are normal or elevated in such patients.

Protein S Deficiency

Protein S serves as a cofactor for activated protein C (**see Fig. 93.2**). In addition, protein S may directly inhibit prothrombin activation because of its capacity to bind factors Va and Xa, components of the prothrombinase complex, in the presence of zinc. The importance of the direct anticoagulant activity of protein S is uncertain.

In the circulation, approximately 60% of total protein S is bound to C4b-binding protein, a complement component; only the remaining free 40% is functionally active. Diagnosis of protein S deficiency requires measurement of both the free and bound forms of protein S. Inherited protein S deficiency can result from reduced synthesis of the protein or synthesis of a dysfunctional protein. Acquired protein S deficiency can be due to decreased synthesis, increased consumption, loss, or shift of free protein S to the bound form. Decreased synthesis can occur in patients with severe liver disease or in those given warfarin or L-asparaginase. Increased consumption of protein S occurs in patients with acute thrombosis or disseminated intravascular coagulation. Patients with nephrotic syndrome can excrete free protein S in their urine, which causes decreased protein S activity. Total protein S levels in these patients are often normal because the levels of C4b-binding protein increase, thus shifting more protein S to the bound form.

C4b-binding protein levels also increase in pregnancy and with the use of oral contraceptives. This shifts more protein S to the bound form and lowers the levels of free protein S and protein S activity. The consequences of this phenomenon are uncertain.

Other Hereditary Disorders

A polymorphism in the gene that encodes the EPCR has been linked to venous thrombosis. Associated with EPCR shedding and high levels of soluble EPCR, this polymorphism reduces endothelial EPCR, and soluble EPCR competes with its endothelial cell counterpart for protein C binding.

A polymorphism in factor XIII that results in more rapid activation by thrombin is associated with a small reduction in the risk for VTE, myocardial infarction, and ischemic stroke in some but not all case-control studies.[33] The frequency of this polymorphism varies among different ethnic populations, and certain environmental factors, such as obesity and estrogen therapy, may augment its protective effect. More work is needed to determine the extent to which this polymorphism modulates the risk for thrombosis.

Acquired Hypercoagulable States (see also Chapter 84)

Acquired hypercoagulable states may develop during surgery and the period of immobilization following it; in persons of advanced age; in those who are obese, have cancer, are pregnant, or are taking estrogen therapy (oral contraceptive or hormone replacement therapy); or in those with a history of VTE, antiphospholipid syndrome, or hyperhomocysteinemia (**see Table 93.1**). These conditions can occur in isolation or in conjunction with hereditary hypercoagulable states.

Surgery and Immobilization

Surgery can directly damage veins, and immobilization after surgery leads to stasis in the deep veins of the leg. The risk for VTE in surgical patients depends on the patient's age, the type of surgery, and the presence of active cancer. Patients older than 65 years have a greater risk, and high-risk types of surgery include major orthopedic procedures, neurosurgery, and extensive abdominal or pelvic surgery, especially for cancer. Because the risk for VTE increases up to 20-fold in these patients, they require thromboprophylaxis until they gain full mobility. Hospitalization and nursing home confinement account for approximately 60% of cases of VTE, again reflecting the impact of immobilization. Hospitalization for medical illness accounts for a similar proportion of cases as hospitalization for surgery, thus highlighting the need for thromboprophylaxis in medical patients as well as in surgical patients.

Advanced Age

Predominantly a disease of older age, VTE in those younger than 50 years has an incidence of 1 per 10,000 and increases approximately 10-fold per decade thereafter. Men have an overall age-adjusted incidence rate approximately 1.2-fold higher than women. Although incidence rates are higher in women during the reproductive years, after 45 years of age, men have higher incidence rates. Many potential mechanisms may increase the incidence of VTE with advanced age, including decreased mobility, associated diseases, and vascular endothelium that is less resistant to thrombosis. Levels of procoagulant proteins also increase with age.

Obesity

The risk for VTE increases approximately 1.2-fold for every 10-kg/m^2 increase in body mass index, but the basis for the association between obesity and VTE is unclear. Obesity leads to immobility; in addition, adipose tissue, particularly visceral fat, expresses proinflammatory cytokines and adipokines, which may promote coagulation by increasing levels of procoagulant proteins or impair fibrinolysis by elevating levels of PAI-1.

Cancer

Approximately 20% of patients with VTE have cancer.[34] Cancer patients with VTE have reduced survival times compared with those without VTE. Patients with brain tumors, pancreatic cancer, or advanced ovarian or prostate cancer have particularly high rates of VTE.[34] Treatment with chemotherapy, hormonal therapy, and biologic agents (such as erythropoietin and antiangiogenic drugs) further increases the risk, as do central venous catheters or surgery for cancer. The pathogenesis of thrombosis in cancer patients is multifactorial and involves a complex interplay between the tumor, patient characteristics, and the hemostatic system. Many types of tumor cells express tissue factor or other procoagulants that can initiate coagulation. In addition to its role in coagulation, tissue factor also acts as a signaling molecule that promotes tumor proliferation and spread.[35] Patient characteristics that contribute to VTE include immobility and venous stasis secondary to extrinsic compression of major veins by tumor. Surgical procedures, central venous catheters, and chemotherapy can injure vessel walls. In addition, tamoxifen and selective estrogen receptor modulators (SERMs) induce an acquired hypercoagulable state by reducing levels of natural anticoagulant proteins.

A proportion of patients with unprovoked VTE have occult cancer. This observation has prompted some experts to recommend extensive screening for cancer in such patients, but the potential harm—including procedure-related morbidity, the psychological impact of false-positive test results, and the cost of screening—offsets any benefits of this approach. Studies comparing extensive cancer screening with little or no screening in patients with unprovoked VTE have not demonstrated a reduction in cancer-related mortality rates with screening. Therefore unless symptoms suggestive of underlying cancer are present, only age-appropriate screening for breast, cervical, colon, and possibly prostate cancer is indicated because screening for these cancers may reduce mortality rates.

Pregnancy

Pregnant women have a fivefold to sixfold higher risk for VTE than do age-matched nonpregnant women. VTE occurs in approximately 1 in 1000 pregnancies, and in approximately 1 in 1000 women VTE develops in the postpartum period. VTE is the leading cause of maternal morbidity and mortality. Patient-related factors influence the risk for VTE in pregnancy and the puerperium, including age older than 35 years, body mass index higher than 29, cesarean delivery, thrombophilia, or a personal or family history of VTE. Ovarian hyperstimulation and multiparity also increase risk for thrombosis.

More than 90% of deep vein thrombi in pregnancy occur in the left leg, probably because the enlarged uterus compresses the left iliac vein. Hypercoagulability occurs in pregnancy because of the combination of venous stasis and changes in blood. Uterine enlargement reduces venous blood flow from the lower extremities. This is not the only contributor to venous stasis, however, because blood flow from the lower extremities begins to decrease by the end of the first trimester. Systemic factors also contribute to hypercoagulability. Thus levels of procoagulant proteins, such as factor VIII, fibrinogen, and vWF, increase in the third trimester of pregnancy. Coincidentally, suppression of the natural anticoagulant pathways takes place. These changes enhance thrombin generation, as evidenced by elevated levels of

F1.2 and thrombin-antithrombin complexes.

About half the episodes of VTE in pregnancy occur in women with thrombophilia. The risk for VTE in women with thrombophilic defects depends on the type of abnormality and the presence of other risk factors. Risk appears highest in women with antithrombin, protein C, or protein S deficiency and lower in those with factor V Leiden or the prothrombin gene mutation. In general, these women have a higher daily risk for VTE in the postpartum period than during pregnancy. The risk during pregnancy is similar in all three trimesters. Therefore, women needing thromboprophylaxis require treatment throughout pregnancy and for at least 6 weeks postpartum.

Sex Hormone Therapy (see also Chapter 92)

Oral contraceptives, estrogen replacement therapy, and SERMs are all associated with an increased risk for VTE. The relatively high risk for VTE associated with first-generation oral contraceptives prompted the development of low-dose formulations. Currently available low-estrogen combination oral contraceptives contain 20 to 50 µg of ethinyl estradiol and one of several different progestins. Even these low-dose combination contraceptives are associated with a threefold to fourfold increased risk for VTE in comparison with nonusers. In absolute terms this translates to an incidence of 3 to 4 per 10,000 as compared with 5 to 10 per 100,000 in nonusers of reproductive age.

Even though smoking increases the risk for myocardial infarction and stroke in women taking oral contraceptives, it is unclear whether smoking affects the risk for VTE. Obesity, however, increases the risk of both arterial and venous thrombosis. The risk for VTE is highest during the first year of oral contraceptive use and persists only for the duration of use. Case-control studies suggest a 20- to 30-fold higher risk for VTE in women with inherited thrombophilia who use oral contraceptives than in nonusers with thrombophilia or users without these defects. Despite the increased risk, routine screening for thrombophilia in young women considering oral contraceptive use is not recommended. Based on the incidence and case fatality rate of thrombotic events, estimates suggest that screening 400,000 women would detect 20,000 factor V Leiden carriers and that prevention of a single death would necessitate withholding oral contraceptives in all these women. Even larger numbers of women with less prevalent thrombophilic defects would require screening.

Hormonal replacement therapy with conjugated equine estrogen, with or without a progestin, is associated with a small increase in the risk for myocardial infarction, ischemic stroke, and VTE. SERMs, such as tamoxifen, are estrogen-like compounds that serve as an estrogen antagonist in the breast but as estrogen agonists in other tissues, such as bone and the uterus. Like estrogens, tamoxifen increases the risk for VTE by threefold to fourfold. The risk is higher in postmenopausal women, particularly those receiving systemic combination chemotherapy. Because of this risk, aromatase inhibitors, which antagonize estrogens by blocking their synthesis from androgens, are sometimes used in place of tamoxifen for the treatment of estrogen receptor–positive breast cancer. Aromatase inhibitors are associated with a lower risk for VTE than tamoxifen. Raloxifene, a SERM used to prevent osteoporosis, increases the risk for VTE threefold when compared with placebo, which contraindicates the use of raloxifene for prevention of osteoporosis in women with a history of VTE.

History of Previous Venous Thromboembolism

A history of previous VTE places patients at risk for recurrence. When anticoagulation treatment stops, patients with unprovoked VTE have a risk for recurrence of approximately 10% at 1 year and 30% at 5 years. This risk appears independent of whether an underlying thrombophilic defect is present, such as

factor V Leiden or the prothrombin gene mutation. The risk for recurrent VTE is lower in patients whose incident event occurred in association with a transient risk factor, such as major surgery or prolonged immobilization. These patients have a risk for recurrence of approximately 1% at 1 year and 5% at 5 years. Patients whose VTE occurred on the background of minor risk factors, such as a long-haul flight have an intermediate risk for recurrence. Patients at highest risk for recurrence are those with inherited deficiencies of antithrombin, protein C, or protein S; those with antiphospholipid antibody syndrome; patients with advanced malignancy; or those homozygous for factor V Leiden or the prothrombin gene mutation. Their risk for recurrence likely ranges from 15% at 1 year to up to 50% at 5 years.

Antiphospholipid Syndrome

A heterogeneous group of autoantibodies directed against proteins that bind phospholipid; some antiphospholipid antibodies, known as lupus anticoagulants (LA), prolong phospholipid-dependent coagulation assays. Others, anticardiolipin (ACL) antibodies, target cardiolipin, and a subset of ACL antibodies recognizes other phospholipid-bound proteins, particularly $beta_2$-glycoprotein I. Patients with thrombosis in association with a persistent LA and/or ACL antibody have antiphospholipid syndrome. Primary antiphospholipid syndrome occurs in isolation, whereas secondary forms are associated with autoimmune disorders, such as systemic lupus erythematosus or other connective tissue diseases. Patients with antiphospholipid syndrome can have arterial, venous, or placental thrombosis. Arterial thrombosis can cause a transient ischemic attack, stroke, or myocardial infarction. Cerebral vein thrombosis can occur in addition to deep vein thrombosis and pulmonary embolism. Placental thrombosis probably causes pregnancy-related complications that characterize antiphospholipid syndrome. Such complications include fetal loss before 10 weeks' gestation and unexplained fetal death after 10 weeks' gestation, intrauterine growth restriction, preeclampsia, and eclampsia. Treatment with aspirin and/or LMWH during pregnancy may reduce the risk for these complications in women with antiphospholipid syndrome but not in those with other documented thrombophilic defects.

Laboratory diagnosis of antiphospholipid syndrome requires the presence of an LA or ACL antibody on tests taken at least 6 weeks apart. Diagnosis of an LA requires a battery of phospholipid-dependent clotting tests, whereas immunoassays detect ACL antibodies. Only ACL antibodies of medium to high titer and of the IgG or IgM subclass are associated with thrombosis. Approximately 3% to 10% of healthy individuals have ACL antibodies. Such antibodies also occur with certain infections, such as mycobacterial pneumonia, malaria, or parasitic disorders, and after exposure to some medications. Frequently, these antibodies are transient and of low titer. Approximately 30% to 50% of patients with systemic lupus erythematosus or other connective tissue disorders have ACL antibodies, and 10% to 20% have an LA.

The mechanism by which antiphospholipid antibodies trigger thrombosis is unclear. These antibodies directly activate endothelial cells in culture and induce the expression of adhesion molecules that can tether tissue factor–bearing leukocytes or microparticles onto their surface. ACL antibodies also interfere with the protein C pathway, inhibit catalysis of antithrombin by endothelial heparan sulfate, and impair fibrinolysis. The relative importance of these mechanisms in humans remains unclear.

Hyperhomocysteinemia (see also Chapter 45)

Homocysteine serves as a methyl group donor during the metabolism of methionine, an essential amino acid derived from the diet. The interconversion of methionine and homocysteine depends on the

availability of 5-methyltetrahydrofolate, a methyl group donor; vitamin B_{12} and folate, cofactors in the interconversion; and the enzyme methionine synthase. Increased levels of homocysteine can result from increased production or reduced metabolism. Severe hyperhomocysteinemia and cystinuria, which are rare, usually result from deficiency of cystathionine beta-synthetase. The more common mild to moderate hyperhomocysteinemia often results from genetic mutations in methyltetrahydrofolate reductase (MTHFR) in association with nutritional deficiency of folate, vitamin B_{12}, or vitamin B_6. The common C677T and A1298C polymorphisms in MTHFR are associated with reduced enzymatic activity and increased thermolability, respectively, thereby increasing the requirement for nutritional cofactors. Hyperhomocysteinemia can also be associated with certain drugs, such as methotrexate, theophylline, cyclosporine, and most anticonvulsants, as well as with some chronic diseases, such as advanced renal disease, severe hepatic dysfunction, or hypothyroidism.

Although elevated levels of fasting serum homocysteine (> 15 mmol/L) were once common, routine fortification of flour in North America with folic acid has lowered homocysteine levels in the general population. Elevated serum homocysteine may be associated with an increased risk for myocardial infarction, stroke, and peripheral artery disease, as well as VTE. Administration of folate along with vitamin B_{12} and vitamin B_6 reduces levels of homocysteine. Nonetheless, randomized trials have shown that such therapy does not lower the risk for recurrent cardiovascular events in patients with coronary artery disease or stroke, nor does it lower the risk for recurrent VTE. Based on these negative trials and the declining incidence of hyperhomocysteinemia, enthusiasm for screening for hyperhomocysteinemia has declined.

Treatment of Thrombosis

Antiplatelet Drugs

The commonly used antiplatelet drugs include aspirin, thienopyridines (ticlopidine, clopidogrel, and prasugrel), ticagrelor, cangrelor, dipyridamole, GPIIb/IIIa antagonists, and vorapaxar. Each agent has a distinct site of action (**see Fig. 93.10**).

Aspirin

Aspirin is the most widely used antiplatelet agent worldwide. Because it is an inexpensive and effective drug, aspirin serves as the foundation of most antiplatelet strategies.

Mechanism of Action

Aspirin produces its antithrombotic effect by irreversibly acetylating and inhibiting platelet COX-1 (**Fig. 93.10**), a critical enzyme in the biosynthesis of thromboxane A_2. At high doses (≈ 1 g/day), aspirin also inhibits COX-2, an inducible COX isoform found in endothelial cells and inflammatory cells.[36] In endothelial cells, COX-2 initiates the synthesis of prostacyclin, a potent vasodilator and inhibitor of platelet activation that antagonizes the effects of thromboxane A_2.

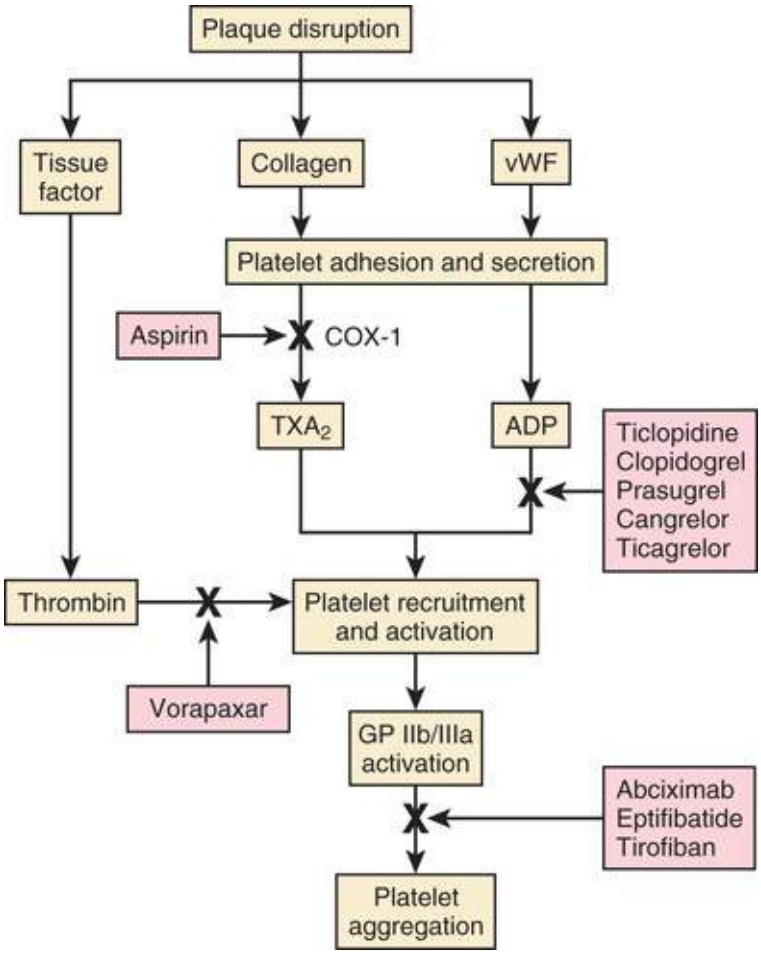

FIGURE 93.10 Sites of action of antiplatelet drugs. Aspirin inhibits the synthesis of thromboxane A_2 (TXA_2) by irreversibly acetylating cyclo-oxygenase 1 (COX-1). The reduced release of TXA_2 attenuates platelet activation and recruitment to the site of vascular injury. Ticlopidine, clopidogrel, and prasugrel irreversibly block $P2Y_{12}$, a key ADP receptor on the platelet surface; cangrelor and ticagrelor are reversible inhibitors of $P2Y_{12}$. Abciximab, eptifibatide, and tirofiban inhibit the final common pathway of platelet aggregation by blocking binding of fibrinogen and vWF to activated GP IIb/IIIa. Vorapaxar inhibits thrombin-mediated platelet activation by targeting protease-activated receptor-1 (PAR-1), the major thrombin receptor on platelets.

Indications

Aspirin is widely used for secondary prevention in patients with established coronary, cerebrovascular, or peripheral artery disease. In such patients, aspirin produces about a 20% reduction in the risk for cardiovascular death, myocardial infarction, or stroke.[36] Use of aspirin for primary prevention is more controversial. Metaanalyses suggest that daily aspirin use produces a 20% to 25% reduction in the risk for a first cardiovascular event in patients at moderate to high risk for cardiovascular disease. Recent studies, however, have questioned whether the benefits of daily aspirin for primary cardiac protection outweigh its associated risks for gastrointestinal and intracerebral hemorrhage.[37] Consequently, aspirin is no longer recommended for primary cardiac prevention unless the baseline cardiovascular risk is at least 1% per year and 10% at 10 years (**see also Chapters 45 and 89**).[38]

Dosages

Usually administered at dosages of 75 to 325 mg once daily, there is no evidence that higher-dose aspirin is more effective than lower doses, and some metaanalyses suggest reduced efficacy with higher doses.[36] Because the side effects of aspirin, particularly gastrointestinal bleeding, depend on the dosage, daily

aspirin dosages of 75 to 150 mg suffice for most indications. Rapid platelet inhibition requires an initial dose of non–enteric-coated aspirin of at least 160 mg.[36]

Side Effects

The most common side effects are gastrointestinal, and they range from dyspepsia to erosive gastritis or peptic ulcers with bleeding and perforation.[36] Use of enteric-coated or buffered aspirin in place of plain aspirin does not eliminate the risk for gastrointestinal side effects. The risk for major bleeding with aspirin is 1% to 3% per year. The concomitant use of aspirin and anticoagulants such as warfarin increases the risk for bleeding. When combined with warfarin, use of low-dose aspirin (75 to 100 mg daily) is best. Eradication of *Helicobacter pylori* infection and administration of proton pump inhibitors may reduce the risk for aspirin-induced upper gastrointestinal bleeding in patients with peptic ulcer disease.

Patients with a history of aspirin allergy characterized by bronchospasm should not receive aspirin. This problem occurs in approximately 0.3% of the general population but is more common in patients with chronic urticaria or asthma, particularly those with coexisting nasal polyps or chronic rhinitis.[39] Clopidogrel can be used in place of aspirin in such patients. Aspirin overdose is associated with hepatic and renal toxicity.

Aspirin Resistance

The term *aspirin resistance* is used to describe both clinical and laboratory phenomena.[40] A diagnosis of clinical aspirin resistance, defined as failure of aspirin to protect patients from ischemic vascular events, can be made only after such an event occurs. This retrospective diagnosis provides no opportunity to modify therapy. Furthermore, it is unrealistic to expect aspirin, which selectively blocks thromboxane A_2–induced platelet activation, to prevent all vascular events. The biochemical definition of aspirin resistance involves failure of the drug to inhibit thromboxane A_2 synthesis and/or arachidonic acid–induced platelet aggregation. Potential mechanisms for aspirin resistance include poor adherence, reduced or delayed absorption of aspirin due to its enteric coating,[41] thromboxane A_2 generation via pathways distinct from COX-1, increased activity of thromboxane A_2–independent pathways of platelet activation, use of concomitant medications that interfere with the action of aspirin, and pharmacogenetic factors. Tests used for the diagnosis of biochemical aspirin resistance include measurements of thromboxane B_2, the stable metabolite of thromboxane A_2, in serum or in urine, and assessment of arachidonic acid–induced platelet aggregation. These tests have not been standardized, however, and there is no evidence that they identify patients at risk for recurrent vascular events or that resistance can be reversed either by giving higher doses of aspirin or by adding other antiplatelet drugs. Until such information is available, testing for aspirin resistance remains a research tool.

Thienopyridines (see also Chapters 59 to 61)

The thienopyridines include ticlopidine, clopidogrel, and prasugrel, drugs that target $P2Y_{12}$, a key ADP receptor on platelet.

Mechanism of Action

The thienopyridines selectively inhibit ADP-induced platelet aggregation by irreversibly blocking $P2Y_{12}$ (**see Fig. 93.10**). These prodrugs require metabolic activation by the hepatic cytochrome P-450 (CYP)

enzyme system. Therefore, when given in usual doses, ticlopidine and clopidogrel have a delayed onset of action. The metabolic activation of prasugrel is more efficient than that of clopidogrel. Consequently, prasugrel acts more rapidly and produces greater and more predictable inhibition of ADP-induced platelet aggregation than clopidogrel.[42] The active metabolites of the thienopyridines bind irreversibly to $P2Y_{12}$. Consequently, these drugs have prolonged action, which can present problems if patients require urgent surgery. To reduce the risk for bleeding, thienopyridine therapy must be stopped approximately 5 days before surgery.

Indications

When compared with aspirin in patients with recent ischemic stroke, myocardial infarction, or peripheral arterial disease, clopidogrel reduced the risk for cardiovascular death, myocardial infarction, and stroke by 8.7%. Therefore, clopidogrel is marginally more effective than aspirin, but it is more expensive, although the cost of clopidogrel has decreased now that generic forms are available. The combination of clopidogrel and aspirin capitalizes on the capacity of each drug to block complementary pathways of platelet activation. For example, this combination is recommended after stent implantation in coronary arteries. **Chapter 62** discusses the use of antiplatelet agents after intervention.

The combination of clopidogrel and aspirin is also effective in patients with unstable angina (**see also Chapter 60**). In 12,562 such patients, the risk for cardiovascular death, myocardial infarction, or stroke was 9.3% in those randomly assigned to the combination of clopidogrel and aspirin and 11.4% in those given aspirin alone. This 20% relative risk reduction with combination therapy was highly statistically significant. However, combining clopidogrel with aspirin increases the risk for major bleeding to approximately 2% per year, a risk that persists even with a daily aspirin dose of 100 mg or less. Therefore use of clopidogrel plus aspirin should be restricted to situations in which there is clear evidence of benefit. For example, this combination has not proved to be superior to clopidogrel alone in patients with acute ischemic stroke or to aspirin alone for primary prevention in those at risk for cardiovascular events.

Prasugrel was compared with clopidogrel in 13,608 patients with acute coronary syndromes scheduled to undergo percutaneous coronary intervention (PCI).[42] The incidence of the primary efficacy endpoint—a composite of cardiovascular death, myocardial infarction, and stroke—was significantly lower with prasugrel than with clopidogrel (9.9% and 12.1%, respectively), mainly because of a reduction in the incidence of nonfatal myocardial infarction. The incidence of stent thrombosis was also significantly lower with prasugrel than with clopidogrel (1.1% and 2.4%, respectively). These advantages, however, were at the expense of significantly higher rates of fatal bleeding (0.4% and 0.1%, respectively) and life-threatening bleeding (1.4% and 0.9%, respectively) with prasugrel. Because patients older than 75 years and those with a history of previous stroke or transient ischemic attack have a particularly high risk for bleeding, prasugrel should be avoided in older patients, and the drug is contraindicated in those with a history of cerebrovascular disease. Caution is required if prasugrel is used in patients weighing less than 60 kg or in those with renal impairment.

Dosages

Clopidogrel is given once daily at a dose of 75 mg.[36] Because its onset of action is delayed for several days, 300- to 600-mg loading doses of clopidogrel are given when rapid ADP receptor blockade is desired (**see also Chapter 62**). After a loading dose of 60 mg, prasugrel is given once daily at a dose of 10 mg.[36] Patients older than 75 years or weighing less than 60 kg should receive a daily prasugrel dose of

5 mg.

Clopidogrel Resistance.
The capacity of clopidogrel to inhibit ADP-induced platelet aggregation varies among subjects.[43] This variability reflects, at least in part, genetic polymorphisms in the CYP isoenzymes involved in the metabolic activation of clopidogrel (**see also Chapters 8, 59, and 60**). The most important of these enzymes is CYP2C19. Clopidogrel-treated patients with the loss-of-function *CYP2C19*2* allele exhibit reduced platelet inhibition in comparison with those with the wild-type *CYP2C19*1* allele and experience a higher rate of cardiovascular events.[44] This is important because estimates suggest that up to 25% of whites, 30% of blacks, and 50% of Asians carry the loss-of-function allele, which may render them resistant to clopidogrel. Even patients with reduced-function *CYP2C19*3*, *CYP2C19*4*, or *CYP2C19*5* alleles may derive less benefit from clopidogrel than do those with the full-function *CYP2C19*1* allele. Patients with polymorphisms in *ABCB1* may exhibit impaired clopidogrel absorption, and polymorphisms in *CYP3A4* can contribute to reduced metabolic activation of clopidogrel. Polymorphisms in both these enzymes have been linked to adverse clinical outcomes. In contrast to their effect on the metabolic activation of clopidogrel, polymorphisms in *CYP2C19* and *CYP3A4* do not appear to influence activation of prasugrel, nor do they affect the response to ticagrelor.

Although concomitant administration of clopidogrel with proton pump inhibitors, which inhibit CYP2C19, reduces the effect of clopidogrel on ADP-induced platelet aggregation, this interaction has questionable clinical significance. Atorvastatin, a competitive inhibitor of CYP3A4, reduced the inhibitory effect of clopidogrel on ADP-induced platelet aggregation in one study, a finding unconfirmed in subsequent investigations.[45]

The influence of genetic polymorphisms on clinical outcomes with clopidogrel has raised the possibility that pharmacogenetic profiling and/or point-of-care platelet function testing could be used to identify clopidogrel-resistant patients so that they could be targeted for more intensive antiplatelet therapy.[46] Although up to 30% of clopidogrel-treated patients have evidence of reduced responsiveness to the drug, randomized clinical trials have failed to show that more intensive antiplatelet therapy improves the outcome in such patients.[47] Consequently, there is no indication for routine clopidogrel resistance testing at this time. Because their antiplatelet effects are more predictable, guidelines recommend prasugrel or ticagrelor instead of clopidogrel for high-risk patients.

Ticagrelor

As an orally active inhibitor of $P2Y_{12}$, ticagrelor differs from the thienopyridines in that it does not require metabolic activation and it produces reversible inhibition of the ADP receptor.

Mechanism of Action

Like the thienopyridines, ticagrelor inhibits $P2Y_{12}$. Because it does not require metabolic activation, ticagrelor has a more rapid onset and offset of action than clopidogrel does and it produces greater and more predictable inhibition of ADP-induced platelet aggregation.

Dosages

Ticagrelor is initiated with an oral loading dose of 180 mg followed by 90 mg twice daily. The dose does

not need adjustment in patients with renal impairment, but caution is needed in patients with hepatic impairment or in those receiving potent inhibitors or inducers of CYP3A4 because ticagrelor is metabolized in the liver via CYP3A4. Ticagrelor is usually administered in conjunction with aspirin; the daily aspirin dose should not exceed 100 mg.

Side Effects

In addition to bleeding, as with all $P2Y_{12}$ inhibitors, the most common side effects of ticagrelor are dyspnea, which can develop in up to 15% of patients, and bradyarrhythmias. The dyspnea, which tends to occur soon after initiating ticagrelor, is usually self-limited and mild in intensity but can be persistent and may necessitate drug discontinuation in some patients. Although the exact mechanism responsible for these side effects is unknown, they may be adenosine-mediated because ticagrelor inhibits its reuptake.

Indications (see also Chapters 59 and 60)

When compared with clopidogrel in patients with acute coronary syndromes,[44] ticagrelor produced a greater reduction in the primary efficacy endpoint—a composite of cardiovascular death, myocardial infarction, and stroke at 1 year—than did clopidogrel (9.8% and 11.7%, respectively; $P = .001$). This difference reflected a significant reduction in both cardiovascular death (4.0% and 5.1%, respectively; $P = .001$) and myocardial infarction (5.8% and 6.9%, respectively; $P = .005$) with ticagrelor relative to clopidogrel. Rates of stroke were similar with ticagrelor and clopidogrel (1.5% and 1.3%, respectively), and there was no difference in rates of major bleeding. When minor bleeding was added to the major bleeding results, however, ticagrelor showed an increase relative to clopidogrel (16.1% and 14.6%, respectively; $P = .008$). Ticagrelor was also superior to clopidogrel in patients with acute coronary syndrome who underwent PCI or cardiac surgery. Based on these observations, guidelines give preference to ticagrelor over clopidogrel, particularly in higher-risk patients.

Cangrelor

Cangrelor is a rapidly acting reversible inhibitor of P2Y12 that is administered intravenously. It has an immediate onset of action, a half-life of 3 to 5 minutes, and an offset of action within an hour. Cangrelor is licensed for use in patients undergoing PCI and produces rapid ADP receptor blockade in those who have not received pretreatment with clopidogrel, prasugrel, or ticagrelor.[48]

Dipyridamole

A relatively weak antiplatelet agent on its own,[36] an extended-release formulation of dipyridamole combined with low-dose aspirin, a preparation marketed as Aggrenox, is used for prevention of stroke in patients with transient ischemic attacks.

Mechanism of Action

By inhibiting phosphodiesterase, dipyridamole blocks the breakdown of cAMP. Increased levels of cAMP reduce intracellular calcium and inhibit platelet activation. Dipyridamole also blocks the uptake of adenosine by platelets and other cells. With more extracellular adenosine, there is a further increase in local cAMP levels because the platelet adenosine A_2 receptor and adenylate cyclase are coupled (**Fig. 93.11**).

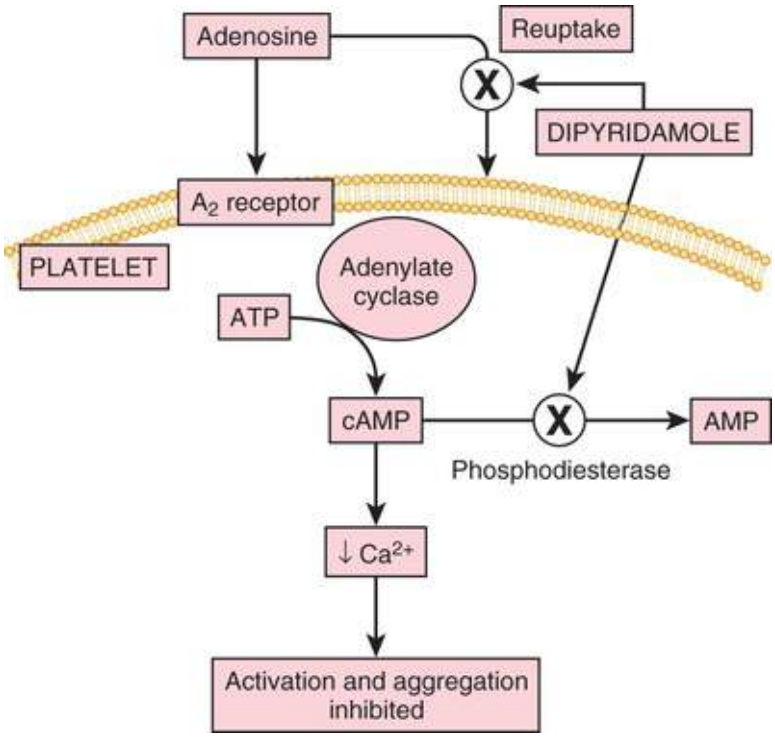

FIGURE 93.11 Mechanism of action of dipyridamole. Dipyridamole increases levels of cAMP in platelets by (1) blocking the reuptake of adenosine, thereby increasing the concentration of adenosine available to bind to the A_2 receptor, and (2) inhibiting phosphodiesterase-mediated cAMP degradation. By promoting calcium uptake, cAMP reduces intracellular levels of calcium. This, in turn, inhibits platelet activation and aggregation.

Dosages

This fixed combination is given twice daily. Each capsule contains 200 mg of extended-release dipyridamole and 25 mg of aspirin.

Side Effects

Because dipyridamole has vasodilatory effects, caution is necessary in patients with coronary artery disease. Gastrointestinal complaints, headache, facial flushing, dizziness, and hypotension can also occur. These symptoms often subside with continued use of the drug.

Indications

Dipyridamole plus aspirin was compared with aspirin or dipyridamole alone and with placebo in patients with an ischemic stroke or a transient ischemic attack. The combination reduced the risk for stroke by 22.1% in comparison with aspirin and by 24.4% in comparison to dipyridamole.[49] A second trial compared dipyridamole plus aspirin with aspirin alone for secondary prevention in patients with ischemic stroke. Vascular death, stroke, or myocardial infarction occurred in 13% of patients given combination therapy and in 16% of those treated with aspirin alone. Although the combination of dipyridamole plus aspirin compares favorably with aspirin, the combination is not superior to clopidogrel. In a large randomized trial that compared dipyridamole plus aspirin with clopidogrel for secondary prevention in patients with ischemic stroke, recurrent stroke event rates were similar (9.0% and 8.8%, respectively), as were rates of vascular death, stroke, and myocardial infarction (13.1% in both treatment arms). However, there was a trend toward more hemorrhagic strokes with dipyridamole plus aspirin than with clopidogrel (0.8% and 0.4%, respectively) and more major bleeding (4.1% and

3.8%, respectively).

Although dipyridamole/aspirin can replace aspirin for stroke prevention, because of the vasodilatory effects of dipyridamole and the paucity of data supporting the usefulness of this drug in patients with symptomatic coronary artery disease, dipyridamole/aspirin is contraindicated in such patients; clopidogrel is a better choice in patients with coronary artery disease.

Glycoprotein IIb/IIIa Receptor Antagonists (see also Chapters 59, 60, and 62)

As a class, parenteral GPIIb/IIIa receptor antagonists have a niche in patients with acute coronary syndromes. The three agents in this class are abciximab, eptifibatide, and tirofiban.

Mechanism of Action

A member of the integrin family of adhesion receptors, GPIIb/IIIa is expressed on the surface of platelets and megakaryocytes. With approximately 80,000 copies per platelet, GPIIb/IIIa is the most abundant receptor. GPIIb/IIIa is inactive on resting platelets. With platelet activation, however, inside-outside signal transduction pathways trigger conformational activation of the receptor. Once activated, GPIIb/IIIa binds fibrinogen and, under high-shear conditions, vWF. Once bound, fibrinogen and vWF bridge adjacent platelets together to induce platelet aggregation.

Although abciximab, eptifibatide, and tirofiban all target the GPIIb/IIIa receptor, they are structurally and pharmacologically distinct (**Table 93.2**).[43] Abciximab is a Fab fragment of a humanized murine monoclonal antibody directed against the activated form of GPIIb/IIIa. Abciximab binds to the activated receptor with high affinity and blocks the binding of adhesive molecules. In contrast to abciximab, eptifibatide and tirofiban are synthetic molecules. Eptifibatide is a cyclical heptapeptide that binds GPIIb/IIIa because it incorporates the KGD motif, whereas tirofiban is a nonpeptidic tyrosine derivative that acts as an RGD mimetic. With its long half-life, abciximab persists on the surface of platelets for up to 2 weeks. Eptifibatide and tirofiban have shorter half-lives.

TABLE 93.2

Features of Glycoprotein IIb/IIIa Antagonists

FEATURE	ABCIXIMAB	EPTIFIBATIDE	TIROFIBAN
Description	Fab fragment of humanized mouse monoclonal antibody	Cyclical KGD-containing heptapeptide	Nonpeptidic RGD mimetic
Specific for GP IIb/IIIa	No	Yes	Yes
Plasma half-life	Short (min)	Long (2.5 hr)	Long (2.0 hr)
Platelet-bound half-life	Long (days)	Short (sec)	Short (sec)
Renal clearance	No	Yes	Yes

KGD, Lys-Gly-Asp sequence; *RGD*, Arg-Gly-Asp sequence.

In addition to targeting the GPIIb/IIIa receptor, abciximab (but not eptifibatide or tirofiban) also inhibits the closely related $\alpha_{v\beta3}$ receptor, which binds vitronectin, and $\alpha_{M\beta2}$, a leukocyte integrin. Inhibition of $\alpha_{v\beta3}$ and $\alpha_{M\beta2}$ may endow abciximab with antiinflammatory and/or antiproliferative properties that extend beyond platelet inhibition.

Dosages

All of the GPIIb/IIIa antagonists are given as an intravenous bolus followed by an infusion. Because of their renal clearance, eptifibatide and tirofiban doses require reduction in patients with renal insufficiency.

Side Effects

In addition to bleeding, thrombocytopenia is the most serious complication. Antibodies directed against neoantigens on GPIIb/IIIa that are exposed on antagonist binding cause thrombocytopenia, which is immune mediated. With abciximab, thrombocytopenia occurs in up to 5% of patients and is severe in approximately 1% of these individuals. Thrombocytopenia is less common with the other two agents and occurs in approximately 1% of patients.

Indications (see also Chapter 62)

Abciximab eptifibatide and tirofiban are used occasionally in patients undergoing PCI, particularly those with acute myocardial infarction, whereas tirofiban and eptifibatide are used in high-risk patients with unstable angina.

Vorapaxar

Unlike the other antiplatelet drugs, vorapaxar inhibits PAR-1, the major thrombin receptor on human platelets. Vorapaxar was compared with placebo for secondary prevention in 26,449 patients with previous myocardial infarction, ischemic stroke, or peripheral artery disease.[50] Overall, vorapaxar reduced the risk for cardiovascular death, myocardial infarction, or stroke by 13% but doubled the risk for intracranial bleeding. In the prespecified subgroup of 17,779 patients with previous myocardial infarction, however, vorapaxar reduced the risk for cardiovascular death, myocardial infarction, or stroke by 20% (from 9.7% to 8.1%). The rate of intracranial hemorrhage was higher with vorapaxar than with placebo (0.6% and 0.4%, respectively; $P = .076$), as was the rate of moderate or severe bleeding (3.4% and 2.1%, respectively; $P < .001$). Based on these data, the drug is now licensed for patients younger than 75 years with myocardial infarction who have no history of stroke, transient ischemic attack, or intracranial bleeding and who weigh more than 60 kg.

Anticoagulants

There are parenteral and oral anticoagulants. Currently available parenteral anticoagulants include heparin, LMWH, fondaparinux, a synthetic pentasaccharide, and bivalirudin. Currently available oral anticoagulants include warfarin; dabigatran etexilate, an oral thrombin inhibitor; and rivaroxaban, apixaban, and edoxaban, oral factor Xa inhibitors.[51]

Parenteral Anticoagulants

Heparin

A sulfated polysaccharide, heparin is isolated from mammalian tissues rich in mast cells (**Table 93.3**). Most commercial heparin is derived from porcine intestinal mucosa and is a polymer of alternating D-glucuronic acid and *N*-acetyl-D-glucosamine residues.[52]

TABLE 93.3

Comparison of Features of Heparin, Low-Molecular-Weight Heparin, and Fondaparinux

FEATURES	HEPARIN	LMWH	FONDAPARINUX
Source	Biologic	Biologic	Synthetic
Molecular weight	15,000	5,000	1,500
Target	Xa and IIa	Xa and IIa	Xa
Bioavailability (%)	30	90	100
Half-life (hr)	1	4	17
Renal excretion	No	Yes	Yes
Antidote	Complete	Partial	No
Heparin-induced thrombocytopenia	<5%	<1%	Rare

Mechanism of Action.

Heparin acts as an anticoagulant by activating antithrombin (previously known as antithrombin III) and accelerating the rate at which it inhibits clotting enzymes, particularly thrombin and factor Xa. Antithrombin, the obligatory plasma cofactor for heparin, belongs to the serine protease inhibitor (serpin) superfamily. Synthesized in the liver and circulating in plasma at a concentration of 2.6 ± 0.4 μM, antithrombin acts as a suicide substrate for its target enzymes.

To activate antithrombin, heparin binds to the serpin via a unique pentasaccharide sequence found on a third of the chains of commercial heparin (**Fig. 93.12**). Heparin chains lacking this pentasaccharide sequence have little or no anticoagulant activity.[53] Once bound to antithrombin, heparin induces a conformational change in the reactive center loop of antithrombin that renders it more readily accessible to its target proteases. This conformational change enhances the rate at which antithrombin inhibits factor Xa by at least two orders of magnitude, but has little effect on the rate of thrombin inhibition by antithrombin. To promote thrombin inhibition, heparin serves as a template that binds antithrombin and thrombin simultaneously. Formation of this ternary complex brings the enzyme in close apposition to the inhibitor, thereby promoting the formation of a stable covalent thrombin-antithrombin complex.

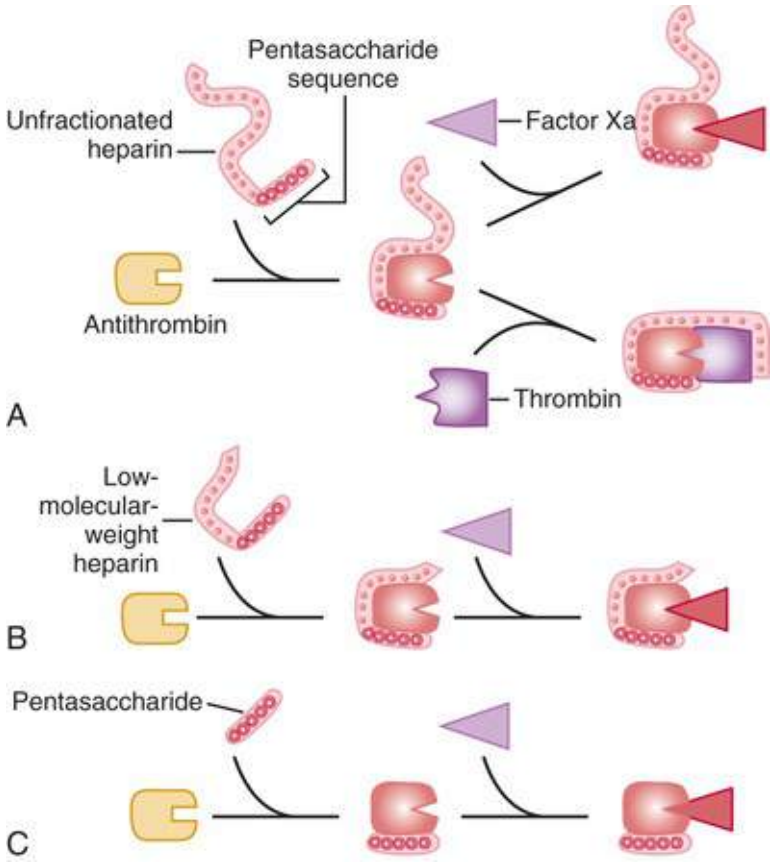

FIGURE 93.12 Mechanism of action of heparin, LMWH, and fondaparinux, a synthetic pentasaccharide. **A,** Heparin binds to antithrombin via its pentasaccharide sequence. This induces a conformational change in the reactive center loop of antithrombin that accelerates its interaction with factor Xa. To potentiate thrombin inhibition, heparin must simultaneously bind to antithrombin and thrombin. Only heparin chains composed of at least 18 saccharide units, which corresponds to a molecular weight of 5400, are of sufficient length to perform this bridging function. With a mean molecular weight of 15,000, all the heparin chains are long enough to do this. **B,** LMWH has greater capacity to potentiate factor Xa inhibition by antithrombin than thrombin does because with a mean molecular weight of 4500 to 6000, at least half of the LMWH chains are too short to bridge antithrombin to thrombin. **C,** Fondaparinux, a synthetic pentasaccharide, only accelerates inhibition of factor Xa by antithrombin because it is too short to bridge antithrombin to thrombin.

Only pentasaccharide-containing heparin chains composed of at least 18 saccharide units (which corresponds to a molecular weight of 5400) have sufficient length to bridge thrombin and antithrombin together.[53] With a mean molecular weight of 15,000 and a range of 5,000 to 30,000, almost all the chains of unfractionated heparin are long enough to provide this bridging function. Consequently, by definition, heparin has equal capacity to promote inhibition of thrombin and factor Xa by antithrombin and has an anti–factor Xa–to–anti–factor IIa (thrombin) ratio of 1 : 1. Heparin causes the release of TFPI from the endothelium. A factor Xa–dependent inhibitor of tissue factor–bound factor VIIa,[8] TFPI may contribute to the antithrombotic activity of heparin. Longer heparin chains induce the release of more TFPI than shorter chains do.

Pharmacology of Heparin.

Heparin requires parenteral administration and is usually administered subcutaneously or by continuous intravenous infusion. If administered subcutaneously for the treatment of thrombosis, the dose must be high enough to overcome the limited bioavailability associated with this method of delivery. In the circulation, heparin binds to the endothelium and to plasma proteins other than antithrombin. Binding of heparin to endothelial cells explains its dose-dependent clearance. At low intravenous doses, the half-life of heparin is short because it rapidly binds to the endothelium. With higher intravenous doses of heparin, the half-life

is longer because heparin clearance is slower once the endothelium is saturated. Clearance is mainly extrarenal; heparin binds to macrophages, which internalize and depolymerize the long heparin chains and secrete shorter chains back into the circulation. Because of its dose-dependent clearance mechanism, the plasma half-life of heparin ranges from 30 to 60 minutes with bolus intravenous doses of 25 and 100 units/kg, respectively.

Once heparin enters the circulation, it binds to plasma proteins other than antithrombin, a phenomenon that reduces the anticoagulant activity of heparin. Some of the heparin-binding proteins found in plasma are acute-phase reactants whose levels are elevated in ill patients. Activated platelets or endothelial cells release other proteins that can bind heparin, such as large multimers of vWF. Activated platelets also release platelet factor 4 (PF4), a highly cationic protein that binds heparin with high affinity. The large amounts of PF4 associated with platelet-rich arterial thrombi can neutralize the anticoagulant activity of heparin. This phenomenon may attenuate heparin's capacity to suppress thrombus growth.

Because levels of heparin binding–proteins in plasma vary from person to person, the anticoagulant response to fixed or weight-adjusted doses of heparin is unpredictable. Consequently, monitoring of coagulation is essential to ensure a therapeutic response, particularly when heparin is administered for the treatment of established thrombosis, because a subtherapeutic anticoagulant response may render patients at risk for recurrent thrombosis, whereas excessive anticoagulation increases the risk for bleeding.

Monitoring the Anticoagulant Effect of Heparin.

The APTT or anti–factor Xa level is used to monitor heparin.[53] Although the APTT is the test most often used for this purpose, there are problems with the assay: APTT reagents vary in their sensitivity to heparin, and the type of coagulometer used for testing can influence the results. Consequently, laboratories must establish a therapeutic APTT range with each reagent-coagulometer combination by measuring both the APTT and anti–factor Xa levels in plasma samples collected from heparin-treated patients. With most APTT reagents and coagulometers in current use, heparin levels are therapeutic with a twofold to threefold prolongation of the APTT. Anti–factor Xa levels can also be used to monitor heparin therapy. With this test, therapeutic heparin levels range from 0.3 to 0.7 units/mL. Although this test is gaining in popularity, anti–factor Xa assays have yet to be standardized, and results can vary widely between laboratories.

Up to 25% of patients with VTE are heparin resistant; they require more than 35,000 units/day to achieve a therapeutic APTT. It is useful to measure anti–factor Xa levels in heparin-resistant patients because many will have a therapeutic anti–factor Xa level despite a subtherapeutic APTT. This dissociation in test results occurs because elevated plasma levels of fibrinogen and factor VIII, both acute-phase proteins, shorten the APTT but have no effect on anti–factor Xa levels.[53] Anti–factor Xa levels are better than the APTT for monitoring heparin in patients who exhibit this phenomenon. Patients with congenital or acquired antithrombin deficiency and those with elevated levels of heparin-binding proteins may also need high doses of heparin to achieve a therapeutic APTT or anti–factor Xa level. If there is good correlation between the APTT and the anti–factor Xa level, either test can be used for monitoring heparin therapy.

Dosages.

For prophylaxis, heparin is usually given in fixed doses of 5000 units subcutaneously two or three times daily. With these low doses, monitoring of coagulation is unnecessary. In contrast, monitoring is essential when the drug is given in higher doses. Fixed-dose or weight-based heparin nomograms are used to standardize heparin regimens and to shorten the time required to achieve a therapeutic anticoagulant

response. At least two heparin nomograms have been validated in patients with VTE, and both reduce the time required to achieve a therapeutic APTT. Weight-adjusted heparin nomograms have also been evaluated in patients with acute coronary syndromes. After an intravenous heparin bolus of 5000 units or 70 units/kg, a heparin infusion rate of 12 to 15 units/kg/hr is usually administered.[53] In contrast, weight-adjusted heparin nomograms for patients with VTE use an initial bolus of 5000 units or 80 units/kg, followed by an infusion of 18 units/kg/hr. Thus achievement of a therapeutic APTT requires higher doses of heparin in patients with VTE than in those with acute coronary syndromes. This difference may reflect differences in thrombus burden. Heparin binds to fibrin, and the fibrin content of extensive deep vein thrombi is greater than that of coronary thrombi.

Traditionally, heparin manufacturers in North America measured heparin potency in USP units, with a unit defined as the concentration of heparin that prevents 1 mL of citrated sheep plasma from clotting for 1 hour after the addition of calcium. In contrast, manufacturers in Europe measured heparin potency with anti-Xa assays that use an international heparin standard for comparison. Because of problems with heparin contamination by oversulfated chondroitin sulfate,[52] which the USP assay system does not detect, North American heparin manufacturers now use the anti-Xa assay to measure heparin potency. Use of international units in place of USP units results in a 10% to 15% reduction in the heparin dose. This change is unlikely to affect patient care because dosing of heparin has been done this way in Europe for many years. Furthermore, heparin monitoring ensures a therapeutic anticoagulant response in high-risk situations, such as cardiopulmonary bypass surgery or PCI.

Limitations of Heparin.

Heparin has pharmacokinetic and biophysical limitations (**Table 93.4**). The pharmacokinetic limitations reflect heparin's propensity to bind in a pentasaccharide-independent fashion to cells and plasma proteins. Binding of heparin to endothelial cells explains its dose-dependent clearance, whereas binding to plasma proteins results in a variable anticoagulant response and can lead to heparin resistance.

TABLE 93.4

Pharmacokinetic and Biophysical Limitations of Heparin

LIMITATIONS	MECHANISM
Poor bioavailability	Limited absorption of long heparin chains
Dose-dependent clearance	Binds to endothelial cells
Variable anticoagulant response	Binds to plasma proteins; levels vary from patient to patient
Reduced activity in the vicinity of platelet-rich thrombi	Neutralized by platelet factor 4 released from activated platelets
Limited activity against factor Xa incorporated into the prothrombinase complex and thrombin bound to fibrin	Reduced capacity of heparin-antithrombin complex to inhibit factor Xa bound to activated platelets and thrombin

The biophysical limitations of heparin reflect the inability of the heparin-antithrombin complex to inhibit factor Xa when it is incorporated into the prothrombinase complex, the complex that converts prothrombin to thrombin, and to inhibit thrombin bound to fibrin. Consequently, factor Xa bound to activated platelets within platelet-rich thrombi can generate thrombin, even in the presence of heparin. Thrombin bound to fibrin protects it from inhibition by the heparin-antithrombin complex. Clot-associated thrombin can then trigger growth of thrombi by locally activating platelets and amplifying its own generation through feedback activation of factors V, VIII, and XI. Neutralization of heparin by the high concentrations of PF4 released from activated platelets within the platelet-rich thrombus further compounds this problem.

Side Effects.

The most common side effect of heparin is bleeding. Other complications include thrombocytopenia, osteoporosis, and elevated levels of transaminases.

Bleeding.

The risk for heparin-induced bleeding increases with higher heparin doses. Concomitant administration of drugs that affect hemostasis, such as antiplatelet or fibrinolytic agents, increases the risk for bleeding, as does recent surgery or trauma.[54] Protamine sulfate will neutralize heparin in patients with serious bleeding. A mixture of basic polypeptides isolated from salmon sperm, protamine sulfate binds heparin with high affinity to form protamine-heparin complexes that undergo renal clearance. Typically, 1 mg of intravenous protamine sulfate neutralizes 100 units of heparin. Anaphylactoid reactions to protamine sulfate can occur, but administration by slow intravenous infusion reduces the risk for this problem.[53]

Thrombocytopenia.

Heparin-induced thrombocytopenia (HIT) is an antibody-mediated process triggered by antibodies against neoantigens on PF4 that are exposed when heparin binds to this protein.[55] These antibodies, which are usually of the IgG subtype, bind simultaneously to the heparin-PF4 complex and to platelet Fc receptors. Such binding activates the platelets and generates platelet microparticles. Circulating microparticles are procoagulant because they express anionic phospholipids on their surface and can bind clotting factors, thereby promoting thrombin generation.

Typically, HIT occurs 5 to 14 days after the initiation of heparin therapy, but it may be manifested earlier if the patient has received heparin within the past 3 months (**Table 93.5**). Even a 50% decrease in the platelet count from the pretreatment value should raise suspicion of HIT in those receiving heparin. HIT is more common in surgical patients than in medical patients and, like many autoimmune disorders, occurs more frequently in females than in males.[55]

TABLE 93.5

Features of Heparin-Induced Thrombocytopenia

FEATURE	DETAILS
Thrombocytopenia	Platelet count of ≤ 100,000/μL or a decrease in platelet count of ≥ 50% from baseline
Timing	Platelet count falls 5-14 days after starting heparin
Type of heparin	More common with unfractionated heparin than with LMWH
Type of patient	More common in surgical patients than in medical patients; more common in women than in men
Thrombosis	Venous thrombosis more common than arterial thrombosis

HIT is associated with either arterial or venous thrombosis. Venous thrombosis, which is manifested as deep vein thrombosis and/or pulmonary embolism, is more common than arterial thrombosis. Arterial thrombosis manifests as ischemic stroke or acute myocardial infarction. Rarely, platelet-rich thrombi in the distal aorta or iliac arteries can cause critical limb ischemia.

The diagnosis of HIT is established via enzyme-linked assays to detect antibodies against heparin-PF4 complexes or via platelet activation assays. Enzyme-linked assays are sensitive but are not specific and can be positive even in the absence of any clinical evidence of HIT.[56] The most specific diagnostic test is the serotonin release assay. This test involves quantification of serotonin release after exposure of washed platelets loaded with labeled serotonin to patient serum in the absence or presence of various concentrations of heparin. If the patient's serum contains HIT antibody, the addition of heparin induces platelet activation and subsequent serotonin release.

To manage HIT, heparin therapy should be stopped in patients with suspected or documented HIT, and

an alternative anticoagulant should be administered to prevent or treat thrombosis (**Table 93.6**).[55] The agents most often used for this indication are parenteral direct thrombin inhibitors, such as lepirudin, argatroban, or bivalirudin, or factor Xa inhibitors, such as fondaparinux or rivaroxaban. Patients with HIT, particularly those with associated thrombosis, often have evidence of increased thrombin generation, which can lead to consumption of protein C. If these patients receive warfarin without a concomitant parenteral anticoagulant, the further decrease in protein C levels induced by the vitamin K antagonist can trigger skin necrosis. To avoid this problem, patients with HIT require treatment with a direct thrombin inhibitor or fondaparinux or rivaroxaban until the platelet count returns to normal levels. At this point, low-dose warfarin therapy can be introduced, and the thrombin inhibitor or fondaparinux can be discontinued when the anticoagulant response to warfarin has been therapeutic for at least 2 days.

TABLE 93.6

Management of Heparin-Induced Thrombocytopenia

Stop all heparin.
Give an alternative anticoagulant, such as lepirudin, argatroban, bivalirudin, fondaparinux, or rivaroxaban.
Do not give platelet transfusions.
Do not give warfarin until the platelet count returns to baseline levels; if warfarin was administered, give vitamin K to restore the INR to normal.
Evaluate for thrombosis, particularly deep vein thrombosis.

Osteoporosis.

Treatment with therapeutic doses of heparin for more than a month can cause a reduction in bone density. This occurs in up to 30% of patients treated over the long term with heparin,[53] and symptomatic vertebral fractures occur in 2% to 3% of these individuals. Studies in vitro and in laboratory animals have provided insight into the pathogenesis of heparin-induced osteoporosis. These investigations suggest that heparin causes bone resorption by decreasing bone formation and enhancing bone resorption. Thus heparin affects the activity of both osteoclasts and osteoblasts.

Elevated Levels of Transaminases.

Therapeutic doses of heparin frequently cause a modest elevation in serum levels of hepatic transaminases without a concomitant increase in the level of bilirubin. Levels of transaminases rapidly return to normal when use of the drug is stopped. The mechanism responsible for this phenomenon is unknown.

Low-Molecular-Weight Heparin

Consisting of smaller fragments of heparin, LMWH is prepared from unfractionated heparin by controlled enzymatic or chemical depolymerization. The mean molecular weight of LMWH is around 5000, one third the mean molecular weight of unfractionated heparin.[53] Because of its advantages over heparin (**Table 93.7**), LMWH has replaced heparin for many indications.

TABLE 93.7

Advantages of Low-Molecular-Weight Heparin and Fondaparinux over Heparin

ADVANTAGE	CONSEQUENCE
Better bioavailability and longer half-life after subcutaneous injection	Can be given subcutaneously once or twice daily for both prophylaxis and treatment
Dose-independent clearance	Simplified dosing
Predictable anticoagulant response	Monitoring of coagulation is unnecessary in most patients
Lower risk for heparin-induced thrombocytopenia	Safer than heparin for short- or long-term administration
Lower risk for osteoporosis	Safer than heparin for long-term administration

Mechanism of Action.

Like heparin, LMWH exerts its anticoagulant activity by activating antithrombin. With a mean molecular weight of 5000, which corresponds to approximately 17 saccharide units, at least half of the pentasaccharide-containing chains of LMWH are too short to bridge thrombin to antithrombin (**see Fig. 93.12**). These chains retain the capacity to accelerate inhibition of factor Xa by antithrombin because this activity results largely from the conformational changes in antithrombin evoked by pentasaccharide binding. Consequently, LMWH catalyzes inhibition of factor Xa by antithrombin more than inhibition of thrombin.[53] Depending on their unique molecular weight distributions, LMWH preparations have anti–factor Xa to anti–factor IIa ratios ranging from 2 : 1 to 4 : 1 (**see Table 93.3**).

Pharmacology of Low-Molecular-Weight Heparin.

Although usually given subcutaneously, LMWH can be administered intravenously if a rapid anticoagulant response is needed. LMWH has pharmacokinetic advantages over heparin. These advantages arise because the shorter heparin chains bind less avidly to endothelial cells, macrophages, and heparin-binding plasma proteins. Reduced binding to endothelial cells and macrophages eliminates the rapid, dose-dependent, and saturable mechanism of clearance that is a characteristic of unfractionated heparin. Instead, clearance of LMWH is not dose dependent and its plasma half-life is longer. Based on measurement of anti–factor Xa levels, LMWH has a plasma half-life of approximately 4 hours. Because of its renal clearance, LMWH can accumulate in patients with renal insufficiency.

LMWH exhibits approximately 90% bioavailability after subcutaneous injection.[53] Because LMWH binds less avidly to heparin-binding proteins in plasma than heparin does, LMWH produces a more predictable dose response, and resistance to LMWH is rare. With a longer half-life and more predictable anticoagulant response, LMWH can be given subcutaneously once or twice daily without monitoring coagulation, even when the drug is administered in treatment doses. These properties render LMWH more convenient than unfractionated heparin. Capitalizing on this feature, studies in patients with VTE have shown that home treatment with LMWH is as effective and safe as in-hospital treatment with continuous intravenous infusions of heparin.[53] Outpatient treatment with LMWH streamlines care, reduces health care costs, and increases patient satisfaction.

Monitoring of Low-Molecular-Weight Heparin.

In most patients, LMWH does not require monitoring of coagulation. If monitoring is necessary, the anti–factor Xa level is measured because most LMWH preparations have little effect on the APTT. Therapeutic anti–factor Xa levels with LMWH range from 0.5 to 1.2 units/mL when measured 3 to 4 hours after drug administration. With prophylactic doses of LMWH, peak anti–factor Xa levels of 0.2 to 0.5 units/mL are desirable.[53]

Situations that may require LMWH monitoring include renal insufficiency and obesity. Monitoring of

LMWH in patients with a creatinine clearance of 50 mL/min or less is advisable to ensure that no drug accumulation takes place. Although weight-adjusted LMWH dosages appear to produce therapeutic anti–factor Xa levels in overweight patients, this approach has not been well studied in those with morbid obesity. It may also be advisable to monitor the anticoagulant activity of LMWH during pregnancy because dose requirements can change, particularly in the third trimester. Monitoring should also be considered in high-risk settings, such as when patients with mechanical heart valves are given LMWH for prevention of valve thrombosis.

Dosages.

The doses of LMWH recommended for prophylaxis or treatment vary depending on the preparation. For prophylaxis, once-daily subcutaneous doses of 4000 to 5000 units are often used, whereas doses of 2500 to 3000 units are given when the drug is administered twice daily. For treatment of VTE, a dose of 150 to 200 units/kg is given if the drug is administered once daily. If a twice-daily regimen is used, a dose of 100 units/kg is given. In patients with unstable angina, LMWH is administered subcutaneously twice daily at a dose of 100 to 120 units/kg. The dose is reduced in patients with renal impairment.

Side Effects.

The major complication of LMWH is bleeding. Metaanalyses suggest that the risk for major bleeding may be lower with LMWH than with unfractionated heparin. HIT and osteoporosis also are less common with LMWH than with unfractionated heparin.

Bleeding.

The risk for bleeding with LMWH increases when antiplatelet or fibrinolytic drugs are given concomitantly.[54] Recent surgery, trauma, or underlying hemostatic defects also increase the risk for bleeding with LMWH. Although protamine sulfate serves as an antidote for LMWH, it incompletely neutralizes the anticoagulant activity of LMWH because it binds only the longer chains.[53] Because longer chains contribute to thrombin inhibition by antithrombin, protamine sulfate completely reverses the anti–factor IIa activity of LMWH. In contrast, protamine sulfate only partially reverses the anti–factor Xa activity of LMWH because the shorter pentasaccharide-containing chains of LMWH do not bind protamine sulfate. Consequently, continuous intravenous unfractionated heparin may be safer than subcutaneous LMWH for patients at high risk for bleeding.

Thrombocytopenia.

The risk for HIT is about fivefold lower with LMWH than with heparin.[55] LMWH binds less avidly to platelets and causes less release of PF4. Furthermore, with lower affinity for PF4 than for heparin, LMWH is less likely to induce the conformational changes in PF4 that trigger the formation of HIT antibodies. LMWH should not be used to treat patients with HIT, because most HIT antibodies exhibit cross-reactivity with LMWH.[55] This in vitro cross-reactivity is not simply a laboratory phenomenon; thrombosis can occur in HIT patients treated with LMWH.

Osteoporosis.

The risk for osteoporosis is lower with long-term LMWH than with heparin.[53] For extended treatment, therefore, LMWH is a better choice than heparin because of the lower risk for osteoporosis and HIT.

Fondaparinux

A synthetic analogue of the antithrombin-binding pentasaccharide sequence, fondaparinux differs from LMWH in several ways (**see Table 93.3**). Fondaparinux is licensed for thromboprophylaxis in medical, general surgical, and high-risk orthopedic patients and as an alternative to heparin or LMWH for the initial treatment of patients with established VTE. Although fondaparinux is licensed as an alternative to heparin or LMWH in patients with acute coronary syndrome in Europe and Canada, it is not approved for this indication in the United States.

Mechanism of Action.

As a synthetic analogue of the antithrombin-binding pentasaccharide sequence found in heparin and LMWH, fondaparinux has a molecular weight of 1728. Fondaparinux binds only to antithrombin (**see Fig. 93.12**) and is too short to bridge thrombin to antithrombin. Consequently, fondaparinux catalyzes inhibition of factor Xa by antithrombin and does not enhance the rate of thrombin inhibition.[53]

Pharmacology of Fondaparinux. (see also Chapter 62).

Fondaparinux exhibits complete bioavailability after subcutaneous injection. With no binding to endothelial cells or plasma proteins, clearance of fondaparinux does not depend on the dosage, and its plasma half-life is 17 hours. The drug is administered subcutaneously once daily. Because of its renal clearance, fondaparinux is contraindicated in patients with creatinine clearance lower than 30 mL/min, and it should be used with caution in those with a creatinine clearance lower than 50 mL/min.[53]

Fondaparinux produces a predictable anticoagulant response after administration in fixed doses because it does not bind to plasma proteins. The drug is given at a dosage of 2.5 mg once daily for prevention of VTE. For initial treatment of established VTE, fondaparinux is given at a dosage of 7.5 mg once daily. The dosage can be reduced to 5 mg once daily for those weighing less than 50 kg and increased to 10 mg for those heavier than 100 kg. When given in these doses, fondaparinux is as effective as heparin or LMWH for the initial treatment of patients with deep vein thrombosis or pulmonary embolism and produces similar rates of bleeding.[52]

Fondaparinux is used at a dosage of 2.5 mg once daily in patients with acute coronary syndromes. When this prophylactic dose of fondaparinux was compared with treatment doses of enoxaparin in patients with non–ST-segment elevation acute coronary syndrome, no difference in the rate of cardiovascular death, myocardial infarction, or stroke was seen at 9 days. The rate of major bleeding, however, was 50% lower with fondaparinux than with enoxaparin, which resulted in a 17% reduction in mortality rates at 1 month with fondaparinux. In patients with acute coronary syndromes who require PCI, there is a risk for catheter thrombosis with fondaparinux unless adjunctive heparin is given.

Side Effects.

Although fondaparinux can induce the formation of HIT antibodies, HIT does not occur.[56] This apparent paradox reflects the fact that induction of HIT requires heparin chains of sufficient length to bind multiple PF4 molecules. Fondaparinux is too short to do so. In contrast to LMWH, there is no cross-reactivity of fondaparinux with HIT antibodies. Consequently, fondaparinux appears to be effective for the treatment of HIT, although large clinical trials supporting its use are lacking.

The major side effect of fondaparinux is bleeding, and it has no antidote. Protamine sulfate has no effect on the anticoagulant activity of fondaparinux because it fails to bind to the drug. Recombinant activated factor VII has reversed the anticoagulant effects of fondaparinux in volunteers, but it is unknown whether this agent controls fondaparinux-induced bleeding.

Parenteral Direct Thrombin Inhibitors

Heparin and LMWH indirectly inhibit thrombin because they require antithrombin to exert their anticoagulant activity. In contrast, direct thrombin inhibitors do not require a plasma cofactor; instead, they bind directly to thrombin and block its interaction with its substrates. Approved parenteral direct thrombin inhibitors include lepirudin, argatroban, and bivalirudin (**Table 93.8**). Lepirudin and argatroban are licensed for the treatment of HIT, whereas bivalirudin is approved as an alternative to heparin in patients undergoing PCI, including those with HIT.

TABLE 93.8

Comparison of the Properties of Hirudin, Bivalirudin, and Argatroban

PROPERTY	HIRUDIN	BIVALIRUDIN	ARGATROBAN
Molecular mass	7000	1980	527
Site or sites of interaction with thrombin	Active site and exosite 1	Active site and exosite 1	Active site
Renal clearance	Yes	No	No
Hepatic metabolism	No	No	Yes
Plasma half-life (minutes)	60	25	45

Lepirudin

A recombinant form of hirudin, lepirudin is a bivalent direct thrombin inhibitor that interacts with the active site of thrombin and with exosite 1, the substrate binding site.[55] For rapid anticoagulation, lepirudin is given by continuous intravenous infusion, but the drug can be administered subcutaneously for thromboprophylaxis. Lepirudin has a plasma half-life of 60 minutes after intravenous infusion and is cleared by the kidneys. Consequently, lepirudin accumulates in patients with renal insufficiency. Antibodies against the drug develop in a high proportion of lepirudin-treated patients. Although these antibodies rarely cause problems, in a small subset of patients they can delay lepirudin clearance and enhance its anticoagulant activity; some of these patients experience serious bleeding.

Lepirudin is usually monitored with the APTT, and the dose is adjusted to maintain an APTT 1.5 to 2.5 times control. The APTT is not an ideal test for monitoring lepirudin therapy because the clotting time plateaus with higher drug concentrations. Although the ecarin clotting time provides a better index of the lepirudin dose than the APTT does, the ecarin clotting time has yet to be standardized, and the test is not available in all coagulation laboratories.

Argatroban

Argatroban, a univalent inhibitor that targets the active site of thrombin, is metabolized in the liver.[55] Consequently, it must be used with caution in patients with hepatic insufficiency. Because it is not cleared by the kidneys, argatroban is safer than lepirudin for patients with HIT and renal impairment. Argatroban is administered by continuous intravenous infusion and has a plasma half-life of approximately 45 minutes. The APTT is used to monitor its anticoagulant effect, and the dosage is adjusted to achieve an APTT 1.5 to 3 times the baseline value, but not to exceed 100 seconds. Argatroban also prolongs the international normalized ratio (INR), a feature that can complicate transitioning of patients to warfarin. This problem can be circumvented by using levels of factor X in place of the INR to monitor warfarin. Alternatively, the argatroban infusion can be stopped for 2 to 3 hours before determination of the INR.

Bivalirudin (see also Chapter 62)

A synthetic 20–amino acid analogue of hirudin, bivalirudin is a divalent thrombin inhibitor.[55] Thus the NH_2-terminal portion of bivalirudin interacts with the active site of thrombin, whereas its COOH-terminal tail binds to exosite 1, the substrate-binding domain on thrombin. Bivalirudin has a plasma half-life of 25 minutes, the shortest half-life of all the parenteral direct thrombin inhibitors. It is degraded by peptidases and is partially excreted via the kidneys. When given in high doses in the cardiac catheterization laboratory, the anticoagulant activity of bivalirudin is monitored with the activated clotting time. With lower doses, its activity can be assessed via the APTT.

Studies comparing bivalirudin with heparin plus a GPIIb/IIIa antagonist suggest that bivalirudin produces less bleeding. This feature, plus its short half-life, renders bivalirudin an attractive alternative to heparin in patients undergoing PCI. Bivalirudin has also been used successfully in patients with HIT who require PCI.[55]

Oral Anticoagulants

For over 60 years, the vitamin K antagonists, such as warfarin, were the only available oral anticoagulants. This situation changed with the introduction of the direct oral anticoagulants, which include dabigatran, rivaroxaban, apixaban, and edoxaban.

Warfarin

A water-soluble vitamin K antagonist initially developed as a rodenticide, warfarin is the coumarin derivative most often prescribed in North America. Like other vitamin K antagonists, warfarin interferes with the synthesis of vitamin K–dependent clotting proteins, which include prothrombin (factor II) and factors VII, IX, and X. Warfarin also impairs synthesis of the vitamin K–dependent anticoagulant proteins C and S.[57]

Mechanism of Action.

All the vitamin K–dependent clotting factors possess glutamic acid residues at their N-terminals. A posttranslational modification adds a carboxyl group to the gamma carbon of these residues to generate gamma-carboxyglutamic acid. This modification is essential for expression of the activity of these clotting factors because it permits calcium-dependent binding of them to anionic phospholipid surfaces. A vitamin K–dependent carboxylase catalyzes the gamma-carboxylation. Thus, vitamin K from the diet undergoes reduction to vitamin K hydroquinone by vitamin K reductase (**Fig. 93.13**). Vitamin K hydroquinone serves as a cofactor for the carboxylase enzyme, which in the presence of carbon dioxide, replaces the hydrogen on the gamma carbon of glutamic acid residues with a carboxyl group. During this process, vitamin K hydroquinone is oxidized to vitamin K epoxide, which then undergoes reduction to vitamin K in a reaction catalyzed by vitamin K epoxide reductase.

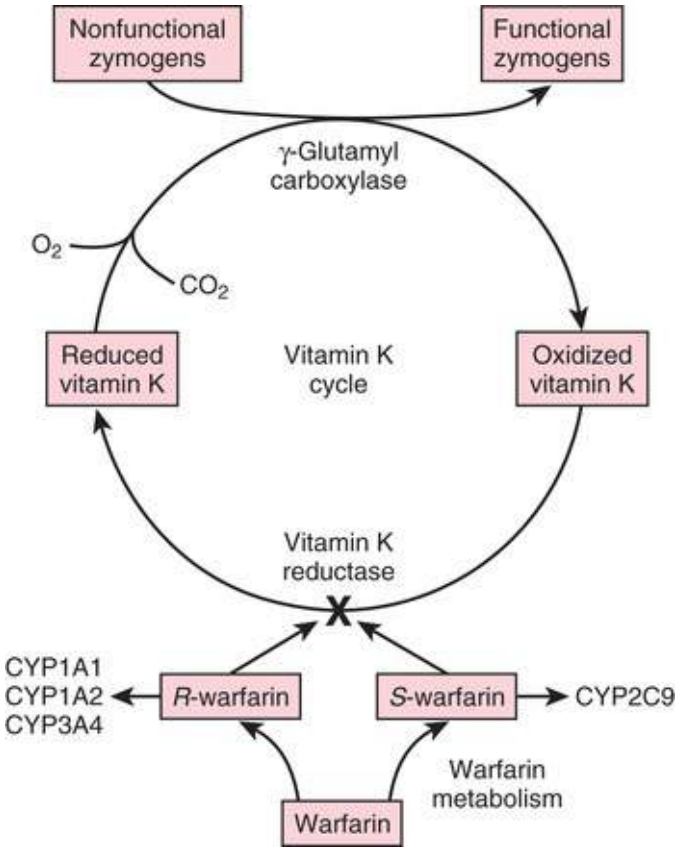

FIGURE 93.13 Mechanism of action of warfarin. A racemic mixture of *S*- and *R*-enantiomers, *S*-warfarin is most active. By blocking vitamin K epoxide reductase, warfarin inhibits the conversion of oxidized vitamin K into its reduced form. This inhibits vitamin K–dependent gamma-carboxylation of factors II, VII, IX, and X because reduced vitamin K serves as a cofactor for a gamma-glutamylcarboxylase, which catalyzes the gamma-carboxylation process, thereby converting prozymogens to zymogens capable of binding calcium and interacting with anionic phospholipid surfaces. *S*-warfarin is metabolized by CYP2C9. Common genetic polymorphisms in this enzyme can influence the metabolism of warfarin. Polymorphisms in the C1 subunit of vitamin K reductase (*VKORC1*) can also affect susceptibility of the enzyme to warfarin-induced inhibition, thereby influencing warfarin dosage requirements.

Warfarin inhibits vitamin K epoxide reductase, thereby blocking the gamma-carboxylation process. This results in the synthesis of partially gamma-carboxylated clotting proteins with little or no biologic activity. Warfarin exerts its anticoagulant activity when the newly synthesized clotting factors with reduced activity gradually replace their fully active counterparts. The antithrombotic effect of warfarin requires a reduction in the functional levels of factor X and prothrombin, clotting factors with half-lives of 24 and 72 hours, respectively.[57] Because the antithrombotic effect of warfarin is delayed, patients with established thrombosis or at high risk for thrombosis require concomitant treatment with a rapidly acting parenteral anticoagulant, such as heparin, LMWH, or fondaparinux.[53]

Pharmacology.

Warfarin is a racemic mixture of *R*- and *S*-isomers. It is rapidly and almost completely absorbed from the gastrointestinal tract. Levels of warfarin in blood peak approximately 90 minutes after administration. Racemic warfarin has a plasma half-life of 36 to 42 hours, and more than 97% of circulating warfarin is bound to albumin. Only the small fraction of unbound warfarin is biologically active.[57]

Warfarin accumulates in the liver, where the two isomers are metabolized via distinct pathways. The more active *S*-enantiomer of warfarin is primarily metabolized by CYP2C9 (**see Fig. 93.12**). Two

relatively common variants, *CYP2C9*2* and *CYP2C9*3*, encode an enzyme with reduced activity. Approximately 25% of whites have at least one variant allele of *CYP2C9*2* or *CYP2C9*3*; these variant alleles are less common in blacks and Asians (**Table 93.9**). Patients with one variant allele require 20% to 30% lower maintenance doses of warfarin, whereas those homozygous for these alleles require 50% to 70% lower doses than do those with the wild-type *CYP2C9*1* alleles. Consistent with the decreased warfarin dose requirement, patients with at least one *CYP2C9* variant allele are at increased risk for bleeding. Thus when compared with individuals with no variant alleles, the relative risk for warfarin-associated bleeding in *CYP2C9*2* or *CYP2C9*3* carriers is 1.9 and 1.8, respectively.[57]

TABLE 93.9

Frequencies of *CYP2C9* Genotypes and *VKORC1* Haplotypes in Different Populations and Their Effect on Warfarin Dose Requirements

GENOTYPE/HAPLOTYPE	FREQUENCY (%)			DOSE REDUCTION COMPARED WITH WILD-TYPE (%)
	Whites	Blacks	Asians	
CYP2C9				
*1/*1	70	90	95	—
*1/*2	17	2	0	22
*1/*3	9	3	4	34
*2/*2	2	0	0	43
*2/*3	1	0	0	53
*3/*3	0	0	1	76
VKORC1				
Non-A/non-A	37	82	7	—
Non-A/A	45	12	30	26
A/A	18	6	63	50

Warfarin interferes with the vitamin K cycle by inhibiting the C1 subunit of vitamin K epoxide reductase (VKORCI).[57] Polymorphisms in *VKORC1* can influence the anticoagulant response to warfarin. Several genetic variations of *VKORC1* are in strong linkage disequilibrium and have been designated as non-A haplotypes. *VKORC1* variants are more prevalent than variants of *CYP2C9*. Asians have the highest prevalence of *VKORC1* variants, followed by whites and blacks. Warfarin dose requirements for patients heterozygous or homozygous for the A haplotype are 25% and 50% lower, respectively, than the dose needed for patients with the non-A/non-A haplotype. Polymorphisms in *CYP2C9* and *VKORC1* explain up to 25% of the variability in warfarin dose requirements.[58-60] These findings prompted the U.S. Food and Drug Administration to amend the prescribing information for warfarin to recommend lower starting doses for patients with the *CYP2C9* and *VKORC1* genetic variants. In addition to genetic factors, fluctuations in the dietary intake of vitamin K, drugs, and various disease states influence the anticoagulant effect of warfarin. Consequently, computerized genotype-based warfarin-dosing algorithms also include pertinent patient characteristics, such as age, body weight, and concomitant medications.[58] Although these algorithms streamline warfarin dosing, randomized trials following time in therapeutic range with genotype-based warfarin dosing have yielded mixed results. It remains unclear whether better dose identification improves patient outcomes in terms of reducing hemorrhagic complications or recurrent thrombotic events.[59,60]

Monitoring.

Warfarin therapy is most often monitored with the prothrombin time, a test sensitive to reductions in the levels of prothrombin, factor VII, and factor X.[57] The test involves the addition of thromboplastin, a reagent that contains tissue factor, phospholipid, and calcium, to citrated plasma and determination of the time until clot formation. Thromboplastins vary in their sensitivity to reductions in the levels of vitamin

K–dependent clotting factors. Consequently, less sensitive thromboplastins will trigger the administration of higher doses of warfarin to achieve a target prothrombin time. This issue can cause problems because higher doses of warfarin increase the risk for bleeding.

The INR was developed to circumvent many of the problems associated with the prothrombin time. To calculate the INR, the patient's prothrombin time is divided by the mean normal prothrombin time, and this ratio is then multiplied by the international sensitivity index (ISI), an index of the sensitivity of the thromboplastin used for determination of the prothrombin time to reductions in levels of the vitamin K–dependent clotting factors. Highly sensitive thromboplastins have an ISI of 1.0. Most current thromboplastins have ISI values that range from 1.0 to 1.4.[57]

Although the INR has helped standardize anticoagulant practice, problems persist. The precision of INR determination varies depending on reagent-coagulometer combinations, which has led to variability in INR results. Unreliable reporting of the ISI by thromboplastin manufacturers also complicates determination of the INR. Furthermore, every laboratory must establish the mean normal prothrombin time with each new batch of thromboplastin reagent. To accomplish this, the prothrombin time must be measured in fresh plasma samples from at least 20 healthy volunteers via the same coagulometer that is used for patient samples.

For most indications, warfarin is administered at doses that produce a target INR of 2.0 to 3.0. An exception is patients with mechanical heart valves in the mitral position or in patients with a mechanical heart valve in other positions who have additional risk factors for stroke, such as atrial fibrillation, in whom a target INR of 2.5 to 3.5 is recommended. Studies in patients with atrial fibrillation demonstrate an increased risk for ischemic stroke when the INR falls below 1.7 and an increase in bleeding with INR values higher than 4.5. These findings highlight the narrow therapeutic window of vitamin K antagonists. In support of this concept, a study in patients receiving long-term warfarin therapy for unprovoked VTE demonstrated a higher rate of recurrent VTE with a target INR of 1.5 to 1.9 than with a target INR of 2.0 to 3.0.

Dosages.

Warfarin is usually started at a dose of 5 to 10 mg. Lower doses are used for patients with *CYP2C9* or *VKORC1* polymorphisms that affect the pharmacodynamics or pharmacokinetics of warfarin and render patients more sensitive to the drug. The dose is then titrated to achieve the desired target INR. Because of its delayed onset of action, patients with established thrombosis or those at high risk for thrombosis are given concomitant treatment with a rapidly acting parenteral anticoagulant, such as heparin, LMWH, or fondaparinux. Initial prolongation of the INR reflects a reduction in the functional levels of factor VII. Consequently, concomitant treatment with the parenteral anticoagulant should be continued until the INR has been therapeutic for at least 2 consecutive days. A minimum 5-day course of parenteral anticoagulation is recommended to ensure that the levels of prothrombin have fallen into the therapeutic range with warfarin.

The narrow therapeutic window of warfarin renders frequent monitoring of coagulation necessary to ensure a therapeutic anticoagulant response. Even patients with stable warfarin dose requirements should have their INR determined every 3 to 4 weeks. Although a recent study has raised the possibility that testing every 12 weeks may suffice in such patients, these results require confirmation in a large number of patients.[61] More frequent INR monitoring is necessary with the introduction of new concomitant medications because many drugs enhance or reduce the anticoagulant effects of warfarin.

Side Effects.

Like all anticoagulants, the major side effect of warfarin is bleeding; a rare complication is skin necrosis. Warfarin crosses the placenta and can cause fetal abnormalities, so it should not be used during pregnancy.

Bleeding.

At least half of the bleeding complications with warfarin occur when the INR exceeds the therapeutic range. Bleeding complications may be mild, such as epistaxis or hematuria, or more severe, such as retroperitoneal or gastrointestinal bleeding. Life-threatening intracranial bleeding can also occur. To minimize the risk for bleeding, the INR should be maintained in the therapeutic range. In asymptomatic patients whose INR is between 3.5 and 9, warfarin should be withheld until the INR returns to the therapeutic range. If the patient is at high risk for bleeding, sublingual or oral vitamin K can be administered. A vitamin K dose of 1 to 2.5 mg is usually adequate for patients with an INR between 4.9 and 9, whereas 2.5 to 5 mg can be used for those with an INR higher than 9. Higher doses of oral vitamin K (5 to 10 mg) produce more rapid reversal of the INR and may be helpful if the INR is excessively high.

Patients with serious bleeding need additional treatment. These patients require 10 mg of vitamin K by slow intravenous infusion with additional doses of vitamin K until the INR is in the normal range and four factor prothrombin complex concentrate to replace the vitamin K–dependent clotting proteins. Prothrombin complex concentrate is preferred over fresh frozen plasma for warfarin reversal because it normalizes the INR more rapidly and because the volume of administration is much smaller.[57]

Warfarin-treated patients who experience bleeding when their INR is in the therapeutic range require investigation of the cause of the bleeding. Those with gastrointestinal bleeding often have underlying peptic ulcer disease or a tumor. Similarly, investigation of hematuria or uterine bleeding in patients with a therapeutic INR may unmask a tumor of the genitourinary tract.

Skin Necrosis.

A rare complication of warfarin, skin necrosis usually occurs 2 to 5 days after initiation of therapy. Well-demarcated erythematous lesions form on the thighs, buttocks, breasts, or toes. Typically, the center of the lesion becomes progressively necrotic. Examination of skin biopsy specimens taken from the borders of these lesions reveals thrombi in the microvasculature.

Warfarin-induced skin necrosis occurs in patients with congenital or acquired deficiencies of protein C or protein S or in patients with HIT who are not receiving an alternate parenteral anticoagulant.[57] Initiation of warfarin therapy in these patients produces a precipitous fall in plasma levels of proteins C or S, thereby eliminating this important anticoagulant pathway before warfarin exerts an antithrombotic effect through lowering the functional levels of factor X and prothrombin. The resultant procoagulant state triggers thrombosis that is localized to the microvasculature of fatty tissues for unknown reasons.

Treatment involves discontinuation of warfarin and reversal with vitamin K, if needed. An alternative anticoagulant, such as heparin or LMWH, or fondaparinux or rivaroxaban in patients with HIT, should be given to patients with thrombosis. Protein C concentrates may accelerate healing of the skin lesions in protein C–deficient patients; fresh frozen plasma may be of value for those with protein S deficiency. Occasionally, skin grafting is necessary in those with extensive skin loss. Because of the potential for skin necrosis, patients with known protein C or protein S deficiency require overlapping treatment with a parenteral anticoagulant when initiating warfarin therapy. Warfarin should be started at low doses in these patients, and the parenteral anticoagulant should be continued until the INR is therapeutic for at least 2 to 3 consecutive days.

Pregnancy.

Warfarin crosses the placenta and can cause fetal abnormalities or bleeding. The fetal abnormalities include a characteristic embryopathy, which consists of nasal hypoplasia and stippled epiphyses. The risk for embryopathy is highest with warfarin administration in the first trimester of pregnancy. Central nervous system abnormalities can also occur with exposure to warfarin at any time during pregnancy. Finally, maternal administration of warfarin produces an anticoagulant effect in the fetus that can cause bleeding. This is of particular concern at delivery, when trauma to the head during passage through the birth canal can lead to intracranial bleeding. Because of these potential problems, warfarin is contraindicated in pregnancy, particularly in the first and third trimesters. Instead, heparin, LMWH, or fondaparinux can be given during pregnancy for prevention or treatment of thrombosis. Warfarin does not pass into breast milk and thus is safe for nursing mothers.

Special Problems.

Patients with a LA or those who need urgent or elective surgery present special challenges. Observational studies have suggested that patients with thrombosis complicating antiphospholipid syndrome require higher-intensity warfarin regimens to prevent recurrent thromboembolic events, an approach that increases the risk for bleeding. Recent randomized trials, however, indicated that usual-intensity warfarin treatment (INR of 2.0 to 3.0) is as effective as higher-intensity therapy and produces less bleeding.[62] Monitoring of warfarin can be problematic in patients with antiphospholipid syndrome if the LA prolongs the baseline INR; factor X levels can be used instead of the INR in such patients.

There is no need to stop warfarin treatment before procedures associated with a low risk for bleeding, including dental cleaning, simple dental extraction, cataract surgery, or skin biopsy.[57] In contrast, warfarin must be stopped 5 days before elective invasive procedures associated with a moderate or high risk for bleeding to allow the INR to return to normal levels. Only patients at high risk for thrombosis while not taking warfarin (such as those with mechanical heart valves or atrial fibrillation patients with a prior history of stroke) require bridging with once- or twice-daily subcutaneous injections of LMWH when the INR falls below 2.0. The last dose of LMWH should be given 12 to 24 hours before the procedure, depending on whether LMWH is administered twice or once daily, respectively. Once hemostasis is secure after the procedure, warfarin can be restarted. Thromboprophylaxis with LMWH can be given starting the day after major surgery and should be continued until the INR is therapeutic.

Direct Oral Anticoagulants (see also Chapters 38, 59, 60, and 84)

Direct oral anticoagulants that target thrombin or factor Xa are now available as alternatives to warfarin. These drugs have a rapid onset of action and half-lives that permit once- or twice-daily administration. Designed to produce a predictable level of anticoagulation, the new oral agents are more convenient to administer than warfarin because they are given in fixed doses without the need for routine monitoring of coagulation. As a class, the direct oral anticoagulants are at least as effective as warfarin and produce less serious bleeding, in particular, they cause less intracranial hemorrhage.

Mechanism of Action.

The new oral anticoagulants are small molecules that bind reversibly to the active site of their target enzyme. **Table 93.10** summarizes the pharmacologic features of these agents.

TABLE 93.10

Comparison of the Features of the New Oral Anticoagulants

FEATURES	RIVAROXABAN	APIXABAN	EDOXABAN	DABIGATRAN
Target	Xa	Xa	Xa	IIa
Molecular weight	436	460	548	628
Prodrug	No	No	No	Yes
Bioavailability (%)	80	60	50	6
Time to peak (hr)	3	3	2	2
Half-life (hr)	7-11	12	9-14	12-17
Renal excretion (%)	33	25	50	80

Dosages.

For prevention of stroke in patients with nonvalvular atrial fibrillation, rivaroxaban is given at a dosage of 20 mg once daily, with a reduction to 15 mg once daily in patients with a creatinine clearance of 15 to 49 mL/min; dabigatran is given at a dosage of 150 mg twice daily, with a reduction to 75 mg twice daily in those with a creatinine clearance of 15 to 30 mL/min; apixaban is given at a dosage of 5 mg twice daily, with a reduction to 2.5 mg twice daily for patients with at least two of the "ABC" criteria (i.e., *a*ge over 80 years, *b*ody weight under 60 kg, and *c*reatinine over 1.5 g/dL); and edoxaban is given at a dosage of 60 mg once daily for patients with a creatinine clearance of 50 to 95 mL/min and with a reduction to 30 mg once daily for patients with any one of the following criteria: creatinine clearance 15 to 50 mL/min, body weight of 60 kg or less, or use of potent P-glycoprotein inhibitors, such as verapamil or quinidine.

Dabigatran, rivaroxaban, apixaban, and edoxaban are also licensed for treatment of patients with VTE. Dabigatran and edoxaban are started after patients have received at least a 5-day course of treatment with a parenteral anticoagulant such as LMWH; dabigatran is given at a dose of 150 mg twice daily provided the creatinine clearance is over 30 mL/min, and the dosage regimen for edoxaban is identical to that used in patients with atrial fibrillation. In contrast, rivaroxaban and apixaban can be given in all-oral regimens; rivaroxaban is started at a dose of 15 mg twice daily for 21 days and is then reduced to 20 mg once daily thereafter, whereas apixaban is started at a dose of 10 mg twice daily for 7 days and is then reduced to 5 mg twice daily thereafter.[63] For long-term secondary prevention, the dosage of apixaban can be lowered to 2.5 mg twice daily and the dose of rivaroxaban can be lowered to 10 mg once daily, doses that have safety profiles similar to those of placebo and aspirin, respectively.[64]

Dabigatran, rivaroxaban, and apixaban are licensed for thromboprophylaxis after elective hip or knee replacement surgery; edoxaban is not licensed for this indication except in Japan. Thromboprophylaxis is started after surgery and is continued for at least 30 days in patients undergoing hip replacement and for 10 to 14 days in patients undergoing knee replacement. Dabigatran is given at a dose of 220 mg once daily, whereas rivaroxaban and apixaban are given at doses of 10 mg once daily and 2.5 mg twice daily, respectively.

Monitoring.

Although administered without routine monitoring, in some situations determination of the anticoagulant activity of the direct oral anticoagulants can be helpful,[65] including assessment of adherence, detection of accumulation or overdose, identification of bleeding mechanisms, and determination of activity before surgery or intervention. For qualitative assessment of anticoagulant activity, the prothrombin time can be used for factor Xa inhibitors and the APTT for dabigatran. Rivaroxaban and edoxaban prolong the prothrombin time more than apixaban does. In fact, because apixaban has such a limited effect on the prothrombin time, anti–factor Xa assays are needed to assess its activity.[65] The effect of the drugs on tests

of coagulation varies depending on the reagents used to perform the tests, and variability increases with conversion of the prothrombin time to an INR. Chromogenic anti–factor Xa assays and the diluted thrombin clotting time or ecarin clotting or chromogenic assays with appropriate calibrators provide quantitative assays to measure plasma levels of the factor Xa inhibitors and dabigatran, respectively.[65]

Side Effects.

As with any anticoagulant, bleeding is the most common side effect of the direct oral anticoagulants. Although the direct oral anticoagulants are associated with less intracranial bleeding than warfarin is, the risk for gastrointestinal bleeding is higher with dabigatran (at the 150-mg, twice-daily dose), rivaroxaban, and edoxaban (at the 60-mg, once-daily dose) than with warfarin. Dyspepsia occurs in up to 10% of patients treated with dabigatran; this problem improves with time and can be minimized by taking the drug with food.

Periprocedural Management.

Like warfarin, the direct oral anticoagulants must be stopped before surgical procedures associated with a moderate or high risk for bleeding.[65] The drugs should be withheld for 1 to 2 days or longer if renal function is impaired. Assessment of residual anticoagulant activity before high-risk procedures is prudent if such assays are available. After surgery, patients should receive thromboprophylaxis with LMWH until hemostasis is restored, at which point the direct oral anticoagulants can be restarted.

Cardiac procedures such as atrial fibrillation ablation or pacemaker implantation can safely be performed without interruption of the direct oral anticoagulants. However, it may be prudent to hold the dose in the morning of the day of the procedure to avoid intervention at peak drug levels.

Management of Bleeding.

With minor bleeding, withholding one or two doses of drug is usually sufficient.[66] With more serious bleeding, the approach is similar to that with warfarin, except that vitamin K administration is of no benefit; the anticoagulant and any antiplatelet drugs should be withheld, the patient should be resuscitated with fluids and blood products as necessary, and the bleeding site should be identified and managed. Coagulation testing will determine the extent of anticoagulation, and renal function should be assessed so that the half-life of the drug can be calculated.[66] Timing of the last dose of anticoagulant is important, and oral activated charcoal may help prevent absorption of drug administered in the past 4 hours particularly in cases of overdose. If bleeding continues or is life-threatening or if it occurs in a critical organ (e.g., the eye) or in a closed space (e.g., the pericardium or retroperitoneum), reversal of the anticoagulant should be considered.

Idarucizumab is licensed for dabigatran reversal in patients with serious bleeding or in those requiring urgent surgery or intervention.[67] A humanized antibody fragment, idarucizumab binds dabigatran with 350-fold higher affinity than that of dabigatran for thrombin to form an essentially irreversible complex that is cleared by the kidneys. (**Table 93.11**) Idarucizumab is given intravenously as a 5-g bolus and is supplied in a box containing two 50-mL vials, each containing 2.5 g of idarucizumab.[67] Idarucizumab rapidly reverses the anticoagulant effects of dabigatran and normalizes the aPTT, diluted thrombin time, or ecarin clot time.[68]

TABLE 93.11

Reversal Agents for Direct Oral Anticoagulants

FEATURE	IDARUCIZUMAB	ANDEXANET ALFA	CIRAPARANTAG
Structure	Humanized antibody fragment	Recombinant human factor Xa variant	Synthetic, small cationic molecule
Mass (Da)	47,776	39,000	573
Mechanism of action	Binds dabigatran with high affinity	Competes with factors Xa (and IIa) for binding	Binds via hydrogen bonding
Target	Dabigatran	Rivaroxaban, apixaban, edoxaban and heparins	Dabigatran, rivaroxaban, apixaban, edoxaban and heparins
Administration	Intravenous bolus	Intravenous bolus followed by a 2 hour infusion	Intravenous bolus
Measurement of Reversal	Activated partial thromboplastin time, diluted thrombin time, or ecarin clotting time or chromogenic assay	Calibrated anti-factor Xa assays	Whole-blood clotting time
Elimination	Renal (catabolism)	Not reported	Not reported
Cost	$3,500 per dose in the United States	Unknown; likely to be at least as much as idarucizumab	Likely to be low

Andexanet alfa and ciraparantag are under development for reversal of rivaroxaban, apixaban, and edoxaban, but neither is licensed (**see Table 93.11**). Until these agents are available, 4-factor prothrombin complex concentrate (25 to 50 units/kg) should be given to reverse them.[66] If there is continued bleeding, activated prothrombin complex concentrate (50 units/kg) or recombinant factor VIIa (90 µg/kg) can be administered.[66]

Andexanet alfa and ciraparantag are specific reversal agents. Andexanet alfa is a recombinant variant of factor Xa. Its active-site serine residue has been replaced with an alanine residue to eliminate catalytic activity, and its membrane-binding domain has been removed to circumvent its incorporation into the prothrombinase complex.[69] Andexanet serves as a decoy and binds rivaroxaban, apixaban, and edoxaban and sequesters them until they can be cleared. It also reverses heparin, LMWH, and fondaparinux by competing with factor Xa and thrombin for the antithrombin-heparin complex. It is administered as an intravenous bolus of 400 mg, followed by a 2-hour infusion of 480 mg, to reverse apixaban or rivaroxaban if the last dose was taken more than 7 hours previously. It is administered as an intravenous bolus of 800 mg, followed by a 2-hour infusion of 960 mg, to reverse edoxaban or rivaroxaban if the last dose was taken within the past 7 hours.[70,71] When given in this manner to patients taking these drugs who presented with serious bleeding, andexanet reversed the anti–factor Xa activity while it was administered and appeared to restore hemostasis.[70,71] Additional efficacy and safety information is needed prior to its approval.

At an earlier stage of development than andexanet, ciraparantag is a synthetic, cationic small molecule that binds rivaroxaban, apixaban, and edoxaban, as well as dabigatran, heparin, LMWH, and fondaparinux. When given as an intravenous bolus to volunteers who took 60 mg of edoxaban, ciraparantag reduced the whole-blood clotting time in a concentration-dependent manner.[72] Because it binds citrate and other calcium chelators, routine tests of coagulation, such as the INR, APTT or anti–factor Xa activity cannot be used to monitor ciraparantag reversal. Although the whole-blood clotting time may be useful for this purpose, the test is not widely available. Therefore, additional studies are needed before ciraparantag will be approved.

Pregnancy.

As small molecules, the direct oral anticoagulants can all pass through the placenta. Consequently, these agents are contraindicated in pregnancy, and when used by women of childbearing potential, appropriate contraception is important. Small amounts of rivaroxaban pass into breast milk, and it is unknown whether the other direct oral anticoagulants also do so. Therefore, direct oral anticoagulants should not be used in nursing mothers.

Novel Anticoagulants in Development

Although the direct oral anticoagulants represent a major advance in oral anticoagulation therapy, the search for more effective and safer anticoagulants continues. Evidence showing that factor XII and factor XI, components on the contact system, are important for thrombus stabilization and growth has caused these factors to emerge as promising targets for novel anticoagulants. Supporting this concept, a phase II, proof-of-concept study revealed that lowering factor XI levels with an antisense oligonucleotide prior to elective knee replacement surgery was more effective than enoxaparin in preventing postoperative VTE without increasing the risk of bleeding.[73] More studies with this and other inhibitors of factor XI or factor XII are needed to identify the better target and to assess efficacy and safety.

Fibrinolytic Drugs (see also Chapter 59)

Used to degrade thrombi, fibrinolytic drugs are administered systemically or are delivered via catheters directly into the substance of the thrombus. Currently approved fibrinolytic agents include streptokinase; acylated plasminogen streptokinase activator complex (anistreplase); urokinase; recombinant t-PA (rt-PA), also known as alteplase or activase; and two recombinant derivatives of rt-PA, tenecteplase and reteplase. Each of these agents acts by converting the proenzyme, plasminogen, to plasmin, the active enzyme.[10] There are two pools of plasminogen—circulating plasminogen and fibrin-bound plasminogen (**Fig. 93.14**). Plasminogen activators that preferentially activate fibrin-bound plasminogen are fibrin specific. In contrast, nonspecific plasminogen activators do not discriminate between fibrin-bound and circulating plasminogen.[74] Activation of circulating plasminogen results in the generation of unopposed plasmin, which can trigger the systemic lytic state. Alteplase and its derivatives are fibrin-specific plasminogen activators, whereas streptokinase, anistreplase, and urokinase are nonspecific agents.

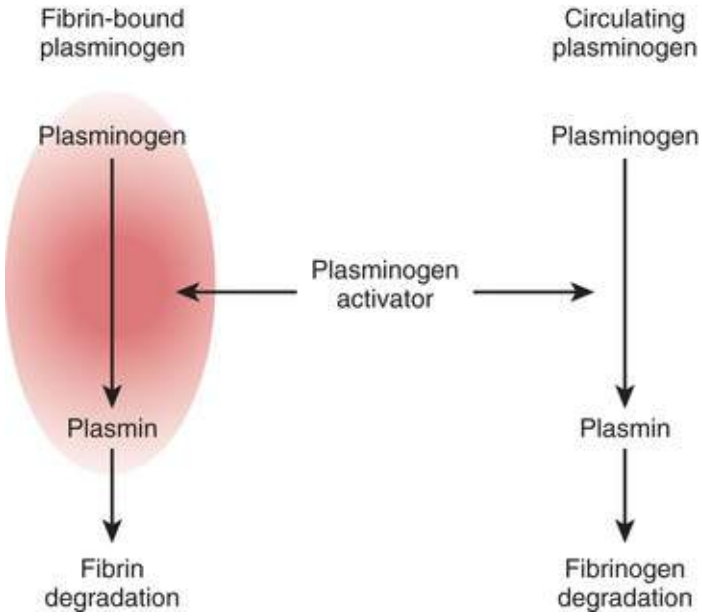

FIGURE 93.14 Consequences of activation of fibrin-bound or circulating plasminogen. The fibrin specificity of plasminogen activators reflects their capacity to distinguish between fibrin-bound and circulating plasminogen, which depends on their affinity for fibrin. Plasminogen activators with high affinity for fibrin preferentially activate fibrin-bound plasminogen. This results in the generation of plasmin on the fibrin surface. Fibrin-bound plasmin, which is protected from inactivation by alpha$_2$-antiplasmin, degrades fibrin to yield soluble fibrin degradation products. In contrast, plasminogen activators with little or no affinity for fibrin do not distinguish between fibrin-bound and circulating plasminogen. Activation of circulating plasminogen results in systemic plasminemia and subsequent degradation of fibrinogen and other clotting factors.

Streptokinase

Unlike other plasminogen activators, streptokinase is not an enzyme and does not directly convert plasminogen to plasmin. Instead, it forms a 1 : 1 stoichiometric complex with plasminogen, thereby inducing a conformational change in plasminogen that exposes its active site (**Fig. 93.15**). This conformationally altered plasminogen then converts additional plasminogen molecules to plasmin.[75] Streptokinase has no affinity for fibrin, and the streptokinase-plasminogen complex activates both free and fibrin-bound plasminogen. Activation of circulating plasminogen generates sufficient amounts of plasmin to overwhelm alpha$_2$-antiplasmin. Unopposed plasmin not only degrades fibrin in the occlusive thrombus but also induces a systemic lytic state.[74]

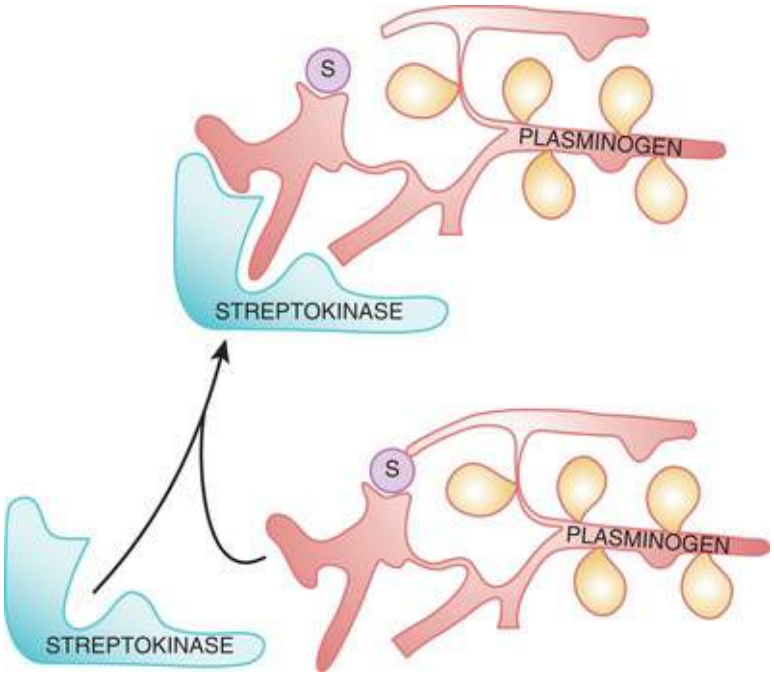

FIGURE 93.15 Mechanism of action of streptokinase. Streptokinase binds to plasminogen and induces a conformational change in plasminogen that exposes its active site. The streptokinase/plasmin(ogen) complex then serves as the activator of additional plasminogen molecules.

When given systemically to patients with acute myocardial infarction, streptokinase reduces mortality rates. For this indication the drug is usually administered as an intravenous infusion of 1.5 million units over a period of 30 to 60 minutes. Patients who receive streptokinase can form antibodies against it, as can patients with previous streptococcal infection. These antibodies can reduce the effectiveness of streptokinase. Allergic reactions occur in approximately 5% of patients treated with streptokinase. They may be manifested as a rash, fever, chills, and rigors; rarely, anaphylactic reactions can occur. Transient hypotension is common with streptokinase and probably reflects plasmin-mediated release of bradykinin. The hypotension usually responds to leg elevation and administration of intravenous fluids and low doses of vasopressors, such as dopamine or norepinephrine.

Anistreplase

To generate anistreplase, streptokinase is mixed with equimolar amounts of Lys-plasminogen, a plasmin-cleaved form of plasminogen with a Lys residue at its N-terminal. The active site of Lys-plasminogen exposed on combination with streptokinase is then blocked with an anisoyl group. After intravenous infusion, the anisoyl group is slowly removed by natural deacylation, which yields a half-life of approximately 100 minutes for the complex.[76] This allows drug administration via a single bolus infusion. Although it is more convenient to administer, anistreplase offers few mechanistic advantages over streptokinase. Like streptokinase, anistreplase does not distinguish between fibrin-bound and circulating plasminogen. Consequently, anistreplase produces a systemic lytic state. Similarly, allergic reactions and hypotension are just as frequent with anistreplase as they are with streptokinase. When anistreplase was compared with alteplase in patients with acute myocardial infarction, reperfusion was achieved more rapidly with alteplase than with anistreplase. Improved reperfusion was associated with a trend toward better clinical outcomes and reduced mortality rates with alteplase. The modest improvement in outcomes and the high cost of anistreplase dampened enthusiasm for its use.

Urokinase

Originally isolated from cultured fetal kidney cells and later synthesized using recombinant DNA technology, urokinase is a two-chain serine protease with a molecular weight of 34,000.[74] Urokinase directly converts plasminogen to plasmin. Unlike streptokinase, urokinase is not immunogenic, and allergic reactions are rare. Urokinase produces a systemic lytic state because it does not discriminate between fibrin-bound and circulating plasminogen. Despite many years of use, systemic urokinase has never been evaluated for coronary fibrinolysis; instead, urokinase was mostly used for catheter-directed lysis of thrombi in the deep veins or in peripheral arteries. Because of production problems, the availability of urokinase is limited and it is rarely used.

Alteplase

A recombinant form of single-chain t-PA, alteplase has a molecular weight of 68,000. Plasmin rapidly converts alteplase into its two-chain form. The interaction of alteplase with fibrin is mediated by the finger domain and, to a lesser extent, by the second kringle domain (**Fig. 93.16**).[10] Alteplase has a considerably higher affinity for fibrin than for fibrinogen. Consequently, the catalytic efficiency of plasminogen activation by alteplase is two to three orders of magnitude higher in the presence of fibrin than in the presence of fibrinogen.[74] Although alteplase preferentially activates plasminogen in the presence of fibrin, it is not as fibrin selective as first thought. Its fibrin specificity is limited because like fibrin, (DD)E, the major soluble degradation product of cross-linked fibrin, binds alteplase and plasminogen with high affinity. As a result, (DD)E is as potent as fibrin as a stimulator of plasminogen activation by alteplase. Plasmin generated on the fibrin surface results in thrombolysis, whereas plasmin generated on the surface of circulating (DD)E degrades fibrinogen. Fibrinogenolysis results in the accumulation of fragment X, a high-molecular-weight clottable fibrinogen degradation product. Incorporation of fragment X into hemostatic plugs formed at sites of vascular injury renders them susceptible to lysis.[77] This phenomenon may contribute to alteplase-induced bleeding.

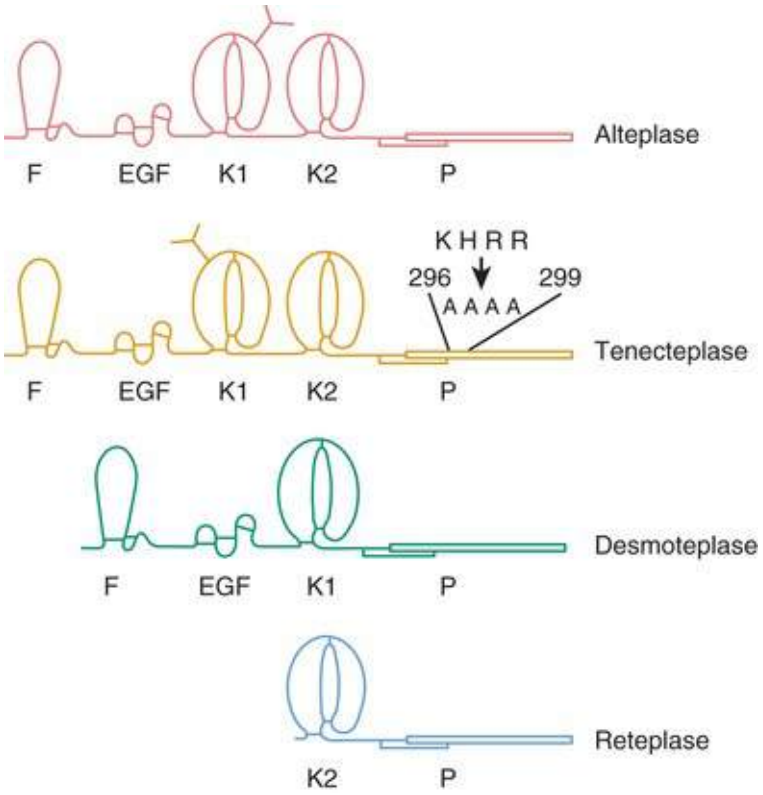

FIGURE 93.16 Domain structures of alteplase, tenecteplase, desmoteplase, and reteplase. The finger (F), epidermal growth factor (EGF), first and second kringles (K1 and K2, respectively), and protease (P) domains are illustrated. The glycosylation site (Y) on K1 has been repositioned in tenecteplase to endow it with a longer half-life. In addition, a tetra-alanine substitution in the protease domain renders tenecteplase resistant to PAI-1 inhibition. Desmoteplase differs from alteplase and tenecteplase in that it lacks a K2 domain. Reteplase is a truncated variant that lacks the F, EGF, and K1 domains.

A trial comparing alteplase with streptokinase for the treatment of patients with acute myocardial infarction demonstrated significantly lower mortality rates with alteplase than with streptokinase, although the absolute difference was small. Patients older than 75 years with anterior myocardial infarction presenting less than 6 hours after the onset of symptoms derived the greatest benefit from alteplase. Acute myocardial infarction or acute ischemic stroke is treated with an intravenous infusion of alteplase over a 60- to 90-minute period. The total dose of alteplase usually ranges from 90 to 100 mg. Allergic reactions and hypotension are rare, and alteplase is not immunogenic.

Tenecteplase

A genetically engineered variant of t-PA, tenecteplase was designed to have a longer half-life than t-PA and to be resistant to inactivation by PAI-1.[78] To prolong its half-life, a new glycosylation site was added to the first kringle domain (**see Fig. 93.16**). Because addition of this extra carbohydrate side chain reduced fibrin affinity, the existing glycosylation site on the first kringle domain was removed. To render the molecule resistant to inhibition by PAI-1, a tetra-alanine substitution was introduced at residues 296 to 299 in the protease domain, the region responsible for the interaction of t-PA with PAI-1.

Tenecteplase is more fibrin specific than t-PA. Although both agents bind to fibrin with similar affinity, the affinity of tenecteplase for (DD)E is significantly lower than that of t-PA. Consequently, (DD)E does not stimulate systemic plasminogen activation by tenecteplase to the same extent as t-PA does. As a result, tenecteplase produces less fibrinogenolysis than t-PA does.

For coronary fibrinolysis, tenecteplase is administered as a single intravenous bolus. In a large phase III trial that enrolled more than 16,000 patients, the 30-day mortality rate with single-bolus tenecteplase was similar to that with accelerated-dose t-PA. Although rates of intracranial hemorrhage were also

similar with both treatments, patients given tenecteplase had less noncerebral bleeding and a reduced need for blood transfusions in comparison with those treated with t-PA. The improved safety profile of tenecteplase probably reflects its enhanced fibrin specificity.

Reteplase

A recombinant t-PA derivative, reteplase is a single-chain variant that lacks the finger, epidermal growth factor, and first kringle domains (**see Fig. 93.16**). This truncated derivative has a molecular weight of 39,000.[76] Reteplase binds fibrin more weakly than t-PA does because it lacks the finger domain. Because it is produced in *Escherichia coli*, reteplase is not glycosylated; this feature endows it with a plasma half-life longer than that of t-PA. Consequently, reteplase is given as two intravenous boluses separated by 30 minutes. Clinical trials in patients with acute myocardial infarction showed improved 30-day survival rates when reteplase was compared with streptokinase, but its noninferiority compared with alteplase.

Other Fibrinolytic Agents.
Other fibrinolytic agents include desmoteplase (**see Fig. 93.16**), a recombinant form of the full-length plasminogen activator isolated from the saliva of the vampire bat, and alfimeprase, a truncated form of fibrolase, an enzyme isolated from the venom of the southern copperhead snake. Clinical studies with these agents have been disappointing. Desmoteplase, which is more fibrin specific than t-PA, was investigated for the treatment of acute ischemic stroke. Patients initially seen 3 to 9 hours after the onset of symptoms were randomly assigned to one or two doses of desmoteplase or to placebo. Overall response rates were low, and no differences from placebo were noted. Mortality rates were higher in the desmoteplase arm.

Alfimeprase is a metalloproteinase that degrades fibrin and fibrinogen in a plasmin-independent fashion. In the circulation, alpha$_2$-macroglobulin inhibits alfimeprase, so alfimeprase must be delivered via a catheter directly into the thrombus. Despite promising phase II results, studies of alfimeprase for the treatment of peripheral arterial occlusion or for restoration of flow in blocked central venous catheters were stopped because of lack of efficacy. The disappointing results with desmoteplase and alfimeprase highlight the challenges of introducing new fibrinolytic drugs.

Future Perspectives

Thrombosis in arteries or veins involves interplay among the vessel wall, platelets, the coagulation system, and fibrinolytic pathways. Activation of coagulation also triggers inflammatory pathways that may contribute to thrombosis. A better understanding of the biochemistry of platelet aggregation and blood coagulation and advances in structure-based drug design have identified new targets and prompted the development of novel antithrombotic drugs. Despite these advances, however, arterial and venous thromboembolic disorders remain a major cause of morbidity and death. The search for better targets and more potent, safer, or more convenient antiplatelet, anticoagulant, and fibrinolytic drugs continues.

Rheumatic Diseases and the Cardiovascular System

Justin C. Mason

Inflammatory rheumatic diseases have a long-recognized relationship with the cardiovascular system. Because the treatment of these diseases has improved considerably over the last 20 years and increased survival rates, the importance and complexity of this interrelationship have achieved prominence. Patients with multisystem rheumatic diseases may on occasion initially be evaluated by a cardiovascular specialist, a cardiologist, or a vascular or cardiothoracic surgeon, and early recognition of the immune-mediated basis of the cardiovascular disease reduces morbidity and mortality rates. The vasculature may represent a primary target organ of the underlying rheumatic disease and can be affected at numerous sites and at all levels. Thus large-vessel vasculitides may affect the entire aortic wall. Systemic sclerosis (SSc) commonly results in pulmonary arterial vasculopathy and pulmonary artery hypertension (PAH). Antineutrophil cytoplasmic antibody (ANCA)–associated systemic vasculitides (AASVs) affect arterioles preferentially. Antiphospholipid syndrome (APS) causes both venous and arterial thromboses. Cardiac complications of systemic lupus erythematosus (SLE) include coronary arteritis, pericarditis, myocarditis, and valvular heart disease. Renal artery stenosis leading to uncontrolled hypertension is a feature of Takayasu arteritis (TA), and occlusive lesions in the subclavian, axillary, or iliac arteries may lead to limb claudication in patients with TA and giant cell arteritis (GCA). Rheumatic diseases have equally important secondary effects on the cardiovascular system. Chronic systemic inflammation predisposes to endothelial dysfunction and increased arterial stiffness, thereby escalating the risk for the development of atherosclerosis. Cardiovascular specialists are increasingly recognizing the significantly increased prevalence of premature myocardial infarction and stroke in patients suffering from rheumatoid arthritis (RA) and SLE. Many outstanding clinical challenges remain, and predominant among them are early recognition, diagnosis, and treatment of patients with rheumatic disease who have the highest risk for cardiovascular complications, alongside improved understanding of the underlying molecular mechanisms and the development of preventive strategies.

Atherosclerosis

Premature Atherosclerosis

Recognition of the role of inflammation in atherosclerosis has highlighted and stimulated study of the potential relationship between systemic inflammatory diseases and premature atherogenesis. This effort has substantially advanced our understanding of both the underlying pathogenic mechanisms and the epidemiology. Current priorities include identification of patients most at risk and the development of preventive therapeutic strategies.[1] Evidence supporting an association between inflammatory diseases and accelerated atherogenesis is best developed for RA and SLE. In addition, ankylosing spondylitis, psoriatic arthritis, AASV, TA, and APS may all be associated with premature atherosclerosis. Cardiovascular specialists should consider an underlying inflammatory disease in young patients with otherwise unexplained angina, myocardial infarction, or stroke. Patients with a rheumatic disease who suffer a myocardial infarction have worse outcomes in terms of both heart failure and mortality than does the age-matched general population.[2]

Endothelial Dysfunction and Vascular Injury

Homeostatic mechanisms promote a quiescent, antithrombotic, antiadhesive vascular endothelium and control vasodilation and permeability (**see Chapters 44 and 57**). Prolonged systemic inflammation such as that seen in RA and SLE may promote endothelial injury, increased endothelial apoptosis, and endothelial vasodilator dysfunction.

Traditional risk factors alone do not explain the increased burden of atherosclerosis, but inflammation may exacerbate the effects of classic risk factors.[3] When compared with the general population, patients with systemic inflammatory diseases more commonly exhibit endothelial dysfunction and increased aortic stiffness. Although the results of individual studies vary, effective treatment of the underlying inflammation may not always reverse the endothelial dysfunction or improve the aortic stiffness.[4,5] This observation and the fact that the plaque burden may not be increased have led to the hypothesis that the systemic inflammatory environment may predispose to increased plaque instability and rupture, a conjecture supported by autopsy studies. Thus, both accelerated atherogenesis and higher-risk plaque may contribute to the observed increased incidence of premature cardiovascular events.[6,7]

Various molecular mechanisms mediate the increased risk for atherosclerotic disease and cardiovascular events. In addition to the traditional cardiovascular risk factors, disease-related factors may include effects of the proinflammatory cytokines tumor necrosis factor-alpha (TNF-α), interleukin-1 (IL-1), and IL-6 on endothelial activation, leukocyte adhesion, endothelial injury, and permeability. Increased endothelial cell apoptosis and a diminished capacity for repair may contribute. Autoantibodies (e.g., antiphospholipid antibodies), $CD4^{+}CD28^{-}$ cytotoxic T cells, $Th17/T_{REG}$ imbalance, complement deficiency or excessive activation, genetic polymorphisms, and the deleterious effects of drugs, including corticosteroids and cyclosporine, may also contribute.[2,3]

Rheumatoid Arthritis

RA, an autoimmune, symmetric inflammatory polyarthritis with a female-to-male ratio of 3 : 1, affects up to 1% of the population in the Western world, with the onset of symptoms most commonly occurring between 30 and 50 years of age. Up to 80% of patients have a positive serum rheumatoid factor and/or anti–cyclic citrullinated peptide (CCP) antibodies. A systemic inflammatory response is evident, with

low-grade fever, weight loss, raised erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), hypoalbuminemia, normochromic normocytic anemia, and thrombocytosis.

A variety of studies have shown subclinical arterial disease with increased carotid intimal-medial thickness (IMT) and early plaque development. Although RA independently raises the risk for atherosclerosis, the precise mechanistic relationship between RA and atherogenesis remains unknown. Similarly, the mechanisms and long-term outcomes of abnormalities in myocardial perfusion and coronary flow reserve that have been reported in patients with RA and normal epicardial arteries remain to be established.[8] The initial abnormalities in vascular function may occur at or before the onset of RA symptoms.[9] The direct effect of chronic inflammation on vascular endothelium may itself promote atherogenesis, in addition to exacerbating the actions of traditional cardiovascular risk factors.[6,10] Moreover, the systemic inflammatory environment might contribute to the features of plaque and blood that promote cardiovascular events in patients with RA.[11]

Patients with RA have increased classic risk factors for atherosclerosis. Tobacco smoking is associated with both cardiovascular risk and the development of RA. Similarly, insulin resistance and the metabolic syndrome are more common in RA. Patients with RA may have a dyslipidemic pattern that includes high triglyceride levels and low levels of high-density lipoprotein (HDL) and low-density lipoprotein (LDL) cholesterol.[12] The risk for myocardial infarction in patients with RA is considered similar to that in those with diabetes mellitus, and women with RA are twice as likely as age-matched controls in the general population to suffer myocardial infarction. Although death rates from both heart attack and stroke are comparable to those in the general population, events occur at an earlier age, with 50% of premature deaths in patients with RA being a direct consequence of cardiovascular disease. The excess mortality rate becomes apparent 7 to 10 years after diagnosis and has been associated with persistent disease activity and the presence of rheumatoid factor and anti-CCP antibodies. Current evidence suggests that patients with RA who suffer a myocardial infarction are less likely to receive acute reperfusion therapy and secondary preventive measures and thus have worse outcomes.[6,13]

Treatment

Drug therapy for RA has undergone a remarkable evolution over the past 20 years, with the focus on biologic therapies and aggressive management of early disease. Clinical trials have demonstrated that this approach reduces symptoms and structural damage to joints. Increasing evidence suggests treatment to target to control synovitis also confers vascular protection.[14]

Methotrexate is now the most widely used disease-modifying antirheumatic drug (DMARD), and since its introduction, mortality rates from myocardial infarction in patients with RA have improved. Similar observations have been made for sulfasalazine and hydroxychloroquine. Patients who do not respond adequately to DMARD therapy should switch to biologic therapies. Such agents now include those targeting TNF-α (infliximab, adalimumab, etanercept, certolizumab, and golimumab), the IL-6 receptor (tocilizumab), CTLA4Ig (abatacept), and the B cell–depleting monoclonal antibody rituximab. An aggressive disease-modifying approach also minimizes the use of nonsteroidal antiinflammatory drugs (NSAIDs) and the requirement for corticosteroid therapy. Glucocorticoids may adversely affect traditional risk factors such as insulin resistance, hypertension, and lipid profiles and may hasten carotid plaque formation in RA.[10] Because NSAIDs and cyclooxygenase-2 (COX-2)-selective NSAIDs (coxibs), although effective, may elevate the blood pressure and increase the frequency of thrombotic cardiovascular events, caution is required regarding their use in patients with cardiovascular complications of inflammatory disease.[15] However, evidence suggests that NSAID use in patients with RA does not confer an increased risk for cardiovascular events, thus indicating that their antiinflammatory

effects predominate.

Definitive demonstration of the potential cardiovascular benefits of the biologic therapies will require the results of long-term prospective studies (see later). TNF-α promotes vascular endothelial activation and dysfunction and may lead to plaque destabilization, and hence blockade would appear to be an attractive therapeutic option. Infliximab therapy may improve endothelial function as measured by flow-mediated dilation 4 to 12 weeks after infusion, whereas etanercept has been reported to reduce aortic stiffness. Analysis of carotid IMT suggests that TNF-α antagonists reduce systemic inflammation and retard progression of IMT.[10] Tight therapeutic control of RA disease activity per se appears to have a beneficial effect on the risk for myocardial infarction.[14] Treatment of the arthritis must be combined with a careful review of classic risk factors and appropriate steps taken to modify them. Although precise guidelines are awaited, most rheumatologists have a low threshold for addition of a statin. Meanwhile, debate continues concerning the pros and cons of disease-specific cardiovascular risk calculators,[16] and new scores are under investigation.[17]

Atherosclerosis and Systemic Lupus Erythematosus

SLE, a systemic autoimmune disease, is found usually in women, at a ratio of 9 : 1, and affects all racial groups but more commonly those of Afro-Caribbean, Asian, and Chinese extraction. Constitutional symptoms at initial evaluation include night sweats, lethargy, malaise, and weight loss. Frequent mucocutaneous features include the classic butterfly facial rash, oral ulcers, and alopecia. Serositis, myalgia, arthralgia, and Jaccoud nonerosive arthropathy also occur. Potentially life-threatening complications include glomerulonephritis leading to renal failure, central nervous system (CNS) involvement with cerebral vasculitis, pneumonitis, shrinking lung syndrome, and PAH. Hematologic involvement includes lymphopenia in most and frequently hemolytic anemia, neutropenia, and thrombocytopenia. Cardiac manifestations of SLE are relatively rare but include pericarditis, myocarditis, endocarditis, aortitis, and coronary arteritis. Understanding of the pathogenesis of SLE continues to improve. A defect in apoptotic cell clearance results in the exposure of nuclear antigens to an immune system with hyperreactive B cells. Loss of immune tolerance results in the generation of autoantibodies and immune complexes. Deposition of immune complexes in target organs leads to activation of complement and tissue injury.[18]

Most patients have high-titer antinuclear antibodies and antibodies against double-stranded DNA (dsDNA). The latter are more specific for the diagnosis of SLE; the presence of antibodies against one or more nuclear antigens, including Sm, Ro, La, and ribonucleoprotein (RNP), reinforces the diagnosis. Complement activation and consumption of C3 and C4 leading to reduced plasma levels characterize active disease. The ESR also rises in active disease, but CRP levels typically remain normal except in those with serositis or secondary infection.

A variety of studies have suggested an increased risk for myocardial infarction and stroke in patients with SLE that is between 2-fold and 10-fold and up to 50-fold greater than that in the general population. The young age of patients with SLE and cardiovascular disease (67% of female patients with SLE and a first cardiac event typically occur before 55 years of age) suggests that SLE accelerates arterial disease.[19] A study of 1874 cases (9485 person-years follow-up) revealed a 2.66-fold increase in the risk of myocardial infarction, stroke, and coronary intervention when compared with the general population.[20] Although the pattern and extent of coronary artery disease in SLE does not appear to differ (**Fig. 94.1**), the plaque may be more vulnerable to rupture. Patients with SLE have worse outcomes following myocardial infarction than the age-matched general population does, with a higher risk for the development of cardiac failure and increased mortality rates.[2,6] This difference may result from the late diagnosis of ischemic

heart disease and a reluctance to treat aggressively.

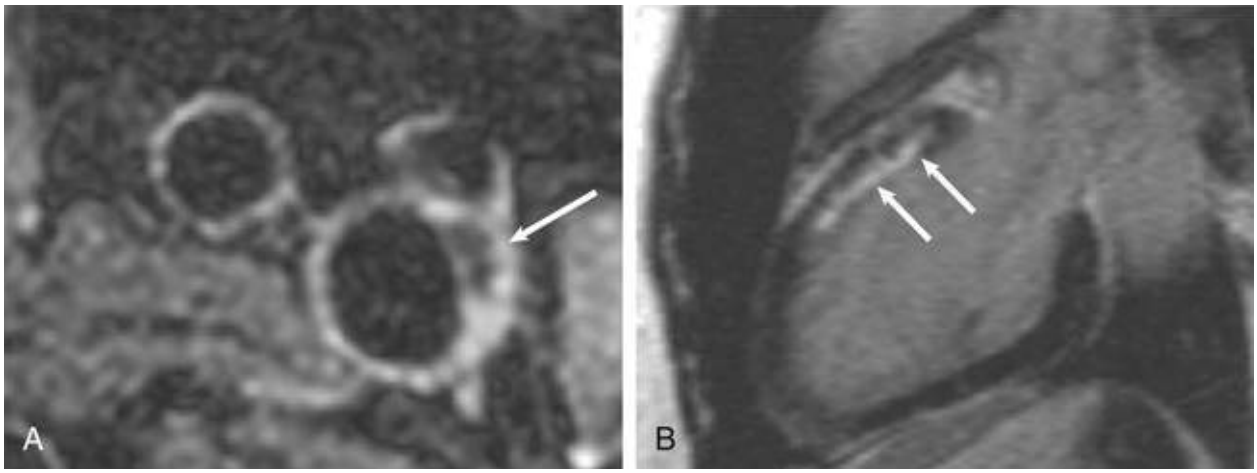

FIGURE 94.1 Atherosclerosis in systemic lupus erythematosus. **A,** Transaxial T2-weighted CMR of the carotid bifurcation showing atherosclerotic plaque *(arrow).* The lipid-filled core and fibrous cap can be seen along with evidence of calcification. **B,** CMR showing a two-chamber view in the late phase after gadolinium injection. Subendocardial late gadolinium enhancement is present in the anteroseptal left ventricle (*arrows*) and extends from the base of the heart to the midventricular region, consistent with a previous subendocardial myocardial infarction.

Hypertension is common in SLE because of renal disease and the use of glucocorticoids in many patients. Similarly, patients with SLE commonly have metabolic syndrome, which is associated with renal impairment, higher corticosteroid doses, and Korean or Hispanic ethnicity.[21] Patients with SLE also have lipid abnormalities, including high levels of very low-density lipoprotein (VLDL) and triglycerides, elevated or normal LDL cholesterol, and reduced HDL cholesterol. Moreover, proinflammatory HDL leading to increased oxidatively-modified LDL cholesterol was seen in 45% of patients with SLE as compared with 20% of those with RA and 4% of the general population.[12] Antibodies against oxidized LDL also occur in SLE and may promote atherogenesis.

Treatment

Mild SLE with rash and arthralgia can be treated with simple analgesics and NSAIDs, with the addition of hydroxychloroquine if required. Organ involvement, including mild renal impairment, hematologic abnormalities, myositis, arthritis, and cutaneous lesions, requires the addition of prednisone and typically an immunosuppressant such as azathioprine, mycophenolate mofetil (MMF), or methotrexate to aid in controlling the disease and to facilitate steroid sparing. Cyclophosphamide and high-dose corticosteroids remain the first-line treatment of life-threatening complications, including myocarditis, cerebritis, severe hematologic involvement, and glomerulonephritis. MMF may replace cyclophosphamide for lupus nephritis because of its equivalent efficacy and concerns regarding the risk for permanent infertility seen in up to 50% of patients treated with cyclophosphamide. Most rheumatologists consider rituximab an effective treatment of severe SLE, although clinical trials to date have proved disappointing and further data are awaited. A variety of regimens have been used, including combinations of rituximab, prednisone, and cyclophosphamide.[22] Belimumab, a monoclonal antibody that binds to the soluble B lymphocyte stimulator and prevents its interaction with B cell surface receptors, has a modest disease-modifying effect in patients with moderate non–renal-related SLE.

Defining effective strategies for prevention of cardiovascular disease in patients with SLE will require long-term prospective trials with adjudicated cardiovascular endpoints. Undertreated and/or persistently

active disease is associated with accelerated atherogenesis. Therefore adequate individualized immunosuppressive therapy should minimize cardiovascular complications. Hydroxychloroquine reduces LDL cholesterol and lowers mortality rates from cardiovascular disease in patients with SLE. Aggressive management of traditional risk factors is also advocated, including diligent monitoring and tight blood pressure control. Statins are widely used, particularly in patients with renal impairment. Caution and careful monitoring should be exercised in patients with active myositis, because statin therapy can exacerbate this complication. The clinical data available do not support significant protection against atherosclerosis by statins 2 to 3 years after initiation, although longer-term analysis is awaited.[18,23]

Atherosclerosis in Association With Other Rheumatic Diseases

The relationship between chronic inflammation and atherogenesis implies that many rheumatic diseases may be associated with a premature and increased cardiovascular risk (**Table 94.1**). Because data in support of this hypothesis are derived from relatively small studies, important current clinical challenges include the need to determine (1) which rheumatic diseases pose the greatest cardiovascular threat, (2) a means of identifying subsets of patients most at risk, and (3) strategies to minimize cardiovascular events.

TABLE 94.1

Coronary Artery Involvement and the Rheumatic Diseases

Churg-Strauss syndrome
Polyarteritis nodosa
Granulomatous polyangiitis
Rheumatoid arthritis

Ankylosing spondylitis, psoriatic arthritis, and gout may also be associated with atherosclerotic disease. Hyperuricemia independently predicts cardiovascular disease, and patients with gout often have hypertension, hyperlipidemia, obesity, and diabetes mellitus. Many drugs used for the treatment of cardiac disease, including diuretics, beta blockers, and low-dose aspirin, can increase serum uric acid levels. In contrast, losartan, angiotensin-converting enzyme (ACE) inhibitors, atorvastatin, and fenofibrate may reduce urate levels.[24] Allopurinol may reduce the risk for congestive cardiac failure and cardiovascular-associated death. In addition to achieving a serum uric acid level lower than 0.36 mmol/L, patients with gout should receive dietary advice and aggressive management of cardiovascular risk factors.

A systematic review of articles on cardiovascular disease in patients with psoriatic arthritis has revealed increased traditional risk factors, endothelial dysfunction, aortic stiffness, and subclinical atherosclerosis. The limited data available also suggest that adequate suppression of inflammatory disease activity leads to improvement in endothelial dysfunction and carotid IMT.[25] Patients with ankylosing spondylitis have demonstrated impaired endothelial function and increased carotid IMT and pulse wave velocity, all of which indicate an increased risk for atherosclerosis.[26] The impact of the increasing use of anti-TNF-α therapies on the incidence of cardiovascular events in these patients should

emerge from international biologic registries.

Vasculitides

The vasculitides, a heterogeneous group of diseases, represent a significant clinical challenge, both diagnostically and therapeutically. The primary systemic vasculitides are classified as large-, medium-, or small-vessel disease. This leaves a small group of unclassified conditions, including Behçet disease, relapsing polychondritis, primary CNS vasculitis, and Cogan syndrome.[27]

The histologic features of vasculitis include perivascular inflammatory infiltrates that may invade the arterial wall, fibrinoid necrosis, thrombosis, fibrosis, and scar formation. Fibrinoid necrosis, a specific feature of the medium- and small-vessel vasculitides, typically affects the tunica media. Complications include stenosis and occlusions resulting in organ ischemia, thrombosis, aneurysm formation, and hemorrhage. Although biopsy is optimal for making the diagnosis, suitable tissue may not always be accessible, or arterial biopsy may present hazards, as in patients with TA. Thus the diagnosis often depends on clinical findings, laboratory indices, and imaging studies.

The vasculitides have a complex, multifactorial, and poorly understood immunopathogenesis. The endothelium may be subject to complement-mediated injury as a consequence of immune complex deposition in polyarteritis nodosa (PAN) or rheumatoid vasculitis. In the medium- and small-vessel vasculitides, ANCAs may activate neutrophils and subsequently damage the endothelium. The proinflammatory cytokines TNF-α, IL-1, IL-6, and interferon-gamma (IFN-γ) may activate the endothelium and induce the expression of adhesion molecules, including E-selectin, vascular cell adhesion molecule-1 (VCAM-1), and intercellular adhesion molecule-1 (ICAM-1), thereby facilitating leukocyte adhesion and recruitment into the vessel wall and surrounding tissue.

Cardiovascular disease in patients with vasculitis, although relatively rare, can be life-threatening. Aortitis, hypertension, coronary arteritis, valvular heart disease, pericarditis, myocarditis, conduction abnormalities, accelerated atherosclerosis, and cardiac failure can all occur. This section focuses on the vasculitides most likely to be encountered by cardiovascular disease specialists.

Large-Vessel Vasculitis

Giant Cell Arteritis

GCA affects large- and medium-sized arteries. The disease affects those older than 50 years, with the incidence increasing with age. GCA occurs most commonly in northern Europe, Scandinavia, and the United States in people of northern European ancestry. GCA typically affects extracranial branches of the aorta and, in addition to the temporal arteries, may involve the subclavian and axillary arteries, the thoracic aorta, and on occasion the femoral and iliac arteries. Clinical features include fever, weight loss, malaise, headache, temporal artery thickening with loss of pulsation, scalp tenderness, and jaw claudication. The most feared complication, anterior ischemic optic neuropathy (AION), may be manifested as amaurosis fugax or sudden permanent visual loss. Up to 25% of patients are initially found to have systemic features without the classic sign of tenderness and temporal artery involvement. ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET) has confirmed earlier autopsy findings and shown widespread arteritis with increased FDG uptake throughout the aorta and subclavian and iliac arteries in more than 50% of patients.

Pathogenesis

Histopathologic examination reveals localized fragmentation of the internal elastic lamina closely associated with an inflammatory infiltrate consisting predominantly of IFN-γ–producing $CD4^+$ T lymphocytes, monocytes/macrophages, and occasional characteristic multinucleated giant cells. Recent studies have revealed that activated $CD83^+$ dendritic cells initiate the arterial wall inflammation and colocalize with activated T cells. Local synthesis of growth factors such as platelet-derived growth factor leads to proliferation of smooth muscle cells and concentric stenosis of the arterial lumen (**Fig. 94.2**). Release of matrix metalloproteinases and generation of reactive oxygen species can result in arterial wall injury and aneurysm formation.

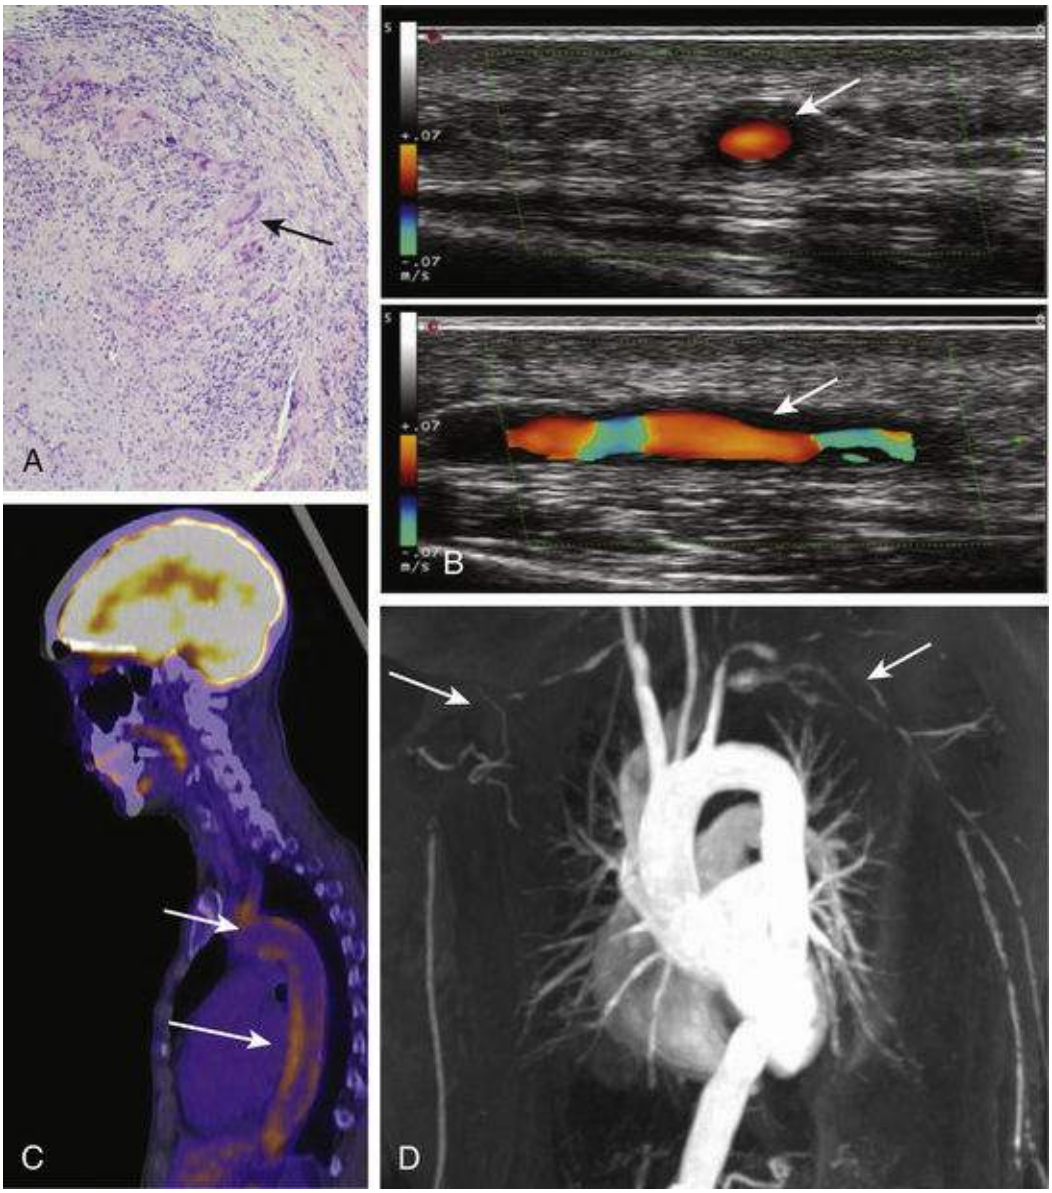

FIGURE 94.2 Giant cell arteritis. **A,** A temporal artery biopsy specimen stained with hematoxylin-eosin shows evidence of myofibroblast proliferation and vessel occlusion, a focal mononuclear cell inflammatory infiltrate, and the presence of multinucleated giant cells *(arrow).* **B,** Dark hypoechoic, circumferential wall thickening (halo sign) *(arrows)* is seen around the temporal artery lumen in active GCA in both the transverse and longitudinal views. **C,** ^{18}FDG-PET-CT scan demonstrating uptake in the thoracic aorta, consistent with active arteritis. **D,** Magnetic resonance angiogram demonstrating bilateral stenosis of the left subclavian and axillary arteries *(arrows)* in a 65-year-old woman with upper limb ischemic symptoms. (**B,** Courtesy Dr. Wolfgang Schmidt, Medical Centre for Rheumatology Berlin-Buch, Berlin, Germany.)

Diagnosis

Biopsy is the definitive means of diagnosis and should be considered for all patients. However, the need for biopsy should not delay treatment. Temporal artery biopsy is positive in up to 80% of patients. Recent interest has focused on temporal artery ultrasound, which can reveal a characteristic halo sign with concentric homogeneous thickening of the arterial wall and evidence of flow disturbance and stenosis (**see Fig. 94.2**).

Cardiovascular Complications

Although rare, severe cardiovascular complications can occur and include dissecting thoracic aortic aneurysms (**Table 94.2**). Imaging and autopsy studies suggest that aortitis and aortic wall thickening are frequent in GCA, although their relationship with the development of aortic aneurysm remains unclear. Increased FDG uptake in the thoracic aorta can be associated with an increased risk for aortic dilation. Overall, patients with GCA have a 17-fold increased risk for thoracic aortic aneurysms. Those with conventional cardiovascular risk factors, poorly controlled disease, and aortic regurgitation have a higher risk. In the absence of guidelines, we recommend annual thoracic aortic screening for those with FDG-PET–positive thoracic aortic uptake or with evidence on magnetic resonance angiography (MRA) or computed tomography angiography (CTA) of aortic wall thickening, and screening every 2 to 3 years for the remainder of patients. CTA and MRA are the optimal imaging techniques. Pericarditis, coronary arteritis, limb ischemia, accelerated atherosclerosis, myocardial infarction, and cerebrovascular accidents are all associated with GCA. Yet most outcome studies do not report increased mortality rates, so the impact of severe cardiovascular disease seems to be small.[28]

TABLE 94.2

Cardiovascular Disease in the Systemic Vasculitides

Vasculitides	Cardiovascular Complications
Large-Vessel Vasculitis	
Giant cell arteritis	Thoracic/abdominal artery aneurysm, limb ischemia, pericarditis, coronary arteritis, IHD, MI
Takayasu arteritis	Aortic regurgitation, limb ischemia, aortic stenosis, aortic aneurysm, stroke, hypertension, coronary arteritis and aneurysm, IHD, MI, myocarditis, cardiac failure
Kawasaki disease	Coronary artery aneurysm, MI, myocarditis, pericarditis, valvular dysfunction, cardiac failure
Medium-Vessel Vasculitis	
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome)	Myocarditis, pericarditis, coronary arteritis, cardiomyopathy, cardiac fibrosis, valvular dysfunction, MI
Polyarteritis nodosa	Myocarditis, pericarditis, coronary arteritis, coronary aneurysm, hypertension, cardiac failure
Wegener granulomatosis (granulomatous polyangiitis)	Myocarditis, pericarditis, coronary arteritis, valvular heart disease, cardiac failure
Microscopic polyangiitis	Pericarditis, coronary microaneurysm, MI

IHD, ischemic heart disease; *MI*, myocardial infarction.

Takayasu Arteritis

TA, a granulomatous panarteritis, affects the aorta and its major branches, typically before the age of 40 years. The disease predominates in women, with a female-to-male ratio of up to 10 : 1. Because the diagnosis is often delayed, substantial arterial injury accrues. The current diagnostic criteria depend on detection of established stenotic disease and do not yet reflect the increasing sensitivity of noninvasive imaging.[29]

The presentation is typically nonspecific and associated with fever, night sweats, arthralgia, malaise, profound tiredness, and lethargy. TA may be accompanied by symptoms of upper limb claudication, and carotidynia occurs in up to 25% of patients. The aorta may be involved throughout its length, and even

though any branches can be diseased, the most commonly affected are the subclavian and common carotid arteries. More than 90% of patients have stenotic/occlusive arterial lesions, whereas approximately 25% have aneurysms. The pulmonary arteries are involved in up to 50% of patients, and aortic valve regurgitation and coronary arteritis may occur (**Fig. 94.3**).

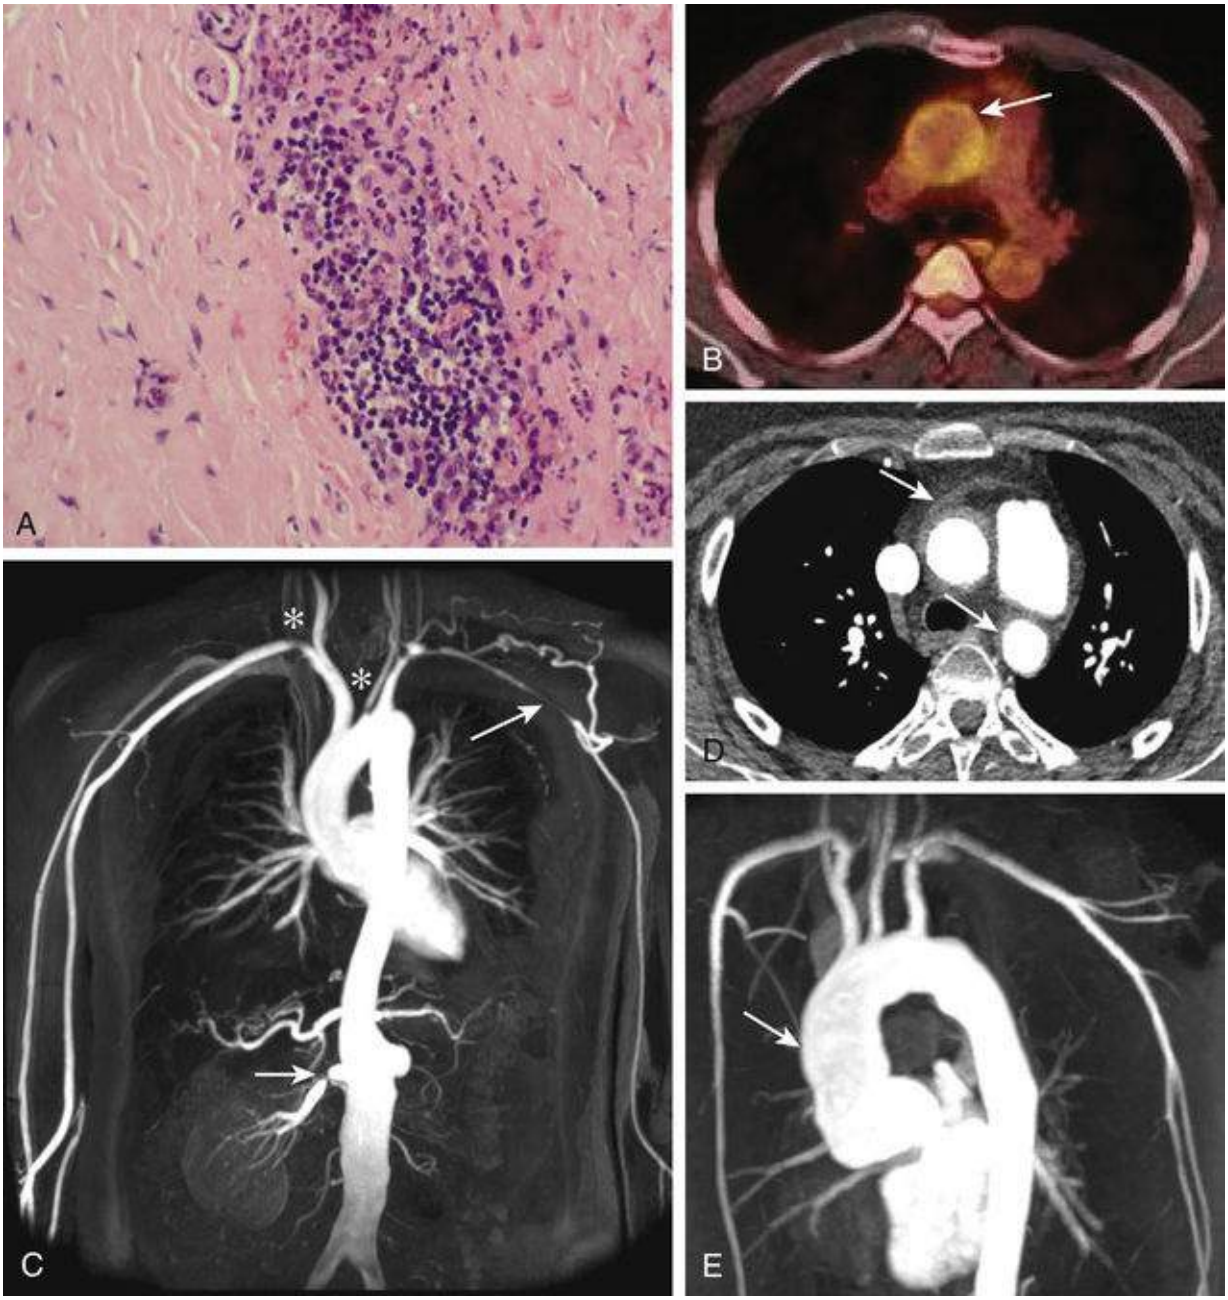

FIGURE 94.3 Takayasu arteritis **A,** Hematoxylin-eosin staining of a common carotid artery biopsy specimen obtained at surgery shows a focal mixed mononuclear cell inflammatory infiltrate with a multinucleated giant cell. **B,** ^{18}FDG-PET-CT scan demonstrating uptake in the aortic arch *(arrow)*, consistent with active arteritis. **C,** MRA demonstrating stenosis of the left subclavian artery with collateral formation *(long arrow)*, proximal stenoses in the right subclavian and left common carotid arteries *(stars)*, proximal stenosis in the right renal artery *(short arrow)*, and an atrophic left kidney. **D,** CT angiogram demonstrating thickening of the wall of the ascending and descending aorta *(arrows).* **E,** MRA revealing severe dilatation of the ascending aorta *(arrow)* requiring aortic valve replacement.

TA has severe consequences, with 74% reporting compromised daily activities and 23% unable to work. In our cohort, survival at 10 years is higher than 95%; similarly, in the United States, survival rates of 94% to 96% are reported, whereas in Korea the survival rate was 87% at 10 years. In Japan, 15-year

survival rates have improved to 96.5%. However, the survival rate fell to 67% in a subset of patients with serious complications and/or a progressive disease course.

Pathogenesis

Arteritic lesions demonstrate adventitial thickening and focal leukocytic accumulation of the media with intimal hyperplasia. The leukocytes include activated dendritic cells, T and B lymphocytes, macrophages, and multinucleated giant cells (**see Fig. 94.3**). Growth factor–driven mesenchymal cell proliferation leads to intimal hyperplasia and fibrosis and subsequent arterial stenosis or occlusion. Local matrix metalloproteinase synthesis may predispose to aneurysmal dilation.

Diagnosis

Diagnosis of TA depends principally on the physician including the disease in the differential diagnosis. The variable nature of the features of TA and the lack of constitutional symptoms in 30% to 50% of patients initially present a challenge to a prompt diagnosis. In addition to improved physician awareness, a list of “red flags” that raise the possibility of TA is helpful (**Table 94.3**).[30] One's index of suspicion must be high in young patients with an unexplained acute-phase response or hypertension. Similarly, common initial signs, including diminished or absent pulsation or arterial bruits, can suggest the diagnosis.

TABLE 94.3

“Red Flags” for Takayasu Arteritis

In patients younger than 40 years the following may be indicative of TA:
Unexplained acute-phase response (raised ESR and/or CRP)
Carotidynia
Hypertension
Discrepant blood pressure between the arms (> 10 mm Hg)
Absent or weak peripheral pulse or pulses
Limb claudication
Arterial bruit
Angina

Laboratory abnormalities during active disease include raised ESR and CRP (in 75% of patients), often accompanied by normochromic normocytic anemia, thrombocytosis, hypergammaglobulinemia, and hypoalbuminemia. No specific autoantibodies or other serologic abnormalities exist, however. Noninvasive imaging is now the optimal means of diagnosis because tissue biopsy is rarely available. High-resolution ultrasound, cardiac magnetic resonance (CMR), MRA, CTA, and PET have all been studied. Although the potential of these techniques is not in doubt, their specificity and sensitivity in the management of TA remain undetermined. ^{18}F-FDG-PET-CT may reveal evidence of active arteritis and lead to early detection of prestenotic disease. A current consensus review has suggested that this technique is particularly useful for the detection of active arteritis in patients not receiving immunosuppressive therapy. Demonstration of arterial wall enhancement, edema, or thickening on MRA and CTA may facilitate the diagnosis of prestenotic disease, and stenoses and aneurysms can be readily identified and monitored (**see Fig. 94.3**). Color duplex ultrasound has particular use in assessing the common carotid and proximal subclavian arteries in TA. Homogeneous, bright concentric arterial wall thickening is a typical finding in affected common carotid arteries.

Cardiovascular Complications

In addition to the sequelae associated with cerebral, internal organ, and limb ischemia, aneurysms, PAH,

or aortic rupture may develop. Cardiac complications include aortic valve insufficiency, accelerated atherosclerosis, cardiac ischemia, myocarditis, myocardial infarction, and heart failure. Coronary disease is often asymptomatic, as illustrated by the identification of silent myocardial injury in 27% of a cohort that we studied.[31] Patients with TA can also have secondary accelerated atherosclerosis. Thallium stress scintigraphy revealed myocardial perfusion defects in 53%, whereas intraarterial angiography has shown that up to 30% have coronary artery lesions typically affecting the ostia and proximal segments, with the left main coronary artery being most commonly affected. Neither MRA nor ^{18}F-FDG-PET-CT reliably identifies coronary arteritis, which is best identified by coronary CTA.[32] Inflammation of the ascending aorta predisposes to coronary artery involvement, as well as to dilation of the aortic root with subsequent aortic valve regurgitation and the need for aortic valve replacement.[33] Left ventricular dysfunction may affect up to 20% and may reflect myocarditis, ischemic heart disease, and hypertension. High blood pressure occurs commonly with renal artery stenosis often in association in TA.

Kawasaki Disease

Kawasaki disease (KD) predominantly affects children younger than 5 years with a peak incidence at 6 to 24 months of age. The vasculitis affects medium and small arteries, notably the coronary arteries. All racial groups may be affected, with the highest incidence recorded in Asia (20 to 100 per 100,000 children < 5 years of age). KD is an acute self-limited illness that typically resolves within 1 to 2 months, although the mortality rate still remains 1% to 2%. Characteristic initial features include fever of 5 days' duration or longer, bilateral conjunctivitis, and mucocutaneous lesions, including red fissured lips and a strawberry tongue. Cervical lymphadenopathy may be prominent, with erythema affecting the palms and soles and a polymorphous exanthema.

Pathogenesis

The cause of KD is unknown, although occasional seasonal epidemics and an increased incidence in siblings suggests infection may trigger the disease and lead to an uncontrolled immunologic response in a genetically susceptible host. A variety of organisms have been implicated, including streptococci, staphylococci, and *Propionibacterium acnes*. Despite this interest, no definitive evidence supports an infectious cause. Tissue specimens show endothelial injury, perhaps caused by proinflammatory cytokines and activated neutrophils. Infiltration of the arterial wall by neutrophils, T cells, and macrophages is associated with the development of arterial stenosis or, more commonly, aneurysms. Coronary artery aneurysms develop in up to 20% of patients during the first month of the illness, and 50% will regress in the following years.

Diagnosis

Neutrophilia, thrombocytosis, and a raised acute-phase response occur acutely. Echocardiography can detect coronary involvement from the second week of illness and can be used to monitor progress. Coronary angiography is not performed acutely because of the risk of precipitating myocardial infarction, but it can be used after 6 months to establish the degree of coronary artery involvement. The electrocardiogram (ECG) demonstrates abnormalities in up to 50% of patients, including tachycardia, T wave inversion, ST depression, atrioventricular block, and rarely, ventricular arrhythmia.

Cardiovascular Complications

Coronary artery aneurysms develop in up to 25% of untreated patients with KD. Sudden death can occur

as a consequence of myocardial infarction following acute coronary thrombosis or rupture of a coronary artery aneurysm. Pericarditis, pericardial effusion, myocarditis, valvular dysfunction, and cardiac failure may all occur, whereas peripheral arterial involvement is less common but may affect the limb, renal, and visceral arteries.

Treatment

Aspirin (80 to 100 mg/kg/day) in four divided doses is recommended, along with intravenous immunoglobulin (IVIG). This treatment combination reduces development of coronary artery aneurysm to 5%, with a significant impact on mortality rates. Twenty percent of patients are resistant to IVIG, however, and these patients can receive corticosteroids, although the results reported are variable.

Most patients with KD have a good outcome. Yet in up to 20% of those with coronary artery aneurysms, coronary stenoses eventually develop, and these patients require follow-up by an experienced cardiologist. Although the risk for long-term complications, including myocardial infarction and sudden death, is greater in those with giant aneurysms,[34] the risk for thrombosis and myocardial infarction still remains increased in those in whom aneurysms have regressed and throughout adult life.

Idiopathic Aortitis

Aortitis can complicate SLE, Cogan syndrome, Behçet disease, human leukocyte antigen (HLA) B27–positive spondyloarthropathy, KD, and GCA. Aortitis may also be idiopathic, although a number of such cases are now recognized to fall within the IgG4-related disease spectrum.[35] The clinical features are nonspecific and include malaise, lethargy, chest pain, fever, and weight loss, and the diagnosis is often made only at the time of surgery. The ESR and CRP are typically raised, and the extent of the disease can be demonstrated by ^{18}F-FDG-CT-PET scanning and aortic MRA or CTA (**Fig. 94.4**). Dilation of the aortic root may require aortic valve and root replacement, whenever possible preceded by immunosuppressive therapy to control aortic wall inflammation. Treatment involves corticosteroids and a steroid-sparing immunosuppressant drug such as azathioprine, methotrexate, or MMF. The B-cell–depleting antibody has proven particularly effective for IgG4-related disease.

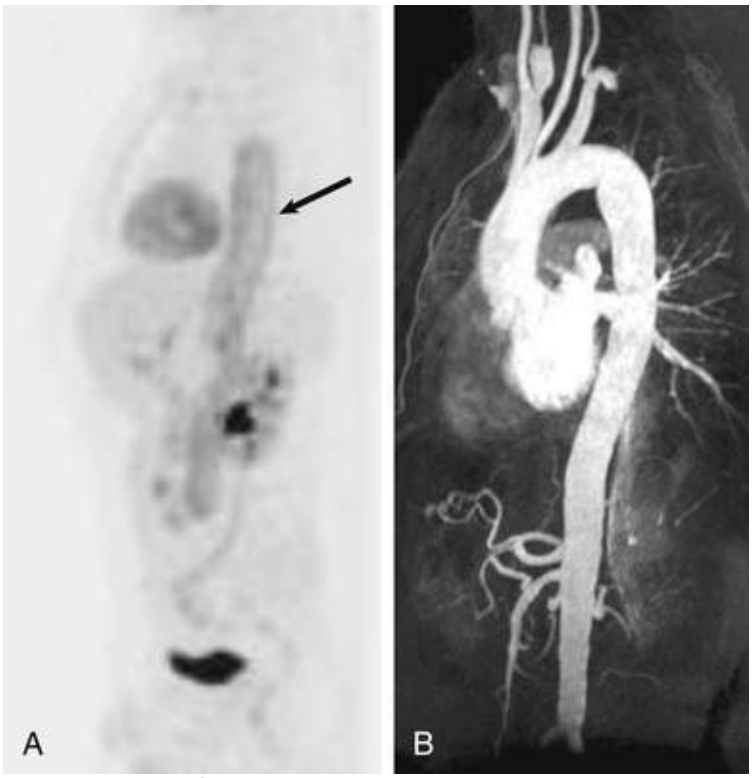

FIGURE 94.4 Idiopathic aortitis. **A,** ^{18}F-FDG-PET scan demonstrating high-grade tracer uptake *(arrow)* in the aorta from below the level of the arch to just above the level of the aortic bifurcation, in keeping with aortitis. The activity is largely concentric around the aortic lumen. **B,** MRA showing aortic ectasia.

Treatment of Large-Vessel Vasculitis

The evidence base for the treatment of large-vessel vasculitis is remarkably small.[36] Although GCA and TA typically respond to steroids, gaining remission requires high doses and a considerable side effect burden. In GCA, the dependence on prednisone and conflicting evidence concerning the efficacy of steroid-sparing drugs, combined with concerns about AION, often result in overtreatment and considerable side effects. Indeed, 86% of patients experience glucocorticoid-related adverse events at 10-year follow-up. Both of these diseases have a high relapse rate when the dose of corticosteroid is tapered, suggesting persistent vasculitis. Potential mechanistic insight into this observation comes from a recent report of two pathogenic pathways in GCA. Raised plasma IL-17 and Th17 cells in the arterial wall were rapidly normalized by prednisone therapy and remained suppressed as the dose was reduced. In contrast, the Th1-promoting cytokine IL-12 and IFN-γ-producing Th1 cells demonstrated corticosteroid resistance, which may account for the reemergence of disease.[37] Corticosteroid treatment of GCA should be tapered carefully to maintain remission and minimize side effects. Although the literature is somewhat conflicting, methotrexate and azathioprine represent suitable corticosteroid-sparing agents for those unable to reduce the dose of prednisone sufficiently. Most patients with active TA require steroid-sparing immunosuppressive drugs. Methotrexate and azathioprine are the most widely prescribed, and small open-label studies support their use. In patients failing to respond or in those with life-threatening disease such as coronary arteritis or myocarditis, aggressive treatment with intravenous pulsed cyclophosphamide is recommended.

Case reports suggest that anti-TNF-α therapy can treat refractory GCA effectively. However, a randomized placebo-controlled trial of the use of infliximab in 44 patients with GCA in remission with corticosteroids ended prematurely when it failed to demonstrate a benefit, either in terms of preventing relapse or as a steroid-sparing agent, and a second trial using etanercept only showed a modest steroid-

sparing effect. Recent reports suggest that the anti–IL-6 receptor monoclonal antibody tocilizumab can treat GCA effectively and results of the first clinical trial are awaited.[38] Open-label studies suggest that TNF-α blockade can treat patients with TA who fail to respond adequately to combination therapy with prednisone and steroid-sparing immunosuppressant drugs, including cyclophosphamide. A recent review of all published cases of TA treated with TNF-α antagonists found complete remission in 37%, partial remission in 53.5%, and no response in 9.5%. Only a small number of patients with TA have received tocilizumab. These patients have generally responded well, at least in the short term, and further data are awaited with interest.[39,40] The suppression of both constitutional symptoms and CRP synthesis by tocilizumab complicates disease monitoring and may be falsely reassuring. Follow-up of patients with TA should therefore include angiographic monitoring, preferably with CMR because it avoids radiation exposure.

Critical analysis of the published results suggests that percutaneous angioplasty or bypass surgery requires caution in patients with TA or GCA. Indications for surgical intervention include aneurysmal enlargement with risk for rupture, severe aortic regurgitation or coarctation, stenotic or occlusive lesions resulting in severe symptomatic coronary artery or cerebrovascular disease, uncontrolled hypertension as a consequence of renal artery stenosis, and stenoses leading to critical limb ischemia. Whenever possible, surgery should be delayed until immunosuppression has achieved clinical remission.[33]

Medium-Vessel Vasculitis

The medium-vessel vasculitides include Churg-Strauss syndrome (CSS, eosinophilic granulomatosis with polyangiitis, EGPA), granulomatosis with polyangiitis (GPA; Wegener granulomatosis), and microscopic polyangiitis (MPA). Although these diseases have overlapping features, they represent distinct clinical entities. GPA is most frequently associated with a cytoplasmic ANCA (cANCA) staining pattern that recognizes the antigen proteinase-3, whereas MPA is most commonly associated with a perinuclear ANCA (pANCA) directed against myeloperoxidase.

Eosinophilic Granulomatosis With Polyangiitis (Churg-Strauss Syndrome)

EGPA, a systemic small-vessel necrotizing vasculitis with a prevalence of 10 to 14 per million population, has three disease phases. An initial prodrome characterized by allergic rhinitis, sinusitis, and asthma precedes peripheral blood eosinophilia and eosinophilic infiltrative lesions in the lung and myocardium. Some years later, a systemic phase follows with necrotizing vasculitis affecting the skin, peripheral nerves, gastrointestinal tract, and kidney (in 30%). Up to 40% of patients with EGPA are ANCA positive and typically have pANCA. ANCA-negative patients are more likely to suffer cardiopulmonary complications, whereas pANCA-positive patients seem to be more at risk for renal and peripheral nerve involvement. The diagnosis depends on the clinical features, imaging studies, ANCA, and whenever possible, biopsy results. Patients have a markedly raised peripheral eosinophil count and evidence of necrotizing vasculitis, including eosinophilic infiltration (**Fig. 94.5**).

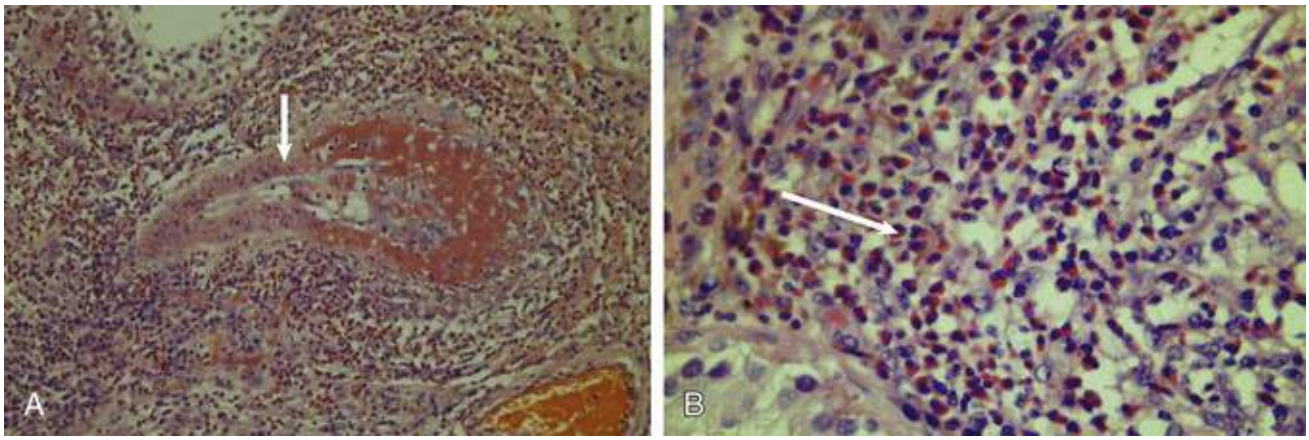

FIGURE 94.5 Churg-Strauss syndrome. **A,** Hematoxylin-eosin staining of a small artery *(arrow)* demonstrates fibrinoid necrosis and a dense perivascular mononuclear cell infiltrate. **B,** At higher magnification the inflammatory cells can be identified as predominantly eosinophils (*long arrow*) with scattered macrophages.

The diagnosis of EGPA requires consideration of a number of alternatives, including GPA and MPA. A history of asthma, the presence of marked peripheral eosinophilia, and a dense eosinophilic infiltrate highly suggest CSS. Viral infections, including cytomegalovirus and hepatitis B and C, must be excluded. In light of the eosinophilia, parasitic infestation, particularly by helminths, should be sought and excluded. Eosinophilia in the absence of demonstrable vasculitis may represent idiopathic hypereosinophilic syndrome or an underlying leukoproliferative disorder.

Cardiovascular Complications

Of all the vasculitides, EGPA is the most likely to be associated with severe and potentially fatal cardiac disease (**see Table 94.2**). Cardiac involvement complicates up to 60% of cases, and the disease spectrum includes pericarditis, myocarditis, coronary arteritis, myocardial infarction, cardiac fibrosis, arterial thrombosis, and valvular dysfunction. Cardiac disease is a prominent cause of death. Cardiomyopathy occurs as a result of ischemia secondary to arteritis affecting the intramyocardial arteries or, less frequently, the epicardial coronary arteries. Myocarditis is associated with eosinophilic infiltration, fibrosis, and occasionally, granuloma formation. Release of major basic protein and eosinophil-derived neurotoxin by infiltrating eosinophils can lead to direct tissue injury. Myocarditis may result in the development of restrictive, congestive, or dilated cardiomyopathy, or death.

Investigation

Cardiac involvement in EGPA requires urgent investigation, aggressive treatment, and initially, a 12-lead ECG and transthoracic echocardiography (**see Fig. 94.5**). Common findings include evidence of left ventricular dilation in 30% of patients, a reduced shortening fraction, and increased cardiac wall echogenicity. Contrast-enhanced CMR provides the most sensitive means of detecting myocardial involvement.[41] If the diagnosis remains in doubt, endomyocardial biopsy may reveal eosinophilic infiltration with or without fibrosis, although vasculitis is rarely seen and the patchy nature of the disease results in a low diagnostic yield.

Treatment

High-dose corticosteroid treatment typically results in a good response and is associated with a 90% remission of disease. Relapses occur frequently on tapering steroid therapy, and prednisone-related side effects are common. In the presence of severe disease, including cardiac, gastrointestinal, CNS, and renal

involvement, an immunosuppressant drug should be prescribed concomitantly. Although further clinical trials are required, the first choice of drug is pulsed intravenous cyclophosphamide. Once remission is achieved, generally by 3 to 6 months, cyclophosphamide can be replaced by azathioprine or methotrexate. In some patients with milder disease and evidence of steroid side effects, azathioprine or methotrexate should be added to aid in steroid tapering. In refractory disease, anecdotal case reports have suggested the effectiveness of IVIG or TNF-α blockade. We await further results from the study of B cell depletion and anti-interleukin-5 inhibition.[42]

Polyarteritis Nodosa

PAN is an increasingly rare disease characterized by a systemic necrotizing vasculitis of medium-sized arteries complicated by aneurysmal nodules. Viral infections, particularly with cytomegalovirus, human immunodeficiency virus, and hepatitis B and C viruses, should be specifically sought and excluded. The classic type of PAN is an ANCA-negative vasculitis with the predominant clinical features including fever, malaise, arthralgia, weight loss, livedo reticularis, cutaneous nodules, and a vasculitic rash. Abdominal, cardiac, and testicular pain may occur, and some patients manifest mononeuritis multiplex. Hematuria, proteinuria, and/or hypertension indicates renal involvement.

The pathogenesis of PAN remains poorly understood. The initial vascular endothelial injury is followed by local release of IL-1 and TNF-α, which predispose to chronic inflammation and up-regulation of cellular adhesion molecules. Recruitment of neutrophils is followed by monocyte infiltration, local endothelial disruption, thrombosis, and fibrinoid necrosis (**Fig. 94.6**). The associated arterial wall injury predisposes to aneurysm formation. The diagnosis of PAN is not straightforward. Although a biopsy can be definitive, the yield is variable and dependent on an accessible lesion. A deep skin biopsy specimen from an involved nodular site is optimal. Combined sural nerve and muscle biopsy may also be helpful. Occasionally, nodules are detected on a medium-sized peripheral artery that can safely undergo biopsy. Renal biopsy should be approached with caution because of the risk for hemorrhage from microaneurysms. Despite increasing use of noninvasive imaging with CTA or MRA, mesenteric arteriography remains the most accurate way of identifying renal or hepatic microaneurysms.

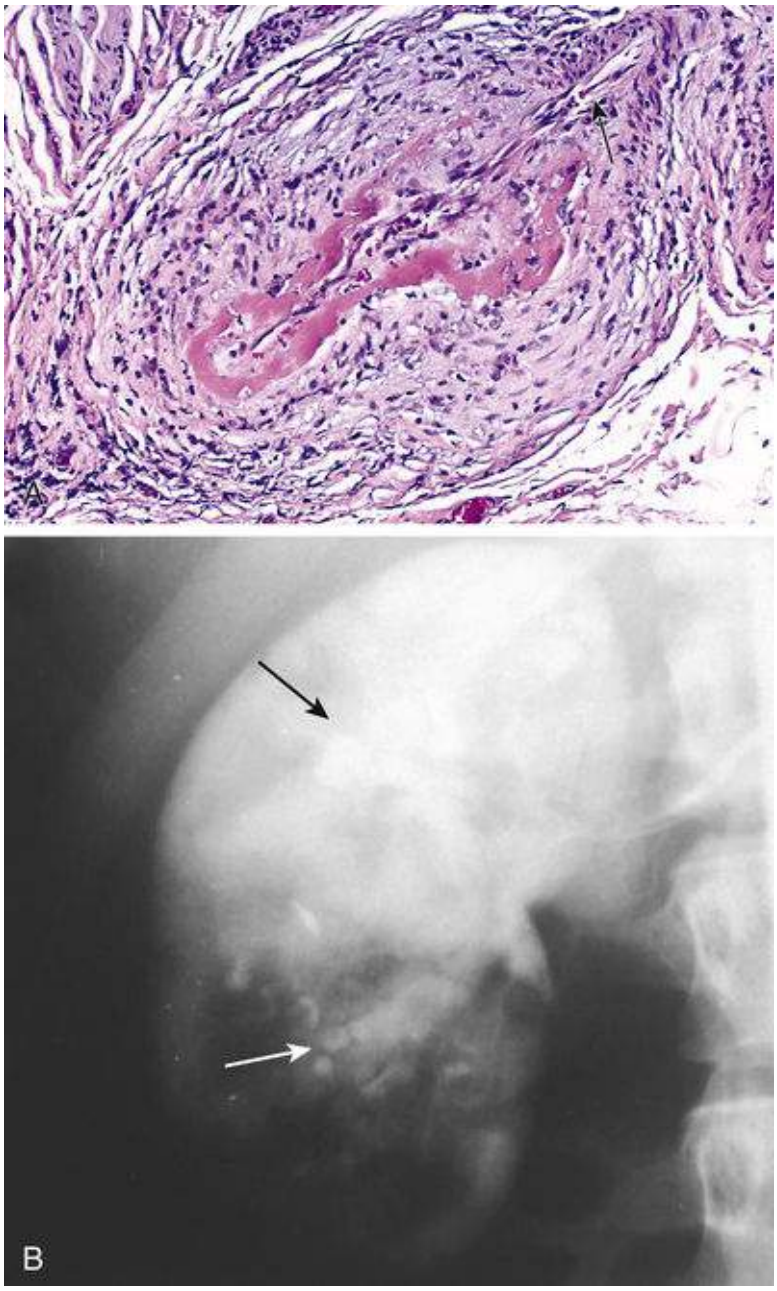

FIGURE 94.6 Polyarteritis nodosa. **A,** Photomicrograph of a hematoxylin-eosin–stained section of an artery biopsy specimen from a patient with PAN showing segmental fibrinoid necrosis, thrombotic occlusion of the lumen, and a small uninvolved remnant *(arrow).* **B,** Right renal angiogram showing multiple small aneurysms *(white arrow)* and a normal calyceal system *(black arrow).* (From Mitchell RN, Schoen FJ: Blood vessels. In Kumar V, Abbas A, Aster JC (editors): Robbins and Cotran pathologic basis of disease, 9th ed. Philadelphia, Elsevier Saunders, 2014.)

Cardiovascular Complications

Cardiac involvement in PAN is often subclinical and clinically apparent in only 10% of patients. Congestive cardiac failure is most commonly seen and may result from a specific myocarditis or coronary arteritis. Alternatively, the underlying cause may be PAN-related renal disease complicated by hypertension. Five percent of patients develop pericarditis, as well as supraventricular tachycardia and valvular disease. Coronary angiography may reveal coronary artery microaneurysms, coronary arteritis, or coronary spasm. Coronary CTA may demonstrate coronary artery aneurysms.

Treatment

Glucocorticoids form the basis of treatment of PAN. In those with cardiac disease, significant proteinuria

with or without renal impairment, CNS involvement, gastrointestinal disease, or mononeuritis multiplex, intravenous cyclophosphamide therapy is used initially. Some physicians prefer oral cyclophosphamide, and although side effects are more common, time until relapse may be longer. Six months of cyclophosphamide is usually sufficient to achieve disease remission, and treatment can be switched to oral azathioprine. In those with refractory disease, infliximab given in combination with methotrexate or azathioprine may provide benefit.

Granulomatosis With Polyangiitis (Wegener Granulomatosis)

GPA is a granulomatous necrotizing vasculitis that commonly affects the sinuses, upper airways, lungs, skin, joints, and kidneys. Diagnosis is based on clinical features, biopsy evidence, and typically a positive cANCA with antibodies against proteinase-3. The disease may be confined to the upper airways or be more generalized and include ocular inflammation, cutaneous vasculitis, arthralgia, cavitating lung lesions (**Fig. 94.7**), pulmonary hemorrhage, and acute renal failure. Clinical cardiac involvement is rare, although it has been reported in up to 30% of autopsy cases. The most frequently encountered problem is pericarditis, which can lead to hemodynamic compromise and tamponade. The presence of congestive cardiac failure is a poor prognostic sign and associated with a 25% mortality rate in the first year. Underlying causes include coronary arteritis, myocarditis, and occasionally valvular heart disease.

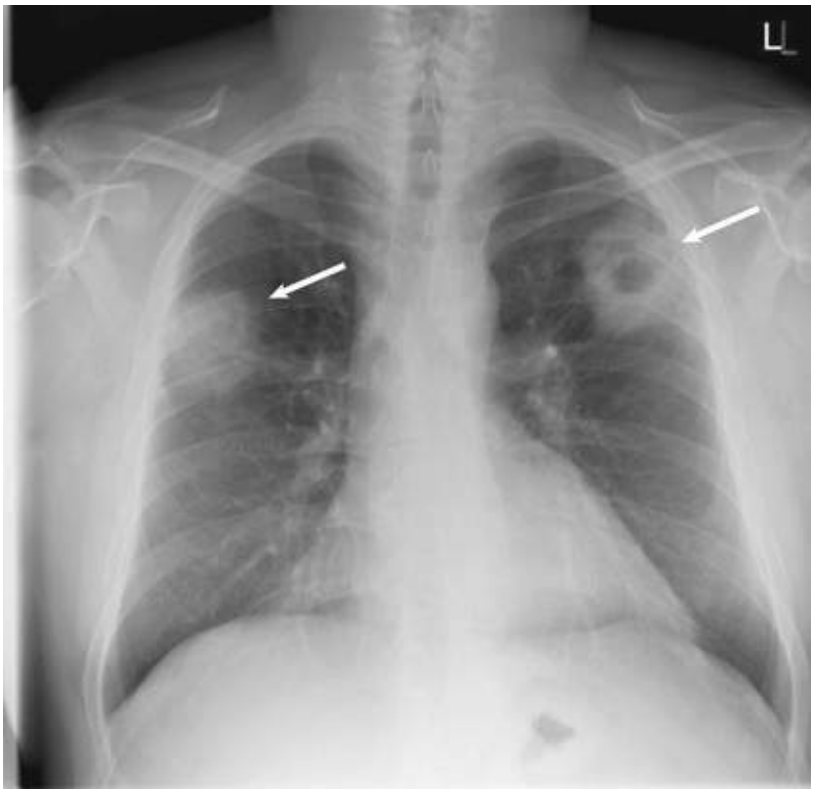

FIGURE 94.7 Granulomatosis with polyangiitis. Chest radiograph of a 36-year-old man showing pulmonary involvement with evidence of opacification and cavitation in the left upper lobe lesion *(arrows).*

Microscopic Polyangiitis

MPA is most commonly associated with glomerulonephritis, renal impairment, and pulmonary hemorrhage. Cardiac disease is rarely clinically significant, but pericarditis occurs in 10% of patients, and congestive cardiac failure develops in up to 18%. Subclinical and occasionally symptomatic acute

myocardial infarction can occur. Evidence from case reports and small series shows that this disease also features symptomatic aortitis and coronary artery microaneurysms.

Investigation

Cardiac involvement should initially be investigated noninvasively with modalities that include rest or stress echocardiography. Contrast-enhanced CMR can sensitively detect the myocardial pathology, and coronary CTA can demonstrate coronary arteritis and microaneurysms. Echocardiography suggests valvular thickening as a common and typically asymptomatic finding in GPA. Aortic valve regurgitation may occur because of distortion and thickening of valve cusps or from aortic root dilation. On occasion, coronary artery catheterization may be required, and as for other vasculitides, it should be used cautiously in those suspected of having active coronary arteritis. When possible, steps should be taken to suppress disease activity with immunosuppressive therapy before angiography. Coronary arteritis can cause multiple small areas of myocardial infarction, which often remain clinically silent until the development of congestive cardiac failure. Occasionally, granulomas in conduction tissue can cause cardiac dysrhythmia.

Treatment

For both GPA and MPA, high-dose prednisone (1 mg/kg/day) is recommended and may be preceded by pulsed intravenous methylprednisolone if indicated. Patients with the most severe disease, including pulmonary hemorrhage, severe cardiac disease, or significant renal impairment, receive pulsed intravenous cyclophosphamide to induce remission over the first 3 to 6 months. Cyclophosphamide can then be replaced with azathioprine, methotrexate, or MMF. In less severe limited disease, remission can be achieved reliably with prednisolone in combination with azathioprine or methotrexate.[43] Increasing evidence suggests that B cell depletion therapy is effective for AASV and achieves remission at a rate comparable to that of cyclophosphamide.[44,45]

Pericarditis and Myocarditis

Pericarditis

Pericarditis commonly complicates the autoimmune connective tissue diseases, particularly SLE, SSc, and RA. Nonetheless, clinically significant pericarditis develops in fewer than 30% of patients. The reported prevalence ranges from 11% to 85%, depending on the type of study used to detect disease. Thus in necropsy studies, prevalence is high, with pericardial involvement reported in 40% of individuals with RA, 40% to 80% of those with SLE, and up to 70% of those with SSc. Pericarditis is diagnosed by echocardiography, which detects pericardial thickening or small effusions in up to 50% of these patients. CMR can also provide accurate definition of the extent of pericardial involvement.

Systemic Lupus Erythematosus

In SLE, pericarditis is usually associated with disease flare and often with polyserositis. The symptoms are typically mild and consist of chest pain, which is worse on lying flat, and dyspnea, which may have a pleuritic component. Complicated pericarditis is rare, and in only 1% to 2% is the effusion sufficiently large to cause cardiac tamponade. Constrictive pericarditis or infective pericarditis occur infrequently.

Rheumatoid Arthritis

Clinically significant pericarditis affects only 1% to 2% of patients with RA, more commonly male, seropositive patients. Constrictive pericarditis can develop over a period of months. Hemodynamically significant pericarditis, although reported, is extremely rare in patients being treated with antirheumatic therapy. Indeed, the more aggressive approach to management of RA and the increasing use of biologic therapies appear to have reduced the incidence of symptomatic pericarditis.

Systemic Sclerosis

The two most commonly encountered forms of scleroderma are diffuse cutaneous SSc (dSSc) and limited cutaneous SSc (lSSc). Following an initial vascular inflammatory phase, the predominant lesion is fibrosis, which affects multiple organs.[46] In addition to the severe cutaneous manifestations, common clinical features include arthralgia, telangiectasia, pulmonary fibrosis, PAH, and esophageal dysmotility. Renal crises are common and complicated by hypertension. Aggressive intervention is essential and includes the use of ACE inhibitors and calcium channel antagonists. This approach has transformed the prognosis. Pericardial disease is common and more frequent in those with dSSc and a history of renal crisis. Echocardiography typically demonstrates small pericardial effusions, which are rarely hemodynamically significant. Rapidly accumulating large effusions may occur occasionally.

Pericardial Fluid Analysis

Analysis of pericardial fluid is rarely useful diagnostically unless infective pericarditis is suspected. Immune complexes, antinuclear and anti-dsDNA antibodies, complement consumption, and normal glucose levels have been reported in pericardial exudates from patients with SLE. In RA the pericardial fluid glucose concentration may be lower than that in plasma, and although rheumatoid factor activity is often detected, it is not considered diagnostic.

Treatment

In most cases a small pericardial effusion appears on a routine chest radiograph or echocardiogram and requires no specific treatment. Those with troublesome symptoms of pericarditis can receive a short course of an NSAID unless contraindicated. Low-dose oral prednisone may be required or used as an alternative. Recurrent cases, in particular, require further optimization of the regular immunosuppressive therapy. Pericardial fluid accumulation may be sufficient to cause hemodynamic compromise and even cardiac tamponade requiring pericardiocentesis or, in recurrent cases, a pericardial window. For immunosuppressed patients, pericardial fluid should be analyzed for an infective cause. Advice should be sought from a microbiologist to ensure that the correct specimens are sent, including those required to exclude tuberculosis.

Myocarditis

Myocarditis is a rare but recognized cause of mortality in patients with autoimmune rheumatic diseases and is most commonly seen in patients with SLE, SSc, and polymyositis or dermatomyositis. Although most commonly present in those with an established rheumatic disease, myocarditis may be an initial feature requiring consideration of these conditions in the differential diagnosis of those with unexplained heart failure. The most common symptom of myocarditis is recent-onset exertional dyspnea with evidence of hypoxia.[47] A patient rarely presents with severe heart failure at the initial evaluation, and

echocardiography usually reveals relatively modest changes in ventricular size and function. PAH must be excluded. In addition to standard blood tests, investigations should include ESR, antinuclear antibody, antibodies against dsDNA and extractable nuclear antigens, rheumatoid factor, a myositis immunoblot screen, and complement factor C3 and C4 levels.

Systemic Lupus Erythematosus

Although the widespread use of more effective immunosuppressive regimens has reduced the prevalence of myocarditis in patients with SLE to fewer than 10%, most of whom have subclinical myocarditis, it remains an important and potentially life-threatening complication. Other potential causes of heart failure include hypertension, ischemic heart disease, valvular heart disease, and complications associated with renal failure.

The initial symptoms of myocarditis vary from low-grade fever, dyspnea, and palpitations to signs of severe heart failure. In addition to complement consumption, a raised ESR, and an increased titer of anti-dsDNA antibodies, the troponin I level may increase markedly. The ECG typically shows nonspecific findings such as sinus tachycardia or ST or T wave changes. Supraventricular or ventricular tachycardias may also occur. Echocardiography aids in assessment (**Fig. 94.8**). Functional abnormalities may include segmental, regional, or global wall motion abnormalities; chamber dilation; and a reduced ejection fraction. In contrast, left ventricular hypertrophy in SLE is more commonly associated with poorly controlled hypertension, whereas systolic and diastolic abnormalities in left ventricular function have been associated with both hypertension and ischemic heart disease. CMR can detect myocarditis and myocardial fibrosis, and gadolinium or adenosine stress first-pass perfusion may demonstrate coronary microvascular dysfunction. Indeed, CMR and PET identifies coronary myocardial dysfunction and reduced coronary flow reserve in patients with SLE.[48]

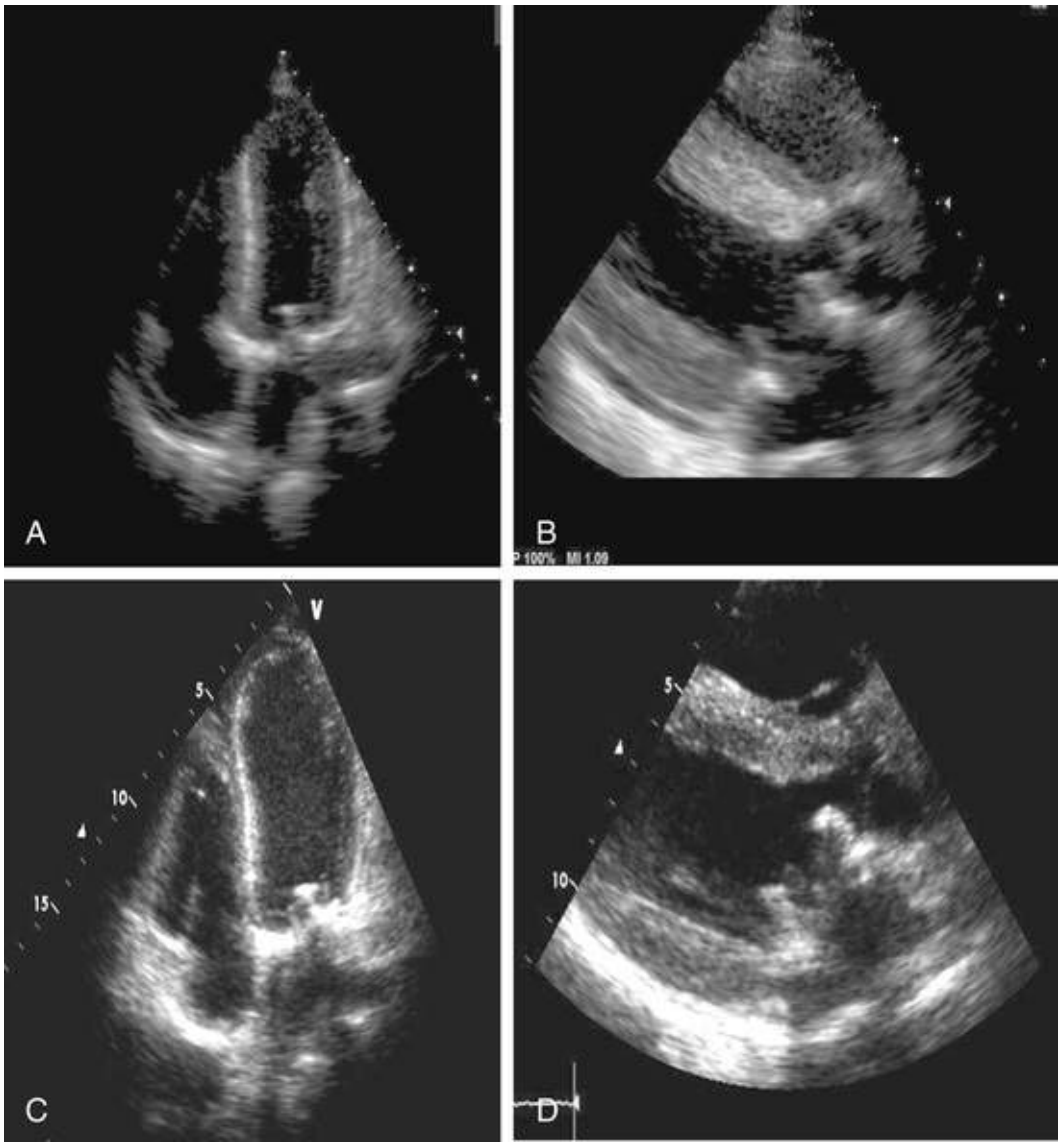

FIGURE 94.8 Myocarditis in systemic lupus erythematosus. **A** and **C,** Four-chamber view, **B** and **D,** Left ventricular view. In a 20-year-old patient with dyspnea and active SLE, the initial echocardiogram (**A** and **B**) showed mild impairment of ventricular function. Following symptomatic deterioration, the echocardiogram was repeated 6 days later and demonstrated markedly increased thickening of the left ventricular wall with a bright signal suggestive of inflammatory infiltration (**C** and **D**). These findings were associated with substantial deterioration in left ventricular function.

Opinion is divided on the use of endomyocardial biopsy. It will not permit a specific diagnosis of SLE per se. Biopsy may, however, demonstrate an underlying inflammatory cause and features suggestive of SLE. Histopathologic analysis typically reveals small focal areas of fibrinoid necrosis with infiltration of lymphocytes and plasma cells, along with evidence of the deposition of immune complexes closely associated with myocyte bundles. Immunofluorescent studies may reveal granular staining and deposition of complement in and around myocardial blood vessels. Biopsy may also help exclude other potential causes of cardiomyopathy.

Systemic Sclerosis

Inflammatory myocarditis rarely results in symptomatic cardiomyopathy in patients with SSc; it affects mostly those with prominent skeletal muscle myositis. Echocardiography may demonstrate impaired diastolic and systolic function and a reduced ejection fraction, occasionally severe enough to cause cardiac failure. Endomyocardial biopsy most commonly reveals myocardial fibrosis. The fibrosis occurs focally and affects both ventricles. As with other lesions in SSc, microvascular disease is considered an

important pathogenic factor. Reduced coronary flow reserve occurs commonly,[49] and subclinical myocardial ischemia probably contributes importantly to the ventricular dysfunction.

Myositis

Polymyositis and dermatomyositis affect the proximal skeletal muscles and can cause severe weakness. In dermatomyositis, additional characteristic cutaneous manifestations include a violaceous heliotrope rash, Gottron papules, and periungual erythema. In pediatric cases, subcutaneous calcification is common and vasculitis may lead to severe gut ischemia and hemorrhage. In adults, particularly those older than 60 years, dermatomyositis may be paraneoplastic in origin. In severe cases, myositis involves the myocardium and pharyngeal or respiratory muscles and can be life-threatening. Creatine kinase levels rise markedly, and electromyography demonstrates fibrillation and polyphasic action potentials. Magnetic resonance imaging of the proximal limb muscles helps identify the muscles involved and most amenable to biopsy. Histopathologic findings include muscle fiber necrosis and regeneration, a predominantly $CD8^+$ T lymphocyte infiltrate, and HLA class I expression. Clinically significant myocarditis affects only 3%. Echocardiography may reveal ventricular dysfunction, whereas endomyocardial biopsy specimens demonstrate interstitial and perivascular lymphocytic infiltrates, contraction band necrosis, variable cardiomyocyte size, and degeneration and patchy fibrosis. Overt cardiac failure is rare; more common are rhythm and conduction abnormalities, including left anterior hemiblock and right bundle branch block.

Other Causes of Myocarditis

Even though postmortem studies have revealed evidence of myocarditis in patients with RA, it is seldom manifested clinically or causes heart failure. Although heart failure affects patients with RA more than it does age- and sex-matched controls, it predominantly reflects atherosclerotic coronary artery disease.[2] Myocarditis is also rarely associated with other rheumatic diseases, including ankylosing spondylitis, adult Still disease, GCA, and TA.

Treatment

Cardiac failure following myocarditis associated with autoimmune disease is treated with standard protocols and supportive interventions (**see Chapter 25**). SLE-related myocarditis requires urgent corticosteroid treatment and, when severe, intravenous methylprednisolone, 1 g/day for 3 days, followed by oral prednisone, 1 mg/kg/day. These patients typically receive pulsed intravenous cyclophosphamide. For more modest disease, treatment can include the addition of or increased dosages of azathioprine or MMF. Some evidence suggests benefit of IVIG in resistant cases. Management of myocarditis complicating dermatomyositis or polymyositis uses a similar approach. Myocarditis in patients with SSc rarely requires aggressive treatment. Because high-dose corticosteroids increase the risk for a renal crisis, early use of intravenous cyclophosphamide is favored.

Valvular Heart Disease

Clinically significant valvular disease can complicate many rheumatic diseases. Mechanisms may include direct damage to cardiac valve leaflets or aortic valve regurgitation as a consequence of aortitis affecting the ascending aorta (**see also Section 8**).

Systemic Lupus Erythematosus

Valvular abnormalities occur commonly in patients with SLE, and necropsy studies have reported lesions in up to 75%. Verrucous endocarditis (Libman-Sacks endocarditis) and nonspecific valvular thickening occur most commonly. Valvulitis with rapid valvular dysfunction may also happen rarely. Transthoracic echocardiography detects verrucae in 2.5% to 12% and thickening in 4% to 38%, which increases to 30% and 43%, respectively, in those undergoing transesophageal echocardiography. Libman-Sacks lesions typically affect both valve surfaces, most commonly the mitral valve. Active valve lesions contain immunoglobulins, fibrin clumps, areas of focal necrosis, and a leukocytic infiltrate, whereas older healed lesions exhibit vascular fibrous tissue predisposing to scarring and valve leaflet deformity. These abnormalities may cause valvular regurgitation. Libman-Sacks endocarditis occurs more commonly in SLE complicated by antiphospholipid antibodies and can accompany primary antiphospholipid syndrome.

Libman-Sacks endocarditis is generally asymptomatic and may not cause a murmur. Assessment of SLE patients with a murmur may not be straightforward, and requires exclusion of bacterial endocarditis. Echocardiography can help distinguish Libman-Sacks endocarditis from infectious endocarditis, an important consideration in immunosuppressed patients. In contrast to the typically nonmobile vegetations of Libman-Sacks lesions, bacterial vegetations usually localize at the valve leaflet closure line and demonstrate mobility that is independent of valve leaflet motion. The presence of Libman-Sacks lesions increases the risk for secondary infective endocarditis, and prophylactic antibiotic prophylaxis should be considered to cover high-risk procedures such as invasive dental treatment (**see Chapter 73**). Complications of SLE-related valvular disease are rare, with hemodynamic effects seen in fewer than 5%. Valve replacement may be required for symptomatic regurgitation and occasionally for stenosis. The verrucous lesions may also embolize or rupture and lead to a cerebrovascular accident or peripheral embolism. Chordae tendineae rupture may also occur.

Treatment

Most patients require no specific treatment, although annual echocardiography can be used to monitor valve function. The introduction of corticosteroid therapy may have reduced the prevalence of Libman-Sacks endocarditis, and thus prednisone treatment may be considered in those with early active lesions. Patients with uncomplicated Libman-Sacks endocarditis with valve thickening on the echocardiogram are not routinely anticoagulated. Those with definitive vegetations or evidence of embolic phenomena should be considered for lifelong anticoagulation therapy.[50]

Seronegative Spondyloarthropathies

The seronegative spondyloarthropathies include ankylosing spondylitis, postinfectious reactive arthritis, inflammatory bowel disease–related arthritis, and psoriatic arthritis. HLA-B27 is associated with ankylosing spondylitis and reactive arthritis. The spondyloarthropathies share overlapping clinical features, including asymmetric, predominantly large-joint oligoarthritis, ocular inflammation, sacroiliitis, spinal disease, and enthesopathy. Ankylosing spondylitis and reactive arthritis commonly involve the aortic root and valve. Aortic valvulitis leads to aortic cusp thickening and retraction and subsequently to symptomatic aortic regurgitation, which may cause heart failure. Proximal aortitis affecting the ascending aorta leads to aortic root thickening and subsequently to dilation and aortic regurgitation, the prevalence of which relates to disease duration.

Treatment

Management of the spondyloarthropathies has traditionally consisted of NSAIDs and, in more severe cases, the addition of DMARDs such as methotrexate, sulfasalazine, and leflunomide. Although these agents have some efficacy in the treatment of peripheral inflammatory arthritis, they have little effect on spinal inflammation. The use of TNF-α antagonists for ankylosing spondylitis and psoriatic arthropathy has markedly improved control of the disease, with beneficial effects on peripheral arthritis, spinal disease, and extraarticular complications, including uveitis.[51] Although evidence is currently limited, initiation of biologic therapy in those with early signs and symptoms of aortitis may reduce the risk for cardiovascular complications, including aortic regurgitation.[52]

Rheumatoid Arthritis

Valvular thickening is commonly associated with RA in echocardiographic studies and at autopsy, but seldom causes clinical problems. Patients with seropositive RA and with prominent extraarticular nodular disease more frequently have valvular lesions. Echocardiography typically reveals mitral valve involvement, with valve thickening, asymptomatic mitral regurgitation, and prolapse being the predominant findings. Histopathologic examination of the valves demonstrates granulomatous nodular lesions. No specific treatment is indicated, although on occasion hemodynamically significant disease develops and requires mitral or aortic valve replacement.

Takayasu Arteritis

Cardiac valve dysfunction commonly complicates TA. In a recent series of 204 Korean patients, 23% had an abnormality in at least one valve, with regurgitation at the aortic valve found in 18% and at the mitral valve in 7.5%.[53] Inflammation of the ascending aorta predisposes to dilation of the aortic root and aortic valve regurgitation. Approximately 15% of patients require aortic valve replacement with or without aortic root replacement with a graft. If possible, surgery should follow control of disease activity with immunosuppressive therapy.[33]

Cardiac Conduction Disturbances

A variety of rheumatic diseases cause conduction abnormalities and cardiac rhythm disturbances.

Systemic Lupus Erythematosus and Sjögren Syndrome

Adult SLE seldom causes primary conduction abnormalities or a rhythm disturbance, which may instead result from underlying ischemic heart disease or myocarditis. Female patients with SLE or Sjögren syndrome who test positive for antibodies against the Ro and/or La antigens carry the risk of bearing a child with a congenital heart block, which may be complicated by myocarditis. These antibodies can cross the placenta and induce myocardial inflammation and can target the conduction system and lead to fibrosis. The precise incidence is not established, but the usual figures quoted are 1 case in 20,000 live births with a range of 11,000 to 25,000. Patients with SLE, the overlap syndromes, and Sjögren syndrome should be screened for anti-Ro and anti-La before pregnancy and be counseled appropriately. The fetus of a mother known to be antibody positive should be screened in utero by echocardiography every 2 weeks from 16 weeks of gestation onward. Incomplete atrioventricular block can reverse, and myocarditis may

respond to dexamethasone therapy. Complete atrioventricular block is irreversible and associated with mortality rates of up to 20%, with 65% requiring insertion of a pacemaker.

Systemic Sclerosis

Conduction system disease affects up to 50% of SSc patients. The patchy myocardial fibrosis characteristically associated with SSc may account for the abnormalities seen with disruption of the conduction pathways. Supraventricular arrhythmias are usually benign and amenable to treatment. Ventricular conduction abnormalities also frequently occur in SSc. In these patients ventricular ectopy is common and closely associated with sudden death.

Spondyloarthropathies

Conduction abnormalities frequently complicate the HLA-B27–related spondyloarthropathies. In ankylosing spondylitis, up to 30% of patients experience conduction system disease, predominantly caused by subaortic fibrosis extending into the septum and affecting the atrioventricular node. Atrioventricular conduction block occurs commonly and may become complete.

Polymyositis and Dermatomyositis

Conduction abnormalities are the most common cardiac manifestation of the myositis syndromes. Left anterior hemiblock and right bundle branch block occur most frequently and occasionally progress to complete heart block. The inflammation and fibrosis associated with polymyositis and dermatomyositis affect the conduction pathways, as demonstrated in 25% of autopsy cases.

Rheumatoid Arthritis

ECG screening studies in patients with RA have revealed arrhythmias or conducting system abnormalities in up to 50%, although they are usually clinically inapparent. Rheumatoid myocarditis and amyloid deposition in the heart can cause atrioventricular node conduction block. Similarly, rheumatoid nodules may disrupt the conduction system and cause all types of conduction abnormality.

Pulmonary Arterial Hypertension

PAH (**see Chapter 85**) can result from the connective tissue diseases and is of concern to rheumatologists as a significant cause of premature death (**Table 94.4**). PAH often manifests late in disease evolution or remains undiagnosed. Furthermore, PAH frequently proves resistant to optimized treatment of the underlying connective tissue diseases. Notwithstanding, increased awareness, recognition of high-risk groups, improved screening, and novel therapies point toward a better outlook.

TABLE 94.4

Pulmonary Arterial Hypertension in Rheumatic Diseases

RHEUMATIC DISEASE	FEATURES OF PULMONARY ARTERIAL HYPERTENSION
Systemic sclerosis	Prevalence of 5% to 12%; more common in limited cutaneous SSc
Polymyositis/scleroderma overlap	Annual screening recommended; survival rate at 3 years of 47% to 56%
Systemic lupus erythematosus	Prevalence of 0.5% to 17.5%; survival rate at 3 years of 74%; thrombotic arteriopathy is most common underlying cause; 83% of patients have anticardiolipin antibodies; patients with severe Raynaud phenomenon, anticardiolipin antibodies, and anti-U1RNP require screening
Rheumatoid arthritis	Prevalence data limited; reported to be up to 20%; clinically significant disease rare, often secondary to chronic obstructive pulmonary disease, chronic thromboembolic disease, or interstitial lung disease; improved rheumatoid arthritis treatment may result in reduced incidence
Sjögren syndrome	Pulmonary arterial hypertension a very rare complication of Sjögren syndrome; usually occurs late in course of disease; prevalence unknown
Takayasu arteritis	Pulmonary arteritis present in up to 50% of patients; pulmonary arterial hypertension prevalence of 12%

RNP, ribonucleoprotein.

Systemic Sclerosis

SSc is the most resistant of the connective tissue diseases to treatment and has the highest mortality rates. PAH has very serious prognostic implications and is the most common single cause of SSc-related death.[54,55] Novel therapeutic options offer renewed hope, and early data suggest improved survival rates.[56]

Pathogenesis

Arterial remodeling is a central component in the pathogenesis of PAH and follows uncontrolled smooth muscle cell proliferation, deposition of extracellular matrix and subsequent fibrosis, vasoconstriction, and in situ thrombosis that together lead to increased pulmonary vascular resistance. Right ventricular dilation, dysfunction, and failure follow the development of PAH. Because PAH may develop very rapidly, effective screening strategies for patients with SSc are essential to detect PAH and allow early therapeutic intervention.

Screening

The prevalence of PAH in patients with SSc is between 5% and 12%. Although more common with lSSc, PAH also frequently occurs in patients with dSSc. Debate continues regarding the frequency of screening and whether to include both symptomatic and asymptomatic patients. Screening of asymptomatic patients may improve survival rates.[57] PAH may occur as an early or a late complication, and there is a lack of reliable predictive risk factors. Annual screening should include echocardiography and pulmonary function testing.[54] In the latter, the carbon monoxide diffusing capacity may predict the development of PAH and the prognosis. Pulmonary fibrosis can also complicate SSc and may exacerbate PAH (**Fig. 94.9**). Echocardiographically assessed pulmonary artery pressure may miss early asymptomatic disease. Positive results from screening should be followed by diagnostic right-heart catheterization.[58] The level of NT-pro-brain natriuretic protein (BNP) relates to the degree of right ventricular dysfunction and the severity of PAH.

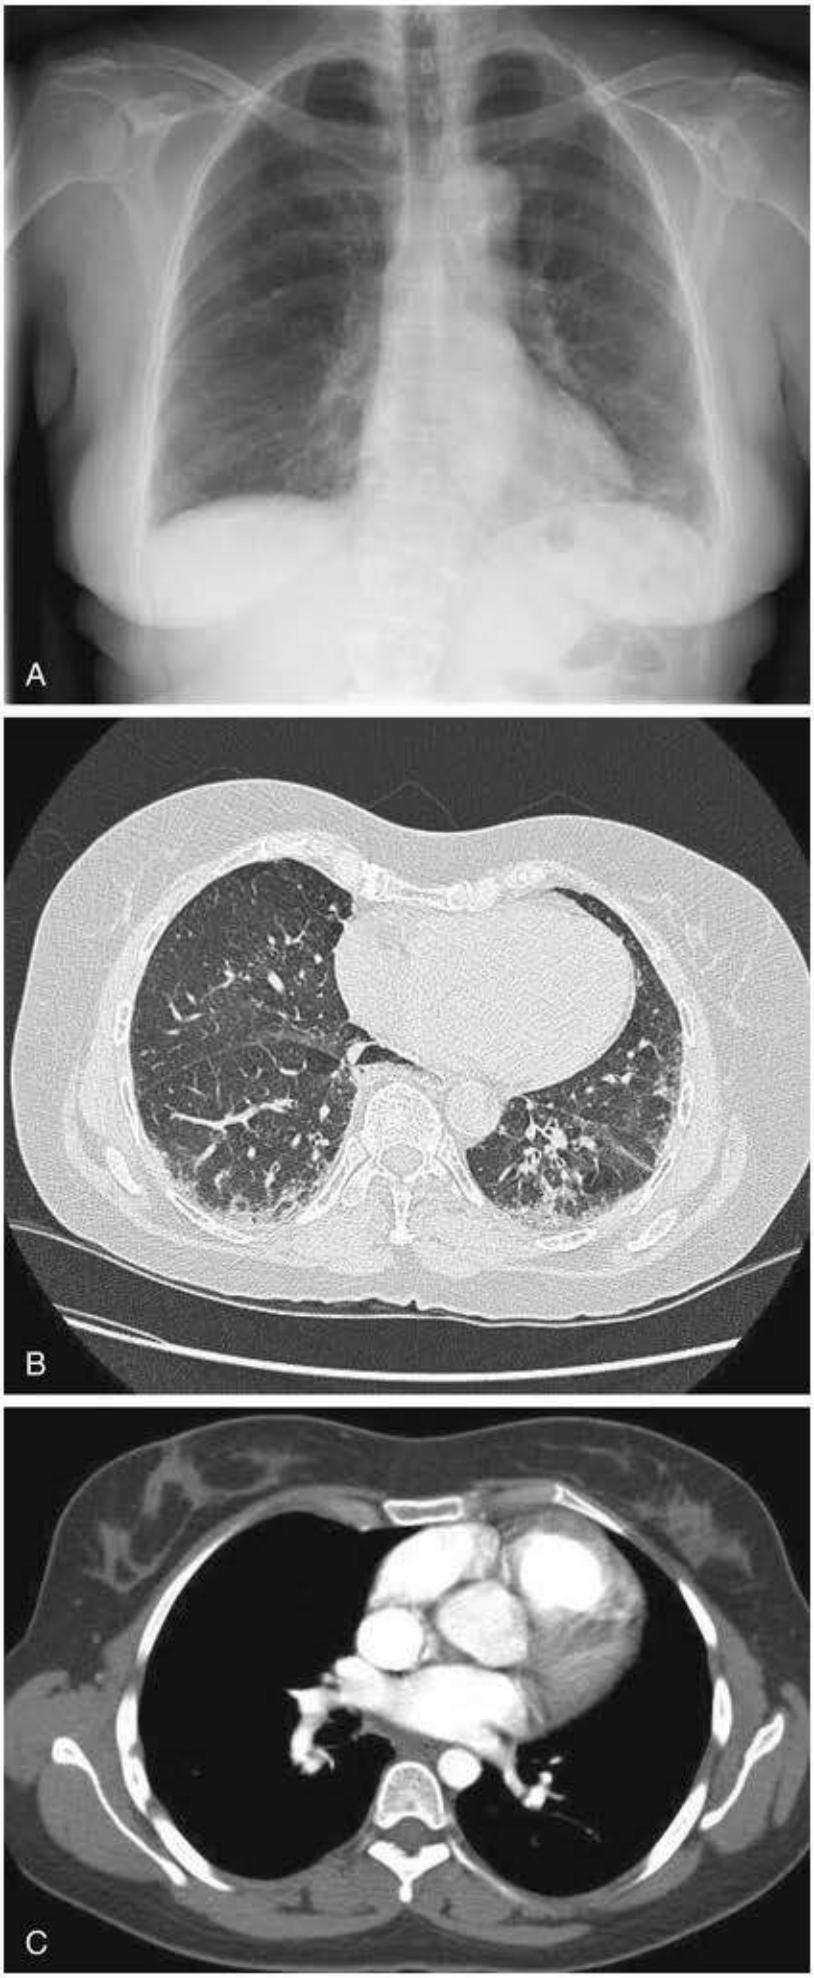

FIGURE 94.9 Systemic sclerosis. **A,** Chest radiograph of a patient with dSSc showing interstitial shadowing, mainly in the lung bases, along with associated loss of volume, consistent with early pulmonary fibrosis. **B,** CT of the thorax demonstrating ground-glass opacity, subpleural honeycombing

with thickening of the interlobular septa, and linear fibrotic bands, in keeping with pulmonary fibrosis. There is also evidence of associated mild traction bronchiectasis. **C,** Pulmonary CTA in a patient with limited cutaneous scleroderma and pulmonary hypertension. The right atrium and right ventricle are enlarged, and there is dilation of the pulmonary trunk.

Treatment and Outcome

The typical initial symptom of PAH is dyspnea, and the diagnosis is often delayed until clinical evidence of hemodynamic impairment is apparent, not the least because of the multiple potential causes of dyspnea in patients with SSc. Delayed diagnosis is also reflected in the very poor 3-year survival rate of 47% to 56%, thus emphasizing the need for early diagnosis and treatment, which may improve the outcome.[58] The aims of treatment have been summarized as improvement in New York Heart Association (NYHA) functional class and quality of life, delay in clinical deterioration, and improved long-term outcome. Although standard PAH outcome measures can assess the response to treatment (**Chapter 85**), not all of them have been validated in patients with SSc and they may be complicated by coexistent conditions, including pulmonary fibrosis and musculoskeletal pain. Supported by clinical trials, treatment targets three main pathways with agents used alone and increasingly in combination.[59] Endothelin-1 receptor antagonists include the original bosentan, sitaxsentan, ambrisentan, and most recently macitentan. Epoprostenol, iloprost, or treprostinil target the prostacyclin pathway, and open-label studies have shown improvements in symptoms and the 6-minute walking distance. Similarly, the phosphodiesterase type 5 antagonist sildenafil improved exercise capacity in a placebo-controlled trial.

Systemic Lupus Erythematosus

The prevalence of PAH in patients with SLE varies between studies and was recently estimated to be between 0.5% and 17.5%. These patients are typically females of reproductive age, in whom PAH during pregnancy markedly increases the risk for death.

Pathogenesis

In situ pulmonary thrombosis or chronic thromboembolic disease leading to thrombotic arteriopathy is the most common cause of PAH in patients with SLE, and 83% of such patients have anticardiolipin antibodies. Additional causes include pulmonary arteritis, underlying interstitial lung disease, and left-sided heart disease secondary to myocarditis, hypertension, or ischemic heart disease.

Clinical Findings and Diagnosis

Dyspnea, which may be associated with fatigue, cough, and chest pain, is the typical initial symptom. The development of PAH does not necessarily reflect the duration of SLE or its severity. Limited data concerning predictive features indicate that patients with severe Raynaud phenomenon, anticardiolipin antibodies, and anti-U1RNP antibodies have more susceptibility to develop PAH. These patients should be screened annually with echocardiography to estimate the pulmonary artery pressure. Raised pressure should be investigated further by right-heart catheterization.

Treatment and Outcome

Management of PAH in patients with SLE uses a dual approach that combines optimized immunosuppression and vasodilator therapy,[60] although protocols vary between centers.[56] Limited

evidence supports therapeutic decisions in PAH associated with SLE; many centers reserve combination therapy for those with NYHA class III or IV disease. In contrast to SSc-related PAH, the response to increased corticosteroids and pulsed intravenous cyclophosphamide can be good, and once response is achieved, switching from cyclophosphamide to azathioprine or MMF can reduce toxicity. Stronger trial evidence is available for the use of vasodilator therapies, which include dual endothelin-1 receptor antagonists such as bosentan, prostacyclin therapy, and sildenafil. In those with anticardiolipin antibodies, life-long anticoagulation with warfarin is indicated. The 3-year survival rate of 74% is higher than that in patients with SSc-related PAH.[60]

Rheumatoid Arthritis

Pulmonary complications in RA include pleural effusions, pulmonary nodules, interstitial lung disease, bronchiolitis obliterans, and occasionally PAH.[61] PAH in patients with RA most commonly results from other underlying diseases, including chronic obstructive pulmonary disease, chronic pulmonary thromboembolism, hyperviscosity syndromes, lung surgery, or left-sided heart disease. PAH, however, may be related to extraarticular manifestations of RA, pulmonary fibrosis, or isolated pulmonary arteritis. Dyspnea is the most common initial symptom. The diagnosis is often delayed, first because dyspnea is frequently attributed to other potential causes and, second, because of a limited exercise capacity in patients with severe arthritis. Diagnosis of PAH by the measures outlined above should be followed by specific investigations such as high-resolution pulmonary CT, CTA, pulmonary function tests, and a ventilation-perfusion scan to determine the underlying cause. No specific guidelines inform the treatment of PAH arising as a primary complication of RA. Any evidence of active RA should be treated aggressively and preferably with biologic agents such as TNF-α or IL-6 receptor antagonists. Specific treatment of PAH should also be considered, including the use of endothelin-1 antagonists or phosphodiesterase type 5 inhibitors.

Sjögren Syndrome

Clinically significant PAH very rarely complicates Sjögren syndrome and usually occurs late, most typically in patients with NYHA functional class III or IV; the diagnosis is established as described for RA above. Little evidence guides therapeutic decisions, and regimens vary considerably.[62] Therapy with corticosteroids and immunosuppressive drugs, including azathioprine and cyclophosphamide, should be optimized to gain control of the underlying Sjögren syndrome activity. These measures may provide at least transient benefit in PAH, particularly in patients with evidence of active interstitial lung disease. Anecdotal evidence suggests beneficial effects of B cell depletion therapy with rituximab in patients with severe disease and may offer a future approach for those with PAH. In the majority, enhanced immunosuppression is combined with standard PAH treatment, including the use of prostanoids, endothelin-1 antagonists, and phosphodiesterase type V inhibitors.[62]

Takayasu Arteritis

Pulmonary artery involvement in TA is often overlooked. Yet 50% of patients with TA have evidence of pulmonary arteritis in autopsy studies, and PAH develops in 12%. Even though pulmonary arteritis typically coexists with disease of the aorta, it can be isolated. Systemic hypertension and left ventricular dysfunction may cause secondary PAH. The pulmonary arterial lesions seen include stenoses, occlusions,

and aneurysms. PAH may develop acutely early in the disease course or later and more insidiously following progressive pulmonary artery narrowing. When present, symptoms may include dyspnea, chest pain, and peripheral edema. These symptoms are often ascribed to other causes, including left ventricular dysfunction, and the diagnosis is typically delayed. Unless specifically sought, pulmonary artery involvement can be missed on initial radiologic studies. Dedicated CMR and contrast-enhanced CTA are the most sensitive detection modalities. Abnormalities should be pursued with echocardiography and other studies as described above.

No available clinical trials guide therapeutic decisions. Aggressive treatment of the underlying arteritis with high-dose corticosteroids and a steroid-sparing drug such as methotrexate is recommended. Pulsed intravenous cyclophosphamide is typically reserved for nonresponders, and the emerging efficacy of biologic therapies for TA, including TNF-α and IL-6 receptor antagonists, suggests that they should be considered early in refractory disease. Warfarin is often used, particularly in those with evidence of thrombosis or pulmonary infarction. Endothelin-1 antagonists or sildenafil may help in patients with more severe or resistant PAH.[63] Open reconstructive surgery or percutaneous angioplasty may prove successful.

Thrombosis in Rheumatic Diseases

Thrombosis is an important pathologic process in many rheumatic diseases and a cause of significant morbidity and mortality (**see also Chapter 93**). Large-vessel thrombosis, both venous and arterial, can occur in Behçet disease and APS. Thrombosis in situ also occurs in small vessels, principally as the end result of chronic vessel wall hyperplasia or inflammation in diseases such as SSc, the vasculitides, and PAH. Chronic thromboembolic PAH can complicate SLE and SSc.

Activation of the coagulation cascade leading to thrombosis may be caused by abnormalities in the vessel wall, blood constituents, or blood flow (**see Chapters 44 and 93**). Abnormalities in endothelial function have particular relevance to rheumatic diseases. The prolonged systemic inflammation in patients with SLE, Behçet disease, and the vasculitides can cause endothelial apoptosis, a local inflammatory response, and endothelial activation. Cytokine-mediated endothelial activation disturbs anticoagulant and fibrinolytic mechanisms. Treatment of prothrombotic risk in these diseases requires consideration of approaches that include immunosuppression to control disease activity and minimize endothelial dysfunction, antiplatelet agents, anticoagulation, and the use of statins.

Antiphospholipid Syndrome (see also Chapter 93)

APS is associated with thrombosis (both arterial and venous) and with first-trimester fetal loss. Laboratory tests demonstrate antiphospholipid antibodies, most commonly anticardiolipin antibodies, and/or a positive lupus anticoagulant test. Anticardiolipin antibodies, typically of the IgG or IgM isotype and present in medium to high titer, or the lupus anticoagulant should be demonstrated on at least two occasions 6 or more weeks apart. Antiphospholipid antibodies directed against $beta_2$-glycoprotein-1 may activate the endothelium, monocytes, and platelets. This leads to surface expression of cellular adhesion molecules and generation of tissue factor by both monocytes and the vascular endothelium. The increased tissue factor and thromboxane A_2 synthesis by platelets results in a procoagulant state. Thrombosis requires a second hit, such as that provided by activation of the complement cascade. Antiphospholipid antibodies may also interact with other proteins in the coagulation cascade such as prothrombin, factor X, protein C, and plasmin and can adversely affect fibrinolysis. Laboratory studies have demonstrated that

antiphospholipid antibodies enhance leukocyte–endothelial cell interactions and induce thrombosis through inhibition of endothelial nitric oxide (eNOS) activation and nitric oxide biosynthesis. The mechanism involves binding of antibody to domain I of beta$_2$-glycoprotein-1 and impaired eNOS phosphorylation.[64]

Cardiovascular Disease

Valvular abnormalities are the most frequently reported cardiac abnormality in patients with APS. The most commonly detected lesions are verrucous endocarditis (Libman-Sacks endocarditis) and nonspecific valvular thickening (see earlier) (**Fig. 94.10**). Although lesions are commonly found, clinically significant features are rare. Symptomatic disease is more frequent in those with high antibody titers. Congestive cardiac failure develops in up to 5% of patients, and 13% require cardiac valve replacement. Histologic analysis of the valves reveals deposition of antiphospholipid antibodies with complement activation. Occasionally, amaurosis fugax, a transient ischemic attack, or a stroke is seen as a consequence of arterial thromboembolism. Coronary thrombosis and myocardial infarction can complicate primary APS in 0.5% to 6% of patients, and intracardiac thrombi can also occur. APS in patients with SLE may enhance their risk for myocardial infarction and stroke.

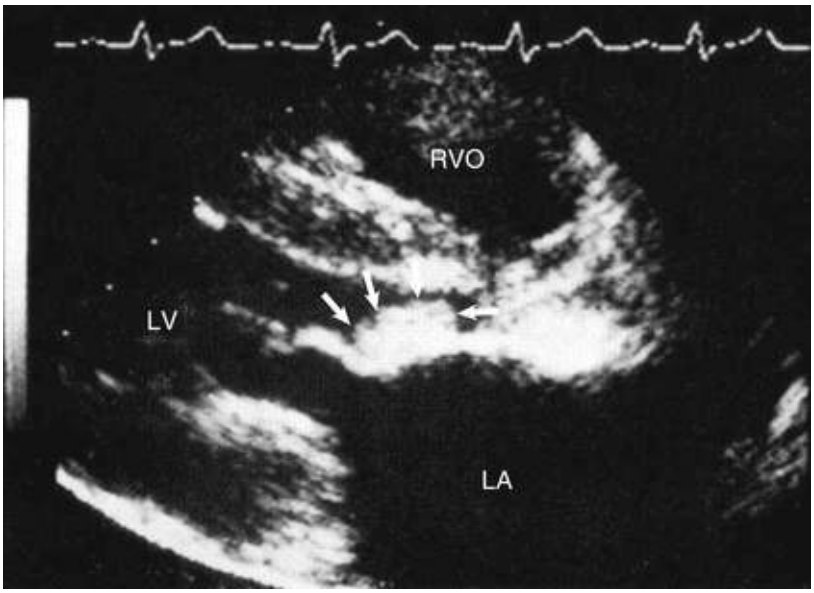

FIGURE 94.10 Parasternal long-axis view of the heart from a patient with SLE and high-titer antiphospholipid antibodies. A massive vegetation is seen on the ventricular surface of the anterior mitral leaflet *(arrows),* but it is not interfering with valve mobility. *LA*, left atrium; *LV*, left ventricle; *RVO*, right ventricular outflow. (Courtesy Professor Petros Nihoyannopoulos, National Heart and Lung Institute, Imperial College, London.)

Treatment

Confirmed thrombosis in patients with APS requires anticoagulation. Most centers target an international normalized ratio (INR) of 2.5 to 3.5. Some evidence supports the use of low-dose aspirin in patients with SLE complicated by antiphospholipid antibodies. In contrast, low-dose aspirin did not protect against deep venous thrombosis or pulmonary embolic disease in a study of men with primary APS.

Behçet Disease

Behçet disease occurs throughout the world but most commonly in Turkey, Iran, Japan, and Korea at 80 cases per 100,000 individuals, which falls to 4 to 8 per 100,000 in the United States, France, Germany, and the United Kingdom. This multisystem disorder includes orogenital ulceration, acneiform skin lesions, and arthralgia. It may cause uveitis and can cause blindness in the young. Arthralgia is common, and less frequently, patients suffer from meningoencephalitis, gastrointestinal ulceration, or vascular complications.

The vasculitis associated with Behçet disease predominantly affects the pulmonary arteries and veins, with thrombosis being a prominent clinical feature. Most thrombi are venous and cause superficial thrombophlebitis and deep venous thrombosis, including superior vena cava obstruction, cerebral vein thrombosis, and Budd-Chiari syndrome. In a small number of cases, pulmonary arterial vasculitis leads to in situ pulmonary arterial thrombosis. Although small studies have suggested that thrombosis is linked to the concurrent presence of a prothrombotic condition such as factor V Leiden or prothrombin mutations, this is not thought to be the cause in most. Indirect evidence suggests that the procoagulant state arises from an activated, adhesive, and prothrombotic endothelium due to chronic vascular inflammation. A clinical trial comparing treatment of thrombosis in Behçet disease with anticoagulation, immunosuppression, or a combination of both therapies supports this hypothesis. A higher proportion of patients treated with anticoagulation alone had recurrent thrombosis than did those prescribed immunosuppression. Pulmonary arterial aneurysms are a rare life-threatening complication in Behçet disease (**Fig. 94.11**), and aneurysms may also occur in other arterial beds. Other cardiovascular complications occur in less than 10% and include pericarditis, myocarditis, intracardiac thrombosis, myocardial infarction, and myocardial aneurysm.[65]

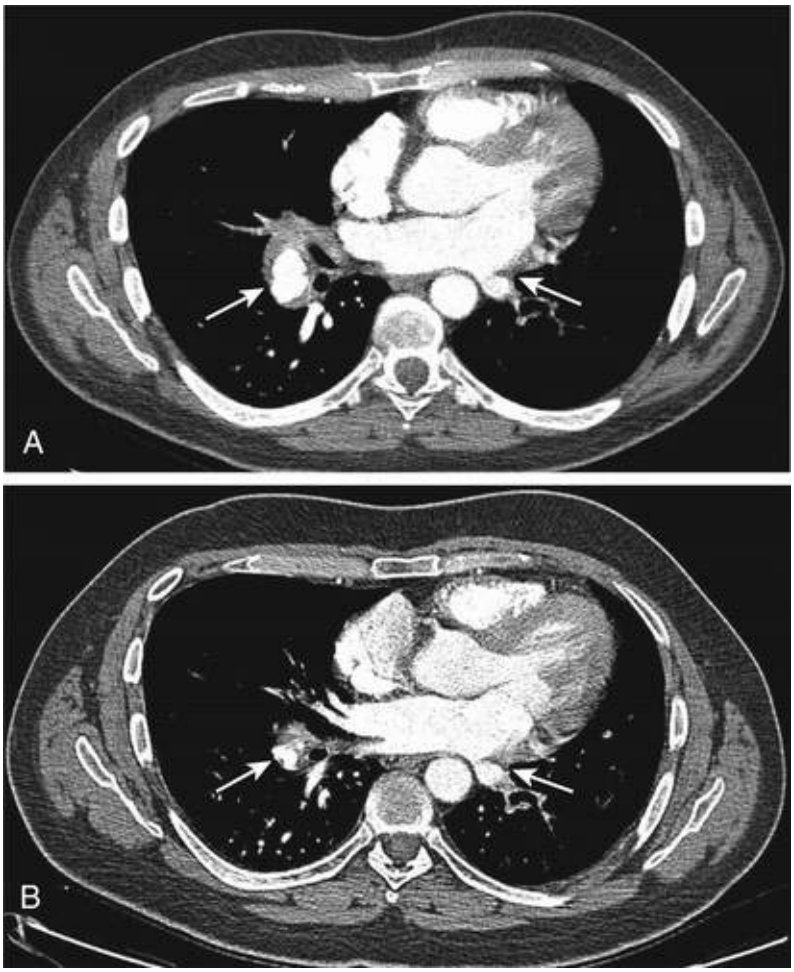

FIGURE 94.11 **A,** CT angiogram of a patient with Behçet disease showing bilateral pulmonary artery aneurysms *(arrows).* **B,** Following 4 months of treatment with the TNF-α antagonist infliximab, some reduction in the size of the pulmonary aneurysm on the right is seen. (Courtesy Professor Dorian Haskard, National Heart and Lung Institute, Imperial College, London.)

Treatment

Scant clinical trial data are available to guide therapeutic decisions for the cardiovascular manifestations of Behçet disease. The European League Against Rheumatism (EULAR) guidelines recommend immunosuppression for the treatment of thrombosis,[66] an approach common in endemic areas.[65] First-line treatment of these patients in emergency units in nonendemic areas is usually anticoagulation. This approach is appropriate because the cause of the thrombosis may not be immediately apparent, although patients with aneurysms have a substantial risk for bleeding. Patients should be seen in a specialist clinic for assessment of the need for long-term anticoagulation, immunosuppressive therapy, and noninvasive angiographic screening for aneurysms. Arterial aneurysms are treated aggressively with cyclophosphamide and high-dose prednisone to reduce inflammatory disease activity before surgical intervention, which may involve stenting via a percutaneous route or open surgical repair. Because the lesions often recur, patients require regular screening. Anecdotal evidence suggests the effectiveness of anti-TNF-α therapy in those with recurrent aneurysms or those who fail to respond to cyclophosphamide (**see Fig. 94.11**).

Antirheumatic Drugs and Cardiovascular Disease

Drug therapy for many rheumatic diseases has advanced dramatically over the past 20 years. Contributory

factors include more accurate diagnostic tests and imaging data, improved understanding of the mechanistic actions of drugs, and the development of novel targeted therapies. This section emphasizes the beneficial and deleterious effects of antirheumatic drugs on the cardiovascular system.

Relationship Between Drug Treatment and Cardiovascular Disease

Although inflammation contributes to atherogenesis and patients with systemic inflammatory rheumatic diseases have a heightened risk for premature myocardial infarction and stroke, causality remains unproven.[6] The impact of antiinflammatory drugs on atherogenesis and the incidence of cardiovascular events might provide insight in this regard.[1] To date, no clinical trial has convincingly demonstrated a beneficial effect of antiinflammatory drugs on cardiovascular outcomes. Indeed, the traditional NSAIDs or coxibs actually lead to a small but measurable increased risk for thrombosis. NSAID use in patients with inflammatory arthritis does not appear to confer increased cardiovascular risk, thus suggesting that their antiinflammatory role predominates. Similarly, statins reduce serum CRP levels, and large clinical trials suggest that in part, statins provide vascular protection independent of their actions on LDL cholesterol, including immunomodulatory and antiinflammatory effects.

Tumor Necrosis Factor-Alpha Antagonists

TNF-α blockade is an effective therapy for patients suffering from active RA. TNF-α can be targeted by monoclonal antibodies given intravenously or subcutaneously or by subcutaneous injection of etanercept, a soluble TNF receptor fusion protein. The use of these agents is contraindicated in patients with established cardiovascular disease and evidence of NYHA class III and IV cardiac failure, and they should be used with caution in those with mild congestive cardiac failure.[67] In RA the combination of systemic inflammation and traditional risk factors is associated with rapid progression of carotid IMT. Treatment with methotrexate and TNF-α antagonists can reduce this progress,[10] with some evidence for a reduction in cardiovascular events.[68] ^{18}F-FDG-PET scanning revealed subclinical arteritis in patients with RA when compared with those with stable cardiovascular disease, and initiation of anti-TNF-α therapy suppressed the arteritis, illustrating a potential underlying mechanism for this effect.[69] The next question is whether the extent of this subclinical arteritis can predict future cardiovascular events and direct targeted therapies.

Interleukin-6 Inhibition

Tocilizumab, an inhibitor of IL-6 signaling, might be expected to have vasculoprotective effects and, at least in the short term, may improve both endothelial function and aortic stiffness. However, tocilizumab has an adverse effect on lipid profiles and may increase LDL cholesterol, thereby requiring the addition of a statin. Thus long-term prospective studies are now required to determine whether effective suppression of IL-6–driven chronic inflammation can reduce the risk for cardiovascular events, in addition to its established efficacy in the control of RA disease activity.

Drugs Causing B Cell Depletion

Rituximab targets CD20 and depletes B lymphocytes. Initially established as a treatment of B cell

lymphoma, rituximab can control RA disease activity and reduce erosions. Similarly, rituximab demonstrated efficacy equivalent to that of cyclophosphamide for the treatment of ANCA-associated vasculitis and may exert disease-modulating effects in SLE. Short-term studies (4 to 6 months) have suggested that rituximab improves lipid profiles, carotid IMT, and endothelial function.[67] A recent study of 33 patients with active RA, however, found no change in arterial stiffness after 6 or 12 months of therapy. Furthermore, rather than improving lipid profiles, LDL cholesterol was significantly increased.[70] Long-term, adequately powered clinical trials with primary cardiovascular endpoints are required. Severe cardiovascular complications have occurred following rituximab infusions. Regulatory agency advice is that this treatment should be used with caution and the infusion rate reduced in those with preexisting cardiorespiratory disease.

Methotrexate

Methotrexate in dosages up to 25 mg/wk has proven to be remarkably effective in treatment of RA and is frequently used as a steroid-sparing drug in patients with the large-vessel vasculitides. Clinical evidence suggests that methotrexate has a cardiovascular protective effect, with those responding to methotrexate therapy demonstrating improvement in endothelial function. A recent metaanalysis confirmed early reports of a relative risk reduction in cardiovascular mortality of up to 70% in patients with RA prescribed methotrexate versus other DMARDs, although with a somewhat lower extent of protection.[71] Novel additional mechanisms potentially underlying vascular protection have been recently reported, including activation of an AMP-activated, kinase and cyclic AMP, response element–binding protein–dependent pathway[72] and beneficial effects on macrophage cholesterol handling.[73]

Other Disease-Modifying Antirheumatic Drugs

The potential cardiovascular benefits of hydroxychloroquine, an antimalarial drug frequently used for the treatment of RA, SLE, and Sjögren syndrome, have become more widely recognized in recent years. Hydroxychloroquine lowers cholesterol and may improve both endothelial function and aortic stiffness. Clinical studies have demonstrated that hydroxychloroquine reduces the risk for cardiovascular events in patients with both RA and SLE. In contrast, high cumulative doses occasionally are associated with restrictive cardiomyopathy and with retinal damage.

Cyclosporine continues to be used for the treatment of rheumatic disease, including polymyositis, SLE, and RA, as well as in many patients following organ transplantation. Clinical studies suggest that cyclosporine impairs flow-mediated vasodilation. At least in part, this effect reflects reduced eNOS activity and nitric oxide bioavailability. The adverse cardiovascular effects seen with cyclosporine may also reflect its propensity to induce hypertension and renal impairment. Alternative immunosuppressive drugs, used predominantly in the transplantation scenario, include tacrolimus and rapamycin (sirolimus), which appear to have a more favorable vascular profile.

Glucocorticoids

Glucocorticoids have undisputed efficacy in the treatment of systemic inflammatory diseases, including RA, SLE, and the vasculitides. Yet the substantial side effect burden concerns patients and physicians alike. The influence of corticosteroid therapy on the progression of atherosclerosis is complex and dependent on the context. The impact of corticosteroids on blood pressure and glucose and lipid

metabolism may have a deleterious effect. In contrast, in SLE, evidence suggests that insufficient use of glucocorticoids risks persistently active and/or relapsing disease, thereby leading to an increased risk for accelerated atherogenesis. Thus combination therapy with a steroid-sparing drug such as azathioprine, MMF, or methotrexate, which allows prednisone to be tapered to 7.5 mg/day or less, may be optimal, with no proatherogenic effect and potentially a vasculoprotective action.

Statins (see also Chapters 45 and 48)

Large primary prevention trials indicate that statins can reduce cardiovascular morbidity and mortality rates, in part independently of changes in LDL cholesterol.[74] These actions have led to interest in statins as adjunctive therapy for rheumatic diseases, including RA and SLE, for which they have the potential to both reduce the disease activity and lower the cardiovascular risk.[75] Clinical trial evidence supporting the routine use of statins in all patients with RA and SLE is lacking. Although no guidelines exist, most rheumatologists currently consider the cardiovascular risk in patients with RA and SLE as equivalent to that in patients with diabetes mellitus. EULAR has suggested adding a 1.5× multiplier to standard cardiovascular risk calculations.[76] Indications for a statin include an LDL cholesterol level of 190 mg/dL or higher, a long history of RA, a family history of hyperlipidemia, a higher age at disease onset, and the presence of any other cardiovascular risk factors.[77] Moreover, recent reports have recommended further expansion of the cardiovascular risk prediction score for RA.[17]

Nonsteroidal Antiinflammatory Drugs

NSAIDs and coxibs are important and effective drugs for the treatment of pain and inflammation. Concerns regarding atherothrombotic complications have, however, raised reservations regarding their use. As a consequence, patients with rheumatic disease are often denied these medications inappropriately. Although current evidence suggests that both classes have a small, manageable, and dose-dependent risk for cardiovascular complications, establishing the degree of risk and the relative safety profiles between individual drugs is difficult because of clinical trial heterogeneity and a lack of randomized controlled trial data for older NSAIDs. Data overall suggest that no traditional NSAID or COX-2 inhibitor is entirely safe and that naproxen has the best cardiovascular profile as a result of its antiplatelet effects.[78] Despite these reservations, the absolute risk for a cardiovascular event is very low, and gastrointestinal bleeding and perforation represent the major long-term risks associated with NSAIDs (**Table 94.5**). Although coxibs are less likely to cause gastrointestinal problems, many guidelines recommend concomitant prescription of a proton pump inhibitor for patients taking either NSAIDs or coxibs for more than 10 to 14 days.

TABLE 94.5

Cardiovascular Versus Gastrointestinal Risk in Prescribing Nonsteroidal Antiinflammatory Drugs

Patients with CV risk who are taking aspirin should avoid tNSAIDs or coxibs if possible
If essential, consider naproxen plus a PPI if GI risk is low or a coxib in those with significant GI risk
CV risk varies between individual tNSAIDs and coxibs
Patients with cardiac failure or hypertension should avoid tNSAIDs and coxibs
Risk for a CV event with a tNSAID or coxib is < 1% in those with < 2 classic risk factors
Risk for a CV event may increase in older adults, men, and those with preexisting CV disease
Aspirin use increases the risk for GI events associated with tNSAIDs and coxibs
Coprescription of a PPI reduces the risk for GI events with tNSAIDs and coxibs
PPIs are more effective than H_2 antagonists or misoprostol for gastroprotection
GI risk varies between individual tNSAIDs
Use the lowest effective dose for the shortest period

Coxibs, COX-2–selective antiinflammatory drugs; *CV*, cardiovascular; *GI*, gastrointestinal; *PPI*, proton pump inhibitor; *tNSAIDs*, traditional NSAIDs.

Concerns regarding a class effect of the coxibs arose from the APPROVE trial, which demonstrated increased thrombotic cardiovascular events with rofecoxib. Other clinical trials and nonrandomized epidemiology studies in primary care reinforced these concerns. Many of these studies, however, compared coxibs with placebo and not with an NSAID. According to the hypothesis proposed to explain the findings, selective blockade of COX-2 leads to an imbalance between COX-1 and COX-2 enzymatic products such that the effects of thromboxane A_2 exceed those of prostacyclin, thereby predisposing to vasoconstriction, platelet aggregation, and thrombosis. This hypothesis depends on endothelial COX-2 being the predominant source of prostacyclin, and data are conflicted on this, with an important role for COX-1 emerging.[79] Furthermore, data from studies comparing NSAIDs and coxibs in patients with arthritis do not support a class effect based on COX-2 selectivity.[80] Thus, COX-2 inhibition per se confers a cardiovascular risk regardless of the compound's COX isoform specificity. Additional findings from large population-based studies suggest that the NSAID diclofenac and the coxib rofecoxib have a particularly poor cardiovascular profile not shared by naproxen or celecoxib.[81] The study population is important, and few studies have looked in detail at patients with inflammatory arthritis. An inception cohort of 923 patients with early inflammatory arthritis was assessed for NSAID use and cardiovascular outcomes. The investigators demonstrated that exposure to NSAIDs was not associated with an increased risk for death and in fact led to a 2.5-fold reduction in cardiovascular mortality rates. The recently reported Prospective Randomized Evaluation of Celecoxib Integrated Safety versus Ibuprofen or Naproxen (PRECISION) trial enrolled 24,081 RA or osteoarthritis patients with an established or significant risk of cardiovascular disease.[15] Following prescription of esomeprazole and randomization to moderate dosages of celecoxib, naproxen, or ibuprofen, the occurrence of cardiovascular death, nonfatal stroke, and myocardial infarction was recorded. Although drug discontinuation rates were high, the trial revealed celecoxib to be noninferior to naproxen and ibuprofen with respect to cardiovascular safety, and it was significantly safer than either comparator in regard to gastrointestinal risk. These data provide important reassurance concerning the safety of moderate doses of celecoxib.

Wherever possible, NSAIDs and coxibs should be avoided in patients with known ischemic heart disease, previous thrombosis, poorly controlled hypertension, and cardiac failure. In patients in whom antiinflammatory drugs are being considered, an individualized assessment of both gastrointestinal and cardiovascular risk should be made.[80] The patient should be encouraged to use these drugs when required and at the minimally effective dose rather than as a standing dose (**see Table 94.5**).

Future Perspectives

The current challenge is to design and perform adequately powered randomized clinical trials to investigate the efficacy of individual antiinflammatory drugs in preventing atherosclerosis-related cardiovascular events. The data from available studies of antirheumatic therapies, although far from conclusive, do provide the impetus for further trials with large numbers of patients because of the relatively low incidence of cardiovascular events.[6] The ultimate challenge is to test the hypothesis that a relatively aggressive antiinflammatory approach, alongside conventional therapy, will confer additional benefit in those with known atherosclerotic coronary artery disease in the absence of an underlying rheumatic problem. A placebo-controlled trial of the potent antiinflammatory drug colchicine given within 12 hours of an acute myocardial infarction has revealed a potential benefit.[82] Two further large trials are under way: first, the Cardiovascular Inflammation Reduction Trial (CIRT), in which methotrexate (10 to 15 mg/wk) will be compared with placebo,[83] and second, the Canakinumab Anti-Inflammatory Thrombosis Outcomes Study (CANTOS) is investigating the ability of an anti–IL-1β approach to reduce the rate of recurrent myocardial infarction, stroke, or cardiovascular death.[84]

Tumors Affecting the Cardiovascular System

Daniel J. Lenihan, Syed Wamique Yusuf, Ashish Shah

Cardiac masses frequently present significant diagnostic and therapeutic clinical challenges. In many

cases, a cardiac mass is detected as an incidental finding and the resultant evaluation may culminate in the confirmation of a cardiac tumor. The finding of a tumor is generally an uncommon event, however; other masses, such as thrombi or vegetations, are much more common. This chapter will begin by describing the initial symptoms and signs that may indicate a cardiac tumor, followed by an explanation of a typical evaluation process, which depends heavily on current sophisticated imaging techniques. Once a cardiac tumor is suspected, the ultimate diagnosis is usually confirmed by a biopsy or surgical procedure because the histologic diagnosis has a direct bearing on further treatment planning. The remainder of the chapter will focus on the delineation and potential management of cardiac tumors and the overall anticipated outcomes. It should be pointed out that this is an inexact science due to the relatively rare occurrence of cardiac tumors. Furthermore, the final pathologic diagnosis is typically confirmed after most of the decisions regarding treatment have been made.

Clinical Manifestations of Cardiac Tumors

Initial Clinical Decision Making Regarding Cardiac Masses

It is interesting to note that patients who have cardiac tumors may present initially with no symptoms or physical findings but have abnormalities on imaging. Alternatively, there may be a host of nonspecific symptoms or physical examination findings, and, of course, there may be specific and detailed symptoms or signs that should alert practitioners to the possibility of a tumor (**Table 95.1**). The most important considerations in confirming the presence of a cardiac tumor are a high index of suspicion and the integration of symptoms, physical findings, and imaging characteristics in a logical way. This process will help to establish a clinically reasonable plan of action.

TABLE 95.1

Range of Clinical Findings That May Indicate a Cardiac Tumor

Completely asymptomatic patient with incidental abnormality on imaging
Low-grade fevers
Transient ischemic attack or cerebral vascular event
Positional dyspnea
Weight loss
Peripheral embolic events
Chest discomfort
Congestive heart failure
Upper extremity and/or neck swelling
Lower extremity venous thrombosis
Palpitations
Arrhythmias
Pericardial effusion or tamponade

The initial evaluation is typically an imaging test, such as two-dimensional (2D) echocardiography[1] or magnetic resonance imaging (MRI),[2] during which a mass is seen. Depending on the characteristics of this mass and the known comorbidities of the patient, additional imaging may be undertaken. These studies might include three-dimensional (3D) echocardiography with contrast,[3] MRI with gadolinium enhancement,[4] coronary angiography (to define the presence of coronary artery disease),[5] position

emission tomography (PET) studies to provide staging for cancer,[5] or computed tomography (CT) imaging to clarify the status of intrathoracic structures.[6,7] Transesophageal echocardiography (TEE) can also provide specific anatomic information that is critical for treatment planning[5] (**Table 95.2**).

TABLE 95.2

Common Testing to Detect Cardiac Tumors

2D or 3D echocardiography
Chest x-ray
Computed tomography
Magnetic resonance imaging
Transesophageal echocardiography
Position emission tomography
Nuclear scintigraphy
Coronary angiography

When one is initially assessing a cardiac mass to determine whether it may be a tumor, the clinical context in which the image is obtained is critical. A differential diagnosis of a cardiac mass is broad and includes tumors, thrombi, infection, and artifacts[8] (**Table 95.3**). For instance, in a patient with new-onset heart failure in whom a 2D echocardiogram shows an apical mass, a cardiac tumor is less likely. The presence of a severe wall motion abnormality plus a mass that appears to be distinct from the myocardial wall, as well as lobulated (**Fig. 95.1**), strongly suggests that the mass is a thrombus as opposed to a tumor. Another scenario might involve routine cardiac imaging in a patient with a history of melanoma that is metastatic to other organs, which reveals a solid mass in an unusual location. Because there is no wall motion abnormality and no significant valvular disease or clinical signs suggestive of infective endocarditis, this is likely to be a metastatic lesion to the heart (**Fig. 95.2**). Motion imaging may be helpful in diagnosing a cardiac tumor. If a tumor is infiltrating the myocardium, it is unlikely to contract in a normal fashion. A left ventricular myocardial apical mass that contracts in a manner similar to the surrounding tissue is likely to be either focal hypertrophy (**Fig. 95.3**) or a left ventricular noncompaction[9,10] (**Fig. 95.4**) as opposed to a cardiac tumor (**Fig. 95.5**). Progression of an image over time may indicate the pathologic process. If a cardiac mass changes in size from one image to the next, suspicion of a cardiac tumor is much higher. However, if an apical mass is stable for months or years, it is unlikely to be a cardiac tumor. Of course, the exact nature and location of a mass is critical in determining whether it is a tumor. A classic example of this principle is lipomatous hypertrophy of the intraatrial septum (**Fig. 95.6**). One might initially suspect a myxoma or other tumor, but a TEE will clearly reveal specific characteristics that are a hallmark for lipomatous hypertrophy, and that will confirm the diagnosis.[11]

Classification of Cardiac Tumors

Cardiac tumors are divided into primary and secondary tumors. Primary cardiac tumors are very rare, with an autopsy incidence of 0.001% to 0.03%.[12] They include benign or malignant neoplasms that may arise from any tissue of the heart. Secondary or metastatic cardiac tumors are 30 times more common than

primary neoplasms, with an autopsy incidence of 1.7% to 14%.[13] **Table 95.4** summarizes some of the pathologic descriptions of cardiac tumors that have been reported, but it is not an exhaustive list. Many specific pathologic descriptions have been reported, and it can be difficult to adequately categorize them. Thus, general categories will be discussed in the remainder of this chapter.

Lung cancer
Sarcoma
Lymphoma
Leukemia

Benign Primary Cardiac Tumors

The majority (>80%) of primary cardiac tumors are benign, and myxoma is by far the most common type.[12,14] Myxomas constitute approximately 50% of all benign cardiac tumors in adults but only a small percentage of such tumors in children.[15] Rhabdomyoma is the most common benign tumor in children, accounting for 40% to 60% of the cases.[14] Other benign cardiac tumors that have been described include fibromas, lipomas, hemangiomas, papillary fibroelastomas, cystic tumors of the atrioventricular (AV) node, and paragangliomas. The remaining 20% of primary cardiac tumors are malignant and usually are pathologically described as sarcomas.[16-18]

Myxomas

Most myxomas (>80%) are found in the left atrium. They are also found in decreasing frequencies in the right atrium, right ventricle, and left ventricle.[17] The incidence of cardiac myxoma peaks at 40 to 60 years of age, with a female to male ratio of approximately 3 : 1.[17] Most myxomas occur sporadically, but they may be familial; occasionally these have been described in relation to a particular syndrome called the *Carney complex*, an autosomal dominant condition associated with cardiac myxomas, myxomas in other regions (cutaneous or mammary), hyperpigmented skin lesions, hyperactivity of the adrenal or testicular glands, and pituitary tumors. The Carney complex occurs at a younger age, and should be considered

when cardiac myxomas are discovered in atypical locations in the heart.[16]

Etiology and Pathophysiology

The exact origin of myxoma cells remains uncertain, but they are thought to arise from remnants of subendocardial cells or multipotential mesenchymal cells in the region of the fossa ovalis, which can differentiate along a variety of cell lines. The hypothesis is that cardiac myxoma originates from a pluripotential stem cell, and myxoma cells express a variety of antigens and other endothelial markers. Myxomas typically form a pedunculated mass with a short, broad base (85% of myxomas), but sessile forms can also occur.[12] Classically, myxomas appear yellowish, white, or brownish and are frequently covered with thrombus (**Fig. 95.7**). The tumor size can range from 1 cm to more than 10 cm, and the surface is smooth in the majority of cases (**Figs. 95.8 and 95.9**). A villous or papillary form of myxoma has been reported and has a surface that consists of multiple fine or very fine villous, gelatinous, and fragile extensions that have a tendency to fragment spontaneously and are associated with embolic phenomena.[19] Histologically, myxomas are composed of spindle- and stellate-shaped cells with a myxoid stroma that may also contain endothelial cells, smooth muscle cells, and other elements surrounded with an acidic mucopolysaccharide substance. Calcifications may also be seen in some cases.[12]

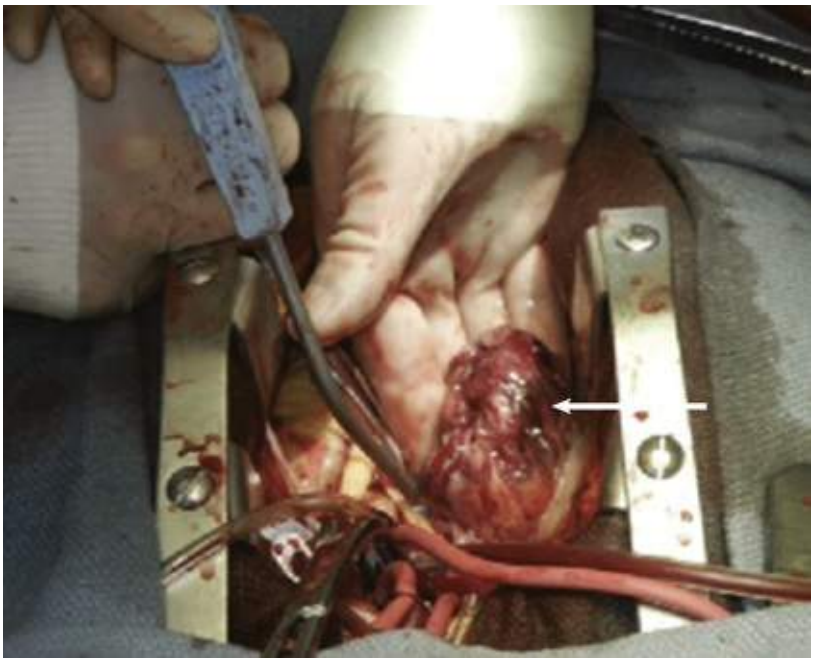

FIGURE 95.9 Gross appearance of a left atrial myxoma. Note the thrombus-appearing material on the surface *(arrow),* which is likely a mechanism for embolic events associated with cardiac myxomas.

Clinical Manifestations

Patients commonly are asymptomatic, and the tumor is seen as an incidental finding on 2D echocardiography. When symptoms are present, dyspnea, especially dyspnea that is worse while lying on the left side, should alert the astute clinician to the possibility of a myxoma. Most clinical presentations related to myxoma result from mitral valve obstruction (syncope, dyspnea, and pulmonary edema) followed by embolic manifestations.[17,19] Patients may present with nonspecific symptoms such as fatigue, cough, low-grade fever, arthralgia, myalgia, weight loss, erythematous rash, and laboratory findings of anemia, an increased erythrocyte sedimentation rate (ESR), and increased levels of C-reactive protein and gamma globulin. Less commonly they may have thrombocytopenia, clubbing, cyanosis, or Raynaud phenomenon. Physical examination findings can reveal a systolic or diastolic murmur suggestive of mitral stenosis. A tumor “plop” may also be heard (a low-pitched diastolic sound heard as the tumor prolapses into the left ventricle).[17,19]

In one study, a cardiac auscultation abnormality was detected in 64% of patients.[20] The most common auscultation findings are a systolic murmur (in 50% of cases) followed by a loud first heart sound (32%), an opening snap (26%), and a diastolic murmur (15%).[19] The reason for the systolic murmur may be damage to the valves, failure of the leaflets to coapt, or narrowing of the outflow tract by the tumor. A diastolic murmur is present due to obstruction of the mitral valve by the myxoma. Tumor plop may be confused with a mitral opening snap or a third heart sound; it can be detected in up to 15% of cases.[20] Chest examination may reveal fine crepitations consistent with pulmonary edema. Extremity examination may also reveal signs of embolic phenomena. The signs vary depending on the vascular territory involved. Involvement of cerebral vessels results in neurologic signs; involvement of coronary arteries may result in an acute coronary syndrome; intestinal arterial obstruction may result in an ischemic bowel; and peripheral arterial obstruction can result in limb-threatening ischemia.

Laboratory Testing

Laboratory test abnormalities may include anemia, elevated serum gamma globulin levels, an elevated

ESR, and elevated levels of serum C-reactive protein, which is present in approximately 75% of patients.[19] There are no specific electrocardiogram (ECG) findings in myxoma. Chest x-ray findings are also nonspecific and include signs of congestive heart failure, cardiomegaly, and left atrial enlargement. In some cases the tumor itself may be visible due to calcification.[20] A 2D echocardiogram usually should demonstrate a mass in the atrium, with the stalk attached to the interatrial septum (**see Fig. 95.8**). A TEE provides specific delineation of the tumor, including the size and origin. CT and MRI scans provide better delineation of the intracardiac mass and the extent of tumor in relation to extracardiac structures, and they provide anatomic definition for preoperative planning.

Treatment

The only definitive treatment of cardiac myxoma is surgical removal. Generally, after median sternotomy, the myxoma is surgically excised using cardiopulmonary bypass and cardioplegic arrest. The tumor is removed by either right or left atriotomy or combined atriotomy, depending on the site and extent of the tumor. Atrial myxomas can also be approached via sternal sparing or minimal access approaches. Using a right limited thoracotomy and peripheral cannulation, patients are placed on cardiopulmonary bypass; cold fibrillatory arrest or cardioplegic arrest may then be used, the atria may be explored, and complete removal of the mass and reconstruction of any defects may be performed. This approach is limited in that only mitral and tricuspid valvulopathy can be corrected. The choice of technique also depends on associated conditions that need surgical intervention, such as valve repair or replacement, and coronary disease if present. Lifelong follow-up is needed because myxomas have some tendency to recur, at rates from 5% to 14%. The time to recurrence in different series varied from 0.5 to 6.5 years.[19,20]

Rhabdomyomas

Rhabdomyomas are usually found in the ventricle and are the most common benign cardiac tumor found in children.[14,15] The majority of these patients have signs of or a family history of tuberous sclerosis.[14] In one study of patients with tuberous sclerosis complex, a cardiac tumor was found in 48% of the patients, with an incidence of 66% in patients less than 2 years old.[21] Frequently, these patients are asymptomatic, although some patients with rhabdomyoma may present clinically with arrhythmias and heart failure.[14,21] These tumors may regress with age; they can sometimes grow or appear during puberty.[21] As a result of these uncertain outcomes, long-term clinical and echocardiographic follow-up is needed in patients with tuberous sclerosis. Most often, surgery can be avoided, although if arrhythmias become a symptomatic problem, antiarrhythmics and ultimately surgery may have to be considered.[14]

Fibromas

Fibromas are histologically composed primarily of fibroblasts or collagen. Typically they occur in children, although they can also occur in adults.[12,17,22] Most often a fibroma is located in the ventricle and interventricular septum, and patients may present with chest pain, pericardial effusion, heart failure, or arrhythmias; the first manifestation may also be sudden death. Cardiomegaly is frequently seen on chest x-ray, which may also show the calcification within the tumor mass.[22] Typically, these tumors are associated with arrhythmias and might require multimodality treatment with medications, electrophysiologic procedures, and/or surgery. If surgical resection is performed, fibromas tend not to recur. A distinguishing feature of fibromas, contrasted to rhabdomyomas, is that there is frequently calcification.[12]

Lipomas

A lipoma is a rare benign cardiac tumor; it makes up only 3% of all benign tumors.[23] Lipomas tend to occur in the left ventricle or the right atrium but may be found anywhere in the heart, as well as the pericardium (**Fig. 95.10**). Although frequently asymptomatic, they may grow large enough to cause obstructive symptoms.

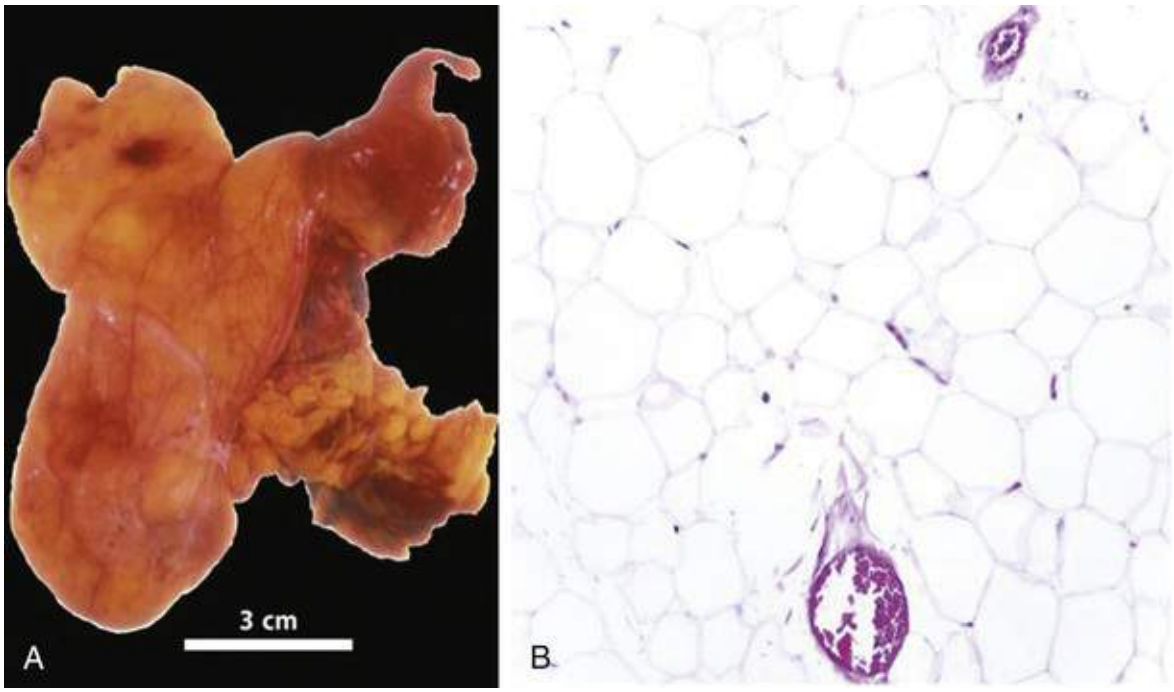

FIGURE 95.10 Pericardial lipoma. **A,** Gross appearance of a pericardial lipoma from a 71-year-old man. **B,** Hematoxylin-and-eosin staining depicts mature adipocytes in the tumor with an associated vascular supply (×200).

Papillary Fibroelastomas

Valvular structures may have a papillary fibroelastoma, which is often found incidentally. They are small in size, typically less than 2 cm, and most commonly occur on the aortic valve, followed by the mitral valve. Rarely they may be found anywhere in the endocardial surface. Most fibroelastomas that have been reported are solitary; multiple ones have been reported rarely.[24] Fibroelastomas may result in embolic phenomena, and when situated on the aortic valve, can cause coronary ostial occlusion. Grossly, a papillary fibroelastoma has a characteristically frondlike appearance, resembling a sea anemone, and histologically it has an inner central core of collagen surrounded by a layer of acid mucopolysaccharides and covered by endothelial cells.[24] For the most part, complete surgical resection is recommended, mainly due to the high likelihood of a systemic embolism (i.e., stroke, myocardial infarction, peripheral embolism, or even sudden death). A recent report with clinical outcomes of a large population of patients with papillary fibroelastomas indicated that rates of cerebrovascular accident or death were increased if surgical removal was not performed.[25] On imaging, especially echocardiographic imaging, there is a characteristic small, mobile, pedunculated, and very echocardiographically dense core that enables the tumor to be differentiated from a vegetation or thrombus. Once the tumor has been completely removed, the chance at recurrence appears low, and there are no compelling data for continuing anticoagulation over the long term unless there are other indications to do so.[24]

Cystic Tumors of the Atrioventricular Node

Because of a location near the AV node, these cystic tumors can present with varying degrees of heart block; sudden death may be the first indication, as well.[26] Cardiac MRI is particularly useful in the diagnosis of this tumor.[27] Cystic tumors of the AV node were previously called mesotheliomas.

Paragangliomas

Paragangliomas are highly vascular tumors and may present with hypertension and chest pain.[28,29] The tumor may be located in the pericardial space with no intracardiac extension.[29] Paragangliomas are often located around the roof of the left atrium and aortic root and may involve the cardiac structures (**eFig. 95.1**).[30] The tumors originating from the roof of the left atrium are often large and require extensive surgery, including cardiac autotransplantation.[30] A coronary angiogram in these patients shows a characteristic “tumor blush” (**Fig. 95.11**).[28,29] Paragangliomas are also known as extraadrenal pheochromocytomas.

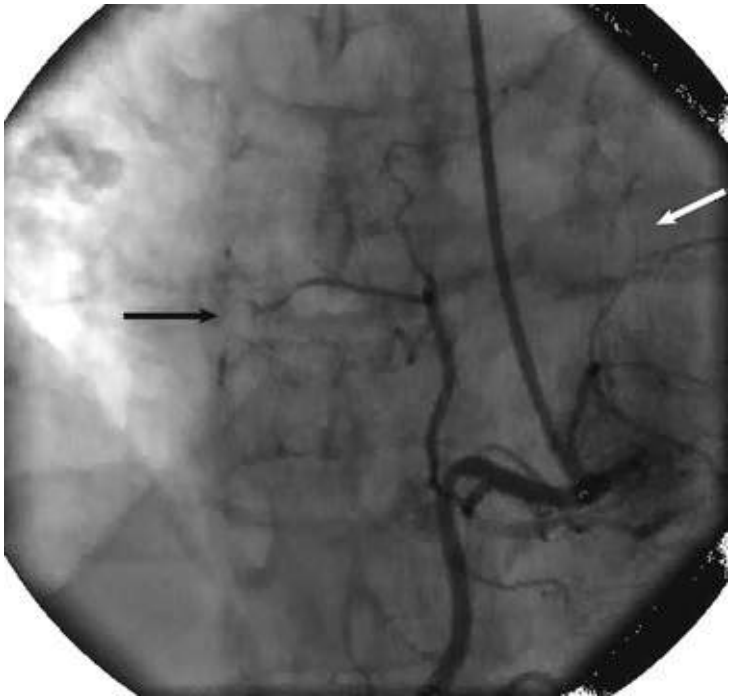

FIGURE 95.11 A tumor blush is noted on angiography *(arrows)* in a patient with a large mediastinal mass.

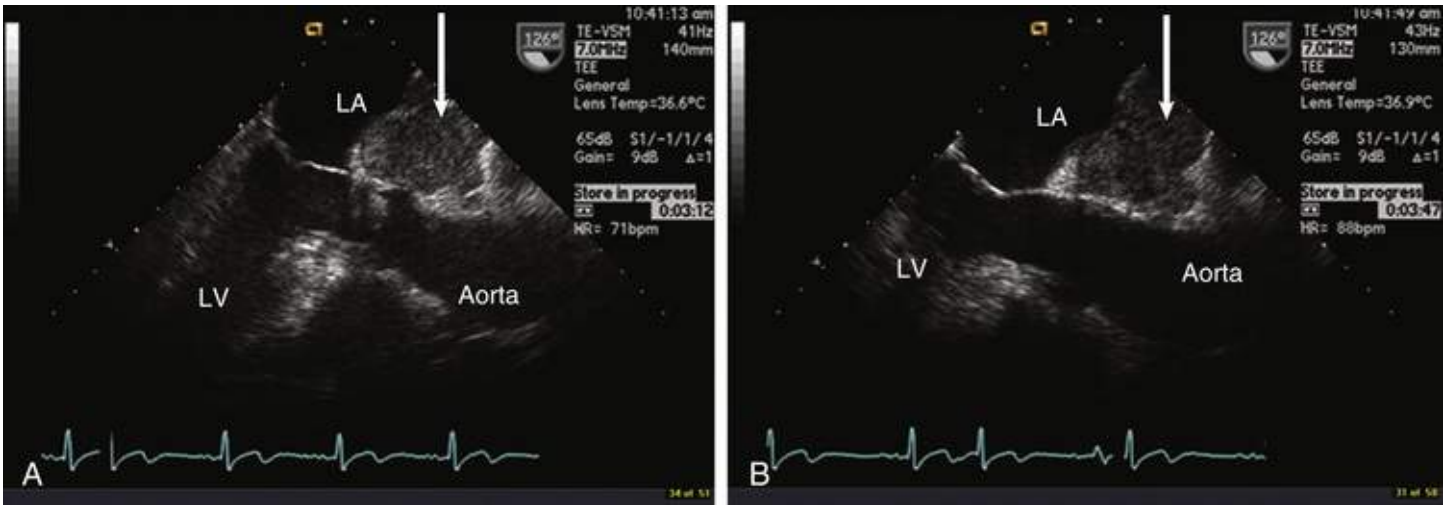

EFIGURE 95.1 A large mass *(arrow)* in **A** and **B** on the roof of the atrium abutting the aorta that is confirmed to be a paraganglioma. *LA*, left atrium; *LV*, left ventricle.

Other Rare Benign Cardiac Tumors

There are a few, but very rare, reports of hemangioma,[31,32] neurofibroma, teratoma,[33] leiomyoma, and lymphangioma, but there are not enough data to summarize expected findings; typically these will be diagnosed after resection. Complete resection is possible for most of the benign primary tumors, compared with malignant tumors; the perioperative death rate is 1.4%.[34] Hemangiomas are characteristically vascular and may be endocardial or epicardial (**Fig. 95.12**).

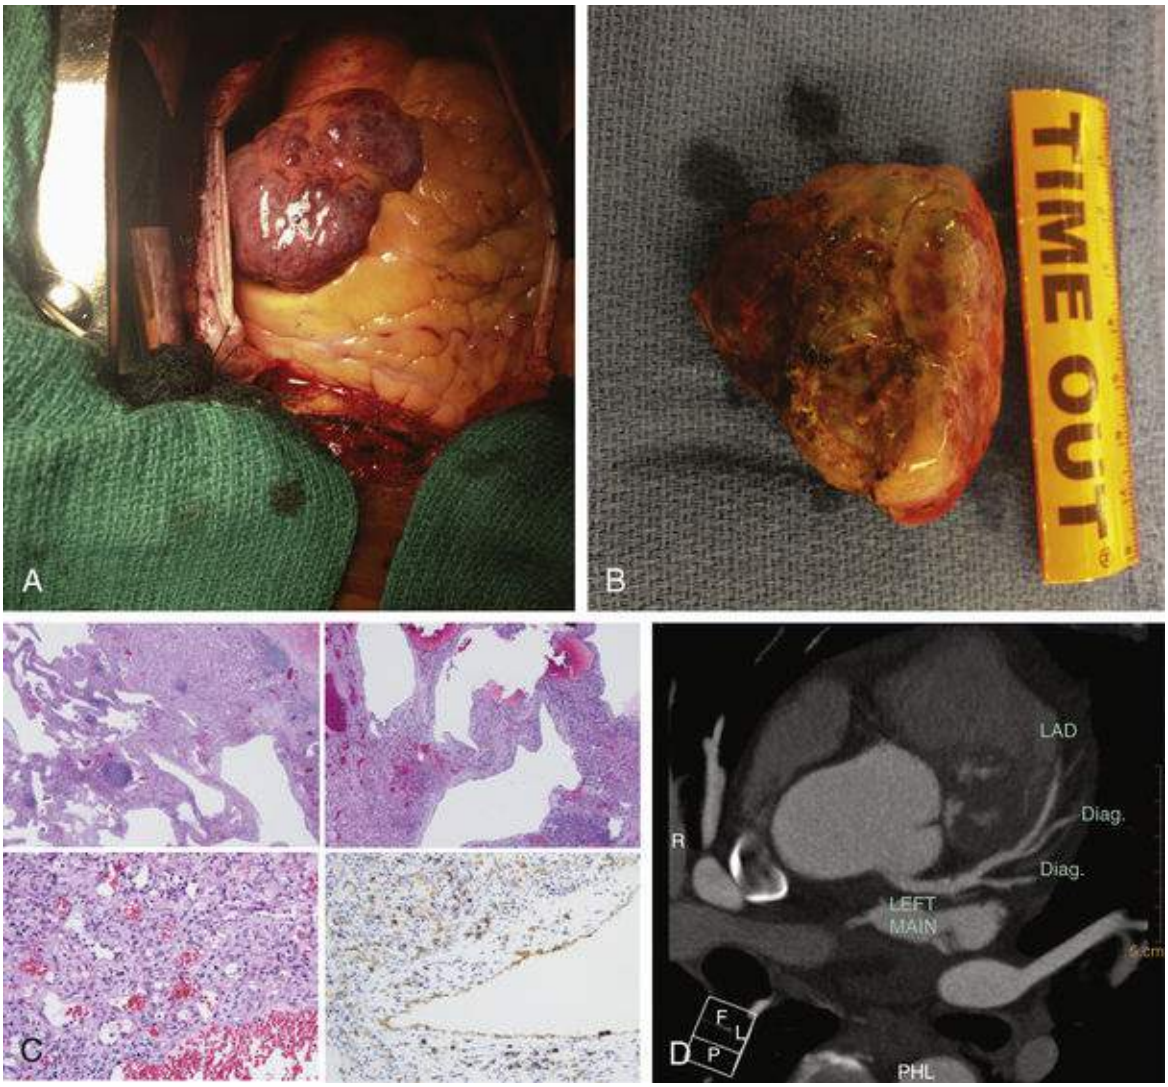

FIGURE 95.12 Primary cardiac hemangioma arising from the right coronary artery at the base of the aorta and right atrium. **A,** Complete resection was possible, with an uneventful postoperative course. **B,** The resected specimen was easily dissected free from adjacent structures and was supplied by the right coronary artery. **C,** Histologic and immunohistochemical features of the tumor. Top left: Low-power view showing large vascular spaces and more solid areas with small capillaries. There is a portion of residual cardiac muscle in the upper right corner (2× magnification). Top right: Medium-power view showing that the vascular spaces are lined by an attenuated endothelial lining with cells with small nuclei. Many of the spaces contain blood and fibrin, and the intervening areas of capillary proliferation have blood and scattered chronic inflammatory cells (4× magnification). Bottom left: High-power view of the capillary-rich area showing plump cells lining the vascular spaces (20× magnification). Bottom right: CD31 immunohistochemistry showing strong brown staining of the lining cells of the large spaces and also of the plump cells in the capillary-rich areas (20× magnification). **D,** CT angiography showing the mass adjacent to the right coronary artery.

Radical Surgical Excision

Most tumors, particularly benign masses, are relatively limited in their size and adjacent cardiac involvement. The surgical approach, whether via median sternotomy or right thoracotomy, allows complete removal and repair of most resulting defects. However, there are a small group of tumors with a complex cardiac involvement. These tumors may invade and obstruct the pulmonary veins or the mitral annulus, rendering complete removal impossible with conventional approaches. Especially in children, an individualized approach is necessary for the best overall resection and outcomes.[35] Pioneered by Reardon and colleagues in Houston, the complete removal of the heart with back-table resection and reconstruction of the pulmonary veins and atria offers a potential cure or palliation for select patients. The approach is

similar to heart transplant cardiectomy, allowing for exposure of the pulmonary veins and complete resection of atrial and even ventricular masses. In their select series, the survival rate was 100% at 1 year among patients with benign tumors and 50% in patients with malignant tumors (primary sarcoma).[36]

Malignant Primary Cardiac Tumors

Sarcomas

Primary cardiac sarcomas constitute approximately 1% of all soft tissue sarcomas and are the most common malignant primary cardiac tumor.[37,38] The age of presentation for cardiac sarcomas ranges from 1 to 76 years, with a mean age of around 40 years.[18,37] Angiosarcomas and unclassified sarcomas account for approximately 76% of all cardiac sarcomas, of which angiosarcomas are the most common.[39] Rhabdomyosarcoma is the most common form of cardiac sarcoma in children. Leiomyosarcoma, synovial sarcoma, osteosarcoma, fibrosarcoma, myxoidsarcoma, liposarcoma, mesenchymal sarcoma, neurofibrosarcoma, and malignant fibrous histiocytoma are other cardiac sarcomas observed.[16,18,39] Angiosarcomas are predominantly found on the right side of the heart, whereas osteosarcomas and unclassified sarcomas are predominantly found on the left side of the heart.[39] Pericardial angiosarcomas are extremely rare.[40]

Clinical Manifestations

Cardiac tumors commonly cause symptoms by three separate mechanisms, obstruction, embolization, and arrhythmias. Rarely pericardial invasion and tamponade may be the first manifestations of the disease. Both atrial and ventricular tumors, when large enough, may result in obstructive symptoms and cause syncope, chest pain, dyspnea, or heart failure. The most common presenting symptoms include dyspnea, followed by chest pain, cough, syncope, hemoptysis, fever, embolic events, and cardiac arrhythmias; sudden death may also be the first manifestation.[18] Large tumors on the right side, besides causing venous congestion, may also limit cardiac filling, with sudden decreases in intravascular volume, potentially precipitating syncope in these patients. Left-sided cardiac tumors, if large enough, can also impair ventricular filling, leading to syncope or heart failure (**Fig. 95.13**). Unfortunately, approximately 29% of cardiac sarcomas are associated with metastatic disease at the time of presentation, typically in the lung.[18,40] Sarcomas, especially left-sided sarcomas, are commonly associated with cardiac embolic events,[16] and arrhythmia can be an important problem as well. A finding of a cardiac mass with pericardial effusion should raise the suspicion of a malignant cardiac tumor.[40] Commonly, pericardial effusion is due to associated pericardial involvement; however, a malignant effusion is not always proven.

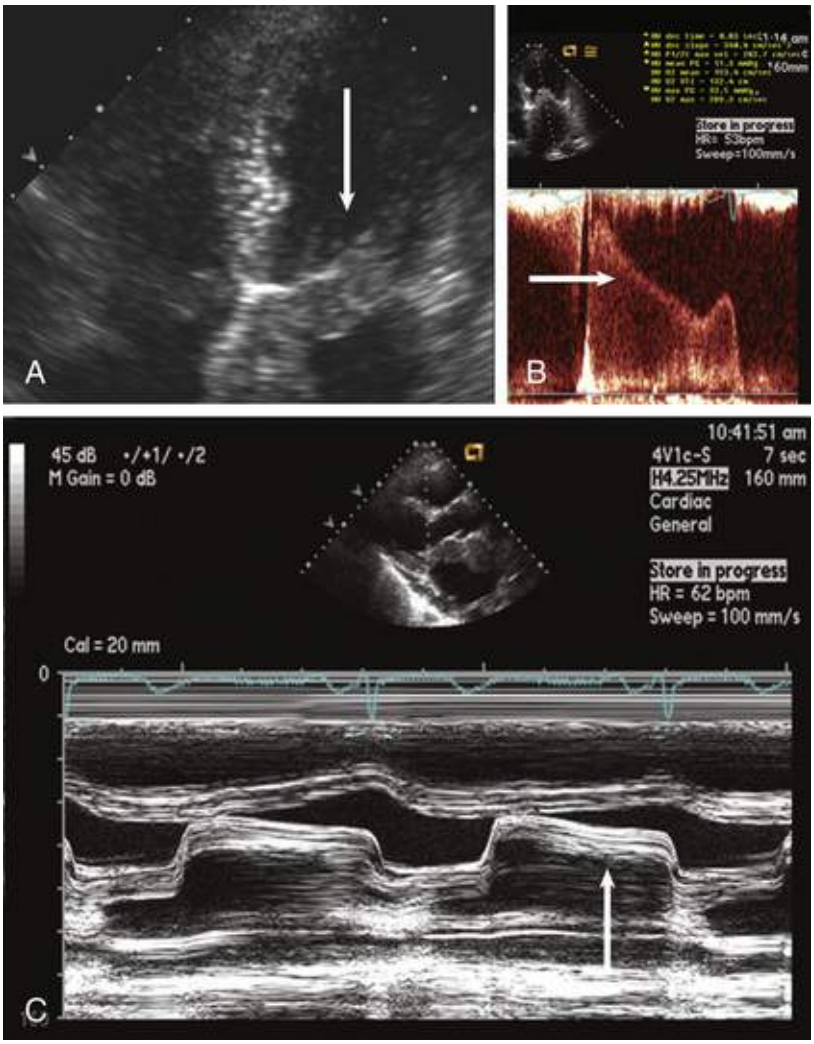

FIGURE 95.13 Echocardiographic Doppler images from a patient with sarcoma who presented with heart failure and mitral stenosis. **A,** Four-chamber image with mitral valve thickening *(arrow).* **B,** Increased velocity across the mitral valve showing stenosis *(arrow).* **C,** M mode showing a classic mitral stenosis pattern.

Laboratory Investigations

Due to the increasing use of CT scanning and better modalities of cardiac imaging, the primary cardiac tumors may be identified at an earlier stage. ECG changes are usually nonspecific; however, heart block, ventricular hypertrophy, bundle branch blocks, atrial flutter, or atrial tachycardia may be present in some cases. Cardiomegaly is a common but nonspecific radiologic finding of cardiac sarcomas.[16] Echocardiography is commonly used in the initial diagnosis of primary cardiac tumors, with transthoracic 2D, 3D, and contrast imaging being appropriate techniques.[41,42] However, transthoracic echocardiography has several well-known limitations: the operator's level of experience is crucial; pulmonary disease may cause the lungs to interfere with the image; or the patient may have narrow rib spaces or an unfavorable body habitus for imaging. TEE can provide more specific and detailed imaging than 2D echocardiography, especially if structures that are more posterior, such as the left atrium, are involved. Cross-sectional imaging methods, such as CT and MRI, have an important role in the evaluation and further assessment of malignant cardiac tumors, especially in the evaluation of myocardial invasion (**Fig. 95.14**), involvement of mediastinal structures, tissue characterization (**Fig. 95.15**), and vascularity.[43,44]

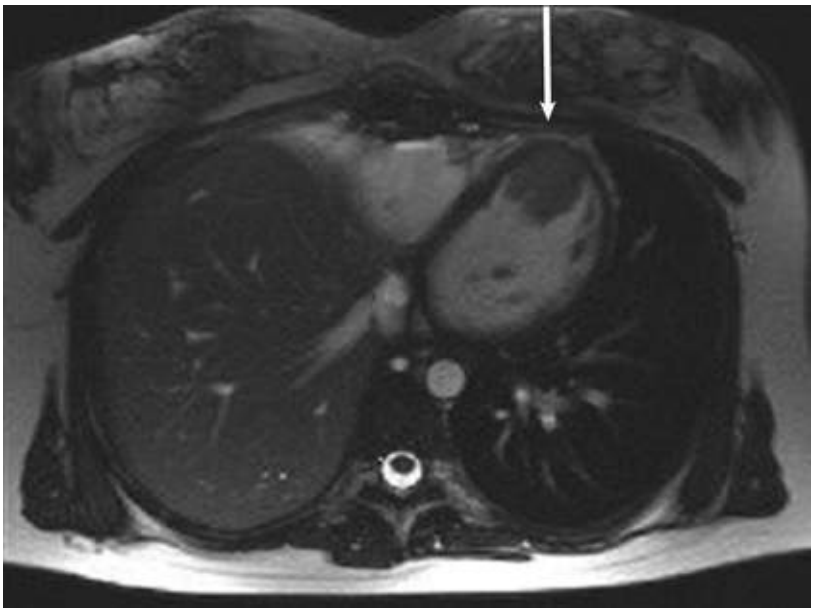

FIGURE 95.14 T_1-weighted cardiac MRI of a left ventricular apical tumor of metastatic alveolar cell sarcoma. Note the indistinct nature of the tumor infiltrating the myocardium *(arrow).* This is in contrast to the distinct line that classically separates thrombus from myocardium.

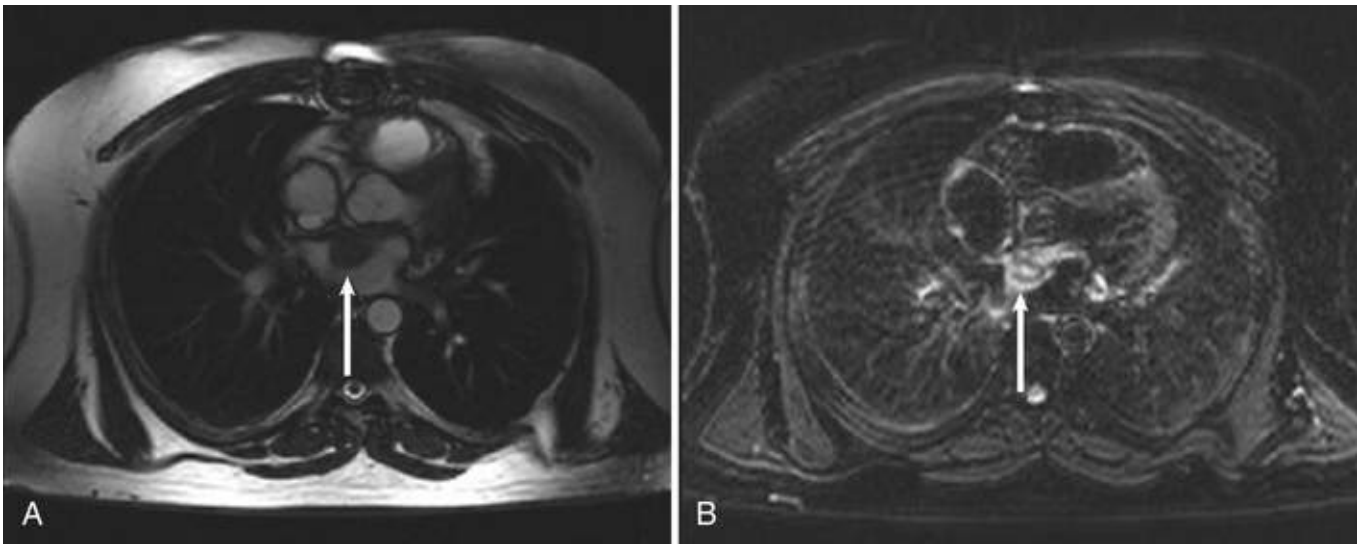

FIGURE 95.15 MRI imaging of a left atrial sarcoma. **A,** T_2-weighted cardiac MRI demonstrating a large left atrial mass near the anterior leaflet of the mitral valve. **B,** Brisk enhancement during first-pass perfusion of the mass confirms a high degree of blood flow, strongly suggesting an angiosarcoma.

Treatment

Complete resection is the optimal goal of surgical treatment.[16,18,45] Once surgical treatment is completed, adjuvant chemotherapy seems prudent, although it has not been widely studied.[45] It is possible that neoadjuvant therapy may be useful, but this is speculative.[46] The most common chemotherapeutic regimen used for cardiac sarcomas is combined doxorubicin and ifosfamide.[40] A combination of docetaxel and gemcitabine also showed some response in various sarcomas and can be used as an alternative chemotherapeutic regimen.[40] Other treatment options include ifosfamide-epirubicin (doxorubicin) and cyclophosphamide, vincristine, doxorubicin, and dacarbazine (CyVADIC).[37] Unlike other sarcomas, cardiac sarcomas overall have a poor prognosis, with a median survival rate of 6 to 25 months after

diagnosis.[12,17,39] The presence of tumor necrosis and metastases is associated with a poor prognosis,[39] as is the presence of a right-sided cardiac sarcoma.[47] Sarcomas other than angiosarcomas, sarcomas on the left side of the heart, and completely resected sarcomas seem to have a better prognosis.[18] At the time of surgical resection patients with negative surgical margins have a better survival rate.[47] Cardiac sarcomas with low-grade histologic findings may appear to have a better survival rate, although in one study there was no significant correlation between the histologic grade and the survival rate.[18,39,48]

Secondary Cardiac Tumors

The autopsy incidence of secondary cardiac tumors ranges from 1.7% to 14% (average, 7.1%) in cancer patients and 0.7% to 3.5% (average, 2.3%) in the general population.[13] In comparison with older series, there is a significant increase in the incidence of cardiac metastases in cancer patients after 1970, predominantly due to improvement in imaging modalities. Cardiac metastases can occur by direct extension, via the circulatory system or lymphatic system, or by intracavitary diffusion through the inferior vena cava (IVC) (**Fig. 95.16**). Pericardial metastasis (69%) is most common, followed by epicardial (34%), myocardial (32%), and endocardial metastases (5%).[49] The pericardium is most often involved due to direct invasion by thoracic cancers, including breast and lung cancers, as well as thoracic lymphomas. Abdominal and pelvic tumors may reach the right atrium through the IVC. The most common tumor exhibiting this tendency is renal cell carcinoma.[40] A recent review suggests that lung cancer is the most common cause of cardiac metastasis, followed by esophageal cancer and hematologic malignancies.[17] The symptoms of cardiac metastases are extremely variable, depending on the location of the tumor. Dyspnea, palpitations, syncope, chest pain, and peripheral edema are common clinical presentations.[40,49] Heart failure, cardiac arrhythmias, heart blocks, acute myocardial infarction, myocardial rupture, systemic embolization, and superior vena cava syndrome (**eFig. 95.2**) are other manifestations of cardiac metastases. A new heart murmur or any new ECG finding without clear symptoms in a cancer patient should raise the suspicion of cardiac metastases. Typical ECG findings encountered in patients with cardiac metastases are ST-T wave changes (mimicking myocardial ischemia or injury), new atrial fibrillation or flutter, and low voltages with electrical alternans indicating a significant pericardial effusion. The ECG findings of myocardial injury may indicate an invasion of the coronary vessels by tumor.[50]

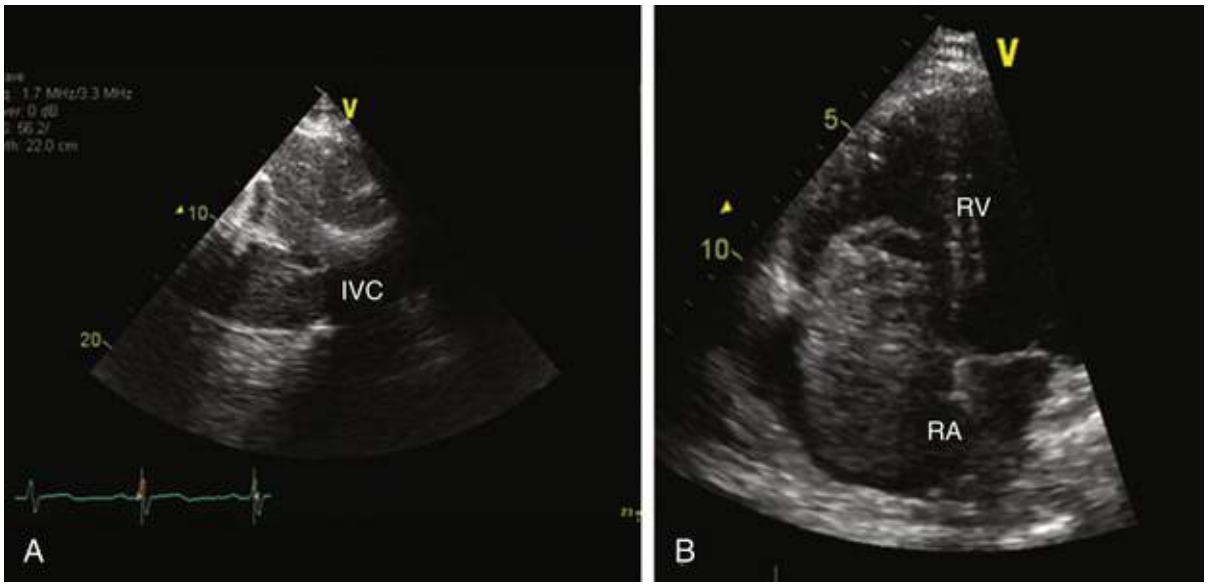

FIGURE 95.16 Renal cell carcinoma. **A,** Renal cell carcinoma invading the inferior vena cava (IVC), **B,** Renal cell carcinoma invading the right atrium (RA) and prolapsing into the right ventricle (RV). A right radical nephrectomy was done, along with removal of the right atrial and IVC tumor.

AO*, aorta; *RA*, right atrium; *SVC*, superior vena cava.

Treatment

Treatment of metastatic cardiac tumors is usually palliative, because the overall prognosis is poor, with more than 50% of patients dying within 1 year.[40] Palliative radiotherapy and chemotherapy in chemosensitive tumors is recommended.[13] In these patients end-of-life care should be discussed and all efforts should be made to improve the quality of life. In highly selected cases, extraordinary surgical approaches can be attempted, such as autotransplantation, but this is an unusual option. The management of a malignant pericardial effusion is typically individualized to a local center's experience, and close

collaboration between oncologists and cardiologists is necessary to ensure an optimal treatment plan.[51] Recent data strongly indicate that infusion of selected chemotherapy may be useful in patients who have a malignant effusion.[52]

Direct and Indirect Complications of Neoplasia

Pericardial Effusion

The differential diagnosis of a pericardial effusion in a patient with a known malignancy includes malignant effusion, radiation-induced or drug-induced pericarditis, idiopathic pericarditis, infectious effusion (including tubercular, fungal, or bacterial), or iatrogenic effusion, secondary to procedures. It is estimated that approximately 40% of patients with cancer and a pericardial effusion were found to have either a radiation-induced effusion (**see also Chapter 80**) or an idiopathic effusion, and only a minority actually have a malignant effusion.[53] Drug-induced pericarditis is typically seen after high-dose anthracycline or cyclophosphamide therapy (**see also Chapter 81**).

Cardiac Tamponade

Approximately one third of patients with pericardial involvement will present with impaired cardiac function, and cardiac compression can progress to tamponade, demanding immediate drainage (**see also Chapter 83**). Patients' symptoms include chest pain, fever, dyspnea, cough, and peripheral edema. Tamponade without two or more signs of an inflammatory process (typical pain, friction rub, fever, diffuse ST segment elevation) is more likely to be malignant (2.9-fold increase in risk).[53] Physical findings and findings on ECG or chest x-ray are typically similar to findings of pericardial effusion due to any cause. Echocardiography demonstrates the effusion, which is usually large, although it does not have to be if the fluid has accumulated quickly. However, tamponade can occur with loculated effusions, and, in these cases, typical echocardiographic signs may be absent. The acute treatment of tamponade includes careful fluid replacement as a temporizing measure if the patient is believed to be volume depleted and hemodynamics are compromised.[53] Echocardiography-guided pericardiocentesis is required. Fluid should be sent for a full battery of diagnostic tests because, as noted, the cause is commonly noncancerous, even in patients with known cancer. In approximately 85% of patients with a malignant effusion, cytologic examination of the pericardial fluid is positive.

Although no randomized clinical trials of various strategies have been done, the risk of recurrence of the effusion appears to be reduced by extended catheter drainage (3 ± 2 days; 11.5% recurrence) as opposed to simple pericardiocentesis.[54] Recurrence of pericardial effusion can often be treated with repeat pericardiocentesis with extended catheter drainage. Some have used intrapericardial instillation of chemotherapeutic agents or sclerosing agents, but it is not clear that this approach is more effective than extended catheter drainage. Occasionally, percutaneous balloon pericardiotomy or pericardiectomy may be required, but patients with malignant effusions have such a poor prognosis (median survival of 135 days in one series of 275 patients) that invasive procedures should be avoided, if possible. Therapy is directed at the underlying tumor.

Constrictive Pericarditis

Constrictive or effusive-constrictive pericarditis is a late complication of chest irradiation that may be

becoming more common because of the longer survival times of patients with breast cancer and Hodgkin disease, who typically receive chest irradiation. This is covered in detail in **Chapter 83**.

Superior Vena Cava Syndrome

In the mid third of the mediastinum, left and right brachiocephalic veins join to form the superior vena cava (SVC). The SVC extends caudally, coursing anterior to the right main stem bronchus, and terminates in the superior right atrium. The SVC is joined posteriorly by the azygos vein and runs posterior to and to the right of the ascending aorta. During its course, the SVC is adjacent to the right paratracheal, azygos, right hilar, and subcarinal lymph node groups. The blood flow in the venous system is under low pressure and the vessel itself is thin walled. Any inflammatory process in the mediastinum or enlargement of the lymph nodes or ascending aorta can cause the SVC to be compressed, resulting in reduced blood flow and eventually complete occlusion (**Fig. 95.17**).

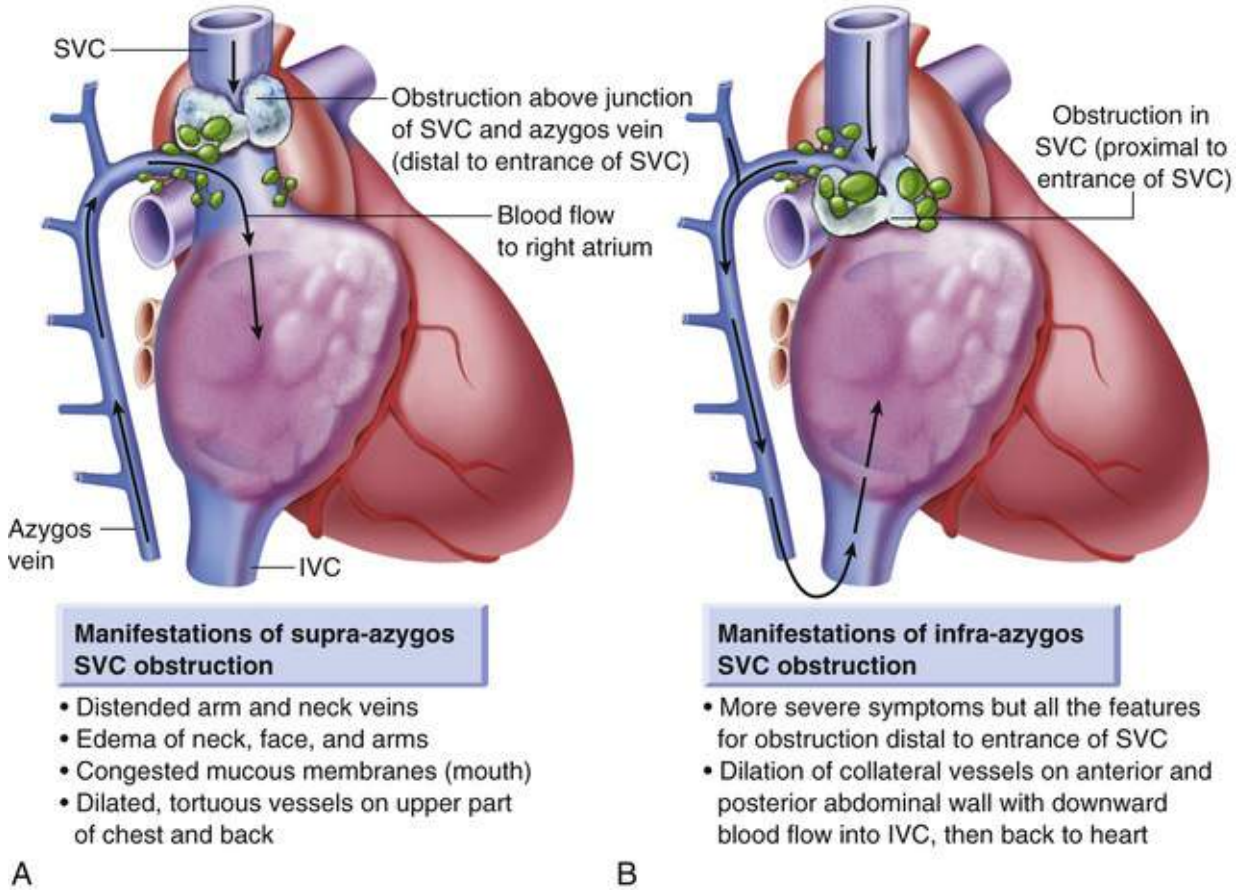

FIGURE 95.17 Anatomy of superior vena cava (SVC) syndrome. **A,** Lymph nodes may obstruct blood return above the entrance of the azygos vein, resulting in edema of the face, neck, and arms and distended veins in the neck and arms and over the upper chest. **B,** Obstruction below the return of the azygos vein results in retrograde flow through the azygos via collateral veins to the inferior vena cava (IVC), causing all the symptoms and signs in **A** plus dilation of the veins over the abdomen. (Modified from Skatin AT (editor): Atlas of diagnostic oncology, 3rd ed. Philadelphia, Elsevier Science, 2003.)

Etiology and Physiology

The SVC syndrome was first described by William Hunter in 1757, in a patient with syphilitic aneurysm of the ascending aorta. Over a period of time, vascular causes have declined, and now the most common

cause of SVC syndrome is malignancy, of which lung carcinoma is the most common, followed by lymphoma and metastatic cancer.[55] Malignancy accounts for more than 85% of causes of SVC syndrome.[56] Other causes of SVC syndrome, which are somewhat benign, account for 3% to 15% of cases and include nonmalignant causes such as thrombosis due to the use of intravascular devices such as catheters or pacemakers, infection, thymoma, substernal thyroid goiter, and aortic aneurysm.[56] Other possibilities include diseases causing systemic vasculitis (e.g., Behçet's disease) and radiation-induced fibrosis.

Clinical Diagnosis

The clinical diagnosis is usually made on the basis of a constellation of symptoms and signs, and a classification system has been proposed.[57] The development of SVC syndrome is usually insidious but occasionally it may develop rapidly. The severity of the syndrome depends on the rapidity of onset of the obstruction and its location. The more rapid the onset, the more severe the symptoms because collateral veins do not have time to distend to accommodate an increased blood flow. A usual patient presentation involves facial edema, dyspnea, and cough.[55,58] Facial edema is most frequently seen; it is worse in the morning and gets better during the day as the patient ambulates. Other less frequent symptoms include stridor, headache, syncope, dizziness, hoarseness, and confusion.[55,58] Common findings on examination include facial edema, distended neck and chest veins, arm edema, and facial plethora.[55]

Laboratory Investigation

Investigations primarily depend on whether the underlying cause is known or not. In the case of a presentation with no prior diagnosis, a chest x-ray, CT image of the chest, and potentially a bronchoscopic examination may reveal lung cancer as the most common cause. CT imaging is usually helpful because it provides a detailed evaluation of the venous system and also helps to identify the principal causes, such as a neoplasm, thrombosis due to central catheters, or infection resulting in sclerosing mediastinitis.[59] Magnetic resonance venography can be used as an alternative to CT scan in patients who are allergic to contrast dyes or in whom a CT scan cannot be obtained for some other reason. Intravenous venography is another option in patients who may not be able to undergo CT scan.

Treatment

The treatment is directly related to the underlying cause. In cases of known malignancy, systemic chemotherapy and radiation therapy are typically carried out. If the main cause of SVC obstruction is thrombosis, stent deployment is an attractive option.[60,61] Surgical bypass of an obstructed SVC is another option, especially if sufficient diagnostic tissue cannot be obtained by other measures.

Valvular Disease

It is certainly common for cardiac tumors to directly affect valvular structures; the type of tumor, its location, its size, and any associated infectious or thrombotic conditions are all factors. An additional tumor that classically has an impact on cardiac valvular structures is the carcinoid tumor. Patients with carcinoid are at substantial risk of developing severe tricuspid regurgitation, which may require surgical repair or replacement. The valvular abnormality includes tethering of the leaflets, resulting in poor coaptation. This can become a difficult condition to manage medically and may require surgical intervention (**Fig. 95.18**).[62]

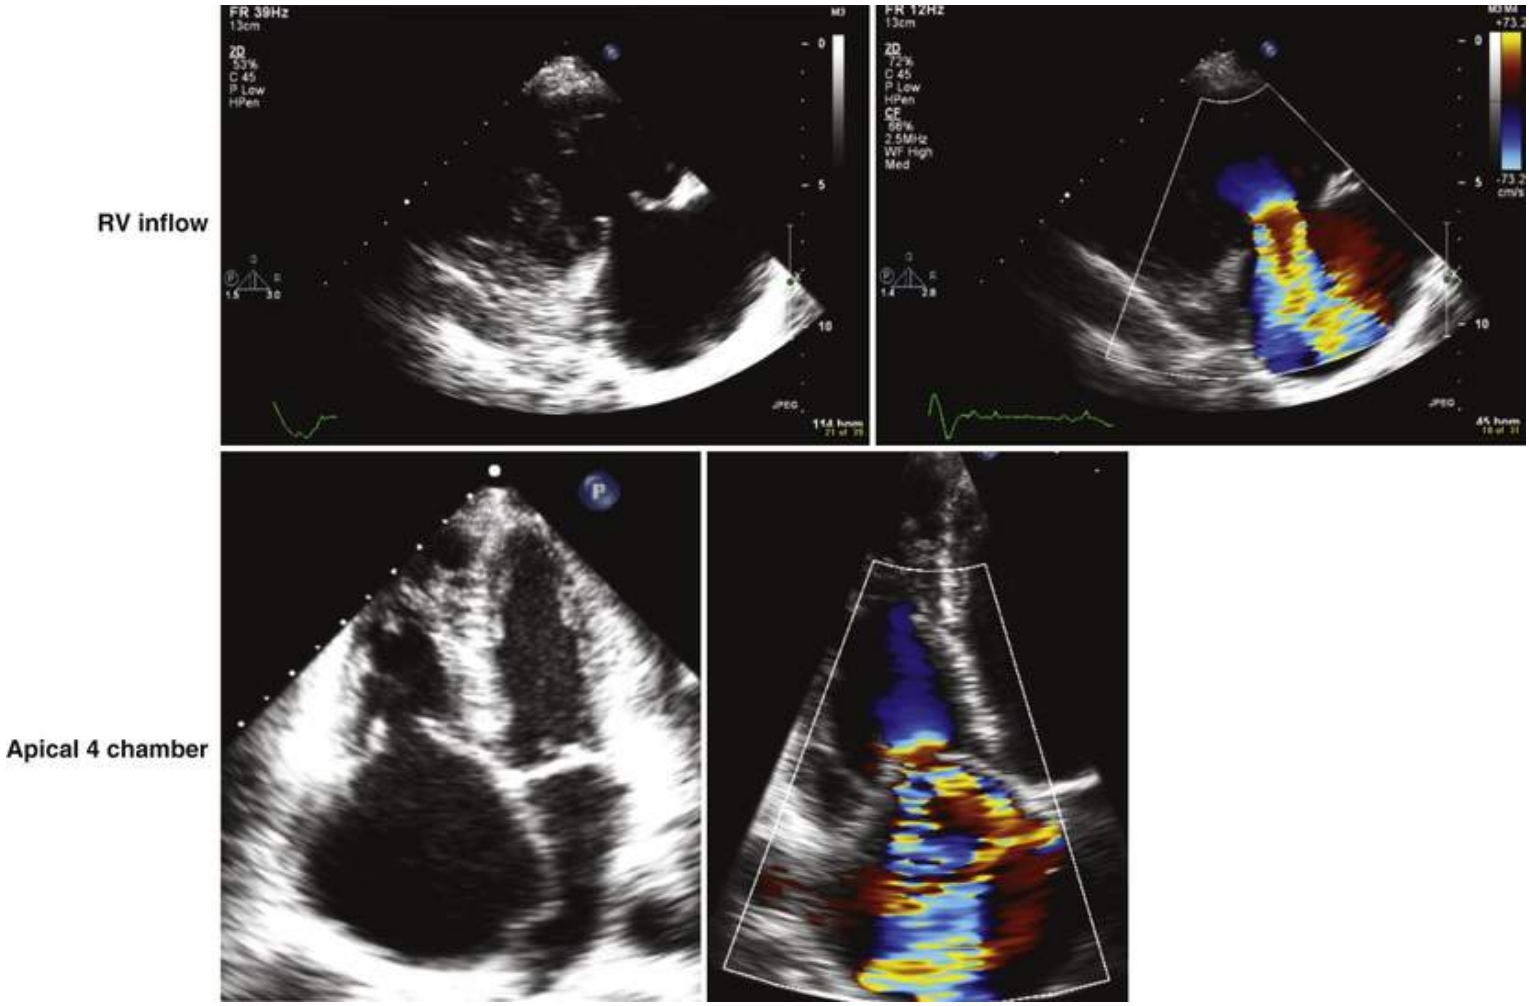

FIGURE 95.18 A typical 2D echocardiographic image of severe tricuspid regurgitation that is commonly encountered in a carcinoid tumor. There is poor coaptation of the tricuspid valve leaflets with tethering, which is seen in many instances.

Future Perspectives

The clinical outcome of patients who have a primary cardiac tumor heavily depend on early detection and prompt, appropriate treatment. Frequently, cardiac tumors are only discovered after a patient experiences a period of a confusing constellation of symptoms, which are ultimately connected to an abnormal image that suggests a cardiac tumor. As a result, the stage of disease is commonly advanced at the time of diagnosis. Once a primary cardiac tumor has been diagnosed, the patient should be managed by a multidisciplinary team, including medical oncologists, radiation oncologists, cardiologists, and cardiac surgeons. Over the last few years, increasing use of imaging modalities (e.g., echocardiography, MRI, and CT) has led to an increasing number of incidental findings of a primary cardiac tumor. Current imaging techniques accurately differentiate tumors from other masses only slightly more than 50% of the time. With improvements in echocardiographic, CT, and MRI imaging techniques, identification of all cardiac tumors will be done with a higher degree of certainty. There is no noninvasive technique that can identify whether the tumor is benign or malignant, and a pathologic sample is needed in all cases for that purpose. Improvement in surgical technique has led to minimally invasive approaches, but surgery still entails general anesthesia and a surgical incision and is a major stress for a patient. Continued refinement in surgical tools and approaches will lead to lower rates of morbidity and mortality. Transvenous biopsy of the cardiac mass for pathologic confirmation (under echocardiographic guidance) is done in some centers. Refinement in this technique will enable better sampling in the future. In some centers, PET scanning is

routinely used to evaluate for metastatic disease. Currently, there are no blood tests available that would point to metastasis, and this represents a large unmet clinical need.

Psychiatric and Behavioral Aspects of Cardiovascular Disease

Viola Vaccarino, J. Douglas Bremner

The cardiovascular system has long been considered vulnerable to the effects of psychological factors, and popular wisdom holds stress and emotions as important risk factors for cardiovascular disease (CVD). Physiologic and experimental data as a whole substantiate this belief and support the notion that psychosocial adversities, stressful exposures, and a person's mental health status contribute to cardiovascular risk. These factors may influence the development of CVD across the life course beginning in early life, and may affect the entire spectrum of pathophysiologic factors, from CVD risk factors, to lifestyle behaviors, to the progression of coronary atherosclerosis, to the triggering of acute coronary events.[1]

The *stress response*, an adaptive physiologic mechanism that allows an organism to counteract potentially damaging stimuli, results in stimulation of the sympathoadrenal system and the hypothalamus-pituitary-adrenal (HPA) axis with release of cortisol and catecholamines (**see also Chapter 99**). Activation of the stress system is physiologically useful to counteract the stressor. However, according to the “reactivity hypothesis,” cardiovascular responses to psychological stressors, if prolonged or exaggerated, can promote the development of CVD.[2] Heightened cardiovascular reactivity is posited to increase the cardiovascular risk through a multitude of mechanisms, including, among others, a repeated or sustained increase in blood pressure and heart rate, insulin resistance and other metabolic abnormalities, systemic vascular resistance, autonomic dysregulation, ventricular arrhythmias, and dysregulation of the inflammatory and immune systems (**Fig. 96.1**). A blunted physiologic response to stress, however, is also considered maladaptive and may have adverse health consequences.[3] Chronic, cumulative effects of stress have also been implicated in cardiometabolic risk secondary to increased circulating levels of stress hormones and disruption of the normal neuroendocrine homeostasis and circadian rhythm of the stress system.[4]

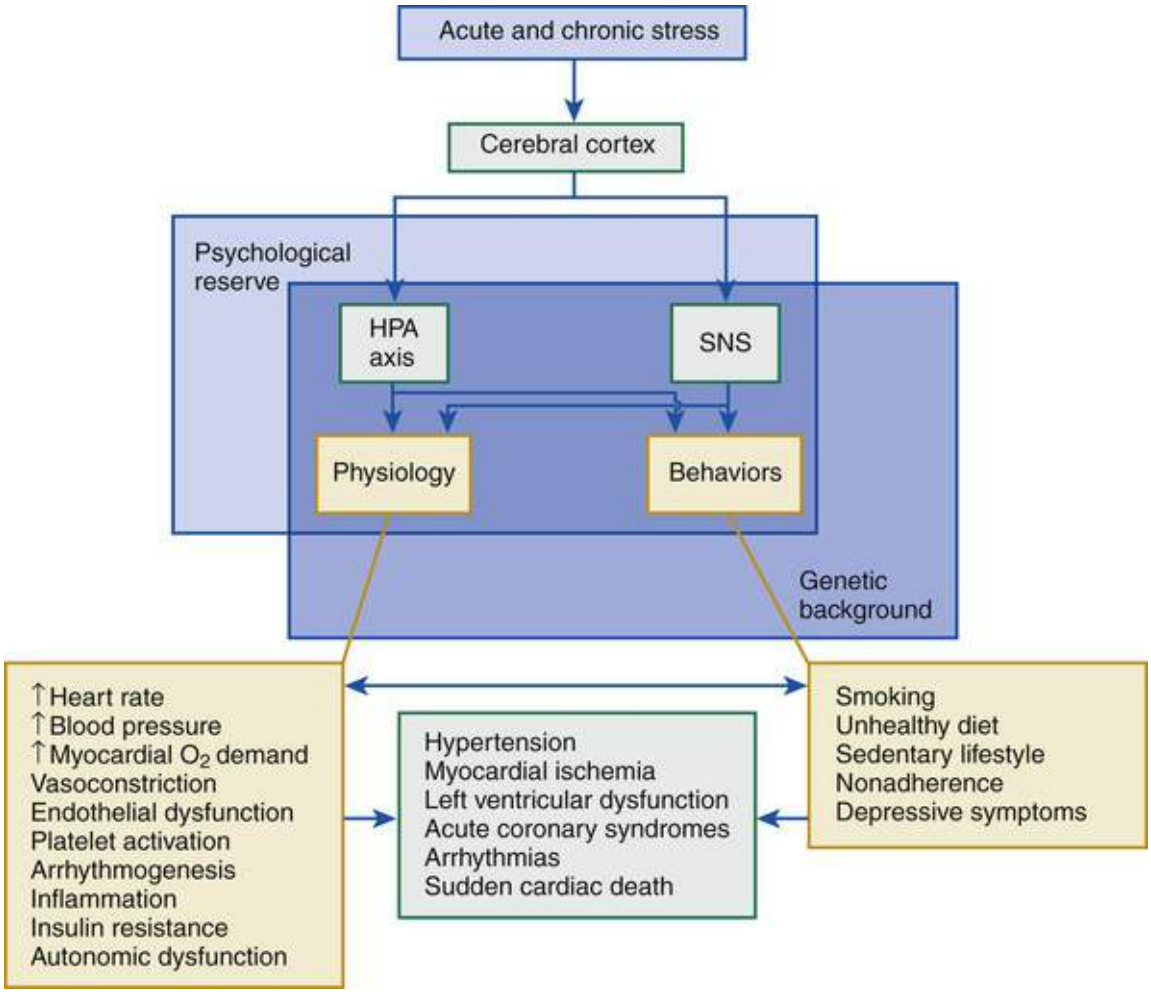

FIGURE 96.1 Potential mechanisms underlying the link between psychological factors and cardiovascular disease. *HPA*, hypothalamic-pituitary-adrenal axis; *SNS*, sympathetic nervous system.

Research in nonhuman primates has provided strong experimental evidence of the adverse cardiovascular effects of chronic stress. Spanning many decades, these studies have demonstrated that chronic psychosocial stress causes endothelial damage and accelerated atherosclerosis.[5] In humans, the adverse effects of experimentally induced stress on the cardiovascular system are well documented (described below under “Mental Stress”). Yet, the effects of naturally occurring stressors on cardiovascular function and CVD risk have been more difficult to demonstrate. One problem is the definition of exposure. Under the general term of “psychosocial stress” investigators have included interrelated but different elements, encompassing a variety of environmental exposures, from traumatic events to job or family difficulties to minor everyday hassles, as well as individuals' responses or emotional states such as perceived distress, depression, and anxiety. Another problem is the lack of standardized measures to consistently define and quantify the type and severity of psychological stress. As discussed in this chapter, to date the most robust evidence implicates a low socioeconomic status, early life adversity, work stress, and depression as risk factors for CVD. In addition to manifest disease, many of these factors have been associated with subclinical markers of CVD. More recently, posttraumatic stress disorder (PTSD) has also been linked to cardiovascular risk. Findings related to other psychosocial/psychiatric factors, such as other forms of self-reported chronic stress/distress, anxiety, and anger/hostility, have been less consistent.

Recognition of psychological and psychiatric factors is important in the management of the cardiac patient, not only because many of these conditions are prevalent and have been linked to adverse cardiovascular outcomes, but also because they are related to health behaviors and lifestyle risk factors that have prognostic significance. These include factors such as lower adherence to treatment

recommendations, lower levels of physical activity, an unhealthy diet, and tobacco smoking. Yet, psychological and psychiatric conditions are less likely to be recognized and managed in current cardiology practice than traditional CVD risk factors. This is because of complexities in definition and assessment, as mentioned above, but also because many symptoms of psychological distress are easily confused with physical disease, for example, fatigue, weight loss, poor appetite, or trouble sleeping.

Current recommendations recognize the need for cardiologists to be more proactive in addressing this important domain of patient care.[6] The goal of this chapter, therefore, is to review key epidemiologic and pathophysiologic evidence linking psychological factors to CVD and discuss their management in the current practice of cardiology. For clarity, we will classify psychiatric and behavioral aspects into general categories of acute stressful events; chronic stressors (including, among others, work stress, low socioeconomic status, and marital and caregiving stress), mental health and psychiatric diagnoses (including depression, anxiety, and posttraumatic stress disorder), and personality traits.

Acute Stress

Stressful and Emotional Triggers of Acute Cardiovascular Events (See Also Chapter 51)

Many studies, albeit not all, have demonstrated an increase in hospital admissions for acute coronary syndromes after emotionally stressful events such as natural and industrial disasters and terroristic attacks.[1] When causes of death were examined, there was no increase in noncoronary deaths. A notable exception to these statistics is the World Trade Center terrorist attack in New York City on September 11, 2001. This event was not linked to a sudden increase in cardiac death or acute coronary care admissions immediately following the attack. It is possible that this event, which was observed by most New Yorkers through news reports on television, did not cause acute stress to the same extent as an incident might that poses a direct threat to personal safety. However, the incidence of cardiovascular ailments diagnosed by physicians increased by more than 50% in the next 3 years. Furthermore, ventricular arrhythmias more than doubled among patients with implantable cardioverter-defibrillators (**see also Chapter 39**), but this increase did not occur until 3 days after the event and persisted in the next 30 days. These data suggest a subacute or chronic impact of the attack rather than an acute triggering effect.

Studies were also conducted during major sporting events such as the Football World Cup, with some evidence of increased cardiac event rates in the cities or regions of the teams involved, especially when the team lost, although not all studies have been consistent.[1] A limitation of these population-level studies is the lack of information on the circumstances surrounding cardiac events for the individuals affected. Apart from emotional stress, cardiac events could be triggered by concomitant factors, for example, vigorous physical exertion (such as running away), heavy eating and drinking, environmental tobacco usage, or outdoor temperature. It is often difficult to rule out these alternative explanations completely. In this respect, studies of emotional triggers at the individual level, where patients are asked about their experiences prior to symptom onset, should provide useful information. On the other hand, patient self-reporting may be affected by recall bias. A study design that attempts to reduce this bias is the case-crossover design, which uses subjects as their own controls by comparing the frequency of a specific exposure in the hours immediately preceding symptom onset with its frequency in a control period, for example, a few days earlier.

Several studies have used this design to examine emotional triggers of acute cardiovascular events.

Among these, acute anger has been studied most extensively. In the Determinants of Myocardial Infarction Onset Study (Onset Study), 2.4% of patients reported being very angry or furious in the 2 hours before acute myocardial infarction[7] (**see also Chapter 58**). In comparison with other times in the previous year, the risk of a myocardial infarction was 2.4 times higher in the 2 hours after self-reported outbursts of moderate or extreme anger, with a greater risk for each increment in anger intensity. The results were not materially different when adjusted for physical activity or consumption of coffee and alcohol. In a systematic review including nine independent case-crossover studies of anger outbursts and acute cardiovascular events, all studies found that there was a higher rate of cardiovascular events in the 2 hours following outbursts of anger compared with other times, although the effect estimate varied across studies.[8] The pooled estimate of risk for acute coronary events was greater than fourfold. Despite this high relative risk, an individual's absolute risk of a cardiovascular event following an anger episode is small. It is higher for individuals with an elevated baseline cardiovascular risk and for those who have frequent outbursts of anger.

In addition to anger, acute negative emotions such as grief and sadness can act as triggers of cardiovascular events.[1] In the Onset Study, using the case-crossover approach, researchers found that the incidence of acute myocardial infarction increased 21-fold in the 24 hours following the death of a significant person.[9] Taking advantage of a large primary care database in the United Kingdom, a recent study reported a prospective relationship between bereavement and increased risk of cardiovascular events. Within 30 days of their partner's death, bereaved people experienced a doubling of the risk of cardiovascular disease, which attenuated after the first 30 days. Other acute stressors that have been linked to increased risk of cardiac events include work-related stress, such as a high-pressure deadline, and exposure to heavy traffic. Again, the absolute risk from these potential triggers is small, but it goes up with an increasing individual cardiovascular risk status.[9] Using population-attributable fractions, it has been estimated that negative emotions play a role in 4% and anger in 3% of acute cardiac events.

Stressful life events have been linked to acute myocardial stunning in susceptible individuals with severe, reversible left ventricular dysfunction, a condition known as takotsubo cardiomyopathy.[10] These patients, almost all women, also show exaggerated sympathetic nervous system stimulation as indicated by markedly elevated plasma catecholamine levels.

Mental Stress

A useful method of assessing the effects of stress and emotion on cardiac function is to measure transient ischemic responses to a standardized psychological stress challenge in the laboratory, or “mental stress test,” using mental arithmetic, color naming, public speeches, and similar tasks (**see also Chapter 57**). This methodology has the advantage of direct experimental manipulation where potential confounding factors can be controlled or eliminated and causal factors and their mechanisms directly investigated. However, this approach is necessarily limited to short-term responses to acute stress artificially induced in the laboratory, and thus may lack practical significance. To address this issue, longitudinal studies have investigated the link between mental stress–induced cardiovascular responses and future CVD events. Greater cardiovascular reactivity to mental stress (mostly defined as acute changes in blood pressure and heart rate) and poor recovery from stress (defined as sustained cardiovascular activation above baseline levels during the posttask period) have been associated longitudinally with cardiovascular outcomes, including elevations in blood pressure and CVD events, whereas evidence of an association with atherosclerosis endpoints such as carotid intima-media thickness and coronary artery calcifications is more limited.[2] Cortisol and catecholamine responses to mental stress have also been related to future

hypertension and other CVD endpoints.

In addition to cardiovascular reactivity, an important phenomenon that has been studied in conjunction with mental stress in cardiac patients is mental stress–induced myocardial ischemia. This condition is analogous to exercise stress ischemia, except that the stimulus is psychological rather than physical.[11]

Mental stress ischemia has been studied with a variety of imaging techniques and a range of stressful stimuli.[12,13] The literature indicates that mental stress ischemia can be induced in one third to two thirds of coronary heart disease patients; younger women with coronary heart disease appear especially susceptible.[14] It is typically painless, and occurs at lower levels of oxygen demand than ischemia due to physical exertion. In addition, mental stress–induced ischemia is generally not related to the severity of coronary artery disease, suggesting that it is not simply a reflection of coronary disease severity. Patients may develop ischemia with mental stress but not with exercise or pharmacologic stress, although results vary. Ischemic responses are induced not only by severe emotional stress, but also by milder challenges similar to those that might be encountered in everyday life. In fact, mental stress–induced (but not exercise-induced) myocardial ischemia is correlated with ischemia measured in daily life ambulatory monitoring. Thus, mental stress testing could potentially provide a means for the identification of patients vulnerable to myocardial ischemia in everyday life.

All the results published to date have indicated that mental stress–induced ischemia is a predictor of a poor prognosis. Five longitudinal studies with a follow-up of 1 to 5 years have found a consistent doubling of the risk of death or subsequent cardiac events. In these studies, coronary heart disease patients with mental stress ischemia were compared with those without mental stress ischemia, independent of coronary disease severity and CVD risk factors.[15] Although the samples of patients followed longitudinally to date are small, current evidence indicates that myocardial ischemic responses to standardized mental stress are prognostically important at least as much as responses to exercise-induced ischemia.

Potential Mechanisms of Acute Stress as a Trigger of Cardiac Events

A key pathophysiologic event underlying an acute coronary event is the progression from a stable plaque to a “vulnerable” plaque. No direct evidence exists to show that acute psychological stress causes atherosclerotic plaque rupture or erosion. However, acute episodes of stress or intense emotions may trigger acute coronary events in susceptible individuals by affecting plaque stability and disruption. This occurs through hemodynamic activation (increases in blood pressure and heart rate), increases in systemic vascular resistance, coronary vasoconstriction, inflammation, and prothrombotic effects, among others. Triggering usually takes place against a background of advanced atherosclerosis; thus it is considered rare in people without underlying coronary artery disease.[16]

The mechanisms behind emotional triggering of acute myocardial ischemia, such as ischemia induced by mental stress, are likely multiple and may include hemodynamic changes, such as increases in blood pressure, heart rate, systemic vascular resistance, and coronary artery vasoconstriction. It is clear, however, that different hemodynamic responses underlie ischemia triggered by acute psychological stress as compared with exercise stress.[11,17] Myocardial ischemic responses to mental stress occur at a lower rate-pressure product than responses to exercise-induced ischemia in the same patients, although the hemodynamic response tends to be larger than in patients who do not become ischemic. Both people with and without preexisting coronary heart disease who develop mental stress ischemia show an increase in systemic vascular resistance, suggesting that a rise in afterload caused by peripheral vasoconstriction may

play a role in ischemia induced by psychological stress.[13] By contrast, systemic vascular resistance is generally decreased by exercise.

Mental stress may also cause abnormal coronary artery vasomotor responses. Patients with atherosclerosis may undergo a paradoxical constriction during mental stress, particularly at points of stenosis, which may reduce myocardial blood flow and thus result in ischemia. Both coronary endothelial dysfunction and vasomotor abnormalities in the coronary microvasculature appear to play a role in myocardial ischemia triggered by psychological stress.

Acute mental stress can also induce cardiac electrical instability, including an increase in T-wave alternans and other measures of abnormal cardiac repolarization that have been related to arrhythmogenesis and sudden cardiac death[18] (**see also Chapter 34**). Autonomic dysfunction and its effects on cardiac electrophysiology form another likely process underlying acute adverse effects of stress on the heart (**see also Chapter 99**). Both sympathetic activation and parasympathetic withdrawal can stimulate arrhythmias and lower the threshold for ventricular fibrillation. Heart rate variability, a measure of the beat-to-beat changes in heart rate as the heart responds to internal and external stimuli, is an accepted noninvasive measure of overall cardiac autonomic function (**see also Chapter 12**). Reduced heart rate variability predicts coronary heart disease in population studies, as well as death, particularly sudden cardiac death, in patients following acute myocardial infarction.[19] Heart rate variability is reduced during acute mental stress in the laboratory, and was found to be reduced during major disasters, such as earthquakes or terroristic attacks, in studies of patients who were undergoing ambulatory electrocardiographic monitoring at the time of the event.[1] These mechanisms may underlie the described connection of acute stress with life-threatening cardiac arrhythmias and sudden cardiac death.

Inflammation and immunity are increasingly recognized as key factors in mediating cellular responses to acute psychological stress. Noradrenaline-dependent adrenergic stimulation due to stress activates the transcription factor nuclear factor κB in circulating monocytes, resulting in initiation of the inflammation cascade. Thus psychosocial stress stimulates mononuclear cell activation and subsequent immune and inflammatory responses, which may result in myocardial ischemia.[20] At the same time, stress-induced neuroimmune circuits involving microglia activation in the brain and sympathetic outflow to the peripheral immune system further reinforce stress-related behaviors and the inflammatory phenotype.[21]

Thus, there are multiple physiologic responses secondary to emotional stress that could trigger cardiac ischemia or sudden death. However, presently little prospective information is available to link these mechanisms of acute stress to cardiovascular endpoints.

Acute Stress and Cardiovascular Disease: Clinical Implications

The clinical significance of acute emotional triggers of cardiac events has not been clearly established. Although the relative risk associated with acute stress is substantial, the absolute risk is smaller, given that these events are relatively uncommon. Accordingly, the population-attributable risk (i.e., the reduction in disease that would be observed if the risk factor were entirely eliminated) is not large (≈4%), but it is fairly similar to that of other acute triggers of coronary events, such as physical exertion, heavy traffic, or excessive alcohol consumption. Furthermore, it is likely that this risk only affects a subset of vulnerable individuals. Some patients may be particularly susceptible to physiologic responses to emotional stimuli and therefore be at higher risk of unfavorable cardiovascular consequences due to stress. If such patients could be identified in advance, specific procedures could be put in place to minimize their exposure to an emotional trigger as well as reduce the risks associated with such exposure.

Although it has been argued that programs that would increase awareness of psychological triggers among clinicians and the public would be beneficial, such programs in general lack evaluation. Whether therapies for CVD prevention, such as aspirin, β-blockers, statins, and angiotensin-converting enzyme inhibitors, also protect against harmful effects of emotional triggers, is similarly not known.

Chronic Stress

Work Stress

Work stress has been extensively studied for its potential adverse cardiovascular effects. A dominant model of work stress includes the "job strain" model developed by Karasek and Theorell.[22] The job strain model postulates that high work demands in combination with low control produce stress, because workers in low-control jobs cannot moderate work pressure by organizing their time or by other means. A third dimension of social support at work was later added, such that the adverse health effects of job stress are greatest in workers who lacked support from colleagues. An alternative model is the effort-reward imbalance model, which proposes that stress occurs when there is a mismatch between high workload and low payback in terms of money, job security, or other forms of recognition. Both these models have been linked to adverse cardiovascular events.[23] In a large metaanalysis including 1.5 million person-years at risk, and 2358 new coronary cases, job strain was associated with a 23% higher rate of coronary heart disease. The association remained after adjustments for socioeconomic status and lifestyle and conventional risk factors, and was noted across sexes, age-groups, socioeconomic strata, and regions.[24] There is less knowledge about whether similar risks apply to patients with established coronary disease; however, studies of patients returning to work after a myocardial infarction reported a 70% or more increase in risk of recurrent events or cardiac death in patients with high job strain or effort-reward imbalance at work.[25] Some studies have suggested gender interactions showing stronger or weaker effects among women than men, but data specific for women are limited, because most studies have included predominantly male working populations.

Low Socioeconomic Status

Socioeconomic status (SES) is generally defined by interrelated factors such as occupational status, economic resources, education, and social class. The existence of a social gradient in health and disease has long been recognized.[22] Beginning many decades ago, the Whitehall Study of British Civil Servants reported that, even among people who are not poor, there is a social gradient in mortality and morbidity, including CVD, from the bottom to the top of society. Such results have been confirmed in many other contexts, including in the United States. Low SES is accompanied by poorer health habits and higher frequencies of standard CVD risk factors, such as hypertension, obesity, smoking, and unhealthy diet, which, however, partially account for the CVD gradient due to social class. In the Whitehall Study, four health behaviors (smoking, alcohol use, diet, and physical activity), and their variation over the follow-up period, explained 45% of the social gradient for the CVD mortality risk.

Psychosocial and material resources play a critical mediating role in the SES and health connection, and the origins of such effects are apparent as early as in childhood. These include financial hardship, poorer housing, neighborhood status, social discrimination and isolation, depression, and adverse working conditions. Employment instability, unemployment, and job loss are additional correlates of SES that have been related to cardiovascular risk.[26]

At least part of the SES effects on health is related to the neighborhood built environment. Degradation of the neighborhood environment, residential turnover, a decline in property values due to foreclosures, safety concerns, lack of access to healthy foods or opportunities to be physically active may contribute to stress, weight gain, increase in blood pressure, and CVD risk.[27,28] Thus, low SES can be viewed as a composite of chronic stressors that may result in adverse behavioral and physiologic consequences.

HPA axis and autonomic dysfunction is observed as SES levels decline, and may increase the risk for central obesity and metabolic risk factors. The Whitehall II study, for example, described a close relationship between lower social position and increased prevalence of metabolic syndrome and its individual components,[22] an association that was minimally affected by differences in health behaviors. Disturbances in neuroendocrine and cardiac autonomic activity, compatible with activation of the neuroendocrine stress axes, were also noted in subjects with metabolic syndrome and subjects of lower SES status. Notably, psychosocial factors (socioeconomic status and job-related stress) explained a large portion of the association between adrenal/autonomic disturbances and metabolic syndrome.

Social Isolation, Lack of Support, and Marital and Caregiving Stress

Both the number and the quality of a person's social contacts have been related to CVD and total mortality rates. Social relationships may improve health in a variety of ways, such as providing instrumental and emotional support and encouraging a person to follow a healthy lifestyle and seek health care if necessary. Emotional support may also buffer the adverse effects of psychological stressors. Reverse causation is possible in individuals who are ill or otherwise at risk for disease, because they may become less engaged with others.

Although a number of population studies have shown an elevated risk of CVD associated with social isolation or lack of support in initially healthy populations, results are not consistent, perhaps because they may reflect variations in measurements and definitions. The effects appear more robust in prognostic studies of patients with coronary heart disease. Both instrumental and emotional aspects of social contacts have been linked to recurrent events and increased mortality rates in cardiac populations, and in general the association persisted after adjusting for lifestyle behaviors and disease severity. In contrast, structural aspects of support, defined as the size of the network of people surrounding an individual, and his or her interactions with this network, have shown a less consistent association with cardiovascular outcomes; social isolation has been associated with increased mortality rates in population studies, however.[29,30]

Marital status is one aspect of a person's social support that has been studied in some detail. Being married has been related to a lower risk for death from ischemic heart disease in both women and men.[31] Conversely, divorce and marital and caregiving stress have been related to an excess CVD risk.[32] The link between marital stress or marital quality and cardiovascular risk is more established among women, although there is little evidence for a true gender difference.[33,34] Caregiving for an ill family member can be quite stressful, and has also been associated with a risk for CVD and death.[35,36] In the Caregiver Health Effects Study, caregiving was associated with a 63% higher adjusted mortality risk. Caregiving may not affect all caregivers adversely, but it seems especially to be a problem for those who report feeling strain.

Adverse Childhood Experiences

Childhood adversity, such as physical, emotional, or sexual abuse, childhood neglect, or household dysfunction, is an emerging risk factor for CVD. Sixty percent of the U.S. population reports at least one

type of such an adverse experience, and 24% report three or more.

Over the years, several studies have documented a link between childhood maltreatment and a number of medical outcomes in adulthood, including CVD and several CVD risk factors such as obesity, diabetes, and hypertension. Most studies, however, have used a retrospective design. More recently, studies using a prospective assessment of outcome events have confirmed that reporting such early exposures predicts the future cardiometabolic health.[37] Exposure to adversity in childhood has also been linked to a faster rise in blood pressure measured longitudinally from childhood to young adulthood.[38] Many potential behavioral, emotional, and biologic explanations may underlie this relationship.[39] In terms of biologic effects, adverse childhood experiences have been related to enduring changes in multiple organ systems, including the nervous, endocrine, and immune systems, changes that have often been observable since childhood.[40] A repeated or chronic activation of the stress systems in exposed youth, especially the HPA axis, is suspected to play a role, and to exert long-term effects on biologic aging and cardiovascular health. Childhood adversity is also a common antecedent of depression and PTSD, which have both been linked to cardiovascular risk through multiple mechanisms.

Chronic Stress and Cardiovascular Disease: Clinical Implications

There are few data on the potential clinical utility of incorporating measures of chronic stress for CVD risk prediction, for prognostic assessment, or for the clinical management of cardiac patients. Some studies, however, suggest that consideration of factors such as work-related stress, long working hours, or measures of SES in addition to standard risk factors may improve the CVD risk prediction. In a nationally representative population in the United Kingdom, incorporating an index of social deprivation based on census data with other risk factors into a clinical algorithm for CVD risk prediction (the QRISK2) improved the accuracy for identification of people at high risk. Accordingly, current European guidelines on CVD prevention recommend assessment of psychosocial stressors by using standardized instruments or even a brief questionnaire, and recommend tailored clinical management of these factors in individual patients (class of recommendation IIa, level of evidence B).[41] In the United States, no established algorithm currently exists that incorporates SES or other measures of chronic stress for CVD risk assessment, and no such indicators are included in prevention guidelines.

Mental Health and Psychiatric Disorders

Depression, anxiety, and PTSD differ from other psychological factors considered in this chapter because they are psychiatric disorders and as such are amenable to clinical diagnosis and management. Most of the evidence linking these factors to CVD risk, however, has involved the measurement of symptom scales rather than psychiatric diagnoses. Depression has received particular attention and has shown the most robust results for a relationship with CVD.

Depression

Depression is a highly prevalent condition and growing global problem. It is three times more common among cardiac patients than controls, and 15% to 30% of cardiac patients have significant depression.[6] This prevalence is higher in women than men, and is especially elevated in young women with heart

disease.[42]

Depression as a risk factor varies from mild (subclinical) depressive symptoms to a clinical diagnosis of major depression. As defined by the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, major depression is characterized by a depressed mood or anhedonia (loss of interest or pleasure) for at least 2 weeks accompanied by significant functional impairment and additional somatic or cognitive symptoms.

Many metaanalyses of observational studies have been conducted and all have provided evidence for an association between clinical depression (or depressive symptoms) and CVD risk, both among individuals initially free of heart disease, and in a variety of heart disease patient populations, including patients with acute coronary syndromes, congestive heart failure, or stable coronary heart disease and those who have undergone coronary bypass surgery. However, individual studies have produced significantly varied risk estimates and have also varied in their ability to adjust for potential confounding factors such as smoking, physical inactivity, and severity of coronary heart disease. In the most recent metaanalyses of 30 prospective cohort studies conducted among individuals initially free of heart disease, depression was associated with a 30% increased risk of future coronary events.[43] The association remained significant in the group of studies that adjusted for potential confounders, such as lifestyle behaviors and sociodemographic factors. Among patients with coronary heart disease (such as a myocardial infarction) with comorbid depression, the risk for recurrent events or death is also generally elevated compared with nondepressed patients, and the risk is especially high for cardiac death, with a pooled odds ratio of 2.7.[6]

Recent literature has also suggested that depression is a heterogeneous condition in its relationship with CVD, and that specific subtypes may be more important, such as new-onset depression after acute coronary syndromes, treatment-resistant depression, or somatic depressive symptoms as opposed to cognitive symptoms. However, there is no clear consensus on whether these different phenotypes carry variations in risk.

Many potential mechanisms have been postulated for the relationship between depression and CVD.[44] Depression is associated with other cardiovascular risk factors, including smoking, sedentary lifestyle, obesity, diabetes, and hypertension. Although many studies have shown an independent effect of depression on cardiac outcomes after adjusting for these factors, most found that these factors account for a significant portion of the risk for cardiac events associated with depression. In coronary heart disease patients, depression is also associated with a severity of functional impairment. If functional limitations become translated into a decrement in physical activity or self-care, this could accelerate the progression of coronary heart disease. In addition, depressed patients show a lower adherence to medication regimens, lifestyle risk factor modification, and cardiac rehabilitation than nondepressed patients. Thus depression may affect cardiac outcomes via behavioral mechanisms involving a healthy lifestyle, a delay in seeking treatment, and nonadherence to secondary prevention. However, whether, and the extent to which, these factors mediate the effect of depression on cardiac outcomes is not clear.

Depression is characterized by dysregulation of the HPA axis and the sympathoadrenal system, with increased, or prolonged, release of cortisol and norepinephrine and disruption of normal circadian patterns. For example, the awakening cortisol response, as well as the nighttime cortisol levels, tends to be increased in depression. In addition, HPA axis hyperactivity has been observed in remitted depression and in nonaffected offspring, suggesting that it may represent a vulnerability factor, possibly a genetic one, rather than a state indicator.[44,45] Although longitudinal data are limited, higher morning cortisol levels and a flatter slope in cortisol across the day have been associated with an increased risk of subsequent cardiovascular death; a higher cortisol response to an acute stressor has also been linked to incident

hypertension.[46]

Several studies have also shown that depressed individuals have reduced parasympathetic flow and lower heart rate variability, a noninvasive measure of cardiac autonomic function, although data are not entirely consistent and antidepressant treatment may also be involved in these effects.[44] Additional indications of autonomic dysfunction that have been described in depressed cardiac patients include an increased heart rate response to orthostatic challenge, an abnormal heart rate response to premature ventricular contractions, and abnormal ventricular repolarization. All these factors are predictors of death in cardiac patients.

Neurobiologic and autonomic abnormalities in depression, as described above, may lead to repeated or sustained elevations in blood pressure, heart rate, and plasma glucose; insulin resistance; and dyslipidemia, as well as systemic inflammation and endothelial dysfunction. In particular, metabolic and immune dysregulation have consistently been reported as frequent correlates of depression. Depression may also facilitate weight gain as a result of inactivity and an unhealthy diet, which in turn promotes metabolic alterations and inflammation. Recent metaanalyses reported significantly higher levels of inflammatory markers, such as interleukin (IL)-6 and tumor necrosis factor (TNF)-α, in depressed subjects compared with controls.[47] However, effect sizes were modest, with slightly stronger effects for studies using clinical diagnoses of depression rather than symptom scales.[48] Furthermore, results in CVD patients are inconsistent, and to date there is no strong evidence that inflammation is a mechanism in the link between depression and cardiovascular outcomes. Rather, it is likely that there is a bidirectional link between inflammation and depression. For example, immunotherapy with interferon-α can precipitate depression. Cytokines produced peripherally can access the brain, and can induce behavioral responses analogous to a depressive episode.[49] Some evidence also suggests that marked inflammation during an acute coronary syndrome predicts depression onset.[50]

Finally, growing evidence suggests that depression and CVD may be different phenotypic expressions of the same genetic substrate.[51] Such genetic pleiotropy may also underlie the relationship between depression and biologic pathways of risk that are implicated in CVD, such as inflammation or autonomic nervous system and metabolic dysregulation.[44,51] Genes involved in these pathways could be precursors of both depression and CVD, leading to a noncausal association between these two phenotypes.

Anxiety

Anxiety, like depression, includes a large spectrum of conditions, from psychiatric diagnoses amenable to clinical treatment, to subthreshold symptoms that are common in the general population. These are prevalent conditions; as many as 18% of Americans may be affected by one or more anxiety disorders. In general, the various anxiety disorders (generalized anxiety disorder, panic disorder, phobic anxiety, and obsessive-compulsive disorder, among others) are distinct, but they also share a broad range of common features and frequently occur together. Most studies examining the relationship between anxiety and coronary heart disease have considered anxiety symptom scales rather than a clinical diagnosis of anxiety disorder. Study results for an association between anxiety and risk of CVD overall point toward a small increased risk.[2] Studies have differed in their measurement of anxiety, and very few examined clinically diagnosed anxiety disorders, which may differ in their biologic substrate and therefore their relationship with CVD. Anxiety often coexists with depression, and few studies have attempted to tease apart these two conditions; this separation may hardly be feasible given the high correlation between them. Alternatively, this high comorbidity may argue for anxiety and depression as linked constructs and their impact on CVD risk may be reflective of shared components of depression and anxiety, such as more

general distress.[52]

One cognitive aspect of anxiety that might be particularly relevant to CVD risk is rumination, a form of uncontrollable intrusive thinking about something distressing. Rumination has not only been implicated in chronic distress and depression, but also in the development of CVD.[52] Phobic anxiety and panic attacks have also been associated with CVD risk and sudden death in population studies.

Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) is caused by exposure to a psychologically traumatic event, defined as a threat to life to self or someone close. Traumas can include events such as military combat, childhood abuse, sexual assault, or a motor vehicle accident. Most people think of PTSD as a disorder of veterans; however, in absolute numbers, there are more civilians with PTSD from noncombat events than there are veterans with combat-related PTSD. The lifetime prevalence of PTSD in civilians has been estimated at 1.3% to 7.8%.[53] Although trauma is required for the development of PTSD, only a minority of individuals exposed to trauma will develop the disorder. PTSD is a highly disabling condition; its symptoms are classified in main clusters of reexperiencing (e.g., recurrent memories of the traumatic event that the patient cannot control), avoidance (avoiding things that would remind the person of the trauma), and hyperarousal (e.g., trouble falling or staying asleep, irritability, outbursts of anger, and difficulty concentrating).

In the neurobiologic aspects of PTSD, brain areas involved in both fear and memory are affected, including the hippocampus, prefrontal cortex, and amygdala,[54] as well as stress-responsive neuroendocrine systems including the HPA axis and the sympathetic nervous system that may affect cardiovascular risk.[53]

Growing evidence links PTSD to an increased risk of CVD; across studies, PTSD has been associated with an approximately 50% increased risk for coronary heart disease.[55] Emerging data also suggest that PTSD may be a consequence of, in addition to a cause of, acute, life-threatening cardiovascular events. Among patients with acute coronary syndromes or acute stroke, PTSD is prevalent (10% to 20%) and leads to approximately a doubling of subsequent events.[56,57]

As for other psychiatric disorders, individuals with PTSD are more likely to engage in adverse lifestyle behaviors, such as inactivity and low adherence, which may predispose to cardiovascular risk factors such as obesity, diabetes, and hypertension. The avoidance symptoms of PTSD can lead to social isolation and a lack of emotional and material resources. PTSD is also frequently comorbid with other psychiatric conditions that may affect cardiovascular risk, such as depression and substance abuse. However, direct biologic mechanisms are also plausible. An emerging model postulates that intrusive memories and other symptoms of reexperiencing in PTSD, as well as hyperarousal symptoms, may lead to repeated, heightened physiologic activation, which, in turn, may cause cumulative long-term damaging effects on the cardiovascular system. These effects may occur through vascular and immune mechanisms.[58]

Mental Health and Psychiatric Disorders: Clinical Implications

Despite the important comorbidity between depression and physical illness, less than half of depressed medical patients are recognized by their physicians, and during an admission for acute myocardial infarction, less than 15% of patients with depression are identified.[59] One reason for this may be uncertainty about whether depression treatment will improve outcomes and thus whether systematic depression screening is warranted in cardiac patients. Indeed, studies to date have not proved that treating

depression can improve cardiovascular outcomes. Investigation in this area has been limited, however. Furthermore, depression remains an important illness in and of itself, which deserves proper evaluation and treatment. In addition to affecting the prognosis, depression substantially affects the quality of life of cardiac patients, and is one of the strongest predictors of nonadherence with medical treatment regimens, which may improve if depression improves.[60] By recognizing and treating depression, we can improve patients' overall well-being and their adherence to medical treatments and healthy lifestyle behaviors. Because the literature overall points to depression as a risk factor and a prognostic factor for CVD, it is reasonable for clinicians to evaluate depression as they would any other risk factor, such as smoking and diabetes.[6]

According to the American Heart Association/American College of Cardiology current guidelines for secondary prevention in patients with CVD, screening for depression is reasonable if patients have access to case management in collaboration with their primary care physician and mental health specialist (class IIa, level of evidence B). Treatment of depression is reasonable for its clinical benefits other than improving CVD outcomes (class IIb, level of evidence C). Patients with severe depressive symptoms or a clinical diagnosis of depression should be evaluated in concert with a mental health specialist as needed.

Anxiety disorders are highly prevalent, and regardless of their possible association with CVD risk, they can cause considerable disability and an impaired quality of life. Anxiety often coexists with depression; in this case, the corresponding impact on quality of life is even higher. Thus, these conditions warrant attention from the cardiologist.

PTSD is emerging as a risk factor for CVD and could also be a consequence of an acute cardiovascular event. Given that almost 1½ million patients are discharged from U.S. hospitals each year with a diagnosis of acute coronary syndrome, over 150,000 patients could develop clinically significant PTSD symptoms as a result (**see also Chapter 58**).[56] Thus, PTSD could contribute substantially to repeat hospitalizations, mortality rates, and health care costs for cardiac patients. Nonetheless, as for depression, the utility of routinely screening for PTSD symptoms in cardiac patients is unknown, particularly in the nonveteran population at large (see also next section). Pharmacologic and psychotherapeutic approaches for the treatment of PTSD and other anxiety disorders are available,[61] and thus recognition and treatment of these disorders could have at least theoretical benefits for symptomatic and functional improvement. The benefit in reducing CVD risk, however, is untested.

Personality Traits

Anger and Hostility

The potentially harmful effects of chronic feelings of anger on health have been suspected since ancient times. Not surprisingly then, anger, hostility, and related constructs have received considerable attention as potential risk factors for CVD. Despite being different constructs, anger and hostility are often used interchangeably, and their interconnection is poorly defined. Hostility is a personality or cognitive trait characterized by a negative attitude toward others. It is one of the dimensions of the type A personality that was believed, in early research, to be a risk factor for CVD, a relationship not supported by later investigation. Anger is an emotional state or trait, characterized by feelings ranging from mild irritation to intense fury or rage toward others. An outburst of anger is a fairly well established trigger of acute coronary events and is discussed earlier in this chapter, in the section on acute stress. Anger as a personality trait, however, is a less established risk factor for CVD. Studies have reported heterogeneous results, with about half of the studies failing to find a significant association between anger or hostility

and coronary heart disease. Although evidence is inconsistent, chronic feelings of anger, cynical distrust, and hostility are at least modestly associated with a risk of both the initiation and progression of CVD.[62] The summary combined estimate for anger and hostility from metaanalyses indicated a modest (<20%), but significant, increase in coronary heart disease incidence in initially healthy populations and a 24% increase in recurrent coronary heart disease events in patients with preexisting coronary heart disease. However, studies of higher quality tended to show smaller and nonsignificant effects. The risk associated with anger and hostility appears to be more marked in men, and is in large part explained by behavioral factors such as smoking and physical activity. Anger and hostility have also been linked to stress reactivity, exaggerated autonomic function, reduced heart rate variability, inflammation, and platelet aggregation.[62]

Type D Personality

The type D (or “distressed”) personality, first introduced in 1995 by Denollet and colleagues, is a personality type that combines negative affectivity and social inhibition.[63] It describes individuals who tend to experience negative emotions (dysphoria, tension, worry) and at the same time are inhibited in their expression of emotions, thoughts, and behaviors in a social context. These investigators were able to link this construct to adverse cardiovascular outcomes and total death in a number of studies of CVD patients. Because type D personality is related to other psychosocial characteristics (hostility, anger, depression, and social isolation), its interconnection with these other factors needs more evaluation. However, this personality type appears to be a predictor independent of depression and other psychosocial stressors. These authors propose that it is the combination of these two traits (negative affect and social inhibition) that is damaging, rather than either one alone.

Personality Traits and Cardiovascular Disease: Clinical Implications

Although literature on personality traits and CVD dates back many decades, consistency of results has been an issue. Particularly for anger and hostility, the effect size appears small; whether personality traits provide predictive and prognostic information above and beyond other better-established psychosocial factors and traditional CVD risk factors needs more evaluation. Finally, it is unclear as to what extent these personality traits may be modifiable by interventions. Because of these issues, the clinical significance of these observations is not well established.

Evaluation and Management of Mental Health in the Cardiac Patient (See Also Chapter 58)

General Considerations

Recognition of psychological and psychiatric factors should be considered in the management of the cardiac patient. Psychological factors are important, not only because these conditions are highly prevalent and affect patients' well-being and quality of life, but also because they act as barriers to treatment adherence, obtaining follow-up care, and enacting lifestyle changes. Yet, psychological and psychiatric conditions are less likely to be recognized and managed in current cardiology practice than traditional CVD risk factors. This is because of complexities in definition and assessment, as mentioned above, but also because many symptoms of psychological distress are easily confused with physical disease, for example, fatigue, weight loss, poor appetite, or trouble sleeping.

There is no consensus on whether screening for and treatment of emotional problems, such as depression, anxiety, and PTSD, should be systematically carried out in cardiac patients. That is because it is uncertain whether screening for and treating these problems will translate into a better quality of life or an improved prognosis. Additionally, clinical trials of psychological or psychiatric interventions have thus far only yielded modest improvements in psychological well-being, with null or uncertain effects on cardiac outcomes. Despite this controversy, psychological interventions, such as individual or group counseling, stress management, support for self-care, and pharmacotherapy, are likely to add benefit for the control of standard risk factors, for the promotion of a healthy lifestyle, and for the management of psychological distress when added to standard cardiac rehabilitation or as part of a coordinated care management approach. Such programs require substantial resources and commitment from both patients and staff. However, their potential benefits in improving psychological well-being should not be discounted.

Current clinical guidelines in the United States only mention depression as a psychosocial factor that is reasonable for the non–mental health clinician to recognize if patients have access to adequate care support systems (class of recommendation IIa, level of evidence B). These guidelines further state that treatment of depression may be reasonable for its clinical benefits other than improving CVD outcomes (class IIb, level of evidence C).[64] In contrast, the European guidelines, while noting limitations for depression screening, recognize the importance of a comprehensive approach for the detection of psychosocial risk factors, using at least a preliminary assessment with a short series of yes-and-no questions, and recommend a multimodal behavioral intervention approach integrating health education, physical activity, and psychological therapy (class Ia, level of evidence A).[41] In the case of clinically significant symptoms of depression or other psychosocial factors, the European guidelines recommend consideration of interventions such as psychotherapy, medication, or collaborative care (class IIa, level of evidence A).

Psychotherapy

Psychotherapy helps people with depression understand the behaviors, emotions, and ideas that contribute to depression, regain a sense of control and pleasure in life, and learn coping skills.[65] Psychodynamic therapy is based on the assumption that a person is depressed because of unresolved, generally unconscious conflicts, often stemming from childhood. Interpersonal therapy focuses on the behaviors and interactions with family and friends. The primary goal of this therapy is to improve communication skills

and increase self-esteem during a short period of time. Cognitive behavioral therapy (CBT) involves examining thought patterns that can be negative and self-defeating, and going over the basis of such thoughts and how they contribute to emotions and poor outcomes. Psychotherapy has been shown to be as effective as medications for depression, and some people, especially with early life stress issues, may not respond to medication without psychotherapy.

Because of the increased risk of death in cardiac patients with depression, it was assumed that successful treatment of depression would reduce this risk. The ENRICHD (Enhanced Recovery in Coronary Heart Disease Patients) trial, however, did not find such a beneficial effect of a psychological intervention involving CBT and social learning for cardiac outcomes (patients with severe depression also received psychopharmacologic intervention). The average improvement in depression in comparison with placebo, however, was modest. In post hoc analyses, patients who responded to treatment did have a better outcome than those who did not respond.[66]

Other types of therapy have been shown to be useful for depression and anxiety. These include interpersonal therapy, stress management and stress reduction techniques such as deep breathing, progressive muscle relaxation, yoga, meditation, and mindfulness-based stress reduction.

Antidepressant Medications

Antidepressant medications are another proven method for the treatment of depression and other mental disorders associated with an increased risk for cardiovascular disease, such as PTSD.[67] Antidepressants appear to be more effective in patients with moderate or severe depression than patients with mild depression. Antidepressants act on the serotonin and norepinephrine systems, as well as other neurotransmitter systems, in the brain. Drugs that increase brain levels of serotonin and norepinephrine have been shown to be effective treatments for both depression and anxiety. Many antidepressants bind to proteins called transporters that are responsible for taking the neurotransmitter back up into the neuron after it has been released into the synapse, therefore causing an increase in neurotransmitter at the synapsis level. Many of the antidepressant drugs block the serotonin transporter or the norepinephrine transporter, or a combination of the two. Other antidepressants exert their actions by binding to various receptors that control neurotransmitter function in the brain. The original drugs, the tricyclics, had a more general effect on neurotransmitter function.

Tricyclic Antidepressants

Tricyclics represent the first class of medications found to work for the treatment of depression. They include imipramine (Tofranil), doxepin (Sinequan), amoxapine (Asendin), nortriptyline (Aventyl, Pamelor), and amitriptyline (Elavil). Tricyclics increase norepinephrine and serotonin levels in the synapse. The most common side effects of the tricyclics are the anticholinergic side effects, which include dry mouth, constipation, memory problems, confusion, blurred vision, sexual dysfunction, and decreased urination. Tricyclics have properties like quinidine, leading to an increase in the PR interval, a prolongation of the QRS duration and QT interval, and a flattening of the T wave on the electrocardiogram (**see also Chapter 12**) . These effects are usually not of clinical significance. However, tricyclics should be avoided in patients with preexisting cardiac conduction defects, a prolonged QT interval, congestive heart failure, or a recent myocardial infarction. Prolongation of the QT interval beyond 0.44 seconds is associated with an increased risk of malignant ventricular arrhythmias (torsade de pointes). Indeed, tricyclic medications have been associated with an increased risk of malignant ventricular arrhythmias and sudden cardiac death (**see also Chapters 8, 34, and 42**). For

patients who suffer a cardiac event while being treated with a tricyclic, abrupt withdrawal from the tricyclic medication can be associated with an increased risk of arrhythmias. Therefore, these medications should be tapered slowly over a period of time, assuming the cardiac arrhythmia is manageable. If prolongation of the QT interval or development of hypotension in patients treated with a tricyclic becomes a problem, patients should be slowly tapered off of tricyclics and treated with a selective serotonin reuptake inhibitor (SSRI), venlafaxine, or bupropion (see below). These latter medications are preferred in patients who develop a new onset of depression after an acute myocardial infarction.

The anticholinergic side effects of the tricyclics are especially troublesome for elderly persons, because these patients are more susceptible to the memory impairment and orthostatic hypotension associated with these medications. For this reason, it is recommended that tricyclics not be prescribed for elderly persons.

Selective Serotonin Reuptake Inhibitors

The selective serotonin reuptake inhibitors (SSRIs) include fluoxetine (Prozac, Sarafem), paroxetine (Paxil), fluvoxamine (Luvox), citalopram (Celexa), escitalopram (Lexapro), and sertraline (Zoloft). They act by blocking the transporter that brings the serotonin back from the synapse into the neuron, and thus have a different side effect profile than tricyclics, specifically fewer to no anticholinergic and cardiac effects, which make them the antidepressant medications of choice in the cardiac patient population.

SSRI medications have not been shown to have greater efficacy in the treatment of depression than the older tricyclics, although a larger number of patients drop out of treatment while taking tricyclics because of side effects. In general, SSRIs, like the older tricyclics, have only modest efficacy over placebo. About 80% of the improvement with antidepressants comes from the placebo response. Patients with mild or moderate depression do not have clinically meaningful responses to antidepressants, whereas those with severe depression have more substantial responses.

The primary advantage of SSRIs in the cardiac patient is less risk of cardiovascular and anticholinergic side effects. Side effects of SSRIs include nausea, diarrhea, headache, insomnia, and agitation. One of the most troubling side effects of the SSRIs is sexual dysfunction, which includes loss of libido, delayed ejaculation, and erectile dysfunction. Antidepressants without sexual dysfunction side effects can be given instead of an SSRI in these cases, including bupropion (Wellbutrin), mirtazapine (Remeron), and trazodone (Desyrel), all drugs not in the SSRI class.

SSRI treatment, especially with fluoxetine, is associated with an increase in risk of bleeding. For the cardiac patient taking aspirin or other antiplatelet or anticoagulation treatment, this can be an important issue. SSRIs stopped suddenly can also result in a potent withdrawal syndrome, including agitation, nervousness, and sometimes suicidal thoughts. SSRIs can cause akathisia and other extrapyramidal side effects, as can the antipsychotics. Akathisia includes feelings of restlessness, pacing, and internal stiffness, which subjectively are very uncomfortable. However, these symptoms are not common, and are treatable with benzodiazepines or low doses of propranolol. A more troubling problem is the potential for suicidality associated with SSRIs. *All* antidepressant medications may carry an increased risk of suicide.

Short-term trials of SSRIs have found them to be safe and effective for cardiac patients. Although treatment of depression has not been demonstrated to improve cardiac outcomes, in a number of trials treatment responders appeared to have better cardiac outcomes than nonresponders, suggesting that the response to treatment may be a key factor.[66] Several observational studies, however, have shown an increased cardiac risk with longer-term use of SSRIs, especially cardiac death. A recent Danish nationwide study, for example, found a significant association between SSRI (as well as tricyclic

antidepressant) use and out-of-hospital cardiac arrest, especially for citalopram and nortriptyline, whereas no association was found for other classes, such as the norepinephrine reuptake inhibitors and the serotonin-norepinephrine dual reuptake inhibitors.[68] An earlier analysis of the Nurses' Health Study in the United States also found that antidepressant use was associated with a threefold higher risk of sudden cardiac death, even after adjusting for the severity of depression and risk factors for coronary heart disease.[69] There was an equal risk for SSRIs as for other antidepressants outside of the SSRI class. However, it should be kept in mind that sudden cardiac death in presumably healthy people is fairly rare, and thus potential risks need to be weighed against potential benefits.

Norepinephrine Reuptake Inhibitors

Antidepressant medications designed to specifically block reuptake of norepinephrine into the synapse are called norepinephrine reuptake inhibitors, or NRIs. Medications in this group include desipramine (Norpramin) and reboxetine (Edronax, Vestra). They have a more favorable profile in terms of anticholinergic side effects and effects on the heart and blood pressure than the tricyclics.

Serotonin and Norepinephrine Dual Reuptake Inhibitors

The latest group of antidepressants has dual reuptake inhibition for serotonin and norepinephrine (SNRIs), and includes venlafaxine (Effexor) and duloxetine (Cymbalta). In general, these drugs have shown a better treatment response for depression than SSRIs and tricyclics. When multiple studies were combined, with the treatment response defined as at least a 50% reduction in symptoms of depression, venlafaxine had a success rate of 74%; this rate was significantly better than SSRIs, with a 61% success rate, and tricyclics, with a 58% success rate.

SNRIs, however, can cause a number of side effects. Both venlafaxine and duloxetine can cause dizziness, constipation, dry mouth, headache, changes in sleep, or more rarely a serotonin syndrome, with restlessness, shivering, and sweating. Venlafaxine has been associated with a dose-dependent increase in blood pressure, which is of particular concern for cardiac patients, especially those with preexisting hypertension. Although not well studied, there is a good possibility that duloxetine has similar effects. Venlafaxine seems to carry the greatest risk of suicidality amongst all of the antidepressants, with a threefold increased risk of attempted or completed suicides.

Monoamine Oxidase Inhibitors

Drugs that block the monoamine oxidase inhibitor enzyme (MAOI drugs), and therefore boost the monoamines (serotonin, norepinephrine), include phenelzine (Nardil) and tranylcypromine (Parnate). They have a more favorable cardiovascular profile than the tricyclics, with little or no effect on cardiac conduction, although they can be associated with orthostatic hypotension and weight gain. They can cause a “wine and cheese reaction” of potentially life-threatening elevations of blood pressure if taken with foods that are high in tyramine content, including wine, cheese, chocolate, and beer. Medications that can precipitate hypertensive reactions if a patient is also taking an MAOI include those with sympathomimetic effects (e.g., amphetamines, ephedrine, cocaine). MAOIs should also not be taken together with meperidine (Demerol). Due to the risk of hypertensive crises, the MAOIs are not recommended for use in cardiac patients, and indeed they are no longer commonly prescribed in general.

Antidepressants with Novel Mechanisms of Action

Some drugs act on various neurotransmitter systems or in general are poorly understood in terms of their

mechanism of action. Bupropion (Wellbutrin) primarily acts on dopamine systems, and is used for both depression and smoking cessation under the brand name Zyban. Side effects include weight loss and restlessness, as well as possible increases in blood pressure; high doses can rarely cause seizures. Mirtazapine (Remeron) is a quatrocyclic antidepressant that has actions on a number of different receptor systems. It blocks presynaptic noradrenergic alpha-2 receptors with associated enhancement of norepinephrine release. Mirtazapine also increases serotonin release. Side effects include sweating and shivering, tiredness, strange dreams, dyslipidemia, weight gain, anxiety, and agitation. It can be associated with mild orthostatic hypotension and anticholinergic side effects. Short-term randomized trials in cardiac patients have not shown an increase in mortality or cardiovascular events associated with these medications.

Other drugs with mixed actions include trazodone (Desyrel) and maprotiline (Ludiomil). The profile of these medications appears safe in terms of anticholinergic side effects and effects on the heart and blood pressure. Trazodone can rarely cause priapism, however (extended painful erection that requires emergency treatment). It is a safe and often effective medication for induction of sleep that does not carry the potential risk of tolerance, as do zolpidem (Ambien) and related insomnia medications.

Electroconvulsive Therapy

Electroconvulsive therapy (ECT) is used as a last resort for the treatment of depression in patients who have had multiple failed trials of psychotherapy and medication. ECT has an 80% response rate, which is a better response rate than for medications, and contrary to popular belief, is a safe procedure. ECT causes profound hemodynamic changes, including bradycardia (up to frank asystole, which may last for a few seconds), followed by tachycardia and hypertension. These effects, however, are transient and typically resolve within 20 minutes. Possible complications include persistent hypertension, arrhythmias, asystole lasting more than 5 seconds, ischemia, and heart failure. Older age and preexisting CVD, including hypertension, coronary artery disease, congestive heart failure, aortic stenosis, implanted cardiac devices, and atrial fibrillation, have been associated with increased complication rates. However, most complications remain minor and transient, and the vast majority of patients can safely complete treatment.

There are no absolute contraindications to ECT. However, the procedure should be delayed in patients who are hemodynamically unstable, or have new-onset or uncontrolled arrhythmias or hypertension. In patients with stable coronary heart disease and controlled hypertension, medications can be continued through the morning of the procedure. In patients with an implanted pacemaker, the pacemaker should be tested before and after ECT; the magnet should be placed at the patient bedside in the event that electrical interference leads to pacemaker inhibition and bradycardia. ECT appears safe in patients with an implantable cardioverter-defibrillator (ICD). The detection mode of the ICD should be turned off during ECT, and continuous electrocardiographic monitoring should be performed, with resuscitative equipment by the patient bedside in the event that external defibrillation is necessary.

Anxiolytic Medications

Benzodiazepine Medications

In the 1960s benzodiazepines displaced barbiturates as the most commonly used treatment for insomnia, and became commonly used in patients with anxiety and depression. They were originally marketed as having less potential for dependence and abuse, although this did not bear out over time. Benzodiazepines

act on a receptor in the brain called the GABA-benzodiazepine receptor complex. This is the same complex that alcohol and the inhibitory transmitter GABA bind to, although benzodiazepines have their own binding site. The benzodiazepines most commonly prescribed today include alprazolam (Xanax), which is mainly used for anxiety attacks and panic disorder; clonazepam (Klonopin), which is used for epilepsy; and temazepam (Restoril). Other benzodiazepine medications that are longer acting and that are still sometimes used in the treatment of insomnia include oxazepam (Serax), lorazepam (Ativan), chlordiazepoxide (Librium), clorazepate (Tranxene), and diazepam (Valium), among others. Differences in the individual benzodiazepines are related to the time of onset of action and duration of effect. On average, benzodiazepines increase the user's sleep time by about 1 hour per night.

The side effects from benzodiazepines during the day can cause serious problems. These include daytime drowsiness, dizziness, light-headedness, and memory problems, as well as increased motor vehicle accidents. Use of benzodiazepine medications is associated with a 60% increase in road traffic accidents. The risk is increased further with concurrent alcohol usage and in older age. All medications for insomnia are not recommended for long-term use.

The primary concern in the cardiac patient using benzodiazepines is a potential risk of respiratory suppression. For this reason, benzodiazepines with a shorter half-life should be preferred to those with a longer half-life in cardiac patients. In patients with cardiac disease and associated pulmonary impairment, these medications should be used with caution.

Nonbenzodiazepine “Z-Drug” Medications

The newer generation of insomnia mediations, zaleplon (Sonata), zolpidem (Ambien), eszopiclone (Lunesta), and zopiclone (Imovane), or Z drugs, act on specific subsets of the GABA receptor. They are commonly called “nonbenzodiazepine” medications, but the name is misleading, because they bind to the same GABA-benzodiazepine receptor complex in the brain to which benzodiazepines and alcohol bind. The difference is that they bind to a different part of the same receptor complex. They have been marketed as having less dependency and fewer side effects than the older generation of benzodiazepine medications, and some argue that these drugs have less potential for abuse than the benzodiazepines. However, studies have not shown them to be more effective or safe than the benzodiazepines, and no difference between the different Z drugs for safety or efficacy has been established. As for benzodiazepines, general side effects for all of these medications include memory impairment, drowsiness, and dizziness. An increased risk of road traffic accidents was also seen with zopiclone. Zaleplon has a much shorter half-life (1 hour) than zolpidem (2.5 hours) or eszopiclone (6 hours), and is therefore promoted as being associated with less drowsiness the next day.

Medications with Other Mechanisms of Action

Rozerem (Ramelteon) is a melatonin receptor agonist that is used for insomnia. Side effects include headache, drowsiness, fatigue, nausea, dizziness, and more rarely diarrhea and depression. Advantages of this medication are the absence of abuse potential and the lack of withdrawal symptoms.

Buspirone (Buspar) is an agonist of the serotonin 1A receptor and relatively free of next-day drowsiness and memory impairment, or the potential for dependence or abuse. Buspirone is efficacious in the treatment of anxiety and is preferable to the benzodiazepines for the treatment of the cardiac patient because it lacks respiratory suppressive effects. Side effects are minimal, and include nausea, headache, and light-headedness. A rare side effect is the perception that someone is standing beside the bed when a patient is asleep. There are no known adverse cardiac effects.

Alternative Medicines and Supplements

There are some natural remedies that have been recommended for depression and anxiety. Few large controlled studies have evaluated these approaches, however, and the quality of the research has been highly variable.

St. John's Wort

St. John's wort *(Hypericum perforatum)* is a popular medication for the over-the-counter treatment of mild depression; 12% of Americans report using it at least once a year. St. John's wort has action similar to antidepressants, including monoamine oxidase inhibition, serotonin reuptake inhibition, and actions on sigma receptors. Overall, studies have found that St. John's wort monotherapy for mild and moderate depression is superior to placebo in improving depressive symptoms, with possibly fewer side effects. However, evidence of heterogeneity and a lack of research on severe depression limit the quality of the evidence.[70] St. John's wort can interact with a number of medications, including digoxin, theophylline, protease inhibitors, and cyclosporine.

Omega-3 Fatty Acids

Low dietary intake and low serum or red blood cell levels of omega-3 fatty acids are associated with depression in patients with and without coronary heart disease, and with an increased risk for cardiac death. Two omega-3 fatty acids, eicosapentaenoic acid and docosahexaenoic acid, are found in high concentrations at neuronal synapses in the human brain and are essential for neuronal functioning. In depressed psychiatric patients who were otherwise medically healthy, several studies have indicated that supplementation with omega-3 fatty acids improves the efficacy of antidepressants; among patients with CVD, however, results have been mostly null.[71]

Exercise

A number of studies, dating from the mid-1990s to more recently, have shown that various forms of exercise improve depression (**see also Chapter 53**). Metaanalyses have consistently reported moderate to large effects of exercise on depression, denoting a clinically significant improvement of the same magnitude as psychological or drug treatment.[72]

It has also been shown that a half-hour a day of exercise 6 days a week is an effective exercise “dose” to improve the mood of people who have mild to moderate depression. Therefore, aerobic exercise at a dose consistent with public health recommendations for CVD prevention is also an effective treatment for mild to moderate depression. Exercise may also complement the effects of antidepressant medication in depressed patients who do not have a complete response to medication.

Summary of Management Considerations

Even though treatment of depression or anxiety has not been shown to improve cardiovascular outcomes in the cardiac patient, it is still necessary to recognize and manage these problems if they are severe or persistent, in order to promote patient wellness and quality of life, as well as improve patients' ability to adhere to treatments and lifestyle recommendations.

In many cases the cardiologist can address the problem without the need for an immediate referral to a psychiatrist. Many patients complaining of “anxiety” may actually be worried about their cardiac

condition. In this situation, educating the patient about the cardiac condition, listening to the patient's concerns, and allowing the patient to talk about the worries may go a long way toward relieving distress. The next step is to determine if the patient is having thoughts of taking his or her own life or is having severe impairment in functioning that would necessitate referral to a psychiatrist, psychologist, or social worker; this depends on the severity of the condition and the type of treatment that might be appropriate (medications versus psychotherapy or counseling).

The cardiologist may also start a trial of medication. Benzodiazepines can be used in the short term to manage anxiety but should be limited to less than 2 weeks in order to reduce the risk of developing dependence. They can be useful, however, in the time period before antidepressants start working. An alternative for the treatment of anxiety that does not have the risk of dependence or respiratory suppression is buspirone. Antidepressants useful in the cardiac patient include SSRIs (paroxetine, fluoxetine, sertraline, and others), mirtazapine, and bupropion. Patients who fail to respond to these medications may respond to venlafaxine or duloxetine, with careful monitoring of blood pressure. A healthy lifestyle, especially with physical activity, should always be recommended, tailored to patients' functional capabilities, to decrease depression and improve well-being. There are many self-help books that patients can buy to teach themselves stress reduction techniques, in addition to resources in the community such as counselors and social workers that can teach these skills either individually or in classes.

Neurologic Disorders and Cardiovascular Disease

William J. Groh, Gordon F. Tomaselli, Douglas P. Zipes

Cardiologists are increasingly being asked to play an integral part in the medical team evaluating and treating patients with a primary neurologic disorder because of the potential for associated cardiac morbidity and mortality. In several disorders, the cardiovascular manifestations are responsible for a greater risk than that attributable to the neurologic manifestations. This chapter reviews those neurologic disorders associated with important cardiovascular manifestations or sequelae.

The Muscular Dystrophies

The muscular dystrophies are a group of inherited skeletal muscle diseases. Most also have direct effects on cardiac muscle, with manifestations including heart failure, conduction disease and heart block, atrial and ventricular arrhythmias, and sudden death. With improved multidisciplinary care, patients are living longer and an increasing proportion manifest cardiac disease. The following muscular dystrophies are associated with cardiovascular involvement:

- Duchenne and Becker muscular dystrophies
- Myotonic dystrophies
- Emery-Dreifuss muscular dystrophies and associated disorders
- Limb-girdle muscular dystrophies
- Facioscapulohumeral muscular dystrophy

Duchenne and Becker Muscular Dystrophies

Genetics

Both Duchenne muscular dystrophy and Becker muscular dystrophy are X-linked recessive disorders caused by mutations in the large dystrophin gene (**see also Chapters 7 and 33**). The dystrophin protein and dystrophin-associated glycoproteins provide a structural link between the myocyte cytoskeleton and extracellular matrix functioning to link contractile proteins to the cell membrane. Dystrophin messenger RNA is expressed predominantly in skeletal, cardiac, and smooth muscle, with lower levels in the brain. Absence of dystrophin leads to membrane fragility resulting in myofibril necrosis and eventual loss of muscle fibers with fibrotic replacement. Abnormalities in dystrophin and in dystrophin-associated glycoproteins underlie the degeneration of cardiac and skeletal muscle in several inherited myopathies, including X-linked dilated cardiomyopathy. Cardiac myocytes lacking dystrophin are susceptible to mechanical damage.[1] Beyond the inherited disorders, the loss of dystrophin plays a role in myocyte failure in other cardiomyopathies, including sporadic idiopathic cardiomyopathy, viral myocarditis, and cardiomyopathies associated with coronary artery disease. In Duchenne muscular dystrophy, dystrophin is nearly absent, whereas in Becker muscular dystrophy, dystrophin is present but reduced in size or amount. This leads to the characteristic rapidly progressive skeletal muscle disease in Duchenne and the more benign course in Becker muscular dystrophy. Cardiac involvement is seen in both disorders, and the severity is not correlated with the severity of skeletal muscle involvement. Mutations in specific domains of the dystrophin gene are associated with a higher risk for cardiomyopathy.[2]

Clinical Presentation

Duchenne muscular dystrophy is the most common inherited neuromuscular disease, with an incidence of 1 case in 3600 to 6000 live male births.[3] Patients typically present with skeletal muscle weakness before the age of 5 years, which progresses if untreated such that boys become wheelchair-bound by their early teens (**Fig. 97.1**). Historically, death occurs by age 25 years, primarily from respiratory dysfunction and less often from heart failure. A multidisciplinary treatment approach, including steroids, scoliosis surgery, ventilatory support, and cardiac therapy, has improved survival rates.[4] Becker muscular dystrophy is less

common than Duchenne muscular dystrophy, is associated with a more variable presentation of skeletal muscle weakness (**see Fig. 97.1**), and carries a better prognosis, with most patients surviving to the age of 40 to 50 years.

FIGURE 97.1 **A,** Calf pseudohypertrophy in an 8-year-old boy with Duchenne muscular dystrophy. **B,** Becker muscular dystrophy in a 24-year-old man. Dystrophy of the shoulder girdle and calf pseudohypertrophy are evident. (**A,** Courtesy Dr. Laurence E. Walsh; **B,** courtesy Dr. Robert M. Pascuzzi.)

In both Duchenne and Becker muscular dystrophies, elevated serum creatine kinase activity is observed, at levels more than 10 and 5 times normal values, respectively.

Cardiovascular Manifestations

Most patients with Duchenne muscular dystrophy develop a cardiomyopathy, but symptoms can be masked by severe skeletal muscle weakness. Preclinical cardiac involvement is present in one fourth by age 6, with the onset of clinically apparent cardiomyopathy after age 10 common. Cardiac involvement can be diagnosed earlier by cardiac magnetic resonance imaging.[5,6] The majority of patients with Duchenne muscular dystrophy 18 years of age or older develop a dilated cardiomyopathy. Early involvement is observed in the inferobasal and lateral left ventricle (**Fig. 97.2**). As with the skeletal muscle weakness, cardiac involvement in Becker muscular dystrophy is more variable than in Duchenne muscular dystrophy, ranging from none or subclinical disease to severe cardiomyopathy requiring transplant. Cardiac involvement in Becker muscular dystrophy is independent of the severity of skeletal muscle involvement, with some but not all investigators observing an increased likelihood of cardiovascular disease in older patients. More than one half of patients with subclinical or benign skeletal muscle disease were noted to have cardiac involvement if carefully evaluated. Progression in the severity of cardiac involvement is common. Cardiomyopathy can initially solely involve the right ventricle.

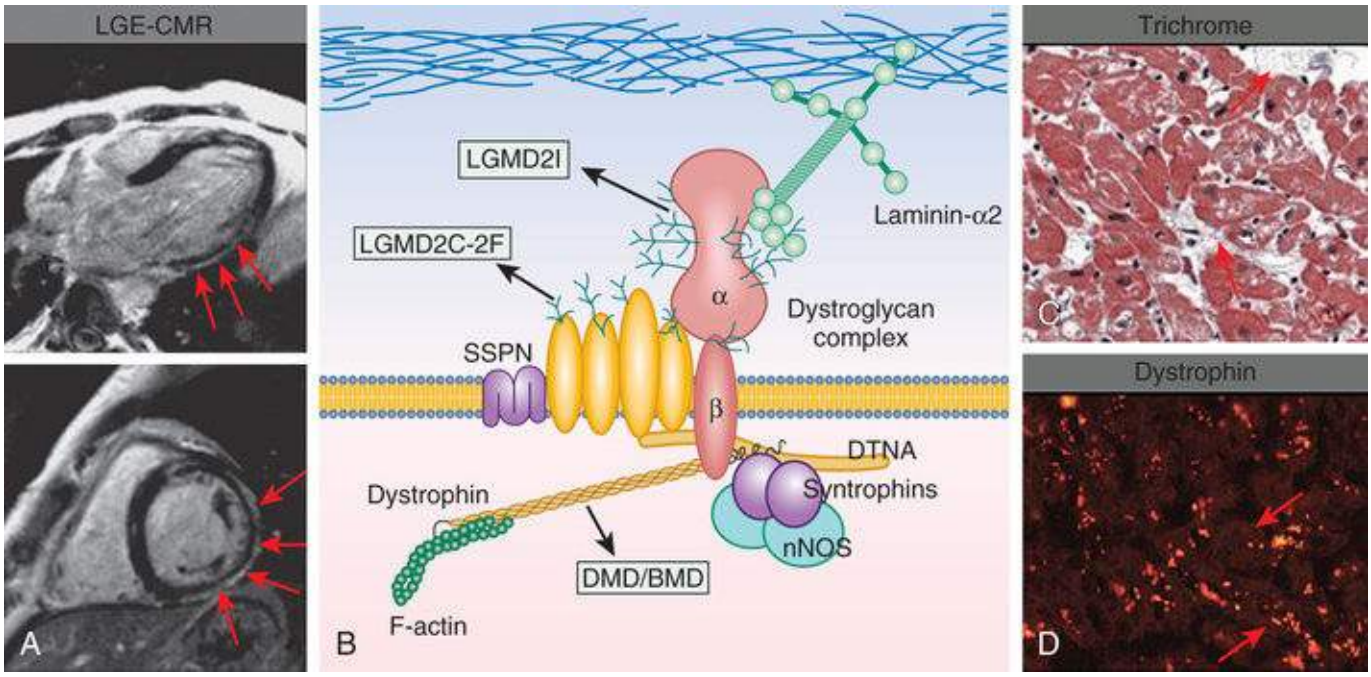

FIGURE 97.2 Cardiac involvement in Duchenne muscular dystrophy. **A**, Late gadolinium enhancement (LGE) images of a patient with Duchenne muscular dystrophy (*red arrows* indicate areas of positive LGE, primarily in the inferior-lateral left ventricle). **B**, Schematic illustration of the constitution of a cardiomyocyte cell membrane, demonstrating connection between intramembranous sarcoglycan complex *(yellow ellipses),* dystroglycan complex (α and β), and dystrophin, which is linked to the intracellular actin cytoskeleton. The dystroglycan complex connects to the basal lamina on the extracellular side via laminin and to syntrophins and nitric oxide synthase (nNOS) via dystrobrevin (encoded by the *DTNA* gene). **C**, Trichrome staining of an endomyocardial biopsy sample taken from the patient shown in (**A**), showing irregular-sized cardiomyocytes in the presence of diffuse interstitial fibrosis *(red arrows).* **D**, Dystrophin staining: A few cardiomyocytes show discontinuous expression of dystrophin in the cell membrane *(red arrows),* whereas most cardiomyocytes have no dystrophin at all in their membranes. *BMD*, Becker muscular dystrophy; *DMD*, Duchenne muscular dystrophy; *LGMD*, limb-girdle muscular dystrophy. (**A, C, D** from American Heart Association; Yilmaz A, Gdynia H-J, Ludolph AC, et al: Images in cardiovascular medicine: cardiomyopathy in a Duchenne muscular dystrophy carrier and her diseased son: similar pattern revealed by cardiovascular MRI. Circulation 2010;121:e237. **B** from Kobayashi YM, Campbell, KP: Skeletal muscle dystrophin-glycoprotein complex and muscular dystrophy. In Hill JA, Olson EN (editors): Muscle fundamental biology and mechanisms of disease. Cambridge, MA, Academic Press, 2012, pp 935-942.)

Thoracic deformities and a high diaphragm can alter the cardiovascular examination in patients with Duchenne muscular dystrophy. A reduction in the anterior-posterior chest dimension is commonly responsible for a systolic impulse displaced to the left sternal border, a grade 1 to 3/6 short midsystolic murmur in the second left interspace, and a loud pulmonary component of the second heart sound. In both Duchenne and Becker types of muscular dystrophy, mitral regurgitation is observed. The presence of mitral regurgitation is related to posterior papillary muscle dysfunction in Duchenne muscular dystrophy and to mitral annular dilation in Becker muscular dystrophy.

Female carriers of Duchenne and Becker muscular dystrophy are at increased risk for dilated cardiomyopathy.

Electrocardiography

In a majority of patients with Duchenne muscular dystrophy, the electrocardiographic tracing is abnormal (**see also Chapter 12**). The classically described electrocardiographic pattern shows distinctive tall R waves and increased R/S amplitude in V_1 and deep narrow Q waves in the left precordial leads possibly related to the posterolateral left ventricular involvement (**Fig. 97.3**). Other common findings include a short PR interval and right ventricular hypertrophy. No association between the presence of a dilated cardiomyopathy and electrocardiographic abnormalities has been established.[7] In Becker muscular

dystrophy, electrocardiographic abnormalities are present in up to 75% of the patients. The electrocardiographic abnormalities observed include tall R waves and an increased R/S amplitude in V_1, akin to that seen in Duchenne muscular dystrophy. Incomplete right bundle branch block also is a frequent finding that may be related to early involvement of the right ventricle. In patients with dilated cardiomyopathy, a left bundle branch block is common.

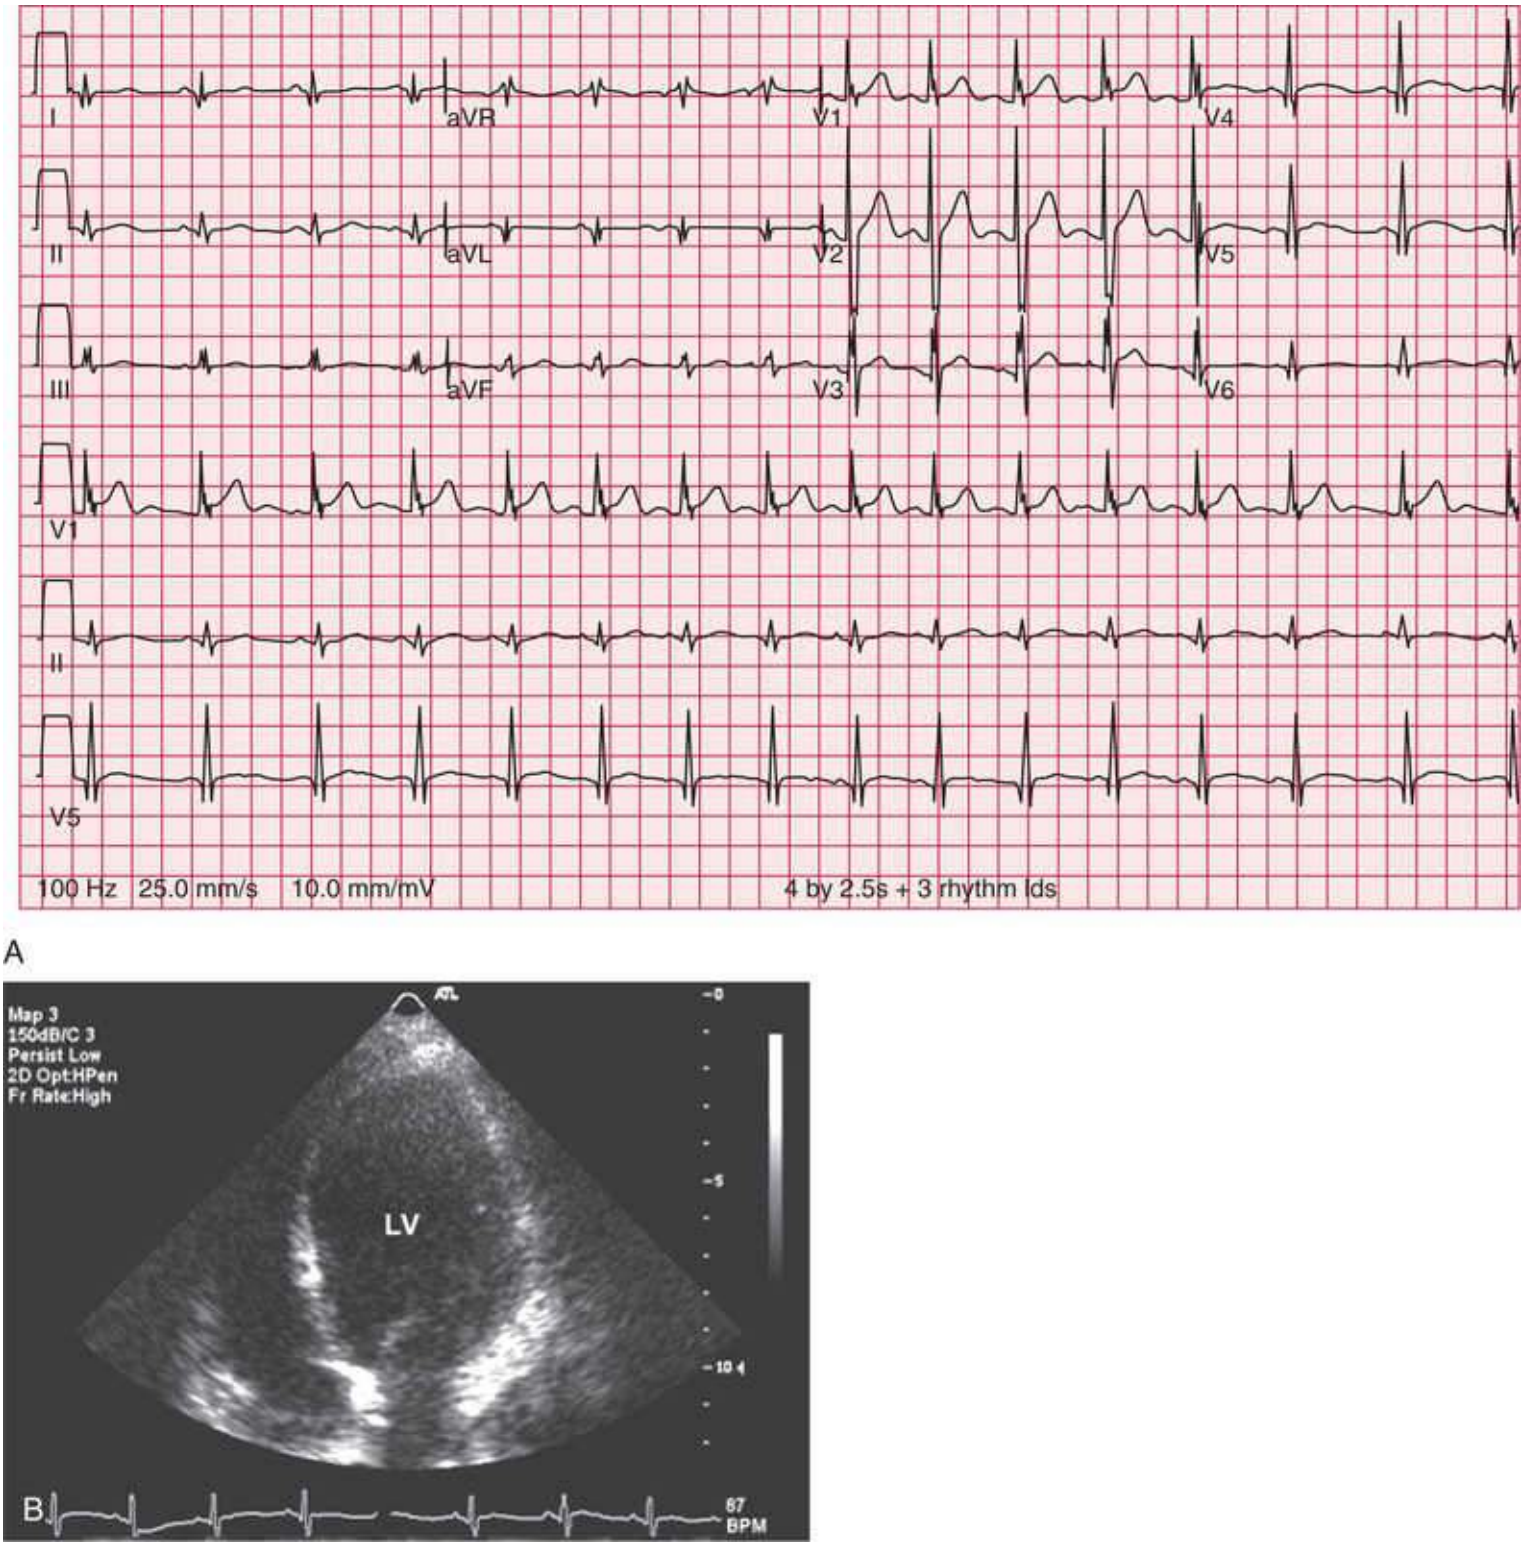

FIGURE 97.3 Dilated cardiomyopathy in a 19-year-old man with Duchenne muscular dystrophy. **A,** ECG showing a QRS complex that is typical of Duchenne muscular dystrophy, with tall R waves in lead V_1 and deep narrow Q waves in leads I and aVL. **B,** Two-dimensional echocardiogram showing a dilated, thinned left ventricle (LV).

Imaging

Clinical care guidelines recommend using screening echocardiography at diagnosis or by the age of 6 years; subsequently every 2 years until the age of 10; and annually thereafter in boys with Duchenne muscular dystrophy (this and other cardiac imaging modalities are described more fully in **Chapters 14 to 18**).[3] Cardiac magnetic resonance imaging, especially with gadolinium contrast, is more sensitive in detecting subclinical ventricular involvement and fibrosis.[2] The presence of fibrosis as indicated by late gadolinium enhancement on MRI predicted a subsequent decrement in left ventricular function.[8] Regional abnormalities in the posterobasal and lateral wall typically occur earlier than in other areas (**see Fig. 97.2**). A process akin to left ventricular noncompaction can be observed, possibly resulting from compensatory mechanisms in response to the failing dystrophic myocardium. Mitral regurgitation can result from dystrophic changes in the posterior leaflet papillary muscles.

Arrhythmias

In Duchenne muscular dystrophy, persistent or labile sinus tachycardia is the most common arrhythmia recognized (**see also Chapter 37**). Atrial arrhythmias, including atrial fibrillation and atrial flutter (**see also Chapter 38**), occur in the setting of respiratory dysfunction and cor pulmonale or are associated with a dilated cardiomyopathy. Abnormalities in atrioventricular conduction have been observed, with both short and prolonged PR intervals recognized. Ventricular arrhythmias occur on monitoring in 30% of patients, primarily ventricular premature beats. Complex ventricular arrhythmias have been reported, more commonly in patients with severe skeletal muscle disease. Sudden death occurs in Duchenne muscular dystrophy, typically in patients with end-stage muscular disease. Whether the sudden death is caused by arrhythmias is unclear. Several follow-up studies have shown a correlation between sudden death and the presence of complex ventricular arrhythmias. The presence of ventricular arrhythmias was not a predictor for all-cause mortality.

Arrhythmia manifestations in Becker muscular dystrophy typically are related to the severity of the associated structural cardiomyopathy. Distal conduction system disease with complete heart block and bundle branch reentry ventricular tachycardia has been observed.

Treatment and Prognosis

Duchenne muscular dystrophy is a progressive skeletal and cardiac muscle disorder. Steroids and steroid derivatives are effective in delaying skeletal muscle disease progression and appear to decrease the progression to a dilated cardiomyopathy.[9] Antisense oligonucleotides facilitate exon skipping of nonsense mutations in the dystrophin gene and have shown promise in early clinical evaluation in appropriate candidates. Gene replacement therapy using novel delivery of functional mini-dystrophin holds future promise. A primary cardiac cause of death is recognized as playing an increasingly significant role because death due to other causes has been with improved respiratory support. There is an equal distribution of cardiac death from heart failure and from sudden death. Angiotensin-converting enzyme (ACE) inhibitors and beta blockers can improve left ventricular function in patients treated early. Angiotensin receptor blockers can be used if the patient cannot tolerate angiotensin-converting enzyme inhibitors. The aldosterone antagonist eplerenone showed benefit in maintaining cardiac magnetic resonance left ventricular circumferential strain in boys already receiving ACE inhibitors or angiotensin receptor blockers.[10] Dosing, age, or clinical status at which pharmacotherapy should be initiated is unclear (**see also Chapters 24 and 25**). Other advanced types of therapy such as implantable cardioverter-defibrillators play an uncertain role but should be considered individually based on clinical

presentation, patient status, and wishes (**see also Chapter 41**). The use of left ventricular mechanical assist devices has been described. Whether heart failure therapies improve long-term outcomes is unclear. However, the age at death has increased, with the majority of patients surviving into their 30s, and recognition and treatment of the associated cardiomyopathy likely plays a role in that success.

In patients with Becker muscular dystrophy, an improvement in left ventricular function also is observed after treatment with ACE inhibitors and beta blockers. Screening left ventricular imaging is recommended as in Duchenne muscular dystrophy. Advanced heart failure therapy, including primary prevention implantable cardioverter-defibrillators, is appropriate in patients with cardiomyopathy. Patients with Becker muscular dystrophy with advanced heart failure can undergo cardiac transplantation, with expected outcomes similar to those for non–muscular dystrophy cohorts of age-matched patients with dilated cardiomyopathy.[11] Female carriers of Duchenne and Becker muscular dystrophies do not develop a cardiomyopathy during childhood, and screening can be delayed until later in adolescence. Whether carriers benefit from heart failure pharmacotherapy is unknown, but such treatment would seem reasonable based on shared mechanisms. Once heart failure is established, conventional therapy is indicated. Cardiac transplantation also has been reported in carriers.

Myotonic Dystrophies

Genetics

The myotonic dystrophies are autosomal dominant disorders characterized by myotonia, which is a delayed muscle relaxation after contraction, weakness and atrophy of skeletal muscles, and systemic manifestations, including endocrine abnormalities, cataracts, cognitive impairment, and cardiac involvement (**Fig. 97.4**). Two distinct mutations are responsible for the myotonic dystrophies. In myotonic dystrophy type 1, the mutation is an amplified trinucleotide cytosine-thymine-guanine (CTG) repeat found on chromosome 19. Whereas unaffected patients have 5 to 37 copies of the repeat, patients with myotonic dystrophy have 50 to several thousand repeats. A direct correlation exists between an increasing number of CTG repeats and earlier age at onset and increasing severity of neuromuscular involvement. Cardiac involvement including conduction disease, arrhythmias, and age at cardiovascular death also correlate with the length of repeat expansion (**Fig. 97.5**). It is typical for the CTG repeat to expand as it is passed from parents to offspring, resulting in the characteristic worsening clinical manifestations in subsequent generations, termed *anticipation*.

FIGURE 97.4 The patient is a 54-year-old man with myotonic dystrophy type 1. Typical characteristics of balding, thin face, and distal muscle atrophy are evident.

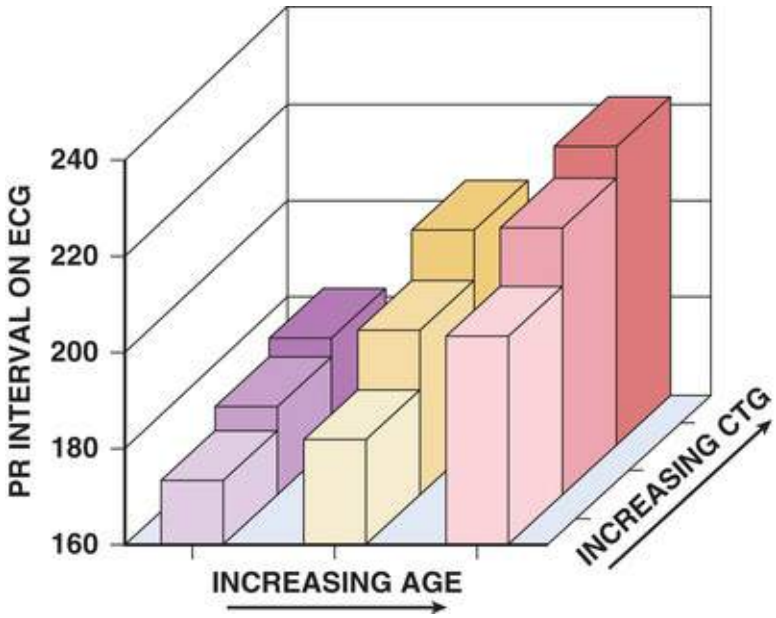

FIGURE 97.5 Relationship between the PR interval on the ECG and age and CTG repeat sequence expansion in 342 patients with myotonic dystrophy type 1. There is a direct relationship between age and CTG repeat sequence expansion and the severity of cardiac conduction disease, as quantified by the PR interval. The relationship suggests that cardiac involvement in myotonic dystrophy type 1 is a time-dependent degenerative process, with the rate of progression modulated by the extent of CTG repeat expansion. (From Groh WJ, Lowe MR, Zipes DP: Severity of cardiac conduction involvement and arrhythmias in myotonic dystrophy type 1 correlates with age and CTG repeat length. J Cardiovasc Electrophysiol 2002;13:444.)

Myotonic dystrophy type 2, also called proximal myotonic myopathy, has generally less severe skeletal muscle and cardiac involvement than type 1. Both congenital presentation and cognitive impairment are

lacking in myotonic dystrophy type 2—typically the most severely involved subsets of the type 1 patients. The genetic mutation responsible for myotonic dystrophy type 2 is a tetranucleotide repeat expansion, cytosine-cytosine-thymine-guanine (CCTG), found on chromosome 3. Intergenerational contraction of the repeat expansion has been reported, and there is no apparent relationship between the degree of expansion and clinical severity.

The molecular mechanism by which both myotonic dystrophies exert their similar phenotypic presentations is by the toxic effects of the large mutant RNA expansion on nuclear RNA–binding proteins. Cardiac involvement is related to the resultant dysregulation of multiple cardiac systems, including sarcomeric proteins, calcium handling, and connexins[12] (**Fig. 97.6**).

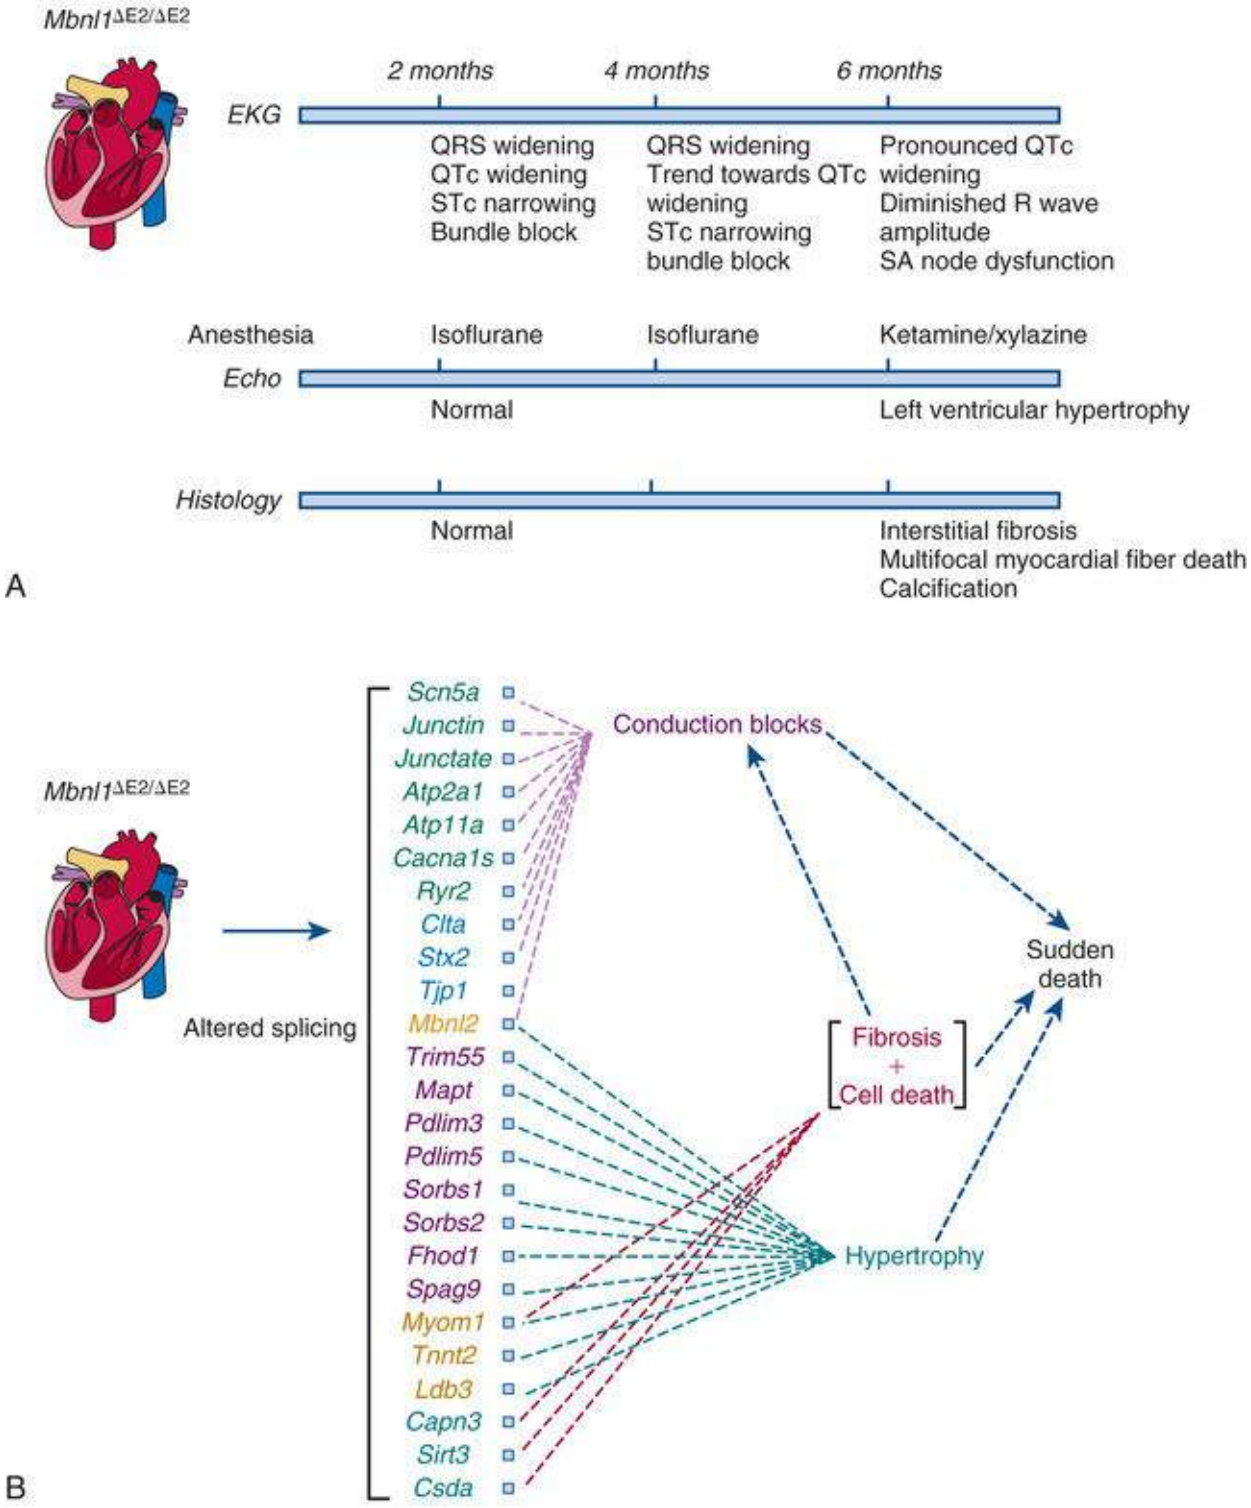

FIGURE 97.6 A mechanism of cardiac pathogenesis in myotonic dystrophy type 1. **A,** Cardiac pathophysiologic findings in a muscleblind-like protein 1 (MBNL1) mouse deletion model. MBNL1 is an RNA splice regulator. It is sequestered and disabled when it binds to the multiple copies of CUG RNA transcribed from the expanded CTG DNA in myotonic dystrophy type 1. Loss of MBNL1 leads to persistence of embryonic splice isoforms in multiple downstream cardiac proteins (**B**). (From Dixon DM, Choi J, El-Ghazali A, et al: Loss of muscleblind-like 1 results in cardiac pathology and persistence of embryonic splice isoforms. Sci Rep 2015;5:9042.)

Clinical Presentation

The myotonic dystrophies are the most common inherited neuromuscular disorders in patients presenting as adults. Until recently, studies have not genetically differentiated myotonic dystrophy types 1 and 2, so the clinical characteristics described probably are for a mixed group of such disorders. Type 1 is significantly more common than type 2, except possibly in certain areas of northern Europe. The global

incidence of myotonic dystrophy type 1 has been estimated to be 1 in 8000, although it is higher in certain populations, such as French Canadians, and lower to nonexistent in other populations, such as African blacks. The age at onset of symptoms and diagnosis averages 20 to 25 years. A congenital presentation is seen in severely affected patients with myotonic dystrophy type 1. Common early manifestations are related to weakness in the muscles of the face, neck, and distal extremities. On examination, myotonia can be demonstrated in the grip, thenar muscle group, and tongue (**Fig. 97.7**). The diagnosis when the patient is asymptomatic is possible using electromyography and genetic testing. Muscle weakness is progressive. Subcapsular cataracts are commonly observed. In general, cardiac symptoms appear after the onset of skeletal muscle weakness but can be the initial manifestation of the disease.

FIGURE 97.7 Grip myotonia in myotonic dystrophy. The patient is unable to fully open the hand **(A)** after exerting a grip **(B).**

Myotonic dystrophy type 2 also manifests with myotonia, muscle weakness, cataracts, and endocrine abnormalities, as in type 1. Age at symptom onset typically is older in myotonic dystrophy type 2.

Cardiovascular Manifestations

Cardiac pathology in the myotonic dystrophies involves degeneration, fibrosis, and fatty infiltration preferentially targeting the specialized conduction tissue, including the sinus node, atrioventricular node, and His-Purkinje system (**Fig. 97.8**). Degenerative changes are observed in working atrial and ventricular tissue but only rarely progress to a symptomatic dilated cardiomyopathy. It is not clear if there are differences in the cardiac pathology observed between myotonic dystrophy type 1 and 2. Patients with type 2 typically demonstrate cardiac involvement later in life or not at all. The primary cardiac manifestations of the myotonic dystrophies are arrhythmias.

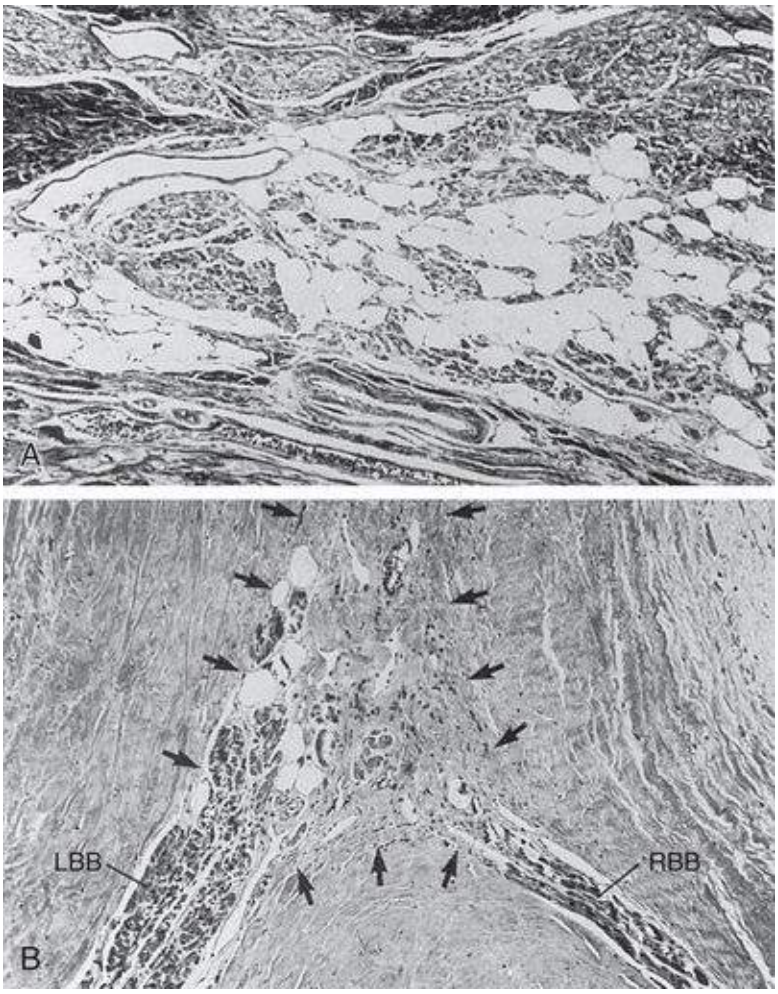

FIGURE 97.8 Histopathologic features of the atrioventricular bundle in myotonic dystrophy. **A,** Fatty infiltration in a specimen from a 57-year-old man (Masson trichrome stain, ×90). **B,** Focal replacement fibrosis and atrophy in a specimen from a 48-year-old woman. *Arrows* demarcate expected size and shape of the branching atrioventricular bundle (hematoxylin-eosin stain, ×90.) *LBB*, left bundle branch; *RBB*, right bundle branch. (From Nguyen HH, Wolfe JT 3rd, Holmes DR Jr, Edwards WD: Pathology of the cardiac conduction system in myotonic dystrophy: a study of 12 cases. J Am Coll Cardiol 1988;11:662.)

Electrocardiography

A majority of adult patients with myotonic dystrophy type 1 exhibit electrocardiographic abnormalities. In a large, unselected, middle-aged U.S. myotonic population, abnormal electrocardiographic patterns were seen in 65% of the patients.[13] Abnormalities included first-degree atrioventricular block in 42%, right bundle branch block in 3%, left bundle branch block in 4%, and nonspecific intraventricular conduction delay in 12%. Q waves not associated with a known myocardial infarction are common. Electrocardiographic abnormalities are less common in younger patients. Conduction disease worsens with advancing age (**Fig. 97.9**).

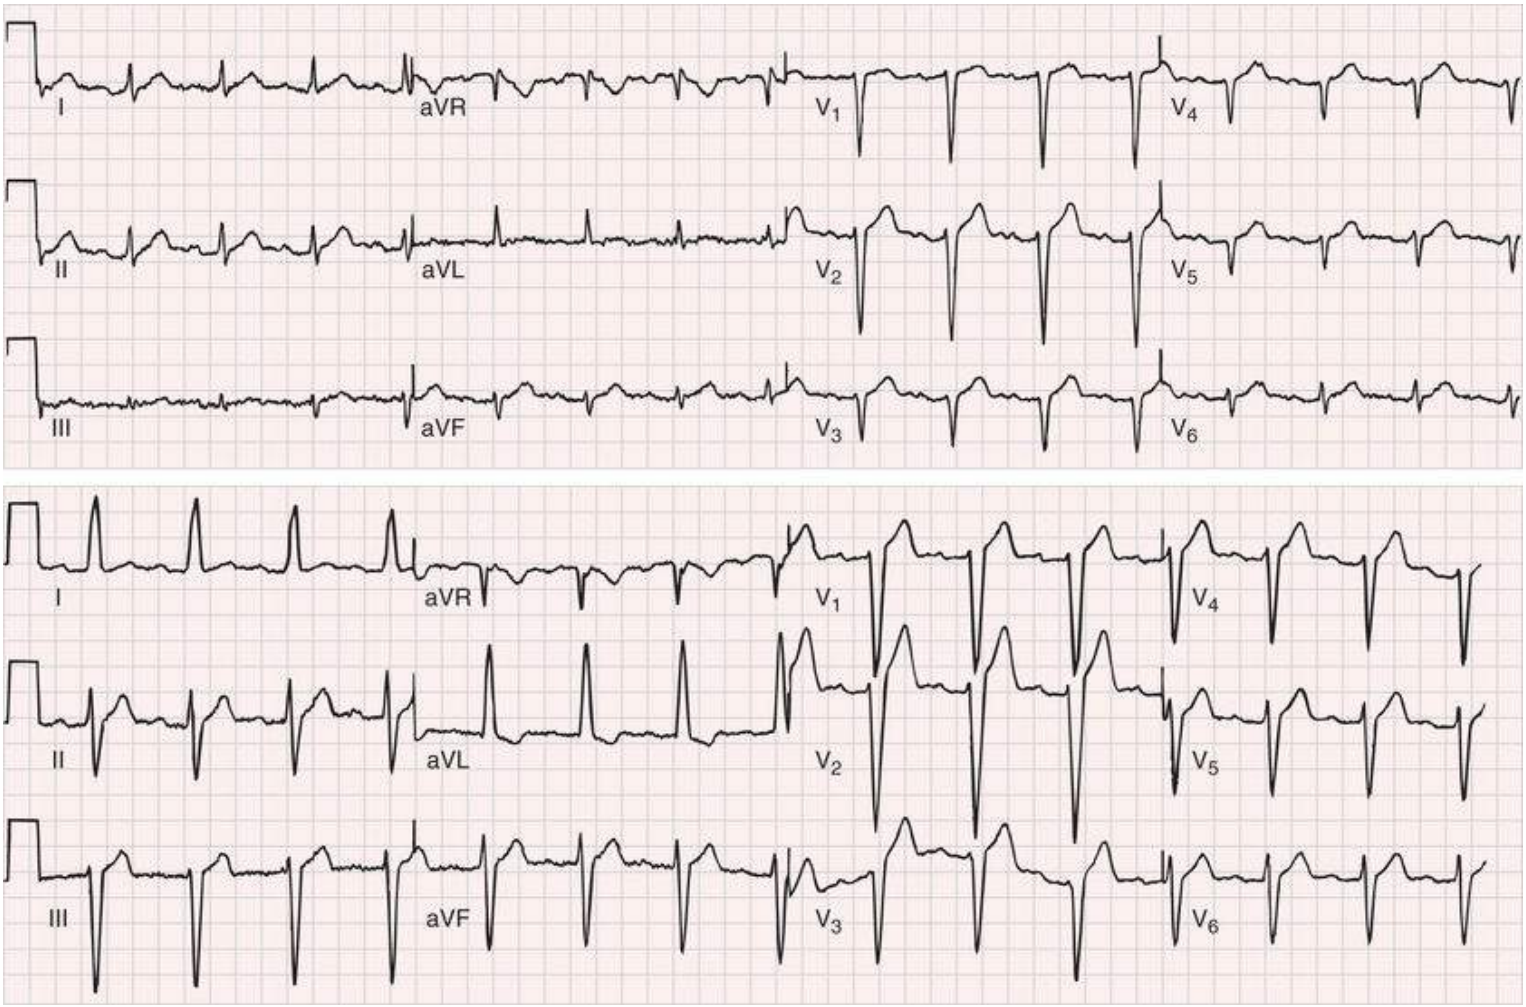

FIGURE 97.9 ECGs obtained 1 year apart in a 36-year-old man with myotonic dystrophy (the *top tracings* are older). Note the abnormal Q waves in the precordial leads. An increasing PR interval and QRS duration are observed, consistent with increasing severity of conduction disease.

Electrocardiographic abnormalities are less common in myotonic dystrophy type 2, occurring in approximately 20% of middle-aged patients.

Imaging and Heart Failure

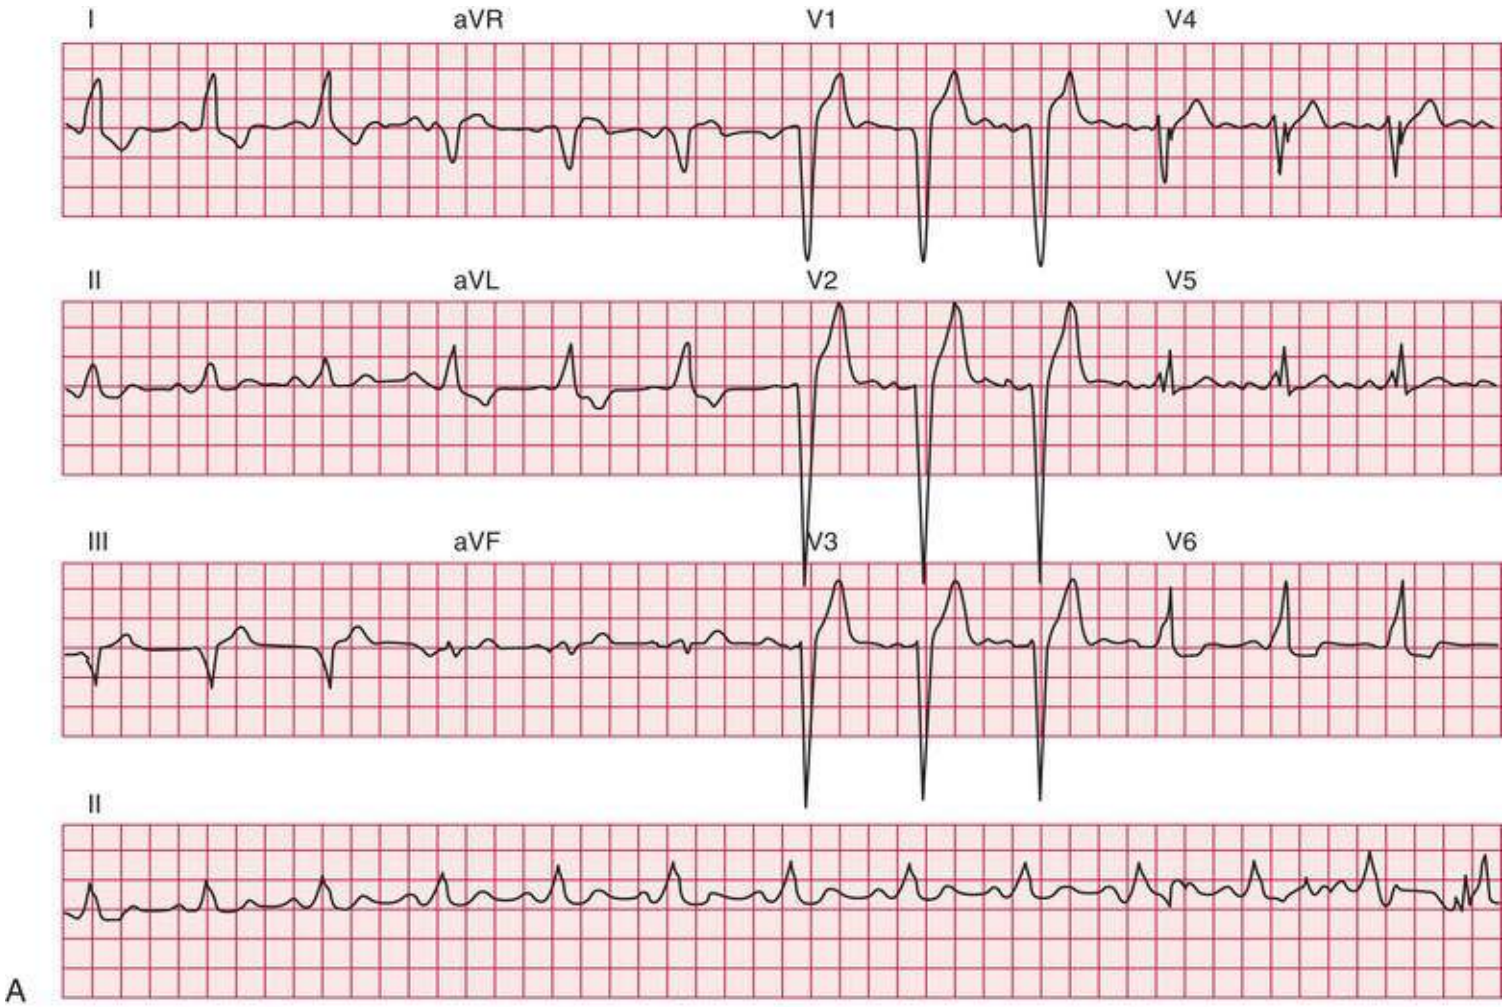
Left ventricular systolic and diastolic dysfunction, left ventricular hypertrophy, mitral valve prolapse, regional wall motion abnormalities, and left atrial dilatation have been reported in patients with myotonic dystrophy type 1 at moderate prevalence rates.[14] Clinical heart failure is observed but is less common than are arrhythmias. Left ventricular hypertrophy and ventricular dilation have been reported in myotonic dystrophy type 2. Cardiac magnetic resonance imaging is more sensitive than echocardiography for detection of early cardiac involvement.[15]

Arrhythmias

Patients with myotonic dystrophy type 1 demonstrate a wide range of arrhythmias. At cardiac electrophysiologic study, the most common abnormality found is a prolonged His-ventricular (H-V) interval (**see also Chapter 34**). Conduction system disease can progress to symptomatic atrioventricular block and necessitate pacemaker implantation. The prevalence of permanent cardiac pacing in patients with myotonic dystrophy type 1 varies widely between studies based on referral patterns and the indications used for implant. Updated practice guidelines have recognized that asymptomatic conduction abnormalities in neuromuscular diseases such as myotonic dystrophy may warrant special consideration

for pacing[16] (**see also Chapter 41**).

Atrial arrhythmias, primarily atrial fibrillation and atrial flutter (**see also Chapter 37**), are the most common arrhythmias observed.[13] Ventricular tachycardia can occur. Patients with myotonic dystrophy type 1 are at risk for ventricular tachycardia occurring as a consequence of reentry in the diseased distal conduction system, as characterized by bundle branch reentry and interfascicular reentry tachycardia (**Fig. 97.10**). Therapy with right bundle branch or fascicular radiofrequency ablation can be curative (**see also Chapter 39**).



A

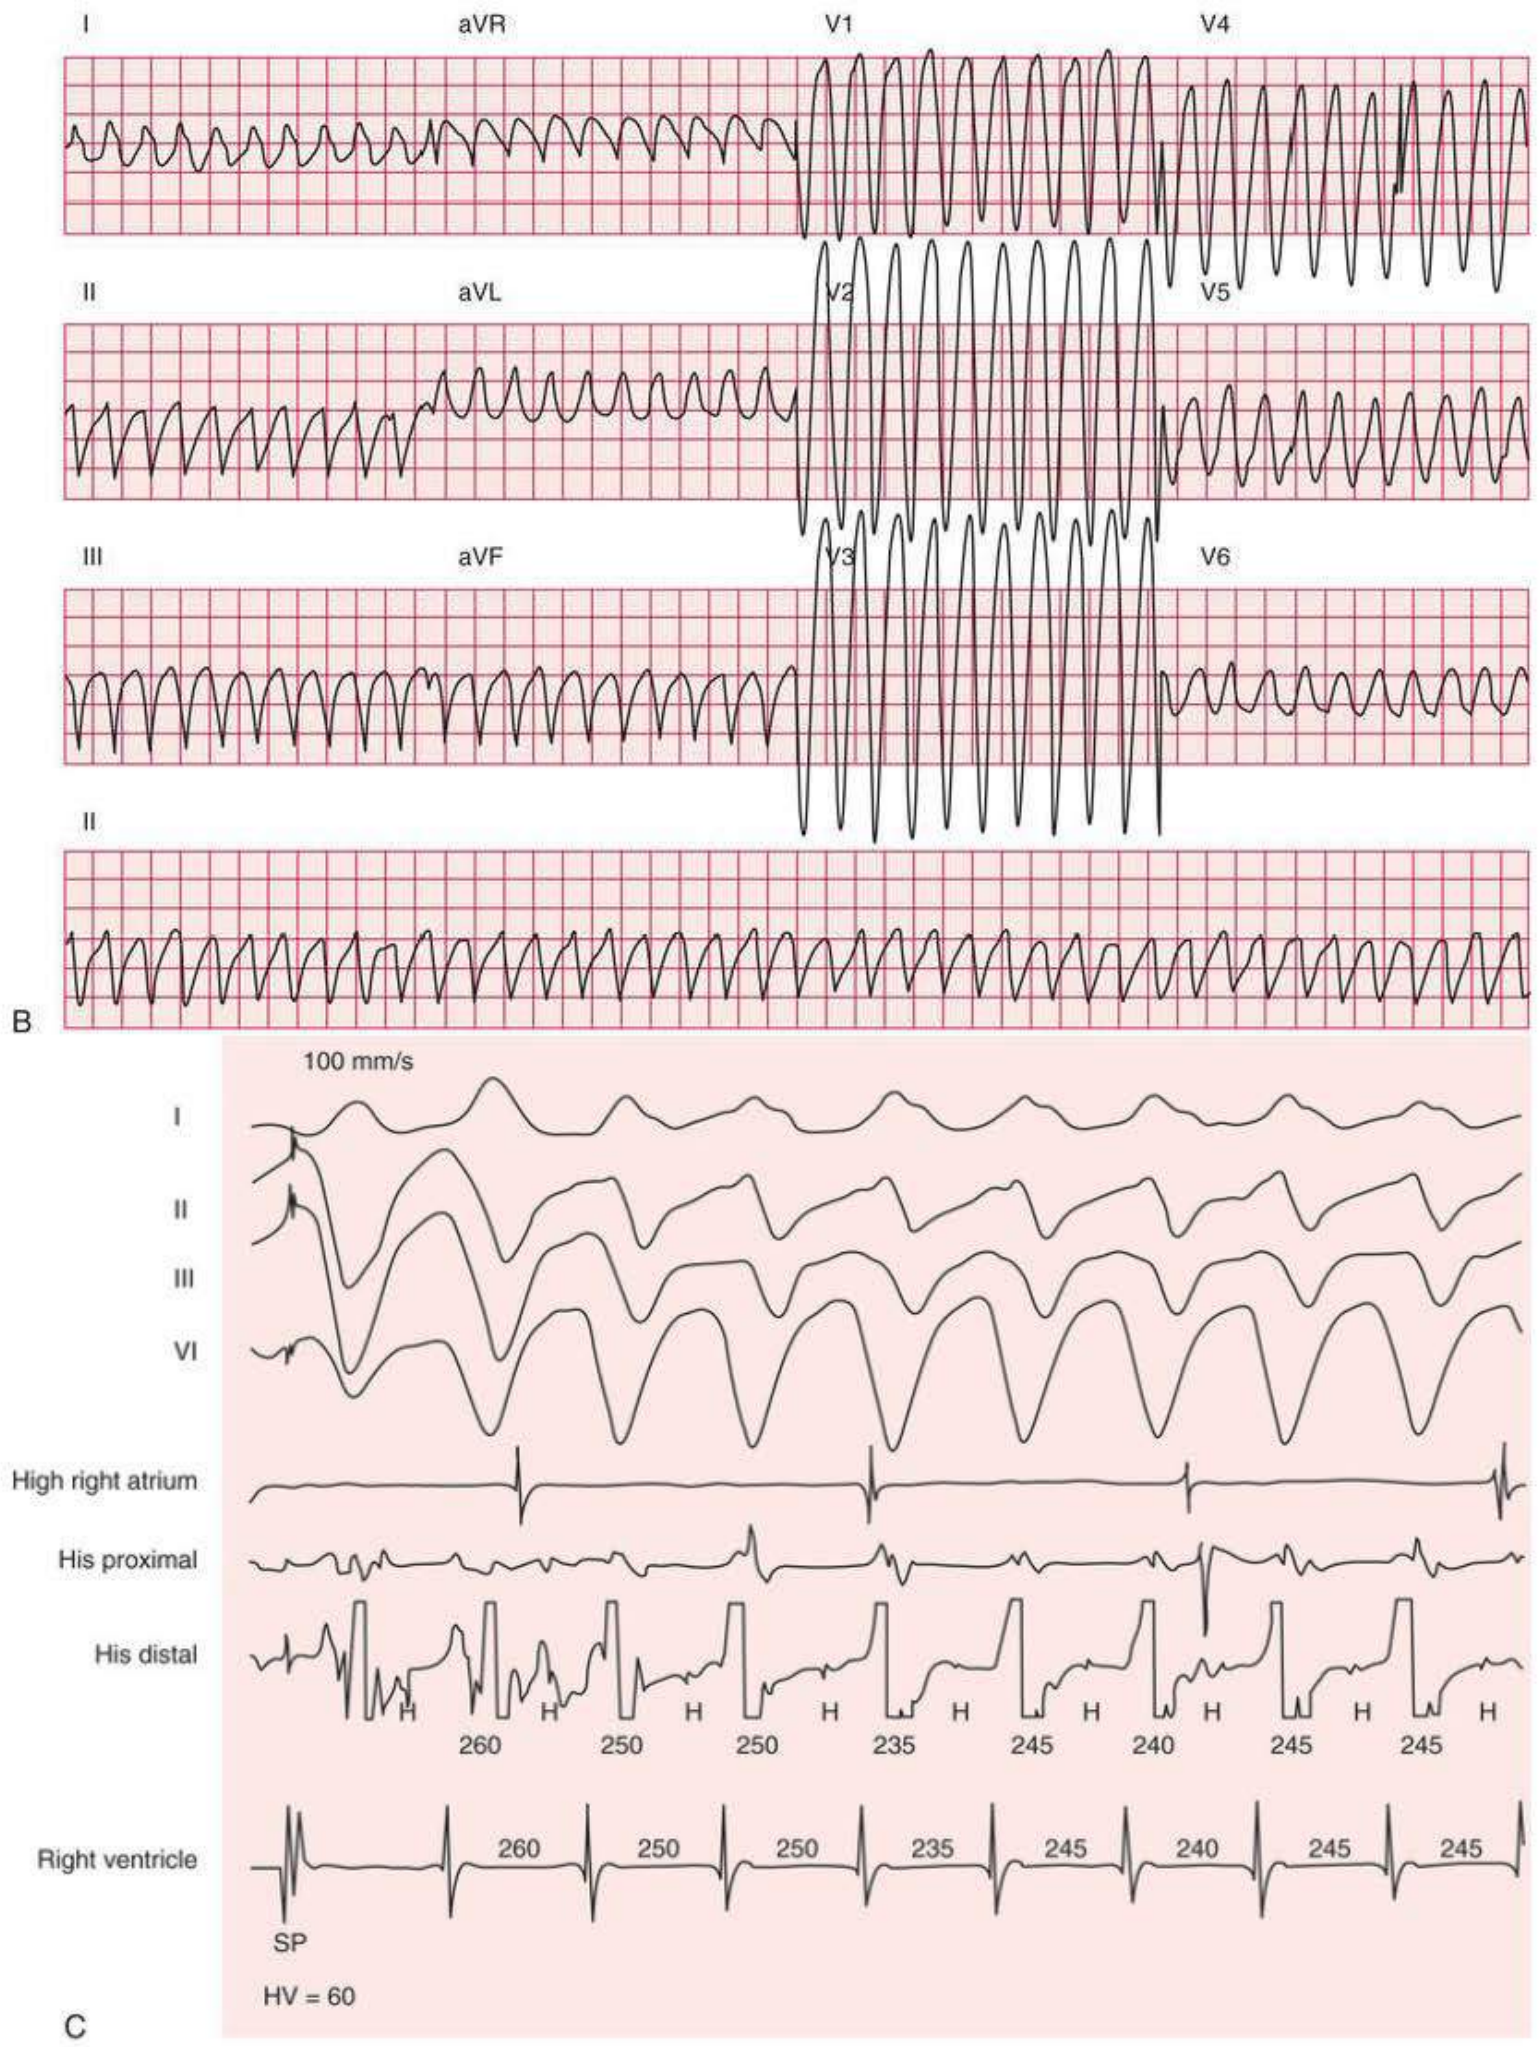


FIGURE 97.10 Bundle branch reentry tachycardia in a 34-year-old woman with myotonic dystrophy type

1 presenting with a symptomatic (recurrent syncope) wide-complex tachycardia. **A,** ECG showing sinus rhythm and a QRS complex with left bundle branch block. **B,** ECG showing a rapid monomorphic tachycardia easily inducible on electrophysiologic study, with left bundle morphology. **C,** Recordings during electrophysiologic study, including the surface ECG (leads I, II, III, V_1) and intracardiac ECGs (high right atrium, His proximal, His distal, and right ventricle). A monomorphic ventricular tachycardia is induced with atrial-ventricular (A-V) dissociation and His association, consistent with bundle branch reentry tachycardia. Note, the H-H interval drives the subsequent V-V interval.

Sudden death is responsible for 18% to 33% of deaths in myotonic dystrophy type 1; presumably, most are due to arrhythmias. Annual rates of sudden death in population studies vary between 0.25% and 2%. The entity of sudden death is second only to respiratory failure as a cause of death. The mechanisms leading to sudden death are not clear. Distal conduction disease producing atrioventricular block can result in the lack of an appropriate escape rhythm and asystole or bradycardia-mediated ventricular fibrillation. Sudden death can occur in myotonic dystrophy type 1 despite pacing, implicating ventricular arrhythmias. Nonarrhythmic causes of sudden death, probably acute respiratory issues, play some role (**see also Chapter 42**).

Arrhythmias and sudden death have been reported in myotonic dystrophy type 2 but seem to be rarer than in type 1.

Treatment and Prognosis

Neurologists recognize the risk for cardiac issues in the myotonic dystrophies and will refer the patient to a cardiologist. Cardiac manifestations occur in both myotonic dystrophy types 1 and 2, and therefore diagnostic evaluation and therapy should be done in both. Cardiac disease is observed at a younger age in myotonic dystrophy type 1 compared with type 2. Echocardiography or other imaging modalities can determine if structural abnormalities are present. Cardiac imaging in adults should be done at diagnosis or with new symptoms. If no significant abnormalities are observed, repeat evaluation every 3 to 5 years is appropriate. In the patient with a dilated cardiomyopathy, standard therapy including ACE inhibitors and beta blockers has improved symptoms. There are no data on the role of ACE inhibitors or beta blockers in preventing the development of a cardiomyopathy in myotonic dystrophy. Patients presenting with symptoms indicative of arrhythmias such as syncope and palpitations should undergo an evaluation, often including a cardiac electrophysiologic study, to determine an underlying causative disorder. Annual electrocardiograms (ECGs) are recommended in asymptomatic patients. The role and interval for ambulatory ECG (Holter) monitoring are not clear (**see also Chapter 35**). The presence of significant or progressive electrocardiographic abnormalities despite a lack of symptoms is an indication for consideration of prophylactic pacing.[16] The presence of severe electrocardiographic conduction abnormalities and atrial arrhythmias were independent risk factors for sudden death.[13] The strategy of pacing when the H-V interval is 70 milliseconds or more decreased sudden death in a large observational trial using propensity analysis for group risk stratification.[17] Implantable cardioverter-defibrillators may be more appropriate prophylactic therapy than pacemakers.[18] The use of cardiac resynchronization therapy may be appropriate in patients requiring ventricular pacing. Anesthesia in patients with myotonic dystrophy increases the risks of both respiratory failure and arrhythmias. Careful monitoring during the perioperative period is mandatory. Monitored anesthesia during cardiac device implants should be done under an anesthesiologist's care.

In patients presenting with wide complex tachycardia, cardiac electrophysiologic study with particular evaluation for bundle branch reentry tachycardia should be done (**see also Chapter 39**).

The course of neuromuscular abnormalities in the myotonic dystrophies is variable. Respiratory failure

from progressive muscle dysfunction is the most common cause of death. Some patients, however, are only minimally limited by weakness up to the age of 60 to 70 years. Sudden death can reduce survival rates in patients with the myotonic dystrophies, including those minimally symptomatic from a neuromuscular status. Decisions regarding prophylactic cardiac devices need to be made with full consideration of all aspects for the care of the myotonic patient.

Emery-Dreifuss Muscular Dystrophy and Associated Disorders

Genetics and Cardiac Pathology

Emery-Dreifuss muscular dystrophy is a rare inherited disorder in which skeletal muscle symptoms are often mild; cardiac involvement is both common and serious. The disease is classically inherited in an X-linked recessive fashion but there is heterogeneity with families that fit an X-linked dominant, autosomal dominant, and autosomal recessive inheritance pattern. The gene responsible for the X-linked Emery-Dreifuss muscular dystrophy, *STA*, encodes a nuclear membrane protein termed emerin. Mutations in genes found on chromosome 1 encoding two other nuclear membrane proteins, lamins A and C, have been identified as responsible for a variety of other disorders with a phenotypic expression similar to X-linked Emery-Dreifuss muscular dystrophy. The disorders include autosomal dominant and recessive Emery-Dreifuss muscular dystrophy, autosomal dominant dilated cardiomyopathy with conduction disease, autosomal dominant limb-girdle muscular dystrophy with conduction disease, and lipodystrophy with associated cardiac abnormalities.[19]

Nuclear membrane proteins such as emerin and lamins A and C provide structural support for the nucleus and interact with the cell's cytoskeletal proteins. Mutations in the tail regions of lamins A and C are responsible for the majority of cases of autosomal dominant Emery-Dreifuss muscular dystrophy with a phenotype of both cardiac and skeletal muscle involvement. Mutations in the rod domain of the lamin A/C gene primarily cause isolated cardiac disease, including dilated cardiomyopathy, conduction system degeneration, and atrial and ventricular arrhythmias.

Clinical Presentation

Emery-Dreifuss muscular dystrophy is characterized by a triad of early contractures of the elbow, Achilles tendon, and posterior cervical muscles; slowly progressing muscle weakness and atrophy, primarily in humeroperoneal muscles; and cardiac involvement (**Fig. 97.11**). The disorder has been labeled “benign X-linked muscular dystrophy” to differentiate the slowly progressive muscular weakness from that of Duchenne muscular dystrophy. In the autosomal dominant and recessive inheritance of Emery-Dreifuss muscular dystrophy, a more variable phenotypic expression and penetrance typically are observed. A mutation in the lamin A/C gene also is responsible for an autosomal dominantly–inherited familial partial lipodystrophy characterized by marked loss of subcutaneous fat, diabetes, hypertriglyceridemia, and cardiac abnormalities.

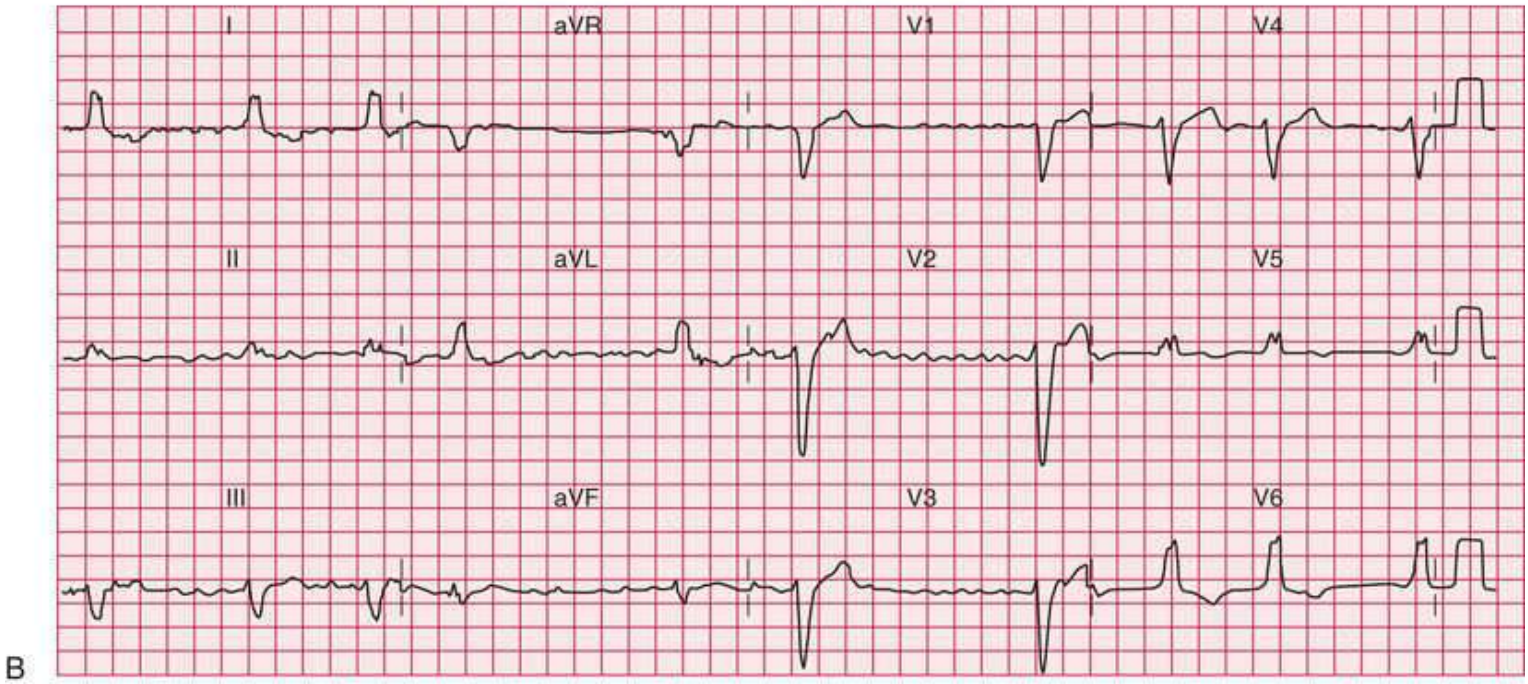

FIGURE 97.11 Emery-Dreifuss muscular dystrophy in a 28-year-old man presenting with syncope. **A,** Contractures of the elbow and atrophy in the humeroperoneal muscles. **B,** ECG obtained at initial presentation showed atrial fibrillation with slow ventricular rate and a QRS complex with left bundle branch block. (Courtesy Dr. Robert M. Pascuzzi.)

Cardiovascular Manifestations

Arrhythmias and dilated cardiomyopathy are the major manifestations of cardiac disease in Emery-Dreifuss muscular dystrophy and its associated disorders. In X-linked recessive Emery-Dreifuss muscular dystrophy, abnormalities in impulse generation and conduction are common. ECGs are abnormal by age 20 to 30 years, commonly showing first-degree atrioventricular block. The atria appear to be involved earlier than the ventricles, with atrial fibrillation and atrial flutter, or more classically, permanent atrial standstill and junctional bradycardia. Abnormalities in impulse generation or conduction are present in virtually all patients by age 35 to 40 years, and requirement for pacing is typical. Ventricular arrhythmias,

including sustained ventricular tachycardia and ventricular fibrillation, occur. Sudden death, presumably due to cardiac disorders, before age 50 is observed. Prophylactic implantable cardioverter-defibrillators are used.[20] Female carriers of X-linked recessive Emery-Dreifuss muscular dystrophy do not exhibit skeletal muscle disease but acquire late cardiac disease, including conduction abnormalities, and sudden death can occur. Although arrhythmias are the most common presentation of cardiac involvement in X-linked recessive Emery-Dreifuss muscular dystrophy, a dilated cardiomyopathy can rarely develop. The dilated cardiomyopathy is more common in patients in whom the survival time has been improved with cardiac device implantation. Both autopsy and endomyocardial biopsy specimens have shown cardiac fibrosis.

Patients with disorders caused by lamin A and C mutations typically present at 20 to 40 years of age with cardiac conduction disease, atrial fibrillation, and dilated cardiomyopathy. Skeletal muscle disease typically is subclinical or absent. Progression of a cardiomyopathy to the extent that heart transplantation is required has been described. Sudden death in those patients with a dilated cardiomyopathy occurs. Pacing often is required for symptomatic heart block. Implantable cardioverter-defibrillators are the appropriate cardiac device for a majority of patients.

Treatment and Prognosis

Patients should be monitored for development of electrocardiographic conduction abnormalities and arrhythmias. Annual evaluation is appropriate. Atrioventricular block can occur with anesthesia. Sudden death even in patients with pacemakers has been observed. Prophylactic placement of an implantable cardioverter-defibrillator is advocated in patients with Emery-Dreifuss muscular dystrophy and its associated disorders if significant electrocardiographic conduction disease is present and pacing is being considered.[20] The use of biventricular pacing should be considered in patients that require ventricular pacing. Whether implantable cardioverter-defibrillators should be considered only in certain subgroups of patients or in all patients with significant conduction disease or cardiomyopathy is not clear. In a large observational European series, risk factors for sudden death and appropriate implantable cardioverter-defibrillator therapy included nonsustained ventricular tachycardia, left ventricular ejection fraction less than 45% at presentation, male sex, and lamin A or C non–missense mutations.[20] Routine imaging for evaluation of left ventricular function is appropriate in all patients with Emery-Dreifuss muscular dystrophy and the associated disorders. Patients with left ventricular dysfunction should benefit from pharmacologic therapy, but data on this issue are limited. Successful heart transplantation has been reported. Female carriers of X-linked recessive Emery-Dreifuss muscular dystrophy develop conduction disease, and electrocardiographic monitoring on a routine basis is appropriate.

Limb-Girdle Muscular Dystrophies

Genetics

The limb-girdle muscular dystrophies are a group of disorders with a limb-shoulder and pelvic girdle distribution of weakness, but with otherwise heterogeneous inheritance and genetic cause.[21] Autosomal recessive (subtypes 2A to 2W), dominant (subtypes 1A to 1H), and sporadic patterns of inheritance have been observed. Genes involved include those encoding dystrophin-associated glycoproteins, sarcomeric proteins, sarcolemma proteins, nuclear membrane proteins, and cellular enzymes. An autosomal dominant limb-girdle muscular dystrophy (subtype 1B) with a high prevalence of arrhythmias and a late dilated cardiomyopathy is caused by mutations encoding lamin A/C, as in Emery-Dreifuss muscular dystrophy.

An autosomal recessive or sporadic limb-girdle muscular dystrophy associated with a progressive dilated cardiomyopathy is caused by mutations affecting the function of the dystrophin-glycoprotein complex, including sarcoglycan and fukutin-related proteins (subtypes 2C to 2F and 2I, respectively). The sarcoglycans complex with dystrophin-associated glycoproteins to counteract mechanical stress associated with contraction. Fukutin-related proteins affect glycosylation of a dystrophin-associated glycoprotein. An autosomal recessive limb-girdle muscular dystrophy associated with a variable onset of a dilated cardiomyopathy is caused by a mutation in a sarcolemmal repair protein termed dysferlin (subtype 2B). Other more recently discovered and rarer subtypes of limb-girdle muscular dystrophy are variably associated with cardiac or arrhythmia abnormalities in limited reports.

Clinical Presentation

The onset of muscle weakness is variable but usually occurs before age 30. The recessive disorders tend to cause earlier and more severe weakness than the dominant disorders. Creatine kinase levels are moderately elevated. Patients commonly present with complaints of difficulty with walking or running secondary to pelvic girdle involvement. As the disease progresses, involvement of the shoulder muscles and then more distal muscles occurs, with sparing of facial involvement. Slow progression to disability and death can occur.

Cardiovascular Manifestations

As with many of the features of the limb-girdle muscular dystrophies, heterogeneity in the presence and degree of cardiac involvement is usual.

The limb-girdle muscular dystrophies types 2C to 2F, termed *sarcoglycanopathies*, manifest with a dilated cardiomyopathy. Cardiac abnormalities are detected in a majority of patients typically a decade after skeletal muscle symptoms occur. Cardiomyopathy is most common in the subtype 2E and least common in the subtype 2D. ECGs show similar abnormalities as in Duchenne and Becker muscular dystrophy, including an increased R wave in V_1 and lateral Q waves. Imaging can show a progressive dilated cardiomyopathy. A severe cardiomyopathy, including presentation with heart failure in childhood, can occur. Sudden death associated with the cardiomyopathy has been reported. Limb-girdle muscular dystrophy type 2I, caused by mutations in fukutin-related proteins, is associated with a dilated cardiomyopathy. The mutation is also responsible for a form of congenital muscular dystrophy. The age at disease onset and severity of skeletal muscle involvement are variable, with symptoms emerging in some patients during childhood but more typically developing after the age of 20 years. Approximately one half of patients with limb-girdle muscular dystrophy type 2I exhibit cardiac involvement (**Fig. 97.12**). Cardiac involvement has been reported as more common in males. Cardiac findings include regional wall motion abnormalities or a dilated cardiomyopathy and heart failure. Advanced heart failure can occur. Conduction disease does not occur separate from the structural cardiac involvement. Limb-girdle muscular dystrophy type 2B, termed a *dysferlinopathy*, has been associated with increased myocardial fibrosis on cardiac magnetic resonance imaging and variably with a dilated cardiomyopathy.

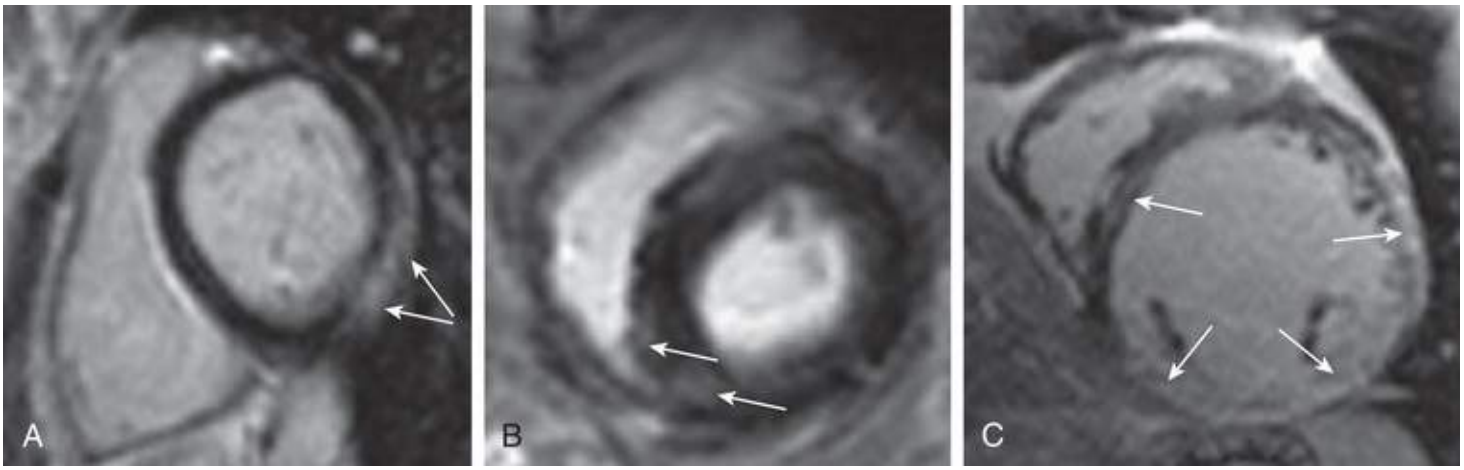

FIGURE 97.12 Cardiac magnetic resonance findings in limb-girdle muscular dystrophy. Late postgadolinium enhancement imaging in limb-girdle muscular dystrophy patients demonstrating **A,** focal epicardial or **B**, midwall enhancement. **C,** a patient with limb-girdle muscular dystrophy 2I and advanced dilated cardiomyopathy had extensive myocardial injury/fibrosis. (From Rosales XQ, Moser SJ, Tran T, et al: Cardiovascular magnetic resonance of cardiomyopathy in limb girdle muscular dystrophy 2B and 2I. J Cardiovasc Magn Reson 2011;13:39.)

The autosomal dominant limb-girdle muscular dystrophy type 1B is caused by mutations in the gene encoding lamins A and C with a clinical phenotype similar to Emery-Dreifuss muscular dystrophy. Skeletal muscle involvement is mild, with cardiac involvement both common and severe. Atrioventricular block develops by early middle age, often necessitating pacing. Sudden death is observed even in patients with pacemakers. A progressive dilated cardiomyopathy can occur, typically after the development of conduction disease.

Treatment and Prognosis

Because of the heterogeneous nature of limb-girdle muscular dystrophy, specific recommendations for routine cardiac evaluation and therapy are based upon the disease type. In patients and families with limb-girdle types that manifest with cardiac involvement, evaluation for ventricular dysfunction, conduction disease, and arrhythmias is indicated. Patients with dilated cardiomyopathies respond to standard heart failure therapy. Heart transplantation has been reported. Prophylactic placement of an implantable cardioverter-defibrillator instead of a pacemaker has been recommended in patients with lamin A and C mutation after conduction disease is observed. In a large observational European series, risk factors for sudden death and appropriate implantable cardioverter-defibrillator therapy included nonsustained ventricular tachycardia, left ventricular ejection fraction less than 45% at presentation, male sex, and lamin A or C non–missense mutations.[20]

Facioscapulohumeral Muscular Dystrophy

Genetics

Facioscapulohumeral muscular dystrophy is the third most common muscular dystrophy after the Duchenne and myotonic types.[22] Underreporting of disease prevalence is likely due to mild subclinical forms. It is a disorder of autosomal dominant inheritance in which the primary genetic mutation occurs at chromosomal locus 4q35, with a contraction of a D4Z4 repeat sequence. The repeat sequence is required to suppress transcription of adjacent genes, and its contraction results in inappropriate protein expression. Genetic heterogeneity with a second mutation has been reported.

Clinical Presentation

Muscle weakness tends to follow a slowly progressive but variable course. The patient initially presents with facial and/or shoulder girdle muscle weakness, which progresses to involve the pelvic musculature.

Cardiovascular Manifestations

Cardiac involvement in facioscapulohumeral muscular dystrophy is reported but does not constitute as significant a problem in prevalence or severity as in other muscular dystrophies. In some series, no evidence of cardiac abnormalities was found. Other series have reported a propensity toward arrhythmias primarily of atrial origin, with atrioventricular conduction abnormalities less common.

Treatment and Prognosis

Because significant clinical cardiac involvement is rare in facioscapulohumeral muscular dystrophy, specific monitoring or treatment recommendations are not well defined. Yearly ECGs have been recommended.

Friedreich Ataxia

Genetics

Friedreich ataxia is a spinocerebellar degenerative disease of autosomal recessive inheritance, characterized clinically by ataxia of the limbs and trunk, dysarthria, loss of deep tendon reflexes, sensory abnormalities, skeletal deformities, diabetes mellitus, and cardiac involvement.[23] The primary genetic abnormality is an expansion of a trinucleotide repeat, guanine-adenine-adenine (GAA), in an intron of a gene that encodes a 210–amino acid mitochondrial protein called frataxin. Loss of frataxin affects mitochondrial iron homeostasis, making the cell susceptible to oxidative stress (**Fig. 97.13**). Messenger RNA for frataxin is highly expressed in the heart. Endomyocardial biopsy samples have shown deficient function in mitochondrial respiratory complex subunits and in aconitase, an iron-sulfur protein involved in iron homeostasis. Impaired mitochondrial lipid metabolism also may play a role in the cardiomyopathy in Friedreich ataxia. Histopathologic examination has revealed myocyte hypertrophy due to proliferation of mitochondria, myocyte degeneration, interstitial fibrosis, active muscle necrosis, bizarre pleomorphic nuclei, and periodic acid–Schiff–(PAS) positive deposition in both large and small coronary arteries. Degeneration and fibrosis in cardiac nerves and ganglia and the conduction system also have been observed. Deposition of calcium salts and iron has been reported.

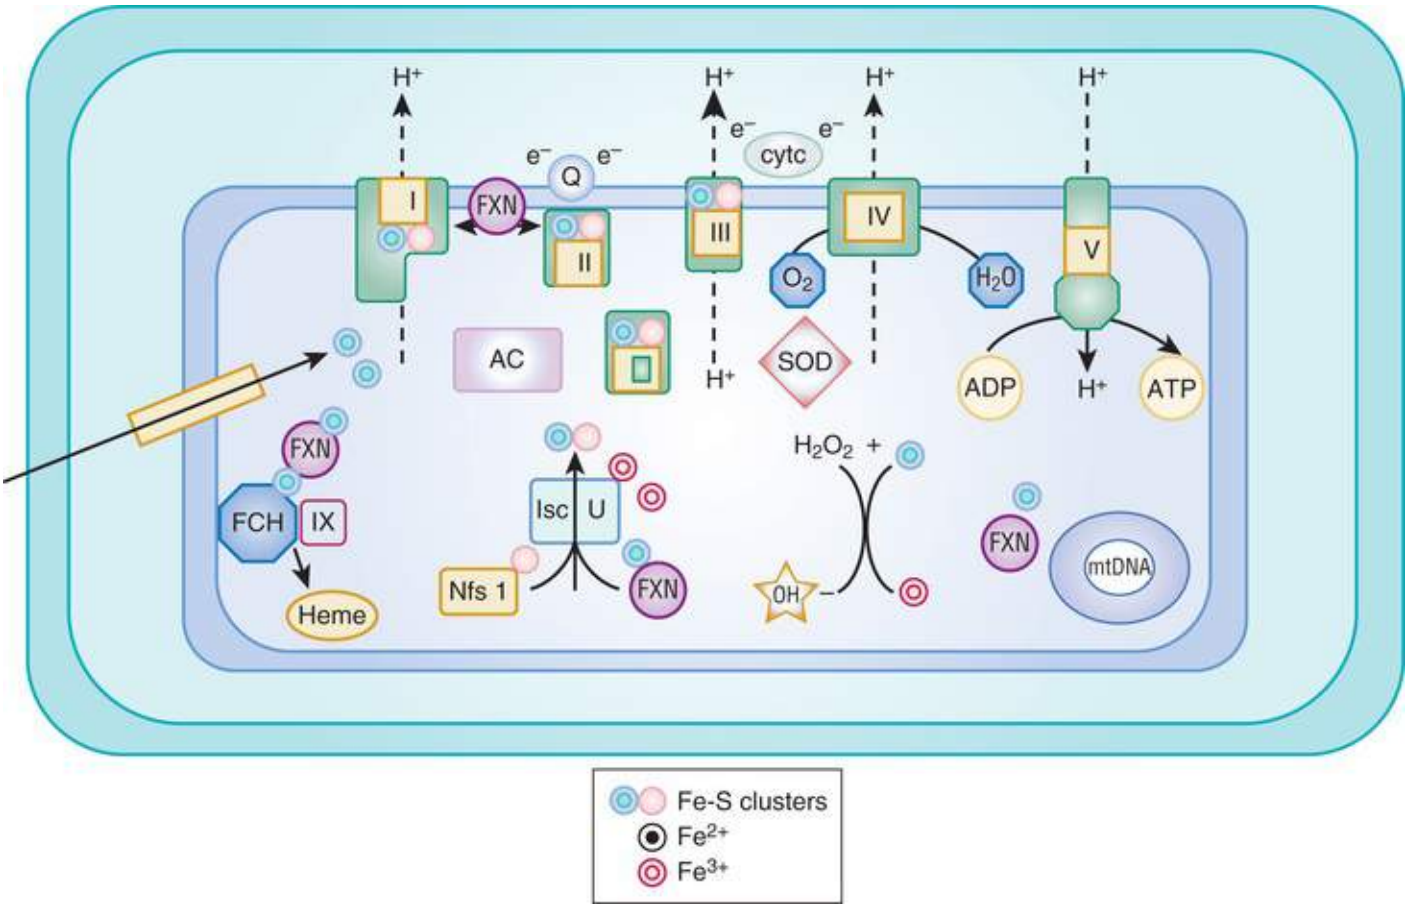

FIGURE 97.13 Postulated functions of frataxin (FXN). 1. Frataxin is a general iron chaperone, providing Fe^{2+} to ferrochelatase (FCH) for heme biosynthesis, mitochondrial iron-sulfur (Fe-S) clusters biogenesis, and maintenance of the mitochondrial aconitase (AC) Fe-S cluster. 2. Frataxin may have a direct interaction with respiratory chain complexes (I-V). 3. Frataxin prevents oxidative stress and protects mitochondrial proteins and mitochondrial DNA (mtDNA) from free Fe^{2+}. It prevents the Fenton reaction by converting Fe^{2+} to Fe^{3+}, and thereby prevents hydroxyl radical formation protecting highly metabolic tissue, including the heart, from oxidative stress. *ADP*, adenosine diphosphate; *ATP*, adenosine triphosphate; *cytc*, cytochrome *c*; e^-, electron; *Isc U*, iron-sulfur cluster scaffold protein; *Nfs*, nitrogen fixation homologue; *Q*, coenzyme Q (ubiquinone); *SOD*, superoxide dismutase. (From Pandolfo M: Friedreich ataxia. Arch Neurol 2008;65:1296.)

An earlier age at symptom onset, increasing severity of neurologic symptoms, and worsening left ventricular hypertrophy are observed in patients in whom genetic testing shows a greater expansion of the GAA repeat.

Clinical Presentation

Friedreich ataxia is the most common inherited spinocerebellar degenerative disease. Neurologic symptoms usually are manifested around puberty and almost always before age 25. Progressive loss of neuromuscular function, with the patient wheelchair-bound 10 to 20 years after symptom onset, is the usual course. Neurologic symptoms precede cardiac symptoms in most but not all cases.

Cardiovascular Manifestations

Friedreich ataxia is associated with a concentric hypertrophic cardiomyopathy (**Fig. 97.14**). Asymmetric septal hypertrophy is rare but has been reported. A left ventricular outflow gradient is atypical but has been observed. The prevalence of hypertrophy increases, particularly with a younger age at diagnosis and also with increasing GAA trinucleotide expansion. Approximately 70% of patients have abnormalities on

imaging studies. Left ventricular hypertrophy is not always present on ECGs despite echocardiographic evidence. Widespread T wave inversions are common (**Fig. 97.15**). Patients with left ventricular hypertrophy without systolic dysfunction typically have no cardiac symptoms. About 10% of patients develop left ventricular systolic dysfunction with an ejection fraction of less than 50%.[24] Presentation with a dilated cardiomyopathy has been reported (**Fig. 97.16**). The dilated cardiomyopathy occurs as a transition from the hypertrophic cardiomyopathy. A severe dilated cardiomyopathy with progressive heart failure can be present.[25]

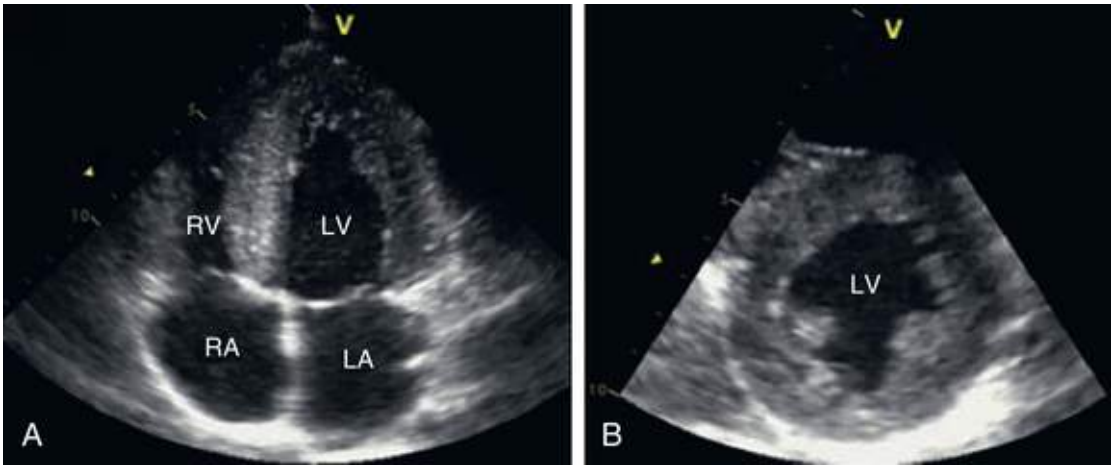

FIGURE 97.14 Hypertrophic cardiomyopathy in Friedreich ataxia. **A**, Echocardiographic apical 4-chamber and **B**, short-axis views from a Friedreich ataxia patient with left ventricular hypertrophy (LV wall thickness 15 mm). *LA*, left atrium; *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle. (From Weidemann F, Stork S, Liu D, et al: Cardiomyopathy of Friedreich ataxia. J Neurochem 2013;126[Suppl 1]:88.)

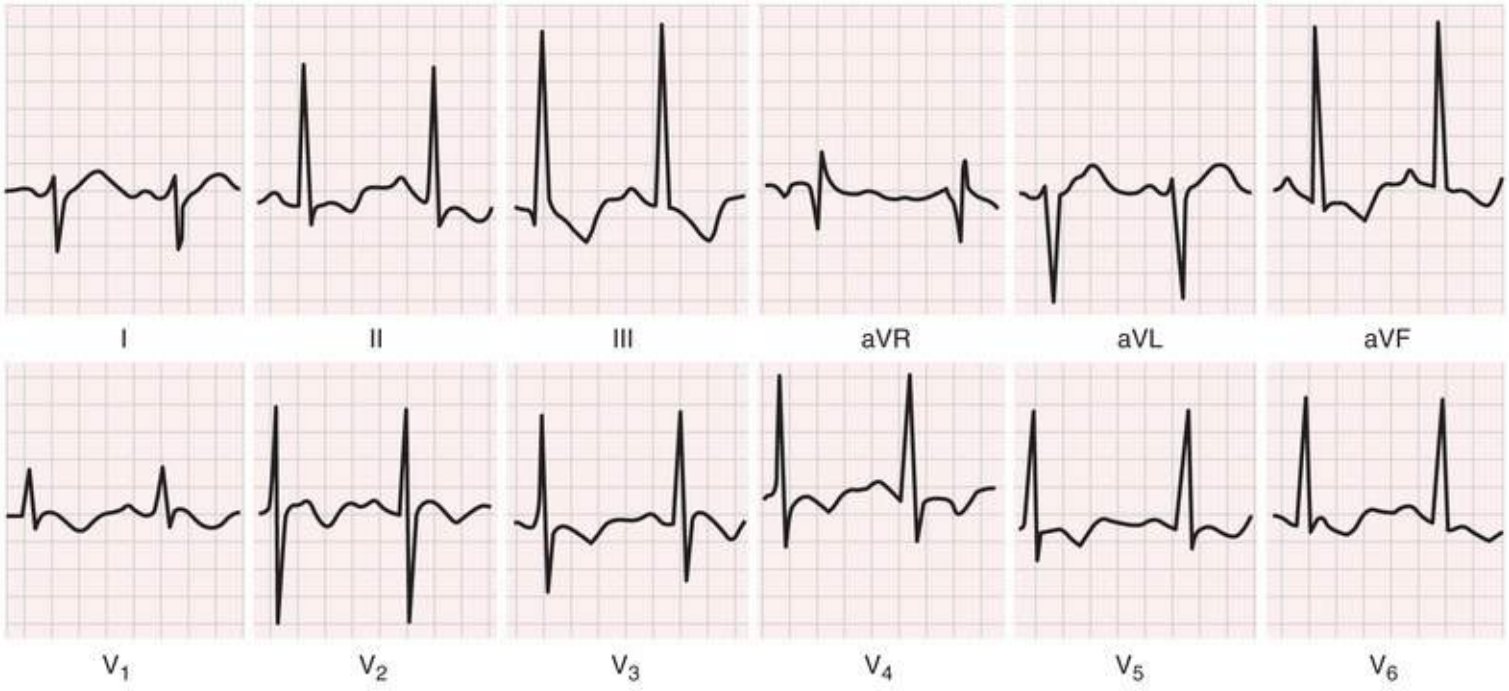

FIGURE 97.15 ECG from a 34-year-old man with Friedreich ataxia. Widespread ST and T changes are evident. (Courtesy Dr. Charles Fisch, Indiana University School of Medicine, Indianapolis.)

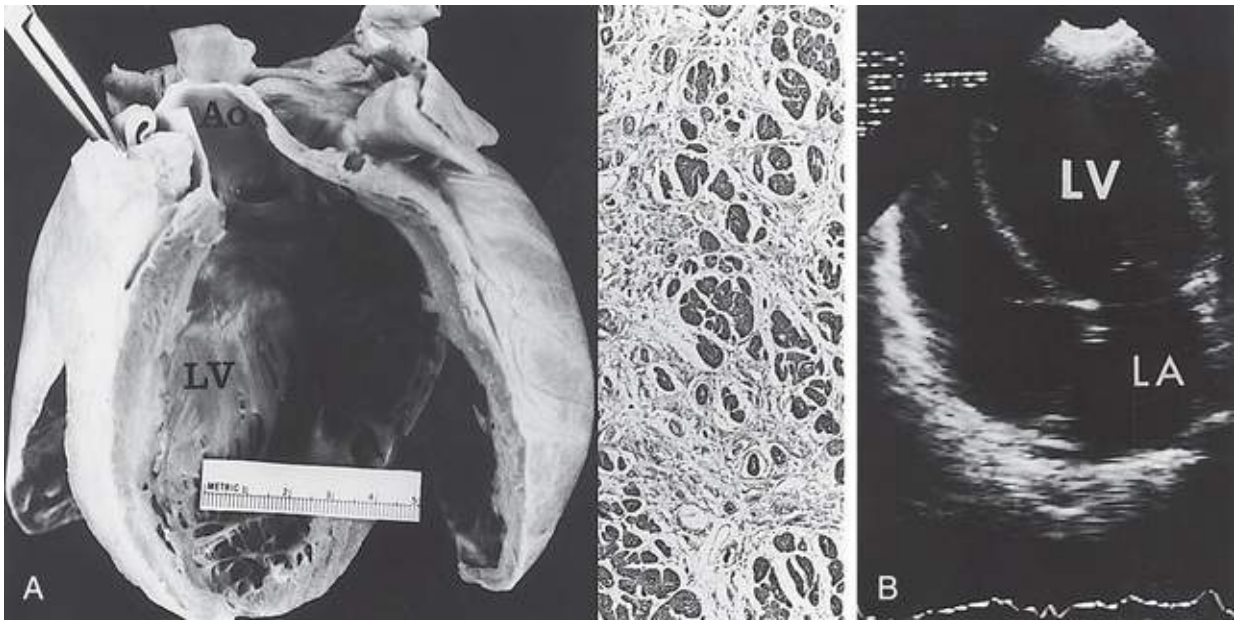

FIGURE 97.16 **A,** Gross and histologic specimens from a 17-year-old boy with Friedreich ataxia whose ECG progressed from a normal appearance at age 13 years to a minimally dilated, hypocontractile left ventricle (LV) 3 to 4 years later. The gross specimen *(left)* shows a mildly dilated LV with normal wall thickness; the walls were flabby. The microscopic section from the left ventricular free wall *(right)* shows marked connective tissue replacement. Although specifically sought, small-vessel coronary artery disease was not identified. **B,** Two-dimensional echocardiogram (apical window) showing the mildly dilated, thin-walled LV. *Ao*, aorta; *LA*, left atrium. (**A, B,** From Child JS, Perloff JK, Bach PM, et al: Cardiac involvement in Friedreich ataxia. J Am Coll Cardiol 1986;7:1370.)

Atrial arrhythmias including atrial fibrillation and flutter are associated with the progression to a dilated cardiomyopathy. Ventricular tachycardia, again in the setting of a dilated cardiomyopathy, has been observed. The hypertrophic cardiomyopathy of Friedreich ataxia is not associated with serious ventricular arrhythmias, as observed in the other types of heritable hypertrophic cardiomyopathies. Myocardial fiber disarray is not commonly observed in the hypertrophic cardiomyopathy of Friedreich ataxia. Sudden death likely due to ventricular arrhythmias has been reported, but a mechanism has not been well characterized.[25]

Treatment and Prognosis

Idebenone, a free radical scavenger, has modest but variable effectiveness for decreasing left ventricular hypertrophy in Friedreich ataxia. Idebenone does not improve left ventricular systolic function. It is unclear whether the modest improvement in cardiac imaging parameters leads to an alteration in the clinical cardiovascular course. Idebenone does not improve neurologic outcomes.

In a majority of patients with Friedreich ataxia, neurologic dysfunction is progressive. Cardiac death occurs in those with a dilated cardiomyopathy. Heart failure is the most common cause of death.[25] Arrhythmias complicate heart failure deaths in one third of patients. Respiratory dysfunction is the second most common cause of death. Death from heart failure occurs earlier than respiratory death, typically before the age of 30 years. The role of pharmacologic or defibrillator therapy in Friedreich ataxia and dilated cardiomyopathy has not been evaluated, but such conventional therapy should be considered until a disease-modifying treatment is available.

Less Common Neuromuscular Diseases Associated With Cardiac Manifestations

The Periodic Paralyses

Genetics and Clinical Presentation

The primary periodic paralyses are rare, nondystrophic disorders of autosomal dominant inheritance resulting from abnormalities in ion channel genes.[26] They can be classified into hypokalemic and hyperkalemic periodic paralyses and Andersen-Tawil Syndrome (**see also Chapter 33**). In addition, acquired hypokalemic periodic paralysis may complicate thyrotoxicosis, especially in men of Asian descent. All patients present with episodic attacks of flaccid paralysis precipitated by variable environmental stimuli including cold and exercise, or with rest after exercise. A late-onset fixed myopathy can occur in hypokalemic and hyperkalemic periodic paralyses.

Hypokalemic periodic paralysis is characterized by episodic attacks of weakness exacerbated by carbohydrate load or occurring during rest after exercise and is associated with decreased serum potassium levels at onset. Penetrance is nearly complete in male patients and 50% in female patients. It is caused by point mutations in the alpha-1 subunit of the dihydropyridine-sensitive calcium channel (CACNA1S) or in the alpha subunit of the skeletal muscle sodium channel (SCN4A). Approximately 20% of cases are of uncertain genetic cause. One third of the cases of thyrotoxic hypokalemic periodic paralysis are caused by mutations in an inward rectifier potassium channel, Kir2.6, which is regulated by thyroid hormone.

Hyperkalemic periodic paralysis also manifests with episodic weakness but with symptoms worsening with potassium supplementation and decreasing with carbohydrate load. Complete penetrance is observed. Potassium levels usually are high but may be normal during an attack. Hyperkalemic periodic paralysis is due primarily to mutations in the alpha subunit of the skeletal muscle sodium channel, *SCN4A*. Multiple different mutations in this gene have been reported that result in a potassium-sensitive failure of inactivation (gain of function) in the sodium channel. Hyperkalemic periodic paralysis is genetically heterogeneous; an *SCN4A* mutation is found in a majority of affected persons, but other loci also have been identified.

Andersen-Tawil syndrome is a distinct periodic paralysis associated with dysmorphic physical features of short stature, low-set ears, micrognathia, hypertelorism, and clinodactyly; abnormalities on the ECG include an abnormal QT-U wave pattern and ventricular arrhythmias[27] (**Fig. 97.17**). Weakness can be triggered by low, normal, or high potassium levels. It can be inherited in an autosomal dominant fashion or can be sporadic. Phenotypic variability and incomplete penetrance can complicate the diagnosis for a given family. Mutations in the *KCNJ2* gene encoding the inward rectifier potassium protein, Kir2.1, that underlie the background current, I_{K1}, are responsible for 60% of cases (type 1 Andersen-Tawil syndrome). The genetic cause(s) in the other 40% of patients (type 2 Andersen-Tawil syndrome) is unknown but seemingly involve other proteins contributing to I_{K1} because the phenotype is indistinguishable from type 1. The loss-of-function of I_{K1} is responsible for the large and prolonged U wave.[28] Andersen-Tawil syndrome has been designated long QT syndrome 7.

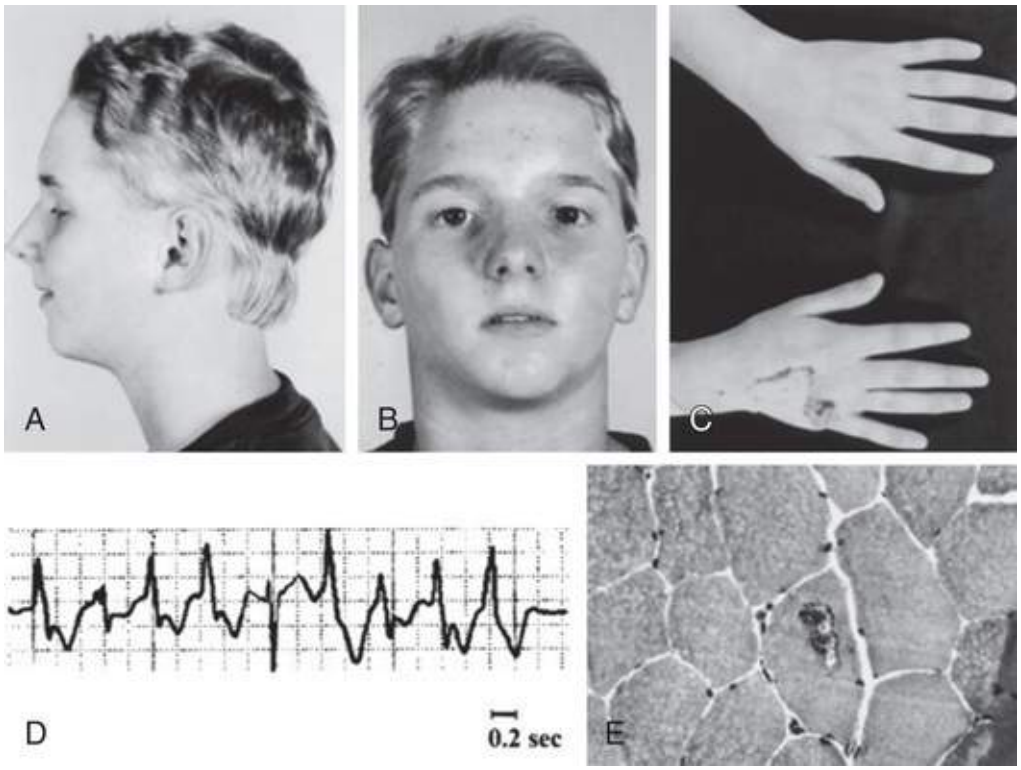

FIGURE 97.17 Andersen-Tawil syndrome. **A, B,** An affected patient exhibits characteristic low-set ears, hypertelorism, micrognathia, and clinodactyly of the fifth digits **(C). D,** ECG rhythm strip demonstrating short runs of polymorphic ventricular tachycardia. **E,** Skeletal muscle biopsy specimen exhibiting tubular aggregates commonly observed in patients with periodic paralysis. (From Plaster NM, Tawil R, Tristani-Firouzi M, et al: Mutations in Kir2.1 cause the developmental and episodic electrical phenotypes of Andersen's syndrome. Cell 2001;105:511.)

Cardiovascular Manifestations

The periodic paralyses are associated with ventricular arrhythmias. Most arrhythmias occur in hyperkalemic periodic paralysis and Andersen-Tawil syndrome. Bidirectional ventricular tachycardia has been observed without digitalis intoxication (**see also Chapters 12 and 34**). The episodes of bidirectional ventricular tachycardia are independent of attacks of muscle weakness, do not correlate with serum potassium levels, and can convert to sinus rhythm with exercise. The tachycardia typically is less than 150 beats/min and well tolerated. Ventricular ectopy is common.

A prolonged QT interval can be observed. It can be episodic, prolonging associated with weakness or hypokalemia, or occurring as a consequence of antiarrhythmia therapy, or it may be constant. Andersen-Tawil syndrome is associated with a modest prolongation in the QT interval but more specifically a prolonged and prominent U wave. Ventricular arrhythmias, including premature ventricular complexes, ventricular bigeminy, and nonsustained polymorphic ventricular tachycardia, primarily bidirectional tachycardia, are observed in Andersen-Tawil syndrome. Cardiac conduction abnormalities, atypical of long QT syndromes, have been observed in Andersen-Tawil syndrome. Torsades de pointes is observed in Andersen-Tawil syndrome but is less common than in the other long QT syndromes. Syncope, cardiac arrest, and sudden death have been reported in the periodic paralyses, most prominently in the Andersen-Tawil syndrome. The factors that portend an increased risk of life-threatening arrhythmias are not clear. The frequency of ventricular ectopy or nonsustained ventricular tachycardia on ambulatory monitoring did not differentiate Andersen-Tawil syndrome patients with and without syncope.[29]

Treatment and Prognosis

The episodes of weakness typically respond to measures that normalize potassium levels. Weakness in hyperkalemic periodic paralysis can respond to mexiletine. Weakness in hypokalemic periodic paralysis can respond to acetazolamide. Treatment targeting electrolyte abnormalities usually does not ameliorate arrhythmias or, if it does, affords only transient benefit. Improvement in symptomatic nonsustained ventricular tachycardia associated with a prolonged QT interval has been reported with beta-blocker therapy. Class 1A antiarrhythmia agents can worsen muscle weakness and exacerbate arrhythmias associated with a prolonged QT interval. Bidirectional ventricular tachycardia, not associated with a prolonged QT interval, may not respond to beta-blocker therapy. Flecainide decreases the frequency of ventricular arrhythmias assessed by ambulatory monitoring and is associated with a good clinical outcome over 2 years in Andersen-Tawil syndrome.[30] Amiodarone and imipramine have also been shown to have efficacy in small series and case reports. The use of implantable cardioverter-defibrillators has been reported in the Andersen-Tawil syndrome, primarily in those with symptomatic and drug-refractory sustained ventricular arrhythmias.[29] Programming of defibrillators to avoid inappropriate discharges is problematic because ventricular tachycardia is often self-terminating. Prognosis in the Andersen-Tawil syndrome is good despite frequent episodes of ventricular ectopy.

Mitochondrial Disorders

Genetics and Clinical Presentation

The mitochondrial disorders, also termed mitochondrial myopathies, encephalomyopathies, or respiratory chain disorders, are a heterogeneous group of diseases resulting from abnormalities in mitochondrial DNA and respiratory chain function.[31] The list of distinct disorders is extensive. Mitochondrial DNA is inherited maternally, and some of these disorders are thus transmitted from mother to children of both sexes. Many other disorders result from abnormalities in nuclear DNA involved in mitochondrial form and function and are inherited in an autosomal or X-linked fashion. Sporadic cases can occur. Disease severity can vary among family members because both mutant and normal mitochondrial DNA can be present in tissue in variable proportions. a phenomenon termed *heteroplasmy*. It is not surprising, in view of the metabolic function of mitochondria, that these disorders manifest with systemic pathology. Tissue with a high respiratory workload such as brain and skeletal muscle, especially extraocular, retinal, and cardiac muscle, are primarily affected.

Mitochondrial disorders that have cardiac manifestations may appear as part of several clinical phenotypes. *Chronic progressive external ophthalmoplegia* is characterized by involvement of the extraocular muscles and can also involve oropharyngeal muscles. It is primarily a sporadic disease. *Kearns-Sayre syndrome*, a subtype of chronic progressive external ophthalmoplegia, is characterized by ocular myopathy, pigmentary retinopathy, and age at onset before 20 years. Diabetes, deafness, and ataxia can also be associated. *Myoclonus epilepsy with red ragged fibers* (MERRF) is characterized by myoclonus, seizures, ataxia, dementia, and skeletal muscle weakness. *Mitochondrial myopathy with encephalopathy, lactic acidosis, and strokelike episodes* (MELAS) is the most common of the maternally inherited mitochondrial disorders and is characterized by encephalopathy, subacute strokelike events, migraine-like headaches, recurrent emesis, extremity weakness, and short stature. *Leber hereditary optic neuropathy* causes subacute blindness, primarily in young men. Other, mitochondrial point mutation disorders, including *NARP* (neuropathy, ataxia, and retinitis pigmentosa) and *Leigh syndrome* (subacute necrotizing encephalomyelopathy) cause neurodegenerative disorders primarily in children. *Barth syndrome* is an X-linked mitochondrial disease manifested by hypotonia, growth retardation, cyclic neutropenia, and 3-methylglutaconic aciduria in children. It is caused by mutations in exons of the nuclear

gene encoding the tafazzin protein.

Cardiovascular Manifestations

Patients with mitochondrial myopathy can present with chest pain or, more typically, dyspnea with exertion.[32] In chronic progressive external ophthalmoplegia, most commonly in the Kearns-Sayre syndrome variant, cardiac involvement manifests primarily as conduction abnormalities. In the Kearns-Sayre syndrome, atrioventricular block is observed, usually manifesting after eye involvement. The H-V interval is prolonged, consistent with distal conduction disease. Permanent pacing often is seen by early- to mid-adulthood. An increased prevalence of electrocardiographic preexcitation has also been reported. Cardiac magnetic resonance imaging demonstrates nonischemic, late gadolinium enhancement in approximately one third of patients.[32] A dilated cardiomyopathy may occur.

In MERRF and MELAS, a hypertrophic (symmetric or asymmetric) or dilated cardiomyopathy can occur. Other disorders caused by mitochondrial point mutations can manifest with a similar cardiac phenotype of hypertrophic or dilated cardiomyopathy, often in children. Whether the dilated cardiomyopathy represents a progression from the hypertrophic cardiomyopathy or a separate syndrome is not clear. The dilated cardiomyopathy can result in heart failure and death. More than one half of patients with MELAS had nonischemic, late gadolinium enhancement on cardiac magnetic resonance imaging.[32] Leber hereditary optic neuropathy can be associated with a hypertrophic cardiomyopathy and a short PR interval or preexcitation syndromes (**see also Chapter 37**). Barth syndrome is associated with left ventricular noncompaction and endocardial fibroelastosis or a hypertrophic or dilated cardiomyopathy. Heart failure and ventricular arrhythmias occur, often in young children. Cardiac transplantation has been reported.

Treatment and Prognosis

In Kearns-Sayre syndrome, the implantation of a pacemaker has been advocated when significant or progressive conduction disease is evident, even for those cases in asymptomatic patients. The degree of conduction disease that warrants prophylactic pacing is not clear. Implantable cardioverter-defibrillators are recommended in patients with both conduction disease and a dilated cardiomyopathy. In the other mitochondrial disorders, an understanding of the potential and specific presentations for cardiac involvement is necessary. Cardiac evaluation, electrocardiography, echocardiography, and other imaging modalities are recommended. Prophylactic or symptomatic heart failure pharmacotherapy, although not studied in these rare diseases, would seem warranted. Improved survival rates in children with Barth syndrome receiving aggressive treatment for cardiomyopathy and neutropenia has been observed.[33]

Spinal Muscular Atrophy

Genetics and Clinical Presentation

Spinal muscular atrophy is a lower motor neuron disorder manifesting as progressive, symmetric proximal muscular weakness.[34] It is the leading inherited cause of infant death. Spinal muscular atrophy is classified clinically by the age at symptom onset and disease severity into type I (Werdnig-Hoffman disease), type II (intermediate form), type III (Kugelberg-Welander disease), and type IV (adult-onset spinal muscular atrophy).

Spinal muscular atrophy is inherited in autosomal recessive fashion or is sporadic. Mutations or deletions in the telomeric *SMN* (survival of motor neuron) gene are observed in most patients. The loss of

functional SMN protein results in premature neuronal cell death. The SMN protein has a role in cardiac development.

Cardiovascular Manifestations

Cardiac abnormalities reported with spinal muscular atrophy include congenital heart disease, cardiomyopathy, and arrhythmias. Congenital heart disease can be seen with types I and III spinal muscular atrophy (**see also Chapter 75**). The most common abnormality is atrial septal defect; other reports have found ventricular septal defects and hypoplastic left heart syndrome. In spinal muscular atrophy type III, a dilated cardiomyopathy can occur, with endomyocardial biopsy demonstrating fibrosis. Arrhythmias reported include atrial standstill, atrial fibrillation, atrial flutter, and atrioventricular block. Permanent pacing for atrial standstill and atrioventricular block has been reported. Recent reports have questioned whether the noncongenital cardiac abnormalities observed in spinal muscular atrophy are primary or are secondary to progressive pulmonary failure.[35]

Treatment and Prognosis

In spinal muscular atrophy type I, severe skeletal muscle involvement with respiratory failure can limit the lifespan, and treatment of cardiac abnormalities is often not done. In spinal muscular atrophy type III, awareness of the potential for associated cardiac abnormalities is necessary. Directed gene therapy to improve the functional SMN protein holds future promise.

Desmin-Related Myopathies

Genetics and Clinical Presentation

Desmin myopathy is a rare inherited dystrophic disorder affecting skeletal and cardiac muscle.[36,37] The disorder is inherited primarily in autosomal dominant fashion, but autosomal recessive inheritance and sporadic disease have been reported. Typically, symptomatic skeletal muscle abnormalities will be recognized before cardiac involvement. Variability in the phenotype is recognized, however, and in members of affected families, a cardiomyopathy can develop without obvious skeletal muscle abnormalities. Desmin is a cytoskeletal protein that functions as the chief intermediate filament providing support to contracting skeletal and cardiac muscle. Mutations in the desmin gene lead to a disruption in forming functioning intermediate filaments.

Patients typically present in their late 20s with distal weakness that progresses proximally. Difficulty with ambulation and, in severe cases, with respiration can occur. Creatine kinase is mildly elevated in some patients. Muscle biopsy is diagnostic, showing desmin and other myofibrillar protein aggregation with immunostaining. Genetic testing is available.

Cardiovascular Manifestations

The cardiomyopathy associated with the desmin-related myopathies can occur prior to or after the diagnosis of a skeletal myopathy. The cardiac involvement observed typically consists of conduction system disease and, more rarely, ventricular arrhythmias, before the onset of a dilated or restrictive cardiomyopathy.[38] An arrhythmogenic right ventricular cardiomyopathy–like phenotype has been reported. Both sudden death and heart failure–related deaths can occur. Sudden death can occur despite pacemaker implantation.

Treatment and Prognosis

The desmin-related myopathies should be considered in the differential diagnosis in individual patients or families presenting with a skeletal or cardiac myopathy, including those with an arrhythmogenic right ventricular cardiomyopathy. Monitoring for the development of cardiac conduction and structural disease is necessary in affected families. Asymptomatic conduction disease on the ECG predicts future adverse cardiac events.[38] Prophylactic pacemakers or implantable cardioverter-defibrillators should be considered in those patients with significant conduction disease. Heart failure pharmacotherapy is indicated.

Guillain-Barré Syndrome

Clinical Presentation

The Guillain-Barré syndrome is an acute inflammatory demyelinating neuropathy characterized by peripheral, cranial, and autonomic nerve dysfunction (**see also Chapter 99**).[39] It is the most common acquired demyelinating neuropathy. Men are more commonly affected than women. In two thirds of affected patients, an acute viral or bacterial illness, typically respiratory or gastrointestinal, precedes the onset of neurologic symptoms within 6 weeks. The disorder typically manifests with pain, paresthesias, and symmetric limb weakness that progresses proximally and can involve cranial and respiratory muscles. One fourth of affected patients require assisted ventilation.

Cardiovascular Manifestations

Nonambulant patients are at increased risk for deep vein thrombosis and pulmonary emboli. Cardiac involvement related to accompanying autonomic nervous system dysfunction is seen in one half of the patients. Cardiac manifestations include hypertension, orthostatic hypotension, resting sinus tachycardia, loss of heart rate variability, electrocardiographic ST abnormalities, and both bradycardia and tachycardias. Pediatric patients typically have hypertension and tachycardia but rarely bradycardia.[40] Microneurographic recordings have shown increased sympathetic outflow during the acute illness, which normalizes with recovery.

Life-threatening arrhythmias occur in Guillain-Barré syndrome, primarily in patients requiring assisted ventilation. Arrhythmias observed include asystole, symptomatic bradycardia, rapid atrial fibrillation, and ventricular tachycardia or fibrillation. Asystole commonly was associated with tracheal suctioning. Death may occur as a consequence of an arrhythmia.

Treatment and Prognosis

Supportive care should include deep vein thrombosis prophylaxis in nonambulant patients. Early plasmapheresis or intravenous immunoglobulin can improve recovery. In severely affected patients, especially those requiring assisted ventilation, cardiac rhythm monitoring is mandatory. It is reasonable to monitor the rhythm via telemetry in all those admitted with Guillain-Barré syndrome. If serious bradycardia or asystole is observed, temporary or permanent pacing can improve survival. Atropine or isoproterenol during tracheal suctioning can be of benefit. The mortality rate in patients hospitalized with Guillain-Barré syndrome is as high as 15%. In patients who recover from Guillain-Barré syndrome, autonomic function also normalizes, and long-term arrhythmia risk has not been observed.

Myasthenia Gravis

Clinical Presentation

Myasthenia gravis is a disorder of neuromuscular transmission resulting from production of antibody targeted to the nicotinic acetylcholine receptor or muscle-specific receptor tyrosine kinase.[41] The primary symptom, fluctuating weakness, usually begins with the eye and facial muscles and later can involve the large muscles of the limbs. Patients can present at any age, typically at a younger age in women and at an older age in men. Myasthenia gravis is commonly associated with hyperplasia or a benign or malignant tumor (thymoma) of the thymus gland. Multiple autoimmune diseases can complicate myasthenia gravis.

Cardiovascular Manifestations

A myocarditis can occur in patients with myasthenia gravis, especially in those with a thymoma (**see also Chapters 79 and 92**). The etiologic mechanism in myocarditis is a humoral immune response against striational proteins, including titin, the ryanodine receptor, and a potassium-channel protein.[42] Up to 16% of patients with myasthenia gravis have cardiac manifestations not explained by another etiologic disorder. Presentation with arrhythmias, which can include atrial fibrillation, atrioventricular block, asystole, ventricular tachycardia, sudden death, or heart failure, is typical. Autopsy findings are consistent with myocarditis, often giant cell myocarditis. A polymyositis affecting both skeletal and cardiac muscle is seen.[43]

Treatment and Prognosis

Myasthenia gravis is treated with anticholinesterases and immunosuppressive agents. Thymectomy is often indicated. Anticholinesterase agents may slow the sinus rate and cause heart block and hypotension. Pacing can be necessary. Whether immunosuppressive agents or thymectomy might improve associated cardiac disease is unknown. Case reports have described the development of rapidly progressive and fatal heart failure within weeks after thymoma resection in patients in whom histologic examination showed giant cell myocarditis.

Epilepsy

Cardiovascular Manifestations

Epilepsy is a complex brain disorder characterized by chronic unprovoked seizures.[44] Patients with epilepsy are at increased risk for sudden death of unknown cause, which has been termed *sudden unexpected death in epilepsy* (SUDEP) (**see also Chapter 42**). It is the leading cause of premature death in patients with epilepsy, with an incidence ranging from 0.1 to 9.3 per 1000 patient-years, depending on the population studied.[45] The mechanisms leading to sudden death in epilepsy are not clear and probably vary. Central or obstructive postictal apnea, mechanical suffocation possibly exacerbated by prone positioning, excessive respiratory secretions, acute pulmonary edema, and arrhythmias all may be involved (**Fig. 97.18**). A number of drugs affecting the brain prolong the QT interval (**see also Chapters 8 and 36**). A majority of witnessed sudden deaths occur at or in proximity to the time of a seizure. Severe bradycardia with sinus arrest has been documented in monitored patients during seizures, including studies with an implantable loop recorder. Periictal bradycardia is more common in patients with temporal lobe seizures. Whether bradycardia has a role in epileptic patients who experience sudden death

is not clear. Primary ventricular arrhythmia disorders such as long-QT syndrome or right ventricular dysplasia can manifest with symptoms suggestive of epilepsy and could be responsible for a small proportion of sudden deaths. Patients can have concomitant epilepsy and heart disease, leading to ventricular arrhythmias and cardiac arrest.[46]

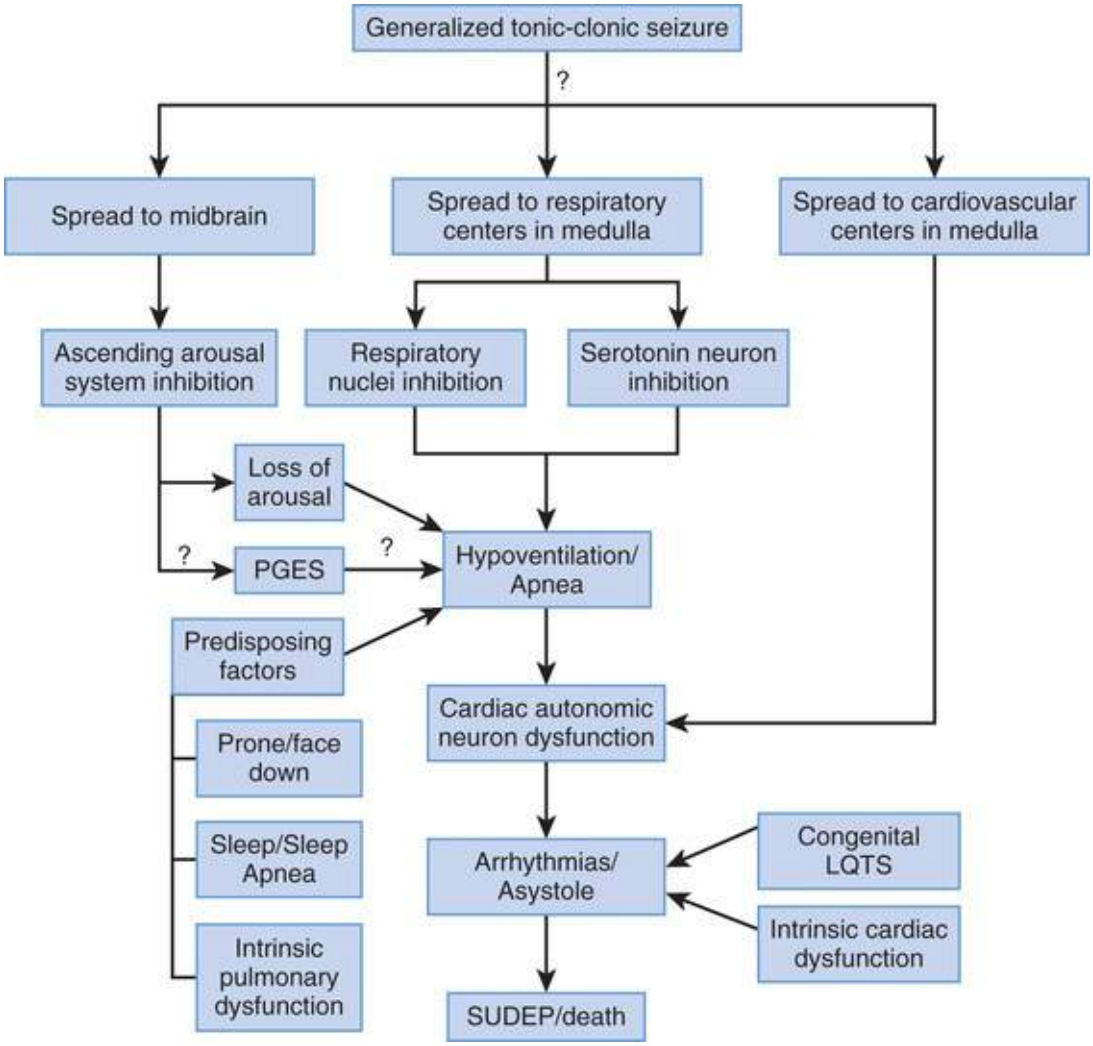

FIGURE 97.18 Pathophysiologic mechanisms underlying sudden unexpected death in epilepsy (SUDEP). SUDEP often results from a generalized tonic-clonic seizure, which leads to inhibition of specific midbrain- and medulla-mediated effects via an unknown pathway. Other factors shown may predispose these patients to SUDEP. *LQTS*, long QT syndrome; *PGES*, postictal generalized EEG suppression. (From Dlouhy BJ, Gehlbach BK, Richerson GB: Sudden unexpected death in epilepsy: basic mechanisms and clinical implications for prevention. J Neurol Neurosurg Psychiatry 2016;87:402.)

Observational studies have assessed risk factors for SUDEP. These include male sex, onset of epilepsy at a young age, a long duration of epilepsy, high seizure frequency especially of generalized tonic-clonic seizures, and the need for polytherapy to control seizures.[45]

Treatment and Prognosis

A primary arrhythmia disorder needs to be considered in the differential diagnosis of epilepsy. Patients with poorly controlled epilepsy should be aggressively evaluated and treated at tertiary epilepsy centers. Epilepsy surgery should be strongly considered. Patients with ictal bradycardia can require pacemaker implantation. Nighttime supervision of the epileptic patient and supine sleeping positions should be considered.

Acute Cerebrovascular Disease

Cardiovascular Manifestations

Acute cerebrovascular diseases, including subarachnoid hemorrhage, other stroke syndromes, and head injury, can be associated with severe cardiac manifestations (**see also Chapter 65**).[47,48] The mechanism by which cardiac abnormalities occur with brain injury is related to autonomic nervous system dysfunction, with both increased sympathetic and parasympathetic output (**see also Chapter 99**). Excessive myocardial catecholamine release is primarily responsible for the observed cardiac pathology. Hypothalamic stimulation can reproduce the electrocardiographic changes observed in acute cerebrovascular disease. Electrocardiographic changes associated with hypothalamic stimulation or blood in the subarachnoid space can be diminished with spinal cord transection, stellate ganglion blockade, vagolytics, and adrenergic blockers.

Electrocardiographic abnormalities are observed in approximately 70% of patients with subarachnoid hemorrhage. Abnormalities including ST elevation and depression, T wave inversion, and pathologic Q waves are observed. Peaked inverted T waves and a prolonged QT interval can occur in a significant proportion of patients with electrocardiographic abnormalities associated with cerebrovascular disease (**Fig. 97.19**). Hypokalemia often seen in patients with subarachnoid hemorrhage can increase the likelihood of QT interval prolongation. Other stroke syndromes often are associated with abnormalities on the ECG, but whether these are related to the stroke syndrome or to underlying intrinsic cardiac disease often is difficult to discern. A prolonged QT interval is more common in subarachnoid hemorrhage than in other stroke syndromes. Closed head trauma can cause electrocardiographic abnormalities similar to those in subarachnoid hemorrhage, including a prolonged QT interval.

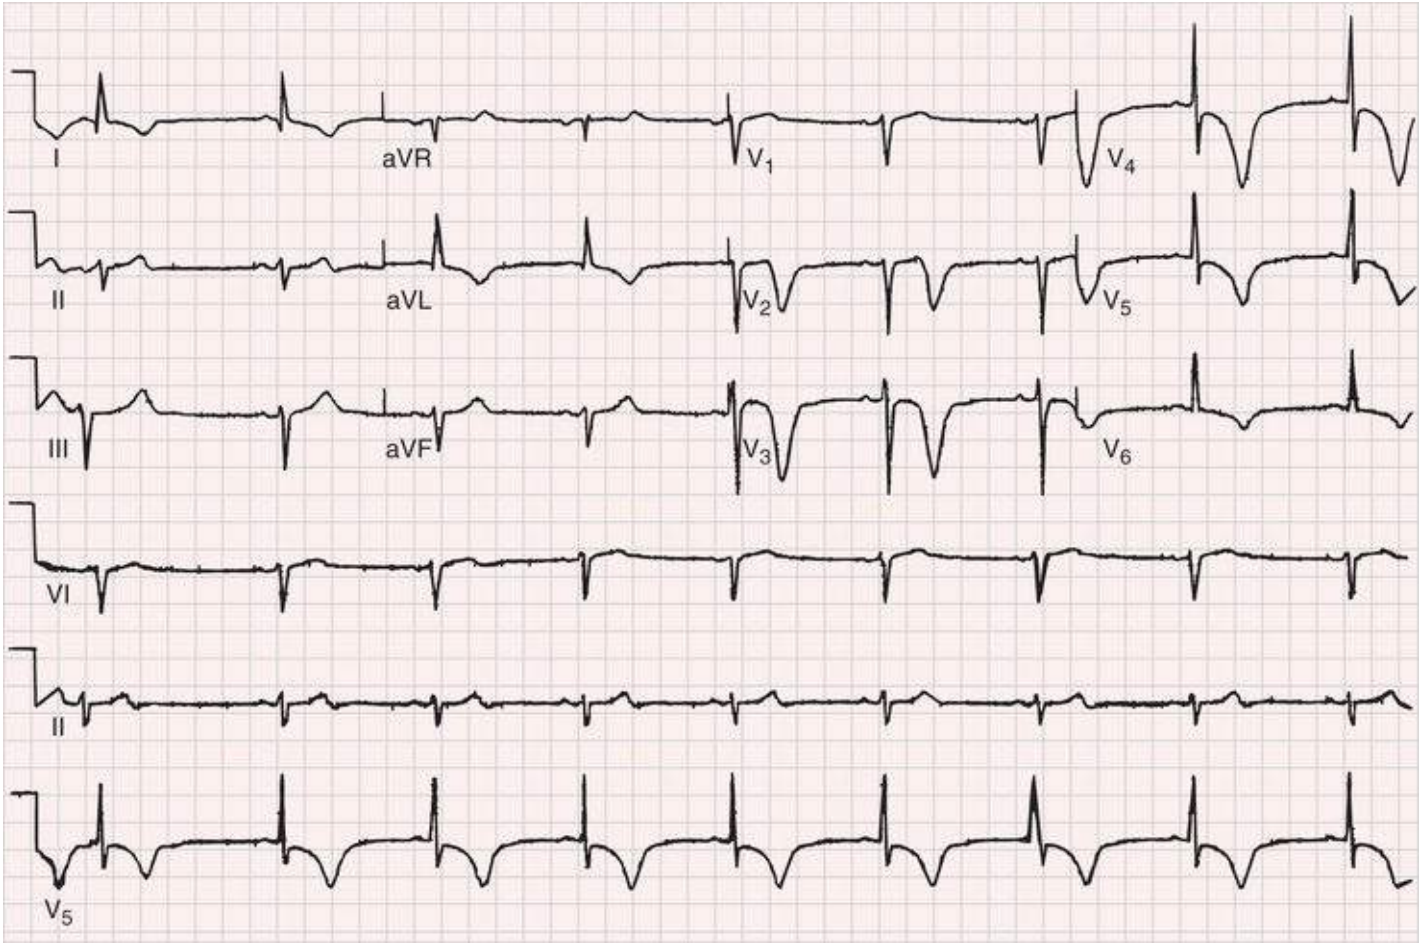

FIGURE 97.19 ECG from a patient with cerebral hemorrhage. Deep and symmetric T wave inversions are evident. (Courtesy Dr. Charles Fisch, Indiana University School of Medicine, Indianapolis.)

Myocardial damage with liberation of enzymes and subendocardial hemorrhage or fibrosis at autopsy can occur in the setting of acute cerebral disease. The term *neurogenic stunned myocardium* is used to describe the reversible syndrome. The process can manifest with selective apical involvement, a takotsubo cardiomyopathy. Cardiac troponin elevation and echocardiographic evidence of left ventricular dysfunction are present in a significant proportion of patients with subarachnoid hemorrhage. Patients with a poorer neurologic status at admission are more likely to have an increased peak troponin level. Women are at higher risk for myocardial necrosis.

Pulmonary edema can accompany the acute neurologic insult. The edema can have both a cardiogenic component, related to systemic hypertension and left ventricular dysfunction, and a neurogenic (pulmonary capillary leak) component.

Life-threatening arrhythmias can occur in the setting of acute cerebrovascular disease. Ventricular tachycardia or fibrillation has been observed in patients with subarachnoid hemorrhage and head trauma. Torsades de pointes–type ventricular tachycardia can occur (**Fig. 97.20**) (**see also Chapter 39**). Often this is observed in the setting of a prolonged QT interval and hypokalemia. Stroke syndromes other than subarachnoid hemorrhage appear to be only rarely associated with serious ventricular tachycardias. Atrial arrhythmias, including atrial fibrillation and regular supraventricular tachycardia, have been observed. Atrial fibrillation is most common in patients presenting with acute thromboembolic stroke. Separating an effect from the cause can be difficult. Bradycardias, including sinoatrial block, sinus arrest, and atrioventricular block, occur in up to 10% of patients with subarachnoid hemorrhage.

FIGURE 97.20 Cardiac manifestations with cerebral hemorrhage in a 49-year-old patient. **A,** ECG recorded within 3 hours of admission and 4 hours after onset of symptoms. QT interval prolongation is evident. **B,** Electrocardiographic monitoring 6 hours after admission. Ventricular bigeminy precedes the onset of polymorphic ventricular tachycardia. Cardioversion was required. The patient subsequently was treated with a beta-adrenergic blocker without further ventricular tachycardia. **C,** On an ECG obtained 2 weeks after hospital admission, the QT interval has normalized.

Treatment and Prognosis

Beta blockers appear to be effective in decreasing myocardial damage and in controlling both supraventricular and ventricular arrhythmias associated with subarachnoid hemorrhage and head trauma. Beta blockers increase the likelihood of bradycardia and cannot be used in patients with hypotension requiring vasopressors. Life-threatening arrhythmias occur primarily in the first day after a neurologic event. Continuous electrocardiographic monitoring during this period is indicated. Careful monitoring of potassium levels, especially in patients with subarachnoid hemorrhage, is warranted. Refractory ventricular arrhythmias have been controlled effectively with stellate ganglion blockade. Electrocardiographic abnormalities reflect unfavorable intracranial factors but do not appear to portend a poor cardiovascular outcome. The magnitude of peak troponin elevation is predictive for adverse patient outcomes, including severe disability at hospital discharge and death.[47]

Head injury (blunt trauma or gunshot wound) and cerebrovascular accidents are the leading causes of brain death in patients being considered as heart donors. These donors can manifest electrocardiographic abnormalities, hemodynamic instability, and myocardial dysfunction related primarily to adrenergic storm and not to intrinsic cardiac disease. Experimental studies on whether contractile performance recovers with transplantation are still controversial. Optimization of volume status and inotropic support with careful echocardiographic evaluation and possibly left-heart catheterization can allow the use of some donor hearts that would have otherwise been rejected.

Future Perspectives

Adult cardiologists and electrophysiologists are increasingly participating in the multidisciplinary management of patients with neurologic disorders that manifest cardiac issues. For many of these complex patients, management in tertiary centers is appropriate. Decisions on the use of pharmacotherapy and device therapy to manage cardiac manifestations will need to extrapolate indications from other patient groups because randomized controlled trial data will not be available for a majority of these rare diseases. Gene-based or molecular-targeted therapy is under current evaluation in many of the neurologic diseases and holds future promise.

Interface Between Renal Disease and Cardiovascular Illness

Peter A. Mccullough

The Cardiorenal Intersection

The heart and kidney are inextricably linked in terms of hemodynamic and regulatory functions. In a

normal 70-kg human, each kidney weighs about 130 to 170 g and receives blood flow of 400 mL/min per 100 g; this is approximately 20% to 25% of the cardiac output, and it allows the needed flow to maintain glomerular filtration by approximately 1 million nephrons (**Fig. 98.1**). This flow is several times greater per unit of weight than in most other organs. Although their oxygen extraction is low, the kidneys account for about 8% of the total oxygen consumption of the body. The kidney has a central role in electrolyte balance, protein production and catabolism, and blood pressure regulation. Communication between the kidney and the heart occurs at multiple levels, including via the sympathetic nervous system (SNS), via the renin-angiotensin-aldosterone system (RAAS), and by means of the substances vasopressin, endothelin, and the natriuretic peptides.

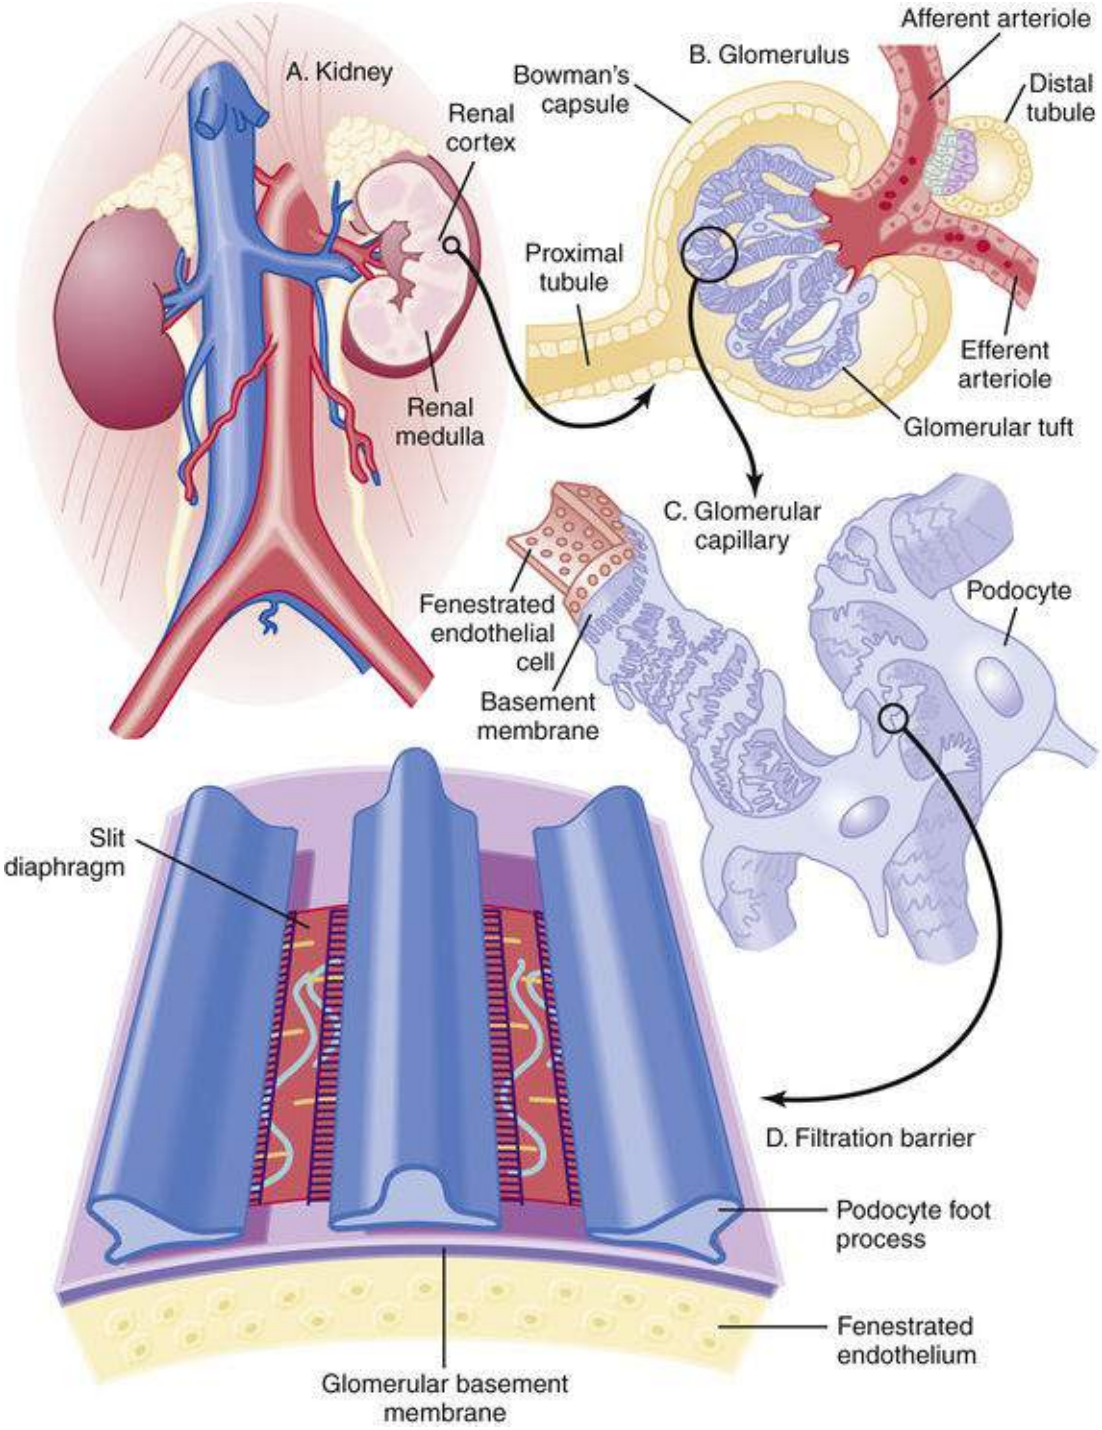

FIGURE 98.1 Normal structure of the glomerular vasculature. Each kidney contains about 1 million glomeruli in the renal cortex (Panel A). Panel B shows an afferent arteriole entering Bowman's capsule and branching into several capillaries that form the glomerular tuft; the walls of the capillaries constitute the actual filter. The plasma filtrate (primary urine) is directed to the proximal tubule, whereas the unfiltered blood returns to the circulation through the efferent arteriole. The filtration barrier of the capillary wall contains an innermost fenestrated endothelium, the glomerular basement membrane, and a layer of interdigitating podocyte foot processes (Panel C). In Panel D, a cross section through the glomerular capillary depicts the fenestrated endothelial layer and the glomerular basement membrane with overlying podocyte foot processes. An ultrathin slit diaphragm spans the filtration slit between the foot processes, slightly above the basement membrane. In order to show the slit diaphragm, the foot processes are drawn smaller than actual scale. (Adapted from Tryggvason K, Patrakka J, Wartiovaara J: Hereditary proteinuria syndromes and mechanisms of proteinuria. N Engl J Med 2006;354(13):1387-401.)

The obesity “pandemic” is spawning secondary epidemics of type 2 diabetes (DM) and hypertension (HTN), disorders that often lead to chronic kidney disease (CKD) and cardiovascular disease (CVD) that is underrecognized in primary care.[1] Among those who have had type 1 or type 2 DM for 25 years or more, the prevalence of diabetic nephropathy as a result of microvascular disease is about 50%.[2]

Approximately half of all cases of end-stage renal disease (ESRD) result from diabetic nephropathy. With the aging of the general population and the shift in cardiovascular care toward the elderly, decreasing levels of renal function, which occur as part of senescence, act as a major adverse prognostic factor after CVD events. CKD accelerates the progression of atherosclerosis, myocardial disease, and valvular disease, and promotes an array of cardiac arrhythmias leading to sudden death.[3]

Chronic Kidney Disease and Cardiovascular Risk

A range of estimated glomerular filtration rate (eGFR) values derived from equations defines CKD.[4] A common definition for CKD stipulates an eGFR of less than 60 mL/min/1.73 m^2 or the presence of kidney damage (**Fig. 98.2**). With aging (age 20 to 80 years) the eGFR declines from about 130 mL/min/1.73 m^2 to 60 mL/min/1.73 m^2. A variety of pathobiologic processes appear to begin when the eGFR drops below 60 mL/min/1.73 m^2 or stage 3 CKD (a serum creatinine [Cr] level of ≈ 1.2 mg/dL in a woman and ≈ 1.5 mg/dL in a man). Because Cr is a crude indicator of renal function and often underestimates renal dysfunction in women and the elderly, calculation of the eGFR or the creatinine clearance (CrCl) by the CKD-EPI (Chronic Kidney Disease Epidemiology Collaboration) and Cockcroft-Gault equation, respectively, is a superior method for the assessment of renal function. The CrCl measurement is used most often for determining drug dosages because it incorporates body weight. For classification of disease, and prognosis, the CKD-EPI equation is preferred because it does not rely on body weight and has the most accurate association with adverse outcomes, including death. The equation is

- **CKD defined as abnormalities of kidney structure or function, present for >3 months, with implications for health.**
- **CKD classified as CGA based on Cause (C), GFR (G) category, and Albuminuria (A) category.**
- **CKD prognosis determined by GFR and Albuminuria Categories.**

GFR categories (mL min/1.73m) Description and range				Persistent albuminuria categories Description and range		
				A1	A2	A3
				Normal to mildly increased	Moderately increased	Severely increased
				<30 mg/g <3 mg/mmol	30-300 mg/g 3-30 mg/mmol	>300 mg/g >30 mg/mmol
	G1	Normal or high	≥90	1 if CKD	1	2
	G2	Mildly decreased	60-89	1 if CKD	1	2
	G3a	Mildly to moderately decreased	45-59	1	2	3
	G3b	Moderately to severely decreased	30-44	2	3	3
	G4	Severely decreased	15-29	3	3	4+
	G5	Kidney failure	<15	4+	4+	4+

GFR (G) and albuminuria (A) grid to reflect the risk of progression by intensity of coloring (green – low risk if no other markers of CKD, yellow – moderately increased risk, orange – high risk, red – very high risk). The numbers in the boxes are a guide to the frequency of monitoring (number of times per year.)

FIGURE 98.2 Diagnostic criteria for chronic kidney disease and kidney damage. *eGFR*, estimated glomerular filtration rate. (Adapted from KDIGO 2012 Clinical Practice Guideline. Kidney Int Suppl 2013;3:63-72.)

$$\mathrm{eGFR} = 141 \times \min(\mathrm{Cr}/\kappa, 1)^{\alpha} \times \max(\mathrm{Cr}/\kappa, 1)^{-1.209} \times 0.993^{\mathrm{Age\ (yrs)}} \times 1.018\ [\text{if female}] \times 1.159\ [\text{if black}]$$

where Cr is serum creatinine in mg/dL, κ is 0.7 for females and 0.9 for males, α is −0.329 for females and −0.411 for males, min indicates the minimum of Cr/κ or 1, and max indicates the maximum of Cr/κ or 1.

Another approved blood test reflecting renal filtration function and used in eGFR equations is cystatin-C.[5] Cystatin-C is a 13-kDa protein produced by all nucleated cells. Its low molecular mass and its high isoelectric point allow it to be freely filtered by the glomerulus and 100% reabsorbed by the proximal tubule. The serum concentration of cystatin-C correlates with the eGFR and, in combination with a stable production rate, provides a sensitive marker of renal filtration function. Serum levels of cystatin-C do not depend on weight and height, muscle mass, age, or sex, so that it is a less variable measure than Cr. Furthermore, measurements can be made and interpreted from a single random sample with reference intervals in women and men being 0.54 to 1.21 mg/L (median, 0.85 mg/L; range, 0.42 to 1.39 mg/L).

In addition, microalbuminuria at any level of the eGFR indicates CKD and occurs as the result of endothelial dysfunction or damage in glomerular capillaries secondary to the metabolic syndrome, DM, and HTN. The most widely accepted definition of microalbuminuria is a random urine albumin/Cr ratio (ACR) of 30 to 300 mg/g. An ACR greater than 300 mg/g is considered gross proteinuria. The random, spot ACR is the office test for microalbuminuria recommended as part of the cardiovascular and renal risk assessment done by cardiologists and other specialists. Microalbuminuria independently predicts the CVD risk for those with and without DM. The amount of albumin and protein in the urine is the most important prognostic factor for the rapid progression of CKD to ESRD.[6] In addition, both the eGFR and degree of albuminuria contribute independently to the risks of future AKI, myocardial infarction (MI), stroke, heart failure (HF), and death (**Fig. 98.3**).[7]

ALL-CAUSE MORTALITY

(Adapted from Chronic Kidney Disease Prognosis Consortium, Matsushita K, van der Velde M, Astor BC, et al: Association of estimated glomerular filtration rate and albuminuria with all-cause and cardiovascular mortality in general population cohorts: a collaborative meta-analysis. Lancet 2010;375(9731):2073-81.)

Implications of Anemia Due to Chronic Kidney Disease

Blood hemoglobin (Hb) levels are associated with CKD and with CVD. The World Health Organization defines anemia as an Hb level of less than 13 g/dL in men and less than 12 g/dL in women; approximately 9% of the general adult population meets this definition. Some 20% of patients with stable coronary disease and 30% to 60% of patients with HF have anemia due to CKD. Hence, anemia is a common and easily identifiable potential cause of constitutional symptoms, as well as a potential diagnostic and therapeutic target, particularly in the setting of iron deficiency or reduced availability of vitamin B_{12} or folic acid.

Anemia contributes to multiple adverse outcomes, in part because of decreased tissue oxygen delivery and utilization.[16] The cause of anemia in patients with CKD can be multifactorial because of impairment in iron transport and a relative deficiency of erythropoietin-α (EPO), an erythrocyte-stimulating protein, which is normally produced by renal parenchymal cells in response to the blood partial pressure of oxygen under the control of the gene regulator hypoxia-inducible factor. Patients with CKD and HF resist the effects of EPO. In addition, increased circulating levels of hepcidin-25, an inhibitor of the ferroportin receptor, impair iron absorption and utilization throughout the body, including in the bone marrow. As the Hb drops over the course of CKD, there is an associated increase in HF hospitalizations and deaths.

Conversely, those patients who have had a spontaneous rise in Hb, whether it be a result of improved nutrition, reduced neurohormonal factors, or other unknown factors, enjoy a significant reduction in endpoints over the next several years. This improvement has been associated with a significant reduction in the left ventricular mass index, suggesting a favorable change in left ventricular remodeling.

Treatment of anemia with exogenous erythrocyte-stimulating proteins (EPO and darbepoetin-α), increasing the Hb level from below 10 g/dL to 12 g/dL, has been linked to favorable changes in left ventricular remodeling, an improved ejection fraction, an improved functional classification, and higher levels of peak oxygen consumption with exercise testing. However, treatment with EPO and supplemental iron, which is needed in approximately 70% of cases of ESRD, is associated with three problems: (1) increased platelet activity and thrombin generation and a resultant increased risk of thrombosis; (2) elevated endothelin and asymmetric dimethylarginine, which theoretically reduces nitric oxide availability, and results in HTN; and (3) worsened measures of oxidative stress. Randomized trials of erythrocyte-stimulating agents (ESAs) as they target higher levels of Hb in CKD have shown higher rates of CVD events and no improvement in rates of mortality, progression of CKD, or health-related quality of life.[8-10] The Reduction of Events with Darbepoetin Alfa in Heart Failure Trial (RED-HF) randomized 2278 patients with systolic HF and mild-to-moderate anemia (Hb = 9 to 12 g/dL) to receive darbepoetin alfa approximately 60 to 600 µg subcutaneously every 2 to 4 weeks (target, Hb 13 g/dL) or placebo and found no reductions in HF hospitalizations or deaths, but a 35% excess risk of thromboembolic complications with the ESA.[11] When the dose exposure of ESA is taken into account, it appears that cardiovascular drug toxicity and not the Hb is responsible for the adverse outcomes reported in ESA trials.[12] As a result of these trials, the current strategy is to use ESA sparingly to maintain an Hb concentration to avoid symptoms and the need for transfusion.

High-dose oral or intravenous iron may overcome the iron-reutilization defect in CKD anemia. In a metaanalysis of 64 trials (including five studies of HF patients) comprising 9004 patients, iron was associated with elevations in Hb and reductions in the need for transfusion.[13] Analysis of the five trials of HF patients with iron deficiency (509 patients received iron therapy and there were 342 controls) showed that intravenous iron was associated with reductions in HF hospitalizations and cardiovascular deaths (odds ratio [OR], 0.39; 95% confidence interval [CI], 0.24 to 0.63; $P = 0.0001$) and improvements in multiple measures of functional status.[14] These results will need confirmation in large-scale clinical trials, but they support consideration of iron repletion in patients with CKD, anemia, and HF when there is evidence of iron deficiency (iron saturation < 20% and ferritin < 200 ng/mL).

Hypoxia-inducible factor has a very short half-life because of a prolyl hydroxylase that breaks down this genetic regulator of EPO as well as vascular endothelial–derived growth factor. There are oral hypoxia-inducible factor, prolyl hydroxylase inhibitors in development that stabilize the hypoxia-inducible factor and allow greater endogenous production of EPO and improved iron transport and elevate Hb concentrations.[15] Phase 3 trials of these agents will assess their efficacy for treating anemia in CKD and allowing for cardiovascular safety.

Contrast-Induced Acute Kidney Injury

Iodinated contrast-induced acute kidney injury (CI-AKI) is most commonly defined by the Kidney Disease International Global Outcomes criteria of a rise in serum Cr of 0.3 mg/dL or more from baseline within 48 hours of intravascular administration or a 50% or more elevation from baseline over the course of hospitalization.[16] The National Cardiovascular Data Registry Cath-PCI (n = 985,737, which studied

patients who underwent elective and urgent percutaneous coronary intervention [PCI]), reported 69,658 (7.1%) cases of CI-AKI (Cr rise ≥ 0.3 mg/dL) and 3,005 (0.3%) cases of AKI requiring dialysis.[17] Transient rises in Cr are associated with longer hospital ward and intensive care unit stays, MI, stroke, HF, rehospitalization, and death after coronary angiography, PCI, and angiography followed by cardiac surgery (**Fig. 98.4**).[18]

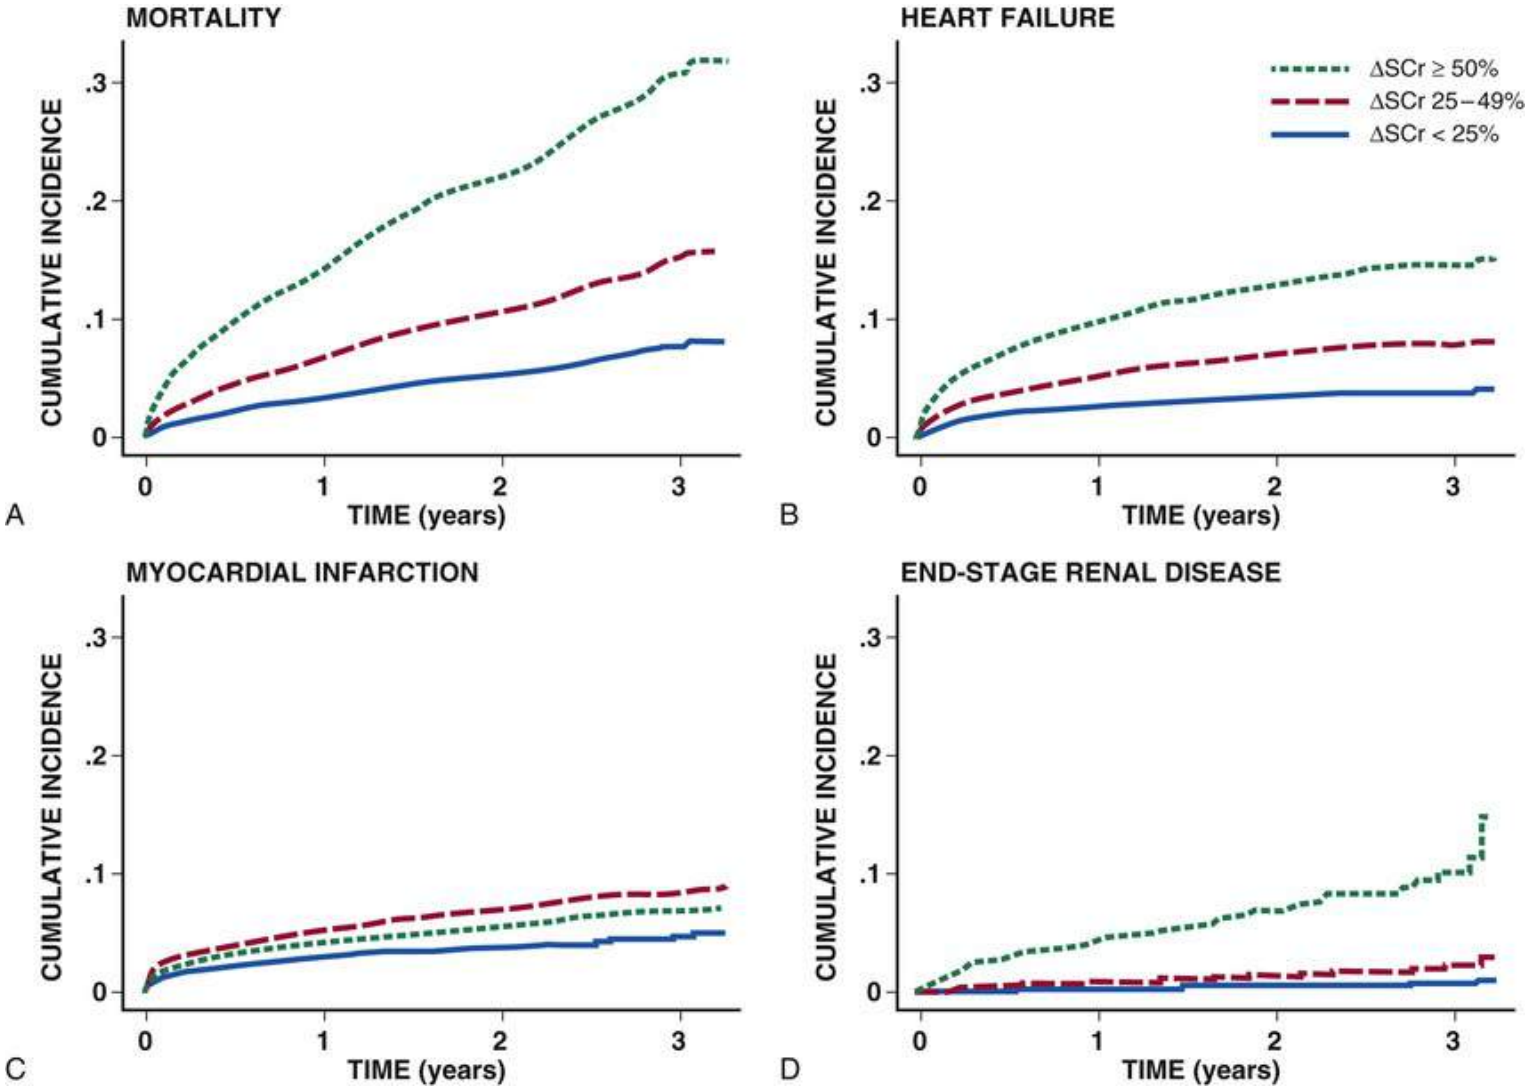

FIGURE 98.4 Cumulative incidence of **(A)** all-cause mortality, **(B)** hospitalization for heart failure, **(C)** hospitalization for myocardial infarction, and **(D)** end-stage renal disease following coronary angiography, according to severity of acute kidney injury as reflected by magnitude of change in serum creatinine (ΔScr) concentration after coronary angiography. Coronary angiography alone = 4219, with PCI = 8205, with cardiac surgery = 2412. (Adapted from James MT, Ghali WA, Knudtson ML, et al: Alberta Provincial Project for Outcome Assessment in Coronary Heart Disease (APPROACH) Investigators: Associations between acute kidney injury and cardiovascular and renal outcomes after coronary angiography. Circulation 2011;123(4):409-16.)

CI-AKI has three potential pathophysiologic mechanisms: (1) direct toxicity of nephrons by iodinated contrast material, (2) microshowers of atheroemboli to the kidneys (due to catheter and wire exchanges above the renal arteries), and (3) intrarenal vasoconstriction induced by contrast material or atheroemboli. Direct toxicity of nephrons by iodinated contrast media appears related to the ionicity and osmolality of the contrast media given in the milieu of CKD.[18] Microshowers of cholesterol emboli may occur in about 50% of percutaneous interventions using an aortic approach; most episodes are clinically silent.[19] However, in approximately 1% of high-risk cases, an acute cholesterol emboli syndrome can develop, manifested by acute renal failure, mesenteric ischemia, decreased microcirculation to the

extremities, and, in some cases, embolic stroke. Because there is less transaortic movement of wires and catheters, transradial coronary intervention is associated with rates of CI-AKI that are 22% to 50% lower.[20,21] Intrarenal vasoconstriction as a pathologic vascular response to contrast media in CKD and perhaps as an organ reaction to superimposed cholesterol microemboli also injure the kidney. Hypoxia triggers activation of the renal SNS and further reduces renal blood flow (**Fig. 98.5**). The most important predictor of CI-AKI is underlying renal dysfunction. When the eGFR falls to less than 60 mL/min/1.73 m^2, the remaining nephrons must assume the residual filtration load with increased oxygen demands in the face of reduced delivery, and hence there is a greater susceptibility to cytotoxic, ischemic, and oxidative injury.[18]

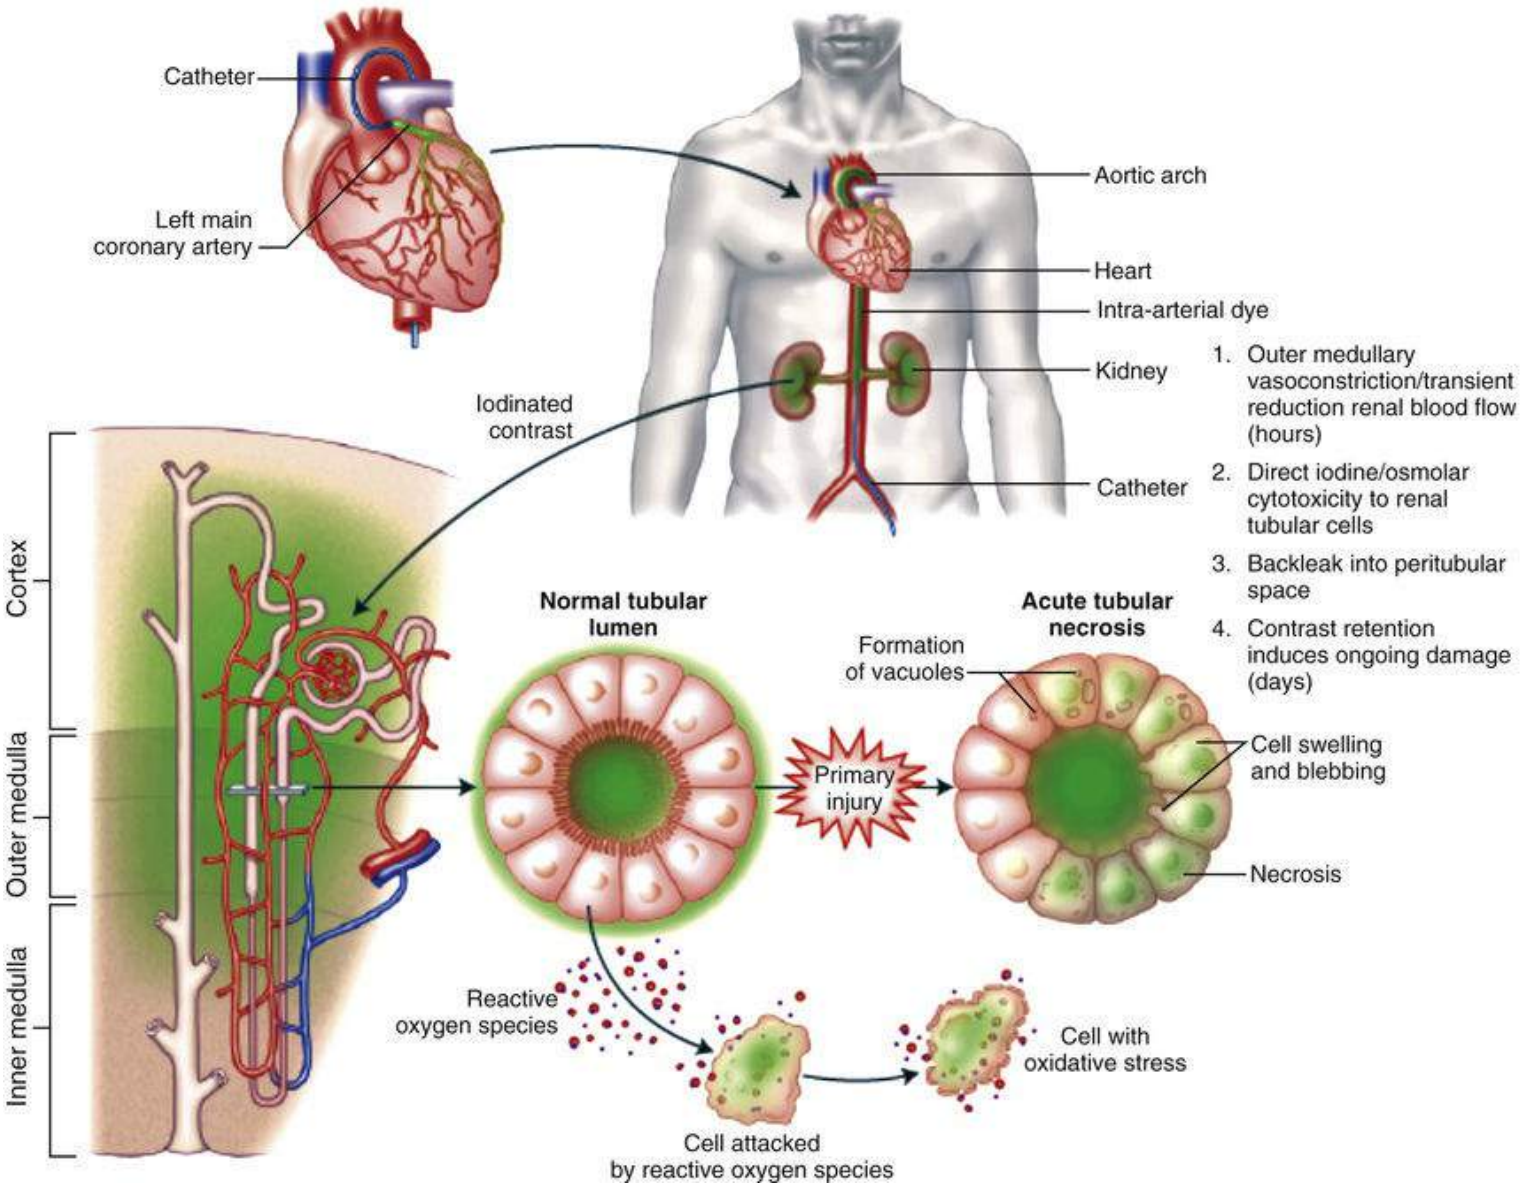

FIGURE 98.5 Pathogenesis of contrast-induced acute kidney injury. (Adapted from Brown JR, McCullough PA: Contrast nephropathy and kidney injury textbook of cardiovascular intervention. New York, Springer, 2011.)

Prevention of Contrast-Induced Acute Kidney Injury

Patients with preexisting CKD (baseline eGFR, < 60 mL/min/1.73 m^2) and, in particular, those with CKD and DM, merit a prevention strategy for CI-AKI. The presence of CKD, DM, and other risk factors,

including hemodynamic instability, use of intraaortic balloon counterpulsation, HF, older age, and anemia, in the same patient entails a risk of CI-AKI of over 50%.[22] The informed-consent process of a high-risk patient before use of intravascular iodinated contrast should include discussion of CI-AKI. CI-AKI prevention involves consideration of four issues: (1) intravascular volume expansion, (2) choice and quantity of contrast material, (3) transradial or femoral approach, and (4) postprocedural monitoring and expectant care.

Because iodinated contrast is water soluble, it is amenable to prevention strategies that expand the intravascular volume and increase the renal filtration and tubular flow of urine into collecting ducts, and then into the ureters and bladder. CI-AKI responds to intravascular administration of isotonic crystalloid solutions to enhance renal elimination of contrast via the urine. Numerous randomized trials have compared isotonic bicarbonate solutions with intravenous saline. The largest and highest-quality trials have shown no differences in the rates of renal outcomes.[23,24] Patient factors should guide the use of either isotonic crystalloid solution. The POSEIDON (Prevention of Contrast Renal Injury with Different Hydration Strategies) trial randomized 396 patients with eGFR of less than 60 mL/min/1.73 m^2 and one additional risk factor to a strategy of measurement of left ventricular end-diastolic pressure and expanding plasma volume versus usual care. Each group had standard of care of normal saline 3 mL/kg for 1 hour before cardiac catheterization. The left ventricular end-diastolic pressure–guided approach was associated with more intensive fluid administration during and after the procedure and with a greater reduction in CI-AKI (6.7%) than in the control group (16.3%); the relative risk (RR) was 0.41; the 95% CI was 0.22 to 0.79; and the *P* 0.000 to 0.005. Thus, it is reasonable to consider intravenous administration of 250 mL of normal saline before the procedure and achieve a urine output of approximately 150 mL/hr throughout and after the procedure.

Randomized trials of iodinated contrast agents have demonstrated the lowest rates of CI-AKI with nonionic, isoosmolar iodixanol. A metaanalysis restricted to 25 head-to-head, prospective, double-blind, randomized, controlled trials compared iodixanol with low-osmolar contrast media (LOCM) in adult patients undergoing angiographic examinations with serum Cr values at baseline and following CM administration.[25] The relative risk of CI-AKI (Cr rise ≥ 0.5 mg/dL) occurring for iodixanol was 0.46 and *P* 0.004, compared with LOCM as summarized in **Fig. 98.6**. These data are consistent with the hypothesis that iodixanol (290 mOsm/kg) is less nephrotoxic than LOCM agents with osmolalities ranging from 600 to 800 mOsm/kg when given intraarterially. However, there appears to be no significant difference in rates of CI-AKI between iodixanol and LOCM when contrast is administered in lower-risk patients or intravenously.[25]

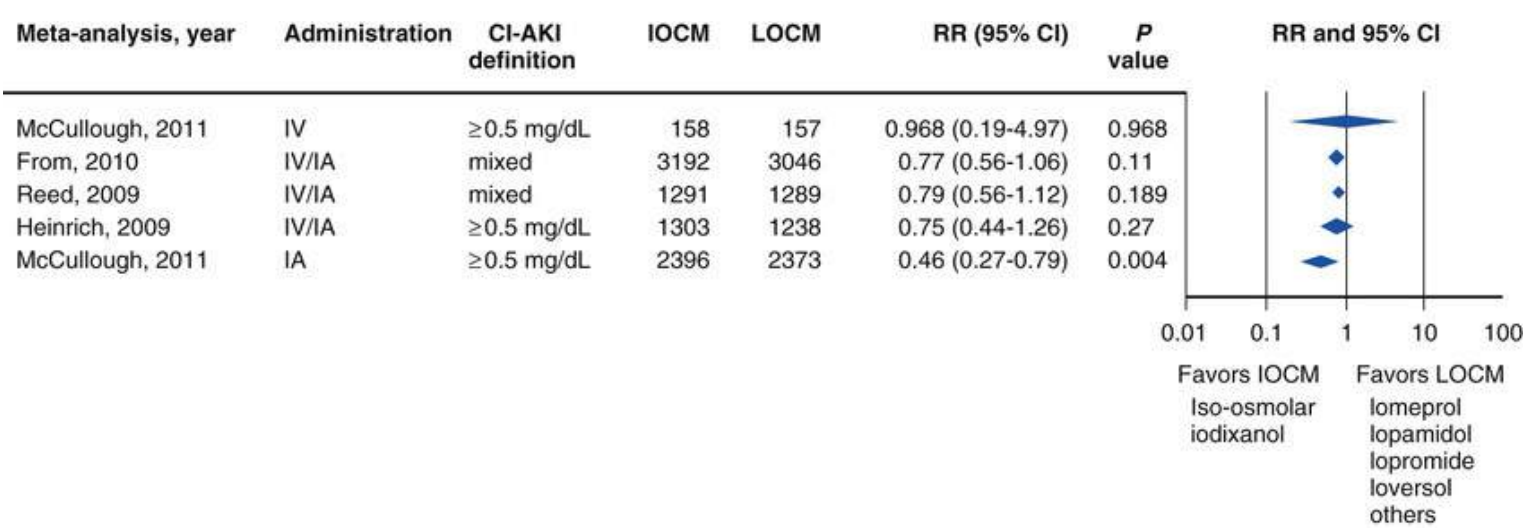

FIGURE 98.6 Compilation of pooled odds ratios from head-to-head trials for IA, IV, and mixed IA and IV metaanalyses of the incidence of CI-AKI (defined as ≥ 0.5 mg/dL increase in sCr from baseline) demonstrating a leftward shift in pooled estimates IV, IV/IA, and IA trials favoring the use of iodixanol. (Adapted from McCullough PA, Brown JR: Effects of intra-arterial and intravenous iso-osmolar contrast medium (iodixanol) on the risk of contrast-induced acute kidney injury: a meta-analysis. Cardiorenal Med 2011;1(4):220-34.)

Although it is desirable to limit contrast to the smallest volume possible in any setting, there is disagreement about a "safe" contrast limit. The lower the eGFR, the less contrast material may cause CI-AKI. In general, it is desirable to limit the contrast medium to less than 30 mL for a diagnostic procedure and less than 100 mL for an interventional procedure. If staged procedures are planned and CI-AKI has occurred with the first procedure, it is advantageous to have more than 10 days between the first and second contrast exposures. As mentioned above, the transradial approach is associated with a significantly lower risk of CI-AKI when controlling for all other factors.

Most trials of preventive strategies for CI-AKI have been small and underpowered and did not find the preventive strategy under investigation superior to placebo. After many small, suggestive studies, a large (n=2308) randomized trial of N-acetylcysteine 1200 mg orally twice a day on the day before and after the procedure showed no differences in the rates of CI-AKI (12.7% for both groups), ESRD, or other outcomes.[26] As a result, neither N-acetylcysteine nor any other drug is approved for the prevention of CI-AKI.

A suggested algorithm for risk stratification and prevention of CI-AKI is shown in **Fig. 98.7**. An eGFR of less than 60 mL/min/1.73 m^2 mandates preprocedural volume expansion, use of transradial access if possible, use of iodixanol or LOCM as the contrast agent, and minimization of contrast volume. Postprocedural monitoring is critical in the current era of short stays and outpatient procedures. In general, high-risk patients in the hospital should have hydration started 1 to 3 hours before the procedure and continued for at least 3 hours afterward. Serum Cr should be measured 24 hours after the procedure. Outpatients, particularly those with an eGFR of less than 60 mL/min/1.73 m^2, should either stay overnight or be discharged to go home with 48-hour follow-up and serum Cr measurement. If severe CI-AKI is going to develop, patients usually have a rise of Cr greater than 0.5 mg/dL in the first 24 hours after the procedure. Thus, for those who do not have this degree of serum Cr elevation and are otherwise uncomplicated, discharge to home may be considered. If a patient has an eGFR of less than 30 mL/min/1.73 m^2, the physician should discuss with the patient the possibility of dialysis and a nephrology consultation for possible preprocedure and postprocedure hemofiltration and dialysis management.

Cardiac Surgery and Acute Kidney Injury

AKI occurs in approximately 15% of patents after some cardiac surgical procedures with or without the use of cardiopulmonary bypass. Rates of AKI are higher when coronary angiography is done on the same day or with relatively few days between the angiogram and the surgery.[27] Cardiac surgery exposes patients to many factors, including endogenous/exogenous toxins (free heme, catalytic iron), metabolic factors, ischemia and reperfusion, neurohormonal activation, inflammation, and oxidative stress, which all may contribute to renal tubular injury heralded by reduced urine output and a rise in serum Cr after cardiac surgery.[28] KDIGO (Kidney Disease Global Outcomes) criteria can be used to identify AKI in this patient group (**Fig. 98.8**).[16] Various markers may predict postoperative AKI.[28] Off-pump cardiac surgery does not seem to lower rates of AKI. Trials of natriuretic peptides, corticosteroids, alpha melanocytic–stimulating hormone agonists, complement inhibitors, and remote ischemic preconditioning have failed to prevent AKI. Thus, at this time, there are no accepted forms of prophylaxis or treatment for AKI

associated with cardiac surgery.

Stage	Serum creatinine	Urine output
1	1.5–1.9 × baseline or ≥0.3 mg/dl (≥26.5 mmol/L) increase	<0.5 mL/kg/h for 6–12 h
2	2.0–2.9 × baseline	<0.5 mL/kg/h for >12 h
3	3.0 × baseline, or increase in serum creatinine ≥4.0 mg/dl (≥353.6 mmol/L), or initiation of RRT, or decrease in eGFR <35 mL/min/1.73 m^2 for patients <18 years	<0.3 mL/kg/h for ≥24 h or anuria for ≥12 h

Acceleration of Vascular Calcification

When the eGFR falls below 60 mL/min/1.73 m^2, the filtration and elimination of phosphorus fall. In addition, a lower production of 1,25 dihydroxyvitamin D leads to a relative hypocalcemia. Thus, subtle degrees of hyperphosphatemia and hypocalcemia trigger increased release of parathyroid hormone, causing liberation of calcium and phosphorus from bone. The bone, in turn, produces greater amounts of fibroblast growth factor-23, which directs the kidneys to increase the clearance of phosphorus but also promotes left ventricular hypertrophy (LVH). As a result of this abnormal bone and mineral metabolism, patients with ESRD have markedly increased absolute values and rates of accumulation of arterial calcification as well as LVH. A variety of in vitro stimuli can induce vascular smooth muscle cells to assume osteoblast-like functions in vitro, including handling of phosphorus, oxidized low-density lipoprotein cholesterol (LDL-C), vascular calcification factor, parathyroid hormone, and parathyroid hormone–related peptide.

No specific strategy to manipulate the calcium-phosphorus balance or treat secondary hyperparathyroidism evaluated so far changes the annual rate of increase in the coronary artery calcium score or cardiovascular events.[29,30,31]

Renal Disease and Hypertension

The kidney is a central regulator of blood pressure and controls intraglomerular pressure through autoregulation. Sodium retention stimulates increases in systemic and renal arteriolar pressure in an attempt to force greater degrees of filtration in the glomerulus. Glomerular injury activates a variety of pathways that further increase the systemic blood pressure (**see also Chapters 46 and 47**). This effect sets up a vicious circle of more glomerular and tubulointerstitial injury and worsened HTN. A cornerstone of management of combined CKD and CVD is strict blood pressure control. In most patients with CKD and proteinuria, three or more antihypertensive agents are needed to achieve a goal blood pressure of less than 130/80 mm Hg.[32] The Systolic Blood Pressure Intervention Trial (SPRINT) randomized 9361 patients without DM having a mean eGFR of 71 mL/min/1.72 m^2 and found that a

systolic blood pressure target of 120 mm Hg was associated with reduced rates of a first occurrence of MI, acute coronary syndrome (ACS), stroke, HF, or death from cardiovascular causes; however, there were no differences in the rates of progression to CKD, ESRD, or any other renal outcome. The key lifestyle issues for management of CKD and HTN include dietary changes with sodium restriction, weight reduction of 15% or more to a target body mass index of less than 25 kg/m^2, and exercise for 60 minutes per day most days of the week. Pharmacologic therapy aims for strict blood pressure control with an agent that antagonizes the RAAS, often in combined action with a thiazide-type diuretic. Dihydropyridine calcium channel blockers alone, because of relative afferent arteriolar dilation, increase intraglomerular pressure and worsen glomerular injury, and thus should be avoided as singular agents for blood pressure control. Combinations of multiple RAAS-blocking drugs (angiotensin-converting enzyme inhibitors [ACEIs], angiotensin II receptor blockers [ARBs], a direct renin inhibitor) provide no additional benefit but cause more complications. Clinical clues such as poorly controlled blood pressure when the patient is taking more than three agents, abdominal bruits, smoking history, peripheral arterial disease, and a marked change in serum Cr with administration of an ACEI or ARB should raise the possibility of bilateral renal artery stenosis.[33] Although renal artery stenosis accounts for less than 3% of ESRD cases, it represents a potentially treatable condition (**see also Chapter 66**). Attempts to reduce SNS activity to the kidneys have not improved the blood pressure or clinical outcomes in properly controlled trials.[34]

Diagnosis of Acute Coronary Syndromes in Patients With Chronic Kidney Disease

Patients with CKD have higher rates of silent ischemia; the disorder clusters with serious arrhythmias, HF, and other cardiac events (**see also Chapters 56 and 58**). About half of stable outpatients with CKD will have a high-sensitivity cardiac troponin I (cTnI) or cTnT level above the 99th percentile of normal.[35] The degree of elevation of cTn is associated with a left ventricular mass, coronary disease, severity of renal disease, and all-cause mortality.[36] Thus with the use of high-sensitivity assays, in general, cTnI is more advantageous in the diagnostic evaluation of CKD or ESRD patients with acute chest discomfort, whereas chronic elevations of cTnT are more common and more prognostic in stable patients. The diagnosis of MI in patients with CKD or ESRD requires serial troponin measurements because so many are above the 99th percentile of normal at baseline. The skeletal myopathy of CKD can elevate the creatine kinase, myoglobin, and some older-generation cTnI/cTnT assays, making these tests less desirable.

Renal Dysfunction as a Prognostic Factor in Acute Coronary Syndromes

Advances in the diagnosis and treatment of acute ACS include early paramedic response and defibrillation, coronary care units, and pharmacotherapy including antiplatelet agents, antithrombotics, beta receptor–blocking agents, RAAS blockade, lipid-lowering therapy, intravenous thrombolytic agents, and percutaneous intervention (**Tables 98.1 to 98.3**). CKD patients represent 30.5% of patients with ST-segment elevation MI (STEMI) and 42.9% of patients with NSTEMI (**Fig. 98.9**), and they have higher rates of in-hospital death in a graded fashion with worsened renal function (**Fig. 98.10**).[37] There is an independent association between the degree of CKD and the 30-day and 1-year mortality rates after ACS. A reduced baseline eGFR also predicts higher rates of AKI, bleeding, the development of HF, recurrent

MI, rehospitalization, and stroke in the setting of ACS. Patients with ESRD have the highest mortality rate after MI of any large population with chronic disease.

TABLE 98.1

Acute and Chronic Treatments for Coronary Artery Disease in Patients With Chronic Kidney Disease

MEDICATION	NORMAL DOSE	CHRONIC KIDNEY DISEASE POPULATION	PHARMACOLOGY
Antiplatelet Agents			
Aspirin	Acute MI: 160–325 mg by mouth as soon as possible MI prophylaxis: 81–162 mg by mouth once daily PCI: 325 mg by mouth 2 h before surgery, then 160–325 mg by mouth maintenance UA: 75–162 mg by mouth once daily	No specific dosing adjustments in patients with CKD Metaanalysis involving patients undergoing dialysis demonstrated a benefit of aspirin therapy on cardiovascular outcomes	Metabolism: liver, microsomal enzyme system Renal clearance: 80% to 100% 24–72 h Excretion: principally in urine (80% to 100%), sweat, saliva, feces
Clopidogrel	UA/NSTEMI: 300–600 mg initial loading dose, followed by 75 mg by mouth once daily with aspirin STEMI: 75 mg by mouth once daily with aspirin 75–162 mg per day Recent MI: 75 mg by mouth once daily	No specific dosing adjustments in patients with CKD	Metabolism: CYP3A4, CYP2C19 (predominantly), and others to generate active metabolite; also by esterase to an inactive metabolite Excretion: urine and feces
Prasugrel	ACS: Loading dose: 60 mg by mouth once Maintenance dose: 10 mg by mouth once daily with aspirin 81–325 mg per day; bleeding risk may increase if weight < 60 kg, consider 5 mg by mouth once daily (efficacy/safety not established)	No specific dose adjustments in patients with CKD	Metabolism: liver; CYP450, CYP2B6, CYP2C9/CYP2C19 (minor), CYP3A4 substrate; CYP2B6 (weak) inhibitor Excretion: urine (68%) and feces (27%)
Ticagrelor	ACS with PCI and stent: Starting dose: 180 mg by mouth once Maintenance dose: 90 mg by mouth twice daily To be given for 1 year with aspirin as an alternative option for dual antiplatelet therapy	No specific dose adjustments in patients with CKD	Metabolism: hepatic CYP450 Excretion: bile primarily, urine < 1%
Angiotensin-Converting Enzyme Inhibitors			
Examples are captopril, zofenopril, enalapril, ramipril, quinapril, perindopril, lisinopril, benazepril, imidapril, trandolapril, fosinopril	Indicated for treatment of hypertension, prevention of cardiovascular events including HF in those at risk, reduction in progression of type 1 diabetic nephropathy, and reduction in cardiovascular events in patients following MI with left ventricular dysfunction or HF Also indicated for treatment of HF	Dosing schedules may need to be individualized for each dialysis session in order to avoid intradialytic hypotension In general, reduce dose by 50% to 75% in ESRD	Elimination: mainly renal, with elimination half-life of 12.6 h in healthy individuals In patients with impaired renal function (CrCl ≤ 30 mL/min), longer half-life and accumulation have been observed without clinical consequences
Angiotensin II Receptor Antagonists			
Examples are losartan, irbesartan, olmesartan, candesartan, valsartan, telmisartan	Indicated for treatment of hypertension, to reduce progression of type 2 diabetic nephropathy, and to reduce cardiovascular events in patients following MI with left ventricular dysfunction or HF Indicated for HF in those intolerant to ACE inhibitors	As first-line treatment in majority of patients with CKD, recommend use of ACE inhibitors or ARBs; both have been shown to reduce LVH in patients undergoing hemodialysis Levels of ARBs do not change significantly during hemodialysis	Losartan has 88% hepatic and 12% renal clearance
Calcium Channel Blockers			
Dihydropyridines, e.g., amlodipine, felodipine, nicardipine, nifedipine, nimodipine, nitrendipine Nondihydropyridines, e.g., diltiazem, verapamil	In UA/NSTEMI, if β–blockers are contraindicated, a nondihydropyridine CCB should be chosen in absence of clinically significant left ventricular dysfunction or other contraindications*	No specific dose adjustments for patients with CKD Management of chronic CAD in patients undergoing dialysis should follow guidelines for general population and use of CCBs as indicated Hemodynamic and electrophysiologic effects of CCBs are markedly different from each other and should be evaluated when selecting suitable therapy	Amlodipine has renal elimination as major route of excretion, with about 60% cleared in urine Diltiazem undergoes primary liver metabolism
Nitrates			
Nitroglycerin	2% ointment Angina: 0.5–2 inches applied in morning and 6 h later to truncal skin HF: 1.5 inches, increase by 0.5–1 inch up to 4 inches, every 4 h Sublingual: 0.4 mg for relief of chest pain in ACS Sublingual: 0.3–0.6 mg every 5 min Maximum: 3 doses within 15 min	No specific dose adjustments for patients with CKD Care must be used to avoid hypotension in low-volume states such as dialysis sessions	Metabolism: mainly in liver, extrahepatic sites such as vascular wall, red blood cells Excretion: urine
Antianginal Medications			

Ranolazine	500–1000 mg by mouth twice daily Max: 2000 mg per day	No specific dose adjustments for patients with CKD Prolongs QTc interval Recommend close monitoring	Excretion: urine 73% to 75%, feces 25%

*See also Roberts WC, Taylor MA, Shirani J: Cardiac findings at necropsy in patients with chronic kidney disease maintained on chronic hemodialysis. Medicine (Baltimore) 2012;91(3):165-78.

ACE, angiotensin-converting enzyme; *ACS*, acute coronary syndrome; *ARB*, angiotensin-receptor blocker; *CAD*, coronary artery disease; *CCB*, calcium channel blocker; *CKD*, chronic kidney disease; *CrCl*, creatinine clearance; *HF*, heart failure; *LVH*, left ventricular hypertrophy; *MI*, myocardial infarction; *NSTEMI*, non–ST-elevation myocardial infarction; *PCI*, percutaneous coronary intervention; *STEMI*, ST–elevation myocardial infarction; *UA*, unstable angina.

TABLE 98.2

Beta-Adrenergic Receptor Blockers in Patients With Chronic Kidney Disease*

MEDICATION	NORMAL DOSE	CHRONIC KIDNEY DISEASE POPULATION	PHARMACOLOGY
Metoprolol	Acute MI Metoprolol tartrate: 2.5–5 mg rapid IV every 2–5 min, up to 15 mg over 10–15 min, then 15 min after last IV dosage and receiving 15 mg IV or 50 mg by mouth every 6 h for 48 h, then 50–100 mg by mouth twice daily Angina Metoprolol tartrate: initially 50 mg by mouth twice daily, then titrated to 200 mg by mouth twice daily Metoprolol succinate: 100 mg by mouth once daily; no more than 400 mg per day	No specific dose adjustments for patients with CKD Recommend close monitoring for adverse effects	Dialysable: Yes Metabolism: hepatic CYP2D6 Metabolites: inactive Excretion: urine 95%
Esmolol	Immediate control For intraoperative treatment give 80 mg (≈ 1 mg/kg) as bolus dose over 30 seconds, followed by a 150 µg/kg per min infusion, if needed Maximum infusion rate: 300 µg/kg per min Gradual control For postoperative treatment, give loading dosage infusion of 500 µg/kg per min over 1 min, followed by a 4-min infusion of 50 µg/kg per min If no effect within 5 min, repeat loading dose and follow with infusion increased to 100 µg/kg per min	No specific dose adjustments for patients with CKD	Metabolism: extensively metabolized by esterase in cytosol of red blood cells Metabolites: major acid metabolite (ASL–8123), methanol (inactive) Excretion: urine < 1% to 2%
Carvedilol	Hypertension and post-MI protection: 6.25–25 mg by mouth twice daily Start at 6.25 mg by mouth twice daily, then increase every 3–14 days to 12.5 mg by mouth twice daily, then 25 mg by mouth twice daily	No specific dose adjustments for patients with CKD In a small study of patients undergoing dialysis with dilated cardiomyopathies, carvedilol improved left ventricular function and decreased rates of hospitalization, cardiovascular deaths, and total mortality	Elimination: mainly biliary Excretion: primarily via feces

*Hemodialysis reduces blood levels of atenolol, acebutolol, and nadolol; by contrast, levels of carvedilol and labetalol do not change significantly.

CKD, chronic kidney disease; *IV*, intravenous; *MI*, myocardial infarction.

TABLE 98.3

Lipid-Lowering Therapy for Primary and Secondary Prevention in Patients With Chronic Kidney Disease

MEDICATION	NORMAL DOSE	CHRONIC KIDNEY DISEASE POPULATION	PHARMACOLOGY
Rosuvastatin	Cardiovascular event protection 10-40 mg by mouth once daily	Efficacy in LDL-C reduction in CKD demonstrated at doses as low as 2.5 mg daily	Metabolism: liver, CYP450 CYP2C9 Excretion: bile primarily, urine < 2%
Simvastatin	Cardiovascular event protection: 20-40 mg by mouth once daily combined with ezetimibe 10 mg by mouth once daily Maximum dose: 40 mg by mouth given at hour of sleep	Consider starting dose at 5 mg in evening in patients with CKD In SHARP, lipid lowering with statin + ezetimibe was beneficial in patients with CKD In HPS, simvastatin reduced renal decline in patients with CKD	Metabolism: liver, CYP450 CYP3A4 Excretion: bile primarily, urine < 2%
Atorvastatin	Cardiovascular event protection: 10-80 mg by mouth once daily	No specific dose adjustments for patients with CKD Atorvastatin 10 mg in patients with CKD revealed a significantly lower risk of primary end point (nonfatal MI or cardiac death) when compared with placebo With TNT and GREACE studies, atorvastatin showed improvement in renal function in patients with CKD	Metabolism: liver, CYP450 CYP3A4 Excretion: bile primarily, urine < 2%
Fluvastatin	Cardiovascular event protection: 40 mg by mouth twice daily Extended release: 80 mg by mouth once daily	No specific dose adjustments for patients with CKD Caution for increased risk of rhabdomyolysis A multicenter, randomized, double-blind, placebo-controlled trial of fluvastatin was conducted in kidney transplant recipients Fluvastatin reduced LDL-C levels by 32%. Although primary end point did not achieve statistical significance, secondary analysis showed that fluvastatin group experienced fewer cardiac deaths and nonfatal MIs than did placebo group. Coronary intervention procedures were not significantly different between the two groups.	Metabolism: liver, CYP450 CYP2C9 isozyme system (75%), and to a lesser extent by CYP3A4 (≈20%) and CYP2C8 (≈5%) Excretion: bile primarily 90%, urine 5%
Pravastatin	Cardiovascular event protection: Start: 40 mg by mouth once daily, may adjust dose every 4 weeks Maximum dose: 80 mg by mouth once daily	Start at 10 mg by mouth once daily in patients with CKD A randomized trial of pravastatin versus placebo in patients with previous MI and CKD in a secondary analysis showed rate of coronary death or nonfatal MI was lower in patients receiving pravastatin, suggesting that pravastatin is effective for secondary prevention of cardiovascular events in patients with CKD	Metabolism: glucuronidation Excretion: bile primarily 70%, urine 20%
Pitavastatin	Lowering LDL-C and total cholesterol: Start: 1 mg by mouth once daily, may adjust every 4 weeks Maximum dose: 4 mg by mouth once daily	Start at 1 mg by mouth once daily in patients with CKD	Metabolism: glucuronidation Excretion: bile primarily 79%, urine 15%

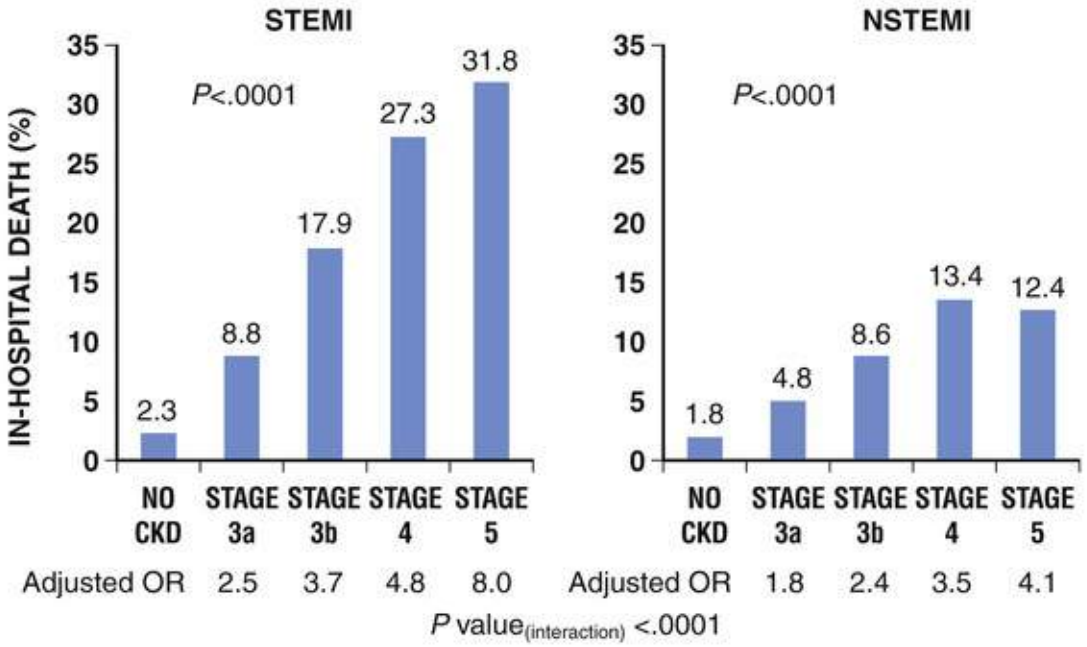

FIGURE 98.10 Crude rates and adjusted odds ratios for death by CKD stages among those presenting with STEMI and NSTEMI, with *Ptrend and Pinteraction for* STEMI vs NSTEMI by CKD stages. Stage 3a CKD was defined as an eGFR between 45 and 59 mL/min/1.73 m^2; stage 3b as an eGFR of 30 to 44 mL/min/1.73 m^2; stage 4 CKD as an eGFR between 15 and 29 mL/min/1.73 m^2; and stage 5 CKD as an eGFR of less than 15 mL/min/1.73 m^2 or dialysis therapy. (Adapted from Fox CS, Muntner P, Chen AY, et al; Acute Coronary Treatment and Intervention Outcomes Network registry: Use of evidence-based therapies in short-term outcomes of ST-segment elevation myocardial infarction and non-ST-segment elevation myocardial infarction in patients with chronic kidney disease: a report from the National Cardiovascular Data Acute Coronary Treatment and Intervention Outcomes Network registry. Circulation 2010;121(3):357-65.)

Reasons for Poor Outcomes After Acute Coronary Syndromes in Patients with Renal Dysfunction

Patients with renal dysfunction may have poor cardiovascular outcomes after ACS for four reasons: (1) excess comorbidities associated with CKD and ESRD, in particular DM and left ventricular dysfunction; (2) therapeutic nihilism; (3) toxicity of therapies; and (4) special biologic and pathophysiologic factors in renal dysfunction that cause worsened outcomes.[38]

The primary defects in thrombosis attributable to uremia are cytokine elevation, excess thrombin generation, and decreased platelet aggregation. Hence, patients with CKD and ESRD can have increased rates of coronary thrombotic events and increased bleeding risks at the same time. In patients with renal dysfunction the risks of bleeding increase with aspirin, unfractionated heparin, low-molecular-weight heparin, thrombolytics, glycoprotein IIb/IIIa antagonists, and thienopyridine antiplatelet agents (**Tables 98.4 and 98.5**). Uremia causes platelet dysfunction by independent mechanisms that add to pharmacologic antiplatelet agents.[39]

TABLE 98.4

Intravenous Glycoprotein IIb/IIIa Inhibitors for Unstable Angina/NSTEMI, STEMI, PCI

AGENT	NORMAL DOSE	CHRONIC KIDNEY DISEASE POPULATION*	PHARMACOLOGY
Abciximab	Adjunct to PCI: 0.25 mg/kg IV bolus over at least 1 min, 10–60 min before start of PCI, then 0.125 µg/kg per min (not to exceed 10 µg per min) continuous IV infusion for 12 h Unstable angina with PCI planned within 24 h: 0.25 mg/kg IV bolus over at least 1 min, then 0.125 µg/kg per min (not to exceed 10 µg per min) IV infusion for 18–24 h concluding 1 h after PCI	No specific dose adjustments for patients with CKD Abciximab should also be considered as adjunctive therapy in patients with ACS who are undergoing dialysis In CKD, safety of abciximab has been shown for Cr levels > 152.5 µmol/L Although increased bleeding with abciximab in patients with CKD has been reported, other studies have shown no increase in bleeding for CKD versus no CKD for abciximab in PCI	Metabolism: unknown, but likely by the reticuloendothelial system CYP450: unknown involvement Excretion: urine
Eptifibatide	ACS: 180 µg/kg IV bolus, then 2 µg/kg per min IV for up to 72 h PCI: 180 µg/kg IV, then a continuous infusion at 2 µg/kg per min, with another 180 µg/kg IV bolus 10 min after first bolus Continue infusion for at least 12 h	CrCl < 50 mL/min and ACS: 180 µg/kg IV, then continuous infusion 1 µg/kg per min Safety and use during hemodialysis are not established	Metabolism: other, minimal CYP450: unknown involvement Excretion: urine 50%
Tirofiban	In patients undergoing PCI, tirofiban is not recommended as an alternative to abciximab† ACS: 0.4 µg/kg per min IV for 30 min, then 0.1 µg/kg per min IV for 48–108 h PCI: Continue 0.1 µg/kg per min IV through procedure and for 12–24 h after	CrCl < 30 mL/min and ACS: reduce dose to 50% of normal rate Safety and use during hemodialysis not established	Excretion: urine 65% (primarily unchanged), feces 25% (primarily unchanged)

*When a glycoprotein IIb/IIIa antagonist is used, abciximab and tirofiban should be considered preferred agents, because no dosing changes are required for abciximab, and dialysis-specific dosing recommendations are available for tirofiban. Increased bleeding but reduced in-hospital mortality rates in CKD patients with ACS treated with glycoprotein IIb/IIIa antagonists has also been shown. (See also Opelami O, Sakhuja A, Liu X, et al. Outcomes of infected cardiovascular implantable devices in dialysis patients. Am J Nephrol. 2014;40(3):280-7.)

TABLE 98.5

Antithrombotic Agents for Acute Coronary Syndrome and Other Thrombotic Indications in Patients With Chronic Kidney Disease

AGENT	NORMAL DOSE	CHRONIC KIDNEY DISEASE POPULATION	PHARMACOLOGY
Indirect Factor Xa Inhibitors			
Unfractionated heparin	Recommended dosage and desired aPTT values as per institutional protocol PCI: 60–100 units/kg IV given once Target ACT 250–350 sec In patients receiving glycoprotein IIb/IIIa inhibitor, give 50–70 units/kg IV to target ACT 200 sec STEMI, adjunct treatment, streptokinase use: 800 units/h when < 80 kg body weight or 1000 units per h when > 80 kg body weight Start: 5000 units IV, adjust dose to target aPTT 50–75 sec NSTEMI: 12–15 units/kg per h IV Start: 60–70 units/kg IV; Max 5000 units bolus, max rate 1000 units per h Adjust dose to target aPTT 50–75 sec	In patients with CKD, suggested starting dose of heparin is 50 IU/kg bolus, then 18 IU/kg per h Monitor aPTT level and adjust accordingly as per institutional protocol	Metabolism: liver (partial) Metabolites: none Excretion: urine
Low-molecular-weight heparin (e.g., enoxaparin)	Unstable angina, non–Q-wave myocardial infarction: 1 mg/kg subcutaneously twice daily STEMI, age < 75 years: 30 mg IV bolus plus 1 mg/kg subcutaneously, then 1 mg/kg subcutaneously every 12 h PCI: additional 0.3 mg/kg IV bolus if last subcutaneous administration given > 8 h before balloon inflation STEMI, age > 75 years: 0.75 mg/kg subcutaneously every 12 h (no IV bolus)	CrCl < 30 mL/min STEMI, age < 75 years: 30 mg IV bolus plus 1 mg/kg subcutaneously, then 1 mg/kg subcutaneously once a day STEMI, age > 75 years: 1 mg/kg subcutaneously once a day	Excretion: urine 40%
Direct Factor Xa Inhibitor			
Fondaparinux	Unstable angina/NSTEMI Conservative strategy: 2.5 mg subcutaneously once daily During PCI: add unfractionated heparin 50–60 units/kg IV bolus for prophylaxis of catheter thrombosis[52]	CrCl 30–50 mL/min: use with caution CrCl < 30 mL/min: not indicated	Excretion: urine (primarily unchanged)
Direct Thrombin Inhibitors			
Bivalirudin	Intended for use with aspirin 300–325 mg per day 0.75 mg/kg IV bolus initially, followed by continuous infusion at rate of 1.75 mg/kg per h for duration of procedure Perform ACT 5 min after bolus dose Administer additional 0.3 mg/kg bolus if necessary May continue infusion following PCI beyond 4 h (optional post-PCI, at discretion of treating health care provider) initiated at rate of 0.2 mg/kg per h for up to 20 h as needed	CrCl 10–29 mL/min: usual bolus dose, then initial infusion of 1 mg/kg per h IV up to 4 h Hemodialysis: usual bolus dose, then initial infusion of 0.25 mg/kg per h IV up to 4 h Bivalirudin is a direct thrombin inhibitor with specific dosing adjustments for patients undergoing dialysis and should be preferentially considered	Dialysable: with 25% reduction in levels Excretion: urine
Dabigatran	Indicated for prevention of stroke and thromboembolism associated with nonvalvular atrial fibrillation CrCl > 30 mL/min: 150 mg by mouth twice daily	CrCl 15–30 mL/min: 75 mg by mouth twice daily CrCl <15 mL/min or hemodialysis: not indicated For patients currently taking dabigatran, wait 12 h (CrCl ≥30 mL/min) or 24 h (CrCl < 30 mL/min) after last dose of dabigatran before initiating treatment with parenteral anticoagulant If possible, discontinue dabigatran 1–2 days (CrCl ≥ 50 mL/min) or 3–5 days (CrCl < 50 mL/min) before invasive or surgical procedures because of increased risk of bleeding	Metabolism liver esterases and microsomal carboxylesterases Excretion: feces 7%, urine 86%
Rivaroxaban	Indicated for prevention of stroke and thromboembolism associated with nonvalvular atrial fibrillation, VTE CrCl > 50 mL/min: 15 mg by mouth bid for 3 weeks (acute anticoagulation for VTE) CrCl > 50 mL/min: 20 mg by mouth at hour of sleep (chronic anticoagulation)	CrCl 15–50 mL/min: 15 mg by mouth at hour of sleep CrCl < 15 mL/min: not indicated	Metabolism: liver CYP450 Excretion: feces 28%, urine 66% Half-life: 5–9 h or 11–13 h in elderly
Apixaban	Indicated for prevention of stroke and thromboembolism associated with nonvalvular atrial fibrillation, VTE 2.5 mg by mouth twice daily (VTE prophylaxis) 5 mg by mouth twice daily (chronic anticoagulation)	Age ≥ 80 years, body weight ≤ 60 kg, or serum Cr ≥ 1.5 mg/dL, the recommended dose is 2.5 mg orally twice daily	Metabolism: liver CYP450 CYP3A4/5 while CYP1A2, 2C8, 2C9, 2C19, and 2J2 are minor Excretion: feces 83%, urine 27%
Edoxaban	Indicated for prevention of stroke and thromboembolism associated with nonvalvular atrial fibrillation, VTE 60 mg by mouth once daily (VTE prophylaxis) 60 mg by mouth once daily (chronic anticoagulation)	CrCl > 95 mL/min: Do not use; increased ischemic stroke compared with warfarin CrCl > 50 to 95 mL/min: 60 mg orally once daily CrCl 15-50 mL/min or < 60 kg: 30 mg orally once daily	Metabolism: minimal Excretion: urine

ACT, activated clotting time; *aPTT*, activated partial thromboplastin time; *CKD*, chronic kidney disease; *Cr*, creatinine; *CrCl*, creatinine clearance; *IV*, intravenous; *NSTEMI*, non–ST-elevation myocardial infarction; *PCI*, percutaneous coronary intervention; *STEMI*, ST–elevation myocardial infarction; *VTE*, venous thromboembolism.

Renal dysfunction is a highly inflammatory state, associated with higher rates of plaque rupture and

incident thrombotic CVD events. Patients with CKD have more proximal and extensive CAD than the general population; thus, they have larger areas of myocardium at risk for ischemia and dysfunction. Finally, patients with acute-on-chronic hyperactivation of neurohormonal systems, including the RAAS, the SNS, or systems using endothelin or vasopressin, who do not have adequate counterregulation by natriuretic peptides, nitric oxide, and other systems, may promote worsened ischemia, myocardial dysfunction, and end-organ injury.

Treatment of Myocardial Infarction in Patients With Renal Dysfunction (see also Chapters 59 and 60)

Therapies that benefit the general population and often yield enhanced benefit in patients with CKD and ESRD include aspirin, beta blockers, ACEIs, ARBs, and aldosterone receptor antagonists.[40] Therapies that require dose adjustments on the basis of CrCl include low-molecular-weight heparins, bivalirudin, and glycoprotein IIb/IIIa antagonists. Given that the major inputs for bleeding risks include older age, low body weight, and renal dysfunction, **Tables 98.4 and 98.5** also list agents that are approved in a weight-adjusted dose form and give the currently recommended dose adjustments for commonly used antiplatelet and antithrombotic agents.[39] Greater utilization of such therapies, despite the heightened risk for complications, might attenuate the excess mortality rate reported in CKD and ESRD populations. There have been no randomized trials of PCI in patients with CKD or ESRD. However, the large Swedish Web-system for Enhancement and Development of Evidence-based Care in Heart Disease Evaluated According to Recommended Therapies (SWEDEHEART) has observed an apparent benefit of revascularization in ACS in CKD groups with an eGFR of 15 mL/min/1.73 m^2 or more (**Fig. 98.11**).[41] Patients with more severe degrees of renal impairment and those undergoing dialysis, although infrequently offered PCI, appeared to have no improvement in survival rates with interventional management.

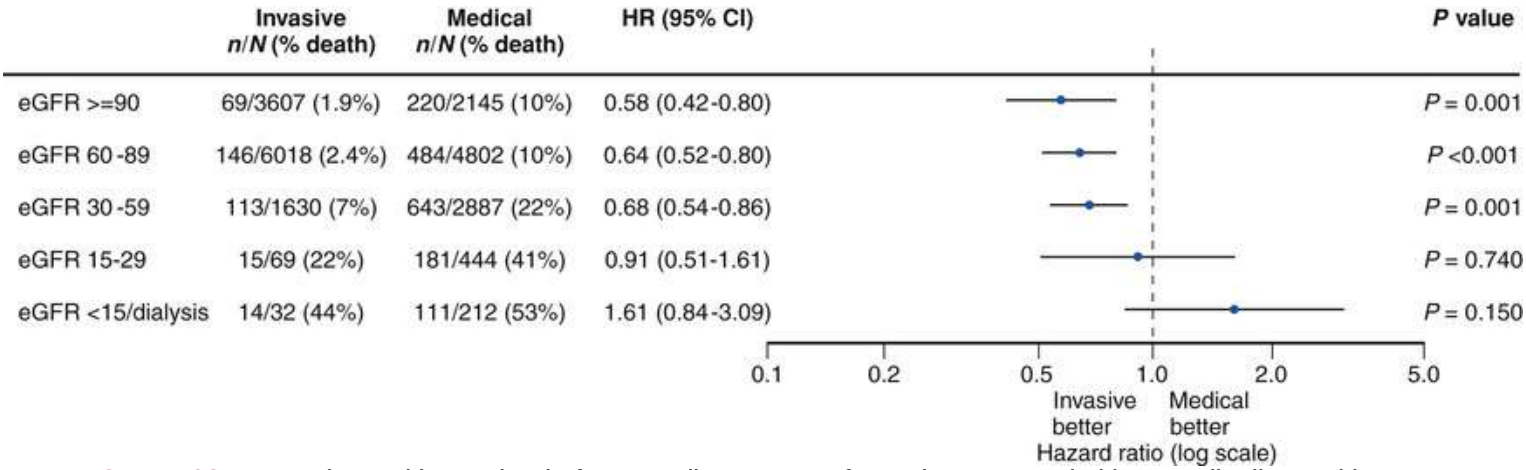

FIGURE 98.11 Estimated hazard ratio for mortality at 1 year for patients treated either medically or with early revascularization. (Adapted from Szummer K, Lundman P, Jacobson SH, et al; SWEDEHEART: Influence of renal function on the effects of early revascularization in non-ST-elevation myocardial infarction: data from the Swedish Web-System for Enhancement and Development of Evidence-Based Care in Heart Disease Evaluated According to Recommended Therapies (SWEDEHEART). Circulation 2009;120(10):851-8.)

Cardiorenal Syndromes

The term *cardiorenal syndrome* (CRS) refers to disorders of the heart and kidneys whereby acute or chronic dysfunction in one organ may induce acute or chronic dysfunction in the other (see also Part IV). Five distinct syndromes have been described according to the clinical scenario and time sequence of organ failure (**Fig. 98.12**). Patients with CKD, and in particular ESRD, have three key mechanical contributors to HF: pressure overload (related to HTN), volume overload, and cardiomyopathy (**Fig. 98.13**). Approximately 20% of patients approaching hemodialysis have a diagnosis of preexisting HF. It is unclear how much of this diagnosis can be attributed purely to chronic volume overload from renal failure and how much is due to impaired systolic or diastolic function. CKD influences the blood levels of B-type natriuretic peptide (BNP) and NT-proBNP. In general, when the eGFR is less than 60 mL/min/1.73 m^2, higher cut points of 200 pg/mL and 1200 pg/mL should be used in the diagnosis of HF with BNP and NT-proBNP, respectively.

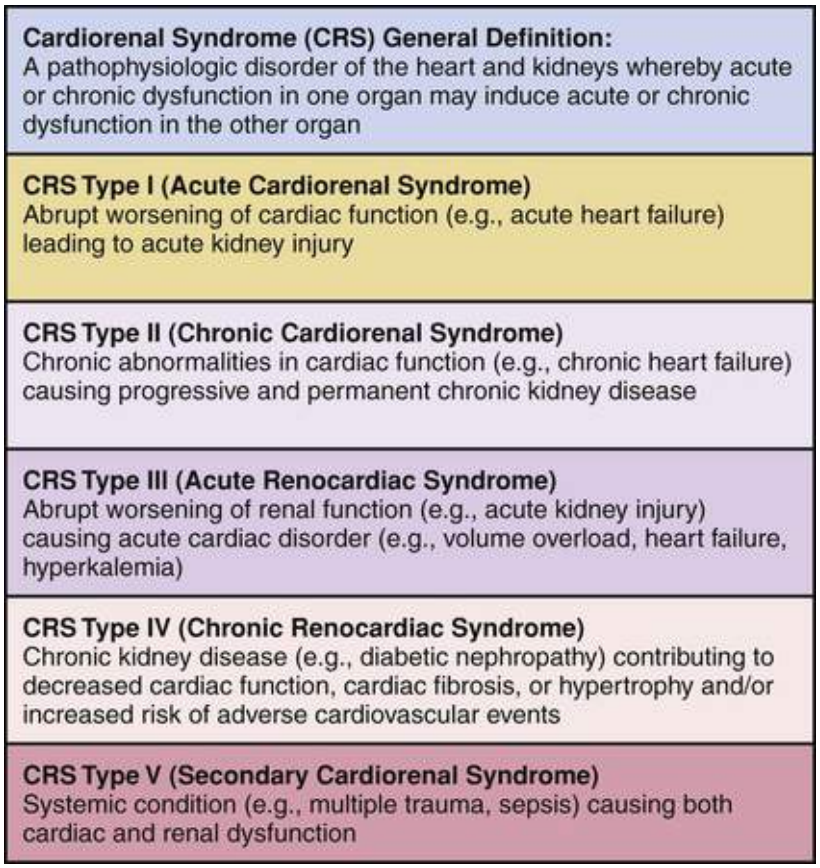

FIGURE 98.12 Definitions of cardiorenal syndromes. (Adapted from Ronco C, Haapio M, House AA, et al: Cardiorenal syndrome. J Am Coll Cardiol 2008;52(19):1527-39.)

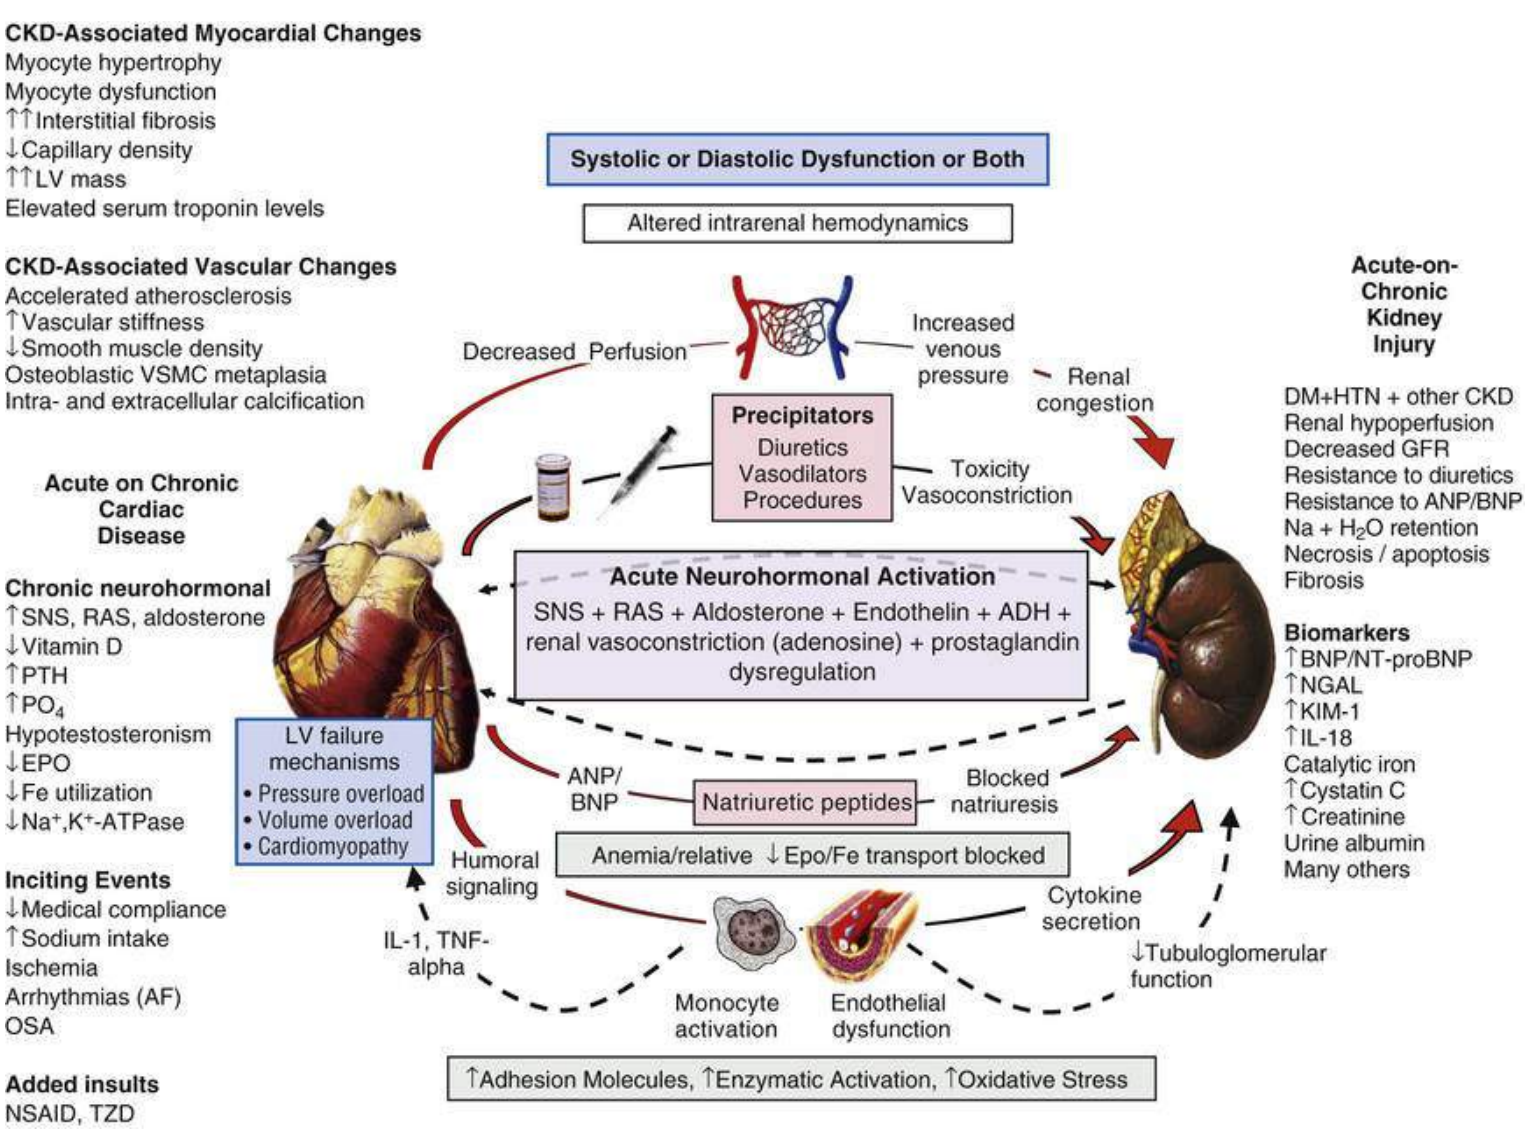

FIGURE 98.13 Pathophysiology of type 1 cardiorenal syndrome or worsening renal function after hospitalization for acutely decompensated heart failure; *KIM-1,* kidney injury molecule-1; *OSA,* obstructive sleep apnea; *TZD,* thiazolidinedione; *VSMC,* vascular smooth muscle cell. (Adapted from Herzog CA, Asinger RW, Berger AK, et al: Cardiovascular disease in chronic kidney disease: a clinical update from Kidney Disease: Improving Global Outcomes (KDIGO). Kidney Int 2011;80(6):572-86.)

Once acute HF is recognized on clinical grounds, approximately 25% of patients will develop a CRS during hospitalization; it will be characterized by a rise in serum Cr of 0.3 mg/dL or more and a reduction in urine output. Of those, approximately one third will return to baseline, one third are left with a worsened eGFR, and the final third have progressive cardiorenal disease resulting in either death or the need for renal replacement therapy.[42] Multiple studies have shown that the predictors of CRS (type 1) include the baseline eGFR, older age, female sex, increased baseline blood pressure, higher initial natriuretic peptide levels, and increased central venous pressure. Because CRS type 1 in patients with HF rarely occurs in the prehospital phase and more commonly develops after treatment is started in the hospital, iatrogenic factors have been implicated. The use of loop diuretics can contribute to CRS type 1, probably by further activating the RAAS and possibly worsening intrarenal hemodynamics.

There are no proven therapeutic strategies for CRS type 1. Failed approaches include continuous furosemide infusions, low-dose dopamine, nesiritide, and programmatic use of inotropic agents. In the setting of poor arterial perfusion, dobutamine or milrinone is commonly used during hospitalizations. Neither agent reduces mortality rates, but both increase the risk of arrhythmias, and milrinone must be dose adjusted when the eGFR is below 45 mL/min/1.73 m^2 (**Table 98.6**) Patients with advanced HF have a reduced renal blood flow, a decreased glomerular filtration rate, enhanced proximal reabsorption of

water, increased absorption of sodium along the loop of Henle, and an overall reduced capacity of the nephron to excrete water. Furthermore, a reduced effective arterial blood volume stimulates vasopressin release, which plays a dominant role in worsening water retention. Hyponatremia and excess body water can be improved with the use of oral tolvaptan or intravenous conivaptan; however, neither therapy reduces rehospitalization or mortality rates in this scenario.

TABLE 98.6

Selected Therapies for Heart Failure in Patients With Chronic Kidney Disease

MEDICATION	NORMAL DOSE	CHRONIC KIDNEY DISEASE POPULATION	PHARMACOLOGY
Dobutamine	Acutely decompensated HF with low cardiac output: continuous infusion of 5-15 µg/kg/min IV Initial rate 5.0 µg/kg/min IV titrate 5-20 µg/kg/min; no more than 40 µg/kg/min	No specific dose adjustments for patients with CKD Recommend close monitoring for adverse effects, including arrhythmias Doses < 5 µg/kg/min may produce hypotension	Principal routes of metabolism are methylation of the catechol and hepatic conjugation May increase renal clearance of other drugs in low cardiac output states.
Milrinone	Acutely decompensated HF with low cardiac output: loading dose of 50 µg/kg IV over 10 minutes, then start maintenance: 0.375 to 0.75 µg/kg/min	Recommended infusion rates (µg/kg/min) CrCl mL/min/1.73 m^2 [CrCl > 50]: No change [50]: 0.43 µg/kg/min [40]: 0.38 µg/kg/min [30]: 0.33 µg/kg/min [20]: 0.28 µg/kg/min [10]: 0.23 µg/kg/min [5]: 0.2 µg/kg/min	Excreted unchanged in urine
Nesiritide	Acutely decompensated HF with pulmonary congestion: 2 µg/kg IV bolus over 1 minute, then 0.01 µg/kg/min IV infusion. If hypotension, discontinue until stabilized, then restart at 30% lower dose	No specific dose adjustments for patients with CKD Recommend close monitoring for adverse effects, including hypotension	Cleared by (1) binding to cell surface clearance receptors with subsequent cellular internalization and lysosomal proteolysis; (2) proteolytic cleavage of peptide by endopeptidases, such as neutral endopeptidase, which are present on vascular luminal surface; and (3) renal filtration
Nitroprusside	Acutely decompensated HF with vasoconstriction: 0.25–0.8 mg/kg/min IV	No specific dose adjustments for patients with CKD Recommend close monitoring for adverse effects, including hypotension and thiocyanate accumulation	Intraerythrocytic reaction but hepatic and renal function impacts thiocyanate accumulation
Valsartan/Sacubitril	Chronic HF with reduced LVEF: sacubitril/valsartan 24/26, 49/51, 97/103 mg orally twice daily	No specific dose adjustments for patients with CKD Monitor Cr, blood urea nitrogen, K+	Metabolism: Sacubitril converted to LBQ657 by esterases; urine 52% to 68%, feces 37% to 48% Valsartan urine ≈ 13%, feces 86%
Ivabradine	Chronic HF with LVEF < 35% and heart rate > 70: start 5 mg orally twice daily and may reduce to 2.5 mg or increase to 7.5 mg twice daily depending on heart rate and tolerability	No specific dose adjustments for patients with CKD	Metabolism: liver CYP450 CYP3A4 Excretion: feces 96%, urine 4%
Hydralazine	Acute and chronic HF, intolerant to RAAS blockers, 25–50 mg by mouth tid or qid	Dose q 8–16 h with CrCl < 10 mL/min	Hepatic clearance, 25% to 40% removed with dialysis
Digoxin	Chronic systolic and diastolic HF, atrial fibrillation with rapid ventricular rate 0.25 mg by mouth qd	0.125 mg po qd or qod	50% to 70% excreted unchanged in urine. Half-life in anuric patients is prolonged to 3.5 to 5 days. Digoxin is not effectively removed from body by dialysis

CKD, chronic kidney disease; *Cr*, creatinine; *CrCl*, creatinine clearance; *HF*, heart failure; *IV*, intravenous; *LVEF*, left ventricular ejection fraction; *RAAS*, renin-angiotensin-aldosterone system.

Treatment efforts should be aimed at reducing congestion within a narrow management window (**see Chapter 25**) and improving left ventricular systolic function, often in the hospitalized setting; the oral and intravenous therapies are used, including diuretics mentioned previously and discussed in detail elsewhere in this text. Observational studies and small trials utilizing continuous venovenous

ultrafiltration have been associated with short-term improvements in symptoms, reductions in fluid weight, shorter hospital stays, and reductions in rehospitalization. However, the Cardiorenal Rescue Study in Acute Decompensated Heart Failure (CARRESS-HF) in patients with persistent congestion and CRS type 1 found no clinical benefits of ultrafiltration over diuretic therapy, and more patients in the ultrafiltration group than in the pharmacologic therapy group incurred serious adverse events (72% vs. 57%; $P = 0.03$).[66] Until larger trials help define the indicated population and optimal timing and mode of ultrafiltration, and until they demonstrate longer-term reductions in hospitalization and mortality rates, ultrafiltration can be considered a last-line approach for the patient with refractory CRS.

The management of the patient who is already receiving dialysis and in HF requires particular care. In general, proven HF therapies, provided they are tolerated, should be employed, along with regular and ad hoc dialysis as needed to control volume overload. Clinicians should keep in mind that ACEIs are dialyzed but ARBs are not. Both agents are associated with reductions in mortality rates in ESRD patients in observational studies. Studies of frequent dialysis performed in the home at lower rates of ultrafiltration have consistently demonstrated lower rates of hospitalization and death in HF patients.[43]

In summary, CKD and HF present a particularly challenging scenario for clinicians and patients. Frequent outpatient monitoring and avoidance of overly aggressive diuresis are advised. Dialysis patients, despite having volume reduction with mechanical fluid removal, should have medical therapy with ACEIs or ARBs, beta blockers, and additional agents for blood pressure control if needed. Ideally, ESRD patients with HF would undergo frequent (daily) hemodialysis treatments at home provided self-care and partner care can be delivered without difficulties.

Chronic Kidney Disease and Valvular Heart Disease

Impaired renal function is linked to mitral annular calcification and to aortic valve sclerosis (see also Section 8). Progressive thickening of the cardiac valves and calcification occur in patients with ESRD.[44] Approximately 80% of patients with ESRD have the murmur of aortic sclerosis. Patients with CKD and ESRD have rates of progressive calcification and valve failure greater than in the general population.[45]

Bacterial endocarditis may develop in patients with ESRD who have temporary access catheters for dialysis (**see also Chapter 73**).[46] Endocarditis with common pathogens, including *Staphylococcus*, *Streptococcus*, and *Enterococcus*, in the mitral, aortic, or tricuspid valves, is associated with a risk of cerebral embolism of 40% and a mortality rate of 50% in ESRD.[46] It becomes very difficult to treat given the continued need for dialysis access and the delay in surgical placement of permanent arteriovenous shunts or fistulas. Unfortunately, surgical mortality rates associated with valve replacement in ESRD related to endocarditis are very high. In the setting of ESRD, when valve surgery is carried out for endocarditis or other causes of valve failure, there has been no difference in survival rates among those who received tissue valves or mechanical valve prostheses. Thus, tissue valves are a reasonable choice given the complicating issue of chronic anticoagulation and bleeding with repeated dialysis vascular access.[47]

Renal Function and Arrhythmias

Uremia, hyperkalemia, acidosis, and disorders of calcium-phosphorous balance are all linked to higher rates of atrial and ventricular arrhythmias (see also Section 5). Given a concurrent substrate of LVH, left ventricular dilation, HF, and valvular disease, it is not surprising that higher rates of virtually all the

arrhythmias have been reported in CKD, including bradyarrhythmias and heart block. Hypokalemia after hemodialysis can be observed for 6 to 8 hours as the plasma potassium concentration equilibrates from approximately 2.0 mEq/L to the normal range of 3.5 to 5.5 mEq/L. During this time, multiple studies indicate an increased risk of sudden cardiac death.[48] There is a general trend to increase the potassium concentration of the dialysis fluid to reduce the large shifts in potassium in ESRD patients. Caveats for practical management include dose adjustment for many antiarrhythmic medications, including dofetilide and sotalol (**Table 98.7**). Observational studies suggest that ESRD patients who survive a sudden death event have a favorable benefit-to-risk ratio for implantable cardioverter-defibrillator (ICD) placement; however, rates of infection are higher and when infection occurs, it is associated with in-hospital mortality rates of approximately 14%.[49] Of concern, CKD, and ESRD in particular, may cause elevated defibrillation thresholds and failure of ICDs and is associated with high rates of shock and antitachycardia pacing therapy (**Fig. 98.14**).[50] Until this association is better understood, patients receiving ICDs should have frequent surveillance and consideration for noninvasive programmed stimulation for appropriate antitachycardia and defibrillation therapy.

TABLE 98.7

Selected Antiarrhythmics in Patients With Chronic Kidney Disease

MEDICATION	NORMAL DOSE	CHRONIC KIDNEY DISEASE POPULATION	PHARMACOLOGY
Amiodarone	Acute ventricular and acute and chronic atrial arrhythmias: First rapid: 150 mg over 10 minutes (15 mg/min) Followed by slow: 360 mg over 6 hours (1 mg/min) Maintenance infusion: 540 mg over the remaining 18 hours (0.5 mg/min) Oral 800 to 1600 mg per day in divided doses until a total of 10 g has been given; then 200 to 400 mg per day	No specific dose adjustments for patients with CKD	Eliminated primarily by hepatic metabolism and biliary excretion; negligible renal excretion
Dronedarone	Atrial fibrillation/atrial flutter: 400 mg orally twice a day with morning and evening meals	No specific dose adjustments for patients with CKD	Dronedarone is extensively metabolized by the liver
Dofetilide	Atrial fibrillation/atrial flutter; 500 µg po bid initially. QTc interval should be measured 2-3 hours after initial dose. If QTc > 15% of baseline, or if QTc is > 500 msec (550 msec in patients with ventricular conduction abnormalities), dofetilide should be adjusted. Continued monitoring for doses 2-5: QTc interval must be determined 2-3 hours after each subsequent dose of dofetilide for in-hospital doses 2-5. If the measured QTc is > 500 msec (550 msec in patients with ventricular conduction abnormalities), dofetilide should be stopped	[CrCl > 60 mL/min]: 500 µg bid [40-60 mL/min]: 250 µg twice daily [20-39 mL/min]: 125 µg twice daily [< 20 mL/min]: contraindicated	Hepatic metabolism accounts for 20% to 30%, 70% to 80% renal elimination
Sotalol	Atrial fibrillation/atrial flutter: 80-160 mg orally twice a day	CrCl 30 to 59 mL/min: Dosage interval should be increased to 24 hours CrCl 10 to 29 mL/min: Dosage interval should be increased to 36 to 48 hours CrCl < 10 mL/min: Dose should be individualized	Excreted unchanged in kidney. Removed with dialysis

CKD, chronic kidney disease; *CrCl*, creatinine clearance; *IV*, intravenous.

Consultative Approach to Severe Kidney Disease and Hemodialysis Patients

The prevalence of angiographically significant coronary artery disease (CAD) ranges from 25% in young, nondiabetic hemodialysis patients to 85% in older ESRD patients with long-standing DM.[51] Of those initiating dialysis, 87% have some structural abnormality on echocardiography, including LVH, reduced LVEF, right ventricular hypertrophy or dysfunction, pulmonary HTN, or valvular disease.[52] Thus, many years of CKD must be associated with these progressive changes, and we cannot attribute them to the dialysis procedure itself in most patients who are in the first few months of treatment. Cardiac death in dialysis patients younger than age 45 may be 100 times greater than that in the general population. The prevalence and severity of CAD among patients with ESRD is daunting in terms of both occurrence and extent of poor outcomes. Medicare beneficiaries with CKD prior to initiation of dialysis are 60% more likely to have a billing claim submitted for the diagnosis of CVD and 70% more likely to have a claim submitted for "atherosclerotic heart disease." Of those claims incident to dialysis, a substantial proportion of patients, perhaps the majority, have established CAD. In diabetic renal transplant candidates, 30% will have one or more lesions with greater than 75% stenosis.[53] When comparing patients who undergo evaluation for CAD, those with ESRD have substantially more numerous, proximal, and severe coronary artery lesions, as well as more severe left ventricular dysfunction. The patient with incipient ESRD on dialysis can be considered the highest cardiovascular risk patient in medicine, with expected rates of CHD death that are many-fold those expected for a non-ESRD patient, even those with a burden of several cardiovascular risk factors.

Despite the use of multiple medications, most published series of ESRD patients from either clinical trials or registries indicate the mean systolic blood pressure is approximately 155 mm Hg. Indeed 80% of ESRD patients have HTN, but it is adequately controlled in only 30% of these patients. Peritoneal dialysis, more frequent in-center, and home hemodialysis are associated with much better blood pressure control than thrice-weekly hemodialysis.[54] Arteriovenous fistulas used for dialysis access cause recirculation of blood in one of the extremities (usually the upper arm), and depending on their size and proximity, can account for as much as 25% shunting. This volume loads the right ventricle and can predispose to the development of HF and right ventricular dysfunction after the onset of ESRD and use of the shunt or fistula.[55] Long-term cardiorenal protection involves two important concepts: (1) blood

pressure control and (2) use of an agent that blocks the RAAS, such as an ACEI or ARB, as the base of therapy. The RAAS appears to have considerable redundancy and is able to maintain its function, if not increase its overall level of activity, without participation by the kidneys. Hence, this hyperactivation of the RAAS is a target for therapy even in anephric patients because the ACEI or ARB can reduce the LVH and possibly improve survival rates. A small trial demonstrated that ramipril can preserve the residual urine output in those receiving peritoneal dialysis, which is a consistently favorable finding in ESRD.[56] A case-matched study of ESRD patients found that those who were taking an ACEI or ARB had improved survival rates, and this benefit appeared to get larger for longer durations of use.[57] ACEI or ARB therapy may worsen hyperkalemia in patients with ESRD. As tolerated, the clinician should consider adjusting the dialysis regimen to improve potassium removal. Patiromer calcium, a gastrointestinal potassium-binding polymer, was approved in starting doses of 8.4 g orally per day for acute and extended treatment of hyperkalemia.[58]

With an ACEI or ARB as a base of therapy, the antihypertensive regimen can be further modified according to the drug's efficacy in lowering the blood pressure and reducing the CAD events. Beta blockers can be used as both antihypertensive and antiischemic agents. In those with HF, beta blockers improve the left ventricular ejection fraction and reduce rates of hospitalization, sudden death, and all-cause mortality. Patients with ESRD who receive beta blockers after CAD events may have large relative risk reductions in all-cause mortality.

Decisions regarding an additional antihypertensive or cardioprotective agent should be based on ease of management, likelihood of patient compliance, and lack of adverse effects. Guidelines for non-ESRD patients state that the optimal office systolic blood pressure should be less than 130 mm Hg. The difficult task in the ESRD patient is to achieve these goals without having hypotension during dialysis sessions. Given the high rates of severe CAD in ESRD, hypotension during dialysis can worsen clinical and subclinical ischemia, which is recognized as chest discomfort, shortness of breath, ST-segment depression on electrocardiography, and elevations of cTn on blood testing.

The goal of LDL-C reduction, in most cases with a statin and ezetimibe, in patients with ESRD is supported by a 17% reduction in major atherosclerotic events shown in the Study of Heart and Renal Protection in patients with predialysis CKD and ESRD.[59] Use of nonstatin lipid-lowering agents can be stylized to treat statin-intolerant patients and those with hypertriglyceridemia at risk for pancreatitis. Among those with CKD and ESRD, there are no clear sources of evidence that these drugs reduce cardiovascular events. Colesevelam, a bile-acid sequestrant, also can aid in lowering serum phosphorus.

In ESRD with DM, blood glucose control to a target glycohemoglobin level of less than 7% can be expected to reduce rates of microvascular complications (retinopathy) and, to a lesser extent, clinically important atherosclerotic disease (MI, stroke, CVD death). Patients with ESRD should stop smoking. The specific use of antiplatelet or antithrombotic agents for the prevention of CVD risk in ESRD requires caution.

In the setting of stable symptomatic CAD, an analysis from the Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation (COURAGE) trial suggested that PCI had no benefit over optimal medical therapy in patients with predialysis CKD.[60] There are no similar trial data available in patients with ESRD. After treatment with optimal medical therapy in a patient with ESRD and symptomatic CAD, the next step is coronary angiography and consideration of revascularization. In the common scenario of multivessel disease, multiple studies have shown that the coronary artery bypass graft (CABG) is associated with superior outcomes over PCI with drug-eluting stents, probably due to more complete revascularization and protection from recurrent MI.[61] Patients with ESRD undergoing coronary revascularization procedures have an increased risk for adverse events, including death.

Dialysis-dependent patients undergoing CABG face a 4.4-fold increased risk of in-hospital death, a 3.1 times greater risk of mediastinitis, and a 2.6-fold increased risk of stroke compared with patients undergoing CABG who are not on dialysis.[40]

In summary, patients with ESRD have a greater coronary heart disease risk than would be calculated from standard risk scores. An aggressive approach with medical management for CAD is warranted, even in the case of subclinical CAD. A low threshold for diagnostic testing should be held in ESRD patients. When significant multivessel CAD is found, ESRD patients appear to benefit from revascularization with CABG compared with PCI. If it is clinically reasonable, patients should be given that opportunity for improved survival times and a reduction in future cardiac events.

Evaluation and Management of the Renal Transplant Recipient

Cardiovascular screening is recommended in high-risk CKD patients prior to renal transplantation.[62] These include persons with DM; men over age 45 years and women over age 55 years; and patients with a history of ischemic heart disease, an abnormal electrocardiogram, left ventricular dysfunction, history of smoking, or duration of dialysis more than 2 years. Controversies exist regarding the ideal screening test for CAD in ESRD patients. The choice of exercise versus pharmacologic stress and echocardiography versus nuclear scintigraphic imaging must be individualized. One suggested algorithm uses dobutamine stress echocardiography (**Fig. 98.15**). Coronary cardiac computed tomographic angiography may be considered as another screening tool with the understanding that it can exclude significant coronary disease and identify very low risk patients who may move on to renal transplantation.[63] Coronary angiography and revascularization can be performed with little loss in renal function in very low eGFR groups if it is done carefully with staged intervals between the diagnostic procedure and PCI or CABG (**Fig. 98.16**).[64] After renal transplantation, treatment with lipid-lowering therapy (i.e., low-potency statins such as fluvastatin or pravastatin) is generally associated with a favorable benefit-to-risk ratio.[65] A metaanalysis of 22 studies (with 3465 participants) has supported the use of statins in renal transplant recipients for the reduction of cardiovascular events.[66]

Clin J Am Soc Nephrol 2009;4(12):1907-13.)

Future Perspectives

Recognition has increased over the last several decades for the fact that patients with CKD have a high risk for CVD. Frequent clinical scenarios in which renal function influences patient care include patients who have undergone PCI or cardiac surgery and patients who have ACS, HF, valvular disease, or arrhythmias. Results from retrospective studies and clinical trial subgroups form the basis of current recommendations, given the lack of prospective randomized trials in CKD and ESRD. Further study of the adverse metabolic milieu of CKD is likely to lead to generalizable diagnostic and therapeutic targets for the future management of renal patients with cardiovascular illness.

Cardiovascular Manifestations of Autonomic Disorders

David Robertson, Rose Marie Robertson

Autonomic disorders in humans commonly present with abnormalities of blood pressure and/or heart rate, with reduced stability of these vital signs, and/or with alterations in their usual responses to external and internal stimuli. Because most of these disorders are uncommon, many clinicians are not familiar with them or with the principles involved in their management. In both acute and chronic clinical situations, consultation with a cardiologist is often appropriately sought, and is expected to provide diagnostic and therapeutic assistance. To facilitate effective consultation, in this chapter we will briefly review the current understanding of normal autonomic cardiovascular control and the normal responses to autonomic function testing, and then review the autonomic disorders that the consulting cardiologist is likely to encounter. We will describe the current understanding of these disorders, address how to arrive at a

diagnosis, and review effective initial approaches to management. Even though many autonomic disorders are rare, it is worth the effort to try to understand them, because understanding provides opportunities to improve or even extend lives and educates us about normal physiology.[2] We will also briefly touch on specific autonomic aspects of several cardiovascular disorders that are primarily covered in other chapters.

Overview of Autonomic Circulatory Control

The autonomic nervous system (ANS) plays an essential moment-to-moment role in adjusting the circulation to meet the needs of the body as its environment changes. The central nervous system receives information about that environment (both internal and external) via a broad range of inputs as diverse as visual sensors, postural sensors, volume and pressure sensors, and others, and integrates this information, primarily in the medulla. The major components of the autonomic response system are the sympathetic, parasympathetic, and enteric components, with the first two providing the major integrated vasomotor response. The effects of autonomic input to the cardiac conduction system, the myocardium itself, and the coronary vasculature are discussed in **Chapters 22, 34, and 46**. Because the integrated control of the BP and its modifications in autonomic disorders are less familiar, we will delineate the relevant physiology here, prior to discussing how it is used in testing the function of the various components of the autonomic nervous system, and how it can be helpful in reaching a diagnosis.

The Baroreflex

In humans, the chronic maintenance of the BP is provided by endocrine, renal, capillary shift, and autonomic mechanisms, but the exquisite control needed to reduce the lability of BP with shifts in posture and other changes is achieved primarily and most rapidly by the baroreflex system. This system is made up of an integrated complex of neurons supporting a group of reflexes (**Fig. 99.1**). It includes (1) the arterial baroreceptors, whose sensory endings lie within the aortic arch, at the origin of the right subclavian artery and within the carotid sinuses, and (2) the cardiopulmonary, or low-pressure, receptors in the walls of the atria and the pulmonary artery. When healthy adult humans are at rest, the baroreflex tonically inhibits sympathetic activity and enhances parasympathetic activity, so that parasympathetic tone predominates. With changes in vascular pressure, multiple mechanisms come into play, primarily driven by information sensed by the baroreceptors and integrated in the vasomotor center of the brain, which alter the sympathetic and parasympathetic outflow to modify the cardiac contractility, HR, and tone of the arterial and venous circulations.

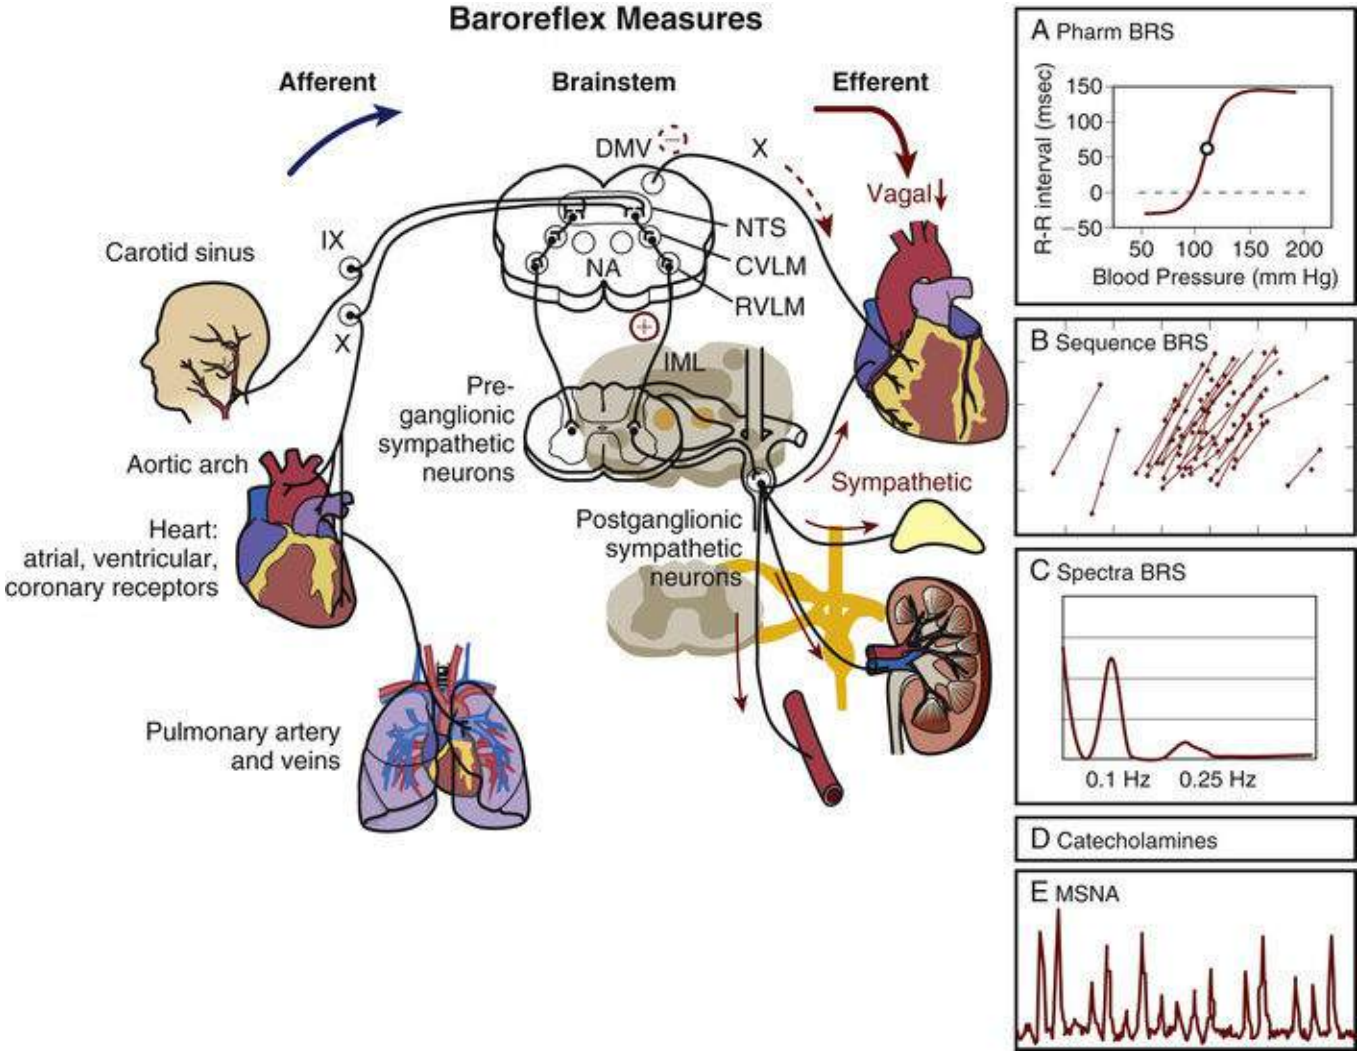

FIGURE 99.1 Diagram of the baroreflex in humans with methods of assessment. In boxes A to E are depicted five methods of assessing baroreflex sensitivity (BRS). **Box A:** Baroreflex properties can be assessed by pharmacologic probing with graduated doses of BP–elevating and/or BP-lowering drugs such as phenylephrine and nitroprusside. Changes in slope of the regression line between R-R interval changes and BP changes is referred to as baroreflex sensitivity. **Box B:** The same can be done by using spontaneous fluctuations of BP and R-R intervals, where sequences of heart beats with increasing or decreasing BP and R-R prolongation are identified and analyzed. **Box C:** Spectral analysis of HR and BP variability allows assessment of sympathetic and vagal modulation of HR and BP. Cross-spectral transfer function analysis can be used to study the interactions and determine baroreflex sensitivity. **Box D:** Plasma catecholamine levels are essential markers for sympathetic activity. **Box E:** Recording of muscle sympathetic nerve activity (MSNA). MSNA is an instantaneous signal of current sympathetic activation, and it allows the estimation of sympathetic baroreflex sensitivity. CVLM, caudal ventrolateral medulla; DMV, dorsal motor nucleus of vagus; IML, intermediolateral column of spinal cord; NA, nucleus ambiguous (vagus); NTS, nucleus tractus solitarius; RVLM, rostral ventrolateral medulla.

Arterial Baroreceptors

The location of the arterial (or high-pressure) baroreceptors is ideal for providing sufficient BP and volume to protect cerebral perfusion (**see Fig. 99.1**). These mechanoreceptors are stretch-dependent, so that elevation of vascular pressure increases the discharge frequency of the branch of the glossopharyngeal nerve innervating the baroreceptors in the carotid sinus, and of the aortic nerve, which innervates the aortic arch baroreceptors, and then combines with the vagus nerve. The arterial baroreceptors are essentially silent when the mean arterial pressure (MAP) is lower than the baroreceptor set point (≈ 70 mm Hg in healthy adults), but when the MAP rises above the set point, the baroreceptors become active.[1] Importantly, baroreceptor function varies between individuals, and the set point can vary in the same individual at different times or in different experimental or disease states. For

example, the set point is often increased in chronic hypertension and decreased in chronic hypotension. The first synapse of both baroreceptor nerves lies in the nucleus tractus solitarius (NTS) in the posterior medulla. In the NTS, afferent information from the baroreceptors is integrated on a beat-to-beat basis and variations in arterial pressure are minimized via the balance of activity of the inhibitory fibers, which run from the NTS to the vasomotor center and determine the efferent sympathetic activity, and the excitatory fibers, which run to the vagal nuclei and regulate the parasympathetic activity. For example, a sudden increase in BP, increasing the stretch of the baroreceptors, causes increased firing, leading to decreased sympathetic and increased parasympathetic activity. Decreased sympathetic activity reduces the arteriolar resistance, venous tone, cardiac contractility, and HR, and increased parasympathetic activity decreases the HR and has a slightly negative effect on contractility. Cardiac output is reduced, and arterial pressure falls toward the baseline. A sudden fall in BP produces the opposite compensatory effects.

Although it is generally recognized that both sympathetic and parasympathetic activity influence the HR, it is often not appreciated that the intrinsic automaticity of the sinus node produces a rate of 95 to 110 beats/min at rest. The normal resting HR of 60 to 70 beats/min in humans is due to parasympathetic dominance, which suppresses the intrinsic sinus nodal rate, along with minimal sympathetic activity at rest. With physical or mental activity, and even with assumption of the upright posture, sympathetic activity increases and parasympathetic activity withdraws, producing an increase in HR. When the activity ceases, parasympathetic dominance and a normal resting HR are restored.[1]

Cardiopulmonary Baroreceptors

The low-pressure cardiopulmonary receptors are located in the heart and the venae cavae, and are activated primarily in response to volume. They send vagal afferents to the NTS and spinal sympathetic afferents to the spinal cord. When stimulated by an increase in intracardiac volume, they produce vasodilation, a fall in BP, and inhibition of vasopressin release. The latter leads to an increase in salt and water excretion and reduces the sensed increase in volume. The cardiopulmonary receptors have minimal direct influence on the HR.

Chemoreflexes and the Diving Reflex

Sympathetic activity can also be modulated by the chemoreflexes, which respond to hypoxemia and hypercapnia. When either or both occur, the reflex response produces hyperventilation and sympathetic vasoconstriction. The actual peripheral chemoreceptors, which respond to hypoxia, are found in the carotid bodies, and the central chemoreceptors, found in multiple areas in the brainstem, sense the pH of the interstitial fluid of the brain. This allows them to integrate information about ventilation (arterial pCO_2), the brain blood flow and metabolism, and the acid-base balance, responding primarily to hypercapnia and modulating the BP via sympathetic tone and adjusting breathing.[3] For example, both hypoxemia and hypercapnia produce hyperventilation and sympathetic vasoconstriction. Inhibitory influences on the overall chemoreflex drive occur with stretch of the pulmonary afferents and with activation of the baroreflex, both of which have a greater influence on peripheral than on central chemoreflexes.

In early hypertension, the ventilatory response to hypoxemia may be increased, in addition to an increase in sympathetic tone, and it has been suggested that an increased chemoreflex drive may contribute to this, as well as impaired baroreflex sensitivity. In obstructive sleep apnea (OSA) (**see also Chapter 87**), the response of the chemoreflexes to hypoxia can be significantly enhanced, with the repetitive episodes of hypoxemia and apnea at night producing bradycardia and a sympathetic

vasoconstrictor response, potentiated because of a reduced or eliminated pulmonary afferent inhibitory influence on the chemoreflex. Responses to hypercapnia do not appear to be enhanced.[4] The tonic chemoreflex drive in patients with OSA can be reversed with 100% oxygen, reducing the sympathetic outflow, HR, and BP. Administering 100% oxygen to patients with borderline hypertension and to spontaneously hypertensive rats reduces not only the ventilator drive but the vasoconstrictor tone, as well.[1]

In diving mammals and sometimes in humans during submersion in water and prolonged apnea, a simultaneous and powerfully increased parasympathetic drive to the heart and an increased sympathetic drive to the vasculature occurs, referred to as the *diving reflex*. In this setting of prolonged hypoxia due to apnea, autonomic mechanisms are utilized to protect oxygen delivery to the most critical organs, the brain and the heart. Whereas sympathetic vasoconstriction reduces the oxygen delivery to much of the body, the cerebral vascular tone is under autoregulatory control and therefore is not increased, and the profound bradycardia that is induced by parasympathetic activation reduces the myocardial oxygen demand. Although this constellation of protective features allows humans and animals to survive and explore underwater without oxygen for 5 or more minutes at a time, it may also be associated with ventricular arrhythmias and increased rates of cardiovascular mortality, especially in susceptible individuals such as those with long QT syndrome (**see also Chapter 33**). The diving reflex has been studied for many years, but the methods used to elicit the relevant stimuli have varied and have not always been standardized, nor has stimulation of other reflexes always been avoided. A reproducible method has been described for such studies, which has included protection for the eyes, so that information can be gathered safely in broader groups of normal persons and patients.[5]

Autonomic Testing

Orthostatic Blood Pressure and the Heart Rate

When we stand, the effect of gravity on the blood volume causes 500 to 800 mL of blood to pool in the lower extremities and splanchnic venous capacitance vessels of the abdomen[6] (**Fig. 99.2**), reducing the venous return, stroke volume, and cardiac output. The reduction in stretch of the arterial and cardiopulmonary baroreceptors is sensed, and the reduced activity of the baroreceptor afferent nerves at their synapses in the NTS leads to a decrease in cardiac vagal tone and an increase in sympathetic activity. The release of norepinephrine causes both arterial vasoconstriction and venoconstriction and an increase in cardiac contractility and heart rate, and protects the arterial pressure and cerebral perfusion. To perform the orthostatic blood pressure test at the bedside, the patient should lie supine for 10 minutes before the baseline BP and HR are measured and recorded, and then should stand at the side of the bed. BP and HR measurements are repeated at 1 and 3 minutes, and at 5 minutes if possible, with the patient queried about symptoms each time. In young healthy persons, baroreflex compensation is so perfect that the systolic BP (SBP) at 1, 3, and 5 minutes of quiet standing is often unchanged, whereas the diastolic BP (DBP) pressure rises 5 to 10 mm Hg and the HR rises less than 10 beats/min. If beat-to-beat BP rather than sphygmomanometric BP is being assessed, as when a Finapres device is being used or an arterial line is in place, one will often see a transient fall (lasting only seconds) in both the SBP and DBP with standing before the compensatory mechanisms readjust the system. In older individuals, compensation is often not as rapid or as complete. Criteria for orthostatic hypotension (OH) are not met in either young or old adults unless there is a fall in SBP of more than 20 mm Hg, or of DBP of more than 10 mm Hg at 3 minutes of standing quietly.[7] An abnormal rise in HR is more than 20 beats/min. A feature of severe

autonomic disorders with OH can be a BP that is extremely posture dependent. Some patients may have marked supine hypertension, with an SBP at or above 200 mm Hg, a nearly normal SBP when seated, and an SBP that falls to less than 60 mm Hg within less than a minute of standing. The upright BP clearly cannot be documented by sphygmomanometry in these patients at the bedside. For safety reasons, in the absence of beat-to-beat BP monitoring or an available tilt table, one may resort to documenting the "standing time" (i.e., the number of seconds the patient can stand before typical symptoms of light-headedness occur and the patient sits). This time can be used to assess the response to medications or other therapeutic maneuvers.

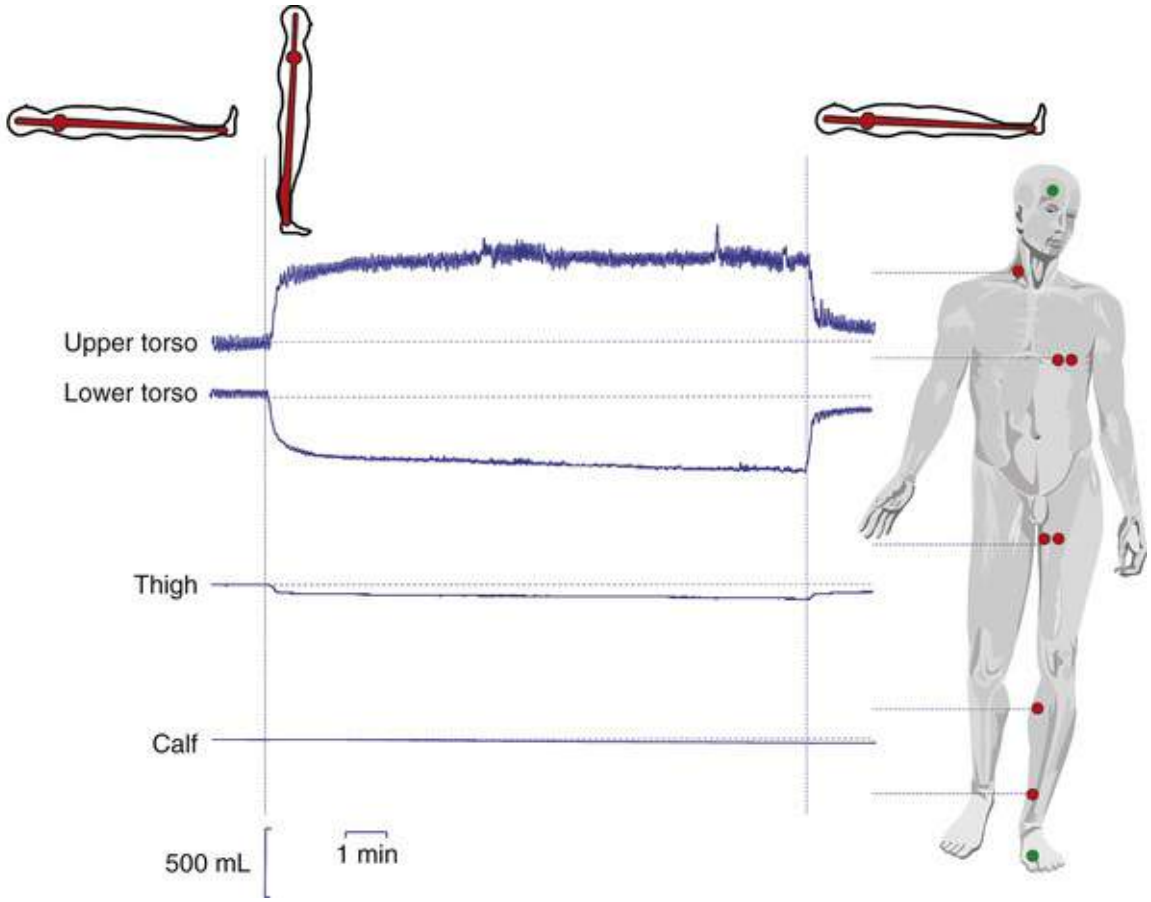

FIGURE 99.2 Orthostatic fluid shifts estimated by impedance. This figure shows the change in impedance within segments of the human body during upright posture, reflecting shifts in fluid volume from the upper torso to the lower torso and to a lesser degree to the thighs. The increase in fluid in the splanchnic circulation forms the basis for considering studies of an abdominal binder to improve orthostatic tolerance in patients with orthostatic hypotension and orthostatic tachycardia.

It is important to realize that in the absence of autonomic disorders, significant OH and even syncope can still be seen, most commonly with volume depletion due to gastrointestinal fluid loss, hemorrhage, excessive sweating, fever, or disorders such as Addison disease (decreased or absent adrenal function, with glucocorticoid and mineralocorticoid insufficiency). OH, especially with prolonged standing, can also be seen with loss of muscle tone and reduced vascular responsiveness, as with prolonged bedrest; it also occurs in astronauts who have been exposed to microgravity during spaceflight. In these situations, the rise in HR with standing will be excessive but appropriate for the fall in BP, unlike the blunted or absent rise seen in sympathetic incompetence.

Valsalva Maneuver

The Valsalva maneuver is a convenient way to test multiple aspects of the autonomic nervous system with a single maneuver. It can be done at the bedside with continuous electrocardiographic monitoring, but it is most useful if performed with continuous beat-to-beat BP, HR, and expiratory pressure. After a baseline recording has been made, the patient is asked to blow into a closed system to a level of 40 mm Hg with an open glottis for 12 seconds (**Fig. 99.3**). In phase I, the increase in expiratory pressure transmitted to the intrathoracic vessels causes a transient increase in BP. In early phase II, there is a dramatic fall in the SBP and pulse pressure because the venous return is blocked and the LV stroke volume falls. By late phase II, arterial and cardiopulmonary baroreceptors have sensed the fall in BP. Sympathetic activation produces a modest rise in BP toward baseline, and the combination of sympathetic cardiac innervation and parasympathetic withdrawal elevate the HR well above baseline. In phase III, the release of the intrathoracic pressure mechanically causes a fall in BP lasting only a few beats. In phase IV, the previously impeded venous return is restored abruptly to the chest and is pumped out by a sympathetically activated heart into a vasoconstricted circulation. The BP rises well above baseline (the overshoot), and that increase in baroreceptor stretch leads to immediate sympathetic withdrawal and parasympathetic activation, greatly slowing the HR. The simplest analysis involves dividing the highest HR during late phase II by the slowest HR in phase IV. A result of less than 1.4 suggests autonomic dysfunction; additional characteristics of the response to the Valsalva maneuver, such as the “sympathetic index” described by Novak, using the change in BP at baseline and during phase II,[8] can provide further information that helps in the diagnosis of autonomic disorders (**Fig. 99.4**). The abnormalities of the Valsalva maneuver can be specific to particular disorders, as demonstrated in this figure; this differentiation will be discussed in detail with the descriptions of the specific disorders below.

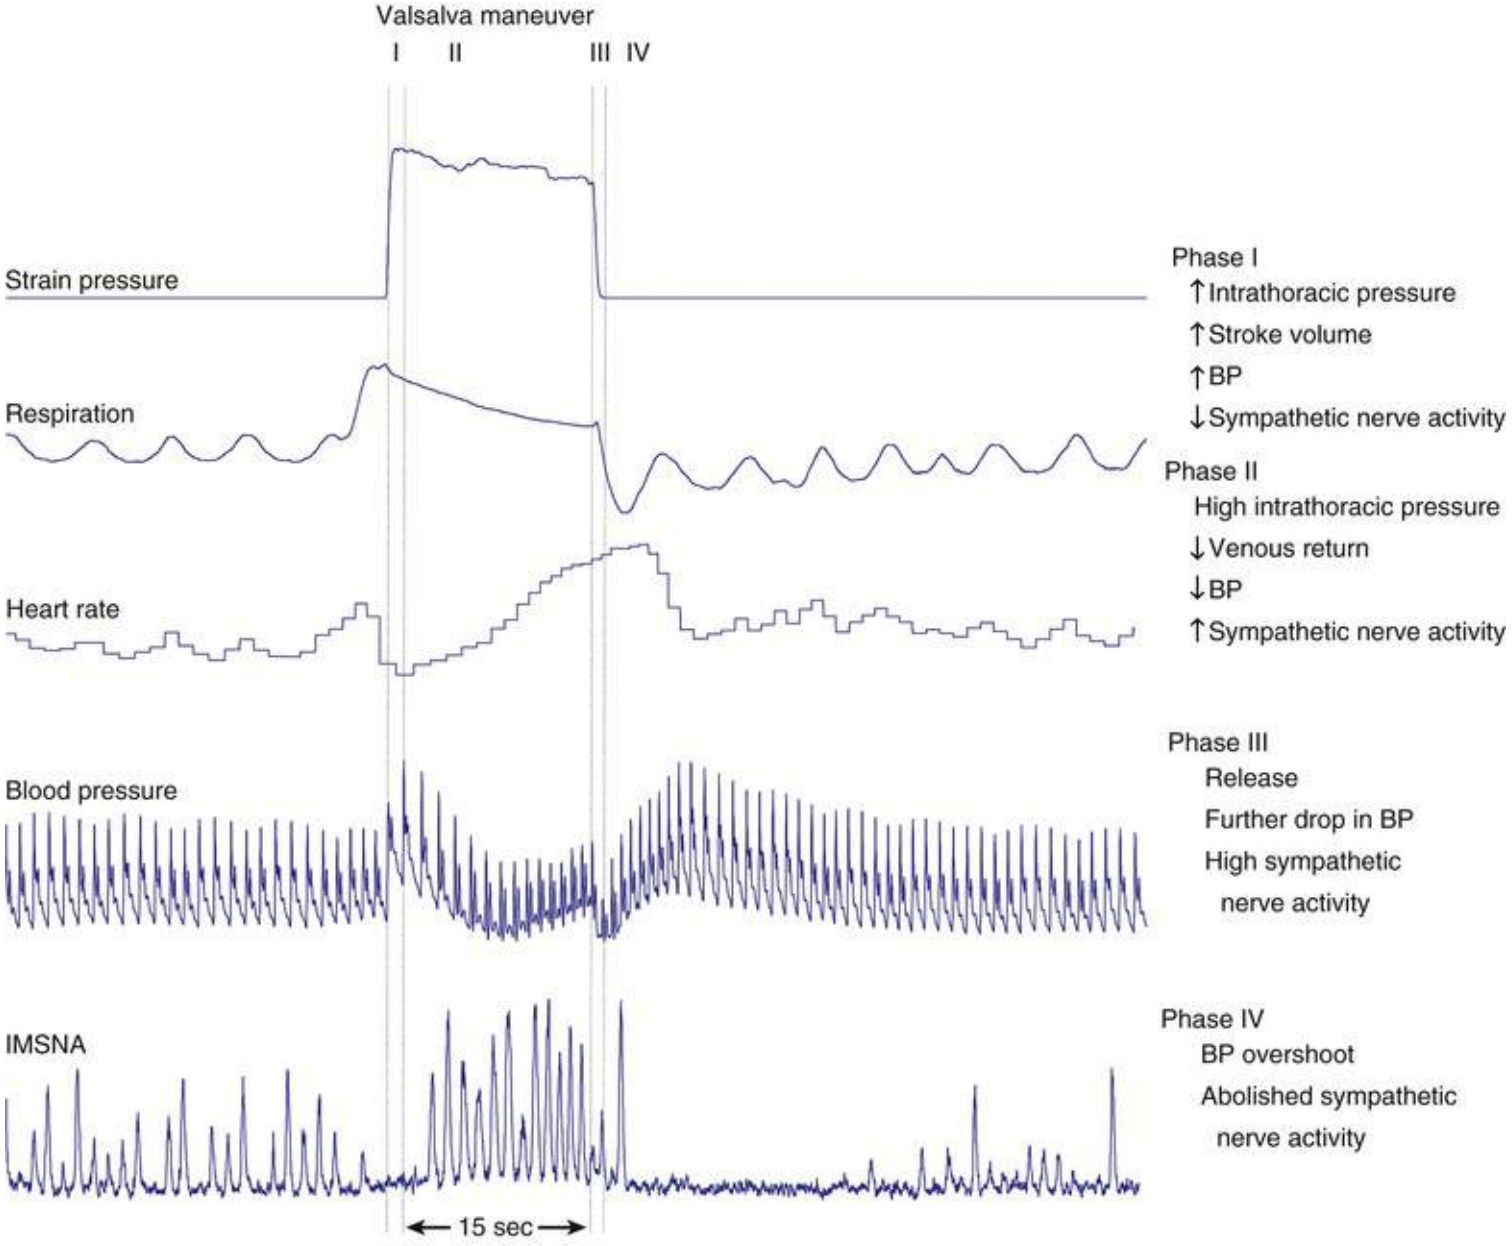

FIGURE 99.3 The Valsalva maneuver in a healthy subject. In phase I, the increase in expiratory pressure transmitted to the intrathoracic vessels causes a very transient increase in BP; in early phase II, there is a dramatic fall in SBP and pulse pressure as venous return is blocked and left ventricular stroke volume falls; by late phase II, arterial and cardiopulmonary baroreceptors have sensed the fall in BP and sympathetic activation produces a modest rise in BP toward baseline. The combination of sympathetic cardiac innervation and parasympathetic withdrawal elevate HR well above baseline. In phase III, the release of intrathoracic pressure mechanically causes a fall in BP lasting only a few beats; in phase IV, the previously impeded venous return is restored abruptly to the chest and is pumped out by a sympathetically activated heart into a vasoconstricted circulation. The BP rises well above baseline (the overshoot), and that increase in baroreceptor stretch leads to immediate sympathetic withdrawal and parasympathetic activation, greatly slowing the HR.

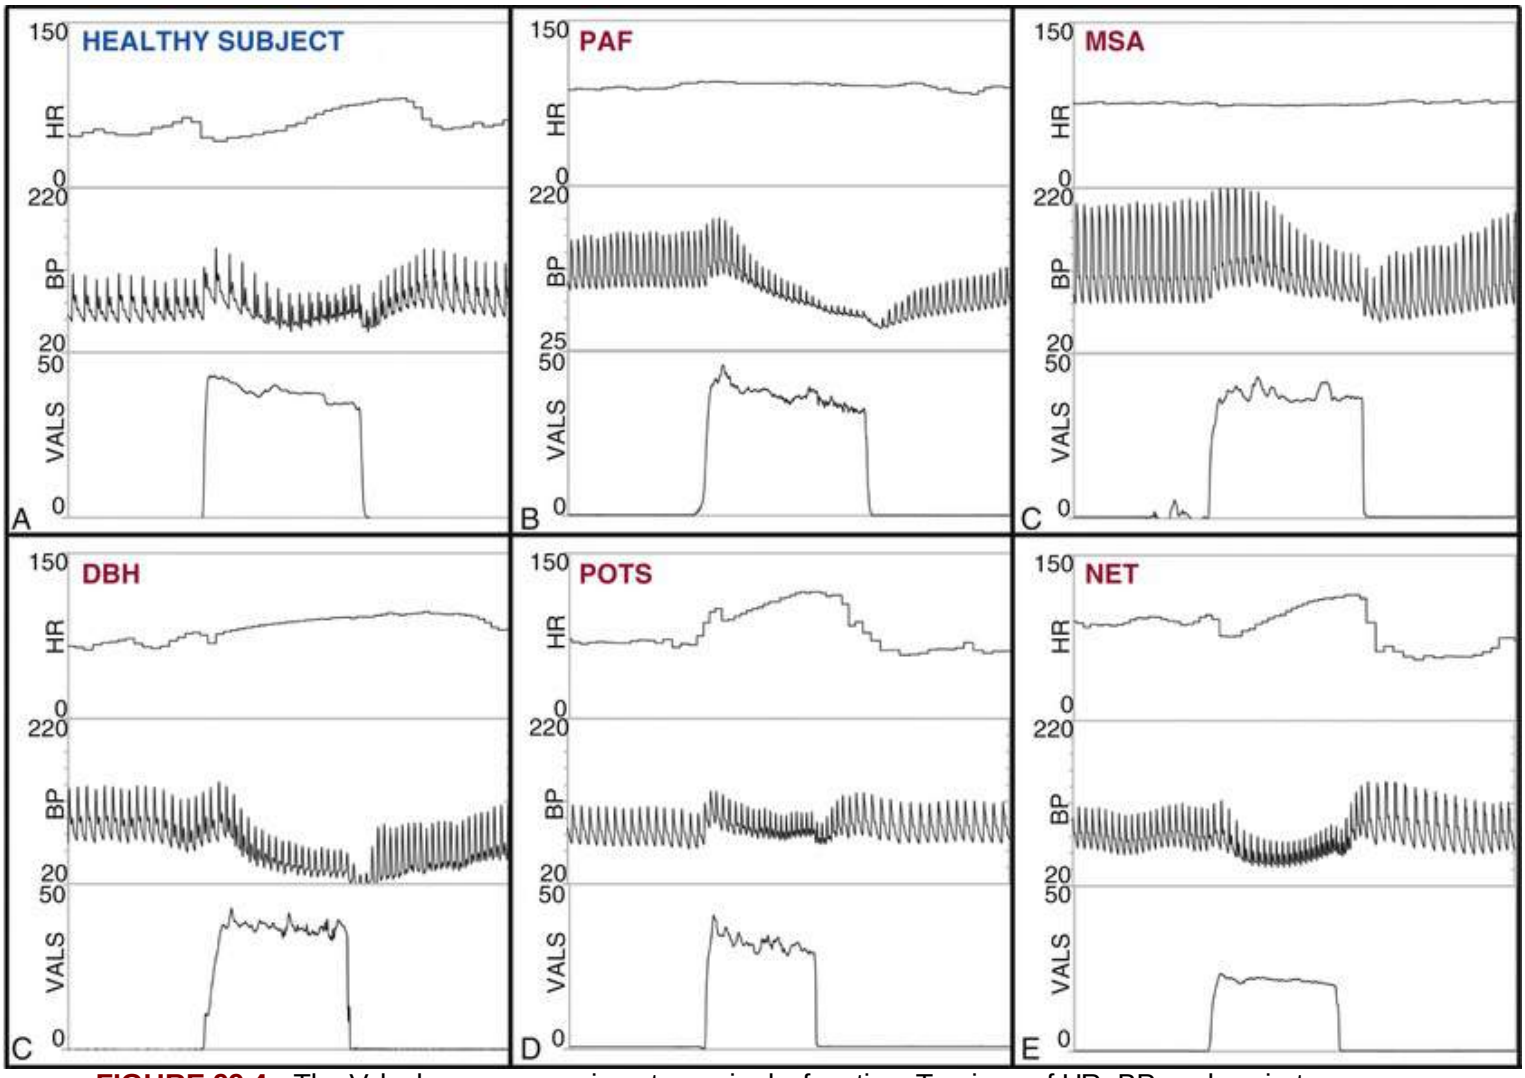

FIGURE 99.4 The Valsalva maneuver in autonomic dysfunction. Tracings of HR, BP, and expiratory pressure in **A,** a healthy subject; **B,** a patient with pure autonomic failure; **C,** a patient with multiple system atrophy; **D,** a patient with dopamine beta-hydroxylase deficiency; **E,** a patient with postural tachycardia syndrome; and **F,** a patient with norepinephrine transporter deficiency.

A further use of the Valsalva maneuver is assessment of the baroreflex sensitivity (**see Fig. 99.1**). The relationship between an increase in SBP and the resultant increase in the R-R interval can be used to define the baroreflex slope, reflecting the sensitivity of the arterial baroreflex and, particularly, its vagal component. This assessment requires the availability of beat-to-beat SBP and the R-R interval, but it can be obtained noninvasively with a continuous ECG recording and Finapres recording of the finger arterial pressure. Spontaneous changes in the SBP and HR can be used,[9] or the SBP can be raised with phenylephrine. To assess the adrenergic component of the baroreflex (the control of peripheral resistance), measurements during and after the Valsalva maneuver have related the recovery of BP to the Valsalva maneuver–induced fall in BP. This characterization of the sympathetic vasoconstrictor response has been effective in differentiating patients with autonomic failure and in documenting the reduction in adrenergic baroreflex sensitivity with age.[1] An additional approach uses a spectral analysis of the HR and BP variability to assess the sympathetic and vagal modulation of the HR and BP. Cross-spectral transfer function analysis can be used to study the interactions and define the baroreflex sensitivity.[10]

Tilt-Table Testing

Tilt-table testing in the evaluation of patients with syncope (**see also Chapter 43**) can also be used as a substitute for standing to evaluate orthostatic changes in the BP, HR, and symptoms. It provides a head-up

posture in patients who are too frail or weak to stand, or whose OH is so severe that standing long enough to obtain BP readings is not possible. Because engagement of the skeletal muscle pump of the lower extremities is not needed, results of this test are not identical to those of orthostatic testing, but it does provide a safe way to assess orthostatic tolerance. The fluid shifts seen with standing occur during this test as well, and are often accentuated by the absence of the function of the skeletal muscle pump (**Fig. 99.5**).

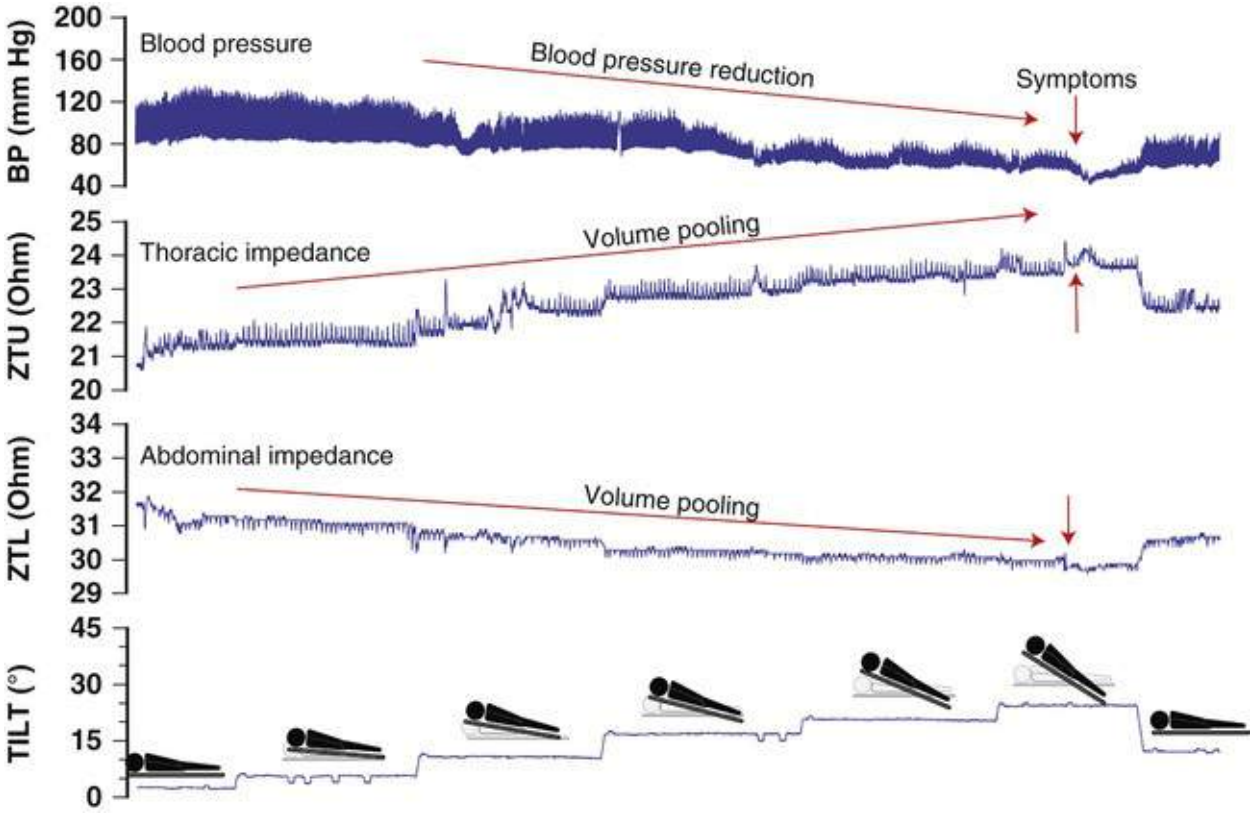

FIGURE 99.5 Impedance assessment of fluid shifts with head-up tilt. Note that with increasing head-up tilt, there is a gradual shift in fluid volume from the chest to the abdomen, reflecting pooling in the splanchnic/mesenteric circulation. Recovery of pooling begins immediately with the assumption of the supine posture. ZTL (ohm), measure of resistance inversely related to fluid volume in the bodily segment referred to.

Cold Pressor Testing

Cold pressor testing of the sympathetic neural response to a nociceptive stimulus is simple to perform at the bedside when beat-to-beat BP and continuous HR recording is available. After 3 to 5 minutes of recording with the patient at rest supine, the hand in which the BP is not being taken is immersed to the wrist in a mixture of ice and water for 1 minute and then removed, with recording continued for 3 to 5 minutes of recovery. Studies using muscle sympathetic nerve recording (**Fig. 99.6**) have demonstrated that this response is an important component of the rise in BP caused by peripheral vasoconstriction in skeletal muscle. Sympathetic outflow to the heart causes an increase in the HR that can be blocked by beta-adrenergic receptor antagonists. The cold pressor test can be used to assess autonomic function and monitor autonomic dysfunction over time.

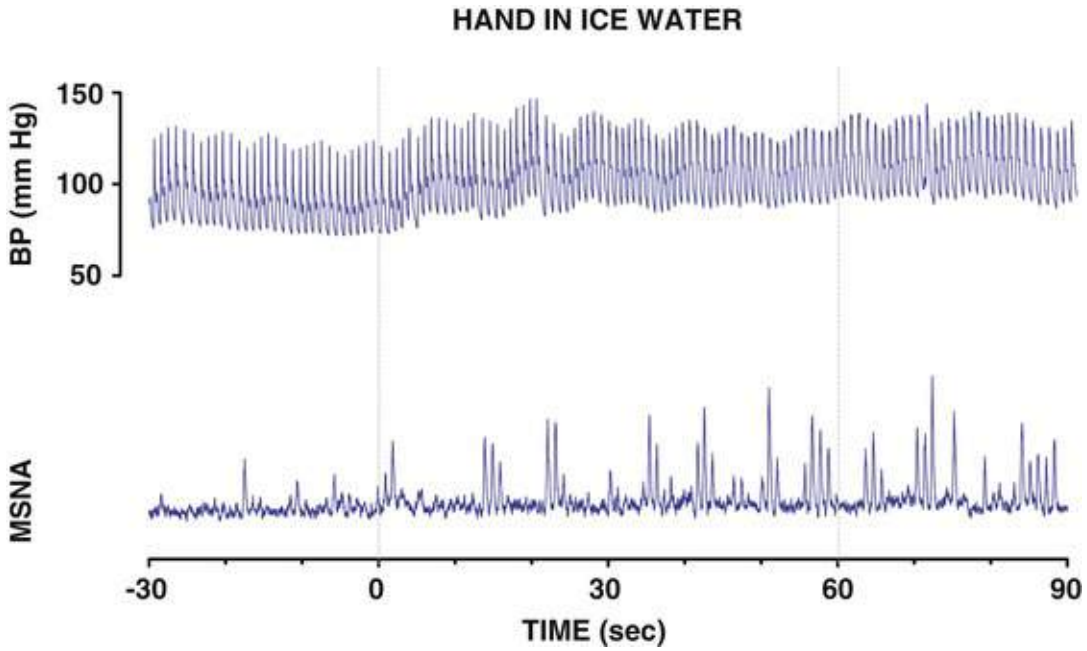

FIGURE 99.6 Cold pressor testing. Placing the hand in a mixture of ice and water for 1 minute elicits a rise in BP of 20 to 30 mm Hg (upper register). The lower register indicates the increase in muscle sympathetic nerve activity (MSNA), which elicits the BP increase.

Plasma Catecholamines

Biochemical assessment of plasma dopamine (D), epinephrine (E), and norepinephrine (NE) and their metabolites can be useful in assessing the function of the autonomic nervous system and diagnosing a number of autonomic disorders. Plasma NE is released from sympathetic nerve endings upon their activation, and most NE is taken back up into the neurons via the norepinephrine transporter (NET), with only 10% to 20% spilling over into the circulation. The plasma E reflects the E produced from NE within the adrenal medulla, with a minimal amount salvaged by the NET and coreleased with NE. Either NE or E (and rarely D) may be produced and released by pheochromocytomas, both benign and malignant, with the clinical picture of these tumors dependent on the neurotransmitter released. The finding of markedly elevated levels of NE, E, or D and an inability to suppress them with clonidine have been useful in the diagnosis of pheochromocytoma. The rare disorder of dopamine- beta-hydroxylase deficiency, a cause of profound orthostatic hypotension due to the inability to convert dopamine to norepinephrine, can easily be diagnosed by the absence of detectable NE and very high levels of D in the plasma.[11] Because effective treatment is available, accurate diagnosis is important. The plasma NE is only an indirect measure of the activity of the sympathetic nervous system (SNS), given the rapid reuptake by the neuron and metabolism by multiple pathways, but its behavior at baseline and with physiologic stimuli can be useful in diagnosis and will be discussed later with specific disorders. Given the rapid response of the SNS to stimuli such as postural changes, practical consideration requires that blood for baseline sampling of catecholamines be drawn from an indwelling catheter after 10 minutes of supine rest. If plasma catecholamines are drawn supine and after 3 minutes of standing, the norepinephrine level should approximately double in healthy individuals, from a combination of increased sympathetic neuronal release and decreased hepatic flow and thus delivery of norepinephrine to its metabolic fate. In volume depletion, after bedrest or after spaceflight, the rise in norepinephrine will generally parallel the elevated rise in the heart rate although the latter is due to a combination of increased sympathetic input to the cardiac conduction system and parasympathetic withdrawal.

Autonomic Disorders

From the perspective of the consultant, autonomic disorders, also referred to as *dysautonomias*, can generally be classified according to their BP abnormalities at presentation and results of a simple bedside evaluation of the history, physical examination, orthostatic BP, and HR. Although there are many different disorders of the ANS and they can produce lesions in many different areas, both central and peripheral, this simple workup will in many cases suggest a presumptive differential diagnosis. This usually will direct the diagnostic workup needed and provide options for management. This last can be critically important for some patients with ANS disorders, who can have marked and dangerous hypersensitivity to commonly used medications. Arriving at the correct diagnosis is important because, although these disorders are rare, some can significantly affect longevity and many seriously impair the quality of life.

It is also useful to consider the settings in which the various autonomic disorders present. Newly acquired autonomic disorders that begin abruptly can appear in hospitalized patients, and they may often prompt consultation because of new and severe hypertension or because a patient cannot be discharged because of profound OH. Patients with gradually progressive disorders over months to years may be referred for consultation in the outpatient setting, but subclinical autonomic disorders can become problematic for the first time during hospitalization for an unrelated problem, with the autonomic disorder enhanced either by that problem or by some aspect of its treatment. In the history, chronic disorders may often seem acute to the patient, especially if the first symptom they note is dramatic, such as syncope or a fall. A careful review of the history by a clinician aware of unusual features such as anosmia or an orthostatic headache relieved by recumbency or of initial presentations, such as erectile dysfunction in men, will often reveal that premonitory symptoms have been present but unrecognized.

Severe Lability of Blood Pressure– and Afferent Dysfunction

Patients with dysfunction of the afferent portion of the baroreflex arc have some of the most remarkably high BPs encountered and are often the subjects of urgent consultation. A detailed personal and family history with attention to possible causative factors can often clarify the diagnosis and greatly improve the patient's outlook.

Baroreflex Failure

The term *baroreflex failure* is sometimes mistakenly used for any disorder impairing the function of the baroreflex system and thus causing autonomic dysfunction. Currently, however, it specifically refers to a syndrome of extremely labile BP that is not buffered by normal baroreflex control mechanisms. The lack of control can be due to a number of different mechanisms that affect afferent neuronal input via injury to the vagus and glossopharyngeal nerves, or their projections to the brainstem, or via damage to the brainstem nuclei themselves or their interneurons. The damage can be caused by trauma, surgery (e.g., carotid endarterectomy, carotid body tumor resection), neoplasm (paragangliomas or other tumors), radiation injury, brainstem stroke,[12] or rare genetic disorders. Ultimately, the damage deprives the integrative central control areas of the information they need to adjust the sympathetic and parasympathetic outflow and stabilize the BP on a moment-to-moment basis. In these patients, it appears that the BP at any given time is dependent on the sum of inputs from higher brain centers to autonomic brainstem nuclei.[13] Thus, the BP tends to be low when the patient is asleep or resting in a quiet room, but to rise excessively with waking, exercising, engaging in conversation (especially if it is emotionally charged), or being exposed to pain or even simply to ambient noise. To assess the response to pain, the

cold pressor test is effective. This stimulus normally results in an elevation of 15 to 40 mm Hg in SBP, with a return to baseline over 1 to 3 minutes, but in these patients, with an absence of baroreflex buffering, SBPs of 250 mm Hg are not uncommon, and pressures as high as 320 mm Hg can sometimes be seen. In addition, the BP may remain elevated for more than 30 minutes after the stimulus is removed.

Baroreflex failure (BRF) can present in several different ways, depending on the cause. In patients with an autosomal dominant disorder causing a high incidence of carotid body, glomus jugulare, or glomus vagale tumors, which can damage the adjacent glossopharyngeal and vagal nerves, baroreflex failure may be related to the phase of disease and its surgical treatment. We have been able to study a large kindred of such patients before and after surgical procedures to remove the tumors, which in some cases cause further unavoidable damage to these nerves. The location of nerve damage in these and other patients can produce a variable presentation. Hypertensive crisis, labile hypertension, usually with concomitant tachycardia, orthostatic tachycardia, and malignant vagotonia have all been described in baroreflex failure; a patient may pass through several of these conditions, each requiring careful assessment and treatment. Recognition of the anatomy and physiology of the baroreflex and how lesions in different locations can affect BP and HR control is instructive (**Fig. 99.7**). In both selective and nonselective BRF, for example, baroreflex afferents are damaged, but in selective BRF, the efferent parasympathetic nerves are intact. Thus, in nonselective BRF, arousal produces a rise in both the BP and HR, but in selective BRF, the intact parasympathetic efferents provide some modulation of the HR during hypertensive crises via vagal withdrawal.[13]

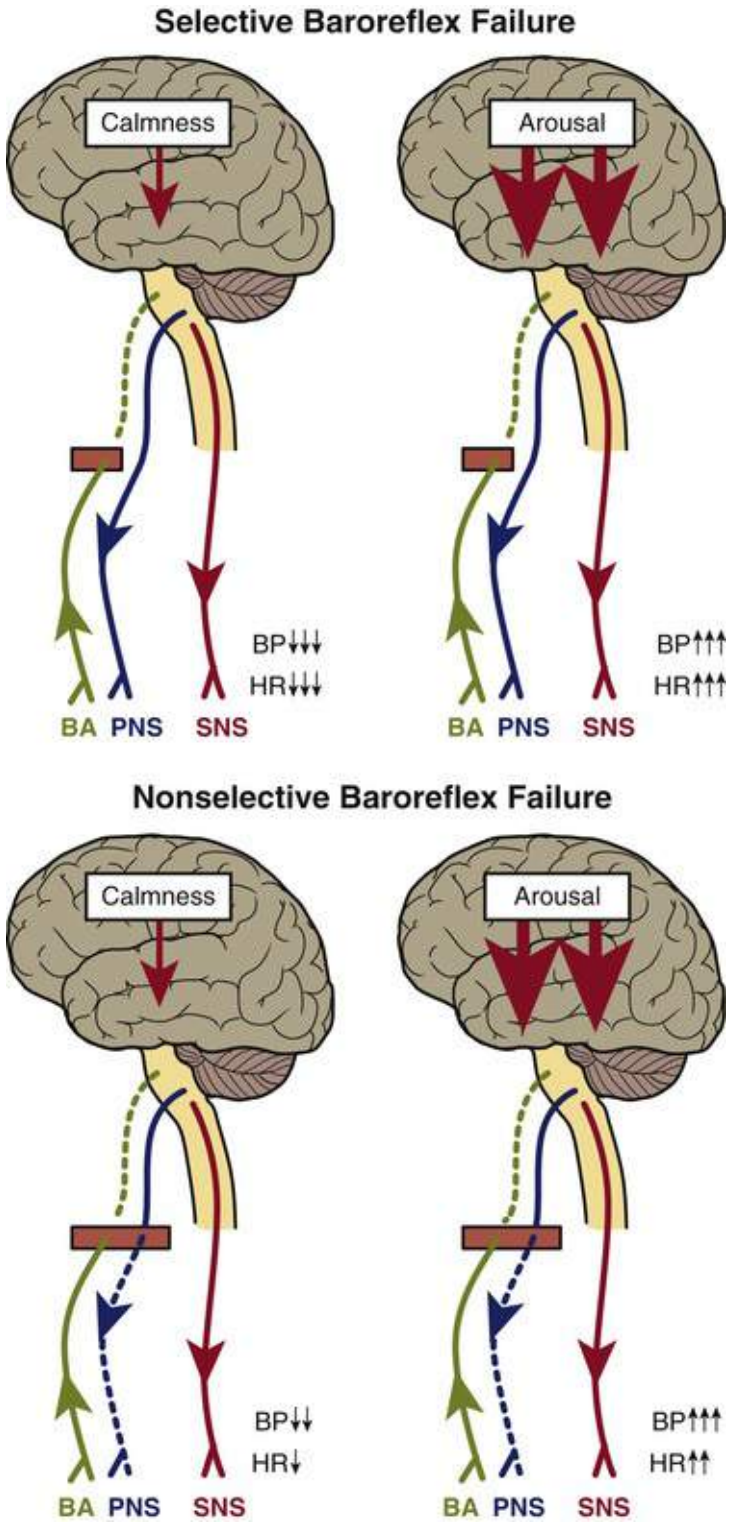

FIGURE 99.7 Selective baroreflex failure (top) contrasted with nonselective baroreflex failure (bottom). Baroreflex afferents (BAs) are damaged in both selective and nonselective baroreflex failure patients. Efferent sympathetic (SNS) and parasympathetic nerves (PNS) are intact in selective baroreflex failure. In nonselective baroreflex failure, efferent parasympathetic nerves are damaged to some degree. These differential changes lead to the differences in BP and HR seen with calm and aroused states. (From Jordan J: Baroreflex failure. In Robertson D, Biaggioni I, Burnstock G, et al (editors): Primer on the autonomic nervous system, 3rd ed. San Diego, Academic Press, 2013.)

BRF is an uncommon condition, and not every patient with labile hypertension suffers from it. Pheochromocytoma, hyperthyroidism, panic attacks, alcohol withdrawal, and 1 such as cocaine and amphetamines can all produce similar hypertensive crises. Pheochromocytoma can be eliminated in the usual manner, but for the other conditions, baroreflex testing should be done. A simple initial approach may be sufficient, because patients with have an exaggerated pressor response to both mental activation (mental arithmetic) and physiologic stimuli, such as cold pressor and isometric handgrip testing. If the

history and signs do not provide a clear diagnosis, pharmacologic baroreflex testing can be used; a rise in BP induced by phenylephrine will assess the bradycardic response, or a fall in BP induced by nitroprusside will assess the tachycardic response. Because patients with BRF exhibit marked hypersensitivity to these and other vasoactive agents, one begins with very low dosages (phenylephrine 12.5 µg; nitroprusside 0.1 µg/kg) and increases the dosage cautiously to produce an eventual change in SBP of 20 to 40 mm Hg. In BRF, the change in the HR will be less than 5 beats/min[12-14] (**Fig. 99.8**). There are other methods for noninvasively assessing the baroreflex control of the HR, for instance, cross-spectral analysis[10] or the sequence method[9] (**see Fig. 99.1**), although they have not been formally assessed in BRF.

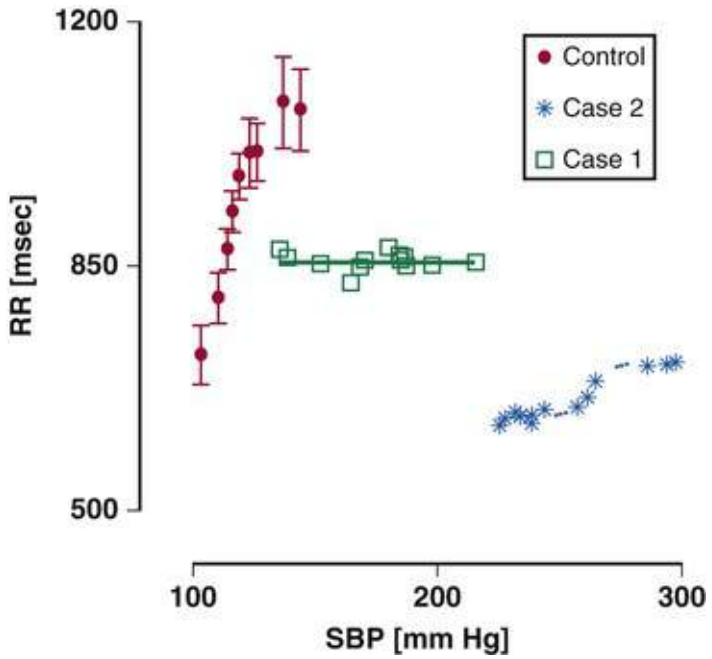

FIGURE 99.8 Pharmacologic assessment of baroreflex sensitivity. Changes in the R-R interval were plotted over changes in SBP during phenylephrine and nitroprusside application to obtain baroreflex HR curves in baroreflex failure patients and in a group of younger healthy subjects. The physiologic baroreflex response is virtually abolished in both baroreflex failure patients. (From Heusser K, Tank J, Luft FC, Jordan J: Baroreflex failure. Hypertension 2005;45(5):834-9.)

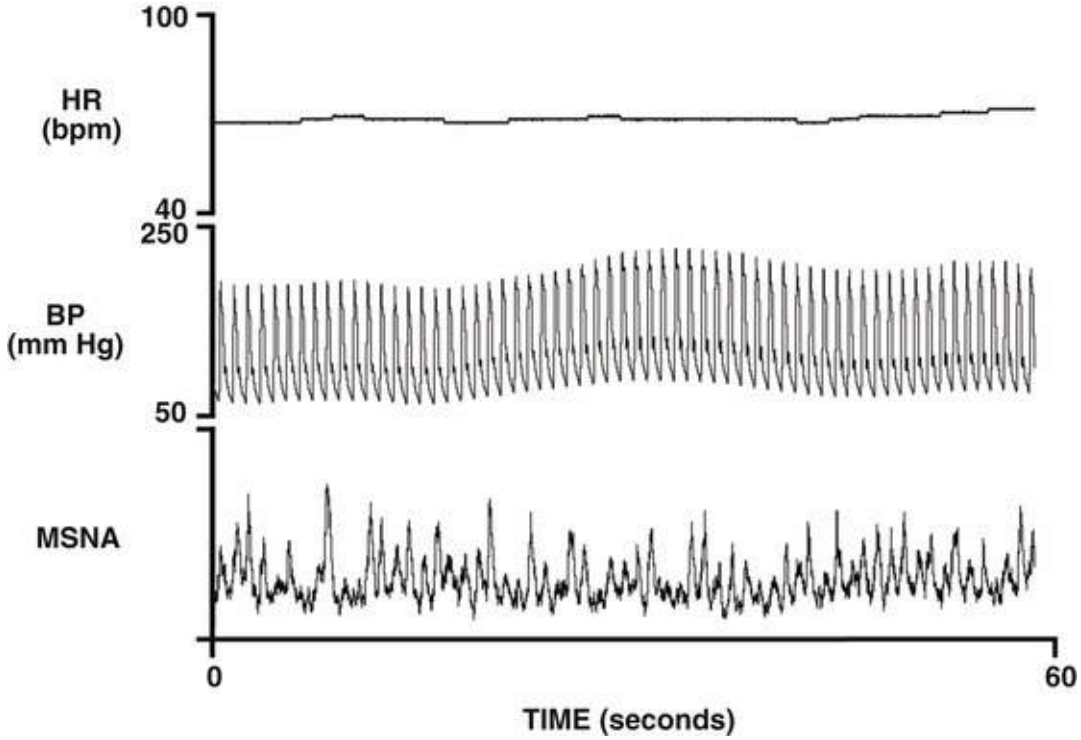
In addition to pharmacologic testing of BR function, plasma catecholamines can also be useful, with dramatic surges of NE to more than 2500 pg/mL seen during hypertensive crises. The ability of clonidine to reduce both the BP and the norepinephrine levels in BRF can differentiate it from pheochromocytoma.

eFig. 99.1 shows a pressor response of 40 mm Hg to phenylephrine 50 µg in a patient with BRF, with no change in HR. Normal subjects would demonstrate a decrease in the HR of 7 to 20 beats/min and a rise in BP of 20 mm Hg.



EFIGURE 99.1 Response to phenylephrine in a patient with baroreflex failure. Note that BP rises in response to the intravenous bolus of phenylephrine, a peripheral vasoconstrictor. Normally, both the HR and muscle sympathetic nerve activity (MSNA) would be reduced by the baroreceptor-mediated increase in parasympathetic activity, but neither change in this patient.

Treatment of patients with BRF is often difficult. It is critical to be certain that patients and any health care providers they encounter know that stimuli and drugs that have a minor effect or no effect on normal persons or other patients may provoke dramatic elevations of BP in baroreflex failure patients. This is especially true of medications that affect vascular tone or sympathetic activity, some of which are available without a prescription. Clonidine, which is available orally or by patch, is helpful in avoiding hypertensive crises, and other centrally acting sympatholytic agents may be helpful as well. **Table 99.1** lists therapeutic options for these patients when they are in a phase with malignant vagotonia.

TABLE 99.1

Indications for Unique Treatment Strategies in Patients with Selective Baroreflex Failure and Malignant Vagotonia

INDICATION	INTERVENTION
Bradycardia, asystole	Cardiac pacemaker
Hypotension	Fludrocortisone/high-salt diet
Tachycardia/hypertension	Guanadrel

Glossopharyngeal Neuralgia

Glossopharyngeal neuralgia results when the glossopharyngeal nerve is traumatized in the area of the carotid sinus, for example, by accident, neoplasm, surgery (either incidental or to remove a neoplasm), or radiation, causing intermittent spontaneous activation of the nerve. The patient experiences sudden, severe, lancinating pain in the neck, face, or jaw on the affected side, and the BP and HR fall suddenly and profoundly. It is often these episodes of sudden hypotension in the surgical intensive care unit that prompt a consultation, with the focus drawn to the hemodynamic instability. The consulting cardiologist may be the first to ask the patient whether pain preceded the events. This critical historical finding strongly suggests the diagnosis, which can be confirmed by simultaneous monitoring of the BP and HR. In

most patients, the episodes are self-limited and resolve as healing proceeds, but in some patients the sudden drops in BP and HR may prevent safe ambulation or even the upright posture. In these cases, yohimbine may improve the situation more rapidly, and can be tapered after recovery. If pain and hemodynamic instability persist, however, transection of the nerve may be necessary.

Carotid Sinus Hypersensitivity

Carotid sinus hypersensitivity is an increased or exaggerated response to stimulation of the arterial baroreceptors in the carotid sinus, producing more than the usual reduction in HR and BP seen with carotid massage (**see also Chapter 43**). To meet current criteria, carotid massage in the supine position must produce asystole lasting more than 3 seconds (a "cardioinhibitory response") or a reduction in SBP greater than 50 mm Hg independent of HR slowing (a "vasodepressor response"), or a combination of the two. Alternatively, carotid massage can be performed both supine and at 60 degrees of head-up tilt as well, with more positive results seen during head-up tilt. Carotid sinus hypersensitivity is seen more frequently in males than females, and it is rarely seen in individuals younger than 50 years old, despite the fact that baroreflex sensitivity generally is reduced with age.[15] It appears to be more frequent in patients with unexplained syncope, which suggests it may contribute to those episodes. If other investigations fail to uncover a potential cause of syncope, carotid sinus hypersensitivity should be considered and the patient evaluated, with care taken regarding contraindications to carotid massage and appropriate technique, including monitoring.

An alternate view of the previous criteria and diagnostic approaches has recently been presented,[16] with the suggestion that the current distinction of carotid sinus hypersensitivity and carotid sinus syncope into a cardioinhibitory, vasodepressor, or mixed response should be discarded. The investigators believe that the isolated cardioinhibitory variety does not occur in the absence of a fall in BP, and that carotid sinus hypersensitivity should be conceived of as always or usually being mixed to some degree, and thus described as a "predominant cardioinhibitory" or "predominant vasodepressor" response. In addition, they suggest that stricter criteria (i.e., > 6 seconds of asystole and a fall in BP of > 75 mm Hg, or a fall in SBP to ≤ 80 mm Hg with the patient supine, or if this maneuver is negative, with the patient standing and carotid sinus massage) would be more consistent with observed data. Therapeutic options including atrioventricular pacing can be considered.

Chronic Autonomic Disorders with Orthostatic Hypotension

When asked to evaluate patients with OH for the possibility of an autonomic disorder, it is useful to first consider and eliminate situations and conditions that can produce OH even in patients without autonomic disorders. Several of them are commonly seen in the emergency department or inpatient setting and are mentioned earlier in discussions of orthostatic BP and HR testing. Whether the OH is caused by an autonomic disorder, such as one of the disorders described later, or a condition other than an autonomic disorder, the physician should recognize that OH in middle-aged individuals carries some population risk for the future.[21] In patients with the chronic autonomic disorders with OH described later, a careful personal and family history, physical examination, and bedside testing will often allow a presumptive diagnosis. Typical HR and BP responses to the Valsalva maneuver for these disorders, as well as for the postural tachycardia syndrome (POTS) and NET deficiency, are seen in **Fig. 99.4**. Although some patients with OH have more complex syndromes, with multiple types of ANS damage, for many patients the features described in **Table 99.2** can help differentiate baroreflex failure from OH.

TABLE 99.2

Distinction Between Baroreflex Failure and Autonomic Failure with Orthostatic Hypotension

	BAROREFLEX FAILURE	AUTONOMIC FAILURE WITH ORTHOSTATIC HYPOTENSION
Labile hypertension	+++	+/-
Orthostatic hypotension	+/-	+++
Orthostatic hypertension	++	—
Supine hypertension	+/-	++
Postprandial hypotension	+/-	++
Episodic tachycardia	++	—
Bradycardic episodes	++*	+/-
Hypersensitivity to vasoactive drugs	+++	+++

*Bradycardia associated with hypotension is a typical feature of malignant vagotonia due to selective baroreflex failure.

Congenital Disorders of Autonomic Function with Symptoms Present From Birth

A number of genetic disorders have been described in patients with abnormalities of autonomic function. An extensive review is available.[17] Continued progress should also be expected.

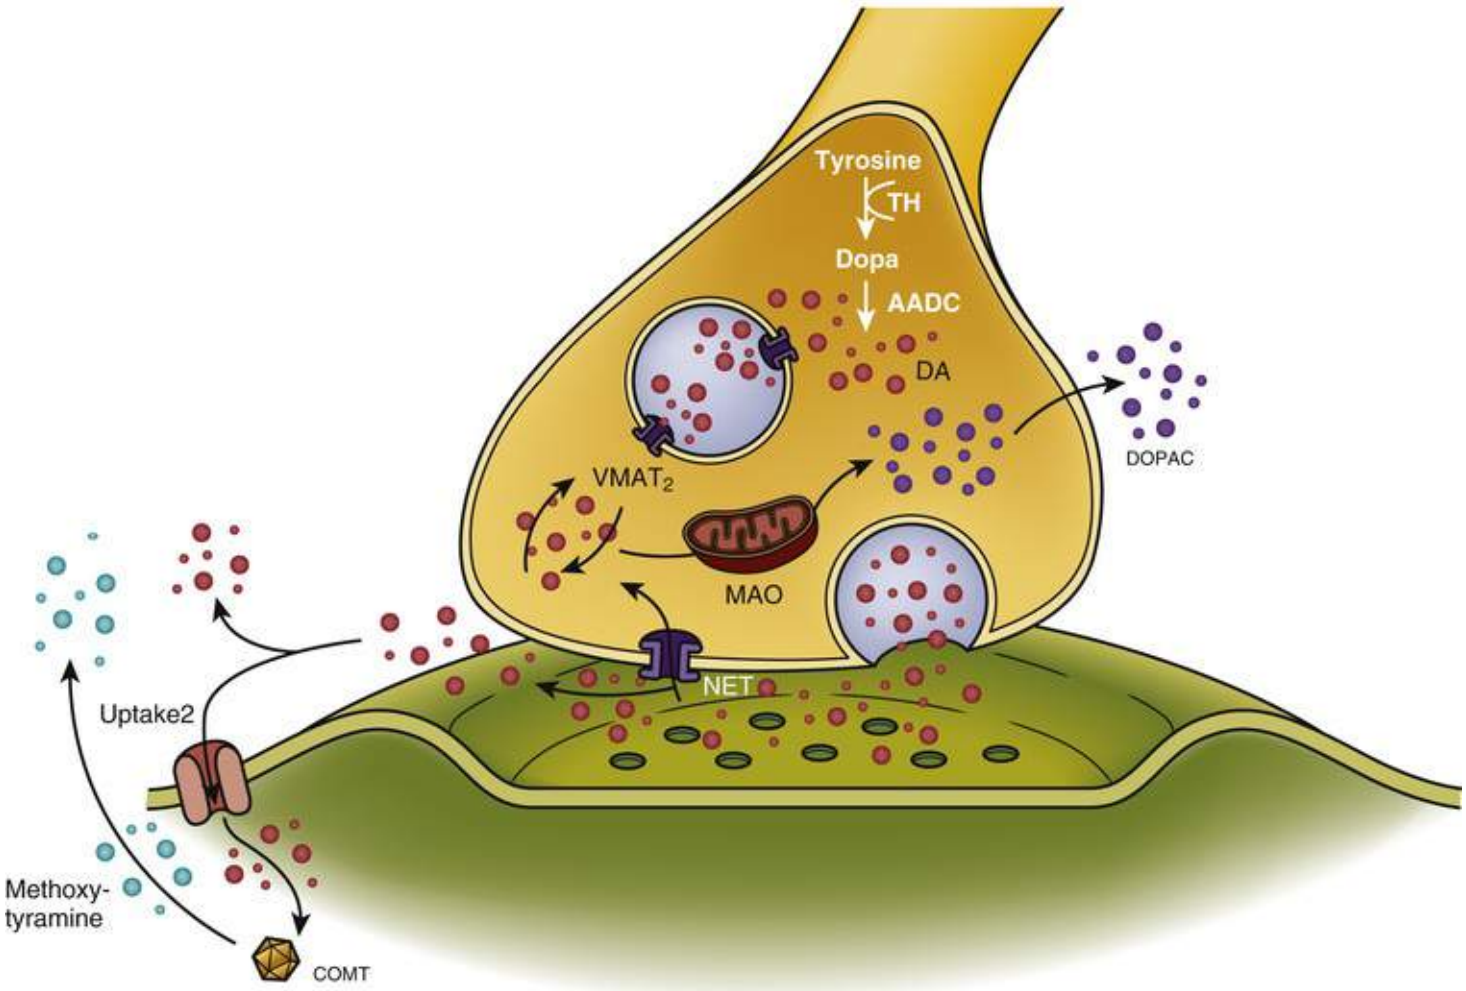
Dopamine Beta-hydroxylase Deficiency

Dopamine beta-hydroxylase deficiency, a rare congenital syndrome, was recognized in Nashville and in Rotterdam, when the evaluation of several adult patients with severe OH revealed remarkable abnormalities of their plasma catecholamines.[11] Norepinephrine levels were below the lower limits of detection at that time, epinephrine levels were likewise impaired, and dopamine levels were elevated to measurements not previously seen. With further testing, norepinephrine and epinephrine were confirmed to be absent not only in blood but also in urine and cerebrospinal fluid. Despite the absence of norepinephrine in the brain, patients given a battery of cognitive tests had no substantial deficits and appeared to have normal intelligence.[18]

Physical findings in these patients included severe OH that had produced lifelong habits of compensatory posture. All patients avoided standing for any length of time and chose occupations that could be done seated. Some patients also were in the habit of folding their legs beneath them when sitting in a chair, and would stand (which was often possible for only a few seconds) with a camptocormic posture (severe anterior flexion of the spine) to reduce the elevation of the head above the heart and with legs twisted and the skeletal muscle pump engaged to reduce pooling. They also demonstrated ptosis of the eyelids, intact sweating, anemia, and retrograde ejaculation in males.

The dramatic plasma catecholamine levels in these patients directed attention to dopamine beta-hydroxylase, the enzyme that converts dopamine to norepinephrine within the sympathetic neuron. The site of the genetic defect that produces the absence of functional dopamine beta-hydroxylase was ultimately determined to be 9q34. Without norepinephrine-mediated negative feedback of tyrosine hydroxylase and with no conversion of dopamine to norepinephrine, increased levels of dopamine are seen, and dopamine responds to physiologic and pharmacologic stimuli in the same manner as norepinephrine would in a normal subject. **eFig. 99.2** is a diagram of the noradrenergic neuron synapse in dopamine beta-hydroxylase deficiency. Measurement of norepinephrine and dopamine levels and their metabolites, DHPG and DHPAA, should be diagnostic. Norepinephrine levels will be less than 25 pg/mL, and dopamine levels are frequently more than 100 pg/mL. An even more definitive measure is the ratio of DHPAA to DHPG, which will be at least over 100 and can be over 1000. In normal healthy persons, the ratio is less than 5. Even in the absence of these data, physiologic testing can be quite helpful. The lack of

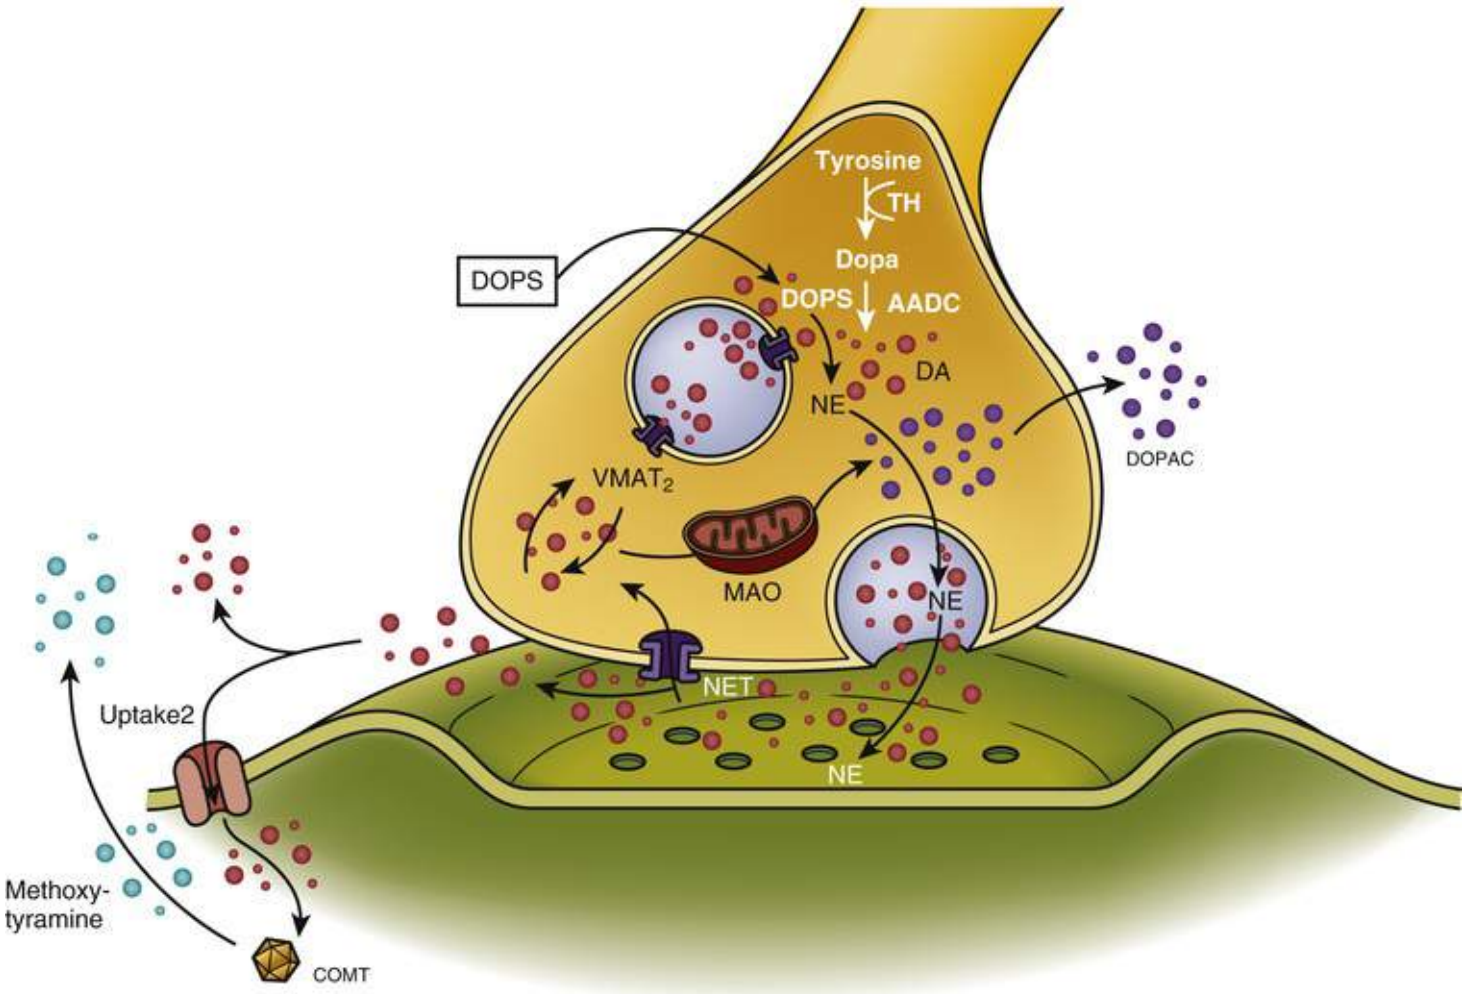
norepinephrine produces an absence of sympathetic noradrenergic function and adrenomedullary function, but the vagal and sympathetic cholinergic function is intact. With the Valsalva maneuver, this leads to exaggerated hypotension with no compensatory vasoconstriction during phase II, but a normal increase in HR. **Fig. 99.4D** shows a typical Valsalva maneuver in dopamine beta-hydroxylase deficiency. In testing the orthostatic BP and HR, the absence of sympathetic noradrenergic function leads to a lower BP at baseline and even more prominently disables the baroreflex's ability to support the BP with sympathetic vasoconstriction while one is standing or even seated.



EFIGURE 99.2 Diagrammatic representation of a noradrenergic synapse in a patient with dopamine beta-hydroxylase deficiency. Because of a mutation at 9q34 in the gene that produces the deficiency, patients with this disorder are unable to convert dopamine (DA) into norepinephrine (NE). Because the remainder of the biosynthetic pathway is intact and there is no norepinephrine-mediated negative feedback of tyrosine hydroxylase (TH), more dopamine is produced than usual, and it replaces norepinephrine as the neurotransmitter released with physiologic and pharmacologic stimuli. However, it produces little vasoconstriction and some diuresis, making these patients significantly affected by OH. *AADC*, aromatic amino acid decarboxylase; *COMT*, catechol-o-methyl transferase; *Dopa*, dihydroxyphenylalanine; *DOPAC*, 3,4-dihydroxyphenylacetic acid; *MAO*, monoamine oxidase; *NET*, norepinephrine transporter; *$VMAT_2$*, vesicular monoamine transporter 2.

Fortunately, L-threo-3,4-dihydroxyphenylserine (droxidopa [DOPS]), a synthetic precursor to norepinephrine that can be given orally, is taken up into the sympathetic neuron and converted to norepinephrine, and it can restore norepinephrine to within the normal range when given at 100 to 600 mg orally three times a day.[11] **eFig. 99.3** is a diagram of the noradrenergic neuron synapse in dopamine beta-

hydroxylase deficiency while a patient is receiving treatment with droxidopa. Droxidopa, unlike norepinephrine, can cross the blood-brain barrier. Restoration of the BP is excellent, orthostasis can be restored, and the quality of life is substantially improved. Truly long-term data are not yet available, but it is known that patients who begin replacement therapy early in life may not only have a greatly improved quality of life but also an increased level of health and longevity.



EFIGURE 99.3 Diagrammatic representation of a noradrenergic synapse in a patient with dopamine beta-hydroxylase deficiency who is being treated with L-threo-3,4-dihydroxyphenylserine (DOPS or droxidopa). Fortunately, DOPS can be taken orally and transported into the neuron, where it can be converted to norepinephrine by AADC (aromatic amino acid decarboxylase). Norepinephrine can then be packaged into vesicles and used as usual.

Familial Dysautonomia (Riley-Day Syndrome)

Familial dysautonomia, a rare congenital syndrome, is due to mutations in the gene encoding the I-K-B kinase complex–associated protein (IKAP), primarily in patients of Ashkenazi Jewish heritage, and the diagnosis is confirmed by genetic testing.[17] The largely conserved gene product is present in all eukaryotic cells, and its complete absence is fatal. However, a common mutation causing familial dysautonomia causes a splicing error that is expressed variably, so that some cells have functional IKAP and others, such as neurons in the central nervous system, have mostly mutant mRNA and produce little if any functional protein. In the past, most patients died in childhood; today, with improved supportive care (much of which was developed and applied at New York University's Medical Center's Familial

Dysautonomia Center by Dr. Felicia Axelrod and her colleagues[17,19,20] and at the Israeli Familial Dysautonomia Center at Tel Hashomer Sheba Hospital in Tel Aviv), patients may live into adulthood.

Patients may be seen because they are having “dysautonomic crises,” with prolonged retching and vomiting, hypertension with SBP over 250 mm Hg, tachycardia, and a blotchy appearance of the skin. Even in the absence of this constellation, they can demonstrate baroreflex failure, with hypertensive episodes that may require the combined use of a benzodiazepine and clonidine. Episodic hypotensive episodes and/or OH can sometimes be improved with fludrocortisone and midodrine prior to prolonged standing. The history can reveal episodic hyperhidrosis, absence of tears, insensitivity to pain and temperature, nausea, difficulty swallowing with aspiration, mild cognitive impairment, scoliosis, bone fractures, and an impaired ventilatory drive. The last issue can be sufficiently problematic that during high-altitude plane flights, positive-pressure ventilation should be available. The syndrome overall remains difficult to treat,[19] and patients will benefit from consultation with one of the centers mentioned above.

Autonomic Symptoms Beginning Later in Life

The Synucleinopathies[22]

In recent years, some common histopathologic features have been recognized in a number of progressive, neurodegenerative autonomic disorders, including pure autonomic failure (PAF), Parkinson disease, multiple system atrophy (MSA), and dementia with Lewy bodies, as well as in several neurodegenerative disorders without autonomic features, such as Alzheimer disease and neurodegeneration with brain iron accumulation type I.[23,24] In these disorders, the intracellular accumulation of α-synuclein aggregates, suggesting that abnormal protein deposition in the cytoplasm of both glial cells and neurons is involved in the development of the central and/or peripheral neurodegenerative disease. Subsequently, it has become clear that some patients with autonomic dysfunction also have abnormal aggregates of tau protein, previously thought to only be characteristic of some forms of dementia; the disorders are referred to as *tauopathies*. Both tau and α-synuclein are abnormal, partially unfolded proteins, and there is evidence that they can form toxic oligomers and promote each other's fibrillization and solubility. In some cases, both α-synuclein aggregates and tau inclusions are seen; this suggests that there may be an interaction or some common mechanism(s) linking them; the precise mechanisms and even conclusive theories remain elusive.[23] In this section, we will describe and differentiate the chronic autonomic disorders in which OH is a major clinical feature.

Pure Autonomic Failure.

Pure autonomic failure (PAF) is a neurodegenerative disorder appearing in middle age, with slowly progressive OH as its primary symptom.[25] First described by Bradbury and Eggleston in 1925, it generally does not shorten the lifespan, and some patients have survived into their 90s, though they can succumb to complications such as sepsis due to urinary tract infections.

Patients with PAF have been thought to differ from those with the other synucleinopathies in that they do not develop symptoms or signs of central nervous system dysfunction and can maintain good functional abilities with treatment. However, there are occasional reports of patients followed with a presumptive diagnosis of PAF who later developed central cerebral lesions; this fortunately appears to be rare. It is important, however, for patients and their families to know whether to expect progression to any of the other OH disorders described later. Directing them to report any new symptoms is essential to

maintaining an accurate prognosis. Hoarseness is often an early sign of multiple system atrophy (MSA), and sleep apnea and disturbances of REM sleep are more commonly seen in patients with MSA or Parkinson disease than PAF. We will here discuss patients with PAF limited to the periphery, because most patients fall into that category.

In these patients, the documented pathology includes a loss of cells in the intermediolateral column of the spinal cord and reduced catecholamine uptake and catecholamine fluorescence in sympathetic postganglionic neurons. In addition to gradually worsening OH as the primary symptom, patients often complain of erectile dysfunction, orthostatic neck pain or headache relieved by sitting or lying, and supine hypertension. They have extremely low levels of plasma norepinephrine when supine, in contrast to patients with MSA, whose supine norepinephrine levels are often near normal. In addition, in PAF, the plasma norepinephrine rises only minimally with standing, and despite marked OH, these patients have little chronotropic response to standing or to the Valsalva maneuver. **Fig. 99.4B** shows the appearance of the Valsalva maneuver in a patient with PAF, with a marked drop in BP during phase II, no vasoconstrictor rise in BP in late phase II, and no overshoot in phase IV. In addition, there is no cardioexcitatory rise in HR during phase II, despite the profound drop in BP. Plasma vasopressin responds normally to hypotension in PAF, but not in MSA.[26]

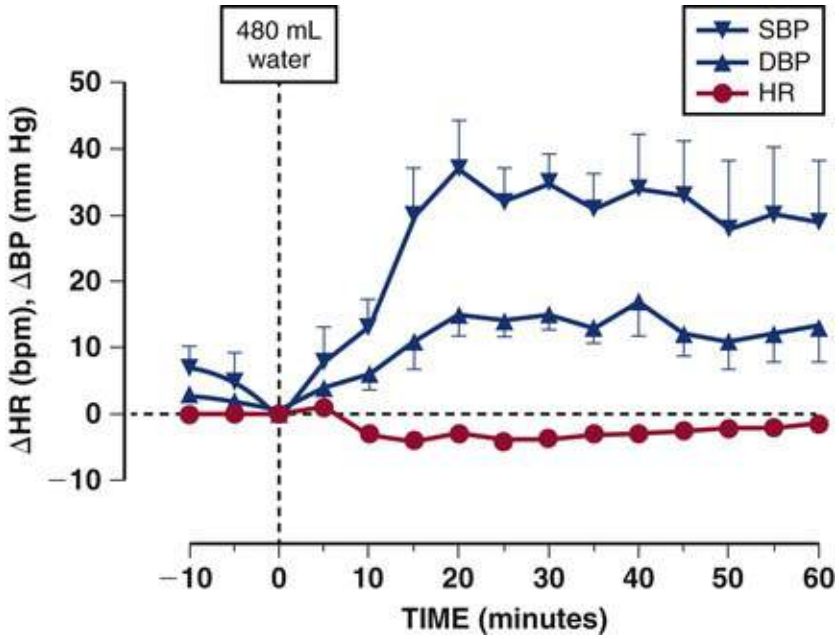
As PAF progresses over a long lifespan, the OH worsens, and there continues to be an inadequate chronotropic response, but the BP can often be managed well enough using the modalities below to allow most normal daily activities.[26,27] The cognitive function does not decline, and patients often become quite adept at their own management.

In patients with PAF, helpful interventions include raising the head of the bed by 30 degrees to reduce both supine hypertension,[27,28] which is commonly seen in PAF, and the nocturnal solute/water diuresis seen with autonomic failure; wearing compression stockings to reduce pooling; and liberalization of fluid and salt intake. The important effects of food and water (**eFig. 99.4**) on the BP can be incorporated to assist with maintaining the orthostatic BP and reducing the supine hypertension (**Table 99.3**).

TABLE 99.3

Factors Altering Blood Pressure in Patients with Autonomic Dysfunction

FACTOR	RAISES BLOOD PRESSURE	LOWERS BLOOD PRESSURE
Intake	Water drinking	Food ingestion
Volume	Hypervolemia	Hypovolemia
Ventilation	Hypoventilation	Hyperventilation
Environment	Cold	Heat
Medications	Sympathomimetics	Vasodilators
Other	—	Infection (even subclinical)



EFIGURE 99.4 The effect on systolic and diastolic BP (SBP and DBP) and on heart rate (HR) of drinking 480 mL of water in patients with pure autonomic failure. Patients were seated comfortably and began drinking tap water at 0 time. SBP and DBP both began to rise by 5 minutes after drinking, and remained elevated for more than 60 minutes. On separate occasions, the patient's upright BP and/or standing time was improved by this intervention. Healthy young persons did not demonstrate an elevation of BP after water drinking, but healthy elderly persons showed a rise in SBP of 11 mm Hg.

Medications may also be helpful and are often required. Midodrine acts as an α-agonist after its conversion to desglymidodrine, and droxidopa is converted to norepinephrine. Because these drugs produce vasoconstriction, they will worsen supine hypertension. Patients should usually be instructed to take their first dose 20 to 30 minutes prior to arising in the morning, and to adjust the timing of their remaining doses to support their ability to stand throughout the day, while allowing time for the drug's effect to wear off before they lie down at night. Frequent assessment of orthostatic BPs at home throughout the day followed by discussion with the health care provider and adjustments of dose and timing is often required over the initial weeks at home after a hospitalization. Fludrocortisone is also commonly used in the treatment of OH, both for its effect on the retention of sodium and water, which is relatively transient, and because its use is also accompanied by an increase in peripheral resistance. A missing area of management has been a method for treating one important mechanism for OH, the failure of sympathetic vasoconstriction of capacitance beds in the splanchnic circulation. This has recently been addressed by the development of a servocontrolled inflatable abdominal binder, which has been shown to be as effective as midodrine in terms of protecting the standing BP, but it can also be deflated by the patient when seated or supine, thus avoiding a deleterious effect on supine hypertension. In addition, for patients with severe OH, its combination with midodrine is greater than additive[6] (**Fig. 99.9**).

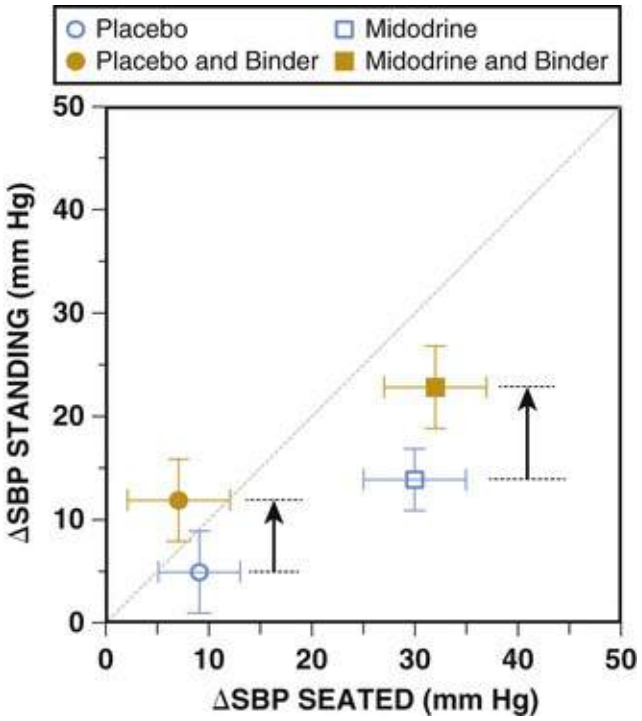


FIGURE 99.9 Effect of a servocontrolled abdominal binder and midodrine on OH. Changes from baseline in seated SBP and standing (1 minute) SBP 1 hour after placebo or midodrine. The *unfilled circle* and *square* indicate the mean change plus SEM for 19 patients with autonomic failure after the administration of placebo or midodrine. The *filled circle* and *square* indicate the same results after these agents plus the inflation of a servocontrolled abdominal binder. Standing SBP is not significantly improved by placebo. In contrast, the *orange circle* indicates the increase in BP with placebo and binder inflation. When the α_1-agonist midodrine alone is introduced, an increase in SBP is seen while seated, and the increase in SBP with the binder is greater than with placebo, suggesting more than an additive effect.

Finally, it is important to note that denervation hypersensitivity can cause dangerous elevations of BP in patients if they are given alpha agonists. For example, norepinephrine infusion markedly increases the BP in PAF patients, and even over-the-counter sympathomimetic agents can be dangerous. Patients undergoing surgery should be certain that their anesthesiologist is knowledgeable about this characteristic response.

Multiple System Atrophy.

Multiple system atrophy (MSA) is a rare, progressive, fatal neurodegenerative disease that generally presents in the 50s, with autonomic failure and complexes of other symptoms. Autonomic failure and the other symptoms do not always present in the same order, and the nonautonomic features can resemble parkinsonism or cerebellar ataxia. The initial diagnosis is therefore often one or the other of these conditions until symptoms appear that are related to OH and thus suggestive of MSA. Whether patients are thought to have Parkinson disease or olivopontocerebellar atrophy (OPCA) depends on the location of the neuropathologic lesions. The lesions consist of neuronal loss or atrophy in several of the following areas: the basal ganglia, cerebellum, pons, inferior olivary nuclei, or intermediolateral column and Onuf's nucleus of the spinal cord. In addition to neuronal loss, the critical neuropathologic feature of MSA is the presence of glial cytoplasmic inclusions in both the oligodendroglia and the neurons.[29,30,31] These structures contain a misfolded, hyperphosphorylated protein, fibrillar α-synuclein, which is also seen in the Lewy bodies of Parkinson disease or dementia with Lewy bodies. However, in MSA the primary problem in the relevant brain regions appears to involve the oligodendroglia, and it has been felt that the α-synucleinopathy there could lead to neurodegeneration. However, studies by Cykowski et al. found that in addition to the glial inclusions, neuronal inclusions in relevant areas are present; this may be important

in the pathology of MSA.[32] Recent studies have shown that α-synuclein can migrate or be transported from one cell to another or from human MSA brain homogenates to mouse cells in culture.[33] It has been suggested that this transmissibility could account for the progression of MSA, and has led some[34] to consider that MSA is due to "the accumulation of toxic α-synuclein prions in the brain."

During history taking, patients are likely to complain of the following symptoms appearing for the first time after the age of 30: light-headedness with upright posture; headache while upright, relieved by lying down; parkinsonian features such as tremor, rigidity, and progressive difficulty with ambulation, poorly responsive to treatment with levodopa; and urinary incontinence and erectile dysfunction in males. Patients with features more like those of OPCA may have, in addition to orthostatic symptoms, a cerebellar syndrome with dysarthria, limb ataxia, or oculomotor dysfunction.

By the time orthostatic symptoms occur, one will generally find an orthostatic decrease in SBP of 30 mm Hg or less within 3 minutes of standing, parkinsonism that is poorly responsive to levodopa, or cerebellar abnormalities. **Fig. 99.4C** shows a typical response of HR and BP to the Valsalva maneuver in a patient with MSA. Note the high resting BP and the absence of HR response to marked changes in BP. Additional features strongly supporting MSA, especially later in the course, include orofacial dystonia, disproportionate antecollis (anterior flexion of the neck), camptocormia (severe anterior flexion of the spine), contractures of hands or feet, inspiratory sighs, dysphonia (especially reduction in loudness of speech), cold hands and feet, and new or increased snoring.[29,30] If stridor is identified early in the course of the disease, it implies a poorer prognosis.[35]

Management.

In managing OH in patients in the earlier stages of MSA, techniques similar to those used in patients with PAF are helpful. These include elevating the head of the patient's bed by 30 degrees to reduce supine hypertension and the nocturnal solute/water diuresis commonly seen. If detrusor hyperactivity adds to the clinical significance of nocturia in patients with OH, peripherally acting anticholinergic agents such as oxybutynin or intermittent self-catheterization may be helpful.

Parkinsonian features are commonly prominent, and treatment with levodopa can be helpful, although it is generally not as effective as in Parkinson disease. It has been suggested that evaluating the pharmacodynamics of a low dose of levodopa can help separate MSA from Parkinson disease.[36] If levodopa causes problematic side effects, such as worsening of postural hypotension, dystonias, or dyskinesias, a dopamine-agonist may be warranted. About 20% of patients benefit from amantadine. However, there is no effective medical treatment for cerebellar symptoms. Spasticity and myoclonus rarely require treatment with baclofen, clonazepam, or valproate, but clonazepam may also ameliorate the REM sleep behavior disorder. Sildenafil is usually not effective in treating male erectile dysfunction in patients with MSA, and it can aggravate postural hypotension. For many patients, practical interventions, such as physical therapy, occupational therapy, and speech therapy including attention to swallowing difficulty, may yield the most benefit. To ensure the patient's safety, visits to the home by social workers and experts who can assess the patient's capacity to effectively use a walker or determine the need for, and ability to use, a motorized wheelchair are vital services, as is recognition by caregivers of the alterations in the ventilatory and cardiac responses to hypercapnia and hypoxia in MSA.[37] In the latter stages of MSA, hospice and palliative care facilities may provide additional relief to overburdened patients and families. Patient organizations, such as the Multiple System Atrophy Support Group and the MSA Coalition, may also provide needed support and information.[29]

Disease-Modifying Therapy.

There are currently no medical agents that slow or stop the progression of MSA. Two drugs that were effective in a transgenic mouse model of MSA have recently been tested in well-designed, adequately powered, placebo-controlled clinical trials but demonstrated no significant benefit. Rasagiline, an MAOB inhibitor, had been suggested to delay disease progression in Parkinson disease and had shown neuroprotective effects in the mouse model of MSA, but was ineffective in patients with MSA and had significant side effects.[38] Rifampicin, an antibiotic that can inhibit the formation of α-synuclein fibrils and remove aggregates of this toxic protein, showed no difference from placebo.[39]

Understandably, families dealing with the difficult course of MSA are concerned about whether this is a heritable disease. Although MSA is primarily a sporadic disease, there have been multiplex families described in Japan and Europe, and an association between single-nucleotide polymorphisms (SNPs) within the SNCA gene and the risk of sporadic MSA has been reported. However, a recent genome-wide association study was performed with more than 5 million genotyped and imputed SNPs in 918 patients with MSA and 3864 controls of European ancestry from North American and European centers. One third of the MSA cases were confirmed by pathologic studies. No significant loci were identified after a stringent multiple-testing correction, and no association of common genetic variants in the genes *SNCA* and *COQ2* with MSA was seen. The investigators suggested several potentially interesting gene loci, including the *MAPT* locus, whose significance must be evaluated in a larger sample set.[24]

Dementia With Lewy Bodies.

Patients who have dementia with Lewy bodies experience detrimentally progressive and fluctuating cognitive decline, with pronounced variations in attention, recurrent visual hallucinations, delusions, depression, and an REM sleep behavior disorder, accompanied by parkinsonism, severe neuroleptic sensitivity, and unexplained episodes of loss of consciousness or syncope.[40] Progressive autonomic dysfunction is also seen and can become quite severe, and OH is often the reason for the cardiac consultation. The order in which the multiple aspects of dementia with Lewy bodies becomes evident is variable, and arriving at an accurate diagnosis may require observation over a number of years. Some patients can present, for example, with autonomic symptoms before cognitive decline is evident.

Parkinson Disease With Autonomic Dysfunction.

Parkinson disease is a neurodegenerative disease that presents with an asymmetric resting tremor, rigidity, bradykinesia, and postural instability. Eosinophilic cytoplasmic inclusions called Lewy bodies are concentrated in the substantia nigra, and there is generally a good response to dopamine replacement therapy. Parkinson disease also is often associated with depression, cognitive dysfunction, anosmia, and sleep abnormalities. Differentiating between MSA and Parkinson disease is important because the prognosis in MSA is much worse, with an average of only 5 to 9 years of survival after the diagnosis. In MSA, as is consistent with a preganglionic lesion, norepinephrine transport is usually preserved. Uptake is impaired in Parkinson disease, suggesting cardiac sympathetic denervation.[1]

Although autonomic symptoms can occur in Parkinson disease, they are more typical and more serious in MSA. It is sometimes difficult to identify clearly the patient with parkinsonian features, but use of the smell test can be extremely helpful because anosmia or hyposmia is much more common in Parkinson disease than it is in MSA.[29]

Autoimmune Autonomic Failure

The syndrome of acute panautonomic failure results from antibodies to the ganglion of acetylcholine

receptors.[41] It manifests as OH, gastrointestinal dysmotility, urinary retention, and pupillary dysfunction. The syndrome usually appears acutely, and frequently but not always follows symptoms of an infectious disease. Once present, it often persists for life. It can be as severe as the late stages of PAF, which it mimics except for the acuteness of onset. It has only rarely been reported in children.[42] An important additional item in the differential diagnosis is the possibility that the antibodies involved are paraneoplastic, and these have appeared even when cancer has not been detected; it becomes clinically apparent only weeks to months later. A diagnostic panel of relevant antibodies is available at the Mayo Clinic, where there has been a long-standing interest in this disorder; the panel can, in some cases, suggest a cause.[41] Supportive treatment can be modeled after that of PAF (see earlier discussion). In terms of the underlying cause, patients may respond well to immunotherapies such as prednisone, intravenous immunoglobulin, plasma exchange, or oral immunosuppressants, although success is variable, and absent in some. The likelihood of full or partial reversal appears greater when the therapies are given as early as possible in the course of the disease, but rare responses have been seen even after years, so the duration of illness should not discourage aggressive treatment. Ancillary treatment of symptomatic patients with cholinergic agents such as pyridostigmine or bethanechol may sometimes be helpful. Increased fiber may help severe constipation.

Secondary Autonomic Neuropathies Associated with Other Diseases

Autonomic neuropathies may appear in the course of several diseases, producing a wide variety of symptoms and signs, including OH, as well as cardiac, gastrointestinal, sudomotor, or genitourinary dysfunction. Although these symptoms can appear late in the course of the underlying disease, some can be the presenting complaint or may even be subclinical, found with autonomic testing. Recognition of the connection between secondary autonomic dysfunction and previously unrecognized underlying diseases can be important clinically in directing attention and appropriate therapy to the primary disease and, occasionally, in better understanding the patient's prognosis. Specific treatment for any autonomic symptoms is not likely to alter the course of the disease, but can improve the quality of life.

The diseases that should be considered in this category include diabetes, amyloidosis, Guillain-Barré syndrome, Fabry disease, Tangier disease, leprosy, HIV neuropathy, connective tissue disorders, plasma cell dyscrasia–associated polyneuropathy, and a number of toxic neuropathies (e.g., *cis*-platinum, vincristine, paclitaxel, thalidomide, organic solvents, acrylamide).

Diabetes Mellitus

In diabetes mellitus, diabetic neuropathy may not only affect the peripheral autonomic nerves, leading to OH, which is generally manageable with the same modalities as in PAF, but may also cause abnormalities in the cardiac response to simple testing, such as measurements of the HR in response to a fall in BP with standing and with the Valsalva maneuver. Diabetic neuropathy and OH are also associated with diabetic nephropathy.[43,44] Optimal care of renal failure is obviously critical and is the most important way to reduce or prevent later nephrotic dysautonomia. Unfortunately, the appearance of autonomic dysfunction in a patient with diabetes presages an increased risk[45] and a reduction in lifespan.

Amyloidosis

In amyloidosis, a progressive, fatal disease, secondary autonomic dysfunction may be an early manifestation and is classically accompanied by carpal tunnel syndrome and small-fiber neuropathy. It is important to consider the underlying diagnosis, so that the amyloidosis can be treated as early and

aggressively as possible. Most cases are sporadic, but rare hereditary amyloidosis can be seen, as well. Physical pressure on nerve fibers or autonomic ganglia produces abnormal pathologic features when examined and has been considered the mechanism of neurologic dysfunction; the same pressure can interfere with blood flow and cause ischemic damage. Immunologic mechanisms have also been suggested. However, regardless of the mechanism, both sympathetic and parasympathetic abnormalities can be seen, and the widespread nature of the disease can lead to similarly widespread autonomic symptoms, including impotence, dysphagia, early satiety, and either diarrhea or constipation. Dry mouth and reduced sweating are often noted by patients, and OH can become a limiting feature. Cardiac involvement includes infiltration of the myocardium, visible on echocardiography, and often a prolonged QT interval, thought to be related to amyloid effects on cardiac nerves. The latter is associated with reduced survival times. Abnormal pupillary reflexes are often seen as well. A combination of several of these multiple autonomic symptoms and signs should suggest amyloidosis. Multiple novel approaches to diagnosis are now available. Examination of tissue during surgery, by abdominal fat aspiration, or by rectal, gingival, or sural nerve biopsy often allows specificity of the amyloid type. Treatment approaches aimed at slowing or reversing the progression of the underlying amyloidosis have expanded in recent years, and treatment of arrhythmias is appropriate, but the prognosis remains poor for most forms of the disease. Attention to mitigating the autonomic symptoms as much as possible can at least improve the patient's quality of life. Limited responsiveness to conventional treatments for OH may in fact suggest underlying amyloidosis if the diagnosis has not already been made. Early satiety may respond to metoclopramide, and octreotide is helpful in treating diarrhea. To improve the OH, fludrocortisone, midodrine, support garments, and an abdominal binder can be helpful. Erythropoietin, pyridostigmine, and L-threo-3,4-dihydroxyphenylserine (DOPS) have also been reported to reduce symptoms.

Guillain-Barré Syndrome

The key features of the Guillain-Barré syndrome are the acute onset of an inflammatory ascending, primarily motor polyradiculoneuropathy with absent reflexes and elevated cerebrospinal fluid protein, first described in 1916. Autonomic dysfunction complicates the course of the disease in approximately two thirds of cases. The disorder is believed to be immune mediated,[46] with three fourths of patients reporting a prior illness consistent with a viral or bacterial infection 7 to 10 days before the neuropathic symptoms appear. The illness is often mononucleosis, cytomegalovirus infection, or an enteric infection due to food poisoning with *Campylobacter jejuni*, and there have been some reports of antecedent *Mycoplasma* pneumonia, influenza, and, recently, Zika virus infection.[47] Guillain-Barré syndrome has been reported to be associated with vaccination in the past, but there has been no association with vaccines developed after 1977. It has been estimated that the risk of developing the syndrome after influenza significantly outweighs the risk from the influenza vaccine. Further supporting an immune cause are pathologic findings on sural nerve biopsy or at autopsy (rarely, because few patients die), the presence of serum antibodies against multiple types of antigens, and the response to immunotherapy.[48] Surgery has also been suggested as a trigger. Loss of tendon reflexes is usual, and ascending weakness (and sometimes sensory dysfunction) progresses over 1 to 2 weeks, followed by a plateau period of about 3 weeks, with severe weakness and respiratory paralysis being common. In some patients, recovery requires months to years, and may not be complete. Not all patients develop autonomic impairment, but it does occur in about two thirds of patients. If it occurs during the acute phase of the illness, it is likely to present as sympathetic hyperactivity, and some patients will have what are referred to as *autonomic storms*, with hypertension, tachycardia, and hyperhidrosis. The autonomic abnormalities may be mild in most patients, but life-threatening dysautonomia can be seen in this phase, especially in those severely

affected with motor abnormalities and/or respiratory failure, and OH may alternate with hypertensive episodes.[49] During the recovery phase, parasympathetic failure can be seen, with resting tachycardia, and testing commonly reveals cardiovagal, sudomotor, and adrenergic vasomotor function abnormalities. Cardiac rhythm abnormalities can include bradycardias, with heart block and periods of asystole sufficient to require a cardiac pacemaker, at least transiently. In this setting, vagal stimulation such as tracheal suction may be particularly likely to cause sinus arrest. The autonomic abnormalities require careful monitoring and adjustment of BP and HR, and recognition that patients may be supersensitive to pressor and depressor drugs. If there is prolonged hypertension, a combination of alpha-adrenergic and beta-adrenergic blockade has been suggested.

In general, the autonomic complications of Guillain-Barré syndrome abate in parallel with the motor and sensory abnormalities, either spontaneously or after treatment with plasma exchange or intravenous immunoglobulin (IvIg), 0.4 g/kg over 4 hours daily for 5 days. IvIg appears to have little effect if begun later than 14 days after the onset of the syndrome.[49] **See Table 99.3** for factors most likely to worsen symptoms in patients with autonomic dysfunction and thus bring subclinical disorders to attention.

Dysautonomias Without Chronic Orthostatic Hypotension

For neurally mediated syncope, **see Chapter 43**.

Postural Tachycardia Syndrome

Postural tachycardia syndrome (POTS) is a common reason for referral, and for many patients represents a disabling change in their lives. As data have accumulated, it seems apparent that POTS is not a single entity but is rather a syndrome that can be caused by multiple mechanisms, some of which will be discussed here, and exacerbated or improved by a number of factors that increasingly are being more precisely defined.

The postural tachycardia criteria for POTS have been defined in a consensus statement in the following way: (1) an increase in the HR of 30 beats/min or more (> 40 beats/man in those 12 to 19 years of age) within 10 minutes of standing or 70 to 80 degrees of head-up tilt for 10 minutes, in the absence of a drop in SBP of more than 20 mm Hg; (2) an associated constellation of symptoms worsened by upright posture and improved with recumbency, and lasting more than 6 months, in the absence of medications (vasodilators, diuretics, antidepressants, or anxiolytic agents) or other disorders known to cause orthostatic tachycardia (e.g., dehydration, anemia, hyperthyroidism).[7,50,51] Criteria are more likely to be met in the morning than in the afternoon or evening. Additional common symptoms not dependent on posture include abdominal pain, bloating, nausea and diarrhea, and fatigue. **Fig. 99.4E** shows a typical response to the Valsalva maneuver in a patient with POTS. The prevalence of patients with POTS in the United States has been thought to be about 0.2% of the population, but patient support groups, who reach individuals who may not yet have presented to the health care system, estimate that there may be as many as 3 million Americans who meet these criteria. This likely includes many groups of patients with a number of different causes and overlapping symptoms, several of which (such as mast cell activation disorder, tryptase excess, Ehlers-Danlos syndrome/joint hyperextensibility, and NET deficiency) are discussed later. Others, including neuropathic POTS, central adrenergic POTS, and autoimmune POTS, were recently reviewed by Garland et al.[50] For many patients, the cause remains unknown. Most patients are recognized at 15 to 35 years of age, with approximately a fivefold greater incidence in women as compared with men. The disorder does not appear to shorten the lifespan. With the increase in recognition of patients with POTS, a number of advocacy groups have emerged and have greatly increased patient

understanding of the disorder. Treatment options will be discussed later after review of some of the recently described disorders that can produce POTS.

Mast Cell Activation Disease

In recent surveys, as many as 20% of patients with POTS have been found to have characteristics that suggest some effects of mast cell activation disease,[52] an umbrella term including mastocytosis, an abnormal proliferation of tissue mast cells,[53] and other disorders in which there is abnormal activation of mast cells, even without excessive proliferation. These patients often have episodes of flushing and can have other associated symptoms, including shortness of breath, headache, excessive diuresis, diarrhea, and nausea. A hyperadrenergic response to posture, sometimes accompanied by light-headedness and even syncope, can occur, but symptoms frequently resolve when the patient is supine. They may in part be due to the fluid shifts and even fluid loss caused by mast cell products. Other patients may experience an increase in HR and BP during mast cell activation episodes, suggesting that other mediators or mechanisms may be involved. Following an episode, patients frequently experience lethargy and extreme fatigue for hours.[52]

The diagnosis of mastocytosis is frequently suggested by small pigmented urticaria pigmentosa skin lesions, but in their absence, evidence of mast cell proliferation can be sought in a skin or bone marrow biopsy, or by high levels of histamine and prostaglandin D_2 in a 4-hour urine aliquot, especially if obtained during or immediately after symptomatic episodes.[54] Effective treatment for episodes of vasodilation has included inhibitors of prostaglandin biosynthesis and antihistamines.[53] However, if a patient is “aspirin hypersensitive,” a prostaglandin inhibitor may provoke severe mastocyte activation.

Recently, an idiopathic activation disorder of mast cells has emerged with episodes of systemic mast cell activation without evidence of abnormal proliferation, and this disorder is now seen more frequently than the uncommon mastocytosis itself.[53] In the majority of cases, symptoms are virtually identical to those seen in systemic mastocytosis. Anaphylaxis can be seen,[55] and OH is frequently experienced during mastocyte activation. Exposure to heat, emotional upset, and exertion are common precipitating triggers, but beta blockers can also trigger episodes. Ketotifen has been effective in treating patients with mast cell activation disorder with idiopathic anaphylaxis episodes due to the drug's antihistamine and mast cell–stabilizing properties.[55] Centrally acting sympatholytic agents such as methyldopa or clonidine are often effective, and antihistamines can also be helpful. When patients frequently or continuously suffer from anaphylactoid dysautonomic episodes, their symptoms are poorly controlled by steroids, epinephrine, and antihistamines. However, infusions of diphenhydramine often effectively suppress mast cell activation, anaphylaxis, and allergic reactions.[52]

Tryptase Abnormalities

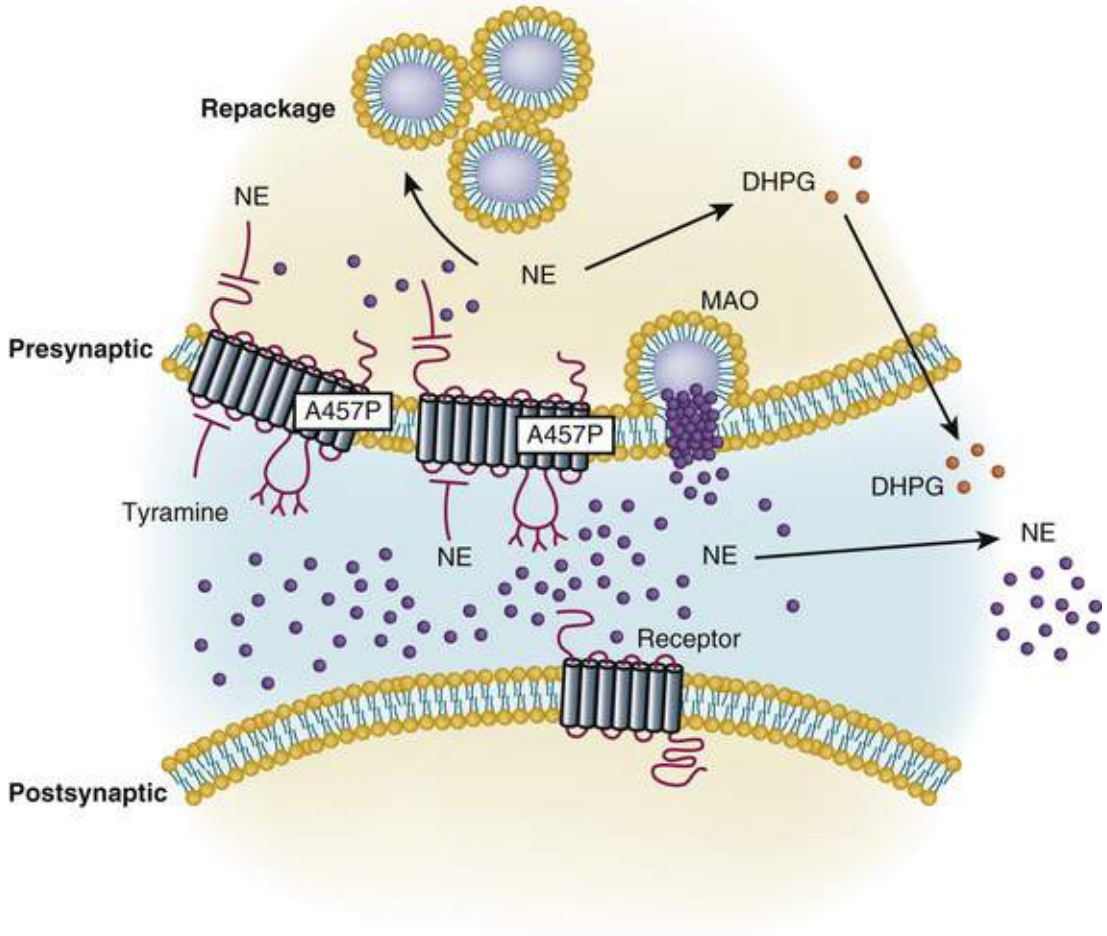
In a recent study, germline duplications and triplications in the *TPSAB1* gene, which encodes alpha-tryptase, a protein often associated with allergic reactions, have been discovered,[56] and an inherited increase in basal serum tryptase levels was found. Duplications in the *TPSAB1* gene were linked with symptoms of dysautonomia, such as orthostatic light-headedness and tachycardia characteristic of POTS, along with skin flushing and itching, gastrointestinal complaints, chronic pain, and bone and joint problems. Those with three copies of α-tryptase had even higher basal serum levels of tryptase and more symptoms than those with two copies, suggesting a gene-dose effect.[56] More studies will be required to confirm this report.

Ehlers-Danlos Syndrome

The Ehlers-Danlos syndrome includes several different disorders united by genetic abnormalities and affecting the structure of collagen. It has been estimated that nearly 20% of patients with POTS[50] may have characteristic features of Ehlers-Danlos syndrome (most commonly, type III), with hyperextensible skin and excessive joint mobility.[57] In patients with Ehlers-Danlos syndrome, orthostatic palpitations and tachycardia, chest pain, presyncope, and syncope are frequently seen, with episodes of these symptoms often triggered by a hot environment, exercise, or meals. Whether the POTS-like symptoms are due to connective tissue abnormalities, with excessive blood pooling with standing leading to orthostatic intolerance, or whether the syndrome is associated with a peripheral neuropathy is uncertain. Support garments and an abdominal binder might be of help, particularly in patients where there is evidence of pooling.

Norepinephrine Transporter Deficiency

One of the very rare specific causes of POTS has been shown to be a deficiency in the ability of the NET to transport released norepinephrine back into the sympathetic nerve terminal. This results in elevated synaptic levels of norepinephrine whenever release is triggered, so that upright posture produces symptoms consistent with the definition of POTS (**eFig. 99.5**). The genetic mutation producing an abnormal NET has been identified, and leads to a more than 98% reduction in transport efficacy. Even heterozygotes can have severe deficiency of norepinephrine transport. This has been explained by studies showing that the mutant form of the gene exerts a dominant negative effect when it is transfected into a heterologous expression system, causing a conformational disruption that interferes with the biosynthetic progression of the transporter and trafficking of both the mutant transporter and the wild-type NET.



EFIGURE 99.5 Schematic representation of the hypothesized effect of the mutation seen in norepinephrine transporter (NET) deficiency (A457P) at a noradrenergic synapse. Normally, the NET takes up released norepinephrine, which once in the cytoplasm can be repackaged into vesicles for exocytosis or be metabolized by monoamine oxidase (MAO) to dihydroxyphenylglycol (DHPG). Some norepinephrine escapes the reuptake process and appears in plasma. DHPG can diffuse out of the neuron and can be measured in plasma. The failure of A457P to transport norepinephrine generates greater than normal norepinephrine in the synapse, norepinephrine spillover, and diminished clearance of norepinephrine from the plasma. The lack of uptake diminishes the flux of norepinephrine through the MAO degradation pathway, and following release of norepinephrine, plasma DHPG levels do not increase as compared with normal. Tyramine is a substrate for the NET; once inside the cell, it displaces norepinephrine from vesicles, thereby increasing cytoplasmic norepinephrine levels and resulting in the exit of norepinephrine from the neuron via a reverse transport mechanism. The effect of tyramine on inducing release of norepinephrine is blunted in the presence of A457P. (From Hahn MK: Norepinephrine transporter deficiency. In Robertson D, Biaggioni I, Burnstock G, et al (editors): Primer on the autonomic nervous system, 3rd ed. San Diego, Academic Press, 2013.)

Medications and Norepinephrine Transporter Blockers

It is important to recognize that a number of medications (vasodilators, diuretics, antidepressants, or anxiolytic agents) can produce a syndrome of orthostatic tachycardia, especially those which act as NET inhibitors or inhibitors of both serotonin and norepinephrine reuptake or which have these characteristics as secondary, off-target effects. These can either worsen orthostatic tachycardia in patients with POTS when used to treat depression or can produce a POTS-like syndrome in patients who have not previously had such symptoms.

Additional uncommon but specific causes of POTS have been described in case reports or series, including neuropathic POTS, central adrenergic POTS, and autoimmune POTS.[50,59] This may account for the heterogeneity of the response to specific medications. Referral to an autonomic center may be helpful

in finding optimal medical management for patients who do not respond to conventional approaches.

Because POTS is a very heterogeneous illness, and the effect of symptoms on the patient's life can have major consequences for both mental and physical health, a number of therapeutic interventions have been proposed to improve health.[50,57] These begin with volume expansion, with a higher salt and fluid intake than is normally recommended for healthy individuals. Although intravenous saline (1 to 2L) can reduce tachycardia and improve symptoms acutely, it is not recommended as a repetitive chronic treatment regimen, given the complications that can accompany frequent venous access. Waist-high compression garments or the use of abdominal binders can reduce the splanchnic-mesenteric pooling of volume with upright posture, and the resultant increase in stroke volume can reduce upright tachycardia. Sustained exercise programs have also been reported to have benefit in patients with POTS, but have been difficult to implement because exercise-provoked symptoms lead most patients to become deconditioned over time. Shibata et al have described a 3-month aerobic and resistance exercise program. It starts with seated, supine, or swimming exercise and progresses slowly. Patients should be told that they may feel worse in the beginning and that the eventual improvement in blood volume and decrease in postural tachycardia can take 5 to 6 weeks.[60]

Although the above measures can improve symptoms, many patients will require medications in addition, and we find that low-dose (10 to 20 mg) propranolol is well tolerated and helpful. If this is insufficient, we usually add either midodrine (2.5 to 10 mg every 4 hours 3 times a day) or fludrocortisone (0.05 to 0.2 mg daily). We may, less commonly, use other medications, depending on the patient's specific characteristics. Garland et al.[50] provide a useful guide to alternative agents, consistent with the consensus statement of the Heart Rhythm Society, endorsed by multiple international organizations.[51] All of these short-term drug therapies may have positive effects, but it is unclear whether there are long-term benefits of drug therapy.

Disorders of Increased Sympathetic Outflow

Obstructive Sleep Apnea

The disorder of obstructive sleep apnea (OSA; **see also Chapter 87**) is a chronic condition in which patients have multiple episodes of partial or complete upper airway collapse during sleep, causing hypoxia and hypercapnia and interruption of normal sleep patterns. The actual prevalence is difficult to determine; it is likely that the disease is significantly underreported, and with the population increase in obesity over recent decades, it presumably is more common than previously thought. During episodes of apnea while sleeping, the hypoxia and hypercapnia cause an increase in sympathetic outflow. It has been suggested that the hyperadrenergic state while awake may be due to a tonic increase in chemoreflex sensitivity. Conventional treatment of OSA with CPAP treatment at night appears to improve the hyperadrenergic state as well.[1]

Pheochromocytoma and Paraganglioma

Pheochromocytoma and paraganglioma are rare catecholamine-secreting tumors derived from the chromaffin cells of the adrenal gland or the paraganglion chromaffin tissue of the SNS[61] (**see also Chapter 95**). They are diagnosed (or excluded) by detection of the catecholamines they produce, whether norepinephrine, epinephrine, and/or dopamine. These can be assayed in plasma, along with free metanephrines and methoxytyramine, but catecholamines have a short half-life in plasma, so 24-hour urine

collection is often beneficial if baseline samples are negative and episodes are infrequent. Paraganglioma effects are described earlier as one of the causes of baroreflex failure. Pheochromocytomas often arise from the adrenal glands, but they may also develop in sympathetic ganglia anywhere. The increased secretion of catecholamines can result in life-threatening hypertension or cardiac arrhythmias, especially with norepinephrine and epinephrine release. Pheochromocytomas can be sporadic or familial and benign or malignant. MRI has nearly 100% sensitivity for the detection of adrenal pheochromocytomas. When clinical suspicion is high because of positive laboratory test results but imaging reveals no source, a ^{131}I-MIBG scan may be useful. Definitive treatment is via surgical resection, with appropriate alpha and beta blockade preoperatively.

Future Perspectives

Progress in the exploration of autonomic cardiovascular control has been substantial in recent years, and multiple areas are at the point of further advances. The recent past has expanded our understanding of testing and of the physiology and pathophysiology of the ANS. This knowledge has the potential to assist in risk assessment and the finding of new therapeutic approaches to improve the outlook for specific disorders.[63] Continued studies of the biochemical and, in some cases, genetic underpinning of disorders such as POTS and MSA[64] are likely to lead to a more precise definition of subsets of patients who may benefit from more specific diagnostic and therapeutic approaches. This has been seen in recent years in amyloidosis, where new discoveries have been made with imaging studies, and in studies of pheochromocytoma and paraganglioma.[61] Uncovering connections between OSA and coronary disease[62] is one example of an area needing further research. New technologies that could provide more continuous monitoring of skin sympathetic activity[65] may also provide information during normal activities, rather than simply in the autonomic laboratory. Spectral analysis of cardiac sympathovagal balance can be useful in assessing cardiovascular risk (e.g., in patients with diabetic neuropathy). The technique has recently suggested that habitual e-cigarette use may be associated with an increase in risk for autonomic disorders.[66]

Acknowledgments

The authors thank Dr. Virend K. Somers for his contributions to the previous edition of this chapter.[1] We are also very grateful to Dr. Andre Diedrich, MD, PhD, for the figures created for this chapter.

Disclosure Index

The following contributors have indicated that they have a relationship which, in the context of their participation in the writing of a chapter for the eleventh edition of *Braunwald's Heart Disease*, could be perceived by some people as a real or apparent conflict of interest, but they do not consider that it has influenced the writing of their chapter. Codes for the disclosure information (institution[s] and nature of relationship[s]) are provided below.

Relationship Codes

A—Stock options or bond holdings in a for-profit corporation or self-directed pension plan
B—Research grants
C—Employment (full or part-time)
D—Ownership or partnership
E—Consulting fees or other remuneration received by the contributor or immediate family
F—Nonremunerative positions, such as board member, trustee, or public spokesperson
G—Receipt of royalties
H—“Speaker's bureau” including CME lectures

Institution and Company Codes

001—ABBIVE
002—Abbott Laboratories
003—Abbott Vascular
004—ACC & ABIM
005—Accumetrics
006—Acorda
007—ACRWH
008—Actelion Pharmaceuticals
009—Aegerion
010—Aetna
011—Agile
012—Aire Pharmaceuticals Inc.
013—AliveCor
014—Allegheny General Hospital
015—Allergan
016—Alliance santé Québec (Université Laval)

017—Alnylam
018—Amarin
019—American Academy of Neurology
020—American Board of Internal Medicine
021—American Board of Vascular Medicine
022—American College of Cardiology
023—American College of Cardiology Foundation
024—American Diabetes Association
025—American Genomics
026—American Heart Association
027—American Medical Association
028—American Society of Echocardiography
