Hypotension and Syncope

Hugh Calkins, Douglas P. Zipes

Definition

Syncope, or transient loss of consciousness (LOC), is a symptom that presents with abrupt, transient, complete LOC associated with the inability to maintain postural tone, with rapid and spontaneous recovery. The presumed mechanism of syncope is cerebral hypoperfusion.[1,2] The metabolism of the brain, in contrast to that of many other organs, is exquisitely dependent on perfusion. Consequently, cessation of cerebral blood flow leads to LOC within approximately 10 seconds. Restoration of appropriate behavior and orientation after a syncopal episode is usually immediate. Retrograde amnesia, although uncommon, can be present in older adults. It is important to recognize that syncope, as previously defined, represents a subset of a much wider spectrum of conditions that can result in transient LOC, including conditions such as cerebrovascular accident (stroke) and epileptic seizures. Nonsyncopal causes of transient LOC differ in their mechanism and duration.[1,2]

Syncope is an important clinical problem because it is common, costly, and often disabling; can cause injury; and can be the only warning sign before sudden cardiac death (SCD)[1-3] (**see Chapter 42**). Patients with syncope account for 1% of hospital admissions and 3% of emergency department (ED) visits. Up to 50% of young adults report a previous episode of LOC, mostly isolated events that never come to medical attention. The prevalence of a first episode of syncope is particularly high between the ages 10 and 20, with additional peaks at approximately 60 and 80 years.[4] Patients who experience syncope also report greatly reduced quality of life; syncope can result in traumatic injury.

The prognosis of patients with syncope varies greatly with the diagnosis. Patients with syncope in the setting of structural heart disease or primary electrical disease have an increased incidence of SCD and overall mortality. Syncope caused by orthostatic hypotension is associated with a twofold increase in mortality, which reflects the presence of multiple comorbid conditions in this patient group. In contrast, young patients with neurally mediated syncope have an excellent prognosis.

Classification

Tables 43.1 and **43.2** present the diagnostic considerations in patients with real or apparent transient LOC and in those with syncope, respectively. Syncope can be distinguished from most other causes of transient LOC by asking whether the LOC was transient, of rapid onset, of short duration, and followed by spontaneous recovery. If the answer to each of these questions is yes and the transient LOC did not result from head trauma, the diagnostic considerations include true syncope in which the mechanism of transient LOC is global cerebral hypoperfusion, epileptic seizures, psychogenic syncope, and other rare causes. It is important to consider nonsyncopal conditions when evaluating a patient with transient LOC, such as metabolic disorders, epilepsy, or alcohol, as well as conditions in which consciousness is only apparently lost (i.e., conversion reaction). These psychogenic causes of syncope, being recognized with increased frequency, are typically diagnosed in patients 40 years or younger and especially in those with a history of psychiatric disease.[1,5]

TABLE 43.1

Causes of Real or Apparent Transient Loss of Consciousness

Syncope (**see Table 43.2**)
Neurologic or cerebrovascular disease
Epilepsy
Vertebrobasilar transient ischemic attack
Metabolic syndromes and coma
Hyperventilation with hypocapnia
Hypoglycemia
Hypoxemia
Intoxication with drugs or alcohol
Coma
Psychogenic syncope
Anxiety, panic disorder
Somatization disorders

TABLE 43.2

Causes of Syncope

Vascular Causes
Anatomic
Vascular steal syndromes (subclavian steal syndrome)
Orthostatic
Autonomic insufficiency
Idiopathic
Volume depletion
Drug and alcohol induced
Reflex Mediated
Carotid sinus hypersensitivity
Neurally mediated syncope (common faint, vasodepressor, neurocardiogenic, vasovagal)
Glossopharyngeal syncope
Situational (acute hemorrhage, cough, defecation, laugh, micturition, sneeze, swallow, postprandial)
Cardiac Causes
Anatomic
Obstructive cardiac valve disease
Aortic dissection
Atrial myxoma
Pericardial disease, tamponade
Hypertrophic obstructive cardiomyopathy
Myocardial ischemia, infarction
Pulmonary embolism
Pulmonary hypertension
Arrhythmias
Bradyarrhythmias
Atrioventricular block
Sinus node dysfunction, bradycardia
Tachyarrhythmias
Supraventricular tachycardia
Atrial fibrillation
Paroxysmal supraventricular tachycardia (AVNRT, WPW)
Other
Ventricular tachycardia
Structural heart disease
Inherited syndromes (ARVD, HCM, Brugada syndrome, long-QT syndrome)
Drug-induced proarrhythmia
Implanted pacemaker or ICD malfunction
Syncope of Unknown Origin

AVNRT, Atrioventricular nodal reentrant tachycardia; *ARVD,* arrhythmogenic right ventricular dysplasia; *HCM,* hypertrophic cardiomyopathy; *ICD,* implantable cardioverter-defibrillator; *WPW,* Wolff-Parkinson-White syndrome.

The differential diagnosis of syncope (**Table 43.2**) most often involves vascular causes, followed by cardiac causes, most frequently arrhythmias. Although knowledge of the common conditions that can cause syncope is essential and allows the clinician to arrive at a probable cause of the syncope in most patients, it is equally important to be aware of several less common but potentially lethal causes of syncope, such as long-QT syndrome, arrhythmogenic right ventricular dysplasia, Brugada syndrome, hypertrophic cardiomyopathy, idiopathic ventricular fibrillation, catecholaminergic polymorphic

ventricular tachycardia, short-QT syndrome, and pulmonary emboli[1,6-11] (**see Chapter 84**).

It is important to recognize that the distribution of causes of syncope varies both with patient age and with the clinical setting in which the patient is evaluated. Neurally mediated syncope and other causes of reflex-mediated syncope are the most frequent causes of syncope at any age and in any setting. Cardiac causes of syncope, especially cardiac tachyarrhythmias and bradyarrhythmias, are the second most common causes of syncope. The incidence of cardiac causes of syncope is higher in older adults and in patients evaluated in the ED. Orthostatic hypotension is extremely uncommon in patients younger than 40 years but is common in very elderly adults (**see Chapter 88**).

Vascular Causes of Syncope

Vascular causes of syncope, particularly reflex-mediated syncope and orthostatic hypotension, are by far the most common causes and account for at least one third of all syncopal episodes.[12,13] In contrast, vascular steal syndromes are exceedingly uncommon causes of syncope.

Orthostatic Hypotension

Standing upright displaces 500 to 800 mL of blood to the abdomen and lower extremities, thereby resulting in an abrupt drop in venous return to the heart. This drop leads to a decrease in cardiac output and stimulation of aortic, carotid, and cardiopulmonary baroreceptors, which triggers a reflex increase in sympathetic outflow. As a result, heart rate, cardiac contractility, and vascular resistance increase to maintain stable systemic blood pressure (BP) on standing. *Orthostatic intolerance* is a term used to refer to the signs and symptoms of an abnormality in any portion of this BP control system. Orthostatic hypotension is defined as a 20–mm Hg drop in systolic BP or a 10–mm Hg drop in diastolic BP within 3 minutes of standing. Orthostatic hypotension can be asymptomatic or associated with syncope, lightheadedness/presyncope, tremulousness, weakness, fatigue, palpitations, diaphoresis, and blurred or tunnel vision. These symptoms are often worse immediately on arising in the morning or after meals or exercise. Initial orthostatic hypotension is defined as less than a 40–mm Hg decrease in BP immediately on standing with rapid (<30 seconds) return to normal.[1,2,11] In contrast, *delayed progressive* orthostatic hypotension is characterized by a slow progressive decrease in systolic BP on standing. Syncope that occurs after meals, particularly in elderly people, can result from a redistribution of blood to the gut. A decline in systolic BP of approximately 20 mm Hg approximately 1 hour after eating has been reported in up to one third of elderly nursing home residents. Although usually asymptomatic, it can result in lightheadedness or syncope.

Drugs that either cause volume depletion or result in vasodilation are the most common causes of orthostatic hypotension (**Table 43.3**). Elderly patients are particularly susceptible to the hypotensive effects of drugs because of reduced baroreceptor sensitivity, decreased cerebral blood flow, renal sodium wasting, and an impaired thirst mechanism that develops with aging (**see Chapter 88**). Orthostatic hypotension can also result from neurogenic causes, which can be subclassified into primary and secondary *autonomic failure* (**see Chapter 99**). Primary causes are generally idiopathic, whereas secondary causes are associated with a known biochemical or structural anomaly or are seen as part of a particular disease or syndrome.

TABLE 43.3
Causes of Orthostatic Hypotension

Drugs
Diuretics
Alpha-adrenergic blocking drugs
Terazosin (Hytrin), labetalol
Adrenergic neuron-blocking drugs
Guanethidine
Angiotensin-converting enzyme inhibitors
Antidepressants
Monoamine oxidase inhibitors
Alcohol
Diuretics
Ganglion-blocking drugs
Hexamethonium, mecamylamine
Tranquilizers
Phenothiazines, barbiturates
Vasodilators
Prazosin, hydralazine, calcium channel blockers
Centrally acting hypotensive drugs
Methyldopa, clonidine
Primary Disorders of Autonomic Failure
Pure autonomic failure (Bradbury-Eggleston syndrome)
Multisystem atrophy (Shy-Drager syndrome)
Parkinson disease with autonomic failure
Secondary Neurogenic Causes
Aging
Autoimmune disease
Guillain-Barré syndrome, mixed connective tissue disease, rheumatoid arthritis
Eaton-Lambert syndrome, systemic lupus erythematosus
Carcinomatosis autonomic neuropathy
Central brain lesions
Multiple sclerosis, Wernicke encephalopathy
Vascular lesions or tumors involving hypothalamus and midbrain
Dopamine beta-hydroxylase deficiency
Familial hyperbradykininism
General medical disorders
Diabetes, amyloid, alcoholism, renal failure
Hereditary sensory neuropathies, dominant or recessive
Infections of the nervous system
Human immunodeficiency virus infection, Chagas disease, botulism, syphilis
Metabolic disease
Vitamin B_{12} deficiency, porphyria, Fabry disease, Tangier disease
Spinal cord lesions

Modified from Bannister SR, editor. Autonomic Failure. 2nd ed. Oxford: Oxford University Press, 1988, p 8.

There are three types of primary autonomic failure. *Pure autonomic failure* (Bradbury-Eggleston syndrome) is an idiopathic sporadic disorder characterized by orthostatic hypotension, usually in conjunction with evidence of more widespread autonomic failure, such as disturbances in bowel, bladder, thermoregulatory, and sexual function. Patients with pure autonomic failure have reduced supine plasma norepinephrine levels. *Multisystem atrophy* (Shy-Drager syndrome) is a sporadic, progressive, adult-onset disorder characterized by autonomic dysfunction, parkinsonism, and ataxia in any combination. The third type of primary autonomic failure is *Parkinson disease* with autonomic failure. A small subset of patients with Parkinson disease may also experience autonomic failure, including orthostatic hypotension. In addition to these forms of chronic autonomic failure is a rare, acute *panautonomic neuropathy.* This neuropathy generally occurs in young people and results in severe, widespread sympathetic and parasympathetic failure with orthostatic hypotension, loss of sweating, disruption of bladder and bowel function, fixed heart rate, and fixed dilated pupils.

Postural orthostatic tachycardia syndrome (POTS) is clinical syndrome characterized by frequent symptoms that occur with standing (e.g., lightheadedness, palpitations, tremulousness, generalized weakness, blurred vision, exercise intolerance, fatigue), an increase in heart rate of 30 beats/min or more on standing (or ≥40 beats/min in those 12 to 19 years of age), and absence of a more than 20–mm Hg reduction in systolic BP.[1,2,12] The precise pathophysiologic basis for POTS has not been well defined.

Some patients have both POTS and neurally mediated syncope.

Reflex-Mediated Syncope

Reflex-mediated, or *situational,* causes of syncope are listed in **Table 43.2**. In this group of conditions, the cardiovascular reflexes that control the circulation become inappropriate in response to a trigger, which results in vasodilation with or without bradycardia and a drop in BP and global cerebral hypoperfusion. In each case the reflex is composed of a trigger (the afferent limb) and a response (the efferent limb). This group of reflex-mediated syncopal syndromes has in common the response limb of the reflex, which consists of increased vagal tone and withdrawal of peripheral sympathetic tone and leads to bradycardia, vasodilation, and ultimately, hypotension, presyncope, or syncope. If hypotension secondary to peripheral vasodilation predominates, it is classified as a *vasodepressor-type* reflex response; if bradycardia or asystole predominates, it is classified as a *cardioinhibitory* response; and when both vasodilation and bradycardia play a role, it is classified as a *mixed* response. Specific triggers distinguish these causes of syncope. For example, micturition-induced syncope results from activation of mechanoreceptors in the bladder, defecation-induced syncope results from neural input from gut wall tension receptors, and swallowing-induced syncope results from afferent neural impulses arising from the upper gastrointestinal tract. The two most common types of reflex-mediated syncope, carotid sinus hypersensitivity and neurally mediated hypotension, are discussed later. Identification of the trigger is of importance because of its therapeutic implications, with avoidance of the trigger, where possible, preventing further syncopal episodes.

Neurally Mediated Hypotension or Syncope (Vasovagal Syncope)

The term *neurally mediated hypotension* or *syncope* (also known as neurocardiogenic, vasodepressor, and vasovagal syncope and “fainting”) has been used to describe a common abnormality in regulation of BP characterized by an abrupt onset of hypotension with or without bradycardia. Triggers associated with the development of neurally mediated syncope include orthostatic stress, such as can occur with prolonged standing or a hot shower, and emotional stress, such as can result from the sight of blood.[1,2,12] A large proportion of patients with neurally mediated syncope may have minor psychiatric disorders. Patients with syncope caused by neutrally mediated hypotension may also have psychogenic pseudosyncope.[5] It has been proposed that neurally mediated syncope results from a paradoxical reflex that is initiated when ventricular preload is reduced by venous pooling. This reduction leads to a decrease in cardiac output and BP, which is sensed by arterial baroreceptors. The resultant increased catecholamine levels, combined with reduced venous filling, leads to a vigorously contracting, volume-depleted ventricle. The heart itself is involved in this reflex by virtue of the presence of mechanoreceptors, or C fibers, consisting of nonmyelinated fibers found in the atria, ventricles, and pulmonary artery. It has been proposed that vigorous contraction of a volume-depleted ventricle leads to activation of these receptors in susceptible individuals. These afferent C fibers project centrally to the dorsal vagal nucleus of the medulla and can result in “paradoxical” withdrawal of peripheral sympathetic tone and an increase in vagal tone, which in turn causes vasodilation and bradycardia. The ultimate clinical consequence is syncope or presyncope. Not all neurally mediated syncope, however, results from activation of mechanoreceptors. In humans the sight of blood or extreme emotion can trigger syncope, thus suggesting that higher neural centers can also participate in the pathophysiology of vasovagal syncope. In

addition, central mechanisms can contribute to the production of neurally mediated syncope.

Carotid Sinus Hypersensitivity

Syncope caused by carotid sinus hypersensitivity results from stimulation of carotid sinus baroreceptors located in the internal carotid artery above the bifurcation of the common carotid artery. It is diagnosed by the reproduction of clinical syncope during carotid sinus massage, with a cardioinhibitory response if asystole is longer than 3 seconds or AV block occurs; or a significant vasodepressor response if there is a more than 50–mm Hg drop in systolic BP; or a mixed cardioinhibitory and vasodepressor response.[1] Carotid sinus hypersensitivity is detected in approximately one third of elderly patients evaluated for syncope or falls.[2] It is important, however, to recognize that carotid sinus hypersensitivity is also frequently observed in asymptomatic elderly patients. Thus the diagnosis of carotid sinus hypersensitivity should be approached cautiously after excluding alternative causes of the syncope. Once diagnosed, dual-chamber pacemaker implantation is recommended for patients with recurrent syncope or falls resulting from carotid sinus hypersensitivity that is cardioinhibitory or mixed (class 2A/IIa, level of evidence [LOE] B-R).[1,2,14]

Cardiac Causes of Syncope

Cardiac causes of syncope, particularly tachyarrhythmias and bradyarrhythmias, are the second most common cause of syncope and account for 10% to 20% of syncopal episodes (**see Table 43.2 and Chapters 37 and 39**). Ventricular tachycardia (VT) is the most common tachyarrhythmia that can cause syncope. Supraventricular tachycardia (SVT) can also cause syncope, although the great majority of patients with supraventricular arrhythmias have less severe symptoms, such as palpitations, dyspnea, and lightheadedness. Bradyarrhythmias that can result in syncope include sick sinus syndrome and atrioventricular (AV) block. Anatomic causes of syncope include obstruction to blood flow, such as massive pulmonary embolism (**see Chapter 84**), atrial myxoma (**Chapter 81**), or aortic stenosis (**Chapter 68**).

Neurologic Causes of Transient Loss of Consciousness

Neurologic causes of transient LOC, including migraines, seizures, Arnold-Chiari malformations, and transient ischemic attacks, are surprisingly uncommon and account for less than 10% of all cases of syncope (**see Chapters 65 and 97**). Most patients in whom a “neurologic” cause of transient LOC is established are in fact found to have had a seizure rather than true syncope.

Metabolic Causes of Transient Loss of Consciousness

Metabolic causes of transient LOC are rare and account for less than 5% of syncopal episodes. The most common metabolic causes of syncope are hypoglycemia (**see Chapter 51**), hypoxia, and hyperventilation (**Chapter 86**). Establishing hypoglycemia as the cause of apparent LOC requires demonstration of

hypoglycemia during the syncopal episode. Although hyperventilation-induced syncope has generally been considered to result from a reduction in cerebral blood flow, one study demonstrated that hyperventilation alone was not sufficient to cause syncope. This observation suggests that hyperventilation-induced syncope may also have a psychological component. Psychiatric disorders can also cause syncope. Up to one fourth of patients with syncope of unknown origin may have psychiatric disorders for which apparent syncope is one of the initial symptoms[1] (**see Chapter 96**).

Diagnostic Tests

Identification of the precise cause of the syncope is often challenging. Because syncope usually occurs sporadically and infrequently, it is extremely difficult to examine a patient or obtain an electrocardiogram (ECG) during an episode of syncope. For this reason, the primary goal in the evaluation of a patient with syncope is to arrive at a presumptive determination of the cause of the syncope.

History, Physical Examination, and Carotid Sinus Massage

The history and physical examination are by far the most important components of the evaluation of a patient with transient LOC and syncope and can be used to identify the cause in more than 25% of patients.[1,2,13,15-17] The 2017 ACC/AHA/HRS syncope guidelines provide a class I (LOE B-NR) recommendation for performing a detailed history and physical examination in patients with syncope.[1] Maximal information can be obtained from the clinical history when it is approached in a systematic and detailed manner. Initial evaluation should begin by determining whether the patient did in fact experience a syncopal episode by asking the following: (1) Did the patient experience complete LOC? (2) Was the LOC transient with a rapid onset and short duration? (3) Did the patient recover spontaneously, completely, and without sequelae? and (4) Did the patient lose postural tone? If the answer to one or more of these questions is negative, other nonsyncopal causes of transient LOC should be suspected. Although falls can be differentiated from syncope by the absence of LOC, an overlap between symptoms of falls and syncope has been reported,[2,18] because elderly individuals may experience amnesia for the LOC episode. When evaluating a patient with syncope, particular attention should then be focused on (1) determining whether the patient has a history of cardiac disease or metabolic disease (i.e., diabetes) or a family history of cardiac disease, syncope, or sudden death; (2) identifying medications that may have played a role in syncope, especially those that may cause hypotension, bradycardia/heart block, or a proarrhythmic response (antiarrhythmics); (3) quantifying the number and chronicity of previous syncopal and presyncopal episodes; (4) identifying precipitating factors, including body position and activity immediately before syncope; and (5) quantifying the type and duration of prodromal and recovery symptoms. It is also useful to obtain careful accounts from witnesses to provide a detailed description of the episode, including how the patient collapsed and the patient's skin color and breathing pattern, duration of unconsciousness, and movements during the episode of unconsciousness. **Table 43.4** summarizes features of the clinical history most helpful in differentiating neurally mediated hypotension, arrhythmia, seizures, and psychogenic syncope.

TABLE 43.4

Differentiation of Syncope Caused by Neurally Mediated Hypotension, Arrhythmias, Seizures, and Psychogenic Causes

	NEURALLY MEDIATED HYPOTENSION	ARRHYTHMIAS	SEIZURES	PSYCHOGENIC
Demographics and clinical setting	Female > male sex Younger age (<55 yr) More episodes (>2) Standing, warm room, emotional upset	Male > female sex Older age (>54 yr) Fewer episodes (<3) During exertion or supine Family history of sudden death	Younger age (<45 yr) Any setting	Female > male sex Occurs in presence of others Younger age (<40 yr) Many episodes (often many episodes in a day) No identifiable trigger
Premonitory symptoms	Longer duration (>5 sec) Palpitations Blurred vision Nausea Warmth Diaphoresis Lightheadedness	Shorter duration (<6 sec) Palpitations less common	Sudden onset or brief aura (déjà vu, olfactory, gustatory, visual)	Usually absent
Observations during the event	Pallor Diaphoresis Dilated pupils Slow pulse, low BP Incontinence may occur. Brief clonic movements may occur.	Blue, not pale Incontinence may occur. Brief clonic movements may occur.	Blue face, no pallor Frothing at the mouth Prolonged syncope (duration >5 min) Tongue biting Horizontal eye deviation Elevated pulse and BP Incontinence more likely* Tonic-clonic movements if grand mal	Normal color Not diaphoretic Eyes closed Normal pulse and BP No incontinence Prolonged duration (minutes) common
Residual symptoms	Residual symptoms common Prolonged fatigue common (>90%) Oriented	Residual symptoms uncommon (unless prolonged unconsciousness) Oriented	Residual symptoms common Aching muscles Disoriented Fatigue Headache Slow recovery	Residual symptoms uncommon Oriented

*May be observed with any of these causes of syncope but more common with seizures; *BP,* blood pressure.

The clinical histories obtained from patients with syncope related to AV block and VT are similar. In each case, syncope typically occurs with less than 5 seconds of warning and few if any prodromal and recovery symptoms. Demographic features suggesting that the syncope results from an arrhythmia such as VT or AV block include male sex, fewer than three previous episodes of syncope, and increased age. Features of the clinical history that point toward a diagnosis of neurally mediated syncope include palpitations, blurred vision, nausea, warmth, diaphoresis, or lightheadedness before syncope and the presence of nausea, warmth, diaphoresis, or fatigue after syncope.

Features of the clinical history useful in distinguishing seizures from syncope include orientation following an event, a blue face or not becoming pale during the event, frothing at the mouth, aching muscles, feeling sleepy after the event, time of seizure relative to onset of syncope—early points to neurologic while late suggests arrhythmic cause—and a duration of unconsciousness of longer than 5 minutes.[16] Tongue biting strongly points toward a seizure rather than syncope as the cause of LOC. One recent study reported that a history of tongue biting during an episode of LOC had 33% sensitivity and 96% specificity in predicting a seizure as the cause of the LOC.[17] Other findings suggestive of a seizure as a cause of the syncopal episode include (1) an aura before the episode, (2) horizontal eye deviation during the episode, (3) elevated BP and pulse during the episode, and (4) a headache following the event. Urinary or fecal incontinence can be observed with either a seizure or a syncopal episode but occurs more often with a seizure. Grand mal seizures are usually associated with tonic-clonic movements. It is important to note that syncope caused by cerebral ischemia can result in decorticate rigidity with clonic movements of the arms. Akinetic or petit mal seizures can be recognized by the patient's lack of responsiveness in the absence of loss of postural tone. Temporal lobe seizures last several minutes and

are characterized by confusion, changes in LOC, and autonomic signs such as flushing. Vertebral basilar insufficiency should be considered as the cause of the syncope if it occurs in association with other symptoms of brainstem ischemia (i.e., diplopia, tinnitus, focal weakness or sensory loss, vertigo, or dysarthria). Migraine-mediated syncope is often associated with a throbbing unilateral headache, scintillating scotomata, and nausea.

Physical Examination

In addition to a complete cardiac examination, particular attention should be focused on whether structural heart disease is present, defining the patient's level of hydration, and detecting the presence of significant neurologic abnormalities suggestive of dysautonomia or a cerebrovascular accident. Orthostatic vital signs are a critical component of the evaluation. The patient's BP and heart rate should be determined while supine and then repeated each minute for approximately 3 minutes while standing. The two abnormalities that should be sought are (1) early orthostatic hypotension, defined as a 20–mm Hg drop in systolic BP or a 10–mm Hg drop in diastolic BP within 3 minutes of standing, and (2) POTS (see earlier, Orthostatic Hypotension). The significance of POTS lies in its close overlap with neurally mediated syncope.

Carotid Sinus Massage

Carotid sinus massage should be performed after checking for bruits by applying *gentle* pressure over the carotid pulsation, first one side and then the other, just below the angle of the jaw where the carotid bifurcation is located. Pressure should be applied for 5 to 10 seconds in both the supine and the upright position because an abnormal response to carotid sinus massage is present only in the upright position in up to one third of patients. Since the main complications associated with performing carotid sinus massage are neurologic, it should be avoided in patients with previous transient ischemic attacks, strokes within the past 3 months, and carotid bruits, except if significant stenosis has been excluded by carotid Doppler studies. A normal response to carotid sinus massage is a transient decrease in the sinus rate, prolongation of AV conduction, or both. Carotid sinus hypersensitivity is diagnosed by the reproduction of clinical syncope during carotid sinus massage and the responses previously noted.[1] Diagnosis of carotid sinus hypersensitivity as the cause of the syncope requires reproduction of the patient's symptoms during carotid sinus massage.

Laboratory Testing: Blood Tests

Routine use of blood tests, such as serum electrolytes, cardiac enzymes, glucose, and hematocrit levels, is of low diagnostic value in syncopal patients and therefore not recommended routinely. The 2017 ACC/AHA/HRS syncope guidelines state that targeted blood tests are reasonable in the evaluation of selected patients with syncope identified based on clinical assessment from history, physical examination, and ECG (class IIa, LOE B-NR).[1]

Tilt-Table Test

The tilt-table test is a valuable diagnostic test for evaluating patients with syncope,[1,2,13] with a positive response indicating susceptibility to neurally mediated syncope. The 2017 ACC/AHA/HRS syncope guidelines state that tilt-table testing can be useful for patients with suspected vasovagal syncope if the diagnosis is unclear after initial evaluation (class IIa, LOE B-NR).[1] Upright tilt testing is generally

performed for 30 to 45 minutes following a 20-minute horizontal pretilt stabilization phase at an angle between 60 and 80 degrees (with 70 degrees being most common). The sensitivity of the test can be increased, along with an associated fall in specificity, by the use of longer tilt durations, steeper tilt angles, and provocative agents such as isoproterenol or nitroglycerin. When isoproterenol is used, it is recommended that the infusion rate be increased incrementally from 1 to 3 μg/min to increase the heart rate 25% greater than baseline. When nitroglycerin is used, a fixed dose of 300 to 400 μg of nitroglycerin spray should be administered sublingually after a 20-minute unmedicated phase with the patient in the upright position. These two provocative approaches are equivalent in diagnostic accuracy. In the absence of pharmacologic provocation, the specificity of the test has been estimated to be 90%; when provocative agents are used, specificity decreases significantly.

The main indication for upright tilt testing is to confirm a diagnosis of neurally mediated syncope when the initial evaluation was insufficient to establish this diagnosis. Tilt-table testing is also of value in diagnosing psychogenic pseudosyncope.[5] Upright tilt testing is not generally recommended in patients in whom the diagnosis can be established from the initial history and physical examination. However, for some patients, confirmation of the diagnosis with a positive response to upright tilt testing is very reassuring. Induction of reflex hypotension/bradycardia without reproduction of the syncope points toward a diagnosis of neurally mediated syncope but is a less specific response. If a patient has structural heart disease, other cardiovascular causes of syncope should be excluded before considering a positive response to upright tilt testing to be diagnostic of neurally mediated syncope. Upright tilt testing is also indicated in the evaluation of patients for whom the cause of the syncope has been determined (i.e., asystole), but the presence of neurally mediated syncope on upright tilt would influence treatment. Upright tilt testing has also been shown to be of value in patients with psychogenic causes of syncope in that it may trigger LOC in association with a normal BP and heart rate. Induction of LOC with no change in vital signs points strongly toward a diagnosis of psychogenic pseudosyncope. Upright tilt testing has no value in assessing the efficacy of treatment of neurally mediated syncope.

Cardiac Imaging

Echocardiograms are frequently used to evaluate patients with syncope (**see Chapter 14**), but current guidelines suggest that an echocardiogram should be performed only in patients suspected of having structural heart disease.[1,2] The 2017 ACC/AHA/HRS syncope guidelines state that echocardiography can be useful in selected patients presenting with syncope if structural heart disease is suspected (class IIa, LOE B-NR).[1] The guidelines also state that routine cardiac imaging is not useful in the evaluation of patients with syncope unless cardiac etiology is suspected on the basis of an initial evaluation including history, physical examination, or ECG (class 3/III, LOE B-NR).[1] These guidelines also recommend that computed tomography (CT) or magnetic resonance imaging (MRI) may be useful in selected patients presenting with syncope of suspected cardiac etiology (class IIb, LOE B-NR).[1] Studies have shown that the diagnostic yield of an echocardiogram in a syncope patient with a normal ECG and physical examination is extremely low. Therefore, routine echocardiograms are not advised in this setting. For example, an echocardiogram should be obtained in patients who have clinical features suggestive of a cardiac cause of the syncope, such as syncope with exertion or while supine, a family history of sudden death, or syncope of abrupt onset. Echocardiographic findings considered diagnostic of the cause of syncope include severe aortic stenosis, pericardial tamponade, aortic dissection, congenital abnormalities of the coronary arteries, and obstructive atrial myxomas or thrombi. Findings of impaired right or left ventricular function, evidence of right ventricular overload or pulmonary hypertension (pulmonary

emboli), or the presence of hypertrophic cardiomyopathy (**see Chapter 78**) are of prognostic importance and justify additional diagnostic testing.

Stress Tests and Cardiac Catheterization

Myocardial ischemia is an unlikely cause of syncope and, when present, is usually accompanied by angina (**see Chapter 56**). The use of stress tests (**see Chapter 13**) is best reserved for patients in whom syncope or presyncope occurred during or immediately after exertion in association with chest pain or in a patient at high risk for coronary artery disease.[1,2] The 2017 ACC/AHA/HRS syncope guidelines state exercise stress testing can be useful to establish the cause of syncope in selected patients who experience syncope or presyncope during exertion (class IIa, LOE C-LD).[1] Syncope occurring during exercise is suggestive of a cardiac cause. In contrast, syncope following exercise is usually caused by neurally mediated syncope. Even in patients with syncope during exertion, exercise stress testing is highly unlikely to trigger another event. Coronary angiography is recommended in patients with syncope suspected to result, directly or indirectly, from myocardial ischemia.

Electrocardiography

The 12-lead ECG is another important component in the workup of a patient with syncope (**see Chapter 12**). The 2017 ACC/AHA/HRS syncope guidelines provide a class I (LOE B-NR) recommendation for performing an ECG in patients with syncope.[1] The initial ECG results in establishment of a diagnosis in approximately 5% of patients and suggests a diagnosis in another 5% of patients. Specific findings that can identify the probable cause of the syncope include QT prolongation (long-QT syndrome), the presence of a short PR interval and a delta wave (Wolff-Parkinson-White syndrome), the presence of a right bundle branch block pattern with ST-segment elevation (Brugada syndrome), or evidence of acute myocardial infarction, high-grade AV block, or T wave inversion in the right precordial leads (arrhythmogenic right ventricular dysplasia) (**see Chapters 33, 37, and 39**). Any abnormal finding on the baseline ECG is an independent predictor of cardiac syncope or increased mortality and suggests the need to pursue evaluation of cardiac causes of syncope.[1] Most patients with syncope have normal findings on ECGs, which is useful because it suggests a low likelihood of a cardiac cause of the syncope and is associated with an excellent prognosis, particularly when observed in a young patient with syncope. Despite the low diagnostic yield of electrocardiography, the test is inexpensive and risk free and is considered a standard part of the evaluation of virtually all patients with syncope.[1]

Signal-Averaged Electrocardiography

Signal-averaged electrocardiography (SAECG) is a noninvasive technique used to detect low-amplitude signals in the terminal portion of the QRS complex (late potentials), which are a substrate for ventricular arrhythmias (**see Chapter 35**). In contrast to a standard ECG, the role of SAECG in the evaluation of patients with syncope is not well established, and it is not recommended as a standard part of the evaluation of patients with syncope.[2] The 2017 ACC/AHA/HRS syncope guidelines make no mention of SAECG in the evaluation of patients with syncope.[1] The only situation in which SAECG may be of diagnostic value is when arrhythmogenic right ventricular dysplasia is being considered.[8]

Cardiac Monitoring

Continuous ECG monitoring via telemetry or Holter monitoring is frequently performed in patients with

syncope but is unlikely to identify the cause of the syncope (**see Chapter 35**). The information provided by ECG monitoring at the time of syncope is extremely valuable in that it allows an arrhythmic cause of syncope to be established or excluded. However, because of the infrequent and sporadic nature of syncope, the diagnostic yield of Holter monitoring in the evaluation of patients with syncope and presyncope is extremely low. Another clinically useful finding is detection of symptoms in the absence of an arrhythmia, which is observed in up to 15% of patients undergoing continuous ECG monitoring. It is important to emphasize that the absence of an arrhythmia and symptoms during continuous ECG monitoring may not exclude an arrhythmia as the cause of the syncope. In patients suspected of having an arrhythmia as the cause of the syncope, additional evaluation, such as electrophysiologic (EP) testing or event monitoring, should be considered. Inpatient telemetry monitoring or Holter monitoring is recommended for patients who have clinical or ECG features suggesting an arrhythmic syncope or a history of recurrent syncope with injury. Holter monitoring and inpatient telemetry monitoring are most likely to be diagnostic when used for the occasional patient with frequent (i.e., daily) episodes of syncope or presyncope.

Some transtelephonic event monitors are worn continuously to capture both retrospective and prospective ECG recordings, whereas other types record only when they are activated by the patient. Continuous-loop event monitors, often programmed with 5 to 15 minutes of preactivation memory stored by the device, are preferred because the data can be retrieved for analysis. Prospective event monitors not worn continuously by the patient are of value to investigate palpitations but play no role in the evaluation of patients with syncope. Event monitors are indicated in the early phase of the evaluation of patients with syncope of uncertain origin who do not have high-risk criteria that require immediate hospitalization or intensive evaluation. They are also indicated in high-risk patients in whom a comprehensive evaluation did not demonstrate a cause of the syncope or lead to specific treatment.[1,2] Over the past 5 years, external devices for real-time outpatient telemetry monitoring have been developed with wireless technology to transmit real-time ECG recordings to a service center. These devices result in higher diagnostic yield in patients with syncope or presyncope than do the conventional event monitors just described.

In patients with extremely infrequent episodes of syncope (e.g., once or twice a year), a traditional event monitor is unlikely to record an event. Implantable event recorders address this problem by triggering automatically on the basis of programmed detection criteria, as well as with a handheld activator, and storing the ECG signal in a circular buffer (**see Chapter 35**). Some of these devices can transmit the signals transtelephonically. These devices allow a longer monitoring period (12 to 36 months) and have higher diagnostic yield, but they have the disadvantages of requiring surgical implantation and increased cost. A recent advancement in this technology is that these implantable event monitors can be accessed by remote monitoring, which further increases their diagnostic effectiveness.[29] Implantable loop recorders with a battery life of 2 to 3 years have also been shown to improve the diagnostic yield in patients with syncope.[19] However, a recent Cochrane meta-analysis showed no impact of implantable loop recorders on mortality.[19]

The 2017 ACC/AHA/HRS syncope guidelines state that the choice of a specific cardiac monitor should be determined on the basis of the frequency and nature of the syncope events (class I, LOE C-EO). The guidelines also state that each of the monitors previously discussed can be useful to evaluate selected ambulatory patients with syncope of suspected arrhythmic etiology (class IIa, LOE B-NR).[1]

Electrophysiologic Testing

EP testing can provide important diagnostic information in patients with syncope by establishing a diagnosis of sick sinus syndrome, carotid sinus hypersensitivity, heart block, SVT, and VT (**see Chapter 35**). **Table 43.5** presents indications for EP testing and diagnostic findings in the evaluation of patients with syncope.[2] The 2017 ACC/AHA/HRS syncope guidelines state that an electrophysiologic study (EPS) can be useful for evaluation of select patients with syncope of suspected arrhythmic etiology (class IIa, LOE B-NR). These guidelines further note that EPS is not recommended for syncope evaluation in patients with a normal ECG and normal cardiac structure and function, unless an arrhythmic etiology is suspected (class III, LOE B-NR).[1] It is generally agreed that EP testing should be performed in patients when the initial evaluation suggests an arrhythmic cause of the syncope,[2] such as those with abnormal findings on an ECG or structural heart disease, those whose clinical history suggests an arrhythmic cause of the syncope, and those with a family history of sudden death. EP testing should not be performed in patients with normal findings on an ECG and no heart disease and in whom the clinical history does not suggest an arrhythmic cause of the syncope. The class II indications for performing EPS are shown in **Table 43.5**, which indicates that EP testing is appropriate when the results may have an impact on treatment and also in patients with "high-risk" occupations, in whom every effort should be expended to determine the probable cause of the syncope. EP testing is no longer indicated for patients with a severely depressed ejection fraction, because in this setting an implantable cardioverter-defibrillator (ICD) is indicated regardless of the presence or mechanism of the syncope.[1,2]

TABLE 43.5

Indications for and Diagnostic Findings of Electrophysiologic (EP) Testing in Evaluation of Patients with Syncope

INDICATIONS/DIAGNOSTIC CRITERIA	CLASS	LEVEL OF EVIDENCE
Indications		
In patients with ischemic heart disease when the initial evaluation suggests an arrhythmic cause and there is no established indication for an ICD.	I	B
In patients with BBB, EPS should be considered when noninvasive tests do not establish a diagnosis.	IIa	B
In patients with syncope preceded by sudden and brief palpitations when noninvasive tests do not establish a diagnosis.	IIb	B
In patients with syncope and Brugada syndrome, ARVD, or hypertrophic cardiomyopathy, EPS is appropriate in selected cases.	IIb	C
In patients with high-risk occupations, in whom every effort to exclude a cardiovascular cause of syncope is warranted.	IIb	C
EPS is not recommended in syncopal patients with normal findings on an ECG, no structural heart disease, and no palpitations.	III	B
Diagnostic Criteria		
EPS is diagnostic and no additional tests are required in the following situations:		
Sinus bradycardia and a prolonged CSNRT (>525 msec)	I	B
BBB and either a baseline H-V interval ≥100 msec or second- or third-degree His-Purkinje block during incremental atrial pacing or with pharmacologic challenge	I	B
Induction of sustained monomorphic VT in patients with a previous myocardial infarction	I	B
Induction of SVT with reproduction of the hypotensive or spontaneous symptoms	I	B
H-V interval between 70 and 100 msec should be considered diagnostic.	IIa	B
Induction of polymorphic VT or VF in patients with Brugada syndrome, patients with ARVD, or patients resuscitated from cardiac arrest.	IIb	B
Induction of polymorphic VT or VF in patients with ischemic disease or DCM should not be considered a diagnostic finding.	III	B

ARVD, Arrhythmogenic right ventricular dysplasia; *BBB,* bundle branch block; *CSNRT,* corrected sinus node recovery time; *DCM,* dilated cardiomyopathy; *EPS,* electrophysiologic study; *H-V,* His-ventricular; *ICD,* implantable cardioverter-defibrillator; *VF,* ventricular fibrillation; *VT,* ventricular tachycardia.

Modified from Moya A, Sutton R, Ammirati F, et al. Guidelines for the diagnosis and management of syncope 2009. Eur Heart J 2009;30:2631.

Electrophysiologic Testing Protocol

A comprehensive EP evaluation should be performed in patients with syncope, including evaluation of sinus node function by measuring the sinus node recovery time (SNRT) and evaluation of AV conduction

by measuring the His-ventricular (H-V) interval at baseline, with atrial pacing, and following pharmacologic challenge with intravenous procainamide. In addition, programmed electrical stimulation using standard techniques should be performed to evaluate the inducibility of ventricular and supraventricular arrhythmias. Although the minimal suggested EP protocol includes only double extra stimuli and two basic drive train cycle lengths, it is common practice in the United States to include triple extra stimuli and three basic drive train cycle lengths. It is also common practice to limit the shortest coupling interval to 200 milliseconds. In select patients in whom suspicion for ventricular arrhythmia is high, EP testing with atrial and ventricular programmed stimulation may be repeated following an infusion of isoproterenol, which is of particular importance for patients suspected of having a supraventricular arrhythmia, such as AV nodal reentrant tachycardia or orthodromic AV reciprocating tachycardia, as the cause of the syncope.

Sinus node function is evaluated during EP testing primarily by determining the SNRT. Identification of sinus node dysfunction as the cause of syncope is uncommon during EP tests (<5%). The sensitivity of an abnormal SNRT or corrected SNRT (CSNRT) is approximately 50% to 80%. The specificity of an abnormal SNRT or CSNRT is less than 95%. It is important to note that the absence of evidence of sinus node dysfunction during EP testing does not exclude a bradyarrhythmia as the cause of the syncope (**see Chapter 35**).

During EP testing, AV conduction is assessed by measuring the AV nodal–to–His bundle conduction time (A-H interval) and the His bundle–to–ventricular conduction time (H-V interval) and also by determining the response of AV conduction to incremental atrial pacing and atrial premature stimuli. If the results of an initial assessment of AV conduction in the baseline state are inconclusive, procainamide (10 mg/kg) can be administered intravenously and atrial pacing and programmed stimulation repeated. Findings on EPS that allow heart block to be established as the probable cause of the syncope are bundle branch block and a baseline H-V interval of 100 milliseconds or longer, or demonstration of second- or third-degree His-Purkinje block during incremental atrial pacing or provoked by an infusion of procainamide (**see Table 43.5**). An H-V interval of 70 to 100 milliseconds is of less certain diagnostic value. In studies of EP testing to evaluate patients with syncope, AV block was identified as the probable cause of syncope in approximately 10% to 15% of patients.

Although it is uncommon for SVT to result in syncope, this is an important diagnosis to establish because most types of supraventricular arrhythmias can be cured with catheter ablation (**see Chapters 36 and 37**). The usual setting in which SVT causes syncope is in a patient with underlying heart disease and/or limited cardiovascular reserve, a patient with SVT of abrupt onset and with an extremely rapid rate, or a patient who has a propensity for the development of neurally mediated syncope. The typical pattern is the development of syncope or near-syncope at the onset of the SVT because of an initial drop in BP. The patient often regains consciousness despite continuation of the arrhythmia as a result of activation of a compensatory mechanism. Completion of a standard EP test allows accurate identification of most types of supraventricular arrhythmias that may have caused the syncope, and it should be repeated during an isoproterenol infusion to increase the sensitivity of the study, particularly for detecting AV nodal reentrant tachycardia in a patient with dual–AV node physiology or catecholamine-sensitive atrial fibrillation. According to the 2009 European guidelines on management of syncope, an EPS is considered diagnostic of SVT as the cause of syncope when induction of a rapid supraventricular arrhythmia reproduces the hypotensive or spontaneous symptoms[2] (**see Table 43.5**). A supraventricular arrhythmia is diagnosed as the probable cause of syncope in fewer than 5% of patients who undergo EP testing for evaluation of syncope of unknown origin, but the probability is increased in patients who report a history of palpitations (“heart racing”) before syncope.

Ventricular tachycardia is the most common abnormality uncovered during EP testing in patients with syncope and was identified as the probable cause in approximately 20% of patients (**see Chapter 39**). In general, an EP test is interpreted as positive for VT when sustained monomorphic VT is induced. Induction of polymorphic VT and ventricular fibrillation (VF) may represent a nonspecific response to EP testing. The diagnostic and prognostic importance of induction of polymorphic VT or VF remains uncertain. According to the 2009 European guidelines on management of syncope, an EPS is considered diagnostic of VT as the cause of the syncope when sustained monomorphic VT is induced[2] (**see Table 43.5**), with less certain diagnostic value with induction of polymorphic VT or VF in patients with Brugada syndrome or arrhythmogenic right ventricular dysplasia and in patients resuscitated from cardiac arrest. The role of EP testing and pharmacologic challenge with procainamide in syncope patients with suspected Brugada syndrome is controversial.[19]

Overall, approximately one third of patients with syncope referred for diagnostic EP testing have a presumptive diagnosis established.

Test to Screen for Neurologic Causes of Syncope

Syncope as an isolated symptom rarely has a neurologic cause. As a result, widespread use of tests to screen for neurologic conditions is rarely diagnostic.[1,2] In many institutions, CT scans, electroencephalograms (EEGs), and carotid duplex scans are overused; these are obtained in more than 50% of patients with syncope. A diagnosis is almost never uncovered that was not first suspected on the basis of a careful history and neurologic examination. Transient ischemic attacks that result from carotid disease are not accompanied by LOC. No studies have suggested that carotid Doppler ultrasonography is beneficial in patients with syncope. EEGs should be obtained only in patients with a relatively high likelihood of epilepsy. CT and MRI should be avoided in patients with uncomplicated syncope (**see Chapters 17 and 18**). Although the low diagnostic yield of screening "neurologic tests" has been recognized for more than a decade, they continue to be overused and result in a dramatic increase in costs.

The 2017 ACC/AHA/HRS syncope guidelines state that MRI and CT of the head are not recommended in the routine evaluation of patients with syncope in the absence of focal neurologic findings or head injury that support further evaluation (class III, LOE B-NR). The guidelines also provide a class III recommendation for the routine use of carotid artery imaging and EEG in the evaluation of patients with syncope.[1]

Approach to the Evaluation of Patients With Syncope

Fig. 43.1 outlines the approach to the diagnostic evaluation of a patient with transient LOC proposed by the European Society of Cardiology Task Force on Syncope.[2] This is consistent with the approach also recommended in the 2017 ACC/AHA/HRS syncope guidelines.[1] The initial evaluation begins with a careful history, physical examination, supine and upright BP, and a 12-lead ECG, followed by additional testing in select patient subgroups, including carotid sinus massage, echocardiography, ECG monitoring, and tilt-table testing, as discussed earlier. The various types of neurologic testing are generally of little or no value except in the case of head trauma and when nonsyncopal causes of transient LOC such as epilepsy are suspected.

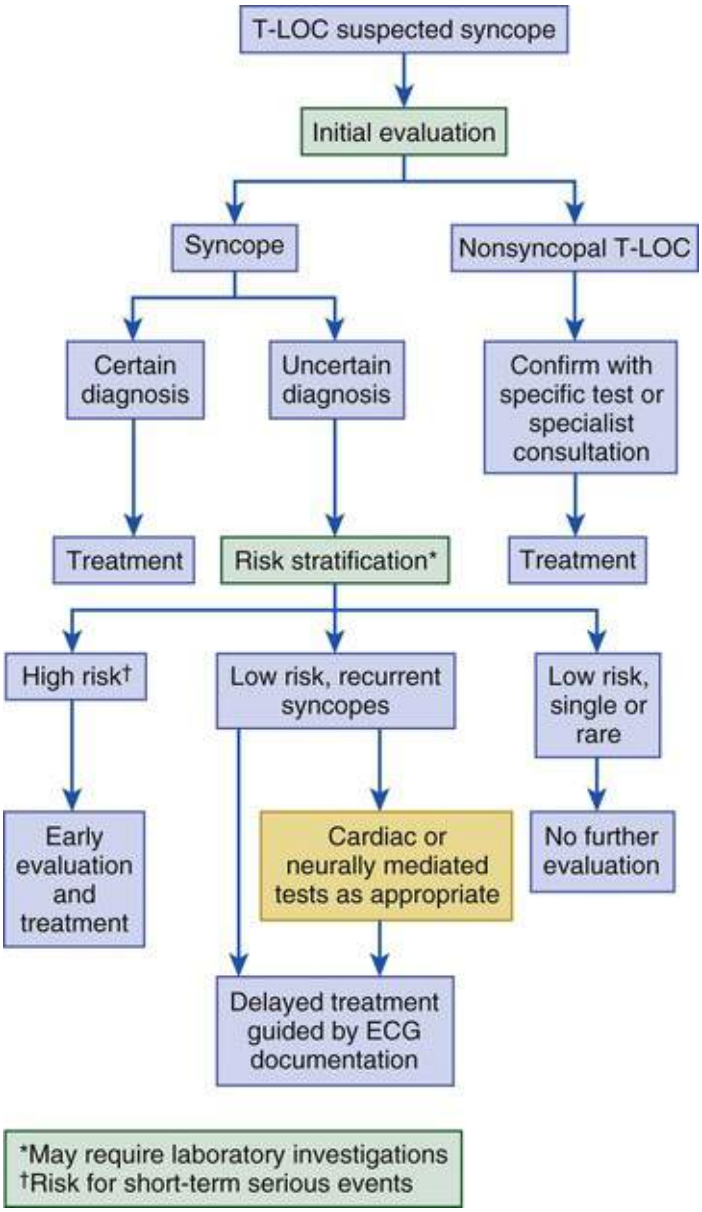

FIGURE 43.1 Diagnostic approach to the evaluation of patients with transient loss of consciousness (T-LOC) and syncope.

Based on this initial evaluation, patients can be classified into those with true syncope and those with nonsyncopal transient LOC. Patients with syncope can be further divided into two groups: those in whom a certain diagnosis has been established and in whom treatment can be initiated and those with an uncertain diagnosis. For the latter, attention should focus on determining whether the patient is at increased risk for a cardiovascular event or death. These patients should be hospitalized and/or should undergo an intensive timely outpatient cardiovascular evaluation that may include exercise stress testing, cardiac catheterization, and EP testing (**Table 43.6**). Conversely, patients who have experienced only a single episode of syncope and are determined to be at low risk for a cardiovascular event or death may require no further evaluation. Patients who fall between these two extremes can undergo further testing based on results of the initial evaluation (**see Fig. 43.1**). When this diagnostic approach has been completed, a probable cause of syncope can be determined in more than three fourths of patients.

TABLE 43.6

Clinical Variables for Identification of High-Risk Syncope Patients Who May Benefit from Hospitalization or an Accelerated Outpatient Evaluation

Severe structural heart disease (low ejection fraction, previous myocardial infarction, heart failure)
Clinical or ECG features suggesting arrhythmic syncope
Syncope during exertion or while supine
Palpitations at the time of syncope
Family history of sudden death
Nonsustained ventricular tachycardia
Bifascicular block or QRS >120 msec
Severe sinus bradycardia (<50 beats/min) in the absence of medications or physical training
Preexcitation
Prolonged or very short QT interval
Brugada ECG pattern (right bundle branch block with ST elevation in leads V_1-V_3)
Arrhythmogenic right ventricular dysplasia ECG pattern (T wave inversion in leads V_1-V_3 with or without epsilon waves)
ECG suggestive of hypertrophic dilated cardiomyopathy
Clinical evidence or suspicion of a pulmonary embolus (clinical setting, sinus tachycardia, shortness of breath)
Severe anemia
Important comorbid conditions
Significant electrolyte abnormalities
Severe anemia

The European and ACC/AHA/HRS guidelines on management of syncope have called attention to the importance of a structured care pathway in the evaluation of patients with syncope.[1,2,20,21] Other studies have reported favorable outcomes when a syncope evaluation unit or standardized approach to the evaluation of syncope is used.[22,23]

Management of Patients With Syncope

Treatment of a patient with syncope has three goals: (1) prolong survival, (2) prevent traumatic injuries, and (3) prevent recurrences of syncope. The approach to treatment of a patient with syncope depends largely on the cause and mechanism of the syncope. For example, the appropriate treatment of a patient with syncope related to AV block would be a pacemaker in most situations. However, a patient with syncope secondary to heart block in the setting of an inferior wall myocardial infarction will not usually require a permanent pacemaker because the heart block usually resolves spontaneously. Similarly, heart block resulting from neurally mediated syncope does not generally require pacemaker implantation. Treatment of a patient with syncope related to Wolff-Parkinson-White syndrome typically involves catheter ablation, and treatment of a patient with syncope related to VT or in the setting of ischemic or nonischemic cardiomyopathy would probably involve placement of an implantable defibrillator (**see Chapter 41**). However, ICD implantation may not be required for patients with VT/VF occurring within 48 hours of an acute myocardial infarction. For other types of syncope, optimal management may involve discontinuation of an offending pharmacologic agent, an increase in salt intake, or education of the patient.[24]

Other issues that need to be considered include the indication for hospitalization of a patient with syncope and the duration of driving restrictions. Current guidelines recommend that patients with syncope be hospitalized when there is known or suspected heart disease, ECG abnormalities suggestive of arrhythmic syncope, syncope with severe injury or during exercise, and syncope in patients with a family history of sudden death (**see Table 43.6**).[1]

Physicians who care for patients with syncope are often asked to address the issue of driving risk. Patients who experience syncope while driving pose a risk both to themselves and to others. A recent study has reported that a prior hospitalization for syncope was associated with a small increase in the risk

of a motor vehicle accident during follow-up.[25] Although some would argue that all patients with syncope should never drive again because of the theoretical possibility of recurrence, this is an impractical solution that would be ignored by many patients. Factors that should be considered when making a recommendation for a particular patient include (1) the potential for recurrent syncope, (2) the presence and duration of warning symptoms, (3) whether syncope occurs while seated or only when standing, (4) how often and in what capacity the patient drives, and (5) whether any state laws may be applicable.

When considering these issues, physicians should note that acute illnesses, including syncope, are unlikely to cause a motor vehicle accident. The American Heart Association and the Canadian Cardiovascular Society have published guidelines concerning this issue. For noncommercial drivers, it is generally recommended that driving be restricted for several months. If the patient remains asymptomatic for several months, driving can then be resumed.

Neurally Mediated Syncope

Because neurally mediated syncope and reflex syncope are so common, treatment options are reviewed[1,13] (**Table 43.7**). Treatment of syncope resulting from neurally mediated hypotension begins with a careful history with particular attention on identifying precipitating factors, quantifying the degree of salt intake and current medication use, and determining whether the patient has a previous history of peripheral edema, hypertension, asthma, or other conditions that may alter the approach used for treatment. For most patients with neurally mediated syncope, particularly those with infrequent episodes associated with an identifiable precipitant, education plus reassurance is sufficient. Patients should be educated about common precipitating factors, such as dehydration, prolonged standing, alcohol, and medications (e.g., diuretics, vasodilators). Patients should also be taught to sit or lie down at the onset of symptoms and to initiate physical counterpressure maneuvers. One recent study reported that a standardized education protocol significantly reduced traumatic injuries and recurrence of syncope.[24] In this trial the syncope burden was reduced from 0.35 ±0.3 at initial evaluation to 0.08 ±0.02 during follow-up. Volume expansion by salt supplementation is also frequently recommended. Ingestion of approximately 500 mL of water acutely improves orthostatic tolerance to tilt in healthy persons and may be of value as prophylaxis for syncope in blood donors. The effectiveness of water ingestion alone in the management of patients with recurrent neurally mediated syncope has not been well studied.

TABLE 43.7

Treatment of Neurally Mediated and Reflex-Mediated Syncope

TREATMENT	CLASS	LEVEL OF EVIDENCE
Patient education on diagnosis and prognosis.	I	C-EO
Physical counterpressure maneuvers can be useful in patients with vasovagal syncope (VVS) who have a sufficiently long prodromal period.	IIa	B-R
Midodrine is reasonable in patients with recurrent VVS with no history of hypertension, heart failure, or urinary retention. Cardiac pacing should be considered with frequent recurrent reflex syncope, age >40 years, and documented spontaneous cardioinhibitory response during monitoring of recurrent syncope.	IIa	B-R
The use of orthostatic training is uncertain in patients with frequent VVS. Midodrine may be indicated in patients with neurally mediated syncope refractory to conservative treatment approaches.	IIb	B-R
Dual-chamber pacing might be reasonable in a select population of patients age 40 or older with recurrent VVS and prolonged spontaneous pauses.	IIb	B-R
Fludrocortisone might be reasonable for patients with recurrent VVS and inadequate response to salt and fluid intake, unless contraindicated.	IIb	B-R
Beta blockers might be reasonable in patients age 42 or older with recurrent VVS.	IIb	B-NR
Encouraging increased salt and fluid intake may be reasonable in select patients with VVS, unless contraindicated.	IIb	C-LD
In select patients with VVS, it may be reasonable to reduce or withdraw medications that can cause hypotension when appropriate.	IIb	C-LD
In select patients with VVS, a selective serotonin reuptake inhibitor might be considered.	IIb	C-LD
Beta blockers are not indicated.	IIb	C-LD

Modified from Shen W, Sheldon RS, Benditt D, et al. 2017 ACC/AHA/HRS guideline for the evaluation and management of patients with syncope. J Am Coll Cardiol 2017 [in press].

A recent important shift in the approach used for the treatment of neurally mediated syncope has resulted from the effectiveness of “physical” measures and maneuvers in the treatment of patients with this condition.[1] Isometric physical counterpressure maneuvers such as leg crossing or handgrip with arm tensing can prevent syncope in many patients with neurally mediated hypotension. The 2017 ACC/AHA/HRS guidelines on management of syncope identify the following physical measures as class IIA treatments of neurally mediated syncope.[1] It has been reported that 2 minutes of an isometric handgrip maneuver initiated at the onset of symptoms during tilt testing rendered two thirds of patients asymptomatic. Other studies have demonstrated that tilt (standing) training is effective in the treatment of neurally mediated syncope. Standing training involves leaning against a wall with the heel 10 inches (25 cm) from the wall for progressively longer periods for 2 to 3 months. Standing time should initially be 5 minutes two times per day with a progressive increase to 40 minutes twice daily. Although the results of nonrandomized studies of standing training have been positive, the results of randomized trials suggest that standing training may have only limited effectiveness.

In contrast to these effective physical maneuvers, the value of pharmacologic agents is less certain. Medications that are generally relied on to treat neurally mediated syncope include beta blockers, fludrocortisone, serotonin reuptake inhibitors, and midodrine. Despite the widespread use of these agents, the quality and quantity supporting these medications in the treatment of neutrally mediated syncope are limited. **Table 43.7** shows the recommendation class for each of these medications based on the 2017 ACC/AHA/HRS syncope guidelines.[1] Even though beta blockers were previously considered by many to be first-line therapy, recent studies have reported that the beta blockers metoprolol, propranolol, and nadolol are no more effective than placebo.[13] A recent subanalysis of data from a randomized prospective study evaluating the effectiveness of fludrocortisone (Florinef) reported weak evidence that fludrocortisone may be of therapeutic value despite missing its primary endpoint.[26]

Even though pacemakers have also been found to be valuable in the treatment of some patients with neurally mediated syncope in nonrandomized and nonblinded clinical trials, blinded randomized clinical trials have shown that pacemakers have no benefit.[27] In contrast, one recent randomized trial demonstrated the benefit of implanted pacemakers in a select population of patients with neurally mediated syncope.[28] This double-blind placebo-controlled clinical trial randomly assigned 77 patients 40 years or older with recurrent neurally mediated syncope, documented by implantable loop monitor as associated with 3 seconds or longer of asystole or a 6-second or greater pause without syncope, to dual-chamber pacing

with rate-drop hysteresis or to sensing only. The 2-year estimated syncope recurrence rate was 57% with pacing off and 25% with pacing on. Overall, the risk for recurrent syncope was reduced by 57% with pacing. Although the 2008 guidelines for device-based therapy state that pacemaker implantation has a class IIb indication for the treatment of patients with highly symptomatic, neurally mediated syncope associated with bradycardia documented spontaneously or at tilt-table testing, this recent prospective randomized clinical trial provides stronger evidence for pacemaker therapy in patients with neurally mediated syncope who meet the clinical profile of the patient population enrolled in this trial. The 2017 ACC/AHA/HRS syncope guidelines provide a class IIb indication for pacing in a specific subgroup of patients with neutrally mediated syncope over 40 years of age[1] (**see Table 43.7**).

When considering pacemaker implantation for patients with neurally mediated syncope, pacemakers that provide specialized pacing algorithms are often selected. These include rate-drop hysteresis or closed-loop stimulation. Closed-loop stimulation is a form of rate-adaptive pacing that responds to myocardial contraction dynamics by measuring variations in right ventricular intracardiac impedance. When an incipient, neurally mediated syncopal episode is detected, the pacing rate is increased. Although no prospective randomized clinical trials exist to determine which pacing feature is superior, several recent nonrandomized or retrospective trials suggest that closed-loop stimulation may be preferable.[28,29] Further research on this evolving approach to the management of neurally mediated syncope is needed.

Future Perspectives

As the U.S. population ages and the prevalence of cardiac disease increases, it is inevitable that syncope will become an increasingly common and important problem that physicians of all types will need to address. The 2017 ACC/AHA/HRS syncope guidelines provide a timely, comprehensive update on syncope and also emphasize that further research is needed. A new generation of experts in syncope must help develop further knowledge regarding the diagnosis and management of patients with syncope. A particularly challenging problem is the management of patients with various types of orthostatic hypotension. Similarly, despite that neurally mediated syncope is the most common cause of syncope, remarkably little progress has been made in understanding the mechanisms of this condition or identifying effective therapies. It is hoped that the next generation of researchers in the field will make important discoveries that will be critical to the development of new treatment approaches for the millions of patients who suffer from this condition.

The Vascular Biology of Atherosclerosis

Peter Libby

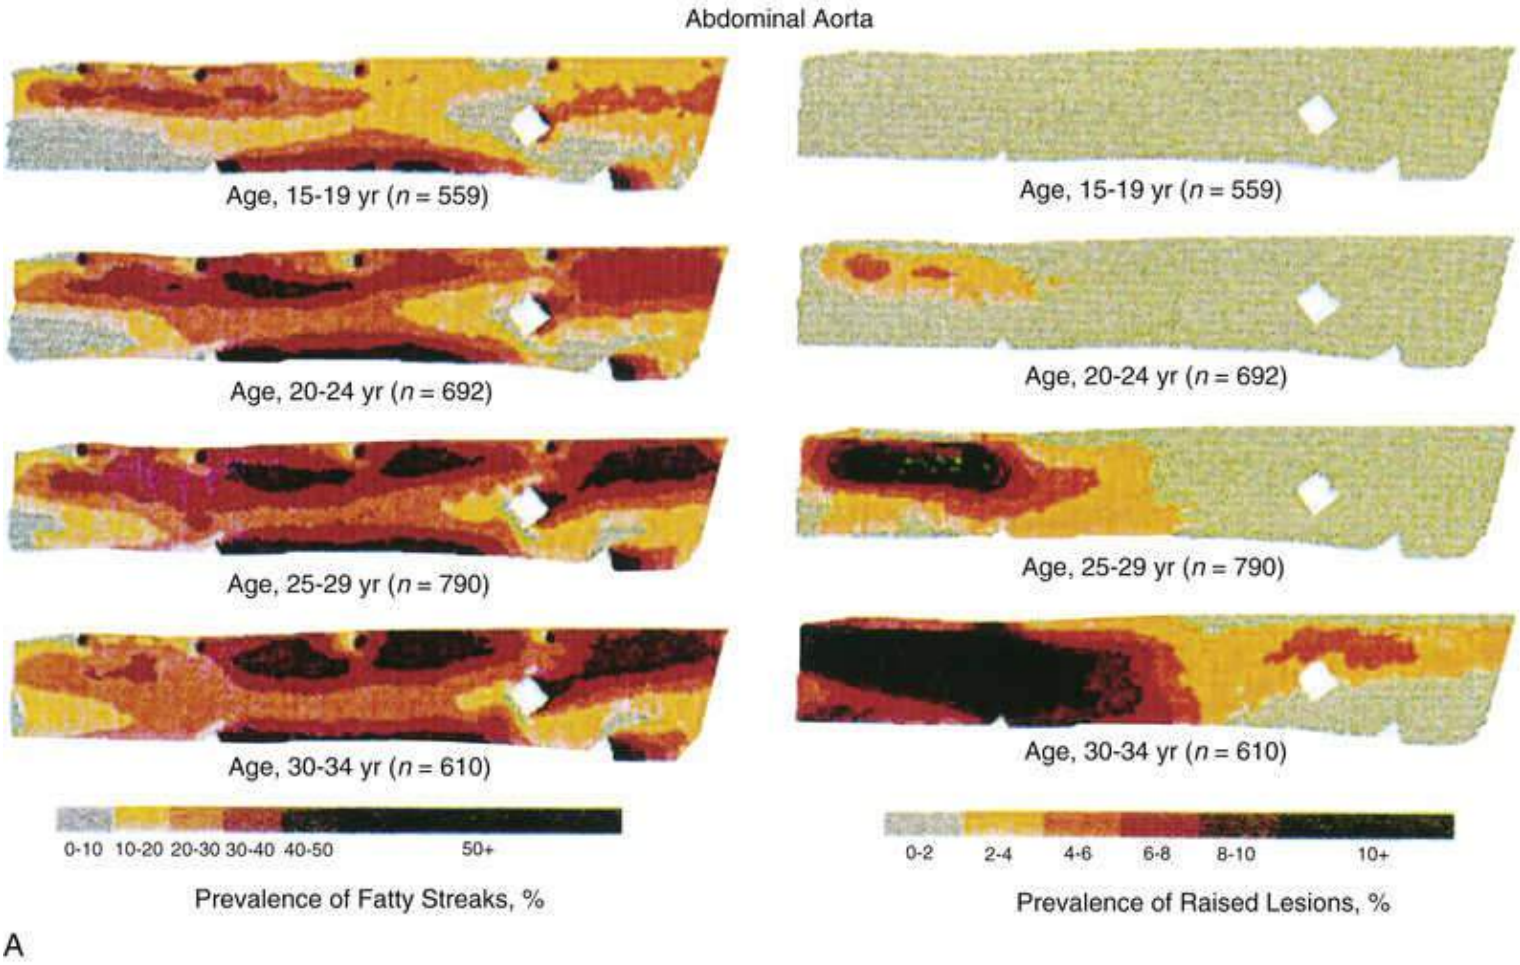
Overview and Background

The 20th century witnessed a remarkable evolution in concepts concerning the pathogenesis of atherosclerosis. This disease has a venerable history, having left traces in the arteries of Egyptian mummies.[1] Atherosclerosis became epidemic as populations increasingly survived early mortality associated with communicable diseases and malnutrition. Economic development and urbanization promoted habits of poor diet (e.g., a surfeit of saturated fats) and diminished physical activity, which can favor atherogenesis (**see Chapters 1, 45, 49, and 50**). These environmental factors have spread steadily, such that we face an epidemic of atherosclerosis that reaches far beyond Western societies.[2]

Currently, arteries are no longer viewed as inanimate tubes. In the mid-19th century, Rudolf Virchow recognized the participation of cells in atherogenesis. A controversy raged between Virchow, who viewed atherosclerosis as a proliferative disease, and Carl von Rokitansky, who believed that atheroma derived from healing and resorption of thrombi. Experiments performed in the early part of the 20th century used dietary modulation to produce fatty lesions in the arteries of rabbits and ultimately identified cholesterol as the culprit. These observations, followed by the characterization of human lipoprotein particles in the mid-20th century, promoted the insudation of lipids as a cause for atherosclerosis. Elements of all these mechanisms indeed contribute to atherogenesis. This chapter summarizes evidence from human studies, animal experimentation, and in vitro work and presents a synoptic view of atherogenesis from the biologic perspective.[3]

Acquaintance with the vascular biology of atherosclerosis should prove useful to the practitioner. Our daily contact with this common disease lulls us into a complacent belief that we understand it better than we actually do. For example, we have begun to understand why atherosclerosis affects certain regions of the arterial tree preferentially and why its clinical manifestations occur only at certain times. Atherosclerosis can involve both large and midsize arteries diffusely.[4] Postmortem and intravascular ultrasound clinical studies have revealed widespread intimal thickening in patients with atherosclerosis. Many asymptomatic persons have intimal lesions in their coronary or carotid arteries even in the early decades of life. At the same time, atherosclerosis produces focal stenoses in certain areas of affected vessels much more often than in others.

Atherosclerosis also displays heterogeneity in time; this disease has both chronic and acute manifestations. Few human diseases have a longer “incubation” period than atherosclerosis, which begins to affect the arteries of many Americans in the second and third decades of life (**Fig. 44.1**). Indeed, many young Americans have abnormal thickening of the coronary arterial intima; yet typically, symptoms of atherosclerosis emerge only after several decades of delay, characteristically appearing even later in women. Despite this indolent time course and prolonged period of clinical inactivity, the dreaded complications of atheroma—myocardial infarction, unstable angina, and stroke—typically occur suddenly and often without warning.



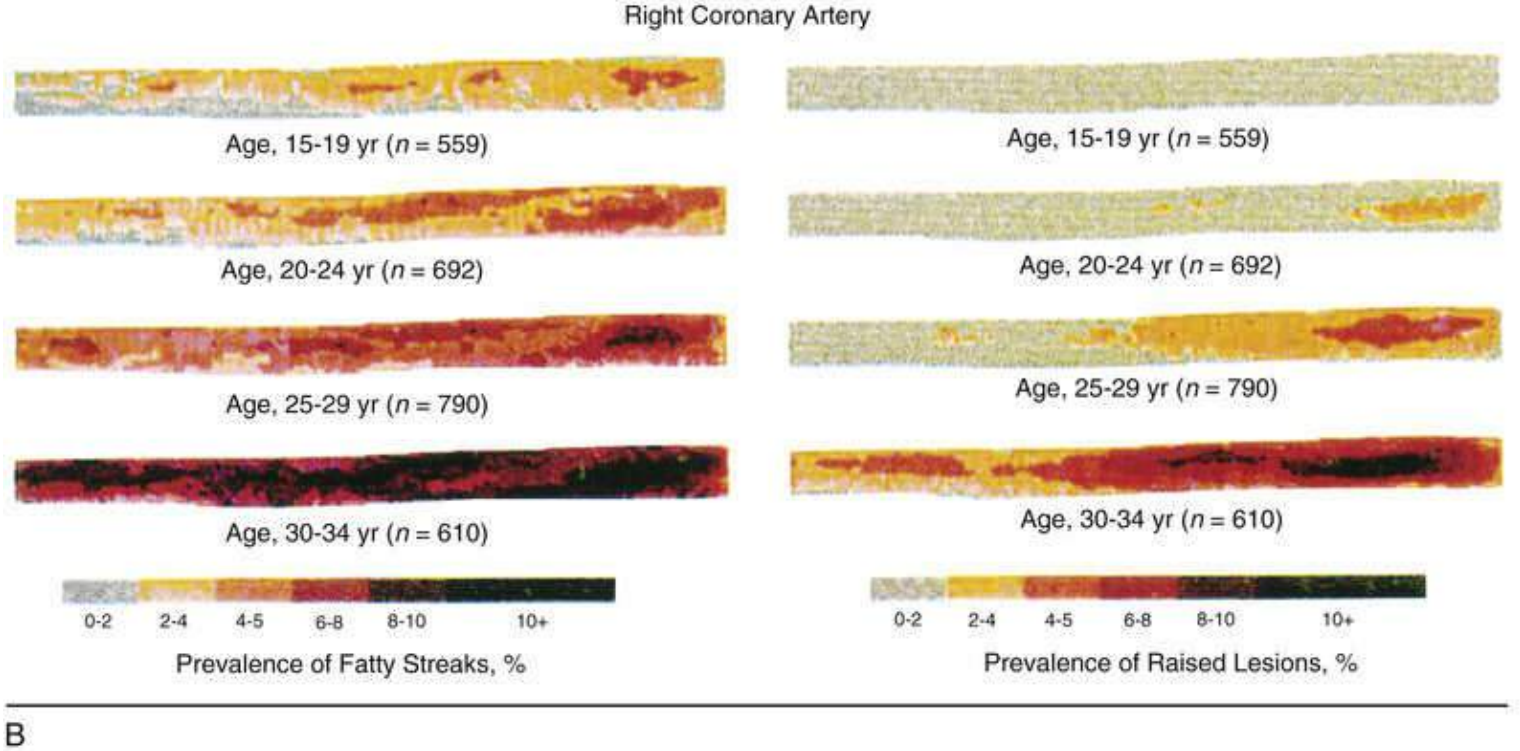


FIGURE 44.1 Prevalence maps of fatty streaks and raised lesions in the abdominal aorta: Pseudocolored representations of morphometric analysis of composite data, from the Pathobiological Determinants of Atherosclerosis in Youth (PDAY) study, on more than 2800 aortas from Americans younger than age 35 who succumbed for noncardiac reasons. **A,** Note the early involvement of the dorsal surface of the infrarenal abdominal aorta by fatty streaks, followed by raised lesions. **B,** A similar but slightly slower progression of lesions affects the right coronary artery. The *bar scales* at bottom in both **A** and **B** show the coding for the pseudocoloring. (From Strong JP, Malcolm GJ, McMahan CA, et al. Prevalence and extent of atherosclerosis in adolescents and young adults. JAMA1999;281:727.)

Another poorly understood issue regarding atherogenesis is its role in the narrowing, or stenosis, of some vessels and in the dilation, or ectasia, of others. Traditionally, cardiologists have focused on stenoses in coronary arteries, but atherosclerosis commonly manifests as aneurysms, as in the aorta. Even in the life history of a single atherosclerotic lesion, a phase of ectasia known as *positive remodeling*, or *compensatory enlargement*, precedes the formation of stenotic lesions. Contemporary vascular biology has begun to shed light on some of these puzzling aspects of atherosclerosis.

Structure of the Normal Artery

Cell Types Composing the Normal Artery

Endothelial Cells

The endothelial cell (EC) of the arterial intima constitutes the crucial contact surface with blood. Arterial ECs possess many highly regulated mechanisms of capital importance in vascular homeostasis that often go awry during the pathogenesis of arterial diseases. For example, the EC provides one of the only surfaces, either natural or synthetic, that can maintain blood in a liquid state during protracted contact (**Fig. 44.2**). This remarkable blood compatibility derives in part from the expression of heparan sulfate proteoglycan molecules on the surface of the EC. These molecules, as with heparin, can serve as a cofactor for antithrombin III, causing a conformational change that allows this inhibitor to bind to and inactivate thrombin. The surface of the EC also contains *thrombomodulin*, which binds thrombin molecules and can exert antithrombotic properties by activating proteins S and C. Should a thrombus begin to form, the normal EC possesses potent fibrinolytic mechanisms associated with its surface. The EC can produce both tissue- and urokinase-type plasminogen activators. These enzymes—t-PA and u-PA, respectively—catalyze the activation of plasminogen to form *plasmin*, a fibrinolytic enzyme. (For a complete discussion of the role of endothelium in hemostasis and fibrinolysis, **see Chapter 93**.)

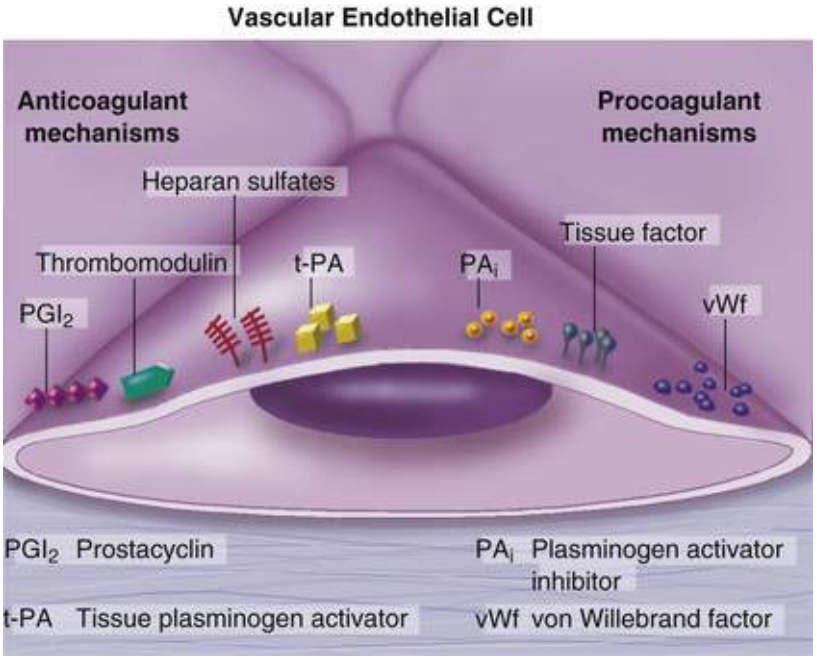

FIGURE 44.2 The endothelial thrombotic balance. This diagram depicts the anticoagulant profibrinolytic functions of the endothelial cell (*left*) and certain procoagulant and antifibrinolytic functions (*right*).

Endothelial cells have a common origin but acquire “bed-specific” characteristics during development. The ECs that form the inner lining of all blood vessels arise during embryogenesis from regions known as the “blood islands,” located on the embryo's periphery. *Angioblasts,* the predecessors of ECs, share this site with the precursors of blood cells. Despite arising from the same site, cells display considerable heterogeneity even during embryologic and early postnatal development. Although ECs presumably derive from a common precursor, the signals they encounter during vessel development differ. As rudimentary blood vessels begin to form, endothelial precursors interact with surrounding cells. The interchange permits spatial and temporal gradients of various stimuli and their receptors on the ECs, leading to this cell type's heterogeneity in the adult. EC heterogeneity depends on both environmental stimuli and epigenetic features acquired during development.[5] Noncoding RNAs also appear pivotal in the regulation of endothelial functions related to atherogenesis[6] (**see Chapter 7**).

Cells that make up various compartments of the arterial wall may originate from bone marrow during postnatal life, as well as from their traditional embryologic sources. In particular, peripheral blood may contain endothelial precursor cells that may help repair areas of endothelial desquamation, a concept that has generated considerable controversy.

Arterial Smooth Muscle Cells

The second major cell type of the normal artery wall, the smooth muscle cell (SMC), has many important functions in normal vascular homeostasis, as a target of therapies in cardiovascular medicine, and in the pathogenesis of arterial diseases.[7] These cells contract and relax and thus control blood flow through the various arterial beds, generally at the level of the muscular arterioles. In the larger types of arteries involved in atherosclerosis, however, abnormal smooth muscle contraction may cause *vasospasm,* a complication of atherosclerosis that may aggravate the embarrassment of blood flow. SMCs synthesize the bulk of the complex arterial extracellular matrix (ECM) that plays a key role in normal vascular homeostasis and in the formation and complication of atherosclerotic lesions. These cells also can migrate and proliferate, contributing to the formation of intimal hyperplastic lesions, including atherosclerosis and restenosis; stent stenosis after percutaneous intervention; or anastomotic hyperplasia, complicating vein grafts. Death of SMCs may promote destabilization of atheromatous plaques or may favor ectatic remodeling and ultimately aneurysm formation.

In contrast with ECs, thought to derive from a common precursor, SMCs can arise from many sources (**Fig. 44.3**). After ECs form tubes, the rudimentary precursor of blood vessels, they recruit the cells that will become SMCs or *pericytes* (smooth muscle–like cells associated with microvessels). In the descending aorta and arteries of the lower body, the regional mesoderm serves as the source of smooth muscle precursors. The mesodermal cells in somites give rise to the SMCs that invest much of the distal aorta and its branches. In arteries of the upper body, however, SMCs actually can derive from a completely different germ layer—neuroectoderm, rather than mesoderm. Before the neural tube closes, neuroectodermal cells migrate and become the precursors of SMCs in the ascending aorta and some of its branches, including the carotid arteries. SMCs in the coronary arteries derive from mesoderm, but in a special way: The precursors of coronary artery SMCs arise from yet another embryologic source, a structure known as the *proepicardial* organ.

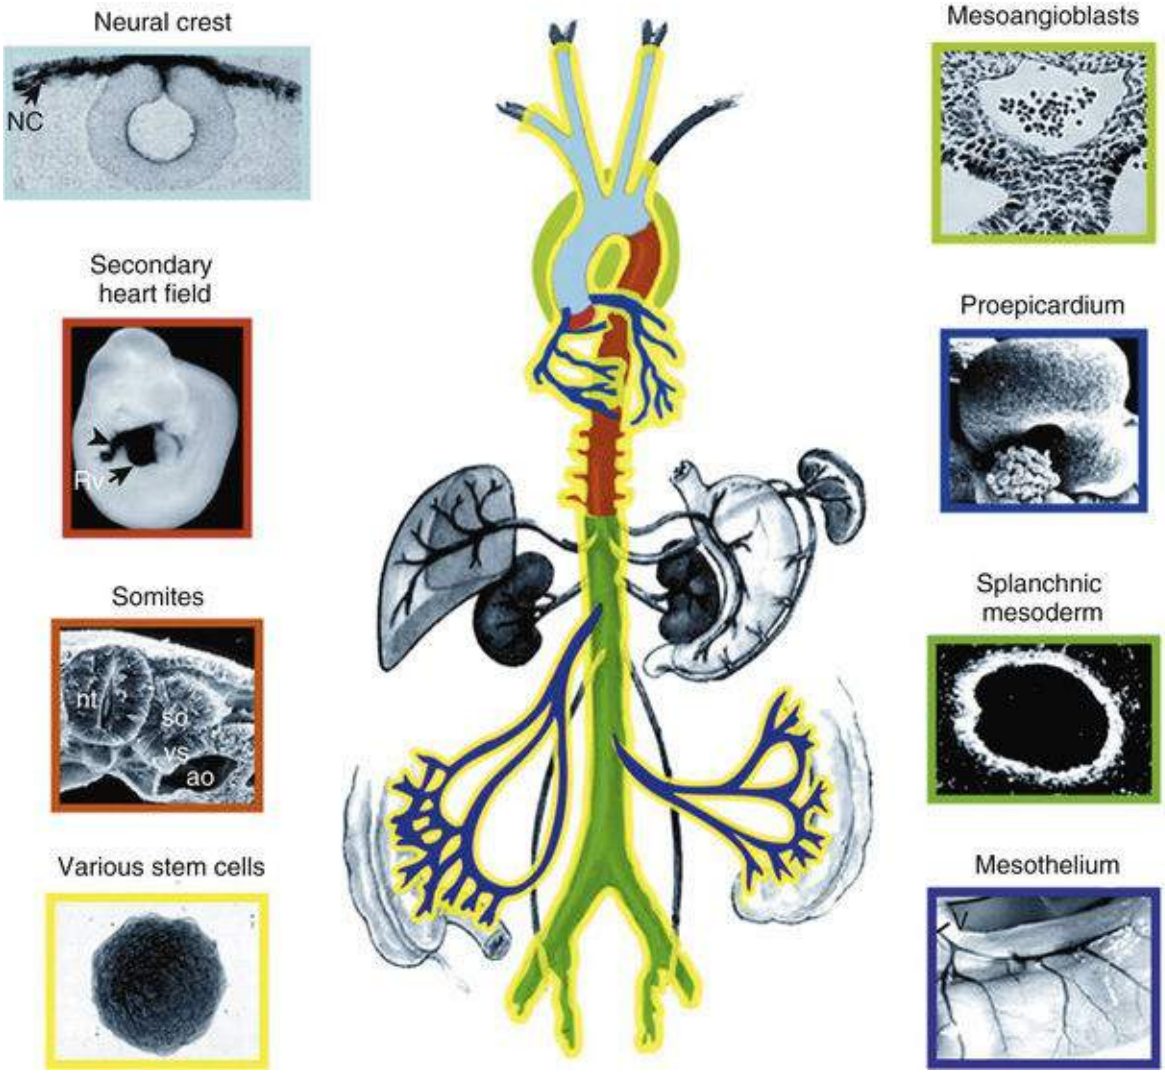

FIGURE 44.3 Diversity of the embryologic origin of vascular smooth muscle cells (SMCs). Different colors represent different embryonic sources for SMCs, as indicated in the outlines on the *boxed images* along the sides of the main drawing. The *yellow outline* indicates local and systemic contributions by various sources of vascular stem cells. The "fate map" (*center*) shows a diverse distribution of SMCs derived from different sources in the aorta and its major branch arteries. With few exceptions, the exact boundaries of SMCs from various sources within the arteries shown are uncertain; accordingly, the boundaries depicted are approximate. In the boxed image at *left* labeled Somites, note the close proximity of the developing dorsal aorta (*ao*) to the ventral sclerotome (*vs*) of the somite (*so*); *NC,* Neural crest; *nt,* neural tube. The lineage-specific boundaries shown may shift during growth and with aging of vessels. *Rv,* Right ventricle. (From Majesky MW. Developmental basis of vascular smooth muscle diversity. Arterioscler Thromb Vasc Biol 2007;27:1248.)

Lineage analyses indicate that large patches of SMCs in arteries arise as expansions of small clones established early in development. A small population of precursor cells may reside in the tunica media of normal arteries that give rise to the SMCs accumulating in injured or atherosclerotic arteries. The transcription factors Krüppel-like factor 4 and myocardin regulate the phenotype of vascular SMCs (**Fig. 44.4**). The heterogeneity of SMCs may have direct clinical implications for understanding several common observations, such as the propensity of certain arteries or regions of arteries to develop atherosclerosis or heightened responses to injury (e.g., proximal left anterior descending coronary artery), and medial degeneration (e.g., proximal aorta in Marfan syndrome). Differential responses of SMCs to regulators of ECM production help explain why the clinical manifestations of systemic defects in fibrillin and elastin characteristically occur locally in the ascending aorta (**see Chapter 63**). The plasticity of SMCs may even extend to giving rise to cells with characteristics and functions of mononuclear phagocytes in murine atherosclerotic plaques.[7]

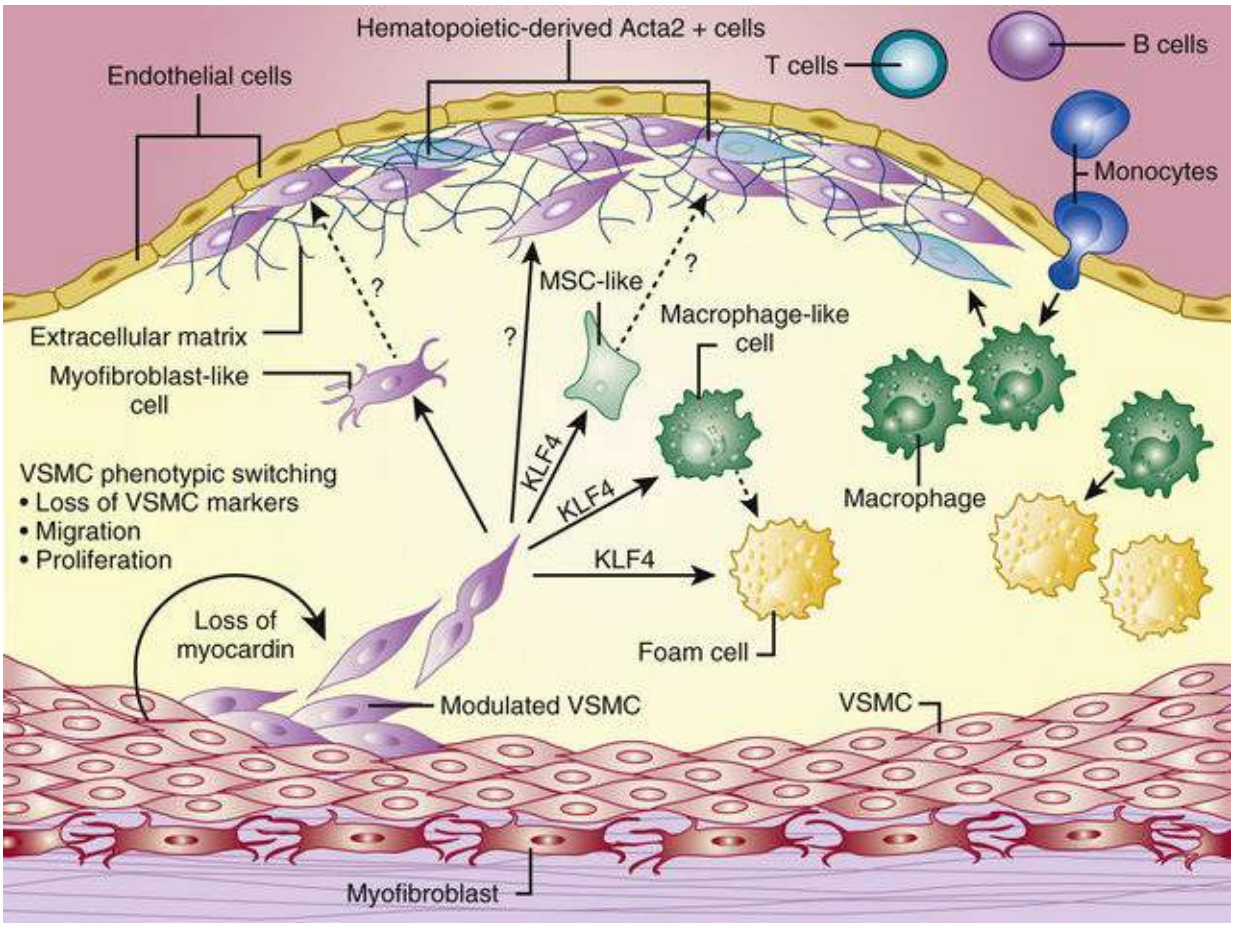

FIGURE 44.4 This diagram summarizes the current knowledge of the identity and origins of vascular smooth muscle cells (VSMCs), mononuclear phagocytes, and their putative derivatives in atheromata. The *solid lines* show pathways known to furnish lesion cells; the *dotted lines* with a "?" indicate possible pathways not yet directly ascertained in animals or in humans. *Acta2,* α-smooth muscle actin; *KLF4,* Krüppel-like factor 4. Layers of the Normal Artery

Intima

An understanding of the pathogenesis of atherosclerosis first requires knowledge of the structure and biology of the normal artery as well as its indigenous cell types. Normal arteries have a well-developed trilaminar structure (**Fig. 44.5**). The innermost layer, the tunica intima, is thin at birth in humans and in many nonhuman species. Although it often is depicted as a monolayer of ECs abutting directly on a basal lamina, the adult human intima actually has a much more complex and heterogeneous structure. The endothelial monolayer resides on a basement membrane containing nonfibrillar collagen types, such as type IV collagen, laminin, fibronectin, and other ECM molecules. With aging, human arteries develop a more complex intima containing arterial SMCs and fibrillar forms of interstitial collagen (types I and III). SMCs produce these ECM constituents of the arterial intima. The presence of a more complex intima, known by pathologists as "diffuse intimal thickening," characterizes most adult human arteries. Some locales in the arterial tree tend to develop a thicker intima than other regions, even in the absence of atherosclerosis (**Fig. 44.6**). For example, the proximal left anterior descending coronary artery often contains a more fully developed intimal cushion of SMCs than that in typical arteries. The diffuse intimal thickening process does not necessarily go hand in hand with lipid accumulation and may occur in persons without substantial burden of atheroma. The internal elastic membrane bounds the tunica intima

abluminally and serves as the border between the intimal layer and the underlying tunica media.

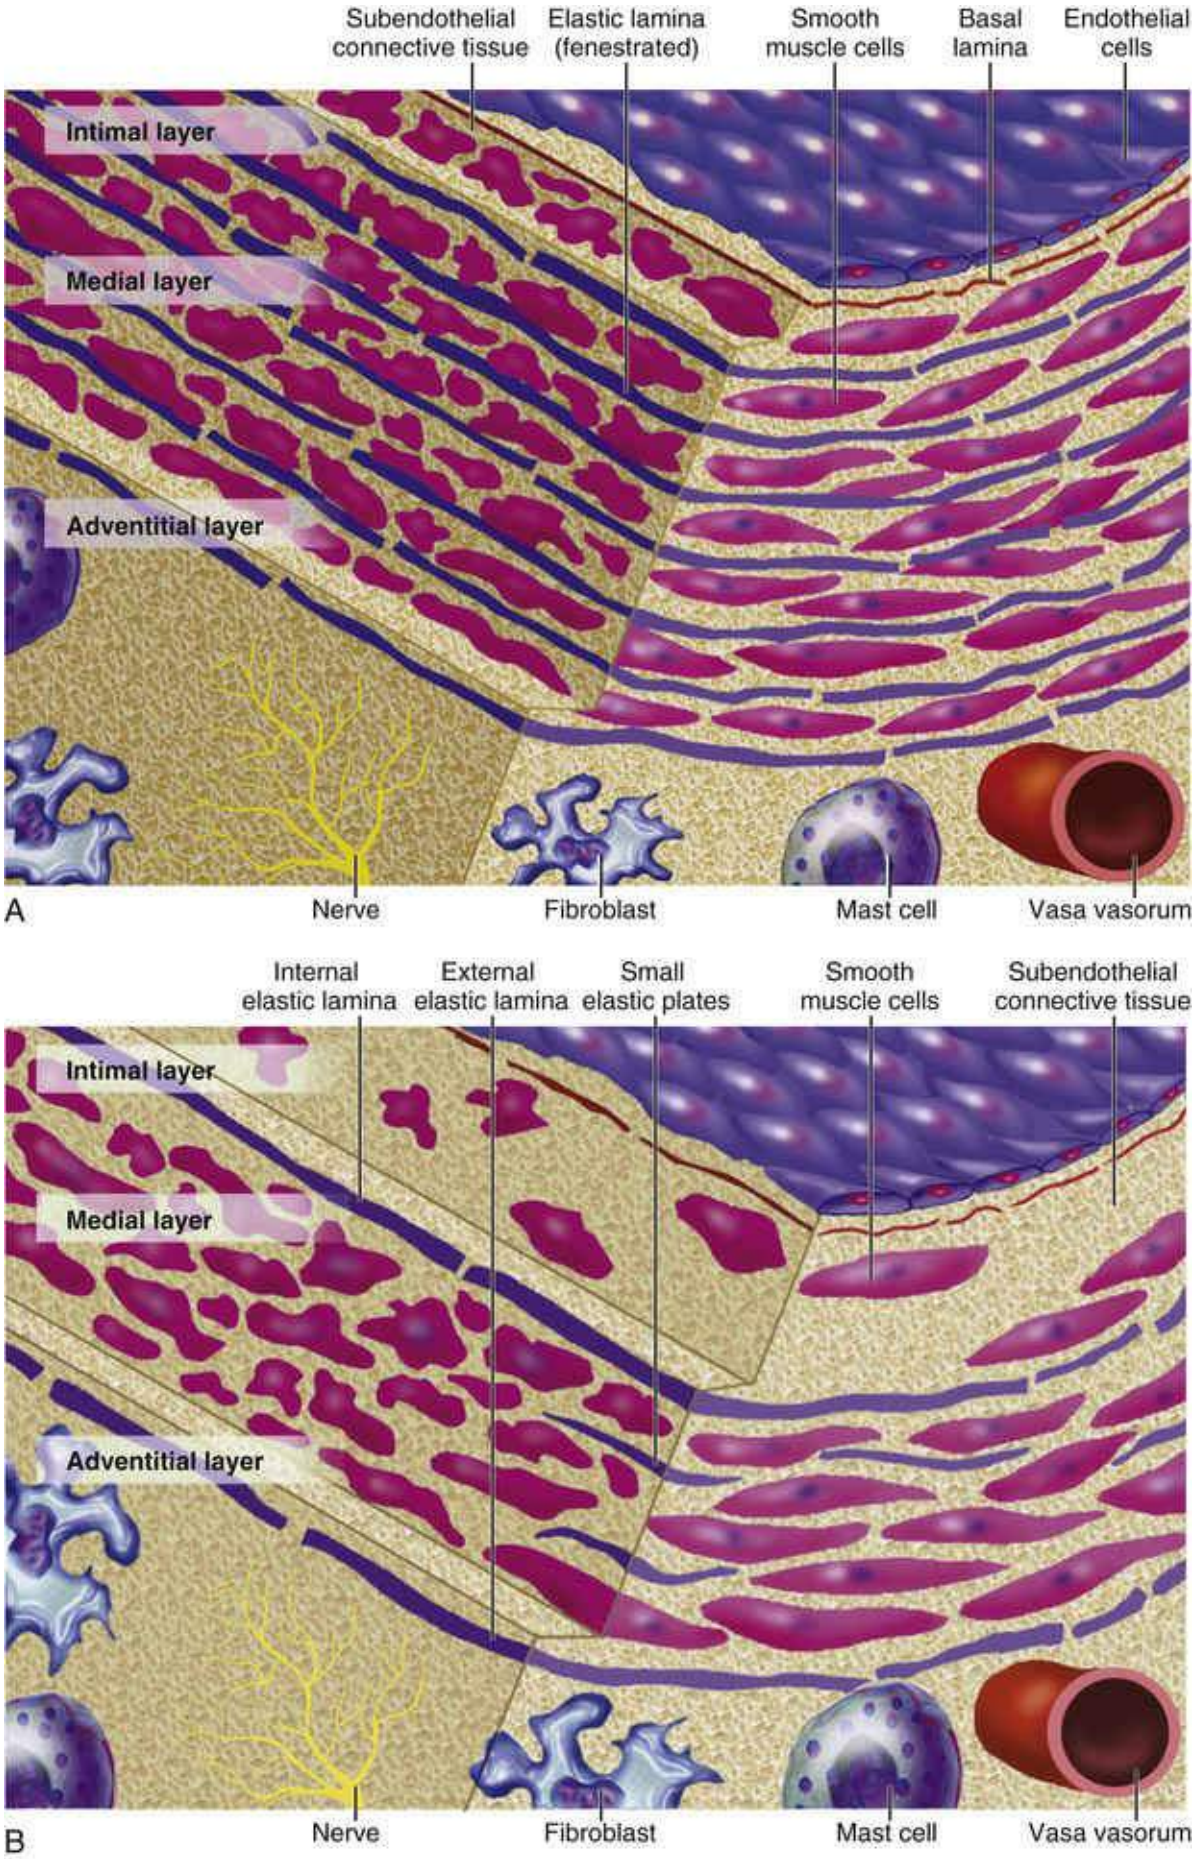

FIGURE 44.5 The structures of normal arteries. **A,** Elastic artery. Note the concentric laminae of elastic tissue that form sandwiches with successive layers of smooth muscle cells (SMCs). Each level of the elastic arterial tree has a characteristic number of elastic laminae. **B,** Muscular artery. In the muscular artery, a collagenous matrix surrounds the SMCs, but the architecture lacks the concentric rings of the well-organized elastic tissue characteristic of larger arteries.

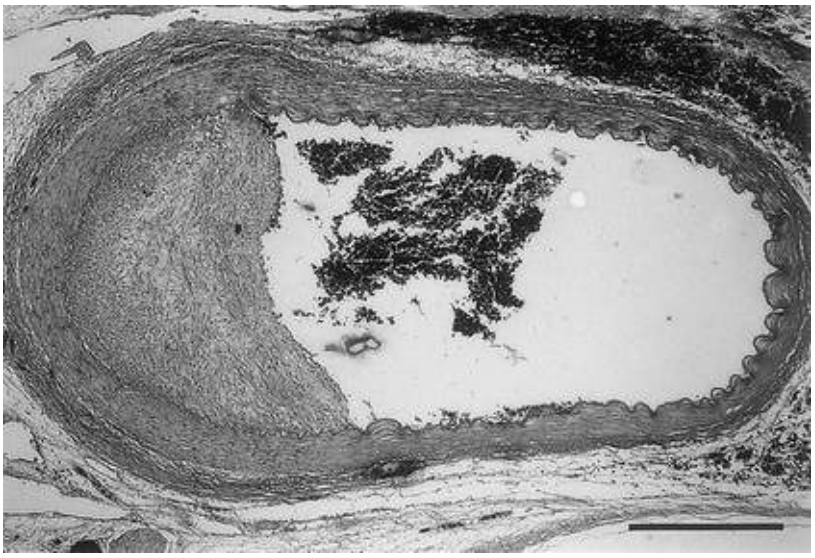

FIGURE 44.6 An intimal cushion shown in cross section through the internal carotid artery of a 10-week-old male infant. Areas in which intimal cushions form in early life tend to develop atheromas more often in later years. *Bar* = 0.5 mm. (From Weniger WJ, Muller GB, Reiter C, et al. Intimal hyperplasia of the infant parasellar carotid artery: Apotential developmental factor in atherosclerosis and SIDS. Circ Res 1999;85:970.)

Tunica Media

The tunica media lies under the intima and internal elastic lamina. The media of elastic arteries such as the aorta has well-developed concentric layers of SMCs, interleaved with layers of elastin-rich ECM (**see Fig. 44.5**). This structure appears well adapted to the storage of the kinetic energy of left ventricular systole by the walls of great arteries. The lamellar structure also certainly contributes to the structural integrity of the arterial trunks. The media of smaller muscular arteries usually has a less stereotypic organization. SMCs in these smaller arteries generally embed in the surrounding matrix in a more continuous than lamellar array. The SMCs in normal arteries seldom proliferate. Indeed, rates of both cell division and cell death are low under usual circumstances. In the normal artery, a state of ECM homeostasis also typically prevails. Because ECM neither accumulates nor atrophies, rates of arterial matrix synthesis and dissolution usually balance each other. The external elastic lamina bounds the tunica media abluminally, forming the border with the adventitial layer.

Adventitia

The adventitia of arteries typically has received little attention, although appreciation of its potential roles in arterial homeostasis and pathology has increased. The adventitia contains collagen fibrils in a looser array than that usually encountered in the intima. Vasa vasorum and nerve endings localize in this outermost layer of the arterial wall. The cellular population in the adventitia is sparser than in other arterial layers. Cells encountered in this layer include fibroblasts and mast cells (**see Fig. 44.5**). Emerging evidence suggests a role for mast cells in atheroma and aneurysm formation in animal models, but their importance in humans remains speculative.[8]

Atherosclerosis Initiation

Extracellular Lipid Accumulation

The first steps in human atherogenesis remain largely conjectural, but the integration of observations of

tissues obtained from young humans with the results of experimental studies of atherogenesis in animals provides hints in this regard. On initiation of an atherogenic diet, typically rich in cholesterol and saturated fat, small lipoprotein particles accumulate in the intima (**Fig. 44.7**, steps 1 and 2). These lipoprotein particles appear to decorate the proteoglycan of the arterial intima and tend to coalesce into aggregates (**Fig. 44.8**). Detailed kinetic studies of labeled lipoprotein particles indicate that a prolonged residence time characterizes sites of early lesion formation in rabbits. The binding of lipoproteins to proteoglycan in the intima leads to their capture and retention, accounting for their prolonged residence time. Lipoprotein particles bound to proteoglycan have increased susceptibility to oxidative or other chemical modifications, considered by many to contribute to the pathogenesis of early atherosclerosis (step 2 in **Fig. 44.7**). Other studies suggest that permeability of the endothelial monolayer increases at sites of lesion predilection to low-density lipoprotein (LDL). Contributors to oxidative stress in the nascent atheroma could include reduced nicotinamide adenine dinucleotide/nicotinamide adenine dinucleotide phosphate (NADH/NADPH) oxidases expressed by vascular cells, lipoxygenases expressed by infiltrating leukocytes, or the enzyme myeloperoxidase.

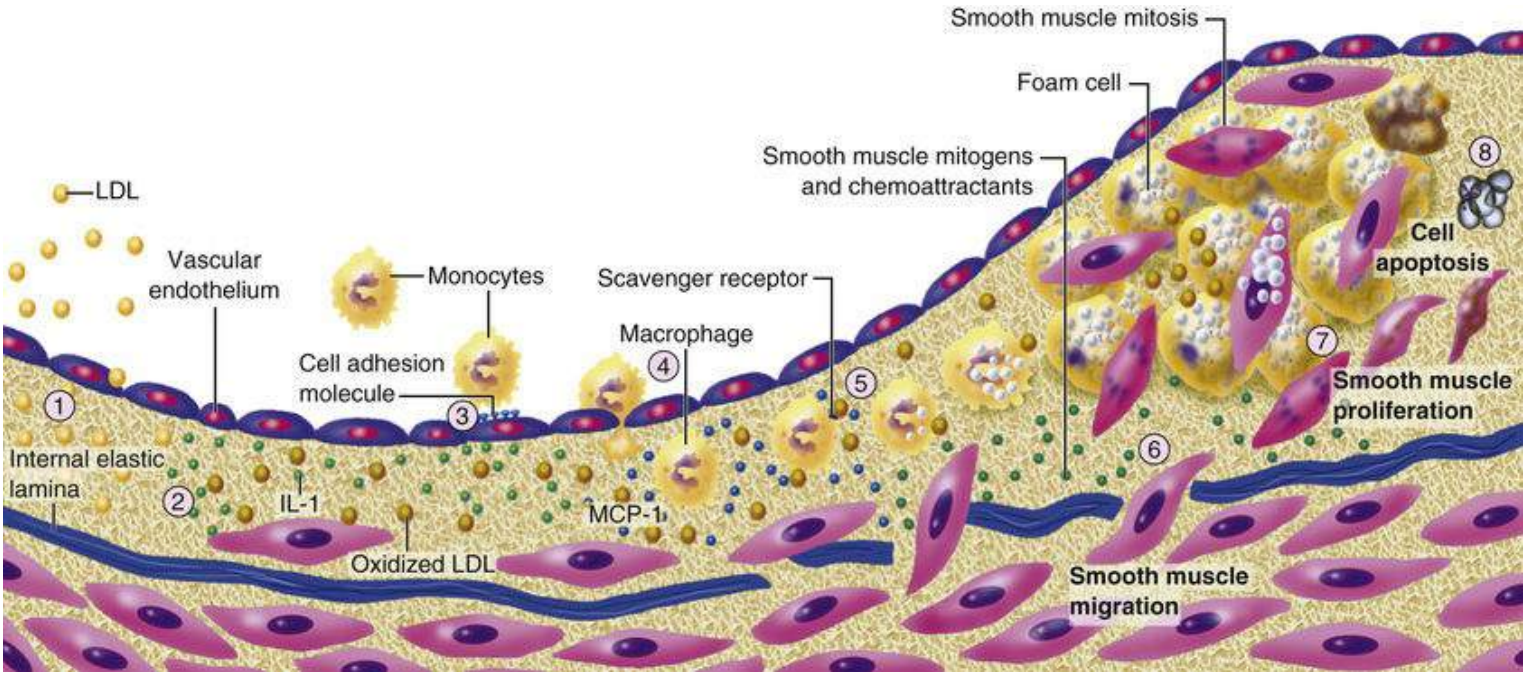

FIGURE 44.7 Schematic of the evolution of the atherosclerotic plaque. *1,* Accumulation of lipoprotein particles in the intima (*yellow spheres*). The modification of these lipoproteins is depicted by the *darker color*. Modifications include oxidation and glycation. *2,* Oxidative stress, including products found in modified lipoproteins, can induce local cytokine elaboration (*green spheres*). *3,* The cytokines thus induced increase expression of adhesion molecules (*blue stalks on endothelial surface*) for leukocytes that cause their attachment and chemoattractant molecules that direct their migration into the intima. *4,* Blood monocytes, on entering the artery wall in response to chemoattractant cytokines such as monocyte chemoattractant protein 1 (*MCP-1*), encounter stimuli such as macrophage colony-stimulating factor that can augment their expression of scavenger receptors. *5,* Scavenger receptors mediate the uptake of modified lipoprotein particles and promote the development of foam cells. Macrophage foam cells are a source of mediators, such as additional cytokines and effector molecules such as hypochlorous acid, superoxide anion (O_2^-), and matrix metalloproteinases. *6,* Smooth muscle cells (SMCs) migrate into the intima from the media. *7,* SMCs can then divide and elaborate extracellular matrix, promoting ECM accumulation in the growing atherosclerotic plaque. In this manner, the fatty streak can evolve into a fibrofatty lesion. *8,* In later stages, calcification can occur (*not depicted*) and fibrosis continues, sometimes accompanied by SMC death (including programmed cell death or apoptosis), yielding a relatively acellular fibrous capsule surrounding a lipid-rich core that also may contain dying or dead cells and their detritus. *IL,* Interleukin; *LDL,* low-density lipoprotein.

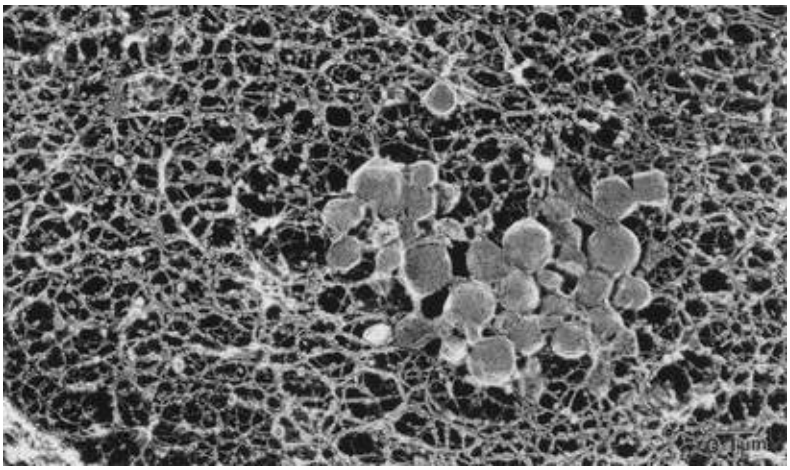

FIGURE 44.8 Scanning electron micrograph of a freeze-etch preparation of rabbit aorta that received an intravenous injection of human low-density lipoprotein (LDL). Round LDL particles decorate the strands of proteoglycan found in the subendothelial region of the intima. By binding LDL particles, proteoglycan molecules can retard their traversal of the intima and promote their accumulation. Proteoglycan-associated LDL appears particularly susceptible to oxidative modification. Accumulation of extracellular lipoprotein particles is one of the first morphologic changes noted after initiation of an atherogenic diet in experimental animals. (From Nievelstein PF, Fogelman AM, Mottino G, Frank JS. Lipid accumulation in rabbit aortic intima 2 hours after bolus infusion of low density lipoprotein: a deep-etch and immunolocalization study of ultrarapidly frozen tissue. Arterioscler Thromb 1991;11:1795.)

Leukocyte Recruitment and Retention

Another hallmark of atherogenesis, leukocyte recruitment and accumulation (step 4 in **Fig. 44.7**), also occurs early in lesion generation (**Fig. 44.9**). The normal EC generally resists adhesive interactions with leukocytes. Even in inflamed tissues, most recruitment and trafficking of leukocytes occurs in postcapillary venules and not in arteries. Very soon after initiation of hypercholesterolemia, however, leukocytes adhere to the endothelium and move between EC junctions, or even penetrate through ECs (transcytosis) to enter the intima, where they begin to accumulate lipids and become foam cells[9-11] (step 5 in **Fig. 44.7**). In addition to the monocyte, T lymphocytes also tend to accumulate in early human and animal atherosclerotic lesions.[12] The expression of certain leukocyte adhesion molecules on the surface of the EC regulates the adherence of monocytes and T cells to the endothelium.[5] Several categories of leukocyte adhesion molecules exist. Members of the *immunoglobulin* (Ig) superfamily include structures such as vascular cell adhesion molecule 1 (VCAM-1), or CD106. This adhesion molecule is of particular interest in the context of early atherogenesis because it interacts with an integrin, very late antigen 4 (VLA-4), characteristically expressed by only those classes of leukocytes that accumulate in nascent atheroma—monocytes and T cells. Moreover, experimental studies have shown expression of VCAM-1 on ECs overlying very early atheromatous lesions. Other members of the Ig superfamily of leukocyte adhesion molecules include intercellular adhesion molecule 1 (ICAM-1). This molecule is more promiscuous, both in the types of leukocytes it binds and in its wide and constitutive expression at low levels by ECs in many parts of the circulation.

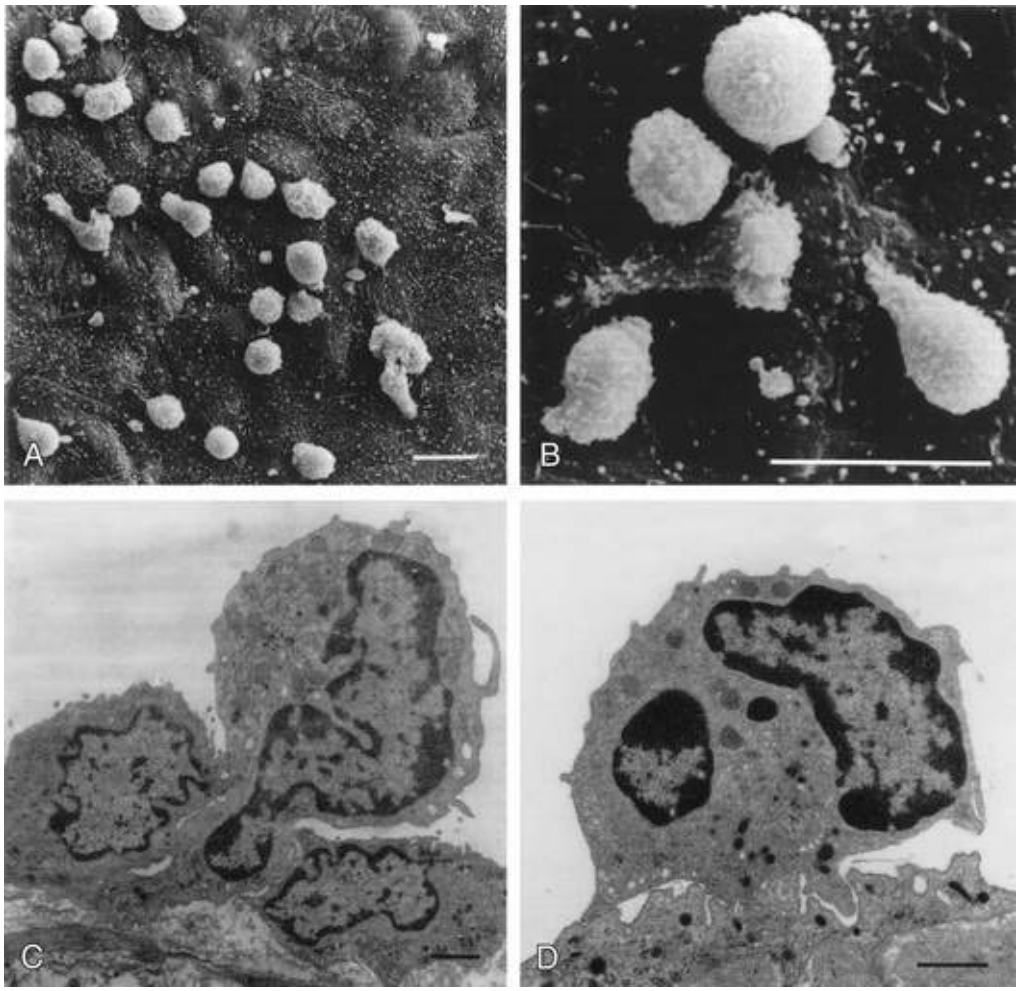

FIGURE 44.9 Electron microscopy of leukocyte interactions with the artery wall in hypercholesterolemic nonhuman primates. **A, B,** Scanning electron micrographs demonstrate the adhesion of mononuclear phagocytes to the intact endothelium 12 days after initiation of a hypercholesterolemic diet in monkeys. **C, D,** Transmission electron micrographs. Note the abundant interdigitations and intimate association of the monocyte with the endothelium in **C.** In **D,** a monocyte appears to come between two endothelial cells to enter the intima. (From Faggiotto A, Ross R, Harker L. Studies of hypercholesterolemia in the nonhuman primate. I. Changes that lead to fatty streak formation. Arteriosclerosis 1984;4:323.)

Selectins constitute the other broad category of leukocyte adhesion molecules. The prototypic selectin, E-selectin or CD62E (E stands for "endothelial," the cell type that selectively expresses this particular family member), probably has little to do with early atherogenesis. E-selectin preferentially recruits polymorphonuclear leukocytes, a cell type seldom found in early atheromata (but an essential protagonist in acute inflammation and host defenses against bacterial pathogens). Moreover, ECs overlying atheroma do not express high levels of this adhesion molecule. Other members of this family, including P-selectin, or CD62P (P stands for "platelet," the original source of this adhesion molecule), may play a greater role in leukocyte recruitment in atheroma, because ECs overlying human atheroma express this adhesion molecule. Selectins tend to promote saltatory or rolling locomotion of leukocytes over the endothelium. Adhesion molecules belonging to the immunoglobulin superfamily tend to promote tighter adhesive interactions and immobilization of leukocytes. Studies in genetically altered mice have proven roles for VCAM-1 and P-selectin (including both platelet-derived and endothelium-derived P-selectin) in experimental atherosclerosis. Increasing evidence supports the accumulation in atheromas of distinct subtypes of mononuclear phagocytes.[13,14] The functional consequences of this heterogeneity of macrophage populations in plaques require further study, especially in humans. In mice, a particularly proinflammatory subset of monocytes accumulates in the spleen and peripheral blood in response to hypercholesterolemia and preferentially populates nascent atheroma.[13]

Once adherent to the endothelium, leukocytes must receive a signal to penetrate the endothelial monolayer and enter the arterial wall (step 4 in **Fig. 44.7**). The current concept of directed migration of leukocytes involves the action of protein molecules known as chemoattractant cytokines, or *chemokines*. Observations on human atheroma and functional studies in vitro and in genetically altered mice point to causal roles of various chemokines in atherogensis.[5,15] In addition to recruitment, the accumulation of leukocytes in the arterial wall depends on factors that cause their retention in the intimal lesions. Retention factors include netrin-1 interacting with its receptor UNC5b (both induced by hypoxia), a protein that impairs macrophages from exiting plaques.[16]

Focality of Lesion Formation

The spatial heterogeneity of atherosclerosis is challenging to explain in mechanistic terms. Equal concentrations of blood-borne risk factors such as lipoproteins bathe the endothelium throughout the vasculature. It is difficult to envisage how injury resulting from inhalation of cigarette smoke could produce any local rather than global effect on arteries, yet stenoses caused by atheromas typically form focally. Some researchers have invoked a multicentric origin hypothesis of atherogenesis, positing that atheromas arise as benign leiomyomas of the artery wall. The monotypia of various molecular markers in individual atheromas supports this monoclonal hypothesis of atherogenesis. The location of sites of lesion predilection at proximal portions of arteries after branch points or bifurcations at flow dividers, however, suggests a hydrodynamic basis for early lesion development. Arteries without many branches (e.g., the internal mammary and radial arteries) tend not to develop atherosclerosis.

Two concepts can aid in understanding how local flow disturbances might render certain foci sites of lesion predilection. Locally disturbed flow could induce alterations that promote the steps of early atherogenesis. Alternatively, the laminar flow that usually prevails at sites that do not tend to develop early lesions may elicit antiatherogenic homeostatic mechanisms (atheroprotective functions).[5] The EC experiences the laminar shear stress of normal flow and the disturbed flow (usually yielding decreased shear stress) at sites of predilection. Multiple transduction mechanisms operate to signal the local shear stress environment to ECs.[17] For example, these cells have cilia on their luminal surface and adhesion receptors in their lateral cell membrane that can sense tension, transmit forces to the cortical cytoskeleton, and potentially regulate ion channels or G protein–coupled receptors that signal changes in gene expression (**Fig. 44.10**). In vitro data suggest that laminar shear stress can augment the expression of genes that may protect against atherosclerosis, including forms of the enzymes superoxide dismutase (SOD) and nitric oxide synthase (NOS). SOD can reduce oxidative stress by catabolizing the reactive and injurious superoxide anion. Endothelial NOS produces the well-known endogenous vasodilator nitric oxide. Beyond its vasodilating actions, however, nitric oxide (NO) can resist inflammatory activation of endothelial functions, such as expression of VCAM-1. NO appears to exert this anti-inflammatory action at the level of gene expression by interfering with the transcriptional regulator nuclear factor kappa B (NF-κB). NO increases the production of IκBα, an intracellular inhibitor of this important transcription factor. NF-κB regulates numerous genes involved in inflammatory responses in general and in atherogenesis in particular.

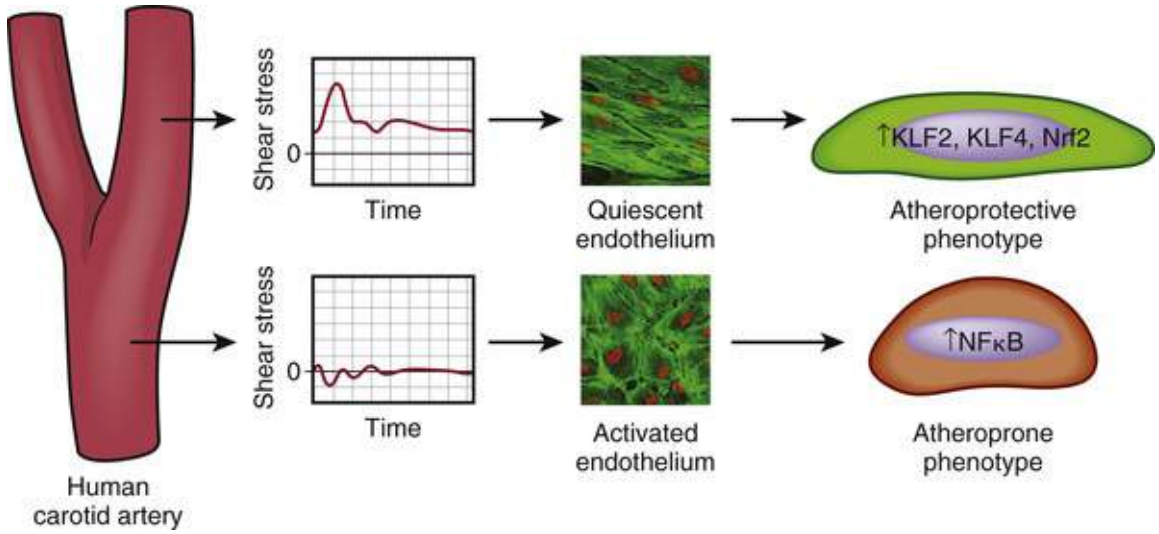

FIGURE 44.10 Hemodynamics determine endothelial functions. Computational analyses of blood flow patterns in vivo in the normal human carotid artery bifurcation provided representative near-wall shear stress waveforms from two hydrodynamically distinct locations known to have distinct predilection to atherogenesis: the distal internal carotid (a region that generally resists lesion formation) and the carotid sinus (a common location for plaque formation). Exposure of monolayers of human endothelial cell in culture to these different biomechanical environments yielded substantially different cell morphologies (depicted by cytoskeletal actin staining) and functions. Pulsatile (unidirectional) laminar flow induced the pivotal transcription factors (Krüppel-like factor [KLF]-2, KLF4, and nuclear factor erythroid 2–related factor [Nrf]-2), which coordinately elicit a palette of atheroprotective functions. In contrast, disturbed (oscillatory) flow enhanced expression of NF-κB, a central transcription factor that governs a number of proinflammatory and proatherogenic functions.

Studies also implicate transcription factors, notably Krüppel-like factor 2 (KLF2), as important regulators of endothelial anti-inflammatory properties. KLF2 can induce endothelial NOS expression and also inhibits NF-κB function by sequestering cofactors needed to boost NF-κB transcriptional activity, resulting in inhibition of the expression of the cassette of NF-κB–dependent genes involved in the inflammatory pathways that operate during atherogenesis.[5] Thus, several atheroprotective mechanisms operate such that under usual conditions of laminar shear stress in normal arteries, the endothelium tonically expresses locally acting anti-inflammatory function. Studies in intact pigs and humans show that sites of low shear stress in coronary arteries are associated with the development of plaque characteristics associated with rupture and thrombosis.[18,19]

Intracellular Lipid Accumulation: Foam Cell Formation

The monocyte, once recruited to the arterial intima, can imbibe lipid and become a foam cell or lipid-laden macrophage (step 5 in **Fig. 44.7**). Although most cells can express the classic cell surface receptor for LDL, that receptor does not mediate foam cell accumulation (**see Chapter 48**). This assertion agrees with the clinical finding of tendinous xanthomas filled with foamy macrophages that develop in patients that lack functional LDL receptors (familial hypercholesterolemia homozygotes). The LDL receptor does not mediate foam cell formation, because of its exquisite regulation by cholesterol. As soon as a cell collects enough cholesterol for its metabolic needs from LDL capture, an elegant transcriptional control mechanism quenches expression of the receptor.[20]

Instead of the classic LDL receptor, various molecules known as *scavenger* receptors appear to mediate the excessive lipid uptake characteristic of foam cell formation. These surface molecules, belonging to several families, bind modified rather than native lipoproteins and participate in their internalization.[21] Because scavenger receptors have functions such as recognition of apoptotic cells and modified lipoproteins, they likely have complex roles during different stages of atherosclerosis. (See

Table 48.3 for a table of that lists scavenger receptors.)

Once macrophages have taken up residence in the intima and become foam cells, they can replicate. In experimental atherosclerosis in mice, monocyte recruitment from blood initially populates the nascent lesion with mononuclear phagocytes, but local proliferation predominates in the established lesion.[11,22] The factors that trigger macrophage cell division in the atherosclerotic plaque probably include hematopoietic growth factors such as macrophage colony-stimulating factor (M-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), and interleukin-3 (IL-3). These co-mitogens and survival factors for mononuclear phagocytes exist in human and experimental atheromatous lesions.

Up to this point in the development of the nascent atheroma, the lesion consists primarily of lipid-engorged macrophages. Complex features such as fibrosis, thrombosis, and calcification do not characterize the *fatty streak*, the precursor lesion of the complex atheroma. Several lines of evidence suggest that such fatty streaks can regress, at least to some extent. The relative contributions of reduced recruitment, death of cells within lesions, and egress of cells to reduced accumulation on mononuclear phagocytes in atheromata under conditions of lipid lowering remain controversial.

Evolution of Atheroma

Innate and Adaptive Immunity: Mechanisms of Inflammation in Atherogenesis

During the past decade, the convergence of basic and clinical evidence has demonstrated a fundamental role for inflammation and immunity in atherogenesis[23-27] (**see Chapter 45**). The macrophage foam cells recruited to the artery wall early in this process serve not only as a reservoir for excess lipid, but in the established atherosclerotic lesion also furnish many proinflammatory mediators, including proteins (e.g., cytokines, chemokines),various eicosanoids, and other lipid mediators. These phagocytic cells also can elaborate large quantities of oxidant species, such as superoxide anion or hypochlorous acid, in the milieu of the atherosclerotic plaque. This ensemble of inflammatory mediators can promote inflammation in the plaque and thereby contribute to the progression of lesions. The term *innate immunity* describes this type of amplification of the inflammatory response that does not depend on antigenic stimulation (**Fig. 44.11**).

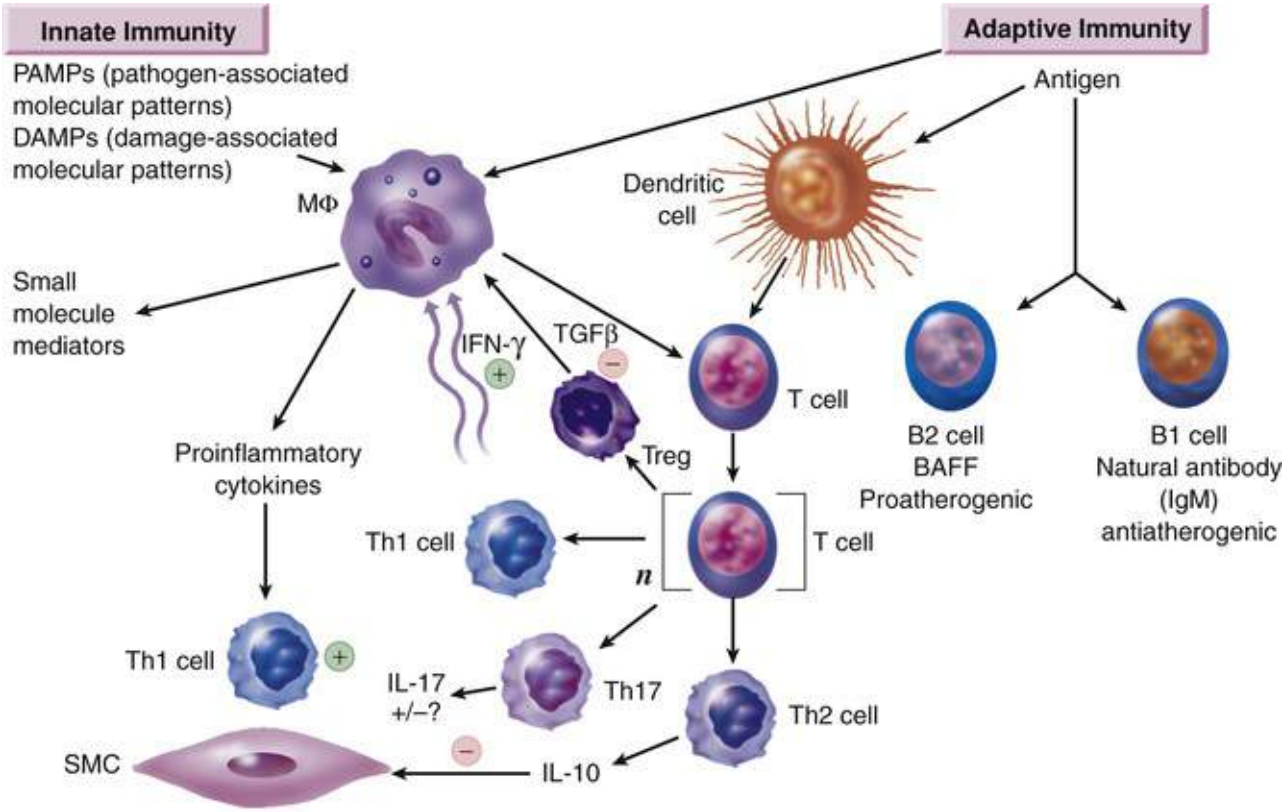

FIGURE 44.11 Innate and adaptive immunity in atherosclerosis. A diagram of the pathways of innate (*left*) and adaptive (*right*) immunity operating during atherogenesis. *BAFF,* B cell–activating factor; *IFN,* interferon; *IL,* interleukin; *MΦ,* macrophage; *SMC,* smooth muscle cell; *Th,* T helper; *TGF,* transforming growth factor. (After Hansson G, Libby P, Schoenbeck U, Yan ZQ: Innate and adaptive immunity in the pathogenesis of atherosclerosis. Circ Res 91:281, 2002.)

In addition to innate immunity, mounting evidence supports a prominent role for antigen-specific or *adaptive immunity* in plaque progression.[25,28] In addition to the mononuclear phagocytes, dendritic cells in atherosclerotic lesions can present antigens to the T cells that constitute an important minority of the leukocytes in atherosclerotic lesions.[11] Candidate antigens for stimulation of this adaptive immune response include modified or native lipoproteins, heat shock proteins, beta$_2$-glycoprotein Ib, and infectious agents.[25] The antigen-presenting cells (macrophages, dendritic cells, or ECs) allow the antigen to interact with T cells in a manner that triggers their activation. The activated T cells can then secrete copious quantities of cytokines that modulate atherogenesis.

The helper T cells (bearing CD4) fall into two general categories. Cells of the T helper 1 (Th1) subtype elaborate proinflammatory cytokines such as interferon (IFN)-γ, lymphotoxin, CD40 ligand, and tumor necrosis factor (TNF)-α. This panel of Th1 cytokines can in turn activate vascular wall cells and orchestrate alterations in plaque biology that can lead to plaque destabilization and heightened thrombogenicity. On the other hand, helper T cells slanted toward the production of Th2 cytokines, such as interleukin-10, can inhibit inflammation in the context of atherogenesis. Cytolytic T cells (bearing CD8) can express Fas ligand and other cytotoxic factors that can promote cytolysis and apoptosis of target cells, including SMCs, ECs, and macrophages. The death of all three of these cell types can occur in the atherosclerotic lesion and may contribute to plaque progression and complication. Regulatory T cells (Tregs) can elaborate transforming growth factor (TGF)-β and interleukin-10. Treg lymphocytes bear the markers CD4 and CD25. Both TGF-β and IL-10 can exert anti-inflammatory effects. Several experimental preparations suggest an antiatherosclerotic function of Tregs in vivo.[25,29] Distinct from such anti-inflammatory mechanisms, the operation mediators of resolution may provide another avenue to dampening the inflammatory response during atherogenesis.[30,31]

The role of B cells and antibody in atherosclerosis remains incompletely explored. Humoral immunity may have either atheroprotective or atherogenic properties, depending on the circumstances.[26] B1 cells that produce natural antibodies, many of which recognize oxidatively modified LDL, can protect against experimental atherosclerosis. B2 cells aggravate atherosclerosis in mice by promoting proinflammatory cytokine production, which created interest in immunotherapy to mitigate atherosclerosis.[32,33]

Smooth Muscle Cell Migration and Proliferation

Whereas the early events in atheroma initiation involve primarily altered endothelial function and recruitment and accumulation of leukocytes, the subsequent evolution of atheroma into more complex plaques also involves SMCs (steps 6 and 7 in **Fig. 44.7**). SMCs in the normal arterial tunica media differ considerably from those in the intima of an evolving atheroma.[7] Some SMCs probably arrive in the arterial intima early in life; others accumulate in advancing atheroma after recruitment from the underlying media into the intima or arise from blood-borne precursors. Some cells bearing macrophage markers in mouse atheromata appear to derive from mononuclear phagocytic leukocytes.[7,34]

SMCs in the atherosclerotic intima appear to exhibit a less mature phenotype than that for the quiescent SMCs in the normal arterial medial layer. Instead of expressing primarily isoforms of smooth muscle myosin characteristic of adult SMCs, those in the intima have higher levels of the embryonic isoform of smooth muscle myosin. Thus, SMCs in the intima seem to recapitulate an embryonic phenotype. These intimal SMCs in atheroma appear to be morphologically distinct as well. They contain more rough endoplasmic reticulum and fewer contractile fibers than do normal medial SMCs.

Although replication of SMCs in the steady state appears uncommon in mature human atheroma, bursts of SMC replication may occur during the life history of a given atheromatous lesion. For example, as discussed later, episodes of plaque disruption with thrombosis may expose SMCs to potent mitogens, including the coagulation factor thrombin itself. Thus, accumulation of SMCs during atherosclerosis and growth of the intima may not occur in a continuous and linear manner. Rather, “crises” may punctuate the history of an atheroma, during which bursts of smooth muscle activity may occur (**Fig. 44.12**).

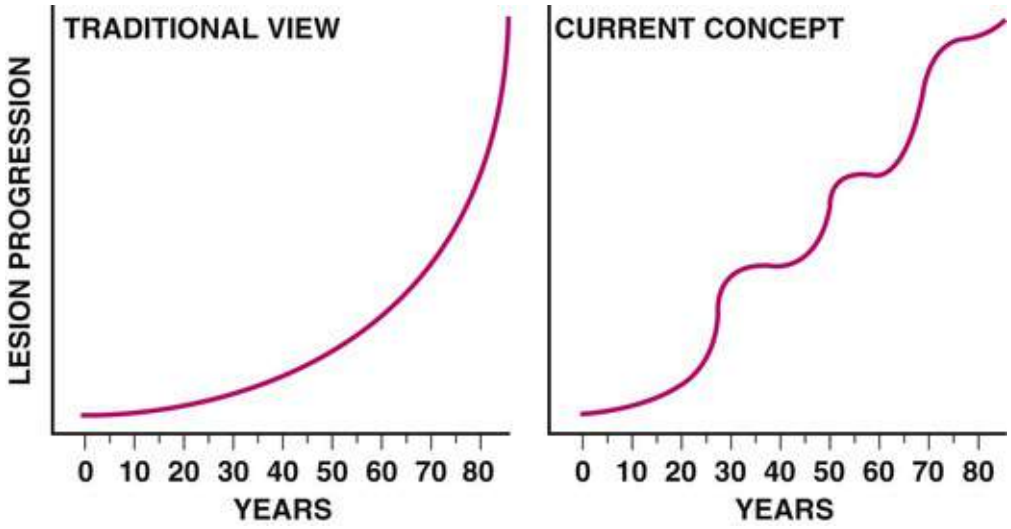

FIGURE 44.12 The time course of atherosclerosis. **Left,** Traditional teaching held that atheroma formation followed an inexorably progressive course with age, as depicted by the smooth upward curve. **Right,** Current thinking suggests an alternative model, a step function rather than a monotonically upward course of lesion evolution in time, as depicted by the serpentine curve. According to this latter model, "crises" can punctuate periods of relative quiescence during the life history of a lesion. Such crises might follow an episode of plaque disruption, with mural thrombosis and healing, yielding a spurt in smooth muscle proliferation and matrix deposition. Intraplaque hemorrhage from rupture of a friable microvessel might produce a similar scenario. Such episodes usually are clinically inapparent. Extravascular events, such as an intercurrent infection with systemic cytokinemia or endotoxemia, could elicit an "echo" at the level of the artery wall, evoking a round of local cytokine gene expression by "professional" inflammatory leukocytes resident in the lesion. The episodic model of plaque progression fits better with human angiographic data than does the traditional model of continuous function.

Smooth Muscle Cell Death During Atherogenesis

In addition to SMC replication, death of these cells also may participate in complication of the atherosclerotic plaque (step 8 in **Fig. 44.7**).[7] Some SMCs in advanced human atheroma exhibit fragmentation of their nuclear DNA that is characteristic of programmed cell death or apoptosis. Apoptosis may occur in response to inflammatory cytokines present in the evolving atheroma. In addition to soluble cytokines that may trigger programmed cell death, T cells in atheroma may participate in eliminating some SMCs. In particular, certain T cell populations known to accumulate in plaques can express Fas ligand on their surface. Fas ligand can engage Fas on the surface of SMCs and, in conjunction with soluble proinflammatory cytokines, lead to SMC death.

Thus, SMC accumulation in the growing atherosclerotic plaque probably results from a tug-of-war between cell replication and cell death. Contemporary cell and molecular biologic research has identified candidates for mediation of both the replication and the attrition of SMCs, a concept that originated from Virchow's careful morphologic observations made in the mid-19th century. Referring to the SMCs in the intima, Virchow noted that early atherogenesis involves a "multiplication of their nuclei" but also noted that cells in lesions can "hurry on to their own destruction."

Arterial Extracellular Matrix

Rather than cells themselves, ECM makes up much of the volume of an advanced atherosclerotic plaque. Accordingly, extracellular constituents of plaque also require consideration. The major ECM macromolecules that accumulate in atheroma include interstitial collagens (types I and III) and proteoglycans such as versican, biglycan, aggrecan, and decorin. Elastin fibers also may accumulate in

atherosclerotic plaques. Arterial SMCs produce these ECM molecules in disease, just as they do during development and maintenance of the normal artery (step 7 in **Fig. 44.7**). Stimuli for excessive collagen production by SMCs include platelet-derived growth factor (PDGF) and TGF-β, a constituent of platelet granules, and a product of many cell types found in lesions, including Treg lymphocytes.

As with accumulation of SMCs, ECM secretion also depends on a balance, as noted earlier. In this case, the counterpoise to biosynthesis of the ECM molecules is breakdown catalyzed in part by catabolic enzymes, notably the matrix metalloproteinases (MMPs). Dissolution of ECM macromolecules undoubtedly contributes to the migration of SMCs as they penetrate into the intima from the media through a dense ECM, traversing the elastin-rich internal elastic lamina.

Extracellular matrix breakdown also likely plays a role in arterial remodeling that accompanies lesion growth. During the early life of an atheromatous lesion, plaques grow outwardly, in an abluminal direction, rather than inwardly, in a way that would lead to luminal stenosis. This outward growth of the intima leads to an increase in the caliber of the entire artery. This so-called positive remodeling or compensatory enlargement must involve turnover of ECM molecules to accommodate the circumferential growth of the artery. Luminal stenosis tends to occur only after the plaque burden exceeds approximately 40% of the cross-sectional area of the artery.

Angiogenesis in Plaques

Atherosclerotic plaques develop their own microcirculation as they grow, because of endothelial migration and replication. Histologic examination with appropriate markers for ECs reveals a rich neovascularization in evolving plaques. These microvessels probably form in response to angiogenic peptides overexpressed in atheroma. These angiogenesis factors include vascular endothelial growth factor (VEGF) forms of fibroblast growth factors, placental growth factor (PlGF), and oncostatin M.

These microvessels within plaques probably have considerable functional significance. For example, the abundant microvessels in plaques provide a relatively large surface area for the trafficking of leukocytes, which could include both entry and exit of leukocytes. Indeed, in the advanced human atherosclerotic plaque, microvascular endothelium displays mononuclear cell–selective adhesion molecules such as VCAM-1 much more prominently than does the macrovascular endothelium overlying the plaque. The microvascularization of plaques also may allow growth of the plaque, overcoming diffusion limitations on oxygen and nutrient supply, analogous to the concept of tumor angiogenic factors and growth of malignant lesions. Consistent with this view, administration of inhibitors of angiogenesis to mice with experimentally induced atherosclerosis limits lesion expansion. Further, the plaque microvessels may be friable and prone to rupture, as with the neovessels in the diabetic retina. Hemorrhage and thrombosis in situ could promote a local round of SMC proliferation and matrix accumulation in the area immediately adjacent to the microvascular disruption (**Fig. 44.13**). This scenario illustrates a special case of the crises described earlier in the evolution of the atheromatous plaque (**see Fig. 44.12**). Attempts to augment myocardial perfusion by enhancing new vessel growth through the transfer of angiogenic proteins or their genes may have adverse effects on lesion growth or may induce clinical complications of atheroma by these mechanisms.

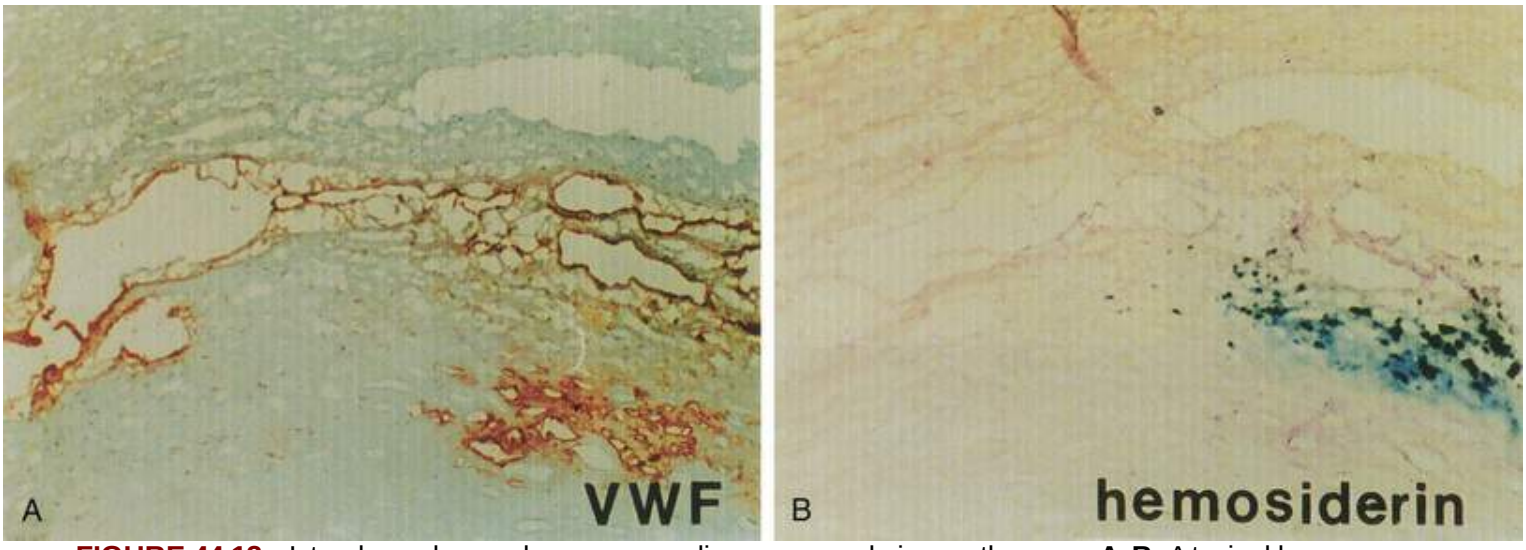

FIGURE 44.13 Intraplaque hemorrhage surrounding neovessels in an atheroma. **A, B,** A typical human atherosclerotic plaque, stained for von Willebrand factor (VWF) **(A)** and for iron by Prussian blue **(B).** The VWF stains the endothelial cells that line the microvascular channels and lakes. Note the extravasated VWF, which colocalizes with iron deposition, indicating hemosiderin deposition consistent with an intraplaque hemorrhage. (After Brogi E, Winkles JA, Underwood R, et al. Distinct patterns of expression of fibroblast growth factors and their receptors in human atheroma and non-atherosclerotic arteries: association of acidic FGF with plaque microvessels and macrophages. J Clin Invest 1993;92:2408.)

Plaque Mineralization

Plaques often develop areas of calcification as they evolve. Indeed, Virchow recognized morphologic features of bone formation in atherosclerotic plaques in early microscopic descriptions of atherosclerosis. Understanding of the mechanism of mineralization during the evolution of atherosclerotic plaques has advanced considerably.[35] Some subpopulations of SMCs may foster calcification by enhanced secretion of cytokines such as bone morphogenetic proteins, homologues of TGF-β. Atheroma calcification shares many mechanisms with bone formation. Receptor activator of NF-κB ligand (RANKL), a member of the TNF family, appears to promote SMC mineral formation through a bone morphogenetic protein 4–dependent pathway. *Osteoprotegerin* can antagonize plaque mineralization by inhibiting RANKL signaling. Genetic absence of osteoprotegerin augments calcification of mouse atheromas, and administration of exogenous osteoprotegerin limits it. The transcription factor Runx-2, activated by inflammatory mediators and oxidative stress among other stimuli, can promote SMC mineral formation by activating AKT (i.e., protein kinase B). Markers of inflammation colocalize with foci of mineralization in nascent mouse atheromata.[35] Microparticles elaborated by macrophages may provide nidi for plaque calcification, yielding another link between inflammatory cells and cardiovascular calcification.[36,37] Sortilin (Sort-1), a genome-wide association study (GWAS) “hit” in atherosclerosis, regulates the loading of alkaline phosphatase into extracellular vesicles, thereby promoting calcification.[38]

Complication of Atherosclerosis

Arterial Stenoses and Clinical Implications

The phases of the atherosclerotic process generally last many years, during which the affected person often has no symptoms. After the plaque burden exceeds the capacity of the artery to remodel outward,

encroachment on the arterial lumen begins. During the chronic asymptomatic or stable phase of lesion evolution, growth probably occurs discontinuously, with periods of relative quiescence punctuated by episodes of rapid progression (**see Fig. 44.12**). Human angiographic studies support this discontinuous growth of coronary artery stenoses. Eventually, the stenoses may progress to a degree that impedes blood flow through the artery. Lesions that produce stenoses of greater than 60% can cause flow limitations under conditions of increased demand. This type of athero-occlusive disease commonly produces chronic stable angina pectoris or intermittent claudication on increased demand. Thus the symptomatic phase of atherosclerosis usually begins many decades after lesion initiation.

In many cases of myocardial infarction (MI), however, no history of previous stable angina heralds the acute event. Acute coronary syndromes may result from thrombi that form as a consequence of disruption of plaques that do not produce a critical stenosis.[39] These findings do not imply that small atheromas cause most MIs. Indeed, culprit lesions of acute MI may be sizable but may not produce a critical luminal narrowing because of compensatory enlargement. Critical stenoses do cause MIs, however, and high-grade stenoses more likely cause acute MI than do nonocclusive lesions. Because the noncritical stenoses by far outnumber the tight focal lesions in a given coronary tree, however, the lesser stenoses cause more MIs, even though high-grade stenoses have a greater individual likelihood of causing infarction.

Thrombosis and Atheroma Complication

Several major modes of plaque disruption provoke most coronary thrombi.[39,40] The first mechanism, accounting for about two thirds of acute MIs, involves a fracture of the plaque's fibrous cap (**Fig. 44.14**, left). Another mode involves a superficial erosion of the intima (**Fig. 44.14, right, and Fig. 44.15**), accounting for a quarter to a third of acute MIs.

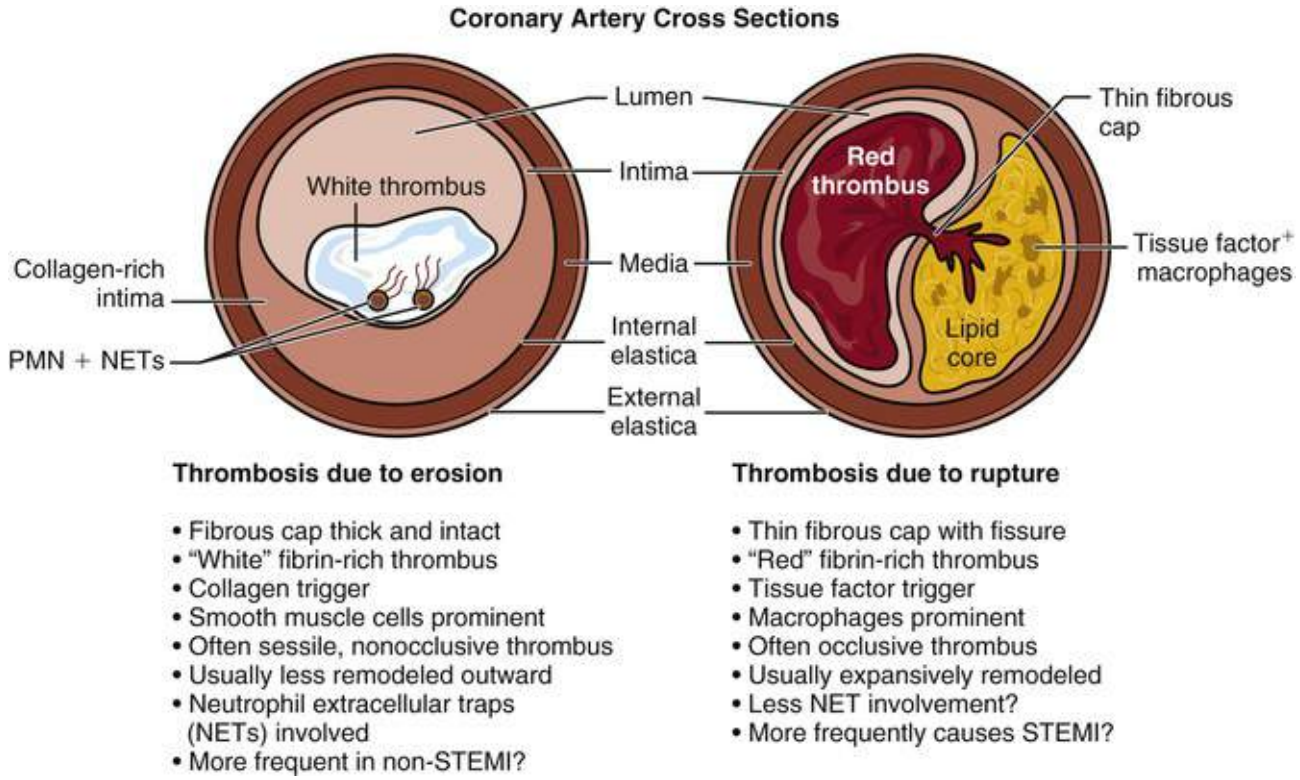

FIGURE 44.14 Distinct mechanisms may cause coronary thrombosis resulting from superficial erosion versus fibrous cap rupture. **Left,** Thrombosis caused by erosion, associated with a sessile, "white" thrombus superimposed on a lesion with abundant extracellular matrix and limited expansive remodeling. Endothelial cell desquamation or death can uncover collagen within the plaque that can trigger such platelet-rich thrombi. Polymorphonuclear leukocytes (PMN) that arrive on the scene can then contribute to a second wave of amplification and propagation of thrombosis resulting from their elaboration of neutrophil extracellular traps (NETs). Erosion may also more frequently cause non–ST-segment elevation myocardial infarction (non-STEMI) than STEMI. **Right,** Thrombosis resulting from rupture, usually associated with lesions with a thin fibrous cap. Such thrombi have more of the character of a "red" fibrin-rich clot. Tissue factor produced by the numerous macrophages in ruptured plaques promote thrombosis. The lesions that rupture and cause thrombi may more often have undergone outward remodeling and are more likely to cause STEMI than non-STEMI.

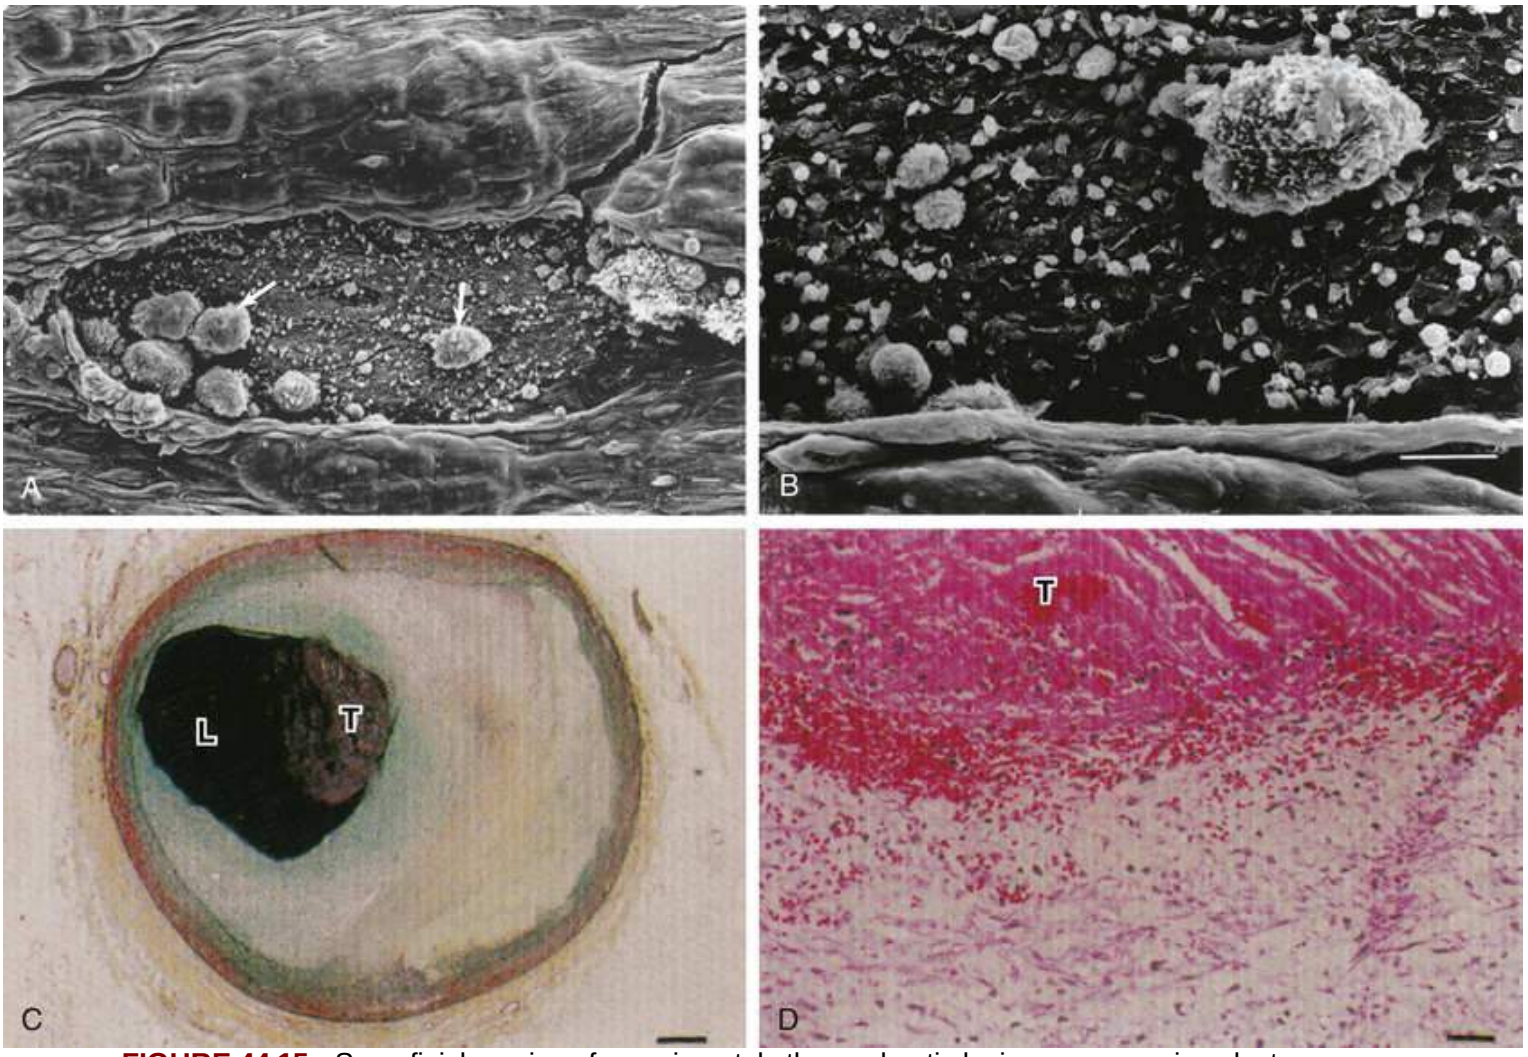

FIGURE 44.15 Superficial erosion of experimental atherosclerotic lesions on scanning electron microscopy. Advanced atherosclerotic plaques can promote thrombosis by superficial erosion of the endothelial layer, exposing the blood and platelets to the subendothelial basement membrane containing collagen platelet activation and thrombosis. **A,** Low-power view shows a rent in endothelium. Leukocytes (*arrows*) have adhered to the subendothelium, which is beginning to be covered with a carpet of platelets. **B,** High-power view is a field selected from the center of **A** that shows the leukocytes and platelets adherent to the subendothelium. **C,** Low-power histologic section through a coronary artery, thrombosed as a result of superficial erosion. **D,** High-power histologic section through a coronary artery, also thrombosed as a result of superficial erosion. *L,* Lumen; *T,* thrombus. (**A, B,** From Faggiotto A, Ross R. Studies of hypercholesterolemia in the nonhuman primate. II. Fatty streak conversion to fibrous plaque. Arteriosclerosis 1984;4:341; **C, D,** from Farb A, Burke AP, Tang AL, et al. Coronary plaque erosion without rupture into a lipid core: a frequent cause of coronary thrombosis in sudden coronary death. Circulation 1996;93:1354.)

Plaque Rupture and Thrombosis

The rupture of the plaque's fibrous cap probably reflects an imbalance between the forces that impinge on the cap and the mechanical strength of the cap. Interstitial forms of collagen provide most of the biomechanical resistance to disruption of the fibrous cap. Thus the metabolism of collagen probably participates in regulating the propensity of a plaque to rupture (**Fig. 44.16**). Factors that decrease collagen synthesis by SMCs can impair their ability to repair and to maintain the plaque's fibrous cap. For example, the T cell–derived cytokine IFN-γ potently inhibits SMC collagen synthesis. On the other hand, as already noted, certain mediators released from platelet granules during activation (e.g., TGF-β, PDGF) can increase SMC collagen synthesis, tending to reinforce the plaque's fibrous structure.

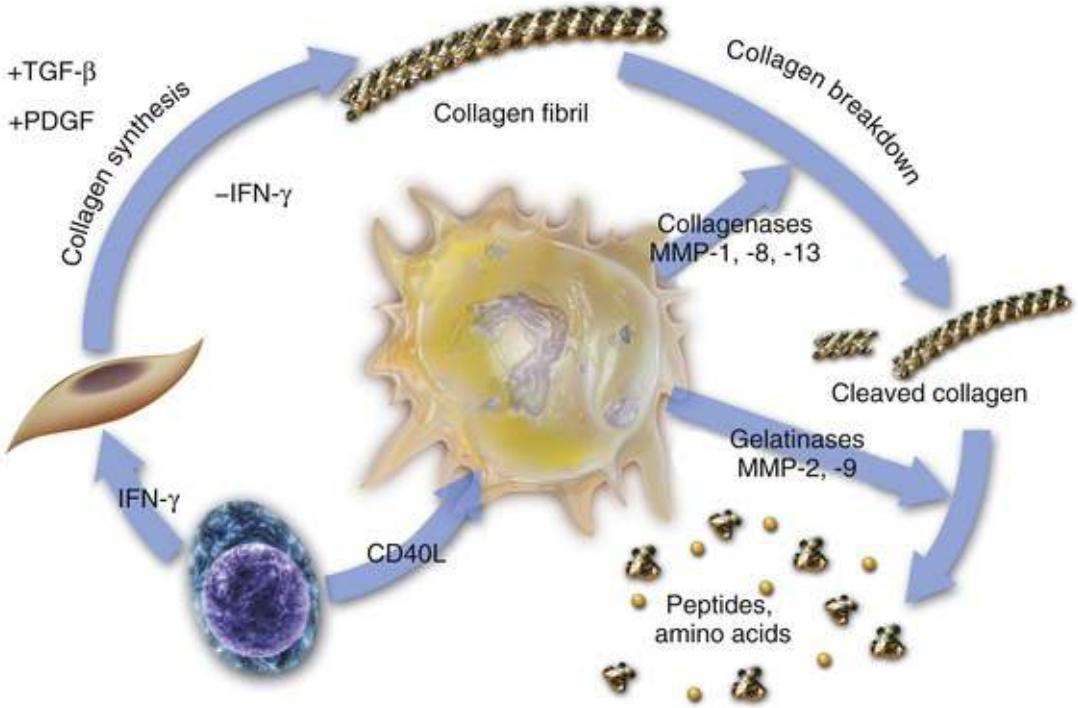

FIGURE 44.16 Inflammation regulates metabolism of fibrillar collagen, which may influence atherosclerotic plaque disruption. The T lymphocyte releases proinflammatory cytokines such as interferon (IFN)-γ (*lower left*) that inhibit smooth muscle cells from producing the new collagen required to lay down the collagenous matrix of the plaque's fibrous cap, which protects the plaque from rupture. The T cell–derived cytokine CD40L stimulates mononuclear phagocytes (*center*) to elaborate interstitial collagenases including matrix metalloproteinase (MMP)-1, MMP-8, and MMP-13, which catalyze the initial proteolytic cleavage of the intact collagen fibril. The cleaved collagen can then undergo additional degradation by gelatinases such as MMP-9. In this way, inflammation can threaten the stability of atherosclerotic plaques and increase their tendency to rupture, thereby causing thromboses, which trigger most acute coronary syndromes. *PDGF,* Platelet-derived growth factor; *TGF,* transforming growth factor. (From Libby P. The molecular mechanisms of the thrombotic complications of atherosclerosis. J Intern Med 2008;263:517.)

In addition to reduced de novo collagen synthesis by SMCs, increased catabolism of the ECM macromolecules that compose the fibrous cap also can contribute to weakening of this structure, rendering it susceptible to rupture and thus thrombosis. The same matrix-degrading enzymes thought to contribute to smooth muscle migration and arterial remodeling also may contribute to weakening of the fibrous cap[39] (**see Fig. 44.16**). Macrophages in advanced human atheroma overexpress MMPs and elastolytic cathepsins, which can break down the collagen and elastin of the arterial ECM. Therefore the strength of the plaque's fibrous cap undergoes dynamic regulation, linking the inflammatory response in the intima with the molecular determinants of plaque stability and thus thrombotic complications of atheroma. Thin fibrous caps are associated with plaque rupture, probably from reduced collagen synthesis and increased degradation.

A relative lack of SMCs also characterizes plaques that have caused fatal MIs. As explained earlier, inflammatory mediators, both soluble and associated with the surface of T lymphocytes, can provoke programmed death of SMCs. Dropout of SMCs from regions of local inflammation within plaques probably contributes to the relative lack of SMCs at points of plaque rupture. Because these cells produce new collagen needed to repair and to maintain the matrix of the fibrous cap, the lack of SMCs may contribute to weakening of the fibrous cap and the propensity of that plaque to rupture.[39]

Plaques that have fatally ruptured exhibit another microanatomic feature: prominent accumulation of macrophages with a large lipid pool. From a strictly biomechanical viewpoint, a large lipid pool can serve to concentrate biomechanical forces on the shoulder regions of plaques, where they frequently fracture. From a metabolic standpoint, the activated macrophage characteristic of the plaque's core region

produces the cytokines and the matrix-degrading enzymes thought to regulate aspects of matrix catabolism and SMC apoptosis in turn. Apoptotic macrophages and SMCs can generate particulate tissue factor, a potential instigator of microvascular thrombosis after spontaneous or iatrogenic plaque disruption. The success of lipid-lowering therapy in reducing the incidence of acute MI or unstable angina in patients at risk may result from a reduced accumulation of lipid and a decrease in inflammation and plaque thrombogenicity. Animal studies and accumulated data from monitoring peripheral markers of inflammation in humans support this concept.[39,41,42]

Thrombosis Caused by Superficial Erosion of Plaques

The underlying molecular and cellular mechanisms of superficial erosion have received much less attention than those involved in plaque rupture[43] (**Fig. 44.14, left**). In experimental atherosclerosis in the nonhuman primate, areas of endothelial loss and platelet deposition occur in more advanced plaques (**see Fig. 44.15**). Apoptosis of ECs could contribute to desquamation of ECs in areas of superficial erosion. Likewise, MMPs, such as certain gelatinases specialized in degrading the nonfibrillar collagen found in the basement membrane (e.g., collagen type IV), also may sever the tetherings of the EC to the subjacent basal lamina and promote their desquamation. Vasospasm of atherosclerotic coronary arteries in rabbits can promote endothelial damage, thrombosis, and MI.[44]

The lesions that provoke superficial erosion appear quite distinct from those that cause plaque rupture (**see Fig. 44.14**). Lesions associated with superficial erosion contain abundant proteoglycan and glycosaminoglycan, as opposed to the collagen-depleted fibrous cap characteristic of ruptured plaques. Eroded lesions have few macrophages, whereas these chronic inflammatory cells abound in ruptured plaques. In contrast, plaques complicated by superficial erosion have thrombi that contain many granulocytes, acute inflammatory cells. Activated granulocytes release many pro-oxidant and proinflammatory mediators, and when they die, they extrude their nuclear DNA to form neutrophil extracellular traps (NETs.) These strands of DNA bind many of the released neutrophil products and provide a “solid-state reactor” that can aggravate the local pro-oxidant, proinflammatory, and prothrombotic environment.[45-47]

Recent work has implicated the innate immune receptor Toll-like receptor 2 (TLR2) in signaling endothelial alterations that may predispose to superficial erosion.[46,48] ECs subjected to disturbed flow in vitro or those overlying atheroma-prone regions of arteries in hyperlipidemic mice overexpress TLR2. Hyaluronic acid in eroded-type plaques may serve as one endogenous ligand for TLR2, causing chronic smoldering endothelial activation that predisposes to sloughing of these cells.[46] Experimentally, neutrophil depletion preserves endothelial barrier function and limits desquamation of intimal ECs in regions of disturbed flow in arteries with fibrous intimal hyperplasia, reminiscent of plaques that undergo erosion in humans.[48]

Thrombosis and Healing in Progression of Atheroma

Most plaque disruptions do not give rise to clinically apparent coronary events. Careful pathoanatomic examination of hearts obtained from patients who have succumbed to noncardiac death has shown a surprisingly high incidence of focal plaque disruptions with limited mural thrombi. Moreover, hearts fixed immediately after explantation from persons with severe but chronic stable coronary atherosclerosis who had undergone transplantation for ischemic cardiomyopathy show similar evidence for ongoing but asymptomatic plaque disruption. Experimentally, in atherosclerotic nonhuman primates, mural platelet

thrombi can complicate plaque erosions without causing arterial occlusion. Therefore, repetitive cycles of plaque disruption, thrombosis in situ, and healing probably contribute to lesion evolution and plaque growth. Such episodes of thrombosis and healing constitute one type of crisis in the history of a plaque that may cause a burst of SMC proliferation, migration, and matrix synthesis (**see Fig. 44.12**).

Plaque disruptions with healing underlie many thrombi that cause sudden death, indicating that nonocclusive thrombosis may precede the fatal event more frequently than previously recognized.[49] TGF-β and PDGF released from platelet granules may promote healing at the site of thrombosis by stimulating migration and collagen synthesis by SMCs, as noted earlier. Thrombin, generated at sites of mural thrombosis, potently stimulates SMC proliferation. The "burned-out" fibrous and calcific atheroma may represent a late stage of a plaque that previously was lipid rich with characteristics associated with rupture, but that has become fibrous and hypocellular because of a wound-healing response mediated by the products of thrombosis and calcification seeded by cell death.

Diffuse and Systemic Nature of Plaque Susceptibility to Rupture and Inflammation in Atherogenesis

Studies at autopsy of atherosclerotic plaques that caused fatal thrombosis brought the notion of the "vulnerable" or "high-risk" plaque to the fore. This observation stimulated many investigators to seek ways of identifying and treating such high-risk atherosclerotic lesions. Current evidence, however, suggests that more than one such high-risk plaque often resides in a given coronary tree. Moreover, the inflammation thought to characterize the so-called vulnerable plaque appears widespread.[50] Studies using various imaging modalities have underscored the multiplicity of such high-risk plaques.[39,50] Angiography, intravascular ultrasound, optical coherence tomography, magnetic resonance imaging, and computed tomographic angiography (among other technologies) all have shed light on the morphology of plaques that cause acute coronary syndromes.[51,52] These various modalities generally have found an association of lesions that cause acute manifestations ("culprit lesions") with positive remodeling or compensatory enlargement of arteries, radiolucency, and spotty calcification.

Several concordant lines of evidence support the systemic and diffuse nature of inflammation associated with acute coronary syndrome (ACS).[50] Moreover, multiple studies have shown that various systemic markers of inflammation, such as C-reactive protein, increase in patients at risk for ACS (**see Chapter 45**). Inflammation precedes ACS, as revealed by profiling of the platelet transcriptome, providing a window on gene transcription many days before the acute event.[53] Thus a combination of imaging studies and investigations using inflammatory markers supports the diffuse and systemic nature of instability of atheromas in individuals with or at risk for ACS. This recognition has important therapeutic implications. In addition to appropriately deployed local revascularization strategies, affected patients also should receive systemic therapy aimed at stabilizing the usually multiple high-risk lesions that may cause recurrent events.

Thrombosis depends not only on the "solid state" of the plaque that may rupture or erode to trigger thrombosis, but also on the "fluid phase" of blood that determines the consequences of a given plaque disruption[54] (**Fig. 44.17**). The amount of tissue factor in the lipid core of a plaque (the solid state) can control the degree of clot formation that will ensue after disruption. The level of fibrinogen in the fluid phase of blood can influence whether a plaque disruption will cause an occlusive thrombus that can precipitate an acute ST-segment elevation myocardial infarction (STEMI) or yield merely a small mural thrombus. Likewise, elevated levels of inhibitors of fibrinolysis, such as plasminogen activator inhibitor 1 (PAI-1), will impede the ability of endogenous thrombolytic enzymes to limit thrombus growth or

persistence. Inflammation regulates both the fluid-phase and the solid-state factors delineated earlier, including tissue factor, fibrinogen, and PAI-1. This helps explain the links between inflammation and thrombotic complications of atherosclerosis that have emerged from laboratory and clinical investigations.

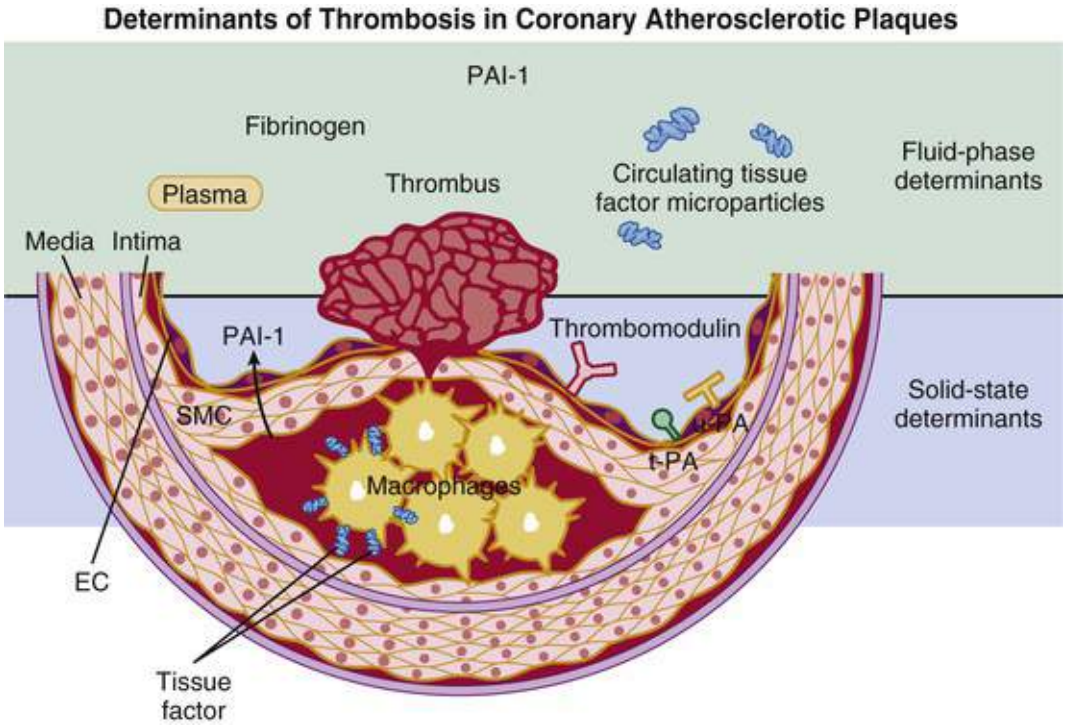

FIGURE 44.17 A two-state concept of atherothrombosis. The high-risk atheroma has a thin fibrous cap overlying a large lipid core that contains tissue factor–bearing macrophages. When the fibrous cap fractures, coagulation proteins in the fluid phase of blood gain access to tissue factor–associated macrophages and tissue factor–bearing microparticles derived from apoptotic cells in the solid state of the plaque. These events trigger thrombus formation on the ruptured plaque. The clinical consequences depend on the amount of tissue factor and apoptosis in the plaque's core and on the levels of fibrinogen and plasminogen activator inhibitor (PAI)-1 in the fluid phase of blood. The interaction of the fluid phase with the solid state will determine whether a given plaque disruption provokes a partial or transient coronary artery occlusion (that can be clinically silent or less often cause an episode of unstable angina) or a devastating persistent and occlusive thrombus that can precipitate an acute myocardial infarction. Inflammation regulates the thrombotic/fibrinolytic balance in both the solid state and the fluid phase, because PAI-1 and fibrinogen both are acute-phase reactants and because the inflammatory mediator CD40 ligand (CD154) induces tissue factor expression. *EC,* Endothelial cell; *SMC,* smooth muscle cell; *t-PA,* tissue plasminogen activator; *u-PA,* urokinase-type plasminogen activator. Special Cases of Arteriosclerosis

Restenosis After Arterial Intervention

The problems of restenosis and in-stent stenosis after percutaneous arterial intervention represent special cases of arterial hyperplastic disease (**see Chapter 62**). After balloon angioplasty, luminal narrowing recurs in approximately one third of cases within 6 months. Work on the pathophysiology of restenosis after angioplasty initially focused on smooth muscle proliferation. Much of the thinking regarding the pathobiology of restenosis or in-stent stenosis depended on extension to the human situation of the results of withdrawal of an overinflated balloon or overexpanded stents in previously normal animal arteries.

Study of balloon-injured rat carotid arteries permitted precise understanding of the kinetics of intimal thickening after this type of injury, but the attempts to transfer this information to human restenosis met with considerable frustration. This disparity between experimental injury of animal arteries and human restenosis should not be surprising. The substrate of the animal studies was usually a normal artery rather than an atherosclerotic one, with all the attendant cellular and molecular differences.[55] These animal studies, however, did reveal evidence for sustained inflammation in injured arteries.

The widespread use of stents refocused the restenosis problem. The process of in-stent stenosis, in contrast with restenosis after balloon angioplasty, depends primarily on intimal thickening as opposed to negative remodeling. The stent provides a firm scaffold that prevents constriction from the adventitia. The use of drug-eluting stents (DESs) that release agents with anti-inflammatory and antiproliferative properties has greatly reduced in-stent stenosis, and newer-generation DESs appear to limit the potential for augmenting late stent thrombosis associated with earlier DESs. The risk of late thrombosis after radiation brachytherapy or with stents that contain antiproliferative agents may relate to impaired endothelial healing, with attendant loss of the anticoagulant and profibrinolytic properties of the normal intimal lining (**see Fig. 44.2**).

Accelerated Arteriosclerosis After Transplantation

Since the advent of effective immunosuppressive therapy such as cyclosporine, the major limitation to long-term survival of cardiac allografts is the development of an accelerated form of arterial hyperplastic disease (**see Chapter 28**). I favor the term *arteriosclerosis* (hardening of the arteries) rather than atherosclerosis (gruel-hardening) to describe this process because of the inconstant association with lipids (the “gruel” in atherosclerosis). This form of arterial disease often presents a diagnostic challenge. The patient may not experience typical anginal symptoms because of post-transplantation cardiac denervation. In addition, graft coronary disease is concentric and diffuse, not only affecting the proximal epicardial coronary vessels but also penetrating smaller intramyocardial branches (**Fig. 44.18**). For this reason, the angiogram, well suited to visualize focal and eccentric stenoses, consistently underestimates the degree of transplantation arteriosclerosis. Computed tomographic angiography provides a newer avenue to diagnose this condition but still has limitations, although it avoids invasive contrast arteriography.[56,57]

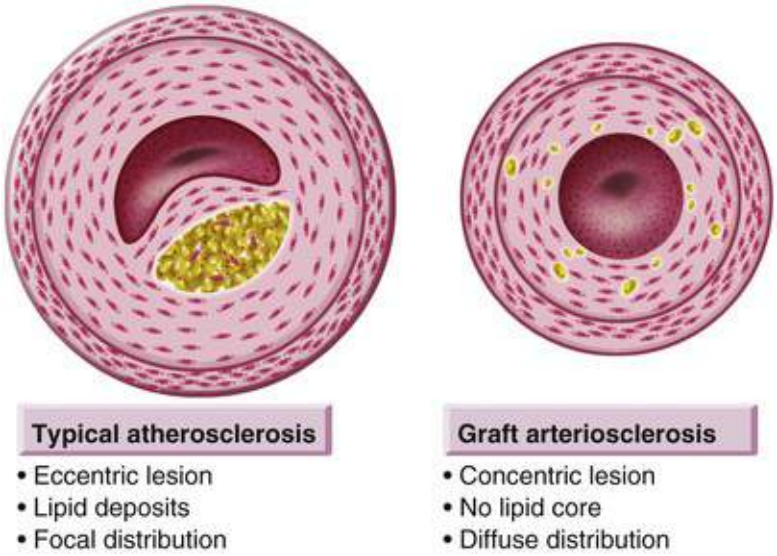

FIGURE 44.18 Comparison of typical and transplantation arteriosclerosis. **Left,** Typical atherosclerosis characteristically forms an eccentric lesion with a lipid core and fibrous cap. **Right,** By contrast, the lesion of transplantation-associated accelerated arteriosclerosis characteristically exhibits a concentric intimal expansion without a clear, central lipid core.

In most centers, most patients undergoing transplantation have atherosclerotic disease and ischemic cardiomyopathy, but a sizable minority undergo heart transplantation for idiopathic dilated cardiomyopathy and may have few (if any) risk factors for atherosclerosis. Even in the absence of traditional risk factors, this latter patient group shares the risk for development of accelerated arteriosclerosis, suggesting that the pathophysiology of this form of accelerated arteriosclerosis differs from that of typical atherosclerosis.

The selective involvement of the engrafted vessels, with sparing of the host's native arteries, suggests that accelerated arteriopathy does not merely result from immunosuppressive therapy or other systemic factors in the transplantation recipient. Rather, these observations suggest that the immunologic differences between the host and recipient vessels might contribute to the pathogenesis of this disease.[23] Considerable evidence from both human and experimental studies currently supports this viewpoint.[58,59] ECs in the transplanted coronary arteries express histocompatibility antigens that can engender an allogeneic immune response from host T cells. The activated T cells can secrete cytokines (e.g., IFN-γ) that can augment histocompatibility gene expression, recruit leukocytes by induction of adhesion molecules, and activate macrophages to produce SMC chemoattractants and growth factors. Interruption of IFN-γ signaling can prevent experimental graft coronary disease in mice.[23]

Therefore, graft arteriosclerosis represents an extreme case of immunologically driven arterial hyperplasia (**Fig. 44.19**) that can occur in the absence of other risk factors. At the other extreme, patients with homozygous familial hypercholesterolemia can develop fatal atherosclerosis in the first decade of life solely as a result of an elevation in LDL. Atherosclerosis in most patients falls somewhere between these two extremes. Analysis of usual atherosclerotic lesions shows evidence for a chronic immune response and lipid accumulation. Thus the study of the extreme cases, such as transplantation arteriopathy and familial hypercholesterolemia, provided insight into elements of the pathophysiology that contribute to the multifactorial form of atherosclerosis that affects the majority of patients.

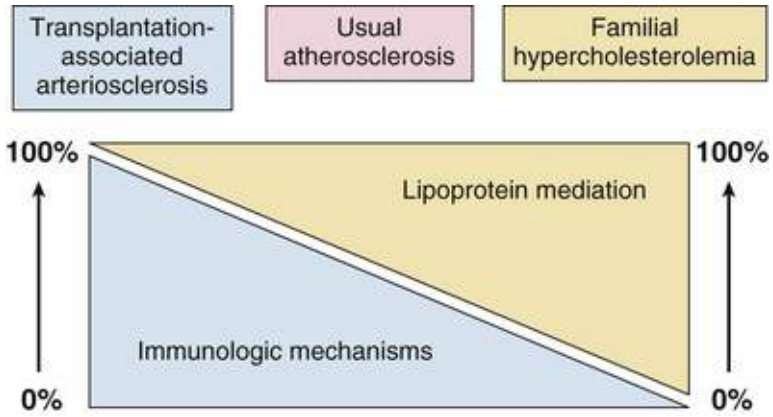

FIGURE 44.19 Multifactorial view of pathogenesis of atherosclerosis, depicting relative contributions of main pathogenic mechanisms in two extreme cases of atherosclerosis. In transplantation-associated disease (*left*), accelerated arteriosclerosis can occur in the transplanted heart in the absence of traditional coronary risk factors. This disease probably represents primarily immune-mediated arterial intimal disease. At the other extreme (*right*), familial hypercholesterolemia, the patient may succumb to rampant atherosclerosis in the first decade of life solely because of an elevated low-density lipoprotein (LDL) level caused by a mutation in the LDL receptor (homozygous familial hypercholesterolemia). Between these two extremes lie most cases of atherosclerosis, probably involving various mixtures of immune and inflammatory or lipoprotein-mediated disease. One can further consider that this diagram extends to a third dimension that would involve other candidate risk factors, such as homocysteine, lipoprotein(a), infection, and tobacco abuse.

Aneurysmal Disease

Atherosclerosis also produces aneurysmal disease (**see Chapter 63**). Why is a single disease process manifested in directionally opposite ways, for example, most often producing stenoses in the coronary arteries but also causing ectasia of the abdominal aorta? In particular, aneurysmal disease characteristically affects the infrarenal abdominal aorta. This region is highly prone to the development of atherosclerosis. Data from the Pathobiological Determinants of Atherosclerosis in Youth (PDAY) study show that the dorsal surface of the infrarenal abdominal aorta has a particular predilection for the development of fatty streaks and raised lesions in Americans younger than 35 years of age who succumbed for noncardiac reasons (**see Fig. 44.1**). Because of the absence of vasa vasorum, the relative lack of blood supply to the tunica media in this portion of the abdominal aorta might explain the regional susceptibility of this part of the arterial tree to aneurysm formation. In addition, the lumbar lordosis of the biped human may alter the hydrodynamics of blood flow in the distal aorta, yielding flow disturbances that may promote lesion formation.

Histologic examination shows considerable distinction between occlusive atherosclerotic disease and aneurysmal disease. In typical coronary artery atherosclerosis, expansion of the intimal lesion produces stenotic lesions. The tunica media underlying the expanded intima often is thinned, but its general structure remains relatively well preserved. By contrast, transmural destruction of the arterial architecture occurs in aneurysmal disease. In particular, the usually well-defined laminar structure of the normal tunica media disappears with obliteration of the elastic laminae. The tunica media of advanced aortic aneurysms have few SMCs, cells often prominent in typical stenotic lesions.

Study of the pathophysiology that underlies these anatomic-pathologic findings has proved frustrating. Experimental aneurysm formation in animals has uncertain relevance to the clinical disease.[55] The human specimens obtainable for analysis generally represent the late stages of this disease. Nonetheless, recent work has identified several mechanisms that may underlie the peculiar pathology of aneurysmal disease. Widespread destruction of the elastic laminae suggests a role for degradation of elastin, collagen, and

other constituents of the arterial ECM. Many studies have documented overexpression of matrix-degrading proteinases, including MMPs, in human aortic aneurysm specimens. Clinical trials have tested the hypothesis that MMP inhibitors can reduce the expansion of aneurysms. In atherosclerotic mice, angiotensin II potentiates aneurysm formation. Alterations in TGF-β signaling can predispose to aneurysm formation. Mutations in TGF-β receptors can cause arterial ectasia.[60,61]

Thus, heightened elastolysis may explain the breakdown of the usually ordered structure of the tunica media in this disease.[62] A slant toward Th2 cell populations in aneurysmal versus occlusive disease may contribute to the overexpression of certain elastolytic enzymes. In addition, aortic aneurysms show evidence for considerable inflammation, particularly in the adventitia. The lymphocytes that characteristically abound on the adventitial side of aneurysmal tissue suggest that apoptosis of SMCs triggered by inflammatory mediators (e.g., soluble cytokines, Fas ligand) elaborated by these inflammatory cells may contribute to SMC destruction and promote aneurysm formation. Although ECM degradation and SMC death also occur in sites where atherosclerosis causes stenosis, these processes appear to predominate in regions of aneurysm formation and to affect the tunica media much more extensively, for reasons that remain obscure.

Infection, the Microbiome, and Atherosclerosis

Interest persists in the possibility that infections may cause atherosclerosis. A considerable body of seroepidemiologic evidence supported a role for certain bacteria, notably *Chlamydia pneumoniae*, and certain viruses, notably cytomegalovirus (CMV), in the etiology of atherosclerosis. These studies spurred a number of in vivo and in vitro experiments that have lent various degrees of support to this concept. Indeed, multiple clinical trials have not shown benefit of antibiotic therapy in secondary prevention of atherosclerotic events.[63]

Several caveats apply in the evaluation of the seroepidemiologic evidence. First, confounding factors should be carefully considered. For example, smokers may have a higher incidence of bronchitis caused by *C. pneumoniae*. Therefore, evidence for infection with *C. pneumoniae* may merely serve as a marker for tobacco use, a known risk factor for atherosclerotic events. In addition, a strong bias favors the publication of positive rather than negative studies. Thus, meta-analyses of seroepidemiologic studies may be slanted toward the positive merely because of underreporting of negative studies. Also, atherosclerosis is a common and virtually ubiquitous disease in developed countries. Many adults have serologic evidence of previous infections with members of Herpesviridae (e.g., CMV) and respiratory pathogens (e.g., *C. pneumoniae*). Sorting out coincidence from causality is difficult when a majority of the population studied exhibit evidence of both infection and atherosclerosis.

Although proof that bacteria or viruses can cause atherosclerosis remains elusive, infections may potentiate the action of traditional risk factors, such as hypercholesterolemia. Based on the vascular biology of atherosclerosis discussed in this chapter, several scenarios might apply. First, cells within the plaque itself may harbor infection. For example, macrophages existing in an established atherosclerotic lesion might become infected with *C. pneumoniae,* which could spur their activation and accelerate the inflammatory pathways currently believed to operate within the atherosclerotic intima. Specific microbial products, such as lipopolysaccharides, heat shock proteins, or other virulence factors, may act locally at the level of the artery wall to potentiate atherosclerosis in infected lesions.

Increased focus on the intestinal microbiome supports the view that exposure of vascular cells to bacterial products such as endotoxin applies in vivo. A slight breach in the integrity of the intestinal epithelium, with release of microbial danger signals, could have a direct effect on vascular cells or could

alter systemic risk factors by activating inflammation in visceral adipose tissue, contributing to insulin resistance and other features of the “metabolic syndrome” cluster.[64] Moreover, metabolites produced by gut microflora from dietary constituents may augment atherogenesis.[65,66]

Extravascular infection also may potentially influence the development of atheromatous lesions and provoke their complication. For example, circulating endotoxin or cytokines produced in response to a remote infection can act locally at the level of the artery wall to promote the activation of vascular cells and of leukocytes in preexisting lesions, producing an “echo” at the level of the artery wall of a remote infection.[67] The acute-phase response to an infection in a nonvascular site also may affect the incidence of thrombotic complications of atherosclerosis by increasing fibrinogen or PAI or by otherwise altering the balance between coagulation and fibrinolysis. Such disturbance in the prevailing prothrombotic, fibrinolytic balance may critically influence whether a given plaque disruption will produce a clinically inapparent, transient or nonocclusive thrombus or sustained and occlusive thrombi that could cause an acute coronary event (**see Fig. 44.16**).

Acute infections also can produce hemodynamic alterations that could trigger coronary events. For example, the tachycardia and increased metabolic demands of fever can augment the oxygen requirements of the heart, precipitating ischemia in an otherwise compensated individual. These various scenarios illustrate how infectious processes, either local in the atheroma or extravascular, may aggravate atherogenesis, particularly in preexisting lesions or in concert with traditional risk factors.

Risk Markers and the Primary Prevention of Cardiovascular Disease

Paul M. Ridker, Peter Libby, Julie E. Buring

Rethinking Core Approaches to Primary Prevention

For almost half a century, interventions to reduce the risk of heart attack and stroke among persons without known heart disease have largely used a two-step process based on absolute risk. First, using a global risk–estimating algorithm such as the Framingham risk score, the Reynolds risk score, or the European Systematic Coronary Risk Evaluation (SCORE), physicians have stratified candidates for primary prevention into lower-, intermediate-, and higher-risk subgroups, typically calculated over a 10-year time frame. Then, guidelines based on such stratification have traditionally targeted lifestyle interventions to those persons at "lower" and "intermediate" risk while limiting more aggressive pharmacologic interventions (e.g., statin therapy) to those with "higher" risk profiles.

Until recently, it was assumed that such a risk-based triage system would distribute primary prevention services efficiently. If the relative benefit of a preventive intervention is similar across all levels of risk, the greatest absolute benefit should occur among persons with the highest absolute risk. Furthermore, treatment allocation on the basis of high global risk should maximize the benefits of intervention (by targeting those at greatest need) while reducing potential adverse actions and cost (by avoiding exposure to treatment among those with the least need).

Currently, however, some in the preventive cardiology community have challenged these long-held beliefs and proposed instead that preventive services should be allocated on the basis of proven randomized trial data—that is, "what works?" and "in whom?"—rather than on the basis of an arbitrary scaling of global risk.[1] This reconsideration has implications for how we think about preventive cardiovascular care as well as for guidelines, for the design of future clinical trials, and for drug treatment.

Consider the situation for statin therapy. Twenty years ago, the volume of trial data on the efficacy of hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors as an adjunct to diet, exercise, and smoking cessation in specific patient groups was limited, safety data were incomplete, and the cost of treatment was relatively high, particularly for higher-potency statin agents. Thus, facing uncertainty, those writing older guidelines chose to model the potential benefits of lipid-lowering treatment on the basis of epidemiologic risk scales, even though those scores had never themselves undergone randomized evaluation for improvement of outcomes, nor were they used as trial enrollment criteria.

Unfortunately, this system of drug allocation based on epidemiologic modeling rather than completed trials has substantive limitations. First, smoking and hypertension are the major drivers of high global risk, yet the interventions of choice for such individuals should be smoking cessation and blood pressure reduction rather than lipid-lowering therapy. Second, risk prediction models often have proved inadequate in terms of discrimination and calibration (**see Chapter 9**). Third, on a population basis, the vast majority of future vascular events occur in persons with intermediate or low 10-year risk estimates, so limiting intervention only to those with highest absolute risk misses large opportunities for prevention. Concepts of lifetime risk suggest that those patients with low 10-year risks often are among those with the highest long-term event rates, for whom early interventions could prove most effective.[2] Finally, genetic modeling shows that earlier interventions (e.g., low-density lipoprotein [LDL]–lowering therapy) confers

much greater benefit than their delayed use.[3,4]

Indeed, the results of multiple randomized trials completed since 2005 do not support the notion that statin therapy has constant relative benefits across all risk groups, yet this assumption remains the fundamental justification for arguments to base therapy on absolute risk. Consider the CORONA (Controlled Rosuvastatin Multinational Trial in Heart Failure), AURORA (A Study to Evaluate the Use of Rosuvastatin in Subjects on Regular Hemodialysis: an Assessment of Survival and Cardiovascular Events), 4D (German Diabetes and Dialysis Study), and GISSI-HF (Gruppo Italiano per lo Studio della Sopravvivenza nell'Insufficienza Cardiaca–Heart Failure) trials, which in total included 13,613 patients and were reported between 2005 and 2009. All four of these well-conducted trials enrolled high–absolute-risk patients who achieved large LDL cholesterol reductions with statin therapy, yet none showed significant clinical benefit.[5]

Consider further the JUPITER (Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin), AFCAPS/TexCAPS (Air Force/Texas Coronary Atherosclerosis Prevention Study), MEGA (Management of Elevated Cholesterol in the Primary Prevention Group of Adult Japanese), and HOPE-3 (Heart Outcomes Protection Evaluation) trials, which included more than 44,000 primary prevention patients and were published between 1998 and 2016.[6] These four trials enrolled low–absolute risk patients, yet each showed marked benefit of statin therapy.

Taken together, these trials challenge the concept that absolute risk alone is the only clinically effective method for allocation of statin therapy. Why then continue to recommend that statins be prescribed on the basis of an epidemiologic calculation of absolute risk? Why not allocate statins instead to patient subgroups proven in clinical trials to benefit from them?

What Works and in Whom? A Simple Evidence-Based Alternative to the Prevention of Cardiovascular Disease

At least with regard to statin therapy, few if any of the basic justifications for a “risk-based” approach to prevention remain relevant. Data on safety now abound, and the evidence base has established that benefits of statin therapy on myocardial infarction (MI), cerebrovascular accident (stroke), revascularization procedures, and cardiovascular death outweigh the risks even for those at the lower end of the absolute vascular risk spectrum. Second, generic formulations of almost all statin agents have become available, and the cost of treatment has declined dramatically. Third, the cardiovascular community currently has abundant data from large-scale, randomized, placebo-controlled trials (RCTs) that cover a wide range of patient groups, enabling the direct application of trial data to clinical care without need for epidemiologic extrapolation.

In view of the current abundance of data, a simple evidence-based guideline for statin therapy using the concepts of “what works?” and “in whom?” from completed RCTs needs no complex modeling. As an example of this emerging approach, preventive cardiologists in the United States, Canada, and Europe have suggested the following list of five recommendations as a simple, easily understood guideline for the use of statin therapy in the prevention of cardiovascular disease (CVD):

1. On this basis of high-quality randomized clinical trial data, statin therapy should be used as an adjunct to diet, exercise, and smoking cessation for secondary prevention patients with a previous

history of MI, stroke, or clinically apparent atherosclerosis (4S [Scandinavian Simvastatin Survival Study], HPS [Heart Protection Study], CARE [Cholesterol And Recurrent Events], LIPID [Long-Term Intervention with Pravastatin in Ischaemic Disease]).

2. High-quality randomized trial data support the use of statin therapy as an adjunct to diet, exercise, and smoking cessation in the setting of primary prevention for those age 50 and over with either diabetes (CARDS [Collaborative Atorvastatin Diabetes Study]), elevated LDL cholesterol (WOSCOPS [West of Scotland Coronary Prevention Study], MEGA), low HDL cholesterol (AFCAPS), elevated high-sensitivity C-reactive protein (hsCRP) (JUPITER), or multiple risk factors (HOPE-3). For patients who do not meet these criteria, physicians may consider issues such as genetic predisposition or a strong family history of premature coronary disease when making decisions for individual patients at different ages in primary prevention. For some of these patients, such as those suspected of having familial hyperlipidemia, referral to lipid or atherosclerosis specialists may be useful for considerations of secondary testing and potential use of alternative or additional lipid-lowering therapies.[7]
3. On the basis of high-quality randomized trial data, when prescribing statin therapy, physicians should seek to maximize the intensity of treatment and then focus efforts on compliance and long-term adherence (PROVE-IT [Pravastatin or Atorvastatin Evaluation and Infection Therapy], TNT [Treating to New Targets], IDEAL [Incremental Decrease in Clinical Endpoints Through Aggressive Lipid Lowering]). The target dose for an individual patient should be a dose close to or at the highest level the individual patient tolerates without side effects.
4. On the basis of high-quality randomized trial data, the use of nonstatin lipid-lowering agents for monotherapy or in combination with a statin should be limited awaiting evidence that such an approach further reduces cardiovascular event rates in specific patient groups. A number of trials with nonstatin agents have failed to show benefits (**see Chapter 48**) (AIM-HIGH [Atherothrombosis Intervention in Metabolic Syndrome with Low HDL/High Triglycerides: Impact on Global Health Outcomes], HPS2-THRIVE [Heart Protection Study 2–Treatment of HDL to Reduce the Incidence of Vascular Events], ACCORD [Action to Control Cardiovascular Risk in Diabetes], FIELD [Fenofibrate Intervention and Event Lowering in Diabetes]). By contrast, trial data have demonstrated that the addition of ezetimibe to statin therapy modestly improves outcomes (IMPROVE-IT [Improved Reduction of Outcomes: Vytorin Efficacy International Trial]).[8] Patients who demonstrate statin intolerance or have familial hyperlipidemia and exceptionally high LDL cholesterol, or who have a risk of pancreatitis may benefit from secondary evaluation by lipid specialists.
5. A guideline based on trial evidence (to determine what works) and on trial entry criteria (to ascertain in whom) is simple, practical, and consistent with evidence-based principles and should therefore result in broad clinical acceptance. New advances in prevention should be incorporated into guidelines as quickly as possible. Thus, if data on new agents demonstrate evidence of event reduction superior to that achieved with statin therapy alone, evidence of event reduction among those who are statin intolerant, or evidence of incremental event reduction as an adjunct to statin therapy, rapid updates to guidelines should address such important advances.

Several recent investigations have evaluated how the incorporation of trial data can best be introduced into guidelines for practice.[9,10] Clinicians should be aware that not all individuals with a calculated risk above the American College of Cardiology (ACC) and American Heart Association (AHA) threshold of 10% would have qualified for a major statin trial (**Fig. 45.1**).

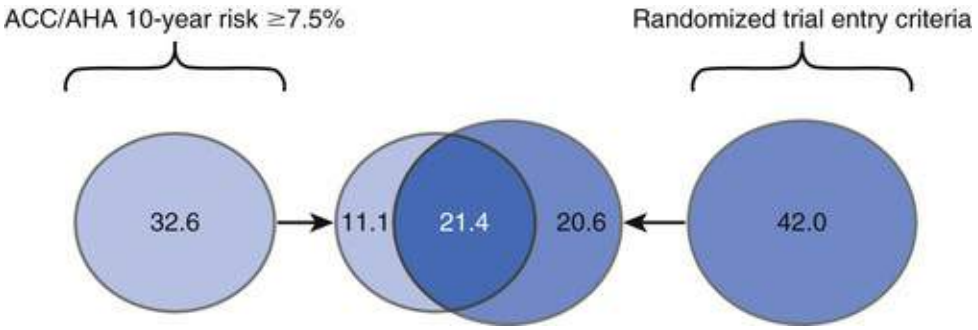

FIGURE 45.1 These Venn diagrams illustrate an approach to statin allocation in primary prevention: Base Case Venn diagram comparing the 10-year absolute risk approach with the trial entry criteria approach for allocation of statin therapy in primary prevention. The ACC/AHA 10-year risk criteria of ≥7.5% would recommend that 32.6 million Americans take statins (*light-blue circle, left*), while 42.0 million Americans would receive statin therapy according to a base case randomized trial entry criteria (*medium-blue circle, right*). The area of intersection of these two approaches indicates that 21.4 million individuals have both a calculated 10-year risk ≥7.5% and would meet eligibility requirements for at least one of the major statin trials that established efficacy (*dark blue, middle*). (From Ridker PM, Rose L, Cook N. A proposal to incorporate trial data into a hybrid ACC/AHA algorithm for the allocation of statin therapy in primary prevention. J Am Coll Cardiol 2015;65:942-8.)

Merging Epidemiology and Randomized Trial Evidence: Why Measure Risk Factors?

This chapter reviews the epidemiologic and clinical trial evidence underlying risk markers and interventions to reduce atherothrombotic risk in three parts. The next section describes the conventional risk factors of smoking, hypertension, hyperlipidemia, and insulin resistance and diabetes, as well as general strategies for reducing risk related to these disorders. This section explores some of the issues and controversy surrounding the concept of the "metabolic syndrome." It also reviews evidence describing the use of low-dose aspirin in primary prevention and briefly discusses the conceptual basis for the "polypill."

Not all coronary events occur in people with multiple traditional risk factors, however, and in some patients, abnormalities of inflammation, hemostasis, and thrombosis appear to contribute decisively. In particular, almost half of all MIs and strokes occur among persons without hyperlipidemia. Thus, after conventional risk factors, another section review atherothrombotic risk markers, including hsCRP and other markers of inflammation, such as interleukin (IL)-1, IL-6, fibrinogen, and lipoprotein-associated phospholipase A_2 (Lp-PLA_2), as well as lipoprotein(a) (Lp[a]). Each case reviews the evidence that these novel risk indicators add to risk prediction beyond conventional factors. This section also addresses the use of direct plaque imaging as a method of risk detection and emerging concepts in the use of genetic biomarkers to help elucidate vascular risk and target novel therapies.

The final section of the chapter addresses a series of environmental exposures and behavioral issues that have a major impact on vascular health. This section reviews mental stress and depression and cardiovascular risk; diet, dietary supplements, obesity, exercise, and weight loss; current evidence supporting moderate alcohol use; controversies surrounding postmenopausal estrogen; and community-based and multiple–risk factor intervention programs.

Each of the following sections begins by focusing on the epidemiologic evidence linking the specific biomarker, exposure, or behavior to subsequent vascular risk. In the setting of primary prevention, it is important to recognize that physicians do not measure biomarkers simply to predict risk (**see Chapter 9**).

Rather, they do so to target therapy better and to improve the lives of their patients. Thus, when considering the use of any biomarker for cardiovascular risk prediction in primary prevention, thoughtful clinicians should insist that two fundamental questions be answered affirmatively: First, does evidence establish that the biomarker of interest predicts future cardiovascular events independent of other risk markers? Second, does evidence show that persons identified by the biomarker of interest benefit from a therapy they otherwise would not have received?

As described later, on the basis of current data, no imaging biomarker can yet answer these questions affirmatively, nor can measurement of a variety of plasma biomarkers, such as Lp(a), homocysteine, and triglycerides. For cholesterol and for hsCRP, however, the answer to both of these questions is "yes," because RCTs have shown that patients identified by either of these biomarkers benefit greatly from statin therapy. These findings are of particular pathophysiologic interest in the modern view of atherothrombosis as resulting from hyperlipidemia interacting with inflammation to initiate and accelerate all phases of the disease process[11] (**see Chapter 44**). Supporting this view, cholesterol crystals trigger IL-1β–activating inflammasome, thus providing a key link between lipids, inflammation, and vascular disease.[12,13]

Finally, we should strive for more "personalized" approaches to treatment in both primary and secondary prevention. Consider for example the three individuals in **Fig. 45.2**, all of whom have known atherosclerosis and are being treated with a higher-intensity statin and other standard-of-care measures. The individual on the left has "residual cholesterol risk" because the on-treatment LDL cholesterol levels remain high; this individual might benefit from the use of ezetimibe or a PCSK9 inhibitor. The middle individual presents a very different profile, with a well-controlled LDL but above-median hsCRP, a situation denoted "residual inflammatory risk." The individual on the right has LDL and hsCRP in an acceptable range, but triglycerides higher than desired; this patient could have "residual triglyceride-remnant risk." Optimum treatment regimens for individuals in these three distinct categories could differ greatly.

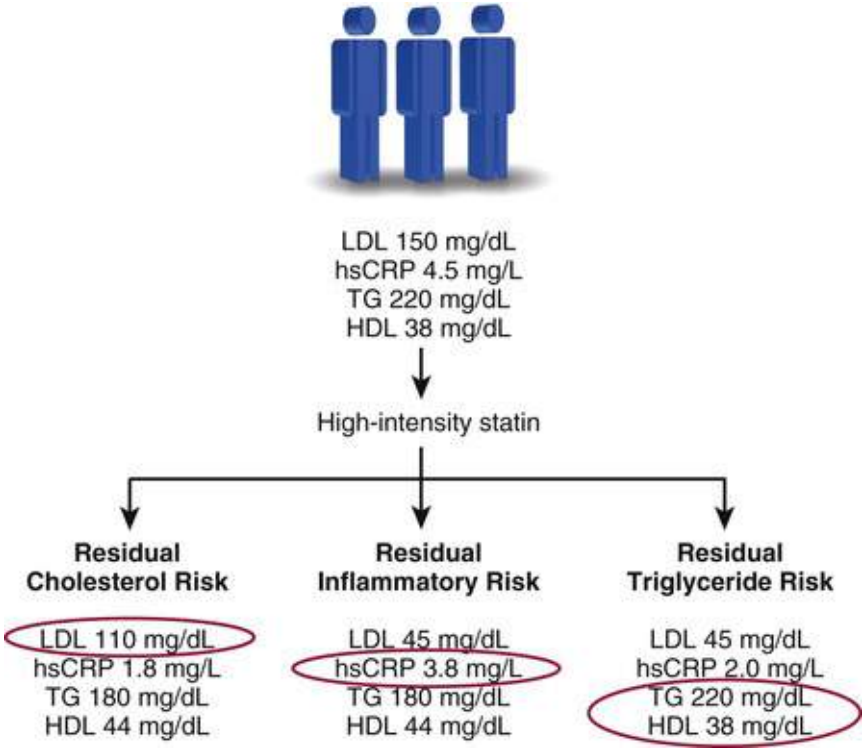

FIGURE 45.2 "Personalized" secondary prevention treatment strategies for patients treated with statins. The figure compares residual inflammatory risk to residual cholesterol risk. LDL, Low-density lipoprotein; hsCRP, high-sensitivity C-reactive protein; TG, triglycerides; HDL, high-density lipoprotein. (From Ridker PM. Residual inflammatory risk: addressing the obverse side of the atherosclerosis prevention coin. Eur Heart J 2016;37:1720.)

Conventional Risk Markers and Associated Interventions

Smoking

Smoking remains the leading preventable cause of death and disease in the United States and the single most important risk factor for coronary artery disease. As described in the 2014 Surgeon General's Report, The Health Consequences of Smoking—50 Years of Progress,[14] more than 20 million premature deaths attributable to smoking and exposure to secondhand smoke have occurred since the first Surgeon General's Report on smoking and health in 1964. Most of these deaths have been among those with a history of smoking, but 2.5 million are among nonsmokers who died from diseases caused by exposure to secondhand smoke. Despite the declines in the prevalence of current smoking, cigarette consumption still accounts for approximately 480,000 deaths from smoking-related illnesses each year. Smoking causes 32% of coronary heart disease deaths. Moreover, the annual smoking-attributable economic costs for the years 2009 to 2012 totaled $300 billion, including direct health care expenditures and loss in productivity.

The prevalence of adults smoking cigarettes declined to 16.8% in 2014 from 42% in 1965;[14,15] for adults 18 to 24 years of age, current smoking prevalence declined from 24.4% to 18.9%. However, the decline in smoking prevalence has slowed recently (**Fig. 45.3**). Males have higher prevalence of smoking than females (18.8% versus 14.8%). Smoking is greater among those 25 to 44 years of age (20.0%) than those 65 years of age and older (8.5%). Large disparities persist in tobacco use across racial/ethnic groups and between groups defined by education level, socioeconomic status, and region. Prevalence is lowest among non-Hispanic Asians (9.5%) and highest among non-Hispanic American Indians and

Alaska Natives (29.2%). Prevalence is also higher among adults living below the federal poverty level (26.3%), those reporting a General Education Development certificate (43.0%), and those receiving Medicaid or who are uninsured (28%) (**eFigs. 45.1 and 45.2**).

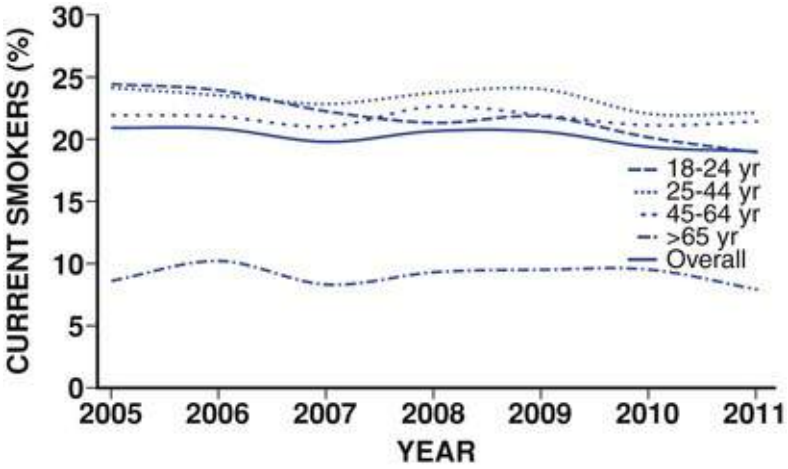

FIGURE 45.3 The percentage of adults aged 18 years and older who self-report as current smokers, by age group. National Health Interview Survey, United States, 2005 to 2011. (From US Centers for Disease Control and Prevention. Current cigarette smoking among adults—United States, 2011. MMWR 2012;61:889.)

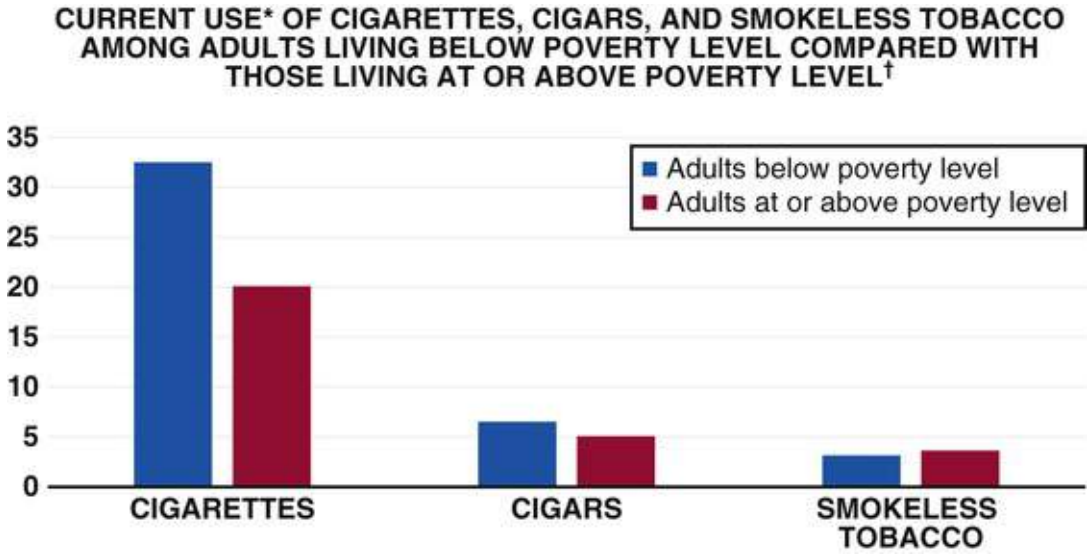
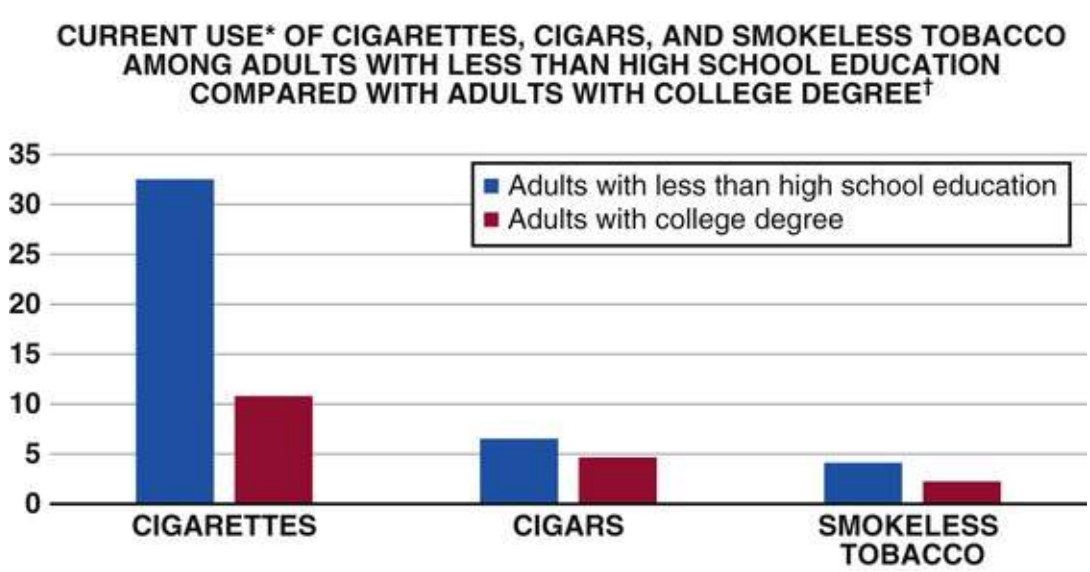


EFIGURE 45.1 *Self-reported use of cigarettes, cigars, or smokeless tobacco in month before the time of survey constituted "Current Use." †These data from the National Survey on Drug Use and Health, 2012, refer to adults ≥18 years old.



EFIGURE 45.2 *Self-reported use of cigarettes, cigars, or smokeless tobacco in month before the time of survey constituted "Current Use." †These data from the National Survey on Drug Use and Health, 2012, refer to adults ≥18 years old.

The U.S. *Healthy People 2020* initiative aims to reduce the national prevalence of cigarette smoking among adults to a target of 12%. The most recent period of 2005 to 2014 saw only a slight overall decline in current smoking prevalence, but the mean number of cigarettes smoked per day among daily smokers declined (16.7 in 2005 to 13.8).[14] However, a significant decline from 2005 to 2011 did not result from smoking cessation; although the proportion who smoked 30 cigarettes or more per day dropped, those smoking 1 to 9 cigarettes per day increased correspondingly.

Consumption of tobacco products is increasing globally, with almost 80% of the world's 1 billion smokers living in low- and middle-income countries[16] (**see Chapter 1**). The use of tobacco products among children is also an increasing global issue; according to the Global Youth Tobacco Survey among students 13 to 15 years of age, the prevalence of use of any tobacco products has a wide range throughout the world, from 1.7% in Kazakhstan to 28.9% in Timor-Leste.[17]

Recent reports indicate the patterns of tobacco use are changing, with increasing use of other products, such as electronic cigarettes and hookahs. Among U.S. working adults, an estimated 3.45 million (4.5%) males and 2.05 million (3.0%) females used e-cigarettes in 2014, with the highest prevalence among 18- to 24-year-olds (5.1%) and whites (4.5%).[18] With regard to high school and middle school students,[19] in 2015 an estimated 3.82 million high school students (25.3%) used any tobacco product, with 16.0% using e-cigarettes, 9.3% cigarettes, and 7.2% hookah pipes. More males than females used any tobacco product, and Hispanics used more than other racial/ethnic groups. An estimated 7.4% (880,000) middle school students used any tobacco product: with 5.3% using e-cigarettes, 2.3% cigarettes, and 2.0% hookah pipes. As with the high school students, more males than females used any tobacco product, and more Hispanics than other racial/ethnic groups.

We currently lack adequate data to assess long-term the patterns of e-cigarette use, the harmful effects, or the beneficial effects on smoking cessation. Recent reviews[20,21] and the U.S. Preventive Services Task Force (PSTF)[22] have concluded that the current evidence is insufficient at this time to recommend electronic nicotine delivery systems for tobacco cessation in adults, including pregnant women. As of August 8, 2016, the U.S. Food and Drug Administration (FDA) has extended the agency's regulatory authority to all tobacco products, including e-cigarettes and hookahs (waterpipes), and required manufacturers to report product ingredients and undergo the agency's premarket review to receive marketing authorization.[23]

Landmark studies in the early 1950s first reported strong positive associations between cigarette smoke

exposure and coronary heart disease (CHD). Over the next 50 years, an exceptionally consistent series of prospective studies have documented the effects of smoking on coronary risk. The 1964 Surgeon General's report reaffirmed the epidemiologic correlation, and by 1983 the Surgeon General had firmly established cigarette smoking as the leading avoidable cause of CVD. Based largely on studies among men, the 1989 Surgeon General's report showed that smoking doubles the incidence of CHD and increases CHD-related mortality by 50%, and that these risks increase with age and the number of cigarettes smoked. “Light” levels of smoking have a major impact on MI and all-cause mortality, even among smokers who do not report inhalation. In addition to MI, cigarette consumption directly relates to increased rates of sudden death, aortic aneurysm formation, symptomatic peripheral vascular disease, and ischemic stroke. Prospective evidence has linked cigarette consumption to an elevated risk of hemorrhagic stroke, including intracranial hemorrhage and subarachnoid hemorrhage, again in a dose-response manner. Continued smoking is also a major risk factor for recurrent MI, as well as adverse clinical outcomes in patients undergoing revascularization with coronary artery bypass grafting (CABG) or percutaneous coronary intervention (PCI).[24] Even among nonsmokers, inhaled smoke, whether from passive exposure or from cigar or pipe consumption, increases CHD risk. Passive smoking exposure can cause endothelial vasodilator dysfunction in the coronary circulation, as well as increased bronchial responsiveness and concomitant pulmonary dysfunction. There is no safe level of exposure to secondhand tobacco smoke.

Beyond acute unfavorable effects on blood pressure and sympathetic tone and a reduction in myocardial oxygen supply, smoking contributes to the pathogenesis of atherothrombosis by several other mechanisms. In addition to impaired endothelium-dependent vasodilation, smoking has adverse hemostatic and inflammatory effects, including increases in levels of C-reactive protein (CRP), soluble intercellular adhesion molecule-1 (ICAM-1), fibrinogen, and homocysteine. Additionally, smoking is associated with spontaneous platelet aggregation, increased monocyte adhesion to endothelial cells, and adverse alterations in endothelium-derived fibrinolytic and antithrombotic factors, including tissue-type plasminogen activator (t-PA) and tissue pathway factor inhibitor. Compared with nonsmokers, smokers have an increased prevalence of coronary spasm and a reduced threshold for ventricular arrhythmias. Accruing evidence has suggested that insulin resistance represents an additional mechanistic link between smoking and premature atherosclerosis.

Smokers lose at least one decade of life expectancy compared with never-smokers.[25] Women's risks for CVD from smoking have risen sharply over the last 50 years and now equal that of men.[14,26] Women incur similar increases in the relative risk for CHD. Moreover, smoking acts synergistically with oral contraceptives (OCs), placing young female smokers who take OCs at particularly elevated risks for premature CHD, stroke, and venous thromboembolism.[27] Smoking is especially hazardous for women with diabetes.

Interventions for Smoking Cessation

The prevalence of smoking is declining, although slowly. If current rates continue, the annual burden of smoking-attributable mortality will remain at high levels for decades, with 5.6 million Americans younger than 18 years of age projected to die prematurely from smoking-related disease.[14] Cessation of cigarette consumption overwhelmingly remains the single most important intervention in preventive cardiology. Although data from large-scale, randomized trials concerning the risk reduction associated with smoking cessation are limited, observational studies consistently demonstrate the benefits of smoking cessation. Smokers who quit reduce their excess risk of a coronary event by 50% within the first 2 years after cessation, with much of this benefit seen even within the first few months (**Fig. 45.4**). CHD risk falls

substantially within 1 to 2 years of cessation, with the risk in former smokers approaching that in never-smokers after 3 to 5 years. Similarly, the risk of stroke decreases steadily after smoking cessation, with former smokers having the same stroke risk as in nonsmokers after 5 to 15 years. Moreover, the beneficial effects on CHD and mortality rates are seen even among elderly persons, supporting the idea that it is never too late to quit smoking for decreasing CHD-associated risks. These risk reductions equal or exceed those for other secondary prevention interventions that have received more attention from physicians and the pharmaceutical industry, including the use of aspirin, statins, beta-adrenergic blocking agents, and angiotensin-converting enzyme (ACE) inhibitors.

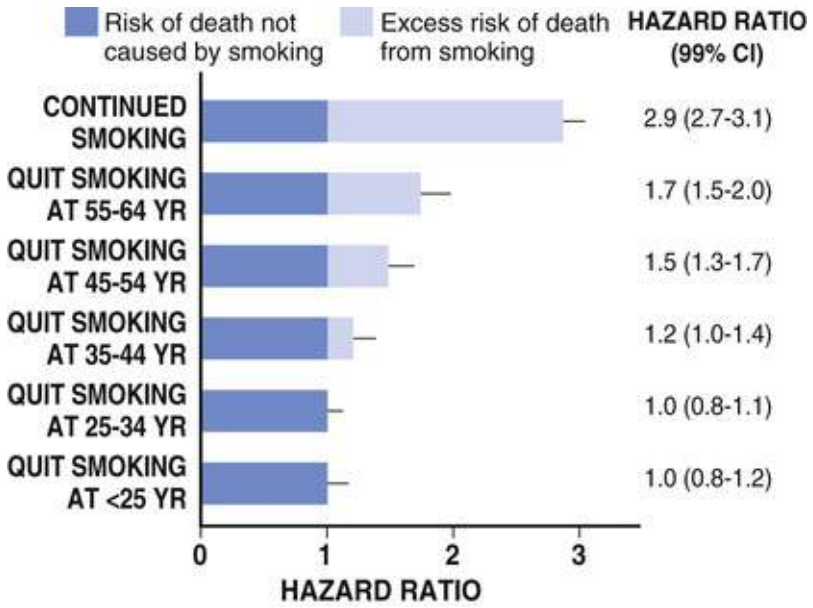


FIGURE 45.4 Risks of death for continuing smokers and those who quit, according to age at time of cessation; CI, confidence interval. (From Jha P, Ramasundarahettige C, Landsman V, et al. 21st-century hazards of smoking and benefits of cessation in the United States. N Engl J Med 2013;368:341.)

In 2012, more than 4 of 10 (42.7%) adult daily cigarette smokers in the United States stopped smoking for more than 1 day because they were trying to quit,[14,28,29] including 48.5% of smokers age 18 to 24. Poor patient understanding of the importance of smoking cessation continues. Substantial misunderstanding surrounds, for example, the observation that smoking predicts better outcome after various reperfusion strategies (the so-called smoker's paradox). Some researchers have regarded this effect as a “benefit” of smoking, but it probably reflects that smokers tend to undergo such procedures at a much younger age and thus have on average lower rates of comorbid illness.[30]

Clinical practice guidelines recognize tobacco dependence as a chronic condition that often requires repeated interventions. Nevertheless, effective evidence-based treatments do exist.[29] Multiple attempts may be necessary, but smokers can and do quit smoking. In fact, since 2002, the number of former smokers has exceeded number of current smokers.[14]

Multifaceted smoking cessation interventions have proved effective. A number of individual-level treatments have shown less efficacy for smokers who want help to quit.[31,32] These approaches include brief clinical interventions (e.g., a physician taking 10 minutes or less to deliver advice and assistance about quitting); counseling (e.g., individual, group, or telephone); behavioral cessation therapies (e.g., training in problem solving); treatments with more person-to-person contact and intensity; and programs to deliver treatments using mobile phones. Cessation medications effective for treating tobacco dependence include nicotine replacement products, either over-the-counter (e.g., nicotine patch, gum,

lozenge) or prescription (e.g., nicotine patch, inhaler, nasal spray), and prescription non-nicotine medications such as bupropion or varenicline. A 2012 Cochrane review[33] of 150 trials of nicotine replacement therapy (NRT) with more than 50,000 people found no overall difference in effectiveness between different forms of NRT; found that NRT was effective with or without counseling; that a combination of NRT and bupropion was more effective than bupropion alone; and found no evidence that NRT increased the risk of heart attacks.

Reductions in smoking from any mechanism improve health outcomes, particularly when linked to lifestyle changes, including exercise and dietary control. Pharmacologic programs, as well as physician-guided counseling, are cost-effective and should be provided as standard prevention services. Smoking low-tar or low-nicotine cigarettes rather than regular cigarettes does not appear to reduce the risk of CHD. Although the elevated cardiovascular risks associated with smoking decrease significantly after cessation, the risk for development of cancer of the lungs, pancreas, or stomach persists for more than a decade, as it does that for chronic obstructive pulmonary disease (COPD). Smoking cessation has clear benefit, but smoking reduction alone appears to have only a marginal effect.

A number of global evidence-based methods for population-based smoking cessation also exist.[29,16] The World Health Organization (WHO) Framework Convention on Tobacco Control, which began in 2005, has been one of the most widely accepted treaties in the history of the United Nations, with more than 180 parties covering 90% of the world's population. In 2008, WHO introduced a package of evidence-based tobacco control measures to help countries implement the WHO Framework Convention. Entitled MPOWER, the interventions include increasing prices of tobacco products; antitobacco media campaigns featuring graphic personal stories on the adverse health impacts of smoking; implementing smoke-free laws for workplaces and public places; barrier-free access to help quitting; and enforcing restrictions on tobacco advertising, promotion, and sponsorship. Studies carried out after the implementation of pictorial package warnings in a number of countries consistently have shown that they significantly increase people's awareness of the harms of tobacco use. Increasing tobacco taxes have also reduced tobacco use.

Accomplishing the goal of *Healthy People 2020* to reduce the U.S. national prevalence of cigarette smoking among adults to a target of 12% will require more extensive implementation of the evidence-based tobacco control interventions just listed. These measures are critical to reduce cigarette smoking among U.S. adults.[31,32] Sustained comprehensive state tobacco control programs funded at the U.S. Centers for Disease Control and Prevention (CDC)–recommended levels could accelerate progress towards reducing the health and economic burdens of tobacco-related diseases. Only two states have funded tobacco control programs at CDC-recommended levels, whereas 27 states are funded at less than a quarter of these levels. State funding in tobacco control programs has in fact decreased during the last 5 years. Good monitoring is important to track the extent and character of the tobacco epidemic and indicates how best to tailor policies.

Several advances in tobacco control have occurred recently in the United States. Four new laws have reinvigorated the national effort, including expansion of the 2009 Family Smoking Prevention and Tobacco Control Act, which grants the FDA the authority to regulate the manufacture, distribution, and marketing of all tobacco products; the Children's Health Insurance Reauthorization Act; the Prevent All Cigarette Trafficking Act; and the Patient Protection and Affordable Care Act (ACA). These laws have granted federal agencies more authority and funding to regulate tobacco products, decrease youth access to tobacco, and increase access to treatment programs. In 2010, the U.S. Department of Health and Human Services (DHHS) presented its first national strategic plan for tobacco control, with 21 action steps involving coverage of cessation treatment, reduction of youth access to tobacco, investments in state and local tobacco control initiatives, and communication efforts to engage the public. A federal mass media

campaign began in early 2012, using graphic personal stories on the adverse health impact of smoking.

In the context of these renewed efforts, however, the low success rates in smoking cessation continue to challenge clinicians. Preventing smoking in the first place should receive greater emphasis. Community education and physician-based primary prevention remain the most important components of any smoking reduction strategy.

Hypertension

Elevated blood pressure (BP) is a major risk factor for CHD, heart failure, cerebrovascular disease, peripheral arterial disease, renal failure, atrial fibrillation, and total mortality, as well as loss of cognitive function and increased incidence of dementia (**see Chapters 46 and 47**). Observational data indicate that death from both CHD and stroke increases progressively from BP levels as low as 115 mm Hg systolic and 75 mm Hg diastolic. For patients 40 to 70 years of age, each increment of 20 mm Hg in systolic or 10 mm Hg in diastolic BP doubles the risk of CVD across a BP range of 115/75 to 185/115 mm Hg. *Prehypertension,* defined as systolic BP of 120 to 139 mm Hg or diastolic BP of 80 to 89 mm Hg, is associated with almost twice the risk of MI and stroke in women compared with normal BP.

More than 75 million adults in the United States and over 1 billion worldwide have *hypertension,* defined as systolic BP of 140 mm Hg or greater or diastolic blood pressure of 90 mm Hg or greater, or taking antihypertensive medicine.[34] Men have a higher percentage of hypertension than women until age 45 years; between 45 and 64, men and women have similar percentages of hypertension; and after 64, a higher percentage of women have diagnosed hypertension than men (**Fig. 45.5**). The prevalence of hypertension increases greatly with age in all races and ethnicities. The age-adjusted prevalence of hypertension in the United States (both diagnosed and undiagnosed) approaches 75% for older women and 65% for older men, and varies geographically, ranging from 23% in Utah to 40% in Alabama.

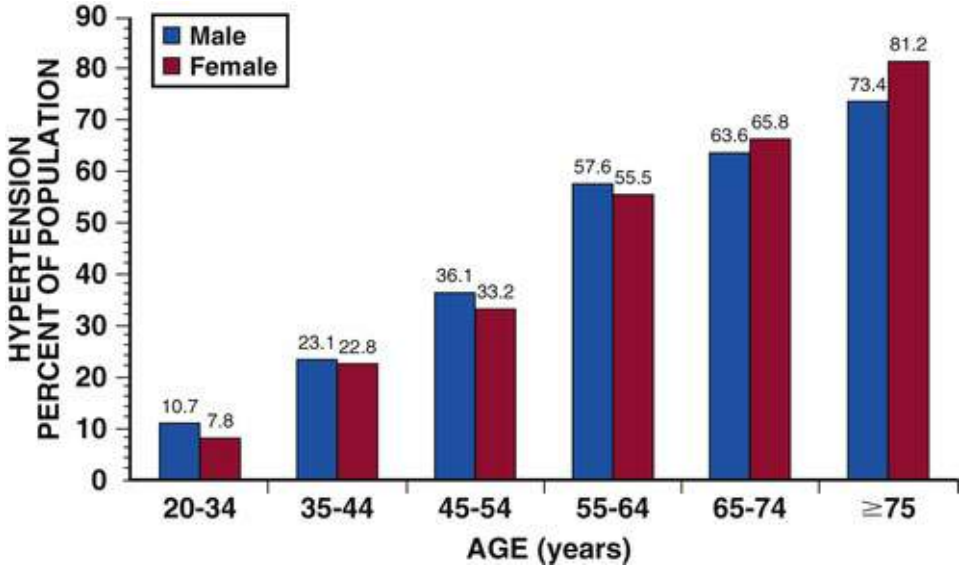

FIGURE 45.5 The prevalence of hypertension in individuals ≥20 years of age according to sex and age (NHANES 2011–2014). Hypertension was defined by systolic blood pressure ≥140 mm Hg or diastolic blood pressure ≥90 mm Hg, a "yes" answer to taking medication for hypertension, or if individual was told twice that she or he had elevated blood pressure. NHANES, National Health and Nutrition Examination Survey. Source: US National Center for Health Statistics and National Heart, Lung, and Blood Institute. (From Benjamin EJ et al. Heart disease and stroke statistics—2017 update: a report from the American Heart Association. Circulation 2017;135:e146.)

Disparities in hypertension by racial and ethnic groups persist (**Fig. 45.6**) (**see Chapter 91**). Blacks develop high BP more often, and at an earlier age, than do whites and Mexican Americans and have higher average BP levels. Among blacks, more women than men have hypertension. As a result, compared with whites, blacks have a 1.3 times greater rate of nonfatal stroke, a 1.8 times greater rate of fatal stroke, a 1.5 times greater rate of death attributable to heart disease, and a 4.2 times greater rate of end-stage kidney disease. Within the black community, rates of hypertension vary substantially, with persons with the highest rates more likely to be middle-aged or older, less educated, overweight or obese, and physically inactive and more likely to have diabetes mellitus, but those with uncontrolled high BP who do not take antihypertensive medication tending to be male and younger and to have infrequent contact with physicians.

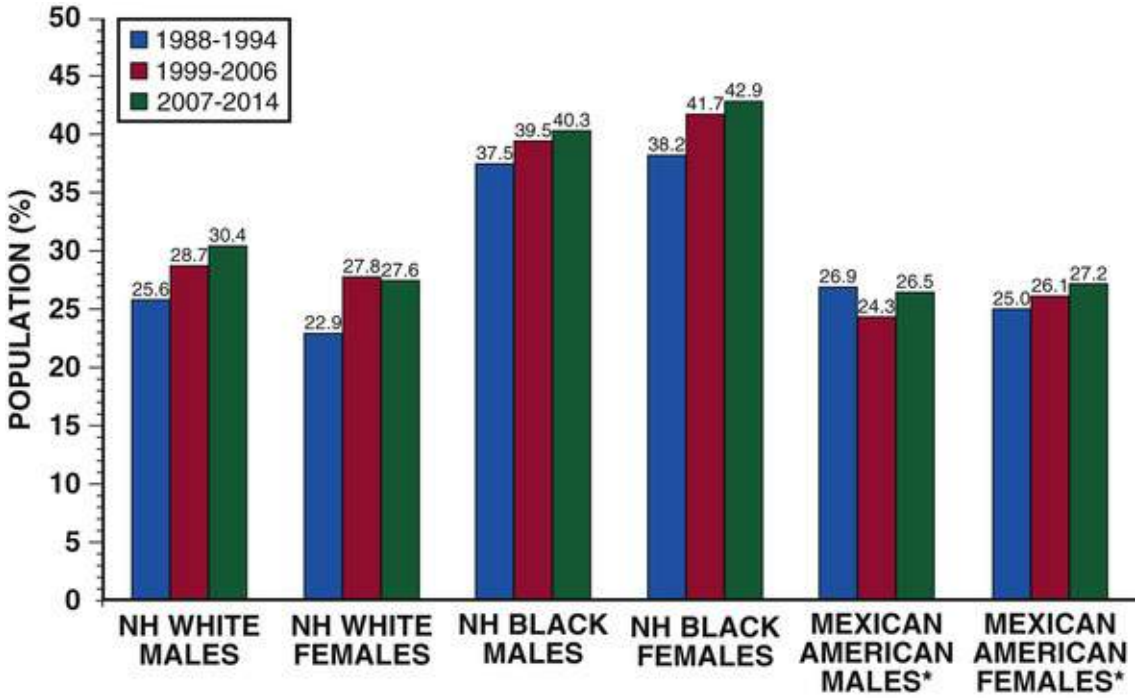

FIGURE 45.6 Age-adjusted prevalence trends for high blood pressure in individuals ≥20 years old according to race/ethnicity, sex, and survey year (NHANES 1988–1994, 1999–2006, and 2007–2014). Hypertension was defined as in **Fig. 45.5**. NH, Non-Hispanic; NHANES, National Health and Nutrition Examination Survey. *All NHANESs collected the category "Mexican Americans," but the use of the combined category of Hispanics only started in 2007. The long-term trend data therefore use the category Mexican American. Source: US National Center for Health Statistics and National Heart, Lung, and Blood Institute. (From Benjamin EJ et al. Heart disease and stroke statistics—2017 update: a report from the American Heart Association. Circulation 2017;135:e146.)

Data from the National Health and Nutrition Examination Survey (NHANES) 2007 to 2010 indicate that 6% of U.S. adults have undiagnosed high BP. Of those with hypertension age 20 or older, 81.5% were aware of hypertension; 74.9% were under current treatment, 52.5% had their BP under control, and 47.5% did not achieve control.[35] Rates of control differ substantially by ethnic and racial groups.

Current evidence indicates that most U.S. patients know their hypertension status, but nearly half do not have their hypertension controlled[36] (**Fig. 45.7**). Data from the Framingham Heart Study show that among those age 80 or older, only 38% of men and 23% of women had BP that met targets set forth in the National High Blood Pressure Education Program's clinical guidelines. Similarly, data from the Women's Health Initiative (WHI) observational study of almost 100,000 postmenopausal women across the country indicate that despite similar treatment rates, older women maintain especially poor hypertensive control.[37]

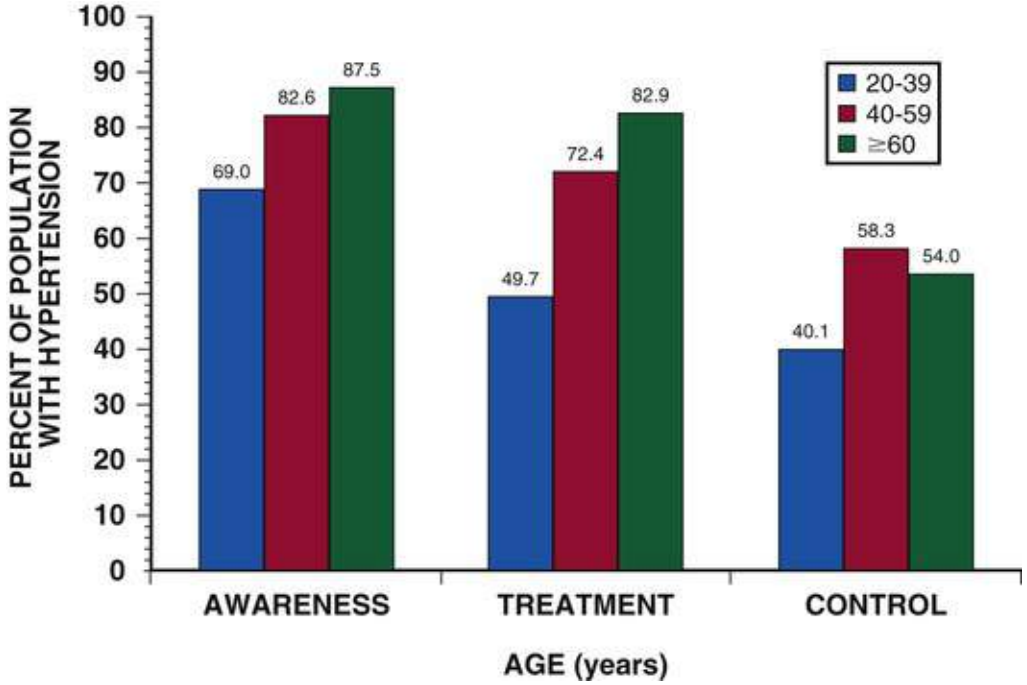

FIGURE 45.7 Extent of awareness, treatment, and control of high blood pressure according to age (NHANES 2007–2012). Hypertension is defined as in **Fig. 45.5**. NHANES, National Health and Nutrition Examination Survey. Source: US National Center for Health Statistics and National Heart, Lung, and Blood Institute. (From Benjamin EJ et al. Heart disease and stroke statistics—2017 update: a report from the American Heart Association. Circulation 2017;135:e146.)

Among U.S. adults with hypertension, 8.9% meet the criteria for resistant hypertension (BP ≥140/90 mm Hg, despite reported use of antihypertensive medications from three different drug classes or drugs from four or more antihypertensive drug classes regardless of BP). This segment represents 12.8% of the population taking antihypertensive medications.[38] On the other end of the spectrum, data from NHANES 1999 to 2006 indicate that 29.7% of U.S. adults age 20 or older have prehypertension, defined as untreated systolic BP of 120 to 139 mm Hg or untreated diastolic BP of 80 to 89 mm Hg and not having been told on two occasions by a physician or other health professional that they have hypertension. Prehypertension is associated with elevated relative and absolute risks for cardiovascular outcomes across the age spectrum, including incident stroke, particularly in nonelderly persons and for those with BP values in the higher prehypertension range.

Costs directly attributable to high BP for the United States total almost $131 billion annually in direct medical expenses and $25 billion in lost productivity, and projections show that by 2030, the total cost of high BP will increase to an estimated $343 billion. By 2025, the total number of adults with hypertension is anticipated to top 1.5 billion. Hypertension causes 7.6 million premature deaths worldwide annually, with 80% of this burden occurring in low-income and middle-income countries[39] (**see Chapter 1**). Approximately three quarters of persons with hypertension (639 million) live in developing countries with limited health resources, and where people have a very low awareness of hypertension and poor BP control. Several hypertension risk factors appear more common in developing countries, including urbanization, aging of the population, changes to dietary habits, and social stress. High illiteracy rates, limited access to health facilities, poor dietary habits, poverty, and high costs of drugs all contribute to poor BP control.

Numerous risk factors and markers for development of hypertension have been identified, including increasing age, ethnicity, family history of hypertension, genetic factors, lower education and socioeconomic status, greater weight, lower physical activity, tobacco use, psychosocial stressors, sleep apnea, and dietary factors (including increased dietary fats, higher sodium intake, lower potassium intake,

and excessive alcohol intake). Patients with concomitant chronic kidney disease (estimated glomerular filtration rate [eGFR] <60 mL/m^2) constitute a high-risk group for focused BP treatment, both to prevent CVD and to slow progression to end-stage renal disease (ESRD). Patients with obesity, the metabolic syndrome, and diabetes also represent high-risk groups for treatment. High BP occurs in more than two thirds of patients with type 2 diabetes, and its development coincides with the development of hyperglycemia.[40] In patients with diabetes, hypertension confers an enhanced risk of CVD. People with controlled diabetes have a similar CVD risk to patients without diabetes but with hypertension. The 10-year risk of a cardiovascular event among women 30 to 74 years of age with uncontrolled hypertension is 6%; however, 56% of these events could be prevented if BP were controlled to normal levels.

Recent (within the last 10 years) and remote antecedent BP levels may contribute importantly to risk beyond the current BP level. Data from the Harvard Alumni Health Study found that higher BP in early adulthood was associated several decades later with higher risk for all-cause, cardiovascular, and coronary heart disease mortality, but not stroke mortality;[41] total life expectancy was 5.1 years longer for normotensive men and 4.9 years longer for normotensive women than for hypertensive people of the same sex at age 50. Similar data have been reported in the CARDIA study, in which cumulative exposure to high BP over 25 years, from young adulthood to middle age, was associated with both systolic and diastolic dysfunction.[42]

Part of the complexity of hypertension as a risk factor relates to changing definitions of risk and the recognition that systolic BP and pulse pressure can contribute as much to risk as does diastolic BP, contrary to decades of clinical teaching. Isolated systolic hypertension, in particular, carries at least as much risk as diastolic BP for the outcomes of total cardiovascular mortality and stroke. Isolated systolic hypertension thus appears to represent a distinct pathophysiologic state in which elevated BP reflects reduced arterial elasticity not necessarily associated with increased peripheral resistance or an elevation in mean arterial pressure.[43]

Pulse pressure, generally reflecting vascular wall stiffness, also predicts first and recurrent MI. Defined as the difference between systolic and diastolic blood pressures, pulse pressure appears to predict cardiovascular events independently and provides prognostic utility beyond that of mean arterial pressure.[44] These data stress the importance of arterial compliance and stiffness in atherogenesis as well as in the development of left ventricular hypertrophy. Arterial stiffness in the carotid distribution is also a major risk marker for incident stroke.[45]

Ambulatory monitoring of BP over 24 hours may provide a stronger predictor of cardiovascular morbidity and mortality than office-based measures. However, studies of home BP evaluation have yielded mixed results. In one cohort of elderly persons, self-measurement of BP had better prognostic accuracy for vascular events than office-based evaluation; another study has determined that nocturnal hypertension diagnosed by continuous monitoring is associated with increased risk of congestive heart failure. By contrast, in a randomized trial comparing office with home BP measurement, self-measurement allowed identification of those persons with “white coat” hypertension, but did not greatly improve overall management or alter objective measures of compliance, such as left ventricular mass. In a recent study from the Dallas Heart Study, both white-coat hypertension (elevated office BP with normal ambulatory BP) and masked hypertension (elevated ambulatory BP with normal office BP) associated independently with increased aortic stiffness, renal damage, and incident vascular events.[46]

Interventions to Reduce Blood Pressure

Past overviews and randomized trials demonstrate that BP reductions as small as 3 to 5 mm Hg result in large and clinically significant reductions in risk for stroke, vascular mortality, congestive heart failure,

and total CHD in middle-aged individuals, elderly persons, and specified high-risk patients such as those with diabetes and peripheral arterial disease. Diet and lifestyle management remain the cornerstone of prevention of hypertension, and clinical trial evidence continues to accrue showing that adopting low-risk dietary measures along with weight reduction, particularly at the societal level, could substantially reduce the burden of BP (**see Chapter 47**).

Experts disagree, however, about the target for pharmacologic BP reduction, an issue of considerable controversy. After many years of a BP goal of less than 140/90 mm Hg, the 7th Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure (JNC 7)[47] suggested lowering the treatment goal to less than 130/80 mm Hg for those with diabetes or renal insufficiency. However, in 2014, another group reversed this trend and, based on available randomized trials, increased the systolic BP goal to less than 150 mm Hg for the majority of individuals age 60 or older.[34] In 2017, another set of guidelines issued jointly by AHA recommended initiation of treatment with lifestyles measures and, in some individuals, medication at a BP as low as 130/80.[48]

Two major clinical trials published in 2015 and 2016 add to the complexity of these seemingly inconsistent guidelines. In the first of these trials, the Systolic Blood Pressure Intervention Trial (SPRINT) investigators randomly assigned 9361 persons without diabetes but with vascular risk and systolic BP greater than 130 mm Hg to a target of less than 120 mm Hg or to a target of less than 140 mm Hg.[49] At 1 year, the mean systolic BPs in the two groups were 121 and 136 mm Hg, respectively. The trial halted early because of a 25% reduction in the incidence of major cardiovascular death in the <120 mm Hg group (hazard ration [HR], 0.75; 95% confidence interval [CI] 0.64 to 0.89), a concomitant 27% reduction in all-cause mortality (HR, 0.73; 95%CI 0.60 to 0.90), and the finding of consistent effects in all major subgroups evaluated (**see Chapter 47 and Fig. 47.5**). Because almost 17 million U.S. adults meet the SPRINT enrollment criteria, these more aggressive BP goals need careful consideration.[50] The ACCORD (Action to Control Cardiovascular Risk in Diabetes) trial evaluated the potential benefits of targeting a systolic BP below 120 mm Hg versus below 140 mm Hg in 4733 patients with type 2 diabetes (individuals excluded from SPRINT.) After a mean of 4.7 years, the annual rate of the primary outcome, a composite of rates of nonfatal MI, nonfatal stroke, and death from cardiovascular causes did not differ significantly between groups (**see Fig. 47.4**). The intensive therapy group experienced fewer strokes but more frequent serious adverse events attributable to BP problems.[51] The investigators thus concluded that the evidence did not justify a systolic BP target below 120 mm Hg in patients with type 2 diabetes.

The Heart Outcomes Prevention Evaluation (HOPE-3) enrolled 12,705 participants at intermediate risk without known CVD allocated to a combination of candesartan (16 mg/day) and hydrochlorothiazide (12.5 mg/day) or to placebo.[52] HOPE-3 was designed as a 2 × 2 factorial trial that also included a statin versus placebo arm described later. HOPE-3 did not require elevated baseline BP for entry. Overall, BP reduction as compared to placebo had no significant effect in HOPE-3 on the trial primary outcomes. However, among those in the top third of the trial's BP range at baseline (>143.5 mm Hg), had a significant benefit on vascular events, whereas effects were neutral among those in the lower two BP categories (**Fig. 45.8**).

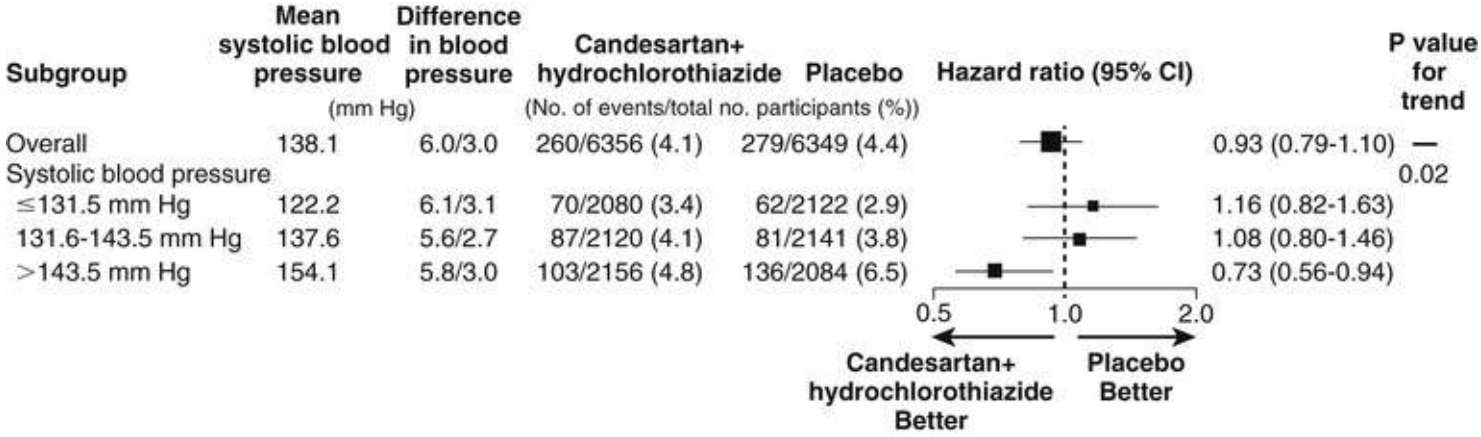

FIGURE 45.8 Forest plot of the co-primary results of the Heart Outcomes Prevention Evaluation (HOPE) 3 trial stratified by systolic blood pressure strata. The difference in BP refers to the average difference of the systolic and diastolic BPs between groups in trial, with the active-treatment group having lower mean values. The composite co-primary outcome included death from cardiovascular causes, nonfatal myocardial infarction, and nonfatal stroke; the size of each square reflects the number of events. (From Lonn EM. et al. Blood-pressure lowering in intermediate-risk persons without cardiovascular disease. N Engl J Med 2016;26;374[21]:2009-20.)

Taken together, the ACCORD, SPRINT, and HOPE-3 trials provide a contemporary new database from which clinicians can decide how aggressive to be with pharmacologic BP reduction. Specific treatment plans for various forms of hypertension are reviewed in detail in **Chapter 47** and the 2017 AHA/ACC guideline. Regardless of pharmacologic treatment plan, for all patients with elevated BP, lifestyle modifications remain important and should include smoking cessation, weight reduction if needed, increased physical activity, limited alcohol intake, limited sodium intake, adequate potassium and calcium intake, and adoption of the Dietary Approaches to Stop Hypertension (DASH) eating plan, a diet with a reduced content of saturated and total fat that also includes abundant fruits, vegetables, and low-fat dairy products.

Initiation of drug therapy depends on BP and the absolute level of risk. Most patients require more than one agent to achieve their BP goals. Meta-analyses have shown that the magnitude of BP reduction determines reduction in cardiovascular risk more than drug choice, and that long-term control usually requires combination therapy, thereby making the choice of drug class less important. Evidence supports the use of ACE inhibitors (or angiotensin receptor blockers [ARBs] in patients who cannot tolerate ACE inhibitors), calcium channel blockers, or thiazide-type diuretics as first-line agents. Available evidence no longer supports the use of beta-adrenergic blocking agents (beta blockers) as first-line therapy for primary prevention, because of less benefit than with other drugs, particularly in elderly persons, and increasing evidence that the most frequently used beta blockers at usual doses carry an unacceptable risk of inducing type 2 diabetes.

Successful treatment of hypertension is difficult despite the availability of several classes of antihypertensive drug and the value of strategies to combat the effect of adverse lifestyle on BP. From 5% to 30% of the overall hypertensive population have resistant hypertension, and approximately 10% of patients have true resistant hypertension without a modifiable cause. Unfortunately, novel interventions such as renal denervation have not demonstrated clinical benefit when tested in rigorous clinical trials.[53]

Low-Density Lipoprotein (LDL) Cholesterol

Of plasma-based atherothrombotic risk factors, LDL cholesterol is the best-established risk factor causally linked to incident MI and cardiovascular death[6] (**see Chapter 48**). High LDL cholesterol levels

consistently predict risk of future cardiovascular events in human populations. Animal studies in multiple species have shown a causal relationship between hypercholesterolemia and atherosclerosis. Abundant evidence provides biologic plausibility for the involvement of LDL in atherogenesis. Furthermore, human mutations that produce hypercholesterolemia on a monogenic basis lead to accelerated atherosclerosis as early as the first decade of life in patients with homozygous familial hypercholesterolemia, while those with heterozygous hypercholesterolemia develop disease approximately 10 to 15 years later. This and other observations have led to the useful office-based concept of a threshold "cumulative lifetime exposure" to LDL cholesterol that, when crossed, results in clinically evident atherosclerosis[54,55] (**Fig. 45.9**). Other recently described mutations that affect LDL metabolism, such as those in the enzyme proprotein convertase subtilisin/kexin type 9 (PCSK9), result in life-long reductions in LDL cholesterol and reduced lifetime risks of events.[56] By contrast, lifetime exposure to moderately elevated levels of LDL cholesterol typically leads to clinical events in the seventh and eighth decades (i.e., 60s and 70s). Finally, interventions in large clinical trials to lower LDL cholesterol levels by various approaches have shown a reduction in cardiovascular events. Thus, LDL cholesterol fulfills the criteria of modified Koch postulates as one causative agent in atherosclerosis.

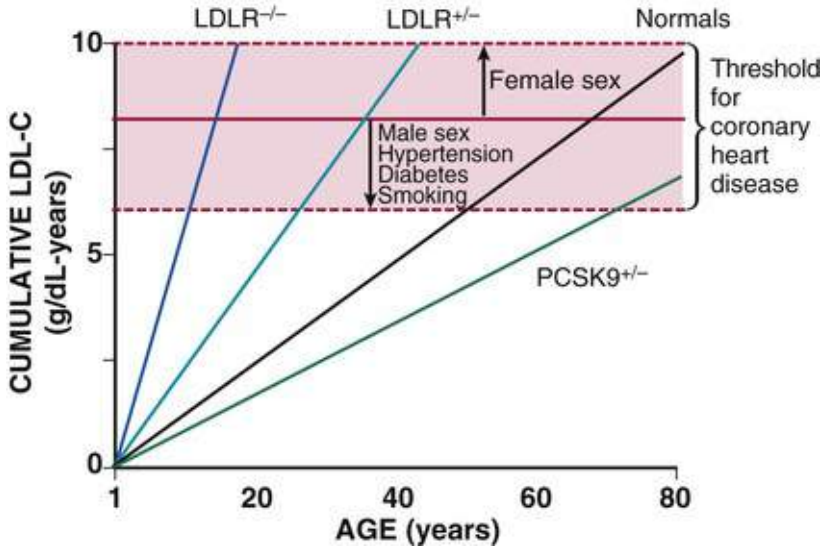

FIGURE 45.9 Graph of the concept of a threshold for cumulative lifetime exposure to LDL cholesterol and the development of clinically manifest atherosclerotic disease. The lines shown are theoretical. (From Horton JD, Cohen JC, Hobbs HH. PCSK9: a convertase that coordinates LDL catabolism. J Lipid Res 2009;50[Suppl]:S172.)

Several independent lines of evidence suggest that what is regarded as "normal" cholesterol levels in Western society exceeds levels that good health requires. In particular, certain rural agrarian societies with very low rates of atherothrombosis exhibit total and LDL cholesterol levels well below those accepted as normal in Western societies. Another line of evidence derives from *phylogeny*. Contemporary humans have much higher total and LDL cholesterol levels than those of many other species of higher organisms that thrive nonetheless. Thus, observational, ecologic, and genetic studies suggest that ever-lower LDLC levels are likely to confer cardiovascular benefits regardless of starting cholesterol levels for an individual patient.[55]

Cholesterol levels measured early in life influence long-term cardiovascular risk and the burden of risk factors for atherosclerosis, including hypercholesterolemia, and correlate with autopsy-proven fatty streak and raised lesion formation in the arterial tree. Studies with long-term follow-up have suggested that cholesterol levels in youth correlate with long-term risk of MI. Substantial evidence suggests that the

burden of risk for CVD begins in young adulthood. Autopsy studies from the Korea and Vietnam conflicts and recent explorations of coronary anatomy by intravascular ultrasonography all indicate that atherosclerosis affects adolescents in Western society, and that this early exposure to elevated levels of LDL cholesterol leads to premature disease in midlife. Visit-to-visit variability in LDL cholesterol is surprisingly wide, and such fluctuations indeed predict subsequent vascular risk.[57]

Interventions to Lower LDL Cholesterol

All patients with elevated LDL cholesterol should undergo aggressive diet and exercise programs before the initiation of pharmacologic therapy. Lowering LDL cholesterol with statins in both primary and secondary prevention, however, is a cornerstone for cardiovascular therapeutics and an elegant demonstration of the power that RCTs can have on the practice of medicine.

In the 2010 Cholesterol Treatment Trialists (CTT) meta-analysis, which included 21 separate statin trials and more than 129,000 participants,[5] every 1.0 mmol/liter reduction in LDL cholesterol was associated with a 22% reduction in vascular events and a 10% reduction in all-cause mortality. Trials that compared statin therapy with placebo and trials that compared higher-intensity regimens with lower-intensity regimens showed similar effects (**see Fig. 48.7**). All subgroups evaluated showed risk reductions of similar magnitude, with no evidence of effect modification according to baseline LDL cholesterol level. With regard to side effects, no evidence was found for any increase in cancer or deaths from nonvascular causes.

In an even more comprehensive CTT 2012 meta-analysis, the benefits associated with statin use are, if anything, at least as impressive in primary prevention as in secondary prevention.[58] Indeed, in the primary prevention trials (WOSCOPS, AFCAPS/TexCAPS, MEGA, JUPITER, and HOPE-3), relative risk reductions exceeded those observed in the remaining trials of secondary prevention trials. Thus, for the endpoints of major coronary events, stroke, coronary revascularization, and major vascular events, the greatest relative risk reductions occur among patients at lowest absolute risk, suggesting that ever-earlier therapy over a lifetime of risk may be the best biologic way to handle elevated cholesterol levels (**Fig. 45.9**). The JUPITER trial (see later, High-Sensitivity C-Reactive Protein) demonstrated almost 50% reductions in MI and stroke with rosuvastatin in a primary prevention population with LDL cholesterol levels below 130 mg/dL at study entry.[6] In this trial, even those with baseline LDL cholesterol level of less than 70 mg/dL showed clinical benefits. On the other hand, as described previously, those with higher absolute risk attain greater absolute risk reductions with statin use. Thus, those with the highest baseline risk and who achieve the greatest LDL cholesterol reductions avoid the most vascular events and vascular deaths.[59] Of particular biologic interest, there appear to be “legacy effects” associated with statin therapy. For example, 20-year follow-up of participants in the West of Scotland Coronary Prevention Study showed that allocation to statin treatment for the first 5 years conferred continued improvement in survival and substantial reductions in vascular events.[60]

Statins can have adverse effects. Some patients suffer myopathy while on statin therapy, an effect that may be genetically determined at least for simvastatin at higher doses. Statin therapy is associated with small increases in the risk of diabetes, an effect that may be greater with more intensive regimens.[61] Development of diabetes occurs mostly in those who already have impaired fasting glucose, a group in whom the net benefits on preventing MI, stroke, and cardiovascular death outweigh these risks, even in primary prevention. As discussed earlier with regard to trials of congestive heart failure and renal failure, high absolute risk does not automatically indicate that statin therapy will be effective. For most patients, however, after initiation of diet, exercise, and smoking cessation, the best evidence supports addition of statin therapy among available pharmacologic interventions, an option that has become increasingly cost-

effective as potent generic statin agents become available.

Not all agents that lower LDL cholesterol (LDLC) lower vascular event rates, so physicians should exercise caution when using nonstatin agents in both primary and secondary prevention. However, the concept that “lower is better” was affirmed in the large-scale Improved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE IT), where the addition of ezetimibe to statin therapy alone further modestly reduced LDLC, hsCRP, and vascular event rates.[8] These effects were larger in analyses considering all vascular events rather than first events only.[62]

Two recent studies demonstrate that the variability in percent LDLC reduction following high-intensity statin therapy is wide and that this response relates directly to efficacy[63,64] (**Fig. 45.10**). These data have clinical importance because they again affirm that “lower is better,” and that on-treatment measurement of LDLC (or apo B) levels is needed for practice.

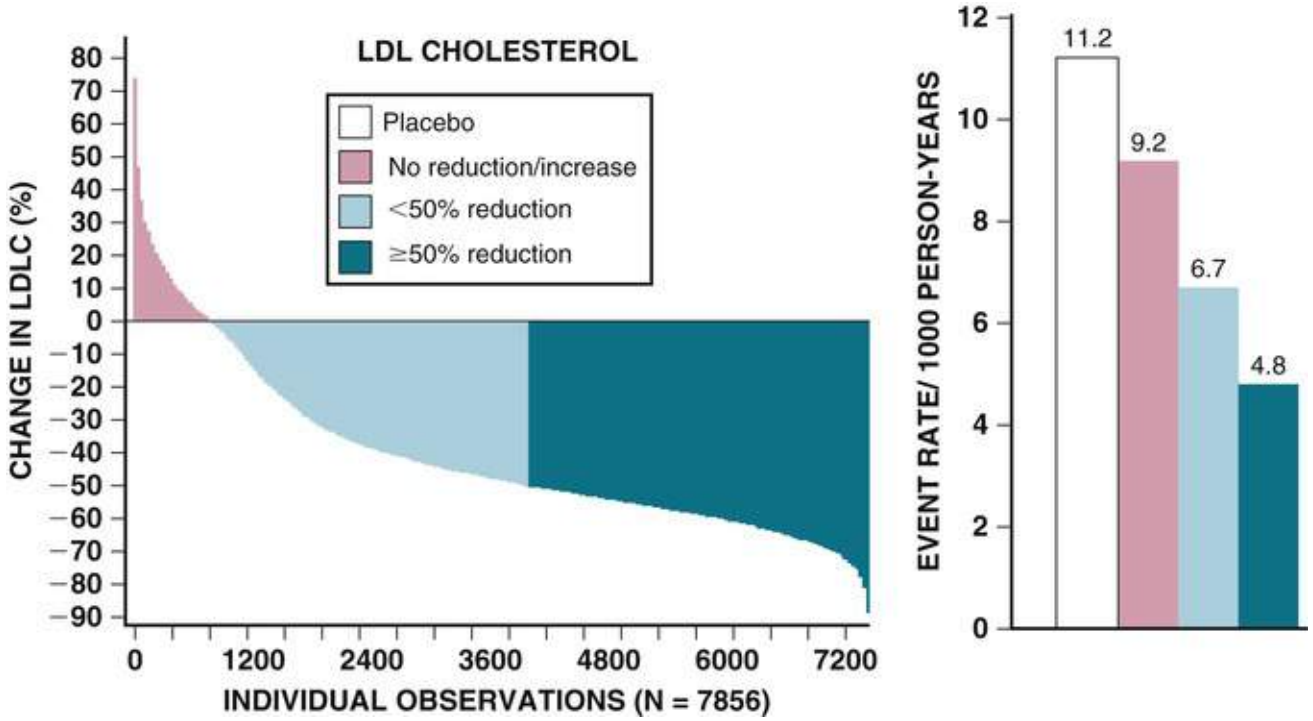

FIGURE 45.10 Waterfall plot for individual Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin Primary Endpoint (JUPITER) trial participants receiving rosuvastatin (20 mg daily) showing the percent change in cholesterol grouped into the three categories shown (*left*) and the incident event rates (per 1000 person-years) for each group (*right*): placebo group (*white bars*), those allocated to rosuvastatin who had no reduction or an increase in low-density lipoprotein cholesterol (LDL-C) (*pink*), a >0 but <50% fall in LDL-C (*light green*), and a ≥50% reduction in LDL-C (*dark green*). (From Ridker PM et al. Percent reduction in LDL cholesterol following high-intensity statin therapy: potential implications for guidelines and for the prescription of emerging lipid-lowering agents. Eur Heart J 2016;37:1373-9.)

Although rare in the general population, statin intolerance can be a more common compliant in specialized referral-based lipid clinics. Some patients have true statin intolerance (often on a genetic basis), but not all statin intolerance is reproducible, and thus clinicians should clearly explain benefits to patients and try different statins at low doses and on potentially alternate-day dosing schedules before abandoning this drug class.[65] Starting an exercise program and statin therapy simultaneously may lead patients who experience muscle aches to ascribe these symptoms incorrectly to the pharmacologic intervention.

Statin therapy is the cornerstone for pharmacologic LDLC reduction, but there is considerable interest in monoclonal antibodies that inhibit PCSK9 binding and consequently prolong the effective half-life of

hepatic surface LDL receptors (LDLRs). These agents reduce LDLC substantially when given as monotherapy, as adjuncts to statin therapy with or without ezetimibe, and among those with statin intolerance. Monoclonal antibodies to PCSK9 are also effective in reducing LDLC in patients with heterozygous familial hypercholesterolemia (in whom LDLR activity is reduced) and those with homozygous familial hypercholesterolemia who are LDLR defective, a rare clinical setting where statin efficacy is limited.[66] Evolocumab and bococizumab reduce cardiovascular events[67,68] (**see Fig. 48.9**), although bococizumab, a non–fully humanized antibody, stimulated the development of neutralizing antidrug antibodies that yielded reduced LDL lowering with time, halting the development of that agent.[69] Evolocumab demonstrated an acceptable safety profile in FOURIER in 2.2 years of mean follow-up.[67] A large-scale outcome trial with alirocumab continues.[70,71] A small interfering RNA that targets PCSK9 (inclisiran) also lowers LDL very effectively, with a much longer duration of action than the anti-PCSK9 antibodies.[72]

High-Density Lipoprotein (HDL) Cholesterol

Abundant prospective epidemiologic data demonstrate a strong inverse relationship between HDL cholesterol and vascular risk. In general, observational data suggest that each incremental increase in HDL cholesterol of 1 mg/dL is associated with a 2% to 3% decrease in risk of total CVD. Patients with angiographically proven CAD more often have low levels of HDL than high levels of LDL, as defined by current criteria. Indeed, a large body of observational and experimental data supports a protective role for HDL in atherosclerosis. Thus, measurement of HDL figures in all global risk prediction algorithms, and the ratio of total to HDL cholesterol remains among the most potent lipid-based predictors of cardiovascular risk. However, recent human genetic data do not support such a protective effect of HDL.[73] A recently described rare variant in scavenger receptor BI raises HDL cholesterol but increases CHD risk.[74] Moreover, multiple pharmacologic attempts to rise HDL have failed to improved cardiovascular outcomes in clinical trials, as described next (**see Chapter 48**). This disparity illustrates the importance of distinguishing between risk markers documented by observational epidemiology and causal risk factors.

Interventions to Raise HDL Cholesterol

The large-scale endpoint trials of HDL-raising interventions completed to date have found no reductions in clinical events and in some cases have suggested harm. For example, in the recent AIM-HIGH and HPS-THRIVE trials, random allocation of high-risk patients to niacin supplementation significantly increased HDL cholesterol (as well as reductions in triglycerides and LDL cholesterol), yet showed no beneficial effects at all on clinical event rates.[75,76] Similarly, in the ACCORD trial, fenofibrate reduced triglycerides and increased HDL cholesterol yet produced no significant reduction in hard vascular events.[77] Of concern, in the Investigation of Lipid Level Management to Understand Its Impact in Atherosclerotic Events (ILLUMINATE) trial, in which patients at high vascular risk who received the cholesteryl ester transfer protein (CETP) inhibitor torcetrapib, showed an unanticipated increase in all-cause mortality.[78,79] Although some of this hazard probably resulted from off-target effects, two further major trials using the CETP inhibitor dalcetrapib and evacetrapib also failed to reduce cardiovascular event rates despite substantial increases in HDL cholesterol and reductions in LDL cholesterol.[78-81] Thus, at least to date, pharmacologic therapy that increases HDL cholesterol shows no benefit, and if anything may cause harm. The recognition that a biomarker such as HDL can have clinical usefulness for risk prediction without being in the causal pathway for disease postulates has importance for clinical practice

and has implications for several other emerging risk factors, such as those that measure vascular inflammation (**see Chapter 9**).

Alternative Lipid and Lipoprotein Measures

LDL particles exhibit considerable heterogeneity. Small, dense LDL particles associated with high levels of triglycerides, low levels of HDL cholesterol, increased inflammation, and considerably increased cardiovascular risk, a common scenario in diabetic patients. By contrast, larger and less dense LDL particles appear less tightly associated with acute vascular events. In univariate analyses, several studies suggest that the measurement of LDL's major apolipoprotein, apo B, predicts cardiovascular risk better than LDL cholesterol in clinical practice. Most of these studies find, however, that non–HDL cholesterol (defined as total cholesterol minus HDL cholesterol) provides clinical risk information as least as strong as that for apo B—an unsurprising observation because non–HDL cholesterol correlates very closely with apo B levels. Furthermore, most studies report that the total cholesterol/HDL cholesterol ratio remains a very strong predictor of risk, superior even to the ratio of apo B to apo A-I, the dominant apolipoprotein carried by HDL cholesterol. Thus, despite evidence favoring apo A-I and apo B100 in univariate analyses as replacements for HDL and LDL cholesterol, only marginal clinical data seem to indicate that these measures improve overall risk prediction over standard lipid testing. In a recent comprehensive meta-analysis of 37 prospective cohort studies of patients without known CVD, the addition of information on apo B and apo A-I led to only slight improvements in risk prediction.[82] Among patients treated with statin therapy, similar overviews have found that on-treatment levels of LDL cholesterol, non–HDL cholesterol, and apo B each was associated with a risk of recurrent vascular events, but non–HDL cholesterol showed the greatest strength of association. This relative advantage has uncertain clinical importance in current practice; in patients treated with more potent statin agents, recent analyses suggest that on-treatment LDL cholesterol predicts residual risk, as does non–HDL cholesterol, apo B, or lipid ratio.[83]

Beyond standard chemical measures of total, LDL, and HDL cholesterol (which appropriately form the basis of current lipid screening and reduction guidelines), the amount of cholesterol carried by different classes of lipoprotein particles may influence specific functions and vary widely among individuals. Therefore, measures of core lipid composition and lipoprotein particle size might provide better measures for risk prediction. Several lines of evidence have indicated that small LDL particles may be more atherogenic than large particles and contribute particularly to the dyslipidemia of diabetes. Currently, a number of technologies can evaluate LDL subclasses and particle size. Studies using density gradient ultracentrifugation and gradient gel electrophoresis generally have found that lipoprotein subclass identifies patients at higher risk for CHD and have shown a preferential benefit of lipid-lowering therapy for those with small, dense LDL particles compared with large LDL particles. LDL particle concentration, as measured by nuclear magnetic resonance (NMR) imaging studies, correlates well with coronary arterial lumen diameter after statin therapy to predict future vascular events. In the Women's Health Study, NMR-measured LDL particle concentration predicted incident vascular events better than standard chemical measurement of LDL cholesterol.[84] In this study, however, lipoprotein profiles evaluated by NMR did not show superiority to standard measures such as the total/HDL cholesterol ratio or non–HDL cholesterol. HDL particle concentration, as measured by NMR, also may predict residual risk after statin therapy to a greater extent than HDL size or HDL cholesterol.

Thus, although data for advanced lipid testing continue to accrue, it remains unclear whether novel

methods of lipid evaluation add importantly to standard lipid screening in routine practices or should remain specialized tools for research and lipid clinics. In this regard, the most recent recommendations from the National Lipid Association recommend caution when using any novel lipid measure among those at low risk, although LDL particle concentration and apo B level were considered “reasonable” for use among patients at intermediate risk. However, discordance between apo B and LDL cholesterol levels is a strong predictor of incident vascular events that correlates with extent of underlying atherosclerosis.[85,86] For all these reasons, measurement of apo B (or non–HDL cholesterol) may enter future clinical guidelines.[87]

Triglycerides

Triglycerides tend to vary inversely with HDL. The compelling association between HDL and cardiovascular protection led to adjustment of risk from triglycerides for HDL that attenuated the relationship. This approach suggested that triglycerides did not contribute causally to CVD. Recent human genetic and clinical trial data have strongly challenged this traditional stance. As noted earlier, genetic variants that confer lifelong increases in HDL are *not* associated with reduction in cardiovascular risk. Multiple pharmacologic interventions that raise HDL cholesterol have failed to show clinical benefit.

In contrast to HDL, recent human genetic studies consistently implicate triglycerides as a causal risk factor for CVD. Lipoprotein lipase (LPL) has emerged as a key regulator of triglyceride (TG) concentrations in blood. This enzyme, associated with the endothelial cell surface, trims triglycerides from triglyceride-rich lipoproteins (TGRL.) Reduced LPL function causes increased TG concentrations caused by slowed clearance of TGRL. Genetic variants that impair LPL function raise TG concentrations and are associated strongly and consistently with increased cardiovascular risk. Conversely, variants that augment LPL activity are associated with lower cardiovascular risk. These variants reside in the genes that encode apolipoprotein CIII, ANGPTL3, ANGPTL4, Apo A5, and LPL itself.[88-92]

Guidelines continue to recommend measurement of triglycerides in the fasting state, yet much of the prognostic value of plasma TG levels may derive from postprandial levels. On this basis, some investigators suggest adoption of nonfasting TG levels to predict vascular risk. TG measurements serve as a biomarker of classes of TGRL that appear to confer cardiovascular risk. Indeed, the cholesterol in the TGRL may mediate this aggravated risk, not the triglycerides themselves.[93] Studies are evaluating their clinical utility of various assays for remnant lipoprotein particles that may resolve some of the issues surrounding assessment of triglyceride-related risk. (**See also Chapter 48**.)

Interventions to Reduce Triglyceride Levels

Dietary discretion, exercise, and weight reduction as recommended for LDL cholesterol control also have relevance for triglyceride management. Agents approved by the FDA for the reduction of TG levels include omega-3 fatty acid supplements. Two ongoing large-scale studies, STRENGTH and REDUCE-IT, are evaluating the effects of different omega-3 fatty acid preparations on cardiovascular events.[94,95] In the large-scale Outcome Reduction with an Initial Glargine Intervention (ORIGIN) trial of high-risk patients with impaired fasting glucose or diabetes, the use of omega-3 fatty acid supplementation reduced triglycerides but did not lower rates of major vascular events.[96] Although fibrate trials did not show significant reductions in vascular events with triglyceride lowering, subgroup analyses raise the hypothesis that further trials focused on patients with elevated triglycerides and low levels of HDL cholesterol merit consideration.

For these reasons, current guidelines do not establish a target value for triglycerides, and

pharmacologic TG reduction is not broadly recommended other than for patients at high risk for pancreatitis. In view of the tight link of TG levels with known risk factors for atherosclerosis (e.g., low HDL cholesterol level, uncontrolled diabetes, hypothyroidism), however, the finding of marked and persistently elevated TG levels should enter into overall risk assessment for an individual and stimulate consideration of the reason for TG level elevation, including careful exclusion of secondary causes such as excessive alcohol consumption, renal disease, Cushing syndrome, and hypothyroidism or the use of concomitant medications such as estrogen, corticosteroids, cyclosporine, and protease inhibitors. Genetic studies also support a causal role for triglycerides in atherogenesis, thus encouraging continued research into triglyceride-lowering approaches.

Metabolic Syndrome, Insulin Resistance, and Diabetes

Insulin resistance and diabetes rank among the major cardiovascular risk factors (**see Chapters 50 and 51**). These effects loom even larger in ethnic minority populations and in patients with other concomitant risk factors. Insulin resistance promotes atherosclerosis even before it produces frank diabetes, and insulin resistance independently increases risk for atherothrombosis. In the Emerging Risk Factors Collaboration, even small increases in fasting glucose were associated with increased rates of vascular deaths, cancer deaths, and nonvascular, noncancer deaths[97] (**Fig. 45.11**). Such findings have prompted interest in the "metabolic syndrome," a cluster of glucose intolerance and hyperinsulinemia accompanied by hypertriglyceridemia, low HDL levels, hypofibrinolysis, hypertension, microalbuminuria, predominance of small dense LDL particles, and central obesity. A harmonized definition proposes cut points for this constellation.[98]

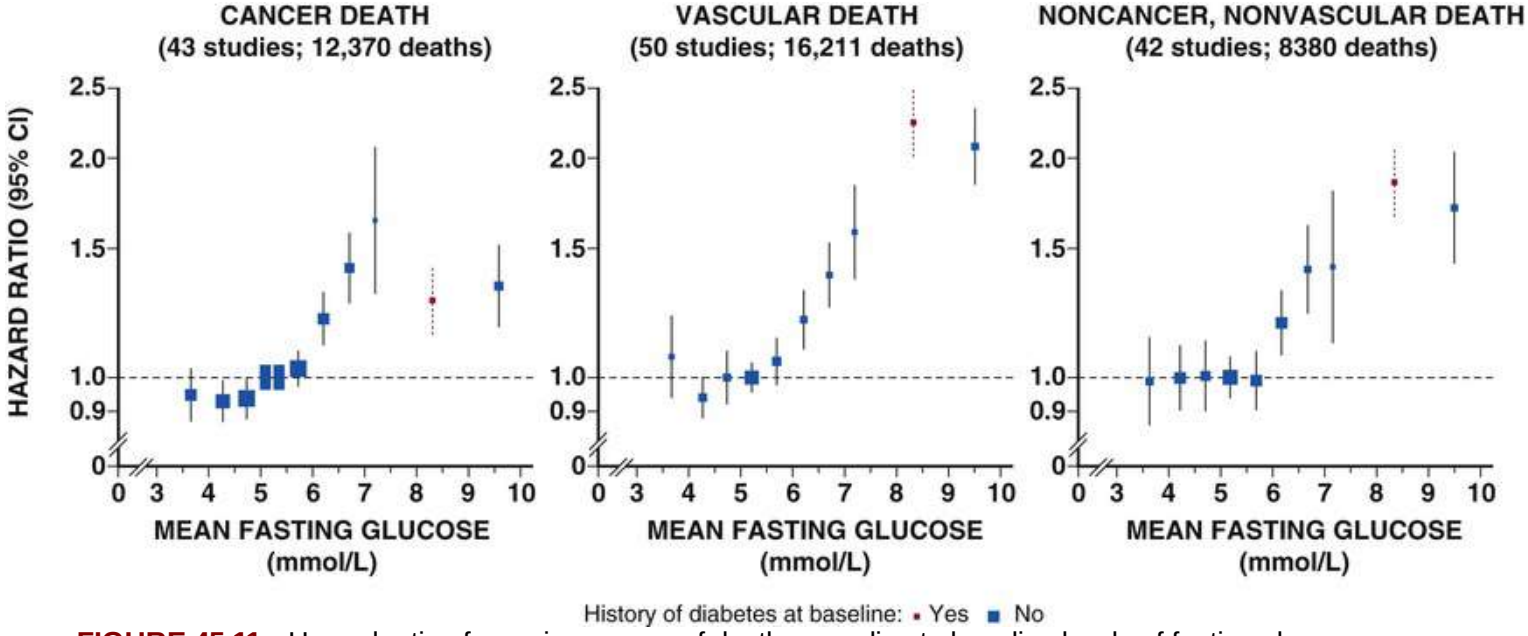

FIGURE 45.11 Hazard ratios for major causes of death according to baseline levels of fasting glucose; CI, confidence interval. (From Seshasai SR et al; Emerging Risk Factors Collaboration. Diabetes mellitus, fasting glucose, and risk of cause-specific death. N Engl J Med 2011;364:829.)

Some have raised concerns regarding the concept of metabolic syndrome. Controversy continues regarding insulin resistance as a unifying pathophysiologic pathway that accounts for all the features of the so-called metabolic syndrome, rendering it a true "syndrome." In addition, the question of whether coalescence of risk factors incorporated in the concept of metabolic syndrome augment risk beyond the

sum of risk attributable to the individual components remains unsettled. Nonetheless, several studies have documented that persons with the metabolic syndrome have elevated vascular event rates. Most definitions of the metabolic syndrome include a measurement of "central obesity," and much evidence supports the visceral adipose depot as a driver of dysmetabolism, including many components of the metabolic syndrome (**see Chapter 50**). Inflammation also provides a unifying concept that links the elements of the metabolic syndrome. Inflammatory biomarkers such as hsCRP may help further stratify clinical risk and improve the prognostic value of metabolic syndrome, and hsCRP concentrations also predict incident type 2 diabetes.[99] Despite the controversies, many clinicians find the concept of metabolic syndrome useful because it fits the profile of many patients presenting in primary care in contemporary practice.

In addition to systemic metabolic abnormalities, hyperglycemia causes accumulation of advanced glycation end products associated with vascular damage. Diabetic patients have impaired endothelial vasodilator function and appear to have increased leukocyte adhesion to vascular endothelium, a critical early step in atherogenesis. Diabetic nephropathy, detected by microalbuminuria, accelerates these adverse processes. Among persons with non–insulin-dependent diabetes, microalbuminuria predicts cardiovascular and all-cause mortality. Diabetic and prediabetic patients also typically have abnormalities of endogenous fibrinolysis. These effects, in concert with the impaired endothelium-dependent (nitric oxide–mediated) vasodilation common in diabetic patients, contribute to endothelial cell dysfunction and accelerated atherogenesis.

Interventions to Reduce Cardiovascular Risk Among Diabetic Patients

We are fortunate to now have evidence that glucose-lowering therapies can reduce cardiovascular risk (**see Chapter 51**). Lifestyle, as implemented in the Look-AHEAD trial, did not reduce cardiovascular events during a median follow-up of almost 10 years in patients with well-established diabetes, despite providing multiple other benefits.[100] The intensive lifestyle intervention focusing on weight loss did not reduce the rate of cardiovascular events in this group, despite beneficial effects on levels of several biomarkers.[100] This study may have implemented interventions too late to alter the course of cardiovascular events in this population. Social effects may also influence diabetes prevention. The opportunity to move from neighborhoods with high poverty levels to those with low poverty levels associated with reductions in both obesity and incident diabetes. In contrast with the case for lipid lowering, surgical approaches to diabetes and diabetes prevention have on several occasions proved superior to medical approaches (**see Chapter 50**).

Aspirin for Primary Prevention

Low-dose aspirin therapy clearly and consistently provides substantial net benefit for persons at high risk for subsequent events secondary to existing CVD. Earlier meta-analyses by the Antithrombotic Trialists' (ATT) Collaboration showed significant reductions in mortality and nonfatal cardiovascular events among those with a previous MI, stroke, bypass surgery, angioplasty, peripheral vascular surgery, or angina.[101] Doses greater than 75 mg/day demonstrated consistent benefit on vascular events, with no trend toward increasing benefit for higher doses. Below 75 mg, a nonsignificant attenuated risk reduction of only 15% was noted, although there were only three trials that used that dose. The most recently updated ATT review in 2009 included 16 secondary prevention trials comparing long-term aspirin versus control among 17,000 high-risk individuals with a total of 3306 serious vascular events (MI, stroke, or vascular death). It underscored the previous conclusions in secondary prevention and indicated that aspirin is

associated with statistically significant reductions of 19% in any serious vascular event, 31% in nonfatal MI, 20% in major CHD events, and 19% in total stroke. In absolute terms, these represented benefits of aspirin versus control in rates of serious vascular events of 6.7% versus 8.2% per year; in total stroke, 2.08% versus 2.54%; and in coronary events, 4.3% versus 5.3%. There was a nonsignificant increase in hemorrhagic stroke. The reductions in serious vascular events were similar for men and women. Thus, for secondary prevention, antiplatelet therapy with aspirin yields substantial net benefit, and use of low-dose aspirin is advised unless there are major contraindications. If the bleeding risk is high, gastrointestinal (GI) prophylaxis such as proton pump inhibitors may be considered. Use of other antiplatelet agents with demonstrated efficacy such as clopidogrel, would be limited to patients with aspirin allergy or intolerance, those with acute coronary syndromes, implanted stents, or those on anticoagulant therapy.

In primary prevention of CVD, however, the role of aspirin is not straightforward.[101] There is a less clear balance of beneficial effects and bleeding hazards, because patients without evidence of CVD have a lower absolute risk for a cardiovascular event, and thus less consequent absolute benefit, whereas the risk of major adverse effects (e.g., bleeding) remains the same. The 2009 updated ATT Collaboration meta-analysis also included six primary trials of long-term aspirin versus control among 95,000 individuals at low average risk, experiencing 3554 serious vascular events.[102] Aspirin use associated with a statistically significant 12% reduction in any serious vascular event (0.51% aspirin versus 0.57% control per year), mainly because of a significant reduction of 23% in nonfatal MI (0.18% versus 0.23% per year). The net effects on vascular mortality and total stroke were not statistically significant. There was a 14% reduction in risk of ischemic stroke and a 32% increased risk of hemorrhagic stroke (0.04% versus 0.03% per year), both of which were of borderline significance. As in secondary prevention, aspirin significantly increased risk of major GI and extracranial bleeds compared to control by 54% (0.10% versus 0.07% per year).

In 2016 the USPSTF published an updated summary of their systematic evidence review of aspirin for the primary prevention of CVD[103] (**Fig. 45.12**). This review supported the previous results, showing a statistically significant 22% reduction in nonfatal MI, a borderline statistically significant 6% benefit for total mortality, and a nonsignificant 5% benefit for nonfatal stroke and 6% benefit on cardiovascular mortality. The observed benefits on nonfatal MI and total stroke persisted for daily doses of 100 mg or less, and the benefit was seen within 5 years of treatment initiation and continued with active use.

AAA, Aspirin for Asymptomatic Atherosclerosis; ABI, ankle-brachial index; BMD, British Male Doctors Trial; CG, control group; ETDRS, Early Treatment Diabetic Retinopathy; HOT, Hypertension Optimal Treatment; IG, intervention group; JPAD, Japanese Primary Prevention of Atherosclerosis with Aspirin for Diabetes; JPPP, Japanese Primary Prevention Project; PHS, Physicians' Health Study; POPADAD, Prevention of Progression of Arterial Disease and Diabetes; PPP, Primary Prevention Project; RR, relative risk; TPT, Thrombosis Prevention Trial; WHS, Women's Health Study. (From Guirguis-Blake JM et al. Aspirin for the primary prevention of cardiovascular events: a systematic evidence review for the U.S. Preventive Services Task Force. Ann Intern Med 2016;164(12): 804-13.)

Bleeding is the major known liability of aspirin use, an important consideration in assessing the likely risk to benefit ratio of aspirin in primary prevention.[104] A systematic review of bleeding risks with aspirin use indicated that in CVD prevention trials, even very-low-dose aspirin (≤100 mg daily) is associated with a statistically significant increase in major GI bleeding of 58% and a nonsignificant 27% increase in the rarer event of hemorrhagic stroke. The risk of bleeding remained constant throughout the use of aspirin. Absolute baseline bleeding rates differed by age, sex, and cardiovascular risk factors such as diabetes, smoking, and high BP, as well as by history of upper GI or peptic ulcer disease. A useful smartphone application "Aspirin-Guide" to calculate the number needed to treat and number needed to harm with aspirin use in primary prevention provides the clinician with an aid in shared decision making with patients in this regard.[105]

Three variables merit particular consideration regarding the efficacy of aspirin in primary prevention of cardiovascular disease: diabetes, sex, and age. The 2009 updated ATT meta-analysis[102] included six primary prevention trials in which patients with diabetes constituted subgroups within the study

population, and an additional three primary prevention trials enrolled exclusively patients with diabetes. The pooled subgroup analyses showed no effect modification in cardiovascular effects of aspirin by diabetes, either in primary or secondary prevention. In the three primary prevention trials among diabetic patients—Early Treatment Diabetic Retinopathy Study (ETDRS), Prevention of Progression of Arterial Disease and Diabetes (POPADAD), and Japanese Primary Prevention of Atherosclerosis with Aspirin for Diabetes (JPAD)—showed no significant effects of aspirin. A recent meta-analysis[106] among patients with diabetes found no significant differences between aspirin and placebo with respect to prevention of total mortality, individual atherosclerotic events, bleeding, GI bleeding, or hemorrhagic stroke. Two ongoing studies of the use of aspirin in patients with diabetes—ACCEPT-D (Aspirin and Simvastatin Combination for Cardiovascular Events Prevention Trial in Diabetes) and ASCEND (A Study of Cardiovascular Events in Diabetes)—should provide additional information concerning the safety and benefit profile of aspirin in patients with diabetes. The ACCEPT-D trial will also assess whether aspirin has any additional benefit among patients who are also receiving statin therapy.[107,108]

With regard to potential effect modification by sex and age, aspirin has proved effective for both men and women in secondary prevention of CVD. Aspirin's efficacy in primary prevention, however, remains less certain.[109] The large-scale Women's Health Study found that aspirin significantly lowered the risk of total stroke and ischemic stroke. Although aspirin did not lower the risk of MI overall, there was a significant reduction with aspirin on MI among women over age 65.[101] This finding contrasted with the significant reduction in MI for men in the Physicians' Health Study but no benefit on stroke.[101] Still, analyses from the 2016 U.S. Preventive Service Task Force[103] concluded that no strong evidence supported effect modification for aspirin in primary prevention by sex. This report also concluded that based on analyses of limited subgroup data, the most consistent evidence of subgroup differences was an increased effect on MI in older age-groups.[103] However, a recent trial of low-dose aspirin for primary prevention of CVD in Japanese patients age 60 or older with atherosclerotic risk factors found no benefit in the reduction of risk of their composite endpoint, but a reduction in risk of nonfatal MI.[110] A large ongoing trial (ASPREE: Aspirin in Reducing Events in the Elderly) will provide further information on this question. An additional ongoing trial (ARRIVE: A Study to Assess the Efficacy and Safety of Enteric-Coated Acetylsalicylic Acid in Patients at Moderate Risk of Cardiovascular Disease) will provide information on primary prevention for those at moderate or higher risk of CVD.[111,112]

Of additional note, long-term follow-up analyses of randomized trials of daily aspirin in primary and secondary prevention of vascular events showed a beneficial effect on cancer.[104] Taken together, a recent review of the systematic evidence[113] indicated no significant benefits of long-term low-dose aspirin use on total cancer mortality and total cancer incidence. However, evidence supports a significant reduction in post-trial incidence of colorectal cancer beginning 5 or even 10 or more years after initiation, and a significant reduction in 20 year colorectal cancer mortality. Given the known hazards of aspirin use, wide adoption of aspirin for the chemoprevention of cancer would require an individual weighing of risks and benefits.[114]

Taken together, the data currently available show no clear net benefit of low-dose aspirin in primary prevention of CVD,[115] in contrast to the established benefit-risk ratio in secondary prevention. The FDA has not approved aspirin for use in primary prevention, in contrast to the use of aspirin in secondary prevention. The 2016 USPSTF recommendation statement for use of aspirin includes both the primary prevention of CVD and colorectal cancer.[115] It represents an update of the 2009 Task Force recommendations on aspirin in primary prevention of CVD, and the 2007 recommendation on aspirin and nonsteroidal anti-inflammatory drug (NSAID) use to prevent colorectal cancer. Unlike the previous report, which had separate guidelines for men and women, this updated statement recommends, without

sex-specific differentiation, initiating low-dose aspirin use for the primary prevention of CVD and colorectal cancer in adults age 50 to 59 who have a 10% or greater 10-year cardiovascular risk, do not have increased risk for bleeding, have a life expectancy of at least 10 years, and are willing to take low-dose aspirin daily for at least 10 years. The decision to initiate aspirin for the prevention of CVD and colorectal cancer for adults age 60 to 69 who have a 10% or greater 10-year risk should be individualized. The current evidence does not permit assessment of the balance of risks and benefits of initiating aspirin for primary prevention of CVD and cancer for those under age 50 or in adults 70 or older. Other guidelines have varying recommendations (**Table 45.1**).[101]

TABLE 45.1

Summary of Guideline Recommendations on the Use of Low-Dose Aspirin for Primary Prevention of Atherosclerotic Cardiovascular Disease (ASCVD)

U.S. Preventive Services Task Force, 2016
Use aspirin for adults aged 50-59 years with 10-year ASCVD risk ≥10%, not at increased risk of bleeding, life expectancy of ≥10 years, and willing to take aspirin for ≥10 years. Individualize the decision for adults aged 60-69 years with 10-year ASCVD risk 10%, not at increased risk of bleeding, life expectancy of ≥10 years, and willing to take aspirin for ≥10 years. No recommendation for adults aged <50 years or ≥70 years.
U.S. Preventive Services Task Force, 2009
Use aspirin when potential benefit outweighs the risk of GI bleeding. *Men* Age 45-59 years with 10-year CHD risk ≥4% Age 60-69 years with 10-year CHD risk ≥9% Age 70-79 years with 10-year CHD risk ≥12% *Women* Age 55-59 years with 10-year stroke risk ≥3% Age 60-69 years with 10-year stroke risk ≥8% Age 70-79 years with 10-year stroke risk ≥11%
American Diabetes Association, 2016
Use aspirin 75 to 162 mg/day for individuals with diabetes who are not at increased bleeding risk and who have 10-year ASCVD risk >10% (includes most men and women ≥50 years with diabetes and with ≥1 other ASCVD risk factors). Individualize for adults with diabetes <50 years, and multiple ASCVD risk factors (10-year ASCVD risk, 5%-10%). Not recommended for adults with diabetes who are at low ASCVD risk (10-year risk <5%).
American College of Chest Physicians, 2012
Suggest aspirin use for adults ≥50 years.
European Society of Cardiology, 2012
Not recommended.
American Heart Association, 2011
Can be useful in women ≥65 years if blood pressure is controlled and benefit outweighs risk. May be reasonable in women <65 years for prevention of ischemic stroke. Not recommended for women <65 years for prevention of myocardial infarction.
Canadian Cardiovascular Society, 2011
Consider only in special circumstances (CHD risk is high and bleeding risk is low). Not recommended for routine use.

CHD, Coronary heart disease; *GI,* gastrointestinal.

Data from Mora S, Manson JE. Aspirin for primary prevention of atherosclerotic cardiovascular disease: advances in diagnosis and treatment. JAMA Intern Med. 2016;176:1195–1204.

Diabetes in itself does not qualify individuals for aspirin therapy. The 2016 statement of the American Diabetes Association[116] supports the last consensus statement of the AHA, ACC Foundation, and American Diabetes Association[117] and recommends consideration of low-dose aspirin for the primary prevention of CVD for type 1 or type 2 diabetic patients who have a 10-year CVD risk of at least 10% and who do not have an increased risk of bleeding. This group consists of men and women with diabetes who are at least 50 years of age and who have at least one additional major CVD risk factor. Aspirin should not be recommended for adults with diabetes mellitus who are at low risk (<50 years of age with no additional atherosclerotic CVD risk factor).

Interventions to Increase Appropriate Use of Aspirin

An analysis of the 2011–2012 NHANES examined the use of aspirin for secondary and primary prevention of CVD.[118] Individuals who reported that a doctor had previously told them that they had been diagnosed with a stroke or heart attack were considered candidates for secondary prevention. Of the secondary prevention population, 75.9% reported being told to take aspirin by their physician, and of these, 89.9% were taking aspirin. Individuals without previously diagnosed CVD were considered candidates for primary prevention and classified into high and low risk based on whether their Framingham Risk Score of 10-year CHD risk was greater than 10% or 10% or less. For those without previously diagnosed CVD, 22.5% were classified as high risk: of these, 40.9% reported being told by their physician to take aspirin, with 79.0% complying. Among those at low risk, 26.0% were told by their physician to take aspirin, with 76.5% complying. Among high-risk individuals, significant predictors of patient-reported physician recommendations for aspirin use for primary prevention included age, race, and insurance status; among those who were low risk, the identified factors were age and insurance status, as well as obesity and education. These results suggest that objective risk level and subsequent risk of future CVD did not lead to recommendations for aspirin.

Clinical decision support tools that could assist physicians in identifying patients at risk might be beneficial. Consideration of the safety of primary prevention with aspirin requires an individualized assessment of both aspirin's expected benefits on CVD as well as expected bleeding risk. The 2016 USPSTF used a calculator derived from the ACC/AHA pooled cohort equations to predict 10-year risk for first hard atherosclerotic cardiovascular event. This is currently the only internally validated calculator that reports risks as a combination of cerebrovascular and coronary events (online version of calculator: http://tools.acc.org/ASCVD-Risk-Estimator/). No validated tool for predicting bleeding risk is available. Other new and novel approaches are being considered to aid physicians in assessing the risk-benefit ratio for aspirin in primary prevention for CVD. For example, the aforementioned Aspirin-Guide[105] is a personalized approach for shared decision making that incorporates information about the patient's risk factors to calculate both a 10-year atherosclerotic cardiovascular event risk score (the ACC/AHA ASCVD score) as well as a bleeding risk score (www.aspiringuide.com; free mobile app: https://appsto.re/us/emRMcb.i). At this time, however, assessing the balance of baseline risk for bleeding against cardiovascular benefits, and the recommendation for low-dose aspirin in the primary prevention of CVD, is a qualitative assessment.

Conceptual Basis for the “Polypill”

In contrast with interventions that separately alter platelet function and reduce BP and cholesterol, a trend has emerged in preventive intervention to consider use of “polypills.” Such preparations might, for example, contain aspirin, folic acid, a statin, and a various BP-lowering agents. In secondary prevention, use of polypill approaches has theoretical advantages particularly in the developing world, where a single inexpensive intervention might provide improved delivery of care at reduced cost, and perhaps through the use of trained nonphysician health care workers. The Indian Polycap Study demonstrated such benefit: a single combined agent significantly reduced BP, lipids, and overall medication compliance.[119]

In primary prevention, however, few of the assumptions underlying the polypill concept have withstood hypothesis testing. With regard to drug selection, randomized trials have found that folic acid does not lower event rates and that aspirin may prove of net benefit only to those at highest risk. Adherence to polypill regimens has also been less than anticipated, and “age-only” screening has largely been replaced by “absolute risk screening.”[120] Most importantly, effects of different therapies have not proved to be additive as assumed. In the HOPE-3 polypill trial of 12,075 intermediate-risk participants, the benefit

observed compared to placebo when two antihypertensive agents were added to rosuvastatin 10 mg (HR, 0.71; 95% CI 0.56 to 0.90) was not significantly greater than that of rosuvastatin 10 mg alone (HR, 0.74; 95% CI 0.60 to 0.93).[121] Given that this magnitude of relative risk reduction was substantially smaller than that observed in the comparable JUPITER trial (which used rosuvastatin 20 mg daily instead of 10 mg daily), moderate- to high-intensity statin therapy (without additional agents) may well serve as an optimum "polypill"[122] (**Fig. 45.13**).

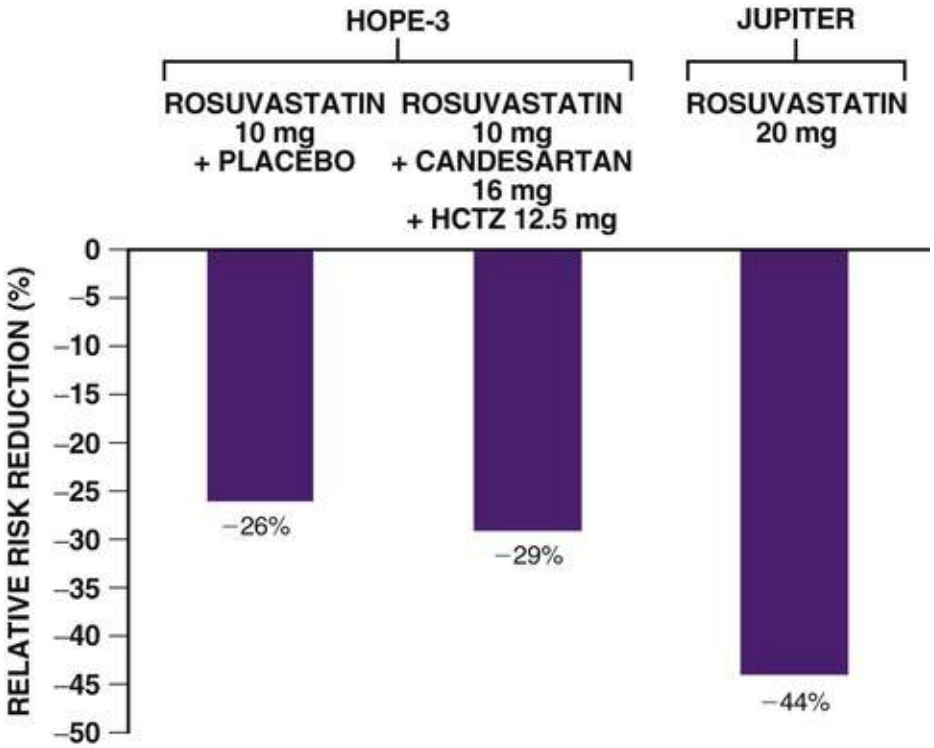

FIGURE 45.13 Statin monotherapy versus the "polypill" concept. This figure plots the relative risk reductions shown by rosuvastatin 10 mg alone (*left*), the combination of rosuvastatin 10 mg plus candesartan 16 mg plus hydrochlorothiazide (HCTZ) 12.5 mg (*center*) (data from Heart Outcomes Prevention Evaluation [HOPE] 3 trial), and rosuvastatin 20 mg alone from Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin (JUPITER, *right*). (From Ridker PM. Is statin monotherapy the perfect polypill? Circulation 2016;134[2]:91-3.)

Nonconventional Risk Markers and Associated Interventions

Despite the importance of blood lipids, half of all heart attacks occur in persons without overt hyperlipidemia, and almost one quarter occur in the absence of any of the major classic vascular risk factors. This fact challenges several basic issues related to current screening programs for risk detection and disease prevention. It is thus not surprising that much recent research has focused on the identification and evaluation of novel atherosclerotic risk markers.

When valuating any novel risk marker as a potential new screening tool, clinicians need to consider (1) whether there is a standardized and reproducible assay for the biomarker of interest; (2) whether there is a consistent series of prospective studies demonstrating that a given parameter predicts future risk; (3) whether the novel marker adds to the predictive value of lipid screening; (4) whether there is evidence that the novel marker adds to global risk prediction scores, such as that in the Framingham Heart Study;

and (5) whether knowledge of the biomarker would lead to a proven intervention to reduce risk that the patient otherwise would not have received. (**See Chapter 9** for a detailed discussion of quantitative approaches to answering these questions.) A discussion of some examples of these basic epidemiologic requirements follows: hsCRP and other markers of inflammation, Lp(a), and homocysteine. Physicians also should consider the relative magnitude of novel markers in terms of risk prediction, particularly compared with lipid screening.

High-Sensitivity C-Reactive Protein

Inflammation characterizes all phases of atherothrombosis and provides a critical pathophysiologic link between plaque formation and acute rupture, leading to occlusion and infarction (**see Chapter 44**.) Inflammatory cytokines such as IL-1 or tumor necrosis factor (TNF) implicated in atherogenesis elicit the expression of the messenger cytokine IL-6, which can travel from local sites of inflammation to the liver, and change in the program of protein synthesis to produce the acute-phase response.

In clinical practice, the best-studied and most easily applied biomarker of this inflammatory process is the downstream acute-phase reactant CRP. Composed of five 23-kDa subunits, CRP, a circulating member of the pentraxin family, functions in the human innate immune response. More than 50 large-scale prospective cohorts conducted worldwide indicate that CRP, when measured with high-sensitivity assays (hsCRP), independently predicts risk of MI, stroke, peripheral arterial disease, and sudden cardiac death (SCD) among apparently healthy persons, even when LDL cholesterol levels are low.[123] In comprehensive meta-analyses, the multivariable hazard associated with hsCRP, if anything, exceeded that associated with either BP or cholesterol, and hsCRP yielded an increment in the C-statistic in terms of predicting future CHD events virtually identical in magnitude to that of total and HDL cholesterol[124,125] (**Fig. 45.14**). hsCRP adds prognostic information at all levels of LDL cholesterol and at all levels of risk, as determined by the Framingham Risk Score.

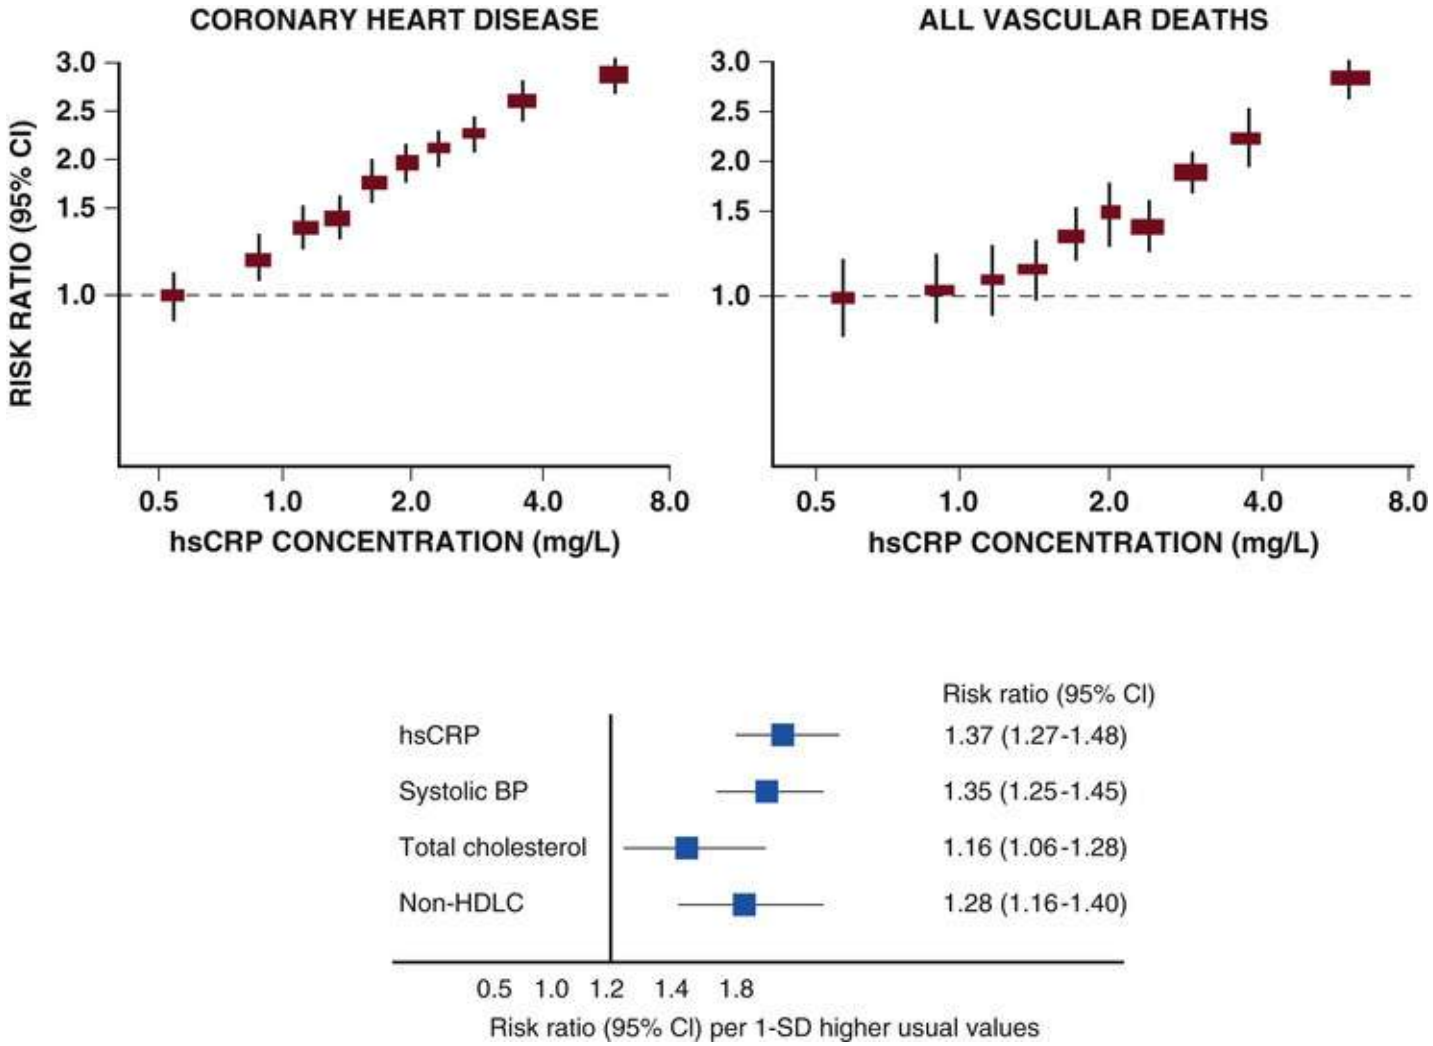

FIGURE 45.14 Predictive ability of high-sensitivity C-reactive protein (hsCRP) in primary prevention. This meta-analysis shows the relationship of hsCRP concentrations in healthy individuals with incident coronary heart disease and vascular death (*top*), and the risk associated with a 1–standard deviation (SD) increase in hsCRP compared to comparable changes in blood pressure or total cholesterol (*bottom*).
(From Ridker PM. Atest in context: high-sensitivity C-reactive protein. J Am Coll Cardiol 2016;67[6]:712-23.)

The AHA and CDC issued the first guidance for the use of hsCRP levels in clinical practice in 2003. Briefly stated, hsCRP levels of less than 1, 1 to 3, and higher than 3 mg/liter should be interpreted as lower, moderate, and higher relative vascular risk, respectively, when considered along with traditional markers of risk (**Fig. 45.15**). Application within the Framingham Heart Study has corroborated this critical finding.[126] Screening for hsCRP should be done at the discretion of the physician as part of global risk evaluation. Although hsCRP predicts risk across the entire population spectrum, it is likely to be of greatest usefulness in patients at intermediate risk—that is, those with anticipated 10-year event rates between 7.5% and 20%. Current AHA/ACC guidelines suggest the use of hsCRP when decision making regarding statin therapy is uncertain. Values of hsCRP in excess of 8 mg/liter may represent an acute-phase response caused by an underlying inflammatory disease or intercurrent infection and should lead to repeat testing in approximately 2 to 3 weeks. Because hsCRP levels have equivalent stability over long periods to that of traditional risk factors, exhibit minimal circadian variation, and do not depend on prandial state, outpatients can undergo screening at the cholesterol evaluation.

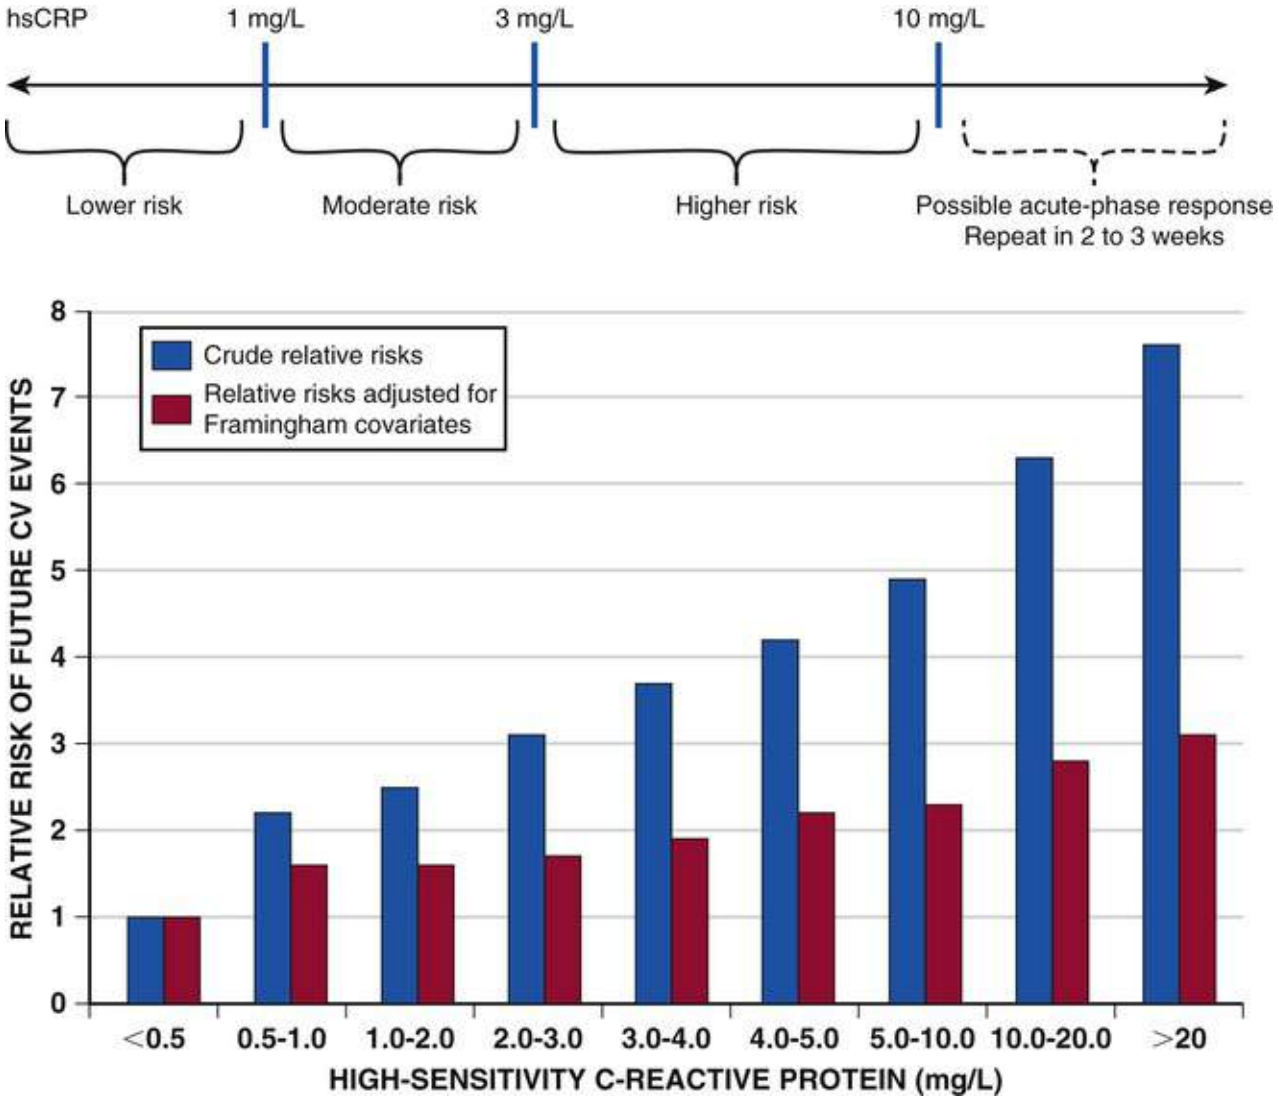

FIGURE 45.15 Clinical interpretation of hsCRP values for cardiovascular (CV) risk prediction. High-sensitivity C-reactive protein (hsCRP) relates linearly to cardiovascular risk across a wide range. The *blue bars* show crude relative risks and the *red bars* show relative risks adjusted for the Framingham risk factors. (From Ridker PM. A test in context: high-sensitivity C-reactive protein. J Am Coll Cardiol 2016;67[6]:712-23.)

In clinical practice, many physicians now use both hsCRP and family history as part of global risk prediction. The freely available Reynolds Risk Score for men and women facilitate this process (www.reynoldsriskscore.com). In several independent cohorts, the Reynolds Risk Score has proved to have superior discrimination and calibration than the Framingham Risk Score or the current AHA/ACC pooled cohort equations.[126,127] Levels of hsCRP greater than 3 mg/liter also predict recurrent coronary events, thrombotic complications after angioplasty, poor outcome in the setting of unstable angina, and vascular complications after bypass surgery.

All these data support the concept that inflammation plays a critical role throughout the atherothrombotic process. Additionally, hsCRP has prognostic usefulness in cases of acute ischemia, even without elevated troponin level, suggesting that enhanced inflammation at hospital admission can determine subsequent plaque rupture. These findings help explain why persons with elevated hsCRP levels may accrue greater benefit from aggressive interventions compared with those with low hsCRP levels. This marker also is associated with vascular events and ischemic episodes in patients with ischemia with angiographically normal-appearing coronary arteries (INOCA), suggesting a role for inflammation in coronary microvascular function.[128]

Levels of hsCRP correlate only modestly with underlying atherosclerotic disease as measured by carotid intimal medial thickness or by coronary calcification. This observation suggests that hsCRP does

not simply reflect the presence of subclinical disease but indicates an increased propensity for plaque disruption and/or thrombosis. Autopsy data support this hypothesis: elevated hsCRP levels are more common in patients with frankly ruptured plaques than in those with erosive disease or those who died of nonvascular causes. Elevated levels of hsCRP predict not only cardiovascular events but also the onset of type 2 diabetes, perhaps because hsCRP levels correlate with several components of the metabolic syndrome, including those not easily measured in clinical practice, such as insulin sensitivity, endothelial dysfunction, and impaired fibrinolysis.

Interventions for Primary Prevention in Patients With Elevated hsCRP Levels

As for those with elevated LDL cholesterol, diet, exercise, and smoking cessation are the first-line interventions for those with elevated hsCRP. At a minimum, an elevated hsCRP level should provide considerable motivation to improve lifestyle, particularly for those previously told that they were not at risk because of an absence of hyperlipidemia. In this regard, the two interventions proven to lower vascular risk in the Mediterranean PREDIMED trial, mixed nuts and olive oil, both reduce hsCRP levels.[129]

Beyond lifestyle change, the use of statin therapy to reduce vascular risk among individuals with elevated hsCRP, even with low LDL cholesterol levels, represents a fundamental change in treatment strategies for CVD prevention. Most importantly, in the JUPITER trial in apparently healthy men and women with LDL cholesterol levels less than 130 mg/dL who were at increased risk because of hsCRP levels of 2 mg/liter or greater, the use of rosuvastatin resulted in a 44% reduction in the trial primary endpoint of all vascular events ($P < 0.000001$), a 54% reduction in MI ($P = 0.0002$), a 48% reduction in stroke ($P = 0.002$), a 46% reduction in need for arterial revascularization ($P < 0.001$), and a 20% reduction in all-cause mortality ($P = 0.02$). All prespecified subgroups within JUPITER significantly benefited from statin therapy, including those previously considered at “low risk,” such as women, nonsmokers, those without metabolic syndrome, and those with Framingham scores less than 10%. From a public policy perspective, the 5-year number needed to treat (NNT) within JUPITER was only 25, a value smaller than the comparable 5-year NNT associated with the treatment of hyperlipidemia or hypertension in primary prevention. In an additional prespecified analysis, rosuvastatin reduced incident venous thromboembolism by 43%, a result with clinical relevance and an important observation regarding pleiotropic effects of statin therapy.[130,131] As described earlier, these vascular benefits outweigh the small hazard of diabetes associated with statin use.

The JUPITER trial also demonstrates that achieving low levels of *both* LDL cholesterol and hsCRP after the initiation of statin therapy might maximize preventive efforts, at least with statin therapy. Within the JUPITER cohort, those who not only reduced LDL cholesterol to less than 70 mg/dL but also reduced hsCRP to below 1 mg/liter had an 80% reduction in risk.[131] This observation made in a primary prevention setting extends prior work in high-risk secondary prevention demonstrating the benefit of lowering both LDL cholesterol and hsCRP.[132] For example, in the Pravastatin or Atorvastatin Evaluation and Infection Therapy–Thrombolysis in Myocardial Infarction 22 (PROVE IT–TIMI 22) trial, conducted in patients with acute coronary syndromes treated with statin therapy, achieving levels of hsCRP less than 2 mg/liter conferred equivalent long-term event-free survival as achieving levels of LDL cholesterol less than 70 mg/dL; indeed, those who met both these levels had the best long-term outcomes.[132] An analysis of the IMPROVE-IT trial of ezetimibe added to simvastatin supports the concept of lowering both LDL and hsCRP[133] (**Fig. 45.16**).

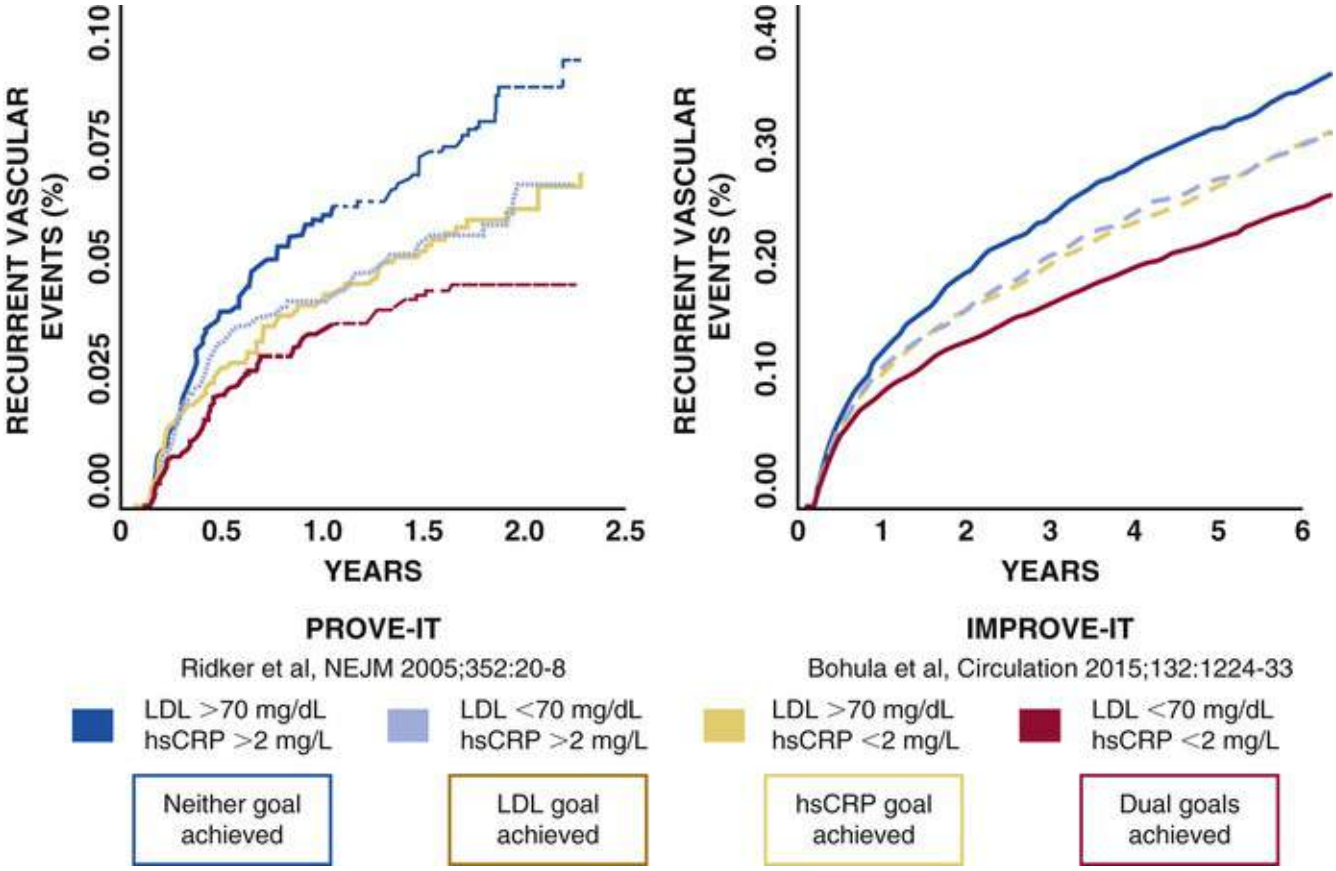

FIGURE 45.16 Recurrent cardiovascular event rates according to whether or not patients achieved below-median low-density lipoprotein (LDL) reduction (<1.8 mmol/L [<70 mg/dL]), high-sensitivity C-reactive protein (hsCRP) reduction below median (<2 mg/L), neither, or both following initiation of statin therapy (PROVE-IT, *left*) or the combination of statin therapy and ezetimibe (IMPROVE-IT, *right*). (From Ridker PM. Residual inflammatory risk: addressing the obverse side of the atherosclerosis prevention coin. Eur Heart J 2016;37:1720.)

Although inflammation participates in vascular injury and hsCRP provides an inexpensive and clinically useful measure of this process, the stimulus that initiates the underlying inflammation remains uncertain. Patients with chronic inflammatory diseases such as rheumatoid arthritis, inflammatory bowel disease, and psoriasis tend to have elevated hsCRP levels and, on average, somewhat elevated vascular risk.[134] Patients with low-grade infections such as gingivitis or those who are chronic carriers of *Chlamydia pneumoniae*, *Helicobacter pylori*, herpes simplex virus, and cytomegalovirus also may have a higher risk for vascular problems on the basis of a chronic systemic inflammation. However, careful prospective studies of antibody titers directed against these organisms have not consistently found evidence of association, and large-scale antibiotic trials have not shown reduced event rates.

It remains uncertain whether lowering inflammation can reduce vascular event rates. Early "mendelian randomization" analyses have not supported a direct causal role for CRP in atherothrombosis, but more recent studies of this type endorse a causal role for related upstream IL-6 pathways.[135,136] These data strongly support ongoing "cardiovascular inflammation reduction trials" such as those evaluating low-dose methotrexate, colchicine, and the anti–IL-1β antibody canakinumab. Further, the concept of "residual inflammatory risk" as being a separate and distinct clinical entity from "residual cholesterol risk" has emerged.[137]

Other Biomarkers of Inflammation

Although hsCRP currently is the best-characterized inflammatory biomarker for clinical use, several

other markers of inflammation have shown promise in predicting vascular risk and provide further insights into the role played by inflammation in atherothrombosis. These include cytokines such as IL-1 and IL-6, soluble forms of certain cell adhesion molecules such as intercellular adhesion molecule (sICAM-1), P-selectin, and the mediator CD40 ligand, as well as markers of leukocyte activation such as myeloperoxidase, pregnancy-associated plasma protein A, and the IL-1 receptor family member ST2. Unfortunately, many of these alternative inflammatory biomarkers have analytic limitations that to date have reduced clinical usefulness. For example, some have too short a half-life for clinical diagnostic testing, and the ability of others to predict risk in settings of broad populations has proved to be marginal thus far. Nonetheless, measurement of several of these inflammatory biomarkers can shed critical pathophysiologic light on the atherothrombotic process, particularly at the time of plaque rupture. For example, soluble CD40 ligand (probably released from activated platelets) may provide insight into the efficacy of specific antithrombotic agents independently of CRP. Similarly, myeloperoxidase may provide prognostic information in cases of acute ischemia beyond that associated with troponin or CRP, whereas clinical studies with ST2 indicate novel associations in heart failure and ischemia.[138]

Although also an acute-phase reactant and thus often considered an inflammatory biomarker, plasma *fibrinogen* additionally influences platelet aggregation and blood viscosity, interacts with plasminogen binding and, in combination with thrombin, mediates the final step in clot formation and the response to vascular injury. Fibrinogen levels associate positively with age, obesity, smoking, diabetes, and LDL cholesterol level and negatively with HDL cholesterol level, alcohol use, physical activity, and exercise level. Given these relationships, fibrinogen was among the first "novel" risk factors evaluated. Early reports from the Gothenburg, Northwick Park, and Framingham heart studies all found significant positive associations between fibrinogen levels and future risk of cardiovascular events. Since then, a number of other prospective studies have confirmed these findings, and in meta-analyses, an approximately linear logarithmic association was seen between usual fibrinogen level and the risk of CHD and stroke.[139] In recent studies, hsCRP and fibrinogen levels showed additive ability to predict risk, although hsCRP appeared to have a larger absolute effect. This observation holds interest because CRP and fibrinogen have distinct genetic determinants. Despite the consistency of these data, measurement of fibrinogen has found limited use in clinical practice because of suboptimal assay standardization and inconsistency across reference laboratories.

Other than hsCRP, the only inflammatory biomarker commercially available is lipoprotein-associated phospholipase A_2 (Lp-PLA_2). As with hsCRP, most but not all published studies indicate a positive relationship between Lp-PLA_2 and vascular risk. In contrast with hsCRP, however, Lp-PLA_2 circulates bound to lipoproteins such as apo B, so its levels strongly correlate with LDL cholesterol. Because of this effect, adjustment for lipid levels largely attenuates the strength of association between Lp-PLA_2 and vascular events, making contributions to risk detection modest. Clinically, the availability of both mass and activity assays, each with suboptimal reproducibility, has further complicated the evaluation of Lp-PLA_2. In two recent large-scale trials, Lp-PLA_2 no longer predicted residual risk after aggressive LDL cholesterol reduction with statin therapy. Accordingly, expert reviews suggest limited clinical applicability of Lp-PLA_2 measurement.[140]

Interventions to Reduce Alternative Markers of Inflammation

To date, four clinical trials have evaluated the potential benefits of fibrinogen reduction, and all have found disappointing results. Specifically, two trials of bezafibrate have shown no reduction in event rates with active therapy despite significant reductions in fibrinogen levels. Similarly, in the Heart and

Estrogen/Progestin Replacement Study (HERS) and in the WHI, hormone replacement therapy lowered fibrinogen but did not improve clinical outcomes. Equally disappointing, two major trials of darapladib, an inhibitor of Lp-PLA$_2$, showed no clinical benefit,[141,142] as has an exploratory trial of losmapimod, a MAP-kinase inhibitor.[143] Nonetheless, at this time, several multinational trials are evaluating whether specific agents that directly or indirectly target inflammation can reduce vascular event rates. Therapies under evaluation include canakinumab (a monoclonal antibody that neutralizes IL-1β), the generic anti-inflammatory agent low-dose methotrexate (LDM) that already sees wide use for the treatment of rheumatoid arthritis, and colchicine, a microtubule inhibitor with anti-inflammatory effects used to treat gout and pericarditis. Trials with these latter agents should provide unconfounded direct tests of the inflammation hypothesis of atherothrombosis. Indeed the recently reported Canakinumab Antiinflammatory Thrombosis Outcome Study (CANTOS) affirmed the inflammatory hypothesis of atherosclerosis and demonstrated the utility of hsCRP as a tool to target anti-interleukin-1-beta therapy.[144]

Lipoprotein(a)

Lp(a) consists of an LDL particle with its apo B100 component linked by a disulfide bridge to apolipoprotein(a) [apo(a)], a variable-length protein that shares sequence similarity with plasminogen (**see Chapter 48**). The apo(a) component of Lp(a) contains a variable number of cysteine-rich kringle IV repeats that result in great heterogeneity. Accordingly, plasma Lp(a) concentrations vary inversely with apo(a) isoform size but also may vary even in isoform size, based on differential levels of production. Underlying its molecular complexity, more than 25 heritable forms of Lp(a) exist, demonstrating the importance of the genome in determining plasma levels, an important issue for risk prediction across different population groups. The close homology between Lp(a) and plasminogen has raised the possibility that this lipoprotein may inhibit endogenous fibrinolysis by competing with plasminogen binding on the endothelium. More recent studies have suggested that Lp(a) binds and inactivates tissue factor pathway inhibitor and may augment the expression of plasminogen activator inhibitor, further linking lipoproteins and thrombosis. Lp(a) also colocalizes within atherosclerotic lesions and may have local actions through oxidized phospholipid pathways. Thus, several mechanisms may contribute to a role for Lp(a) in atherothrombosis.[145]

In an updated meta-analysis of 36 prospective studies that included more than 12,000 cardiovascular endpoints, the adjusted risk ratios for each standard deviation (SD) increase in plasma Lp(a) level were 1.13 for CHD and 1.10 for ischemic stroke.[146] Adjustment for classic cardiovascular risk factors only modestly attenuated these effects, in part because Lp(a) and other markers of risk correlate minimally. Whether the assessment of Lp(a) truly adds prognostic information to overall risk in primary prevention remains uncertain, however, because in most studies, Lp(a) typically has proved to be predictive for persons already known to be at high risk because of the presence of other risk factors, in particular elevated levels of LDL cholesterol. By contrast, recent data from the Bruneck study suggest that discrimination and new reclassification of cardiovascular risk can be improved modestly with Lp(a) assessment, particularly for those with markedly elevated levels.[147] Some investigators have advocated Lp(a) assessment in certain patient groups, such as those with established coronary disease or renal failure. Evidence that children with recurrent ischemic stroke have elevated Lp(a) levels also supports the potential use of this biomarker in unusual high-risk settings.

Standardization of commercial Lp(a) assays has improved considerably, with most reference laboratories using commercial assays that measure Lp(a) in a manner independent of apo(a) isoform size. In several recent investigations using these assays, the risk increase with Lp(a) was nonlinear and limited

to patients with concomitant elevations of LDL cholesterol levels, confirming earlier work. Thus the presence of threshold effects and interactions with LDL cholesterol may limit the routine measurement of Lp(a) for cardiovascular risk stratification in the general population. However, there remains considerable interest in those with greatly elevated Lp(a) levels resulting from genetic effects.[148,146]

Interventions to Reduce Lipoprotein(a)

With the exception of high-dose niacin, few approved interventions lower Lp(a) level, and no study to date has shown that Lp(a) reduction lowers vascular risk. However, the genetic investigations previously noted have provided important insights into Lp(a) regulation and suggest the potential for a causal relationship between Lp(a) and vascular events. For these reasons, there is considerable interest in exploring agents with Lp(a)-lowering effects.[145] Several novel agents, including PCSK9 inhibitors and a modified antisense oligonucleotide drug, have shown substantial ability to reduce Lp(a) levels and are now undergoing outcome evaluations.[145] Enthusiasm is somewhat tempered by the failure of CETP inhibitors such as evacetrapib to lower event rates despite substantial Lp(a) reduction. Mechanisms of Lp(a) reduction may prove important, and definitive trials may need to focus on those with marked elevations, a difficult group to screen.

Homocysteine

Homocysteine is a sulfhydryl-containing amino acid derived from the demethylation of dietary methionine. In patients with rare inherited defects of methionine metabolism, severe hyperhomocysteinemia (plasma levels >100 mmol/liter) can develop; such patients have a greatly elevated risk for premature atherothrombosis as well as venous thromboembolism. Mechanisms that may account for these effects include endothelial dysfunction, accelerated oxidation of LDL cholesterol, impairment of flow-mediated endothelium-derived relaxing factor with subsequent reduction in arterial vasodilation, platelet activation, and oxidative stress. In contrast with severe hyperhomocysteinemia, mild to moderate elevations of homocysteine (plasma levels >15 mmol/liter) are more common in the general population, primarily because of insufficient dietary intake of folic acid. Other patient groups who may have elevated levels of homocysteine include those receiving folate antagonists such as methotrexate and carbamazepine and those with impaired homocysteine metabolism caused by hypothyroidism or renal insufficiency.

A common polymorphism in the methylene tetrahydrofolate reductase gene (*MTHFR*) that encodes a thermolabile protein is also linked to elevated homocysteine levels and to increased vascular risk, at least among persons homozygous for the variant. Familial association studies have reported higher homocysteine levels in offspring of parents with premature CAD. The *MTHFR* polymorphism appears to have modest clinical importance, however, and heterozygous persons display little evidence of elevated homocysteine levels, even in those with low folate intake. In a meta-analysis of 40 observational studies, patients homozygous for the *MTHFR* 677 TT variant had a 16% increase in relative risk (odds ratio [OR], 1.16; 95% CI 1.05 to 1.28), and this observation was evident only in studies originating in Europe.[149] In populations in which folate fortification exists, such as in North America, little compelling evidence supports genetic evaluation of *MTHFR* to predict vascular risk.

Reliable immunoassays for total plasma homocysteine (the combination of free homocysteine, bound homocysteine, and mixed disulfides), now widely available, have largely replaced the use of high-performance liquid chromatography. Despite the availability of newer assays, measurement of

homocysteine remains controversial, and recent guidelines have not advocated their use. This lack of enthusiasm reflects modest overall effects reported in prospective cohort studies and the publication of several large trials of homocysteine reduction. In the United States, fortification of the food supply has greatly reduced the frequency of low folate and elevated homocysteine levels, particularly for persons with values initially in the moderately elevated range. Thus the number of patients potentially identifiable by screening for homocysteine has decreased considerably.

Interventions to Reduce Homocysteine.

With regard to clinical trials of homocysteine reduction, several major studies have been completed, and none has shown substantive benefit. These null trials include the Vitamin Intervention for Stroke Prevention (VISP) trial, the Norwegian Vitamin Trial (NORVIT), the Heart Outcomes Prevention Evaluation (HOPE-2) trial, and a Department of Veterans Affairs trial, all of which demonstrated reduced homocysteine levels but no reduction in vascular event rates.[150-153] These consistently negative trial results conflict with the supposition made from studies of mendelian randomization that had previously argued for a clear causal role between homocysteine concentration and vascular events.[149]

Despite reduced enthusiasm and lack of evidence that homocysteine reduction lowers vascular risk, continuing folate supplementation in the general population is crucial to reduce the risk of neural tube defects—an inexpensive practice that has been in place in the United States for more than a decade, yet remains a public health challenge for much of Europe and the developing world.

Direct Plaque Imaging

In contrast with biologic factors that predispose to disease, direct imaging of preclinical atherosclerosis provides an alternative method to detect high-risk individuals who might benefit from early preventive interventions.[154,155] Although several novel imaging tests are in development, the best studied to data are ultrasound measures of the *common carotid intima-media thickness* (CIMT) and computed tomography (CT) to detect coronary artery calcification. Both these imaging modalities can detect high-risk individuals, but both have engendered controversy in preventive practice. With regard to CIMT, a meta-analysis of 14 population-based cohorts reported a consistent and statistically significant 9% increase in future vascular risk for each 0.1-mm increase in CIMT thickness; however, that same analysis found CIMT unlikely of clinical importance once risk estimates and reclassification underwent adjustment for usual risk factors.[155] The Framingham investigators also have recently reported limited usefulness for CIMT in risk prediction,[156] and current ACC/AHA guidelines do not endorse this approach to risk detection.

To date, multiple studies have shown increased levels of *coronary artery calcification* (CAC) to predict strongly vascular risk, and advocates of this approach correctly note that unlike CIMT, CAC can provide substantial reclassification in primary prevention. Both the Heinz Nixdorf Recall Study and the Multi-Ethnic Study of Atherosclerosis (MESA) have shown that CAC, ankle-brachial index (ABI), hsCRP levels, and family history (but not CIMT) independently predict incident vascular events among persons at “intermediate risk”; in MESA, CAC also modestly improved discrimination when added to the ACC/AHA pooled cohort equations.[157,158] Similar data have been presented from the BioImage study for carotid and coronary vessels using a combination of CAC and three-dimensional ultrasound.[159] CAC scanning, however, causes radiation exposure and results in increased downstream testing from unanticipated false-positive findings. Thus, whether CAC can cost-effectively improve prevention remains controversial. To date, trials have shown CAC to have quite limited impact on changing patient or physician behavior with regard to preventive interventions.[160]

Part of the difficulty with coronary calcification as a clinical biomarker is that CT imaging probably detects the plaques least likely to rupture and does not detect the noncalcified, thin-capped lesions that appear to cause most clinical events. Thus, although coronary calcium provides a noninvasive measure of atherosclerotic burden, patients with low calcium scores cannot be dismissed as being at low risk. In a major study of currently asymptomatic individuals, 41% of all future vascular events occurred in those with a coronary artery calcium score (CACS) less than 100, and 17% occurred in those with a CACS of 0.[161] In this study, those with high Framingham risk scores but low coronary calcium scores remained at high risk. Thus the absence of CAC does not preclude occurrence of coronary events over longer-term follow-up. Moreover, statin use increases CAC, despite consistently reducing cardiovascular events.[162,163]

Imaging of atherosclerosis has already extended well beyond anatomic evaluation to focus instead on functional properties that define vascular inflammation and unstable plaque.[164] Such studies exploit the ability of different imaging modalities and selective imaging probes to detect molecular and microanatomic targets that have specificity for plaque rupture. In part, the impetus for this new research stems from recognition that “stable” plaques with a fibrotic morphology have relatively low rupture rates, whereas plaques with inflammatory activity have a higher likelihood of causing vascular events, even though both look similar on current macroanatomic imaging. Potential new targets for this functional imaging approach include measures of glucose uptake, specific adhesion molecules, and biomarkers of apoptosis and protein degradation (**Fig. 45.17**). Magnetic resonance imaging (MRI), positron emission tomography (PET), and contrast-enhanced ultrasonography (CEUS)—each linked to specific molecular targets—all are now under investigation, as are functional measures of vascular reactivity such as coronary flow reserve.

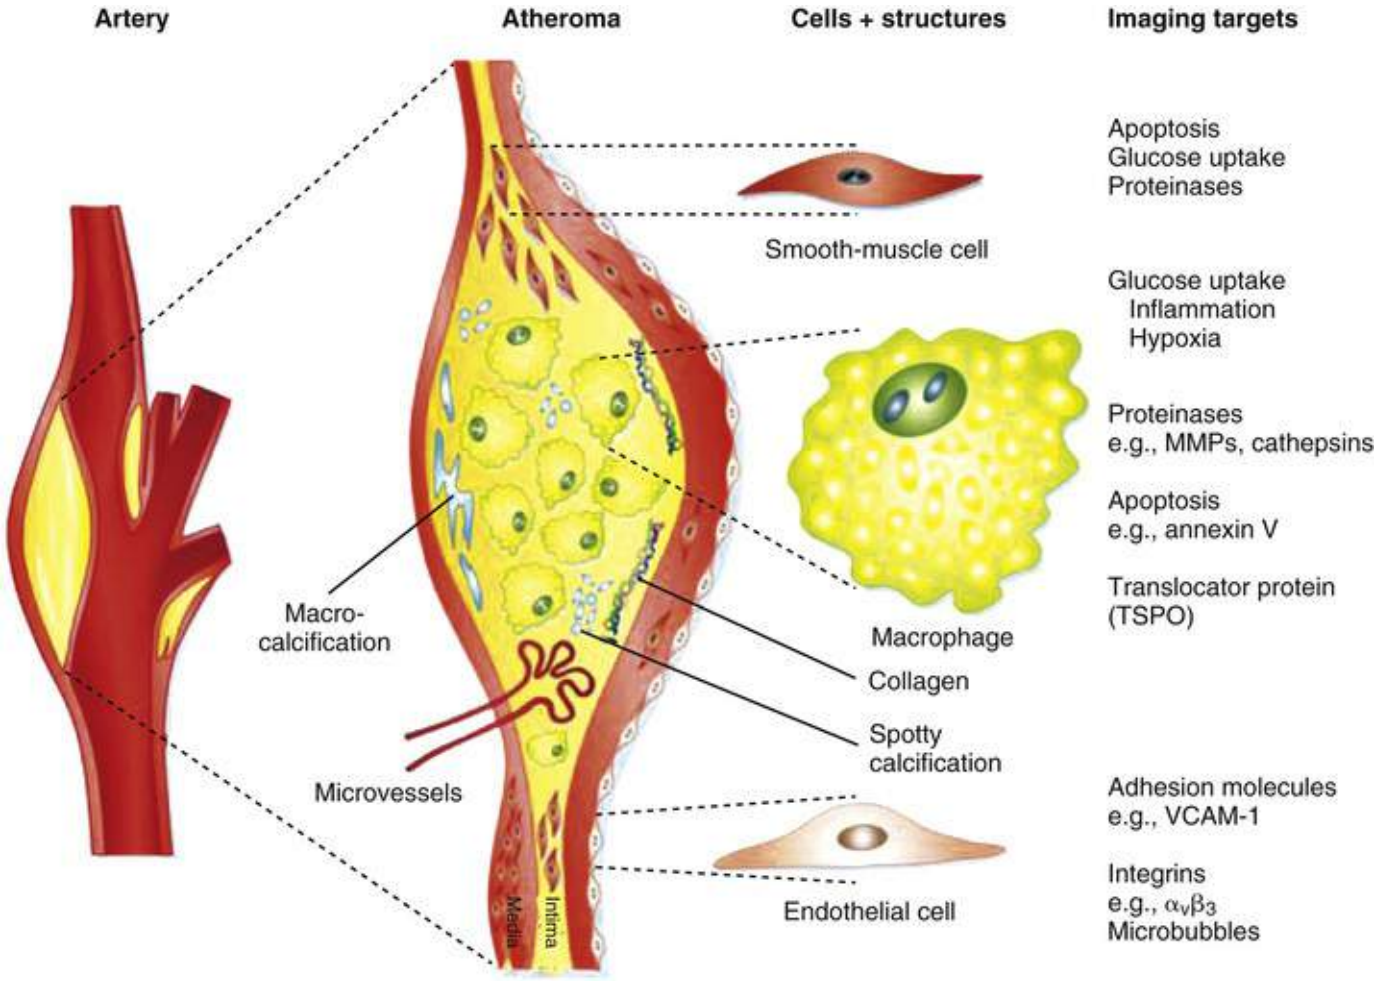

FIGURE 45.17 Targets for noninvasive vascular imaging of the atherosclerotic plaque. MMPs, Matrix metalloproteinases. (From Camici PG, Rimoldi OE, Gaemperli O, Libby P. Non-invasive anatomic and functional imaging of vascular inflammation and unstable plaque. Eur Heart J 2012;33:1309.)

Interventions Based on Vascular Imaging

A major limitation of all imaging modalities is that, unlike the situation for plasma biomarkers such as LDL cholesterol or hsCRP, scant trial data indicate that patients identified by any imaging biomarker benefit from a therapy they otherwise would not have received. The Detection of Ischemia in Asymptomatic Diabetics (DIAD) trial underscores the importance of performing such trials. In DIAD, random allocation to ischemia screening with myocardial perfusion imaging failed to reduce incident MI, vascular death, or episodes of ischemia during follow-up.[165] Furthermore, little evidence exists that imaging improves general preventive measures; as noted in the randomized Early Identification of Subclinical Atherosclerosis by Noninvasive Imaging Research (EISNER) trial, knowledge of CAC failed to improve rates of smoking cessation or exercise and had no impact on total cholesterol, HDL cholesterol, triglycerides, glucose, body weight, or adherence to preventive medicines including statins or aspirin. In symptomatic patients, a major 10,000-participant clinical trial failed to show improved outcomes when anatomic imaging with coronary computed tomographic angiography (CTA) was employed as an alternative to common functional stress testing methods.[166] Observational nonrandomized data suggest that CAC testing could serve to allocate statin therapy;[167] however, since statins increase CAC, the biologic mechanisms of lipid lowering and arterial calcification may diverge. Thus, in view of issues of cost (and, in some cases, radiation exposure), the expanded use of imaging as a screening tool for vascular risk detection in the setting of primary prevention should await substantive work, including hard-outcome trials.

Genetic Markers for Cardiovascular Risk

Heritability accounts for up to one half of the susceptibility to coronary heart disease (**see Chapter 7**). Until recently, however, genetic risk factors predisposing to CHD were difficult to quantify. This situation has markedly changed with the advent of very-large-scale genome-wide association studies (GWASs) capable of defining small but highly significant risks for individual single-nucleotide polymorphisms (SNPs) common in the general population[168] (**Fig. 45.18**). In an up-to-date meta-analysis, 58 common polymorphisms are associated with CHD while an additional 100 loci are associated with various lipid phenotypes, which together explain 28% of the estimated heritability of CHD.[169] Other informative genetic studies have focused on inflammation phenotypes such as CRP and the IL-6 receptor pathway, the latter suggesting a causal role of inflammation in the atherothrombotic process.[135,136]

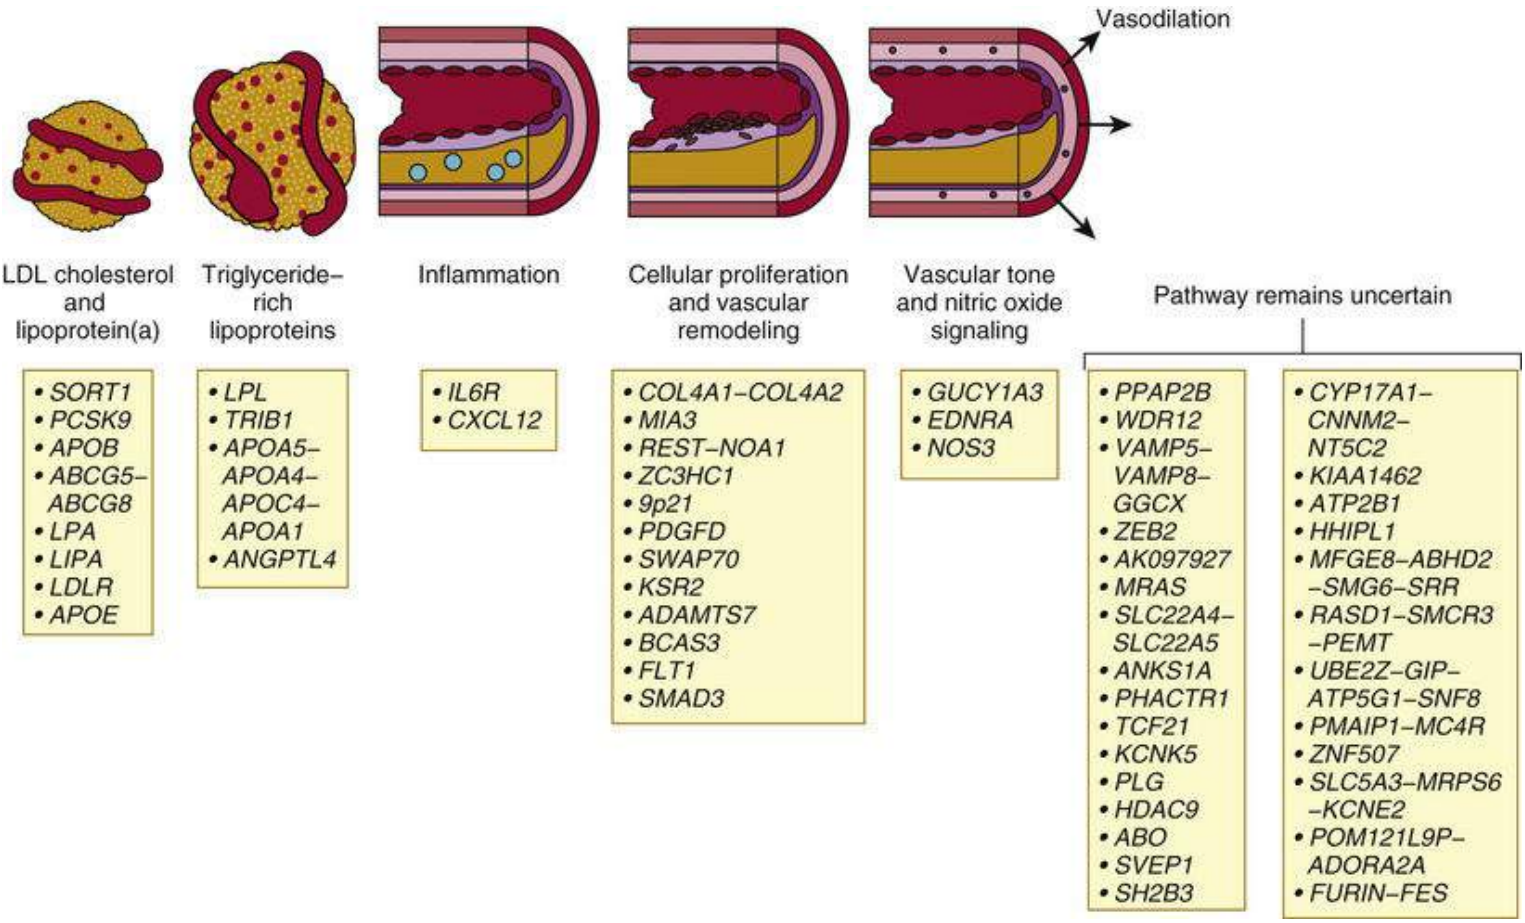

FIGURE 45.18 Pathophysiologic pathways related to regions in the genome that are associated with coronary artery disease. The presumed causal pathways on *top* relate to the positions of genetic variants listed below. We lack definitive identification of the causal genes and variants in many cases, so this compilation lists the nearest neighboring genes; this approach may require revision in some cases. (From Khera AV, Kathiresan S. Genetics of coronary artery disease: discovery, biology and clinical translation. Nat Rev Genet 2017;18:331.)

Several important observations result from these accumulating data. First, although some genetic variants mediate risk through lipids and hypertension, many loci identified by GWASs appear to act on the process of atherothrombosis independent of known or traditional risk factors.[92,170] This observation has considerable importance because it suggests that novel pathways not yet exploited for vascular prevention can play substantial roles in susceptibility to vascular events. Other genetic data provide strong suggestions that pathways related to Lp(a) and triglyceride-rich lipoproteins may be causal for

atherothrombosis and thus support further intervention trials that target these particles.

Second, the magnitude of risk associated with any one genetic variant tends to be small, yet specific patients such as those with early-onset disease often carry as many as 30 known variants, which together may contribute substantively to individual risk. The observation that most of the genetic variants associated with CHD localize in DNA sequences that do not code for a protein product has considerable relevance for future work. The need for functional genomics and translation of these data from loci to clinically relevant biology is paramount.[171]

Third, although early studies were disappointing, more recent evaluations inclusive of 50 or more genetic loci have found that risk prediction can improve at least modestly with genetic screening and that this effect is largely independent of family history[172,173] (**Fig. 45.19**). However, the magnitude of these effects is small, and thus genetic screening for the general population is unlikely to have clinical utility.[174] In specific situations, however, genetic screening should be considered, most importantly when LDL cholesterol levels exceed 190 mg/dL and concern exists about heterozygous or homozygous familial hypercholesterolemia (FH). Family cascade screening is particularly important in children, in whom decades of life may be gained by early detection and treatment, a perspective that has led some to call for universal FH screening in childhood.[175,176]

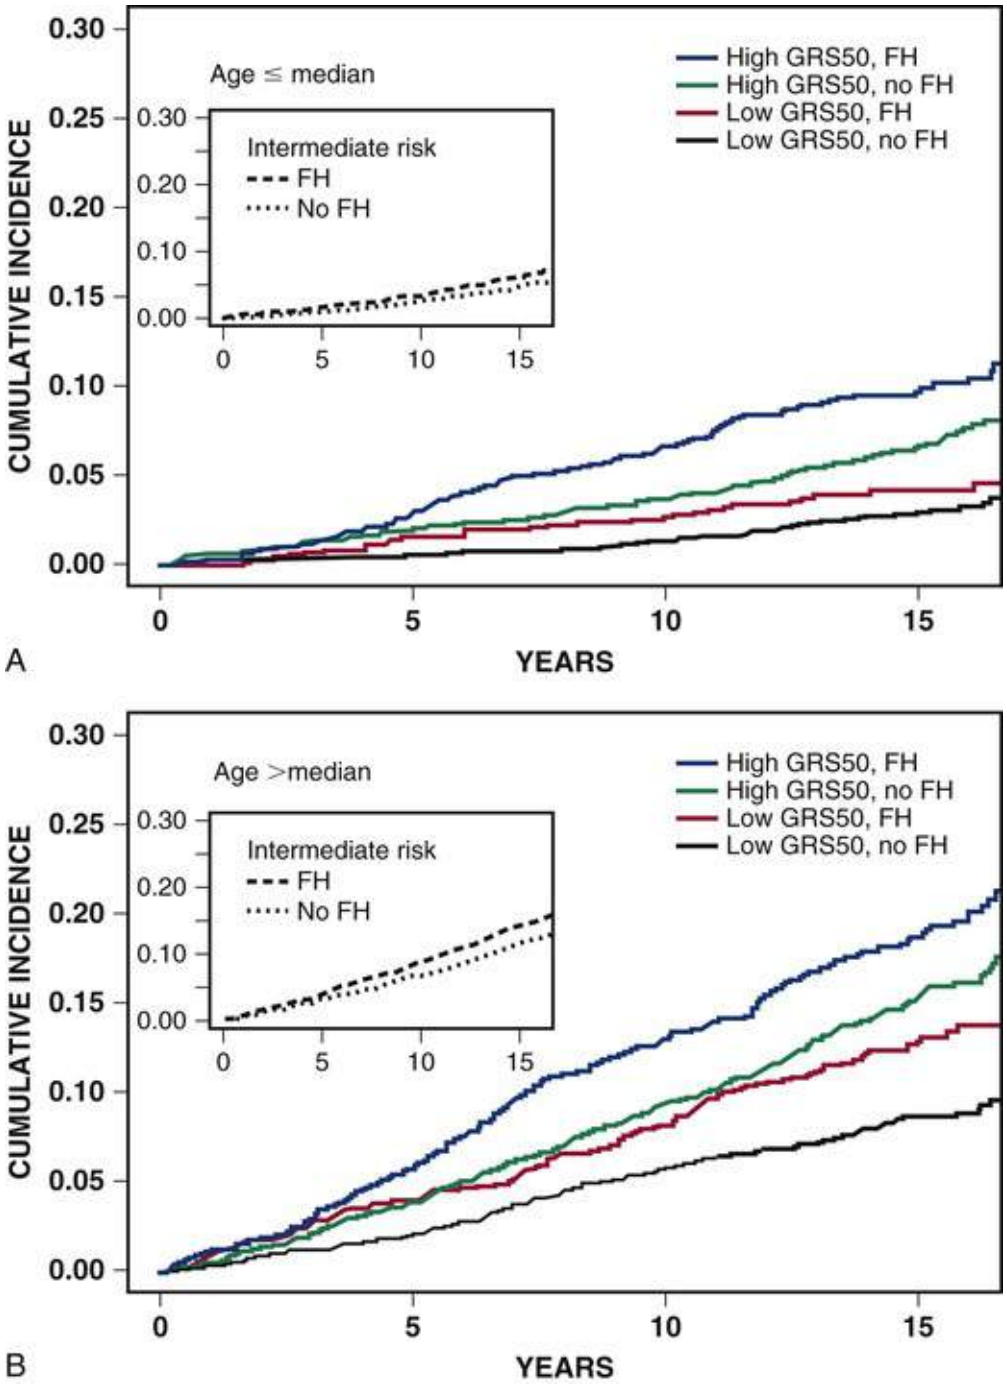

FIGURE 45.19 Cumulative incidence of coronary heart disease events according to self-reported family history (FH) of coronary heart disease and 50-variant genetic risk score (GRS50). *Blue* and *green*: Those with high GRS50 with (*blue*) or without (*green*) a self-reported FH. *Red* and *black*: Those with low GRS50 with (*red*) or without (*black*) a self-reported FH. *Inset*: Those with intermediate GRS50 with (*dashed*) or without (*dotted*) a self-reported FH. Cumulative incidence was estimated while considering non–coronary heart disease death as competing risk. **A,** Participants younger than median age (≤57.6). Median age for this younger group is 51.4 (interquartile range, 48.8-54.2). **B,** Participants older than median age (>57.6). Median age for this older group is 64.7 (interquartile range, 61.1-67.7). (From Tada H, Melander O, Louie JZ, et al. Risk prediction by genetic risk scores for coronary heart disease is independent of self-reported family history. Eur Heart J 2016;37:561-7.)

Interventions for Prevention Based on Genotype

Advancing knowledge of cardiovascular genetics not only is producing novel targets for therapy but also is introducing to clinical practice the potential for improved drug safety and efficacy. Broadly stated, *pharmacogenetics* is the study of inherited and acquired genetic variation in drug response that can affect both individuals and selected populations[177] (**see Chapter 8**). Prominent examples of clinical

applications in which knowledge of genotype has potential impact for cardiovascular medicine are in the prediction of statin-induced efficacy and myopathy, in clopidogrel efficacy, and in warfarin dosing.

With regard to statins and adverse effects, in a pharmacogenetic study conducted within the Study of the Effectiveness of Additional Reductions in Cholesterol and Homocysteine (SEARCH) identified a common variant in *SLCO1B1* associated strongly with an increased risk of simvastatin-induced myopathy.[178] *SLCO1B1* encodes an organic anion-transporting protein known to regulate the hepatic uptake of statins. For the relevant SNP in this region, the hazard ratio for myopathy was 4.5 per copy of the C allele (and almost 17 in the CC compared with TT homozygotes). With regard to efficacy, a recently described genetic risk score has shown the ability to detect both high risk and those with the largest relative and absolute risk reductions attributable to statin therapy.[179] While this risk score is not needed to prescribe statins because their efficacy is well known in broad patient groups, these data reinforce emerging concepts of drug-genome interactions that may impact other vascular interventions (**Fig. 45.20**).

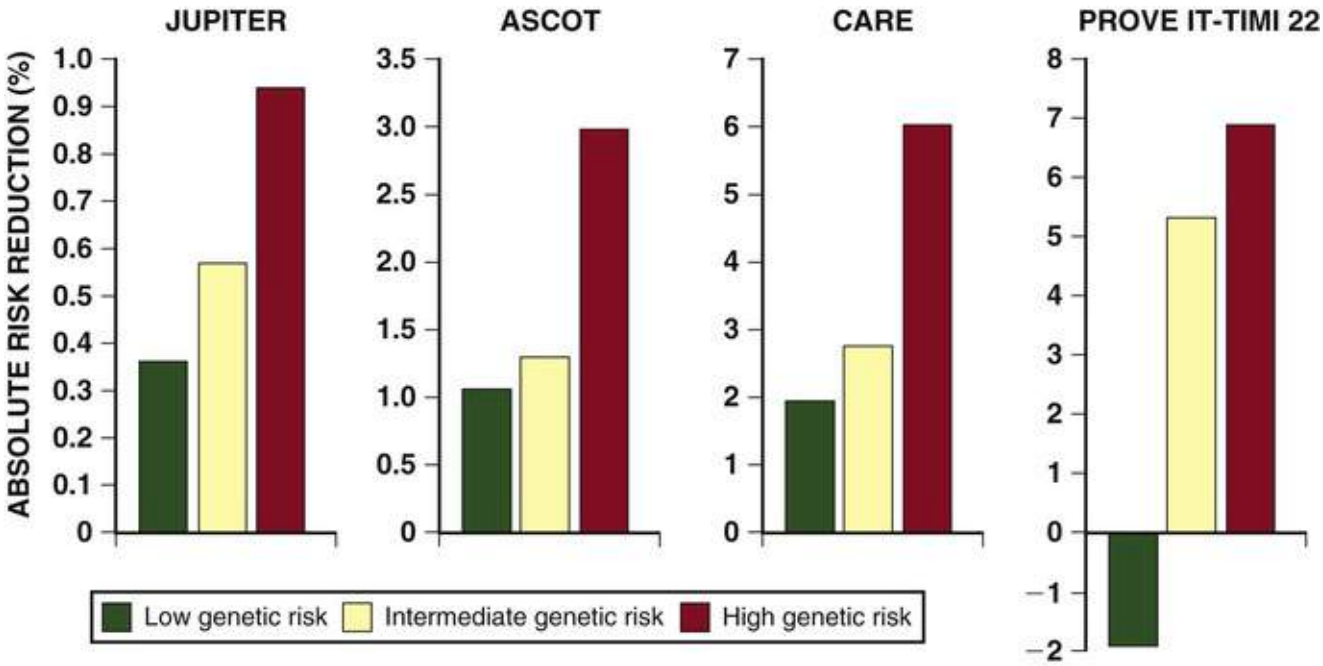

FIGURE 45.20 Genetic risk and efficacy of statin therapy. Those with higher strata of genetic risk show the greatest absolute risk reductions of coronary heart disease events in statin-treated participants in the trials shown. JUPITER, Justification for the Use of Statins in Prevention trial: an Intervention Trial Evaluating Rosuvastatin; ASCOT, Anglo Scandinavian Cardiac Outcomes Trial; CARE, Cholesterol and Recurrent Events trial; PROVE IT-TIMI 22, Pravastatin or Atorvastatin Evaluation and Infection Therapy–Thrombolysis in Myocardial Infarction 22 trial. (From Mega J, Stitziel NO, Smith JG, et al. Genetic risk, coronary heart disease, and the clinical benefit of statin therapy: an analysis of primary and secondary prevention trials. Lancet 2015;385:2264-71.)

Regarding antiplatelet therapy with agents such as clopidogrel or prasugrel, several investigators have found that polymorphisms in *CYP2C19* (where clopidogrel undergoes prodrug metabolism) and in *ABCB1* (which encodes an efflux transporter for clopidogrel) are associated with antiplatelet response and clinical outcomes. These data initially led the FDA to impose warnings about clopidogrel pharmacogenetics, but the ACC and AHA have suggested selective genetic testing because of a lack of clear outcome data. Ongoing clinical trials are comparing genetic screening to standard clinical approaches in this evolving arena.[180]

With regard to warfarin dosing, several genetic polymorphisms that interfere with hepatic metabolism and vitamin K epoxide reductase affect the dose of warfarin required to achieve a specific therapeutic

target and the speed with which an individual patient achieves that goal. However, controversy persists regarding whether any of these pharmacogenetic effects should lead to clinical testing, since only marginal effects have been seen in clinical trials to date[181,182] (**see Chapter 93**).

Finally, pharmacogenetics in theory can substantially improve patient outcomes, even for drugs that have failed in the general population. For example, polymorphism in the *ADCY9* gene may modify the effects of the CETP inhibitor dalcetrapib.[183] Incorporating genetic risk scores into clinical practice may increase compliance with lipid-lowering therapy.[184] Although each of these latter studies may reflect overoptimism about the clinical potential for genetic screening, certainly routine preventive practice should include evaluation of family history. In the Framingham Offspring Study, when compared with those with no parental history of CVD, men with at least one parent with premature atherothrombosis (onset before age 55 for fathers and before 65 for mothers) had an age-adjusted OR of 2.6 (95% CI 1.7 to 4.1), whereas the similar OR for women was 2.3 (95% CI 1.2 to 3.1).[19] These effects compare in magnitude with those of smoking, hypertension, and hyperlipidemia in the Framingham cohort itself.

Environmental Exposures and Associated Interventions

Physical Activity

A large body of epidemiologic evidence has accumulated since the 1950s demonstrating that physical activity is associated with reduced rates of cardiovascular morbidity and mortality, as well as all-cause mortality (**see Chapters 53 and 54**). This correlation pertains across a wide age range, in both sexes, as well as among different racial/ethnic groups.[109,185] Notable advances in recent years include elucidation of the dose-response relation (i.e., what percent risk reduction is associated with different levels of physical activity), as well as suggestive, but not yet definitive, research showing that sedentary behavior may constitute an independent risk factor, even among persons who engage in sufficient physical activity to meet the current guidelines. Unfortunately, in 2015, only 49.0% of U.S. adults age 18 and older met the 2008 federal physical activity guidelines for aerobic activity based on leisure-time activity. However, the percentage meeting the guidelines has increased from 41.1% in 2006. As age increased, the percentage meeting the guidelines decreased, and women were less likely than men to meet the guidelines. Non-Hispanic white adults were more likely to meet the guidelines than Hispanic adults and non-Hispanic black adults. This lack of activity is worldwide, such that inactivity may cause as many deaths globally each year as those from smoking, because inactive persons outnumber smokers.[186]

The U.S. Federal Government issued its physical activity guidelines in 2008 and received reinforcement from the most recent AHA/ACC lifestyle guidelines.[187] The heart-healthy guidelines recommend that adults should engage in 150 minutes per week of moderate-intensity physical activity (e.g. walking), or 75 minutes per week of vigorous-intensity aerobic activity (e.g. jogging), or a combination of moderate- and vigorous-intensity aerobic physical activity. Aerobic activity should be performed in episodes of at least 10 minutes, preferably spread throughout the week, which may also minimize the risk of musculoskeletal injuries. Additionally, muscle-strengthening exercises should be performed on 2 days of the week.

For those persons who do not meet the recommended minimum, the guidelines encouragingly state that "some physical activity is better than none." Data have quantified the inverse dose-response relationship, showing that persons meeting the recommended minimum have a 14% lower risk of CHD compared with those engaging in no leisure-time activity.[188] Twice the minimum guideline level yielded a 20% risk reduction. Risks continued to decline at higher levels of energy expenditure, although with more modest magnitudes of additional risk reduction. Even achievement of half the guideline-recommended amount of physical activity yielded a significant risk reduction.

In secondary prevention, a Cochrane systematic review and meta-analysis of RCTs of exercise-based cardiac rehabilitation has shown, compared with usual care, reductions in cardiovascular mortality as well as reductions in hospital admissions and improvements in quality of life that applied consistently across patients and intervention types[189] (**see Chapter 54**). The findings related to the primary prevention of cardiovascular disease have come from observational epidemiologic studies. Although such study designs cannot prove causality, the totality of evidence strongly indicates a causal relationship. Randomized trials that support this inverse relationship have demonstrated many plausible biologic mechanisms.[187]

Regular physical activity reduces myocardial oxygen demand and increases exercise capacity (i.e.,

improving cardiorespiratory fitness). Physical activity also lowers systolic and diastolic BP; improves insulin sensitivity and glycemic control, with major benefits for diabetic patients, including reductions in glycated hemoglobin along with reduced requirements for therapy; and improves dyslipidemia, as well as vascular inflammation. Regular physical activity is associated with lower CRP levels (particularly when adiposity decreases) and improvement in hemostatic variables, including tissue-type plasminogen activator, fibrinogen, von Willebrand factor, fibrin D-dimer, and plasma viscosity. It also enhances endogenous fibrinolysis and coronary endothelial function. Physical activity helps control body weight, and lower levels of adiposity improve many of the physiologic variables that contribute to cardiovascular risk. The AHA/ACC lifestyle management guidelines explicitly advise adults to engage in aerobic physical activity to reduce LDL and non-HDL cholesterol, as well as BP, with three or four sessions per week of moderate- to vigorous-intensity physical activity, lasting on average 40 minutes per session, and resulting in a total amount consistent with the 2008 federal guidelines.[187]

For people who consume a usual American diet, the level of physical activity recommended by the federal guidelines may not be sufficient to prevent weight gain with age. Nonetheless, the available data clearly indicate that physical activity lowers cardiovascular risk among not only individuals with normal body mass index but also those who are overweight or obese (see later). Because of the difficulty in maintaining sustained weight loss among overweight and obese persons, the importance of physical activity—even without weight loss—for cardioprotection should be emphasized to patients. An analysis pooling data from several studies[190] demonstrated that persons of normal weight who met physical activity guidelines lived 4.7 years longer than normal-weight persons with no leisure-time physical activity. Among overweight persons, the corresponding years of life gained were 3.9; even class I and class II or more obese persons gained 3.4 and 2.7 years, respectively.

A current area of great interest relates to understanding the role of sedentary behavior on health[191] distinct from physical activity level, since one can be both sedentary and physically active (e.g., an office worker who sits during most of the workday but who also jogs regularly). It is estimated that adults spend 6 to 8 hours per day in sedentary behavior (e.g., sitting, watching TV, using electronic devices/computers). It is not yet clear whether the prevalence of sedentary behavior differs by sex or race/ethnicity. This relationship between sedentary behavior and CVD has biologic plausibility, since animal and human studies show that sedentary behavior is associated with elevated levels of cardiometabolic biomarkers and a poor cardiovascular risk factor profile. A meta-analysis of prospective cohort studies[192] estimated that if every adult in the United States decreased sitting time to less than 3 hours per day, life expectancy of the population would increase by 2.0 years, and if every adult reduced television viewing time to less than 2 hours per day, life expectancy would increase by 1.4 years. Further evidence is required to better inform interventions and guidelines on sedentary behavior and primary prevention of CVD.

Finally, physical activity can be associated with adverse events[187] (**see Chapter 53**). The most common adverse events are musculoskeletal injuries and risks related directly to the amount and intensity of physical activity undertaken. At the level recommended by the federal guidelines, risk is low. One of the most severe adverse events related to physical activity is the risk of a sudden cardiac event (e.g., sudden death) during or shortly after exercise, but these events are extremely rare. Vigorous-intensity activities can precipitate such events, particularly when unaccustomed. Adding a small amount of light- to moderate-intensity activity (e.g., walking, 5 to 15 minutes per session, two or three times a week) carries no known risk for sudden severe cardiac events, compared with periods of less intense activity or at rest. Compared with inactive people, active people are at lower overall risk for CVD, because when averaged over the whole day, the risk during activity and during all other periods in active people yields a lower

average risk than in inactive people. The benefits of regular physical activity clearly outweigh the inherent risk of adverse events.

Interventions to Increase Physical Activity

How can clinicians help patients increase their physical activity levels? A meta-analysis examined the effectiveness of physical activity promotion in the primary care setting, based on RCTs with at least 12 months of follow-up.[193] Studies have employed a wide range of interventions, with most including the use of written materials and two or more sessions of physical activity counseling, delivered in person or by telephone. A range of professionals—including primary care physicians, nurses, physiotherapists, exercise or physical activity specialists, health educators, health promotion specialists, and trained facilitators from a range of health professions—delivered the interventions. The interventions resulted in significant, small to medium-sized effects, with an estimated NNT of 12 for one additional sedentary adult to achieve recommended levels of physical activity at 12 months, which compares favorably with the 50 to 120 estimated NNT for smoking cessation. Provision of pedometers to participants in physical activity promotion programs can improve cardiovascular risk biomarkers.[194]

Workplace wellness programs are increasing in the United States and include exploration of approaches such as providing financial incentives for health promotion.[195] However, individual approaches toward increasing physical activity levels, although important, have limited impact because they focus only on a single patient. A comprehensive public health approach would involve health agencies; schools; businesses; policy, advocacy, nutrition, recreation, planning, and transport agencies; and health care organizations. A recent review identified several evidence-based interventions that increase physical activity levels in populations.[196] These included community-wide campaigns, mass media campaigns, and decision prompts encouraging the use of stairs versus lifts and escalators; initiatives to increase social support for physical activity within communities, specific neighborhoods, and worksites; school-based strategies for children and adolescents, which include physical education, classroom activities, afterschool sports, and active transport; and environmental and policy approaches (e.g., active transport policies) to create or enhance access to places for physical activity.

Obesity and Weight Loss

Obesity is a major and growing public health problem worldwide,[197,198] both in adults and children,[199] with effects on increased morbidity and mortality, decreased quality of life, increased medical costs, and losses to productivity (**see Chapter 50**). Obesity is a major risk factor for comorbidities, such as type 2 diabetes, CVD, musculoskeletal disorders, and certain forms of cancer. Governments and health agencies have launched a multitude of campaigns, but with limited effects on reducing obesity for anything but the short term. Obesity is very difficult to treat after it has developed,[200] and preventing unhealthy weight gain is easier and more effective than reversing it afterward. Obesity is indeed a chronic disease.[201] There is an immense need for the development of effective treatments, but the focus of antiobesity campaigns must have prevention as a priority for both individuals and populations to provide long-term health gains. To improve prevention and treatment strategies is challenging, and a better understanding of factors contributing to obesity is essential.[202-207]

For population-level comparisons, overweight and obesity are defined using the measure of body mass index (BMI), calculated as weight in kilograms divided by height in meters squared. A BMI of 25 or greater defines *overweight*, and *obesity* is a BMI of 30 or greater. Obesity class I (moderately obese) is a BMI range from 30 to 35; class II (severely obese) is from 35 to 40; and class III (very severely obese) is

a BMI greater than 40.

Based on analyses of data from the most recent NHANES, for the years 2013 to 2014, the overall age-adjusted prevalence of obesity in the United States was 37.7%, with 35.0% in men and 40.4% in women.[197] The prevalence of class III obesity overall was 7.7%, with 5.5% in men and 9.9% in women. Analyses of changes over the decade from 2005 to 2014, adjusted for age, race/Hispanic origin, smoking status, and education, showed significant increasing linear trends among women for overall obesity and class III obesity, but not among men. Early release data from NHANES 2015 indicate that the level of obesity continues to be a risk overall, although at a slower rate,[208] and that the prevalence of obesity differs substantially by race and ethnic group. Non-Hispanic black women were most likely to be obese (45.0%), followed by Hispanic women (32.6%) and non-Hispanic white women (27.2%). Non-Hispanic black men (35.1%) were more likely to be obese compared with non-Hispanic white men (30.2%). Higher-income women were less likely have obesity than low-income women. Prevalence of obesity also increases with lower levels of education. There is no relationship between obesity and education among men, but women with college degrees are less likely to be obese than less educated women.

Overweight and obesity are the fifth leading risk for global deaths.[209] Approximately 44% of the diabetes burden and 23% of the ischemic heart disease burden are attributable to overweight and obesity. Worldwide, obesity has more than doubled since 1980. In 2014, more than 1.9 billion adults over age 18 were overweight, 600 million of whom were obese, representing 39% of adults being overweight and 13% obese. About 41 million children under age 5 were overweight or obese, and most of the world's population now lives in countries where overweight and obesity kill more people than overweight. The Non-Communicable Disease (NCD) Risk Factor Collaboration[198] estimated that if the post-2000 trends in obesity continue, the probability of meeting the global obesity target of halting the rise in obesity at its 2010 levels will be “virtually zero.”

Childhood obesity has caused increasing concern in the United States and worldwide. With obesity defined as a BMI at or above the sex-specific 95th percentile on the CDC growth chart, and extreme obesity as a BMI of 120% or greater, the most recent data from NHANES indicated that the prevalence of obesity in 2011–2014 was 17.0% and extreme obesity 5.8%.[199] Trends in child and adolescent obesity vary by age, race/Hispanic origin, and education level of the household head. During 1988 to 2014, for children age 2 to 5 years, the prevalence increased until 2003–2004, but then decreased; for children age 6 to 11, the prevalence increased until 2007–2008, and then leveled off; and among those 12 to 19 years, the prevalence of obesity has consistently increased during this time. Extreme obesity showed no change for children age 2 to 5 years, but increased among children 6 to 11 and adolescents 12 to 19. The odds of obesity among children and adolescents were higher among non-Hispanic blacks (19.5%) and Hispanics (21.9%) than non-Hispanic whites (14.7%) and lower for non-Hispanic Asians (8.6%).

Overweight and obesity are consistently associated with increased all-cause mortality, as shown in a U.S.-wide evaluation between 2001 and 2014,[207] a systematic review,[210] and a pooled analysis of 1.46 million white adults.[211] Obesity strongly predicts incident CVD and CHD, as well as hypertension, dyslipidemia, type 2 diabetes mellitus, gallbladder disease, osteoarthritis, sleep apnea, some cancers, low quality of life, mental disorders (e.g., depression, anxiety), and physical function limitations, with risk increasing as BMI levels rise. Obese children have a risk for short-term health consequences, including the dramatic increases in type 2 diabetes among children and adolescents, breathing difficulties, increased risk of fracture, hypertension, early markers of CVD, insulin resistance, and psychological effects. However, childhood obesity is also a long-term condition with associated comorbidities. Obese children are at risk for long-term tracking of obesity to adulthood. Overweight or obese children who are obese as adults have increased risks of cardiovascular outcomes, but nonobese adults who were

overweight or obese during childhood have risks of these outcomes similar to those who were never obese.[212] An elevated BMI in adolescence constitutes a substantial risk factor for obesity-related disorders in midlife.[213] Although the risk of diabetes is associated with increased BMI close to the time of diagnosis, the risk of CHD is related to elevated BMI both in adolescence and in adulthood.

Some have raised doubt whether obesity itself is a true risk factor for CVD beyond its impact on vascular risk mediated solely through interrelations with glucose intolerance, insulin resistance, hypertension, physical inactivity, and dyslipidemia. Midlife obesity, however, strongly correlates with risk factors for hospitalization and future complications of CHD, even among those with few or no other major risk factors. In terms of the relative importance of obesity and physical activity as predictors of CHD risk, both fitness and fatness have implications for vascular risk. Obesity alone is associated with all-cause mortality regardless of level of physical activity.[214] The distribution of body fat also is a factor in the development of CHD, with abdominal obesity posing a substantially greater risk in both men and women. The waist-to-hip ratio, a surrogate for centripetal or abdominal obesity, independently predicts vascular risk in women and in older men. The prevalence of abdominal obesity increases with age and varies by race and ethnicity. **Chapter 50** discusses the mechanisms that link these anthropometric measures and CHD risk, which require further research, particularly among disproportionally affected racial and ethnic minority groups,

Obesity is a complex issue to address. An increased intake of energy-dense foods, a decrease in physical activity, and an increase in being sedentary because of changes in work, transportation, and urbanization have contributed to this epidemic.[209] Effective treatment strategies generally involve a multifaceted approach, including dietary counseling, behavioral modification, increased physical activity, and psychosocial support, and potentially pharmacologic intervention. Even modest behavioral and environmental improvements for individuals can attenuate or reverse weight gain and adiposity. Key diet-related priorities to reduce adiposity are reductions in refined grains, starches, sugars, and meats and increasing intake of fruits, vegetables, nuts, yogurt, fish, vegetable oils, and whole grains, in the context of regular physical activity and adequate sleep.[215] Data from the PREDIMED trial of the Mediterranean diet indicated that an increase in vegetable fat intake from natural sources in this setting had little effect on body weight or central adiposity in older individuals who were mostly overweight or obese at baseline.[216] This finding addresses the concern of weight gain from high-fat foods as an obstacle to adherence to a dietary pattern such as the Mediterranean diet that provides clinical and metabolic benefits.

Observational studies and clinical trials suggest that surgical intervention (bariatric surgery) holds promise in promoting weight loss. Joint statements by the American Society for Metabolic and Bariatric Surgery, National Lipid Association, and Obesity Medicine Association,[217,218] as well as AHA,[219] endorse the ability of surgical intervention to improve and maintain over time excess weight and comorbidities, including type 2 diabetes mellitus, dyslipidemia, liver disease, hypertension, obstructive sleep apnea, cardiovascular dysfunction, and prolonged survival. Bariatric procedures may also favorably affect bile acid metabolism and the intestinal microbiome, which may also improve dyslipidemia.[206] Bariatric procedures improve multiple cardiovascular risk factors, including glucose metabolism, BP, thrombosis, kidney function, adipocyte and adipose tissue function, inflammatory markers, and vascular markers. The greater the fat mass loss, the greater is the improvement in lipid variables such as triglycerides and especially LDL cholesterol. Bariatric procedures can decrease the use of drug treatment for dyslipidemia. After bariatric procedures, HDL cholesterol may transiently decrease for the first 3 to 6 months, often followed by an increase in HDL cholesterol to above the baseline value before the bariatric procedure.

Bariatric surgery can yield long-term benefits.[220,221] The Veterans Administration patients receiving

bariatric surgery lost substantially more weight than nonsurgical matches, and only 19 of 564 patients receiving gastric bypass regained weight back to within an estimated 5% of their baseline weight by 10 years.[220] A multicenter, prospective study of bariatric surgery in adolescents documented the durability of clinically meaningful weight loss and improvements in key health conditions (prediabetes, diabetes, abnormal kidney function, elevated BP) and weight-related quality of life among adolescents who underwent gastric bypass surgery or sleeve gastrectomy.[221] Significant improvements were seen in weight, cardiometabolic health, and weight-related quality of life at 3 years after the procedure. Risks associated with the procedure included specific micronutrient deficiencies and the need for additional abdominal procedures (**see Chapter 50**).

Recent technological advances in *epigenome profiling* have led to an increasing number of studies investigating the role of the epigenome in obesity, as well as the role that environmental exposures during early life plays in inducing persistent alterations in the genome, which may lead to an increased risk in later life (**see Chapter 7**). Multiple studies have investigated the association between obesity and global, site-specific or genome-wide methylation of DNA.[222] These investigations provided no consistent evidence for a relationship between global methylation and obesity but did identify multiple obesity-associated differentially methylated sites, mainly in blood cells. Extensive but small alterations in methylation were seen at specific sites in weight loss intervention studies, with several associations between methylation marks at birth and later-life obesity. This research may help in predicting an individual's obesity risk at a young age and may offer possibilities for introducing targeted prevention strategies.

Intervention Studies of Weight Loss

Data from numerous observational studies and small or short-term randomized clinical trials have supported the substantial health benefits of weight loss. Modest weight loss of 5% to 10% is associated with a significant improvement in BP among persons with and without hypertension; improves the lipoprotein profile, yielding lower levels of serum triglycerides, higher levels of HDL cholesterol, and small reductions in total cholesterol and LDL cholesterol; and results in improvements in glucose tolerance and insulin resistance. However, longer-term behavioral-nutrition weight loss trials have not been able definitively to evaluate a reduction in total mortality, CVD, or CHD, primarily because of the participants' inability to maintain long-term weight loss in these trials.

Despite promising data from cohort studies, randomized trials of weight loss interventions have provided mixed results. In a comparison of four popular diet regimens, as well as in a study of carbohydrate substitution, all interventions yielded modest weight reductions and beneficial effects, but with limited long-term adherence levels. In one of the few trials to attempt follow-up evaluation beyond 1 year, reduced caloric intake resulted in clinically meaningful weight loss regardless of which macronutrients were emphasized, suggesting that caloric intake is more important than any specific dietary plan (**see Chapters 49 and 50**).

A review of published trials evaluating the effectiveness of treatments for obesity in adults relevant to primary care indicates that a behaviorally based approach resulted in a 6.6-pound greater weight loss in the intervention group than in control participants after 12 to 18 months, with more treatment sessions associated with greater loss, and with limited data suggesting weight loss maintenance for 1 year or longer.[223] A number of individual trials have examined the importance of counseling, behavioral factors, and motivation in conjunction with lifestyle modification, including diet and exercise.[214,224,225] A trial for a new weight loss program that emphasized reducing unhealthy relationships with food, body image dissatisfaction, and internalized weight bias, versus a program that emphasized environmental

modification and habit formation and disruption, found equivalent weight loss outcomes during treatment but significant differences in outcomes at 6 months. In a trial of weight loss during a 2-year period in response to three lifestyle interventions, all delivered by primary care providers in collaboration with auxiliary health professionals (lifestyle coaches) in their practices,[226] enhanced weight loss counseling helped approximately one third of obese patients achieve long-term, clinically meaningful weight loss. Nonetheless, even trials limited to motivated participants have shown only modest weight reduction and maintenance in the long term.

The rising prevalence of obesity requires a larger focus beyond a biologic approach alone, with examination of how the built environment in which choices are made can influence physical activity, diet, and weight change. Similarly, because a substantial burden of obesity and poor dietary intake exists among poor and less educated groups, community-based efforts to make healthy choices an easier part of people's lives is essential. This challenge merits a sustained worldwide effort to monitor, prevent, and control obesity, with many parties, including governments, international organizations, the private sector, and civil society, needed to contribute complementary actions in a coordinated approach.[206] Such policies require outcomes assessment.[227] Approaches can move beyond traditional environmental-focused policy measures, such as collaboration with the food and restaurant industry,[203,204] to achieve responsible marketing especially to children, expand available health food choices, and reduce the fat, sugar, and salt content of processed foods. In addition, there is a need for better prediction of who will become obese, including the development of “precision prevention” to tailor appropriate policies and courses of action for the individual.[202,227] In the meantime, all preventive cardiology practices should encourage individual weight control, given obesity's strong association with CVD and its ability to be measured by easily obtainable BMI or waist circumference.

Diet, Dietary Supplements, and Moderate Alcohol Consumption

Diet

A large body of evidence, both from epidemiologic and intervention studies, has demonstrated that dietary factors have an important impact on CHD risk (**see Chapters 49 and 50**). Dietary habits also influence multiple cardiovascular risk factors, including both established risk factors (BP, lipoprotein profiles, glucose levels, and obesity), as well as cardiometabolic risk factors including inflammation. A global analysis of behavioral, environmental, occupational, and metabolic risk factors derived from 188 countries revealed that 87.9% of CVD disability-adjusted life-years were largely caused by 25 factors, 9 of which were related to diet and included low intakes of fruit, vegetables, nuts and seeds, omega-3 fatty acids, and fiber.[228]

A solid body of evidence has demonstrated that in addition to the identification of individual foods and nutrients that can improve health and prevent CVD, several heart healthy dietary patterns have been identified to assess more global dietary quality.[215] Patterns such as the Healthy Eating Index, Alternative Healthy Eating Index, western versus prudent dietary patterns, Mediterranean dietary pattern, and the DASH-type diet are consistent in emphasizing fruits, vegetables, other plant foods (e.g., beans, nuts), and in many patterns, whole grains and fish, and limiting processed red meats and sugar-sweetened beverages. These dietary patterns conform with the food-based priorities for cardiovascular health that include foods that are higher in dietary fiber, mono- and polyunsaturated fatty acids, vitamins, potassium and other minerals, and phytochemicals, and lower in poor-quality carbohydrates, salt, saturated fatty

acids, and *trans* fat.

Meta-analyses of randomized clinical trials and prospective cohorts reveal statistically significant reductions (relative risk; 95% CI) in the risk of CHD with increased number of daily or weekly servings of fruits (0.94; 0.91, 0.98) and vegetables (0.95; 0.92, 0.98),[229] whole grains (0.78; 0.71, 0.86),[230] nuts and seeds (0.76; 0.69, 0.84),[231] and fish (0.79; 0.67, 0.92).[232] In contrast, an increased risk was associated with processed red meats (1.24; 1.09, 1.40),[233] while no significant correlations were found with total dairy (0.94; 0.82, 1.07)[234] or eggs (0.99; 0.85, 1.15).[235] The magnitude of these overall changes in individual foods and food groups would predict modest to substantial reductions in risk of CVD. The choice of protein sources influences other components of diet and may be a critical determinant of CVD risk. For example, a 26- to 32-year follow-up of two large prospective cohorts found high–animal protein diets were positively associated (1.08; 1.01, 1.16) and high–plant protein diets inversely associated (0.88; 0.80, 0.97) with cardiovascular mortality.[236] Indeed, examining overall high-quality food patterns, rather than focusing on single nutrients and foods, may better address the inherent complexity of dietary exposures and their association with CVD risk.[237]

AHA/ACC guidelines on lifestyle management to reduce cardiovascular risk stress modifying diet and increasing physical activity.[187] Dietary recommendations for lowering LDL cholesterol and BP emphasize a dietary pattern that includes greater intake of vegetables, fruits, and whole grains, including low-fat dairy products, poultry, fish, legumes, nontropical vegetable oils, and nuts. The recommendations limit consumption of sweets, sugar-sweetened beverages, and red meats. They suggest dietary planning and nutritional counseling to help patients adapt this dietary pattern to appropriate calorie requirements, personal and cultural food preferences, as well as nutrition therapy for other medical conditions, such as diabetes. These recommendations broadly agree with those proffered by the 2013 AHA/ACC/Obesity Society Guideline for the Management of Overweight and Obesity in Adults[238] and the Dietary Guidelines for Americans 2015–2010.[239]

Despite the general consensus on healthy dietary patterns in the United States by government agencies and professional biomedical societies, the typical eating pattern by Americans is in marked contrast to these recommendations.[239] About three fourths of the population has an eating pattern that is low in vegetables, fruits, dairy, and unsaturated oils. More than half the population meets or exceeds total grain and total protein food guidelines but fall outside the recommended intakes within the subgroups of these two food categories. Most Americans substantially exceed the recommendations for added sugars, saturated fats, sodium, and total calories. Beyond motivating and facilitating behavioral change at the individual level, implementing dietary guidelines and related policy recommendations will require changes in the food environment at household, community, and national levels.[239] For example, reducing the frequency of eating at fast-food restaurants, limiting screen time, and increasing the frequency of family-shared meals can enhance the effectiveness of interventions. Efforts within communities can include providing food and nutrition assistance programs, promoting food and calorie label education through schools and retail programs, and facilitating access to healthy and affordable food choices that respect cultural preferences.

Optimizing an individual's compliance with choosing and consuming foods consistent with healthy dietary patterns requires consideration of the social, economic, and cultural context in which people live in their homes and communities. Thus, current efforts try to place dietary guidance within a socioecologic framework across the life span. This type of framework incorporates individual factors, social environment or networks, physical or built environment, and macrolevel environments and can help inform potential strategies to improve diet and develop partnerships to translate into action the recommendations for choosing healthy foods and dietary patterns.

Dietary Supplements

Dietary patterns in the United States result in micronutrient intakes that fall below the Estimated Average Requirement (EAR), the average daily nutrient intake level estimated to meet the requirement of half the healthy individuals in a particular life stage and gender group. For several vitamins and minerals, a substantial percent of the population consumes less than the EAR, including potassium (97.0%), vitamin D (94.3%), choline (91.7%), vitamin E (88.5%), vitamin K (66.9%), magnesium (52.2%), vitamin A (43.0%), calcium (43.0%), and folate (15.0%), several of which may support heart health. In addition, overall consumption of dietary fiber also falls below recommended Adequate Intakes (95.0%). Dietary supplement use is common among Americans, with slightly more than half of adults using these products, most commonly multivitamins and minerals.[240-242] Results from the 2007–2010 NHANES indicates the most commonly reported reasons adults used supplements were to “improve” or “maintain” overall health.[242] Observational studies have often reported lower rates of CHD events among those who take dietary supplements, particularly multivitamins.[243,244] However, large-scale randomized trials of most dietary supplements have generally shown no significant benefits for cardiovascular risk, and even have raised potential for harm.

Currently available evidence suggests provides greater justification for a focus on evidence-based foods and overall dietary patterns than on individual nutrients or supplements for primary prevention of CVD. While some cohort studies suggest that low intakes or serum status of beta-carotene are associated with increased CVD risk, these results contrast with those from randomized clinical trials of beta-carotene supplementation.[245] Meta-analyses of calcium supplementation are conflicting, with some showing a null association and others an increased risk of MI.[246,247] Several prospective cohort studies have linked vitamin E intake from supplements with a lower risk of CHD, but meta-analyses of observational studies and clinical trials indicate either no such benefit or an increased risk of mortality.[245] Observational studies of people with poor intakes of folate, vitamin B_6, and vitamin B_{12} and corresponding high levels of total plasma homocysteine are at increased risk of CVD, but clinical trials of supplementation with folic acid with or without vitamins B_6 and B_{12} have generally not shown a benefit.[149] In 2013 the USPSTF systematically reviewed the evidence for the benefit and harms of vitamin and mineral supplements in community-dwelling adults without known nutrient deficiencies for the primary prevention of CVD and cancer.[248] Although most of the studies considered were conducted in older adults, had durations of less than 10 years, and employed various doses with individual or combinations of nutrients, they concluded that limited evidence from randomized clinical trials supported any benefit from vitamin or mineral supplementation for the prevention of CVD or cancer.

Data from laboratory studies, ecologic studies, prospective cohort studies, and secondary analyses of small randomized trials have suggested a protective effect for vitamin D against a number of chronic diseases, including CVD. Many clinicians now include vitamin D blood tests as part of routine laboratory work and recommend vitamin D supplements to patients without definitive randomized trial data supporting efficacy. Possible mechanisms of protection against CVD include inhibition of inflammation, inhibition of vascular smooth muscle proliferation and vascular calcification, regulation of BP and volume homeostasis, and regulation of glucose metabolism.[249] However, the Institute of Medicine critically reviewed the dietary requirements for calcium and vitamin D in relation to a wide variety of health outcomes and concluded that unlike the available scientific evidence supporting a key role of calcium and vitamin D in skeletal health, the evidence that vitamin D or calcium affects CVD risk is inconsistent and inconclusive, and does not meet criteria for establishing a cause-and-effect relationship.[249]

The marine omega-3 fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), components of fish and fish oil supplements, have shown considerable promise for the prevention of CVD in laboratory and observational studies, as well as large randomized trials in secondary prevention or high-risk settings. These polyunsaturated fatty acids may have a number of mechanisms for cardioprotection, including lowering triglycerides and BP, decreasing platelet aggregation, reducing susceptibility of the heart to ventricular arrhythmias, and providing anti-inflammatory actions.[250,251] However, meta-analyses of placebo-controlled trials show either modest or null effects for CVD and mortality.[252,253] The recent AHA guidelines for CVD prevention in women recommend consideration of omega-3 fatty acids in the form of fish or in capsule form (e.g., EPA 1800 mg/day) in women with hypercholesterolemia or hypertriglyceridemia for primary and secondary prevention (with pregnant women being counseled to avoid eating fish with the potential for the highest level of mercury contamination).[254] However, no trials have studied marine omega-3 fatty acid supplements for the primary prevention of CVD in a general population. Two ongoing large-scale cardiovascular trials are evaluating EPA or EPA plus DHA in patients with or at high risk for atherosclerotic CVD.[94,95] Whether alpha-linolenic acid, the short-chain omega-3 fatty acid found in walnuts and other plant sources, provides the same potential cardiovascular benefit attributed to the EPA and DHA found in fish requires more research.

At this time, the available trial data do not support the recommendation of vitamin D or fish oil supplementation for the primary prevention of CVD. Trials to evaluate definitively the roles of vitamin D and fish oil in CVD prevention are addressing this gap. These trials include the VITamin D and OmegA-3 TriaL (VITAL), an NIH-funded, large-scale randomized trial of vitamin D (cholecalciferol, 2000 IU/day) and a marine omega-3 fatty acid supplement (in the form of a fish oil supplement, EPA plus DHA, 1 g/day) for the primary prevention of CVD and cancer. This currently ongoing trial enrolled more than 25,000 participants (women older than 55 years and men older than 50, with an oversampling of African Americans) with no known CVD at baseline.[255,256]

Moderate Alcohol Consumption

Alcohol consumption has complex effects on CVD; the difference between daily intake of small to moderate quantities and large quantities may tip the balance between preventing and causing disease. The 2015–2020 Dietary Guidelines for Americans[239] recommends that if alcohol is to be consumed, it should be consumed in moderation—up to one drink per day for women and two drinks per day for men—and only by adults of legal drinking age. A drink-equivalent is described using the reference beverages of 12 fl oz of regular beer (5% alcohol), 5 fl oz of wine (12% alcohol), or 1.5 fl oz of 80-proof distilled spirits (40% alcohol). Each drink-equivalent delivers about 12 to 14 grams of alcohol.

Habitual heavy alcohol consumption, defined as 8 or more drinks per week for women and 15 or more drinks a week for men,[239] is a major cause of preventable death in most countries. It increases risk of total mortality, CVD mortality, CHD, and stroke; fatal traffic accidents; liver damage; harm in pregnancy; risk of developing breast and other cancers in both men and women; and depression and violence. By contrast, a consistent body of observational epidemiologic evidence has shown that light to moderate alcohol consumption, compared with either nondrinkers or heavy drinkers, is associated with lower risk of heart attack, ischemic stroke, death from all cardiovascular causes, peripheral vascular disease, sudden cardiac death, diabetes mellitus, gallstones, and increased health and well-being. This relationship represents a U-shaped curve, s moderate alcohol consumption confers lower risk of CVD compared to both heavy drinkers and nondrinkers.[215,257-260]

More than 100 prospective studies have shown an inverse association between moderate drinking and

risk of heart attack, ischemic stroke, peripheral vascular disease, sudden cardiac death, and death from all cardiovascular causes. The effect is fairly consistent, corresponding to a 25% to 40% reduction in risk. It applies to men and women, older individuals, and to primary prevention as well as secondary prevention among those with at high risk for a cardiovascular event, including those with existing CVD, type 2 diabetes, and hypertension. However, even moderate alcohol is associated with risk. An immediately higher cardiovascular risk appears to follow any alcohol consumption, although by 24 hours, only heavy alcohol intake conferred continued risk.[261] Demonstrated physiologic effects from basic research and randomized trials underlying the observed benefits of moderate alcohol consumption on risk of CVD include raising of HDL cholesterol, improvements in fibrinolytic capacity and insulin resistance, and reductions in platelet aggregation and systemic inflammation.[257,262] Although some investigators have suggested that red wine may have particular cardioprotective properties because of its nonalcohol component of resveratrol and other components, evidence from trials of risk factors as well as prospective cohort studies of clinical endpoints have found equal benefits for all forms of alcohol when consumed in moderation, supporting that alcohol per se accounts for most of the observed protective association with alcoholic beverage consumption.[263] The pattern of drinking affects the observed benefit of moderate alcohol on CVD, with no benefit seen with binge drinking (4 or more drinks for women on one or more occasions and 5 or more drinks for men within about 2 hours); drinking 7 drinks a week but on one night does not confer the observed benefit on CVD seen in those having one drink a day.[264]

Researchers have questioned whether it is the alcohol itself that causes the observed benefits on CVD, because people who drink in moderation are different from nondrinkers or heavy drinkers in ways that could influence health and disease.[265,266] Previous studies have shown that moderate drinkers are more likely to be at a healthy weight, get adequate sleep, and exercise regularly. Benefits among moderate drinkers remain after control for such differences, suggesting that alcohol itself, in moderation, is responsible for the reduced risk of CVD.

Any individual or public health recommendation must consider the complexity of alcohol's metabolic, physiologic, and psychological effects.[215] Because of the health hazards of alcohol associated with higher intake, moderate alcohol use does not offer a population-based strategy to reduce cardiovascular risk. Discussions of alcohol consumption require individual considerations and should take into account other medical problems, coronary risk factors, comorbid conditions, concurrent medications, pregnancy, and family history of medical conditions or alcoholism. Patients who are heavy drinkers should be counseled to limit intake. The initiation of moderate alcohol drinking to reduce risk of heart disease is not recommended, especially in view of other known preventive measures, such as physical activity.

Postmenopausal Hormone Therapy

Age-specific coronary heart disease (CHD) death rates in women lag approximately 10 years behind those of men. Rates of CHD mortality among women rise exponentially with age and vary substantially by race and ethnicity. Cardiovascular disease (CVD) afflicts relatively few women younger than 45 years in developed countries, but by age 60, it is the leading cause of death among women, both in the United States and worldwide. More than 80% of CVD deaths in women now occur in low-income and middle-income countries as a result of increasing longevity and large population sizes. Although men exhibit a higher incidence of CHD at every age as well as higher CHD mortality rates, the gap narrows substantially because women's rates increase after either natural menopause or bilateral oophorectomy.[35,267]

A wide range of factors may explain the increased risk of CHD after menopause. These include

adverse changes in lipid and glucose metabolism that result in an increase in LDL cholesterol and a decrease in HDL cholesterol, an increase in glucose intolerance, and changes in hemostatic factors and vascular function. These changes appear to result not only from the decline in endogenous estrogen that accompanies menopause, but also from the hormonal shift toward androgen dominance as estradiol levels fall[268] (**see Chapter 89**).

In regard to the observed increase in CHD in women after menopause, numerous observational studies consistently demonstrated that ever and current use of postmenopausal hormone therapy was associated with a reduced risk of CHD. Recommendations from professional societies all led to the widespread use in the 1990s of hormone therapy in postmenopausal women to prevent CVD as well as other diseases, such as osteoporosis and cognitive decline and dementia.[109]

The physiologic effects of exogenous estrogen are compatible with a cardioprotective effect. Estrogen reduces LDL and increases HDL cholesterol levels; reduces lipoprotein(a), plasminogen activator inhibitor type 1, and insulin levels; inhibits oxidation of LDL; and improves endothelial vascular function. Estrogen has complex effects on inflammation: levels of fibrinogen decrease, whereas levels of hsCRP increase. Estrogen also may improve glucose tolerance.

Although the observational study data among women who began hormone therapy around menopause consistently suggested CHD benefits of hormone replacement therapy (HRT), the randomized trial data have not demonstrated that replacement with estrogen and progestin, or estrogen alone, confers cardioprotection.[269,270] The Heart and Estrogen/Progestin Replacement Study (HERS), while finding benefits on the lipid profile, did not find significant differences in cardiovascular endpoints. The National Institutes of Health (NIH)–funded Women's Health Initiative (WHI) evaluated the role of hormone therapy in the prevention of CVD and assessed the balance of benefits and risks of HRT when used for chronic disease prevention. For many outcomes, the WHI is the only large, long-term randomized trial of postmenopausal women using hormone therapy.

One WHI arm evaluated the relative benefits and risks of combined hormone therapy of conjugated estrogen plus medroxyprogesterone acetate versus placebo among 16,608 postmenopausal women, 50 to 79 years of age, with an intact uterus at baseline during a planned 8-year period. After a mean follow-up period of 5.2 years, the trial's Data and Safety Monitoring Board recommended stopping the trial 3 years early because the overall risk-benefit ratio of estrogen-progesterone therapy was unfavorable. Risks in the hormone therapy group in terms of increases in CHD, stroke, venous thromboembolism, and breast cancer exceeded the benefits on reductions of fracture and colon cancer.

The increased risk of CVD and the adverse risk-benefit ratio was unexpected, and seemed apparently inexplicable in the face of the existing body of literature supporting the concept that HRT was cardioprotective. After the release of these results, HRT prescriptions abruptly and dramatically declined. Two years later, the unopposed estrogen versus placebo arm of the WHI, which included 10,739 generally healthy postmenopausal women age 50 to 79 without a uterus, also was halted early because of an increased risk of stroke, particularly in women age 60 or older, in the absence of net health benefits.

The discrepancies between the observational study results and the randomized trial findings led to a careful examination of how the clinical trials may have differed from the observational studies in ways that may have affected the results. Detailed scrutiny of subgroups of the trial data suggested that age and time since menopause modulate the effect of estrogen on cardiovascular risk.[271] The WHI demonstrated a number of demographic and biologic differences from the observational studies that limited generalizing the findings to all postmenopausal women. Perhaps most importantly, the WHI and the observational studies were conducted in different populations. The WHI enrolled generally healthy, largely

asymptomatic postmenopausal women age 50 to 79 in a prevention trial, whereas the observational studies generally included primarily relatively young and symptomatic women who began HRT early in menopause. WHI participants were on average 63 years of age and more than 10 years beyond menopause, whereas the observational study participants were younger than 55 at the time HRT was initiated and within 2 to 3 years of menopause. Analysis of the relevant data by age and time since menopause showed that the estrogen-only arm of the WHI appeared to agree generally with the observational studies suggesting that estrogen therapy reduces CHD risk when initiated in younger and more recently postmenopausal women without a uterus. Further analyses indicated that women who start HRT more than 10 years beyond menopause had increased risk for CHD, but the women in whom heart disease was diagnosed within 10 years of menopause tended to have a lower CHD risk. A meta-analysis of more than 39,000 women concluded that menopausal hormone therapy reduces coronary risk in women under 60 but not in older women.[271]

The WHI showed that postmenopausal hormone therapy did not prevent coronary disease in women who started treatment distant from menopause onset. Yet the question remained of whether estrogen therapy initiated close to menopause onset may reduce CHD risk. Two subsequent trials addressed the issue of timing of initiation of HRT and atherosclerosis progression using noninvasive imaging, but the results have not been consistent. The Kronos Early Estrogen Prevention Study (KEEPS) was a 4-year randomized trial of low-dose oral conjugated equine estrogens (CEE) or transdermal estradiol and cyclic monthly progesterone in 727 healthy women (mean age, 52 years) within 3 years after menopause at randomization.[272] Hormone therapy decreased menopausal symptoms, depression, and anxiety; increased in HDL (with oral CEE); and improved of insulin sensitivity (with transdermal E2).[109] There were no significant differences in frequency of adverse events, including diagnosis of breast cancer, endometrial cancer, MI, stroke, transient ischemic attack, and venous thromboembolic disease, although the absolute numbers of such events were extremely small. Although the data reassured that no increases in cardiac risk occurred during this short-term use of HRT, neither hormone regimen significantly reduced or accelerated progression of atherosclerosis, as measured by carotid intimal medial thickness (CIMT) and coronary artery calcium.[273] In the Early Versus Late Intervention Trial with Estradiol (ELITE), 643 healthy women stratified by time since menopause (<6 years or ≥10 years) were randomized to oral estradiol plus progesterone vaginal gel versus placebo. After 5 years, oral estradiol therapy was associated with less progression of subclinical atherosclerosis, measured as CIMT, than was placebo when therapy was initiated within 6 years after menopause, but not when initiated 10 or more years after menopause.[274]

Interventions of Hormone Therapy for Cardioprotection

Over the last decade, a consensus has developed regarding the overall central recommendations related to the safety and benefits of hormone therapy in menopausal management.[275] Menopausal hormone therapy remains an appropriate treatment for menopausal symptoms, used in early menopause (<60 years of age, or within 10 years of menopause) at the lowest effective dose and period of time, and in the absence of contraindications. The evidence does not, however, support its prescription for the focused purpose of preventing CVD.[276,277]

Statements from a number of different societies support this general recommendation. The joint Global Consensus Statement on menopausal hormone therapy,[278] the 2015 Endocrine Society Clinical Practice Guidelines,[279] and the 2016 Recommendations of the International Menopause Society on women's midlife health and menopause hormone therapy[280] all agree with these principles. The 2012 Hormone Therapy Position Statement[281] of the North American Menopause Society added that the more favorable benefit-

risk ratio for estrogen-only therapy allows more flexibility in extending the duration of use compared with estrogen-progestogen therapy, where the earlier appearance of increased breast cancer risk precludes a recommendation for use beyond 3 to 5 years. In 2015 the North American Menopause Society issued an additional statement supporting continuing use of systemic hormone therapy after age 65, as needed to address continuing duration of vasomotor symptoms into the late 60s and 70s.[282]

All the recommendations explicitly note that the necessity of individualizing the decision to use menopausal hormone therapy, including a personal benefit-risk profile with clinical and biologic variables as well as quality-of-life priorities. Methods to assist in this personalized decision-making process are becoming available.[283,284]

Community-Based and Multiple–Risk Factor Intervention Programs

Many primary prevention measures have focused on targeting a single risk factor in individuals, and while great progress has been made, few Americans have ideal cardiovascular health. Moreover, the prevalence of many risk factors is still high, the prevalence of obesity is still increasing,[35] and the favorable trends in total cholesterol and LDL cholesterol have leveled off and may be reversing.[285] Thus the need exists for complementary population approaches such as community-based interventions, as well as interventions that target multiple risk factors.

In 2011, to reduce the cardiovascular burden in the United States and to help meet the goals of *Healthy People 2020*, the DHHS launched the Million Hearts initiative to prevent 1 million heart attacks and strokes in 5 years.[286,287,288] With leadership from the CDC as well as the Centers for Medicare and Medicaid Services (CMS), the Million Hearts initiative (www.millionhearts.hhs.gov) emphasizes the formation of public-private partnerships at the federal, national, state, and local levels. This initiative takes two complementary approaches to cardiovascular prevention, clinical and community based. Clinically, Million Hearts focuses on improving the management of the "ABCS"—aspirin for high-risk patients, blood pressure control, cholesterol reduction, and smoking cessation. This effort increased the focus on improving ABCS care; health information technology and standardization of core ABCS metrics that will allow better tracking of the goals across all types of health systems; and clinical innovations such as use of patient-centered medical homes. At the same time, Million Hearts aims to expand population initiatives through policies and programs to reduce smoking, improve nutrition, and reduce BP. This undertaking includes endorsing at the community level policies for sodium restriction and the elimination of artificial *trans* fats from the diet; implementing policies and programs designed to dramatically lower cigarette consumption and exposure to secondhand smoke; and emphasizing programs designed to increase community access to exercise facilities and to programs that target weight reduction and nutrition. Million Hearts is designed to "leverage, focus and align" existing investments, not require extensive new monetary expenditures.[287]

The Affordable Care Act (ACA) has provided great opportunities for accomplishing prevention on a community level. Tax-exempt status hospitals must perform a community health needs assessment on a regular basis and develop plans to address identified needs. To facilitate collaborative efforts to improve both health care and non–health care determinants of health outcomes, in 2015 the CDC released its online Community Health Improvement Navigator.[289] This resource allows the user to search for multisector, collaborative, evidence-based interventions to address tobacco use and exposure, physical inactivity, unhealthy diet, high cholesterol, high BP, and diabetes. The 2016 Annual Report to Congress of the Community Preventive Services Task Force ranked CVD prevention and control as the first of their 11

priority areas for new Community Guide reviews in the coming years.[290] The AHA guide for improving cardiovascular health at the community level, updated in 2013, provides a comprehensive inventory of evidence-based goals, strategies, and recommendations for CVD prevention appropriate for implementation at a community level.[291]

Past success in federally sponsored programs that use evidence-based policy approaches to improve population dietary habits supports the efficacy of such community-based approaches.[215] An initiative in a rural county of Maine demonstrated that collaboration among health systems, public health, and community organizations can substantially improve risk factors and clinical health outcomes.[292] This study documented health outcomes associated with an integrated, multicomponent, sustained community-wide program for cardiovascular risk reduction program in Franklin County, Maine, a low-income rural community. Over a 40-year follow-up period, community-wide programs targeted hypertension, cholesterol, and smoking, as well as diet and physical activity. Over these 40 years, rates of control of hypertension, control of elevated cholesterol, and quitting smoking showed clinically significant improvements. In addition, total hospitalizations and hospitalizations per capita (with lower mortality) fell compared to other counties in the state over the same periods. This program demonstrated that a coordinated, evidence-based, sustained community-wide effort can measurably improve cardiovascular health in a community. This successful experience from a socioeconomically disadvantaged community could serve as a model for implementation and study in other rural communities, as well as urban and communities outside the United States.[293]

Recent studies have evaluated the effect of simultaneous control of multiple risk factors. Analyses in the BARI 2D trial (Bypass Angioplasty Investigation Revascularization 2 Diabetes) demonstrated the feasibility of simultaneous control of six risk factors (smoking, non-HDL cholesterol, triglycerides, systolic and diastolic blood pressure, and glycosylated hemoglobin) through protocol-guided intensive medical therapy, and that the number of risk factors under control was related strongly to total mortality and cardiovascular morbidity and mortality.[294] These observations support previous studies. The Stepathlon Cardiovascular Health Study[295] evaluated an international, low-cost, mass-participation mHealth (mobile health) intervention on physical activity, sitting, and weight and demonstrated its association with short-term, large scale, across-the-board improvements in these risk factors. The Fifty-Fifty study[296] evaluated a year-long peer group–based intervention versus self-management in improving healthy behavior in individuals with cardiovascular risk factors. The peer group intervention had beneficial effect on cardiovascular risk factors, with significant improvement in the composite score of BP, exercise, weight, diet, and tobacco, with specific benefit on tobacco cessation.

Community-based interventions have particular relevance to prevention in addressing lifetime risk rather than 10-year risk. As shown in a meta-analysis of 18 cohort studies involving 257,000 persons across the United States, those with “optimal” risk factor profiles had substantially lower risks of death from CVD up to 80 years of age, compared with those with two or more major risk factors. Those with controlled risk factors also had markedly lower lifetime risks of fatal CHD or nonfatal MI as well as of fatal and nonfatal stroke[297] (**Fig. 45.21**). These effects maintained consistency across birth cohorts and ethnic groups and between men and women. Lifetime risk estimates thus suggest that efforts to lower the burden of CVD will require prevention of the development of risk factors (primordial prevention) in concert with treatment of established risk factors (primary prevention).

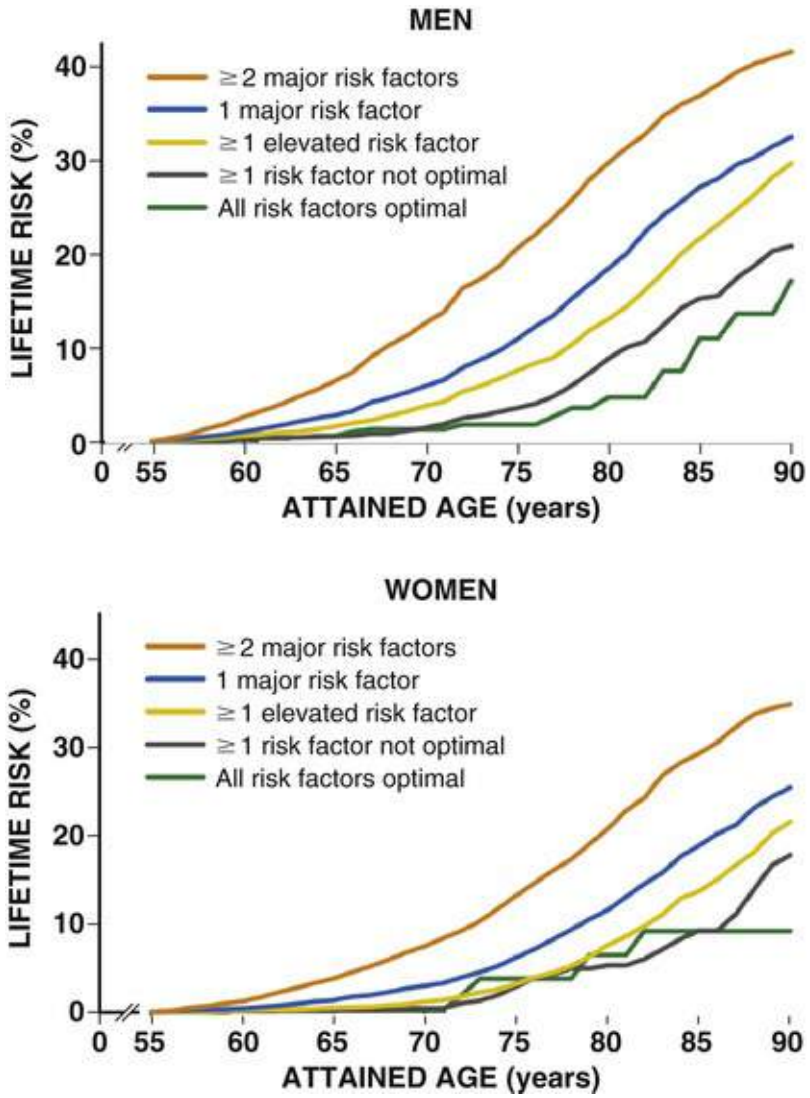

FIGURE 45.21 Lifetime risk of death from cardiovascular disease in men **(top)** or in women **(bottom)** at 55 years of age, with varying burden of risk factors, adjusted for competing mortality risks. (From Berry JD, Dyer A, Cai X, et al. Lifetime risks of cardiovascular disease. N Engl J Med 2012;366:321.)

The AHA has recommended a prescription for health called Life's Simple 7,[298] encouraging the population to meet seven cardiovascular metrics for ideal cardiovascular health. These include four modifiable risk factors (not smoking, healthy weight, eating healthy, and being physically active) and three biometric measures (blood pressure, cholesterol, and blood sugar). These simplified metrics, easily introduced in the primary care office as well as in community wellness centers, correlate closely with all-cause mortality, cardiovascular mortality, and ischemic heart disease mortality.[299] Thus the reduction to practice of the precepts and evidence base reviewed in this chapter and related chapters could produce prodigious public health benefits worldwide.

Systemic Hypertension

Mechanisms and Diagnosis

Ronald G. Victor

Overview of Hypertension

Affecting 80 million people in the United States and over 1 billion worldwide, hypertension remains the most common, readily identifiable, and reversible risk factor for myocardial infarction (MI), stroke, heart failure, atrial fibrillation, aortic dissection, peripheral arterial disease, and cognitive decline.[1] The global burden of hypertension is rising due to escalating obesity and population aging, and is projected to affect 1.5 billion persons—one third of the world's population—by 2025.[2] The prevalence of hypertension is increasing most rapidly in developing countries (80% of the world), where poor hypertension treatment and control contribute to the growing epidemic of cardiovascular disease (CVD). High blood pressure (BP) continues to be the largest single contributor to the global burden of disease, causing two thirds of all cerebrovascular accidents (strokes) and half of all ischemic heart disease worldwide, and thus 9.4 million deaths each year.[2] Half of this disease burden occurs in people with hypertension (i.e., BP ≥140/90 mm Hg); the other half occurs in people with lesser degrees of high BP (*prehypertension*). During the past four decades, the highest worldwide BP levels have shifted from high-income countries to low-income countries in south Asia and sub-Saharan Africa, while BP remained persistently high in central and eastern Europe.[3] Thus, high BP remains the leading cause of death worldwide and one of the world's great public health problems (**see Chapters 1 and 45**).

The asymptomatic nature of systemic hypertension delays diagnosis. Effective treatment requires continuity of care by a knowledgeable clinician and frequent medical checkups, which are less accessed by men and members of low-income minority groups. Most patients diagnosed with hypertension do not manifest a single disease-causing mechanism. Treatment thus remains empiric, often requiring three (or more) BP-lowering drugs with synergistic mechanisms of action along with lipid-lowering drugs (and drugs for concomitant medical conditions such as diabetes).[4,5] Pill burden, prescription drug costs, medication side effects, and insufficient time for patient education contribute to medication noncompliance. Physicians often undertreat hypertension[6] (**see Chapter 47**). For all these reasons, BP remains elevated—140/90 mm Hg or higher—in half of affected individuals in the United States, Canada, and other developed countries.[2] Even among patients whose hypertension appears controlled by conventional standards, fewer than one in three may yet develop subsequent stroke, MI, or heart failure. The resultant annual cost to the U.S. health care system exceeds $48 billion, a value that is projected to increase to $274 billion by the year 2030.[7] This chapter and **Chapter 47** review the scientific basis for rapidly evolving recommendations for the diagnosis, evaluation, and management of hypertension, and present emerging concepts from clinical and basic research that affect clinical decision making.

Definition

Hypertension is defined as a usual office BP of 140/90 mm Hg or higher.[8] Yet, epidemiologic data show continuous positive relationships between the risk of coronary artery disease (CAD) and stroke deaths with systolic or diastolic BP down to values as low as 115 or 75 mm Hg, respectively[9] (**Fig. 46.1**). The artificial dichotomy between *hypertension* and *normotension* may delay medication management until irreversible compromise of vascular health by elevated BP values previously considered normal.

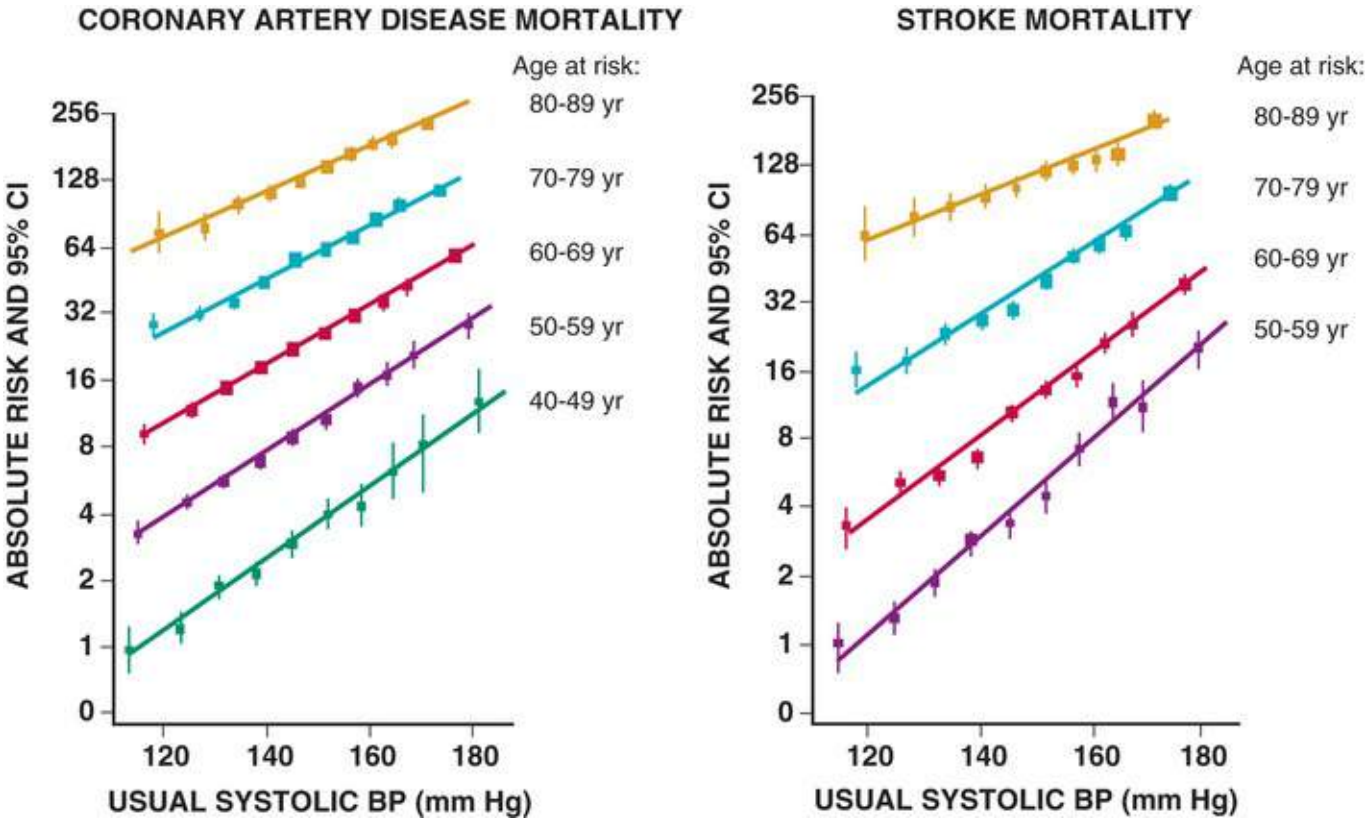

FIGURE 46.1 Absolute risks of coronary artery disease mortality **(left)** and stroke mortality **(right)** for each decade of life (plotted on a logarithmic scale) by usual systolic blood pressure (BP) level (plotted on a linear scale); CI, confidence interval. (From Lewington S, Clarke R, Qizilbash N, et al. Age-specific relevance of usual blood pressure to vascular mortality: a meta-analysis of individual data for one million adults in 61 prospective studies. Lancet 2002;360:1903.)

Prevalence

In the United States and other developed countries, the prevalence of hypertension increases with age, rising exponentially after 30 (**see Chapter 1**). Before 50 years of age, women have a somewhat lower prevalence of hypertension than men. After menopause, the prevalence of hypertension increases rapidly in women and surpasses that in men. Eventually, by age 78—below the average life span of U.S. men and women—almost 90% will have hypertension.

Currently, 41% of non-Hispanic black adults in the United States have hypertension, compared with 28% of non-Hispanic white adults, 25% of Asian adults, and 26% of Hispanic adults.[10] Black Americans also have earlier onset, more severe hypertension, and greater target organ damage, leading to excess premature disability and death. Hypertension and its complications are even more prevalent in many predominantly white European countries than among black Americans, but are much less prevalent among black Africans[11,12] (**Fig. 46.2**). Hypertension prevalence does not vary between black and non-black Hispanic adults in Cuba. Genetic factors may contribute to the disproportionate burden of hypertension in black Americans, but these international data underscore the importance of environment. From 90% to 95% of hypertensive patients have no apparent single reversible cause of elevated BP, thus the term *primary hypertension*. The remaining 5% to 10%—cases denoted *secondary* (identifiable) *hypertension*—demonstrate a more discrete mechanism.

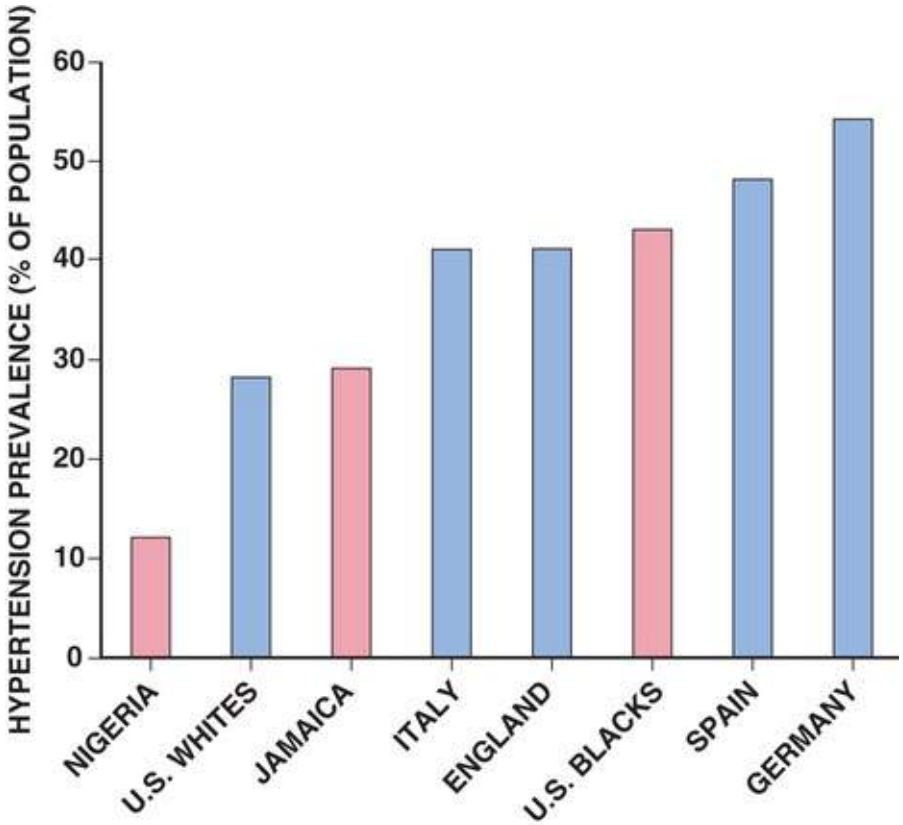

FIGURE 46.2 Geographic variation in hypertension prevalence in populations of African descent (*pink bars*) and European descent (*blue bars*). (Modified from Cooper RS, Wolf-Maier K, Luke A, et al. An international comparative study of blood pressure in populations of European vs. African descent. BMC Med 2005;3:2.)

Blood Pressure Variability and Its Determinants

Behavioral Determinants

In most patients with primary hypertension, readily identifiable behaviors contribute to the elevated BP. The nicotine in cigarette smoke transiently raises BP by 10 to 20 mm Hg, thereby elevating the average daytime BP in habitual smokers. Moderate alcohol drinkers (one or two drinks per day) generally have less hypertension than teetotalers, but the risk for development of hypertension increases in heavy drinkers (three or more drinks per day). Hypertension is rare in Asian men who abstain from alcohol to avoid the nausea and flushing reaction associated with their loss-of-function mutation in the alcohol dehydrogenase gene (*ALDH2*).[13] Caffeine consumption typically causes only a small transient rise in BP, which in some individuals habituates after the first cup of coffee. The risk for development of hypertension does not vary with coffee consumption, but increases steeply when caffeine is consumed in diet sodas; thus coffee may contain protective antioxidant polyphenols not present in sodas. Physical inactivity also increases the risk for developing hypertension.

Lifetime dietary habits clearly influence the risk for developing hypertension (**see Chapter 49**). Across populations, hypertension prevalence increases linearly with average body mass index (BMI). However, the impact of weight gain or weight loss on BP is less clear than the major impact on glucose metabolism and diabetes. On the other hand, there is abundant evidence that the risk for developing hypertension increases with dietary sodium intake and decreases with dietary potassium intake. In adolescent girls, a high-potassium diet appears to negate the adverse effect of a high-salt diet on BP.[14] Potassium ingestion acts like a thiazide-type diuretic: it acutely decreases the activity of the thiazide-sensitive Na^+/K^+ cotransporter, thus lowering renal Na^+ reabsorption.[15] Epidemiologic studies have not settled the debate

as to whether or not very-low-sodium diets can cause reflex activation of neural and hormonal mechanisms that can increase CVD despite preventing hypertension.[16,17] In practical terms, it is very difficult to achieve and maintain very low levels of sodium intake in Western countries. Individual variability in BP responses to dietary sodium loading and sodium restriction indicates an important genetic underpinning.

Genetic Determinants

Concordance of BP is higher in families than in unrelated individuals, higher between monozygotic than dizygotic twins, and higher between biologic than adoptive siblings living in the same household. Although approximately 50% of BP variability is heritable, the associated genetic variations identified to date explain at most 2% to 3% of this variability.[18] The large gap between estimated and observed variance, termed “missing heritability,” may be caused in part by epigenetic mechanisms such as DNA methylation.[19]

The complex regulation of BP has thwarted the genetic dissection of primary human hypertension. Whereas mutations in 20 salt-handling genes cause ultrarare monogenic forms of severe early-onset hypotension (salt-wasting syndromes) and hypertension (all inherited as mendelian traits), applicability to common primary hypertension has proved elusive. Data from the Framingham Heart Study indicate that 1% to 2% of the general adult population has gene mutations underlying the pediatric salt-wasting syndromes (Bartter, Gitelman) that may confer resistance against primary hypertension[20] (**Fig. 46.3**). Although the rare monogenic forms of severe hypertension all emphasize renal mechanisms—defects in the kidneys' ability to excrete sodium—as the primary driver of hypertension, the largest study thus far to investigate the genomics of BP variation in the general population found a new set of 66 variants that commonly affect vascular endothelial cell regulation and a separate set associated with hypertensive target-organ damage in heart, cerebral vessels, carotid artery, and eye, but not the kidney.[18] These new data confirm the importance of vascular mechanisms in the pathogenesis and progression of hypertension, with the hope of uncovering new drug targets.

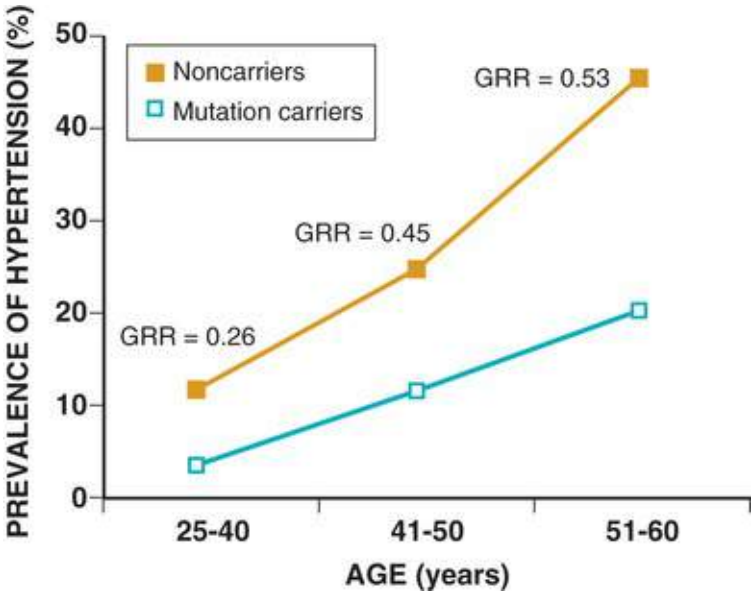

FIGURE 46.3 Reduced prevalence of hypertension among mutation carriers. Prevalence of hypertension at the last examination within ages 25-40, 41-50, and 51-60 years, for mutation carriers and noncarriers of genes causing Bartter and Gitelman syndromes. The genotype relative risk (GRR) for mutation carriers is shown. (From Ji W, Foo JN, O'Roak BJ, et al. Rare independent mutations in renal salt handling genes contribute to blood pressure variation. Nat Genet 2008;40:592.)

Mechanisms of Primary (Essential) Hypertension

Hemodynamic Subtypes

Primary hypertension falls into three distinctly different hemodynamic subtypes that vary sharply by age.

Systolic Hypertension in Teenagers and Young Adults

Typically associated with hypertension in elderly patients (see later), *isolated systolic hypertension* (ISH) also is the main type in young adults (typically 17 to 25 years of age). The key hemodynamic abnormalities are increased cardiac output and a stiff aorta, both presumably reflecting an overactive sympathetic nervous system. The prevalence may reach as high as 25% in young men, but only 2% of young women. Several recent studies show that young persons with ISH have elevated central as well as brachial systolic BP, indicating significantly increased hemodynamic burden.[21] Thus, ISH in youth may predispose to diastolic hypertension in middle age.

Diastolic Hypertension in Middle Age

Hypertension diagnosed in middle age (typically 30 to 50 years) usually has the elevated diastolic pressure pattern, with normal systolic pressure (isolated diastolic hypertension) or elevated systolic pressure (combined systolic-diastolic hypertension). This pattern constitutes classic “essential hypertension.” Isolated diastolic hypertension is more common in men and often is associated with middle-age weight gain. Without treatment, isolated diastolic hypertension often progresses to combined systolic-diastolic hypertension. The fundamental hemodynamic fault is an elevated systemic vascular resistance (SVR) coupled with an inappropriately normal cardiac output. Vasoconstriction at the level of the resistance arterioles results from increased neurohormonal drive and an autoregulatory reaction of vascular smooth muscle to an expanded plasma volume, the latter because of impairment in the kidneys' ability to excrete sodium.

Isolated Systolic Hypertension in Older Adults

After 55 years of age, ISH (systolic BP >140 mm Hg and diastolic BP <90 mm Hg) predominates. In developed countries, systolic pressure rises steadily with age; in contrast, diastolic pressure rises until about 55 years of age, then falls progressively thereafter (**Fig. 46.4**). The resultant widening of pulse pressure indicates stiffening of the central aorta and a more rapid return of reflected pulse waves from the periphery, augmenting systolic aortic pressure[22] (**eFigs. 46.1 to 46.3**). Accumulation of collagen (which is poorly distensible) adversely affects its ratio to elastin in the aortic wall.

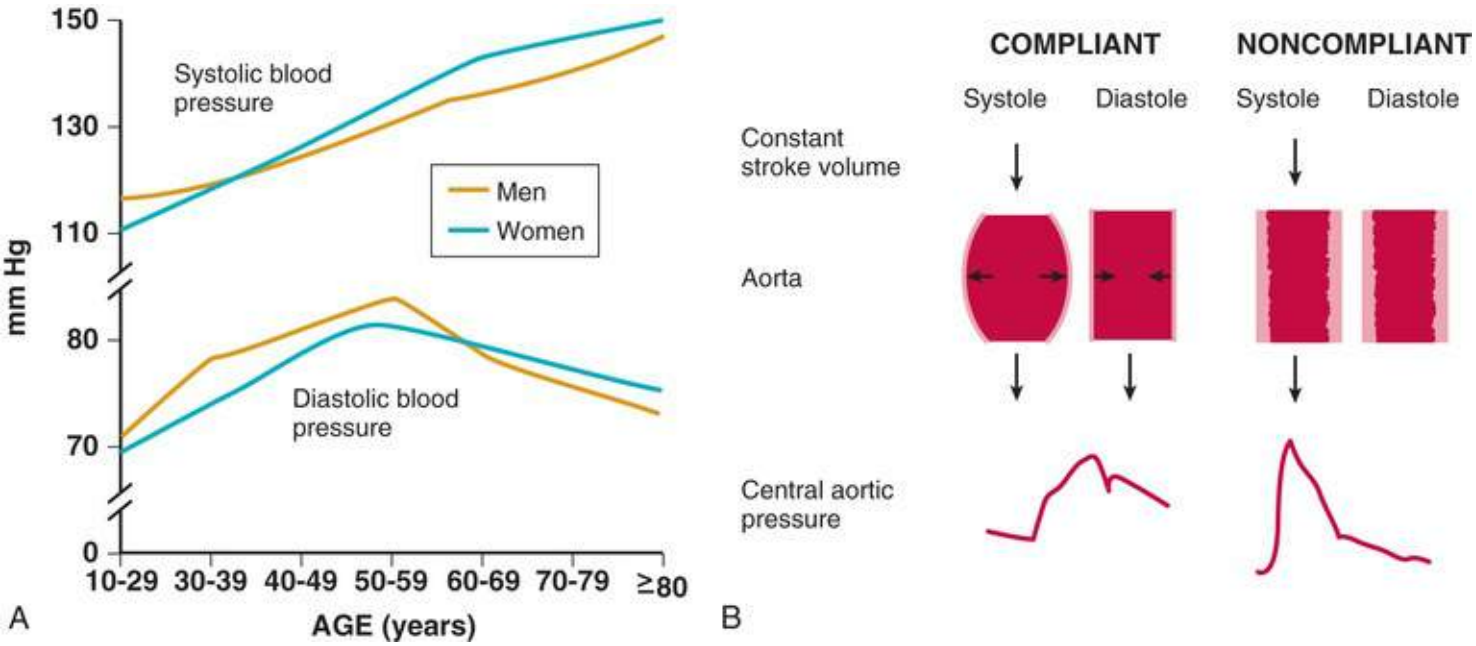

FIGURE 46.4 **A,** Age-dependent changes in systolic and diastolic blood pressure in the United States. **B,** Schematic representation of the relationship between aortic compliance and pulse pressure. (**A,** From Burt V, Whelton P, Rocella EJ, et al. Prevalence of hypertension in the U.S. adult population: results from the Third National Health and Nutrition Examination Survey, 1988–1991. Hypertension 1995;25:305; **B,** from Dr. Stanley Franklin, University of California at Irvine.)

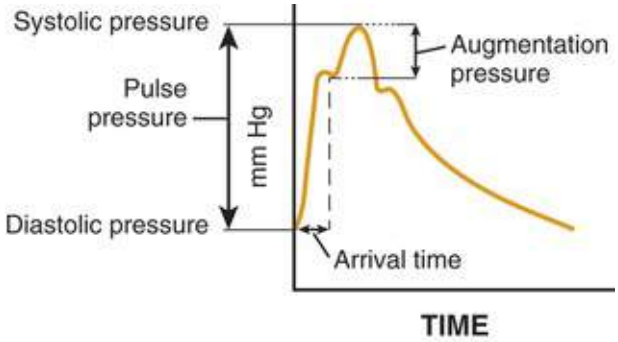
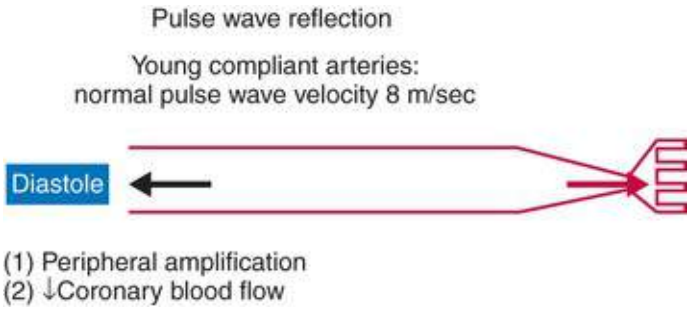
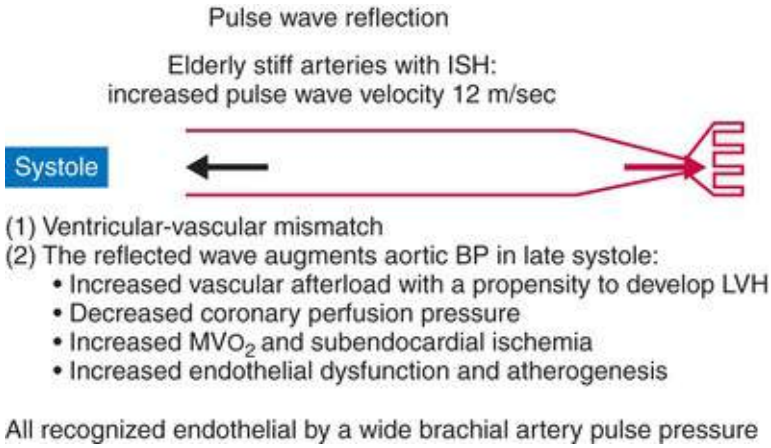


EFIGURE 46.1 Central aortic pressure waveform. The height of the late systolic peak above the inflection defines the augmented pressure, and the ratio of augmented pressure to pulse pressure defines the augmentation index (in percentage). (Modified from Laurent S, Cockcroft J, Van Bortel L, et al. Expert consensus document on arterial stiffness: methodological issues and clinical applications. Eur Heart J. 2006;27:2588–2605.)



EFIGURE 46.2 Artist's rendering of normal pulse wave velocity and the timing of the reflected wave. In a young person with compliant arteries, pulse wave velocity is 8 m/sec. The reflected pulse wave reaches the central aorta in diastole, thereby amplifying central diastolic pressure and thus coronary perfusion pressure. (Courtesy Dr. Stanley Franklin, Cedars-Sinai Heart Institute/Hypertension Center, Los Angeles.)



EFIGURE 46.3 Artist's rendering of increased pulse wave velocity in isolated systolic hypertension (ISH) and resultant changes in central aortic pressure and hemodynamic load. In an elderly patient with ISH and stiff arteries, pulse wave velocity is 12 m/sec, abnormally fast. The reflected pulse wave reaches the central aorta in systole, thereby amplifying central systolic pressure and widening the central pulse pressure. The augmented aortic systolic pressure accelerates the development of left ventricular hypertrophy (LVH), increases myocardial oxygen demands (MVO_2), and accelerates endothelial dysfunction and atherosclerosis. The rapid diastolic runoff can compromise coronary perfusion pressure, thereby predisposing to subendocardial ischemia. (Courtesy Dr. Stanley Franklin, Cedars-Sinai Heart Institute/Hypertension Center, Los Angeles.)

ISH may represent an exaggeration of this age-dependent stiffening process, although systolic BP and pulse pressure do not rise with age in the absence of urbanization (e.g., cloistered nuns). ISH is more common in women and is associated prominently with heart failure with preserved systolic function, a syndrome also more prevalent in women (**see Chapters 26 and 89**). Compared with young or middle-aged adults with optimal BP, those with BP in the high-normal range (prehypertension) will more likely develop ISH after 55 years of age. Many neurohormonal, renal, and vascular mechanisms interact to varying degrees to the pathogenesis and progression of the different hemodynamic forms of hypertension.

Neural Mechanisms

Two device-based interventional approaches to treat hypertension—baroreflex activation therapy (BAT) and renal denervation (RDN)—have rekindled interest in neural mechanisms of clinical hypertension.[23,24] **Fig. 46.5** shows the major central and reflex mechanisms that drive sympathetic overactivity in human hypertension, including resetting of the baroreceptors and activation of renal sensory nerves termed *renal afferents*.

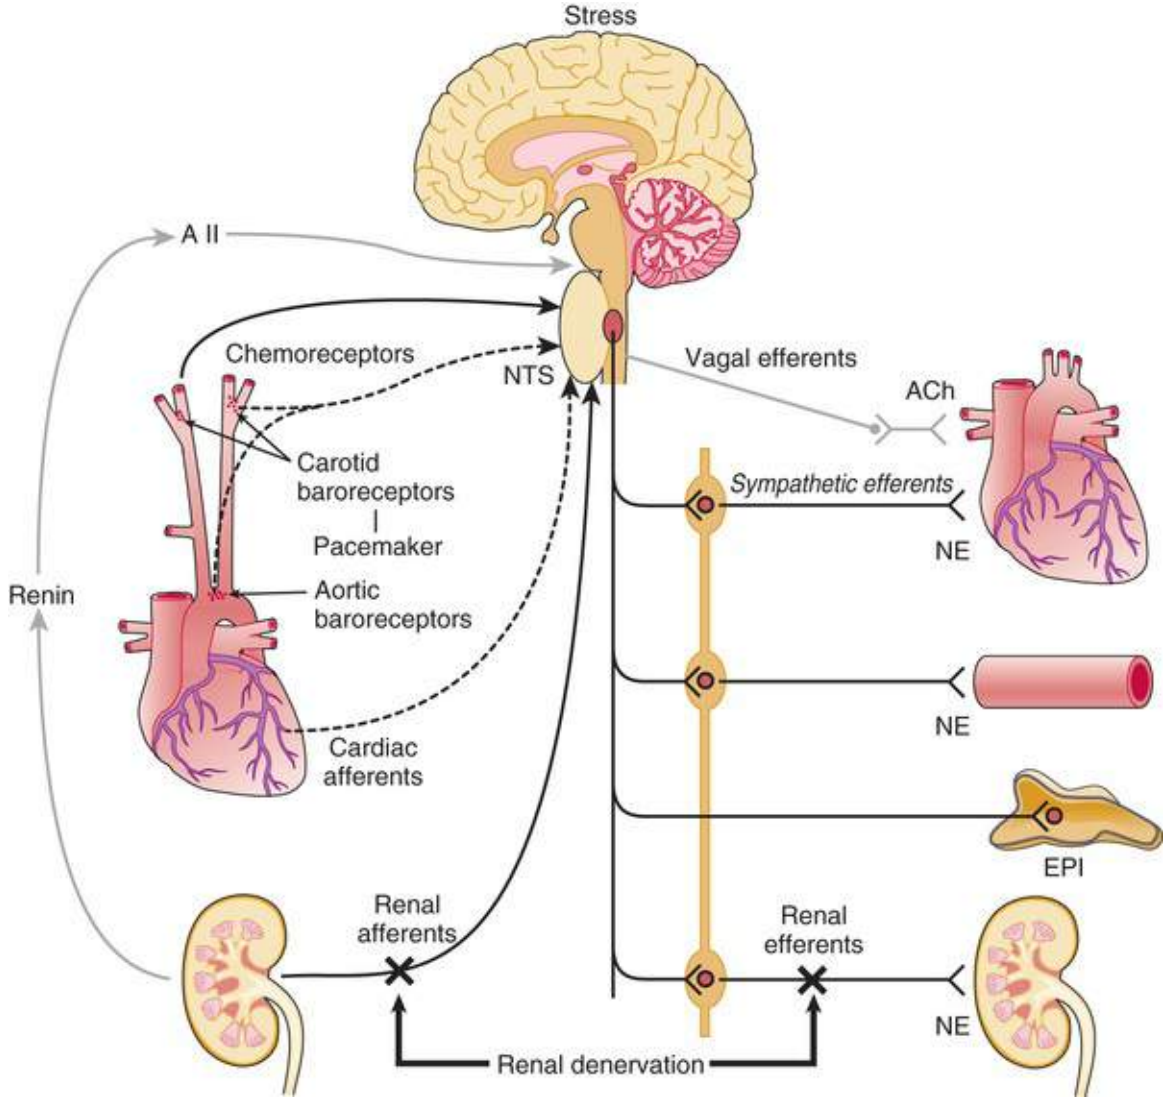


FIGURE 46.5 Sympathetic neural mechanisms of blood pressure regulation and treatment targets of carotid baroreceptor pacing and renal denervation. Note that aortic baroreceptors, which also influence blood pressure, are not paced. Also note that renal denervation affects afferent and efferent renal nerves. *Dotted arrows* represent inhibitory neural influences, and *solid arrows* represent excitatory neural influences on sympathetic outflow to the heart, peripheral vasculature, and kidneys. *A II,* Angiotensin II; *Ach,* acetylcholine; *EPI,* epinephrine; *NE,* norepinephrine; *NTS,* nucleus tractus solitarius. (Modified from Martin EA, Victor RG. Premise, promise, and potential limitations of invasive devices to treat hypertension. Curr Cardiol Rep 2011; 13:86-92).

Fig. 46.5 also shows the specific mechanisms that are targeted by the device-based therapies. With carotid BAT, electrical field stimulation of the carotid sinus nerve sends afferent neural signals that the brainstem interprets as a rise in BP, evoking a reflex reduction in BP. The efferent arm of this reflex arc involves decreased efferent sympathetic nerve activity to the heart, which slows heart rate; to the peripheral circulation, which lowers SVR; and to the kidney, which reduces renin release and increases renal sodium excretion. With RDN, a catheter is inserted into the renal arteries and radiofrequency or ultrasound is used to ablate the renal nerves, which are located on the adventitial surface of the renal arteries. The RDN aims to destroy both efferent and afferent renal nerves. The efferent renal (sympathetic) nerves contribute to hypertension by causing renal vasoconstriction and vascular hypertrophy via $alpha_1$-adrenergic receptors, stimulate renin release via $beta_1$-adrenergic receptors, and enhance renal sodium and water reabsorption via $alpha_1$ receptors (**Fig. 46.6**). Renal afferent nerves contribute to hypertension by evoking reflex activation of central sympathetic outflow triggered to multiple tissues and vascular beds. However, with both BAT and RDN, U.S. sham-controlled phase 3 randomized controlled trials (RCTs) yielded disappointing results (**see Chapter 47**). Neither device

gained U.S. Food and Drug Administration (FDA) approval, but research continues.

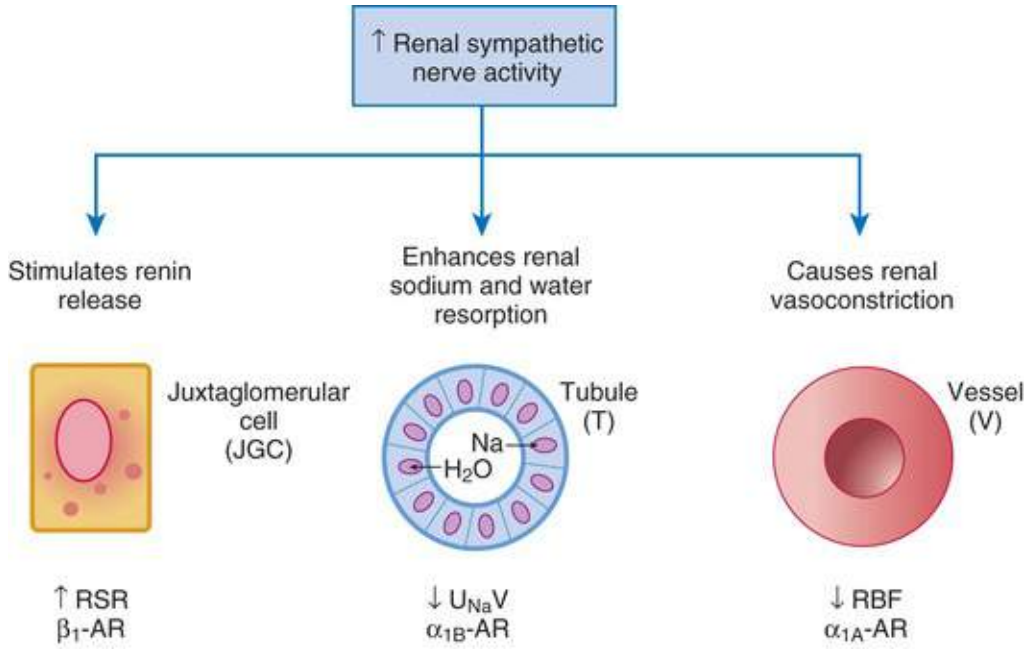

FIGURE 46.6 Effects of increased renal sympathetic nerve activity on the three renal neuroeffectors: juxtaglomerular granular cells (JGC) with increased renin secretion rate (RSR) via stimulation of the β_1-adrenoceptors (AR); renal tubular epithelial cells (T) with increased renal tubular sodium reabsorption and decreased urinary sodium excretion (UNaV) via stimulation of α_{1B} AR; and the renal vasculature (V) with decreased renal blood flow (RBF) via stimulation of α_{1A} AR. (From DiBona GF. Physiology in perspective: the wisdom of the body. Neural control of the kidney. Am J Physiol Regul Integr Comp Physiol 2005;289:R633.)

Overactivity of the sympathetic nervous system may play a greater role in the initiation of primary hypertension than in its progression.[25] A sympathetic component may contribute to the pathogenesis of hypertension associated with obesity, sleep apnea, metabolic syndrome, chronic kidney disease (CKD), heart failure, and immunosuppressive therapy with calcineurin inhibitors such as cyclosporine. Increased sympathetic activity may also drive some drug-resistant hypertension.[26] In these conditions, central sympathetic activation can result from deactivation of inhibitory neural inputs (e.g., baroreceptors), activation of excitatory neural inputs (e.g., carotid body chemoreceptors, renal afferents), or from circulating angiotensin II (A II), which activates pools of excitatory brainstem neurons without a blood-brain barrier (**see Fig. 46.5**).

In hypertension the baroreceptors reset to defend a higher level of BP. Baroreflex control of sinus node function is abnormal even in mild hypertension, but baroreflex control of SVR and BP is well preserved until diastolic function is impaired.[25] Complete baroreflex failure causes labile hypertension, most often seen in throat cancer survivors as a late complication of radiation therapy, which causes a gradual destruction of the baroreceptor nerves (**see Chapter 99**). Partial baroreceptor dysfunction is common in elderly hypertensive patients and typically manifests with a triad of orthostatic hypotension, supine hypertension, and symptomatic postprandial hypotension—the last initiated by splanchnic pooling after carbohydrate-rich meals.

Obesity-Related Hypertension

With weight gain, reflex sympathetic activation is an important compensation to burn fat, but at the expense of sympathetic overactivity in target tissues such as vascular smooth muscle and kidney that

produces hypertension. Hypertensive patients with the metabolic syndrome have near-maximal rates of sympathetic firing. Although the sympathetic activation is associated with insulin resistance, the precise stimulus to sympathetic outflow is unknown; candidates include leptin, other adipokines, and angiotensin II (A II). Why weight loss improves hypertension much less than diabetes remains unknown.[25]

Obstructive Sleep Apnea as a Cause of Neurogenic Hypertension

Patients with obstructive sleep apnea (OSA) can have greatly elevated plasma and urine catecholamine levels, mimicking those seen in patients with pheochromocytoma (**see Chapters 87 and 92**). With repeated arterial desaturation during apneas, activation of carotid body chemoreceptors triggers BP surges throughout the night and resets the chemoreceptor reflex; daytime normoxia is misinterpreted as hypoxia, producing sustained reflex sympathetic activation and hypertension even during waking hours. Frequent nocturnal arousal with fragmented sleep also triggers daytime sympathetic excitation regardless of OSA severity.[27] The OSA accelerates the emergence of hypertensive complications such as atrial fibrillation and stroke.[28]

Renal Mechanisms

A fundamental abnormality in hypertension is an acquired or inherited defect in the kidneys' ability to excrete the excessive sodium load imposed by a modern diet high in salt. Humans evolved in a low-sodium/high-potassium environment, and the human kidney handles poorly exposure to high sodium and low potassium. Renal sodium retention expands the plasma volume, increasing cardiac output and triggering autoregulatory responses that increase SVR. Salt retention also augments the smooth muscle contraction produced by endogenous vasoconstrictors. Beyond raising BP, a high-salt diet also accelerates hypertensive target-organ damage.

The typical U.S. diet is high in NaCl, with most dietary salt coming from processed food (**see Chapter 49**). Whereas men consume an estimated 10.7 g of NaCl daily, and women 7.3 g, the U.S. Department of Agriculture and Department of Health and Human Services recommend a daily intake of less than 5.8 g of NaCl (2300 mg of sodium) for the general population, and 3.7 g for persons with hypertension or prehypertension. If the food industry agreed to a palatable reduction in the salt content of processed food, reducing dietary salt by 3 g per day likely would reduce the annual number of new cases of coronary heart disease by 60,000 to 120,000, new cases of stroke by 32,000 to 66,000, and new cases of MI by 54,000 to 99,000, and would reduce the annual number of deaths from any cause by 44,000 to 92,000. All segments of the population would benefit, with blacks benefiting proportionately more, women benefiting particularly from stroke reduction, older adults from reductions in coronary heart disease events, and younger adults from lower mortality rates.[29]

Resetting of Pressure-Natriuresis

In normotensive individuals, BP elevation invokes an immediate increase in renal sodium excretion to shrink plasma volume and to return BP to normal. In hypertension, this pressure-natriuresis curve is shifted to the right, and in salt-sensitive hypertension, the slope is reduced. Resetting of pressure-natriuresis prevents the return of BP to normal so that fluid balance is maintained, but at the expense of high BP. Pressure-natriuresis causes profound nocturia in rare patients with pure autonomic failure who have supine nocturnal hypertension. Nocturia also may be an unrecognized symptom of uncontrolled primary hypertension.[30]

Low Birth Weight

Because of fetal undernutrition, low birth weight with reduced nephrogenesis increases the risk for development of adult salt-dependent hypertension. Hypertensive adults have fewer glomeruli per kidney but very few obsolescent glomeruli, suggesting that nephron dropout with decreased total filtration surface area is the cause and not the consequence of the hypertension. When low-birth-weight children consume a fast-food diet, they are susceptible to rapid postnatal weight gain, leading to adolescent obesity and hypertension.

Genetic Contributions

Animal and human studies have implicated an important genetic contribution to salt-sensitive hypertension. Rats with inbred defects in the kidneys' ability to excrete sodium remain relatively normotensive on a sodium-restricted diet, but become severely hypertensive when fed a high-sodium diet—a model of salt-sensitive hypertension that can be cured by interstrain renal transplantation. A similar gene-environment interaction may explain why persons of sub-Saharan African ancestry remain normotensive on a sodium-restricted diet, but are predisposed to hypertension when they encounter a high-sodium diet. Ancestral gene analysis has not defined the molecular basis for salt-dependent human hypertension, but has identified a common genetic predisposition of African-origin populations to all nondiabetic forms of CKD, including focal glomerulosclerosis, acquired immunodeficiency syndrome (AIDS), and hypertensive nephropathy. Sequence variations in the *APOL1* gene associate strongly with African ancestry and confer a twofold to fourfold increased risk of end-stage renal disease (ESRD). In such patients, strict control of hypertension may slow progression to ESRD.[31] As the kidneys fail, BP becomes increasingly salt dependent.

Vascular Mechanisms

Alterations in the structure and function of small and large arteries are pivotal in the pathogenesis and progression of hypertension.

Endothelial Cell Dysfunction

The endothelial lining of blood vessels is critical to vascular health and constitutes a major defense against hypertension (**see Chapter 57**). Dysfunctional endothelium displays impaired release of endothelium-derived relaxing factors (e.g., nitric oxide, endothelium-derived hyperpolarizing factor) and enhanced release of endothelium-derived constricting, proinflammatory, prothrombotic, and growth factors[32] (**Fig. 46.7**).

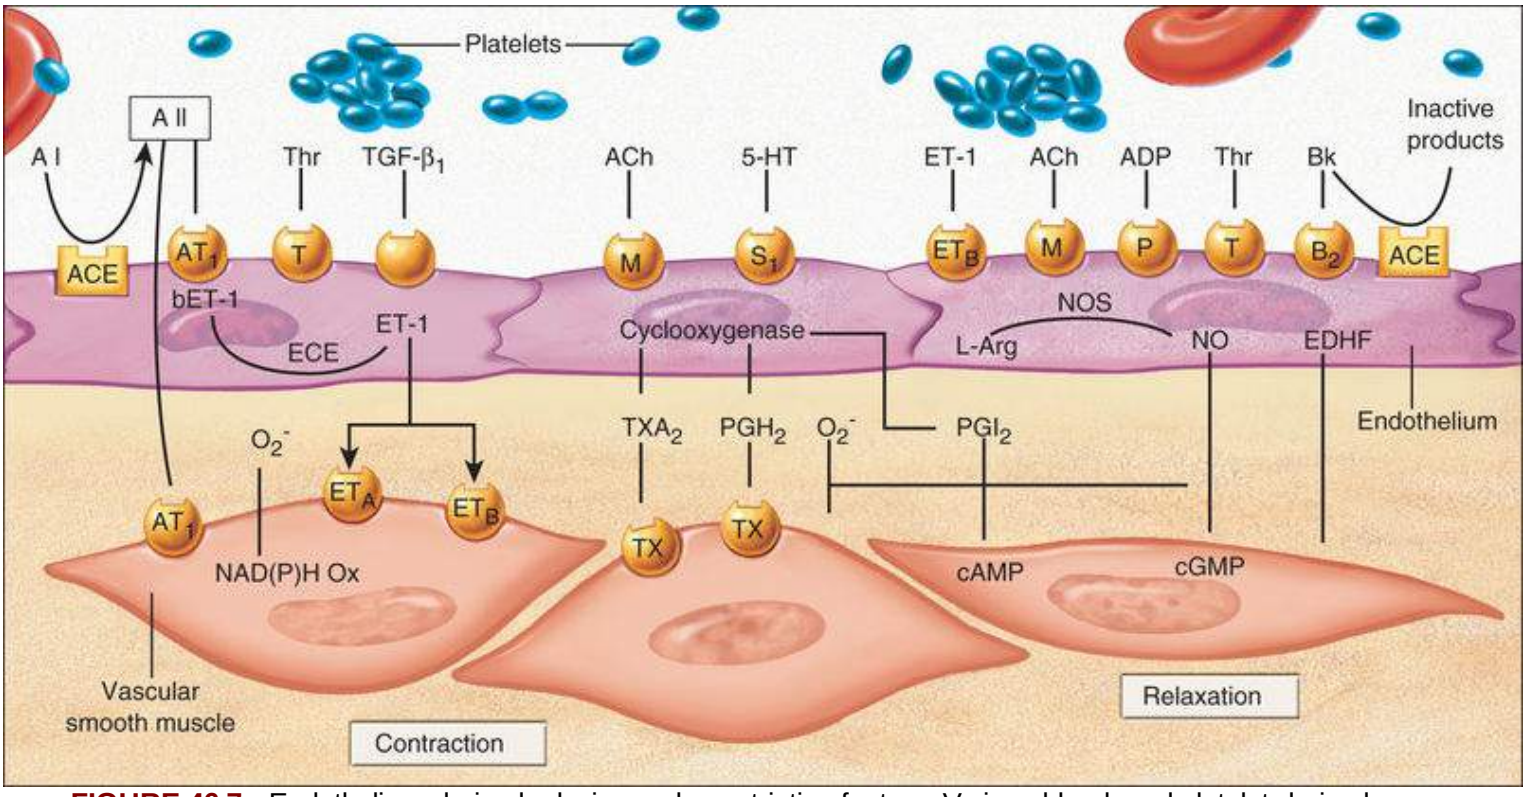

FIGURE 46.7 Endothelium-derived relaxing and constricting factors. Various blood- and platelet-derived substances can activate specific receptors (*orange circles*) on the endothelial membrane to release relaxing factors such as nitric oxide (NO), prostacyclin (PGI_2), and an endothelium-derived hyperpolarizing factor (EDHF). Contracting factors also are released, such as endothelin (ET-1), angiotensin (A II), and thromboxane A_2 (TXA_2), as well as prostaglandin H_2 (PGH_2). ACE, Angiotensin-converting enzyme; 5-HT, serotonin; Bk, bradykinin; ECE, endothelin-converting enzyme; L-Arg, L-arginine; NOS, nitric oxide synthase; O_2^-, superoxide; TGF-β_1, transforming growth factor β_1; Thr, thrombin. (From Ruschitzka F, Corti R, Noll G, et al. Arationale for treatment of endothelial dysfunction in hypertension. J Hypertens 1999;17[Suppl 1]:25.)

The endothelium of all blood vessels expresses the enzyme nitric oxide synthase (NOS), which can be activated by bradykinin, acetylcholine (ACh), or cyclic laminar shear stress. NOS generates nitric oxide (NO), a volatile gas that diffuses to the adjacent vascular smooth muscle and activates a series of G protein kinases that culminate in vasodilation (**Fig. 46.7**). In humans, endothelium-dependent vasodilation can be assessed by measuring increases in the large artery (forearm or coronary) diameter after intra-arterial infusion of ACh or release of ischemia (e.g., arrested forearm circulation) or a sudden elevation in BP (cold pressor test).

Mounting evidence indicates that smoldering vascular inflammation contributes to the genesis and complications of high BP. C-reactive protein (CRP), an easily measured serum biomarker, reports on inflammation.[33] Cross-sectional studies show strong correlations between elevated CRP and arterial stiffness and elevated pulse pressure. Longitudinal studies implicate elevated CRP levels as a risk marker for new-onset hypertension and accelerated progression of hypertensive target-organ disease, possibly beyond that explained by BP elevation alone (**see Chapters 9 and 45**).

Oxidative stress also contributes to endothelial cell vasodilator dysfunction in hypertension. Superoxide anion and other reactive oxygen species (ROS) quench NO, thereby reducing its bioavailability.[32] Several pathways produce superoxide in arteries: nicotinamide adenine dinucleotide phosphate (NADPH) oxidases, which are expressed in all vascular cell types and activated by circulating A II; NOS, which produces superoxide only when an important cofactor (tetrahydrobiopterin)

is deficient, a process known as NOS uncoupling; xanthine oxidase, which produces uric acid; and mitochondria. Generation of ROS by xanthine oxidase accounts for the association of hyperuricemia with endothelial dysfunction and hypertension. The xanthine oxidase inhibitor allopurinol can normalize BP in two thirds of adolescents with hyperuricemia and recently diagnosed hypertension and can rectify prehypertension in obese adolescents,[34] but cannot be recommended as a routine antioxidant because of its side effect profile. The weak oral antioxidants vitamins C and E have little effect on BP.

Vascular Remodeling.

Over time, endothelial cell dysfunction, neurohormonal activation, and elevated BP cause remodeling of blood vessels, which further perpetuates hypertension[35,36] (**Fig. 46.8**). An increase in the medial thickness relative to the lumen diameter (increased media-to-lumen ratio) is the hallmark of hypertensive remodeling in small and large arteries. Vasoconstriction initiates small-artery remodeling, which normalizes wall stress. Normal smooth muscle cells (SMCs) rearrange themselves around a smaller lumen diameter, a process termed *inward eutrophic remodeling*. The media/lumen ratio increases, but the medial cross-sectional area remains unchanged. By decreasing lumen diameter in the peripheral circulation, inward eutrophic remodeling increases SVR, the hemodynamic hallmark of diastolic hypertension.

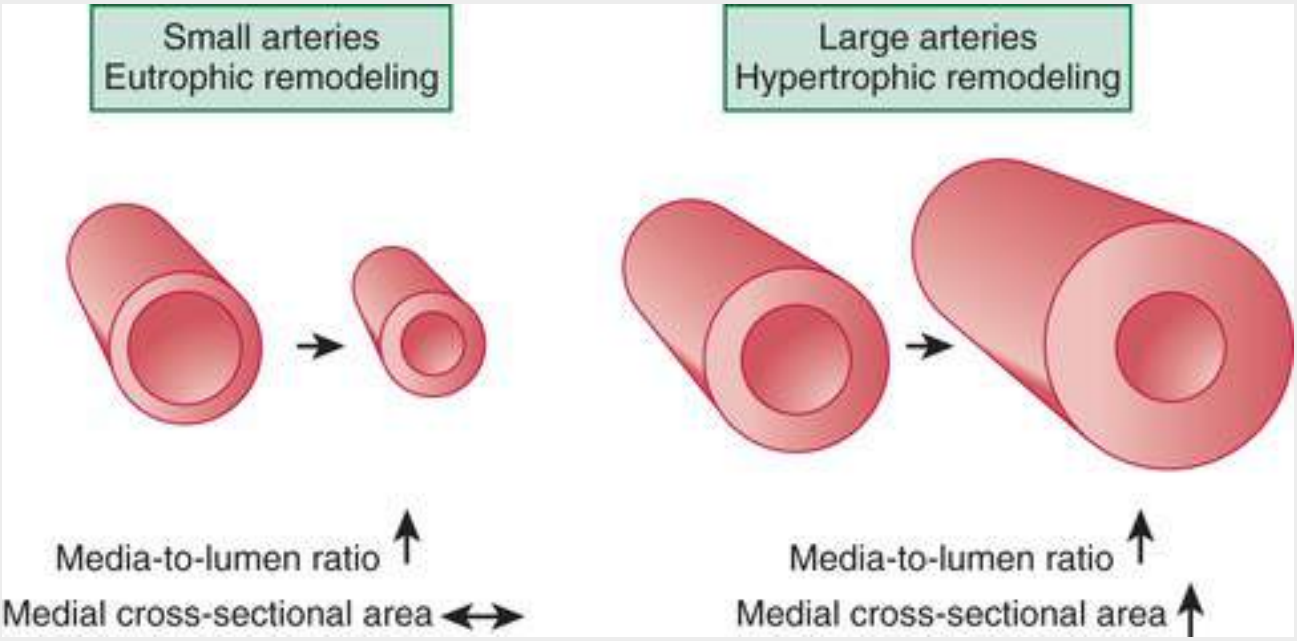

FIGURE 46.8 Vascular remodeling of small and large arteries in hypertension. Diagrams represent arteries in cross section showing the tunica adventitia, tunica media, and tunica intima. (Modified from Duprez DA: Role of renin-angiotensin-aldosterone system in vascular remodeling and inflammation: Aclinical review. J Hypertens 24:983, 2006.)

In contrast, large-artery remodeling is characterized by the expression of hypertrophic genes, triggering increases in medial thickness and media/lumen ratio. Such hypertrophic remodeling involves an increase in the size of vascular SMCs and an accumulation of extracellular matrix proteins, such as collagen, due to activation of transforming growth factor (TGF)-β. The resultant large-artery stiffness is the hemodynamic hallmark of ISH. Antihypertensive therapy may not provide optimal cardiovascular protection unless it prevents or reverses vascular remodeling by normalizing hemodynamic load, restoring normal endothelial cell function, and eliminating the underlying neurohormonal activation.[35]

Hormonal Mechanisms: Renin-Angiotensin-Aldosterone System

Activation of the renin-angiotensin-aldosterone system (RAAS) is one of the most important mechanisms contributing to endothelial cell dysfunction, vascular remodeling, and hypertension (**Fig. 46.9**; **see also Fig. 23.3**). Renin, a protease produced solely by the renal juxtaglomerular cells, cleaves angiotensinogen (renin substrate produced by the liver) to A I, which is converted to A II by angiotensin-converting enzyme (ACE). ACE is most abundant in the lungs but is also present in the heart and systemic vasculature (tissue ACE). Chymase, a serine protease in the heart and systemic arteries, provides an alternative pathway for conversion of A I to A II. The interaction of A II with G protein–coupled AT1 receptors activates numerous cellular processes that contribute to hypertension and accelerate hypertensive end-organ damage (**Fig. 46.9**), including vasoconstriction, ROS generation, vascular inflammation, vascular/cardiac remodeling, and production of aldosterone, the principal mineralocorticoid. Aldosterone, A II, and prorenin activate multiple signaling pathways that can damage vascular health and cause hypertension.

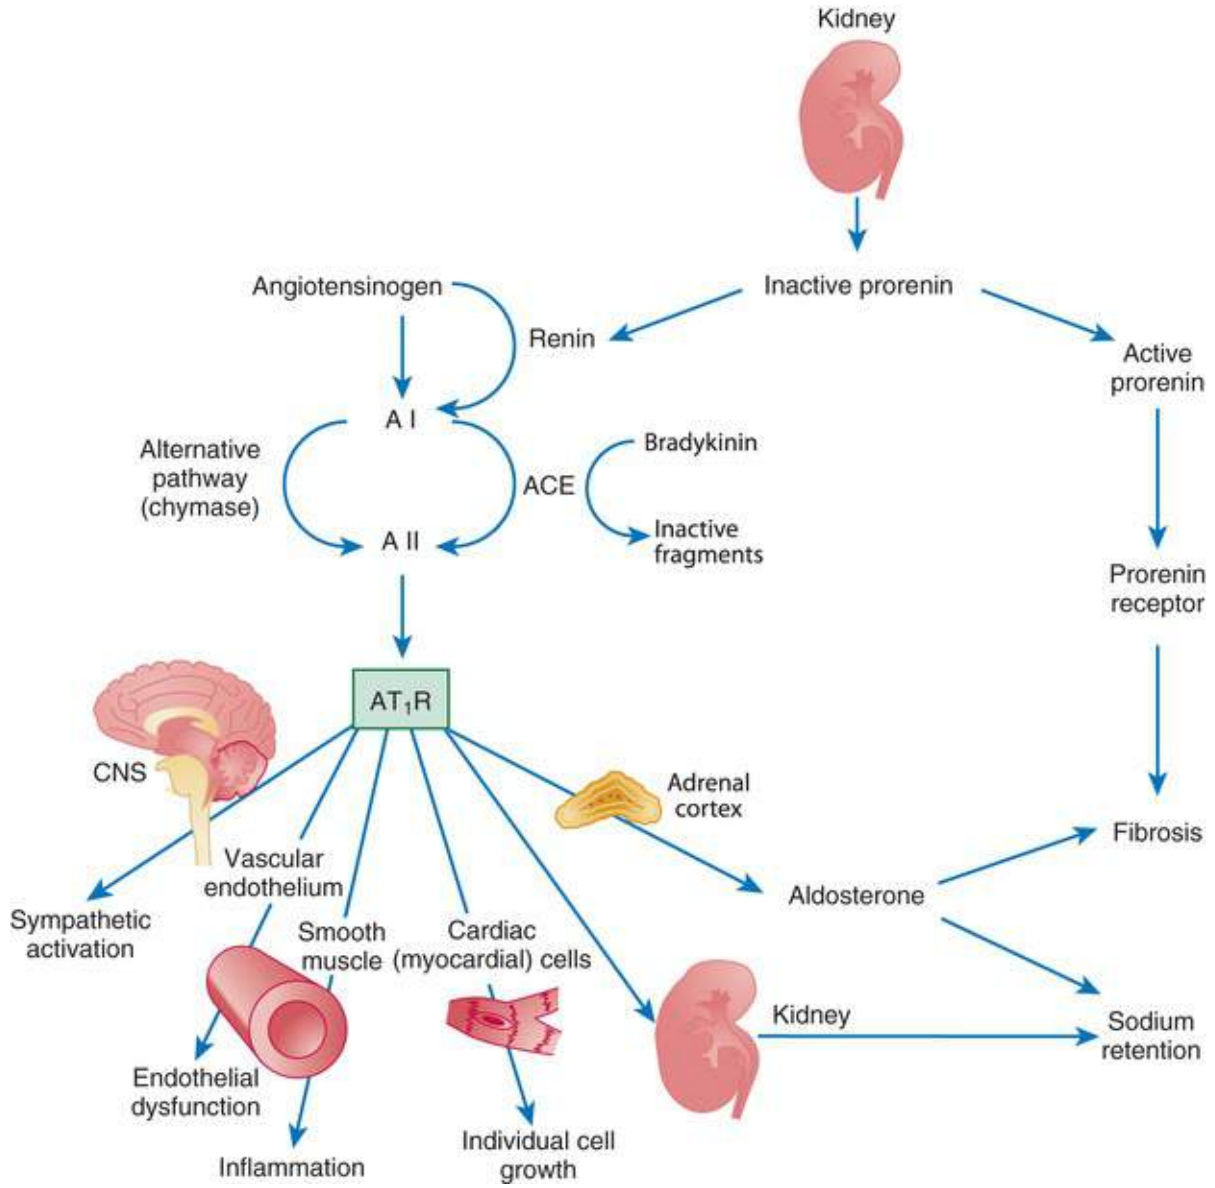

FIGURE 46.9 The renin-angiotensin-aldosterone system. A I, Angiotensin I; A II, angiotensin II; ACE, angiotensin-converting enzyme; AT_1R, angiotensin type 1 receptor; CNS, central nervous system.

RAAS activation is a major homeostatic mechanism to counter hypovolemic hypotension (as with hemorrhage or salt and water deprivation). Interaction of aldosterone with cytosolic mineralocorticoid receptors in the renal collecting duct cells recruits sodium channels from the cytosol to the surface of the renal epithelium. The recruited epithelial sodium channels (ENaCs) increase Na^+ reabsorption, thereby reexpanding plasma volume. Conversely, modern high-salt diets should engender continual feedback inhibition of the RAAS. Suppression of serum aldosterone triggers sequestration of ENaCs by endocytosis and increased renal Na^+ excretion, thereby shrinking plasma volume to protect against salt-sensitive hypertension.

Thus, in the setting of high dietary sodium and elevated BP, the RAAS should be completely suppressed, and any degree of RAAS activity is inappropriate. In normotensive individuals the risk for development of hypertension increases with increasing levels of serum aldosterone that are well within the normal range. By stimulating mineralocorticoid receptors in the heart and kidney, circulating aldosterone may contribute to the development of cardiac and renal fibrosis in hypertension.[37] Also, aldosterone contributes to sympathetic overactivity by stimulating mineralocorticoid receptors in the brainstem.

Two main angiotensin receptor types (AT) are known. AT1 receptors are widely expressed in the vasculature, kidneys, adrenals, heart, liver, and brain. A I receptor activation explains most of the hypertensive actions of A II. Furthermore, enhanced AT1-mediated signaling provides a central mechanistic explanation for the frequent coexistence of elevated BP with insulin resistance and atherosclerosis and constitutes a major therapeutic target for interruption of every step in CVD progression, from vascular remodeling and formation of atherosclerotic plaque to stroke, MI, and death (**Fig. 46.10**).

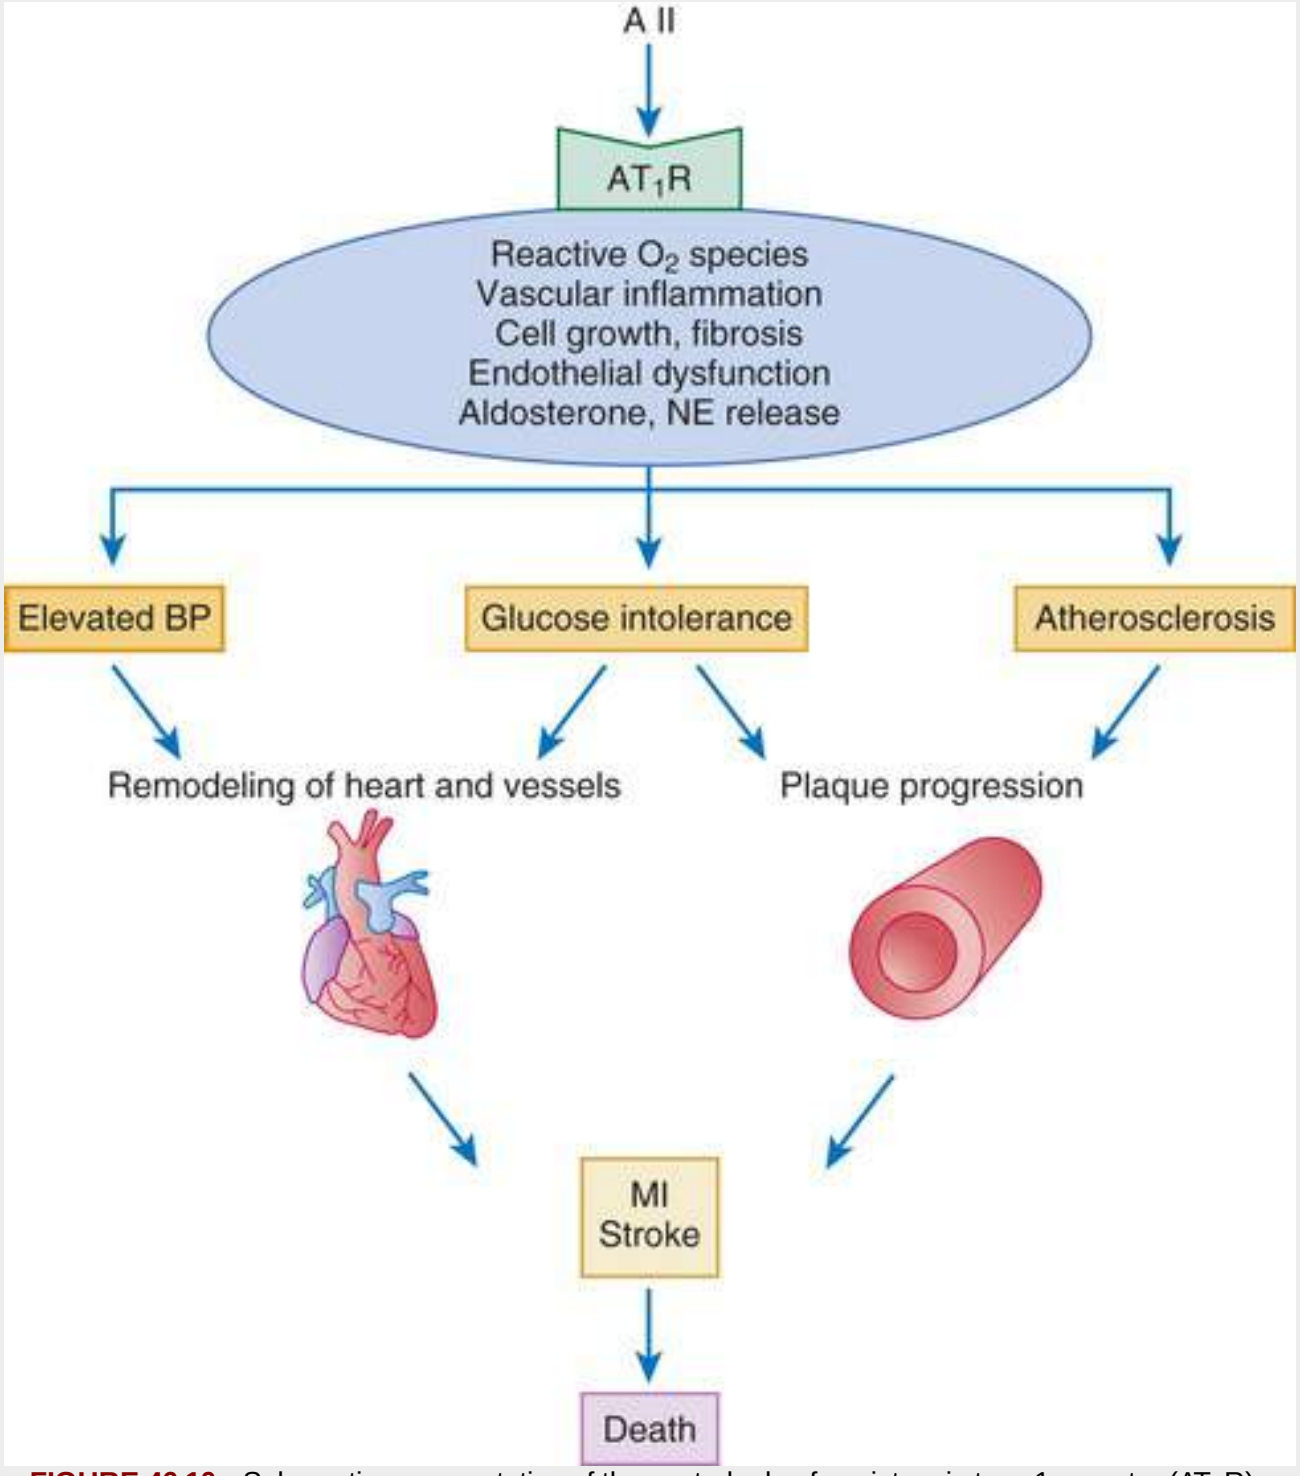

FIGURE 46.10 Schematic representation of the central role of angiotensin type 1 receptor (AT_1R)–mediated signaling in cardiovascular disease progression. A II, Angiotensin II; MI, myocardial infarction; NE, norepinephrine.

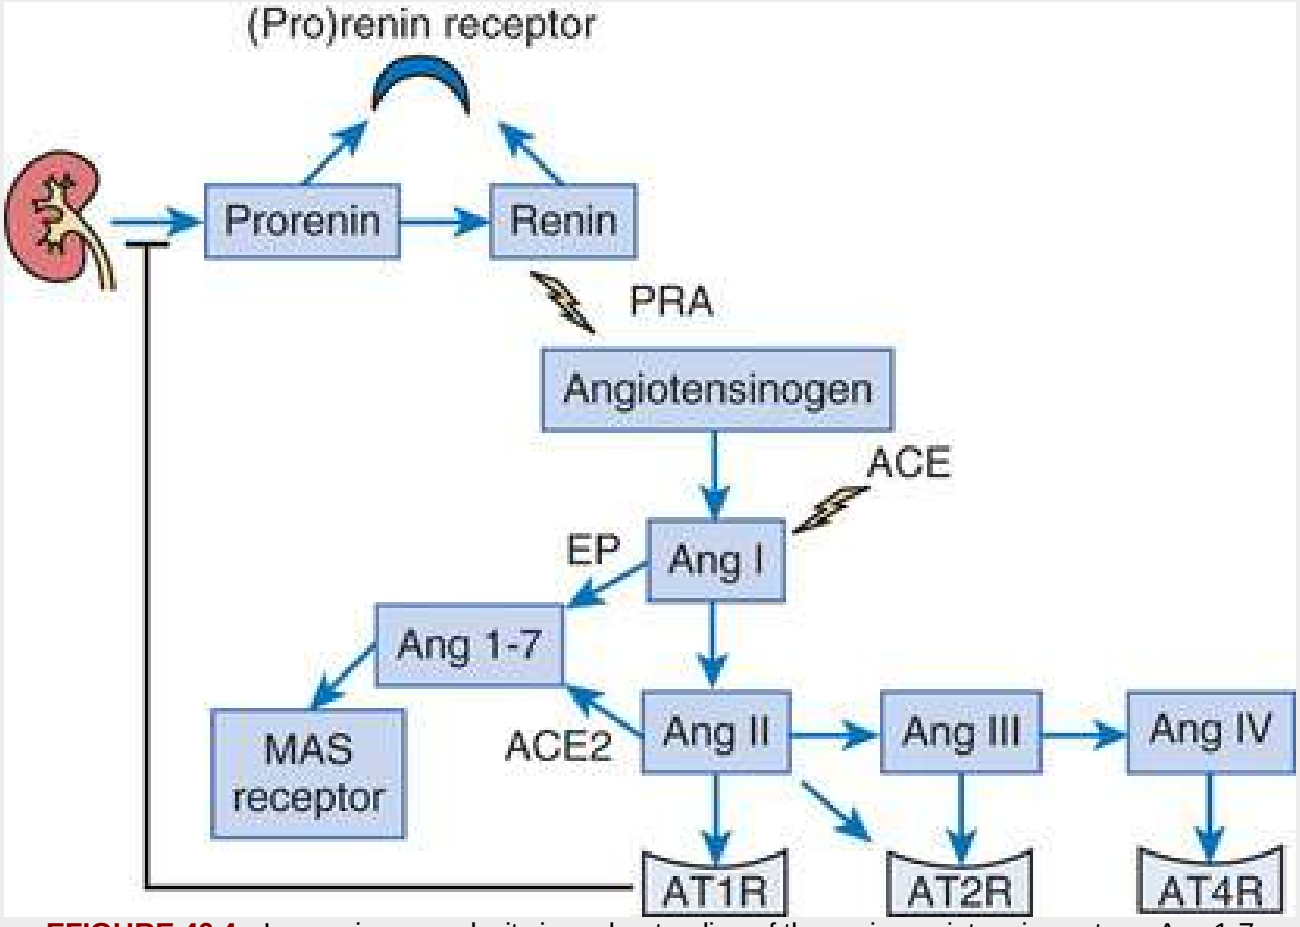
In contrast, AT2 receptors distribute widely in the fetus, but in adults localize only in the adrenal medulla, uterus, ovaries, vascular endothelium, and distinct brain regions. In rodents, AT2 receptor activation opposes some of the deleterious effects of AT1 receptors by promoting endothelium-dependent vasodilation by bradykinin and NO pathways. Animal studies have suggested that AT2 receptors can be profibrotic, but their role in human hypertension remains speculative (**eFig. 46.4**).



EFIGURE 46.4 Increasing complexity in understanding of the renin-angiotensin system. Ang 1-7 interacts with a specific G protein–coupled MAS receptor and generally opposes the vasoconstrictor and proliferative actions of Ang II. ACE, Angiotensin-converting enzyme; ACE2, type 2 angiotensin converting enzyme; Ang I, angiotensin I; Ang II, angiotensin II; Ang III, angiotensin III; Ang IV, angiotensin IV; Ang 1-7, angiotensin one through seven; AT1R, type 1 angiotensin receptor; AT2R, type 2 angiotensin receptor; AT4R, type 4 angiotensin receptor; EP, endopeptidase; PRA, plasma renin activity.

Prorenin is both the inactive precursor of renin and also binds to a prorenin receptor that increases TGF-β production, leading to collagen deposition and fibrosis. All RAAS blockers trigger large, reactive increases in prorenin production that may counter some of the cardiovascular protection afforded by reduced AT1 receptor activation.

Hypertension as an Immunologic Disorder.

Macrophages and T cells accumulate and promote inflammation in the central nervous system (CNS), perivascular fat, heart, and kidneys of mice with experimental hypertension, particularly that caused by infusion of A II. Renal sympathetic activation initiates A II–induced hypertension, whereas systemic T cell activation in perinephric and perivascular fat is key in progression of experimental hypertension[38] (**Fig. 46.11**). Translation of this preclinical work to human hypertension is beginning.[39]

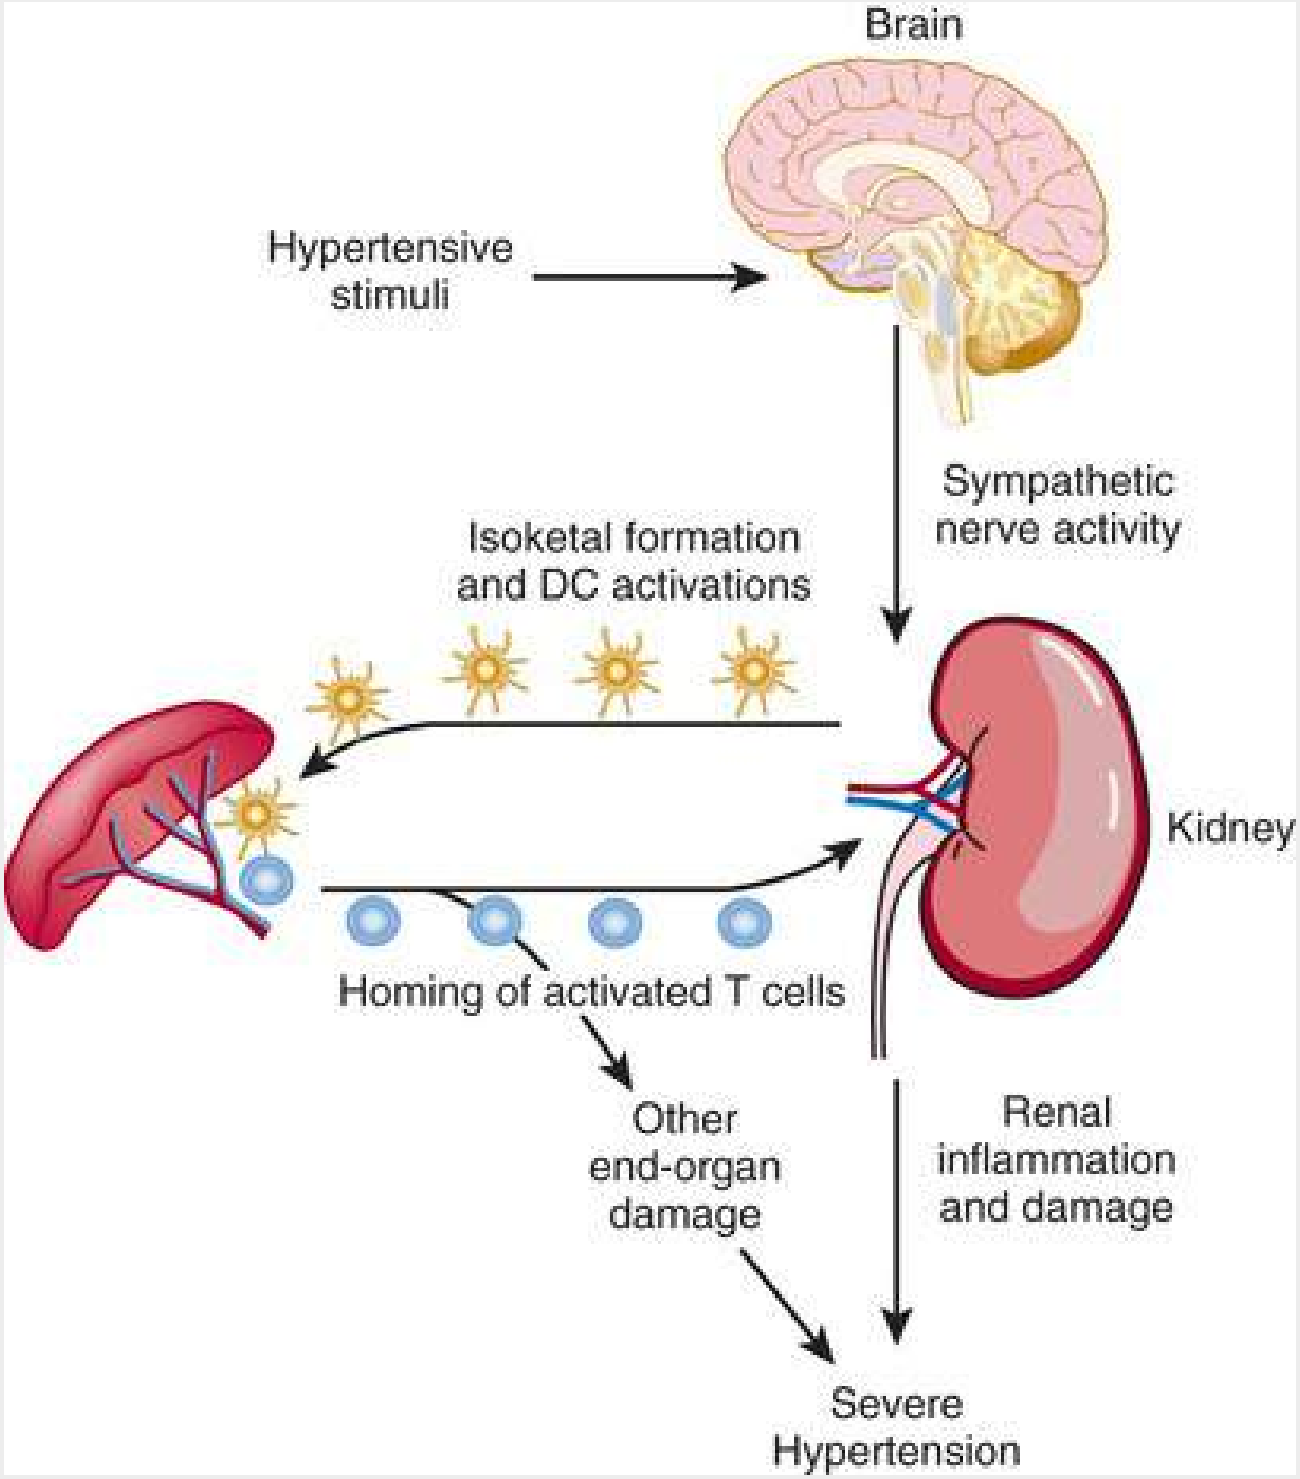


FIGURE 46.11 Proposed scheme for the contribution of renal sympathetic nerves in the activation of adaptive immunity in hypertension. Hypertensive stimuli such as angiotensin II and sodium act in the central nervous system to increase renal sympathetic nerve activity. The sympathetic activation promotes inflammation and damage in the kidney and other organs (especially the systemic vasculature) leading to severe hypertension. The mechanism involves accumulation of proteins oxidized by high reactive gamma-ketoaldehydes termed *isoketals* in antigen-presenting *dendritic cells* (DC), which in turn promote T cell activation. The activated T cells are homed by local expression of adhesion molecules (e.g., VCAM-1) to perinephric fat (and perivascular fat), where they produce proinflammatory cytokines (e.g., IL-17, TNF-α) causing renal (and vascular) inflammation and damage. (From American Heart Association; Xiao L, Kirabo A, Wu J, et al. Renal denervation prevents immune cell activation and renal inflammation in angiotensin II-induced hypertension. Circ Res 2015;117:547.)

Initial Evaluation of the Hypertensive Patient

Hypertension is the “silent killer,” an asymptomatic chronic disorder that, undetected and untreated, silently damages the blood vessels, heart, brain, and kidneys. However, it may not be entirely asymptomatic. In double-blind placebo-controlled trials, patients' quality of life rating often improves with successful drug treatment of hypertension. Hypertension control can improve exertional dyspnea caused by diastolic dysfunction, nocturia caused by resetting of pressure-natriuresis, and possibly even erectile dysfunction caused by endothelial dysfunction.

The initial evaluation for hypertension should accomplish three goals: (1) the accurate measurement of BP; (2) the assessment of the patient's global cardiovascular disease (CVD) risk; and (3) the detection of secondary (i.e., identifiable and potentially curable) forms of hypertension.

Measurement of Blood Pressure

There are now four approaches to BP measurement: (1) conventional office BP, (2) automated office BP, (3) home monitoring, and (4) ambulatory BP monitoring.[40] In all cases, BP should be measured with appropriate technique using validated devices with “AA” ratings from the British Hypertension Society protocol on the Educational Trust website: http://dableducational.org/. **Table 46.1** provides the cutoff values for the diagnosis of hypertension.

TABLE 46.1

Criteria for Diagnosis of Hypertension Using Different Methods of Blood Pressure (BP) Measurement (Systolic and/or Diastolic)

METHOD	SYSTOLIC (mm Hg)	DIASTOLIC (mm Hg)
Office		
Conventional office BP	≥140	≥90
Unattended automated office BP (AOBP)	≥135	≥85
Home		
Home BP	≥135	≥85
Ambulatory BP Monitoring (ABPM)		
Daytime (awake)	≥135	≥85
Nighttime (asleep)	≥120	≥70
24 or 48 hour (average)	≥130	≥80

Modified from Gabb GM, Mangoni A, Anderson CS, et al. Guideline for the diagnosis and management of hypertension in adults—2016. Med J Aust 2016;205:85.

Conventional Auscultatory Office Blood Pressure.

Auscultatory measurement of BP by medical personnel is the conventional approach to the diagnosis of hypertension in the United States and the method used, until recently, in most RCTs. The latest 2016 hypertension guidelines from the National Heart Foundation of Australia stages office BP by the average of two or more readings taken at two or more office visits[41] (**Table 46.2**). The BP should be measured at least twice after 5 minutes of rest, with the patient seated in a chair, the back supported, and the arm bare and at heart level. A large adult-sized cuff should be used to measure BP in overweight adults, because the standard-sized cuff can spuriously elevate readings. Tobacco and caffeine should be avoided for at least 30 minutes. BP should be measured in both arms and after 5 minutes of standing, the latter to exclude a significant postural fall in BP, particularly in older persons and in those with diabetes or other conditions (e.g., Parkinson disease) that predispose to autonomic insufficiency. In practice, conventional office-based readings often are inaccurate because of too common measurement errors, the small number

of readings, the “white coat” (alerting) reaction, and the large number of factors that influence BP outside the medical office.

TABLE 46.2

Staging of Office Blood Pressure*

BP STAGE	SYSTOLIC (mm Hg)	DIASTOLIC (mm Hg)
Normal	<120	<80
Prehypertension (high-normal)	120-139	80-89
Stage 1 (mild) hypertension	140-159	90-99
Stage 2 (moderate) hypertension	160-179	
Stage 3 (severe) hypertension	≥180	≥110
Isolated systolic hypertension	≥140	<90

*Calculation of seated BP is based on the mean of two or more readings on two separate office visits.

Modified from Gabb GM, Mangoni A, Anderson CS, et al. Guideline for the diagnosis and management of hypertension in adults—2016. Med J Aust 2016;205:85.

Automated Office Blood Pressure (AOBP).

The Systolic Blood Pressure Intervention Trial (SPRINT) was the first to utilize unattended AOBP.[4] An oscillometric monitor was set to take three readings at 1-minute intervals after the patient was unattended by medical staff and unaccompanied by family members in the examination room for 5 minutes.[42] Other protocols take five readings at 1-minute intervals (or on STAT mode) and average all five readings or the last three readings.[6] The 2016 hypertension guidelines from both Australia and Canada (where AOBP was pioneered by Dr. Martin Myers) endorse AOBP as the preferred method over conventional office BP because it (1) minimizes the white coat reaction, (2) correlates better with home or awake ambulatory BP, and (3) eliminates digit preference.[41,43] On average, AOBP is 15/10 mm Hg lower than conventional office BP, but there are large interindividual differences.[44] Hypertension is diagnosed when the AOBP is 135/85 mm Hg or higher.

Home Blood Pressure Monitoring (HBPM).

Office BP can both overestimate and underestimate a person's BP measured at home. HBPM improves medication adherence by actively involving patients in their own medical care. The latest guidelines[45] recommend that patients be carefully instructed to perform HBPM as follows: rest quietly for 5 minutes in the seated position with the back supported and the arm supported on a table at heart level; take two readings in the morning and two readings in the evening for at least 3 consecutive days (preferably 7 days). The first day's readings should be discarded as being falsely elevated, and all other readings be averaged to make clinical decisions. Hypertension is diagnosed when the average home BP is 135/85 mm Hg or higher. Each patient's monitor needs to be checked in the office for accuracy and cuff size. Monitors with sizable memory storage eliminate reporting bias. Wrist monitors are inaccurate and not recommended. The oscillometric method may not work well in patients with atrial fibrillation or frequent extrasystoles. Some patients become obsessive about taking their BP and must be advised to stop self-measurement altogether.

Ambulatory Blood Pressure Monitoring

Ambulatory BP monitoring (ABPM) is the “gold standard”: it provides automated measurements of BP during a 24-hour or (better) a 48-hour period while patients are engaged in their usual activities, including sleep. Prospective studies show that ABPM predicts fatal and nonfatal MI and stroke better than standard office measurement does[46] (**Fig. 46.12**). Current consensus guidelines[47] define *out-of-office*

hypertension as average daytime BP of 135/85 mm Hg or higher, nighttime BP 120/70 mm Hg or higher, or 24-hour BP 130/80 mm Hg or higher (**see Table 46.1**). Moreover, optimal values are daytime BP less than 130/80, nighttime BP less than 110/65, and 24-hour BP less than 125/75. At least two measurements per hour should be taken during the patient's waking hours, and the average value of at least 14 measurements during that time confirms the diagnosis of hypertension.[45]

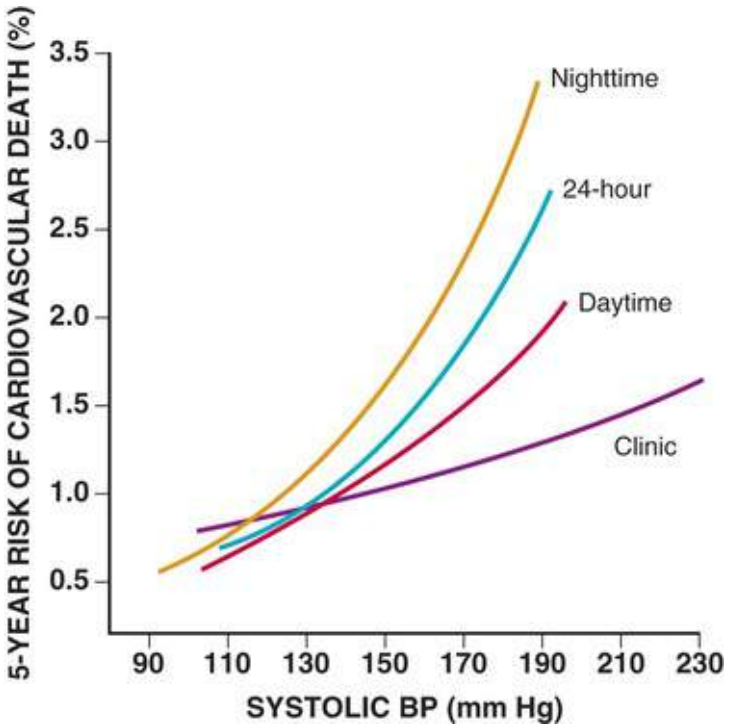

FIGURE 46.12 Superiority of ambulatory over office BP measurement as a measure of cardiovascular risk. Shown is the adjusted 5-year risk of cardiovascular death (number of deaths per 100 individuals) in the study cohort of 5292 patients for office BP and ambulatory BP. (From Dolan E, Santon A, Thijs L, et al. Superiority of ambulatory over clinic BP measurement in predicting mortality: The Dublin Outcome Study. Hypertension 2005;46:156.)

White Coat Hypertension

Patients with elevated office BP can have normal home and ambulatory BPs. If the daytime BP is less than 135/85 mm Hg and there is no target-organ damage despite consistently elevated office readings, the patient has “office-only” or “white coat” hypertension, caused by a transient adrenergic response to the measurement of BP only in the physician's office. Patients with white coat hypertension typically do not show exaggerated pressor reactions to stressful stimuli in their daily lives. Debate continues as to whether white coat hypertension is completely benign or confers an intermediate level of CVD risk.[48] White coat hypertension is benign if global CVD risk is low[49] (**Fig. 46.13A**), especially if the mean awake and sleep BP are optimal (<130/80 and <110/65 mm Hg, respectively). Both the prevalence and the severity of white coat hypertension increase sharply with age (**Fig. 46.13B**). In elderly persons, most of the CVD risk associated with white coat hypertension is caused by aging or isolated systolic hypertension incorrectly diagnosed as white coat hypertension.[49] Many patients do not have pure white coat hypertension but rather “white coat aggravation,” a white coat reaction superimposed on a milder level of out-of-office hypertension that nevertheless requires treatment (**eFig. 46.5**).

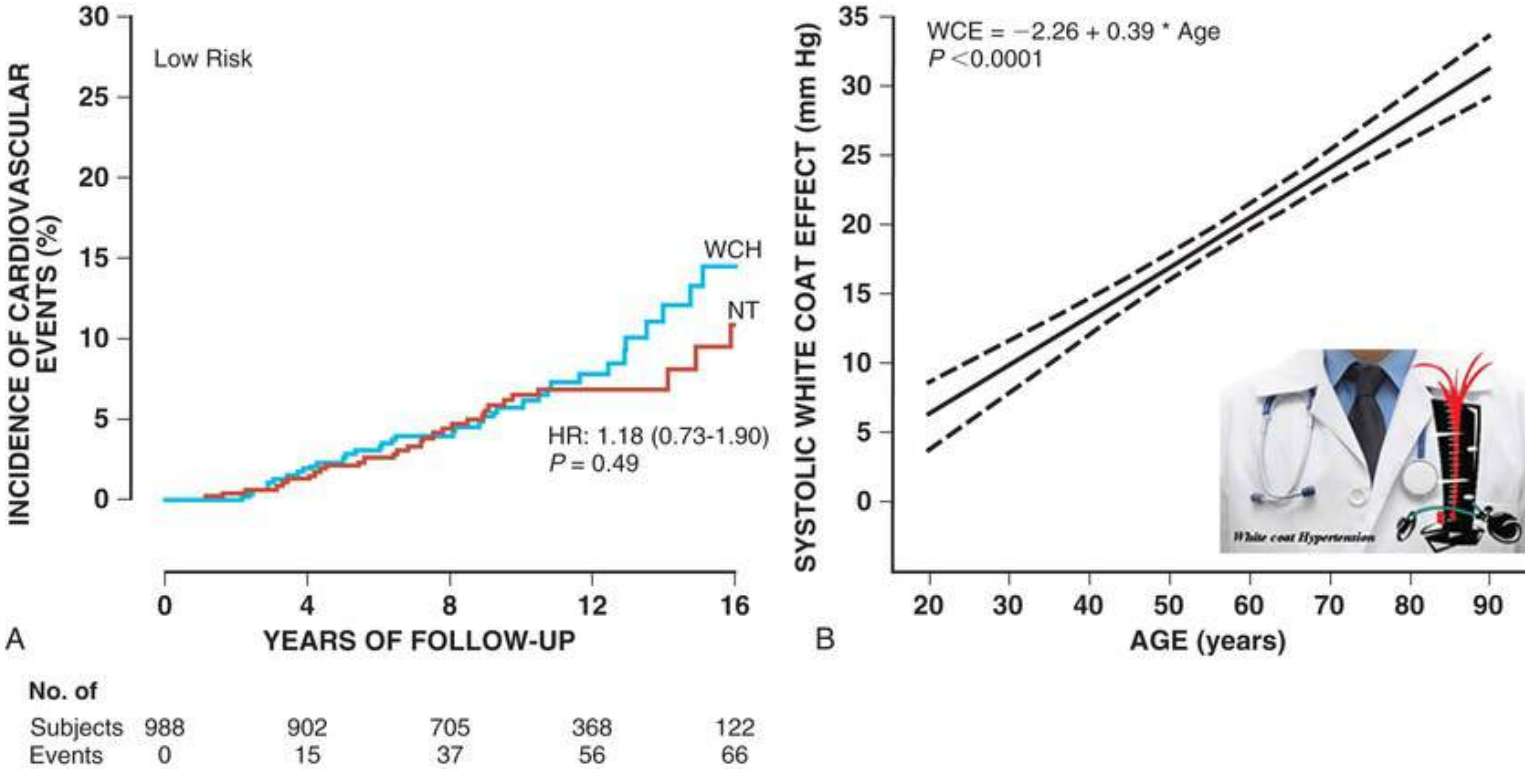

FIGURE 46.13 "White coat" hypertension from the 11-country International Database on Ambulatory Blood Pressure Monitoring in Relation to Cardiovascular Outcomes (IDACO). **A,** Kaplan-Meier cumulative incidence of cardiovascular disease (CVD) events in a cohort of patients with white coat hypertension (WCH) and low CVD risk compared with a cohort of approximately age-matched normotensive (NT) controls. **B,** Prevalence of WCH increases linearly with age. (From Franklin SS, Thijs L, Asayama K, et al. The cardiovascular risk of white-coat hypertension. J Am Coll Cardiol 2016;68:2033.)

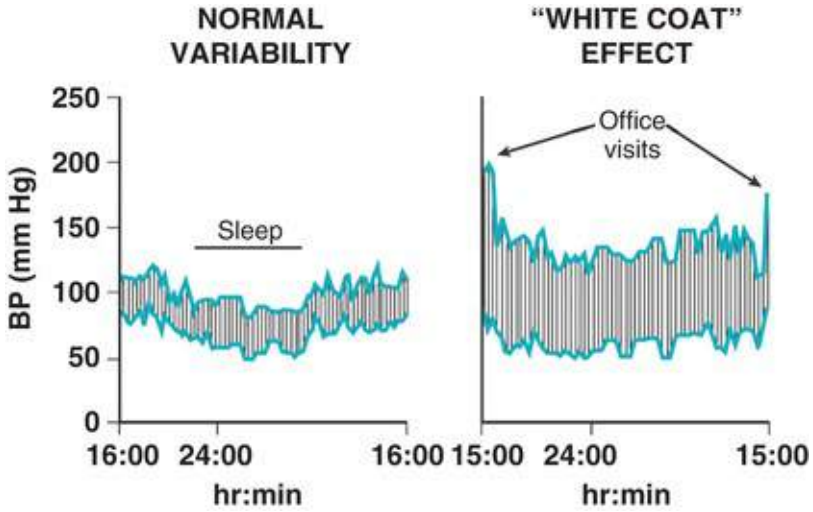

EFIGURE 46.5 Twenty-four-hour ambulatory blood pressure (BP) monitor tracings in two different patients. **Left,** Optimal BP in healthy 37-year-old woman. Note the normal variability in BP, nocturnal dip in BP during sleep, and sharp increase in BP on awakening. **Right,** Pronounced "white coat" effect in an 80-year-old woman referred for evaluation of medically refractory hypertension. Documentation of the white coat effect prevented overtreatment of the patient's isolated systolic hypertension. (**Left,** Courtesy Dr. Ronald G. Victor, Heart Institute/Hypertension Center, Cedars-Sinai Medical Center, Los Angeles; **Right,** Provided by Dr. Wanpen Vongpatanasin, Hypertension Division, Department of Internal Medicine, University of Texas Southwestern Medical Center, Dallas.)

Masked Hypertension

Also, ABPM is key to detect patients in whom office readings underestimate out-of-office BP, presumably because of sympathetic overactivity in daily life caused by job or home stress, tobacco abuse, or other adrenergic stimulation (OSA) that dissipates when they come to the office (**Fig. 46.14**). Such documentation prevents undertreatment of this *masked hypertension*, which unequivocally increases CVD risk, despite normal office BP readings.[47] Masked hypertension is defined as daytime BP of 135/85 mm Hg or higher or nighttime BP of 120/70 mm Hg or higher despite conventional office BP lower than 140/90 mm Hg. It is particularly common in African American patients and in patients with diabetes or those with CKD.[47] Masked hypertension is more common in patients being treated with BP medication than in untreated patients.[47] One reason is that some patients are more likely to take their BP medication the morning of their doctor visit. Another reason is that short-acting medication such as hydrochlorothiazide (HCTZ), when dosed in the morning, causes a sizable decrease in BP for the clinic visit but wears off before bedtime, providing no protection against nocturnal hypertension.[50]

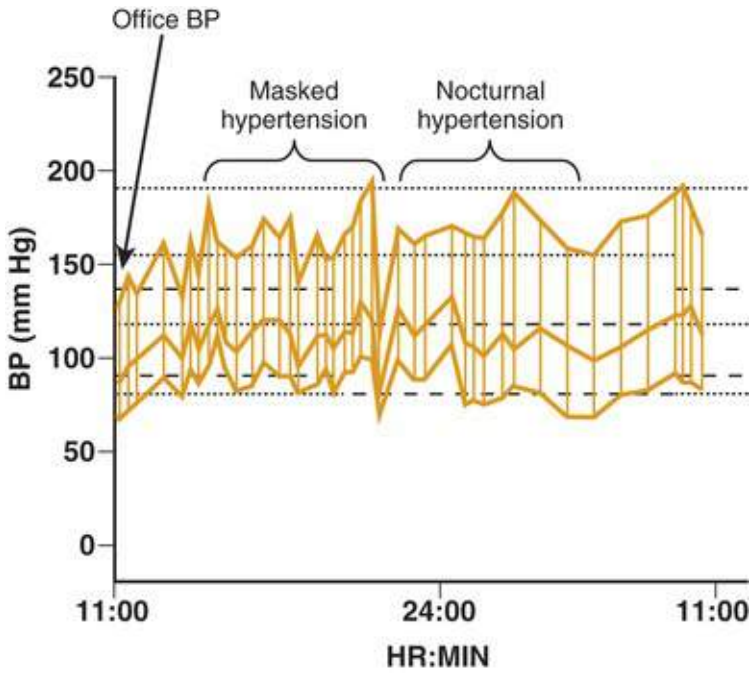

FIGURE 46.14 A 24-hour ambulatory BP recording in a patient with normal office BP but with masked daytime (awake) and masked nocturnal (asleep) hypertension. (From Dr. R. G. Victor, Cedars-Sinai Heart Institute/Hypertension Center, Los Angeles.)

ABPM is the only way to detect high BP during sleep (**Fig. 46.14**). BP normally dips during sleep and increases sharply when a person awakens and becomes active (**eFig. 46.5**). Nocturnal hypertension increases the aggregate hemodynamic load on the cardiovascular system and predicts CVD outcomes better than either daytime ambulatory BP or conventional office measurement[46] (**see Fig. 46.13**). Thus, high nocturnal BP, which accounts for most masked uncontrolled hypertension, is an especially ominous CVD risk factor.[51]

Indications for Ambulatory BP Monitoring

Currently, the U.S. Centers for Medicare and Medicaid Services (CMS) reimburses ABPM (CPT code 93784) only for one indication: elevated BP without a diagnosis of hypertension (ICD 796.2), that is, suspected white coat hypertension. The following strict criteria must be met: office BP of 140/90 mm Hg or higher on at least three separate office visits, with two measurements made at each visit; at least two

out-of-office BP readings lower than 140/90 mm Hg; and no evidence of target-organ damage. Based on a wealth of compelling evidence, expansion of the CMS-approved indications for ABPM is long overdue.

The 2015 U.S. Preventive Services Task Force concluded that "ABPM is the best method for diagnosing hypertension."[52] ABPM prevents unnecessary treatment of large numbers of patients with white coat hypertension and is a powerful CVD risk factor independent of the office BP. This task force document and the 2016 Canadian and 2016 Australian hypertension guidelines all recommend ABPM to confirm or reject the diagnosis of hypertension in the patients with an initially high office BP, except those with extremely high office BP of 180/110 mm Hg or higher. Also, a cogent argument can be made for ABPM in routine screening of high-risk populations to prevent undertreatment of masked hypertension: African American patients and those with diabetes or CKD. ABPM also is invaluable in the management of patients with apparent drug-resistant hypertension and in those with orthostatic hypotension or supine hypertension resulting from autonomic failure.

Cardiovascular Disease Risk Stratification

In hypertensive individuals, cardiovascular risk increases sharply with BP stage, but this is not the only factor to consider. The gradient between increasing levels of BP and CVD risk becomes progressively steeper as additional risk factors accumulate. Cardiovascular risk also increases dramatically with hypertensive target-organ damage and with additional CVD risk factors often present in patients with hypertension or prehypertension[53] (**Table 46.3**). The vast majority of hypertensive patients meet current criteria for initiation of lipid-lowering therapy (**see Chapter 48**). Thus the minimal laboratory testing required for the initial evaluation of hypertension includes determination of a fasting lipid panel, blood electrolyte values, fasting glucose concentration, and serum creatinine level with estimated glomerular filtration rate (GFR); hematocrit; spot urinalysis, including urine albumin/creatinine ratio; and resting 12-lead electrocardiogram (ECG). The patient's global cardiovascular risk can be estimated from the 2013 American Heart Association and American College of Cardiology (AHA/ACC) Pooled Cohort Calculator (http://tools.acc.org/ASCVD-Risk-Estimator/). **Chapter 45** addresses the process of tailoring goals of therapy to CVD risk.

TABLE 46.3

Risks Influencing Prognosis in Patients with Hypertension

Risk Factors for Cardiovascular Disease
Systolic and diastolic BP levels
Levels of pulse pressure (in elderly patients)
Age: men >55 years; women >65 years
Smoking
Dyslipidemia (LDL-C >115 mg/dL)
Impaired fasting glucose (102-125 mg/dL) or abnormal glucose tolerance test result
Family history of premature cardiovascular disease
Abdominal obesity
Diabetes mellitus
Subclinical Target Organ Damage
Left ventricular hypertrophy
Carotid wall thickening or plaque
Low estimated glomerular filtration rate ≤60 mL/min/1.73 m^2
Microalbuminuria
Ankle-brachial BP index <0.9
Established Target Organ Damage
Cerebrovascular disease: ischemic stroke, cerebral hemorrhage, transient ischemic attack
Heart disease: myocardial infarction, angina, coronary revascularization, heart failure
Renal disease: diabetic nephropathy, renal impairment
Peripheral arterial disease
Advanced retinopathy: hemorrhages or exudates, papilledema

BP, Blood pressure; *LDL-C,* low-density lipoprotein cholesterol.

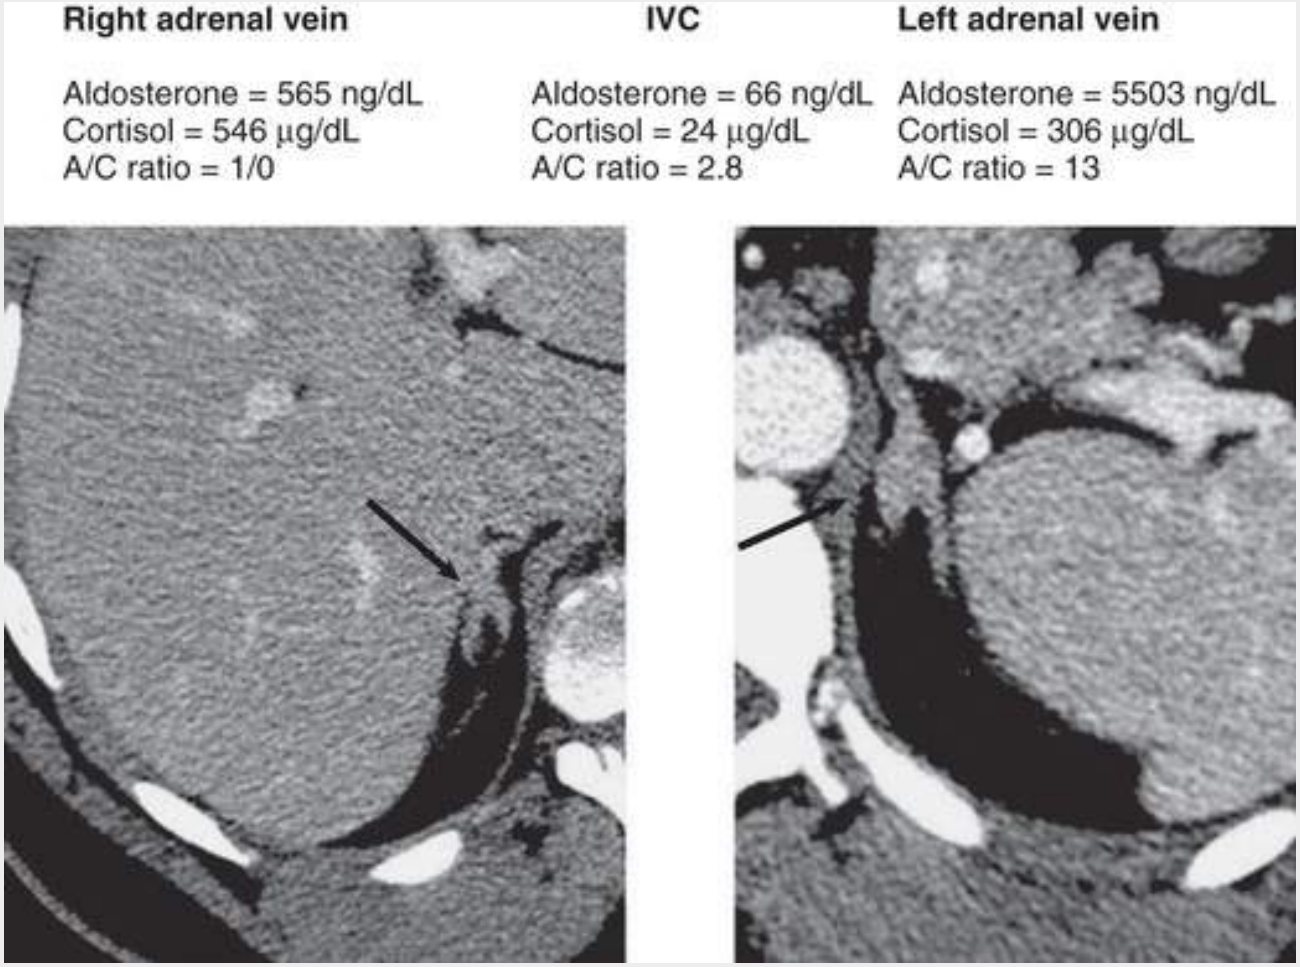
Modified from Mancia G, Fagard R, Narkkiewicz K, et al. 2013 ESH/ESC practice guidelines for the management of arterial hypertension: Blood Pressure 2014;23:3.

Methods to Improve CVD Risk Stratification in Hypertension

Visit-to-Visit Blood Pressure Variability

In addition to high average BP, mounting evidence indicates that high visit-to-visit variability in systolic BP independently predicts risk of CVD and CKD.[54] This fluctuation is most common in elderly patients and may represent a stiff aorta with impaired arterial baroreflexes and/or generalized anxiety disorder.[55]

Noninvasive Measurement of Aortic Stiffness and Central Aortic Pressure by Pulse Tonometry. Aortic stiffness is both the cause and the consequence of isolated systolic hypertension.[56] The central aortic pressure waveform is the sum of the pressure wave generated by the left ventricle and reflected waves from the peripheral circulation. When the large conduit arteries are healthy and compliant, the reflected wave merges with the incident wave during diastole, which enhances coronary blood flow. When the conduit arteries become stiff (as in ISH), however, pulse wave velocity increases such that the reflected and incident waves merge in systole, thereby augmenting systolic rather than diastolic pressure, which increases left ventricular afterload and reduces diastolic coronary flow. Sphymocor (AtCor Medical, Houston, Texas) is a commercial device that uses brachial artery BP and a generalized transfer function (proprietary software) to convert the radial waveform, measured by applanation tonography, to a derived central aortic BP waveform (**see eFig. 46.1**). This device has received FDA approval for clinical use (CPT code 93784). Pulse tonometry provides two principal measures of aortic stiffness that are typically increased in hypertension: pulse wave velocity and augmentation index.[40] Recently, a 24-hour ambulatory central BP monitor has received approval for clinical use.



EFIGURE 46.6 Computed tomography showing a left adrenal mass (*arrow*) and nodularity to the right adrenal gland. Adrenal vein sampling confirmed the diagnosis of a left aldosterone-producing adenoma. IVC, Inferior vena cava. (Case provided by Dr. Richard Auchus, Internal Medicine Department/Endocrinology Division, University of Michigan, Ann Arbor.)

Erectile Dysfunction.

Self-reported erectile dysfunction occurs in more than half of men with hypertension and independently predicts fatal and nonfatal cardiovascular events.[57]

Evaluation of Target-Organ Disease.

Traditionally, the complications of hypertension are viewed as *hypertensive* (caused by the increased level of BP per se) or *atherosclerotic* (caused by concomitant atherosclerosis), with BP elevation playing a variable role. This view is oversimplified, however, because both types of complications frequently coexist, as exemplified by hypertensive retinopathy[58] or hypertensive heart disease.

Pathogenesis of Hypertensive Heart Disease

Hypertension is a major risk factor not only for CAD, but also for left ventricular hypertrophy and heart failure.

Pressure Overload Hypertrophy

Left ventricular hypertrophy (LVH) is the anatomic hallmark of hypertensive heart disease. In hypertensive patients, LVH constitutes a powerful independent risk factor for heart failure (HF), ventricular arrhythmias and sudden cardiac death (SCD), ischemic stroke, atrial fibrillation, and embolic stroke.[59] It represents a failure to diagnosis and to treat hypertension effectively. Major advances have increased our understanding of the molecular signal transduction pathways underlying the hypertensive

myocardium.[60] These include myocyte hypertrophy *plus* medial hypertrophy of the intramyocardial coronary arterioles, collagen deposition leading to perivascular and interstitial fibrosis, capillary rarefaction, and cardiomyocyte apoptosis and autophagy; these processes culminate in altered contraction, relaxation (lusitropy), perfusion, and electrical activity[59] (**Fig. 46.15**). These alterations result from both pressure overload *plus* accompanying neurohormonal activation, fetal reprogramming of cardiomyocyte genes, and inflammation. In animal experiments, A II, aldosterone, norepinephrine, and prorenin accelerate pressure-overload cardiomyocyte hypertrophy and promote cardiac fibrosis, the hallmark of pathologic LVH (in contrast to physiologic hypertrophy of exercise training, which involves less fibrosis). Non–contrast-enhanced cardiac magnetic resonance imaging (MRI) can now quantify the extent of the fibrosis by using T1 mapping.[61]

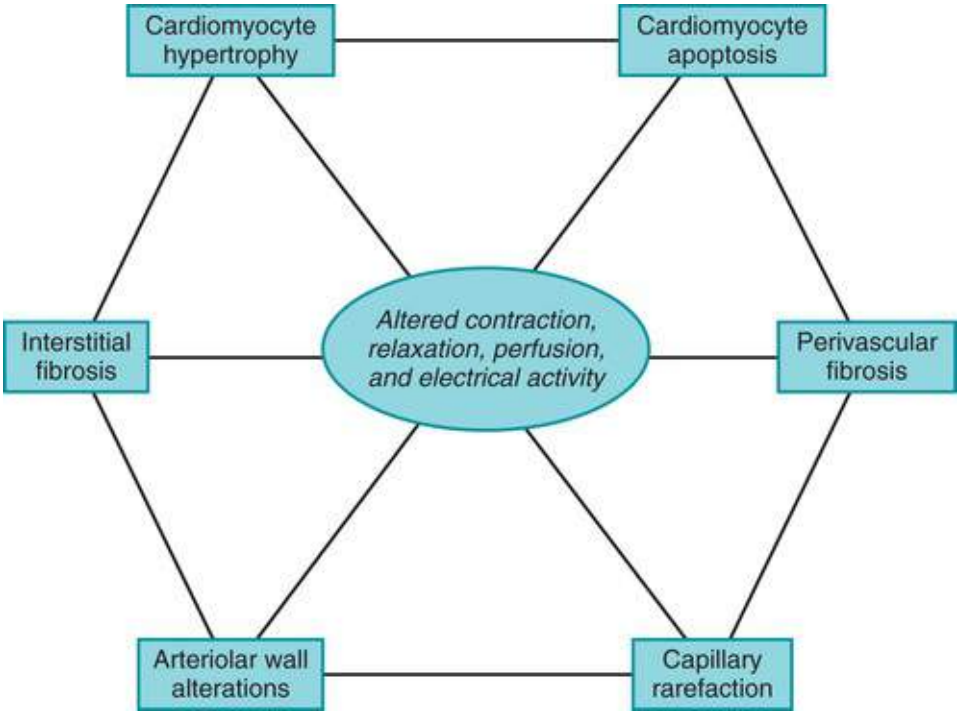


FIGURE 46.15 Mosaic of interactions among the microscopic lesions found in the hypertensive myocardium, which result in alterations in left ventricular function, demand ischemia, and arrhythmia.
(From Morena, MU, Eiros R, Gavira JJ, et al. The hypertensive myocardium. Med Clin North Am 2017;101:43, 2017.)

Classification and Complications

Hypertensive heart disease is classified by the severity of the complications[59] (**Table 46.4**). These range from mild asymptomatic diastolic dysfunction to heart failure with preserved (HFpEF) or reduced (HFrEF) ejection fraction. Hypertension is most likely to cause LVH and HF in black patients and patients with CKD.

TABLE 46.4

Classification of Hypertensive Heart Disease

Class I: Subclinical diastolic dysfunction by echocardiography without left ventricular hypertrophy
Asymptomatic patients with abnormal left ventricular relaxation/stiffness by Doppler echocardiography, a common finding in hypertensive individuals >65 years
Class II: Left ventricular hypertrophy
IIA: with normal functional capacity (NYHA Class I)
IIB: with abnormal functional capacity (NYHA Class >II)
Class III: Heart failure with preserved ejection fraction (HFpEF)
Class IV: Heart failure with reduced ejection fraction (HFrEF)

NYHA, New York Heart Association.

Impaired Coronary Vasodilator Reserve and Heart Failure

The hypertrophied hypertensive heart has normal resting coronary blood flow, but vasodilator reserve becomes impaired because a proportionate increase in the myocardial microvasculature does not accompany the increased myocyte mass, but rather by capillary rarefaction. Microvascular ischemia is a hallmark of hypertensive heart disease and is more common in women. Even in the absence of atherosclerosis, the hypertensive heart has blunted or absent coronary vasodilator reserve, producing subendocardial ischemia under conditions of increased myocardial oxygen demand. The combination of subendocardial demand ischemia and cardiac fibrosis impairs diastolic relaxation, leading to exertional dyspnea and HFpEF (**see Chapter 26**).

Large-Vessel Disease

Hypertension also constitutes a major risk factor for, and is present in, an overwhelming majority of patients with aortic dissection,[62] as well as abdominal aortic aneurysm (AAA), and peripheral arterial disease (**see Chapters 63 and 64**). One-time abdominal ultrasound screening for AAA is recommended after age 65 in smokers and in those with severe systolic hypertension, and it should be performed if aortic pulsations are detected below the umbilicus, because most AAAs occur below the origin of the renal arteries. Hypertension occurs in 50% of patients with Takayasu arteritis (**see Chapter 94**).

Cerebrovascular Disease

Hypertension is a major risk factor for stroke and dementia, often the two most dreaded complications of aging (**see Chapter 65**). Hypertension accounts for 50% of strokes. In hypertensive individuals, 80% of strokes are ischemic (thrombotic or embolic) and 20% are hemorrhagic. The onset of ischemic stroke greatly increases on awakening, corresponding to the morning surge in BP. Hypertensive patients with asymptomatic carotid bruits should undergo Doppler ultrasonography. Older patients with ISH have a particular risk of stroke. In middle-aged and elderly hypertensive patients, remarkably common asymptomatic cerebral white matter lesions on MRI likely accelerate the brain atrophy and vascular dementia that occur with aging.

Chronic Kidney Disease

Hypertension is second only to diabetes as a major risk factor for CKD. Traditionally, the typical pathologic change of small, scarred kidneys (termed *hypertensive nephrosclerosis*), likely the result of chronic exposure of the renal parenchyma to excessive pressure and flow, is the most common cause of end-stage renal disease among blacks. The greater susceptibility of non-Hispanic black hypertensive patients to nephrosclerosis is in part genetically determined by an African ancestral risk allele on

chromosome 22 (*APOL1* variants).[31]

Quantitative estimates of urinary albumin excretion and GFR (the latter from www.kdoqi.org) should be obtained from a spot urine collection. Microalbuminuria (defined as a urine albumin/creatinine ratio of 30 to 300 mg/day) is a sensitive early marker of CKD and independently predicts CVD complications from hypertension, because it reflects systemic vascular disease. In patients with hypertension, renal damage dramatically increases CVD risk. Most patients with hypertension-associated CKD die of MI, stroke, or SCD before developing ESRD.

Identifiable (Secondary) Forms of Hypertension

The third goal of the initial evaluation of the hypertensive patient is to detect identifiable causes of hypertension, thereby offering the possibility of cure to some patients, particularly those with severe or refractory hypertension (**Table 46.5**).

TABLE 46.5

Overall Guide to Workup for Identifiable Causes of Hypertension

DIAGNOSIS	DIAGNOSTIC PROCEDURE	
	Initial	**Additional**
Primary aldosteronism	Plasma renin, serum aldosterone	Salt loading, adrenal vein sampling
Chronic kidney disease	Urinalysis, serum creatinine, renal sonography	Isotopic renography, renal biopsy
Renovascular disease	Duplex Doppler sonography	Magnetic resonance or computed tomography (CT) angiography, digital subtraction renal angiography
Coarctation of the aorta	Blood pressure in legs	Echocardiography, magnetic resonance imaging (MRI), aortography
Cushing syndrome	1-mg dexamethasone suppression test	24-hour urinary cortisol, salivary cortisol, adrenal CT
Pheochromocytoma	Plasma-free metanephrines	24-hour urinary metanephrines and catecholamines; adrenal CT or MRI

Renal Parenchymal Disease

Renal parenchymal disease is the most common cause of secondary hypertension, responsible for 2% to 5% of cases. As chronic glomerulonephritis has become less common, diabetes and hypertension are the most common risk factors for CKD. Chronic kidney disease, defined by a reduction in the GFR to less than 60 mL/min/1.73 m^2 or persistent albuminuria of more than 300 mg/day, affects about 11% (19.2 million) of the adult U.S. population (**see Chapter 98**).

As previously noted, microalbuminuria of 30 to 300 mg/day relates closely to target-organ damage and should be determined in every new hypertensive patient by testing of a single-voided urine specimen. Measurement of the serum creatinine level by itself is an inadequate screening test for significant renal damage, particularly in elderly patients. Creatinine clearance should be calculated with the Cockcroft-Gault equation or the Modification of Diet in Renal Disease (MDRD) equation, although the latter does not account for other factors that affect creatinine generation by muscle, such as diet and physical conditioning. Serum cystatin C, an endogenous 13-kDa protein filtered by the glomeruli and reabsorbed and metabolized by the proximal tubular epithelium, with very little being excreted in the urine, has promise as a replacement for serum creatinine because it is less affected by muscle mass.[63] Once renal disease begins, it usually progresses, following the concept that a loss of filtration surface leads to both glomerular and systemic hypertension, which engenders more glomerular sclerosis, setting up a cycle of progressive disease. Identifying renal damage early therefore is critical, because removal of causal or aggravating factors can prevent the otherwise inexorable progress of renal damage. These factors include obstructive uropathy, hypovolemia, nephrotoxic agents, and most important, uncontrolled hypertension.

Acute Renal Diseases

Hypertension may appear with any sudden, severe insult to the kidneys that markedly impairs excretion of salt and water, which leads to volume expansion, or that reduces renal blood flow (e.g., sudden bilateral renal ischemia because of cholesterol emboli), or that activates the RAAS (e.g., bilateral ureteral obstruction). Reversal of hypertension has been particularly striking in men with high-pressure chronic retention of urine, who may manifest renal failure and severe hypertension, both of which may improve after relief of the obstruction. Hypertension can be the presenting sign of systemic vasculitis involving the kidney.

Two common classes of drugs—nonsteroidal anti-inflammatory drugs (NSAIDs) and RAAS inhibitors—can precipitate acute kidney injury (AKI) in patients with preexisting CKD. NSAIDs block the synthesis of prostaglandins, which act as vasodilators within the kidney. Renin-angiotensin inhibitors, including ACE inhibitors (ACEIs) and angiotensin receptor blockers (ARBs), may precipitate acute renal failure in patients with bilateral renovascular disease whose renal perfusion depends on high levels of A II.

Chronic Renal Diseases

The kidney is both the culprit and the victim in hypertension. In patients with CKD, an overly aggressive antihypertensive regimen, especially based on a potent RAAS inhibitor and potent diuretic, can precipitate AKI. However, a modest increase in the serum creatinine level, averaging 30% above baseline, predicts better preservation of renal function, presumably reflecting a successful reduction in intraglomerular pressure. About two thirds of patients with CKD have nocturnal masked hypertension detectable only by ABPM (**see Fig. 46.14**).[47]

Patients with diabetic nephropathy show particular protection against progressive renal damage by reduction of elevated BP with an ARB-based or ACEI-based regimen (**see Chapters 51 and 98**). The results of the Aliskiren Trial in Type 2 Diabetes Using Cardio-Renal Endpoints (ALTITUDE) show that addition of the direct renin inhibitor aliskiren to standard RAAS blockade with either an ACEI or an ARB in high-risk patients with type 2 diabetes did not improve cardiovascular or renal outcomes compared with standard RAAS blockade alone, but produced higher rates of adverse events, especially hyperkalemia and hypotension.[64] Thus the FDA issued a “black box” warning that aliskiren is contraindicated in patients with type 2 diabetes being treated with an ACEI or ARB and should be avoided in nondiabetic patients taking an ACEI or ARB for nondiabetic CKD. Most CKD patients require at least two more drugs in addition to an ACEI or ARB—typically, a loop diuretic or potent thiazide-type diuretic and a calcium channel blocker—to control their hypertension.

Hemodialysis Patients

In patients on dialysis, hypertension is a risk factor for mortality. Beyond the primary influence of excess fluid volume, the accumulation of endogenous inhibitors of NOS and sympathetic overactivity can accentuate hypertension. The BP may be particularly labile and sensitive to changes in fluid volume. In patients receiving maintenance hemodialysis every 48 hours, elevated BPs tend to fall progressively after dialysis, remain low during the first 24 hours, and rise again during the second day due to fluid retention. Gradually achieving and maintaining dry weight, as with 8-hour nocturnal hemodialysis, can greatly improve BP control.

Renal Transplantation

Although successful renal transplantation may cure primary hypertension, various problems can result, with about 50% of recipients becoming hypertensive within 1 year. These problems include stenosis of the renal artery at the site of anastomosis, rejection episodes, high doses of glucocorticoids and cyclosporine or tacrolimus, and excess renin derived from the retained diseased kidneys. ACEI or ARB therapy may obviate the need to remove the native diseased kidneys to relieve hypertension caused by their persistent secretion of renin. The source of the donor kidney may also play a role in the subsequent development of hypertension in the recipient. Hypertension occurs more frequently when donors have a family history of hypertension or when donors have died of subarachnoid hemorrhage and probably had high BP.

Renovascular Hypertension

Renovascular hypertension is a conundrum. Although the pathophysiology clearly involves A II–dependent hypertension, this involves a wide spectrum of disorders, beginning with (1) *incidental, hemodynamically insignificant renal artery stenosis* and progressing to (2) *renovascular hypertension* with reduced perfusion and activation of RAAS; (3) *accelerated cerebrovascular disease* with diastolic dysfunction, heart failure, and stroke; and (4) *ischemic nephropathy* with renal tissue hypoxia, extensive microvascular disease, and progressive renal atrophy.[65]

Classification

In the United States, *atherosclerotic renal artery stenosis* (ARAS) causes more than 85% of cases of renovascular disease (**Fig. 46.16**). Affecting the origin of the main renal artery, ARAS occurs mostly in older patients with CVD risk factors. In contrast, *fibromuscular disease* (FMD) involving mainly the distal two thirds and branches of the renal arteries appears most frequently in women between 20 and 60 years of age[66] (**see also Chapter 64 and Fig. 64.15**). FMD typically affects the media but can also affect the intima and adventitia. Carotid FMD and less often coronary artery FMD may accompany renal artery FMD, frequently presenting with dissection before the diagnosis of FMD.[67]

FIGURE 46.16 Computed tomography angiogram with three-dimensional reconstruction, showing a severe proximal atherosclerotic stenosis of the right renal artery and mild stenosis of the left renal artery **(A)** and the classic "string of beads" lesion of fibromuscular dysplasia (bilateral in this patient) **(B)**. (**See also Fig. 64.15**.) (Courtesy of Bart Dolmatch, MD.)

Other intrinsic and extrinsic causes of renovascular hypertension include arterial emboli in the renal artery or extrinsic compression of this vessel by nearby tumors. Renovascular stenosis is often bilateral, although usually one side predominates. Bilateral disease should be suspected in those with renal insufficiency, particularly if rapidly progressive oliguric renal failure develops without evidence of obstructive uropathy, and even more so if it develops after the start of ACEI or ARB therapy.

Mechanisms

Renovascular hypertension is triggered initially by renal ischemia causing secondary activation of the RAAS. At first, the normal contralateral kidney responds to the A II–dependent hypertension with pressure natriuresis, thus maintaining normal blood volume. With time the contralateral kidney becomes damaged, and as a result the increased BP no longer is offset by increased sodium excretion, leading to volume expansion and a secondary reduction in renin secretion from the stenotic kidney. The renal parenchyma can tolerate partial renal ischemia for a remarkably long time but eventually develops irreversible microvascular disease with inflammation, renal atrophy, and fibrosis.

Diagnosis

Table 46.6 lists the clinical features of patients with renovascular hypertension.[65] Most patients with ARAS are older persons with hypertension, hyperlipidemia, and evident CAD and/or peripheral artery disease and cerebrovascular disease. The three most specific presentations of severe ARAS are drug-refractory hypertension, flash pulmonary edema, and ischemic nephropathy. Such patients (<5% of all hypertensive persons) should be screened for renovascular hypertension. Young to middle-age women who have moderate to severe hypertension with little or no family history of hypertension should be screened for FMD. A whooshing or swishing sound with each heartbeat is a pathognomonic symptom of carotid FMD.[66] The initial screening test is noninvasive Duplex ultrasonography, which has a sensitivity of 75% and specificity of 90% when performed in an experienced vascular laboratory. If stenosis is detected and the resistive index is less than 80, indicating insignificant microvascular disease, high-grade stenosis should be confirmed by spiral CT or MR angiography (**Fig. 46.16**) unless there is advanced CKD, which increases the risk of contrast-induced AKI or gadolinium-induced fatal nephrogenic systemic fibrosis. Digital subtraction angiography (DSA) is the reference standard for making the diagnosis of a severe lesion with a gradient amenable to intervention.

TABLE 46.6

Clinical Clues for Renovascular Hypertension

1. Onset of hypertension before age 30 or after 50
2. Acceleration of treated primary hypertension
3. Deterioration in renal function in treated primary hypertension
4. Acute kidney injury (AKI) during treatment of hypertension
5. Flash pulmonary edema
6. Progressive renal failure
7. Refractory heart failure
8. Unilateral small (atrophic) kidney size by ultrasound examination

Modified from Textor SC. Renal arterial disease and hypertension. Med Clin North Am 2017;101:65.

Management

Balloon angioplasty without stenting is the treatment of choice for renal artery FMD (**see Chapters 64**

and 66). Outcomes are excellent when technically excellent results are achieved in experienced centers. With three negative major RCTs of stenting versus medical management, however, a conservative approach based on medical management of cardiovascular risk factors—with ACEI- or ARB-based antihypertensive regimen, statins, antiplatelet therapy, and smoking cessation—is the cornerstone for the treatment for ARAS. Notably, all three RCTs failed to enroll patients with the most severe ARAS who stand to benefit the most from stenting, namely, those with (1) intractable hypertension, (2) AKI induced by ACEI or ARB treatment of hypertension, or (3) recurrent, episodic (flash) pulmonary edema. Registry data strongly indicate that such patients are the best candidates for renal artery stenting.[65]

Renin-Secreting Tumors

Composed of juxtaglomerular cells or hemangiopericytomas, renin-secreting tumors occur mostly in young patients with severe hypertension, with very high renin levels in both peripheral blood and the kidney harboring the tumor, and with secondary aldosteronism manifested by hypokalemia. The tumor can generally be recognized by selective renal angiography, usually performed for suspected renovascular hypertension, although a few are extrarenal. More often, children with Wilms tumors (nephroblastoma) may have hypertension and high plasma renin and prorenin levels that revert to normal after nephrectomy.

Adrenal and Other Causes of Hypertension

Adrenal causes of hypertension include primary excesses of aldosterone, cortisol, and catecholamines; more rarely, excess deoxycorticosterone is present with congenital adrenal hyperplasia. Together, these conditions cause less than 1% of all cases of hypertension in general practice, yet primary aldosteronism accounts for 10% to 20% of patients referred to hypertension specialists. Despite their relative ease of recognition and the availability of simple efficient screening tests, these adrenal disorders are easily overlooked (**see Chapter 92**).

An increasingly common clinical problem is an incidentally discovered solitary adrenal mass—the *incidental adrenaloma*—which is found on 5% of abdominal CT scans obtained for nonadrenal indications.[8] Although most are benign and nonfunctional, an adrenal incidentaloma must never be ignored, because 10% to 15% will be either functional or malignant. The probability of adrenal cancer varies by the imaging characteristics. The risk of cancer is low if a non–contrast-enhanced CT scan shows a tumor density of less than 10 HU, consistent with low-density lipid; if an MRI scan confirms a high lipid content by loss of signal on out-of-phase images; or if the tumor is smaller than 4 cm. Tumors 4 cm or larger should be resected because many are malignant.

Table 46.5 lists the screening and confirmatory tests for adrenal hyperfunction: increased cortisol production (of subtle elevations with subclinical Cushing syndrome) in up to 33%, pheochromocytoma in 6%, and primary aldosteronism (Conn syndrome) in 1%.

Primary Aldosteronism and Other Forms of Mineralocorticoid-Induced Hypertension

Several syndromes of mineralocorticoid excess exist (**Table 46.7**). Of these, primary aldosteronism is by far the most common; it also is the most common reversible form of hypertension. Systemic hyperaldosteronism causes cardiac fibrosis (producing severe LVH, atrial fibrillation, CAD, ventricular tachycardia, and SCD), renal fibrosis with CKD, hypokalemia, endothelial dysfunction,

hyperparathyroidism, sleep apnea, and anxiety/depression. Spontaneous and inherited potassium channel mutations are the disease-causing mechanism in at least 50% of aldosterone-producing adenomas. The mutations make the potassium channel abnormally permeant to sodium, which depolarizes the adrenal glomerulosa cells to produce excessive calcium entry, the signal for both aldosterone secretion and cell proliferation.[68]

TABLE 46.7
Syndromes of Mineralocorticoid Excess

Adrenal Origin
Aldosterone Excess (Primary)
Aldosterone-producing adenoma Bilateral hyperplasia Primary unilateral adrenal hyperplasia Glucocorticoid-remediable aldosteronism (familial hyperaldosteronism, type I) Adrenal carcinoma Extra-adrenal tumors
Deoxycorticosterone Excess
Deoxycorticosterone-secreting tumors Congenital adrenal hyperplasia 11β-Hydroxylase deficiency 17α-Hydroxylase deficiency
Cortisol Excess
Cushing syndrome from ACTH-producing tumor Glucocorticoid receptor resistance
Renal Origin
Activating mutation of mineralocorticoid receptor Pseudohypoaldosteronism, type II (Gordon) 11β-Hydroxysteroid dehydrogenase deficiency *Congenital*: Apparent mineralocorticoid excess *Acquired*: Licorice, carbenoxolone

Pathophysiology of Mineralocorticoid Excess

Hyperaldosteronism results in excessive stimulation of the mineralocorticoid receptor in the distal nephron, causing excessive sodium retention through the ENaCs. This both expands the blood volume, causing severe hypertension, and drives the renal Na^+,K^+-ATPase, causing renal potassium wastage. Whereas the classic picture of primary aldosteronism is a young adult with severe systolic/diastolic hypertension and hypokalemia, in some patients the degree of renal potassium loss may be insufficient to decrease serum K^+ into the frankly hypokalemic range.

Diagnosis.

As detailed in the 2016 Endocrine Society guidelines,[69] the three steps to the systematic evaluation of suspected primary aldosteronism are screening, salt loading for biochemical confirmation, and adrenal vein sampling for localization. Screening is recommended only for hypertensive patients who have a higher likelihood of aldosterone-producing adenoma, including those with unprovoked hypokalemia or excessive hypokalemia on diuretic therapy, a family history of aldosteronism, resistant hypertension, or an adrenal incidentaloma. Hyperaldosteronism occurs in as many as 20% of patients with resistant hypertension, with two thirds of these having unilateral disease and thus surgical candidates.

Screening involves measurement of both plasma renin activity (PRA) and serum aldosterone. Although the test ordered is the aldosterone/renin ratio, a positive result should be based not on the ratio but rather on the finding of both an elevated plasma aldosterone level (>15 ng/dL) and a suppressed PRA (<1 ng/mL • h; with <0.6 being severely suppressed). Hypokalemia causes underestimation of the serum

aldosterone level; if the aldosterone level is borderline, the screening test should be repeated after giving enough KCl supplementation to bring the serum K^+ to greater than 4.0.

If the screening test is positive, the next step is 3-day oral salt-loading suppression of 24-hour urine aldosterone to document the autonomy of hyperaldosteronism; rapid intravenous saline suppression testing is less accurate and not recommended.[70] If the suppression test result is abnormal, adrenal vein sampling by an experienced tertiary center is strongly recommended to differentiate unilateral adenoma from bilateral hyperplasia and to confirm exactly which gland should be removed by laparoscopic surgery (**eFig. 46.6**). Because detection of microscopic adenomas may be below the resolution of CT scanning, and because minor adrenal nodularity and nonfunctioning adrenal incidentalomas are common, CT findings alone lead to the wrong conclusion in almost half the cases.[69] Adrenal vein sampling is reserved for patients who are surgical candidates and prefer surgery over medical management with an aldosterone antagonist–based regimen.

Differential Diagnosis: Mendelian Forms of Hypertension

In patients presenting with severe hypertension and hypokalemia, primary aldosteronism requires distinguishing from rare forms of mineralocorticoid-induced hypertension that are inherited as mendelian traits. Clinical clues of syndromic hypertension are premature onset (often before age 30), severity of the hypertension (frequently dramatic), and a compelling family history indicative of mendelian inheritance. All these familial syndromes involve excessive activation of ENaC as a final common mechanism, caused either by gain-of-function mutations of ENaC or the mineralocorticoid receptor or by increased production or decreased clearance of the mineralocorticoid receptor ligands, aldosterone, as well as deoxycorticosterone and cortisol (**Fig. 46.17**).

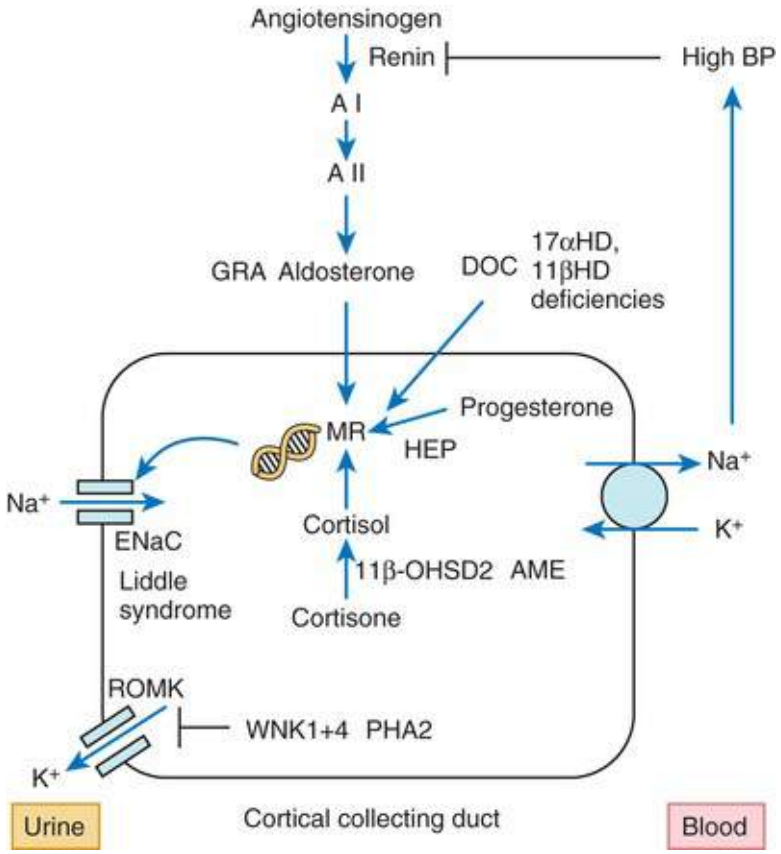

FIGURE 46.17 Mendelian forms of hypertension that cause mineralocorticoid-induced hypertension. AME, Apparent mineralocorticoid excess; A I, angiotensin I; A II, angiotensin II; BP, blood pressure; GRA, glucocorticoid-remediable aldosteronism; 11β-OHSD2, 11β-hydroxysteroid dehydrogenase type 2; DOC, deoxycorticosterone; ENaC, epithelial sodium channel; MR, mineralocorticoid receptor; PHA2, pseudohypoaldosteronism type II; ROMK, rectifying outer medullary potassium channel; WNK, with no lysine kinases; HEP, hypertension exacerbated by pregnancy; 11βHD, 11β-hydroxylase; 17αHD, 17α-hydroxylase. The effect of PHA2 on the activity of the thiazide-sensitive Na-Cl cotransporter in the distal collecting duct is not shown. See text for explanation. (Modified from Lifton RP, Gharavi AG, Geller DS. Molecular mechanisms of human hypertension. Cell 2001;104:545.)

One type, *familial glucocorticoid-remediable aldosteronism,* results from recombination of genes encoding the aldosterone synthase enzyme (CYP11B2), normally found only in the outer zona glomerulosa, and the 11β-hydroxylase enzyme (CYP11B1) in the zona fasciculata. The chimeric gene induces an enzyme that catalyzes the synthesis of 18-hydroxylated cortisol in the zona fasciculata. The glucocorticoid suppressibility of the syndrome occurs because this zone is under the control of adrenocorticotropic hormone (ACTH). Genetic testing for the chimeric gene should diagnose the syndrome, treatable by glucocorticoid suppression.

Another rare form is apparent mineralocorticoid excess caused by deficiency of the enzyme 11β-hydroxysteroid dehydrogenase type 2 (11β-OHSD2) in the renal tubule, where it normally converts cortisol, which can act on the mineralocorticoid receptor, to cortisone, which cannot. Persistence of high levels of cortisol induces all the features of mineralocorticoid excess. The 11β-OHSD2 enzyme may be congenitally absent (the syndrome of apparent mineralocorticoid excess) or inhibited by the glycyrrhizic acid contained in licorice. Another unusual syndrome with hypertension and hypokalemia but suppressed mineralocorticoid secretion is *Liddle syndrome,* in which the kidney reabsorbs excess sodium and wastes potassium because of a mutation in the beta or gamma subunits of the ENaC.

In most of these cases, volume expansion and severe hypertension cause feedback suppression of

plasma renin, and mineralocorticoid receptor activation leads to renal potassium wasting and hypokalemia. One exception is *pseudohypoaldosteronism type II*, in which the disease-causing mutation produces both low-renin and salt-sensitive hypertension caused by overactivity of the thiazide-sensitive Na^+/Cl^- cotransporter in the distal collecting duct and hyperkalemia caused by underactivity of the renal outer medullary potassium channel.

Therapy.

Laparoscopic adrenalectomy is recommended for patients with a unilateral aldosterone producing adenoma (*Conn syndrome*).[69] Those with bilateral hyperplasia are treated medically with an aldosterone antagonist (eplerenone or spironolactone) and other antihypertensive drugs as needed. Aldosterone antagonists also are an option for patients with unilateral adenoma who do not want surgery or do not have access to a tertiary hospital with both an interventional radiologist and endocrinologist with considerable experience in the performance and interpretation of adrenal vein sampling, a technically demanding procedure.[71] Laparoscopic adrenalectomy eliminates the need for antihypertensive medication in up to 50% of patients and reduces medication requirements in patients who may have coexisting primary hypertension or renal damage from prolonged exposure to elevated BP and undiagnosed hyperaldosteronism.

Cushing Syndrome

Hypertension occurs in about 80% of patients with Cushing syndrome. If left untreated, it can cause marked LVH and congestive heart failure. As with hypertension of other endocrine causes, the longer it is present, the less likely it will improve when the underlying cause is relieved (**see Chapter 92**).

Mechanism of Hypertension.

BP can increase for a variety of reasons. The secretion of mineralocorticoids can increase along with cortisol, which itself is a potent activator of the mineralocorticoid receptor. The excess cortisol can overwhelm the ability of renal 11β-OHSD2 to convert it to cortisone, which is not a mineralocorticoid receptor ligand; the excess cortisol overstimulates renal mineralocorticoid receptors to retain sodium and expand plasma volume. Cortisol stimulates the synthesis of renin substrate and the expression of A I receptors, which may cause enhanced pressor effects.

Diagnosis.

Cushing syndrome should be suspected in patients with truncal obesity, wide purple striae, thin skin, muscle weakness, and osteoporosis. If clinical features are suggestive, the diagnosis often can be either ruled out or virtually ensured by the measurement of free cortisol in a 24-hour urine sample, the simple overnight dexamethasone suppression test, or the determination of late-night salivary cortisol. Some cases of metabolic syndrome may be caused by subclinical Cushing syndrome.

Therapy.

In about two thirds of patients with Cushing syndrome, the process begins with overproduction of ACTH by the pituitary, which leads to bilateral adrenal hyperplasia (BAH). Although pituitary hyperfunction may reflect a hypothalamic disorder, most patients have discrete pituitary adenomas that can usually be resected by selective transsphenoidal microsurgery. An adrenal tumor, if present, should be removed surgically, with appropriate steroid coverage to avoid acute adrenal insufficiency. With earlier diagnosis and more selective surgical therapy, more patients with Cushing syndrome might be cured without the need for lifelong glucocorticoid replacement therapy and with permanent relief of their hypertension. Therapy may require a drug temporarily, but rarely permanently.

Congenital Adrenal Hyperplasia.

Enzymatic defects may induce hypertension by interfering with cortisol biosynthesis. Low levels of cortisol lead to increased ACTH levels; this increases the accumulation of precursors proximal to the enzymatic block, specifically deoxycorticosterone, which induces mineralocorticoid hypertension. The more common of these is *11-hydroxylase deficiency,* which has been attributed to various mutations in the gene and leads to virilization (from excessive androgens) and hypertension with hypokalemia (from excessive deoxycorticosterone). The other is *17-hydroxylase deficiency,* which also causes hypertension from excess deoxycorticosterone, in addition to failure of secondary sexual development because sex hormones are also deficient. Affected children are hypertensive, but the defect in sex hormone synthesis may not become obvious until pubertal failure is recognized in adolescence.

Pheochromocytoma and Paraganglioma

Pheochromocytomas are rare catecholamine-secreting tumors of the adrenal chromaffin cells. Paragangliomas are even rarer, extra-adrenal tumors of the sympathetic or vagal ganglion cells. For clinical purposes, the term *pheo* generally refers to any catecholamine-secreting tumor, whether a true adrenal pheochromocytoma or a functional extra-adrenal paraganglioma. The wild fluctuations in BP and dramatic symptoms of pheo usually alert both patient and physician to the possibility of this diagnosis (**Table 46.8**). However, such fluctuations may be missed, or as occurs in 50% of patients, the hypertension may be persistent. On one hand, the spells typical of a pheochromocytoma (with headache, sweating, palpitations, and pallor) may be incorrectly attributed to migraine, menopause, or panic attacks. On the other hand, most patients with severe paroxysmal hypertension do not have a pheochromocytoma but rather marked anxiety. When correctly diagnosed and treated, most pheos are curable. When undiagnosed or improperly treated, pheos can be fatal.[72,73] (**See Chapter 92** for details regarding the pathophysiology, diagnosis, and treatment of pheochromocytoma.)

TABLE 46.8

Features Suggestive of Pheochromocytoma

Hypertension, Persistent or Paroxysmal
Markedly variable blood pressures (± orthostatic hypotension)
Sudden paroxysms (± subsequent hypertension) in relation to:
Stress: anesthesia, angiography, parturition
Pharmacologic provocation: histamine, nicotine, caffeine, beta blockers, glucocorticoids, tricyclic antidepressants
Manipulation of tumors: abdominal palpation, urination
Rare patients persistently normotensive
Unusual settings
Childhood, pregnancy, familial
Multiple endocrine adenomas: medullary carcinoma of the thyroid (MEN-2), mucosal neuromas (MEN-2B)
Von Hippel–Lindau syndrome
Neurocutaneous lesions: neurofibromatosis
Associated Symptoms
Sudden spells with headache, sweating, palpitations, nervousness, nausea, vomiting
Pain in chest or abdomen
Associated Signs
Sweating, tachycardia, arrhythmia, pallor, weight loss

Other Causes of Hypertension

Hypertension has a host of other causes. One that is probably becoming more common is the ingestion of various drugs: prescribed (e.g., cyclosporine, tacrolimus, erythropoietin), over the counter (e.g., NSAIDs, ephedra), and illicit (e.g., cocaine, methamphetamine). As previously noted, obstructive sleep apnea

commonly coexists with hypertension, but causal attribution is unclear.

Coarctation of the Aorta

Congenital narrowing of the aorta can occur at any level of the thoracic or abdominal aorta, but typically localizes just beyond the origin of the left subclavian artery or distal to the insertion of the ligamentum arteriosum (**see Chapter 75**). With less severe postductal lesions, symptoms may not appear until the teenage years or later, particularly during pregnancy. Hypertension in the right arm with weak femoral pulses and a loud murmur heard over the back in a young adult strongly suggest coarctation. Up to 12% of young women with Turner syndrome have coarctation. The pathogenesis of the hypertension can involve more than simple mechanical obstruction and seems to involve systemic endothelial dysfunction. The diagnosis is usually made by suprasternal notch echocardiography and confirmed by cardiac MRI. Preoperative management with an ACEI followed by early repair in childhood is recommended to reduce recurrence of the coarctation and persistent or recurrent hypertension in adulthood.[8] Once repaired, patients may continue to have hypertension, which requires careful monitoring and treatment.

Hormonal Disturbances

As many as half of patients with various hormonal disturbances, including acromegaly, hypothyroidism, and hyperparathyroidism, have hypertension. Diagnosis of the last two conditions has been facilitated by readily available blood tests, and affected hypertensive patients can have high BP relieved by correction of the hormonal disturbance. Such relief occurs more frequently in patients with hypothyroidism than in those with hyperparathyroidism (**see Chapter 92**).

Future Perspectives

There now exists abundant evidence that masked hypertension—especially masked nocturnal hypertension, which can be diagnosed only by ambulatory blood pressure monitoring (ABPM)—constitutes a potent independent risk factor for myocardial infarction, stroke, end-stage renal disease, and death. There is an urgent need for properly powered, multicenter RCTs to prove unequivocally that treating masked nocturnal hypertension improves cardiovascular disease outcomes and renal outcomes and saves lives. Such findings would provide the rigorous evidence needed to expand the indications for ABPM, causing a sea change in the approach to the diagnosis and management of hypertension.

Systemic Hypertension

Management

Ronald G. Victor, Peter Libby

Hypertension remains the most common diagnosis in adult outpatient medicine and the most frequent indication for prescription drugs. Lifestyle modification, particularly at the societal level, can prevent or delay the development of hypertension. However, hypertension is becoming more prevalent in both developed and developing countries and remains poorly identified and poorly controlled in the United States and abroad.[1,2]

High blood pressure (BP) treatment yields large reductions in the risk for stroke, heart failure, renal failure, aortic dissection, coronary events, and death. Patients with the highest global cardiovascular (CV) risk benefit the most (**Fig. 47.1**).[1] With important exception of some forms of secondary hypertension, most cases of hypertension cannot be cured. Although interventions such as renal denervation or baroreflex activation therapy remain in development, effective tools—lifestyle modifications and antihypertensive drugs—permit management of hypertension. In this chapter, we discuss deployment of these tools based on the available evidence. Then, with hypertension guidelines in flux[3-15] because of different conclusions—from major new trials, meta-analyses, observational studies, and expert opinions—we provide a practical clinical approach to the management of hypertensive patients.

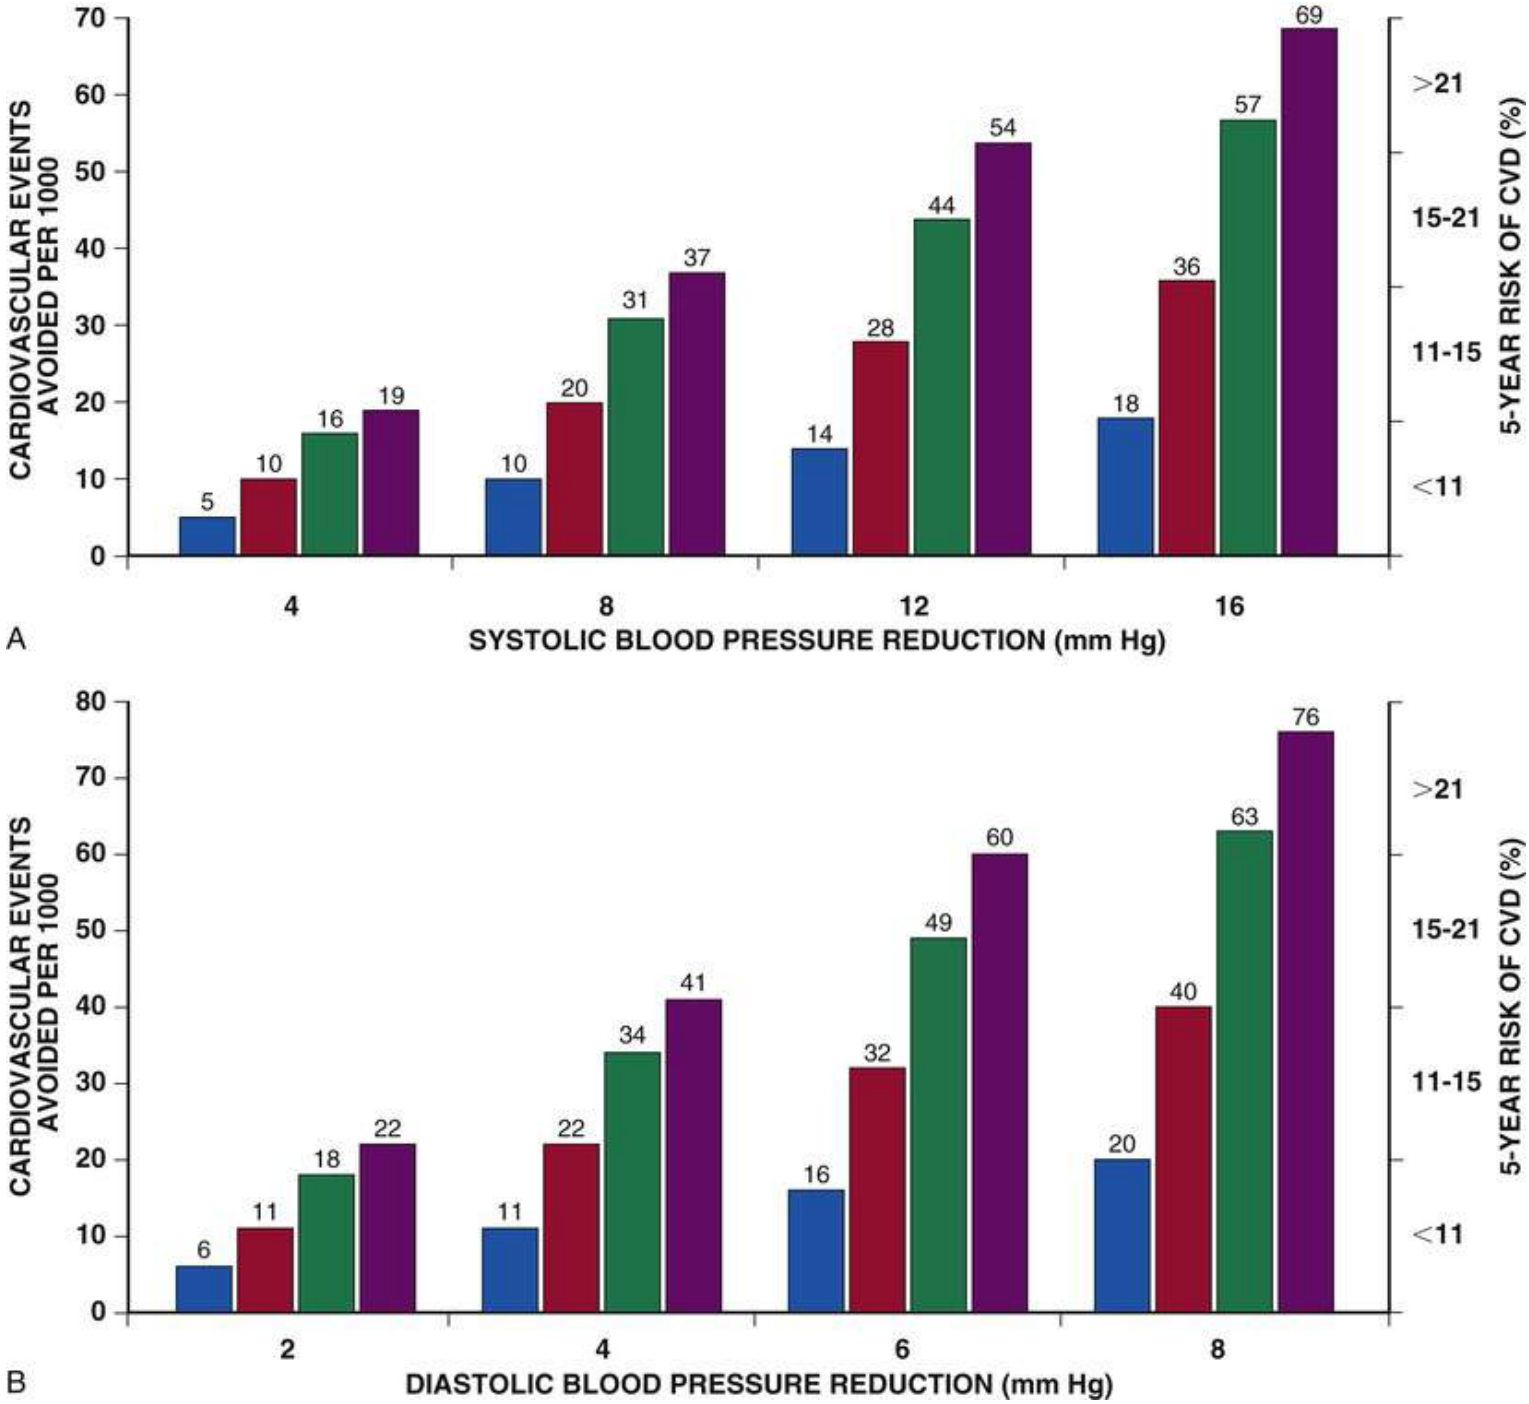

FIGURE 47.1 Avoidable cardiovascular disease (CVD) events by baseline risk and extent of lowering of systolic blood pressure **(A)** or diastolic blood pressure **(B).** (From Sundstrom J; The Blood Pressure Lowering Treatment Trialists' Collaboration. Blood pressure-lowering treatment based on cardiovascular risk: a meta-analysis of individual patient data. Lancet 2014;384:595.)

Lifestyle Modification

Lifestyle choices and interventions can influence BP and furnish a foundation for prevention and treatment of hypertension. The current evidence base regarding dietary patterns and specific dietary components has sufficient strength to merit recommendations both on a population, public health level and for the management of individual patients. Evidence regarding physical activity interventions has lagged behind the evidence base on dietary approaches to the treatment of hypertension. Limitations in the evidence base regarding lifestyle and BP management require consideration. First, few studies have examined the effects of lifestyle interventions on CV outcomes; most rely on BP as a surrogate endpoint. Second, the effect of

lifestyle modification on BP and CV outcomes may vary depending on sex, age, and ethnicity.[16-19] Few studies of lifestyle intervention have incorporated sufficient numbers of older adults or minority populations to provide strong evidence for specific recommendations for these important groups.

Dietary Interventions for Blood Pressure Control

Traditional approaches to the study of diet and BP have focused on individual nutrients. A more recent concept recognizes that consumption of specific nutrients occurs in the context of food in a diet (**see Chapter 49**). Thus the contemporary approach to studies of nutrition and health focuses more on dietary patterns than on specific nutrients. This section first considers dietary patterns that have undergone evaluation with respect to BP control, followed by individual macronutrients and micronutrients of particular interest in this regard.

Two dietary patterns in particular have undergone contemporary and rigorous study in relation to BP control: the Mediterranean diet pattern and the Dietary Approaches to Stop Hypertension (DASH) diet pattern. **Table 47.1** provides brief definitions of the Mediterranean and DASH diet patterns derived from the 2013 American Heart Association (AHA) and American College of Cardiology (ACC) guideline on lifestyle management to reduce CV risk[20-23] (**see Chapters 45, 46, and 49**).

TABLE 47.1

Descriptions of Dietary Patterns

Mediterranean Pattern
There is no uniform definition of the Mediterranean diet in the randomized controlled trials and cohort studies examined. The most common features in these studies were diets that were higher in fruits (particularly fresh fruits), vegetables (emphasizing root and green varieties), whole grains (cereals, breads, rice, pasta), and fatty fish (rich in omega-3 fatty acids); were lower in red meat (and emphasizing lean meats); had lower-fat or fat-free dairy products substituted for higher-fat dairy foods; and had oils (olive or canola), nuts (walnuts, almonds, or hazelnuts), or margarines blended with rapeseed or flaxseed oil instead of butter and other fats. The Mediterranean patterns examined tended to be moderate in total fat (32% to 35% of total calories), relatively low in saturated fat (9% to 10% of total calories), high in fiber (27 to 37 g/day), and high in polyunsaturated fatty acids (particularly omega-3 fatty acids).
Dietary Approaches to Stop Hypertension Pattern
The DASH dietary pattern is high in vegetables, fruits, low-fat dairy products, whole grains, poultry, fish, and nuts; low in sweets, sugar-sweetened beverages, and red meats; low in saturated fat, total fat, and cholesterol; and rich in potassium, magnesium, and calcium, as well as in protein and fiber.

Modified from the Eckel RH, Jakicic JM, Ard JD, et al. 2013 AHA/ACC guideline on lifestyle management to reduce cardiovascular risk: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. J Am Clin Cardiol 2014;63(25 Pt B):2960-84.

Mediterranean Diet Pattern

The PREDIMED (Prevención con Dieta Mediterránea) study stimulated interest among CV specialists in the potential benefits of a Mediterranean diet.[24] This trial showed an overall reduction in CV outcomes in the dietary intervention groups driven by a decrease in stroke, an endpoint closely associated with BP.[25] Meta-analysis shows small overall reductions in BP associated with a Mediterranean diet. Consumption of a Mediterranean diet pattern correlated with improvement in numerous biomarkers associated with CV benefit, including anti-inflammatory effects, as assessed by reduced C-reactive protein levels.[26] However, the most recent AHA/ACC guidelines on lifestyle management assessed the strength of evidence as “low” regarding consumption of a Mediterranean diet pattern versus a low-fat dietary pattern.

DASH Diet Pattern

The DASH diet (**Table 47.1**) evolved from studies supported by the U.S. National Heart, Lung and Blood

Institute (NHLBI).[27,28] These randomized, controlled DASH feeding studies showed that this dietary pattern could lower systolic blood pressure (SBP) by more than 5 mm Hg in adults with hypertension compared with the control diet, findings buttressed by meta-analyses. Members of minority groups may have larger drops in BP than white participants. The 2013 AHA/ACC guidelines consider the strength of evidence "high" for adherence to the DASH diet in individuals with hypertension.[20]

Sodium Consumption and Blood Pressure

The relationship between sodium and BP provides a particularly important example of the necessity of considering public health interventions, as well as lifestyle change, in individual patients to control CV risk. The effects of sodium intake on BP and the CV benefits of limiting sodium consumption continue to generate controversy. In May 2013 the U.S. Institute of Medicine (IOM) released a report on sodium intake in populations that assessed the evidence in this regard.[29] The IOM committee identified many methodologic concerns about studies of sodium intake and health, yet the report concluded that the weight of the evidence supported a link between higher levels of sodium consumption and CV risk but judged the evidence insufficient to support a restriction in sodium intake to below 2.3 g daily. A compilation of results from four studies affirmed the relationship between high sodium excretion and increased SBP and CV events, but with a "J curve" showing worsened outcomes at very low levels.[30] An analysis of TOHP (Trials of Hypertension Prevention) showed during long-term follow-up a lower but nonsignificant reduction in mortality in the active sodium reduction group, but a significant continuous relationship between sodium intake and mortality by spline analysis, without evidence of nonlinearity.[31] The different conclusions may be related to the method used to estimate dietary sodium consumption: four to seven 24-hour urine sodium collections per patient in TOHP compared with either a single 24-hour urine sodium or a single spot urine sodium in the studies indicating a J curve. Some question the justification for a population-wide policy to encourage very low sodium intake.[32] For hypertensive individuals or those with or at high risk for CV events, at least moderate sodium restriction does appear appropriate. An estimated 1.65 million deaths worldwide could result from sodium intake above 2 g daily.[33]

The 2013 AHA/ACC lifestyle management guidelines concluded that in adults age 25 to 80 with SBP of 120 to 159 mm Hg, reducing sodium intake lowers BP.[20] The guidelines further found the evidence "strong" that for adults age 30 to 80 with or without hypertension, reduction of sodium intake by approximately 1 g daily lowers SBP by 3 to 4 mm Hg. The guidelines judged the strength of evidence insufficient to support an association between sodium intake and the development of heart failure (HF) or worsened CV outcomes in patients with established HF.

Potassium Intake and Blood Pressure

Considerable observational data suggest an association between high potassium intake and lower BP. Increased consumption of potassium may lower BP, particularly in blacks compared with whites. Even though the American Society of Hypertension (ASH) recommends an increase in potassium intake to 4.7 g daily (the level provided in the DASH diet), the 2013 AHA/ACC lifestyle guidelines find the strength of evidence insufficient to establish a relationship between increased dietary potassium and lower BP or altered risk for coronary heart disease (CHD), HF, or CV mortality.[20]

Carbohydrate Consumption and Blood Pressure

The observational data base yields disparate data regarding the effect of the amount and composition of dietary carbohydrates on BP. The 2013 AHA/ACC lifestyle guidelines considered the strength of

evidence insufficient to make recommendations regarding the potential benefits of low-glycemic diets versus high-glycemic diets for individuals without diabetes.[20]

Ethanol Intake and Blood Pressure

A large body of observational evidence supports higher levels of BP in association with excessive alcohol intake.[34] Based on observational data and this meta-analysis, the ASH recommends limiting consumption to one alcoholic drink per day in women and no more than two alcoholic drinks per day in men.

Sugar-Sweetened Beverages

The increased consumption of sugar-sweetened beverages (SSBs) worldwide has been linked to the epidemic of obesity, particularly in young persons.[35] Evidence also supports an association between increased consumption of SSBs and higher levels of BP. A prospective analysis of the PREMIER study showed that after adjustment for confounders, a reduction in SSBs by one serving daily resulted in an almost 2–mm Hg decrease in SBP.[36] An international study of the effect of macronutrients and micronutrients on BP reported cross-sectional associations of SSBs with BP and found that one serving of an SSB daily was associated with a difference in SBP of greater than 1.5 mm Hg. This and other analyses showed a direct relationship between fructose and glucose intake with BP.[36,37] These observational and trial data suggest that curbing SSB consumption could lower BP in the population, and that restriction of SSB intake should be considered in individuals with established hypertension.

Other Macronutrients and Micronutrients and Blood Pressure Control

Many studies have linked other macronutrients and micronutrients with BP control. The previous discussion considered those supported by the strongest evidence base. **Table 47.2** provides a more ample list of the dietary factors and dietary patterns implicated in BP control, with estimates of the strength of the evidence adapted from the ASH position paper on dietary approaches to lower BP.[16]

TABLE 47.2

Effects of Dietary Factors and Dietary Patterns on Blood Pressure: Summary of the Evidence

	HYPOTHESIZED EFFECT	EVIDENCE*
Weight	Direct	+/+
Sodium chloride (salt)	Direct	+/+
Potassium	Inverse	+/+
Magnesium	Inverse	+/−
Calcium	Inverse	+/−
Alcohol	Direct	+/+

DASH, Dietary Approaches to Stop Hypertension.

Modified from Appel LJ. ASH position paper: Dietary approaches to lower BP. J Am Soc Hypertens 2009;3:321.

Obesity and Body Weight

Considerable observational data support a relationship between body mass index (BMI) and the development of hypertension across broad populations and outcomes, including mortality in those with morbid obesity.[38] Visceral adiposity and other ectopic fat deposits may also be associated with hypertension.[39] As with other components of "metabolic syndrome," hypertension may develop in Asians at a lower waist circumference than in whites or blacks. Weight reduction might eliminate considerable morbidity associated with hypertension and lessen the number and dosage of BP drugs and thus unwanted medication side effects (**Table 47.3**)[40] (**see Chapter 50**).

TABLE 47.3

Risk for Hypertension According to Individual Factors Evaluated on the Basis of Estimated Population Attributed Risk

FACTOR	RISK (95% CI)
BMI ≥25 kg/m^2	50% (49-52%)
Non-narcotic analgesic use	17% (15-19%)
No DASH diet	14% (10-17%)
No vigorous exercise	14% (10-19%)
No or excessive alcohol	10% (8-12%)
Folic acid use ≤400 μg/day	4% (1-7%)

Modified from Liebson PR. Diet, lifestyle, and hypertension and Mediterranean diet and risk of dementia. Prev Cardiol 2010;13:94.

Physical Activity

Epidemiologic and observational studies have linked insufficient physical activity to increased CV risk. Because physical activity influences both CV fitness and body weight and visceral adiposity, the mechanisms through which exercise interacts with CV risk factors—and potentially with outcomes—remain difficult to define. Moreover, the effects of physical activity depend on whether the activity involves aerobic exercise, strength training, or a combination of both. In the case of BP control, the response to physical activity may be heterogeneous. Some individuals may have increases in BP when they undergo exercise training, whereas others may have reductions. The effects of physical activity on BP also depend on whether acute effects during or immediately following exercise are measured versus chronic changes in this risk factor.[41] An occasional hypertensive patient may even experience symptomatic hypotension immediately after exercise, thereby requiring a reduction in the dose of BP medication. As in other aspects of lifestyle intervention, few studies have examined actual CV outcomes rather than biomarkers or surrogate endpoints.[37] Meta-analyses support benefits of exercise interventions.[42] Some evidence supports a genetic basis in determining the BP response to exercise, but no clinically applicable findings have emerged from such genomic analyses thus far.[43] Some evidence supports a decrease in biomarkers of inflammation with interval exercise training in patients with hypertension.[44]

The 2013 AHA/ACC guideline summarizes an extensive evidentiary review that includes the 2008 report of the Physical Activity Guidelines Advisory Committee of the U.S. Department of Health and Human Services.[45] The 2013 guideline database included 15 recent meta-analyses. The guideline states that in adults with or without hypertension, aerobic physical activity reduces SBP up to 5 mm Hg, with high strength of evidence. The committee concluded that the evidence was insufficient to provide an assessment of the effect of resistance exercise training on BP. They similarly pointed to a paucity of data regarding combined aerobic and resistance exercise intervention on regulation of BP. The committee provided a grade B recommendation that all adults engage in regular physical activity (**Table 47.4**). An AHA Scientific Statement on Alternative Approaches to Lowering Blood Pressure found the evidence strongest for resistance and aerobic exercise as an adjunct to treatment of hypertension.[46]

TABLE 47.4

Diet and Physical Activity Recommendations for Lowering Blood Pressure (BP)

Dietary Recommendations
1. Advise adults who would benefit from BP lowering to consume a dietary pattern that emphasizes intake of vegetables, fruits, and whole grains; includes low-fat dairy products, poultry, fish, legumes, nontropical vegetable oils, and nuts; and limits intake of sweets, SSBs, and red meat: a. Adapt this dietary pattern to appropriate calorie requirements, personal and cultural food preferences, and nutrition therapy for other medical conditions (including diabetes mellitus). b. Achieve this pattern by following plans such as the DASH dietary pattern, the U.S. Department of Agriculture (USDA) Food Pattern, or the AHA Diet.
NHLBI grade: A (strong); ACC/AHA COR: I; LOE: A.
2. Advise adults who would benefit from BP lowering to lower sodium intake.
NHLBI grade: A (strong); ACC/AHA COR: I; LOE: A.
3. Advise adults who would benefit from BP lowering to a. Consume no more than 2400 mg/day of sodium. b. Further reduce sodium intake to 1500 mg/day because it is associated with an even greater reduction in BP. c. Reduce sodium intake by at least 1000 mg/day because this will lower BP even if the desired daily sodium intake is not yet achieved.
NHLBI grade: B (moderate); ACC/AHA COR: IIa; LOE: B.
4. Advise adults who would benefit from BP lowering to combine the DASH dietary pattern with lower sodium intake.
NHLBI grade: A (strong); ACC/AHA COR: I; LOE: A.
Physical Activity Recommendations
In general, advise adults to engage in aerobic physical activity to lower BP: 3-4 sessions a week lasting on average 40 minutes per session and involving physical activity of moderate to vigorous intensity.
NHLBI grade: B (moderate); ACC/AHA COR: IIa; LOE: A.

COR, Class of recommendation; *LOE,* level of evidence; *DASH,* Dietary Approaches to Stop Hypertension; *SSBs,* sugar-sweetened beverages.

Modified from the Eckel RH, Jakicic JM, Ard JD, et al. 2013 AHA/ACC guideline on lifestyle management to reduce cardiovascular risk: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. J Am Clin Cardiol 2014;63(25 Pt B):2960-84.

Cigarette Smoking

The effect of cigarette smoking on hypertension and outcomes in hypertensive patients remains difficult to define because of confounding by increases in waist girth with smoking cessation.[47] Each cigarette evokes a transient pressor response that dissipates over the next hour. Despite the lack of precise mechanistic information regarding smoking and BP control, the overwhelming deleterious effect of smoking on CV risk, as well as the public health benefits of preventing the start of smoking and promoting cessation of smoking, renders this issue moot for public health and individual patient management.

Barriers to Adoption and Maintenance of Lifestyle Change and Possible Solutions

In practice, encouraging sustainable lifestyle change has proved extremely difficult. Substantial recent efforts have explored strategies and tools for encouraging the adoption of healthier lifestyles, including weight control, diet, and physical activity. Some challenges to lifestyle change identified in the literature will resonate with practitioners. Individuals often express a low desire for, interest in, or awareness of dietary change, including weight loss, decreased sodium intake, smoking cessation, or reduced alcohol consumption. Barriers to adoption of physical activity recommendations include comorbid conditions that limit physical activity, as well as limited time.[48] Contemporary adjuncts to the usual medical model for lifestyle intervention include Internet-based interventions, which are currently under intense evaluation.[40,49-51] Given its critical importance for CV and metabolic health, effective measures for implementing and sustaining lifestyle change should remain an important goal for research and process improvement.

Antihypertensive Drugs

Although all hypertensive individuals should heed the lifestyle measures previously outlined, most also will require drug therapy to optimize outcomes. Metaregression analyses of hundreds of thousands of hypertensive patients in randomized controlled trials (RCTs) have indicated that reduction in BP (hemodynamic load) explains most of the CV benefits of treating hypertension, with minor differences noted across major drug classes.[52] The U.S. Food and Drug Administration (FDA) has approved numerous oral antihypertensive drugs (**Table 47.5**). Some drug classes have contraindications (**Table 47.6**). Certain patient subsets have preferred antihypertensive drug classes (**Table 47.7**).

TABLE 47.5

Oral Antihypertensive Drugs

DRUG	DOSE RANGE, TOTAL mg/day (DOSES PER DAY)
Diuretics	
Thiazide-Type Diuretics	
Indapamide	0.625-2.5 (1)
Chlorthalidone	6.25-50 (1)
HCTZ	6.25-100 (1)
Metolazone	2.5-5 (1)
Loop Diuretics	
Furosemide	20-160 (2)
Torsemide	2.5-0 (1-2)
Bumetanide	0.5-2 (2)
Ethacrynic acid	25-100 (2)
Potassium-Sparing Diuretics: Mineralocorticoid Receptor Antagonists	
Eplerenone	25-100 (1-2)
Spironolactone	12.5-100 (1-2)
Other Potassium-Sparing Diuretics	
Amiloride	5-20 (1)
Triamterene	25-100 (1)
Beta Blockers	
Standard Beta Blockers	
Acebutolol	200-800 (2)
Atenolol	25-100 (1)
Betaxolol	5-20 (1)
Bisoprolol	2.5-20 (1)
Carteolol	2.5-10 (1)
Metoprolol	50-450 (2)
Metoprolol XL	50-200 (1-2)
Nadolol	20-320 (1)
Penbutolol	10-80 (1)
Pindolol	10-60 (2)
Propranolol	40-180 (2)
Propranolol LA	60-180 (1-2)
Timolol	20-60 (2)
Vasodilating Beta Blockers	
Carvedilol	6.25-50 (2)
Carvedilol CR	10-40 (1)
Nebivolol	5-40 (1)
Labetalol	200-2400 (4)
Calcium Channel Blockers	
Dihydropyridines	
Amlodipine	2.5-10 (1)
Felodipine	2.5-20 (1-2)
Isradipine CR	2.5-20 (2)
Nicardipine SR	30-120 (2)
Nifedipine XL	30-120 (1)
Nisoldipine	10-40 (1-2)
Nondihydropyridines	
Diltiazem CD	120-540 (1-2)
Verapamil HS	120-480 (1-2)
Angiotensin-Converting Enzyme Inhibitors	
Benazepril	10-80 (1-2)
Captopril	25-150 (2)
Enalapril	2.5-40 (2)
Fosinopril	10-80 (1-2)

Lisinopril	5-80 (1-2)
Moexipril	7.5-30 (1)
Perindopril	4-16 (1)
Quinapril	5-80 (1-2)
Ramipril	2.5-20 (1)
Trandolapril	1-8 (1)
Angiotensin Receptor Blockers	
Azilsartan	40-80 (1)
Candesartan	8-32 (1-2)
Eprosartan	400-800 (1-2)
Irbesartan	75-300 (1)
Losartan	25-100 (2)
Olmesartan	5-40 (1)
Telmisartan	10-80 (1)
Valsartan	80-320 (2)
Direct Renin Inhibitor	
Aliskiren	75-300 (1)
Alpha Blockers	
Doxazosin	1-16 (1)
Prazosin	1-40 (2-3)
Terazosin	1-20 (1)
Phenoxybenzamine	20-120 (2) for pheochromocytoma
Central Sympatholytics	
Clonidine	0.3-1.2 (3)
Clonidine patch	0.1-0.6 (weekly)
Guanabenz	2-32 (2)
Guanfacine	1-3 (1) (at bedtime)
Methyldopa	250-1000 (2)
Reserpine	0.05-0.25 (1)
Direct Vasodilators	
Hydralazine	25-300 (3)
Minoxidil	2.5-100 (1-2)
Fixed-Dose Combinations	
Aliskiren/HCTZ	75-300/12.5-25 (1)
Amiloride/HCTZ	5/50 (1)
Amlodipine/benazepril	2.5-5/10-20 (1)
Amlodipine/valsartan	5-10/160-320 (1)
Amlodipine/olmesartan	5-10/20-40 (1)
Amlodipine/telmisartan	5-10/40-80 (1)
Atenolol/chlorthalidone	50-100/25 (1)
Azilsartan/chlorthalidone	40/12.5-25 (1)
Benazepril/HCTZ	5-20/6.25-25 (1)
Bisoprolol/HCTZ	2.5-10/6.25 (1)
Candesartan/HCTZ	16-32/12.5-25 (1)
Enalapril/HCTZ	5-10/25 (1-2)
Eprosartan/HCTZ	600/12.5-25 (1)
Fosinopril/HCTZ	10-20/12.5 (1)
Irbesartan/HCTZ	15-30/12.5-25 (1)
Losartan/HCTZ	50-100/12.5-25 (1)
Olmesartan/amlodipine	20-40/5-10 (1)
Olmesartan/HCTZ	20-40/12.5-25 (1)
Olmesartan/amlodipine/HCTZ	20-40/5-10/12.5-25 (1)
Spironolactone/HCTZ	25/25 (1/2-1)
Telmisartan/HCTZ	40-80/12.5-25 (1)
Telmisartan/amlodipine/HCTZ	40-80/2.5-10/12.5-25 (1)
Trandolapril/verapamil	2-4/180-240 (1)
Triamterene/HCTZ	37.5/25 (½ -1)
Valsartan/HCTZ	80-160/12.5-25 (1)
Valsartan/amlodipine/HCTZ	80-160/5-10/12.5-25 (1)

HCTZ, Hydrochlorothiazide.

TABLE 47.6

Contraindications to Use of Specific Antihypertensive Drugs

DRUG	COMPELLING	POSSIBLE
Diuretics (thiazides)	Gout	Metabolic syndrome Glucose intolerance Pregnancy Hypercalcemia Hypokalemia
Beta blockers	Asthma Atrioventricular block (grade 2 or 3)	Metabolic syndrome Glucose intolerance (except for vasodilating beta blockers) Athletes and physically active patients Chronic obstructive pulmonary disease
Dihydropyridine calcium channel blockers		Tachyarrhythmia Heart failure
Nondihydropyridine calcium channel blockers	Atrioventricular block (grade 2 or 3, trifascicular block) Severe left ventricular heart dysfunction Heart failure	
Angiotensin-converting enzyme inhibitors	Pregnancy Angioedema Hyperkalemia Bilateral renal artery stenosis	Women with childbearing potential
Angiotensin receptor blockers	Pregnancy Hyperkalemia Bilateral renal artery stenosis	Women with childbearing potential
Aldosterone antagonists	Acute or severe renal failure (estimated glomerular filtration rate <30 mL/min) Hyperkalemia	

TABLE 47.7

Preferred Antihypertensive Drugs for Specific Conditions

CONDITION	DRUG OR DRUGS
Patients with prehypertension	ARB?
Hypertensive patients in general	CCB, ARB or ACEI, D
Hypertension in older patients	CCB, ARB or ACEI, D
Hypertension with LVH	ARB, D, CCB
Hypertension in patients with diabetes mellitus	CCB, ACEI or ARB, D
Hypertension in patients with diabetic neuropathy	ARB, D
Hypertension in patients with nondiabetic chronic kidney disease	ACEI, BB, D
BP reduction for secondary prevention of coronary events	ACEI, CCB, BB, D
BP reduction for secondary prevention of stroke	ACEI + D, CCB
BP for patients with heart failure	D, BB, ACEI, ARB, MR antagonists
Pregnancy	BB (labetalol), CCB (nifedipine)
Aortic aneurysm	BB
Atrial fibrillation, ventricular rate control	BB, non-DHP CCB

ACEI, Angiotensin-converting enzyme inhibitor; *ARB,* angiotension receptor blocker; *CCB,* calcium channel blocker; *BB,* beta blocker; *D,* diuretic; *LVH,* left ventricular hypertrophy; *MR,* mineralocorticoid receptor; *DHP,* dihydropyridine.

Modified from Mancia G, Fagard R, Narkiewicz K, et al: 2013 ESH/ESC guidelines for the management of arterial hypertension: The Task Force for the Management of Arterial Hypertension of the European Society of Hypertension (ESH) and of the European Society of Cardiology (ESC). Eur Heart J 31:1281, 2013.

First-Line Drug Classes

The current practice guidelines[3-15] (see end of chapter) all recommend initiating treatment of hypertension with one or more of three classes of first-line BP-lowering agents: (1) calcium channel blockers (CCBs); (2) renin-angiotensin system (RAS) inhibitors, either angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin receptor blockers (ARBs); and (3) thiazide-type diuretics. These drugs reduce the risk for nonfatal and fatal CV events. They have additive effects when used in combination. Although beta-adrenergic blockers (beta blockers) are first-line drugs for angina and HF, experts disagree whether they

should be included among the first-line drugs for uncomplicated hypertension because of their inferior stroke protection and increased risk for incident diabetes. Experts also differ in the emphasis placed on diuretics.

Calcium Channel Blockers for Hypertension

As popular antihypertensive drugs, CCBs are generally well tolerated, do not require monitoring with blood tests, and have proved safe and effective in many large RCTs. CCBs also have antianginal and some antiarrhythmic effects and seem to provide more protection against cerebrovascular accident (stroke) than other antihypertensive agents. ALLHAT (Antihypertensive Lowering to Prevent Heart Attack Trial) and subsequent RCTs showed that CCBs (represented by amlodipine) prevent coronary events as effectively as diuretics and RAS blockers.[53] These data allayed earlier concerns that long-acting CCBs might cause excess coronary events.

Mechanism of Action

All CCBs block the opening of voltage-gated (L-type) calcium (Ca^{2+}) channels in cardiac myocytes and vascular smooth muscle cells. They lower BP by causing peripheral arterial dilation, with the rank order of potency being dihydropyridines > diltiazem > verapamil.

Clinical Use

Amlodipine, by far the best studied of the dihydropyridine CCBs, has undergone evaluation in multiple RCTs. In ALLHAT, amlodipine was equivalent to chlorthalidone (a potent thiazide-like diuretic) and lisinopril (an ACEI) in protecting against nonfatal coronary events, stroke, and death but provided less protection against HF.[53] Advantages of amlodipine include predictable dose-dependent potency, once-daily dosing because of its long half-life, tolerability, and cost (≤$10 per month for generic amlodipine). Unlike diuretics and RAS inhibitors, a high-salt diet or concurrent nonsteroidal anti-inflammatory drug (NSAID) therapy does not compromise the effectiveness of dihydropyridine CCBs. These drugs have some diuretic action (due to dilation of the afferent renal arteriole), which may reduce requirements for additional diuretic therapy for mild hypertension. Unlike ACEIs, they lower BP and prevent hypertensive complications equally in black and nonblack patients.[53] ASCOT (Anglo-Scandinavian Cardiovascular Outcomes Trial)[54] and the ACCOMPLISH (Avoiding Cardiovascular Events Through Combination Therapy in Patients Living with Systolic Hypertension)[55] trial indicated that amlodipine plus an ACEI is one of the most effective drug combinations for preventing CV complications of hypertension. For comparable reductions in office (and ambulatory) BP, amlodipine/ACEI combination therapy improved CV outcomes better than did beta-blocker/thiazide combination therapy in ASCOT or than did ACEI/thiazide combination therapy in ACCOMPLISH.[55] Multiple fixed-dose single-pill combinations of amlodipine with an ACEI or an ARB are available; some have added a thiazide for triple therapy (**see Table 47.5**).

Dihydropyridine CCBs such as amlodipine are less renoprotective than ACEIs or ARBs in patients with proteinuric chronic kidney disease (CKD); such patients should not receive amlodipine as first-line therapy, but a CCB may be useful as adjunctive therapy after initiation of appropriate first-line therapy with an ACEI or ARB and a diuretic. Verapamil is weakly antihypertensive and has limited usefulness because of dose-dependent constipation. Diltiazem is intermediate in potency between verapamil and the dihydropyridines and is usually well tolerated.

Side Effects

The principal side effect of the dihydropyridines is dose-dependent ankle edema. With amlodipine, ankle edema is much more common with a 10-mg dose than with 2.5- or 5-mg doses. The edema is mainly vasogenic because of selective arterial dilation and can be improved by concomitant therapy with an ACEI or ARB that causes balanced arterial and venous dilation. Long-acting dihydropyridine CCBs are rarely associated with flushing and headache. All CCBs can cause gingival hyperplasia, a rare but serious side effect that is reversible if detected early. Verapamil and diltiazem can impair cardiac conduction, especially in older patients also receiving digoxin, beta blockers, or central sympatholytic agents.

Renin-Angiotensin Inhibitors for Hypertension: Angiotensin-Converting Enzyme Inhibitors, Angiotensin Receptor Blockers, and Direct Renin Inhibitors

RAS inhibitors are among the best tolerated of the antihypertensive drugs. The large study ONTARGET (Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial) showed comparable effects of the ACEI ramipril and the ARB telmisartan with regard to reducing CV events and preventing deterioration of renal function in high-risk hypertensive patients.[56] Other data suggest that ARBs may provide slightly more protection against stroke. The outcomes of many RCTs have not substantiated the hypothesis that RAS inhibitors produce BP-independent benefits in hypertensive patients. There is no compelling indication to prescribe the direct renin inhibitor aliskiren. “Dual RAS blockade”—either with an ACEI plus an ARB or with aliskiren plus an ACEI or ARB—is now contraindicated. These combinations must be avoided because they can precipitate hypotension, acute kidney injury (AKI), and hyperkalemia (see Side Effects).

Mechanisms of Action

ACEIs block conversion of the inactive precursor angiotensin I (A I) to A II. ARBs block the action of A II on the type 1 angiotensin receptor. Aliskiren blocks the conversion of prorenin to renin, thereby blocking RAS activation at its origin. High levels of circulating prorenin may stimulate A I receptor–independent signaling pathways, which are both potentially beneficial and potentially harmful (**see Fig. 46.9**).

Clinical Use

ACEIs offer ease of use and have rather flat dose-response curves. In ALLHAT, ACEI monotherapy with lisinopril was equivalent to amlodipine or chlorthalidone monotherapy in all aspects except for producing a smaller reduction in BP and thus less stroke protection in black hypertensive individuals.[53] As monotherapy, ACEIs are generally less effective in lowering BP in black patients and in older patients with low-renin hypertension, but they are quite effective in these groups when combined with a CCB or low-dose diuretic. Meta-analyses show ACEIs equivalent to CCBs in protecting against coronary events, slightly less effective in protecting against stroke, but better in protecting against HF.[57]

ARBs confer the same benefits as ACEIs in treating hypertension while avoiding the ACEI-related cough (see Side Effects). Potent, once-daily, long-acting ARBs are olmesartan, irbesartan, telmisartan, and azilsartan (the last being most potent). By contrast, losartan is a weak antihypertensive agent. The shorter half-life of valsartan requires twice-daily dosing.

ACEIs and ARBs have become standard first-line antihypertensive therapy for patients with diabetic

and nondiabetic CKD, but evidence indicates that RAS inhibitors provide superior renal protection than do other antihypertensive agents, mainly for nondiabetic proteinuric CKD,[12] as in AASK (African American Study of Kidney Disease). Head-to-head comparison in ONTARGET has indicated that ACEIs and ARBs have comparable effects on renal outcomes.[58] A recent meta-analysis indicates that diabetes mellitus should no longer be a compelling indication for RAS inhibitors: for hypertensive patients with diabetes, ACEIs and ARBs are not superior to other antihypertensive agents at reducing the risk of CV outcomes or end-stage renal disease.[59] RCTs have not substantiated the attractive hypothesis that RAS blockers slow progression from glucose intolerance to type 2 diabetes. In meta-analyses, ARBs produce somewhat more regression of left ventricular hypertrophy (LVH) than do other antihypertensive drugs.[60]

Side Effects

All RAS inhibitors are contraindicated in pregnancy because they cause fetal renal agenesis and other birth defects. The most common side effect of ACEIs is a dry cough, which is more common in black patients and more common still in Asian patients. ACEIs block the degradation of bradykinin, which activates nociceptive sensory fibers in the lungs that trigger cough. Bradykinin may also underlie ACEI-induced angioedema, a much less common but more serious adverse effect. If a cough develops in a patient taking an ACEI who needs RAS inhibition, an ARB should be substituted. Only isolated reports link cough or angioedema with ARBs. ACEIs and ARBs can provoke hyperkalemia in the setting of CKD or diabetes with type 4 renal tubular acidosis. In patients with stage 3 CKD with proteinuria, initiation of ACEI or ARB therapy is often associated with a small transient increase in serum creatinine; therapy can be continued unless the elevation in creatinine is greater than 30%, an indication to decrease the dose or temporarily withhold therapy.

ACEIs and ARBs have been used together for extrarenal protection in proteinuric patients. However, ONTARGET showed that such dual RAS blockade increases serious renal outcomes, hypotensive events, and hyperkalemia compared with monotherapy using either agent alone.[58] The combination of an ACEI or ARB with aliskiren entails similar risks,[61,62] which caused the FDA to issue a “black box” warning and to halt marketing of the fixed-dose combination. Moreover, the COOPERATE (Combination Treatment of Angiotensin-II Receptor Blocker and Angiotensin-Converting-Enzyme Inhibitor in Non-diabetic Renal Disease) trial, which had provided the earlier evidence supporting the practice of “dual RAS blockade,” was retracted from publication in *Lancet* on the basis of scientific misconduct.[63]

Diuretics for Hypertension

Diuretics are among the oldest and most effective antihypertensive medications. They have furnished the cornerstone of antihypertensive therapy since the first Joint National Committee (JNC) report in 1977 through the 2003 JNC 7 report. The 2013 scientific advisory statement from the AHA/ACC/Centers for Disease Control and Prevention (CDC) and the 2016 Canadian Hypertension Guidelines[7,11] still recommend thiazide-type diuretics as the best choice to initiate antihypertensive therapy, whereas most other recent guidelines list them as one of three first-line choices (see **Table 47G.2** in the Guidelines section). Multiple RCTs have shown that thiazide-type diuretics reduce the risk of coronary events, strokes, and HF in elderly patients. In ALLHAT the diuretic was equally effective as the ACEI and CCB in preventing coronary events and strokes, more effective than the CCB in preventing HF, and in black patients, more effective than the ACEI in preventing strokes. When combined with most other classes of antihypertensive drugs, diuretics exert a synergistic effect on BP reduction, but in the ACCOMPLISH trial, the combination of an ACEI with a CCB yielded better outcomes than did combination with

hydrochlorothiazide (HCTZ).[55]

Despite the widespread popularity of HCTZ in the United States, the bulk of clinical trials supporting the benefits of diuretic therapy for hypertension did not use HCTZ but rather indapamide or chlorthalidone, thiazide-type diuretics that are more potent and longer lasting than HCTZ (see later). Thiazide-type diuretics (especially in higher doses) cause more metabolic mischief and possibly more erectile dysfunction (the latter being controversial) than do ACEIs or CCBs and have higher discontinuation rates.[64]

Mechanisms of Action

With initiation of diuretic therapy, contraction of blood volume causes the initial fall in BP. With continued therapy, blood volume is partially restored, and vasodilator mechanisms (e.g., opening of adenosine triphosphate [ATP]–sensitive potassium [K^+] channels) sustain the antihypertensive action. Loop diuretics block Na^+-K^+-$2Cl^-$ transport in the thick ascending loop of Henle. Thiazide and thiazide-like diuretics (chlorthalidone, indapamide) block the Na^+-Cl^- cotransporter in the distal convoluted tubule. Spironolactone and eplerenone prevent aldosterone from activating the mineralocorticoid receptor, thereby inhibiting activation of the epithelial sodium channel (ENaC), whereas triamterene and amiloride block ENaC directly; because less sodium is presented to the Na^+,K^+-ATPase on the vascular side of the collecting duct cells, less potassium is excreted in urine.

Clinical Use: Indapamide or Chlorthalidone Is Superior to Hydrochlorothiazide

HCTZ is the most commonly prescribed drug for hypertension, yet the most commonly prescribed daily dose of 12.5 mg is insufficient to control hypertension and has never been shown to improve CV outcomes, even when combined with other drugs. Greater effectiveness of chlorthalidone (CTD) than HCTZ is shown by post hoc analysis of the MRFIT (Multiple Risk Factor Intervention Trial) data, which showed better outcomes with CTD,[65] by a network meta-analysis,[66] and by two separate monotherapy studies in which ambulatory blood pressure monitoring (ABPM) showed a much longer duration of action.[67,68]

The ABPM data show that, with 12.5 mg of HCTZ every morning (qAM), the antihypertensive effect disappears by late afternoon, providing no protection against nocturnal hypertension during sleep (**Fig. 47.2**),[67] which is the strongest risk factor for stroke. By comparison, 6.25 mg of CTD qAM reduces BP for the full 24 hours; at 4 AM, systolic BP was 35 mm Hg lower on average with 6.25 mg of CTD than with 12.5 mg of HCTZ (**Fig. 47.2**).[67] The drop in daytime clinic SBP of approximately 15 mm Hg with 12.5 mg of HCTZ qAM (or with 6.25 mg of CTD qAM), lulls physicians into believing in the efficacy of low-dose HCTZ (while minimizing dose-dependent metabolic side-effects), but this regimen actually just converts untreated/uncontrolled hypertension to partially treated/masked uncontrolled hypertension (**see Chapter 46**).

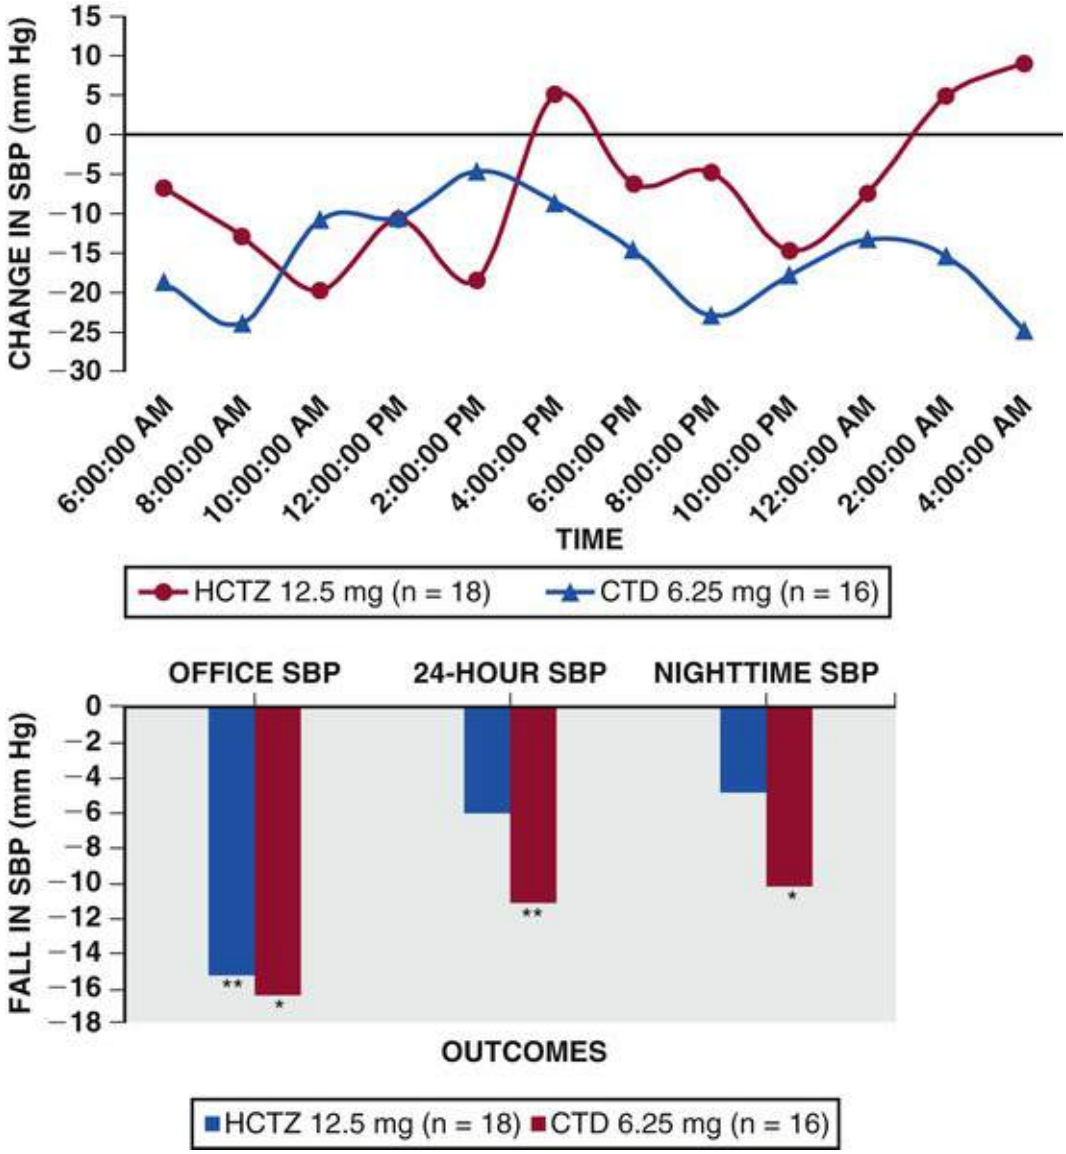

FIGURE 47.2 Comparative effects on systolic blood pressure (SBP) in patients with stage 1 hypertension randomized to monotherapy with either hydrochlorothiazide (HCTZ), 12.5 mg every morning, or chlorthalidone (CTD), 6.25 mg every morning. **Top,** Mean changes from baseline to week 12 in ambulatory blood pressure. **Bottom,** Bar graphs showing group mean reductions in office SBP, 24 hour SBP, and nighttime SBP. (From Pareek AK, Messerli FH, Chandurkar NB, et al. Efficacy of low-dose chlorthalidone and hydrochlorothiazide as assessed by 24-h ambulatory blood pressure monitoring. J Am Coll Cardiol 2016;67:383.)

Similar ABPM data are not yet available for indapamide, but a recent meta-analysis found that indapamide is more potent than HCTZ at commonly prescribed doses without causing any more adverse metabolic side-effects.[68] Indapamide, mainly in combination with perindopril, has performed well in several major phase III RCTs, including HYVET (Hypertension in the Very Elderly Trial)[69] and the PROGRESS (Preventing Strokes by Lowering Blood Pressure in Patients with Cerebral Ischemia) Trial.[70] Indapamide is available in the United States in 1.25- and 2.5-mg tablets, but the starting dose is 0.625 mg daily (one-half the low-dose tablet). For comparable reduction in office BP: 1.25 mg indapamide = 25 mg CTD = 50 to 60 mg HCTZ.[68] For uninsured patients, indapamide is more affordable than CTD.[71] Loop diuretics are less effective BP-lowering agents and should be reserved for treating hypertension in the setting of advanced CKD (stage 3 or higher). Indapamide or CTD also may be effective in patients with stage 3 CKD.

Diuretics enhance the potency of all other classes of antihypertensive agents. Thiazide-type diuretics combine particularly well with ACEIs and ARBs, which blunt the reactive RAS activation and thus increase antihypertensive efficacy. Such low-dose combinations should also reduce dose-dependent

diuretic side effects, a conjecture as yet not substantiated in formal dose-finding studies.

Side Effects

Thiazide-type diuretics can aggravate glucose intolerance (particularly in higher doses and when used in combination with a standard beta blocker), cause hypokalemia and hypomagnesemia and hyponatremia (see later), precipitate gout, and elevate serum lipids with increased hepatic triglyceride content;[72] they can also cause photosensitive dermatitis. They may be more likely than other antihypertensive drugs to cause erectile dysfunction but evidence is limited.[73] Thiazide-type diuretics are the most common cause of severe hyponatremia, especially in older women[74,75] (**Fig. 47.3**). Although less well recognized than thiazide-induced hypokalemia, thiazide-induced hyponatremia is a common reason why some elderly hypertensive individuals simply cannot tolerate even low-dose thiazides. In hypertensive patients with CKD, high doses of loop diuretics may precipitate acute renal failure, especially if combined with high-dose ACEI or ARB therapy.

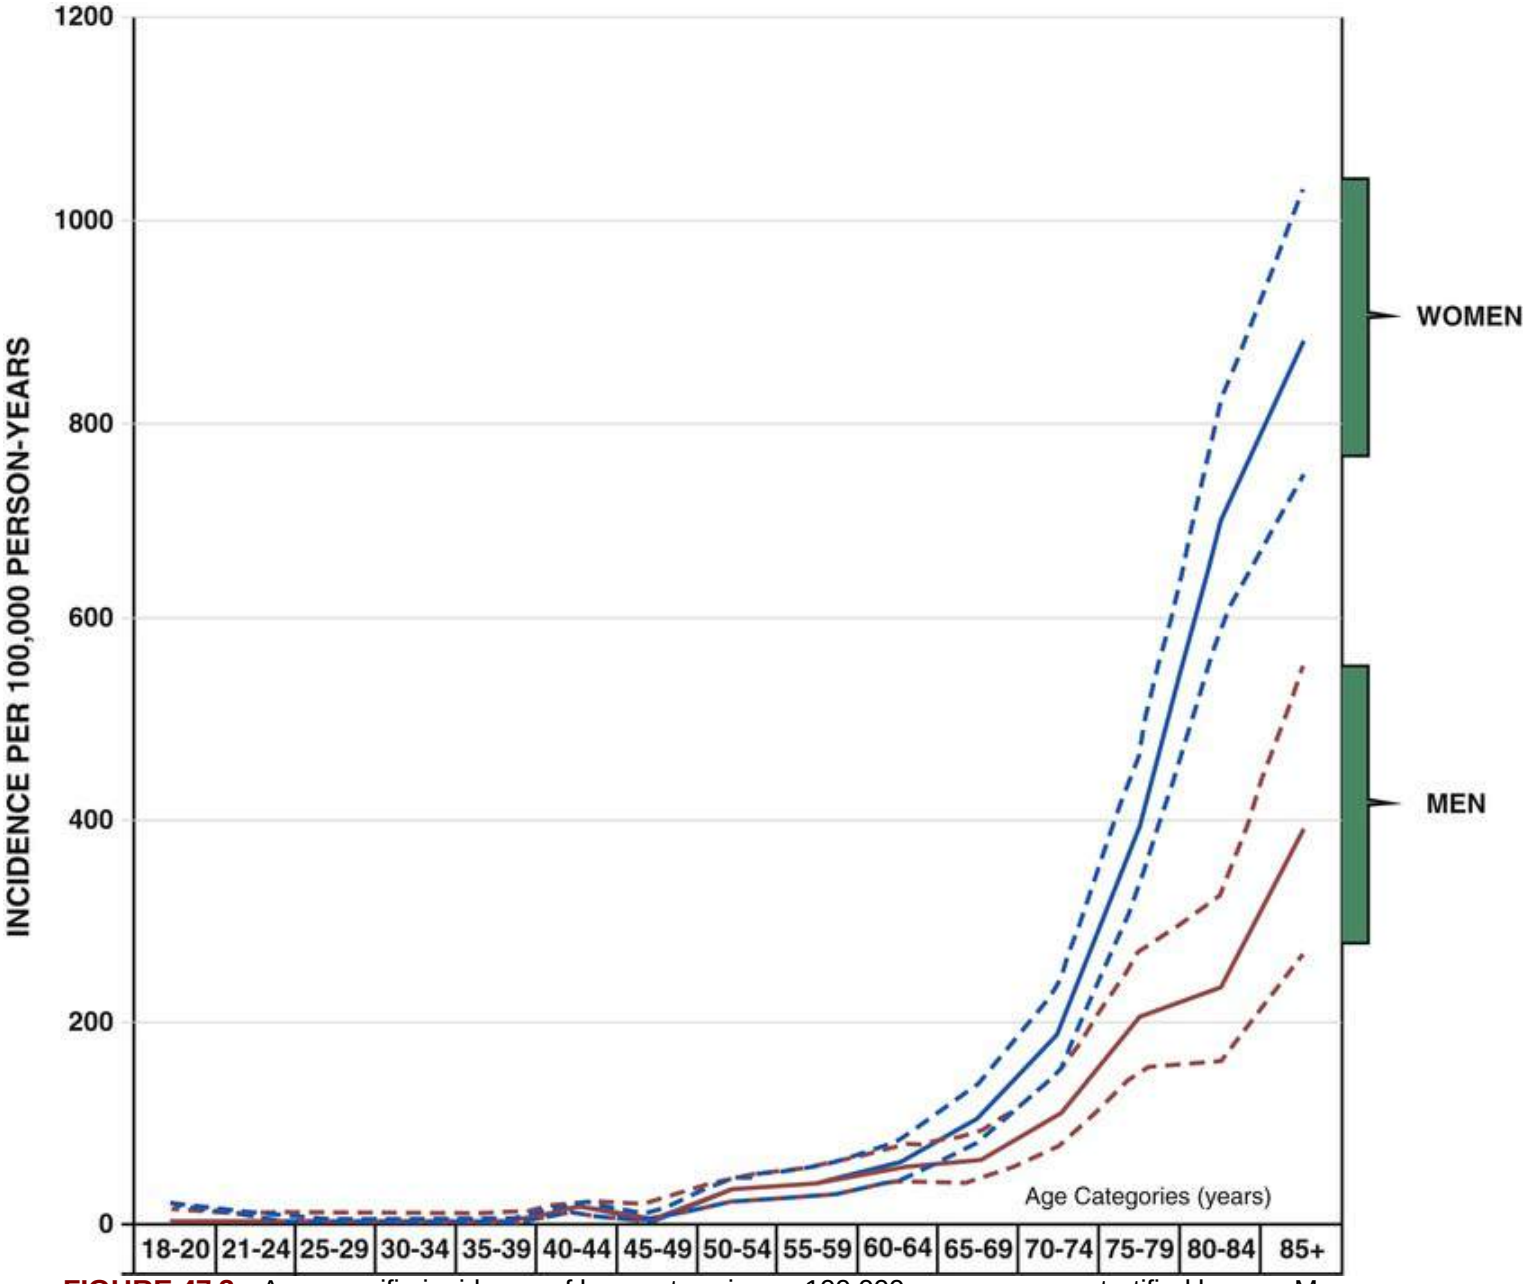

FIGURE 47.3 Age-specific incidence of hyponatremia per 100,000 person-years stratified by sex. Means (*solid lines*) and 95% confidence intervals (*dashed lines*) are shown. A total of 1033 cases of hyponatremia (serum sodium <130 mmol/L) from the Dutch Integrated Primary Care Information database between 1996 and 2011. (Modified from van Blijderveen JC, Straus SM, Rodenburg EM, et al. Risk of hyponatremia with diuretics: chlorthalidone versus hydrochlorothiazide. Am J Med 2014;127:765.)

Add-On Drug Classes for Difficult Hypertension

Aldosterone Antagonists

Low-dose spironolactone (12.5 to 50 mg daily) or eplerenone (25 to 100 mg daily) are highly effective add-on drugs for difficult cases of hypertension.[76,77] The PATHWAY-2 trial, the first RCT to compare spironolactone with other BP-lowering drugs for patients with resistant hypertension, showed that spironolactone was far superior to doxazosin ($alpha_1$-adrenergic blocker) or bisoprolol ($beta_1$-adrenergic blocker).[77] After 3 months, spironolactone was twice as effective as either of the other two active drugs in lowering home SBP, the study's primary outcome. The efficacy of spironolactone related inversely to the patients' plasma renin activity, implicating a pivotal role for excessive renal sodium retention in the pathogenesis of difficult primary hypertension. This study provides new evidence for an old idea: “The

Miracle of Low-Dose Spironolactone" [for resistant hypertension]—the title of a 1972 "clinical pearls" article penned by the late Dr. John Laragh, a concept bolstered by recent work of Dr. David Calhoun and coworkers.[78] Eplerenone is a much more specific antagonist that avoids the infrequent but disconcerting sexual side effects of low-dose spironolactone (painful gynecomastia, erectile dysfunction, nonmenstrual uterine bleeding). Hyperkalemia must be avoided when using these agents in patients with CKD.

Beta-Adrenergic Blockers

The vasodilating beta blockers carvedilol and nebivolol also are highly effective add-on drugs for difficult hypertension; standard beta blockers such as metoprolol are not.[79]

Mechanism of Action

With the initiation of standard beta-blocking drug therapy, BP changes little at first because a compensatory increase in peripheral resistance offsets the fall in cardiac output. Over time, BP falls progressively as the peripheral vasculature relaxes. Thus the antihypertensive effect of beta blockade involves decreases in cardiac output ($beta_1$ receptors), renin release ($beta_1$ receptors), and norepinephrine release (prejunctional $beta_2$ receptors). The prototype beta blocker propranolol nonselectively blocks both $beta_1$ and $beta_2$ receptors. Other standard beta blockers (metoprolol, atenolol, acebutolol, and bisoprolol) are relatively cardioselective. In low doses, they exert a greater inhibitory effect on $beta_1$ receptors than on $beta_2$ receptors, but loose selectivity at high doses. Vasodilating beta blockers such as labetalol or carvedilol also block alpha-adrenergic receptors, whereas nebivolol stimulates endogenous production of nitric oxide.

Clinical Use and Side Effects

Standard beta blockers have rather weak BP-lowering action. Atenolol and metoprolol provide little if any stroke protection compared with that afforded by ACEIs, ARBs, CCBs, or diuretics. Standard beta blockers provide modest protection against CV events but do not reduce all-cause mortality. They also increase the risk for diabetes, particularly when combined with a diuretic. Common side effects such as fatigability cause high discontinuation rates.[64] Beta blockers can impair cardiac conduction and precipitate acute bronchospasm in adults who had asthma in childhood. All beta-blocking drugs promote weight gain. Vasodilating beta blockers are much more potent antihypertensive agents and do not adversely affect glucose tolerance, but they have not undergone evaluation in large RCTs in hypertension. Data are also lacking on whether branded nebivolol is more cardioprotective than generic carvedilol, which is now included in $4/month formularies. The main limitations with generic carvedilol are the short half-life requiring twice-daily dosing and inconsistent gastrointestinal (GI) absorption, which is improved by dosing after breakfast and after dinner. Nebivolol can be dosed once daily with more consistent absorption independent of food intake. Labetalol is effective treatment of hypertensive urgency but is too short-acting to be recommended for chronic hypertension management.

Alpha-Adrenergic Blockers

Mechanism of Action

By blocking the interaction of norepinephrine on vascular alpha-adrenergic receptors, these drugs cause peripheral vasodilation, thereby lowering BP. By increasing blood flow in skeletal muscle, alpha

blockers increase insulin sensitivity. By dilating urethral smooth muscle, they improve symptoms of prostatism. Prazosin, doxazosin, terazosin, and intravenous phentolamine selectively block $alpha_1$ adrenoceptors; phenoxybenzamine blocks both $alpha_1$ and $alpha_2$ receptors.

Clinical Use and Side Effects

Phenoxybenzamine remains the drug of choice for preoperative management of pheochromocytoma (**see Chapter 92**); after alpha blockade is achieved, a beta blocker should be added to block an otherwise excessive reflex tachycardia. Selective $alpha_1$-blocking drugs are not first-line agents and should not be used as monotherapy because their propensity to cause fluid retention can lead to tachyphylaxis and unmask or exacerbate HF. When used in a combination regimen that includes a diuretic, however, they are effective add-on therapy for difficult hypertension and are particularly useful in older men with prostatism. Although marketed specifically for prostatism and not as an antihypertensive agent, the selective $alpha_{1A}$ blocker tamsulosin lowers BP and can precipitate symptomatic orthostatic hypotension in some older men.

Central Sympatholytics

Mechanism of Action

Stimulation of postsynaptic $alpha_2$-adrenergic receptors and imidazoline receptors in the central nervous system (CNS) lowers central sympathetic outflow, whereas stimulation of presynaptic $alpha_2$ receptors causes feedback inhibition of norepinephrine release from peripheral sympathetic nerve terminals. These combined actions reduce adrenergic drive to the heart and peripheral circulation.

Clinical Use and Side Effects

The central sympatholytics are best reserved for short-term oral treatment of hypertensive urgency when beta blockers (i.e., labetalol) are contraindicated. The central sympatholytics are potent antihypertensive agents that may be needed as add-on therapy for very difficult hypertension, but their troublesome CNS side effects reduce quality of life. To avoid rebound hypertension between doses, short-acting clonidine must be given every 6 to 8 hours or, whenever possible, discontinued through gradual tapering.[80] Rebound hypertension is less of a problem with guanfacine, a longer-acting oral central sympatholytic that is dosed at bedtime. The transdermal clonidine has erratic absorption and causes frequent dermatitis. Alpha-methyldopa is poorly tolerated and no longer a first-line therapy for hypertension in pregnancy.

Direct Vasodilators

Mechanism of Action

The potent hyperpolarizing arterial vasodilators minoxidil and hydralazine act by opening vascular ATP-sensitive K^+ channels.

Clinical Use

By causing selective and rapid arterial dilation, both drugs induce profound reflex sympathetic activation and tachycardia. Hydralazine is useful for the treatment of preeclampsia and as rescue therapy for very

difficult hypertension. A combination of hydralazine plus nitrates is useful for the treatment of HF, specifically in non-Hispanic black patients, in whom hypertensive heart disease causes HF most frequently (**see Chapters 25 and 26**). Severe hypertension accompanying advanced CKD is the main indication for minoxidil, which must be combined with a beta blocker to prevent excessive reflex tachycardia and with a loop diuretic to prevent excessive fluid retention. Initiation of chronic hemodialysis usually is a more effective means of controlling hypertension in this setting.

Percutaneous Interventions for Management of Blood Pressure

Renal Denervation

Percutaneous catheter-based radiofrequency ablation of the renal nerves, referred to as renal denervation (RDN), entered clinical practice in Europe and Asia as a novel treatment of drug-resistant hypertension, with clinical guidelines published by 2013. Based on unblinded data from phase I and phase II trials and office BP measurements, these guidelines are being reevaluated because of the disappointing results of the blinded sham-controlled phase III Symplicity HTN-3 Trial, which did not reach its primary efficacy endpoint.[81] Ongoing research hopes to define the extent of renal nerve destruction at the point of care, relative merits of RDN versus optimal medication management, patient subsets who would be most likely and least likely to benefit, sustainability of the therapeutic benefit in view of possible reinnervation, and long-term safety (**see Chapter 46**).

Carotid Baroreflex Activation Therapy

Electrical field stimulation of the carotid sinus, known as carotid baroreflex activation therapy, holds promise as a device-based intervention to supplement, but not replace, drug therapy for patients with resistant hypertension.[82] Acute electrical field stimulation of even one carotid sinus can cause a sufficiently large reflex decrease in BP to overcome offsetting reflexes from the contralateral carotid baroreceptors and aortic baroreceptors that are not paced. However, the initial phase III Rheos Pivotal Trial on continuous carotid baroreceptor pacing for resistant hypertension with the first-generation baroreceptor pacemaker yielded equivocal data on efficacy and adverse effects due to facial nerve injury during surgical implantation.[83] A miniaturized second-generation pacing electrode has seemingly overcome the safety issue, and early results with the new device suggest efficacy of unilateral carotid sinus stimulation in HF.

Evidence-Based Approach to Hypertension Management

A large body of RCTs has produced unequivocal evidence that drug treatment of hypertension reduces the risk of major cardiovascular events, end-stage renal disease, and death. In most hypertension trials, the follow-up is 3 to 5 years. The reported short-term risk reductions underestimate the lifetime benefit accrued over decades of effectively managed high BP.

Important questions remain, however. This section reviews the evidence, keyed to **Tables 47.8 to 47.11**, to address two issues: how far to lower BP and which drugs for which patients.

TABLE 47.8

Recent Hypertension Trials Randomizing Patients to More Intensive vs. Less Intensive Drug Therapy

	ACCORD (2010)	SPRINT (2015)	SPRINT (age ≥75) (2016)	HOPE-3 (2016)	SPS3 (2014)

How Far to Lower Blood Pressure

Considerable current controversy surrounds the optimal threshold level of SBP to initiate medication therapy and the optimal target level of BP to be achieved.[84,85] Epidemiologic data establish that CV risk begins to increase with BP above 110/70 mm Hg (**Chapter 46**), a level much below any currently recommended threshold for initiation of BP-lowering medication. However, in most hypertension RCTs published before 2014, the active treatment group never achieved a mean SBP below 140 mm Hg and in older patients rarely achieved a mean systolic BP below 150. Most of these RCTs were designed to compare a new drug with an old drug or to compare different drug classes, not to compare more intensive with less intensive treatment goals. Based on the available evidence and with concern that overtreatment of high BP in older patients could cause symptomatic orthostatic hypotension with injurious falls, the 2014 JNC 8 report[8] relaxed the recommended treatment thresholds for hypertensive patients age 60 or older from 140/90 to 150/90 mm Hg. Based largely on the results of the 2010 ACCORD (Action to Control Risk in Diabetes) trial,[86] this report also relaxed the recommended treatment threshold for patients with diabetes from 130/80 to 140/90 mm Hg. Subsequently, new trials have addressed this issue (**see Table 47.8**), as have recent meta-analyses (**Table 47.9**), and observational studies (**Table 47.10**). With the new data reviewed next, some but not all expert panels have begun to endorse more intensive therapy for hypertension for selected high-risk groups of patients (**see Tables 47G.2 and 47G.3** in the Guidelines section).

Recent Trials

Table 47.8 compares ACCORD with subsequent major trials regarding the outcomes of more intensive versus less intensive antihypertensive drug therapy. ACCORD was underpowered with fewer-than-expected CV events for patients with type 2 diabetes;[86] nonetheless, there was a significant reduction in relative stroke risk (**Fig. 47.4**).[86] Then, in 2015–2016, publication of SPRINT (Systolic Blood Pressure Intervention Trial)[87,88] directly challenged the 2014 recommendation to relax the BP treatment target for older patients—at least for nondiabetic patients with high CV risk scores but without prior stroke, prior HF, or advanced CKD. With twice the sample size as ACCORD, SPRINT was well powered for the primary composite CV outcome and was stopped early because of a 27% reduction in mortality for the overall group (**Fig. 47.5**)[87] and a 33% reduction in those age 75 or older.[88] In subgroup analysis, all the point estimates show approximately a 25% reduction in CV events with intensive therapy, but the 95% confidence intervals cross the line of identity for several important subgroups, including women, blacks, or those with prior CV disease or prior CKD (**Fig. 47.5**).[87] Because each of these subgroups comprised approximately 30% of the total cohort, the lack of a statistically significant intervention effect may be caused by subgroup sample size. The lack of a statistically significant intervention effect on stroke or on myocardial infarction (MI), another limitation of SPRINT,[84] also may result from statistical power. In direct challenge to the 2014 guidance, the greatest risk reduction was in patients age 75 and older (**Table**

47.8) and in those with baseline SBP of 132 mm Hg or higher (Fig. 47.5). Intensive therapy did not increase rates of symptomatic orthostatic hypotension, injurious falls, or acute coronary syndrome, even in those 75 or older.

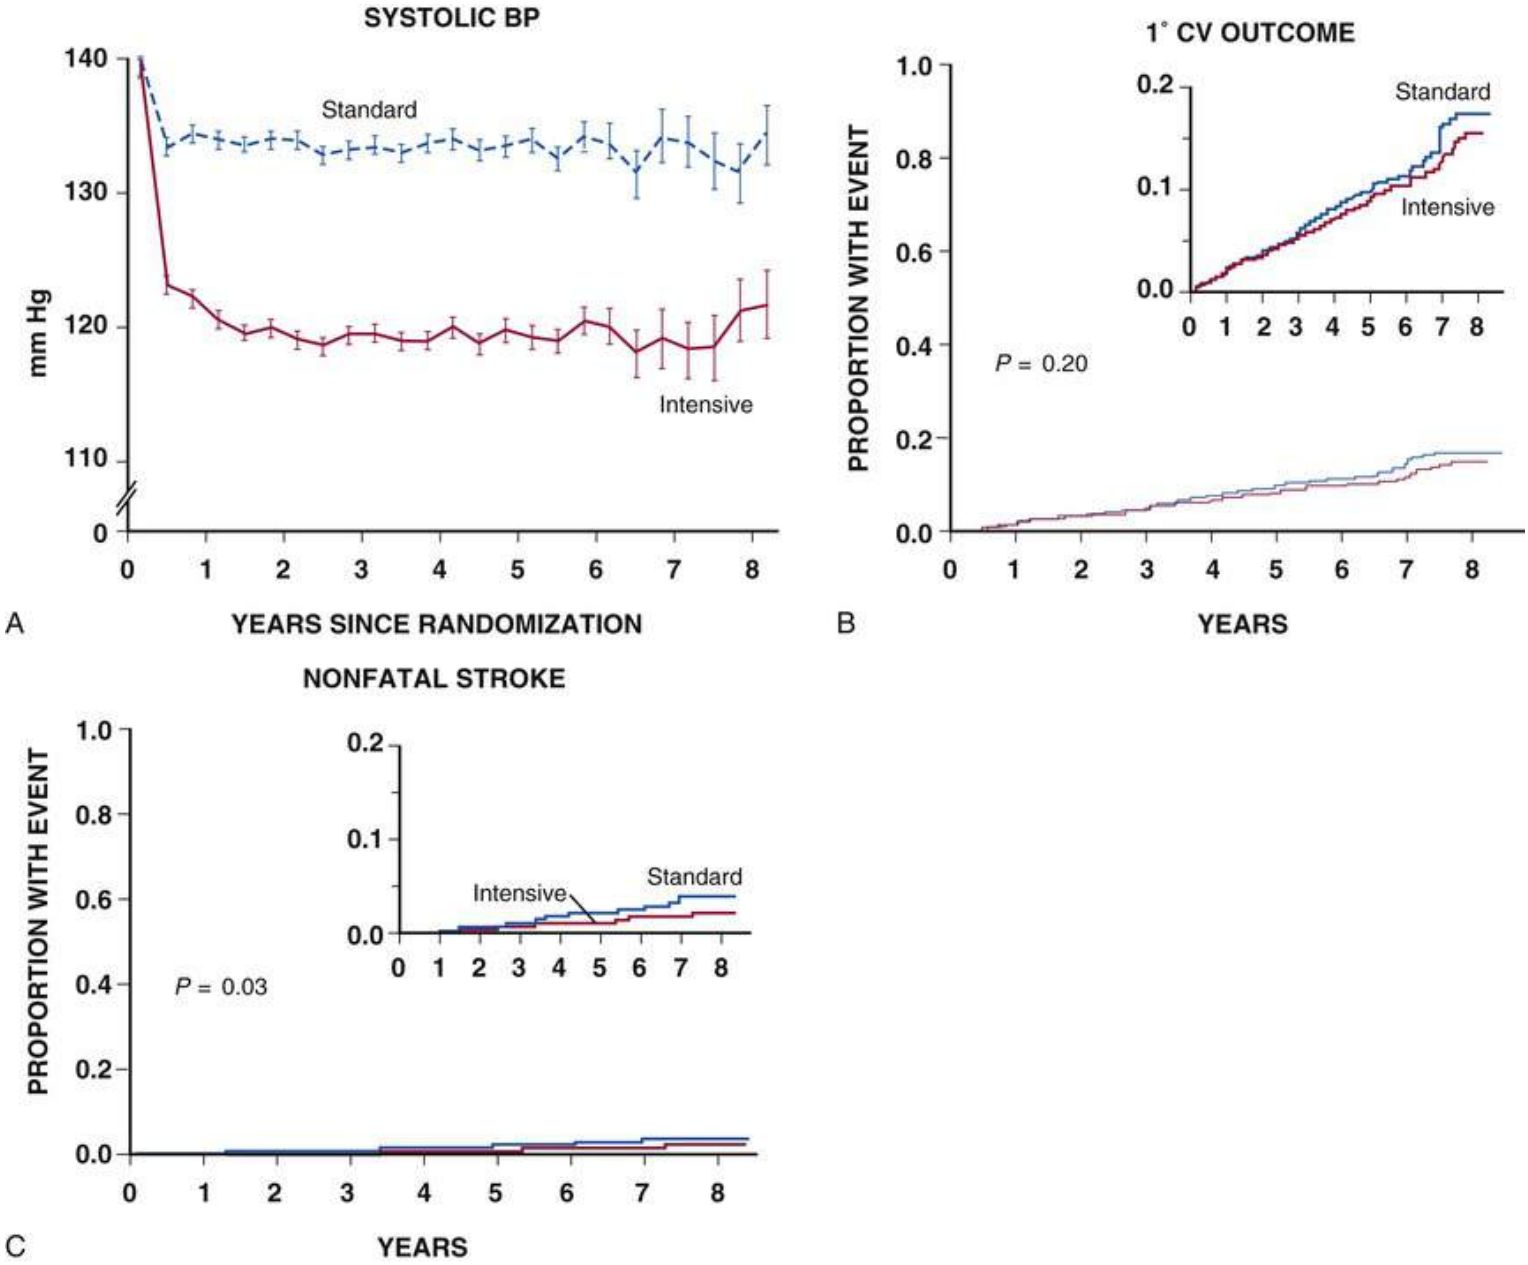

FIGURE 47.4 Major outcomes of the ACCORD study. **A,** Systolic blood pressure (BP) levels achieved with standard and intensive treatment are shown, along with corresponding Kaplan-Meier analyses for **B,** the primary cardiovascular (CV) outcome (nonfatal myocardial infarction, nonfatal stroke, or death from CV causes), and **C,** nonfatal stroke. FIGURE 47.5 Major outcomes of SPRINT. **A,** Systolic blood pressure levels achieved with standard and intensive treatment are shown, along with corresponding Kaplan-Meier analyses for **B,** the primary outcome (nonfatal myocardial infarction, nonfatal stroke, or death from CV causes) and death from any cause (*insets* showing close-up versions of the graphs), and **C,** forest plot of the primary outcome according to subgroup; CI, confidence interval; CKD, chronic kidney disease. (From The SPRINT Research Group, Wright JT, Williamson JD, Whelton PK et al.: A randomized trial of intensive versus standard blood-pressure control. N Engl J Med 2015;373(22):2103-16.)

However, the benefits of intensive therapy came at a price: increased rates of adverse events, including hyponatremia, hypokalemia, hypotension, and acute kidney injury (AKI), all of which may related to combination therapy with the most potent ARB (azilsartan) and the most potent thiazide-type diuretic (CTD). Also, the results of SPRINT do not apply directly to patients excluded from the trial: patients with diabetes, those with low or intermediate CV risk scores, elderly patients who are institutionalized, or those with advanced CKD or prior HF or stroke. In this regard, the SPS3 (Secondary Prevention of Small Subcortical Strokes) trial compared more to less intensive therapy for secondary stroke prevention in patients with lacunar infarcts.[89] This likely underpowered study yielded equivocal results except for a positive effect on hemorrhagic stroke (**Table 47.8**).

SPRINT also has been compared with the HOPE (Heart Outcomes Prevention Evaluation) 3 BP trial (**Table 47.8**), which used a mild fixed-dose BP regimen of candesartan (16 mg daily) plus HCTZ (12.5 mg daily) versus placebo. HOPE-3 was not a hypertension trial per se: the patients had intermediate CV risk scores, no prior CV disease, and only one third had hypertension.[90] The candesartan dose was half-maximum and the 6–mm Hg greater reduction in SBP in the active treatment group represents an overestimate of the BP reduction actually afforded because, as shown earlier in **Fig. 47.2**, the BP-lowering effect of 12.5 mg HCTZ qAM dissipates in the afternoon with no effect on nocturnal

hypertension.[67]

When comparative efficacy of more intensive versus less intensive BP treatment targets is a trial's primary objective, the accuracy of BP measurement is a key consideration. Although HOPE-3 and SPS3 relied on casual office BP measurements and ACCORD measured office BP with an oscillometric monitor, only SPRINT utilized automated office blood pressure (AOBP, **Chapter 46**), in an effort to minimize the "white coat" (alerting) reaction that plagues conventional office-based measurement of BP.[87] With the patient unattended in the examination room for 5 minutes, an automatic monitor took three readings (one per minute), which were averaged. The AOBP is at least 5/5 mm Hg lower than conventional office readings, but this approach does not fully eliminate the white coat reaction.[11] Moreover, a medication regimen that corrects the patient's AOBP may leave ambulatory and nocturnal hypertension uncorrected. As such, lack of ABPM is a key limitation of SPRINT (and most other hypertension trials). Antihypertensive medication converts uncontrolled hypertension to masked ambulatory/nocturnal hypertension in as many as 40% to 70% of hypertensive patients with type 2 diabetes, those with CKD, and those of non-Hispanic black race/ethnicity (**see Chapter 46**).[91] Because unknown numbers of patients in these trials were overtreated or undertreated, the optimal benefit of therapy was underestimated.

Recent Meta-Analyses

Several recent meta-analyses compared the benefits of more intensive versus less intensive antihypertensive drug therapy by including RCTs that enrolled hypertensive patients with comorbidities that were exclusion criteria for SPRINT: diabetes, prior stroke, and advanced CKD (**Table 47.9**). Meta-analyses have potential inherent biases related to the RCTs the authors chose to include and exclude. Yet, the results of these separate analyses support and extend the SPRINT outcomes in important ways. Analyses that included RCTs of both diabetic and nondiabetic patients generally indicate that the benefits of more intensive BP-lowering therapy apply not only to the composite endpoint of CV events but also to the separate components of stroke and MI.[92,93] However, the benefit of more intensive therapy does not seem to apply to end-stage renal disease (ESRD), raising the possibility that in some patients the optimum level of SBP to preserve renal function is higher than to prevent MI and stroke.[93] Analyses that included RCTs of diabetic patients exclusively[94,95] indicate that for patients with type 2 diabetes, the 2014 recommendation treatment target of office SBP of 130 to 140 mm Hg provides optimal protection against CV death, MI, and ESRD, whereas the more intensive treatment target of office SBP below 130 mm Hg provides less protection against those outcomes and even may be detrimental, while providing better protection against stroke and retinopathy.[95] In contrast, a new large-scale Swedish registry study indicates that an achieved SBP of 110 to119 mm Hg provides optimal CV protection in patients with type 2 diabetes (see later).[96]

Recent Observational Studies on Cardiac J-Curve Hypothesis

Several new observational studies have rekindled the debate over the J-curve hypothesis (**Table 47.10**). This hypothesis holds that intensive reduction of diastolic blood pressure (DBP)—coronary perfusion pressure—can cause coronary underperfusion and provoke myocardial ischemia, MI, and death, especially in patients with obstructive coronary disease and LVH.[97] Although a DBP of 0 obviously is lethal, the question is, "Does reduction in DBP to the levels routinely achieved in outpatient practice provoke myocardial ischemia?" The 2015 ACC/AHA/ASH scientific statement on the treatment of hypertension in patients with CAD relaxed the recommended treatment target from office BP less than

130/80 mm Hg to less than 140/90 mm Hg.[14] The authors compromised by saying that the previously recommended lower office BP target of less than 130/80 may be appropriate in some patients with coronary artery disease (CAD) or CAD risk equivalents. They also cautioned that overzealous reduction of DBP to less than 60 mm Hg may precipitate myocardial ischemia in patients with stable CAD over 60 years of age or those with diabetes.

Subsequent observational studies both support and contradict the J-curve hypothesis and raise concerns about reverse causality: comorbidity (e.g., advanced cancer) or isolated systolic hypertension (which itself carries a high CV risk) may have caused the low DBP. Because forward blood flow in the epicardial coronary arteries occurs only during diastole (a unique feature of the coronary circulation due to systolic compression), the hypothesis also holds that there is no cardiac "J curve" for SBP reduction and no selective diastolic J-curve for stroke risk. Indeed, none of the recent studies in **Table 47.10** showed any J curve for stroke.

Of the two studies restricted to patients with established CAD, post hoc analysis of the large ONTARGET study found no cardiac J curve,[98] whereas the equally large CLARIFY Registry study found a cardiac J curve for both DBP (<70 mm Hg) and SBP (<120 mm Hg) (**Fig. 47.6**).[99] In the Swedish registry study previously mentioned, of over 186,000 patients with type 2 diabetes and no prior CV events, both MI and stroke risk fell progressively with reduced SBP as low as 110 to 119 mm Hg; DBP was not reported, yet patients with a mean age of 60 years have low DBP because of isolated systolic hypertension (**Fig. 47.7**).[96] Post hoc analysis of the VALUE (Valsartan Antihypertensive Long-term Use Evaluation) trial found no diastolic J curve in patients with or without preexisting CAD.[100] In contrast, post hoc analysis of the ARIC cohort, which also included patients with or without CAD, found a cardiac-specific diastolic J curve for both high-sensitivity cardiac troponin T (hs-cTNT) (**Fig. 47.8**) and for incident coronary heart disease (CHD) events and death.[101] However, DBP of 70 to 79 mm Hg associated with an increased risk of CHD but a reduced level of the myocardial injury biomarker, which increased only with DBP less than 60 mm Hg. Because only 28% of the cohort was being treated for hypertension, treatment-induced myocardial injury cannot be distinguished from other causes. In a Canadian community-based AOBP registry study, composite CV event risk was lowest with on-treatment DBP of 60 to 69 mm Hg or SBP of 110 to 119 mm Hg, then increased with DBP less than 60 or SBP less than 110, indicating a diastolic and a systolic J curve.[102] The mixed results of these and earlier observational studies may result in part from dwindling sample size at the critically important levels of DBP below 60 to 70 mm Hg (**Fig. 47.8**).

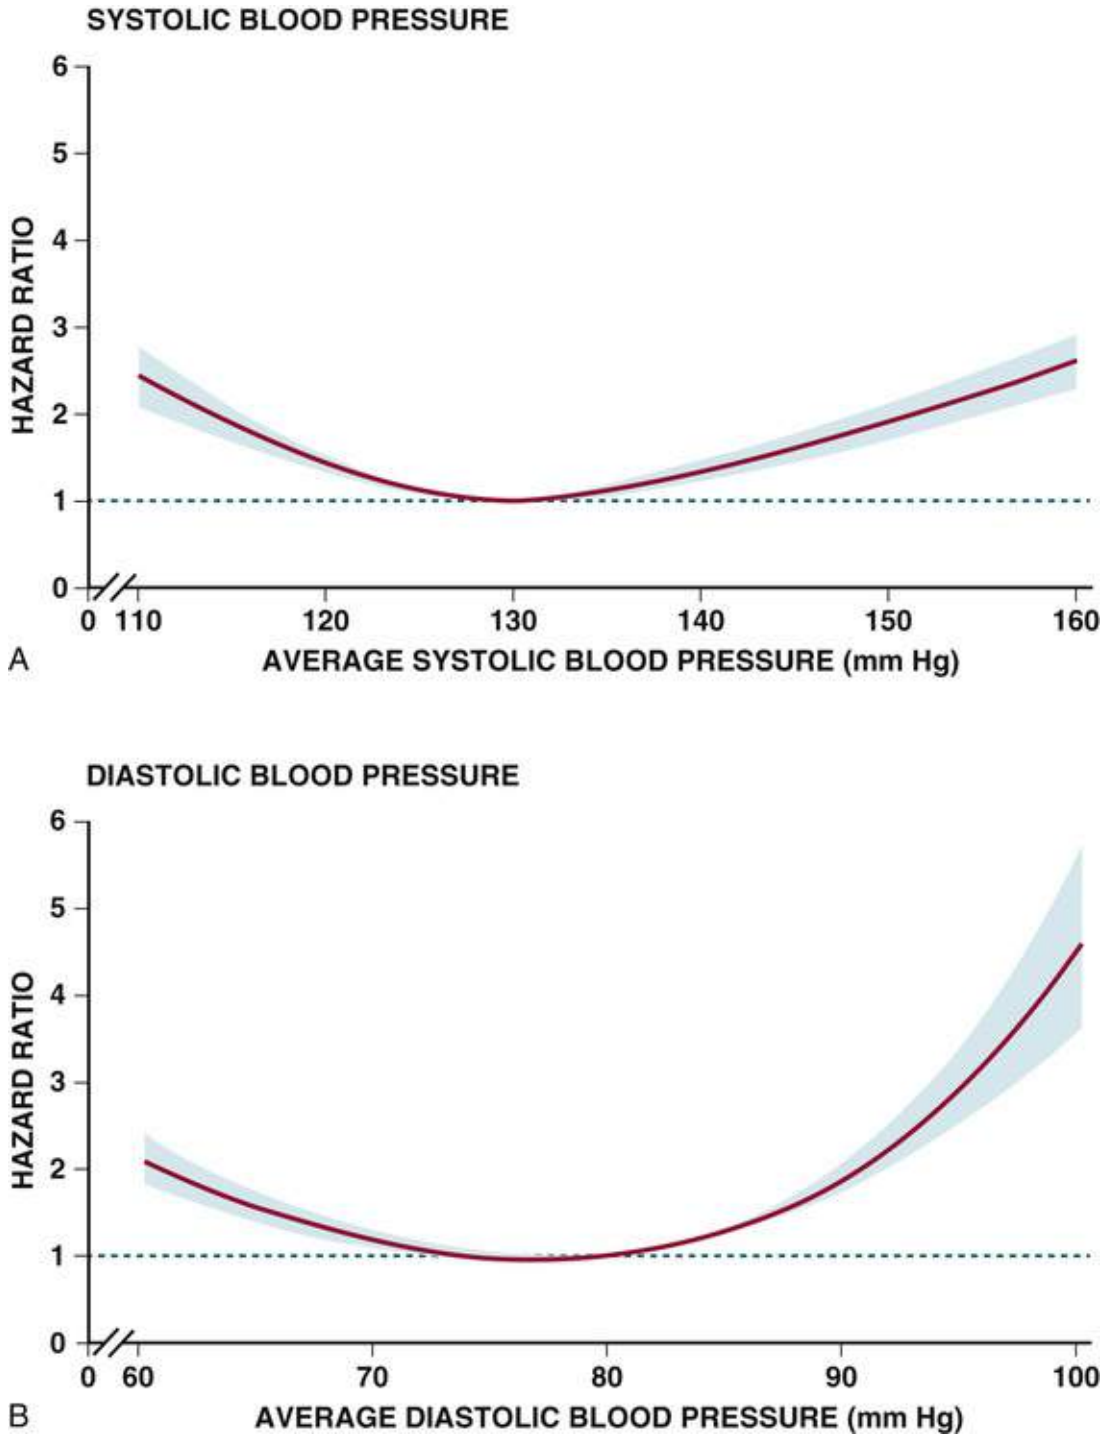

FIGURE 47.6 Data derived from analysis of 22,672 patients with stable coronary artery disease (CAD) in the CLARIFY Registry; patients from 45 countries were treated for hypertension. Graphs plot the primary outcome (cardiovascular death, myocardial infarction, or stroke) against average systolic **(A)** or diastolic **(B)** blood pressure as splines. These analyses were adjusted using a Cox proportional hazards model that accounted for numerous risk factors and drug treatments. (From Vidal-Petiot E, Ford I, Greenlaw N et al. Cardiovascular event rates and mortality according to achieved systolic and diastolic blood pressure in patients with stable coronary artery disease: an international cohort study. Lancet 2016;S0140-6736(16)31326-5.)

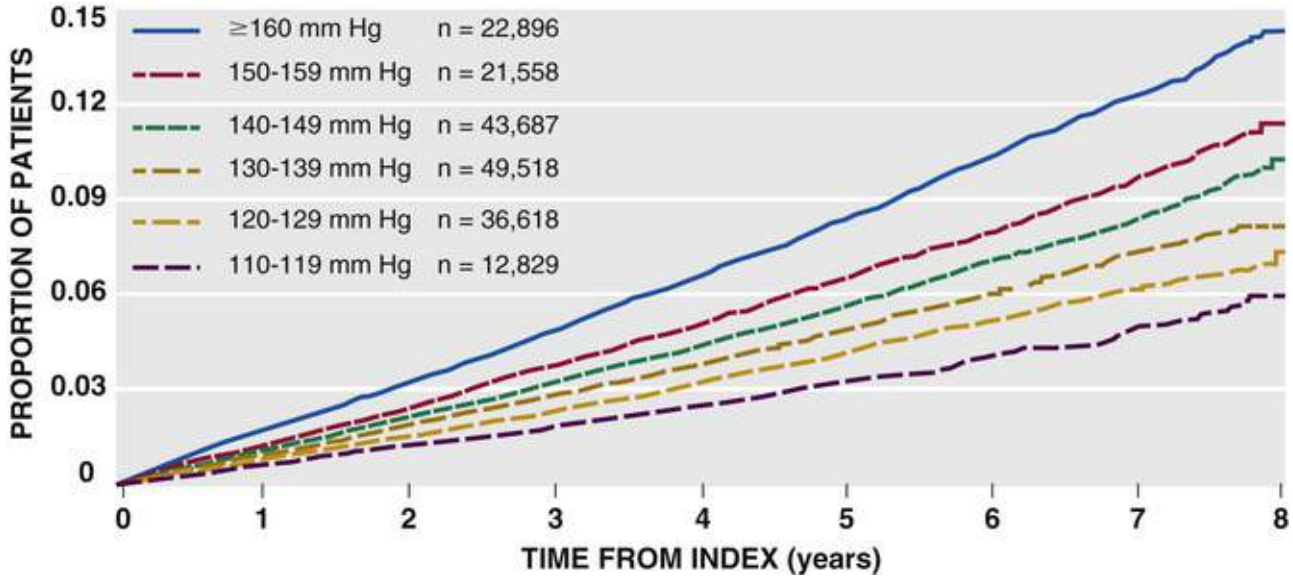

FIGURE 47.7 Kaplan-Meier analysis of nonfatal cardiovascular events, showing proportion of patients with events (composite of nonfatal myocardial infarction or stroke) stratified by different levels of achieved systolic blood pressure. (From Adamsson Eryd S, Gudbjornsdottir S, Manhem K, et al. Blood pressure and complications in individuals with type 2 diabetes and no previous cardiovascular disease: national population based cohort study. BMJ 2016;254:i4070.)

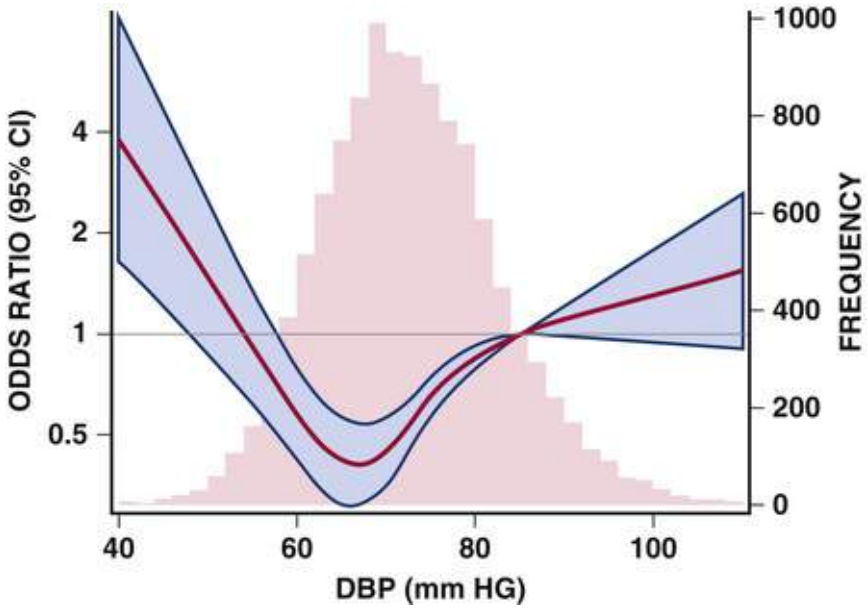

FIGURE 47.8 When diastolic blood pressure (DBP) was less than 65 mm Hg, a linear inverse relationship between DBP and high-sensitivity cardiac troponin-T (hs-cTnT) emerged when DBP was modeled continuously using linear splines. The odds ratio was adjusted for age (years), race-center, sex, body mass index, smoking, alcohol intake, systolic BP, hypertension medication use, diagnosed diabetes, low- and high-density lipoprotein cholesterol, triglycerides, current use of cholesterol-lowering medication, and estimated glomerular filtration rate. Restricted cubic spline provided odds of elevated hs-cTnT (14 ng/L) with background distributional histogram of baseline DBP. Frequency ¼ number of participants at each point on background histogram. The *shaded area* around the regression line represents the 95% confidence interval (CI). (From McEvoy JW, Chen Y, Rawlings A, et al.: Diastolic blood pressure, subclinical myocardial damage, and cardiac events: implications for blood pressure control. J Am Coll Cardiol 2016;68:1717.)

The most direct evidence against the cardiac J-curve hypothesis is that the two major RCTs that compared more intensive versus less intensive antihypertensive therapy (SPRINT and ACCORD) showed no evidence for a cardiac J curve, at least when intensive treatment achieved a mean SBP of 120 mm Hg.[86,87] The associated reductions in DBP were not reported in the major outcomes publications.

Parenthetically, the concept of the strictly diastolic cardiac J curve is partially flawed: while flow in the epicardial coronary arteries occurs mainly in diastole, blood flow within the myocardium (in intramyocardial nutrient microvessels) occurs throughout the cardiac cycle.[103]

Therefore, although cautious BP reduction is advised for patients with critical coronary stenosis or those with CKD (especially in the setting of longstanding diabetes), undertreatment of hypertension rather than overtreatment is much more common in outpatient medical practice, with missed opportunities to prevent needless MIs, strokes, and other hypertensive complications.

Which Drugs for Which Patients

Patients with Prehypertension

Prehypertension may precede stage 1 hypertension and predicts augmented CV risk. The outcomes of TROPHY (Trial of Preventing Hypertension) suggest that pharmacologic treatment of prehypertension with an ARB—together with lifestyle coaching—can postpone stage 1 hypertension.[104]

Hypertensive Patients in General

In RCTs, group differences in CV event rates are largely explained by small group differences in reduction of SBP (hemodynamic load) rather than drug class, with three caveats. First, beta blockers provide less stroke protection and CCBs more stroke protection than do other drugs. Second, the combination of an ACEI (or ARB) and a CCB is an excellent option to initiate medication management for hypertension, because it prevented more CV events than did the beta blocker/thiazide diuretic combination in ASCOT[54] and the ACEI/HCTZ combination in the ACCOMPLISH trial,[55] with the caveat that indapamide or chlorthalidone (CTD) likely would have provided better CV protection than the HCTZ used in ACCOMPLISH. CCBs are better tolerated and avoid the metabolic cost of the thiazides, including hyponatremia, hypokalemia, aggravation of glucose intolerance, increased hepatic triglyceride content, and gout. Yet, the 2013 scientific advisory from the AHA/ACC/CDC[7] and the 2016 Canadian hypertension guidelines[11] still emphasize thiazide-based therapy, believing the totality of the evidence is greater than with any other drug class. Third, ONTARGET showed that “dual RAS blockade” is dangerous as combined treatment with both an ACEI and an ARB (ramipril plus telmisartan) has no advantage on CV outcomes over monotherapy with either drug alone,[56] but results in more symptomatic hypotension and more renal impairment.[58]

Systolic Hypertension in Elderly Patients

Most hypertensive patients are older than 65 years, and most have isolated systolic hypertension (**see Chapter 46**). Six placebo-controlled trials have provided unequivocal proof that any BP-lowering regimen reduces CV events in elderly hypertensive patients (**Table 47.11**). The mean age of the patients at baseline ranged from 70 to 76 years except for HYVET (Hypertension in the Very Elderly Trial), in which all patients were 80 years or older.[69] The benefits of treatment include fewer coronary events, strokes, HF events, and deaths.[57] However, the intensity of the BP reduction in elderly patients must be weighed against increased risk for hypotension, which can precipitate falls and ischemic events. In SPRINT, patients age 75 or older had a large reduction in CV events and death and no increase in injurious falls with intensive reduction in systolic AOBP to a mean value of 124 mm Hg, regardless of frailty, as measured by walking speed.[88] Those results do not apply to nursing home residents. Perindopril and indapamide were the drugs used in HYVET; amlodipine, azilsartan, and CTD were used most often in

SPRINT.

The 2013 European Society of Hypertension (ESH) and European Society of Cardiology (ESC) guidelines and the 2016 Canadian and 2016 Australian hypertension guidelines place far greater emphasis than any U.S. guidelines do on home and ambulatory BP monitoring for clinical decision making (see Guidelines section).[6,11,12] Based on registry data from the 11-country International Database on Ambulatory BP in Relation to Cardiovascular Outcomes (IDACO), ambulatory and home BP monitoring should be routine in hypertensive elderly individuals; white coat (office only) hypertension and masked (out-of-office only) hypertension are so common in older adults that conventional office BP readings alone will promote either overtreatment or undertreatment of hypertension in three of four patients.[91] Likewise, the recent Masked Hypertension Study indicates that 1 in 8 U.S. adults—17 million people—and 1 in 3 people age 75 or older have masked hypertension.[105] Moreover, ambulatory monitoring is key to detecting *postprandial hypotension* and *orthostatic hypotension*, which are common in hypertensive elderly patients (**Fig. 47.9**). Management of postprandial hypotension is challenging. Useful strategies include frequent small low-carbohydrate meals, caffeine with meals, and liberalized salt intake. If these non–drug-related strategies prove insufficient, fludrocortisone (Florinef) can be added but often causes or worsens supine hypertension, which can be managed by elevation of the head of the bed (with 6-inch cinder blocks to produce a 30-degree head-up tilt) and a low-dose short-acting ARB (losartan, 25 to 50 mg) at bedtime.[106] The evidence is insufficient to recommend the use of midodrine, an alpha-adrenergic agonist, for orthostatic hypotension, whereas recent evidence indicates that abdominal compression garments and droxidopa are the most effective and safest approaches to manage severe orthostatic hypotension.[107-109]

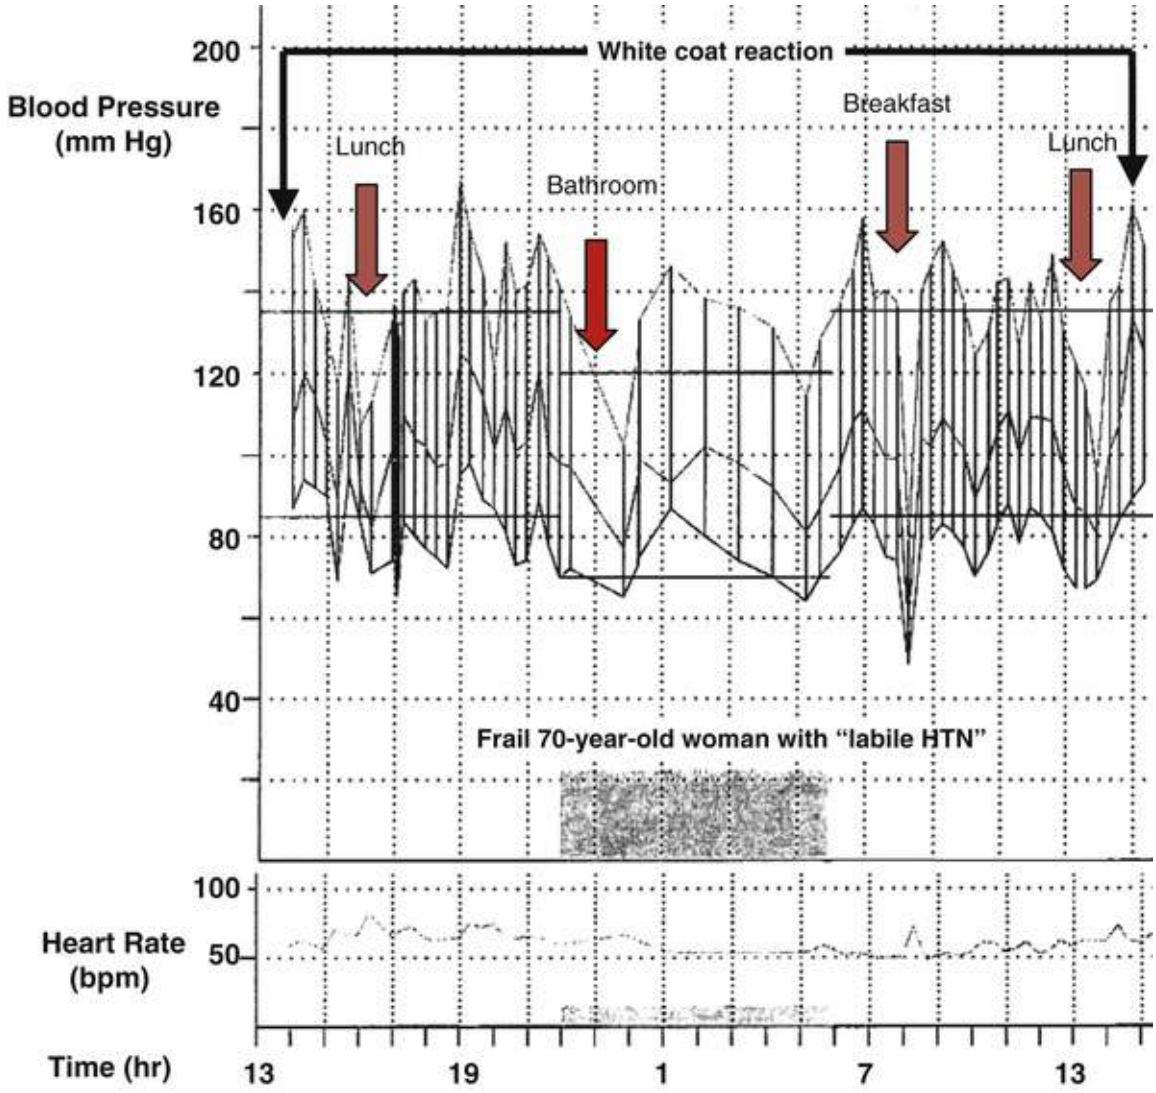

FIGURE 47.9 Postprandial and orthostatic hypotension demonstrated by ambulatory blood pressure (BP) monitoring. The 24-hour ambulatory BP recording is from a frail 70-year-old woman referred for evaluation of labile hypertension and dizziness. *Red arrows* show repeated episodes of postprandial hypertension and one episode of orthostatic hypotension when the patient walked to the bathroom 90 minutes after going to sleep. "White coat" reactions also seen when the patient came to the clinic to have the monitor placed and then to have it removed. HTN, Hypertension; bpm, beats per minute.

Several expert consensus documents including the 2016 Canadian guidelines recommend initiating antihypertensive therapy for isolated systolic hypertension with any one of the three first-line drugs CCB, ACEI or ARB, or thiazide, while placing the most emphasis on thiazide-type diuretics.[11] Most patients will require combination therapy with two or three drugs, so it is important to titrate more slowly in elderly patients and to check frequently for orthostatic hypotension and adverse drug reactions, especially thiazide-induced hyponatremia,[74,75] which are more common. On average, elderly patients take more than six prescription drugs, heightening concern regarding polypharmacy, noncompliance, and potential drug interactions. Regimens with combination drugs and agents or formulations that permit less frequent dosing can simplify the treatment program and promote persistence. Therapy should be individualized and be based more on the person's overall health than on chronologic age (see later, Practical Clinical Approach to Evaluation and Management of Ambulatory Hypertensive Patients).

Hypertension with Left Ventricular Hypertrophy

More than one third of hypertensive patients have electrocardiographically apparent LVH by the time of diagnosis, a finding that places them at increased risk for hypertensive complications, including HF, stroke, sudden death, and atrial fibrillation. The LIFE (Losartan Intervention for Endpoint Reduction in

Hypertension) trial exclusively enrolled patients with electrocardiographically confirmed LVH and showed superiority of an ARB/HCTZ-based regimen over a beta blocker/HCTZ–based regimen for regression of LVH and prevention of CV events, especially stroke. Subsequent meta-analyses have confirmed the superiority of ARBs for regression of LVH.[6] Beta blockers are the least effective; alpha- rather than beta-adrenergic receptors mediate the trophic effect of catecholamines on cardiac myocytes.

Hypertension in Patients with Diabetes Mellitus and Normal Renal Function

Patients with diabetes mellitus frequently have hypertension. No compelling evidence supports an indication for RAS blockers in type 2 diabetes.[59] Antihypertensive therapy should be instituted with one or more of the standard first-line drugs for hypertension. If additional drugs are needed to control hypertension, vasodilating beta blockers do not aggravate glucose tolerance in patients with type 2 diabetes. ALTITUDE (Aliskiren Trial in Type 2 Diabetes Using Cardiorenal Endpoints) showed that addition of aliskiren to background therapy with an ACEI or ARB increases the incidence of hyperkalemia and hypotension while producing no added CV benefit; these results led to the “black box” FDA warning against this form of dual RAS blockade.[62]

Hypertension in Patients with Diabetic Nephropathy

Diabetic nephropathy is characterized by proteinuria, loss of renal autoregulation, hypertension, progression to ESRD, and a high incidence of CV events. In RCTs, addition of an ARB to background antihypertensive therapy slowed progression of nephropathy in patients with type 2 diabetes, whereas amlodipine did not.[110,111] Thus, type 2 diabetes with nephropathy is an indication for an ARB, even though the trials were not powered to determine whether this regimen also afforded CV protection. Evidence supports a recommend office BP goal of 140/90 mm Hg or lower for patients with type 2 diabetic nephropathy (**Table 47.11**). The 2013 Kidney Disease Improving Global Outcomes (KDIGO) guideline[9] recommends a goal of less than 130/80 mm Hg and a RAS blocker in those with significant proteinuria (urine-to–plasma albumin–to-creatinine ratio ≥30 mg/g, corresponding to ≥30 mg of urinary albumin excretion in 24 hours), as applies to most patients.

Hypertension in Patients with Nondiabetic Chronic Kidney Disease

Almost all patients with nondiabetic CKD have hypertension. Control of hypertension in patients with CKD has two goals: (1) slowing further deterioration in renal function and (2) preventing CV events, which are the main cause of death. In AASK, the ACEI ramipril was more renoprotective than either amlodipine or metoprolol in black patients with baseline proteinuria.[112] Long-term follow-up of the AASK participants and a recent meta-analysis indicate that intensive reduction of SBP to below 130 mm Hg rather than a less intense goal of 140 mm Hg slows progression of renal disease only in patients with baseline proteinuria.[113,114] These trials lacked power to assess CV outcomes. Thus the 2012 KDIGO guideline recommends a goal office BP of lower than 140/90 mm Hg for patients with nondiabetic nonproteinuric CKD and a stretch goal of less than 130/80 mm Hg with an ACEI- or ARB-based regimen for those with proteinuria. These guidelines are in flux with the SPRINT data showing that reducing SBP to 120 mm Hg—by triple therapy with the most potent ARB, thiazide-type diuretic, and CCB—increased the risk of AKI but, at least in the short duration of the trial, did not increase the risk of ESRD in the subgroup of patients with baseline CKD.[87]

Reduction of Blood Pressure for Secondary Prevention of Coronary Events

The 2015 AHA/ACC/ASH Scientific Statement on Treatment of Hypertension in Patients with Coronary Artery Disease,[14] which predated SPRINT, emphasized that most of the cardioprotective effects of antihypertensive agents result from reduction in BP independent of drug class. For secondary prevention of coronary events in patients with stable CAD, first-line agents include the combination of beta blockers and dihydropyridine CCBs, both of which are antianginal. Other first-line agents are ACEIs or ARBS, and thiazide-type diuretics. Nondihydropyridine CCBs are recommended for beta blocker–intolerant patients. Aldosterone antagonists are reserved for patients with HF or difficult hypertension. In INVEST, combination therapy with CCB/ACEI was equally effective as beta blocker/thiazide for secondary prevention.[14] As previously reviewed, prospective data from RCTs have not defined the critical lower limit of on-treatment BP that increases the risk for ischemic events in patients with stable CAD. Current data support caution in decreasing DBP to lower than 60 mm Hg in patients with coronary stenoses.

Reduction of Blood Pressure for Secondary Prevention of Stroke

Stroke survivors are at high risk for recurrent stroke and thus further disability and death. Reduction in SBP by more than 10 mm Hg can reduce these risks.[115] In PROGRESS (Perindopril Protection Against Recurrent Stroke Study), patients who had survived ischemic or hemorrhagic stroke, a reduction of SBP by 12 mm Hg to a value of 135 mm Hg with an ACEI/diuretic (perindopril/indapamide) combination reduced the relative risk for recurrent ischemic stroke by 36% and that for recurrent hemorrhagic stroke by 76% in comparison to placebo, but a smaller reduction in BP of just 5 mm Hg with perindopril monotherapy showed no stroke protection.[70] Similarly, the PROFESS (Prevention Regimen for Effectively Avoiding Second Strokes) trial of patients with ischemic stroke showed no statistical benefit when SBP was reduced by only 4 mm Hg with ARB (telmisartan) monotherapy versus placebo.[116] In the SPS3 trial of hypertensive patients with lacunar infarcts, reduction in SBP to less than 130 mm Hg rather than less than 140 mm Hg reduced the risk of subsequent hemorrhagic stroke.[89] Emergency management of BP during acute stroke is discussed later (see Management of Hypertensive Crises).

Special Considerations in Management

Special Populations

Hypertension in Non-Hispanic Black Patients

Hypertension proves particularly devastating in non-Hispanic black adults, who have a higher prevalence of hypertension than other groups and higher rates of hypertensive complications and death (**see Chapter 46**). Black hypertensive patients were exclusively recruited in AASK (discussed earlier) and, by design, accounted for 25% of ALLHAT participants and 30% of SPRINT participants, but otherwise have been underrepresented in most RCTs of hypertension. Among the subset of black participants in ALLHAT, the ACEI provided less BP reduction and thus less stroke protection than either the diuretic or the CCB. In clinical practice, achieving BP targets and thus CV protection requires combining an ACEI with either a CCB or a diuretic, or both. A higher prevalence of masked and nocturnal hypertension in black persons argues for greater use of home and ambulatory BP monitoring in clinical practice.[91,117,118] An RCT showed that a barber-based BP monitoring and physician referral program can improve control of hypertension in black men.[119]

Hypertensive Disorders of Women (See Chapter 89)

Oral Contraceptives and Hormonal Replacement Therapy

Estrogen-containing oral contraceptives (OCs) occasionally cause hypertension, which is often mild. BP normalizes within 6 months of stopping OC therapy in 50% of patients. The hypertensive mechanism involves both RAS activation and volume expansion. Use of OCs should be limited in women older than 35 years or those who are obese or have preexisting hypertension. BP should be monitored closely with initiation of OCs; if BP rises into the prehypertensive range, an alternative contraceptive method should be offered. If OCs remains the only acceptable contraceptive method, drug therapy can reduce the elevated BP. Unlike OCs, hormonal replacement therapy (HRT) does not appear to elevate BP.

Hypertension in Pregnancy

Hypertensive disorders in pregnancy are a major cause of maternal-fetal morbidity and mortality, including a 25% incidence of preterm births (**see Chapter 90**). Current guidelines are provided by the 2013 executive summary of the American College of Obstetricians and Gynecologists (ACOG).[120] Four categories of hypertension in pregnancy are recognized: (1) preeclampsia, (2) chronic hypertension, (3) chronic hypertension with superimposed preeclampsia, and (4) gestational hypertension. *Preeclampsia* is a severe progressive multisystem disorder diagnosed by hypertension accompanied by any one of the following: proteinuria, BP of 160/110 mm Hg or higher despite bed rest, thrombocytopenia, impaired liver function, progressive renal insufficiency, pulmonary edema, or new-onset cerebral or visual disturbance (**Table 47.12**). Preeclampsia causes 15% of maternal deaths. *Gestational hypertension* is BP elevation after 20 weeks of gestation in the absence of the additional systemic features listed in **Table 47.12**. Chronic hypertension predates pregnancy. In all cases, ambulatory BP monitoring is very useful and was reported to be superior to conventional office measurement of BP for prediction of outcomes. Although the pathogenesis of gestational hypertension/preeclampsia remains enigmatic, risk factors include maternal age younger than 20 or older than 35, positive personal or family history of gestational hypertension, preexisting hypertension, obesity, diabetes, and antiphospholipid antibodies. Preeclampsia is a risk factor for peripartum cardiomyopathy, conditions that may share common causative factors.[121,122]

TABLE 47.12
Diagnostic Criteria for Preeclampsia

Blood pressure	≥140/90 mm Hg on two occasions at least 4 hours apart after 20 weeks of gestation in a woman with a previously normal pregnancy
	≥160/110 mm Hg; hypertension can be confirmed within a short interval (minutes) to facilitate timely antihypertensive therapy
and	
Proteinuria	≥300 mg per 24-hour urine collection
	or
	Protein/creatinine ratio ≥0.3
or in the absence of proteinuria, new-onset hypertension with new onset of any of the following:	
Thrombocytopenia	Platelet count <100,000/mL
Renal insufficiency	Serum creatinine >1.1 mg/dL or doubling of serum creatinine in the absence of other renal disease
Impaired liver function	Serum liver transaminases elevated twice normal
Pulmonary edema	
Cerebral or visual symptoms	

Modified from Hypertension in pregnancy. Report of the American College of Obstetricians and Gynecologists' Task Force on Hypertension in Pregnancy. Obstet Gynecol 2013;122:1122.

Low-dose aspirin (60 to 80 mg daily beginning in the first trimester) is recommended as being slightly effective in reducing the risk for recurrent preeclampsia. Women with gestational hypertension or chronic

hypertension should be monitored closely for the development of preeclampsia with serial measurements of BP twice weekly and weekly assessment of platelet counts, liver enzymes, and proteinuria. Weight loss and salt restriction are not recommended. Currently, antihypertensive medication is not recommended for uncomplicated stage 1 gestational hypertension and is reserved only for stage 2 hypertension (BP >160/110 mm Hg). Drug treatment of stage 1 maternal hypertension does not improve perinatal outcome and may be associated with fetal growth restriction. However, these guideline recommendations do not consider the long-term risk to the mother of untreated stage 1 hypertension during pregnancy.

Definitive cure of preeclampsia is termination of pregnancy. The decision regarding premature termination of pregnancy depends on findings of fetal growth restriction, evidence of impaired placental blood flow by umbilical artery Doppler assessment, and condition of the mother. Intravenous (IV) magnesium sulfate is not a reliable antihypertensive agent but is effective in treating or preventing seizures in the setting of eclampsia or severe preeclampsia. IV labetalol has replaced hydralazine as the drug of choice for treating severe preeclampsia/eclampsia. Compared with hydralazine, labetalol carries a lower risk for *overshoot hypotension*, which can impair fetal blood flow, and does not cause reflex tachycardia. Beyond delay of pregnancy until after the teenage years and better prenatal care, the only other effective strategy to prevent preeclampsia is the use of low-dose aspirin. The only cure for preeclampsia is delivery, which removes the diseased placenta. To achieve this apparently simple end, the clinician must detect the often-symptomless prodromal condition by screening all pregnant women, admitting those with advanced preeclampsia to the hospital to keep track of an unpredictable situation, and timing preemptive delivery to maximize safety of the mother and baby.

Pregnant women with stage 2 hypertension but without severe preeclampsia/eclampsia who are prescribed oral drug therapy should initially receive any one of three preferred drugs: labetalol, nifedipine, or methyldopa. Despite being the conventional drug of choice, methyldopa is poorly tolerated and, if used after delivery, may cause postpartum depression. All RAS inhibitors must be discontinued. Delivery soon after maternal stabilization is recommended regardless of gestational age for women with superimposed preeclampsia and any of the following: uncontrollable severe hypertension, eclampsia, pulmonary edema, abruptio placentae, disseminated intravascular coagulation, or fetal distress. IV nitroglycerin is the treatment of choice when pulmonary edema accompanies preeclampsia, a main cause of maternal death. Preeclampsia can start in the early postpartum period. Preeclampsia constitutes an important major CV risk factor for later life. Women with preeclampsia causing preterm delivery have an almost 10-fold increased risk for CV disease in later life and thus require exquisite global risk factor modification. Women with preeclampsia or even gestational hypertension should have close BP monitoring in the hospital for 72 hours postpartum and again on outpatient basis 7 to 10 days after delivery. All BP drugs enter into human breast milk.

Pediatric and Adolescent Hypertension

Historically, childhood hypertension was a rare occurrence caused mainly by parenchymal renal disease. The worldwide childhood obesity epidemic, however, has increased the prevalence of primary juvenile hypertension, which has now become one of the most common health conditions in young people. The 2016 European Society of Hypertension (ESH) Guidelines for Management of Hypertension in Children and Adolescents continues to define pediatric hypertension as SBP or DBP higher than the 95th percentile for age, sex, and height according to normative data.[123] The prevalence of hypertension is now 5% and that of prehypertension is 10% in U.S. children. The frequency of primary (largely obesity-related) hypertension in pediatric referral series has risen steadily and now exceeds 90%.[124] College football players have a disproportionate prevalence of hypertension compared with collegiate athletes in other

sports; in one cross-sectional series, 19% of college football players had hypertension and 62% had prehypertension, which is partially explained by a high BMI.[125] In a longitudinal series, a single season of freshman collegiate football consistently caused increases in SBP and DBP associated with increased concentric left ventricular mass; these increases were greatest in linemen, who are heavier and gain more weight than those who are not linemen.[126]

Ambulatory BP monitoring is the method of choice for confirming the diagnosis of pediatric or adolescent hypertension, but it is underused.[127] The initial evaluation should include an echocardiogram for detection of LVH, as well as urine microalbumin, serum creatinine, and urinalysis to test for renal parenchymal injury. Glomerulonephritis and reflux nephropathy can also be associated with pediatric hypertension. A history of recurrent urinary tract infections in girls may indicate reflux nephropathy, a condition that can lead to renal scarring (suggested by renal asymmetry). This situation should prompt consultation with a pediatric nephrologist to consider reimplantation of the ureters. Renovascular hypertension occurs in almost 10% of hypertensive pediatric patients. Coarctation of the aorta, the most common cause of hypertension in infants, responds well to stenting.[128] Rare causes of secondary pediatric hypertension are syndromic pheochromocytoma/paraganglioma, monogenic disorders (**see Chapters 46 and 92**), and congenital adrenal hyperplasia caused by deficiency of either 11β-hydroxylase or 17α-hydroxylase. No data from RCTs inform the decision on when to initiate antihypertensive drug therapy in children or adolescents or on which drug classes are preferred. ACEIs are typically used to treat primary pediatric hypertension and secondary hypertension caused by renal parenchymal disease; CCBs may be added as a second drug if needed.[123]

Hypertension and Erectile Dysfunction

Two thirds of men with hypertension have erectile dysfunction (ED).[129] TOMHS (Treatment of Mild Hypertension Study) is the only RCT on hypertension to include ED as a prespecified patient-reported outcome.[130] Among men with a mean age of 50 years and previously untreated hypertension, most ED preceded initiation of antihypertensive medication and was related both to age and to baseline SBP. After men were randomly assigned to monotherapy with one of five main classes of BP medication or placebo, CTD was the only drug that increased incident ED more than placebo did. However, this result has not received systematic confirmation.[73] Overall, phosphodiesterase-5 inhibitors have had a very good safety record in treating ED, even in men with high CV risk, but they should be avoided in those taking nitrates or alpha blockers to prevent hypotension.

Hypertension and Hypertrophic Cardiomyopathy

Hypertension is at least as prevalent in patients with hypertrophic cardiomyopathy (HCM) as in the general population. Management of hypertension in HCM patients presents challenges because all the first-line antihypertensive drugs—dihydropyridine CCBs, RAS blockers, and thiazides—can exacerbate outflow tract obstruction and thus may prove harmful. Hypertension is best treated with a beta blocker and/or verapamil or diltiazem, with central sympatholytics and very-low-dose thiazide reserved as add-on drugs.[131]

Hypertension and Atrial Fibrillation

Hypertension is the most common comorbid condition in atrial fibrillation (AF), found in almost 90% of patients. In the ARISTOTLE (Apixaban for Reduction in Stroke and Other Thromboembolic Events) trial of more than 18,000 patients (mean age 70 years) with nonvalvular AF, any elevated office reading of

SBP ≥140 or DBP ≥90 mm Hg at any point during the 2-year trial was associated with a 53% increased risk of ischemic stroke and an 85% increased risk of hemorrhagic stroke.[132] These new data underscore the importance of intensive antihypertensive drug therapy to achieve strict BP control to reduce the risk of stroke in older patients with nonvalvular AF.

Resistant Hypertension

Resistant hypertension, defined as high BP uncontrolled with three or controlled with at least four antihypertensive drugs (including a diuretic), is associated with a higher prevalence of secondary hypertension and worse CV and renal outcomes. With aging of the population, the prevalence of resistant hypertension is increasing and may affect 13% to 20% of the adult U.S. population.[76] More than half these patients will have pseudo–resistant hypertension from improper BP measurement technique, white coat reactions, medication noncompliance, pressor substances (e.g., NSAIDs, excessive alcohol, psychiatric drugs), or an inadequate BP regimen (**Table 47.13**). Common correctable issues include clonidine rebound (especially with as-needed dosing) and inadequate diuretic therapy: inappropriate use of a loop diuretic in a patient with normal renal function, infrequent dosing with a short-acting loop diuretic (e.g., once-daily furosemide), or low-dose HCTZ in a patient with impaired renal function.

TABLE 47.13
Causes of Resistant Hypertension

Pseudoresistant Hypertension
Inadequate blood pressure regimen
Pressor substances
White coat reaction
Medication nonadherence
Improper blood pressure measurement
True Resistant Hypertension
Chronic kidney disease
Primary aldosteronism
Other secondary hypertension
Difficult primary hypertension

Truly drug-resistant patients are a special high-risk population because of their severe hypertension along with target-organ damage and concomitant CV risk factors. Patients should be screened for secondary hypertension, especially primary aldosteronism and CKD, as well as pheochromocytoma. In the absence of an identifiable cause of the hypertension, a mineralocorticoid receptor antagonist or a vasodilating beta blocker can serve as highly effective add-on therapies. Low-dose spironolactone (or eplerenone) can be remarkably effective for resistant hypertension, even when serum aldosterone is within the normal range.[77,78]

Perioperative Management of High Blood Pressure

Preexisting hypertension should be well controlled before elective surgery (**see Chapter 11**). Preoperative correction of diuretic-induced potassium depletion requires particular attention. Antihypertensive agents should be taken the morning of surgery, particularly to avoid withdrawal from beta blockers or clonidine. Some surgeons prefer to withhold ACEIs and ARBs before cardiac surgery to prevent postoperative vasodilation and hypotension, but little evidence supports this practice. Beta blockers have not proved to reduce perioperative risk in patients with uncomplicated hypertension undergoing noncardiac surgery and might even increase risk of major CV events.[133] Fortunately, IV

formulations of most agents are available if oral intake is not possible; labetalol is particularly useful in this regard. Hypertension may appear or worsen in the perioperative period, perhaps more frequently with cardiac than noncardiac surgery. Hypertension is of particular concern after heart transplantation and develops for a variety of reasons, including immunosuppression with calcineurin inhibitors (cyclosporine and tacrolimus) and possibly cardiac denervation; treatment includes dihydropyridine CCBs, diuretics, and central sympatholytics.

Management of Hypertensive Crises

Definitions

Hypertensive crises are a heterogeneous group of hypertensive disorders characterized by severe hypertension and acute target-organ damage to the brain, heart, kidney, retina, or blood vessels. Typically, BP is 220/130 mm Hg or higher but may be much lower in women with preeclampsia who do not have preexisting hypertension, such that cerebral autoregulation has not been reset. Hypertensive crises require immediate reduction of BP with IV medication and intra-arterial monitoring in an intensive care unit. In contrast, *hypertensive urgency* denotes severe uncontrolled hypertension without evidence of acute target-organ damage. In the absence of symptoms and acute target-organ damage, a patient with a BP of 220/130 mm Hg should be treated with a short-acting oral medication. *Severe hypertension*, defined as a BP of 180/110 to 220/130 mm Hg without symptoms or acute target-organ damage, almost always occurs in patients with chronic hypertension who depleted or discontinued their BP medication. Long-acting oral medication can simply be restarted. Patients with either hypertensive urgency or severe hypertension require outpatient follow-up within 24 to 72 hours by either a primary care physician or hypertension specialist.

Specific Hypertensive Crises

Adapted from the updated Dutch guidelines,[134] **Table 47.14** summarizes treatment recommendations for hypertensive crises by affected organ system. **Table 47.15** summarizes the recommended parenteral drugs for treatment of hypertensive crises.

TABLE 47.14

Intravenous Drugs for Treatment of Hypertensive Emergencies

DRUG	ONSET OF ACTION	HALF-LIFE	DOSE	CONTRAINDICATIONS AND SIDE EFFECTS
Labetalol	5-10 min	3-6 hr	0.25-0.5 mg/kg; 2-4 mg/min until goal BP is reached, thereafter 5-20 mg/hr	Second- or third-degree AV block; systolic heart failure, COPD (relative); bradycardia
Nicardipine	5-15 min	30-40 min	5-15 mg/hr as continuous infusion, starting dose of 5 mg/hr, increase q15-30 min with 2.5 mg until goal BP achieved, thereafter decrease to 3 mg/hr	Liver failure
Nitroprusside	Immediate	1-2 min	0.3-10 μg/kg/min, increase by 0.5 μg/kg/min q5min until goal BP achieved	Liver/kidney failure (relative), cyanide toxicity
Nitroglycerin	1-5 min	3-5 min	5-200 μg/min, 5-μg/min increase q5min	
Urapidil	3-5 min	4-6 hr	12.5-25 mg as bolus injections; 5-40 mg/hr as continuous infusion	
Esmolol	1-2 min	10-30 min	0.5-1.0 mg/kg as bolus; 50-300 μg/kg/min as continuous infusion	Second- or third-degree AV block, systolic heart failure, COPD (relative); bradycardia
Phentolamine	1-2 min	3-5 min	1-5 mg, repeat after 5-15 min until goal BP is reached; 0.5-1 mg/hr as continuous infusion	Tachyarrhythmia, angina pectoris

AV, Atrioventricular; *COPD,* chronic obstructive pulmonary disease.

TABLE 47.15

Recommended Treatment of Hypertensive Emergencies by End-Organ Involved

TYPE OF EMERGENCY	TIMELINE, TARGET BLOOD PRESSURE	FIRST-LINE THERAPY	ALTERNATIVE THERAPY
Hypertensive crisis with retinopathy, microangiopathy, or acute renal insufficiency	Several hours, MAP −20% to −25%	Labetalol	Nitroprusside Nicardipine Urapidil
Hypertensive encephalopathy	Immediate, MAP −20% to −25%	Labetalol	Nicardipine Nitroprusside
Acute aortic dissection	Immediate, SBP <110 mm Hg	Nitroprusside + metoprolol	Labetalol
Acute pulmonary edema	Immediate, MAP 60-100 mm Hg	Nitroprusside with loop diuretic	Nitroglycerin Urapidil with loop diuretic
Acute coronary syndrome	Immediate, MAP 60-100 mm Hg	Nitroglycerin	Labetalol
Acute ischemic stroke and BP >220/120 mm Hg	1 hour, MAP −15%	Labetalol	Nicardipine Nitroprusside
Cerebral hemorrhage and SBP >180 mm Hg or MAP >130 mm Hg	1 hour, SBP <180 mm Hg and MAP <130 mm Hg	Labetalol	Nicardipine Nitroprusside
Acute ischemic stroke with indication for thrombolytic therapy and BP >185/110 mm Hg	1 hour, MAP less than −15%	Labetalol	Nicardipine Nitroprusside
Cocaine/XTC intoxication	Several hours, SBP <140 mm Hg	Phentolamine (after benzodiazepines)	Nitroprusside
Pheochromocytoma crisis	Immediate	Phentolamine	Nitroprusside Urapidil
Perioperative hypertension during or after CABG	Immediate	Nicardipine	Urapidil Nitroglycerin
During or after craniotomy	Immediate	Nicardipine	Labetalol
Severe preeclampsia/eclampsia	Immediate, BP <160/105 mm Hg	Labetalol (plus $MgSO_4$ and oral antihypertensives)	Ketanserin Nicardipine

CABG, Coronary artery bypass graft; *MAP,* mean arterial pressure; *$MgSO_4$,* magnesium sulfate; *XTC,* "Ecstasy" (3,4-methylenedioxymethamphetamine).

Modified from van den Born BJ, Beutler JJ, Gaillard CA, et al: Dutch guideline for the management of hypertensive crisis—2010 revision. Neth J Med 69:248, 2011.

Hypertensive Crisis with Advanced Retinopathy

Patients with full-blown hypertensive crisis are critically ill with BP of 220/130 mm Hg or higher and grade 3 or grade 4 hypertensive retinopathy (**Fig. 47.10**), accompanied by headache, visual disturbances, nausea/vomiting, HF, neurologic sequelae (encephalopathy), electrocardiographically confirmed LVH, renal impairment, and microangiopathic hemolytic anemia. African American patients are more likely to

have hypertensive HF. First-line drug options are IV labetalol (a combined alpha/beta blocker), nitroprusside, nicardipine (a dihydropyridine CCB), or urapidil (a new central sympatholytic that acts on central serotonergic pathways and also selectively blocks peripheral $alpha_1$-adrenergic receptors). In patients with impaired cerebral autoregulation (see later), labetalol causes a smaller adverse fall in cerebral blood flow than nitroprusside but has a longer half-life, which leads to more adverse episodes of systemic hypotension. IV nicardipine appears to produce a more predictable and consistent reduction in BP than labetalol, but with a similar safety profile; however, physicians and hospital pharmacies are less familiar with nicardipine.[135]

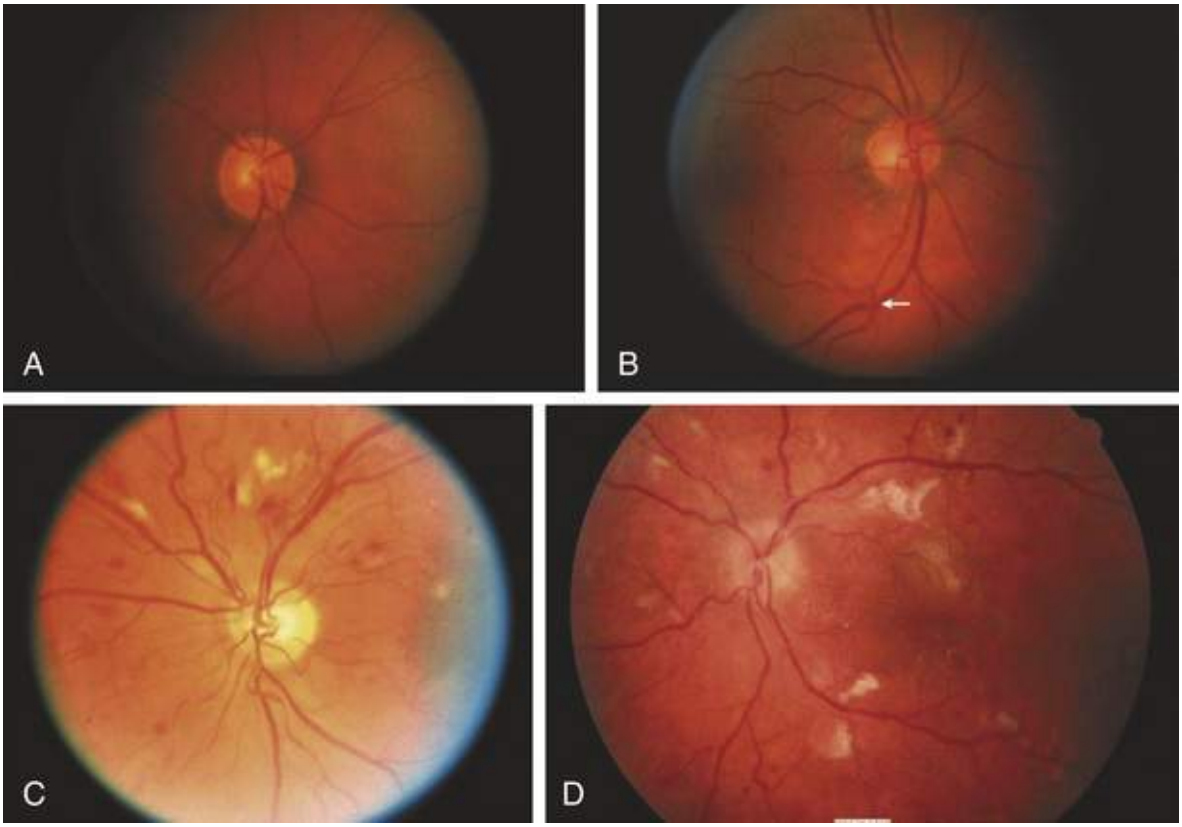

FIGURE 47.10 Retinal photographs showing the stages of hypertensive retinopathy. **A,** Mild diffuse arteriolar narrowing. **B,** Arteriovenous nicking *(arrow).* **C,** Hemorrhages and exudates. **D,** Papilledema. (From Grosso A, Veglio F, Porta M, et al. Hypertensive retinopathy revisited: some answers, more questions. Br J Ophthalmol 2005;89:1646.)

Hypertensive Crisis with Encephalopathy

Findings in hypertensive encephalopathy include a reduced level of consciousness, delirium, agitation, stupor, seizures, or cortical blindness in the setting of acute severe high BP. Focal neurologic signs are rare and suggest ischemic or hemorrhagic stroke rather than encephalopathy. Hypertensive encephalopathy is a cause of reversible *posterior leukoencephalopathy syndrome,* which is often seen in the setting of cyclosporine- or tacrolimus-induced hypertension (particularly in heart transplant recipients) or that caused by bevacizumab or bortezomib. Brain computed tomography (CT) or magnetic resonance imaging (MRI) showing areas of cerebral edema confirms the diagnosis of encephalopathy. The edema typically localizes in posterior brain regions perfused by the vertebral arteries, which have less sympathetic innervation and thus less dampening of BP oscillations than the carotid arteries. The areas of brain edema will resolve with timely treatment of the hypertensive crisis.

Encephalopathy occurs when BP exceeds the upper limit of cerebral autoregulation, which normally maintains cerebral blood flow constant over a range of mean arterial pressure from 60 to 150 mm Hg. In patients without preexisting hypertension, such as those with preeclampsia, encephalopathy will develop when mean arterial pressure exceeds 150 mm Hg. In those with chronic hypertension, the autoregulatory curve shifts to the right to defend against a higher level of BP, but this adjustment makes patients vulnerable to cerebral underperfusion if BP is lowered too quickly into the normotensive range. Thus, patients with hypertensive encephalopathy should receive IV antihypertensive therapy, preferably with labetalol, immediately to lower BP in a controlled manner that avoids cerebral hypoperfusion and thus irreversible brain damage. A good rule of thumb is to lower the initially elevated arterial pressure by 10% in the first hour and by an additional 15% during the next 12 hours to a BP of no less than 160/110 mm Hg. BP can be reduced further during the next 48 hours. IV saline is often needed to prevent hypovolemic hypotension from pressure natriuresis and nausea/vomiting.

Acute Ischemic or Hemorrhagic Stroke

In acute ischemic stroke, BP should be lowered cautiously to avoid ischemic insult to potentially salvageable tissue (termed the *ischemic penumbra*), which would extend the infarct (**see Chapter 65**). Acknowledging a limited evidence base, the 2013 guidelines from the AHA/American Stroke Association[136] recommend the following: (1) if the stroke cannot be treated with thrombolytic therapy, BP should be treated if it remains higher than 220/120 mm Hg and initially lowered by no more than 15%, and (2) if the stroke can be treated with thrombolytic therapy, BP needs to be lowered to less than 185/110 mm Hg. Results of INTERACT2 (Intensive BP Reduction in Acute Hemorrhage Trial 2) showed improved functional outcomes without more adverse events in patients with acute hemorrhagic stroke randomly assigned to intensive treatment to lower SBP to less than 140 mm Hg than to the conservative guideline-recommended goal of less than 180 mm Hg.[137] Optimal protection against death or major disability after acute hemorrhagic stroke was observed in patients without severe hemorrhage and early planned surgery who achieved the greatest SBP reductions of 30 mm Hg in the first hour after randomization and maintained it consistently for 7 days.[138] For either ischemic or hemorrhagic stroke, agents of choice to lower BP include urapidil, nicardipine, or labetalol; nitroprusside and hydralazine should be avoided because they may increase intracranial pressure.

Acute Coronary Syndrome

In hypertensive patients with acute coronary syndrome (ACS), BP should be lowered with IV nitroglycerin after the administration of a beta blocker such as IV metoprolol to prevent reflex tachycardia. IV esmolol lowers BP more than metoprolol, is rapidly reversible, and produces a more predictable dose-dependent reduction in BP than IV nitroglycerin (which alleviates angina more reliably than lowering BP). Nitroprusside can cause coronary steal and should be avoided. Hypotension must be avoided in ACS patients to prevent infarct extension (**see Chapters 59 and 60**).

Acute Heart Failure

Nitroprusside is the drug of choice to treat hypertensive crisis and acute HF. Concomitant loop diuretics both decrease acute pulmonary edema and further lower BP (**see Chapter 24**).

Adrenergic Crisis

Pheochromocytoma crisis should be treated acutely with phentolamine followed by administration of a

beta blocker. Nitroprusside and urapidil are effective alternatives. Clonidine withdrawal can be aborted by reintroduction of this agent. Based on limited evidence, cocaine- or methamphetamine-induced acute hypertension should be treated with IV benzodiazepines and labetalol[139] (**see Chapter 24**).

Practical Clinical Approach to Evaluation and Management of Ambulatory Hypertensive Patients

Unlike the preceding seven reports of the Joint National Committee, the 2014 majority report of members invited to serve on the JNC 8 panel was not sanctioned by the NHLBI or any professional organization and thus does not constitute an official U.S. hypertension guideline.[8] Following the IOM guidelines for strict interpretation of the evidence from RCTs, this panel recommended (1) less intensive drug treatment of high BP for patients age 60 or older, (2) conventional office BP—the metric for clinical decision making in most prior hypertension RCTs, and (3) dose escalation to match the high drug doses proven effective in RCTs. New evidence obtained from 2015 to 2017 calls each of these recommendations into question. The SPRINT results favor more intensive—not less intensive—therapy for older patients, but with important caveats related to the trial's strict eligibility criteria. Application of the SPRINT eligibility criteria to the entire U.S. population would classify an additional 16.8 million adults as eligible for either initiation or intensification of antihypertensive drug therapy.[140] Achieving the stricter BP goals would require more careful titration of medication, greater use of fixed-dose drug combinations, more frequent monitoring for adverse effects, and thus more frequent patient visits than ever before.[141] The seemingly contradictory outcomes of other RCTs, meta-analyses, and observational studies have generated confusion among internists and cardiologists, who are left in a quandary regarding an ideal BP.[141,142] Replacing manual with automated office BP measurement would represent a sea change in clinical medicine and mental recalibration of what clinicians consider normal versus high BP values. Despite ever-increasing evidence that ambulatory BP monitoring is far superior to office-based BP measurement for prediction of CV risk, the guidelines are less clear about how to use this information to gauge drug therapy. Although combination drug therapy with two or three drugs of different classes is needed to achieve the BP goals in SPRINT (and ACCORD), experts differ as to whether a thiazide-type diuretic is the best drug to initiate therapy for most patients, and whether their dose-dependent side-effects are common or uncommon, serious or trivial.

We therefore offer the following approach for practical office-based evaluation and management of hypertension.[143]

Initial Evaluation (See Chapter 46)

Staging of Blood Pressure

We have started using automated office BP (AOBP) measurement to make the diagnosis of hypertension. With the patient seated quietly alone in the examination room for 5 minutes, a highly rated oscillometric monitor takes five readings on STAT mode. Hypertension is diagnosed if the average of the last three readings is 135/85 mm Hg or higher *and* the patient has electrocardiographically confirmed LVH or other evidence of hypertension-induced target-organ damage.

In the absence of target-organ damage or very severe AOBP (≥180/110 mm Hg), we routinely use ambulatory BP monitoring (ABPM) or home BP monitoring to confirm the diagnosis of hypertension and stage the BP, because AOBP can overestimate and often underestimates out-of-office BP. We generally

initiate antihypertensive drug therapy if the average awake BP is 135/85 mm Hg or higher, or the average sleeping BP is 120/70 mm Hg or higher. Most private insurance plans will reimburse ABPM, but Medicare currently will not, except for suspected white coat hypertension without target-organ damage. For home BP monitoring, the key is to calibrate the patient's monitor in the office against the validated AOBP monitor. Most BP monitors are graded by the British Hypertension Society (http://www.dableducatioonal.org/). Patients should take a set of three readings every morning before taking their pills and again every evening for 4 days consecutively and record all the readings. The first day's readings and the first reading of each set are discarded as being artificially high, and the rest are averaged; if the mean is 135/85 mm Hg or higher, we diagnose and treat hypertension.

Global Cardiovascular Risk Assessment

We use the 2013 ACC/AHA pooled cohort calculator to estimate 10-year CV risk both to help set each patient's personal BP goal and to decide about starting concomitant high-potency statin therapy, which is indicated in 75% or more of hypertensive individuals. This practice is based on compelling data from both the recent HOPE-3 trial[144] and the earlier ASCOT trial[145] showing that addition of 10 mg of rosuvastatin or 10 mg of atorvastatin (the only two high-potency statins) provides additional CV risk reduction in hypertensive patients (or prehypertensive patients with intermediate CV risk in the case of HOPE-3) and an average baseline low-density lipoprotein (LDL) cholesterol of 130 mg/dL. Thus, we initiate statin therapy with 10 mg of rosuvastatin or atorvastatin if the calculated 10-year CV risk is 7.5% or more or LDL cholesterol is 130 mg/dL or greater.

Secondary Hypertension

Secondary hypertension should be suspected whenever the BP elevation is unusually severe (160/100 or especially if 180/110 mm Hg). The two most common forms of secondary hypertension are CKD and primary aldosteronism. A spot urine microalbumin/creatinine ratio is part of our initial evaluation for hypertension. A spot 8 AM plasma renin activity (PRA) and serum aldosterone is ordered if the serum potassium (K^+) level is less than 3.5 mmol/L or the patient has stage 2 hypertension (BP >160/100 mm Hg) even with normal serum K^+, or if abdominal imaging studies show an incidental adrenal mass. A positive screening test for primary aldosteronism requires both a suppressed PRA below 1.0 ng/mL/hr (<0.6 is severely suppressed) and an elevated serum aldosterone above 12 ng/dL.[146] We ignore the reported aldosterone/renin ratio, which will be falsely high if the PRA is less than 1.0 ng/mL/hr, even if serum aldosterone is low. Although obese hypertensive patients often have obstructive sleep apnea, we have not routinely ordered formal polysonography, because the only large RCT of continuous positive airway pressure (CPAP) found that it is not effective in lowering BP or preventing CV events (e.g., AF).[147] We screen for fibromuscular dysplasia (FMD) with a CT angiogram mainly in women of any age with a unilateral small kidney or with stage 2 systolic/diastolic hypertension, or who complain of a pulsatile swishing sound, which suggests carotid FMD; in experienced centers, percutaneous angioplasty (without stenting) has a high cure rate.[148]

We screen for atherosclerotic renal artery stenosis only in selected patients, because percutaneous intervention with stenting is reserved for patients with medically refractory hypertension, rapidly progressive CKD, or recurrent flash pulmonary edema; absence of microalbuminuria may identify patients without microvascular renal disease and a more favorable outcome with stenting.[149] We screen for pheochromocytoma with plasma metanephrines in any patient with an incidental adrenal mass; otherwise, we only screen if symptoms are compelling (e.g., paroxysmal hypertension with pallor rather than

flushing) or family history of syndromic pheochromocytoma.

Management

Blood Pressure Thresholds and Goals of Therapy

Given the recent SPRINT outcomes and the totality of the evidence, we believe the relaxed drug treatment threshold (SBP ≥150 mm Hg) for patients age 60 years or older, recommended by both the 2014 JNC 8 panelists' report[8] and the 2017 American College of Physicians/American Academy of Family Physicians guidelines,[13] is too conservative to be broadly applied. It is based solely on conventional office BP and trials that were not designed to address this key issue. The recommendation does not account for large interindividual differences in CV risk or frailty.

We take a more personalized approach. For most patients, we initiate antihypertensive drug therapy if the average awake BP (by ABPM, home monitoring, or AOBP) is ≥135/85 mm Hg or the average sleep BP (by ABPM) is ≥120/70 mm Hg, even if the AOBP is <135/85 mm Hg. This is masked hypertension. It is associated with a high CV risk, and we treat it. If the AOBP is ≥135/85 mm Hg, we will withhold drug therapy only if the awake BP and the sleeping BP are unequivocally normal (<130/80 and <110/60 mm Hg, respectively), the global 10-year CV risk score is low (<7.5%), and there is no evidence of target-organ damage. This is white coat hypertension, and, when so strictly defined, it should not be treated. However, many patients with suspected white coat hypertension have a white coat reaction superimposed on mild hypertension that requires treatment.

For high-risk patients, we consider initiating or intensifying drug therapy if the average awake BP is ≥130/80 mm Hg or the sleeping BP is ≥115/65 mm Hg. *High-risk patients* are those meeting one or more of the following SPRINT inclusion criteria:

- Documented CAD, MI, or angina
- Estimated glomerular filtration rate (eGFR) of 20 to 59 mL/min/1.73 m^2
- 10-year CV risk of 15% or greater
- Age 75 years or older

High-risk patients are also those with:

- African ancestry
- LVH by electrocardiography (without critical coronary stenosis)
- Diabetes mellitus without orthostatic hypotension
- Prior stroke or transient ischemic attack (TIA)
- Prior heart failure admissions

For intensive therapy in robust patients age 75 or older, we start with low-dose medication and intensify the regimen slowly. We involve the patient in the clinical decision making. We schedule more

frequent follow-up office visits to avoid causing orthostatic hypotension, symptomatic postexercise hypotension, acute kidney injury (renal J curve), or worsening angina (cardiac J curve), which would require less intensive therapy.

For frail elderly patients (orthostatic or postprandial hypotension or unsteady gait), we relax the goal of therapy such that standing systolic BP is 135 mm Hg or greater without orthostatic symptoms. This often means that a rather high supine BP must be accepted to permit safe ambulation. We discuss this trade-off with the patient and family member or caretaker. Ambulatory monitoring is extremely helpful if available. A seated home BP of 155 mm Hg may be an appropriate treatment target for a frail 70-year-old patient with marked orthostatic and postprandial hypotension (**as in Fig. 47.9**), whereas a home seated BP of 130 mm Hg may be an appropriate treatment target for a vigorous healthy 85-year-old patient whose chief concern is to avoid a disabling stroke. Symptomatic orthostatic hypotension must be avoided, particularly when treating older adults and patients with longstanding diabetes who have developed autonomic neuropathy.

ABPM is particularly informative in patients with stage 3 CKD or higher because most will have masked (otherwise undertreated) nocturnal hypertension and because overtreatment of hypertension can precipitate AKI. As a rule of thumb, average awake BP should be 135/85 mm Hg or lower and nighttime BP 120/70 mm Hg or lower, but these goals will require relaxation if renal function deteriorates (due to loss of renal autoregulation) during intensification of the BP regimen in patients with CKD.

Lifestyle Modification

The DASH diet and other lifestyle modifications are indicated for all patients with hypertension or prehypertension, as detailed in the 2013 AHA/ACC guideline on lifestyle management to reduce CV risk.[20] Because recidivism is common, patients need continual encouragement from their physicians and support from family and peers. We recommend lifestyle modification as an essential adjunct—but not as a substitute—for antihypertensive drug therapy. We start both simultaneously.

First-Line Drugs

The three first-line drug classes for hypertension are (1) a CCB, (2) an ACEI or ARB, and (3) a thiazide-type diuretic. We use amlodipine as the preferred CCB for most patients because it is long acting (once-daily dosing), is the best studied of the CCBs and performed well in multiple RCTs, and is now available in generic form. The choice of an ACEI or ARB involves consideration of cost and tolerability. We use a long-acting ARB for once-daily dosing. For diuretic therapy, the evidence overwhelmingly favors indapamide or chlorthalidone over HCTZ; low doses minimize metabolic side effects.

Low-Dose Combination Therapy

We typically initiate medication management with low-dose combination therapy, both for synergistic efficacy and to minimize dose-dependent side effects. Our go-to combination is amlodipine plus either telmisartan or irbesartan (long-acting, once-daily, potent generic ARBs that performed well in RCTs). Most adults require 5 to 10 mg of amlodipine and either 40 to 80 mg telmisartan or 150 to 300 mg irbesartan daily to effectively manage their hypertension. The starting doses rarely cause side-effects in patients with uncomplicated hypertension.

The higher (10-mg) dose of amlodipine will cause some degree of ankle edema in approximately 20% of patients. The higher dose of irbesartan or telmisartan increases the risk of AKI and hyperkalemia if there is underlying CKD or hypovolemia. We inspect the patient's gums because any CCB can rarely

cause gingival hyperplasia, which resolves (slowly) if diagnosed and the medication is stopped; if not diagnosed and the CCB is continued, it can cause serious dental problems. Most ambulatory patients can achieve BP goals safely and without any side effects in 6 to 12 weeks. This rather rapid intensification of therapy requires home monitoring, frequent clinic follow-up initially, and lifestyle modification.

For patients with uncomplicated hypertension, we generally reserve diuretic therapy for triple therapy, not initial therapy, because of the drugs' metabolic side effects and high-discontinuation rates. Whereas the JNC 8 panelists 2014 report recommended prescribing the high target doses of thiazides used in RCTs, in practice we use the lowest dose of a thiazide-type diuretic needed to achieve the desired BP. The evidence clearly supports the use of long-acting indapamide or CTD over short-acting HCTZ. For patients with hypertension that is not controlled with amlodipine plus telmisartan or irbesartan, we will add half of a 1.25-mg tablet of indapamide, which is less costly than CTD and is a superoxide scavenger.

We prescribe a vasodilating beta blocker, such as carvedilol or nebivolol, as first-line therapy for hypertension in patients with CAD or HF. These vasodilating beta blockers are much better antihypertensive agents than metoprolol. However, they are less effective than metoprolol in treating supraventricular tachycardia, if SVT is an important comorbidity. We also will use one of these drugs as first-line therapy if hypertension accompanies significant chronic anxiety, particularly if the patient's resting heart rate is 80 beats/min or more. Generic carvedilol is on most formularies at $4 per month, whereas nebivolol and Coreg CR are branded and expensive. Carvedilol should be taken after breakfast and after dinner on a full stomach to optimize absorption and to prevent GI upset. Nebivolol is more convenient with once-daily dosing and absorption unaffected by food.

Resistant Hypertension

Many cases of apparent drug-resistant hypertension are pseudoresistant. A common issue is an inadequate medication regimen. If white coat hypertension and medication compliance have been excluded, if screening tests for secondary hypertension are negative, if NSAIDs have been eliminated, and if the goal BP still cannot be achieved with appropriate *first-line triple therapy* (amlodipine *plus* a long-acting ARB *plus* indapamide or CTD), the best add-on drugs are mineralocorticoid receptor antagonists (spironolactone, eplerenone) and vasodilating beta blockers (carvedilol, nebivolol). Low-dose spironolactone (12.5 to 25 mg/day) may take 8 weeks or more to achieve peak BP reduction, which can be impressive. Eplerenone avoids the sexual side effects of spironolactone but is more expensive, and higher daily doses (50 to 100 mg) and twice-daily dosing may be required. Clonidine should be avoided whenever possible and should not be prescribed for patients to self-medicate on an as-needed basis, because this practice will create labile rebound hypertension.

Table 47.16 furnishes tips on optimal BP management. Undertreatment of hypertension and underuse of combination drug therapy—even for resistant hypertension—is common in outpatient office-based practice.[150-152] Impressive data from Kaiser-Permanente show that a large managed care organization can improve hypertension control rates in their population from 45% to over 80% by (1) continually reviewing their registry data to identify patients with elevated BP and contacting the patients proactively, (2) using a simple system-wide medication intensification protocol with fixed-dose/once-daily combination pills, and (3) increasing access with walk-in BP checks performed by medical assistants as part of a pharmacist-based hypertension management team.[153] Pharmacists can work with patients to develop shared goals and reconcile medications, and in most states they may implement a preset medication intensification protocol under collaborative practice agreement with physician oversight. Pharmacist-based team interventions for the management of hypertension have proved effective in more than 50 RCTs[154] and allow the physician time to focus on health care team leadership, diagnostic

evaluations, and other complex issues.[155] With all these measures, hypertension control rates of up to 80% can be achieved in office-based practice. Patients with drug-resistant hypertension should be referred to a hypertension specialist.

Best tolerated drug classes
Fixed-dose single-pill combinations
Long-acting once-daily drugs
Low-cost generics
Patient Level
Patient activation
Shared goals
Self-monitoring of blood pressure
Social support

Future Perspectives

Large randomized controlled trials are needed to test the appealing but unproven hypothesis that effective treatment of masked hypertension—especially nocturnal hypertension—reduces the attendant risk of major cardiovascular events and death.

Guidelines

Treatment of Hypertension

Ronald G. Victor and Peter Libby

The Systolic Blood Pressure Intervention Trial (SPRINT) is the most important hypertension trial to be published since the last edition of this textbook.[1,2] SPRINT used a novel, unattended automated office blood pressure (AOBP) protocol to minimize the “white coat” reaction. The trial's positive outcomes favor more intensive rather than less intensive treatment of hypertension for select patients with high cardiovascular (CV) risk. Thus, SPRINT has potentially profound implications for changing both the routine diagnosis and the outpatient management of hypertension for tens of millions of patients in the United States[3] and hundreds of millions of patients worldwide. The question is to what extent SPRINT will impact the different practice guidelines from the United States and other countries,[4-16] given the exclusion of patients with diabetes and some other important comorbidities from SPRINT; the seemingly contradictory null outcome of the third Heart Outcomes Protection Evaluation (HOPE-3) blood pressure (BP) trial, which treated lower-risk patients with a much milder BP drug regimen than SPRINT;[17] and the

real concern that overzealous reduction in high BP can cause hypotension with falls in frail elderly patients, myocardial ischemia in patients with significant coronary disease, and acute kidney injury (AKI) in patients with chronic kidney disease (CKD).

In fact, SPRINT already has impacted the new 2016 guidelines from Canada[5] and from Australia[6] (both written by leading hypertension specialists in their respective countries) but not the 2017 guideline from the American College of Physicians/American Academy of Family Physicians (authored entirely by generalists).[4] It is not surprising that practicing physicians are confused. The 2015 AHA/ACC/ASH Scientific Statement on Treatment of Hypertension in Patients with Coronary Artery Disease[7] predated SPRINT, as did the 2014 Report of JNC 8 panelists (referred to as JNC 8 for convenience).[8]

Diagnosis of Hypertension

Table 47G.1 summarizes the different methods and cutoff BP values used to diagnose hypertension. The new 2016 Canadian hypertension guidelines[5] strongly endorsed AOBP as the preferred method of measuring office BP: with the patient alone without medical personnel in a quiet exam room for 5 minutes, the automated monitor takes a set of five readings at a rate of one reading per minute; the monitor displays the mean of the five readings, which is the AOBP.[5] An initially elevated office BP ≥135/85 mm Hg by AOBP or ≥140/90 mm Hg by conventional manual cuff measurement, must always be confirmed either by ambulatory or home blood pressure monitoring—as emphasized by the current guidelines from Canada, Australia, Europe, and the United Kingdom[5,6,11,14]—or laboriously remeasured during three to five more clinic visits over 4 to 6 weeks to ensure that hypertension is present.[5] All guidelines, except those from the United States, emphasize the importance of ambulatory blood pressure monitoring (ABPM) as the gold standard. Only if the office level is very high (>180/110 mm Hg) or if symptomatic target-organ damage is present should therapy be begun before the diagnosis is carefully established.

TABLE 47G.1

Definition of Hypertension by Conventional Office, Automated Office, and Out-of-Office Blood Pressure (BP) Levels

CATEGORY	SYSTOLIC BP (mm Hg)		DIASTOLIC BP (mm Hg)
Conventional Office BP	≥140	*and/or*	≥90
Automated Office BP (AOBP)	≥135		≥85
Home BP	≥135	*and/or*	≥85
Ambulatory BP Monitor (ABPM)			
Daytime (awake)	≥135	*and/or*	≥85
Nighttime (sleep)	≥120	*and/or*	≥70
24 hour	≥130	*and/or*	≥80

Modified from Parati G et al. European Society of Hypertension practice guidelines for ambulatory blood pressure monitoring. J Hypertens 2014;32:1359; and Gabb GM et al. Guideline for the diagnosis and management of hypertension in adults—2016. Med J Aust 2016;205:64.

Management of Hypertension

Lifestyle Modification

All patients with hypertension or prehypertension should receive counseling on lifestyle modification using the 2013 ACC/AHA Guideline on Lifestyle Management to Reduce Cardiovascular Risk.[18]

Drug Therapy

Table 47G.2 compares 13 sets of hypertension guidelines last updated between 2010 to 2017. With gaps in the evidence base, expert panels (and individual panelists) disagree on some key aspects but agree on others, as when to start or intensify drug therapy and which drugs are best for which patients.

TABLE 47G.2

Comparison of Recent Guidelines for Adults with Hypertension

GUIDELINE	POPULATION	THRESHOLD OFFICE BP LEVEL (mm Hg) FOR INITIATION OR INTENSIFICATION OF THERAPY	INITIAL DRUG THERAPY OPTIONS
2017 ACP/AAFP[4]	≥60 yr:		Thiazide, ACEI or ARB, CCB
	General Stroke or TIA High CV risk	≥150 ≥140 ≥140	
2016 Hypertension Canada's CHEP[5]	Low risk Macrovascular TOD or other risk factors Selected high risk (including ≥75 yr)	≥160/100 ≥140/90 Consider goal SBP <120 by SPRINT criteria)	Thiazide,* or BB (<60 yr), or ACEI or ARB (nonblack), or long-acting CCB Thiazide-type diuretic + ARB + CCB for intensive therapy
	Diabetes	≥130/80	ACEI or ARB, CCB, thiazide-type
	CKD	≥140/90	ACEI or ARB, CCB, thiazide-type
2016 Australia[6]	Low risk Moderate risk Selected high risk (including ≥75 yr)	≥160/100 ≥140/90 Consider goal SBP <120 by SPRINT criteria	Thiazide, or BB (<60 yr), or ACEI or ARB (nonblack), or long-acting CCB Thiazide-type diuretic + ARB + CCB for intensive therapy
	Diabetes	≥140	ACEI or ARB, CCB, thiazide-type
	CKD	≥140/90	ACEI or ARB, CCB, thiazide-type
2015 AHA/ACC/ASH Patients with CAD[7]	Stable CAD	≥140/90 ≥130/80 for some patients with CAD, prior MI, prior stroke or TIA, or CAD risk equivalents (carotid disease, PAD, AAA) Avoid reducing DBP <60 in patients with diabetes or ≥60 yr	BB, ACEI or ARB; thiazide or thiazide-type diuretic; non-DHP CCB for BB-intolerant patients; DHP CBB for add-on therapy
2014 JNC 8 Committee[8]	General ≥60 yr General <60 yr	≥150/90 ≥140/90	Nonblack: thiazide,* ACEI or ARB, CCB Black: thiazide, CCB
	Diabetes	≥140/90	Thiazide, ACEI or ARB, CCB
	CKD	≥140/90	ACEI or ARB
2014 ASH/ISH[9]	General ≥80 yr General <80 yr Diabetes CKD	≥150/90 ≥140/90 ≥140/90 ≥140/90	Nonblack/stage 1: thiazide, ACEI or ARB, CCB Black/stage 1: thiazide, CCB Stage 2: CCB or thiazide + ACEI or ARB ACEI or ARB ACEI or ARB
2013 AHA/ACC/CDC[10]	General	≥40/90	Stage 1: thiazide for most or ACEI or ARB, CCB Stage 2: thiazide + ACE-I or ARB *or* thiazide + CCB *or* ACEI or ARB + CCB
2013 ESH/ESC[11]	General ≥80 yr General 60-79 yr General ≤60 yr Diabetes CKD, no proteinuria CKD + proteinuria	≥160/90 ≥150/90 *or* ≥140/90 ≥140/90 ≥140/85 ≥140/90 ≥130/90	BB, thiazide, CCB, ACE-I or ARB ACEI or ARB ACEI or ARB ACEI or ARB
2013 ADA[12]	Diabetes	≥140/80	ACEI or ARB
2012 KDIGO[13]	CKD, no proteinuria CKD + proteinuria	≥140/90 ≥130/80	ACEI or ARB
2011 UK NICE[14]	General ≥80 yr General <80 yr	≥150/90 ≥140/90	≥55 yr or black: CCB, thiazide <55 yr: ACEI or ARB
2011 ACCF/AHA: elderly hypertensive patients[15]	General ≥80 yr General <80 yr	≥150/90 ≥40/90	ACEI or ARB, CCB, thiazide
2010 ISHIB[16]	Black Black + target-organ disease or CVD risk	≥135/85 ≥130/80	Thiazide, CCB

*Evidence from randomized controlled trials supports the use of indapamide or chlorthalidone, thiazide-like diuretics, rather than hydrochlorothiazide.

ACEI, Angiotensin-converting enzyme inhibitor; *ARB,* angiotension receptor blocker; *CCB,* calcium channel blocker; *BB,* beta blocker; *DHP,* dihydropyridine.

AAA, Abdominal aortic aneurysm; *CKD,* chronic kidney disease; *CVD,* cardiovascular disease; *DBP,* diastolic blood pressure; *MI,* myocardial infarction; *PDA,* peripheral artery disease; *SBP,* systolic blood pressure; *TIA,* transient ischemic attack; SPRINT, Systolic Blood Pressure Intervention Trial.

ACP, American College of Physicians; AAFP; American Academy of Family Physicians; CHEP, Canadian Hypertension Education Program; ASH, American Society of Hypertension; ISH, International Society of Hypertension; AHA, American Heart Association; ACC, American College of Cardiology; CDC, Centers for Disease Control and Prevention; ADA, American Diabetes Association; KDIGO, Kidney Disease: Improving Global Outcome; UK, United Kingdom; NICE, National Institute for Health and Clinical Excellence.

Modified from James PA et al. 2014 Evidence-based guideline for the management of high BP in adults: report from the panel members appointed to the Eighth Joint National Committee (JNC 8). JAMA 2014;311:507.

When to Start or Intensify Drug Therapy

Table 47G.3 emphasizes the differences between the recommendation of the panelists concerned for JNC 8 and the newer guidelines from Canada and Australia, which incorporated SPRINT into their updated recommendations. Unlike past JNCs, JNC 8 was endorsed by neither the U.S. National Institutes of Health nor any professional medical society, and thus the 2014 report does not constitute the official U.S. hypertension guidelines. The most controversial recommendation by JNC 8 was to relax the threshold for initiating or intensifying drug therapy for patients age ≥60 years from a systolic BP of 140 to 150 mm Hg. It also recommended relaxing the threshold for patients with diabetes or CKD from a BP of 130/80 to 140/90 mm Hg, the latter being the same for general patients with hypertension. These recommendations were based strictly on conventional office BP. They did not account for the patient's overall CV risk. Statin therapy for additional risk reduction was not addressed.

TABLE 47G.3

Comparison of 2014 JNC 8 Panelists Report with New Recommendations Common to the 2016 Canadian and 2016 Australian Hypertension Guidelines

	2014 JNC 8 REPORT*	2016 GUIDELINES†
Blood pressure (BP) threshold for initiation of drug therapy	≥150/90 mm Hg for patients ≥60 yr ≥140/90 mm Hg for general patients <60 yr and patients with diabetes or chronic kidney disease	Risk-based thresholds: ≥160/100 mm Hg for low risk ≥140/90 mm Hg for moderate risk Consider intensified therapy (goal SBP ≤120 mm Hg by AOBP for selected high-risk patients meeting SPRINT inclusion criteria.
Office BP measurement	Conventional manual sphygmomanometer	Automated office blood pressure (AOBP) or conventional sphygmomanometer
Combination drug therapy	An option to initiate therapy for stage 1 or 2 hypertension	For high-risk patients meeting SPRINT inclusion criteria for intensified therapy
	Combine any two of the first-line drugs	Triple therapy with potent/long-acting drugs: CCB + ACEI or ARB + thiazide-type diuretic
Statin therapy	Not addressed	Recommended for hypertensive patients with high cardiovascular risk

*Modified from James PA et al. 2014 Evidence-based guideline for the management of high BP in adults: report from the panel members appointed to the Eighth Joint National Committee (JNC 8). JAMA 2014;311:507.

†Modified from Leung AA, et al. Hypertension Canada's 2016 Canadian Hypertension Education Program guidelines for blood pressure measurement, diagnosis, assessment of risk, prevention, and treatment of hypertension. Can J Cardiol 2016;32:569, 2016; and Gabb GM et al. Guideline for the diagnosis and management of hypertension in adults—2016. Med J Aust 2016;205:64.

ACEI, Angiotensin-converting enzyme inhibitor; *ARB,* angiotension receptor blocker; *CCB,* calcium channel blocker; *SBP,* systolic blood pressure; SPRINT, Systolic Blood Pressure Intervention Trial.

In contrast, the new Canadian and Australian guidelines[5,6] are risk based. They recommend an even higher treatment threshold of office BP ≥160/100 mm Hg for low-risk patients, office BP ≥140/90 mm Hg for moderate-risk patients, and to consider intensified therapy with a goal of achieving systolic BP <120 mm Hg by AOBP for select high-risk patients who meet one or more of the SPRINT inclusion criteria

(**Table 47G.4**). These were age ≥50 years, systolic BP 130 to 180 mm Hg, and high CV risk: clinical coronary disease, or estimated glomerular filtration rate (eGFR) of 20 to 59 mL/min/1.73 m^2, 10-year CVD risk ≥15%, or age ≥75 years.[1,3] Exclusion criteria were diabetes, history of stroke, >1 g/24 hr of proteinuria daily, heart failure, history of stroke or transient ischemic attack (TIA), eGFR <20 mL/min/1.73 m^2, or receiving dialysis.[1,3]

TABLE 47G.4

SPRINT Inclusion and Exclusion Criteria

Inclusion Criteria
1. Age ≥50 years, *and* 2. Systolic BP 130-180 mm Hg, *and* 3. High CVD risk (one or more) • Clinical coronary disease (MI, CHD, angina) • eGFR 20-59 mL/min/1.73 m2 • Framingham risk score for 10-year CVD risk ≥15% • Age ≥75 years
Exclusion Criteria
1. Diabetes, *or* 2. History of stroke, *or* 3. Proteinuria >1 g in 24 hr, *or* 4. Heart failure, *or* 5. eGFR <20 mL/min/1.73 m^2 *or* dialysis

CHD, Coronary heart disease; *CVD,* cardiovascular disease; *MI,* myocardial infarction; *eGFR,* estimated glomerular filtration rate.

Modified from Bress AP et al. Generalizability of SPRINT results to the U.S. adult population. J Am Coll Cardiol 2016;67:465.

Several other points merit consideration regarding the different sets of guidelines in **Table 47G.2**:

- Most of the guidelines that predated SPRINT recommended relaxed BP treatment thresholds for elderly patients. The SPRINT outcomes challenge this recommendation.[1,2]
- Only the 2014 statement from the JNC 8 panelists defined “elderly” as 60 years or older. The other guidelines defined elderly as 80 years or older.
- Most guidelines relaxed the treatment threshold in CKD to ≥140/90 mm Hg, except for the 2013 KDIGO guidelines,[13] which recommended ≥130/80 mm Hg for proteinuric CKD.
- There is no consensus about the recommended BP treatment threshold for patients with diabetes. This reflects the large gap in the evidence base (left by the underpowered ACCORD trial).[19] Less intensive therapy may be indicated for patients with longstanding diabetes who already are prone to orthostatic hypotension from diabetic autonomic neuropathy, AKI and hyperkalemia from loss of renal autoregulation and type 4 renal tubular acidosis, and myocardial ischemia from

coronary disease and microvascular rarefication.
• All except the recent U.S. guidelines use global CV risk in considering when to initiate therapy. The European guidelines remain the most conservative, reserving drug therapy in stage 1 hypertension only for those with clinical CV disease, target-organ damage, diabetes, CKD, or an estimated 10-year CV disease risk of ≥20%.[11]
• The 2010 ISHIB guidelines[16] were risk-based, recommending initiation of drug therapy for office BP ≥135/85 mm Hg in black patients with uncomplicated hypertension (who are at higher risk of developing complications than other groups) and for BP ≥130/80 mm Hg in the presence of target-organ disease, comorbidity, or an estimated 10-year CV disease risk of ≥10%.

With all these guidelines, the goal of therapy is to achieve average systolic and diastolic BP levels just below the thresholds for initiating or intensifying therapy.

Which Drugs for Which Patients

• There is consensus that most hypertensive patients—regardless of their age, race/ethnicity, and absence or presence of target-organ damage or comorbidities—will require double-, or more often, triple-drug combination therapy with a calcium channel blocker (CCB), an angiotensin-converting enzyme inhibitor (ACEI) or angiotensin receptor blocker (ARB), and a diuretic. The only issue is which drug(s) to prescribe first.
• Most guidelines prefer both a thiazide and a CCB over an ACEI or ARB to initiate therapy in black patients.
• There is consensus that alpha blockers are not first-line therapy for hypertension.
• There is consensus that beta blockers are not first-line therapy for uncomplicated hypertension in patients ≥60 years of age. The expert panels disagree whether beta blockers should be considered a first-line option for nonblack patients younger than 60.
• The newer guidelines no longer list diabetes as a compelling

indication for an ACEI or ARB. Any of the first-line drugs is recommended.

• There is overwhelming consensus that an ACEI or ARB is first-line antihypertensive therapy for patients with CKD.

• There is overwhelming consensus to avoid dual renin-angiotensin system (RAS) blockade (ACEI *plus* ARB), which increases the risk of AKI.

Lipoprotein Disorders and Cardiovascular Disease

Jacques Genest, Peter Libby

The burden of cardiovascular disease (CVD), especially atherosclerotic cardiovascular disease (ASCVD), on national health care systems remains a formidable challenge, although public health measures and targeted pharmacologic therapies can modify cardiovascular risk.[1-3] Lipoprotein disorders, especially those that increase exposure of the arterial wall to cholesterol, constitute a major modifiable cardiovascular risk factor. Modulation of plasma cholesterol levels by lifestyle or, when required, pharmacologic therapy (statins), have proved to be one of the most efficacious intervention for the prevention and treatment of ASCVD.

Lipids constitute approximately 70% (by mass) of the dry weight of plasma. Amino acids (proteins), nucleic acids, and carbohydrate make up the remainder. Approximately half of circulating lipids are sterols, and the other major components include glycerophospholipids (phospholipids) and glycerolipids (triglycerides), which circulate in lipoproteins.[4] Thus, circulating lipoproteins continuously bathe vascular endothelial cells, and the interaction between lipoproteins and cells of the arterial wall contribute causally to the pathogenesis of human atherosclerosis (**see Chapter 44**).

Convincing data affirm the "lipid hypothesis." Observational data described in **Chapter 45** show a strong and consistent association across populations between elevated blood cholesterol and low-density lipoprotein cholesterol (LDL-C) and CVD, especially coronary artery disease (CAD). Experimental data in animals show that the development of atherosclerosis requires cholesterol. Human genetic studies provide strong support of causality for genes related to LDL-C levels.[5-7] Reduction of LDL-C levels reduces the risk for CAD, and the effect size is associated with the magnitude of the reduction in LDL-C. Thus, LDL meets the modified Koch postulates as a causal risk factor for ASCVD.[8-10]

The terms *dyslipidemia* or *dyslipoproteinemia* reflect disorders of the lipid and lipoprotein transport pathways associated with arterial disease more appropriately than "hyperlipidemia." Dyslipidemia encompasses patterns often encountered in clinical practice, such as low high-density lipoprotein cholesterol (HDL-C) and elevated triglyceride concentrations but average total plasma cholesterol level. Dyslipidemia also includes elevated lipoprotein(a) and uncommon genetic or acquired disorders of lipoprotein metabolism. Certain rare lipoprotein disorders can cause overt clinical manifestations, but most common dyslipoproteinemias seldom cause symptoms or clinical signs. Rather, these disorders require laboratory tests for detection. Proper recognition and management of dyslipoproteinemias can reduce cardiovascular and total mortality rates. The fundamentals of lipidology presented here have importance for the daily practice of cardiovascular medicine.

Lipoprotein Transport System

Biochemistry of Lipids

Biologic lipids usually refer to a broad grouping of naturally occurring molecules that include fatty acids, waxes, eicosanoids, monoglycerides, diglycerides, triglycerides, phospholipids, sphingolipids, sterols, terpenes, prenols, and fat-soluble vitamins (A, D, E, and K), in contrast to the other major groupings of biologic molecules, such as nucleic acids, proteins, amino acids, and carbohydrates. The major biologic functions of lipids include critical contributions to biologic membranes, energy storage, and the

backbones or modifiers of many signaling molecules. Certain lipids, especially fatty acids, readily undergo oxidation and can generate substances highly toxic to cells. Fatty acids can be degraded in the mitochondrion by beta-oxidation, whereas the sterol nucleus resists enzymatic degradation. Elimination of cholesterol therefore requires excretion as bile acids or shedding with skin cells.

Lipids generally do not dissolve in water. The lipid transport system has evolved in animals over eons of evolution to carry hydrophobic molecules (fat) from sites of origin (the intestinal system) to sites of utilization (muscles and rapidly dividing tissues) through the aqueous (water) environment of plasma. Proteins highly conserved through evolution, termed *apolipoproteins* (apo), mediate this process. Most apolipoproteins derive from an ancestral gene and contain both hydrophilic and hydrophobic domains. This amphipathic structure enables these proteins to bridge the interface between the aqueous environment of plasma and the phospholipid constituents of lipoprotein. The major types of lipids that circulate in plasma include cholesterol and cholesteryl esters, glycerophospholipids, sphingolipids, and glycerolipids (triglycerides) (**Fig. 48.1**). The LIPIDmaps (Lipid Metabolites and Pathways Strategy) Consortium has provided standardized nomenclature for lipids.[11]

Sphingomyelin

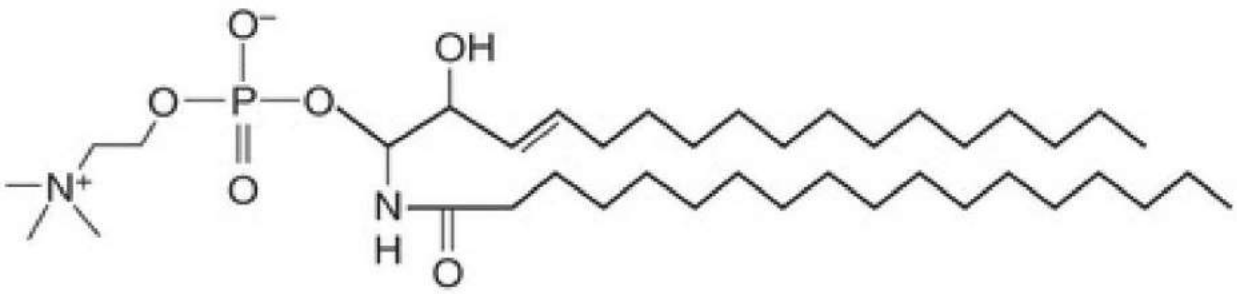

FIGURE 48.1 Biochemical structure of the major lipid molecules: cholesterol, cholesteryl esters, glycerolipids (triglycerides), and glycerophospholipids (e.g., phosphatidylcholine) and sphingomyelin. R indicates a fatty acyl chain.

The membranes of mammalian cells and their subcellular organelles require *cholesterol*. This lipid gives rise to steroid hormones and bile acids and contributes to the integrity of the epidermis. Many cell functions depend critically on membrane cholesterol, and cells regulate tightly their cholesterol content. Most of the cholesterol in plasma circulates as *cholesteryl esters* in the core of lipoprotein particles. The enzyme lecithin-cholesterol acyltransferase (LCAT) forms cholesteryl esters in the blood compartment by transferring a fatty acyl chain from phosphatidylcholine to cholesterol.

Glycerolipids (*triglycerides*) consist of a three-carbon glycerol backbone covalently linked to three fatty acid chains ($R_{1\text{-}3}$). The fatty acid composition varies in terms of chain length and the presence of double bonds (degree of saturation). The highly hydrophobic triglyceride (TG) molecules circulate in the core of the lipoprotein. Hydrolysis of triglycerides by lipases generates the free fatty acids (FFAs) used for energy.

Glycerophospholipids are constituents of all cellular membranes and consist of a glycerol molecule linked to two fatty acids (designated R_1 and R_2; **see Fig. 48.1**). Fatty acids differ in length and in the number of double bonds. The third carbon of the glycerol backbone carries a phosphate group linked to one of four molecules: *choline* (phosphatidylcholine, also called lecithin), *ethanolamine* (phosphatidylethanolamine), *serine* (phosphatidylserine), or *inositol* (phosphatidylinositol). More complex phospholipids include *phosphatidylglycerol* (e.g., cardiolipin is formed by fusion of two phosphatidylglycerol molecules; antibodies against cardiolipin often occur in systemic lupus) and *plasmalogens,* an important constituent of eukaryotic membranes. Another phospholipid, *sphingomyelin*, has special functions in the plasma membrane in the formation of membrane microdomains such as rafts and caveolae. The structure of sphingomyelin resembles that of phosphatidylcholine. The backbone of sphingolipids uses the amino acid serine rather than glycerol. Phospholipids are polar molecules, more water soluble than triglycerides or cholesterol or its esters. Phospholipids participate in signal transduction pathways: hydrolysis by membrane-associated phospholipases generates second messengers, including diacylglycerols, lysophospholipids, phosphatidic acids, and FFAs such as arachidonate, that regulate many cell functions. The phosphorylation of phosphatidylinositol contributes critically to membrane and cell organelle signaling and transport.

Lipoproteins, Apolipoproteins, Receptors, and Processing Enzymes

Lipoproteins are complex macromolecular structures coated by a water-compatible envelope of phospholipids, free cholesterol, and apolipoproteins covering a hydrophobic core of cholesteryl esters and triglycerides. Lipoproteins vary in size, density in the aqueous environment of plasma, and lipid and apolipoprotein content (**Fig. 48.2 and Table 48.1**). The classification of lipoproteins reflects their density in plasma (the density of plasma is 1.006 g/mL) as gauged by flotation in an ultracentrifuge. The triglyceride-rich lipoproteins (TRLs) consist of chylomicrons, chylomicron remnants, and very-low-density lipoprotein (VLDL) and have a density of less than 1.006 g/mL. The rest (bottom fraction) of the ultracentrifuged plasma consists of low-density lipoprotein (LDL), high-density lipoprotein (HDL), and lipoprotein(a) (Lp[a]).

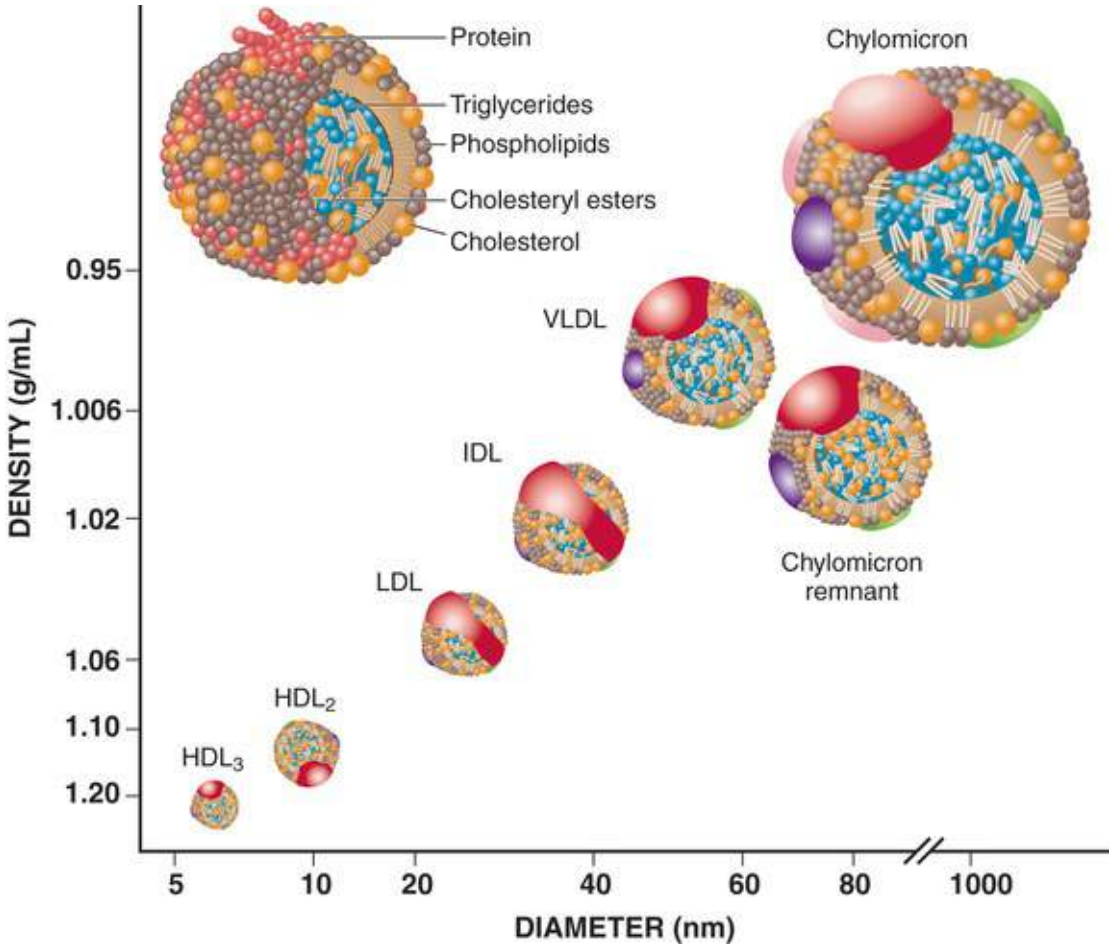

FIGURE 48.2 Relative size of plasma lipoproteins according to their hydrated density. The density of plasma is 1006 g/mL. *Inset,* Structure of lipoproteins. Phospholipids are oriented with their polar group toward the aqueous environment of plasma. Free cholesterol is inserted within the phospholipid layer. The core of the lipoprotein is composed of cholesteryl esters and triglycerides. Apolipoproteins are involved in the secretion of lipoprotein, provide structural integrity, and act as cofactors for enzymes or as ligands for various receptors.

‡In the fasted state, serum (or plasma) should not contain chylomicrons or their remnants.

Apo, Apolipoprotein; *LDL,* Low-density lipoprotein; *IDL,* intermediate-density lipoprotein; *HDL,* high-density lipoprotein; *VLDL,* very-low-density lipoprotein; *Lp(a),* lipoprotein(a).

Apolipoproteins have four major roles: (1) assembly and secretion of the lipoprotein (apo A-I, B100, and B48), (2) structural integrity of the lipoprotein (apo B, E, A-I, and A-II), (3) coactivators or

inhibitors of enzymes (apo A-I, A-V, C-I, C-II, and C-III), and (4) binding or docking to specific receptors and proteins for cellular uptake of the entire particle or selective uptake of a lipid component (apo A-I, B100, and E) (**Table 48.2**). The role of several apolipoproteins (A-IV, A-V, D, H, J, L, and M) remains incompletely understood.

TABLE 48.2
Apolipoproteins

NAME	PREDOMINANT LIPOPROTEIN	MOLECULAR WEIGHT (kDa)	PLASMA CONCENTRATION (mg/dL)	ROLE	HUMAN DISEASE
Apo (a)	Lp(a)	250-800	0.2-200	Unknown	Lp(a) excess
Apo A-I	HDL	28.3	90-160	ACAT activation, structural	HDL deficiency
Apo A-II	HDL	17	25-45	Structural

Apo J	HDL	70	10	Complement system	
Apo L1-6	HDL	43.9	—	Unknown	
Apo M	HDL	25	1 μM	Unknown	

See Tables 48.1 and 48.3 for abbreviations. *TRL,* Triglyceride-rich lipoprotein.

Many proteins regulate the synthesis, secretion, and metabolic fate of lipoproteins; their characterization has provided insight into molecular cellular physiology and targets for drug development (**Table 48.3**). Discovery of the LDL receptor (LDL-R) represented a landmark in understanding cholesterol metabolism and receptor-mediated endocytosis.[12] The LDL-R regulates the entry of cholesterol into cells, and tight control mechanisms alter its expression on the cell surface, depending on intracellular cholesterol. The LDL-R belongs to a superfamily of membrane receptors that include LDL-R, VLDL-R, LDL-R–mediated peptide type 1 (LRP1; apo E receptor), LRP1B, LRP4 (MGEF7), LRP5 and LRP6 (involved in the process of bone formation), LRP8 (apo E receptor-2), and LRP9.[13] LRP1, which mediates the uptake of chylomicron remnants and VLDL, preferentially recognizes apo E. LRP1 also interacts with hepatic lipase. The complex interaction between hepatocytes and the various lipoproteins containing apo E involves cell surface proteoglycans that provide scaffolding for lipolytic enzymes (lipoprotein lipase [LPL] and hepatic lipase) involved in recognition of remnant lipoproteins. Macrophages express receptors that bind modified (especially oxidized) lipoproteins. These scavenger lipoprotein receptors mediate the uptake of oxidatively modified LDL into macrophages. In contrast to the exquisitely regulated LDL-R, high cellular cholesterol content does not suppress scavenger receptors, thereby enabling intimal macrophages to accumulate abundant cholesterol, become foam cells, and form fatty streaks. Sterol accumulation in the endoplasmic reticulum (ER) may lead to cell apoptosis via the unfolded protein response.[14] Endothelial cells can also take up modified lipoproteins through specific receptors such as the oxidized LDL-R LOX-1.

TABLE 48.3

Lipoprotein Processing Enzymes, Receptors, Modulating Proteins

ABBREV	NAME	ROLE	Gene	HUMAN DISEASE
ABCA1	ATP-binding cassette A1	Cellular phospholipid efflux	*ABCA1*	Tangier disease
ABCG5/G8	ATP-binding cassette G5 and G8	Intestinal sitosterol transporter	*ABCG5 ABCG8*	Sitosterolemia
ACAT1	Acetyl-CoA acetyltransferase 1	Cellular cholesterol esterification	*ACAT1*	
ACAT2	Acetyl-CoA acetyltransferase 2	Cellular cholesterol esterification	*ACAT2*	
ANGPTL3	Angiopoietin-like protein 3	Inhibit LDl and EL	*ANGPTL3*	Familial hypolipoproteinemia 2
Apo E-R	Apo E–containing lipoprotein receptor	TRL uptake	*APOER2*	
CD36	Fatty acid translocase	Fatty acid transport	*CD36*	
CETP	Cholesteryl ester transfer protein	Lipid exchange in plasma	*CETP*	Elevated HDL-C
Cyp27A1	Cytochrome	Sterols hydroxylation	*CYP27A1*	Cerebrotendinous xanthomatosis
DGAT1	Acyl-CoA:diacylglycerol acyltransferase 1	Triglyceride synthesis	*DGAT1*	Elevated triglycerides
EL	Endothelial lipase	Phospholipid hydrolysis	*LIPG*	
HL	Hepatic lipase	Triglyceride hydrolysis	*LIPC*	Remnant accumulation
HSL (LIPE)	Hormone-sensitive lipase	Fatty acid release from adipocytes	*LIPE*	
LCAT	Lecithin-cholesterol acyltransferase	Cholesterol esterification (plasma)	*LCAT*	LCAT deficiency, low HDL
LDL-R	Low-density lipoprotein receptor	LDL uptake	*LDLR*	Familial hypercholesterolemia
LDL-R AP1	LDL-R adapter protein	LDL uptake	*LDLRAP1*	Recessive FH
LAL	Lysosomal acid lipase	Cholesteryl ester (CE) storage	*LIPA*	Wollman disease, CE storage disease
LOX-1	Scavenger receptor	OxLDL uptake, endothelium	*OLR1*	Oxidized lipoprotein uptake
LPL	Lipoprotein lipase	Triglyceride hydrolysis	*LPL*	Hyperchylomicronemia
LRP1	LDL-R–related protein	Protease uptake, many ligands	*LRP1*	
LRP2	LDL-R–related protein 2 (megalin)	Protease uptake, apo J	*LRP2*	
MTTP	Microsomal triglyceride transfer protein	Apo B assembly	*MTTP*	Abetalipoproteinemia
NPC1	Niemann-Pick C gene product	Cellular cholesterol transport	*NPC1*	Niemann-Pick type C
NPC1L1	Niemann-Pick C1-like 1 protein	Intestinal cholesterol absorption	*NPC1L1*	
PLTP	Phospholipid transfer protein	Lipid exchange in plasma	*PLTP*	
PCSK9	Proprotein convertase subtilisin/kexin type 9	Protein cleavage	*PCSK9*	Hypercholesterolemia
SMPD1	Sphingomyelinase phosphodiesterase 1	Sphingomyelin hydrolysis	*SMPD1*	Niemann-Pick types A and B
SRA	Macrophage scavenger receptor A	OxLDL uptake, macrophages	*MSR1*	
SR-B1	Scavenger receptor B1	HDL cholesteryl ester uptake	*SCARB1*	
VLDL-R	Very-low-density lipoprotein receptor	VLDL uptake	*VLDLR*	

At least three physiologically relevant receptors interact with HDL particles: the scavenger receptor class B (SR-B1) and the adenosine triphosphate (ATP)–binding cassette transporters A1 (ABCA1) and G1 (ABCG1). SR-B1 is a receptor for HDL (also for LDL and VLDL, but with less affinity). SR-B1 mediates the selective uptake of HDL cholesteryl esters in steroidogenic tissues, hepatocytes, and endothelium. ABCA1 mediates cellular phospholipid (and possibly cholesterol) efflux and HDL formation. The ABCG1 transporter transfers cellular cholesterol to already-formed HDL particles.

Lipoprotein Metabolism and Transport

The lipoprotein transport system has two major roles: (1) efficient transport of triglycerides from the intestine and liver to sites of utilization (fat tissue or muscle) and (2) transport of cholesterol to peripheral tissues for membrane synthesis and steroid hormone production or to the liver for bile acid synthesis (**Fig. 48.3**).

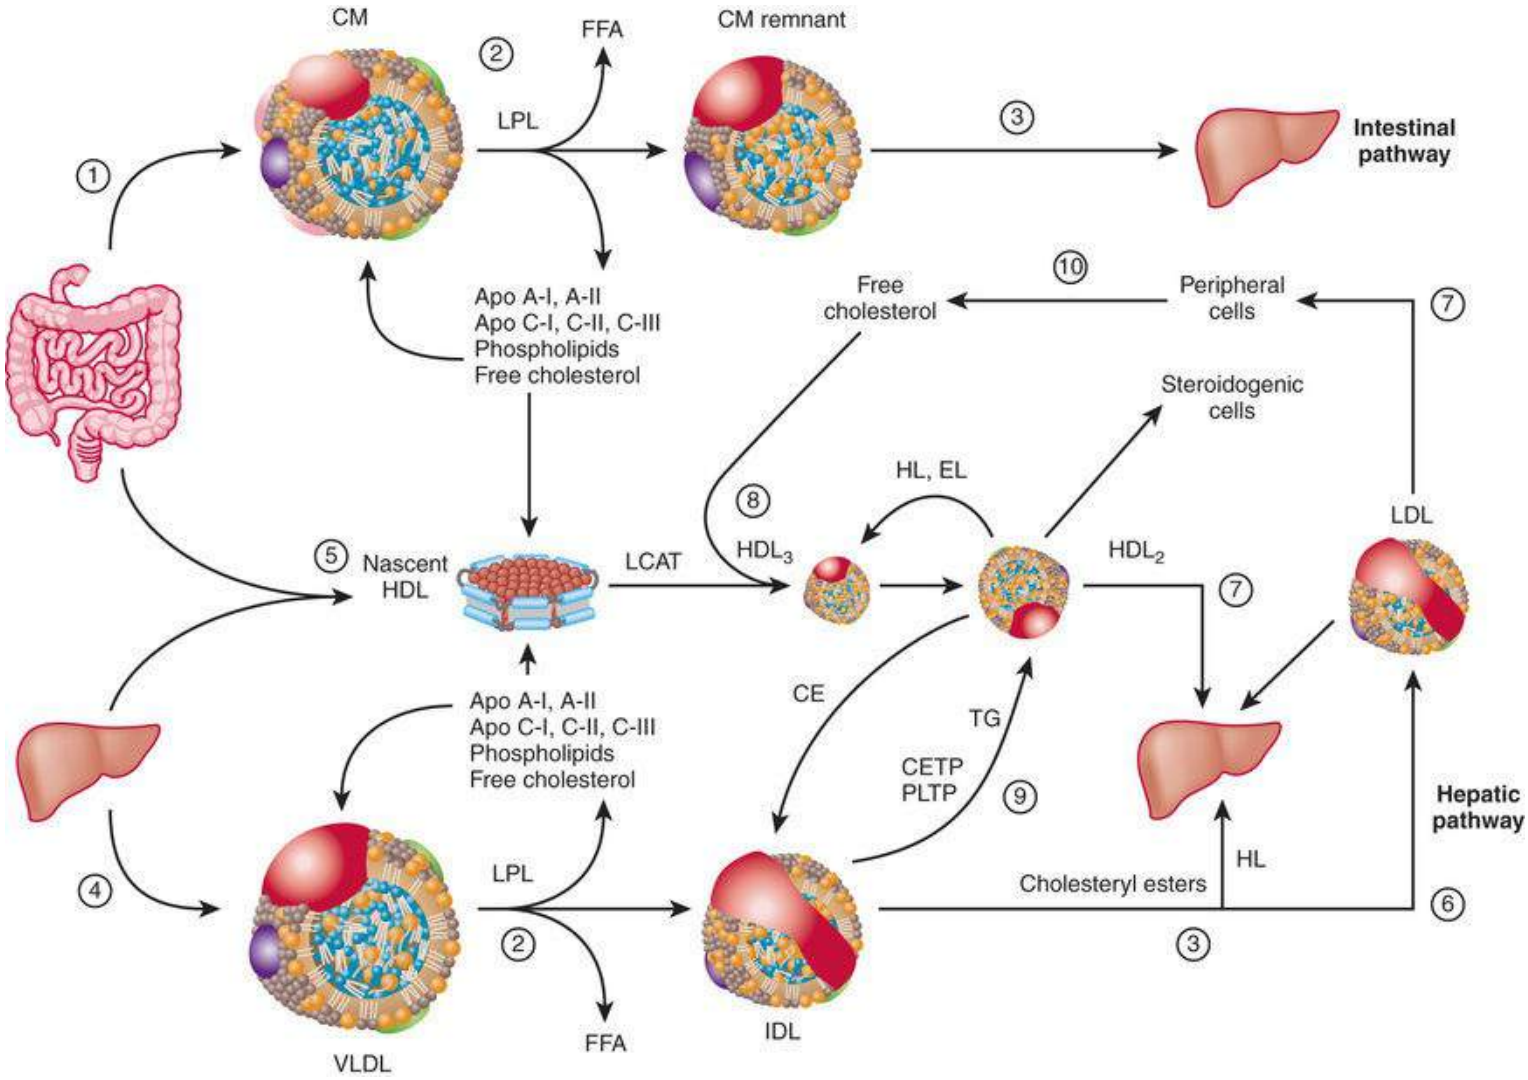

FIGURE 48.3 Schematic diagram of the lipid transport system. Numbers in circles refer to explanations in text. Refer to **Tables 48.1 and 48.3** for abbreviations. *CM,* Chylomicron; *FFA,* free fatty acid.

Intestinal Pathway (Chylomicrons to Chylomicron Remnants).

Life requires fats. The human body derives from the diet essential fatty acids that it cannot make (*linoleic acid*, from which arachidonic acid is derived, and *linolenic acid*, which leads to the formation of eicosapentaenoic acid). Fat typically furnishes 20% to 40% of the daily calories. Triglycerides account for the major portion of ingested fats. For an individual consuming 2000 kcal/day, with 30% in the form of fat, this represents approximately 66 g of triglycerides and 250 mg (0.250 g) of cholesterol per day. The intestine has very efficient fat absorption mechanisms, probably evolved to maximize provision of the organism with nutrients under circumstances of limited or irregular availability of food.

On ingestion, lingual and pancreatic lipases hydrolyze triglycerides into FFAs and monoglycerides or diglycerides. Emulsification by bile salts leads to the formation of intestinal micelles. Micelles resemble lipoproteins in that they consist of phospholipids, free cholesterol, bile acids, diglycerides and monoglycerides, FFAs, and glycerol. The mechanism of micelle uptake by intestinal brush border cells still engenders debate. The Niemann-Pick C1-like 1 (NPC1L1) protein is part of an intestinal cholesterol transporter complex and the target for the selective cholesterol absorption inhibitor ezetimibe. After uptake into intestinal cells, fatty acids undergo re-esterification to form triglycerides and packaging into chylomicrons inside the intestinal cell and enter the portal circulation (**Fig. 48.3, part 1**). Chylomicrons

contain apo B48, the amino-terminal component of apo B100. In the intestine, the apo B gene is modified during transcription into messenger RNA (mRNA) by substitution of a uracil for a cytosine via an apo B48–editing enzyme complex (ApoBec). This mechanism involves a cytosine deaminase and leads to a termination codon at residue 2153 and a truncated form of apo B. Only intestinal cells express ApoBec. Apo B48 does not bind to LDL-R. Intestinal cells absorb plant sterols (sitosterol, campesterol), sort these compounds into a separate cellular compartment, and resecrete them into the intestinal lumen via the ABCG5/8 heterodimeric transporter. Mutations of the *ABCG5/8* genes cause the rare disorder sitosterolemia.

Chylomicrons rapidly enter the plasma compartment after meals. In capillaries of adipose tissue or muscle cells in the peripheral circulation, chylomicrons encounter the enzyme LPL attached to heparan sulfate proteoglycans on the luminal surface of endothelial cells (**Fig. 48.3, part 2**). Apo C-II or apo A-V activate and apo C-III inhibits LPL activity. LPL has broad specificity for triglycerides; it cleaves all fatty acyl residues attached to glycerol and in the process generates three molecules of FFA for each molecule of glycerol. Muscle cells rapidly take up fatty acids. Fatty acids provide the energy substrate for muscle contraction by the generation of ATP during beta-oxidation of fatty acyl residues in mitochondria. Adipose cells can store triglycerides made from fatty acids for energy utilization, a process that requires insulin. The triglyceride lipase hormone–sensitive lipase, which is activated by cyclic adenosine monophosphate (cAMP) in response to stress, releases stored fatty acids from adipose tissues. Fatty acids can also travel to the liver bound to fatty acid–binding proteins or albumin and undergo repackaging into VLDLs. Peripheral resistance to insulin can thus increase the delivery of FFAs to the liver, with a consequent increase in VLDL secretion and increased apo B particles in plasma, a characteristic of the “metabolic syndrome” and type 2 diabetes. The remnant particles, derived from chylomicrons following LPL action, contain apo E and enter the liver for degradation and reutilization of their core constituents (**Fig. 48.3, part 3**).

Hepatic Pathway (Very-Low-Density Lipoprotein to Intermediate-Density Lipoprotein). Food is not always available, and dietary fat content varies. The body requires readily available triglycerides to meet energy demands. Hepatic secretion of VLDL particles serves this function (**Fig. 48.3, part 4**). VLDLs are TRLs smaller than chylomicrons (**see Table 48.1 and Fig. 48.2**). They contain apo B100 as their main lipoprotein. Unlike apo B48, apo B100 contains a domain recognized by LDL-R (the apo B/E receptor). VLDL particles follow the same catabolic pathway as chylomicrons through LPL (**Fig. 48.3, part 2**). During hydrolysis of TRLs by LPL, an exchange of proteins and lipids takes place: VLDL particles (and chylomicrons) acquire apo Cs and apo E, in part from HDL particles. VLDLs also exchange triglycerides for cholesteryl esters from HDL (mediated by cholesteryl ester transfer protein [CETP]) (**Fig. 48.3, part 9**). Such bidirectional transfer of constituents between lipoproteins serves several purposes: acquisition of specific apolipoproteins by lipoproteins that will dictate their metabolic fate, transfer of phospholipids onto nascent HDL particles mediated by phospholipid transfer protein (PLTP) (during loss of the core triglycerides, the phospholipid envelope becomes redundant and sheds apo A-I to form new HDL particles), and transfer of cholesterol from HDL to VLDL remnants so that it can be metabolized in the liver. This exchange constitutes a major part of the “reverse cholesterol transport pathway.”

Apo CIII, a small but important 79–amino acid peptide, has a high affinity for TRLs and attenuates the activity of LPL and the clearance of TRLs, thus contributing to elevated triglycerides. Apo CIII also resides within HDL, which seems to act as a “reservoir” for this apolipoprotein. Recent work identified an intracellular role for apo CIII for the assembly and secretion of VLDL.[15] Mendelian randomization experiments and epidemiologic studies have established that apo CIII can contribute causally to

ASCVD.[16,17] This recognition has spurred therapeutic efforts to decrease apo CIII (see later).

After hydrolysis of triglycerides removes some triglycerides from VLDL, these particles have relatively more cholesterol, shed several apolipoproteins (especially the C apolipoproteins), and acquire apo E. The VLDL remnant lipoprotein, called *intermediate-density lipoprotein* (IDL), undergoes liver uptake via its apo E moiety (**Fig. 48.3, part 3**) or further delipidation by hepatic lipase to form LDL particles (**Fig. 48.3, part 6**). At least four receptors take up TRLs, TRL remnants, and apo B–containing lipoproteins: VLDL-R, the remnant receptor (apo ER2), LDL-R (also called the apo B/E receptor), and LRP1. Most hepatic receptors share the ability to recognize apo E, an engagement that mediates the uptake of several classes of lipoproteins, including VLDL and IDL.[5] The complex interaction between apo E and its ligand involves the "docking" of TRLs on heparan sulfate proteoglycans to present the ligand to its receptor.

Low-Density Lipoproteins

LDL particles contain predominantly cholesteryl esters packaged with apo B100. Normally, triglycerides constitute only 4% to 8% of the LDL mass (**see Table 48.1**). Elevated plasma TG levels can become enrich LDL particles in triglycerides and deplete their core cholesteryl esters. Such changes in core constituents influence LDL particle size: an increase in triglycerides and a relative decrease in cholesteryl esters yields smaller, denser LDL particles.

Humans are unusual among mammals because they use LDL as a major cholesterol transporter. Nonhuman primates fed a cholesterol-enriched diet also carry cholesterol in LDL. In other mammals, such as rodents or rabbits, VLDL carries triglycerides, and HDL particles transport most of the cholesterol. Cells can either make cholesterol from acyl coenzyme A (CoA) through enzymatic reactions requiring at least 33 steps or obtain it as cholesteryl esters from HDL or LDL particles. Cells internalize LDL via LDL-R[12] (**Fig. 48.4**). LDL particles contain one molecule of apo B. Although several highly lipophilic domains of apo B are associated with phospholipids, a region surrounding residue 3500 binds with high affinity to LDL-R. LDL-R localizes in a region of the plasma membrane rich in the protein *clathrin* (**Fig. 48.4**; **also see Fig. 48.3, part 7**). Once bound to the receptor, clathrin polymerizes and forms an endosome that contains LDL bound to its receptor, a portion of the plasma membrane, and clathrin. This internalized particle then fuses with lysosomes whose hydrolytic enzymes (cholesteryl ester hydrolase, cathepsins) release free cholesterol and degrade apo B. LDL-R releases its ligand and can recycle to the plasma membrane. The chaperone *proprotein convertase subtilisin/kexin type 9* (PCSK9), secreted by hepatocytes, undergoes autocatalytic cleavage and binds to the LDL-R. Association with PCSK9 diverts the complex to the "lysosomal degradative pathway," thus preventing the normal recycling of the LDL-C[18] (**Fig. 48.5**). Gain-of-function mutations in the *PCSK9* gene cause autosomal dominant hypercholesterolemia, whereas loss-of-function mutations increase LDL-R and lower LDL-C substantially.[19]

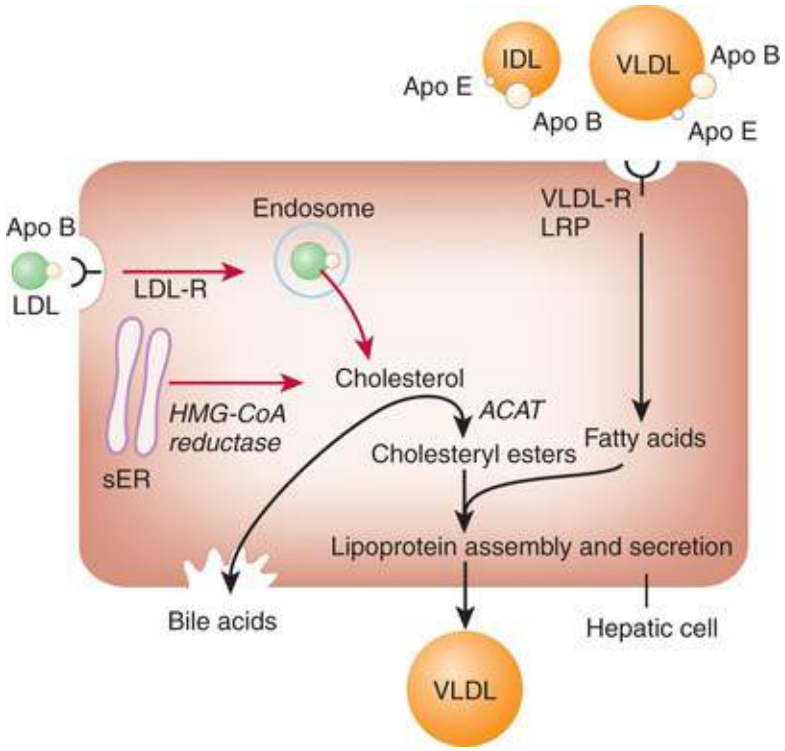

FIGURE 48.4 Cellular cholesterol homeostasis in hepatocytes. Refer to **Tables 48.1 and 48.3** for abbreviations. *sER,* Smooth endoplasmic reticulum.

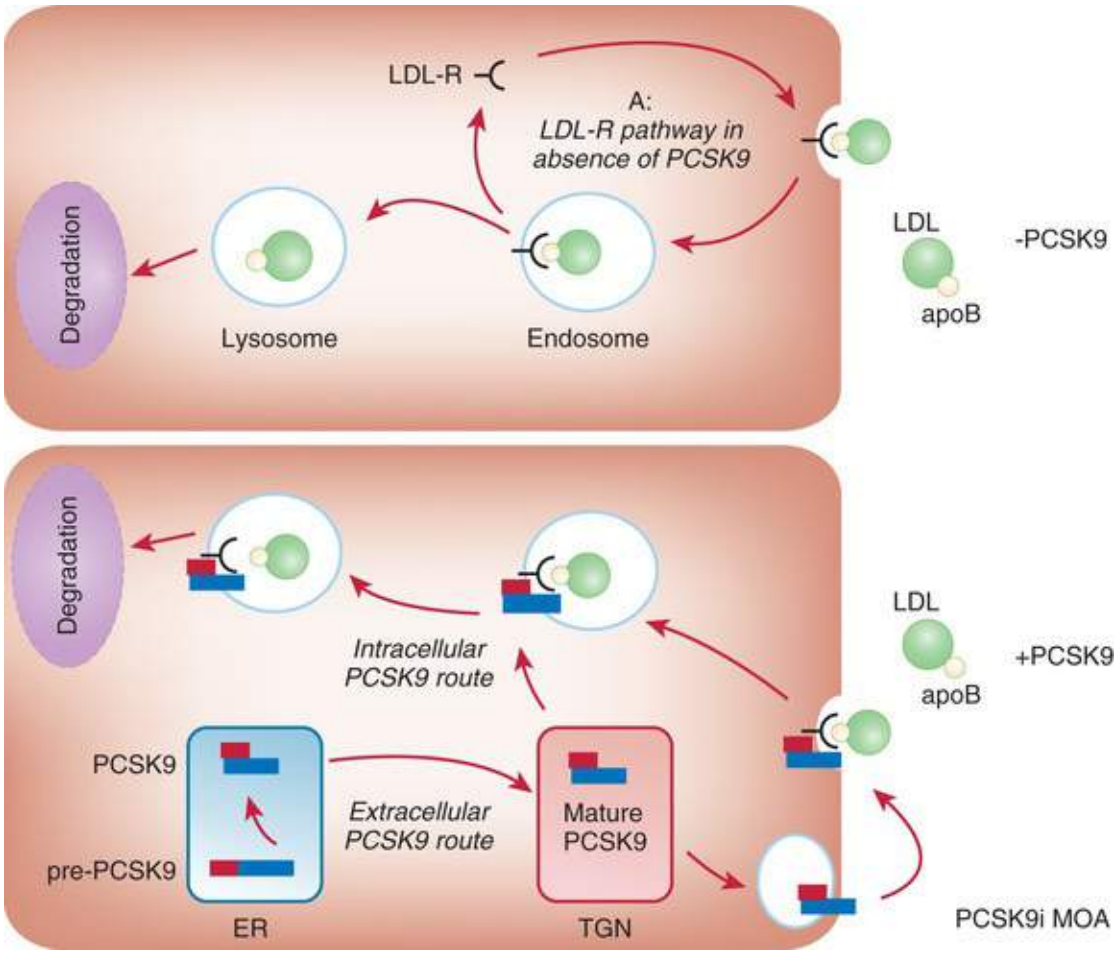

FIGURE 48.5 Diagram of a hepatocyte expressing the low-density lipoprotein receptor (LDL-R). **Top panel,** In the absence (or mAb blockade) of PCSK9, the LDL-R recycles rapidly to the cell surface. LDL particles are cleared by LDL by receptor-mediated endocytosis, thereby lowering LDL-C concentration in the blood. **Bottom panel,** PCSK9 chaperones the internalized LDL-R/LDL particle complex to the endosome-lysosomal compartment, where it undergoes degradation. The consequent decrease in LDL-R impairs LDL clearance, yielding accumulation of cholesterol-rich LDL particles in the blood. *ER,* Endoplasmic reticulum; *TGN*, Trans Golgi network.

Cells regulate their cholesterol content tightly by (1) synthesis of cholesterol in the smooth ER (via the rate-limiting step hydroxymethylglutaryl-CoA [HMG-CoA] reductase), (2) receptor-mediated endocytosis of LDL (two mechanisms under control of steroid-responsive element binding protein-2 [SREBP-2]), (3) efflux of cholesterol from the plasma membrane to cholesterol acceptor particles (predominantly apo A-I and HDL) via the ABCA1 and ABCG1 transporters, and (4) intracellular cholesterol esterification via the enzyme acetyl-CoA acetyltransferase (ACAT) (**see Fig. 48.4**). SREBP-2 coordinately regulates the first two pathways at the level of gene transcription. Cellular cholesterol binds to SCAP (SREPB cholesterol-activated protein), which localizes on the ER. Cholesterol inhibits the interaction of SCAP with SREPB. In the absence of cholesterol, SCAP mediates the cleavage of SREBP at two sites by specific proteases with the release of an amino-terminal fragment of SREBP. This SREBP fragment migrates to the nucleus and increases the transcriptional activity of genes involved in cellular cholesterol and fatty acid homeostasis.[12] The ACAT pathway regulates the cholesterol content in membranes. Humans express two separate forms of ACAT. ACAT1 and ACAT2 derive from different genes and mediate cholesterol esterification in cytoplasm and in the ER lumen for lipoprotein assembly and secretion.

High-Density Lipoprotein and Reverse Cholesterol Transport

Regulation of cholesterol efflux from cells depends in part on the ABCA1 pathway, controlled in turn by hydroxysterols (especially 24- and 27-OH cholesterol, which act as ligands for the liver-specific

receptor [LXR] family of nuclear transcription factors). In conditions of cholesterol sufficiency, the cell can decrease cholesterol synthesis. The cell can also limit the amount of cholesterol that enters the cell via the LDL-R, thereby augmenting the amount stored as cholesteryl esters, and can promote cholesterol removal by increasing its movement to the plasma membrane for efflux.

Epidemiologic studies have consistently shown an inverse relationship between plasma levels of HDL-C and the presence of CAD (**see Chapter 45**). HDL promotes reverse cholesterol transport and can prevent lipoprotein oxidation and exert anti-inflammatory actions in vitro, among many other seemingly salutary functions.[20,21] Yet, mendelian randomization analyses have cast doubt on the causal role of HDL as a protective cardiovascular (CV) risk factor. Mutations of the genes for ABCA1 that cause lifelong HDL deficiency do not impart additional CV risk, and conversely, genetic polymorphisms of genes that increase HDL-C are not associated with protection from CV events.[22]

HDL has a complex and incompletely understood metabolism. The complexity arises because HDL particles acquire their components from several sources, and these components undergo metabolism at different sites. In addition, steady-state levels of HDL in plasma may not reflect the dynamic nature of HDL-mediated cholesterol trafficking, in contrast to the situation with LDL. The intestine and liver synthesize apo A-I, the main protein of HDL. Approximately 80% of HDL originates from the liver and 20% from the intestine (**see Fig. 48.3, part 5**). Lipid-free apo A-I acquires phospholipids from cell membranes and from redundant phospholipids shed during the hydrolysis of TRLs. Lipid-free apo A-I binds to ABCA1 and promotes the transporter's phosphorylation via cAMP, which increases the net efflux of phospholipids and cholesterol onto apo A-I to form a nascent HDL particle (**see Fig. 48.3, part 10**). This particle contains apo A-I, phospholipids, and some free cholesterol (**Fig. 48.6**). These nascent HDL particles will mediate further cellular efflux of cholesterol. Currently, standard laboratory tests do not measure these HDL precursors because they contain little or no cholesterol. On reaching a cell membrane, the nascent HDL particles capture membrane-associated cholesterol and promote the efflux of free cholesterol onto other HDL particles (**see Fig. 48.3, part 10**). Conceptually, the formation of HDL particles appears to involve two steps. The first step involves binding of HDL apo A-I to ABCA1 and generation of a specific membrane microdomain that allows the subsequent lipidation of apo A-I. Efflux of cellular cholesterol from peripheral cells, such as macrophages, does not contribute importantly to overall HDL-C mass but could export cholesterol from atheromas. Macrophages can transfer cholesterol to apo A-I and apo E, to nascent discoid or ellipsoid HDL particles, via the ABCA1 transporter (**Fig. 48.6**). The ABCG1 transporter does not promote cellular cholesterol efflux to lipid-free or lipid-poor apo A-I but to mature HDL particles. In vitro assays can measure HDL-mediated cellular cholesterol efflux by plasma samples, a process that appears altered in many disease states, including diabetes and CAD. LCAT, an enzyme activated by apo A-I, then esterifies the free cholesterol (**see Figs. 48.1, 48.3 part 8, and 48.6**). HDL also furnishes cholesterol to steroid hormone–producing tissues and the liver through *selective uptake of cholesterol* mediated by the scavenger receptor SR-B1.

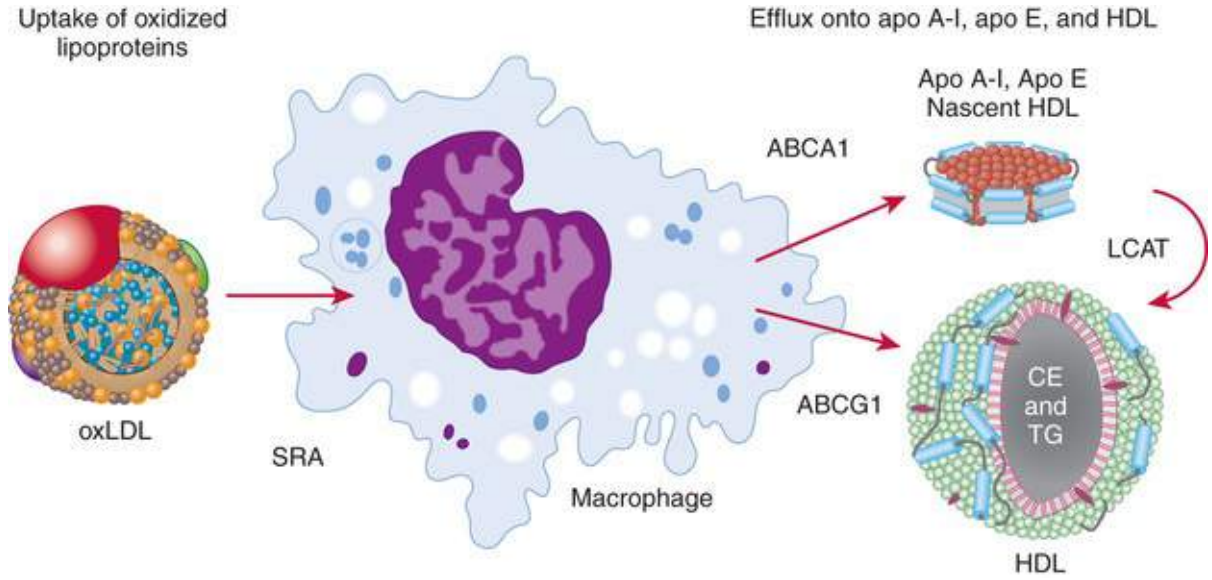

FIGURE 48.6 Initial step in cellular cholesterol efflux from macrophages and HDL formation. *CE,* Cholesterol esters; *LCAT,* lecithin-cholesterol acyltransferase; *SRA,* macrophage scavenger receptor A; *TG,* triglyceride.

Because of their hydrophobicity, cholesteryl esters move to the core of the lipoprotein, and the HDL particle now assumes a spherical configuration (a particle denoted HDL_3). With further cholesterol esterification, the HDL particle increases in size to become the more buoyant HDL_2. The cholesterol within HDL particles can transfer to TRLs via CETP, which mediates an equimolar exchange of cholesterol from HDL to TRL and movement of triglyceride from TRL onto HDL (**see Fig. 48.3, part 9**). Inhibition of CETP increases HDL-C in blood and has undergone exploration as a therapeutic target for prevention of CVD. PLTP mediates the transfer of phospholipids between TRL and HDL particles. Triglyceride-enriched HDLs are denoted HDL_{2b}. Hepatic lipase can hydrolyze triglycerides and endothelial lipase can hydrolyze phospholipids within these particles and thereby convert them back to HDL_3 particles.

Reverse cholesterol transport involves the uptake of cellular cholesterol from extrahepatic sources, such as lipid-laden macrophages, and its esterification by LCAT, transport by large HDL particles, and exchange for one TG molecule by CETP. Hepatic receptors can now take up the cholesterol molecule originally on an HDL particle and residing in a TRL or LDL particle after this exchange. HDL particles therefore act as shuttles among tissue cholesterol, TRL, and the liver.

Reverse cholesterol transport by HDL constitutes a small but potentially important portion of the plasma HDL mass. Indeed, selective inactivation of macrophage ABCA1 does not change HDL-C levels in mice but increases atherosclerosis. The protein component of HDL particles is exchangeable with lipoproteins of other classes. The kidneys appear to be a route of elimination of apo A-I and other HDL apolipoproteins.

Lipoprotein Disorders

Definitions

Time and new knowledge have stimulated changes in the classification of lipoprotein disorders. The original classification of lipoprotein disorders by Fredrickson, Lees, and Levy (1967) depended on analysis of lipoprotein patterns by ultracentrifugation or electrophoresis and has fallen into disuse (see prior editions of this textbook for details). Most clinicians now classify lipoprotein disorders by which

specific lipoprotein lipid is elevated and, when carefully characterized, by the genetic defect (e.g., familial hypercholesterolemia). For example, a young patient with eruptive xanthomas and a plasma TG level of 22 mmol/L (2000 mg/dL) probably has familial hyperchylomicronemia as a result of LPL deficiency or other monogenic defects. An obese, hypertensive middle-aged man with a cholesterol level of 6.4 mmol/L (245 mg/dL), TG level of 3.1 mmol/L (274 mg/dL), HDL-C level of 0.8 mmol/L (31 mg/dL), and calculated LDL-C level of 4.2 mmol/L (162 mg/dL) probably has metabolic syndrome, and this should trigger the clinician to seek other components of this cluster, including hypertension and hyperglycemia. Conversely, an obese middle-aged man with a plasma TG level of 7 mmol/L (620 mg/dL) probably has mutations in several genes associated with plasma TG levels.

The clinical usefulness of apolipoprotein levels has stirred debate (**see Chapter 45**). Taken as a single measurement, the apo B level provides information on the number of potentially atherogenic particles and can be used as a goal of lipid-lowering therapy. Similarly, LDL particle size correlates highly with plasma HDL-C and TG levels, and most studies do not show it to be an independent CV risk factor. Small, dense LDL particles tend to track with features of metabolic syndrome, which usually involves dyslipoproteinemia with elevated plasma TG and reduced HDL-C levels. The Emerging Risk Factors Collaboration studies have shown that measurement of non–HDL-C is equivalent to measurement of apo B in determination of CV risk. Indeed, measurement of non–HDL-C captures the cholesterol content in apo B–containing lipoproteins. Similarly, HDL-C tracks as well with CVD risk as apo A-I does.[23]

Genetic Lipoprotein Disorders

Understanding of the genetics of lipoprotein metabolism has expanded rapidly. Classification of genetic lipoprotein disorders usually requires a biochemical phenotype in addition to a clinical phenotype. With the exception of familial hypercholesterolemia, monogenic disorders tend to be infrequent or very rare. Disorders considered heritable on careful family study may be difficult to characterize unambiguously because of age, sex, penetrance, and gene-gene and environmental interactions. Most common lipoprotein disorders encountered clinically result from the interaction of increasing age, lack of physical exercise, weight gain, and a suboptimal diet with individual genetic makeup. Genetic lipoprotein disorders can either raise or lower levels of LDL, Lp(a), remnant lipoproteins, TRLs (chylomicrons and VLDL), or HDL (**Table 48.4**).

TABLE 48.4
Genetic Lipoprotein Disorders

DISORDER	GENE	FIGURE 48.3
Low-Density Lipoprotein (LDL) Particles		
Autosomal dominant hypercholesterolemia (ADH)		
Heterozygous familial hypercholesterolemia (HeFH)	*LDLR*	7
Homozygous familial hypercholesterolemia (HoFH)	*LDLR*	7
Familial defective apo B100	*Apo B*	7
Gain-of-function PCSK9 mutations	*PCSK9*	7
Autosomal recessive hypercholesterolemia	*LDLRAP1*	7

Cerebrotendinous xanthomatosis	*CYP27A1*	

CETP, Cholesteryl ester transfer protein; *LCAT,* lecithin-cholesterol acyltransferase.

Low-Density Lipoproteins (Type II Hyperlipidemia)

Familial Hypercholesterolemia

Elucidation of the pathway by which complex molecules enter the cell by receptor-mediated endocytosis and discovery of LDL-R represent landmarks in cell biology and clinical investigation.[12] Affected persons have an elevated LDL-C level greater than the 95th percentile for age and sex, approximately 190 mg/dL (5.0 mmol/L) in adults. In adulthood, clinical manifestations include corneal arcus, tendinous xanthomas over the extensor tendons (metacarpophalangeal joints, patellar, triceps, and Achilles tendons), and xanthelasmas. Transmission is autosomal codominant. The diagnosis of familial hypercholesterolemia (FH) is usually made according to the Dutch Lipid Clinics Network (**Table 48.5**) or the Simon-Broome criteria (**Table 48.6**).[24] Both are highly concordant and rely on the absolute levels of LDL-C, family history of premature ASCVD, family history of elevated LDL-C, cutaneous manifestations, and if available, DNA analysis. FH affects approximately 1 in 250 persons,[25,26] and this prevalence is higher in populations with a founder effect. Patients with FH have high risk for the development of CAD by the third to fourth decade in men and approximately 8 to 10 years later in women. Diagnosis is based on an elevated plasma LDL-C level, family history of premature CAD, and the presence of xanthomas. The presence of a mutation in a gene known to cause FH increases CV risk by more than 20-fold.[27] Remarkably, prompt recognition in childhood or early adulthood and treatment (statins) can normalize life expectancy.[24]

TABLE 48.5

Diagnosis of Familial Hypercholesterolemia (FH) According to Dutch Lipid Clinic Network Criteria

CRITERIA	DIAGNOSTIC POINTS*
Family History	
First-degree relative known with premature (men <55 yr, women <60 yr) coronary and vascular disease *or* First-degree relative known with low-density lipoprotein cholesterol (LDL-C) >95th percentile *or* First-degree relative with tendon xanthomata and/or arcus cornealis	1 point
Or	
Children <18 yr with LDL-C >95th percentile	2 points
Clinical History	
Patient has premature (men <55 yr, women <60 yr) coronary artery disease	2 points
Patient has premature (men <55 yr, women <60 yr) cerebral or peripheral vascular disease	1 point
Physical Examination	
Tendon xanthomata	6 points
Arcus cornealis <45 yr	4 points
Laboratory Analysis	
LDL-C >8.5 mmol/L	8 points
LDL-C 6.5-8.4 mmol/L	5 points
LDL-C 5.0-6.4 mmol/L	3 points
LDL-C 4.0-4.9 mmol/L	1 point
Dna Analysis	
Functional mutation *LDLR* gene present	8 points

*Diagnosis of FH is:

Certain when >8 points.
Probable when 6-8 points.
Possible when 3-5 points.

TABLE 48.6

Simon-Broome Criteria for Familial Hypercholesterolemia (FH)

Diagnose a person with **DEFINITE FH** if she/he has:
- Total cholesterol >7.5 mmol/L in adults or total cholesterol >6.7 mmol/L in children <16 yr **OR** LDL-C >4.9 mmol/L in adults or LDL-C >4.0 mmol/L in children **AND** tendon xanthomas or evidence of these signs in first- or second-degree relative

OR

- DNA-based evidence of an *LDLR* mutation, familial defective of apo B-100, or a *PCSK9* mutation

Diagnose a person with **PROBABLE FH** if she/he has:
- Total cholesterol >7.5 mmol/L in adults or total cholesterol >6.7 mmol/L in children <16 yr **OR** LDL-C >4.9 mmol/L in adults or LDL-C >4.0 mmol/L in children

PLUS

- Family history of myocardial infarction <50 yr in a second-degree relative or <60 yr in a first-degree relative

OR

- Family history of elevated total cholesterol concentration >7.5 mmol/L in a first- or second-degree relative

Low-Density Lipoprotein Receptor Gene.

Defects in the *LDLR* gene cause an accumulation of LDL particles in plasma and thus alter the function of the LDL-R protein and cause FH (**see Fig. 48.3, part 7**). Well in excess of 1700 mutations of the *LDLR* gene can cause FH.

Familial Defective Apolipoprotein B.

Mutations within the *APOB* gene that lead to an abnormal ligand-receptor interaction can cause a form of autosomal dominant hypercholesterolemia clinically indistinguishable from FH. Several mutations at the postulated binding site to LDL-R cause familial defective apo B100 (**see Fig. 48.3, part 7**). The defective apo B has reduced affinity (20% to 30% of control) for LDL-R. LDL particles with defective apo B have

a plasma half-life threefold to fourfold greater than the half-life of normal LDL. Because of their increased persistence, these LDL particles can more readily undergo oxidative modifications that can enhance their atherogenicity. Affected persons usually have LDL-C levels elevated up to 400 mg/dL (10.4 mmol/L) but may also have normal levels. Familial defective apo B100 has a lower prevalence than *LDLR* mutations (1 in 500).

Proprotein Convertase, Subtilisin/Kexin Type 9.

Gain-of-function mutations in the *PCSK9* gene decrease surface availability of the LDL-R protein and cause accumulation of LDL-C in plasma. A loss-of-function mutation in *PCSK9* confers lower LDL-C than in individuals without the mutation. Black Americans had a higher prevalence of this protective mutation than did whites in the ARIC (Atherosclerosis Risk in Communities) study, and participants with lifelong low LDL-C because of a mutation at the *PCSK9* gene locus had a marked reduction in coronary events,[19] thus confirming that genetically low LDL-C states lower CV risk. Although PCSK9 is a therapeutic target, small-molecule inhibition has not succeeded in blocking PCSK9 function. Parenteral administration of injectable, humanized or fully human monoclonal antibodies (mAbs) directed against PCSK9 greatly reduces LDL-C in humans.[28,29] Large-scale clinical trials examining the effect of further LDL-C lowering with PCSK9 inhibitors will determine the clinical usefulness of these agents for ASCVD prevention and treatment.

Polygenic Hypercholesterolemia.

In most cohorts of "definite FH" patients, as many as 20% do not have a mutation in the *LDLR*, *APOB*, or *PCSK9* genes. Exome-wide sequencing has identified several other genes causing a phenocopy of FH, but some patients have an accumulation of single-nucleotide polymorphisms (SNPs) of genes known to elevate LDL-C in large-scale genome-wide association studies (GWASs).[30]

Autosomal Recessive Hypercholesterolemia.

An autosomal recessive form of FH identified in a kindred from Sardinia results from a mutation in the gene encoding the LDL-R adaptor protein (*LDL-RAP-1* gene), which encodes a protein involved in recycling of LDL-R.[31] Other genes, including *APOE* del166LEU,[32,33] *STAP1*,[34] and lysosomal acid lipase (LIPA),[35] cause a phenocopy of FH.

Hypobetalipoproteinemia and Abetalipoproteinemia.

Mutations within the *APOB* gene can lead to truncations of the mature apo B100 peptide. Many such mutations cause a syndrome characterized by reduced LDL-C and VLDL-C but little or no clinical manifestations and no known risk for CVD, a condition referred to as *hypobetalipoproteinemia*. Apo B truncated close to its amino terminus loses the ability to bind lipids and produces a syndrome similar to *abetalipoproteinemia*, a rare recessive lipoprotein disorder of infancy that causes mental retardation and growth abnormalities. Abetalipoproteinemia results from a mutation in the gene coding for the microsomal triglyceride transfer protein (*MTTP*), which is required for assembly of apo B–containing lipoproteins in the liver and the intestine. The resulting lack of apo B–containing lipoproteins in plasma causes a lack of fat-soluble vitamins (A, D, E, and K) that circulate in lipoproteins. In turn, this deficiency result in mental and developmental impairment in affected children.

Sitosterolemia.

A rare condition of increased intestinal absorption and decreased excretion of plant sterols (sitosterol

and campesterol) can mimic severe FH with extensive xanthoma formation.[36] Premature atherosclerosis, often apparent clinically well before adulthood, occurs in patients with sitosterolemia. Diagnosis requires specialized analysis of plasma sterols documenting an elevation in sitosterol, campesterol, cholestanol, sitostanol, and campestanol. Patients with sitosterolemia have normal or reduced plasma cholesterol levels and normal TG concentrations. Patients with sitosterolemia have rare homozygous (or compound heterozygous) mutations in the *ABCG5* and *ABCG8* genes. The gene products of ABCG5 and ABCG8 are half ABC transporters and form a heterodimer localized in the villous border of intestinal cells that actively pumps plant sterols back into the intestinal lumen. A defect in either of the genes inactivates this transport mechanism, and net accumulation of plant sterols (because of impaired elimination) ensues.

Lipoprotein(a)

Lp(a) (pronounced "lipoprotein little a") consists of an LDL particle linked covalently with one molecule of apo (a). The apo (a) moiety consists of a protein with a high degree of homology with plasminogen. The gene for apo (a) appears to have arisen from the plasminogen gene. The apo (a) gene has multiple repeats of one of the kringle motifs (kringle IV), which vary in number from 12 to more than 40 in each individual. Plasma Lp(a) levels depend almost entirely on genetics and correlate inversely with the number of kringle repeats and therefore with the molecular weight of apo (a). Human genetic data implicate Lp(a) as a causal CV risk factor. Lp(a) concentrations follow a skewed distribution in the population, and black Americans tend to have higher Lp(a) levels than do other ethnic groups in the United States. Few environmental factors or medications modulate plasma Lp(a) levels. The pathogenesis of Lp(a) may result from an antifibrinolytic potential and ability to bind oxidized lipoproteins.[37] Genetic polymorphisms at the *LPA* gene have shown a strong association with aortic calcification and may have a causal role in aortic stenosis.[38]

Triglyceride-Rich Lipoproteins

In persons with metabolic syndrome and in diabetic patients, elevation of plasma TG levels occurs most often in the presence of visceral (abdominal) obesity and a diet rich in calories, carbohydrates, and saturated fats (**see Chapters 45 and 50**). Severe elevation of plasma triglycerides can result from genetic disorders of the processing enzymes or apolipoproteins and poorly controlled diabetes. Controversy regarding a causal role of triglycerides in the pathogenesis of ASCVD continues. It is likely that the cholesterol content of TRLs, their remnants, and associated apo CIII, rather than triglycerides themselves, constitute the causal moiety in this lipoprotein class.[39]

Familial Hypertriglyceridemia (Type IV Hyperlipoproteinemia)

Familial hypertriglyceridemia is not associated with clinical signs such as corneal arcus, xanthoma, and xanthelasmas. Plasma triglycerides, VLDL-C, and VLDL triglycerides are moderately to markedly elevated; the LDL-C level is usually low, as is HDL-C. Total cholesterol is normal or elevated, depending on VLDL-C levels. Fasting plasma TG concentrations range from 2.3 to 5.7 mmol/L (200 to 500 mg/dL). After a meal, plasma triglycerides may exceed 11.3 mmol/L (1000 mg/dL). The disorder clusters in first-degree relatives but varies phenotypically depending on sex, age, hormone use (especially estrogens), and diet. Alcohol intake potently stimulates hypertriglyceridemia in these patients, as does caloric or carbohydrate intake. Familial hypertriglyceridemia has a weaker relationship with CAD than familial combined hyperlipidemia, and not all studies support this association. Depending on the criteria

used, the prevalence of familial hypertriglyceridemia ranges from 1 in 100 to 1 in 50. This highly heterogeneous disorder probably results from several genes, as well as a strong environmental influence.[40]

An unrelated X-linked genetic disorder, *familial glycerolemia,* may mimic familial hypertriglyceridemia because most measurement techniques for triglycerides use the measurement of glycerol after enzymatic hydrolysis of triglycerides. Diagnosis of familial hyperglycerolemia requires ultracentrifugation of plasma and analysis of glycerol.

Hepatic overproduction of VLDL causes familial hypertriglyceridemia (**see Fig. 48.3, part 4**); the catabolism (uptake) of VLDL particles can be normal or reduced. Lipolysis by LPL appears adequate under basal conditions, but not with excess TG load, especially following fatty meals. Human genetic studies have shown that many cases of severe hypertriglyceridemia result from mutations in one or more of the genes associated with TG metabolism.[40] Treatment is based first on lifestyle modifications, including weight reduction in overweight individuals, limiting alcohol intake, reducing caloric intake, increasing exercise, and withdrawal of hormones (estrogens and progesterone or anabolic steroids).

An uncommon disorder characterized by a severe elevation in plasma TG levels (both VLDL and chylomicrons) is associated with a fat-rich diet, obesity, and poorly controlled diabetes. Recognized as *type V hyperlipidemia,* the pathogenesis is multifactorial and results from overproduction of both VLDL and chylomicrons and decreased catabolism of these particles.

Familial Hyperchylomicronemia Syndrome (Type I Hyperlipidemia).
This rare disorder of severe hypertriglyceridemia elevates fasting plasma triglycerides to greater than 11.3 mmol/L (>1000 mg/dL). These patients have recurrent bouts of pancreatitis and eruptive xanthomas. Severe hypertriglyceridemia can also be associated with lipemia retinalis, xerostomia, xerophthalmia, and behavioral abnormalities. The hypertriglyceridemia results from markedly reduced or absent LPL activity or, more rarely, absence of its activator apo C-II (**see Fig. 48.3, part 2**). These defects lead to a lack of hydrolysis of chylomicrons and VLDL and their accumulation in plasma, especially after meals. Extreme elevations of plasma triglycerides (>113 mmol/L; >10,000 mg/dL) can result. Mutations at several genes associated with TG metabolism can result in elevated chylomicron levels.

Plasma from a patient with very high TG levels is milky white, and a clear band of chylomicrons can be seen on top of the plasma after it stands overnight in a refrigerator. Populations with a founder effect can a have high prevalence of LPL mutations. At least 60 LPL mutations can cause LPL deficiency. LPL_{188}, $LPL_{asn291ser}$, and LPL_{207} are frequently associated with hyperchylomicronemia. Heterozygotes for the disorder tend to have an increase in fasting plasma triglycerides and smaller, denser LDL particles. Many patients with complete LPL deficiency exhibit failure to thrive in childhood and have recurrent bouts of pancreatitis. To underscore the importance of the role of LPL, *lpl* deficiency in the mouse leads to a perinatal lethal phenotype. Treatment of acute pancreatitis includes intravenous hydration and avoidance of fat in the diet (including fat in parenteral nutrition), and only rarely requires plasma filtration. Chronic treatment includes avoidance of alcohol and dietary fat. Addition of short-chain fatty acids (which are not incorporated in chylomicrons) can increase palatability of the diet. An antisense RNA (volanesorsen, IONIS-APOCIIIRx) directed against apo CIII shows promise in the treatment of severe hypertriglyceridemia[41] but requires long-term safety assessment. Inhibition of diacylglycerol acyltransferase 1 (DGAT1), which mediates chylomicron TG synthesis, with the compound pradigastat, represents a potential therapeutic avenue for these patients.[42]

Type III Hyperlipoproteinemia.
Also referred to as *dysbetalipoproteinemia* or *broad beta disease*, type III hyperlipoproteinemia is a rare genetic lipoprotein disorder characterized by accumulation of remnant lipoprotein particles in plasma. Lipoprotein agarose gel electrophoresis shows a typical pattern of a broad band between the prebeta (VLDL) and beta (LDL) lipoproteins, thus the name "broad beta disease." Patients with this disease have increased CV risk. Clinical findings include of pathognomonic tuberous xanthomas and palmar striated xanthomas. The lipoprotein profile shows increased cholesterol and TG levels and reduced HDL-C. Remnant lipoproteins (partly catabolized chylomicrons and VLDL) accumulate in plasma and become enriched with cholesterol esters. The defect results from abnormal apo E, which does not bind to hepatic receptors that recognize apo E as a ligand (**see Fig. 48.3, part 3**). Patients with type III hyperlipoproteinemia have an elevated ratio of VLDL cholesterol to triglycerides, normally less than 0.7 (when measured in mmol/L; <0.30 in mg/dL), because of cholesteryl ester enrichment of remnant particles. Thus, calculation of LDL-C in such patients is unreliable, requiring direct LDL-C measurement. Diagnosis includes plasma ultracentrifugation for lipoprotein separation, lipoprotein electrophoresis, and apo E phenotyping or genotyping. Patients with type III hyperlipoproteinemia have the apo $E_{2/2}$ phenotype or genotype. Apo E has three common alleles: E_2, E_3, and E_4. The apo E_2 allele has greatly decreased binding to the apo B/E receptor.

The apo $E_{2/2}$ genotype has a prevalence of approximately 0.7% to 1.0%. Type III hyperlipoproteinemia occurs in approximately 1% of persons bearing the apo $E_{2/2}$ genotype. Reasons for the relative rarity of type III dyslipoproteinemia are not fully understood. Mutations in other genes associated with TG metabolism contribute to phenotypic expression of the apo $E_{2/2}$ genotype.[40] Other rare mutations of the gene for apo E can cause type III hyperlipoproteinemia. In general, type III dyslipoproteinemia responds well to dietary therapy, correction of other metabolic abnormalities (diabetes, obesity, hypothyroidism), and in patients requiring drug therapy, use of fibric acid derivatives or statins. The importance of the apo E gene and protein is underscored by the widespread use of the apo E–deficient mouse, which develops atherosclerosis.

Familial Combined Hyperlipidemia

Familial combined hyperlipoproteinemia is one of the most common familial lipoprotein disorders. Described initially in survivors of myocardial infarction (MI), the definition of familial combined hyperlipoproteinemia has undergone several refinements. It is characterized by the presence of elevated total cholesterol and/or TG levels based on arbitrary cut points in several members of the same family. Advances in analytic techniques have added measurement of LDL-C and, in some cases, apo B levels. Because of the lack of a clear-cut clinical or biochemical marker, considerable overlap exists between familial combined hyperlipoproteinemia, familial dyslipidemic hypertension, metabolic syndrome, and hyperapobetalipoproteinemia. Genetic heterogeneity probably underlies familial combined hyperlipoproteinemia, which has a prevalence of approximately 1 in 50 and accounts for 10% to 20% of patients with premature CAD. The condition has few clinical signs; corneal arcus, xanthomas, and xanthelasmas occur infrequently. Biochemical abnormalities include elevation of plasma total cholesterol and LDL-C levels (>90th to 95th percentile) and/or elevation of plasma triglycerides (>90th to 95th percentile)—a type IIb lipoprotein phenotype, often in correlation with low HDL-C and elevated apo B levels; small, dense LDL particles occur frequently. Diagnosis of familial combined hyperlipoproteinemia requires identification of the disorder in at least one first-degree relative. Underlying metabolic disorders appear to include hepatic overproduction of apo B–containing lipoproteins, delayed postprandial

clearance of TRLs, and increased flux of FFAs to the liver.

Experimental data have shown that substrate levels drive hepatic apo B secretion, the most important substrates being FFAs and cholesteryl esters. Increased delivery of FFAs to the liver, as occurs in states of insulin resistance and visceral obesity, leads to increased hepatic apo B secretion. Familial combined hyperlipoproteinemia has complex genetics. It was initially considered an autosomal codominant trait; modifying factors include gender, age at onset, and comorbid states such as obesity, lack of exercise, and diet. Novel loci in the upstream transcription factor 1 (*USF1*) and stearoyl-CoA desaturase 1 genes are promising candidate genes related to familial combined hyperlipoproteinemia. The description of loss of function in the angiopoietin-like protein-3 gene (*ANGPTL3*) in a kindred with familial hypolipidemia renewed interest in the angiopoietin-like proteins 3, 4 and 5, which modulate the activities of LPL and endothelial lipase[43,44] (**Fig. 48.3, part 2**).

The genetic basis for type III dyslipidemia and familial combined hyperlipidemia likely lies in the combination of multiple genetic defects, the cumulative sum of which produces a clinical phenotype, especially in the context of a poor lifestyle.[40]

High-Density Lipoproteins

Reduced plasma levels of HDL-C consistently correlate with the development or presence of CAD. Most cases of reduced HDL-C result from elevated plasma triglycerides or apo B levels and often keep company with other features of metabolic syndrome. Genetic disorders of HDL can result from decreased production or abnormal maturation and increased catabolism. Genetic lipoprotein disorders leading to moderate to severe elevations in plasma triglycerides cause a reduction in HDL-C levels. Familial hyperchylomicronemia, familial hypertriglyceridemia, and familial combined hyperlipoproteinemia all are associated with reduced HDL-C levels. In complex disorders of lipoprotein metabolism such as familial combined hyperlipidemia, metabolic syndrome, and common forms of hypertriglyceridemia, several factors most likely correlate with low HDL-C level. Plasma TG and HDL-C levels vary inversely. Several reasons exist for this association: (1) decreased lipolysis of TRLs decreases the availability of substrate (phospholipids) for HDL maturation, (2) HDL enriched with triglyceride has an increased catabolic rate and thus reduced plasma concentration, and (3) the augmented pool of TRLs saps cholesterol from the HDL compartment by CETP-mediated exchange.

Disorders of High-Density Lipoprotein Biogenesis[44]

Apolipoprotein A-I Gene Defects.

Primary defects affecting the production of HDL particles may be caused by mutations in the apo A-I–C-III–A-IV-AV gene complex. More than 50 mutations affect the structure of apo A-I and lead to a marked reduction in HDL-C levels. Not all these defects are associated with premature CVD. Clinical findings can vary from extensive atypical xanthomatosis and corneal infiltration of lipids to no manifestations at all. Treatment of these apo A-I gene defects generally fails to raise HDL-C. Other mutations of apo A-I lead to an increased catabolic rate of apo A-I and may not be associated with CVD. One such mutation, apo $A\text{-}I_{Milano}$ (apo $A\text{-}I_{Arg173Cys}$), appears not to increase risk for CVD despite very low HDL levels.

Tangier Disease and Familial High-Density Lipoprotein Deficiency.

A rare disorder of HDL deficiency, identified in a proband from Tangier Island, Tangier disease and

familial HDL deficiency result from mutations in the *ABCA1* gene, which encodes the ABCA1 transporter (**see Fig. 48.6**). More than 200 mutations in *ABCA1* can cause Tangier disease (homozygous or compound heterozygous mutations) or familial HDL deficiency (heterozygous mutations). Patients with Tangier disease or familial HDL deficiency may be at increased risk for CAD, counterbalanced by their very low levels of LDL-C. Mendelian randomization analysis has not supported a causal relationship between mutations in the *ABCA1* gene and ASCVD.

Niemann-Pick type C disease is a disorder of lysosomal cholesterol transport. In these patients, mental retardation and neurologic manifestations occur frequently. The cellular phenotype involves greatly decreased cholesterol esterification and a defect in the cellular transport of cholesterol to the Golgi apparatus. The gene for Niemann-Pick type C disease (*NPC1*) shuttles cholesterol between the "late endosomal pathway" and the plasma membrane. Niemann-Pick type C cells lack NPC1 protein; intracellular cholesterol sequestration suppresses ABCA1, impairing cellular cholesterol efflux and HDL assembly.

Disorders of High-Density Lipoprotein–Processing Enzymes.

Lecithin-Cholesterol Acyltransferase Deficiency.

Genetic defects in the HDL-processing enzymes give rise to interesting phenotypes. Deficiencies of LCAT, the enzyme that catalyzes the formation of cholesteryl esters in plasma, cause corneal infiltration of neutral lipids and hematologic abnormalities as a result of the abnormal constitution of red blood cell membranes. LCAT deficiency can lead to an entity called "fish eye disease" because of the characteristic pattern of corneal infiltration observed in affected individuals. Despite the profound HDL-C deficiency, LCAT deficiency does not appear to increase risk for CAD.

Cholesteryl Ester Transfer Protein Deficiency.

Patients without CETP have very elevated levels of HDL-C, which is enriched in cholesteryl esters. Because CETP facilitates the transfer of HDL cholesteryl esters into TRLs, a deficiency of this enzyme causes accumulation of cholesteryl esters within HDL particles. CETP deficiency is not associated with premature CAD but may not afford protection against CAD. Because of its effects on HDL-C, CETP inhibition has undergone testing as a therapy, which thus far has proved disappointing.

Niemann-Pick type I disease (subtypes A and B), which is caused by mutations in the sphingomyelin phosphodiesterase 1 (*SMPD1*) gene, is associated with a low HDL-C level. The *SMPD1* gene encodes a lysosomal (acidic) and secretory sphingomyelinase. The low HDL-C level in patients with Niemann-Pick A and B disease appears to result from a decrease in LCAT reaction because of abnormal HDL constituents.

Recent GWASs have identified multiple gene loci associated with plasma lipid levels, thus raising the possibility of identifying novel pathways in lipoprotein metabolism and potential novel therapeutic targets.

Secondary Causes of Hyperlipidemia and Metabolic Syndrome (Table 48.7)

Hormonal Causes

Hypothyroidism often manifests as elevated LDL-C, triglycerides, or both (**see Chapter 92**). An elevated level of thyroid-stimulating hormone (TSH) provides the key to the diagnosis, and the lipoprotein abnormalities often revert to normal after correction of thyroid status. Rarely, hypothyroidism may uncover a genetic lipoprotein disorder such as type III hyperlipidemia. Estrogens can elevate plasma TG

and HDL-C levels because of increases in both hepatic VLDL and apo A-I production. In postmenopausal women, estrogens may reduce LDL-C by up to 15%. Use of estrogens for the treatment of lipoprotein disorders is no longer recommended because of the slight increase in CV risk with prolonged use of estrogens in the postmenopausal period (**see Chapter 89**). Rarely, pregnancy causes severe increases in plasma triglycerides on a background of LPL deficiency or yet-to-be-identified genetic defects. Such cases present a serious threat to mother and child and require referral to specialized centers. Male sex hormones and anabolic steroids can increase hepatic lipase activity and have been used for the treatment of hypertriglyceridemia in men. However, these agents can also contribute to an elevated TG level, reduced HDL-C, increased blood pressure, and other features of metabolic syndrome. Growth hormone can reduce LDL-C and increase HDL-C but is not recommended for the treatment of lipoprotein disorders.

TABLE 48.7

Secondary Causes of Dyslipoproteinemias

CAUSE	DISORDER
Metabolic	Diabetes Lipodystrophy Glycogen storage disorders
Renal	Chronic renal failure Glomerulonephritis with nephritic syndrome
Hepatic	Cirrhosis Biliary obstruction Porphyria Primary biliary cirrhosis (with secondary LCAT deficiency)
Hormonal	Estrogens Progesterones Growth hormone Thyroid disorders (hypothyroidism) Corticosteroids
Lifestyle	Physical inactivity Obesity Diet rich in fats, saturated fats Alcohol intake Smoking
Medications	Retinoic acid derivatives Glucocorticoids Exogenous estrogens Thiazide diuretics Beta-adrenergic blockers (selective) Testosterone and other anabolizing steroids Immunosuppressive medications (cyclosporine) Antiviral medications (HIV protease inhibitors) Antischizophrenic medications

HIV, Human immunodeficiency virus; *LCAT,* lecithin-cholesterol acyltransferase.

Metabolic Causes

The most frequent secondary cause of dyslipoproteinemia is probably the constellation of metabolic abnormalities seen in patients with metabolic syndrome (**see Chapters 45 and 50**). The finding of increased visceral fat (abdominal obesity), elevated blood pressure, and impaired glucose tolerance often clusters with increased plasma triglycerides and a reduced HDL-C level and represents the major components of metabolic syndrome. Overt diabetes, especially type 2 diabetes, frequently elevates plasma triglycerides and reduces HDL-C. These abnormalities have prognostic implications in patients with type 2 diabetes (**see Chapter 51**) Poor control of diabetes, obesity, and moderate to severe hyperglycemia can yield severe hypertriglyceridemia with chylomicronemia and increased VLDL-C levels. Patients with poorly controlled type 1 diabetes can also have severe hypertriglyceridemia.

Familial lipodystrophy (complete or partial) may be associated with increased VLDL secretion. *Dunnigan lipodystrophy*, a genetic disorder with features of metabolic syndrome, results from mutations within the lamin A/C gene and is associated with limb-girdle fat atrophy. Excess plasma triglycerides often accompany glycogen storage disorders.

Renal Disorders

In patients with glomerulonephritis and protein-losing nephropathies (**see Chapter 98**), a marked increase in secretion of hepatic lipoproteins can raise LDL-C, which may approach the levels seen in patients with FH. By contrast, patients with chronic renal failure have a pattern of hypertriglyceridemia with reduced HDL-C. Patients with end-stage renal disease (ESRD), including those undergoing hemodialysis or chronic ambulatory peritoneal dialysis, have a poor prognosis and accelerated atherosclerosis. Statin treatment has not improved outcomes in ESRD patients. After organ transplantation, the immunosuppressive regimen (glucocorticoids and cyclosporine) typically elevates triglycerides and reduces HDL-C levels. Because transplant recipients generally have an increase in CV risk, this secondary hyperlipidemia may warrant treatment. Patients receiving the combination of a statin plus cyclosporine merit careful dose titrations and monitoring for myopathy. The Kidney Disease: Improving Global Outcomes (KDIGO) group recommends statin treatment for patients with chronic kidney disease but does not recommend lipid-lowering treatment initiation in patients undergoing dialysis.[45]

Liver Disease

Obstructive liver disease, especially primary biliary cirrhosis, may lead to the formation of an abnormal lipoprotein termed *lipoprotein-x*. This type of lipoprotein, also associated with LCAT deficiency, consists of an LDL-like particle with a marked reduction in cholesteryl esters. Extensive xanthoma formation on the face and palmar areas can result from accumulation of lipoprotein-x.

Lifestyle

Factors contributing to obesity, such as an imbalance between caloric intake and energy expenditure, lack of physical activity, and a diet rich in saturated fats and refined sugars, contribute in large part to the lipid and lipoprotein lipid levels within a population (**see Chapters 45 and 50**).

Medication

Several medications can alter lipoproteins (**see Table 48.8**). Thiazide diuretics can increase plasma TG levels. Beta-adrenergic blocking agents (beta blockers), especially non–$beta_1$-selective agents, increase triglycerides and lower HDL-C levels. Retinoic acid and estrogens can increase TG levels, sometimes dramatically. Corticosteroids and immunosuppressive agents can elevate plasma triglycerides and lower HDL-C. Estrogens can increase plasma HDL-C and often raise TG concentrations. Anabolic steroids, frequently used by endurance or body-building athletes, can cause hypertriglyceridemia and very low HDL-C. The exact composition, dosage, and frequency of use of anabolic steroids are often impossible to determine from the patient history. The use of antipsychotic medications may lead to metabolic disorders, weight gain, and lipoprotein abnormalities. Highly active antiretroviral therapy (HAART) agents may cause severe lipoprotein disorders and an increase in CAD in patients with chronic human immunodeficiency virus (HIV) infection (**see Chapter 82**).

TABLE 48.8

Current Lipid-Lowering Medications

GENERIC NAME	TRADE NAME	RECOMMENDED DOSE RANGE
Statins		
Atorvastatin	Lipitor	10-80 mg
Fluvastatin	Lescol	20-80 mg
Lovastatin	Mevacor	20-80 mg
Pravastatin	Pravachol	10-40 mg
Rosuvastatin	Crestor	10-40 mg
Simvastatin	Zocor	10-80 mg
Pitavastatin	Questran	2-4 mg
Bile Acid Absorption Inhibitors		
Cholestyramine	Questran	2-24 g
Colestipol	Colestid	5-30 g
Colesevelam	Welchol	3.8-4.5 g
Cholesterol Absorption Inhibitors		
Ezetimibe	Zetia (Ezetrol)	10 mg
Fibrates*		
Bezafibrate	Bezalip	400 mg
Fenofibrate	Tricor, Trilipix Lipidil (Micro, EZ)	40-200 mg
Gemfibrozil	Lopid	600-1200 mg
Niacin†	Niacin	1-3 g
Nicotinic acid	Niaspan	1-2 g

*Avoid in patients with renal insufficiency.

†Use with caution in patients with diabetes or glucose intolerance.

In clinical practice, many dyslipoproteinemias, other than the genetic forms mentioned earlier, share an important environmental cause. Lifestyle changes (diet, exercise, reduction of abdominal obesity) should form the foundation for the treatment of most dyslipidemias. The effects of marked alterations in lifestyle, reduction in dietary fats (especially saturated fats), and exercise can improve CV risk factors. Rigorous clinical data showing that these measures improve outcomes, as well as implementing them in a sustained manner in practice, however, have proved more difficult (**see Chapters 45 and 50**).

Pharmacologic Management of Lipid Risk (Tables 48.8 and 48.9)[46,47]

Hydroxymethylglutaryl–Coenzyme A Reductase Inhibitors (Statins)

Mechanisms of Action

Statins inhibit the enzyme HMG-CoA reductase and prevent the formation of mevalonate, the rate-limiting step of sterol synthesis. To maintain cellular cholesterol homeostasis, expression of LDL-R increases and rate of cholesteryl ester formation declines. These homeostatic adjustments to HMG-CoA reductase inhibition increase clearance of LDL-C from plasma and decrease hepatic production of VLDL and LDL. In addition to blocking the synthesis of cholesterol, statins also interfere with the synthesis of lipid intermediates with important biologic effects. Two of these intermediates, geranylgeranyl and farnesyl, participate in protein *prenylation,* the covalent attachment of a lipid moiety to a protein, thereby allowing anchoring into cell membranes and enhancing its biologic activity. Prenylated proteins important in CV signaling include the guanosine triphosphate (GTP)–binding proteins Rho A, Rac, and Ras. Statins may increase HDL-C in part by preventing the geranylgeranylation of Rho A and phosphorylation of peroxisome proliferator–activated receptor-alpha (PPAR-α), a factor that regulates apo A-I transcription.

Altered protein prenylation may also mediate some of the effects attributed to statins not related to a reduction in LDL-C levels.

TABLE 48.9

Expected Decrease in Low-Density Lipoprotein Cholesterol (LDL-C) with Lipid-Lowering Medications

Drug	MEAN REDUCTION BY DOSE: PERCENT CHANGE FROM BASELINE				
	5 mg	10 mg	20 mg	40 mg	80 mg
Rosuvastatin	−40%	−46%	−52%	−55%	—
Atorvastatin	—	−37%	−43%	−48%	−51%
Simvastatin	−26%	−30%	−38%	−41%	−47%
Lovastatin	—	−21%	−27%	−31%	−40%
Pravastatin	—	−20%	−24%	−30%	−36%
Fluvastatin	—	—	−22%	−25%	−35%
Ezetimibe alone	—	−20%	—	—	—
Bile acid sequestrants (cholestyramine, colestipol, colesevelam): add a mean 15% decrease					

Modified from Hou R, Goldberg AC. Lowering low-density lipoprotein cholesterol: statins, ezetimibe, bile acid sequestrants, and combinations: comparative efficacy and safety. Endocrinol Metab Clin North Am 2009;38(1):79-97, and Stroes ES et al. Statin-associated muscle symptoms: impact on statin therapy. European Atherosclerosis Society Consensus Panel Statement on Assessment, Aetiology and Management. Eur Heart J 2015;36(17):1012-22.

Atherosclerosis involves inflammation (**see Chapter 44**). Statins decrease C-reactive protein (CRP), augment the collagen content of atherosclerotic plaque, alter endothelial function, and decrease the inflammatory component of plaque.

Statin Pharmacology

The currently available drugs are fluvastatin (Lescol), 20 to 80 mg/day; lovastatin (Mevacor), 20 to 80 mg/day; pravastatin (Pravachol), 20 to 40 mg/day; simvastatin (Zocor), 10 to 40 mg/day (the 80-mg dose may increase risk for rhabdomyolysis, especially within the first year of treatment); atorvastatin (Lipitor), 10 to 80 mg/day; and rosuvastatin (Crestor), 5 to 40 mg/day. Pitavastatin (Livalo), 2 to 4 mg/day, is available in some countries. Statins do not reduce LDL in a linear manner; for every doubling of the statin dose, LDL-C drops by about an additional 6% (**Tables 48.8 and 48.9**).

Concomitant drugs that interfere with the metabolism of statins by inhibiting the cytochrome P-450 (CYP) 3A4 and 2C9 systems can increase plasma concentrations of statins. Such agents include antibiotics, antifungal medications, certain antiviral drugs, grapefruit juice, cyclosporine, amiodarone, and several others. The major side effects of statins have been attributed to muscle symptoms ranging from diffuse myalgias (normal creatinine kinase [CK] levels), seen in up to 10% to 15% of statin users, to myositis, defined as diffuse muscle pain with evidence of muscle inflammation and elevated CK levels. A minority of statin users have increased CK levels, and a causal link with muscle symptoms must be established by rechallenge.[48,49] In many cases of statin-associated myositis, a neuromuscular disease is identified (inclusion body myositis and myopathies of genetic origin and spinal cord compression). Rarely, statin use is associated with rhabdomyolysis. This life-threatening situation is often related to predisposing factors: advanced age, frailty, renal failure, shock, concomitant use of antifungal agents, antibiotics, the fibric acid derivative gemfibrozil, and hypothyroidism.[48,49] Statin intolerance has been shown to affect CV outcomes adversely.[49]

Statins are generally well tolerated; side effects include reversible elevation of transaminases and myositis, which necessitates discontinuation of the drug in less than 1% of patients. After initiation of statin therapy, the response should be checked within the first 3 to 6 months, along with transaminase and

CK levels. Thereafter, clinical judgment should dictate the interval between follow-up visits. Although frequent visits are probably not useful for the detection of serious side effects, they serve to encourage compliance and adherence to diet and lifestyle changes.

Clinical Trials with Statins

Twenty-seven trials with more than 1000 participants randomized to a statin versus a placebo (or a statin comparator) have reported effects of statins on CV outcomes, as reviewed in previous versions of this chapter and elsewhere[8,9] (**Fig. 48.7**) (**see Chapter 45**). Imaging studies have shown that treatment with more potent statins can actually produce limited regression of atheromata. With the advent of PCSK9 inhibitors, the GLAGOV study tested the hypothesis that lowering LDL-C with evolocumab, 420 mg monthly by subcutaneous (SC) injection, resulted in a greater change in coronary atheroma volume from baseline than placebo in 968 participants treated for 78 weeks (all participants received maximally tolerated statin therapy)[50] (**Fig. 48.8**).

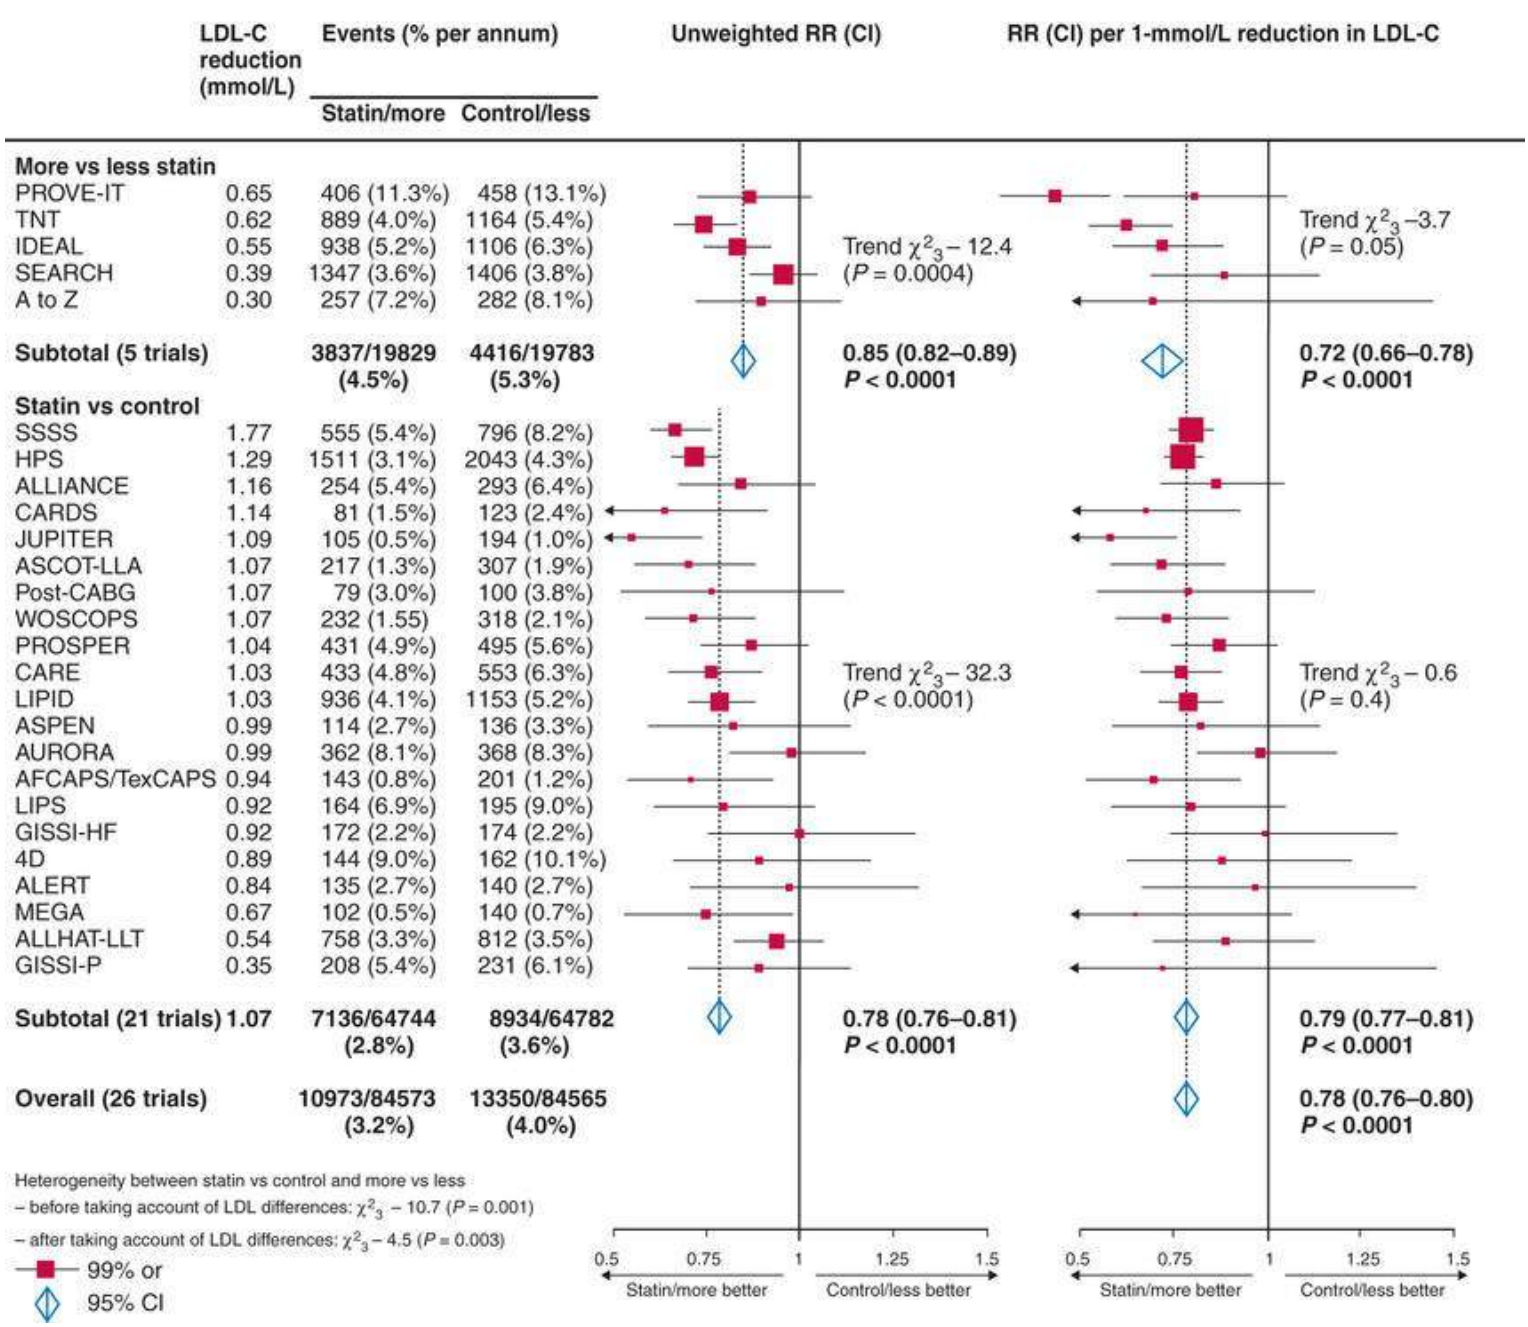

FIGURE 48.7 Meta-analysis of clinical trials of statin therapy: proportional reduction in nonfatal myocardial infarction or coronary heart disease (CHD) death versus absolute LDL-C reduction. The effects on major vascular events are shown for each of the 26 studies included in the meta-analysis. **Left panel,** Unweighted rate ratios (RR) for each trial are plotted along with 99% CI. **Right panel,** RRs are weighted per 1.0 mmol/L LDL-C difference at 1 year. Subtotals and totals with 95% confidence intervals (CIs) are shown by *open diamonds*. (From Baigent C et al. Efficacy and safety of more intensive lowering of LDL cholesterol: a meta-analysis of data from 170,000 participants in 26 randomised trials. Lancet 2010;376:1670-81.)

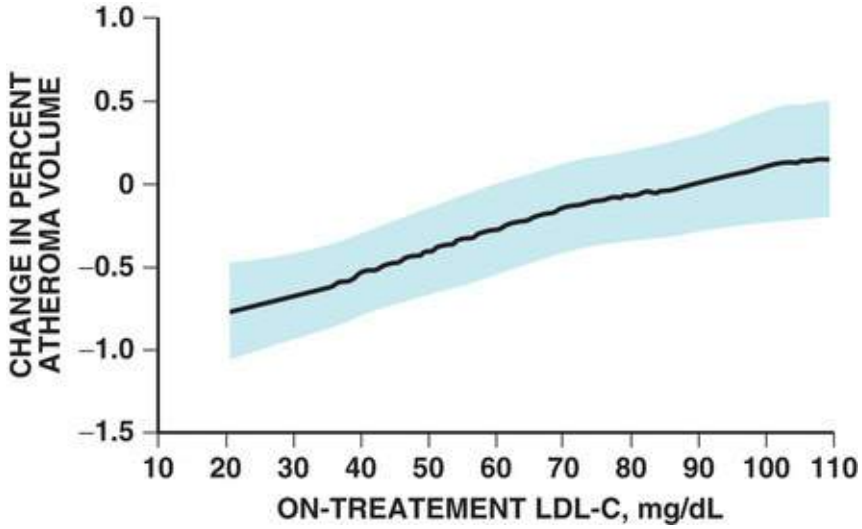

FIGURE 48.8 Meta-analysis of angiographic regression studies, including the Global Assessment of Plaque Regression with a PCSK9 Antibody as Measured by Intravascular Ultrasound (GLAGOV) study. Compared with placebo, the evolocumab group achieved lower mean, time-weighted LDL-C levels. (From Nicholls SJ et al. Effect of evolocumab on progression of coronary disease in statin-treated patients: the GLAGOV randomized clinical trial. JAMA 2016;316(22):2373-84.)

Use of Statins in Special Populations

Diabetic Patients

Patients with diabetes should receive a statin. Multiple observational studies have documented a greatly increased risk for ASCVD in adult diabetic patients over the long term. Preventive strategies with aspirin, angiotensin-converting enzyme inhibitors, tight glycemic control, and statins have all shown benefit. Data from the CTT (Cholesterol Treatment Trialists) meta-analysis of statin trials in patients with diabetes showed a 21% reduction in CVD events and a 9% all-cause mortality benefit in favor of statins.[51]

Statins and Risk for Diabetes

The use of statins is associated with a small but significant increase in diabetes.[52,53] Further analysis of the clinical study data shows that statins hasten the diagnosis almost exclusively in patients with preexisting risk factors for the development of diabetes, such as baseline elevation of plasma glucose levels. Based on the available data, the benefits of statin use in persons at high CV risk or in the secondary prevention of CVD far exceed the small risk for development of diabetes. Nevertheless, statin therapy should accompany a diet and exercise program aimed at achieving a healthy diet and ideal body weight.

Older Patients

Elderly patients represent a special challenge; age accounts for most of the attributable CV risk in patients older than 75 or 80 years, and the predictive value of elevated cholesterol decreases with increasing age. A recent meta-analysis of statin trials using data on patients older than 75 showed a 22% relative reduction in all-cause mortality. This analysis supports continued use of statins in older patients if clinically indicated. Physicians must nevertheless exercise caution in implementing preventive strategies in older patients already taking multiple medications. However, age is a major determinant of CV risk. Starting statins in an otherwise healthy elderly patient requires clinical judgment and shared decision making.

Women

Most clinical trials are not statistically powered to show an effect in women as a subgroup. A meta-analysis of statin studies involving women showed a statistically significant reduction in the primary endpoint of acute MI, stroke, CVD-related death, arterial revascularization, and hospitalization for unstable angina in favor of statins. The available outcomes data support the contention that statins confer CV protection in women.

Non-Caucasian Populations

The INTERHEART study has shown the universality of CV risk factors in a study of almost 15,000 patients with acute MI versus healthy controls.[3] Even though most studies underrepresent the number of nonwhite and various ethnic groups, current data provide no indication that lipid-lowering therapy will not reduce CV risk in various ethnic groups. The MEGA study included Japanese men and women. JUPITER included more than 4400 black or Hispanic individuals and showed no heterogeneity in response to statin therapy compared with whites. The third Health Outcomes and Population Evaluation (HOPE-3) study randomized 12,705 participants in 21 countries at intermediate risk of ASCVD to rosuvastatin (10 mg/day) or placebo. After a mean follow-up of 5.6 years, the primary outcome (death from CV causes, nonfatal MI, or nonfatal stroke) occurred in 235 participants (3.7%) in the rosuvastatin group and in 304 participants (4.8%) in the placebo group (hazard ratio [HR], 0.76; 95% confidence interval [CI] 0.64 to 0.91; $P = 0.002$). The results were consistent in race and ethnic groups.[54]

Advanced Heart Failure

Recent studies have addressed the issue of statin treatment of patients with advanced heart failure (left ventricular ejection fraction <30%). The CORONA (Controlled Rosuvastatin in Multinational Trial in Heart Failure) and GISSI heart failure trials examined the effect of rosuvastatin on CV outcomes in patients with reduced systolic function. These studies suggest that statin therapy does not reduce CVD-related morbidity or mortality in patients with advanced heart failure of ischemic or nonischemic cause.

Renal Failure

Several trials have examined the use of statins in patients with renal failure and in patients undergoing hemodialysis for ESRD. Patients with chronic kidney disease have CV risk at least equivalent to that in patients with diabetes, thus emphasizing the need for prompt recognition and aggressive therapy. Patients with end-stage renal failure do not appear to benefit from statin therapy.[45]

Taken together, the heart failure trials and the renal failure trials suggest that lipid management strategies in patients with end-stage disease produce limited improvement in outcomes. Clinical judgment must carefully weigh the benefits of such preventive measures in these patients.

Risks Associated with Low Levels of Low-Density Lipoprotein Cholesterol

The cumulative evidence from large-scale clinical outcomes data supports the concept that reaching a low level of total cholesterol and LDL-C state decreases CV risk. Some have expressed concern that low LDL-C could impair health. Several lines of evidence argue against this concern. First, most animals have little or no LDL-C and produce LDL particles only when dietary consumption of cholesterol and saturated fats increases. Second, because of its importance in cellular functions, most (if not all) cell types have the cellular machinery to make cholesterol endogenously. Third, the HDL transport system, via the SR-B1

receptor, appears to be able to deliver cholesterol from hepatic sources to organs. Fourth, LDL deficiency states in humans, hypobetalipoproteinemia caused by *APOB* mutations, and loss-of function *PCSK9* mutations are associated with normal health and a marked reduction in life-long CV events.[55] The CTT meta-analysis of more than 170,000 patients treated with statins has not shown an increase in cancers,[9] and the JUPITER trial showed no increase in cancers, renal or hepatic diseases, or hemorrhagic strokes despite one fourth of the patients having reached an LDL-C concentration lower than 44 mg/dL (1.2 mmol/L) for up to 5 years. CTT did not identify any signal of harm in patients treated with statins.[9] The EBBINGHAUS trial examined the effect of evolocumab on cognitive function in 1204 patients enrolled in the large outcomes trial FOURIER. After a mean follow-up of 20 months, there was no evidence of cognitive events in patients treated with evolocumab compared with placebo. Importantly, these conclusions apply to patients who reached a very low LDL-C (<25 mg/dL; 0.7 mmol/L).[56]

Cholesterol Absorption Inhibitors

The development of selective inhibitors of intestinal sterol absorption has added to the treatment of lipoprotein disorders. Ezetimibe is the first such compound. Ezetimibe limits selective uptake of cholesterol and other sterols by intestinal epithelial cells by interfering with NPC1L1. This agent has seen use in patients with LDL-C levels above target while receiving the maximally tolerated statin dose. Ezetimibe lowers LDL-C by about 18% and adds to the effect of statins. Because ezetimibe also prevents the intestinal absorption of sitosterol, it might be the drug of choice in patients with sitosterolemia.

The IMPROVE-IT trial tested the hypothesis that adding ezetimibe to simvastatin results in a greater reduction in LDL-C and a further decrease in CV events. This randomized trial involved 18,144 patients who had a recent acute coronary syndrome (within 10 days) with LDL-C levels of 50 to 100 mg/dL (1.3 to 2.6 mmol/L) in those receiving lipid-lowering therapy or 50 to 125 mg/dL (1.3 to 3.2 mmol/L) in those not receiving therapy. The difference in LDL-C was 69.5 mg/dL (1.8 mmol/L) in the simvastatin-only group and 53.7 mg/dL (1.4 mmol/L) in the simvastatin-ezetimibe group ($P < 0.001$). The rate for the primary endpoint at 7 years was 34.7% in the simvastatin-only group and 32.7% in the simvastatin-ezetimibe group, (absolute risk difference, 2.0 %; HR, 0.936; 95% CI 0.89 to 0.99; $P = 0.016$).[58] The effect on ASCVD reduction was modest and correlated with the relatively small decrease in LDL-C obtained in the trial. With a meta-analysis of statin trials and IMPROVE-IT, taken together, these data support prompt initiation of highly effective statin therapy in patients with acute coronary syndromes, treatment of ASCVD patients with statins, and use of statins in high-risk individuals. Starting statins in the hospital may also improve compliance on discharge.

Fibric Acid Derivatives (Fibrates)

Two derivatives of fibric acid are currently available in the United States. Gemfibrozil (Lopid), 300 to 600 mg twice daily, is indicated for hypertriglyceridemia and in the secondary prevention of CVD in patients with low HDL-C levels, the latter based on VA-HIT (Veterans Administration HDL Intervention Trial). The dose of fenofibrate (TriCor, Trilipix, Lipidil Micro, Lipidil EZ) is 200 mg/day, and a new formulation is available to vary the dose from 40 mg/day (especially in patients with renal failure) to 267 mg/day. In other countries, ciprofibrate (Lypanthyl, Lipanor), clofibrate (Atromid), and bezafibrate (Bezalip) are available. The U.S. Food and Drug Administration (FDA) took the unusual step of withdrawing approval for fenofibric acid with statins to treat high cholesterol, citing a lack of CV benefit.

The mechanism of action of fibrates involves interaction with the nuclear transcription factor PPAR-α,

which regulates transcription of the LPL, apo C-II, and apo A-I genes. Side effects of fibrates include cutaneous manifestations, gastrointestinal (GI) effects (abdominal discomfort, increased bile lithogenicity), erectile dysfunction, elevated transaminase levels, interaction with oral anticoagulants, and elevated plasma homocysteine, especially with fenofibrate and, to a lesser extent, with bezafibrate. Because fibrates increase LPL activity, LDL-C levels may rise in patients with hypertriglyceridemia treated with this class of medications. Fibrates, especially gemfibrozil, can inhibit the glucuronidation of statins and thus impair their elimination. For this reason, gemfibrozil combined with statins may increase the risk for myotoxicity, and therefore such a combination is contraindicated. The clinical usefulness of fibrates is not well established, particularly in view of failure of the FIELD and ACCORD trials to achieve their primary endpoints. Subgroup analyses suggest a benefit of some fibrates in individuals with baseline high triglyceride levels, but no large endpoint study has tested this conjecture rigorously. Some advocate their use in very-high-risk groups such as diabetic patients with CVD and patients with renal failure.

Older fibrate trials such as the Helsinki Heart Study, BIP, and VA-HIT have little relevance to current practice because they did not use statins, which now are considered the standard of care for most patients eligible for fibrate therapy. Gemfibrozil was used in these older studies but has little relevance to current therapy because of a drug-drug interaction that renders concomitant administration with statins contraindicated. Even though the overall effect of fibrates is neutral on CV mortality, subgroup analysis suggests that fibrates might be indicated in high-risk patients with residual CV risk characterized by elevated TG levels, reduced HDL-C, and elevated non–HDL-C who are receiving statin therapy.

Another consideration with the use of fibrates is the theoretical prevention of pancreatitis in patients with severe hypertriglyceridemia (>11 mmol/L; 1000 mg/dL). However, fibrates have little usefulness in LPL-deficient patients with hyperchylomicronemia. Lifestyle changes, including a marked reduction in fats (especially saturated fats), tight control of glycemia in diabetic patients, avoidance of alcohol, frequent small meals during the acute phase of a severe episode of hypertriglyceridemia, fish oil consumption, and avoidance of estrogens in women, remain the fundamentals of prevention of pancreatitis in hypertriglyceridemic individuals.

Nicotinic Acid (Niacin)

Niacin increases HDL-C and lowers TG levels but has more modest effects on LDL levels. Niacin requires doses in the range of 2000 to 3000 mg/day in three separate doses to maximize effects on lipid levels. An escalating dose schedule to reach the full dose in 2 to 3 weeks rather than starting with the full dose can help manage the adverse effects of this agent. Slow-release forms of niacin, including Niaspan (1 to 2 g/day), decrease the side effect profile of the drug. Daily aspirin intake can attenuate skin flushing, as does the prostaglandin D_2 receptor (DP1) antagonist laropiprant. Niacin decreases the hepatic secretion of VLDL and reduces FFA mobilization in the periphery. In the long-term follow-up of the Coronary Drug Project, which was conducted before the availability of statins, niacin decreased mortality at 15 years. Significant and common minor side effects, less frequent serious adverse actions, and statin development hamper niacin use. Side effects of niacin include flushing, hyperuricemia, hyperglycemia, hepatotoxicity, dysglycemia, bleeding, acanthosis nigricans, and gastritis. Recent clinical trials do not support the ability of niacin therapy to improve CV outcomes in patients receiving statins. AIM-HIGH (Atherothrombosis Intervention in Metabolic Syndrome with Low HDL/High Triglycerides: Impact on Global Health Outcomes) tested the hypothesis that patients with CAD optimally treated with a

statin but with residual atherogenic dyslipidemia (low HDL-C and high triglycerides) would benefit from niacin, 2 g/day. The trial was abruptly stopped after 3 years because of a lack of beneficial effect on the primary outcome. The large HPS2-THRIVE (Heart Protection Study 2—Treatment of HDL to Reduce the Incidence of Vascular Events) study randomized 25,673 people with CVD to a strategy of LDL-C reduction with simvastatin (with ezetimibe, if required, to reach target goals) alone or in combination with niacin, 2 g/day, or laropiprant to limit the cutaneous flushing.[59] The THRIVE investigators found that this intervention did not produce clinically meaningful reductions in CV events. The results of AIM-HIGH and THRIVE cast doubt on niacin's ability to lower CV risk, reinforced its undesired effects, and present yet another challenge to the hypothesis that elevation of HDL can improve outcomes of individuals treated with statins. As for fibrates, the FDA withdrew approval for the combination of niacin with statins to treat high cholesterol, citing a lack of CV benefit.

Bile Acid–Binding Resins

Bile acid–binding resins interrupt the enterohepatic circulation of bile acids by inhibiting their reabsorption in the intestine, the site of reabsorption of more than 90% of bile acids. Currently, their main use is adjunctive therapy in patients with severe hypercholesterolemia secondary to increased LDL-C. Because bile acid–binding resins are not absorbed systemically (they remain in the intestine and are eliminated in stool), they are considered safe in children and in pregnant women. Cholestyramine (Questran) is used in 4-g unit doses as a powder, and colestipol (Colestid) is used in 5-g unit doses. Effective doses range from 2 to 6 unit doses/day, always taken with meals. The most important side effects are predominantly gastrointestinal: constipation, a sensation of fullness, and GI discomfort. These drugs can cause hypertriglyceridemia. Decreased absorption of concomitantly administered drugs dictates careful scheduling of other medications 1 hour before or 4 hours after the patient takes bile acid–binding resins. Bile acid–binding resins can be used in combination with statins and/or cholesterol absorption inhibitors in patients with severe hypercholesterolemia. *Colesevelam* is a bioengineered bile acid–binding resin that has approximately twice the capacity to bind cholesterol as cholestyramine does. In doses of 3.8 to 4.5 g/day, it can be a useful third-line therapy for patients not meeting their LDL-C targets or in whom the side effects of statins preclude their optimal use. Colesevelam can also decrease hemoglobin (Hb) A_{1c}, thus making this drug a potentially useful adjunct in the treatment of complicated diabetic patients. Even though relatively few drug-drug interactions have been reported with colesevelam, prudence still warrants a careful dosage schedule (4 hours), which makes the use of all bile acid–binding resins cumbersome in patients taking multiple medications.

Cholesteryl Ester Transfer Protein Inhibitors

Inhibition of CETP by pharmacologic agents mimics the genetic heterozygous CETP deficiency state (**see Fig. 48.3, part 9**). Of several agents tested in humans, torcetrapib proved toxic and increased mortality, an effect attributed to off-target effects. Dalcetrapib, another CETP inhibitor, had more modest effects on HDL-C and LDL-C, and investigations on its use were stopped because of lack of effect in clinical trials. Similarly, the ACCELERATE trial tested the hypothesis that evacetrapib would prevent CV disease in optimally treated patients. Those who received evacetrapib demonstrated a 130% increase in HDL-C (46 to 104 mg/dL) and a 37% drop in LDL-C (84 to 55 mg/dL). The trial was stopped prematurely for clinical futility on the recommendation of the data monitoring committee.[60] Two CETP inhibitors, anacetrapib and TA-8995, remain. Anacetrapib is undergoing a large, outcome-driven clinical trial, Randomized Evaluation of the Effects of Anacetrapib Through Lipid-Modification (REVEAL). CETP inhibitors greatly increase larger, more buoyant HDL particles; these particles appear to promote cellular cholesterol efflux efficiently. Results of these ongoing trials are expected by 2018. Because of the

significant LDL-C–lowering effects of the CETP inhibitor anacetrapib, it may prove difficult to determine whether any benefit is derived from raising HDL-C levels.

Fish Oils

Fish oils are rich in polyunsaturated fatty acids (PUFAs) such as eicosapentaenoic acid (EPA) or docosahexaenoic acid (DHA), with the first double bond on the omega-3 position. These fatty acids lower plasma TG levels and have antithrombotic properties. Although used to treat hypertriglyceridemia, fish oils are reserved for patients with severe hypertriglyceridemia refractory to conventional therapy. Fish oils decrease VLDL synthesis and decrease VLDL apo B. The response to fish oils depends on the dose, with a daily intake of up 10 g of EPA or DHA required for maximal reduction of plasma TG levels. Fish oils may raise LDL levels. A prescription form of omega-3 fatty acids is available in the United States for patients with extreme hypertriglyceridemia (>500 mg/L, or 5.6 mmol/L). A diet containing polyunsaturated fats may be beneficial in terms of CV health. We lack robust and rigorous clinical trials to examine the effects of fish oil on MI and stroke events. Two large-scale trials are currently investigating this issue.

Phytosterols

Phytosterols are derivatives of cholesterol from plants and trees. They interfere with the formation of micelles in the intestine and prevent intestinal absorption of cholesterol. Phytosterols are available as "nutraceuticals" and are incorporated in soft margarines. Sterols may prove useful for the adjunctive management of lipoprotein disorders. The safety of plant sterols has not been established.

PCSK9 Inhibitors

Inhibiting proprotein convertase subtilisin/kexin type 9 (PCSK9) currently requires the use of monoclonal antibodies (mAbs) administered subcutaneously every 2 weeks or monthly. Evolocumab and alirocumab are fully human mAbs, and both recently approved in the United States, Canada, and Europe. The development of bococizumab, a humanized mAb, was stopped because of the development of neutralizing antibodies in a large percentage of participants.[61] LY3015014 is a second humanized mAb undergoing phase 3 clinical trials.[62]

In the large phase 2/3 clinical program, both evolocumab[28] and alirocumab[29] have demonstrated excellent LDL-C–lowering capacity (50% to 70%), regardless of background therapy, in many different patients, including those taking statins. The observation of a large and concordant relative reduction (approximately 50%) in clinical outcomes in LDL-C efficacy studies (OSLER and ODYSSEY LONG TERM) is consistent with the LDL hypothesis and with the metaregression results from the CTTC. The Further Cardiovascular Outcomes Research with PCSK9 Inhibition in Subjects with Elevated Risk (FOURIER) trial examined the effect of evolocumab (140 mg every 2 weeks or 420 mg monthly SC) added to the standard of care in 27,564 high-risk patients. Compared with placebo, LDL-C was reduced by 59% from 92 mg/dL (2.4 mmol/L) to 30 mg/dL (78 mmol/L). Evolocumab treatment significantly reduced the risk of the primary composite endpoint (9.8% versus 11.3%; HR, 0.85; 95% CI 0.79 to 0.92; $P < 0.001$) and the secondary endpoint of CV death, nonfatal MI, and stroke (5.9% versus 7.4%; HR, 0.80; 95% CI 0.73 to 0.88; $P < 0.001$)[63] (**Fig. 48.9**). The ODYSSEY outcomes trial will examine CV outcomes in 18,000 patients post–acute coronary syndrome treated with alirocumab.[64] The SPIRE-1 and SPIRE-2 studies compare bococizumab (a humanized PCSK9 mAb, 150 mg SC every 2 weeks) to matching placebo in 28,000 patients at high CV risk. The trial was stopped, but a slight clinical benefit was found in participants with LDL-C higher than 100 mg/dL (2.6 mmol/L) with a median follow-up of 10

months.[65]

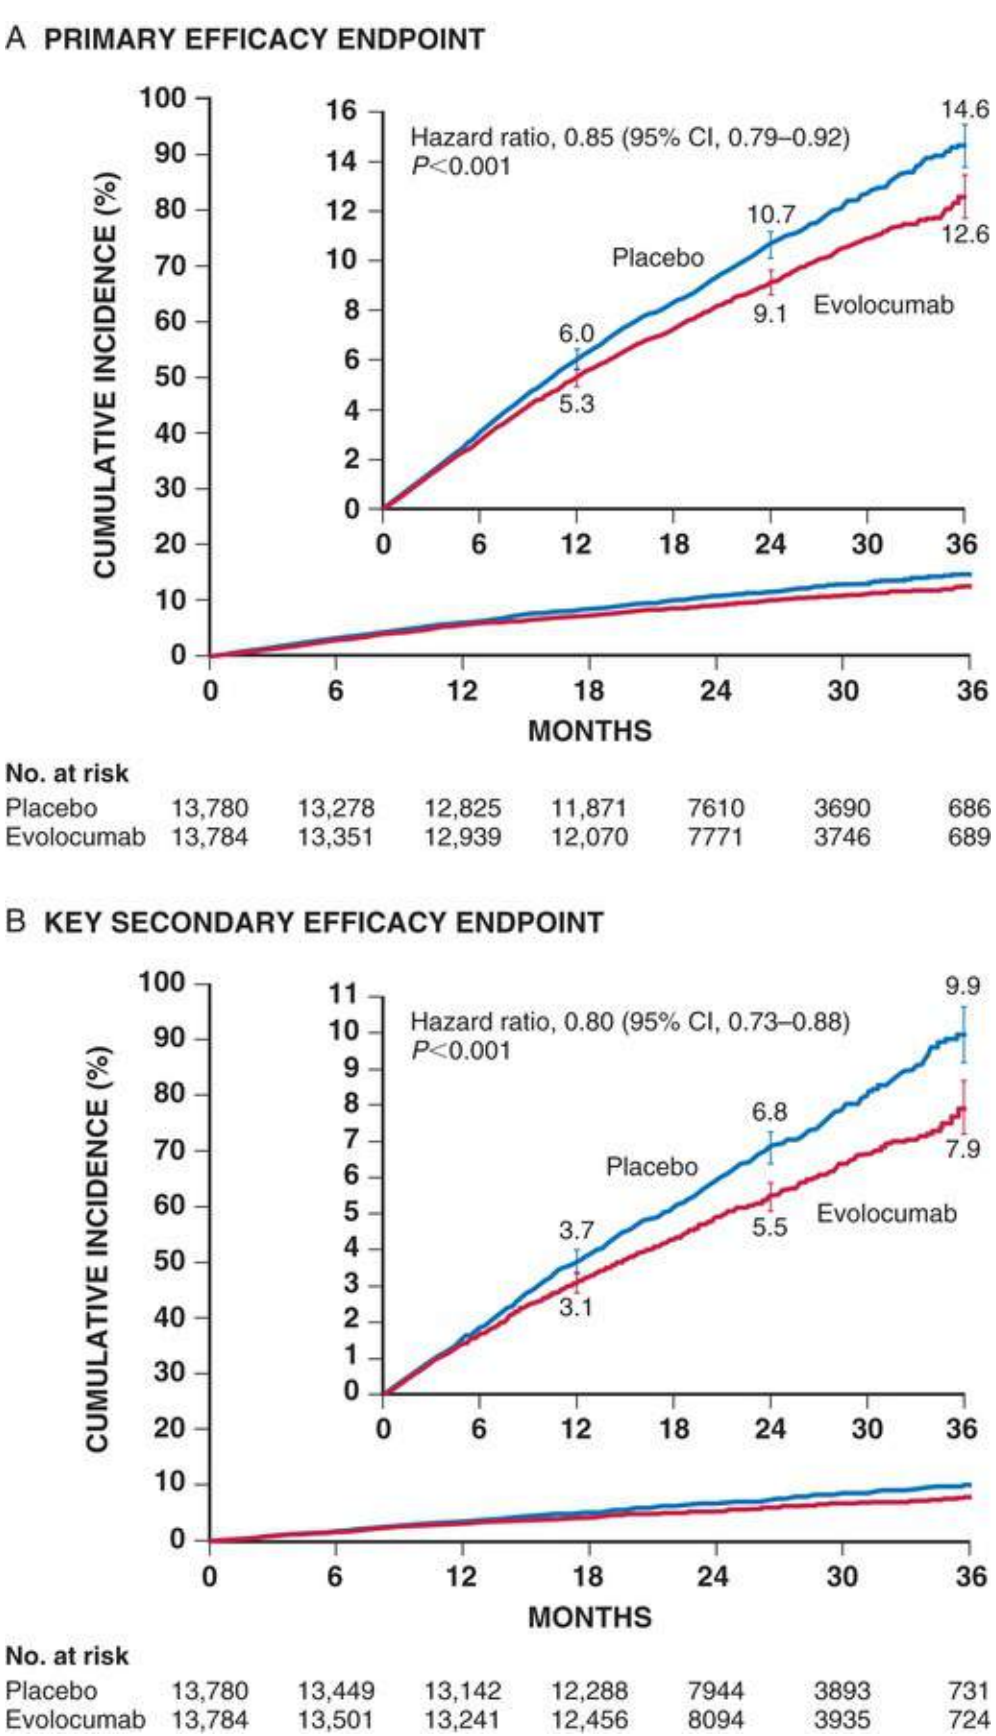

FIGURE 48.9 Results of the Further Cardiovascular Outcomes Research with PCSK9 Inhibition in Subjects with Elevated Risk (FOURIER) trial. Evolocumab reduced the risk of the primary composite endpoint of cardiovascular (CV) death, myocardial infarction (MI), stroke, hospitalization for unstable angina, and coronary revascularization in 1344 patients (9.8%) in the evolocumab group and in 1563 patients (11.3%) in the placebo group (hazard ratio, 0.85; 95% CI 0.79 to 0.92; $P < 0.001$). Evolocumab significantly reduced the risk of the key secondary composite endpoint of CV death, MI, and stroke in 816 patients (5.9%) in the evolocumab group and in 1013 patients (7.4%) in the placebo group (hazard ratio, 0.80; 95% CI 0.73 to 0.88; $P < 0.001$). (From Sabatine MS et al; FOURIER Steering Committee and Investigators. Evolocumab and clinical outcomes in patients with cardiovascular disease. N Engl J Med 2017;376(18):1713-22.)

Overall, more than 46,000 individuals at high or very high risk of ASCVD will be exposed to PCSK9 inhibitors to determine the effect of this new class of drugs on CV outcomes.

Approval to date for evolocumab (Repatha), 140 mg SC every 2 weeks or 420 mg monthly, and alirocumab (Praluent), 75 mg or uptitrated to 150 mg SC every 2 weeks, has been given for patients with established clinical atherosclerotic vascular disease or familial hypercholesterolemia and whose LDL-C remains above target despite maximally tolerated statin dosing with or without ezetimibe. In statin-intolerant patients, evolocumab proved superior to ezetimibe in the carefully designed GAUSS-3 study; only patients with statin intolerance who did not tolerate atorvastatin, 20 mg, were randomized to ezetimibe or evolocumab. The mean percent LDL-C change was −16.7% (95% CI −20.5% to −12.9%) in those taking ezetimibe and was −54.5% (95% CI, −57.2% to −51.8) in those taking evolocumab (P = 0.001).[66] Similar findings were reported in the ODYSSEY ALTERNATIVE randomized trial with alirocumab.[67]

The use of liver-targeted antisense RNA against PCSK9 was shown to lower PCSK9 and LDL-C markedly in a phase 2 study, with a dosing interval of 3 to 6 months, making this approach clinically appealing.[68] It is not yet clear if there are safety concerns for blocking the intracellular PCSK9 pathway.

Novel Agents

In severe hypercholesterolemia, especially autosomal dominant hypercholesterolemia, several approaches have been approved to reduce LDL-C. Inhibition of MTTP with the small-molecule *lomitapide* reduces LDL-C by approximately 30% to 50%.[69] Another approach is to inhibit apo B mRNA with phosphorothioate-linked antisense oligonucleotides. *Mipomersen* is the first such compound approved for limited use in patients with homozygous FH.[70] Mipomersen reduces LDL-C by 20% to 30%. Although safety concerns were raised with these compounds, the severity of homozygous FH was deemed to warrant novel therapeutic avenues.[71] Inhibition of apo B synthesis and secretion is associated with accumulation of fat in the liver. Because of the small number of patients included in these trials, no outcome data are likely to become available.

Patients with elevated Lp(a) represent a therapeutic challenge. Statins have little effect on Lp(a) levels; niacin can lower Lp(a) by 20% to 30%, but its use is accompanied by adverse events.[62] PCSK9 inhibitors evolocumab[72] and alirocumab[73] lower Lp(a) significantly by 20% to 25%. Antisense RNA directed against apo(a) markedly decreased Lp(a) levels in humans in a proof-of-concept study, paving the way for clinical trials.[74]

A novel compound, bempedoic acid, inhibits ATP-citrate lyase (ACL), a key enzyme in the "cholesterol biosynthesis pathway." Phase 1 and 2 studies show a 20% to 39% reduction in LDL-C in a variety of individuals.[75]

Clinical Approach to Treatment of Lipoprotein Disorders

Patients with lipoprotein disorders should undergo comprehensive evaluation and management in the context of a global risk reduction program. Most patients with dyslipoproteinemias lack symptoms, except for those with severe hypertriglyceridemia, who can have acute pancreatitis, and those with familial lipoprotein disorders, who have cutaneous manifestations (xanthomas, xanthelasmas). Evaluation of patients with dyslipidemia should include seeking and treating secondary causes. Clinical evaluation

should include a thorough history, including a complete family history, which may reveal clues to a genetic cause, as well as clues to a genetic susceptibility to CVD. The physician should seek and address other risk factors (cigarette smoking, obesity, diabetes, hypertension, lack of exercise) and institute a management plan to improve lifestyle, such as diet, physical activity, and alcohol intake. Such interventions should make use of nonphysician health professionals (e.g., those with training in diet and nutrition, physical therapy, and smoking cessation).

The physical examination should include a search for xanthomas (in extensor tendons, including the hand, elbow, knee, and Achilles tendons, as well as palmar xanthomas) and the presence of xanthelasmas, corneal arcus, and corneal opacifications. Blood pressure, waist circumference, weight, and height should be recorded and signs of arterial compromise sought, and a complete cardiovascular examination must be performed. Evaluation of peripheral pulses and determination of the ankle-brachial index may reveal important clues to the presence of peripheral vascular disease.

The diagnosis of lipoprotein disorders depends on laboratory measurements. A nonfasting lipid profile generally suffices for most lipoprotein disorders, and specialized laboratories can refine the diagnosis and provide expertise for extreme cases. A fasting lipid profile is indicated in patients with moderately severe hypertriglyceridemia (>400 mg/dL, or >4.5 mmol/L) because the calculated LDL-C is not reliable. Additional tests often involve considerable expense and may not increase the predictive value beyond that of the lipid profile, although these can help in refining the diagnosis. To assess baseline risk in individuals receiving lipid-lowering therapy, the medication should be stopped for 1 month before measuring a lipid profile, unless clinical circumstances contraindicate such a treatment gap. Advanced lipid tests seldom add to the clinical assessment just specified.

After diagnosis of a lipid disorder (based on at least two lipid profiles), measurement of TSH and glucose help in evaluating secondary causes. Measurement of HbA_{1c} and the urinary albumin/creatinine ratio may provide additional information in diabetic and hypertensive patients. Patients who will receive medications should undergo measurement of baseline liver function (alanine transaminase) and CK. Drug treatment of high-risk patients (e.g., with an acute coronary syndrome or after MI or coronary revascularization) should start immediately, with concomitant lifestyle changes.

Lifestyle Changes: Diet

Individuals with dyslipoproteinemias should always adopt dietary therapy. High-risk patients should have medications started concomitantly with a diet because in many cases, diet may not suffice to reach target levels. The diet should have three objectives: (1) allow the patient to reach and maintain ideal body weight, (2) provide a well-balanced diet with fruits, vegetables, and whole grains, and (3) have restrictions on sodium, saturated fats, and refined carbohydrates. Dietary counseling should involve a professional dietitian. Frequently, the help of dietitians, weight loss programs, or diabetic outpatient centers can aid in achieving sustained weight loss. (**See also Chapters 45 and 49**.)

Treatment of Combined Lipoprotein Disorders

Combined lipoprotein disorders, characterized by an increase in plasma total cholesterol and triglycerides, frequently occur in clinical practice and present difficult challenges. Patients with combined lipoprotein disorders have an increase in LDL-C and LDL particle number (as reflected by an increase in total or LDL apo B or non–HDL-C), small dense LDL particles, increased VLDL-C and VLDL triglycerides, and a reduced HDL-C level. Patients with this pattern of combined dyslipidemia often have

obesity and metabolic syndrome. Treatment should begin with lifestyle modifications consisting of a diet reduced in total calories and saturated fats, weight reduction, and increased physical activity. Drug treatment, when warranted, aims to correct the predominant lipoprotein abnormality. Statins can reduce plasma TG levels, particularly in individuals with high baseline levels. Fibrates reduce triglycerides and may change the composition of LDL to larger and less dense particles. The combination of a statin with a fibrate or with niacin, however, has proved effective in correcting the laboratory abnormalities that characterize the combined dyslipoproteinemias, but as noted earlier, currently available clinical trials have not established that this approach prevents CV events. Because of the effects of gemfibrozil on glucuronidation of statins, we advise against use of gemfibrozil in combination with statins. Patients taking a fibrate plus a statin merit close medical follow-up for evidence of hepatotoxicity or myositis within the first 6 weeks of therapy and every 6 months thereafter. The results of IMPROVE-IT support the combined use of a statin and ezetimibe.[57]

The use of other combinations, including fibric acid derivatives with bile acid–binding resins and niacin with these resins, lacks support from outcome trials and regulatory agencies and requires caution because of the risk of adverse effects such as hepatotoxicity and myositis. The search for correctable causes (e.g., uncontrolled diabetes, obesity, hypothyroidism, alcohol use) of combined dyslipidemia and the benefit of lifestyle modifications require reemphasis. Again, the help of dietitians, weight loss programs, or diabetic outpatient centers often adds considerably to management. (**See also Chapters 45 and 50**.)

Extracorporeal Filtration of Low-Density Lipoprotein

Patients with severe hypercholesterolemia, especially those with homozygous FH or severe heterozygous FH, may warrant treatment by extracorporeal elimination of LDL. These techniques use selective filtration, adsorption, or precipitation of LDL (or apo B–containing particles) after plasma separation. Specialized centers have LDL apheresis available. This approach can dramatically reduce the risk for development of CVD and improve survival.

Future Perspectives

The development of novel pharmaceutical agents for the treatment of lipoprotein disorders will probably continue because CVD secondary to atherosclerosis represents the largest burden of disease worldwide for the foreseeable future. Newer therapies, especially PCKS9 inhibitors, show considerable promise for the treatment of severe hypercholesterolemia. These new agents will offer personalized medicine based on genotype and phenotype. Better targeting of high-risk individuals will allow optimization of expensive therapies.

Therapies aimed at raising HDL-C have proved disappointing. Other therapeutics under evaluation seek to increase HDL biogenesis, especially from lipid-laden macrophages.

Gene Therapy

Severe, homozygous, monogenic disorders may eventually be treated by gene therapy. The initial trials of gene therapy in patients with homozygous FH proved disappointing. Refinement in viral delivery vectors has rekindled interest in disease-specific gene therapy. Especially for homozygous familial hypercholesterolemia, this approach could prove lifesaving for a disease associated with considerable

morbidity and premature mortality. Other diseases, such as abetalipoproteinemia, LPL deficiency, Niemann-Pick type C disease, sitosterolemia, and Tangier disease, may become targets for gene therapy. If the approach to correcting these disorders is successful, the more widespread application of gene-based therapies to reduce potential CV risk will become a challenging medical, social, and ethical problem.

Societal Changes

It is extremely unlikely that drugs alone will prevent and cure atherosclerosis. Societal changes encouraging healthy lifestyles as well as public health measures and infrastructure can provide overall, not just cardiovascular, health benefits. Public health measures to reduce cigarette smoking have already reduced rates of MI. As humanity continues to accommodate more than half the population in cities, organization of neighborhoods into local networks allowing energy expenditure (rather than conservation via easy access to motorized transportation) will become necessary, especially in affluent countries. Personal changes with respect to food consumption and caloric intake will remain a major challenge. Indeed, the changes in diet and physical activity that have occurred in the past 50 years (now spreading globally) probably contributed to the epidemic of obesity and the increased prevalence of lipoprotein disorders, hypertension, and diabetes, with consequent ASCVD. (**See also Chapters 45, 49, and 50.**)

Guidelines

Lipid Management

Jacques Genest and Peter Libby

Since 1985, originally under the auspices of the National Heart, Lung and Blood Institute (NHLBI) of the U.S. National Institutes of Health (NIH), various organizations have offered guidelines for the detection and treatment of dyslipidemias.[1] Certain common broad principles informed these various recommendations: (1) assessing the global risk of atherosclerotic cardiovascular disease (ASCVD) by including known risk factors, (2) treating patients with established or at high risk of ASCVD; and (3) treating patients according to specific targets. As scientific knowledge accrued and clinical trials became increasingly focused on outcomes rather than specific lipoprotein levels or surrogate endpoints, guidelines adapted. Increasingly, the process of rating the evidence, using specific tools such as the Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) standards; PICO (population, intervention, comparator, outcomes) questions; and outlining areas of uncertainty have continuously changed recommendations.

In the past few years, some confusion has risen among clinicians regarding cardiovascular risk stratification and the use of biomarkers and imaging techniques for CV risk stratification and target levels. The 2013 the American College of Cardiology/American Heart Association (ACC/AHA) cholesterol guidelines proposed a new tool for assessing absolute risk assessment: a pooled cohort equation for ASCVD, including thromboembolic strokes.[2,3] (See the previous edition of this text for a summary of this guideline.) This risk calculator includes a broader distribution of gender and ethnic background. The guideline lowered the threshold for defining “high risk” for ASCVD to a 7.5% 10-year risk. Second, statins became the only class of medications with a strong recommendation, based on the large outcome studies then available. Third, this guideline abandoned targets in favor of recommending the intensity of

statin therapy (moderate or high), depending on risk category. Finally, this guideline aimed to reflect the trial evidence base rather than mere expert opinion. In 2016, based on data that became available after the release of the 2013 AHA/ACC lipid guideline,[4] participants in that process issued a consensus statement on the use of nonstatin therapies (including ezetimibe) for LDL lowering in the management of ASCVD risk[5] (**Fig. 48.G1**).

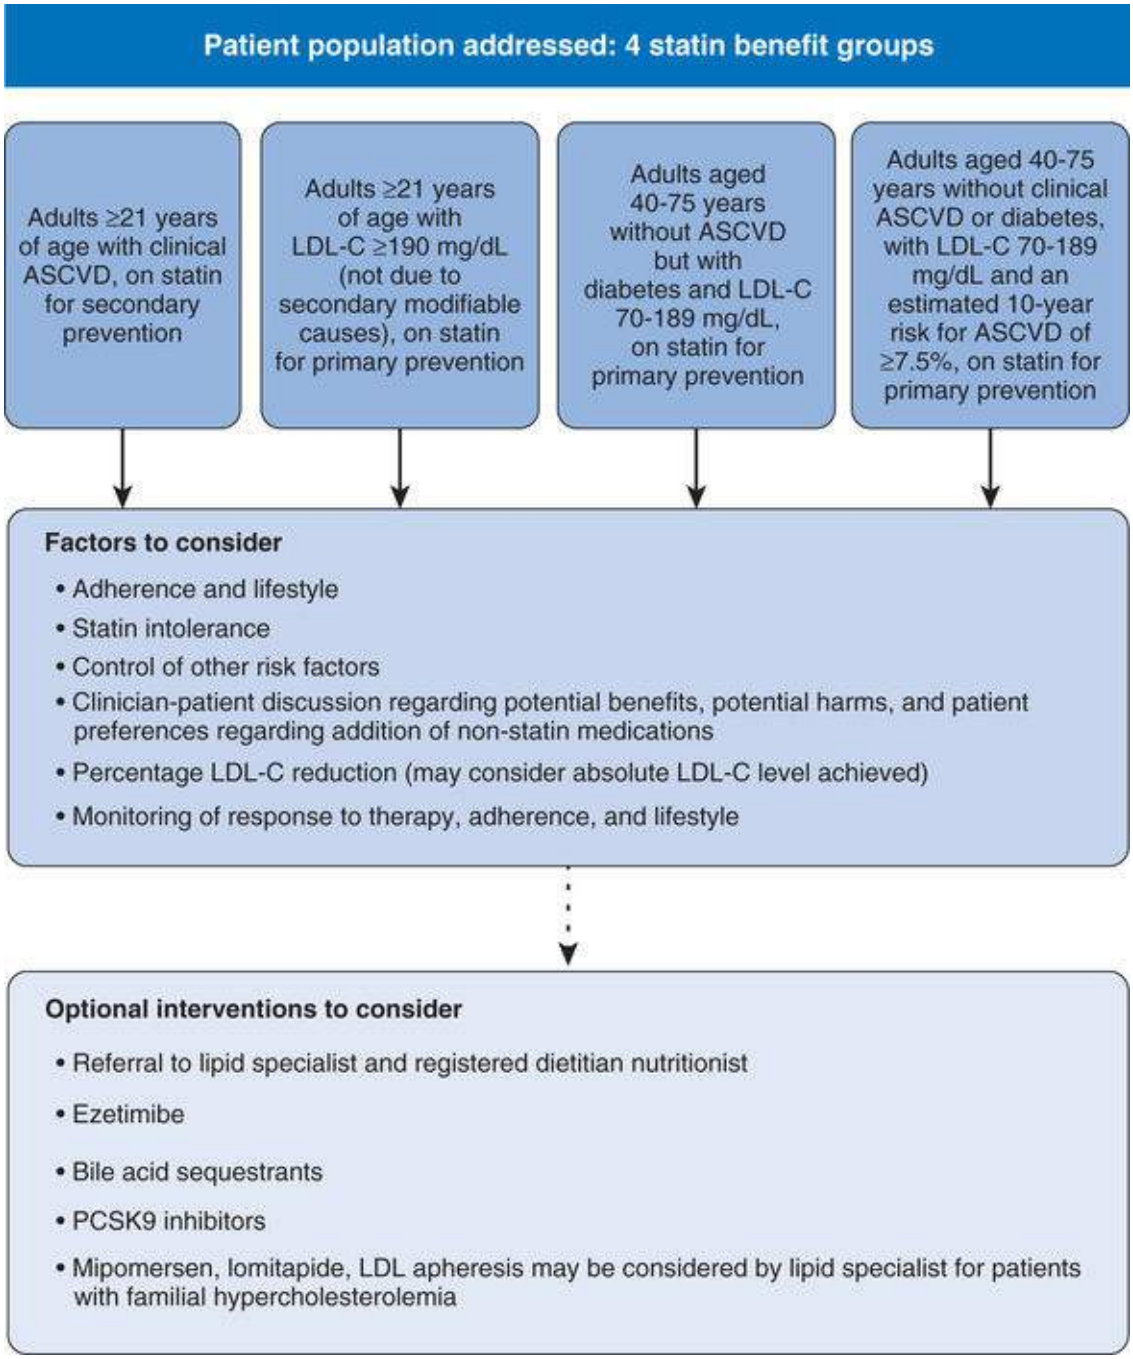

FIGURE 48.G1 Patient populations addressed and factors and interventions to consider for statin therapy. ASCVD, Atherosclerotic cardiovascular disease; LDL-C, low-density lipoprotein cholesterol. (From Lloyd-Jones DM et al. 2016 ACC expert consensus decision pathway on the role of non-statin therapies for LDL-cholesterol lowering in the management of atherosclerotic cardiovascular disease risk: a report of the American College of Cardiology Task Force on Clinical Expert Consensus Documents. J Am Coll Cardiol 2016;68(1):92-125.)

The release of this guideline led to enthusiastic and robust discussions, but also to some confusion among societies, experts, and clinicians who apply these new recommendations. Indeed, all have free access to the body of evidence that serves as the basis for guidelines and recommendations. The major

discussions surround the interpretation of the data and applicability in the clinical setting. Despite the controversies, the broad principles of assessing CV risk and statin treatment aimed at lowering LDL-C to prevent ASCVD outcomes remain the foundation of all guidelines. Although guidelines may differ, they share much more commonality. **Tables 48.G1 and 48.G2** summarize the major guidelines since 2013.

TABLE 48.G1

Comparison of Atherosclerotic Cardiovascular Disease (ASCVD) Risk Assessment Tools

YEAR	SOURCE	RECOMMENDED RISK ASSESSMENT TOOL	FORECAST CAPABILITY OF TOOL	RISK FACTORS INCLUDED FOR RISK ESTIMATION	ASCVD OUTCOME PREDICTED	POPULATION USED FOR DERIVATION/VALIDATION OF RISK ALGORITHM
2013	2013 ACC/AHA guidelines* United States	Pooled cohort risk equations	10 yr Lifetime or 30 yr (for ages 20-59 yr)	Age, sex, ethnicity (Caucasian or African American), TC, HDL-C, systolic BP, treatment for hypertension, DM	Nonfatal MI, CHD death, fatal or nonfatal stroke	ARIC, CHS, CARDIA, FHS African American, white men and women Ages 40-74 yr
2014	IAS United States	Updated Framingham Risk Score with recalibration coefficients for different patient populations	Lifetime	Risk factor status age 50 yr: TC, systolic BP, diastolic blood pressure, smoking status, diabetes	MI, coronary insufficiency, angina, stroke, claudication, CVD death based on measured risk factors at age 50 yr	Framingham original and offspring cohorts
2014	NICE United Kingdom	QRISK2	10-yr risk of CHD death, MI or angina, stroke or TIA	Age, sex, cholesterol/HDL-C, HP, BP treatment, DM, smoking, family history of CHD, high BMI, CKD, RS, and atrial fibrillation	CHD death, MI or angina, stroke or TIA	British population from medical practices, annual update
2014	NLA United States	Risk factor counting	10 or 30 yr, depending of risk calculator used	Age, family history, smoking, high BP, low HDL-C	ASCVD	Not specified. FRS, PCE, Framingham 30-yr risk
2016	ESC/EAS European Union	SCORE (with risk adjustment algorithm/tables provided based on population, country)	10-yr risk of CV death	TC or TC/HDL-C ratio, sex, smoking status, systolic BP	Fatal atherosclerotic event (MI, stroke, occlusive arterial disease, sudden cardiac death)	104,961 participants from 7 pooled European (Belgium, Britain, Denmark, Finland, Germany, Italy, Spain) prospective studies Men, 55% (20-89 yr) Women, 45% (20-99 yr)
2016	CCS Canada	FRS: global CVD risk	10 yr	Age, sex, TC, HDL-C, systolic BP, BP treatment, smoking status, DM, vascular age	Absolute ASCVD event (CHD, cerebrovascular, peripheral vascular, and heart failure)	Framingham original and offspring cohorts

*On treatment of blood cholesterol to reduce ASCVD risk in adults.

See Table 48.G2 footnote for abbreviations.

TABLE 48.G2

Lipoprotein Lipid Assessment, Statin Indication, and Target Levels

YEAR	SOURCE	LIPOPROTEIN MEASUREMENT FOR RISK ASSESSMENT	SPECIFIC TARGETS	STATIN INDICATION	TARGETS
2013	2013 ACC/AHA guidelines* United States	Fasting lipid profile	None	ASCVD; most diabetes, LDL-C >190 mg/dL (4.9 mmol/L, pooled cohort equation risk ≥7.5%, LDL-C ≥70 mg/dL (1.8 mmol/L)	No specific target Expected 50% reduction in LDL-C with high-dose statins
2014	IAS United States	Fasting or nonfasting lipid profile	Yes	According to risk level to age 80 yr	LDL-C <70 mg/dL and non–HDL-C <100 mg/dL in secondary prevention
2014	NICE United Kingdom	Nonfasting lipid profile	None	10-yr risk >10%	No specific target Expect 40% reduction in non–HDL-C
2014	NLA United States	Fasting or nonfasting lipid profile	Yes	Non–HDL-C.>100 mg/dL in high-risk subjects	Non–HDL-C <100 mg/dL (LDL-C<70 mg/dL)
2016	ESC/EAS European Union	Nonfasting lipid profile	Yes	LDL-C >190 mg/dL; LDL-C mg/dL and 10-yr risk >10%; LDL-C >1.8 mmol/L	LDL-C (non–HDL-C, apo B)
2016	CCS Canada	Nonfasting lipid profile	Yes	ASCVD, most DM, LDL-C >190 mg/dL (5.0 mmol/L); FRS >20% 10-yr risk	LDL-C <80 mg/dL (2.0 mmol/L) or LDL-C reduction 50% in high-risk patients Alternate: non–HDL-C <3.2 mmol/L

ASCVD, Atherosclerotic cardiovascular disease; *apo B,* apolipoprotein B; *BMI,* body mass index; *BP,* blood pressure; *CHD,* coronary heart disease; *CKD,* chronic kidney disease; *CV,* cardiovascular; *DM,* diabetes mellitus; *HDL-C,* high-density lipoprotein cholesterol; Hb_{A1c}, hemoglobin A_{1c}; *hsCRP,* high-sensitivity C-reactive protein; *LDL-C,* low-density lipoprotein cholesterol; *MI,* myocardial infarction; FRS, Framingham Risk Score; *TC,* total cholesterol after LDL-C; *TIA,* transient ischemic attack.

ACC, American College of Cardiology; AHA, American Heart Association; ARIC, Atherosclerosis Risk in Communities; CARDIA, the Coronary Risk Development in Young People; CCS, Canadian Cardiovascular Society; CHS, Cardiovascular Health Study; EAS, European Atherosclerosis Society; ESC, European Society of Cardiology; FHS, the Framingham Heart Study; FRS, Framingham Risk Score; IAS, International Atherosclerosis Society; NICE, National Institutes for Clinical Excellence; NLA, National Lipid Association; SCORE, Systematic Coronary Risk Evaluation.

The 2013 ACC/AHA cholesterol guidelines considered the evidence derived from randomized, controlled clinical trials (RCTs), [2] whereas the 2014 International Atherosclerosis Society (IAS),[6] 2014 National Institute of Clinical Excellence (NICE, UK),[7] 2014 National Lipid Association (NLA, U.S.),[8,9] 2016 European Society of Cardiology/European Atherosclerosis Society (ESC/EAS, European Union),[10] and 2016 Canadian Cardiovascular Society (CCS)[11] lipid guidelines used comprehensive literature reviews to make their recommendations.[12] The critical questions posed by the 2013 ACC/AHA cholesterol guidelines were as follows: (1) What is the evidence for LDL-C and non–HDL-C goals in the secondary prevention of ASCVD? (2) What is the evidence in the primary prevention of ASCVD? and (3) What are the efficacy and safety of lipid-lowering drugs in the primary and secondary prevention of ASCVD?[2] The goal was to ensure an unbiased assessment of the evidence and eliminate lower-quality studies.

The risk assessment tool differs differ greatly between guidelines, especially in the United States. The new pooled cohort equation is derived from four cohort studies sponsored by the NHLBI: Atherosclerosis Risk in Communities (ARIC), Cardiovascular Health Study (CHS); Coronary Risk Development in Young People (CARDIA), and Framingham Heart Study (FHS).[3] This new model allows more gender and ethnic diversity than the FHS. The IAS recommends the Framingham Risk Score (FRS), and NLA guidelines recommend the FRS, pooled cohort equation, or the Framingham 30-year risk assessment tool. NICE updates annually the QRISK2 calculator, depending on data obtained from medical clinics across the

UK.[13] The EU uses the Systematic Coronary Risk Evaluation (SCORE), adjusted for region-specific risk of CVD, to determine risk.[14] CCS guidelines continue to recommend the FRS[11] (**Table 48.G1**).

Most guidelines advocate target levels of LDL-C (or non-HDL-C) since the inception of the National Cholesterol Education Program.[15] Clinicians have become familiar with the use of targets for lipid values and blood pressure over the past three decades. A generation of clinicians therefore has embedded lipid targets in their clinical practices, and change often proves difficult. Both the AHA/ACC and the NICE guidelines have proposed statin therapy (high or moderate intensity) according to the absolute risk of ASCVD. Nevertheless, both recommend follow-up lipid testing, with an expected 50% decrease in LDL-C[2] and 40% decrease in non–HDL-C.[7] In contrast, other guidelines recommend LDL-C or non–HDL-C targets depending on absolute risk.

The use of (biochemical) biomarkers of CV risk or imaging techniques, especially coronary calcium score and carotid ultrasound, has received limited endorsement for clinical decision making, but the language used allows clinicians to use their judgment. The initial assessment of global CV risk generally does not use these biomarkers or imaging techniques, but some guidelines sanction their use to reclassify a patient's risk in the primary prevention setting.

Equally important, all guidelines recommend involving the patient in clinical decision making and take into account values and preferences of individual patients. The QRISK2 score uses intuitive computer designs to frame the risk of developing ASCVD compared to age- and gender-matched controls.[16] In the end, physicians may elect to adopt guidelines that are recognized nationally and internationally and that undergo regular updates.

These considerations indicate that lipid management in primary prevention should not rely solely on any simple algorithm or complicated set of flowcharts unlikely to be used routinely by busy practitioners. Rather, primary prevention should involve consideration of the benefits and risks from trials that actually provide evidence, along with respectful interpretation of patient preferences in shared decision making. Physicians should recognize that the guidelines emanating from various organizations in different locales do not constitute hard and fast rules, but rather provide informed and thoughtful suggestions to guide approaches to management and conversations with patients.

Nutrition and Cardiovascular and Metabolic Diseases

Dariush Mozaffarian

Together with smoking and physical activity, dietary habits constitute the foundation for causation, prevention, and treatment of most cardiometabolic diseases, including coronary heart disease (CHD), stroke, type 2 diabetes mellitus (DM), and related conditions. In 2010, eight of the top 25 modifiable causes of global disease were dietary, largely because of their contributions to these diseases (**see also Chapter 1**). The top burdens resulted from insufficient intake of fruits, nuts, whole grains, vegetables, seafood omega-3 fats, and dietary fiber and excess intake of salt and processed meats.[1] In the United States, suboptimal diet is now the leading cause of poor health, estimated to cause 1 in 4 deaths and 14% of lost disability-adjusted life-years (DALYs).[2]

These burdens have increased in recent decades as a result of rapid social, cultural, and environmental transitions, transmitted primarily through changes in diet and other lifestyle habits.[1] Familiarity with the evidence for effects of different dietary factors is essential to prioritize interventions for individual patients and for populations and reduce the considerable disease caused by suboptimal diets.

The science of nutrition and chronic diseases has progressed rapidly in the 21st century. Whereas prior dietary guidance derived largely from ecologic (cross-population) studies, short-term experiments, and animal studies, nutritional science has undergone transformation by more robust evidence from prospective cohorts and randomized trials with cardiovascular disease (CVD) endpoints and well-conducted metabolic trials of multiple risk markers and pathways. Several key lessons have emerged.[3] First, dietary habits influence a wide range of established and emerging risk factors, including blood pressure (BP), glucose-insulin homeostasis, lipoprotein concentration and composition, weight gain, inflammation, endothelial function, and cardiac function and arrhythmia (**Fig. 49.1**). Consequently, the full effects of any dietary factor should not be inferred only from its effects on any single biomarker, such as blood cholesterol concentration. Rather, valid conclusions should be derived from concordant evidence across different research avenues. A second key lesson is the importance of foods and overall dietary patterns, rather than single isolated nutrients, for preventing and managing cardiometabolic diseases. A third lesson is the consistent observed benefits for “foods that give rise to life,” including fruits, seeds, nuts, beans, and whole grains. Such foods are naturally rich in phytochemicals and nutrients that function to preserve and nurture new life, which appears increasingly relevant for promotion of healthy aging.

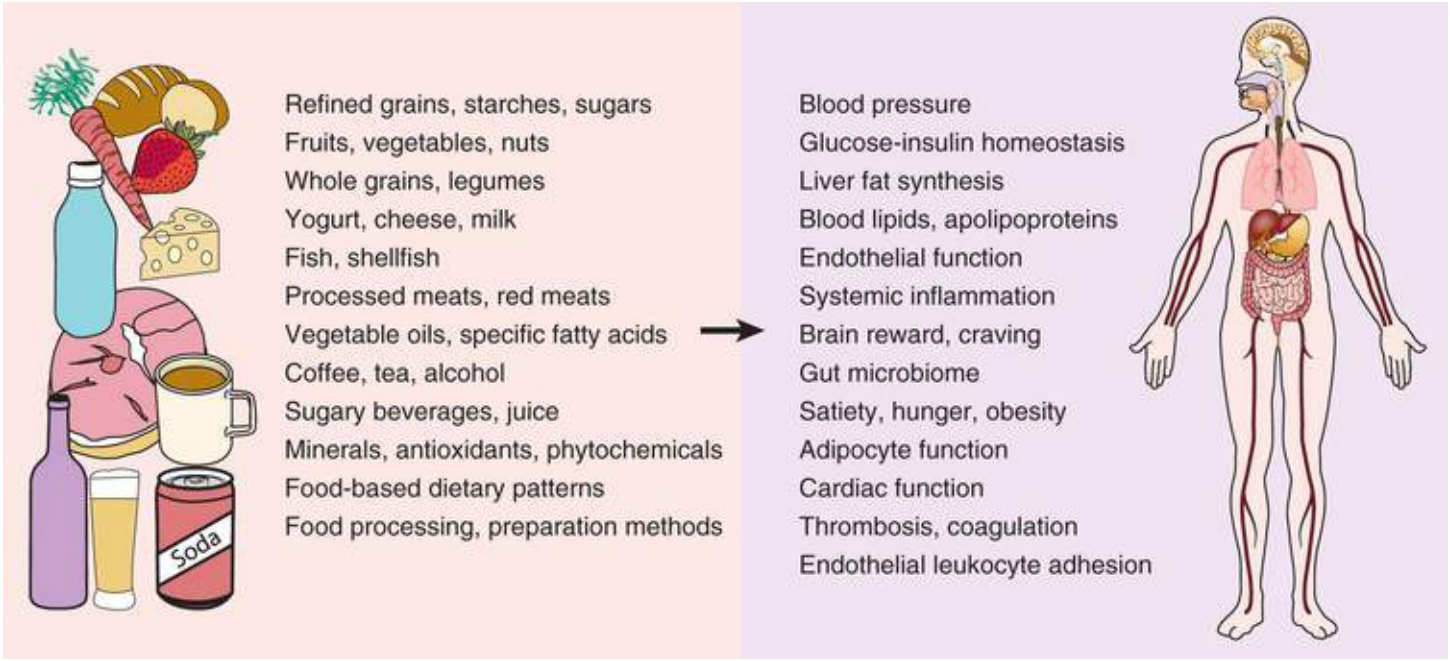

FIGURE 49.1 Diet and cardiovascular and metabolic risk: pathways and mechanisms. Multiple dietary factors influence diverse pathways of risk, and these effects are in some cases further modified by underlying individual characteristics. Selected major effects are detailed in the text sections on each dietary factor. (From Mozaffarian D. Dietary and policy priorities for cardiovascular disease, diabetes, and obesity: a comprehensive review. Circulation 2016;133:187-225.)

This chapter reviews the dietary factors with the strongest evidence for cardiometabolic effects and highlights key knowledge gaps. Because translation of knowledge into action is essential, this chapter also reviews effective individual- and population-based strategies for behavior change.

Foods

In the early and mid-20th century, nutritional science and dietary guidelines focused on nutrient deficiency diseases (e.g., scurvy, rickets), leading to reductionist approaches that emphasized isolated single nutrients.[4] As chronic diseases emerged as a major public health problem in the late 20th century, this scientific emphasis on single nutrients lingered. For example, dietary fat was considered the major cause of obesity, and saturated fat and cholesterol the major causes of heart disease. With the exception of additives such as sodium or *trans* fat, however, a single nutrient in isolation has minimal effects on cardiometabolic diseases. Modern nutrition science recognizes the relevance of foods and dietary *patterns*, comprising a complex matrix of fatty acids, proteins, carbohydrate quality, micronutrients, and phytochemicals that together modify cardiometabolic risk. Such a focus on foods, rather than single nutrients, also facilitates dietary guidance and behavior change.

Fruits and Vegetables

Higher fruit and vegetable intake is associated with lower incidence of CHD and cerebrovascular accident (stroke); and fruit, with a nonsignificant trend toward less diabetes[5,6] (**Fig. 49.2**). Total vegetable intake is not associated with DM, perhaps because of the greater importance of certain subtypes, such as green leafy vegetables.[7] In controlled trials lasting up to 2 years, diets with an emphasis on consuming fruits and vegetables improved several cardiometabolic risk factors, including BP, lipid levels, insulin resistance, inflammation, adiposity, and endothelial function.[3] Such benefits likely derive from the sets of micronutrients, phytochemicals, and fiber in fruits and vegetables, as well as from their replacing less

healthful foods. Together, these studies provide strong evidence that fruit and vegetable consumption lowers CVD risk. Although individual studies suggest that phytochemical-rich fruits, such as berries, may have particular benefit,[8-11] the effects of specific subtypes, as well as of 100% juice,[12-14] require further study.

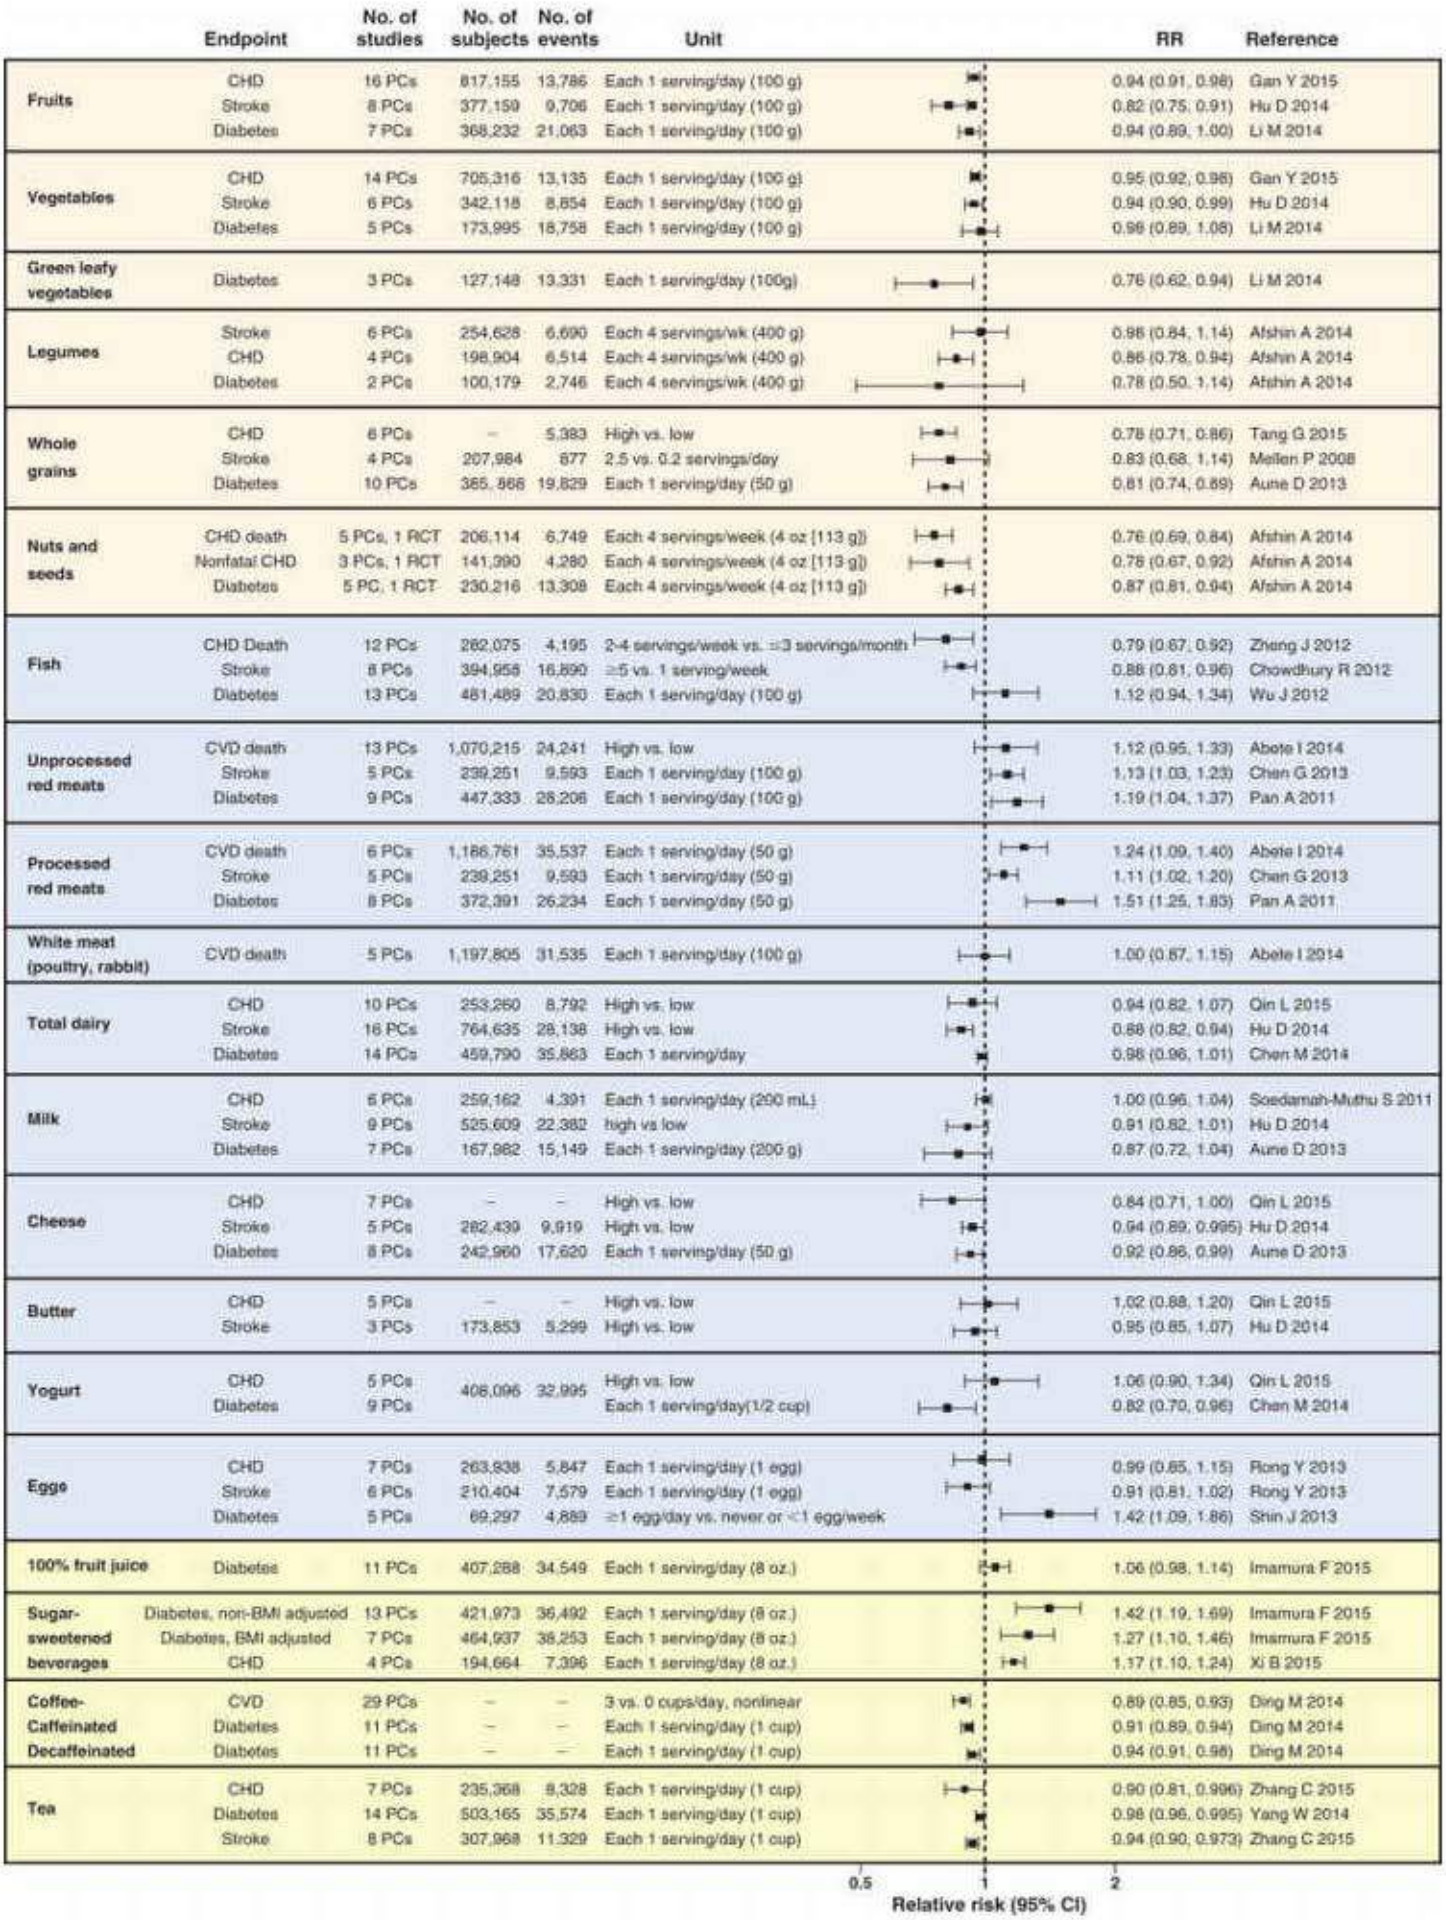

FIGURE 49.2 Meta-analyses of foods and incidence of coronary heart disease, stroke, and diabetes. BMI, Body mass index; CHD, coronary heart disease; CI, confidence interval; CVD, cardiovascular disease; PCs, prospective cohorts; RCT, randomized clinical trial; RR, relative risk. (From Mozaffarian D. Dietary and policy priorities for cardiovascular disease, diabetes, and obesity: a comprehensive review. Circulation 2016;133:187-225.)

Nuts and Legumes

Nuts are rich in unsaturated fats, vegetable protein, fiber, folate, minerals, tocopherols, and phenolic compounds. Consumption of nuts lowers low-density lipoprotein cholesterol (LDL-C) and apolipoprotein (apo) B in randomized trials;[15] was associated with lower incidence of CHD and DM in prospective studies (**Fig. 49.2**);[16] and in the large, randomized PREDIMED trial, was a key component of the Mediterranean dietary intervention that reduced risk of hard CVD endpoints by 30%.[17] Although the energy density of nuts has raised theoretical concerns for weight gain, both long-term observational studies and controlled trials demonstrate that nuts and seeds do not promote, and actually may reduce, weight gain and visceral adiposity.[18-20]

Cardiovascular effects of legumes (beans) are less well established. Like nuts, legumes contain bioactive compounds, including phenolics, minerals, and fiber, although also more starch, compared with unsaturated fat-rich nuts. In a limited number of cohorts, legume intake was inversely associated with CHD, but not diabetes or stroke[16] (**Fig. 49.2**). Meta-analyses of small trials of soy foods suggest modest improvements in blood cholesterol levels, especially in diabetic patients, and small to no effects on other risk factors, such as glycemic control, BP, inflammation, and body weight, although with occasional positive findings in post hoc patient subgroups.[21-25] Based on available evidence, increased intake of nuts is a clear priority for cardiovascular health; legumes require further research.

Whole Grains, Refined Grains, Starches, and Sweets

Similar to dietary fat, the total carbohydrate content of the diet is less relevant than overall carbohydrate *quality* and specific food choices (**Fig. 49.2**). Because both simple sugars and refined carbohydrates can be rapidly digested after ingestion, the conventional separation into simple (e.g., sugars) versus complex (e.g. starches in grains and potatoes) carbohydrates has little relevance. Rather, carbohydrate quality is better characterized by dietary fiber content, glycemic load (GL), and whole-grain content,[3] each of which is related to cardiometabolic risk (**Fig. 49.3**; see later, Carbohydrates).

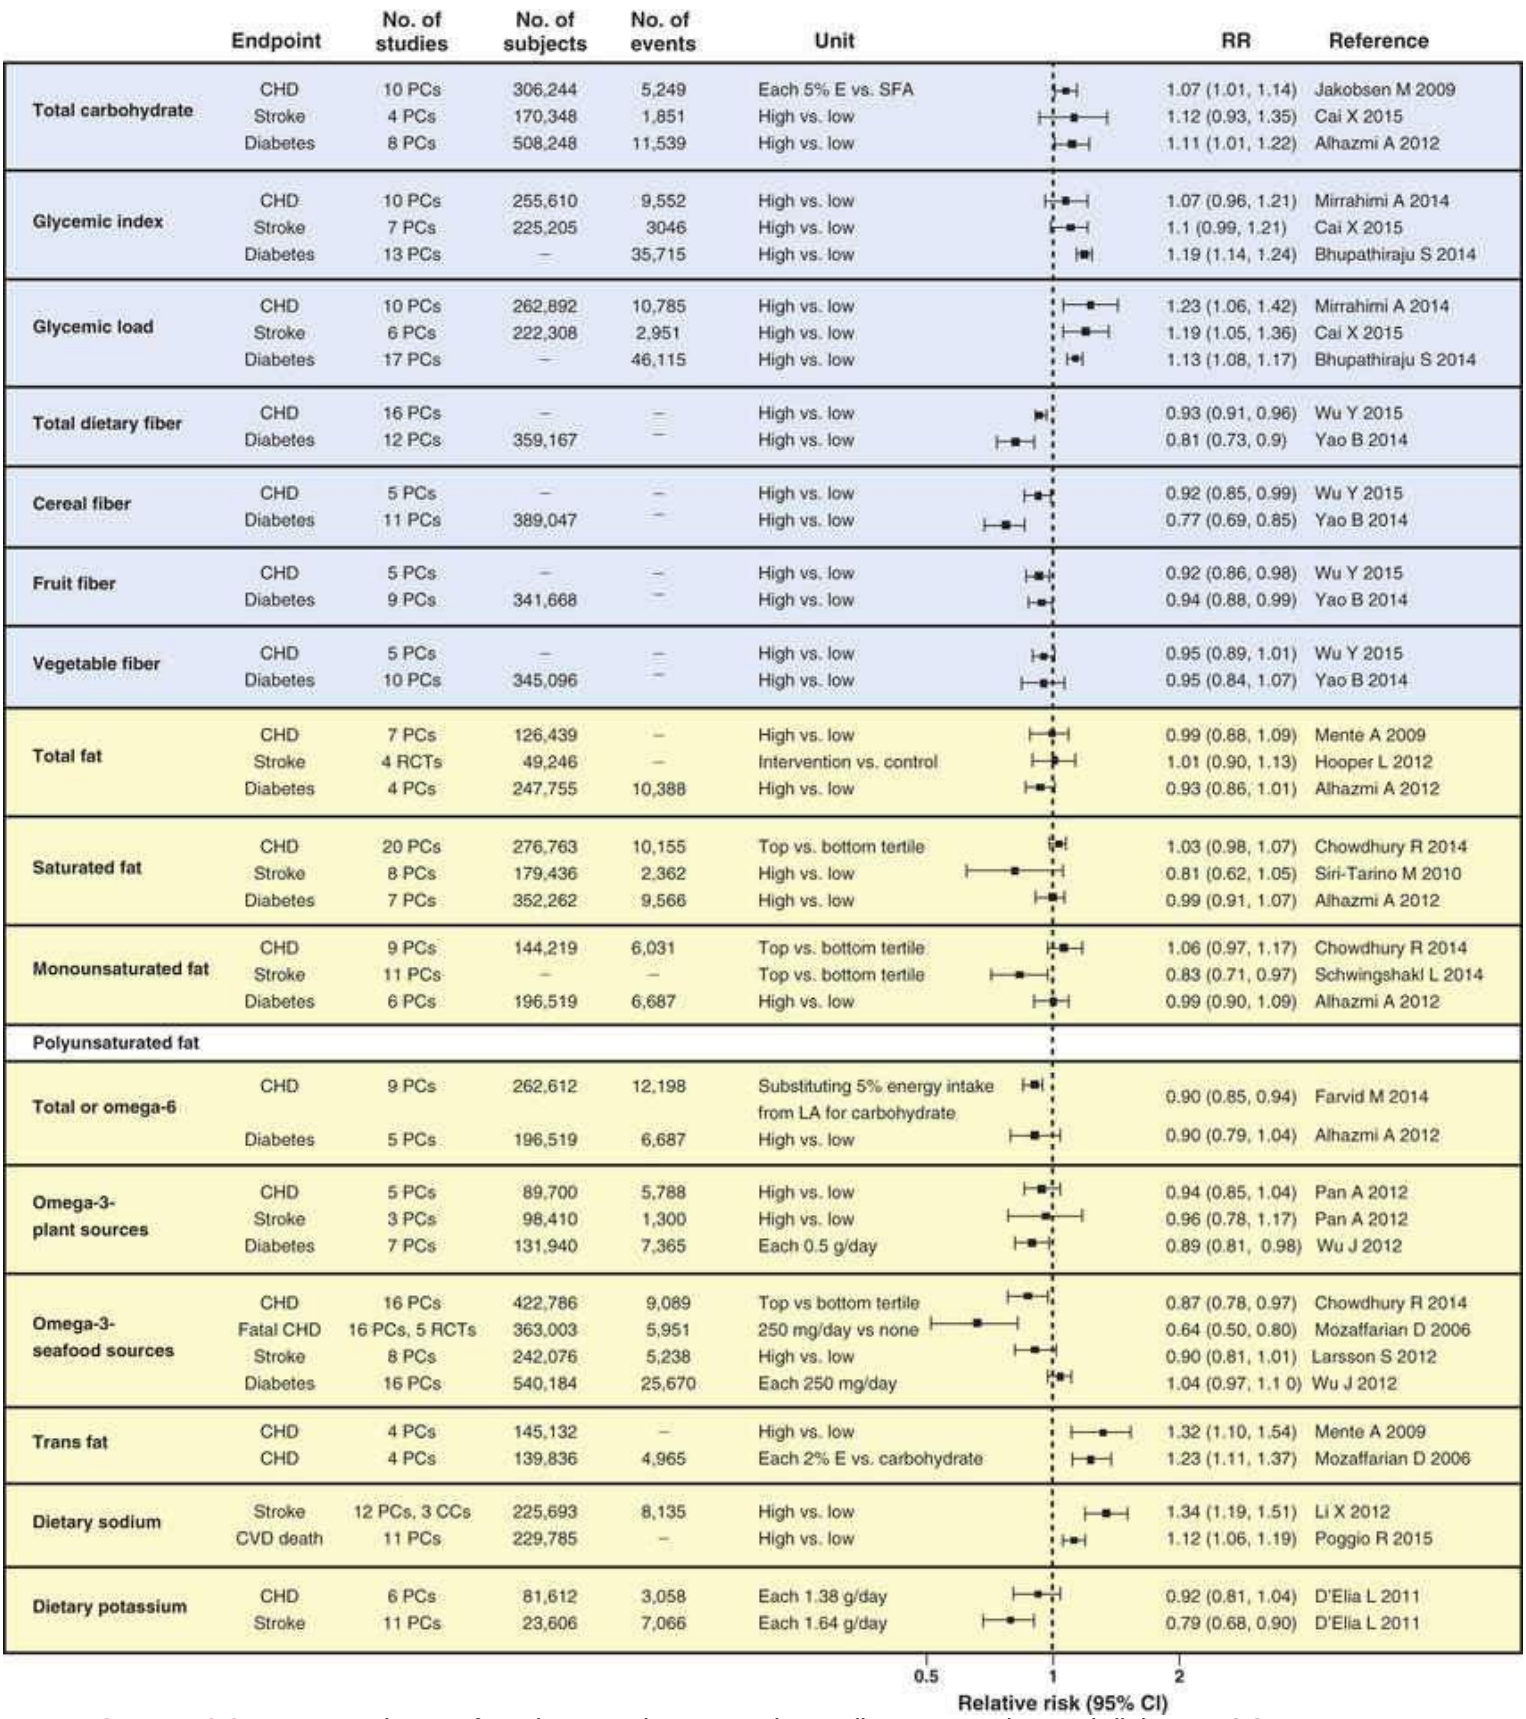

FIGURE 49.3 Meta-analyses of nutrients and coronary heart disease, stroke, and diabetes. CCs, case-control studies; CHD, coronary heart disease; CI, confidence interval; E, energy; LA, linoleic acid; PCs, prospective cohorts; RCTs, randomized clinical trials; RR, relative risk; SFA, saturated fatty acid. (From Mozaffarian D. Dietary and policy priorities for cardiovascular disease, diabetes, and obesity: a comprehensive review. Circulation 2016;133:187-225.)

Whole grains are seeds made up of bran (exterior skin), endosperm (starchy interior), and germ (plant embryo). The bran provides fiber, B vitamins, minerals, flavonoids, and tocopherols, while the germ provides fatty acids, antioxidants, and phytochemicals. Refined grains (e.g., white flour, white rice) have

been stripped of their bran and germ, leaving the starchy endosperm (chains of glucose). Whole-grain intake is associated with lower risk of CHD and DM[26,27] (**Fig. 49.2**), as well as less weight gain.[18] In trials, whole grains improve glucose-insulin homeostasis, LDL-C, and possibly endothelial vasodilator function and inflammation.[28] As with fruits and vegetables, no single nutrient appears to accounts for these benefits, which may arise from multiple synergistic effects.

Many commercially available whole-grain products (e.g., breads, cereals, crackers) contain the bran and germ, but have been finely milled during their preparation. Thus, while beneficial fiber and nutrients are retained, the loss of intact food structure exposes the endosperm to rapid digestion by salivary and pancreatic enzymes, increasing the glycemic index (GI) compared with less finely milled whole grains (e.g., steel-cut oats, stone-ground bread). The relevance of this distinction to health has not been adequately studied, but it seems reasonable to select less finely milled whole-grain products, when available. Carbohydrates in liquid form, such as sugar sweetened beverages, seem especially harmful (see later), perhaps related to high doses and lower satiation compared with solid foods.

Refined grains (e.g., white bread, rice, most breakfast cereals), starches (e.g., white potatoes), and sweets are associated with greater weight gain[29] and drive dietary GL, a risk factor for CHD, stroke, and DM (see later, Carbohydrates). These effects may result from both direct metabolic harms (e.g., on postprandial glucose-insulin, endothelial, and inflammatory responses) and displacement of healthier choices (e.g., whole grains, fruits, vegetables). Effects may be greatest in people who are sensitive to insulin resistance and atherogenic dyslipidemia, such as women and persons with DM, lower physical activity, and greater adiposity. Based on their prevalence in most diets, reducing refined grains, starches, and sugars, with replacement by whole grains, fruits, vegetables, nuts, and other healthier foods, is a major dietary priority.

Dietary fiber content, whole-grain content, GI/GL, and extent of processing can be separately altered in carbohydrate-rich products, creating a complex hierarchy of choices (**Fig. 49.4**). As a simple rule of thumb, choosing grain-rich foods with at least 1 g of fiber for every 10 g of carbohydrate (carb/fiber ratio <10 : 1) appears to identify the most healthful grain choices, compared with other recommended approaches.[30]

Type	Processing and Structure	Examples
Intact whole grains	Whole grain with the bran, germ, and endosperm from the natural cereal intact	Brown rice, bulgur wheat, amaranth, wheat berries
Minimally processed whole grains	Some processing is performed to improve palatability or digestibility, yet the bran and germ remain partially intact	Stone-ground whole wheat bread, cracked wheat, steel-cut oats
Milled whole grains	The whole grain, including bran, germ, and endosperm, is milled to fine flour	Most commercially available whole grain breads, whole grain breakfast cereals, whole grain pasta
Refined grains*	The bran and germ are removed during processing, leaving the endosperm comprised largely of refined starch	White bread, white rice, most ready-to-eat breakfast cereals, instant oatmeal, regular pasta
Starchy vegetables*	Plants that have been bred or engineered to contain high levels of starch with relatively low dietary fiber and micronutrients	Potatoes, corn†
Refined sugars*	Natural and industrially produced monosaccharides, disaccharides, and oligosaccharides, including sucrose, glucose, fructose, high-fructose corn syrup, maltose, dextrose, and maltodextrin	Candies, other sugars added to foods
Sweetened refined grains*	Refined grains with added refined sugars	Sweetened breakfast cereals, grain-based desserts (cakes, cookies, pies, doughnuts, sweet rolls, muffins)
Refined sugars in liquid form	Natural and industrially produced monosaccharides and disaccharides in liquid form	Sugar-sweetened beverages, including sodas, iced teas, sports drinks, and fruit drinks

FIGURE 49.4 A hierarchy of carbohydrate quality. Partly overlapping characteristics that influence cardiometabolic effects of carbohydrate-rich foods include dietary fiber content, whole grain (bran, germ) content, glycemic response to ingestion, and food structure (e.g., solid, liquid). Such effects may be especially relevant postprandially and among individuals predisposed to insulin resistance. Based on these characteristics, carbohydrate-rich foods can be classified from healthiest (*dark green*) to most harmful (*dark red*). For instance, minimally processed whole grains may have greater benefits than milled whole grains due to intact food structure and lower glycemic index; while refined sugars in liquid form may have greater adverse effects than other refined carbohydrates due to additional unfavorable effects on satiety and weight gain. *Simple and complex refined carbohydrates induce similarly high glycemic responses following ingestion and, in amounts typically consumed in Western diets, induce hepatic de novo lipogenesis, i.e., conversion of carbohydrates to fat. †Corn provides reasonable fiber and modestly lowers glycemic responses than many types of potatoes. Yams and sweet potatoes are not included here due to higher nutrient contents and lower glycemic responses.

Fish

Fish consumption is associated with less fatal CHD (**Fig. 49.2**), but not total CHD or nonfatal myocardial infarction (MI), suggesting potential specificity to pathways of fatal ventricular arrhythmia.[31,32] Because fish are a rich source of omega-3 fats (see later, Macronutrients), several clinical trials of fish oil supplements have been performed. Although pooled meta-analyses are consistent with lower risk of fatal CHD and not total CHD,[33] individual trial results have been conflicting, with largely null findings in multiple recent studies. Reasons for these discrepancies remain unclear; one possibility is a nonlinear benefit, with modest fish intake (2 servings/wk) providing significant benefit compared with no consumption, but higher consumption (as achieved with supplements) not producing appreciable further effects.[31]

In observational studies, fish consumption is associated with less ischemic stroke, but fish oil

supplements have not influenced stroke in post hoc analyses of CHD trials.[33,34] Some observational studies have evaluated other CVD outcomes, such as atrial fibrillation and heart failure, but with mixed findings.[31] Meta-analyses suggest no significant associations with incident DM, although inverse associations are seen in Asian populations.[35,36]

Types of fish consumed and preparation methods may influence CVD effects. Greatest benefits may accrue from nonfried oily (dark-meat) fish, which contain up to 10-fold more omega-3 fats than other types.[31] Fish also contain other unsaturated fats, selenium, and vitamin D, which could provide benefit. Methylmercury in fish has no detectable influence on CVD events or incident hypertension.[37,38] Presence of persistent organic pollutants (e.g., dioxins, polychlorinated biphenyls) may partly reduce but do not appear to fully offset cardiometabolic benefits of fish intake.[39,40]

Red Meats

Although prevalent guidelines recommend lean meats to lower dietary cholesterol and saturated fat, effects of meat intake on cardiometabolic risk appear more complex, with other factors (e.g., preservatives, heme iron) being potentially more relevant.[41] The available evidence suggests that processed meats (preserved with sodium or other additives; e.g., delicatessen meats, sausage, hot dogs) increase risk of CHD, stroke, and DM, whereas unprocessed red meats have generally smaller effects[42-44] (**Fig. 49.2**). Because unprocessed and processed meats contain similar amounts of average total fat, saturated fat, and cholesterol,[45] the stronger associations for processed meats suggest the importance of other ingredients. For example, *sodium content* is approximately 400% higher in processed meats, a difference that can explain about two thirds of the observed higher CHD risk.[41] Similarly, *heme iron,* rather than fat content, may explain associations of both unprocessed and processed meats with incident DM.[41]

These findings, together with evidence for relatively neutral effects of total saturated fat on CHD and diabetes (see Macronutrients), suggest that lean meats are not necessarily healthier choices than higher-fat options; and that extent of processing may be most relevant. In this light, low-fat, processed deli meats are not better, and may be worse choices, than unprocessed red meats. Based on available evidence, unprocessed meats can be occasionally consumed (e.g., 1 or 2 servings/wk), whereas processed meats should be avoided.

Poultry and Eggs

In long-term observational studies, poultry intake appears generally neutral for CVD risk[44] and has mixed associations with incident diabetes and hypertension.[46,47] When combined with its relatively low levels of bioactive nutrients, these findings suggest that poultry consumption has minimal cardiometabolic effects. Findings appear similar for eggs and CVD, at least in general populations[48,49] (**Fig. 49.2**). Eggs may influence and interact with diabetes. In some studies,[49] frequent consumers (7+ eggs/wk) have a higher rate of new-onset diabetes; however, these findings may not be generalized outside the United States,[50] suggesting potential bias from other dietary or other lifestyle factors associated with frequent egg intake in some countries. Among patients with prevalent diabetes, frequent consumers experience more clinical CVD events.[49] Yet, higher egg consumption is also associated with lower risk of hemorrhagic stroke,[48] perhaps related to protective effects of dietary cholesterol on vascular fragility.[51,52] Relevance of these conflicting findings remains uncertain. Overall evidence suggests little cardiometabolic effect of occasional egg intake (e.g., up to 2 or 3/wk); consistent with recent similar conclusions on dietary

cholesterol[53] (see later, Dietary Cholesterol). Based on current knowledge, it appears prudent to consider poultry and eggs as healthful alternatives to certain foods (e.g., processed meats, starch, sugars) but less beneficial than others (e.g., fruits, nuts, beans, fish).

Dairy Foods

Conventional guidelines for dairy foods are based on predicted effects of isolated nutrients (e.g., eat 3 servings/day to provide calcium and vitamin D), while choosing reduced-fat options to minimize fat, saturated fat, and calories. Growing evidence suggests that effects are much more complex, depending on other factors, such as fermentation, branch-chain and medium-chain fatty acids, probiotics, and milk fat globule membrane content, which may alter lipoprotein and genetic effects.[54,55] In long-term cohorts, total dairy intake was associated with lower risk of stroke, whereas yogurt, cheese, and possibly butter, but not milk, was associated with lower risk of diabetes[56-61] (**Fig. 49.2**). In contrast, fat content (regular versus reduced-fat) is not consistently associated with cardiometabolic risk. Indeed, emerging evidence suggests that dairy fat may have metabolic benefits: in seven cohorts, individuals with higher blood biomarkers of dairy fat intake experienced about a 50% lower incidence of diabetes.[62]

Dairy intake may also benefit adiposity. In randomized trials, milk or dairy consumption reduced body fat and increased lean mass in the setting of energy-restricted diets, with little effect in ad libitum diets.[63,64] In long-term observational studies, yogurt is associated with relative weight loss,[29] potentially related to probiotic-microbiome interactions.[65] In summary, current evidence supports recommendations for modest dairy intake (2 or 3 servings/day), especially of yogurt and cheese, with insufficient data to define the most relevant active ingredients or health differences between whole-fat and reduced-fat dairy foods.

Beverages

Sugar-Sweetened Beverages

Ecologic data, prospective cohorts, and trials together provide convincing evidence that sugar-sweetened beverage (SSB) intake increases adiposity. In the United States, calories from beverages nearly doubled, from 11.8% to 21.0% of all calories consumed, between 1965 and 2002, an increase of 222 kcal per person per day, largely from SSBs (sodas, energy drinks, sweetened ice teas, fruit drinks)[66] (**Fig. 46.2**). The average American teenager consumes 18 (boys) and 14 (girls) 8-oz servings of SSBs weekly,[67] mostly at home.[68] Per serving, SSBs are more strongly associated with long-term weight gain than almost any other dietary factor.[29] Randomized trials confirm that reducing SSBs decreases weight gain and fat accumulation.[69,70] Calories in liquid form, compared with solid foods, appear to be less satiating and increase total calories consumed.[71] SSB intake is also associated with significantly higher incidence of DM and metabolic syndrome,[72] likely related to both weight gain and independent harms of the high-sugar and glycemic load. Given clear evidence for harms and multiple alternatives (e.g., water, seltzer, unsweetened tea, diet soda, milk), SSBs should be largely eliminated from the diet.

Alternative sweeteners can be artificial (e.g., saccharin, sucralose, aspartame) or naturally low calorie (e.g., stevia).[73] Based on observational studies and clinical trials,[18,74] beverages with alternative sweeteners are better options than SSBs. Yet, alternative sweeteners may not be completely benign: animal experiments and limited human data suggest influences on brain reward, taste perception, oral-gastrointestinal taste receptors, glucose-insulin and energy homeostasis, metabolic hormones, and the gut

microbiome.[75-78] For example, if a child's taste becomes accustomed to intense sweetness, will that reduce attractiveness of naturally sweet foods such as apples or carrots? In sum, alternative sweeteners can be a useful bridge to eliminate SSBs, but should not be considered innocuous; and subsequent shifts to nonsweetened drinks (e.g., seltzer, tea) should be encouraged.

Milk

See earlier, Dairy Foods.

Coffee and Tea

Although coffee and tea elicit thoughts of caffeine, these plant extracts derived from beans and leaves contain other bioactive compounds. Unrelated to caffeine content, frequent coffee intake (e.g., 3 to 4 cups/day) is associated with less insulin resistance, DM, CVD, and in a few studies, heart failure[79,80] (**Fig. 49.2**). However, physiologic benefits have not been documented in trials to support these observations. Acutely, caffeinated coffee worsens BP, insulin resistance, and glucose intolerance[81,82] longer term, but habitual coffee intake does not affect BP or insulin resistance, suggesting tachyphylaxis or other partly offsetting factors.[83-85] In a mendelian randomization analysis, genetic variants linked to coffee intake were not associated with any cardiovascular or metabolic risk factors.[86]

As with coffee, frequent tea drinking (e.g., 3+ cups/day) is associated with lower CVD and DM, although with borderline statistical significance[87,88] (**Fig. 49.2**). In trials, certain types of tea modestly lower BP (green, black, herbal roselle)[89-91] and LDL-C (green, black),[92-94] but clear effects on glucose-insulin homeostasis have not been identified.[95,96] Overall, observational evidence supports possible cardiometabolic benefits of frequent coffee or tea drinking, but strong conclusions require better demonstration of these associations as well as biologic plausibility in long-term physiologic trials.

Alcohol

Habitual heavy alcohol intake can cause severe, often irreversible nonischemic dilated cardiomyopathy.[97] Alcohol use is also associated with higher risk of atrial fibrillation in a dose-response manner[98] and with greater long-term weight gain.[29] Compared to nondrinkers, moderate drinkers (≤2 drinks/day in men, 1 to 1.5 drinks/day in women) experience lower incidence of CVD and DM; higher intakes are often linked to harm.[97,99,100] Although analyses of some cohorts suggest red wine may be superior, others show similar associations for white wine, beer, or spirits. Drinking patterns appear more relevant than type: lower risk is observed for regular moderate drinking, not irregular or binge drinking.[101]

In short- and medium-term trials, alcohol use does not significant alter glycemic measures in patients with DM.[102] but favorably affects high-density lipoprotein cholesterol (HDL-C) and inflammation.[103] The consistency of observed lower CVD risk with moderate drinking across many populations, together with these latter physiologic benefits, support a potential casual effect. However, mendelian randomization studies have not confirmed the lower risk seen in observational cohorts,[97,104] raising concern for bias caused by unmeasured poor health in subsets of people who elect not to drink, even lifelong nondrinkers.[105] In addition, across the population, alcohol-related cancers, liver disease, cardiomyopathy, accidents, homicides, and suicides cause greater harms than potential CVD benefits.[1,106] Thus, alcohol use should not be advised as a means to reduce CVD risk; for adults who already drink, counseling should emphasize no more than moderate use. (**See also Chapter 80**.)

Macronutrients

Carbohydrates

For decades, carbohydrates were considered the foundation of a healthful diet, e.g., grain products formed much of the base of the 1992 Food Guide Pyramid. It is now evident that the types, rather than total amount, of carbohydrate-rich foods is most relevant for cardiometabolic health.[3] Certain carbohydrate-containing foods are protective (e.g., fruits, beans, vegetables, minimally processed whole grains), while others are harmful (e.g., white bread, white rice, crackers, cereals, bakery desserts, sweets) (see earlier, Whole Grains, Refined Grains, Starches, and Sweets). Because most carbohydrates in modern diets derives from the latter group, a "low-carb" diet will often produce metabolic benefit. Yet, healthful carbohydrate-containing foods should not be avoided. For most patients, the focus should be to reduce refined grains, starch, and added sugars (glycemic load) and increase dietary fiber, not reduce "carbohydrate" consumption per se[107-113] (**Fig. 49.3**).

Refined grains and starches (essentially long chains of glucose) are rapidly digested, producing similar glycemic responses as table sugar. While marketing claims are often made about different forms of sugar, all types (cane or beet sugar, honey, high-fructose corn syrup) are molecularly similar: about half glucose and half fructose. Thus, few health differences are expected or observed between them.[114-116] In contrast, glucose and fructose, each present in both natural sugars and high-fructose corn syrup, have some differing physiologic effects. When consumed at high, rapidly digested doses, both cause metabolic harms. Glucose induces postprandial hyperglycemia, hyperinsulinemia, and related disturbances, as well as hepatic de novo lipogenesis; whereas fructose has minimal influence on blood glucose or insulin, but more directly stimulates hepatic de novo lipogenesis, hepatic and visceral adiposity, and uric acid production.[115-117] In comparison, such harms are avoided by modest, slowly digested doses of either glucose or fructose (e.g., as found in fruit or beans). Thus the dose, rapidity of digestion, and accompanying nutrients in the sugar-containing foods modify the health effects of sugars.

Fats

Total Fat

Whereas early ecologic (cross-national) studies suggested that fat intake increased cardiometabolic risk, robust evidence from prospective cohorts and randomized trials shows that the percent of total fat in foods or diets has negligible effects on CVD, DM (**see Fig. 49.3**), or weight loss, weight gain, or overweight/obesity[108,118-120] (see later, Energy Balance). In contrast, the types of fats and fatty acids consumed are quite relevant. Conventionally, dietary fats are categorized based on chemistry—the number and position of double bonds—rather than their physiologic effects. This classification obscures differences in dietary sources and biologic effects of individual fatty acids, which influence gene transcription, cell membrane fluidity, receptor function, and lipid metabolites. This chapter follows the conventional categories, but discusses effects of individual fatty acids where sufficient data exist.

Saturated Fatty Acids

Major sources include meats, dairy products, and tropical oils (e.g., palm, coconut). Based on ecologic comparisons, effects on LDL-C, and animal experiments, saturated fatty acid (SFA) intake would be expected to increase CHD risk. However, actual health effects appear more complex. Compared with total carbohydrate, SFA increases LDL-C but has small effects on apo B (i.e., increased LDL-C

concentrations partly reflect larger particles), while also lowering triglyceride-rich particles and lipoprotein(a) and raising HDL-C and apo A1.[121,122] In comparison to total carbohydrate, SFA does not significantly effect fasting glucose, hemoglobin (Hb) A_{1c}, or insulin resistance.[123] Together, these physiologic effects suggest relatively neutral net effects on clinical CVD risk, compared with carbohydrate or the average background diet. Prospective cohort studies confirm this prediction[108,124,125] (**Fig. 49.3**). Similarly, in a large randomized trial targeting total fat reduction, SFA intake was reduced by approximately 27%, largely replaced with carbohydrates, without effects on incident CHD (relative risk [RR] = 0.98), stroke (RR = 1.02), or diabetes (RR = 0.96).[119,120]

The relatively neutral effect of total SFA results at least part from the divergent cardiometabolic effects of its different major food sources (see Foods, above). Individual SFA may also have heterogeneous effects, e.g., comparing medium-chain SFA; lauric (12:0), myristic (14:0), palmitic (16:0), and stearic (18:0) acid; and very long-chain SFA. These fatty acids have known different effects on blood lipids; yet beyond such individual surrogate outcomes, long-term health effects of different SFA remain unclear.121 Replacement of SFA with polyunsaturated fatty acids (PUFA) reduces CHD risk (see PUFA, below), but this appears largely attributable to benefits of PUFA, rather than harms of SFA.

Monounsaturated Fatty Acids

Monounsaturated fatty acids (MUFAs) favorably affect BP and cholesterol levels,[121,126] but are not consistently associated with incident CHD, stroke, or DM[108,125,127] (**Fig. 49.3**). In nonhuman primates, oleic acid (18:1 n-9), by far the most common MUFA, reduces LDL-C levels yet increases atherosclerosis, possibly by enriching LDL-C particles with potentially proatherogenic cholesteryl oleate.[128] In contrast, in controlled feeding trials, replacing carbohydrate with MUFA lowers HbA_{1c}, postchallenge insulin, and insulin resistance, indicating metabolic benefits.

Because both animal fats and vegetable oils (e.g., olive, canola) provide MUFAs, the food source may modify overall health effects. For example, olive oil, but not mixed animal and plant sources of MUFA, is associated with lower CHD;[127] whereas vegetable oil sources of MUFA reduce LDL proteoglycan binding, suggesting antiatherogenic effects.[129] Thus, focusing on specific foods and oils, rather than MUFA content per se, may be most prudent. Extra-virgin olive oil and mixed nuts, and perhaps high-oleic canola oil, are good dietary choices to improve cardiometabolic health.[16,17,130-133]

Polyunsaturated Fatty Acids

Polyunsaturated fatty acids (PUFAs) are classified as n-6 or n-3, based on the carbon location of the first double bond. The predominant PUFA is n-6 linoleic acid (LA, 18 : 2 n-6), derived principally from vegetable oils. Flaxseed, canola, walnuts, and soybeans provide alpha-linoleic acid (ALA, 18 : 3 n-3); and seafood, eicosapentaenoic acid (EPA, 20 : 5 n-3) and docosahexaenoic acid (DHA, 22 : 6 n-3).

n-6 PUFAs

Although speculative harms of n-6 PUFAs have been popularized, metabolic interventions, cohort studies, and clinical trials demonstrate clear benefits. LA lowers LDL-C and triglyceride-rich lipoproteins and raises HDL-C.[134] LA also lowers HbA_{1c}, lowers fasting insulin, and improves insulin secretion capacity.[123] Proinflammatory effects have been theorized,[135] but such effects are not seen in practice.[136] Indeed, LA appears to reduce hepatic steatosis and systemic inflammation.[137,138] Arachidonic acid (AA), the prototypic metabolite of LA, is also generally considered proinflammatory, but also gives rise to *specialized proresolving mediators* (SPMs) of inflammation,[139] and in prospective studies, is associated

with lower CHD.[125] LA also is associated with lower CHD (**see Fig. 49.3**), whether replacing carbohydrate or saturated fat.[140] In meta-analysis of clinical trials, intake of n-6–rich vegetable oils, in place of animal fats, reduces CHD events.[134]

n-3 PUFAs

CVD effects of ALA, the plant-derived n-3 PUFA, remain inconclusive[141-143] (**Fig. 49.3**). In a Dutch trial, an ALA-rich margarine did not significantly reduce CVD events (RR, 0.91; 95% CI 0.78 to 1.05).[144] Seafood-derived EPA and DHA produce multiple physiologic benefits, including on heart rate, BP, triglyceride-rich lipoproteins (TRLs), endothelial function, adiponectin, cardiac function, and inflammatory responses.[31,145] In observational studies of different clinical endpoints, dietary EPA plus DHA was most consistently associated with fatal CHD,[125,143,146,147] consistent with dog and primate experiments showing benefits for ischemia-induced ventricular fibrillation.[31]

Multiple clinical trials have evaluated n-3 PUFA supplements in the form of fish oil, with mixed findings.[31] Meta-analyses suggest reductions in cardiac death, but not total CVD, CHD, or stroke.[33] Such pooled results obscure temporal differences; four of five older trials, but no newer trials, demonstrate benefits.[148] These discrepant findings could be related to more aggressive lipid- and BP-lowering drug treatment or higher background intake of fish, in recent trials, which may diminish the ability to detect additional benefits of fish oil.[148] Other clinical trials of fish oil supplements, including in patients with hypertriglyceridemia, are ongoing.

Effects of fish consumption on other vascular conditions, such as stroke, heart failure, atrial fibrillation, and cognitive decline, remain unclear, with conflicting findings.[31,34,147,149] Fish and omega-3 intake have little association with diabetes, although protective associations are seen in Asian populations,[143,150] and fish oil supplementation modestly raises adiponectin.[145] Types of fish consumed and preparation methods may be relevant, with potential larger benefits from nonfried, dark (oily) fish that contain up to 10-fold higher n-3 levels than white fish.[31]

Overall, strong evidence supports cardiovascular benefits of LA-rich foods, including vegetable oils (e.g., soybean, canola) and nuts. Although recent trials of fish oil are conflicting, the clear physiologic effects, consistent protective associations in cohorts, and an excellent safety profile support recommendations to eat fish once or twice weekly, with fish oil a safe adjunct that may provide further benefits.

Trans Fatty Acids

Trans fatty acids (TFAs) are unsaturated fats that cannot be synthesized by mammals, with one or more double bonds in a *trans*, rather than *cis*, position. The small amounts naturally present in ruminant meats and milk (e.g., from cows, sheep, goats; formed by gut microorganisms) contribute minimally to diet (<0.5% energy [E]) and are not associated with CVD risk.[151] Indeed, higher blood levels of *trans*-16 : 1 n-7, a natural TFA present in dairy fat, is strongly associated with lower risk of diabetes.[62]

Conversely, industrial TFAs, formed by partial hydrogenation of vegetable oils, can be consumed at high levels and are consistently associated with higher CHD (**see Fig. 49.3**), as well as sudden death.[118,152] Industrial TFAs have advantages for commercial deep frying, baking, and shelf stability for packaged snacks and shortening. However, TFA also have uniquely adverse effects on blood lipid and lipoproteins, raising LDL-C, apo B, triglycerides, and lipoprotein(a) and lowering HDL-C and apo A1.[153] TFAs also have nonlipid adverse effects, promoting inflammation, endothelial dysfunction, insulin resistance, visceral adiposity, and arrhythmia, although strength of evidence for these nonlipid effects

varies.[154] In summary, the implicated pathways suggest effects on adipocyte dysfunction and insulin resistance. Emerging evidence suggests that 18 : 2 TFA isomers may be most adverse, which can be formed not only by partial hydrogenation but also by other industrial processes, such as oil deodorization and high-temperature cooking.[155,156] Because partially hydrogenated oils are food additives with clear adverse effects, their elimination is a public health priority.

Dietary Cholesterol

Dietary cholesterol raises both LDL-C and HDL-C, resulting in small net change in the total cholesterol/HDL-C ratio. In certain animals, dietary cholesterol is proatherogenic. In long-term prospective studies, however, neither dietary cholesterol nor its major sources (e.g., eggs, shellfish) were associated with incident CHD or total stroke, and may be protective against hemorrhagic stroke.[48,118,157] Among patients with prevalent DM, however, dietary cholesterol was associated with higher CHD risk;[48] associations with incident DM appear mixed.[49,50] In summary, dietary cholesterol appears to have minor CVD effects in the general population, but may increase CVD among diabetic patients; reasons for this potential difference require further investigation.

Protein

Cardiometabolic effects of dietary protein are not well established. In randomized trials, protein intake has little effect on adiposity, lipids, BP, inflammation, or glucose.[158] Few longitudinal studies have evaluated total protein and CHD events, with generally null results.[159,160] These observations agree with findings for total fat and total carbohydrate: total protein intake derives from diverse foods (e.g., red meats, processed meats, milk, cheese, yogurt, fish, nuts, legumes) with widely varying health effects. Overall, a focus on dietary protein per se appears less relevant for CVD than considering specific types of foods consumed.

Micronutrients

Sodium

In Western countries, most sodium (approximately 75%) comes from packaged foods and restaurants, and little from home cooking or table salt, whereas in Asian countries, most sodium comes from soy sauce and salt added during cooking or at the table.[161] Almost every country in the world exceeds the recommended mean sodium intake of 2000 mg/day.[162] (**See also Chapters 46 and 47**.)

Sodium raises BP in a dose-dependent manner, with stronger effects among older individuals, hypertensive persons, and blacks.[163] In meta-analyses, high sodium intakes was associated with incident total stroke, stroke mortality, and CHD mortality[164-166] (**see Fig. 49.3**). The strength of BP as a surrogate endpoint, as well as ecologic and experimental studies of sodium and CVD, supports such harms.[163,167] Indeed, animal studies suggest that habitually high sodium induces additional, BP-independent damage to renal, myocardial, and vascular tissues.[168]

Most observational studies demonstrate a positive association between very high sodium intakes (e.g., 4000+ mg/day) and CVD, in particular stroke.[164-166] Some studies have also observed a potential J-shaped relationship, with higher CVD risk at low intakes (e.g., <3000 g/day).[169-171] These findings have generated recent controversy about optimal lowest levels of sodium intake.[172]

It remains unclear what physiologic effects could offset, let alone reverse, BP-lowering benefits of

sodium reduction to explain a true J-shaped effect on CVD. For example, although large, rapid sodium reductions can increase renin-aldosterone and serum triglyceride levels,[173] more moderate, gradual reductions may have small effects. For example, a meta-analysis of 74 sodium reduction trials found that renin elevations significantly decline over time.[174]

Furthermore, assessment of sodium in observational studies, whether by urine spot, 24-hour urine, or dietary questionnaire, has unique potential biases that could produce a spurious J shape.[175] These include potentially incomplete 24-hour collections (leading to underestimation of sodium intake in less compliant, sicker individuals), reverse causation (at-risk individuals, as with higher BP or diabetes, actively lowering sodium intakes), confounding by physical activity (which increases total energy intake, which is highly correlated with total sodium intake[176]), and confounding by frailty (which reduces total energy intake, again correlated with total sodium). These limitations together could explain the J shapes seen in certain observational studies.

In comparison, during extended surveillance in a large sodium study that excluded sick individuals at baseline and used serial 24-hour urine collections, participants with lowest intakes (<2300 mg/day) experienced a 32% lower CVD risk than those consuming high intake, with evidence for linearly decreasing risk.[177,178] In ecologic studies, the lowest mean intake level associated with both lower systolic BP and lower age-BP slope is 614 mg/day.[179] In randomized trials, BP reductions have been documented down to intakes of 1500 mg/day.[180] In meta-analyses of prospective observational studies, the mean intakes associated with lower risk of CVD events range from 1787 to 2391 mg/day.[163,165] Taken together, these findings support target intakes in current official guidelines, which range from 1200 to 2400 mg/day.[163]

Potassium, Calcium, and Magnesium

Vegetables, fruits, whole grains, beans, nuts, and dairy are major sources of minerals. In trials, potassium lowers BP, with stronger effects among hypertensive individuals and when dietary sodium intake is high.[181] Consistent with this, potassium-rich diets are associated with lower risk of stroke[182] (**see Fig. 49.3**). Potassium also attenuates, whereas insufficient dietary potassium exacerbates, the BP-raising effects of sodium.[180,182] Overall, the evidence strongly supports the importance of potassium-rich foods for reducing BP and CVD.

In short-term trials, calcium and magnesium supplements also modestly lower BP, although with substantial heterogeneity between studies. However, calcium supplements with or without vitamin D may increase risk of MI in long-term trials.[183,184] In observational analyses, dietary and blood magnesium levels were inversely associated with CVD, especially fatal CHD;[185] long-term trials have not been performed. Calcium and magnesium supplements cannot yet be recommended for general CVD prevention.

Antioxidant Vitamins

Several dietary vitamins and nutrients are associated with lower CVD in observational studies, but fail to lower risk in trials of supplements, including folate, B vitamins, beta-carotene, vitamin C, vitamin E, and selenium.[118,186,187] Most of these trials, for reasons of power, evaluated up to a few years of treatment in high-risk patients or those with established CVD. In contrast, most observational studies evaluated long-term or habitual intake among generally healthy people. Thus, discrepancies in findings could partly relate to different time periods of biologic sensitivity (e.g., some vitamins and nutrients could be important only early in the disease course). Such explanations require confirmation in prospective

studies and trials. Discrepancies between observational studies and supplement trials may also be related to residual bias in observational studies from other lifestyle behaviors (i.e., observed benefits are not caused by diet) or from other nutritional factors in vitamin-rich foods (i.e., observed benefits are caused by diet, but not by the specific identified vitamins or nutrients). For example, diets higher in antioxidant vitamins tend to be rich in fruits, vegetables, nuts, and whole grains, foods that contain multiple other beneficial factors, including other vitamins, minerals, phytochemicals, and fiber, as well as being foods that can provide benefit by replacing unhealthful foods. Thus, isolating one or even several components of these foods may not produce similar effects as would occur from consuming the whole food.[4,188]

Vitamin D

Higher plasma vitamin D is associated with lower CVD, yet levels are largely driven by sun exposure, not diet; and large supplement trials have not found benefits.[189] If higher plasma vitamin D does prove to lower CVD risk, brief sun exposure can efficiently provide such levels. Ongoing trials are testing whether higher doses of vitamin D influence CVD; for now, such supplementation is not indicated to improve cardiometabolic health.

Phenolic Compounds

Bioactive polyphenols include flavanols (in onions, broccoli, tea, various fruits), flavones (in parsley, celery, chamomile tea), flavanones (in citrus fruits), flavanols (flavan-3-ols) such as catechins and procyanidins (in cocoa, apples, grapes, red wine, tea), anthocyanidins (in colored berries), and isoflavones (in soy). In laboratory studies and randomized trials, flavonoid-rich cocoa has small but measurable benefits on BP, endothelial function, insulin resistance, and blood lipids.[190-192] BP-lowering occurs with as little as 6.3 g/day (30 kcal/day) of dark chocolate and is related to increased endothelial nitric oxide production.[193] The latter mechanism suggests potential benefits beyond BP lowering. A few short-term trials of other dietary sources (e.g., tea, red wine, grapes) or specific flavonoid extracts have not consistently improved BP, lipid levels, or endothelial function.[190-192] Some observational studies evaluating total or selected dietary flavonoids observe lower risk of cardiometabolic events;[194,195] a first large clinical trial is ongoing. The heterogeneity of different flavonoids and their dietary sources limits inference for class effects, and clinical benefits and dose-response effects remain unclear. However, many foods with evidence for cardiometabolic benefits, including berries, nuts, and extra-virgin olive oil, are rich in phenolics, and their physiologic and molecular effects are highly promising for further study.

Energy Balance

In most countries, the current obesity epidemic is a striking change from decades of relative stability; in the United States, obesity began steeply rising only about 35 years ago.[196] Abdominal adiposity, which produces the greatest metabolic harms, has also increased more than overall weight in many nations, especially in younger women.[197] The breadth, depth, and pace of this epidemic, including in young children,[198] suggest strong environmental drivers rather than population-wide changes in genetics or willpower. (**See also Chapter 50**.)

Current concepts of obesity treatment prioritize energy balance: count calories, reduce portion sizes, eat less, and move more. As seen for cardiometabolic health, however, the complex effects of different foods and diet patterns may be more relevant for long-term weight homeostasis than reductionist

approaches focused on total calories. For short-term weight loss, total calories are most relevant, which is why almost any type of diet may initially work. For long-term weight maintenance, however, and more importantly for cardiometabolic health, healthful food-based patterns appear especially important.[53]

Humans have multiple, redundant biologic mechanisms to maintain weight homeostasis. Current concepts postulate that different foods may, over years, help or hinder these intrinsic mechanisms.[3] For example, foods rich in refined grains, starches, and sugar appear especially harmful,[18,199] driving obesogenic pathways.[200-204] Other foods, such as milk, appear relatively neutral, neither helping nor perturbing homeostatic mechanisms for long-term weight control.[199,205] Effects of meats, cheese, and eggs may vary as to whether they are eaten with refined carbohydrates (in which case they seem to worsen weight gain) or in place of refined carbohydrates (which are associated with less weight gain or even relative weight loss).[199] Also, fruits, nonstarchy vegetables, beans, nuts, yogurt, fish, and whole grains appear to protect against chronic weight gain.[9,18,199,205] Mechanisms underlying these observations are being elucidated but may involve satiety, brain craving and reward,[203] glucose-insulin responses,[200] hepatic fat synthesis,[201] adipocyte function,[206] visceral adiposity,[202] metabolic expenditure,[204] and the gut microbiome.[18,199,205,207-209] Because habitual excess energy intakes as small as 50 to 100 kcal/day may explain much of the obesity epidemic,[67] very subtle effects on these pathways may be sufficient, when sustained, to account for population shifts in weight.

Other factors appear to interact with diet to influence adiposity, including TV watching, sleep duration, circadian alignment, and possibly maternal-fetal (e.g., placental) influences.[18,196,210-213] For example, lower sleep duration and altered circadian rhythms predict weight gain and obesity, altered hunger and food preferences, and changes in leptin, ghrelin, insulin, and gut-peptide concentrations.[18,210] TV watching increases obesity and weight gain,[18,211] at least partly mediated by changes in diet, rather than physical activity, because of increased eating while watching TV and altered choices from TV marketing.[214,215] Increasing physical activity has complementary benefits on weight maintenance and metabolic health. More liquid calories, larger portion sizes, and more meals away from home are also linked to risk of adiposity. Changes in social norms and networks, industry marketing, and local food availability also appear important.[216-218]

In summary, these complex and often insidious influences can make unintended weight gain very easy. Conversely, these drivers can also serve as positive levers to attenuate or reverse chronic energy gaps, weight gain, and adiposity. Regardless of body weight, overall dietary quality strongly influences cardiometabolic health,[3,53] analogous to weight-independent health benefits of physical activity. In contrast, other conventional dietary metrics, such as calorie content, total fat, and energy density, may not reliably identify how specific foods influence long-term weight gain.[18,199,205] Based on current evidence, key diet-related priorities to reduce adiposity include fewer refined grains, starches, sugars, and red meats; more fruits, vegetables, beans, nuts, yogurt, fish, vegetable oils, and whole grains; less TV watching; sleeping at least 7 to 8 hours nightly; and further elucidating maternal-fetal, microbiome, and sleep/circadian influences.

Dietary Patterns

Dietary patterns represent overall combinations of foods consumed, which together can produce synergistic health effects. Evidence-based beneficial diet patterns share several key characteristics: more minimally processed, bioactive-rich foods, such as fruits, nuts/seeds, nonstarchy vegetables, beans, whole grains, seafood, yogurt, and vegetable oils, and fewer red meats, processed (sodium-preserved) meats,

and processed and packaged foods rich in refined grains, starches, added sugars, salt, and *trans* fat (**Table 49.1**). Two of the best studied, each consistent with this description, are the traditional Mediterranean and Dietary Approaches to Stop Hypertension (DASH) dietary patterns.[53,186]

TABLE 49.1

Food-Based Components of Dietary Patterns That Improve Cardiometabolic Health*

	GOAL†	SERVING SIZES
Consume More:		
Fruits	3 servings per day	Approximately 100 g, e.g., 1 medium-sized fruit; ½ cup of fresh, frozen, or canned fruit; ¼ cup of dried fruit; ½ cup of 100% juice. Goals should not be met with juice alone.
Vegetables and beans	3-4 servings per day	Approximately 100 g, e.g., 1 cup of raw leafy vegetable; ½ cup of cut-up raw vegetables, cooked vegetables, or 100% juice. Limit potatoes to ½ cup or less per day.
Whole grains‡	3 servings per day, in place of refined grains	Approximately 50 g, e.g., 1 slice of whole-grain bread; 1 cup of high-fiber whole-grain cereal; ½ cup cooked whole-grain rice, pasta, or cereal
Nuts	4 to 5 servings per week	Approximately 28 g (1 oz)
Fish and shellfish	2+ servings per week, preferably oily	Approximately 100 g (3.5 oz). Goals should not be met with commercially prepared deep-fried or breaded fish.
Dairy products§	2 to 3 servings per day	1 cup of milk or yogurt; 1.5 oz of cheese
Vegetable oils	2 to 6 servings per day	Approximately 1 teaspoon of oil, e.g., in cooking or salad dressing; or 1 tablespoon of vegetable spread
Consume Less:		
Foods containing partially hydrogenated vegetable oils (*trans* fat)	Avoid intake.	
Refined grains and starches		
Processed meats (e.g., bacon, sausage, hot dogs, processed deli meats)	Avoid intake or at most modest intake, e.g., up to 2 servings per week	Approximately 100 g (3.5 oz)
Sugar-sweetened beverages, sweets, and bakery foods	Avoid intake or at most modest intake, e.g., up to 5 servings per week	8 oz of soda; 1 small cookie, doughnut, or muffin; 1 slice of cake or pie
Alcohol	Up to 2 daily drinks for men, 1 daily drink for women	5 oz of wine; 12 oz of beer; 1.5 oz of spirits
Energy Balance:	Eat healthy foods as above, reduce portion sizes, eat fewer fast-food and prepared meals, increase physical activity, limit TV watching, and ensure adequate (7-8 hours) sleep.	

*Adapted from the evidence described in this chapter.

†Based on a 2000-kcal/day diet. Servings should be adjusted accordingly for higher or lower energy consumption.

‡A practical rule of thumb for selecting healthier grain or carbohydrate-rich products is to choose foods containing at least 1 g of dietary fiber for every 10 g of total carbohydrates per serving (carb:fiber ratio <10:1), based on the Nutrition Facts Panel.[30]

§Based on available evidence, the types of dairy (yogurt, cheese, milk, butter) appears more relevant than fat content (whole or reduced fat); see text for details.

Randomized trials in both primary and secondary prevention populations confirm cardiometabolic benefits of such healthful, food-based diet patterns.[17,132,219,220] In comparison, observational cohorts and randomized trials confirm little clinical effect of diets focused on isolated nutrient targets, such as low-fat, low-saturated fat diets.[119-121,125] Because sodium and *trans* fats can be added to or removed from otherwise similar foods and dietary patterns, a specific nutrient focus on these industrial additives is warranted.[53] Focusing on overall diet patterns can lead to health benefits from modest changes across multiple foods, rather than large changes in a few factors, potentially increasing effectiveness and compliance. This flexibility can also facilitate behavioral counseling, permitting a more personalized focus[53] (**Table 49.2**).

TABLE 49.2

Effects of Food and Nutrients on Specific Cardiometabolic Risk Factors and Disease Endpoints

	STRENGTH OF EVIDENCE FOR BENEFITS*			INSUFFICIENT EVIDENCE FOR EFFECTS
	Convincing	**Probable**	**Possible**	
Hypertension	Higher intakes of: Mediterranean- or DASH-type dietary pattern Dietary fiber Fruits and vegetables Fish or fish oil Cocoa or dark chocolate Potassium Lower intakes of: Sodium Alcohol	Higher intakes of: Tea Lower intakes of: Caffeine	Higher intakes of: Whole grains Magnesium Calcium Vitamin D Soy foods MUFAs in place of SFAs	Isoflavones Coffee or tea PUFAs or carbohydrate in place of SFAs
High LDL-C	Higher intakes of: MUFAs or PUFAs Dietary fiber Fruits and vegetables Green tea Soy protein Lower intakes of: *Trans* fat SFAs (12:0-16:0) Dietary cholesterol	Higher intakes of: Butter Whole grains Soy foods Tea Lower intakes of: Unfiltered coffee	Higher intakes of: Cheese Yogurt Cream	
Atherogenic dyslipidemia (low HDL-C, high triglycerides)	Higher intakes of: Mediterranean- or DASH-type dietary pattern MUFAs or PUFAs Fish or fish oil Lower intakes of: Simple or complex refined carbs (high GI or GL) *Trans* fat	Lower intakes of: SSBs	Higher intakes of: Fruits and vegetables Dairy foods	
Insulin resistance, type 2 diabetes	Higher intakes of: Whole grains Dietary fiber PUFAs or vegetable oils Lower intakes of: Processed meats SSBs Simple or complex refined carbs (high GL)	Higher intakes of: MUFAs Lower intakes of: Unprocessed meats	Higher intakes of: Fruits Beans Coffee Cheese Yogurt Dairy fat Lower intake of: Eggs Dietary cholesterol *Trans* fat	Carbohydrate in place of SFAs Vegetables Beans Poultry Fish or fish oil Milk Butter Tea
Obesity	Higher intakes of: Whole unprocessed foods (e.g., whole grains, nuts, fruits, vegetables, beans) Lower intakes of: SSBs Simple or complex refined carbs (high GL)	Higher intakes of: Dietary fiber Yogurt Lower intakes of: Large portion sizes Red meats Processed meats Less TV watching Greater sleep duration	Higher intakes of: Green tea Protein Lower intakes of: Deep-fried foods Meals from quick service restaurants *Trans* fat	Total fat (% E) SFAs, MUFAs, or PUFAs
Systemic inflammation	Higher intakes of: Fruits and vegetables	Higher intakes of: Mediterranean- or DASH-type diet pattern Whole grains Fish oil (supplements). Lower intakes of: TFAs	Higher intakes of: Fish, fish oil (diet), ALA PUFAs Nuts Lower intakes of: Simple or complex refined carbs (high GI/GL)	SFAs or MUFAs
Coronary heart disease	Higher intakes of: Mediterranean- or DASH-type dietary pattern Fruits and vegetables Whole grains Nuts Dietary fiber PUFAs in place of SFAs Fish (CHD mortality) Lower intakes of: Trans fat Processed meats	Higher intakes of: Beans Lower intakes of: Simple or complex refined carbs (high GI or GL) Sodium Moderate alcohol use	Higher intakes of: Fish or fish oil (nonfatal CHD) Cheese ALA MUFAs in place of SFAs Vitamin D Lower intakes of: Unprocessed meats Dietary cholesterol in patients with diabetes	Total fat (% E) Carbohydrate in place of SFAs Antioxidant or vitamin supplements Poultry Eggs Yogurt Milk Coffee or tea Dietary cholesterol in patients without diabetes
Ischemic stroke	Higher intakes of: Mediterranean- or DASH-type dietary pattern Fruits Lower intakes of: Sodium		Higher intakes of: Whole grains Vegetables SFAs Fish or fish oil Tea Cheese Lower intakes of: Processed meats Red meats	Poultry Eggs Milk ALA Antioxidant or vitamin supplements

Hemorrhagic stroke		Higher intakes of: Whole grains Mediterranean- or DASH-type dietary pattern Lower intakes of: Sodium	Higher intakes of: Total fat SFAs Animal protein Tea	Fish or fish oil
Heart failure[†]	Lower intakes of: Heavy alcohol use		Higher intakes of: Mediterranean- or DASH-type dietary pattern Whole grains Fish Moderate alcohol use	
Atrial fibrillation		Lower intakes of: Heavy alcohol use	Higher intakes of: Fish or fish oil	

[*]Strength of evidence based on Bradford-Hill and World Health Organization criteria: Micha R, Kalantarian S, Wirojratana P, et al. Estimating the global and regional burden of suboptimal nutrition on chronic disease: methods and inputs to the analysis. Eur J Clin Nutr 2012;66:119-29. For most dietary factors, evidence is derived from controlled trials of risk factors plus long-term prospective cohorts of disease endpoints. For fish/EPA plus DHA, n-6 PUFAs, total fat, and Mediterranean-type dietary patterns, evidence is also derived from randomized clinical trials of clinical endpoints.

[†]Incidence. Limited data on dietary treatment for secondary prevention, except for one large randomized trial of EPA plus DHA supplementation that reduced total mortality, and clinical experience with sodium restriction to prevent fluid overload.

ALA, Alpha-linoleic acid; *CHD,* coronary heart disease; *DASH,* Dietary Approaches to Stop Hypertension; *E,* energy; *GI,* glycemic index; *GL,* glycemic load; *MUFAs,* monounsaturated fatty acids; SFAs, saturated fatty acids; *PUFAs,* polyunsaturated fatty acids; *SSBs,* sugar-sweetened beverages; TFAs, *trans* fatty acids.

Other popular dietary patterns include vegetarian or vegan, low-carbohydrate, and “paleo” diets. People who follow these patterns may be health conscious and tend to make better choices. Yet, these dietary patterns can vary dramatically in their healthfulness; each can range from excellent to poor, depending on the specific foods selected. A cardioprotective diet pattern is best characterized by being rich in specific healthful foods (**see Table 49.1**).

Changing Behavior

Because dietary changes can be low risk, low cost, and broadly available, strategies for effective behavior change are essential at individual, health system, and population levels.[216,217,221]

Clinical (Individual-Based) Strategies

Numerous controlled trials have identified effective approaches for individual behavior change: setting proximal, targeted goals; self-monitoring; regular feedback; peer support; increasing self-efficacy; and motivational interviewing.[221,222] These strategies should be incorporated into practice to improve specific dietary priorities. Providers should remember that patient compliance with both lifestyle counseling and medication prescriptions is similarly incomplete, yet such strategies, even imperfectly implemented, improve clinical outcomes.[223]

Novel Technologies

Novel personal technologies such as mobile applications (mHealth), Internet programs, and personal devices (e.g., FitBits) hold promise due to scalability, lower cost, and opportunities for continuous, personalized modifications and improvements. Optimally, deployment of these approaches should incorporate established individual-based behavior change strategies. A systematic review of randomized trials and quasi-experimental studies demonstrated general effectiveness of these approaches for dietary change and/or weight loss.[224] While promising, most of these studies had a duration of 6 weeks to 6

months and thus require evaluation of long-term effectiveness and sustainability.

Health Systems

For many clinicians, certain barriers may limit their ability to implement effective behavior change strategies: limited patient visit time, insufficient financial or other provider incentives, suboptimal knowledge or experience, and inadequate electronic tools for assessing diets and monitoring changes over time. Specific health system changes, now being introduced for tobacco and obesity control, can support and facilitate behavior change.[217,222,225,226] Expansion of these approaches to target diet quality is crucial. Integrated systems can provide coordinated care by multidisciplinary teams; with alignment of payments, practice goals, and quality benchmarks to reward dietary change efforts.

Policy Strategies

Given the key roles of social and environmental forces in shaping dietary habits, policy (population-based) approaches are crucial to achieve broad success. When widespread, even modest behavioral changes meaningfully alter population risk. Effective strategies can be implemented at local (e.g., schools, worksites, communities) as well as city, state, national, and international levels. These include focused media/education, product labeling/point-of-purchase information, comprehensive school and workplace wellness programs, built-environmental changes in types and locations of food outlets, economic incentives such as taxes and subsidies, and quality standards (e.g., on marketing to children, levels of *trans* fat or sodium).[216] Available evidence suggests that education or information alone, without additional economic or environmental changes, has lower efficacy.[216,227,228] Integrated, multicomponent approaches that include upstream policy measures, midstream educational efforts, and downstream community and environmental approaches appear especially effective, as seen with reducing tobacco use and deaths from motor vehicle accidents. Policy strategies can complement individual and health system efforts while also reducing social and racial disparities caused by clustering of suboptimal diet habits, local environments, and disease risk factors in disadvantaged groups.

Obesity and Cardiometabolic Disease

Jean-Pierre Després, Eric Larose, Paul Poirier

A medical perspective defines obesity as excess body fat associated with comorbid conditions and increasing mortality risk. This chapter discusses basic concepts on the etiology of obesity as it relates to cardiovascular outcomes, including (1) fat accumulation in selective adipose depots and nonadipose tissues as related to various health outcomes, (2) the tools to assess the risk associated with the different forms of overweight and obesity, and (3) the options available in clinical practice to prevent or reduce the risk of cardiovascular disease (CVD) in overweight and obese patients. (**See also Chapter 49**.)

Epidemiology

Traditional Definition of Obesity

Obesity increases risk of developing numerous health outcomes, including cardiovascular events[1-4] (**Fig. 50.1**). In clinical practice the most common index used to estimate adiposity has been the body mass index (BMI, expressed in kg/m^2), initially introduced by Quetelet more than a century ago and largely popularized by the American physiologist Ancel Keys.[3,4] Since then, many population-based studies, including a recent international study pooling data of about 4 million individuals from 189 studies who were followed for an average of 13 years, have shown that a BMI value above approximately 25 kg/m^2 is associated with a progressive increase in mortality rate and risk of chronic conditions.[1] A BMI of 25 kg/m^2 or higher defines *overweight*, BMI of 30 kg/m^2 or higher defines *obesity*, and BMI of 40 kg/m^2 or higher, or 35 kg/m^2 or higher with comorbidities, defines *severe obesity*.[2-4] The prevalence of obesity has increased worldwide, particularly since the early 1980s, with little evidence of plateauing[5,6] (**eFig. 50.1**). The prevalence of severe obesity has reached epidemic proportions in the United States and elsewhere[5-8] (**see Chapter 1**).

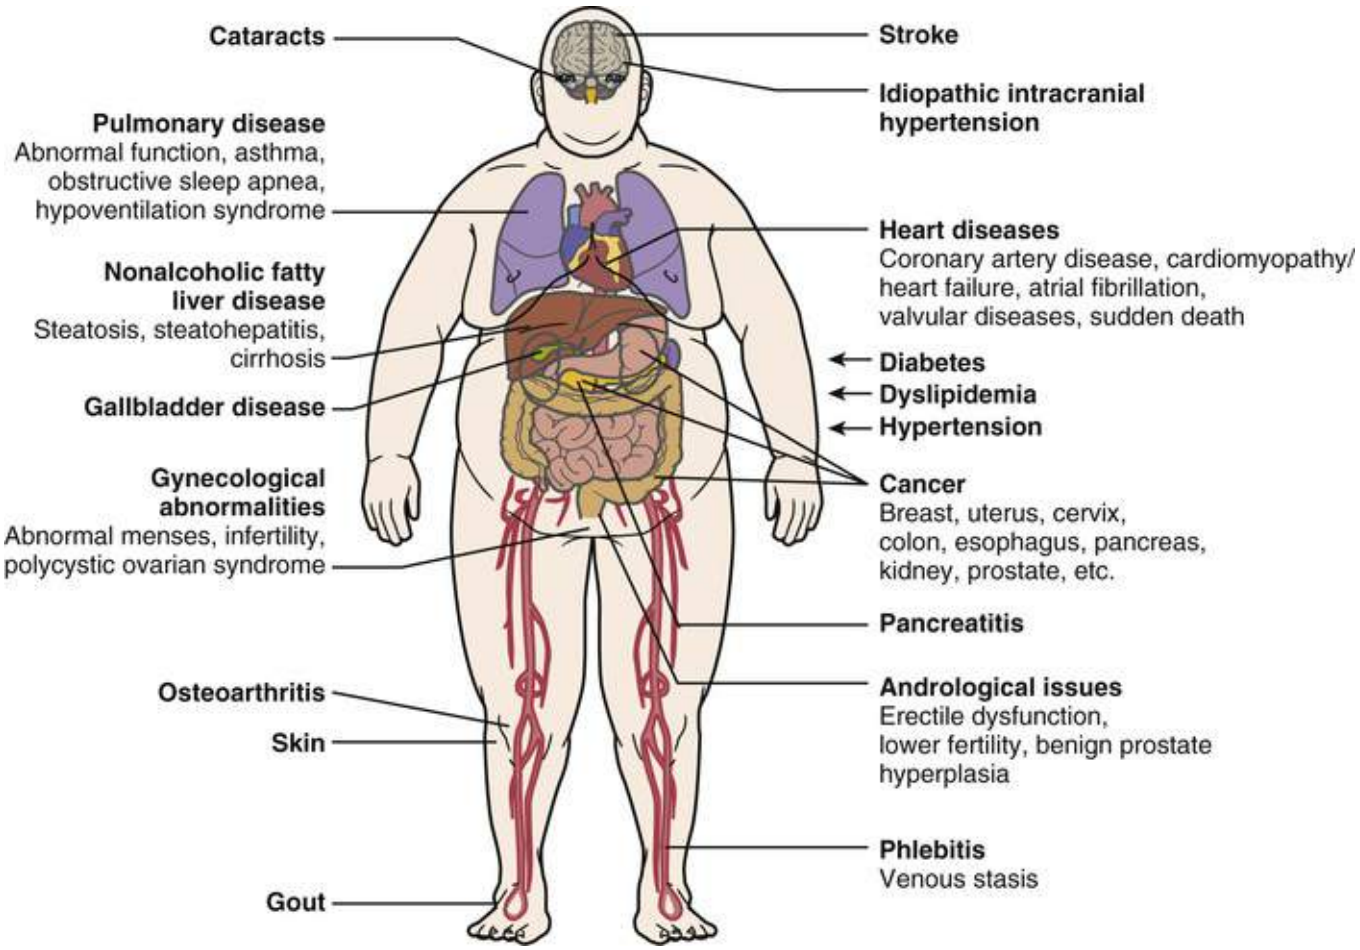

FIGURE 50.1 Some of the key medical complications associated with obesity.

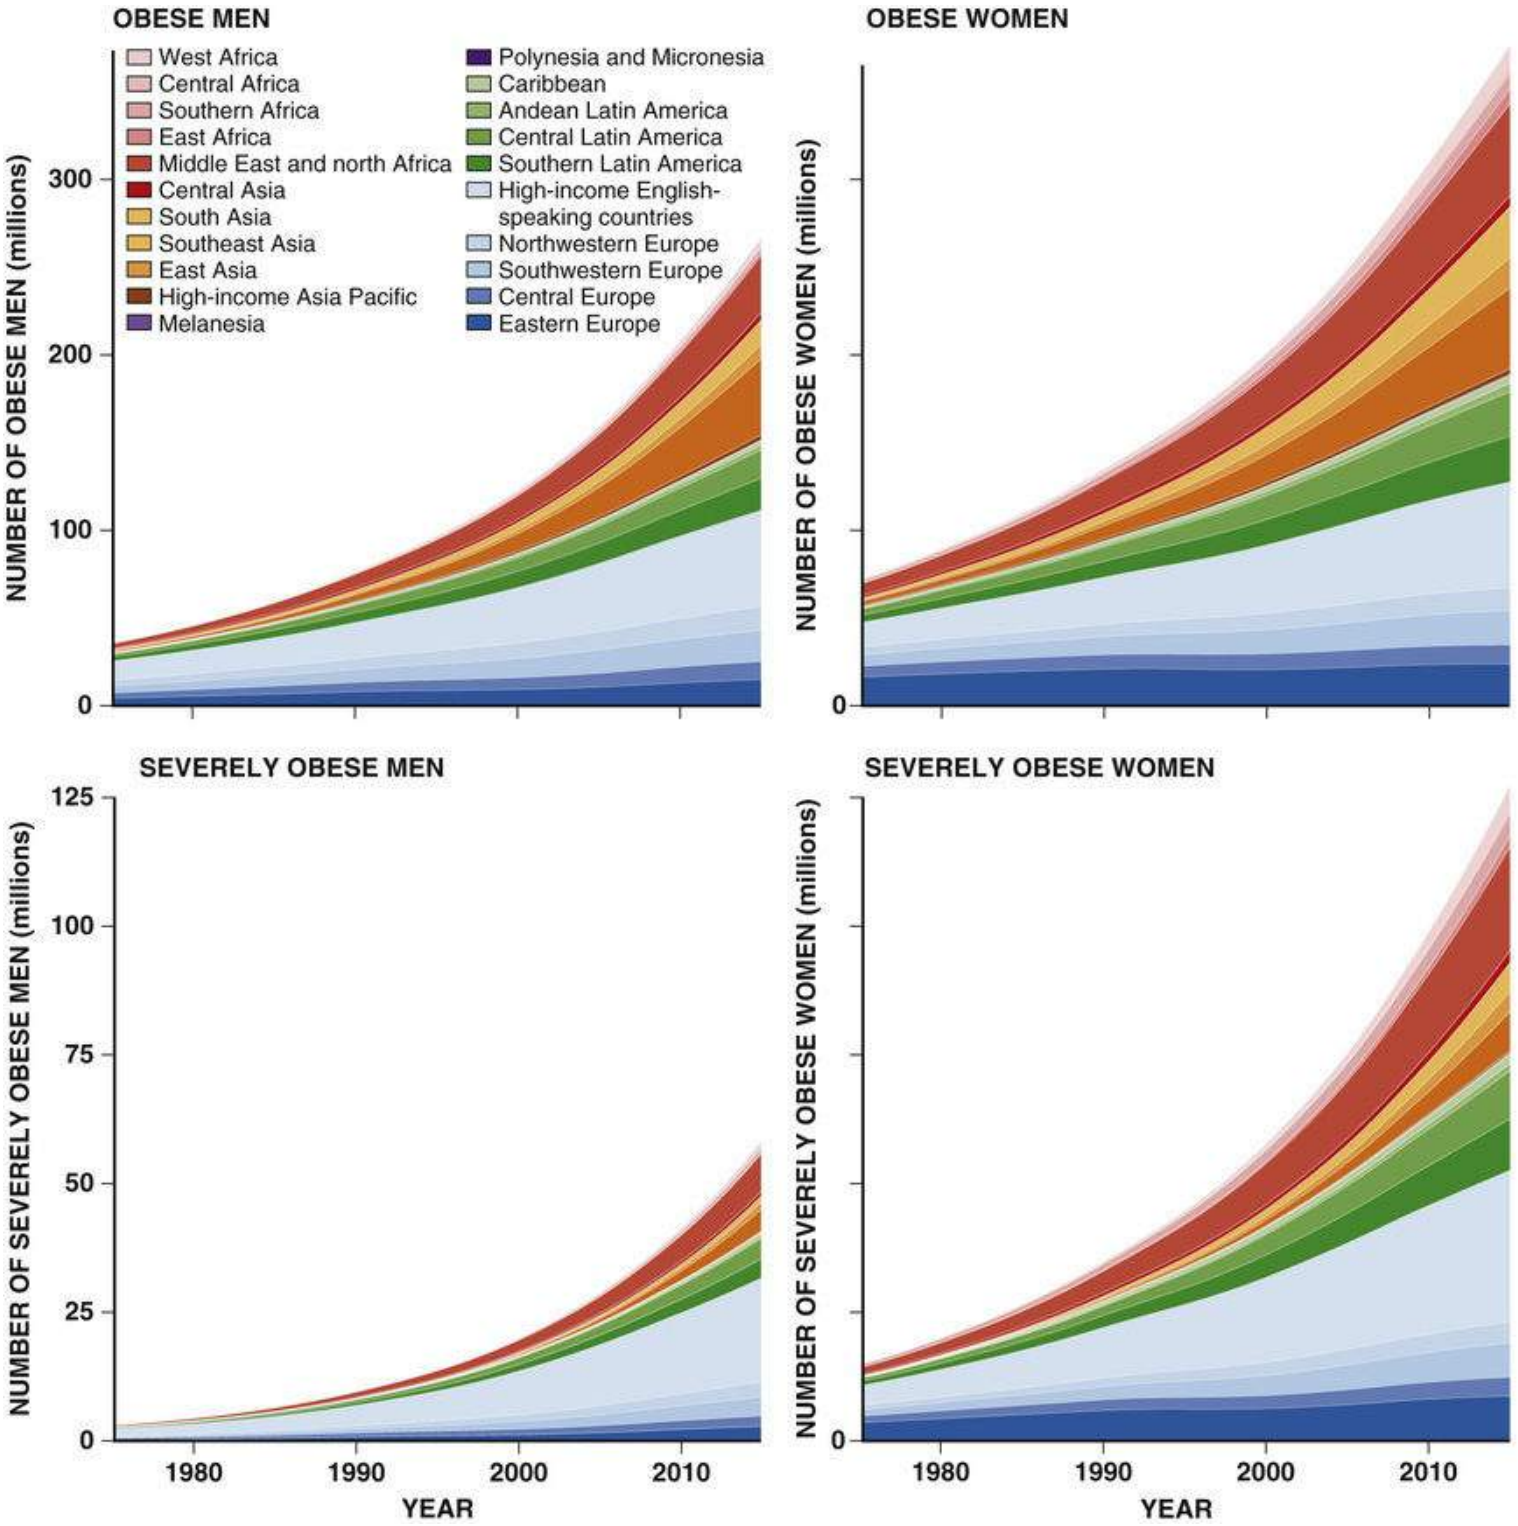

EFIGURE 50.1 Trends in the number of obese and severely obese people by region. A person is obese if they have a body mass index (BMI) of 30 kg/m^2 or higher, or is severely obese if they have a BMI of 35 kg/m^2 or higher. (From NCD Risk Factor Collaboration. Trends in adult body-mass index in 200 countries from 1975 to 2014: a pooled analysis of 1698 population-based measurement studies with 19.2 million participants. Lancet 387:1377-1396, 2016. http://creativecommons.org/licenses/by/4.0/.)

Puzzling Relationship of Excess Body Weight and Fat with Cardiovascular Disease

Although excess body weight or obesity is associated with an increased risk of many health complications (**Fig. 50.1**), equally overweight or obese patients display a remarkable heterogeneity in CVD risk[9,10] (**Fig. 50.2**). Thus, although an elevated BMI increases the risk of finding CVD risk factors or health

complications, not every overweight/obese patient develops risk factors or health issues. Some investigators use the term “metabolically healthy” or “fit fat” obesity to refer to such individuals.[9-12] The existence of such metabolically healthy obese individuals has engendered debate. Indeed, there is no healthy pattern of increased weight.[13] Nevertheless, reasons for such major individual differences in the cardiometabolic risk profile of equally obese patients had remained unclear until imaging studies (computed tomography [CT] and then magnetic resonance imaging [MRI]) revealed marked individual differences in the way people store adipose tissue in the visceral depot. For any given level of total body fat, individuals characterized by a low accumulation of abdominal visceral adipose tissue generally have a lower CVD risk profile than individuals closely matched for BMI or for total body fat but with high levels of visceral adipose tissue. Those with excessive visceral fat display a constellation of metabolic abnormalities, including insulin resistance, glucose intolerance leading to type 2 diabetes, atherogenic dyslipidemia (including increased triglyceride levels, increased concentrations of non-high-density lipoprotein [HDL] cholesterol and apolipoprotein B, low HDL cholesterol levels, small dense low-density lipoprotein [LDL] and HDL particles), elevated blood pressure (BP), subtle chronic inflammation, and a prothrombotic profile[9,10,14] (**Fig. 50.2**). This risk cluster characterizes the so-called metabolic syndrome.[10,14]

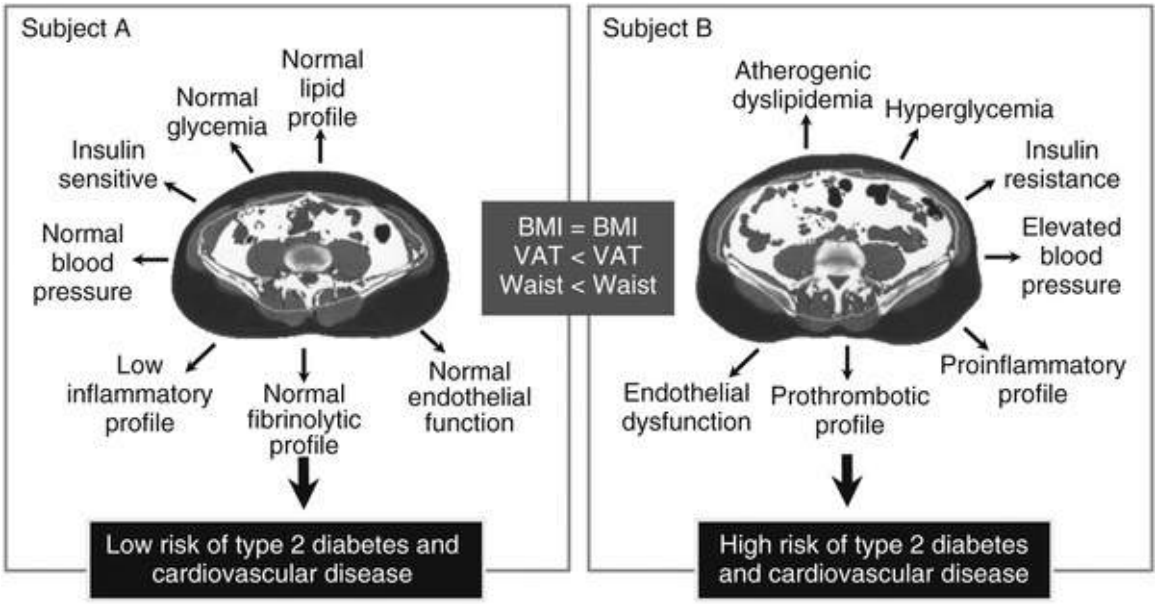

FIGURE 50.2 Marked differences in visceral adipose tissue (VAT) accumulation measured by computed tomography in two individuals having the same body mass index (BMI). However, subject B has a greater cross-sectional accumulation of VAT than subject A. This higher accumulation of VAT in subject B is associated with an altered cardiometabolic risk profile increasing the risk of type 2 diabetes and cardiovascular disease compared to subject A.

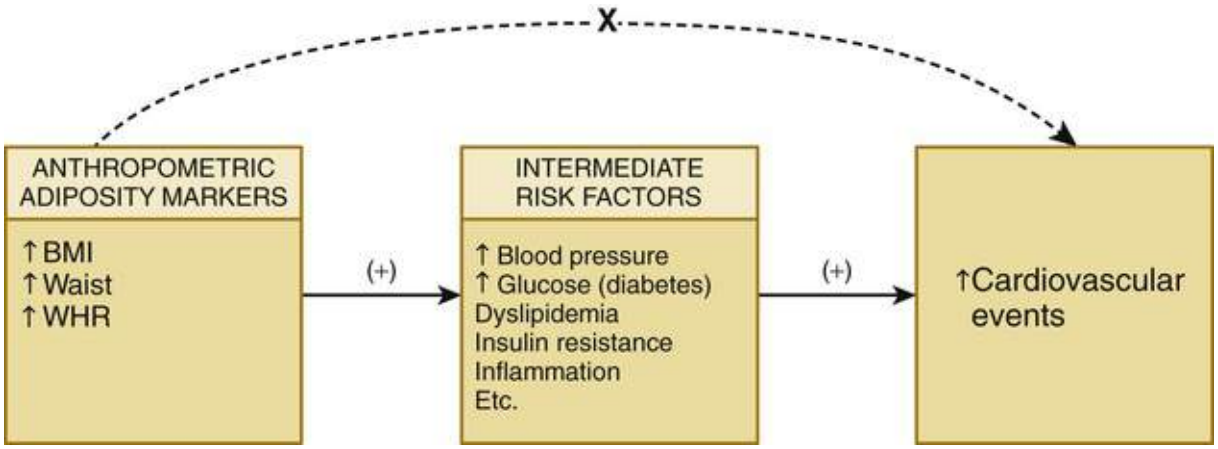
In clinical practice, assessing CVD risk specifically related to obesity or excess adiposity has remained a challenge. One large study concluded that, after control for intermediate CVD risk factors (BP, lipids, diabetes), anthropometric adiposity indices such as BMI or waist circumference are not independently related to CVD mortality.[15] The study reported very strong associations between adiposity indices and intermediate CVD risk factors, however, suggesting that increased adiposity changed CVD risk[16] (**eFig. 50.2**). Thus the clinician must decide whether to reduce CVD risk by lowering BP, lipids (LDL cholesterol), and blood glucose with pharmacologic agents or to target weight loss. Whereas randomized trials have shown the clinical benefits of targeting BP, lipids, and glucose control (within certain limits), no weight loss drug targeting obesity has unequivocally been proven to reduce

cardiovascular events and mortality, with the exception of new diabetes drugs, which are not neutral in terms of body weight.[17,18] A large well-conducted diet and weight loss trial in obese patients with type 2 diabetes (Look AHEAD) showed no reduction in CVD events as a result of an intensive lifestyle intervention that yielded weight loss, despite beneficial effects on some CVD risk factors and quality of life.[19] Various explanations may account for this result.[20]



EFIGURE 50.2 Relationships among adiposity indices, intermediate risk factors, and cardiovascular events in the general population. Under this model, most of the association between adiposity indices and cardiovascular disease is explained by altered levels of intermediate risk factors. BMI, Body mass index; WHR, waist-to-hip ratio. (From Bastien M et al. Overview of epidemiology and contribution of obesity to cardiovascular disease. Prog Cardiovasc Dis 2014;56:369-81.)

Risk Assessment in Overweight/Obese Patients: Waistline as Key Indicator

Because excess visceral adiposity exacerbates CVD risk in overweight and obese patients, it remains essential to measure the patient's waist circumference in addition to BMI.[21] This variable should be assessed while the patient is standing, placing the tape just above the iliac crest. If a given patient has a large waistline for a given BMI, with altered risk factors, the CVD risk factor profile likely reflects excess abdominal visceral fat.[9,10,22] Simple clinical alterations (e.g., high-triglyceride low–HDL cholesterol dyslipidemia, elevated BP, increased fasting blood glucose levels) confirm a dysmetabolic state. Additional tests to confirm insulin resistance include fasting insulin, 2-hour glucose tolerance, hemoglobin (Hb) A_{1c} level and C-reactive protein (CRP) concentrations. In overweight or obese patients, the presence of these abnormalities along with an elevated waist circumference suggests an excess of abdominal visceral fat.[9,10,14]

Because the waistline and BMI are strongly correlated, waist circumference alone largely reflects total adiposity. For any given BMI value, however, waist circumference can vary considerably and reflects CVD risk[23] (**Fig. 50.3 and eFig. 50.3**). Thus, although clinical guidelines have proposed waist cutoff values to define abdominal obesity, interpretation of these cutoffs requires caution. For example, a waist circumference of 105 cm reflects *abdominal* obesity in a man with a BMI of 26 kg/m^2. However, the same waistline value would simply reflect *overall* obesity in another individual with a BMI of 31 kg/m^2. Further work is required to refine clinically relevant BMI-specific waist cutoff values beyond those specified in current guidelines[2,24] (**Table 50.1**).

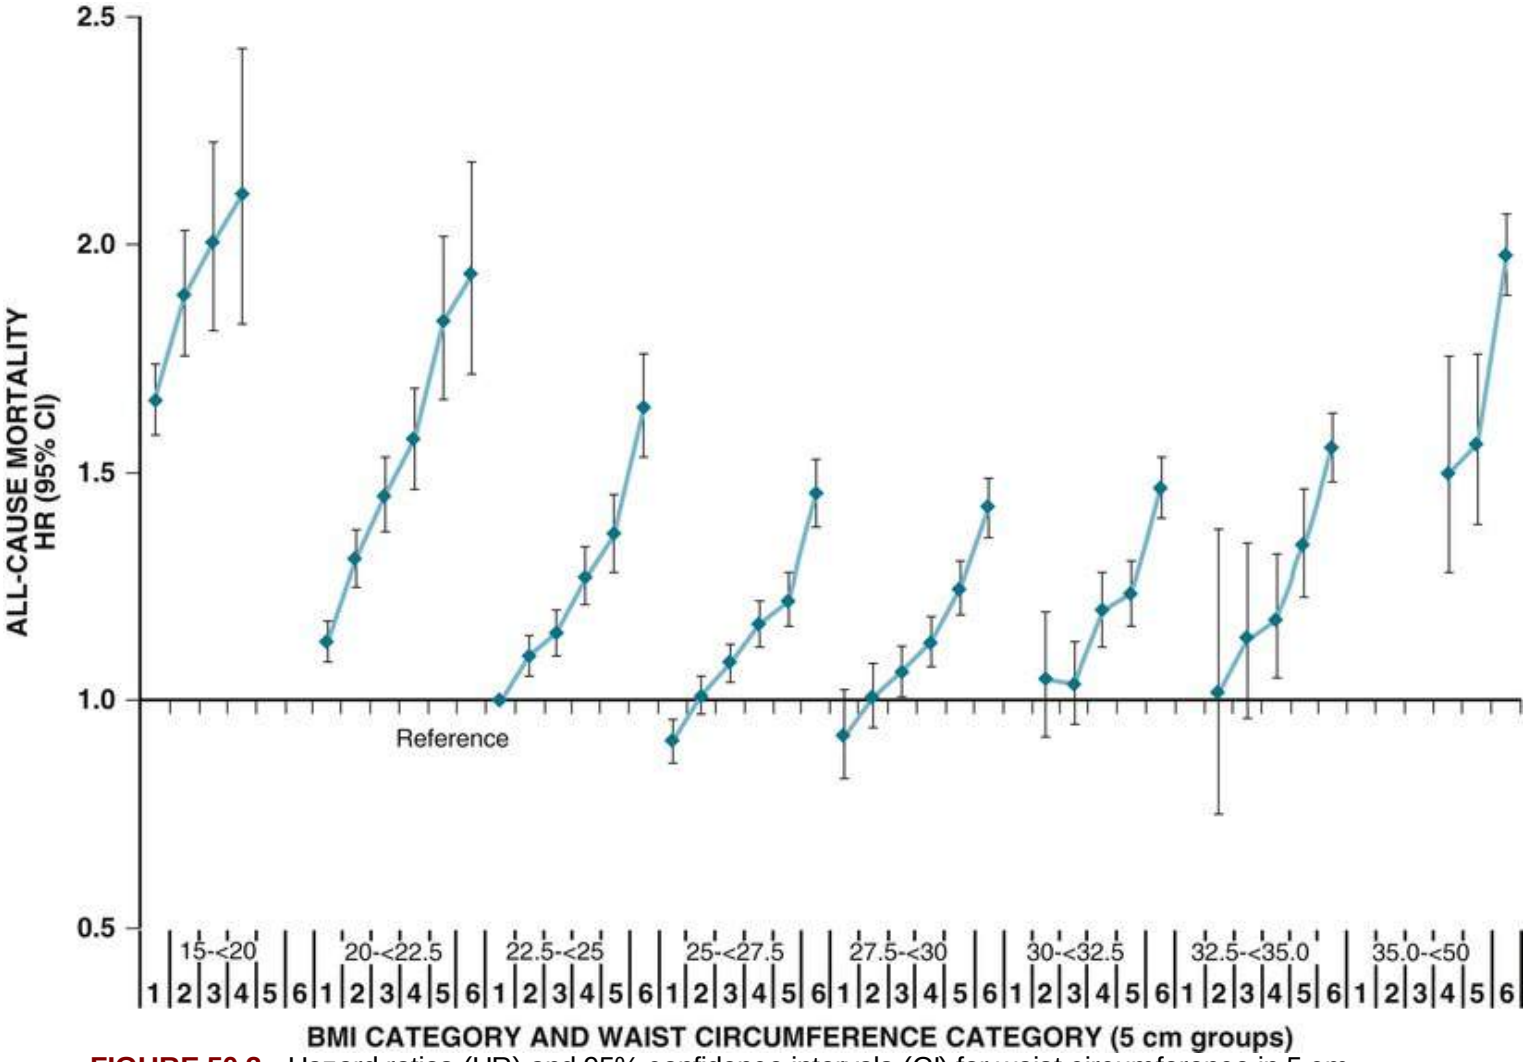


FIGURE 50.3 Hazard ratios (HR) and 95% confidence intervals (CI) for waist circumference in 5 cm increments* and all-cause mortality by body mass index (BMI) category (men and women combined), adjusted for education, marital status, smoking status, alcohol consumption, physical activity, and BMI. *Waist circumference cut points (cm) for men, <90.0, 90.0-94.9, 95.0-99.9, 100.0-104.9, 105.0-109.9, and 110.0+; and for women, <70.0, 70.0-74.9, 75.0-79.9, 80.0-84.9, 85.0-89.9, and 90.0+. (From Cerhan JR et al. A pooled analysis of waist circumference and mortality in 650,000 adults. Mayo Clin Proc 2014;89:335-45.)

TABLE 50.1

Health Risk Classification According to Body Mass Index (BMI) and Waist Circumference

OBESITY CLASS		BMI (KG/M^2)	DISEASE RISK* RELATIVE TO NORMAL WEIGHT AND WAIST CIRCUMFERENCE	
			Waist Circumference (cm)	
			Men ≤102 Women ≤88	Men >102 Women >88
Underweight		<18.5	Increased	Increased
Normal		18.5-24.9	Least	Increased
Overweight		25.0-29.9	Increased	High
Obesity	I	30.0-34.9	High	Very high
	II	35.0-39.9	Very high	Very high
Severe obesity	III	≥40	Extremely high	Extremely high

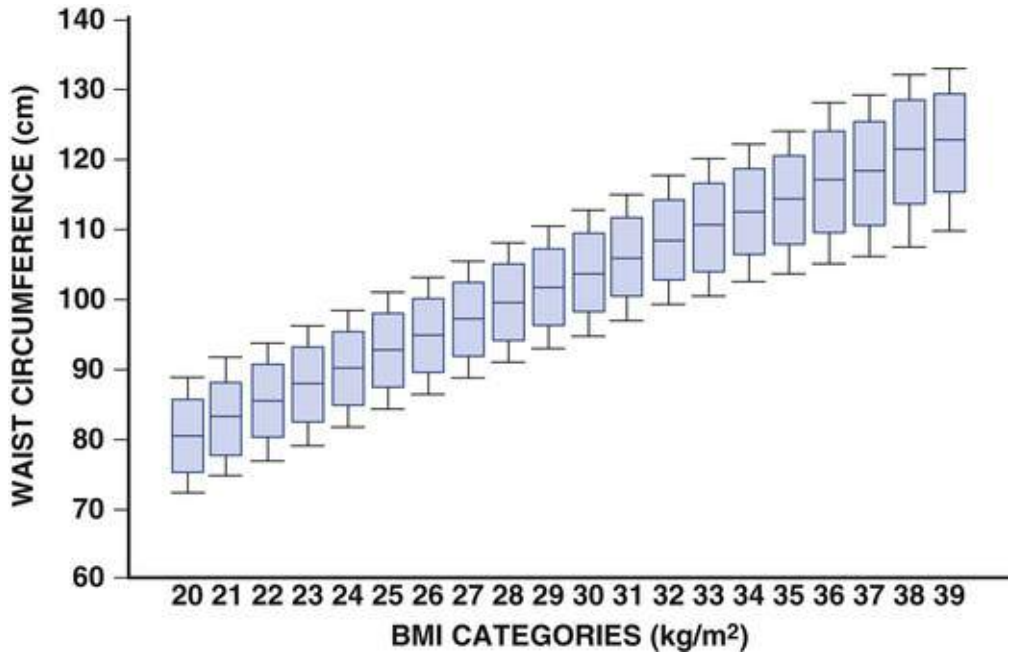
*Risk of type 2 diabetes, hypertension, cardiovascular disease, sleep apnea, and certain forms of cancer relative to normal BMI and a normal waist circumference.

Waist circumference and BMI cutoff values presented in the table are to be used in Europids/Caucasians only.

Individuals with BMI <18.5 kg/m^2 and ≥40 kg/m^2 are considered at, respectively, increased risk and extremely high risk, independent of their waist circumference value.

The International Chair on Cardiometabolic Risk has proposed that desirable waist circumference values should be <90 cm in men and <85 cm in women.

Modified from US National Institutes of Health, National Heart, Lung, and Blood Institute, in cooperation with National Institute of Diabetes and Digestive and Kidney Diseases. Clinical guidelines on the identification, evaluation, and treatment of overweight and obesity in adults: the evidence report. 1998. NIH Pub No 98-4083.



EFIGURE 50.3 Box-and-whisker plots showing the distribution of waist circumference values (age-adjusted) per unit of body mass index (BMI) in the subsample of 64,624 men of the IDEA study who had BMI values of 20 kg/m^2 or higher and less than 40 kg/m^2. Data shown are medians, quartiles, and 10th and 90th percentiles. (From Després JP. Excess visceral adipose tissue/ectopic fat: the missing link in the obesity paradox? J Am Coll Cardiol 2011;57:1887-9.)

Evolving Focus from Adipose Tissue Mass to Quality and Functionality

As mentioned, the regional distribution of body fat is much more important than adipose tissue mass.[9,10,14,25] For instance, excess accumulation of body fat in the lower part of the body (hips and thigh) is not associated with an increased risk of CVD or type 2 diabetes. Indeed, a large accumulation of lower body fat rather is associated with a reduced risk of developing these outcomes,[26] consistent with previous findings that hip and thigh fat is associated with a favorable CVD risk profile.[10] In contrast, excess abdominal fat, particularly *visceral adipose tissue*, confers risk as previously detailed.[9,10,14] Imaging also showed substantial individual differences in the size of these inner fat depots, particularly the amount of fat in the abdominal cavity, which includes omental fat, mesenteric fat, and retroperitoneal adipose tissue.[9,10,14,27]

Visceral Obesity

Marker of Ectopic Fat Deposition

The mechanisms underlying the independent association between excess visceral fat and cardiometabolic alterations remain an unsettled issue. Three non–mutually exclusive scenarios may pertain: (1) the portal free fatty acid (FFA) hypothesis, (2) the endocrine functions of visceral adipose tissue, and (3) excess visceral adipose tissue as a marker of dysfunctional subcutaneous adipose tissue.[9,10,14]

Portal Free Fatty Acid Hypothesis

In vitro studies of the metabolic properties of visceral adipose tissue—mainly the omental fat depot drained by the portal vein—have shown that these omental adipocytes exhibit a hyperlipolytic state poorly inhibited by insulin compared to subcutaneous adipose tissue.[10] Therefore the hypertrophied omental adipocytes in visceral adipose tissue deliver FFAs directly through the portal vein, leading to overproduction of triglyceride-rich lipoproteins, reduction of insulin extraction, and increased hepatic glucose production, hallmarks of obesity and type 2 diabetes. Despite its appeal, the finding that most circulatory FFAs originate from subcutaneous adipose tissue has challenged this hypothesis. Dog experiments indicated that excess visceral adiposity does elevate nocturnal FFA levels.[28]

Visceral Adipose Tissue as an Endocrine Organ

The visceral adipose depot preferentially expands through adipose cell hypertrophy, generating very large fat cells that are prone to rupture and have a different FFA composition than subcutaneous adipose tissue.[10] Macrophages accumulate especially in visceral adipose tissue, contributing to local inflammation and an expanding list of “adipokines” that could exacerbate the metabolic risk profile of the patient with excess visceral adiposity.[29,30] Also, activation of the sympathetic nervous system may particularly occur in visceral adipose tissue.[31]

Visceral Adipose Tissue: Marker of Dysfunctional Subcutaneous Adipose Tissue?

Excess visceral adipose tissue may also accumulate when subcutaneous adipose tissue fails to expand in an energy surplus[32] (**Fig. 50.4**). Subcutaneous adipose tissue normally expands first by adipocyte hypertrophy, followed by proliferation of surrounding preadipocytes (hyperplasia).[10,32] If the hyperplastic response is adequate, subcutaneous adipose tissue will expand and act as a “sink” for excess calories[10] and will maintain autonomic balance.[33]

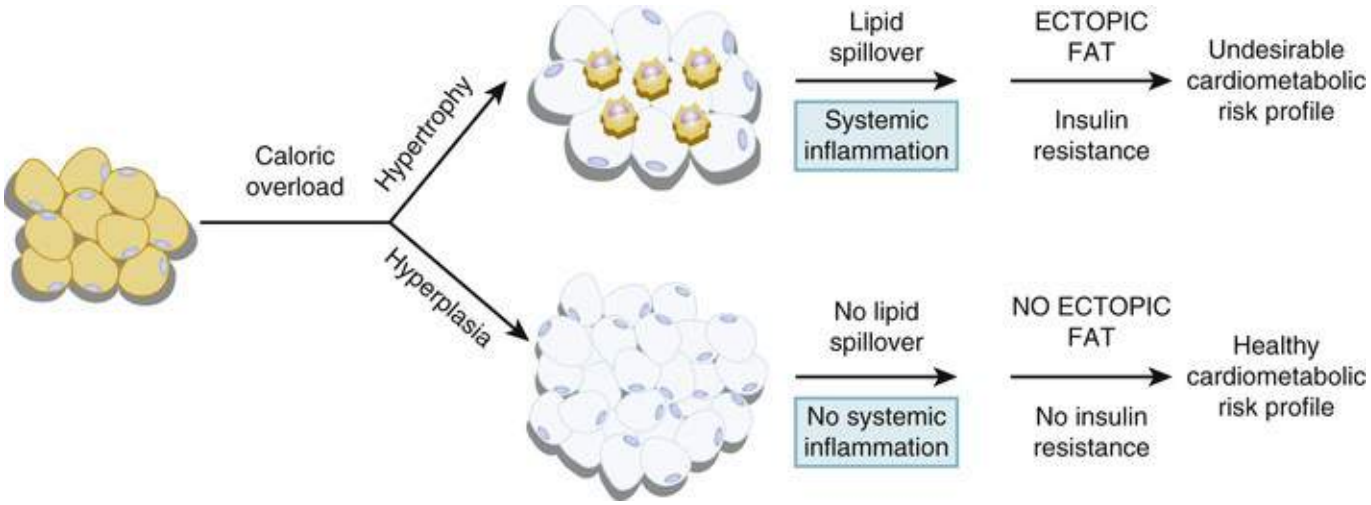


FIGURE 50.4 Simplified model to illustrate the concept that when facing a chronic energy surplus, inability of subcutaneous adipose tissue to expand through hyperplasia may lead to hypertrophic and "inflamed" adipose tissue. Resulting systemic inflammation and lipid spillover would lead to ectopic fat deposition, insulin resistance, and a deteriorated cardiometabolic risk profile. (From Després JP. Abdominal obesity and cardiovascular disease: is inflammation the missing link? Can J Cardiol 2012;28:642-52.)

Genetic forms of lipodystrophy illustrate the importance of properly functioning and expanding (when required) adipose tissue.[10] Individuals lacking subcutaneous fat develop an excess of visceral adipose tissue as well as fat accumulation in normally lean tissues. Large cohort imaging studies have revealed that viscerally obese individuals have an increased accumulation of fat in lean tissues such as the liver, heart, skeletal muscle, and kidney, a phenomenon described as "ectopic fat deposition."[9,10,14,34,35] Thus, excess visceral adipose tissue may be a marker or consequence of the relative inability of subcutaneous adipose tissue to act as a protective "metabolic sink" and thus reflects ectopic fat deposition (**Fig. 50.5**).

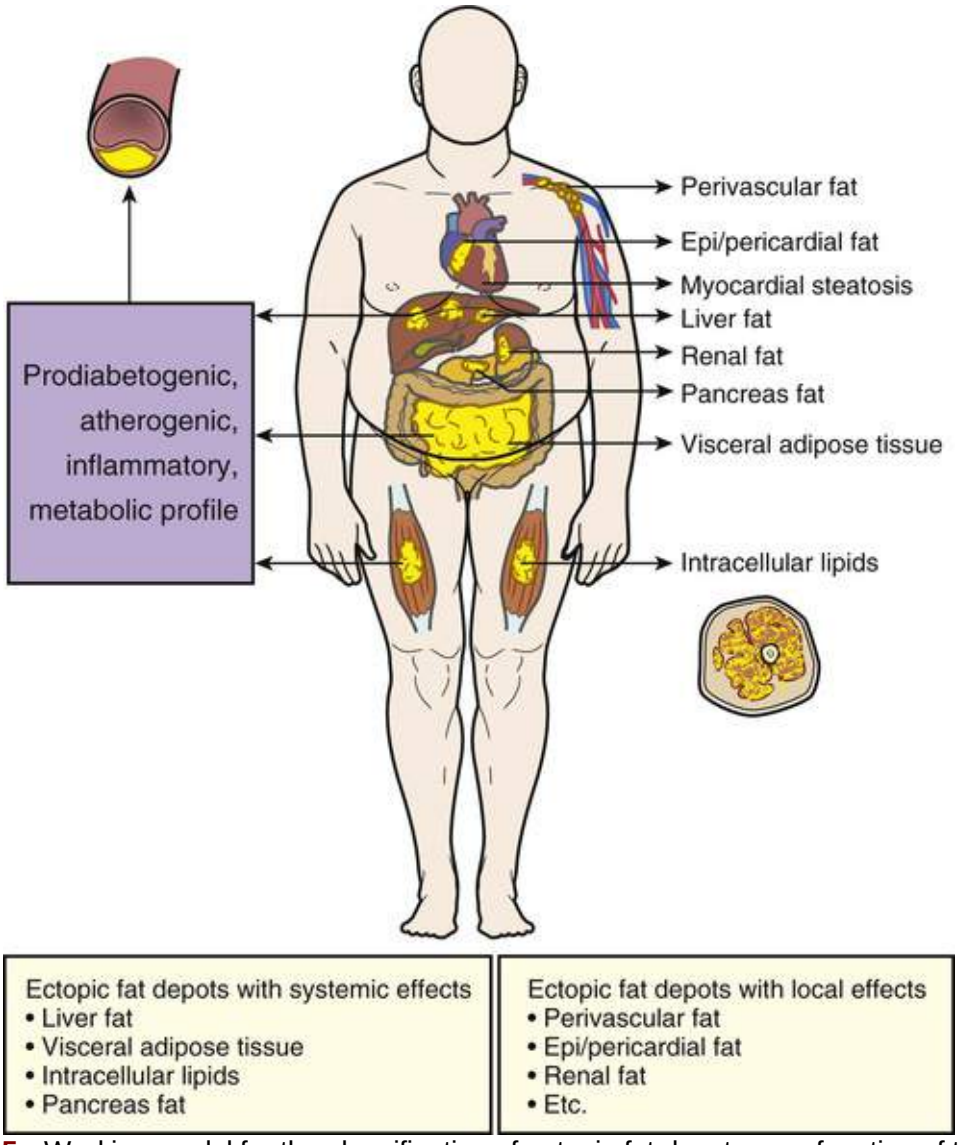

FIGURE 50.5 Working model for the classification of ectopic fat depots as a function of their putative systemic and local effects. (From Després JP. Body fat distribution and risk of cardiovascular disease: an update. Circulation 2012;126:1301-13.)

The extent to which each of these ectopic fat depots contributes to various cardiovascular outcomes is currently under investigation in several laboratories.[22,36-39] Considerable evidence suggest that excess liver fat is a key abnormality responsible for the several cardiometabolic complications found in viscerally obese individuals.[40,41] Similar data linking excess epi/pericardial fat with various clinical outcomes have also been reported.[36-38,42] On the other hand, the healthy cardiometabolic risk profile and low levels of visceral/ectopic fat observed in healthy premenopausal obese women with large hips and selective accumulation of lower body fat remain consistent with the protective role of healthy lower body subcutaneous adipose tissue.

Key Factors Associated with Visceral Obesity

The study of factors associated with the selective deposition of visceral/ectopic fat has generated considerable interest.[10]

Age and Sex

Age and sex show marked association with visceral adiposity. With age, visceral adipose tissue can accumulate and contribute to progressive cardiometabolic risk. Before menopause, women have on

average 50% less visceral adipose tissue than men.[10] At menopause, the relative decline in some key sex steroids contributes to a progressive and selective deposition of visceral adipose tissue.[10] Such sex difference in visceral adipose tissue contributes to sex-dependent cardiometabolic risk. After menopause, because of the acceleration in visceral adipose tissue deposition, women progressively catch up to men (over 10 to 15 years), as can their cardiometabolic risk profile.

Sex Hormones

The major sex difference in visceral adiposity and cardiometabolic risk profile has stimulated exploration of the link between regional body fat distribution and sex hormones. The most informative intervention study supporting a major role of sex steroids involved transsexual patients. Male-to-female transsexuals receiving sex hormone therapy show substantial changes in regional body fat accumulation, with loss of visceral/ectopic fat and increase in the size of lower body fat.[10] Female-to-male transsexuals show the reverse pattern, with related deterioration in their cardiometabolic risk profile.[10,43]

Genetics

Genes can regulate susceptibility to visceral obesity.[10] Offspring of viscerally obese parents often develop the same pattern when they reach their 30s and 40s, a finding that may reflect both heritability and shared environmental factors. When exposed to the same standardized energy excess for 100 days, monozygotic twin pairs tend to show the same pattern of accumulation of visceral and subcutaneous adipose tissue.[44] No major gene associated with this process has yet been identified, although numerous investigations worldwide continue to explore this topic.

Ethnicity

Ethnicity is also associated with variations in visceral adiposity and ectopic fat.[45] Large imaging cardiometabolic studies have shown susceptibility to visceral adiposity/ectopic fat greatest in Asians, then Caucasians, and then African Americans.[10,46,47] Indeed, Asians develop diabetes because of excess visceral/ectopic fat at lower BMI values than whites or blacks.[48,49]

Hypothalamic-Pituitary-Adrenal Axis and Endocannabinoid System

The hypothalamic-pituitary-adrenal (HPA) axis and the endocannabinoid (EC) system can also modulate visceral adiposity/ectopic fat. Maladaptive responses to stress are associated with chronic exposure of various tissues, including adipose tissue, to glucocorticoids, which can contribute to visceral and liver fat accumulation.[10] Adipose tissue contains EC receptors, and overactivation of the EC system may occur in visceral obesity, leading to altered metabolism of visceral adipocytes.[50] Lifestyle changes inducing weight loss can mitigate such overactivity of the EC system.[51] Drugs developed to reduce the activity of the EC system had shown promising results in inducing selective losses of visceral adipose tissue and liver fat, but their unwanted effects compromised their clinical use.[52]

Drugs

Clinicians should consider whether medications might contribute to a patient's excess weight and body fat.[53] **Table 50.2** lists some key drugs that induce weight gain.[54]

TABLE 50.2

Drugs That May Lead to Weight Gain

CATEGORY	DRUGS
Antidiabetics	Insulin, sulfonylureas (many), meglitinides (nateglinide, repaglinide), glitazones (pioglitazone, rosiglitazone)
Antidepressants or mood stabilizers	Monoamine oxidase inhibitors (many), tricyclics (some; e.g., doxepin), serotonin reuptake inhibitors (some; e.g., paroxetine), mirtazapine, lithium
Antipsychotics	Clozapine, risperidone, olanzapine, quetiapine, haloperidol, perphenazine
Anticonvulsants	Carbamazepine, gabapentin, valproate
Antihistamines	Cycloheptadine, diphenhydramine, doxepin
Adrenergic blockers	Propranolol, doxazosin
Adrenal steroids	Corticosteroids

From Bray GA et al. Management of obesity. Lancet 2016;387:1947-56.

Lifestyle: Key Contributor to Visceral Obesity

Once identified, the overweight or obese patient with excess visceral/ectopic fat and increased CVD risk may benefit from pharmacotherapy, including antihypertensive and lipid-lowering agents, to improve risk factors, in accord with guidelines and the results of clinical trials.[55-58] Because excess body weight and obesity result largely from lifestyle, however, even for those with a genetic susceptibility, the clinician should also evaluate factors such as nutritional quality and level of physical activity.[59] Tools available for use in clinical practice have helped identify sedentary individuals and those with poor nutritional habits who could benefit substantially from improving lifestyle habits.[59,60] Our own lifestyle intervention studies have shown the value of targeting nutritional quality and sedentary behaviors to reduce waist circumference and improve cardiorespiratory fitness as well as CVD risk factors, irrespective of concomitant pharmacotherapy targeting intermediate CVD risk factors.[59,61] Patients in the waiting room may complete simple standardized questionnaires regarding diet and physical inactivity/activity. Food-based recommendations (less of some specific food categories and more of other, less-processed foods of high nutritional value and low energy density) combined with a written “lifestyle prescription” to reduce sedentary/sitting time and to introduce regular physical activity could contribute to substantially improve a patient's health profile.[59,62]

Clinical Tools to Identify Patients

Simple anthropometric tools can help to identify overweight and obese individuals with an excess of visceral adipose tissue/ectopic fat in clinical practice. As previously discussed, the simultaneous presence of an increased waistline for a given BMI and altered CVD risk factors should alert the clinician to the presence of excess visceral adiposity/ectopic fat. However, a large waistline alone cannot distinguish excess subcutaneous from visceral adiposity. Another simple clinical marker, plasma triglyceride levels, suggests the presence of excess visceral adipose tissue, a phenotype that we defined as “hypertriglyceridemic waist.”[63] For instance, the simultaneous presence of an increased waistline (≥90 cm in men, ≥85 cm in women) and high triglyceride levels (≥2.0 mmol/L in men, ≥1.5 mmol/L in women) predicted a 75% to 80% probability that a given individual had an excess of visceral adipose tissue and an altered cardiometabolic risk profile, a finding showing the importance of paying attention to these two markers..[63-65]

Clinical Management

Key Nutritional Factors (Toward a Food-Based Approach)

Although excess visceral adiposity and ectopic fat has a genetic basis, diet clearly plays a pivotal role. A diet rich in added sugar, refined carbohydrates, and saturated fat may favor the selective accumulation of visceral adipose tissue through as-yet poorly understood mechanisms.[66-69] Some simple precepts can guide clinician conversations with patients about dietary choices (**Table 50.3**). Recent guidelines and authoritative reviews have highlighted the potential of such an approach that is clearly more "user friendly" to patients than technical recommendations about diet macronutrient and fatty acid composition.[62,70,71] For example, the public health recommendation to decrease *saturated fat* in our diet, while still relevant, has unfortunately drifted to a reduction in *diet fat* content, which boosted the intake of refined carbohydrates and of refined products with a considerable amount of added sugar. Thus the low dietary fat message likely contributed to the current epidemic of obesity and type 2 diabetes.[62,72] Accordingly, lifestyle intervention trials focusing on reducing the fat content of the diet[73] and on caloric restriction and weight loss[19] have not improved cardiovascular outcomes. On the other hand, a trial that used a simple approach in overweight and obese patients (50% with diabetes), giving participants olive oil and mixed, nuts (PREDIMED), reported a significant reduction in cardiovascular outcomes, particularly the incidence of stroke.[74] The dietary intervention did not cause weight loss.[75] These results illustrate how overall nutritional quality, rather than caloric restriction and fat content of the diet, can improve cardiovascular outcomes.[75] (**See also Chapter 49**.)

International Chair on Cardiometabolic Risk "Eat Well, Drink Well, Move" Recommendations for Adults

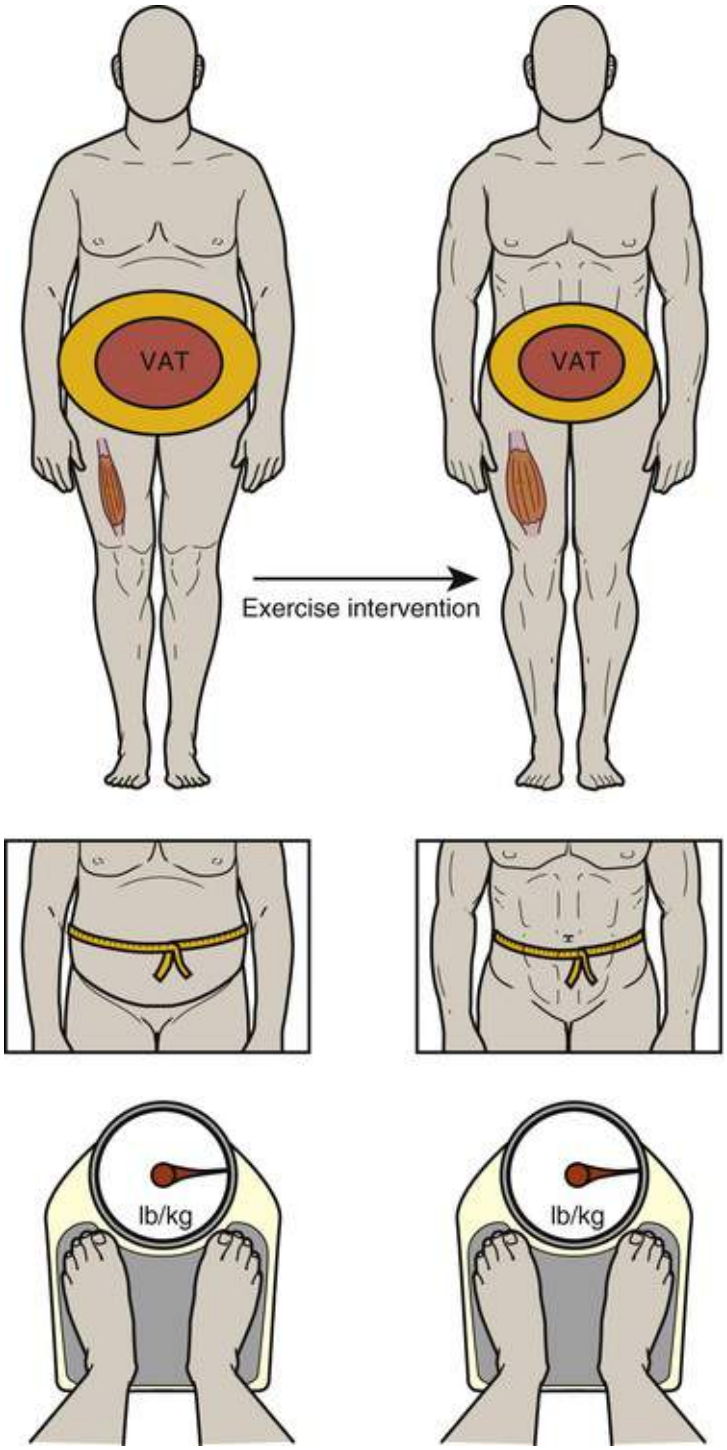
Eat Well*
• Olive and vegetable oils, nuts, seeds, legumes, grains (mostly whole), fruits, vegetables *Base every meals on these foods* • Eggs, poultry, cheese, yogurt, other dairy *Daily to weekly* • Fish, seafood *Often, at least two times per week* • Processed meat, red meat, sweets *Less often*
Drink Well†
• Water *On several occasions daily* • Tea or coffee *Daily* • Low-fat milk and soya-based beverages *Daily to weekly* • Diet drinks and 100% fruit juices *Occasionally* • Sugar-sweetened beverages *Sparingly*
Move
• Move as much as you can. • Do at least 150 minutes of moderate-intensity aerobic physical activity weekly or 75 minutes of vigorous-intensity aerobic physical activity weekly or a mix of both. • Do muscle-strengthening activities 2 or more days a week. • Limit screen time and sitting time.

*Drink water to hydrate yourself. Drink wine in moderation. This healthy diet pattern is good for humans and for the planet.

†Sugar-sweetened beverages (SSBs) refer to any beverages with added sugar and include, but are not limited to, regular soda, sugar-sweetened fruit drinks such as fruit punch and lemonade, and sports or energy drinks. The 100% fruit juices contain natural fruit sugars. Tea and coffee should be consumed preferably unsweetened.

Physical Activity and Exercise

Physical inactivity and sedentary behaviors (for which sitting and screen time are good markers) predict increased risk of developing chronic diseases, including cardiovascular conditions.[59,76] This association does not depend solely on adiposity. Moderate- to vigorous-intensity physical activity or exercise increases cardiorespiratory fitness, one of the key predictors of the risk of developing CVD, independent of adiposity.[77] Therefore, practitioners should include assessment of physical inactivity/activity level in their patient evaluations. Advice regarding physical activity along with nutritional counseling can reduce visceral adiposity while improving all features of the cardiometabolic risk profile.[59,78-80] Furthermore, because physical activity and exercise can increase lean body mass, body weight may not always reflect beneficial changes in body composition, and thus an increase in lean body mass can balance the loss of harmful visceral/ectopic fat, an outcome particularly beneficial for the elderly frail patient (**eFig. 50.4**). Weight loss should not be the sole target for CVD risk reduction in the management of overweight and obese patients.[60,81]



EFIGURE 50.4 Effects of exercise intervention on body weight, waist circumference, and visceral adipose tissue (VAT) in a sedentary, viscerally obese individual. Even in the absence of weight loss resulting from an increase in muscle mass, exercise is associated with a reduction in waist circumference and VAT in a sedentary individual.

Sleep and Stress Management

Sleep duration and quality can also influence energy balance and metabolism.[82] The most obvious group of patients with disturbed sleeping habits are those with *sleep apnea,* a condition frequently observed among sedentary overweight and obese patients, particularly those with an excess of visceral/ectopic fat.[83] The viscerally obese patient with sleep apnea or with episodes of apnea/hypopnea may enter a vicious cycle in which the fatigue associated with the poor quality of sleep may lead to additional inactivity, exacerbating their already disturbed cardiometabolic risk profile. Several mechanisms may link visceral adiposity/ectopic fat to sleep apnea, including physical obstruction of the upper airways by

soft tissues infiltrated with fat.[84] Treatment of sleep apnea by positive-pressure devices may help progressively improve sleep quality of the viscerally obese patient and help break this cycle. Lifestyle intervention studies have also shown that weight loss in sleep apnea patients substantially improves their cardiometabolic risk profile.[82] In addition, because stress contributes to the selective accumulation of visceral/ectopic fat,[10] stress management strategies may constitute another measure to improve the lifestyle of these high-risk patients. (**See also Chapter 87**.)

Pharmacotherapy

Pharmacologic tools to treat high-risk overweight and obese patients are limited by a lack of evidence for efficacy or long-term benefit.[54] Drugs currently approved for the chronic management of obesity have not yet demonstrated improved cardiovascular outcomes or efficacy in reducing visceral adipose tissue or ectopic fat[54] (**Table 50.4**).

TABLE 50.4

Weight Loss Drugs Available in the United States* and European Union†

DRUGS	MECHANISM OF ACTION
Phentermine* (15-30 mg orally)	Sympathomimetic
Orlistat*† (120 mg orally three times a day before meals)	Pancreatic lipase inhibitor
Lorcaserin* (10 mg orally twice a day)	5-HT_{2C} serotonin agonist with little affinity for other serotonergic receptors
Phentermine/Topiramate ER* (7.5 mg/46 mg or 15 mg/92 mg orally indicated as rescue; requires titration)	Sympathomimetic anticonvulsant (GABA receptor modulation, carbonic anhydrase inhibition, glutamate antagonism)
Naltrexone SR/bupropion SR*† (32 mg/360 mg orally; requires titration)	Opioid receptor antagonist; dopamine and noradrenaline reuptake inhibitor
Liraglutide*† (3.0 mg injection; requires titration)	GLP-1 receptor agonist

ER, Extended release; *SR,* sustained release; *GLP,* glucagon-like peptide.

From Bray GA et al. Management of obesity. Lancet 2016;387:1947-56.

Recently, trials of diabetes drugs with mechanisms that also impact energy balance and induce weight loss have shown, for the first time, a significant influence on reducing adverse cardiovascular outcomes[17,18] (**see Chapter 51**). Imaging studies could test to what extent the loss of visceral/ectopic fat that may be associated with these drugs could contribute to the observed reduction in CVD risk.

Severe Obesity and Bariatric Surgery

Between 1986 and 2000, individuals with a BMI ≥30, ≥40, and ≥50 kg/m^2 have doubled, quadrupled, and quintupled, respectively, in the United States.[85] In Canada the prevalence of severe obesity, defined as a BMI of ≥40 or ≥35 kg/m^2 with comorbidities, rose by 533% between 1985 and 2011.[86] Severe obesity is associated with increased morbidity and all-cause mortality and represents a major health care problem.[87] Caucasian women 20 to 30 years old with BMI ≥45 kg/m^2 will lose 8 years of life, and their male counterparts will lose 13 years.[8] The three principal treatments for severe obesity are changes in lifestyle habits, pharmacotherapy, and bariatric surgery. Bariatric surgery can be either *restrictive* or *hybrid*, a combination of restriction and malabsorption[88] (**Fig. 50.6**). From an evidence-based perspective, of these three options, only bariatric surgery yields substantial long-term weight loss and durably improves cardiometabolic risk in the severely obese patient (**Table 50.5**).

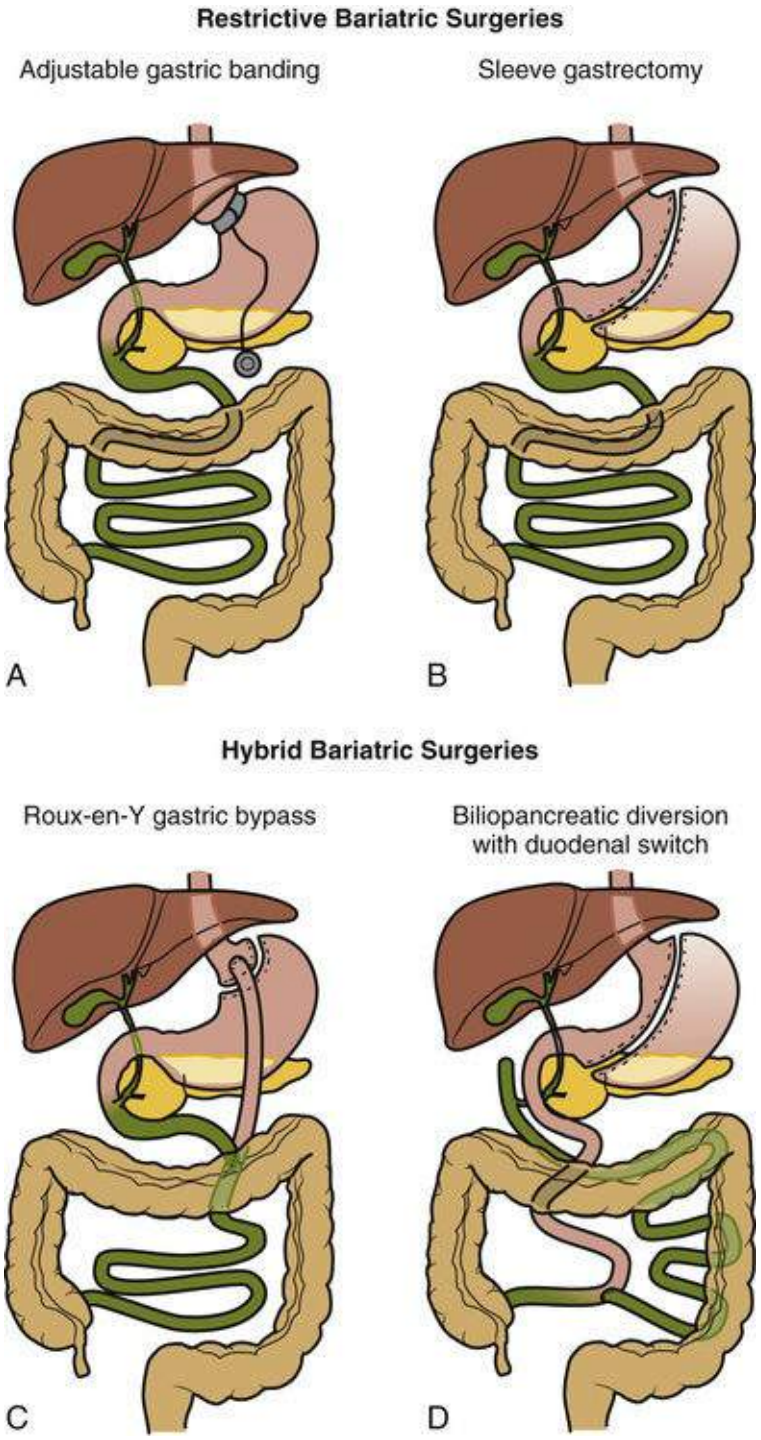


FIGURE 50.6 Restrictive (**A** and **B**) and hybrid (**C** and **D**) bariatric surgeries. *Dark pink,* Alimentary limb, food passage. *Light green,* Biliopancreatic limb, digestive juices from the stomach, bile, and pancreas. *Dark green,* Common limb, food mixed with digestive juices from the stomach, bile, and pancreas.

TABLE 50.5

Outcomes of Bariatric Surgery

	RESTRICTIVE PROCEDURES		HYBRID PROCEDURES	
	Adjustable Gastric Banding	**Sleeve Gastrectomy**	**Roux-en-Y Gastric Bypass**	**Biliopancreatic Diversion With Duodenal Switch**
Mortality Rates				
<30-day	0-0.10%	0.13-0.50%	0.15-1.15%	0.30-1.20%
Complications	0.2% to 20.0% (all procedures)			
Weight Loss				
1 year	14-30%	20-28%	23-43%	38-52%
2-5 years	17-35%	21%	30-42%	34-53%
≥6 years	13-14%	22%	25-28%	36-55%
Comorbidities Resolution				
Type 2 Diabetes				
1 year	23-61%	37-81%	17-93%	59-95%
2-5 years	20-74%	14-86%	50-84%	90-100%

1 year	17%	16-83%	33-47%	33-65%
2-5 years	23-61%	5-48%	52-97%	70-100%
Hypertension				
1 year	19-55%	15-82%	20-45%	24-53%
2-5 years	17-64%	25-75%	29-80%	57-85%
Sleep Apnea				
1 year	78%	52-100%	33-100%	100%
2-5 years	33-96%	39-91%	67-80%	74-92%

From Piché MA et al. How to choose and use bariatric surgery in 2015. Can J Cardiol 2015;31:153-66.

Bariatric surgery improves CVD risk factors and reduces the incidence of type 2 diabetes, cancer, and overall mortality.[89,90] The Swedish Obese Subjects study showed that bariatric surgery reduced cardiovascular events by 30% and cardiovascular deaths by 50% in almost 15 years of follow-up in severely obese patients, compared with those who received usual care.[90]

In obese patients with type 2 diabetes, bariatric surgery provides clinical benefits such as improved glycemic control and cardiometabolic risk profile.[91,92] Debate surrounds whether less severely obese patients should undergo surgical intervention.[93]

Surgical techniques differ in terms of morbidity and mortality, magnitude of weight loss, weight loss maintenance, and rate of resolution of comorbidities over time.[7,88] Hybrid procedures appear most effective in terms of the amount of weight loss and the improvement in comorbidities.[8,91,92] Early complications (<30 days) after bariatric surgery are less than 10% and tend to be lower in restrictive surgeries than hybrid surgeries, and 30-day operative mortality rates range from 0.1 to 1.2%.[88] Severe obesity disturbs cardiac structure and function as a result of left ventricular (LV) remodeling and LV systolic and diastolic dysfunction.[88] Increased pulmonary vascular resistance and pulmonary artery pressure resulting in an increase in right ventricular (RV) afterload may also occur in patients with severe obesity, causing RV hypertrophy, enlargement, and dysfunction.[94,95] Bariatric surgery can improve cardiac geometry as well as diastolic and systolic function of both ventricles.[89,96]

In the 1991 consensus the U.S. National Institutes of Health reported that bariatric surgical therapy should be proposed to those patients with a BMI >40 or >35 kg/m^2 with serious obesity-related comorbidities such as systemic hypertension, type 2 diabetes, and obstructive sleep apnea (OSA).[97] Currently, several guidelines provide eligibility criteria for bariatric surgery. The American Diabetes Association,[98] International Diabetes Federation,[99] and other organizations[2,93] have issued consensus statements identifying bariatric surgery as the only proven effective option for sustainable weight loss and weight control inducing beneficial clinical outcomes in patients with severe obesity. They have proposed bariatric surgery therapy for adult patients with BMI ≥40 kg/m^2 or BMI ≥35 kg/m^2 with obesity-related comorbidities (e.g., hypertension, diabetes, OSA) that are difficult to control with lifestyle and

pharmacotherapy. No guideline suggests that one procedure is more appropriate than the others for cardiac patients.

Summary and Perspectives

It is important to assess and manage high-risk overweight and obese patients in cardiovascular practice. Because of the increasing worldwide prevalence of overweight/obesity, cardiovascular specialists manage many overweight and obese patients, a number of whom also have excessive visceral adipose tissue/ectopic fat. Several simple metrics can alert practitioners to this metabolically dangerous condition, notably an elevated waistline (for a given BMI) and increased triglycerides. In addition, the clinician's evaluation should include simple lifestyle markers such as duration and quality of sleep, overall food-based nutritional quality, sedentary/sitting time, level of moderate/vigorous physical activity, and cardiorespiratory fitness, as well as medications that promote weight gain.

Many current curricula provide only limited exposure of physicians and trainees to the importance of and tools for assessing and targeting lifestyle in overweight and obese patients. Physicians should never underestimate the potential impact on their patients' lifestyle as role models. A patient could be greatly influenced by a physician who would pay equal attention to his/her waistline, nutritional quality, physical activity level, and quality of sleep as to his/her cholesterol, BP and blood glucose.[100] Finally, we must recognize that the epidemic proportions reached by obesity and type 2 diabetes reflect societal conditions that extend beyond the traditional medical model. As key stakeholders, physicians can advocate for environments that promote human health rather than disease.[101]

Diabetes and the Cardiovascular System

Darren K. Mcguire, Silvio E. Inzucchi, Nikolaus Marx

Scope of the Problem

Diabetes Mellitus

Diabetes mellitus involves insufficient production of insulin, failure to respond appropriately to insulin, or both, resulting in hyperglycemia. **Table 51.1** summarizes the current diagnostic criteria.[1] Insulin resistance and relative insulin deficiency characterizes type 2 diabetes (>90% of all diabetes cases),

whereas absolute insulin deficiency characterizes type 1 diabetes. In view of the excess and increasing prevalence of type 2 diabetes and its incremental cardiovascular (CV) risk compared with type 1 diabetes, this chapter focuses on type 2 diabetes, except when specifically indicated otherwise.

TABLE 51.1

American Diabetes Association Diagnostic Criteria for Diabetes Mellitus*

1. Fasting plasma glucose (FPG) ≥126 mg/dL (7.0 mmol/L). Fasting is defined as no caloric intake for at least 8 hours. *or*
2. Two-hour plasma glucose ≥200 mg/dL (11.1 mmol/L) during an oral glucose tolerance test (OGTT). The test should be performed as described by the World Health Organization, using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water. *or*
3. Glycated hemoglobin (A_{1c}) ≥6.5% (48 mmol/mol). The test should be performed in a laboratory using a method that is National Glycohemoglobin Standardization Program (NGSP) certified and standardized to the Diabetes Control and Complications Trial (DCCT) assay. *or*
4. In a patient with classic symptoms of hyperglycemia or hyperglycemic crisis, a random plasma glucose ≥200 mg/dL (11.1 mmol/L).

*Criteria 1 to 3 require confirmatory testing; criterion 4 does not.

Modified from American Diabetes Association: Diagnosis and classification of diabetes mellitus. Diabetes Care 2016;39(Suppl 1):S13-22.

Diabetes, one of the most common chronic diseases in the world, affects an estimated 285 million adults in 2010.[2] The mounting incidence and prevalence of type 2 diabetes, driven by increasing population age, obesity, and physical inactivity, compound this high global burden (**see Chapters 1, 45, and 50**), as does the increasing longevity of patients with the disease. It is estimated that diabetes will affect more than 430 million persons, 7.7% of the global adult population, by 2030[2] (**Fig. 51.1**).

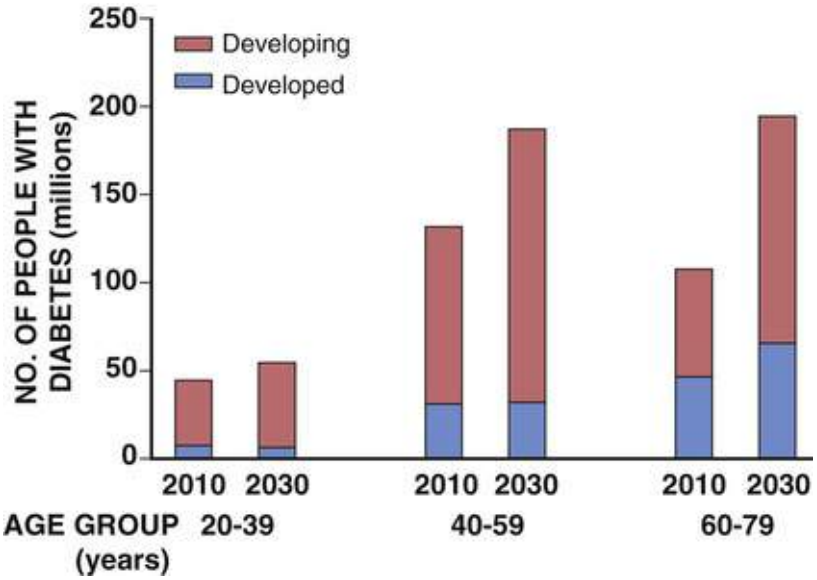

FIGURE 51.1 Estimated number of adults with diabetes in 2010 and projected for 2030 stratified by age group, with projections for the overall global population, and by developed and developing country categories. (From Shaw JE, Sicree RA, Zimmet PZ. Global estimates of the prevalence of diabetes for 2010 and 2030. Diabetes Res Clin Pract 2010;87:4, 2010.)

Cardiovascular disease (CVD) remains the principal comorbid condition and primary contributor to mortality in the patient with diabetes, usually in the form of coronary heart disease (CHD), but also in the incremental risk associated with diabetes for cerebrovascular disease, peripheral vascular disease, heart failure (HF), and atrial fibrillation (AF). For these reasons, continuing effort toward mitigating the risk of CVD in diabetes remains a global public health imperative.

Atherosclerotic Vascular Disease

Patients with diabetes have a twofold to fourfold increased risk for CHD, CV mortality, and all-cause mortality compared to those without diabetes[3] (**Fig. 51.2**). Although older studies suggested a diabetes-associated CVD risk similar to that for nondiabetic patients with a prior myocardial infarction (MI), more recent observations from trials of patients with diabetes demonstrate substantially lower risk, most likely reflecting effectiveness of contemporary therapeutic interventions.[4] Still, CV risk and mortality in patients with diabetes remain significantly increased over those without diabetes, underscoring the substantial remaining residual CVD risk of diabetes and its unmet clinical need[5] (**Fig. 51.3**).

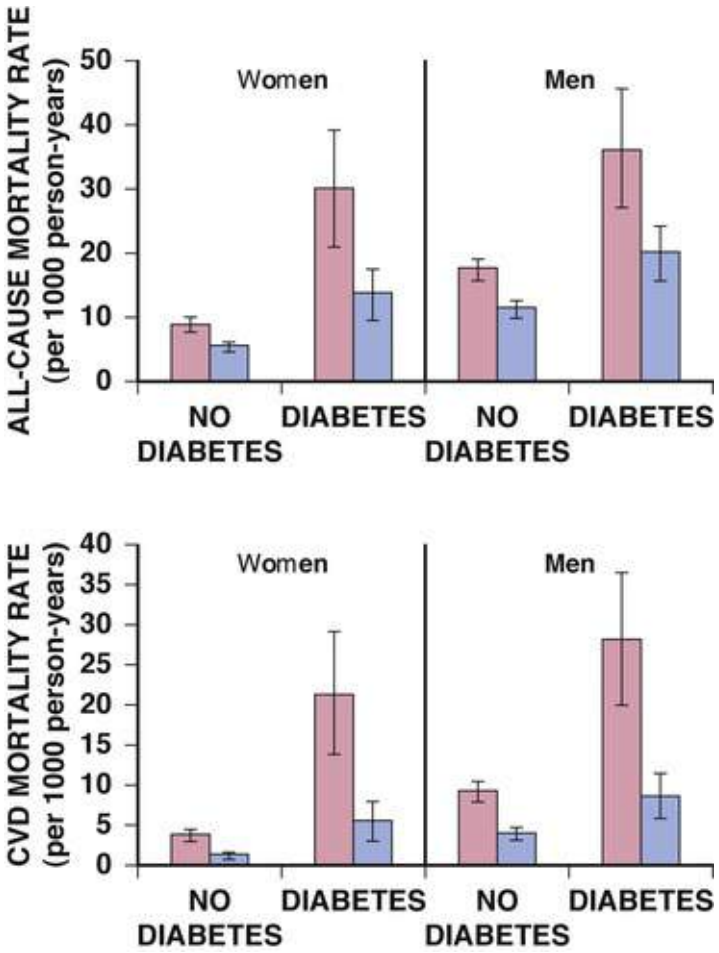

FIGURE 51.2 Age-adjusted all-cause **(top)** and cardiovascular disease (CVD) **(bottom)** mortality rates among Framingham Heart Study participants with and without diabetes mellitus by sex and time period. *Pink bars* represent earlier time period (1950 to 1975); *blue bars* represent later time period (1976 to 2001). Bars indicate 95% confidence intervals. Rates are adjusted for age in 10-year intervals. (From Preis SR, Hwang SJ, Coady S, et al. Trends in all-cause and cardiovascular disease mortality among women and men with and without diabetes mellitus in the Framingham Heart Study, 1950 to 2005. Circulation 2009;119:1728.)

Disease status at baseline	No. of participants	No. of deaths	Person-years	Mortality rate (95% CI)[a]	Hazard ratio (95% CI)	I^2 (95% CI)
Diabetes, stroke, and MI	541	379	3584	59.5 (47.0–71.9)	6.9 (5.7–8.3)	51 (38–62)
Stroke and MI	1836	1174	14,210	32.8 (28.1–37.6)	3.5 (3.1–4.0)	61 (52–69)
Diabetes and stroke	1321	778	10,234	32.5 (27.0–37.9)	3.8 (3.5–4.2)	18 (0–38)
Diabetes and MI	3233	1794	25,321	32.0 (28.1–35.9)	3.7 (3.3–4.1)	69 (62–75)
MI	21,591	9636	216,081	16.8 (15.2–18.3)	2.0 (1.9–2.2)	84 (80–86)
Stroke	8583	3814	82,208	16.1 (14.4–17.8)	2.1 (2.0–2.2)	50 (36–61)
Diabetes	24,677	8087	254,608	15.6 (14.1–17.0)	1.9 (1.8–2.0)	76 (70–80)
None	627,518	103,181	8,772,977	6.8 (6.2–7.4)	1 [Reference]	

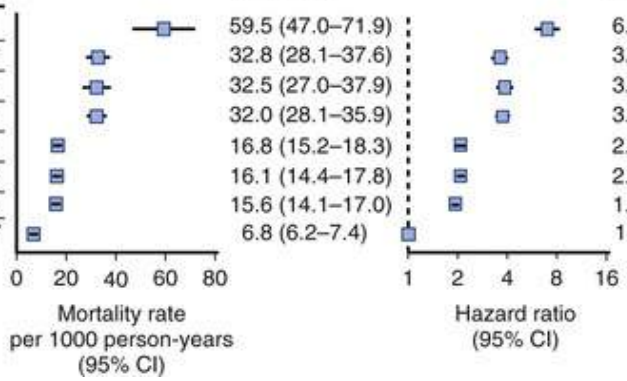

FIGURE 51.3 All-cause mortality by disease status of participants at baseline for the Emerging Risk Factors Collaboration. The mortality rates were calculated using a Poisson regression model and are sex-adjusted rates to age 60 years. The hazard ratios were calculated using a Cox proportional hazards regression model and are stratified by sex and adjusted by age at baseline. Analyses were based on participants from 91 studies. MI, Myocardial infarction. [a]Mortality rate is per 1000 person-years. (From Di Angelantonio E, Kaptoge S, Wormser D, et al; Emerging Risk Factors Collaboration. Association of cardiometabolic multimorbidity with mortality. JAMA 2015;314:52-60.)

Diabetes is associated with an increased risk for MI. Across the spectrum of acute coronary syndrome (ACS) events, in which diabetes may affect more than one in three patients, those with diabetes have worse CVD outcomes after ACS events[6] (**see Chapters 58 to 60**). Despite overall improvements in outcomes during the past several decades for ACS patients with and without diabetes, the gradient of risk associated with diabetes persists (**Fig. 51.4**), although incremental in-hospital mortality risk associated with diabetes after an ACS event has declined (**Fig. 51.5**).[6] Furthermore, the graded association of increased risk observed with diabetes in the setting of ACS extends to glucose values in the range well below the diabetes threshold (**Fig. 51.6**).

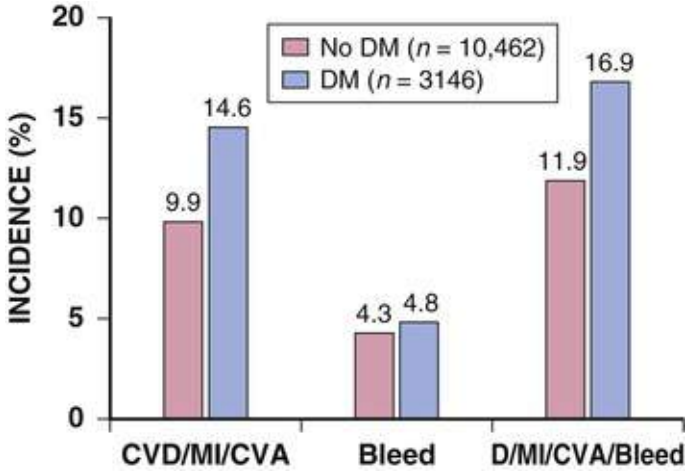

FIGURE 51.4 Adverse clinical outcomes after acute coronary syndromes during more than 1 year of follow-up, according to diabetes status, among patients participating in the TRITON–TIMI 38 randomized trial. CVA, Cerebrovascular accident (stroke); CVD, cardiovascular death; D, death; DM, diabetes mellitus; *MI,* myocardial infarction. (Modified from Wiviott SD, Braunwald E, Angiolillo DJ, et al. Greater clinical benefit of more intensive oral antiplatelet therapy with prasugrel in patients with diabetes mellitus in the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel-Thrombolysis in Myocardial Infarction 38. Circulation 2008;118:1626.)

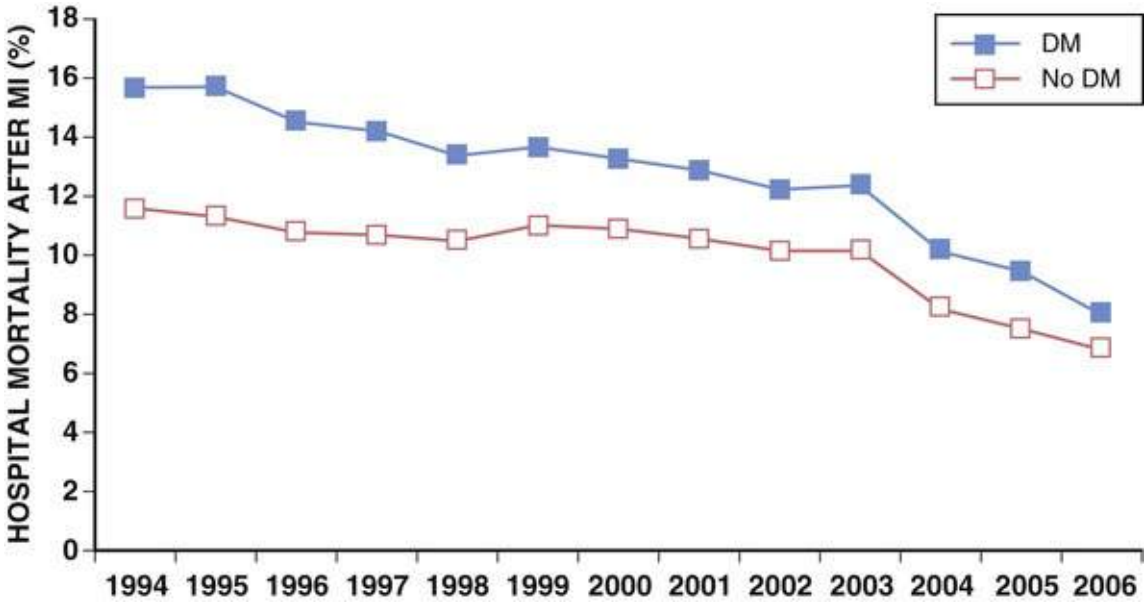

FIGURE 51.5 Unadjusted hospital mortality after myocardial infarction (MI) by year of study enrollment according to diabetes mellitus (DM) status (in-hospital deaths as percentage of total number of patients enrolled during each year of the study) among 1,734,431 patients with acute MI registered in the National Registry of Myocardial Infarction (NRMI), 1994 to 2006. (From Gore MO, Patel MJ, Kosiborod M, et al. Diabetes mellitus and trends in hospital survival after myocardial infarction, 1994 to 2006: data from the National Registry of Myocardial Infarction. Circ Cardiovasc Qual Outcomes 2012;5:791.)

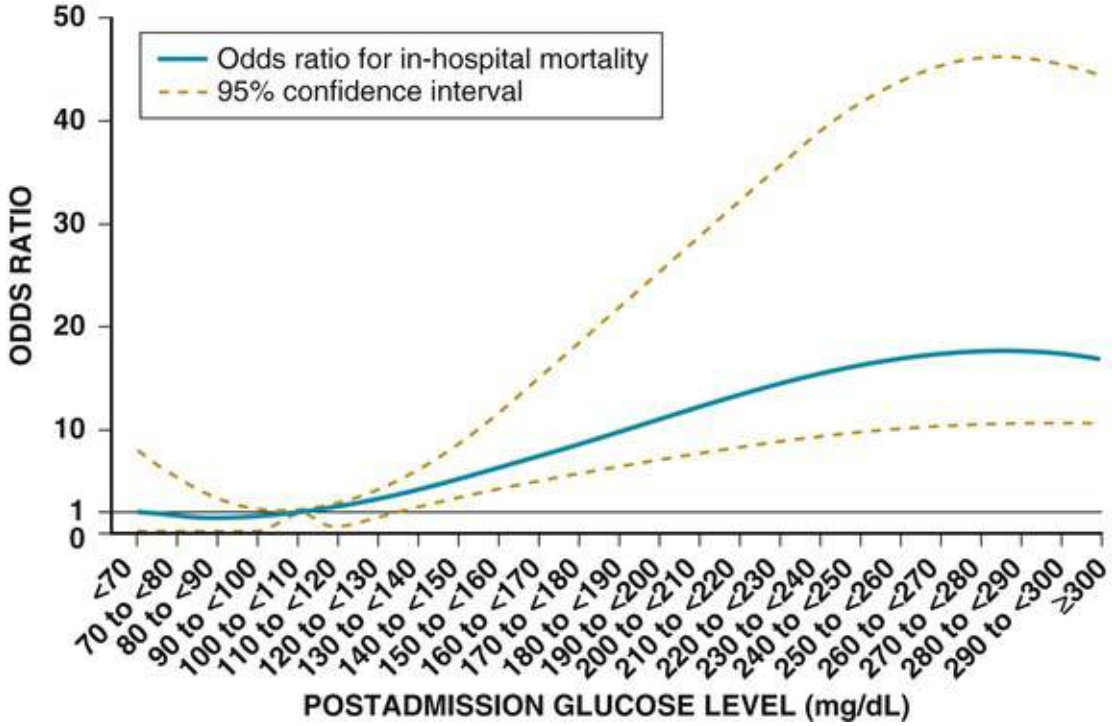

FIGURE 51.6 Postadmission glucose levels and mortality in cohort of patients admitted for acute MI with hyperglycemia on arrival, after multivariable adjustment (to convert glucose values to millimol/liter, multiply by 0.0555). (From Kosiborod M, Inzucchi SE, Krumholz HM, et al. Glucose normalization and outcomes in patients with acute myocardial infarction. Arch Intern Med 2009;169:438.)

In addition to CHD, diabetes increases the risks of stroke, cerebrovascular disease, and peripheral arterial disease. Diabetic patients have a twofold increased stroke risk compared with nondiabetic persons[5] (**see Chapter 65**). Multiple diabetes-related factors contribute to the incremental stroke risk, including multiple common comorbidities of type 2 diabetes mellitus (DM), each independently

associated with stroke risk, such as AF, hypertension, ischemic heart disease, obesity, and dyslipidemia. Hyperglycemia affects approximately one in three patients with acute stroke and is associated with a twofold to sixfold increased risk for subsequent adverse clinical outcomes.

Heart Failure

In the ambulatory setting, diabetes is associated independently with a twofold to fivefold increased risk for HF over that in persons without diabetes, and patients with diabetes have worse outcomes once HF has developed.[7] For decades, basic science research, as well as the development of novel therapeutic options for CV risk reduction in patients with diabetes, focused primarily on atherosclerosis-related events. Only recently, HF in diabetes has gained recognition as a key driver of CV morbidity and mortality, leading to the inclusion of HF as a major endpoint in contemporary clinical trials.[7]

Atrial Fibrillation

Diabetes increases risk for AF, and in the patient with AF, diabetes increases absolute stroke rate/year by 2% to 3.5% (**see Chapter 65**).[8] However, it remains uncertain as to what degree diabetes independently augments risk for AF, largely because of the difficulty in adjusting for risk factors common to both diseases. The inclusion of diabetes as one of seven categorical classifications used in the CHA_2DS_2–VASc score[9] and guideline recommendations for anticoagulation for all diabetes patients who have AF affirm the stroke risk associated with diabetes in the setting of AF.[10]

Coronary Heart Disease in the Patient With Diabetes

Mechanistic Considerations Linking Diabetes and Atherosclerosis

Traditional CHD risk factors such as hypertension, dyslipidemia, and adiposity cluster in patients with diabetes (**see Chapters 45 to 50**). However, this clustering does not completely account for the increased CHD risk observed among patients with diabetes, with numerous other implicated mechanisms (**Table 51.2**).

TABLE 51.2

Examples of Mechanisms Implicated in Diabetic Vascular Disease

Endothelium	↑ NF-κB activation ↓ Nitric oxide production ↓ Prostacyclin bioavailability ↑ Endothelin 1 activity ↑ Angiotensin II activity ↑ Cyclooxygenase type 2 (COX-2) activity ↑ Thromboxane A_2 activity ↑ Reactive oxygen species ↑ Lipid peroxidation products ↓ Endothelium-dependent relaxation ↑ RAGE expression
Vascular smooth muscle cells and vascular matrix	↑ Proliferation and migration into intima ↑ Increased matrix degradation Altered matrix components
Inflammation	↑ IL-1β, IL-6, CD36, MCP-1 ↑ ICAMs, VCAMs, and selectins ↑ Activity of protein kinase C ↑ AGEs and AGE-RAGE interactions

AGEs, Advanced glycation end products; *ICAMs,* intracellular adhesion molecules; *IL,* interleukin; *MCP,* monocyte chemoattractant protein; *NF,* nuclear factor; *RAGE,* receptor for advanced glycation end products; *VCAMs,* vascular cell adhesion molecules.

Modified from Orasanu G, Plutzky J. The pathologic continuum of diabetic vascular disease. J Am Coll Cardiol 2009;53:S35.

The mechanisms by which hyperglycemia may increase atherosclerotic risk remain poorly understood, but given the associations between severity of hyperglycemia and risk for atherosclerosis in both type 1 and type 2 DM, it probably directly influences atherosclerosis development, progression, and instability. The principal vascular perturbations linked to hyperglycemia include endothelial vasomotor dysfunction, vascular effects of advanced glycation end products, adverse effects of circulating free fatty acids, increased systemic inflammation, and a prothrombotic state. *Endothelial vasomotor dysfunction,* a hallmark of diabetic vascular disease, is associated with increased hypertension and adverse CVD outcomes. The myriad mechanisms contributing to endothelial dysfunction include abnormal nitric oxide biology, increased circulating endothelin and angiotensin II, and reduced prostacyclin (i.e., prostaglandin I_2) activity, all of which contribute to perturbations in the regulation of blood flow. Abnormalities in lipid metabolism also contribute to the increased atherosclerotic risk associated with diabetes (**see Chapters 45 and 48**). High triglyceride (TG) levels, low levels of high-density lipoprotein cholesterol (HDL-C), and increased small, dense low-density lipoprotein (LDL) particles characterize diabetic dyslipidemia, and each may contribute to the accelerated development and progression of atherosclerosis.

Perturbations in the coagulation and fibrinolytic pathways and in platelet biology add to the vascular risk of diabetes, yielding a constitutive prothrombotic milieu.[11] These abnormalities include increased circulating tissue factor, factor VII, von Willebrand factor, and plasminogen activating inhibitor 1, with decreased levels of antithrombin III and protein C. In addition, disturbances of platelet activation, aggregation, morphology, and life span further contribute to increased thrombotic potential, as well as to the acceleration of atherosclerosis.

Increased systemic inflammation portends an increased risk for diabetes and associated CVD, associated with increased oxidative stress and the accumulation of advanced glycation end products.[11] For example, diabetes is associated with lipid-rich atherosclerotic plaque with increased inflammatory cell content, expression of tissue factor, and expression of the receptor for advanced glycation end products.

Prevention of Coronary Heart Disease and Its Complications

in the Diabetic Patient

Therapeutic lifestyle interventions remain the cornerstone of prevention of the atherosclerotic complications associated with diabetes. As recommended by the American Diabetes Association (ADA), American Heart Association (AHA), European Society of Cardiology (ESC), and European Association for the Study of Diabetes (EASD), therapeutic lifestyle targets include smoking abstinence, 150 minutes or more of aerobic activity weekly, weight control, and healthy diet habits.[10,12-14]

Beyond lifestyle, pharmacologic strategies effectively reduce CVD risk in diabetes.[10,13,15] Such interventions include assiduous blood pressure (BP) and LDL cholesterol (LDL-C) management for all patients, and for patients at highest risk, angiotensin-converting enzyme (ACE) inhibitors independent of BP, and consideration for daily aspirin.[10,13,15] In the context of these evidence-based CVD interventions, the accumulated data regarding the effects of glucose control on CVD risk mitigation remain far less robust.[14,15]

Lipid Management

Type 2 DM is associated with a characteristic pattern of dyslipidemia, reviewed in detail in **Chapter 48**. Each component of the diabetic dyslipidemia profile is independently associated with CVD risk, including increased small dense LDL particles, increased apolipoprotein B concentration, increased TG levels, and decreased HDL-C. Despite extensive research in modifying TG and HDL-C levels with a variety of pharmacologic agents, however, the net influence on CVD risk of these strategies remains uncertain, and statin treatment remains the cornerstone of therapeutic lipid intervention in patients with diabetes (**see Chapter 45**).

Statins

Contemporary guidelines for the management of diabetic dyslipidemia focus on the use of statin medications,[10,13,15,16] with estimates of numbers needed to treat to prevent one major adverse CVD complication over 5 years in the setting of diabetes: 39 for primary prevention and 19 among patients with prevalent CVD (**see Chapters 45 and 48**). These guidelines do not require elevation of LDL-C as a requisite for statin therapy for patients with diabetes and are recommended for all diabetic patients age 40 or older with one or more CVD factors, as well as younger patients with prevalent CVD, with most endorsing a target of at least LDL-C less than 100 mg/dL, or 35% to 50% reduction from baseline.[10,13,15] A recent update has endorsed an optional more intensive target for patients with diabetes of LDL-C less than 70 mg/dL and non–HDL-C less than 100 mg/dL.[13] The AHA/American College of Cardiology Foundation (ACCF) lipid management guideline recommends statin prescription at an intensity predicated on estimated 10-year risk for atherosclerotic vascular disease (ASCVD),[16] independent of LDL-C level or specified LDL-C or non-HDL-C targets. Patients with diabetes exceeding 7.5% estimated 10-year ASCVD risk should receive at least moderate-intensity statin therapy. These guidelines also discourage add-on lipid-modifying therapies, such as ezetimibe, bile acid binders, fibric acid derivatives, fish oil, or niacin, reserving their use for patients intolerant of statins.

Intensive-dose versus moderate-dose statin therapy further reduces CVD risk. Intensive-dose statin is associated with hastened onset of diabetes due to unknown mechanisms.[17] Whether intensive-dose statin therapy adversely affects glucose control among patients with diabetes remains uncertain. In view of the potent favorable influence of statin therapy at reducing CVD risk, however, the observed adverse effects on glucose indices should not discourage aggressive use of intensive-dose statin therapy in eligible patients with diabetes.

The ESC guidelines endorse a treat-to-target approach.[18,19] According to their individual risk estimation, patients with diabetes have high or very high CVD risk, with "very high risk" defined by the presence of target-organ damage, such as proteinuria, or with at least one additional major CV risk factor, such as smoking, marked hypercholesterolemia, or marked hypertension. These patients should achieve an LDL-C target of less than 70 mg/dL, or achieve a decrease in LDL-C of at least 50%. Most other patients with diabetes are categorized as "high risk," with an LDL-C target of less than 100 mg/dL.

Ezetimibe.

Ezetimibe inhibits the intestinal cholesterol transporter Niemann-Pick C1-like 1 (NPC1L1). The Improved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT) assessed the effect of more intensive LDL-C targets with simvastatin/ezetimibe versus standard target control using simvastatin in 18,144 patients following ACS events, with LDL-C levels above contemporary targets.[20] After a mean follow-up of 5.7 years, ezetimibe/simvastatin reduced LDL-C to 53.7 mg/dL versus 69.5 mg/dL in the simvastatin group and yielded a significant 6.7% relative risk reduction (RRR) for the primary composite endpoint of CV death, MI, stroke, hospitalization for unstable angina, or revascularization. Subgroup analyses of IMPROVE-IT showed that the benefit in the overall trial was mainly driven by a robust benefit in the diabetes subset. The results demonstrate that lowering LDL-C to levels below contemporary targets translates into a further reduction of CV events.

PCSK9 Inhibitors.

Another novel LDL-C–lowering strategy is inhibition of proprotein convertase subtilisin/kexin type 9 (PCSK9) with antibodies such as alirocumab or evolocumab (both approved in Europe and the United States), which has shown promising results in various patient populations, including those with diabetes (**see Chapter 48**). These antibodies potently reduce LDL-C by 40% to 60%, with similar effects in patients with or without diabetes.[21,22] The recently published FOURIER trial (NCT01764633) showed a significant 15% relative risk reduction for the primary composite endpoint of CV death, myocardial infacrtion, stroke, hospitalization for unstable angina, or coronary revascularization with evolocumab versus placebo in 27,564 patients with clinically evident CVD.[22a] At study baseline, 11,031 patients (40%) had diabetes. Evolocumab significantly reduced cardiovascular outcomes consistently in patients with and without diabetes at baseline. Evolocumab did not increase the risk of new-onset diabetes in patients without diabetes at baseline (HR 1.05, 0.94-1.17), including patients with prediabetes (HR 1.00, 0.89-1.13).[22b] The ongoing ODYSSEY outcome trial (NCT01663402) will examine the effect of alirocumab versus placebo on CV risk in 18,313 post-ACS patients who have been enrolled in the trial. The study includes a large number of patients with diabetes and should report in 2018.

Fibric Acid Derivatives (Fibrates).

Fibrates are agonists of the nuclear transcriptional regulator peroxisome proliferator–activated receptor alpha (PPAR-α) that lower triglycerides and modestly increase HDL-C, in addition to modest lowering of LDL-C. Although fibrates favorably affect two of the fundamental abnormalities of diabetic dyslipidemia beyond LDL-C lowering, the net CVD effects of this drug class remain uncertain, with no significant benefit observed in two CV outcomes trials of patients with type 2 DM, many of whom were treated with statins.[16] Subanalyses of these trials suggest that the subset of patients with baseline high triglycerides concomitant with low HDL-C may derive incremental CVD risk reduction with fibrates added to background therapy—a hypothesis pending confirmation in a dedicated randomized trial. Fibrates remain an option for patients with statin intolerance, for isolated hypertriglyceridemia in

patients with diabetes at otherwise low CVD risk, and as add-on therapy to maximally tolerated statin when patients do not achieve therapeutic targets, with the recognition of some increased myopathy risk when combined with a statin, in particular with gemfibrozil, which should *never* be combined with statin treatment.[23]

Omega-3 Fatty Acids.

Omega-3 fatty acids (fish oil) can reduce circulating triglycerides up to 40% (**see Chapters 45 and 48**), and hold promise in the treatment of diabetic dyslipidemia. With no interactions with statins, fish oil is attractive as an add-on therapy to statins for incremental TG reduction. A series of randomized trials demonstrated beneficial effects on CVD outcomes with fish oil, but subsequent results from the Outcome Reduction with an Initial Glargine Intervention (ORIGIN) randomized trial have challenged these findings. In ORIGIN, 12,536 patients with impaired fasting glucose, impaired glucose tolerance, or diabetes randomly received either a 1-g capsule containing at least 900 mg (≥90%) of ethyl esters of n-3 fatty acids or a capsule containing 1 g of olive oil daily.[24] The primary outcome was CV mortality. Over a median follow-up of 6.2 years with 1155 CV deaths to analyze, there was no effect on the primary outcome with fish oil versus control (9.1% versus 9.3%, respectively; $P = 0.72$). Fish oil remains a reasonable adjunct to statin therapy in patients with extremely high triglycerides (>500 mg/dL) to mitigate hyperviscosity or pancreatitis complications, with no clear evidence that it reduces CV risk.

Niacin.

The net CVD effects and safety of niacin, which potently raises HDL-C and lowers triglycerides, appears unfavorable. Two large-scale randomized outcome trials comprising evaluation of almost 30,000 patients demonstrated no CV benefit of niacin.[25,26] Thus, current data do not support the use of niacin.

Hypertension Management

Hypertension affects approximately 70% of patients with diabetes, with a steep-graded association between increasing BP and adverse CV outcomes[27] (**Fig. 51.7**) (**see Chapters 46 and 47**). Numerous classes of antihypertensive medications have proved especially effective at reducing CVD risk in patients with diabetes.[27] BP targets for diabetic patients have historically been more aggressive than for the overall population, with a goal of less than 130/80 mm Hg for diabetic patients who can tolerate such aggressive management without undue clinical burden, and a target of less than 140/80 mm Hg for all others.[10,12,15,27,28]

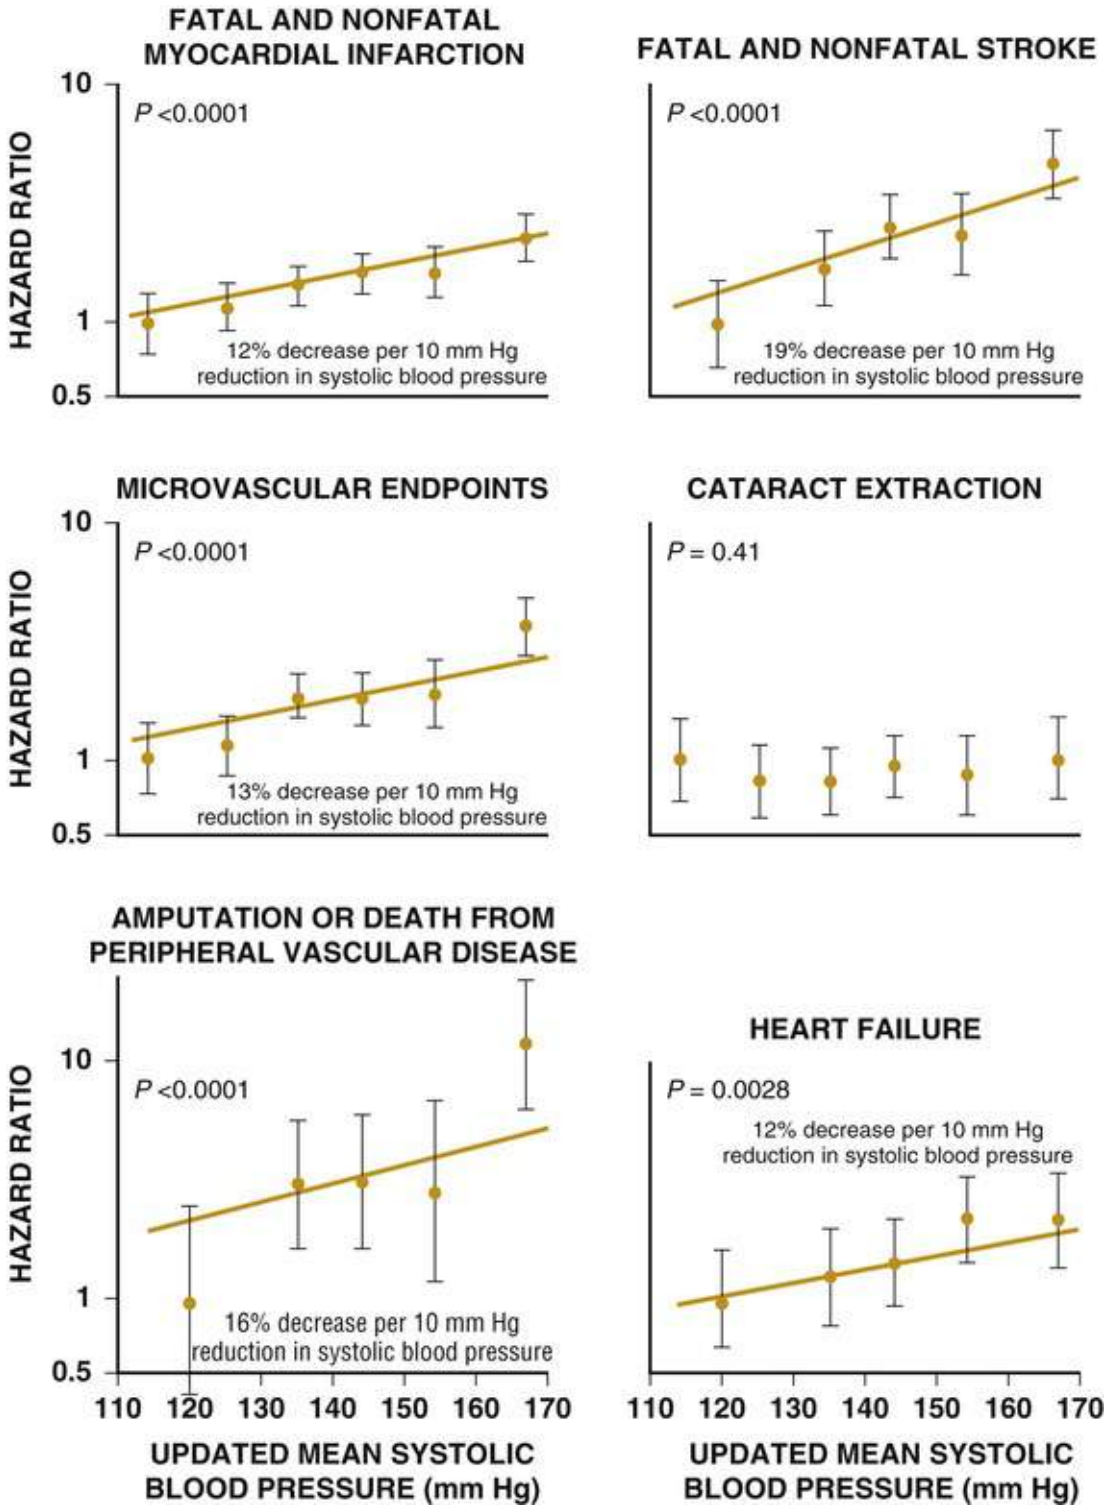

FIGURE 51.7 Hazard ratios (HR; 95% confidence intervals as floating absolute risks) as estimate of association between category of updated mean systolic blood pressure (BP) and myocardial infarction (MI), stroke, and heart failure (HF), with log linear scales. Reference category (HR of 1.0) is systolic BP less than 120 mm Hg for MI and less than 130 mm Hg for stroke and HF; *P* values reflect contribution of systolic BP to multivariable model. Data adjusted for age at diagnosis of diabetes, ethnic group, smoking status, presence of albuminuria, HbA_{1c}, HDL and LDL cholesterol, and triglyceride. (Modified from Adler AI, Stratton IM, Neil HA, et al. Association of systolic blood pressure with macrovascular and microvascular complications of type 2 diabetes [UKPDS 36]: a prospective observational study. BMJ 2000;321:412.)

Renin-Angiotensin-Aldosterone System Antagonists

ACE inhibitors and angiotensin II receptor blockers (ARBs) are cornerstones of therapy for hypertension in diabetes because of their favorable effects on diabetic nephropathy and CVD outcomes.[13,15,27]

Angiotensin-Converting Enzyme Inhibitors.

Data from randomized trials of patients with and without hypertension underpin the recommendation for ACE inhibitors as first-line agents for treatment of hypertension in the patient with diabetes. For example, the Heart Outcomes Prevention Evaluation (HOPE) trial compared ramipril (10 mg daily) with placebo in patients at increased risk for CVD and found that ramipril was superior to placebo in the diabetes subset of 3577 patients for the primary outcome of CV death, MI, and stroke (RRR, 25%; $P = 0.004$) and for overt nephropathy (RRR, 24%; $P = 0.027$).[27] Similar observations were reported from the diabetes subanalysis of the EUROPA (European Trial on Reduction of Cardiac Events with Perindopril in Stable Coronary Artery Disease) trial,[27] which tested perindopril versus placebo; with RRR of 19% among the 1502 participants with diabetes. On the basis of these results and support from meta-analyses of data from reported trials,[27] ACE inhibitors should be considered for all patients with diabetes who have prevalent CVD, a clustering of CVD risk factors, or nephropathy with or without albuminuria.[10,13,15]

Angiotensin II Receptor Blockers.

CV outcomes data for ARBs are much less robust than for ACE inhibitors, particularly in patients with diabetes. The Telmisartan Randomized Assessment Study in ACE Intolerant Subjects with Cardiovascular Disease (TRANSCEND) trial enrolled 5926 patients with intolerance to ACE inhibitors, randomly assigned to receive telmisartan (80 mg daily) or placebo, including 2118 patients with diabetes.[27] The overall trial failed to achieve statistical superiority for telmisartan versus placebo on the primary composite of CVD death, MI, stroke, and HF hospitalization (hazard ratio [HR], 0.92; 95% confidence interval [CI] 0.81 to 1.05), with the point estimate of effect completely neutral in the subset with diabetes. Guidelines from the ADA and AHA have endorsed ARBs and ACE inhibitors with similar levels of recommendation,[10,13,15] acknowledging the much weaker evidence for ARBs. ACE inhibitors should remain first-line agents, with ARBs reserved for patients intolerant of ACE inhibitors, and the two classes of medications should not be combined.[10]

Calcium Channel Blockers

Dihydropyridine calcium channel blockers (e.g., amlodipine, felodipine, nitrendipine, nisoldipine) are generally well tolerated and effectively lower BP. Analyses of data for diabetes subsets in randomized clinical trials suggest a magnitude of CVD clinical benefit similar to or greater than that observed in nondiabetic cohorts.[27]

Thiazide Diuretics

Concern about the adverse glycemic and triglyceridemic effects of the thiazide diuretic class of medications, including hydrochlorothiazide, chlorthalidone, indapamide, and bendroflumethiazide, has resulted in some degree of hesitancy regarding use of these medications in patients with diabetes. However, randomized trials of chlorthalidone and indapamide that included substantial numbers of patients with diabetes have consistently demonstrated CVD benefits. In a subanalysis of the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), the CVD effects of chlorthalidone compared with both lisinopril and amlodipine were similar in patients with diabetes or impaired fasting glucose, despite modest but statistically significant increases in incident diabetes associated with chlorthalidone use.[29] Also, the use of indapamide combined with perindopril in the Action in Diabetes and Vascular Disease: Preterax and Diamicron-MR Controlled Evaluation (ADVANCE) trial of 11,140 patients with diabetes was associated with superior CV outcomes.[30] A meta-

analysis of randomized trials further supports the benefits of chlorthalidone and indapamide in the treatment of patients with diabetes.[27] Given the absence of outcomes data with hydrochlorothiazide and bendroflumethiazide, their use is not recommended for patients with or without diabetes.[29]

Beta Blockers

Beta blockers have largely fallen out of favor for routine use as antihypertensive therapies[31] and in patients with diabetes. Beta blockers offer no benefit over other evidence-based classes of medications, with some concern for increased risk for a composite of CV disease, stroke, and HF based on recent meta-analysis.[27] Therefore, use of beta blockers should be primarily limited to patients with systolic HF (carvedilol, metoprolol succinate, or bisoprolol) and after MI. Beta blockers can also be used for antianginal therapy and for rate control of AF.

Antihypertensive Therapy Summary

Four classes of antihypertensive medications reduce CVD risk in patients with diabetes: ACE inhibitors, ARBs, calcium channel blockers, and thiazide diuretics (specifically, chlorthalidone, indapamide). Beta blockers have some evidence of efficacy but have no advantage for hypertension treatment over the other drugs, and their use for BP control should be reserved for patients not achieving target or unable to tolerate combinations of the other four medication classes. In addition, evidence supports a BP target of at least less than 140/80 mm Hg for all patients with diabetes, with a more intensive systolic BP target of less than 130 mm Hg for those patients who can achieve that target without excessive adverse effects.

Antiplatelet Therapy

Daily Aspirin

The ADA and AHA recommend daily aspirin (75 to 162 mg/day) for all patients with diabetes who have established CVD and for primary prevention in diabetic men older than 50 and diabetic women older than 60 who have additional CVD risk factors (or younger in those with prevalent CVD risk).[13,15] The 2013 ESC/EASD guidelines for primary prevention use of aspirin are more restrictive, recommending consideration for daily aspirin for only those patients with diabetes at the highest estimated CV risk.[10] A substantial evidence base in the setting of secondary CVD risk modification supports these recommendations, but a meta-analysis of primary prevention with aspirin in patients with diabetes failed to show statistically significant benefit.[32] Two randomized clinical trials are under way to explore further the role of aspirin for primary CVD risk prevention in patients with diabetes, ASCEND (NCT00135226) and ACCEPT-D (ISRCTN48110081). For patients with aspirin indication but with aspirin allergy or intolerance, $P2Y_{12}$ receptor antagonists may be considered, such as clopidogrel, prasugrel, or ticagrelor.[13,15]

Glucose Management

A total of 12 drug classes of antihyperglycemic medications are presently available for type 2 DM (**Table 51.3**), with complementary mechanisms of action, such as increasing endogenous or exogenous insulin supply, improving insulin action, enhancing the incretin system, delaying intestinal carbohydrate absorption, or increasing urinary glucose excretion. These agents are often used in combination, typically two or three drugs, to reduce hyperglycemia.

TABLE 51.3

Glucose-Lowering Medications for Type 2 Diabetes Mellitus

CLASS	COMPOUND(S)	CELLULAR MECHANISM	MAIN PHYSIOLOGIC ACTION(S)	ADVANTAGES	DISADVANTAGES	COST
Biguanides	Metformin	Activates AMP-kinase ? Other	↓ Hepatic glucose production ? Other	Extensive experience No weight gain No hypoglycemia Likely ↓ CVD events (UKPDS)	GI side effects (diarrhea, abdominal cramping) Lactic acidosis risk (rare) Vitamin B_{12} deficiency Multiple contraindications: advanced CKD, acidosis, hypoxia, dehydration, ethanol abuse, other	Low
Sulfonylureas	*Second generation*: Glyburide (glibenclamide) Glipizide Gliclazide* Glimepiride	Closes K_{ATP} channels on beta cell plasma membranes	↑ Insulin secretion	Extensive experience ↓ Microvascular risk (UKPDS)	Hypoglycemia Weight gain ? Blunts myocardial ischemic preconditioning Low durability	Low
Meglitinides (glinides)	Repaglinide Nateglinide	Closes K_{ATP} channels on beta cell plasma membranes	↑ Insulin secretion	↓ Postprandial glucose excursions Dosing flexibility	Hypoglycemia Weight gain ? Blunts myocardial ischemic preconditioning Frequent dosing schedule	High
Thiazolidinediones	Pioglitazone Rosiglitazone†	Activates the nuclear transcription factor PPAR-γ	↑ Insulin sensitivity	No hypoglycemia Durability ↑ HDL-C ↓ Triglycerides (pioglitazone) ↓ Albuminuria ? ↓ CVD events (pioglitazone)	Weight gain Edema/heart failure Bone fractures ↑ LDL-C (rosiglitazone) ? ↑ MI (meta-analyses, rosiglitazone)	Moderate
α-Glucosidase inhibitors‡	Acarbose Miglitol Voglibose*§	Inhibits intestinal α-Glucosidase	Slows intestinal carbohydrate digestion/absorption	No hypoglycemia ↓ Postprandial glucose excursions Nonsystemic	Generally modest HbA_{1c} efficacy GI side effects (flatulence, diarrhea) Frequent dosing schedule	Moderate
DPP4 inhibitors	Vildagliptin* Sitagliptin Saxagliptin Alogliptin Linagliptin	Inhibits DDP4 activity, increasing postprandial active incretin (GLP-1, GIP) concentrations	↑ Insulin secretion (glucose dependent) ↓ Glucagon secretion (glucose-dependent)	No hypoglycemia Well tolerated	Generally modest HbA_{1c} efficacy Urticaria/angioedema ? Pancreatitis Possible ↑ heart failure (saxagliptin; alogliptin)	High
Bile acid sequestrants‡	Colesevelam	Binds bile acids in intestinal tract, increasing hepatic bile acid production ? Activation of farnesoid receptor (FXR) in liver	Unknown ? ↓ Hepatic glucose production ? ↑ Incretin levels	No hypoglycemia ↓ LDL-C	Generally modest HbA_{1c} efficacy Constipation ↑ Triglycerides May alter absorption of other medications	High
Dopamine-2 agonists‡	Bromocriptine (quick release)§	Activates dopaminergic receptors	Modulates hypothalamic regulation of metabolism ↑ Insulin sensitivity	No hypoglycemia ? ↓ CVD events (Cycloset Safety Trial)	Generally modest HbA_{1c} efficacy Dizziness/syncope Nausea Fatigue Rhinitis	High
SGLT2 inhibitors	Dapagliflozin Canagliflozin Empagliflozin	Inhibits SGLT2 in the proximal renal tubule	Decreases glucose reabsorption, leading to glucosuria	Effective at all disease stages No hypoglycemia Weight loss Blood pressure reduction ↓ Albuminuria Reduced risk for CV death and hospitalization for heart failure (empagliflozin, canagliflozin) Reduced risk for progression of diabetic kidney disease (empagliflozin, canagliflozin)	Diabetic ketoacidosis Genitourinary infections Polyuria Volume depletion ↑ LDL-C Reversible ↓ eGFR ? Fracture risk (canagliflozin) ? Acute kidney injury ? Toe amputations (canagliflozin)	High
GLP-1 receptor agonists	Exenatide Exenatide (once weekly) Liraglutide Albiglutide Dulaglutide Lixisenatide	Activates GLP-1 receptors	↑ Insulin secretion (glucose-dependent) ↓ Glucagon secretion (glucose-dependent) Slows gastric emptying ↑ Satiety	No hypoglycemia Weight reduction ↓ CV risk factors Reduced risk for CV death and MACE (liraglutide) Reduced risk for progression to macroalbuminuria (liraglutide)	GI side effects (nausea/vomiting) ↑ Pulse rate ? Acute pancreatitis ? Mitogenicity/cancer risk Injectable Training requirements	High
Amylin mimetics‡	Pramlintide§	Activates amylin receptors	↓ Glucagon secretion Slows gastric emptying ↑ Satiety	↓ Postprandial glucose excursions Weight reduction	Generally modest HbA_{1c} efficacy GI side effects (nausea/vomiting) Hypoglycemia unless insulin dose is simultaneously reduced Injectable Training requirements Frequent dosing schedule	High

Insulins	Human NPH Human regular Lispro Aspart Glulisine Glargine Detemir Degludec Premixed (several types)	Activates insulin receptors	↑ Glucose disposal ↓ Hepatic glucose production	Universally effective Theoretically unlimited efficacy ↓ Microvascular risk (UKPDS)	Hypoglycemia Weight gain ? Mitogenicity/cancer risk Injectable Training requirements "Stigma" (for patients)	Variable[¶]

Cardiovascular Effects of Selected Medications for Diabetes

Until 2008, the approval of drugs for diabetes depended almost exclusively on proof of glucose lowering, without required demonstration of efficacy on clinical outcomes.[33] The regulatory landscape for diabetes drugs more recently underwent major changes, such that all glucose-lowering agents must now demonstrate designated margins of CV safety to achieve regulatory approval. This has led to a rapid proliferation of CV outcome trials of antihyperglycemic therapies, some recently concluded but many still underway (**Table 51.4 and Fig. 51.8**). In this context, the available data on the net CVD safety and efficacy of such medications has been quite limited, and current management strategies and most guidelines remain grounded on the proven microvascular disease benefits demonstrated through glucose control alone.[14,15]

Circulation 2010;121:2694.)

Metformin.

Metformin, in the biguanide class, likely reduces blood glucose primarily by decreasing hepatic glucose output and with some improvement in peripheral insulin sensitivity.[30] Recent data suggest that metformin

stimulates incretin hormone release (e.g., glucagon-like protein [GLP]-1, glucose-dependent insulinotropic polypeptide [GIP]) from the lower intestines, which augment endogenous insulin secretion. In addition, metformin use is associated with modest weight reduction, favorable effects on lipid levels, decrease in inflammatory markers, improvement in coagulation profiles, and low risk for hypoglycemia. In the United Kingdom Prospective Diabetes Study (UKPDS) of various glucose-lowering strategies in a population of patients with newly diagnosed type 2 DM, patients who were overweight at study entry were eligible for randomization to a policy of more intensive glucose control with metformin versus usual care. Those treated with metformin had statistically superior outcomes for all diabetes-related endpoints (RRR, 32%; 95% CI 13% to 47%), diabetes-related death (RRR, 42%; 95% CI 9% to 63%), and all-cause mortality (RRR, 36%; 95% CI 9% to 55%).[30] A second trial, the HOME study, randomized 390 patients with insulin-treated type 2 DM to metformin versus placebo.[30] The effect on the primary composite outcome, including micro- and macrovascular complications, proved neutral. However, the secondary outcome of major adverse CV events fell in the metformin group (RRR, 39%; 95% CI 6% to 60%), similar in magnitude to the macrovascular risk reductions seen in the UKPDS. Given the relatively small size and few CV events to analyze in both these trials, the CV efficacy of metformin remains uncertain.

Concerns about the potential of metformin to cause lactic acidosis delayed its regulatory approval in the United States and hindered its clinical uptake, stemming from earlier observations with another biguanide, phenformin, that clearly caused lactic acidemia and was removed from the market on that basis. In response to this concern, metformin has been contraindicated for use in patients with impaired kidney function, for 48 to 72 hours after the administration of iodinated contrast, and in unstable HF. Despite widespread global use of metformin for more than five decades, however, and a substantial aggregated database of comparative clinical trials, no convincing signal for increased lactic acidemia with metformin treatment has emerged.[34,35] Given this absence of data supporting the concern for lactic acidosis with metformin, in 2006 the U.S. Food and Drug Administration (FDA) removed the product label warning for its use in patients with HF. More recently, the FDA also adjusted the prescribing guidelines for metformin products with regard to kidney contraindications.[36] Previously contraindicated with serum creatinine in men of 1.5 mg/dL or higher and in women of 1.4 mg/dL or higher, the updated recommendations allow for use in those with stable, mild-moderate chronic kidney disease (CKD). The new cut points are based on estimated glomerular filtration rate (eGFR) instead of serum creatinine. Metformin is now allowed with eGFR less than 60 mL/min/1.73 m^2, with safety reassessed for those taking metformin with eGFR less than 45 mL/min/1.73 m^2, and with metformin contraindicated or to be stopped for eGFR less than 30 mL/min/1.73 m^2. These changes should allow use of this effective, safe, and inexpensive medication to hundreds of thousands of patients in the United States alone. As for recommendations after iodinated contrast administration, metformin need not be interrupted if the eGFR is greater than 60 mL/min/1.73 m^2, but should still be held in patients whose kidney function is below this level until no decrement in kidney function can be documented.

On the basis of safety, tolerability, low hypoglycemia risk, CV clinical outcomes data, and relatively low cost of the generic formulation, metformin is widely considered the first-line drug for type 2 DM in the absence of contraindications or intolerance.[14,15] Metformin is the only oral antihyperglycemic medication routinely recommended to be continued in combination with insulin therapy.

Sulfonylureas.

Sulfonylureas, in clinical use since 1950, are the oldest oral antihyperglycemic medications. They lower glucose by augmenting insulin release through inhibition of adenosine triphosphate (ATP)–dependent

potassium (K_{ATP}) channels in pancreatic beta cells. Although sulfonylureas typically are well tolerated and are relatively potent, their use results in the highest rate of hypoglycemia of any available oral antihyperglycemic drug. They are also associated with weight gain. Although tolbutamide, a first-generation sulfonylurea, increased CV and all-cause mortality in an early randomized trial, no such adverse CV safety signals have emerged from subsequent randomized trials with assignment to second- and third-generation sulfonylureas.[30] On the basis of the extensive clinical experience, the availability of low-cost generics, and the efficacy of glucose control demonstrated in several clinical trials, sulfonylureas constitute a category of second-line drugs (after metformin) for the treatment of type 2 DM.[14]

Concerns persist, however, about the use of sulfonylureas in CVD cohorts, driven by their associated weight gain, increased risk for hypoglycemia and consequent stimulation of the adrenergic stress-response system with potential adverse CVD effects, and the potential of these drugs to inhibit so-called ischemic preconditioning through blockade of myocardial K_{ATP} channels. In animal models of MI, activation of myocardial K_{ATP} channels reduces infarct size, an effect termed *ischemic preconditioning* that is blocked by sulfonylureas. The relevance of these observations in humans remains poorly understood, but this blocking effect is one potential explanation for the increased MI case-fatality rate observed in the more intensively treated patients in the ACCORD trial—a conjecture that remains unproved because of limited ability to analyze outcomes according to drug allocation in that trial.[30] Observations from the UKPDS trial counter the likelihood of such an effect, because an intensive glucose control policy with two different sulfonylureas, chlorpropamide and glibenclamide (glyburide in U.S.), yielded MI and CV death outcomes similar to those with insulin, metformin, and usual (diet) therapy.[30]

On the basis of these concerns, sulfonylureas that are relatively specific for pancreatic K_{ATP} channels have been developed (e.g., glimepiride), although no CV clinical outcomes trials have yet evaluated the CV safety and efficacy of these newer members of the class. More recent observational data from a Danish national registry, however, support ongoing concerns with regard to the all-cause and CV mortality effects of sulfonylureas. Statistically significant increased odds after multivariable and propensity adjustment were associated with all sulfonylureas analyzed compared with metformin, including the pancreatic-specific glimepiride, except for gliclazide, which had no associated mortality signal but is not FDA approved.[37] Data from other observational studies have been inconsistent,[38-40] with some finding an association with adverse CV outcomes.

This potential discrepancy between the apparent safety of sulfonylureas when studied in randomized trials versus their purported risk that emerges in observational studies has two leading explanations. First, the observational studies could be wrong, their findings influenced by confounders not assessable in the datasets, most importantly indication. Alternatively, under the careful observation of clinical trials the drugs could be safe, but their potential dangers may only emerge when used in the general practice setting. The ongoing CV outcomes trial CAROLINA (NCT01243424) comparing the DPP4 inhibitor linagliptin versus glimepiride may shed additional light on this issue.[41]

Thiazolidinediones.

Thiazolidinediones (e.g., rosiglitazone, pioglitazone) decrease glucose levels in type 2 DM by increasing insulin sensitivity of target tissues and induce a wide variety of nonglycemic effects mediated through activation of the nuclear receptor PPAR-γ, including some favorable effects on intermediate markers of CVD and CVD risk. This led to much early interest in their effects on CVD morbidity and mortality.[14] The Prospective Pioglitazone Clinical Trial in Macrovascular Events (the PROactive study) was the first

randomized trial designed to assess the effect of a glucose-lowering medication on CV clinical outcomes. Treatment with pioglitazone yielded a significant 16% RRR for the prioritized secondary composite major adverse cardiovascular event (MACE) endpoint of all-cause mortality, nonfatal MI, and stroke compared with placebo in patients with type 2 DM and prevalent CVD at study entry, treated during a 34.5-month follow-up period, although the effect on the primary endpoint did not achieve statistical significance.[30] These data were considered hypothesis generating because of failure to meet the primary outcome. More recently, in a 4.5-year study involving patients with insulin resistance but without diabetes who had a recent stroke or transient ischemic attack (TIA), pioglitazone versus placebo was associated with a 24% RRR in recurrent stroke or MI (HR, 0.76; 95% CI 0.62 to 0.93).[42] These data, admittedly in patients without diabetes, support the original PROactive MACE findings. In IRIS, pioglitazone was associated with a 52% reduction in risk of developing diabetes (HR, 0.48; 95% CI 0.33 to 0.69).[43] Pioglitazone is the only drug to show both CV risk reduction and diabetes prevention in the same trial, although it is unknown if these effects are necessarily linked.

By contrast, rosiglitazone was at one point suspected of increasing CVD risk—specifically, MI risk.[14] These data from a controversial meta-analysis of phase 2 and 3 data initially led to severe product label restrictions for use in the United States and to withdrawal of rosiglitazone from the market elsewhere. However, a randomized open-label CV outcome trial, RECORD, showed a neutral effect of rosiglitazone on CV outcomes in high-risk patients taking metformin or sulfonylureas. The rosiglitazone product label has since undergone updating to reflect this finding, but the drug remains infrequently used.

Either rosiglitazone or pioglitazone increase the risk for peripheral edema, with a small but consistent increase in risk for new or worsening HF. On that basis, the labels for both agents warn against their use in patients with HF, with a contraindication for initiation in patients with New York Heart Association (NYHA) Class III or IV HF and a caution against their use in any patient with HF. Although the mechanism of the observed increase in edema and HF remains unclear, it appears to result primarily from increased renal sodium reclamation and plasma volume expansion, with no evidence to date of pernicious cardiac effects of these drugs. In IRIS, HF outcomes did not differ between the two randomized groups, likely a reflection of HF being an exclusion in the trial and on-trial protocols for study drug dose reduction if significant edema or excessive weight gain occurred.[42]

Insulin.

Suggested CVD benefits with insulin derive from trials including both type 1 and type 2 DM, but these studies all had limited statistical power to assess such effects. Most recently, results emerged from the ORIGIN trial.[44] This study randomly assigned 12,537 patients with CV risk factors plus impaired fasting glucose, impaired glucose tolerance, or prevalent type 2 diabetes to treatment with insulin glargine or standard care management, with dual primary trial outcomes of (1) nonfatal MI, nonfatal stroke, or death from CV causes and (2) these events plus revascularization or hospitalization for HF. After a median follow-up of 6.2 years, no differences were found between the insulin glargine and placebo groups in the rate of the first co-primary outcome (2.94 versus 2.85 events per 100 patient-years; $P = 0.63$) or the second co-primary outcome (5.52 versus 5.28 per 100 person-years; $P = 0.27$). Although ORIGIN did not demonstrate superiority of insulin glargine, the co-primary outcomes had point estimates of effect of 1.02 and 1.04, respectively, both with an upper confidence limit of 1.11—well within the current regulatory standard of upper confidence limit for CV effects of less than 1.3 to demonstrate CV safety of glucose-lowering drugs. As expected, insulin use is associated with more hypoglycemia and weight gain. Only one trial has assessed CV outcomes between two different types of basal insulins. DEVOTE randomized 7637 patients with T2DM to either insulin degludec or glargine or insulin.[44a] The incidence of the primary

MACE outcome proved similar at 8.5% vs. 9.3% (HR, 0.91; 95%, CI 0.78-1.06). Fewer patients using degludec, however, experience severe hypoglycemia (4.9 vs. 6.6%; rate ratio, 0.60; $p < 0.001$).

Dipeptidyl Peptidase 4 (DPP4) Inhibitors.

The DPP4 inhibitors selectively inhibit the action of dipeptidyl peptidase 4, a circulating enzyme that degrades the endogenous incretin hormones' glucagon-like protein (GLP)-1 and glucose-dependent insulinotropic polypeptide (GIP), which stimulate glucose-appropriate insulin secretion and/or inhibit glucagon release. Inhibiting DDP4 therefore potentiates GLP-1 and GIP action, reducing glucose levels. Four DPP inhibitors—saxagliptin, alogliptin, sitagliptin, and linagliptin—have been approved for clinical use in the United States, with a fifth drug (vildagliptin) approved elsewhere. Each of these is administered as a once-daily tablet, with modest glucose-lowering potency and with the clinical benefits of neutral effects on weight and low risk for hypoglycemia.

Randomized CV outcomes trials of three DPP4 inhibitors have been completed, with two other trials ongoing (**Table 51.4 and Fig. 51.9**). In the Saxagliptin Assessment of Vascular Outcomes Recorded in Patients with Diabetes Mellitus (SAVOR)–Thrombolysis in Myocardial Infarction (TIMI) 53 trial, 16,492 patients with type 2 diabetes with or at increased risk for atherosclerotic CV disease randomly received blinded treatment with saxagliptin, 5 mg daily (or 2.5 mg daily in patients with eGFR ≤50 mL/min/1.73 m^2) versus placebo.[45] Saxagliptin had no effect on the primary composite outcome of CV death, MI, and ischemic stroke (HR, 1.00; 95% CI 0.89 to 1.12), but unexpectedly increased hospitalization for HF (HR, 1.27; 95% CI 1.07 to 1.51), an observation that remains poorly understood and requires further exploration and assessment in the other outcomes trials evaluating the DPP4 inhibitors.

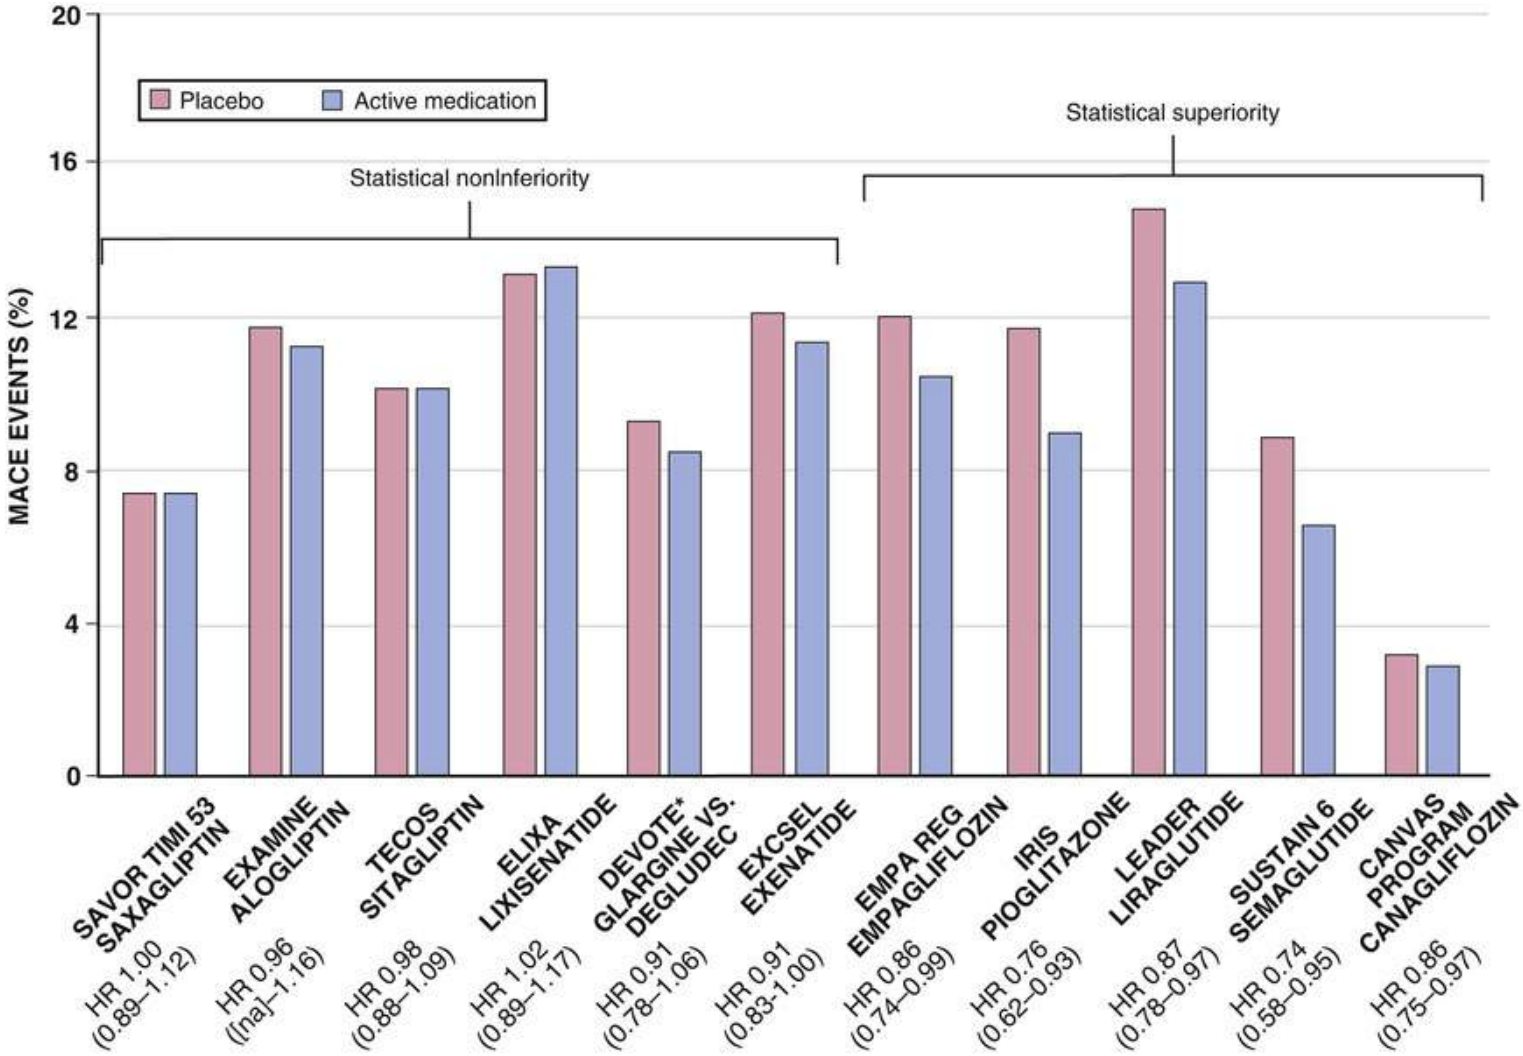

FIGURE 51.9 Summary results of the primary composite cardiovascular outcome results from completed trials of antihyperglycemic therapies reported to date. *Active-controlled trial. SAVOR TIMI 53 (Saxagliptin Assessment of Vascular Outcomes Recorded in Patients with Diabetes Mellitus–Thrombolysis in Myocardial Infarction);[45] EXAMINE (Examination of Cardiovascular Outcomes with Alogliptin Versus Standard of Care);[46,47] TECOS (Trial Evaluating Cardiovascular Outcomes With Sitagliptin);[48] ELIXA (Evaluation of Lixisenatide in Acute Coronary Syndrome);[51] EMPA REG (Empagliflozin Cardiovascular Outcome Event Trial in Type 2 Diabetes Mellitus Patients);[54] IRIS (Insulin Resistance Intervention after Stroke);[42] LEADER (Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results);[52] EXSCEL (Exenatide Study of Cardiovascular Event Lowering);[52a] DEVOTE (Degludec Cardiovascular Outcomes Trial);[44a] SUSTAIN 6 (Trial to Evaluate Cardiovascular and Other Long-term Outcomes with Semaglutide in Subjects with Type 2 Diabetes-6);[53] CANVAS (Canagliflozin Cardiovascular Assessment Study).[58a] *MACE,* Major adverse cardiovascular events, comprising the composite of cardiovascular death, nonfatal myocardial infarction, and nonfatal stroke for all trials; also including hospitalization for unstable angina for TECOS and ELIXA.

In the Examination of Cardiovascular Outcomes with Alogliptin versus Standard of Care (EXAMINE) trial, 5380 patients with type 2 diabetes and a recent ACS event were randomly assigned to blinded treatment with alogliptin versus placebo.[46] Alogliptin had no effect on the primary composite outcome of CV death, MI, and stroke (HR, 0.96; upper 97.5% confidence limit = 1.16). In a subsequent report, HF hospitalization as the first event of an expanded MACE composite that included HF occurred similarly between patients assigned to alogliptin versus placebo (HR, 1.07; 95% CI 0.79 to 1.46), yet hospitalization for HF was statistically higher in alogliptin-treated patients without prevalent HF at trial entry (HR, 1.76; 95% CI 1.07 to 2.90).[47]

In the Trial Examining Cardiovascular Outcomes with Sitagliptin (TECOS), the CV effects of sitagliptin versus placebo was assessed in 14,671 patients with type 2 DM and prevalent ASCVD.[48]

Sitagliptin had no effect on the primary composite outcome of CV death, MI, stroke, and hospitalization for unstable angina (HR, 0.98; 95% CI 0.88 to 1.09). In contrast to SAVOR and EXAMINE, the sitagliptin group did not experience increased HF hospitalization rates (HR, 1.0; 95% CI 83 to 1.20) in subgroups with or without HF at baseline.[49]

When data from these 3 CV outcome trials were pooled, the HR for HF hospitalization with active therapy was 1.15 (0.98, 1.34), mainly driven by the outcomes in SAVOR-TIMI 53.[49] In a meta-analysis involving 84 DPP4 inhibition trials, the overall risk of HF hospitalization was greater in patients randomized to a DPP4 inhibitor compared with placebo or active comparator (odds ratio [OR], 1.19; 95% CI 1.03 to 1.37). In an observational study involving almost 60,000 patients with type 2 DM with average follow-up of 2.4 years, use of DPP4 inhibitors was not associated with increased HF ($OR_{adjusted}$, 0.88; 95% CI 0.63 to 1.22.).[50] Based on the randomized trial data, in February 2016, the FDA added an HF warning to the prescribing labels for both saxagliptin and alogliptin, but not sitagliptin, nor the DPP4 inhibitor yet to report its CV outcome trials, linagliptin. The warning states that prescribers should consider stopping the medications if patients develop HF on therapy. In summary, the DDP4 inhibitors in relatively short-term clinical trials appear neutral regarding effects on CV outcomes (**Fig. 51.9**), with some concern about a modest increase in in HF hospitalization rates with at least two DPP4 inhibitors, saxagliptin and alogliptin.

Glucagon Like Peptide (GLP)-1 Receptor Agonists.

The GLP-1 receptor agonists (RAs) are injectable agents that enhance the incretin system.[30] The incretin hormones GLP-1 and GIP are neuroendocrine hormones secreted by the intestine in response to meal ingestion. They have variable effects on glucose metabolism that include the stimulation of glucose-dependent insulin secretion, suppression of glucagon (also in a glucose-dependent fashion), a slowing of gastric emptying, and satiety enhancement. Therapeutic benefits with GLP-1 RAs in addition to glucose lowering include associated weight loss (typically 3 to 4 kg), and modest improvement in BP and lipid profiles. They do not increase the risk of hypoglycemia unless used with other drugs that themselves increase the risk (e.g., sulfonylureas, insulin).

In the first GLP-1 RA CV outcomes trial, the Evaluation of Lixisenatide in Acute Coronary Syndrome (ELIXA) trial, lixisenatide was tested 6068 patients with recent ACS and found to be neutral with regard to the primary composite MACE outcome (HR, 1.02; 95% CI 0.89 to 1.17).[51] However, in the second CV outcome trial of this class to report, Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results (LEADER),[52] liraglutide reduced CV death, MI, and stroke by 13% (HR, 0.87; 95% CI 0.78 to 0.97), with directionally concordant results with CV death (HR, 0.78; 95% CI 0.66 to 0.93), nonfatal MI (HR, 0.88; 95% CI 0.75 to 1.03), and stroke (HR, 0.89; 95% CI 0.72 to 1.11) (**Fig. 51.9**). There was no difference in HF hospitalization. In EXSCEL, exenatide once weekly proved neutral for MACE (HR, 0.91; 95% CI, 0.83-1.00; p = 0.061 for superiority), although adherence to study drug was lower than in most trials and likely reduced the trial's power to detect a benefit.[52a] It should be noted that all-cause mortality was reduced in the active therapy arm in this trial (HR, 0.86; 0.77-0.91; p = 0.016).

Other GLP-1 RAs are under CV outcome investigation, including albiglutide and dulaglutide. Semaglutide is an investigational once-weekly GLP-1 RA whose CV outcome trial, SUSTAIN 6, showed a significant decrease in CV death, nonfatal MI, or nonfatal stroke in patients receiving semaglutide compared to placebo.[53]

Sodium-Glucose Cotransporter 2 (SGLT2) Inhibitors.

SGLT2 inhibitors, the newest class of antihyperglycemic drugs, block the SGLT2-receptor in the proximal tubule of the kidney, increasing urinary excretion of glucose as well as sodium. This effect results not only in glucose lowering but also in modest reductions in body weight (approximately 2 kg) and BP (approximately 4/2 mm Hg). The first completed CV outcome trial to assess the effect of an SGLT2 inhibitor, EMPA-REG OUTCOME, tested whether empagliflozin compared with placebo influences the incidence of CV events.[54] The study enrolled a high-risk population of patients with type 2 DM and prevalent ASCVD. It enrolled 7020 patients with longstanding diabetes (57% for >10 years) with mean follow-up of 3.1 years; 75% of the patients had coronary artery disease (CAD), 46% had prior MI, and about 10% had a history of HF. The patient population in EMPA-REG OUTCOME was very well treated at baseline, with more than 75% taking a statin, more than 95% receiving antihypertensive therapy, and about 90% taking anticoagulant/antiplatelet drugs. Such evidence-based therapies resulted in good risk factor management, with mean BP of 135/77 mm Hg and mean LDL-C of 85 mg/dL. The trial demonstrated a significant 14% reduction of the primary composite outcome of CV death, nonfatal MI, and nonfatal stroke (HR, 0.86; 95% CI 0.74 to 0.99) (**Fig. 51.9**). A 38% reduction in CV death (5.9% versus 3.7%; HR, 0.62; 95% CI 0.49 to 0.77) drove this result, translating into a number needed to treat (NNT) of 39 over 3.1 years to prevent a CV death. In addition, empagliflozin significantly reduced hospitalization for HF by 35% (HR, 0.65; 95% CI 0.50 to 0.85). All-cause mortality was reduced by 32% (HR, 0.68; 95% CI 0.57 to 0.80). The HF benefit appeared to extend to both those with and those without a prior HF, suggesting that empagliflozin could prevent not only the clinical deterioration of HF but also its occurrence.[55] In this light, ESC has endorsed the consideration of empagliflozin as a preventive therapy for HF in patients with type 2 DM in its latest set of guidelines.[56]

The event curves for both CV death and HF hospitalization outcomes diverged early during the first few weeks of EMPA-REG OUTCOME. Along with the nonsignificant effect of empagliflozin on MI, stroke, or unstable angina, this suggests that the benefits of empagliflozin did not depend on the effects on atherosclerosis, but instead may occur through hemodynamic effects related to its diuretic mechanism of action and other effects on glomerular hemodynamics.[7,57,58] This issue is under intense investigation to understand the surprising effects of this SGLT2 inhibitor, the first drug to actually demonstrate a clear CV benefit in high-risk CV patients with diabetes.

The second SGLT2 inhibitor CV outcome trial to report, the CANVAS program, involved 10,142 patients with type 2 diabetes at high CV risk who were randomized to either canagliflozin or placebo.[58a] About two-thirds had established CVD while approximately one-third had risk factors only. The canagliflozin group experienced nearly identical risk reductions to those seen in EMPA-REG OUTCOME for MACE (HR, 0.86; 95% CI, 0.75-0.97), heart failure hospitalization (HR, 0.67; 95% CI, 0.52-0.87), and progression of CKD (HR, 0.60; 95% CI, 0.47-0.77). As for the components of MACE, each HR was <1.00, but none achieve statistical significance. Specifically, the point estimate for CV mortality (HR, 0.87; 95% CI, 072-1.06) did not approach the major reduction observed in EMPA-REG OUTCOME. In addition, two adverse effects of canagliflozin were found in CANVAS: a doubling in the risk of lower limb amputations (HR, 1.97; 95% CI, 1.41-2.75) and a smaller increase in the risk of fracture (HR, 1.23; 95% CI, 1.04-1.52). The mechanisms behind these complications of therapy are unknown. Similar effects with empagliflozin and dapagliflozin have not been reported.

So far, only data for the effects of empagliflozin and canagliflozin on CV events are available within the SGLT2 inhibitor class, while awaiting the results of the ongoing CV outcome trials with dapagliflozin (NCT01730534), and ertugliflozin (NCT01986881) to discern whether the beneficial CV outcome effects reported from the EMPA-REG-OUTCOME and CANVAS trials are a class effect.

Other Glucose-Lowering Medications.

Data on CVD outcomes are limited for other glucose-lowering medications, with numerous new classes of medications recently becoming available or in late stages of phase III investigation, summarized in **Tables 51.3 and 51.4**.[30] These newer agents share the advantage of a very low risk for hypoglycemia, and many are weight-neutral or cause weight loss. *Colesevelam,* a bile acid sequestrant initially approved for the treatment of hypercholesterolemia, is also approved for use as a glucose-lowering drug to treat type 2 DM, and *alpha-glucosidase inhibitors* impair intestinal carbohydrate absorption. The effects of these drugs on CV outcomes remain unknown, with the exception of a reduced incidence of MIs reported with *acarbose* in a diabetes prevention trial, STOP NIDDM.[30] However, in the larger ACE trial, involving 6522 Chinese patients with coronary heart disease and impaired glucose tolerance, acarbose had no effect to reduce a CV composite outcome (HR, 0.98; 95% CI, 0.86-1.11).[58b] Gastrointestinal intolerance has limited their clinical use.[14]

Cardiovascular Effects of More Intensive Versus Less Intensive Glucose Control Strategies

The UKPDS trial randomly assigned 5102 patients with newly diagnosed type 2 DM to intensive glucose control with sulfonylurea or insulin or to management with diet alone; those overweight at study entry (n = 795) also could be randomized in the intensive arm to receive metformin.[30] In the insulin and sulfonylurea analyses, resulting in hemoglobin (Hb) A_{1c} levels of 7.0% versus 7.9%, respectively, during an average follow-up of 10 years, intensive control decreased risk for a composite endpoint of all diabetes-related complications (RRR, 12%; P = 0.029) and significantly improved microvascular disease risk (RRR, 25%; P = 0.01). Although intensive control showed a trend toward decreased risk of MI (14.8% versus 16.8%; P = 0.052), the number of strokes was increased, although the difference did not achieve statistical significance (5.6% versus 5.2%; P = 0.52). In overweight patients, metformin yielded better glucose control (HbA_{1c} 7.4% versus 8.0%) and significantly decreased risk for MI (RRR, 39%; P = 0.01) and all-cause mortality (RRR, 36%; P = 0.011). The long-term follow-up of the UKPDS trial cohort has extended these observations to an average duration of 10 years,[30] during which glucose control converged rapidly after discontinuation of the study treatment. These analyses reveal a significantly reduced risk for MI in those originally randomly assigned to intensive control, both in the insulin and sulfonylurea group (RRR, 15%; P = 0.01) and in the metformin group (RRR, 33%; P = 0.005). The continued divergence of the CV event curves throughout the entire follow-up after randomized study treatment was discontinued, and despite rapid convergence of average glycemic control at study end, suggests a “legacy” of CV benefit of early assiduous glycemic control, a finding similarly observed in the long-term follow-up of the Diabetes Control and Complications Trial (DCCT) in patients with type 1 DM.[30] The biologic underpinnings of such an effect are not well understood.

Results from three trials assessed the CVD effects of more intensive versus standard glucose control among patients with type 2 diabetes at high CV risk.[30] Comprising more than 23,000 patients treated on study protocol from 3 to 5 years, all three trials showed no significant CVD benefit of intensified glucose control compared with contemporary glucose management.

The ACCORD trial compared intensive versus standard glucose control in 10,251 patients with type 2 DM who had high CVD risk, achieving a HbA_{1c} of 6.4% versus 7.5%.[30] This trial halted early due to an excess of all-cause mortality in the intensively treated group (257 versus 203 events; P = 0.04), with no significant difference observed in the primary composite CVD endpoint of CV death, MI, and stroke (HR, 0.90; 95% CI 0.78 to 1.04). The initial trial observations persisted up to 17 months of follow-up in this

cohort,[30] during which the primary composite outcome risks remained similar between groups. The risk of death from any cause was 19% higher in patients randomly assigned to the more intensive glucose control strategy in the trial ($P < 0.05$), and the HR for nonfatal MI was 0.83 ($P < 0.05$). The basis for the increased mortality remains unresolved; possible explanations include increased hypoglycemia precipitating CV death, pernicious effects of specific drugs or drug combinations, and a chance finding in the context of the other reported trials. The absence of randomization to specific therapies renders post hoc analysis of cause especially difficult.

The ADVANCE trial enrolled 11,140 patients with type 2 diabetes who had CVD, microvascular disease, or another vascular risk factor at study entry.[30] Patients randomly received either intensive glucose control with gliclazide plus other drugs in the intensive arm, compared with standard control with other drugs. Similar to the ACCORD trial, the ADVANCE trial did not show statistically significant improvement in the composite CVD outcome of CV death, MI, and stroke with intensive control (achieved HbA^{1c} of 6.4% versus 7.0%), despite the ascertainment of 1147 events (RRR, 6%; 95% CI −6% to 16%). In contrast to the effects seen in UKPDS, 5-year follow-up data from ADVANCE did not show a reduction in macrovascular events in the group treated initially with intensive control.[59]

In the Veterans Affairs Diabetes Trial (VADT), 1791 U.S. veterans with type 2 DM and inadequate glucose control were randomly assigned to either intensive or standard glucose control.[30] Despite a wide separation in glucose control values (HbA_{1c} of 6.9% versus 8.4%) and ascertainment of 499 primary MACEs, this trial also found no significant improvement in CV outcomes with intensive control (29.5% versus 33.5%; $P = 0.14$). However, follow-up data obtained 3.3 years later in 78% of the initial study population suggest that intensive glucose control compared with standard therapy leads to a significant 17% reduction ($P = 0.04$) of the primary endpoint.[60]

From post hoc analyses of data for each of these trials and supported by the long-term observations from UKPDS in patients with newly diagnosed diabetes at study entry, the concept has emerged that more intensive glycemic control may be safer and may have more favorable CV effects when used in patients earlier in the course of diabetes, particularly among those without prevalent CVD. The corollary to this strategy is that more liberal glycemic targets may be acceptable for selected patients at increased risk, such as very elderly patients and those with a high burden of underlying comorbidities, especially those with prevalent CVD. Although these hypotheses require confirmation in additional clinical trials, the most recent ADA/EASD guidelines for chronic glucose management for patients with type 2 DM endorse such a strategy of targeting intensity of glucose control in the context of global CVD risk, advocating HbA_{1c} target of 8% (or possibly higher) for selected patients, including those with moderate to severe CVD.[14,15] An overriding consideration of such an approach is the limited evidence of short-term benefits from any reduction in microvascular disease in those with limited life expectancy.

In summary, whereas these recent randomized trials did not demonstrate significant incremental CV benefits with more intensive glucose control compared with contemporary targets, the analyses of the primary composite endpoints for each trial revealed point estimates of RRR ranging from 6% to 12%, each with upper 95% confidence limits of 1.04 to 1.06. Such results provide significant assurance of a margin of CV safety with more intensive glucose control, supported by recently published meta-analyses of the available data, demonstrating statistically significant reductions in MI (HR, 0.83; 95% CI 0.75 to 0.93), with no significant effects on stroke (HR, 0.93; 95% CI 0.81 to 1.06) or all-cause mortality (HR, 1.02; 95% CI 0.87 to 1.19). These observed upper confidence limits are well within the noninferiority margins recently adopted by U.S. and European regulatory agencies for diabetes drug registration, to exclude the upper noninferiority 95% confidence limit of 1.3 (or 95% certainty of no greater than 30% worse than comparator) for CV safety.

Summary of Glucose Management

Intensive glucose control favorably affects microvascular disease risk, but its importance in CVD risk modification remains uncertain. Reflecting the accumulated data, the most recent guidelines from the ADA and EASD endorse a more individualized approach than previously recommended, with more liberal HbA_{1c} targets for patients with shorter expected life span and with significant comorbidity, including prevalent CVD (**Fig. 51.10**), suggesting a HbA_{1c} target of 8% (or higher).[14,15] Until recently, in the context of the paucity of clinical outcomes data for most antihyperglycemic therapies used for type 2 DM, the ordered addition of subsequent glucose-lowering medications after metformin was left to the discretion of the provider, taking individual patient and drug characteristics into such treatment determinations. Given the landmark findings from EMPA-REG OUTCOME, LEADER, IRIS, and SUSTAIN-6 trials, the *method* that lowers glucose levels matters, particularly those with established CVD. Whether empagliflozin, liraglutide, semaglutide, or pioglitazone would prove effective in primary prevention remains unknown.

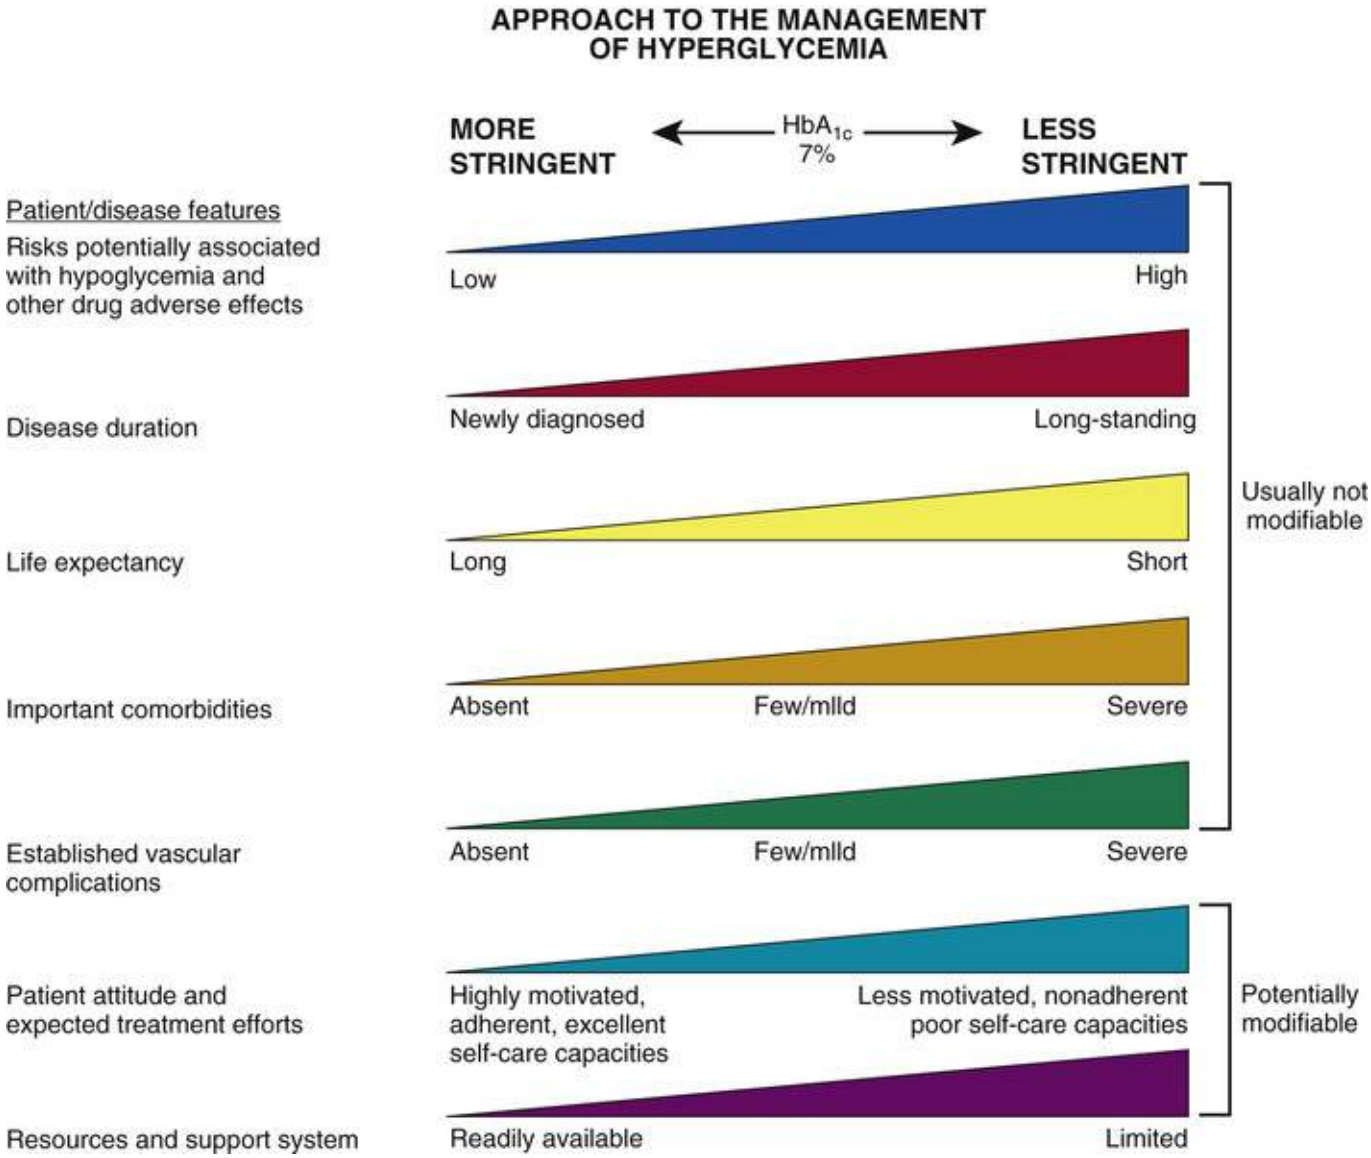

FIGURE 51.10 Modulation of the intensiveness of glucose lowering in type 2 diabetes mellitus (DM). Depiction of patient and disease factors that may be used by the practitioner to determine optimal HbA_{1c} targets in patients with type 2 DM. Greater concerns regarding a particular domain are represented by increasing height of the corresponding ramp. Thus, characteristics/predicaments toward the *left* justify more stringent efforts to lower HbA_{1c}, whereas those toward the *right* suggest (indeed, sometimes mandate) less stringent efforts. Where possible, such decisions should be made with the patient, reflecting his or her preferences, needs, and values. This "scale" is not designed to be applied rigidly but to be used as a broad construct to guide clinical decision making. (From Inzucchi SE, Bergenstal RM, Buse JB, et al. Management of hyperglycemia in type 2 diabetes, 2015: a patient-centered approach: update to a position statement of the American Diabetes Association and the European Association for the Study of Diabetes. Diabetes Care 2015;38:141.)

Acute Coronary Syndromes

In view of the high risk associated with diabetes in the setting of ACS, much investigation has focused on this population. In general, as endorsed by the most recent ACS guidelines,[61,62] the treatment of patients with diabetes should mimic that of the overall population (**see Chapters 58 to 60**). Some specific therapies also are recommended for diabetic patients.

Screening for Diabetes in ACS Patients

Patients with ACS events frequently have diabetes, with approximately one third of ACS patients having diabetes previously diagnosed.[6,63] In addition, many patients present with an ACS event as the first

complication of diabetes, and in this context, previously undetected diabetes is also common, affecting up to an additional 20% to 25% of ACS patients.[63] Therefore, all patients with non–ST-segment elevation (NSTE) ACS should be screened for diabetes.[63,64] Given the stress hyperglycemia associated with ACS events that may confound blood glucose testing, screening should extend beyond assessment of fasting blood glucose and include HbA_{1C} testing and/or predischarge oral glucose tolerance testing.[10,63,65] The diagnosis of diabetes early in the hospital course is important because it influences later therapeutic decisions.

Insulin Administration and Glucose Control

Research over decades has evaluated the role of myocardial metabolic modulation during ACS events, with insulin delivery as the primary focus of investigation. Almost all trials completed to date evaluating the role of intravenous (IV) insulin in ACS used very high insulin dosing supported by exogenous glucose administration to avoid hypoglycemia, with or without adjunctive delivery of potassium, so-called glucose-insulin-potassium (GIK) therapy. These protocols typically targeted permissive hyperglycemia of 126 to 200 mg/dL during the infusion. This strategy ultimately proved futile in contemporary ACS management in the CREATE ECLA GIK trial of 20,201 patients with ST-segment elevation MI (STEMI), randomized to GIK therapy versus usual care and accumulating 1980 mortality events—demonstrating no benefit of GIK therapy compared with usual care.[66] These results have led to the abandonment of GIK treatment for ACS patients.

No adequately powered clinical outcomes trial has been completed to date in the ACS setting evaluating targeted glucose control with IV insulin or any other therapy. The Diabetes Mellitus Insulin-Glucose Infusion in Acute Myocardial Infarction (DIGAMI) trial enrolled 620 patients with hyperglycemia at presentation with MI, randomly assigned to insulin infusion acutely, followed by multidose subcutaneous insulin injection or usual care, with significant mortality reduction demonstrated in the insulin-treated group during long-term follow-up.[66] DIGAMI used an acute infusion of high-dose insulin (5 units/hr), coupled with IV glucose administration with protocol-targeted permissive hyperglycemia of 126 to 198 mg/dL, an insulin-dosing protocol used in subsequent GIK trials, including the negative CREATE ECLA GIK trial previously summarized. Often misinterpreted as a trial of intensive glucose control, this study provided the basis of ACCF/AHA guideline recommendations for intensive glucose control in the management of ACS events since 2004. However, in the absence of evidence of beneficial effects of intensive glucose control in ACS populations, and a series of trials in other intensive care unit (ICU) settings demonstrating no significant benefit for the most part,[66] and increased mortality with intensive glucose control with IV insulin in the medical and surgical intensive care units in the largest trial to date, guidelines for the management of hyperglycemia in the ACS setting have changed considerably.[66] Both ACCF/AHA and ESC guidelines currently advocate IV insulin to target glucose levels less than 180 mg/dL in the patient with ACS, with a key focus of avoiding hypoglycemia.[10,62,64]

The risk of hypoglycemia associated with intensive glucose control in acutely ill patients remains an important concern, with an incidence of severe hypoglycemia as high as 19% in the reported randomized trials from various ICU settings. This concern may be especially important in the treatment of ACS, in which the counterregulatory response associated with hypoglycemia may prove particularly deleterious to ischemic myocardium. Data from observational studies have shown increased risk associated with hypoglycemia among ACS cohorts, but whether hypoglycemia simply marks disease severity or contributes to adverse outcomes remains unclear.[66] In the Normoglycemia in Intensive Care Evaluation–Survival Using Glucose Algorithm Regulation (NICE-SUGAR) trial,[66] the incidence of hypoglycemia

associated with the insulin infusion was the lowest (6.8%) among of all reported trials, yet this is the only trial to demonstrate statistically significant increased mortality with intensive glycemic control in the ICU setting, suggesting that alternative mechanisms may mediate the adverse effects of the insulin infusion. This observation implies that the ability to avoid excess hypoglycemia does not justify the continued use of insulin infusions targeting tight glycemic control for ICU patients, including those with ACS.[66]

Antiplatelet Medications

Aspirin therapy is effective in an ACS setting, with or without diabetes. Because of the aberrations of platelet function associated with diabetes, however, significant interest and investigation have centered on the potential for more intensive antiplatelet therapies to provide particular benefit to diabetic patients experiencing ACS events.

$P2Y_{12}$ Receptor Antagonists

The incremental efficacy of adding thienopyridine and nonthienopyridine antagonists of the platelet receptor $P2Y_{12}$ (clopidogrel, prasugrel, and ticagrelor) to aspirin therapy in the treatment of ACS (**see Chapters 59 and 60**) has been demonstrated in randomized clinical trials that included substantial numbers of patients with diabetes.[67,68] In the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial,[67] which included 2840 patients with diabetes, the estimate of treatment benefit of clopidogrel in this subpopulation of 15% RRR was numerically similar to the overall trial results (14.2% versus 16.7%; $P > 0.05$). Prasugrel (a third-generation thienopyridine) added to aspirin therapy, compared with clopidogrel plus aspirin, significantly reduced CVD risk in the diabetes subset of the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel–Thrombolysis in Myocardial Infarction 38 (TRITON–TIMI 38) trial, including patients with ACS undergoing a primary invasive management strategy (12.2% versus 17.0%; $P < 0.001$).[69] Of note, the incremental reduction in CVD risk with prasugrel within the diabetes subset did not entail a significant increase in major bleeding complications (2.6% versus 2.5%). The subsequent Targeted Platelet Inhibition to Clarify the Optimal Strategy to Medically Manage Acute Coronary Syndromes (TRILOGY ACS) trial, however, which enrolled patients with MI treated medically without revascularization, randomly assigned to treatment with clopidogrel or prasugrel,[70] found no significant differences between the groups in the primary composite outcome of CV death, MI, and stroke in the overall trial population, or in the diabetes subset, in which the interaction of treatment efficacy of prasugrel by diabetes status observed in the TRITON trial was not evident. Finally, in the Platelet Inhibition and Patient Outcomes (PLATO) trial, which enrolled 18,624 patients with an ACS, with or without ST-segment elevation, randomly assigned to receive ticagrelor or clopidogrel, ticagrelor (a nonthienopyridine $P2Y_{12}$ antagonist) significantly reduced the primary composite outcome of death from vascular causes, MI, and stroke (9.8% versus 11.7%; $P < 0.001$).[69] Similar findings pertained to the subset of 4662 patients with diabetes at study entry.[68]

In aggregate, these observations support the incremental benefits of more potent antiplatelet treatment added to aspirin therapy in diabetic patients with ACS events, with superiority of both prasugrel and ticagrelor over clopidogrel. The $P2Y_{12}$ receptor antagonists should be considered as part of routine clinical management for patients with diabetes and ACS.

Renin-Angiotensin-Aldosterone System Antagonists

The ACE inhibitors have several favorable effects in the setting of ACS events that may be especially beneficial in the patient with diabetes, including improvements in ventricular structure and function, endothelial function, fibrinolytic system, and metabolic and neurohormonal effects. On the basis of observational data and subanalyses of diabetic patients in randomized trials, beneficial effects on HF incidence and mortality appear greater in the setting of diabetes. Thus the routine use of ACE inhibitors for patients with diabetes is a level I (A) recommendation across the spectrum of ACS events.[10,62,71]

Although ARBs have similar effects on intermediate markers of myocardial structure and function to those of ACE inhibitors, the evidence base for their overall effects on clinical outcomes remains less robust, especially for the subset of patients with diabetes. For example, in the Optimal Trial in Myocardial Infarction with Angiotensin II Antagonist Losartan (OPTIMAAL), a randomized trial comprising patients with MI events complicated by HF, losartan versus captopril was associated with a trend toward increased mortality (RR, 1.13; 95% CI 0.99 to 1.28), although the observed differences were not statistically significant.[27] In contrast, the Valsartan in Acute Myocardial Infarction Trial (VALIANT), which enrolled patients within 10 days of an acute MI complicated by HF, including 3400 patients with diabetes, showed no significant difference in mortality between patients randomly assigned to treatment with captopril and those treated with valsartan, and effects in the diabetes subset mirroring those observed in the overall study cohort.[27,28] Thus, ARBs should be considered an alternative only for patients intolerant of ACE inhibitors.

In addition to its effects on sodium retention and potassium excretion, *aldosterone* also may directly stimulate the production of inflammatory mediators, cause myocardial fibrosis, and promote endothelial dysfunction and vascular stiffening, prompting investigation into the role of aldosterone blockade in the setting of ACS. The Eplerenone Post–Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS) compared the mineralocorticoid-selective aldosterone antagonist eplerenone to placebo, added to optimal therapy, in a population of 6632 patients with MI and decreased ejection fraction (EF) who had either clinical HF or, in the absence of manifest HF, diabetes.[72] In the overall study cohort, treatment with eplerenone compared with placebo reduced the risk of CV death by 17% (RR, 0.83; 95% CI 0.72 to 0.94), with numerically similar observations in the subset of 2232 patients with diabetes. On the basis of this trial, the use of an aldosterone antagonist for patients with diabetes and reduced EF (with or without clinical HF) after MI is recommended across the spectrum of ACS events,[62,71] with the important caveat that such therapy should not be used in patients with impaired kidney function (creatinine >2.0 mg/dL) or hyperkalemia (potassium concentration [K^+] >5.0 mEq/liter). In addition, patients with diabetes should have serial monitoring of [K^+], given the high prevalence of type 4 renal tubular acidosis in the diabetic population.

Beta-Adrenergic Blocking Agents

Despite evidence of their incremental effectiveness in the treatment of patients with diabetes after ACS events, beta blockers continue to be underprescribed in this group.[6] Biologic effects that support the incremental efficacy of beta blockers in the setting of diabetes include the restoration of sympathovagal balance in diabetic patients with autonomic neuropathy and decreasing fatty acid metabolism within the myocardium, reducing myocardial oxygen demand. Therefore, beta blockers should be prescribed for all patients after ACS events, independent of diabetes status, unless other contraindications exist.[10,62,64,71] In the selection, one may consider the variable effects of available beta blockers on glycometabolic parameters, with favorable effects of some (e.g., carvedilol, labetalol) and unfavorable for others (e.g., metoprolol, atenolol), although the clinical relevance of these considerations remains less clear.[73]

Primary Invasive Strategy for Non–ST-Segment Elevation ACS

In randomized trials comparing primary invasive versus noninvasive strategies for the treatment of ACS events, the subsets of patients with diabetes derived similar or greater benefits than those without diabetes associated with a primary invasive management strategy, although mortality and reinfarction rates were still higher in the groups with diabetes in both treatment arms[64,71] (**see Chapter 62**). Despite these benefits, a primary invasive strategy for patients with diabetes continues to be underused in patients with ACS events.[6]

Primary Reperfusion Therapy for ST-Segment Elevation MI

Analyses from trials of primary percutaneous coronary intervention (PCI) suggest greater benefit in patients with diabetes than in those without diabetes, with primary angioplasty proving superior to thrombolysis in these patients.[74] Similarly, in analyses of diabetic subsets from randomized trials of thrombolytics, patients with diabetes derive greater absolute benefit from thrombolytic therapy than nondiabetic patients.[62] Therefore, diabetic patients with STEMI should undergo reperfusion therapy in the absence of contraindications, preferentially with a strategy of primary PCI when available[10] (**see Chapter 60**).

Coronary Revascularization Considerations

The main goals of coronary revascularization in diabetic patients with stable CAD are the improvements in symptoms and prognosis.[75] Current guidelines recommend medical treatment, including anti-ischemic drugs as first-line treatment of this patient population. For patients requiring revascularization, the optimal revascularization strategy remains controversial. Thus, careful evaluation of the general treatment indication and consideration of the optimal therapeutic strategy has particular importance in this high-risk population.

Optimal Medical Therapy Versus Revascularization in Diabetes

Studies examining optimal medical therapy (OMT) versus a revascularization strategy in patients with diabetes with stable CAD are scarce. The largest such trial, the Bypass Angioplasty Revascularization Investigation 2 Diabetes (BARI-2D) trial, randomized 2368 diabetic patients with obstructive CAD either to immediate revascularization (coronary artery bypass grafting [CABG] $n = 347$; PCI, $n = 765$) in addition to OMT or to OMT alone. Regarding the entire study cohort, the BARI-2D trial did not show a significant difference in terms of freedom from major adverse cardiac and cerebrovascular events (MACCE) or death between the revascularization and the OMT-alone group (88.3% versus 87.8%; $P = 0.97$) after 5 years. Still, the CABG stratum subgroup, despite having more advanced CAD, showed a significantly higher rate of freedom from MACCE and death compared with OMT alone (77.5% versus 69.6%; $P = 0.01$). In contrast, in the PCI stratum compared with OMT alone, there was no difference in freedom from MACCE (77% versus 78.9%; $P = 0.15$).[74] Thus, BARI-2D demonstrated that OMT is a reasonable therapeutic option in patients with diabetes and less advanced CAD. independent of the presence of ischemia. Moreover, regarding the indirect comparison between CABG and PCI in this trial, overall mortality was significantly lower with CABG compared with PCI at 5-year follow-up (19.4% versus 34.5%; $P = 0.003$).[74] This suggests that in patients with more extensive CAD and proven ischemia, CABG may be the preferred treatment modality, whereas in low-risk patients with diabetes (less advanced CAD on angiogram, stable clinical situation, normal left ventricular function) with reliable

compliance to medical therapy, a conservative pharmacologic approach may be a preferable option.[74]

A pooled analysis of completed trials with a total of 5034 patients with diabetes,[76] including the diabetic subgroup of the Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation (COURAGE) trial, BARI-2D, as well as the FREEDOM trial that compared PCI directly with CABG in patients with diabetes (see later), investigated the achievement of the four main targets of OMT (BP, LDL-C, smoking abstinence, HbA_{1c}) with disillusioning results: only 18% of patients in COURAGE, 23% of patients in BARI-2D, and 8% of patients in FREEDOM reached all four prespecified treatment targets at 1-year follow-up. These data strongly suggest that treatment targets of OMT are often not achieved, calling for more intensive efforts to ensure appropriate risk factor management and medical adherence.

Percutaneous Coronary Intervention Versus CABG

Patients with diabetes have worse clinical outcomes after revascularization by either PCI or CABG than those without diabetes. Patients with diabetes have a significantly higher risk of recurrent CV events after PCI, particularly in-stent restenosis, target-vessel revascularization, MI, and stent thrombosis.[77] After CABG, patients with diabetes are especially prone to sternal wound infections, acute kidney injury, HF, and death.[74] The optimal strategy of coronary revascularization for patients with diabetes remains controversial.

Several large trials have compared PCI versus CABG,[78-81] but given technical advances in both interventional cardiology as well as coronary surgery over recent decades, some of the results of these trials apply only partially today.[82] The Coronary Artery Revascularization in Diabetes (CARDia) trial comparing PCI versus CABG in 510 patients with diabetes and multivessel CAD found no difference between groups for the primary composite endpoint of death or MI (PCI 13.0% versus CABG 10.5%; $P = 0.39$).[79] However, the addition of repeat revascularization to the composite outcome showed a benefit favoring CABG (11.3% versus 19.3%; $P = 0.016$) at 1-year follow-up. Important limitations of the CARDia trial were the mixed use of bare-metal stents (BMS, 31%) and first-generation (sirolimus) drug-eluting stents (DES) in the PCI arm and the relatively small sample size.[79]

A subanalysis of the 452 patients with diabetes with left main or three-vessel CAD enrolled in the Synergy Between Percutaneous Coronary Intervention with Taxus and Cardiac Surgery (SYNTAX) trial of PCI versus CABG demonstrated higher rates of MACCE with PCI using paclitaxel-eluting stents (PES) compared with CABG at 1 year (26% versus 14.2%; $P = 0.003$), as well as after 5 years of follow-up (46.5% versus 29.6%; $P < 0.001$),[78] differences driven by more repeat revascularization in the PCI group at 1 year (PCI 20.3% versus CABG 6.4%; $P < 0.001$) and at 5 years (PCI 35.3% versus CABG 14.6%; $P < 0.001$). With respect to lesion complexity according to SYNTAX score, only patients with diabetes with more complex disease (SYNTAX score ≥33) had a treatment benefit of CABG.[78]

In contrast to these studies, the Future Revascularization Evaluation in Patients with Diabetes Mellitus: Optimal Management of Multi-Vessel Disease (FREEDOM) trial was designed and conducted in a cohort limited to patients with type 2 DM and multivessel disease.[81] Among 1900 enrolled patients, the primary composite endpoint (death, MI, or stroke) was lower in patients treated with CABG versus PCI at 1 year (CABG 18.7% versus PCI 26.6%; $P = 0.005$), as well at 5 years of follow-up (CABG 11.8% versus PCI 16.8%; $P = 0.004$).[81] Of note, this result was driven largely by significant differences favoring CABG in death (CABG 10.9% versus PCI 16.3%; $P = 0.049$) and MI (CABG 6.0% versus PCI 13.9%; $P < 0.001$) at 5 years. Moreover, the incidence of repeat revascularization at 1 year after initial revascularization was significantly higher with PCI versus CABG (12.6% versus 4.8%; $P < 0.01$). However, stroke risk was conversely higher in the CABG group (5.2% versus 2.4%; $P = 0.03$), and no differences in CV

mortality were observed. Challenging contemporary generalizability, first-generation DES (sirolimus-eluting stent [SES] 51% and paclitaxel-eluting stent [PES] 43%) were used, and relatively low proportions of women (28.6%), patients with EF less than 40% (2.5%), and patients with less advanced CAD (SYNTAX score <22; 35.5%) were enrolled.[81]

Based on these trials, for patients with diabetes with stable CAD, the 2014 ACC/AHA guideline upgraded its previous recommendation in favor of CABG over PCI from class II (A) to class I (A),[83] in particular if a left inferior mammary artery (LIMA) graft can be anastomosed to the left anterior ascending (LAD) artery, provided the patient is otherwise a good candidate for surgery. Similarly, the 2014 ESC/EACTS Guideline on Myocardial Revascularization updated its previous recommendation of CABG over PCI in patients with diabetes and multi-vessel disease with an acceptable surgical risk to a class 1 (A) recommendation.[84] It bears consideration that the recommendations of these guidelines are based on trials that did not employ stents of the latest generation, with meta-analysis suggesting superiority of the newer stents compared with first-generation DES in patients with diabetes.[85]

Heart Failure in the Patient With Diabetes

Scope of the Problem

Although MI and hypertension are the most common risk factors associated with HF, diabetes also independently predicts HF risk, with an associated twofold to fivefold increased risk[7,86,87] (see Part IV, Heart Failure), Once HF is present, diabetes portends an especially adverse prognosis for subsequent morbidity and mortality.[7] In patients with diabetes and prevalent ASCVD observed in a registry over 4 years, HF at baseline was independently associated with increased CV death ($HR_{adjusted}$, 2.5; 95% CI 2.2 to 2.8).[87] In view of these observations, improved understanding of the pathobiologic underpinnings linking diabetes with HF and optimization of strategies for the prevention and treatment of HF in this population remain key public health considerations.

Mechanistic Considerations

Patients with and without diabetes share common causes of HF, such as ischemic heart disease, hypertension, left ventricular hypertrophy, and AF. Yet, these common risk factors do not completely account for the incremental HF risk with diabetes, suggesting increased myocardial vulnerability in the setting of diabetes and probable synergistic effects between such factors and diabetes that increase HF risk,[7] yielding the concept of “the ominous octet” of common conditions in diabetes that may underpin HF risk[7] (**Fig. 51.11**).

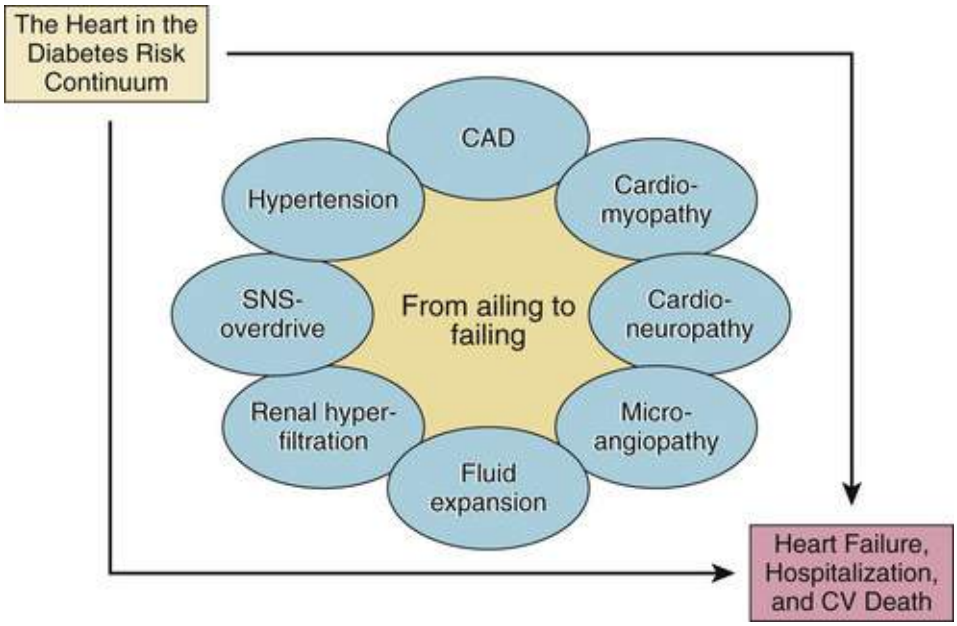

FIGURE 51.11 Heart failure in type 2 DM: the "ominous octet"—multiple comorbidities typically associated with type 2 DM that individually and in aggregate contribute to the increased risk for heart failure in such patients. CAD, Coronary artery disease; CV, cardiovascular; SNS, sympathetic nervous system. (From Standl E, Schnell O, McGuire DK. Heart failure considerations of antihyperglycemic medications for type 2 diabetes. Circ Res 2016;118:1831.)

Ischemic Heart Disease and Hypertension

In view of its high prevalence among patients with diabetes, ischemic heart disease remains the principal risk factor for HF in these patients, both in the chronic ambulatory setting and after ACS events. In addition to the burden of coronary atherosclerosis, other contributors to this increased risk may include increased prevalence of silent or atypical symptoms of ischemia delaying diagnosis and intervention, suboptimal use of therapeutic interventions, perturbed sympathovagal balance, a prothrombotic milieu, impaired coronary endothelial function, and disordered ischemic myocardial metabolism.[7] In aggregate, these effects and others probably increase ischemic burden, increase infarct size, and adversely affect remodeling in the setting of ischemic heart disease and ACS events. Affecting both ischemic heart disease and HF risk, hypertension prevalence exceeds 70% in populations with diabetes. Among patients with type 2 DM, risk of HF increases 12% to 14% for every increment of 10 mm Hg in systolic BP[27] (**see Fig. 51.7**).

Myocardial Metabolism and Structure

The direct effects of hyperglycemia and insulin resistance on myocardial cellular metabolism may contribute to cardiac dysfunction in diabetes,[7] with altered energy substrate supply and impairment of metabolic substrate switching under conditions of stress (**see Chapter 23**). The myocardium uses predominantly free fatty acids (FFAs) under aerobic conditions, but increasingly shifts to glycolysis and pyruvate oxidation during ischemia (**Fig. 51.12**).[7] In the diabetic heart, insulin resistance impairs such substrate switching and glucose transport into cells, resulting in anaerobic fatty acid oxidation and compromising the efficiency of myocardial energetics, as well as generating pernicious oxidative byproducts. Systemic FFA excess, combined with cellular dysregulation of lipid metabolism in type 2 DM, contributes to the accumulation of myocellular triglyceride (myocardial steatosis), resulting in further perturbations of myocyte metabolism and inducing apoptosis due to lipotoxicity, in addition to the adverse influence of cardiac mechanical function attributable to the increased myocardial mass.[7]

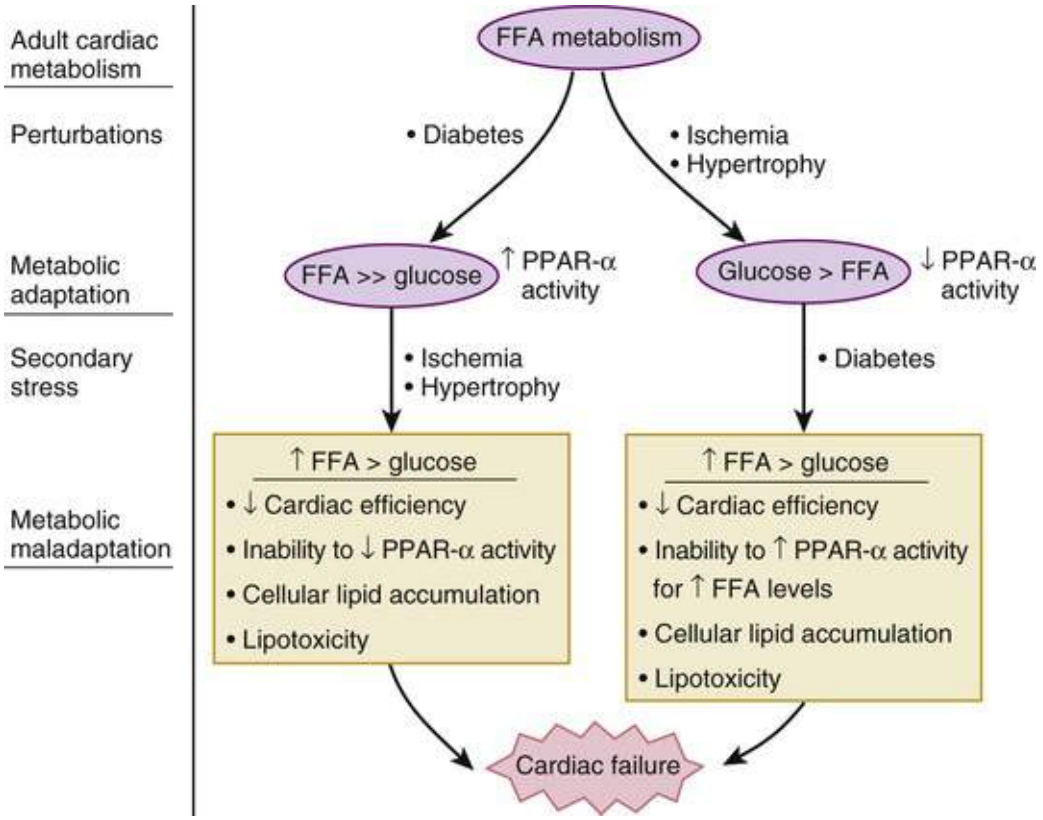

FIGURE 51.12 Schematic summary of cardiac adaptive and maladaptive metabolic modifications occurring in response to diabetes with or without superimposed ischemia or hypertrophy, culminating in overt cardiomyopathy. *FFA,* Free fatty acid; *PPAR*-α, peroxisome proliferator–activated receptor alpha.
(From Saunders J, Mathewkutty S, Drazner MH, McGuire DK. Cardiomyopathy in type 2 diabetes: Update on pathophysiological mechanisms. Herz 2008;33:184.)

Diabetes causes a variety of morphologic changes in the myocardium, with abnormalities in myocytes, extracellular matrix (ECM), and microvasculature.[7] Whereas such abnormalities are usually present across causes of cardiomyopathy, they tend to be more common and severe in the setting of diabetes. In addition, more specific to diabetes, the myocardial accumulation of advanced glycation end products (AGEs), including macromolecules nonenzymatically modified by glucose, the formation and accumulation of which depend on the severity of hyperglycemia, may contribute to HF risk. Deposition of AGEs within the myocardial ECM adversely affects both systolic and diastolic cardiac function, largely attributable to AGE cross-linking of matrix collagen.

Prevention and Management of Heart Failure in Diabetes

In general, drug therapies for HF evaluated in the overall population of patients with risk and disease generally have similar if not better efficacy in patients with diabetes compared with those without diabetes (**see Chapter 25**).

Modulation of the Renin-Angiotensin-Aldosterone System

In patients with diabetes, meta-analysis of the effects of ACE inhibitors demonstrates a trend to reduce incident HF (RR, 0.87; 95% CI 0.72 to 1.06),[27,28] and in patients with moderate to severe systolic dysfunction, significantly reduce mortality (RR, 0.84; 95% CI 0.7 to 1.0)[56,88]—numerically similar observations to those observed in patients without diabetes. Likewise, meta-analysis of placebo-controlled trials demonstrates significant reduction for incident HF with ARBs (HR, 0.70; 95% CI 0.59 to 0.83).[27] In the treatment of patients with prevalent HF, the data for ARBs are less consistent. Therefore,

ACE inhibitors should be first-line agents for the prevention and treatment of HF in patients with diabetes, and ARBs may be considered alternatives for patients intolerant of ACE inhibitors.[10,72]

The effect of aldosterone antagonists (e.g., spironolactone, eplerenone) in patients with diabetes and systolic HF has not been extensively studied. In the EPHESUS randomized trial in post-MI patients, superior efficacy of eplerenone was observed in the diabetes subset of 2122 patients, similar to that in the overall trial. On the basis of these results, eplerenone is recommended for all patients with diabetes and acute MI with decreased EF, except in the presence of contraindications such as kidney dysfunction or hyperkalemia, as described earlier.[10,62,64]

Angiotensin-Neprilysin Inhibition

Neprilysin is a circulating endopeptidase that degrades several vasoactive peptides, including natriuretic peptides, bradykinin, and adrenomedullin. Neprilysin inhibition increases the levels of these substances and augments their favorable effects on vasomotor tone and renal sodium handling. The clinical efficacy and safety of the neprilysin inhibitor *sacubitril* in fixed-dose combinations with valsartan (LCZ696) was compared with enalapril in patients with systolic HF in the PARADIGM HF trial.[89] The trial enrolled 8442 patients with class II to IV HF and with EF of 40% or less to receive either LCZ696 (200 mg) or enalapril (10 mg), each twice daily. Overall, LCZ696 significantly reduced the risk for composite outcome of HF hospitalization and CV death (HR, 0.80; 95% CI 0.73 to 0.87), death from any cause (HR, 0.84; 95% CI 0.76 to 0.93), and CV death (HR, 0.80; 95% CI 0.71 to 0.89). In the subset of 2907 patients with diabetes at baseline (39.4%), LCZ696 versus enalapril had comparable efficacy on the composite of HF hospitalization and CV death as observed in the overall trial, but there was heterogeneity of the effect on CV death, with the effect numerically smaller in the group with versus without diabetes ($P_{interaction}$ = 0.05), with a difference that was no longer significant. Therefore, in patients with diabetes, morbidity seems to be improved by LCZ696 over enalapril in patients with or without diabetes, but there is no clear mortality benefit of LCZ696 over enalapril in patients with diabetes.

Beta Blockers

Beta blockers and diuretic medications significantly reduce incident HF among patients with diabetes.[27] In addition, some beta blockers, including metoprolol succinate, carvedilol, and bisoprolol, have demonstrated benefit in the setting of HF with systolic dysfunction (**see Chapter 25**), and these effects appear to be similar independent of diabetes status.[10,72,88] Carvedilol may offer advantages in diabetic patients because of its favorable effects on insulin sensitivity and plasma lipid profiles, but the clinical relevance of these observations remains uncertain.[73] All beta blockers proven effective in the treatment of HF appear to yield similar effects in patients with diabetes.[10,72]

Heart Failure Considerations for Glucose Management Strategies and Antihyperglycemic Medications

Poor glycemic control is associated with risk of HF in patients with diabetes, with a stronger association in women than men. Whether dysglycemia is causal or simply an associated marker of underlying CVD risk remains uncertain. No trials to date have rigorously assessed the effect of targeting glucose control to any specific therapeutic levels, or the comparative effect of existing therapies alone or in combination with regard to their influence on major adverse HF events.[7] Meta-analyses of available data demonstrate no significant effect of more versus less aggressive glucose control on the risk for HF. Therefore the role of glucose control in the prevention and treatment of HF remains poorly understood, and pending further

data, patients with diabetes and HF should be treated to achieve the recently liberalized HbA_{1c} target of less than 8% with the avoidance of hypoglycemia, as endorsed for patients with recognized moderate to severe CVD.[14,15]

Some specific considerations warrant attention with regard to drugs and strategies used to treat hyperglycemia in the setting of HF.[7] Drugs with a propensity to precipitate hypoglycemia, especially sulfonylureas and exogenous insulin administration, should be used with some caution, because the stress response to hypoglycemia stimulates the neurohormonal axis implicated in the clinical complications of HF.

Thiazolidinedione medications have a propensity to increase plasma volume and to precipitate incident or worsening HF; their use requires caution in patients with any degree of HF, and they are contraindicated in patients with NYHA Class III or IV HF.[90] Although the modulators of the incretin axis, the GLP-1 RAs and DPP4 inhibitors, appear to have some favorable effects on a variety of intermediate markers associated with myocardial dysfunction and HF, thus far, large CV outcome trials involving several members of these two classes have shown no benefit on HF outcomes, with saxagliptin and alogliptin potentially increasing HF risk,[49] as now reflected in their U.S. product labeling.

Although metformin historically was thought to be contraindicated in the setting of HF, those product cautions were removed in 2006 on the basis of no incremental risk for lactic academia in a meta-analysis of all comparative data,[34] as well as observational studies in populations with HF yielding no sign of lactic acidosis risk and suggesting net clinical benefit. The product label did retain a caution for use specifically in the setting of acute or decompensated HF. The best available evidence supports consideration of metformin in patients with stable and compensated HF, especially in the context of the available CVD outcomes data, low risk of hypoglycemia, low cost, and favorable tolerability profile.

Insulin therapy remains an option in patients who fail to achieve benefit with conventional oral glucose-lowering therapies, although some concern persists based on the plausibility that insulin may exacerbate signs and symptoms of HF by increasing renal sodium reclamation, contributing to increased intravascular volume.[7] In the ORIGIN trial, patients randomly assigned to receive insulin glargine versus usual care tended to have fewer hospitalizations for HF, although this difference was not statistically significant (4.9% versus 5.5%; $P = 0.16$).[44] These observations from a large randomized trial analyzing 653 adjudicated HF hospitalization events support the probability that epidemiologic associations of worse outcomes in patients with HF treated with insulin result from confounding by indication, rather than from a pernicious effect of insulin, and challenge the concept that insulin may be detrimental because of its effects on sodium handling. Therefore, in patients with HF who fail to achieve acceptable HbA_{1c} targets with oral agents, insulin remains an acceptable option.[7]

As noted previously, the SGLT2 inhibitor empagliflozin reduced HF hospitalization by 38% in the EMPA-REG-OUTCOME trial that involved more than 7000 patients with type 2 DM and established CVD.[54,55] This benefit appeared to extend from those with and without HF at baseline, the latter comprising about 10% of the study cohort. A similar effect was seen with canagliflozin in CANVAS. Studies are currently underway with other SGLT2 inhibitors to assess whether this effect extends to the entire class, potentially related to their diuretic properties.

In summary, HF is common among patients with diabetes, and in addition to usual pathologic contributors to HF in common with the overall population, numerous metabolic and pathologic abnormalities associated with diabetes may explain the increased HF risk and inform drug development efforts toward new therapeutic targets.[7] Although the safety and efficacy of drugs and strategies of glucose control in patients with HF remain uncertain, the bulk of the evidence accumulated for the broader therapeutic arsenal for HF treatment in the overall population suggests that patients with diabetes derive

at least as much benefit (and often more) from such evidence-based therapies. Accordingly, in addition to ongoing research in this area, clinical efforts should focus on the optimal application of existing risk-mitigating therapies in patients with diabetes and HF. As for specific glucose-lowering agents, metformin may provide an advantage, as is also likely with SGLT2 inhibitors. Thiazolidinediones should be avoided. The GLP-1 RAs appear safe. Data regarding the DPP4 inhibitors varies from drug to drug. Saxagliptin and alogliptin should probably be avoided for patients with HF until more safety data have accumulated.

Atrial Fibrillation

Type 2 DM is independently associated with AF[8] and aggravates risk for stroke and systemic thromboembolism,[9] resulting in guideline recommendations for systemic anticoagulation for all patients with diabetes who have AF.[10] Although warfarin has historically been the mainstay of systemic anticoagulation for AF, the direct oral anticoagulants dabigatran, rivaroxaban, apixaban, and edoxaban now offer alternatives. For each therapy, the subanalyses of efficacy and safety for patients with diabetes participating in the pivotal registration trials of these medications suggest similar or even favorably amplified benefit/risk balance.[91] In fact, with similar relative risk reductions with the novel agents versus warfarin and the greater absolute risk for stroke observed in each trial, patients with versus without diabetes have more favorable number needed to treat (NNT) for benefit.[91]

Summary and Future Perspectives

Overall, diabetes increases risk for virtually all CVD complications and, most notably, atherosclerotic vascular disease, heart failure, and atrial fibrillation. Virtually all the advances in the care of patients at risk for CVD complications during the past few decades apply to patients with diabetes, with similar or even greater benefit in this high-risk population. Nonetheless, the gradient of risk associated with diabetes persists. Further progress requires continued efforts in two areas: First, increased and optimal application of the existing evidence for CVD risk reduction is of paramount importance, with studies consistently demonstrating a substantial gap between the accumulated evidence and its application in patients with diabetes. Second, continued investigation into specific therapies and strategies targeting the unique risks for CVD associated with diabetes remains a critical global public health imperative. In that light, driven largely by the regulatory evolution toward requiring CVD safety and efficacy evaluations for all antihyperglycemic medications developed for diabetes management, a proliferation of randomized CVD clinical outcomes trials currently are underway or in development, providing great promise for the future management of diabetic CVD. Currently, three such medications have proven CVD benefit: empagliflozin, liraglutide, and semaglutide, as well as pioglitazone in patients with insulin resistance.

Guidelines

Diabetes and Heart Disease

Darren K. McGuire, Silvio E. Inzucchi, and Nikolaus Marx

Recommendations for the management of patients with diabetes appear in various guidelines and

scientific statements from the American College of Cardiology Foundation (ACCF)/American Heart Association (AHA), European Society of Cardiology (ESC), and other cardiovascular societies; from the American Diabetes Association (ADA), European Association for the Study of Diabetes (EASD), and other endocrinologic societies; and from the National Cholesterol Education Program—Adult Treatment Panel and Joint National Committee, among others. Principal among these publications are dedicated scientific statements, developed by the ACCF and/or the AHA in collaboration with the ADA, and the ESC in collaboration with the EASD, focused on the care of patients with diabetes for the primary prevention of cardiovascular disease (CVD),[1-3] the management of hyperglycemia for hospitalized patients,[4] and the use of aspirin for primary prevention of CVD complications.[3,5] In addition, diabetes-specific guidance appears in ACCF/AHA guidelines for the management of non–ST-segment elevation acute coronary syndromes[6,7] and ST-segment elevation myocardial infarction (STEMI),[8] as well as the management of patients with heart failure (HF).[9-11] For the most part, guidelines are harmonious between the American and European societies regarding specific recommendations for patients with diabetes, with additional comments or clarifications included when such recommendations differ. Finally, the ADA provides recommendations for the global management of patients with diabetes, including but extending well beyond cardiovascular issues in the Standards of Medical Care in Diabetes,[12,13] updated annually—a breadth of guidance well beyond the scope of this chapter—and specific guidance in collaboration with the EASD on chronic glucose management targets and strategies.[14]

Primary and Secondary Prevention of Cardiovascular Disease

Therapeutic Lifestyle Counseling

Therapeutic lifestyle counseling (TLC) interventions are the cornerstone for the treatment of all patients with diabetes, including counseling for regular physical activity, nutritional counseling for weight management and healthy food choices, and counseling for smoking abstinence.[2,3,12,15] Medical nutrition therapy should be targeted at caloric restriction for weight management, increased dietary fiber intake, and limited fat intake (<30% of daily energy; <7% from saturated fats per ADA;[12] <35% of daily energy, saturated fat <10%, and monounsaturated fatty acids >10% per ESC/EASD.[3] Leisure time physical activity targets are at least 150 minutes weekly of modest-intensity exercise, or at least 90 minutes weekly of vigorous exercise. Beyond these, specific recommendations are available for the treatment of other cardiovascular (CV) risk factors, with the ACCF/AHA recommendations (**Table 51G.1**).

TABLE 51G.1

ACCF/AHA Recommendations for Primary Prevention of Cardiovascular Disease (CVD) in People with Diabetes

Lifestyle Management
Weight
Structured programs that emphasize lifestyle changes such as reduced fat (<30% to 35% of daily energy) and total energy intake and increased regular physical activity, along with regular participant contact, can produce long-term weight loss on the order of 5% to 7% of starting weight, with improvement in blood pressure.
For persons with elevated plasma triglycerides and reduced high-density lipoprotein (HDL) cholesterol, improved glycemic control, moderate weight loss (5% to 7% of starting weight), dietary saturated fat restriction, increased physical activity, and modest replacement of dietary carbohydrate (5% to 7%) by either monounsaturated or polyunsaturated fats may be beneficial.
Medical Nutrition Therapy
To achieve reductions in low-density lipoprotein (LDL) cholesterol: Saturated fats should be less than 7% of energy intake. Dietary cholesterol intake should be less than 200 mg/day. Intake of *trans*-unsaturated fatty acids should be less than 1% of energy intake. Total energy intake should be adjusted to achieve body weight goals.
Total dietary fat intake should be moderated (<30% to 35% of total calories) and should consist mainly of monounsaturated or polyunsaturated fat.
Ample intake of dietary fiber (≥14 g/1000 calories consumed) may be of benefit.
If individuals choose to drink alcohol, daily intake should be limited to one drink for adult women and two drinks for adult men. One drink is defined as 12 ounces (oz) of beer, 4 oz

of wine, or 1.5 oz of distilled spirits. Alcohol ingestion increases caloric intake and should be minimized when weight loss is the goal.
Individuals with elevated plasma triglyceride levels should limit intake of alcohol, because it may exacerbate hypertriglyceridemia.
In both normotensive and hypertensive persons, a reduction in sodium intake may lower blood pressure. The goal should be to reduce sodium intake to 1200 to 2300 mg/day (50 to 100 mmol/day), equivalent to 3000 to 6000 mg/day of sodium chloride.

Physical Activity

To improve glycemic control, assist with weight loss or maintenance, and reduce risk of CVD, at least 150 minutes of moderate-intensity aerobic physical activity or at least 90 minutes of vigorous aerobic exercise per week is recommended. The physical activity should be distributed over at least 3 days per week, with no more than 2 consecutive days without physical activity.
For long-term maintenance of major weight loss, a larger amount of exercise (7 hours of moderate or vigorous aerobic physical activity per week) may be helpful.

Blood Pressure

Blood pressure (BP) should be measured at every routine diabetes visit. Patients found to have systolic blood pressure (SBP ≥130 mm Hg or diastolic blood pressure (DBP) ≥80 mm Hg should have BP confirmed on a separate day.
Patients with diabetes should be treated to achieve SBP at least <140 mm Hg and DBP <90 mm Hg, and for patients who can tolerate without adverse symptoms, can target as low as SBP <130 mm Hg and DBP <80 to 85 mm Hg. Patients with SBP of 130 to 139 mm Hg or DBP of 80 to 89 mm Hg should initiate lifestyle modification alone (weight control, increased physical activity, alcohol moderation, sodium reduction, and emphasis on increased consumption of fresh fruits, vegetables, and low-fat dairy products) for a maximum of 3 months. If, after these efforts, targets are not achieved, treatment with pharmacologic agents should be initiated.
Patients with hypertension (SBP ≥140 mm Hg or DBP ≥90 mm Hg) should receive drug therapy in addition to lifestyle and behavioral therapy.
All patients with diabetes and hypertension should be treated with a regimen that includes either an ACE inhibitor, or if intolerant to an ACE inhibitor, an ARB. If one class is not tolerated, the other should be substituted. Other drug classes demonstrated to reduce CVD events in patients with diabetes—dihydropyridine calcium channel blockers, thiazide diuretics (chlorthalidone and indapamide), and beta blockers—should be added, in listed order of preference, as needed to achieve BP targets.
If ACE inhibitors, ARBs, or diuretics are used, kidney function and serum potassium levels should be monitored within the first 3 months. If BP is stable, follow-up could occur every 6 months thereafter.
Multiple-drug therapy generally is required to achieve BP targets.
In elderly hypertensive patients, BP should be lowered gradually to avoid complications.
Orthostatic measurement of BP should be performed in people with diabetes and hypertension when clinically indicated.
Patients not achieving target BP despite multidrug therapy should be referred to a physician specializing in the care of patients with hypertension.

Lipids

In adult patients with diabetes, lipid levels should be measured at least annually and more often if needed to achieve goals. In adults with diabetes younger than 40 with low-risk lipid values (LDL-C <100 mg/dL, HDL-C >50 mg/dL, triglycerides <150 mg/dL), lipid assessments may be repeated every 2 years.
Lifestyle modification deserves primary emphasis in all individuals with diabetes. Patients should focus on the reduction of saturated fat and cholesterol intake, weight loss (if indicated), and increases in dietary fiber and physical activity. These lifestyle changes have been shown to improve the lipid profile in patients with diabetes. In persons with diabetes who are older than 40, without overt CVD, statin therapy should be considered for primary prevention with recommendation to use at least moderate-dose and ideally intense-dose statins, independent of baseline LDL-C levels. On maximally tolerated statin, the goal is a LDL-C level <100 mg/dL (2.6 mmol/L), and ideally <70 mg/dL (1.8 mmol/L) for those as highest CVD risk. If LDL-lowering drugs are used, a reduction of at least 50% in LDL-C levels should be obtained.
If baseline LDL-C is <100 mg/dL, statin therapy should be initiated based on risk factor assessment and clinical judgment. Major risk factors in this category include age, sex, race/ethnicity, cigarette smoking, hypertension (BP >140/90 mm Hg or use of antihypertensive medication), high total cholesterol and low HDL-C (<40 mg/dL), and family history of premature coronary heart disease (CHD in male first-degree relative ≤55 years of age; CHD in female first-degree relatives ≤65 years of age).
In people with diabetes who are younger than 40, without overt CVD, but who are estimated to be at increased risk for CVD either by clinical judgment or by risk calculator, at least moderate-intensity statin therapy is recommended, with LDL-C goal of <100 mg/dL.
Combination therapy with LDL-lowering drugs (e.g., statins, ezetimibe, PCSK9 inhibitors) and fibrates or niacin may be necessary to achieve lipid targets, but to date, only the addition of ezetimibe to statin therapy has proven incremental CV outcomes benefit.
Beyond the consensus of therapeutic lifestyle intervention, the ADA and AHA guidelines have evolved significantly over recent years, no longer recommending pharmacologic treatment of low HDL-C or high triglyceride levels, except for those with extremely high fasting triglyceride levels, to consider fish oil or a fibrate to mitigate pancreatitis risk.

Tobacco

All patients with diabetes should be asked about tobacco use status at every visit.
Every tobacco user should be advised to quit.
The tobacco user's willingness to quit should be assessed.
The patient can be assisted by counseling and by developing a plan to quit.
Follow-up, referral to special programs, or pharmacotherapy (including nicotine replacement and bupropion) should be incorporated as needed.

Antiplatelet Agents

The ADA and AHA recommend aspirin therapy (75 to 162 mg/day) for primary prevention in patients with diabetes at increased CV risk (e.g., estimated 10-year risk >10%), including most age 50 and older who have additional risk factors (e.g., family history of CVD, hypertension, smoking, dyslipidemia, albuminuria). In contrast, the ESC/EASD guidelines discourage aspirin for primary prevention in patients with diabetes, except for those estimated to be at the very highest CV risk, in whom such use may be considered.
People with aspirin allergy, bleeding tendency, existing anticoagulant therapy, recent gastrointestinal bleeding, and clinically active hepatic disease are poor candidates for aspirin, especially for primary prevention. Other antiplatelet agents may be a reasonable alternative for patients with high risk.

Glycemic Control

The HbA_{1c} goal for most patients with diabetes in general is less than 7% in the absence of CVD, with higher targets such as 8% (or higher) endorsed for patients with moderate to severe CVD or other serious comorbidities.

Type 1 Diabetes Mellitus

At present, all the recommendations listed above for patients with type 2 DM appear to be appropriate for those with type 1 DM as well.

Data from Fox CS et al. Update on prevention of cardiovascular disease in adults with type 2 diabetes mellitus in light of recent evidence: a scientific statement from the American Heart Association and the American Diabetes Association. Circulation 2014;129(Suppl 2):S1-45.

Lipids (see also Guidelines Section, Chapter 48)

Lipid profiles should be obtained in all adults with diabetes.[2,3,12,15] As an adjunct to TLC interventions, the primary treatment for dyslipidemia is statin therapy,[2,3,12,15] with combination therapy reserved for those patients not tolerating statin therapy, acknowledging the limited outcomes data available to support the efficacy of any of the presently available add-on therapies. Statin medications should be prescribed for all patients with diabetes between ages 40 and 75 with low-density lipoprotein cholesterol (LDL-C) levels greater than70 mg/dL.[2,3,12,15,16] The U.S. guidelines endorse prescribing at least a moderate-intensity statin for patients with diabetes meeting indications, without specifying a therapeutic target.[12,16] The ESC/EASD guidelines have a slightly different approach, recommending statin therapy in patients with type 1 and type 2 diabetes mellitus (DM) at very high-risk (i.e., if combined with documented CVD, severe chronic kidney disease [CKD], or with one or more CV risk factors, and/or target-organ damage) with an LDL-C target of less than 1.8 mmol/L (<70 mg/dL) or at least a 50% or more LDL-C reduction if this target goal cannot be reached. Patients with type 2 DM at high risk (without any other CV risk factor and free of target-organ damage) should receive statins with an LDL-C target of less than 2.5 mmol/L (<100 mg/dL).[3] At present, no medical therapies are recommended specifically to target treatment of low levels of high-density cholesterol (HDL-C) or high levels of triglycerides. Also, no consensus has been reached, and no compelling data are available, to endorse any one additional therapy over another for this purpose, with options including ezetimibe, PCSK9 inhibitors, bile acid binders, fish oil, fibrates, and niacin.[12,15]

Blood Pressure

Blood pressure (BP) should be measured at every clinical encounter in patients with diabetes.[1-3,12] All patients with diabetes should be treated to a BP target of no higher than 140/80-85 mm Hg,[2,3,17] with a more intensive target of below 130/80 mm Hg for those who can achieve it without side effects or undue clinical burden of therapy.[12] TLC interventions, including physical activity, weight management, and dietary sodium restriction, form the cornerstone for the management of hypertension. Angiotensin-converting enzyme (ACE) inhibitors should be used as the primary antihypertensive therapy in the absence of contraindications or intolerance, or alternatively, angiotensin receptor blockers (ARBs) can be used in persons who experience cough, rash, or angioedema while taking ACE inhibitors. Other drug classes should be added as needed to achieve therapeutic targets, with dihydropyridine calcium channel blockers, thiazide diuretics (chlorthalidone or indapamide), and beta blockers, in order of preference based on evidence of CVD risk reduction in populations with diabetes.[2,3,12,17]

Aspirin

For primary prevention, the American guidelines endorse daily aspirin for patients with diabetes, age 50 years or older with one or more additional CVD risk factors.[2,13] The dose of aspirin recommended is 75 to 162 mg daily. The European guidelines discourage the use of aspirin for primary prevention for most patients, including those with diabetes, advising only that daily low-dose aspirin may be considered in highest-risk patients with DM on an individual basis (class IIb, level of evidence C).[3] The international guidelines are consistent in recommending daily low-dose aspirin (75 to 160 mg) for secondary prevention in patients with DM.

Glucose Management

In general, a hemoglobin (Hb) A_{1c} target of below 7% is recommended for most patients with diabetes.[2,3,12,14] The most recent guidance from ADA/EASD endorses a more personalized approach to

determination of the most appropriate HbA_{1c} targets based on patient and drug characteristics, with the consideration of more intensive control for younger patients, shorter duration of diabetes, and/or fewer comorbid conditions, and more liberal HbA_{1c} targets for higher-risk patients.[14] In addition to TLC, metformin is recommended for all patients with type 2 DM in the absence of contraindication or intolerance, with the addition of other therapies left to the discretion of the care provider, taking into account anticipated adverse effects and patient tolerance, contraindications, potential additional benefits, HbA_{1c} lowering potency, and cost.[14] In addition, in the wake of recent data demonstrating superiority of effects with regard to CV outcomes, recommendations have emerged supporting the use of selected antihiyperglycemic medications for patients with T2DM, independent of indication for glucose control, to reduce cardiovascular risk. The European Society of Cardiology guidelines for the diagnosis and treatment of heart failure recommend the use of empagliflozin specifically for the prevention of HF in patients with type 2 DM,[11] and the ESC Guidelines for the prevention of CVD recommend the use of an SGLT2 inhibitor for patients with T2DM and ASCVD early in the course of disease to reduce CV and all-cause mortality.[18] Similarly, the American Diabetes Association Standards of medical care for type 2 diabetes recommends empagliflozin, as well as liraglutide, for patients with T2DM and prevalent ASCVD.[19]

Secondary Prevention

In general, guidelines for the management of secondary CVD prevention are similar for patients with and without diabetes. **Table 51G.2** summarizes diabetes-specific recommendations for secondary prevention.[2,3,20]

TABLE 51G.2

ACCF/AHA Recommendations for Secondary Prevention of Cardiovascular Disease (CVD) Specific to Patients with Diabetes

CLASS	INDICATION	LEVEL OF EVIDENCE
I	Care for diabetes should be coordinated with the patient's primary care physician and/or endocrinologist.	C
	Lifestyle modifications including daily physical activity, weight management, blood pressure control, and LDL cholesterol management are recommended for all patients with diabetes.	B
	ACE inhibitors (or ARBs for those with ACE inhibitor intolerance) should be started and continued indefinitely in patients with diabetes, unless contraindicated.	A
	Use of aldosterone blockade in post-MI patients without significant kidney dysfunction or hyperkalemia is recommended in patients who are already receiving therapeutic doses of an ACE inhibitor and beta blocker, who have a left ventricular ejection fraction ≤40% and diabetes.	A
IIa	Metformin is an effective first-line pharmacotherapy and can be useful if not contraindicated.	A
	Individualizing the intensity of blood glucose–lowering interventions based on the individual patient's risk of hypoglycemia during treatment is reasonable.	C
IIb	Initiation of pharmacotherapy interventions to achieve target HbA_{1c} may be reasonable.	A
	A target HbA_{1c} of 7% or lower may be considered, whereas the ADA/EASD endorse a target of 8% or higher for those with moderate to severe CVD.	C
	Less stringent HbA_{1c} goals may be considered for other patients with a history of severe hypoglycemia, limited life expectancy, advanced microvascular complications, or extensive comorbidity, or those in whom the goal is difficult to attain despite intensive therapeutic interventions.	C

Data from Fox CS et al. Update on prevention of cardiovascular disease in adults with type 2 diabetes mellitus in light of recent evidence: a scientific statement from the American Heart Association and the American Diabetes Association. Circulation 2015;132:691-718; Ryden L et al. ESC guidelines on diabetes, pre-diabetes, and cardiovascular diseases developed in collaboration with the EASD. Eur Heart J 2013;34:3035-87; ADA Standards of Medical Care in Diabetes—2016: abridged for primary care providers. Diabetes Care 2016;34:3-21; Inzucchi SE et al. Management of hyperglycemia in type 2 diabetes, 2015: a patient-centered approach—update to a position statement of the American Diabetes Association and the European Association for the Study of Diabetes. Diabetes Care 2015;38:140-149; and Stone NJ et al. 2013 ACC/AHA guideline on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. Circulation 2014;129(Suppl 2):S1-45.

Acute Coronary Syndromes

With few exceptions, the management of patients with diabetes and unstable angina/non–ST-segment elevation myocardial infarction (UA/NSTEMI) or STEMI should be similar to that of patients without diabetes.[2,3,7,8,21] **Table 51G.3** summarizes diabetes-specific recommendations. In general, the recommendations unique to the diabetes population focus on an increased level of evidence for ACE inhibitors for all patients and aldosterone antagonists for those with left ventricular ejection fraction less than 40%, with or without clinical HF, following acute coronary syndrome (ACS) or myocardial infarction (MI) events; a higher level of recommendation for the adjunctive use of GP IIb/IIIa antagonists for patients with UA/NSTEMI; and preferential use of coronary artery bypass grafting (CABG) over percutaneous coronary intervention (PCI) for patients with more extensive coronary artery disease (CAD), independent of left ventricular systolic function. In addition, recommendations provide guidance for the use of insulin for targeted glucose control, noting a substantial evolution from the original guidelines in 2004 and 2007 that advocated normal or near-normal glucose target levels,[6,22] to the present targets of permissive hyperglycemia, reserving insulin only to maintain blood glucose below 180 mg/dL.[8,21]

TABLE 51G.3

ACCF/AHA Recommendations for Management of Unstable Angina/Non–ST-Segment Elevation Myocardial Infarction (UA/NSTEMI) and ST-Segment Elevation Myocardial Infarction (STEMI) in Patients with Diabetes

CLASS	INDICATION	LEVEL OF EVIDENCE
I	ACE inhibitors should be given and continued indefinitely for patients recovering from MI with diabetes unless contraindicated.	A
	Long-term aldosterone receptor blockade should be prescribed for patients with MI without significant renal dysfunction (estimated creatinine clearance should be >30 mL/min) or hyperkalemia (potassium should be <5 mEq/liters) who are already receiving therapeutic doses of an ACE inhibitor, have an ejection fraction less than 40%, and have diabetes, with or without clinical heart failure.	A
IIa	Use of an insulin-based regimen to achieve and maintain glucose levels less than 180 mg/dL while avoiding hypoglycemia for hospitalized patients with acute coronary syndromes, with either a complicated or uncomplicated course, is reasonable.	B
	For patients with UA/NSTEMI and multivessel disease, CABG using the internal mammary arteries can be beneficial over PCI in patients with medically treated diabetes.	B
	PCI is reasonable for UA/NSTEMI patients with diabetes with single-vessel disease and inducible ischemia.	B
IIb	The use of upstream GP IIb/IIIa inhibitors may be considered in UA/NSTEMI patients with diabetes already receiving aspirin and a $P2Y_{12}$ receptor inhibitor (clopidogrel, prasugrel, or ticagrelor) who are selected for an invasive strategy and are not otherwise at high risk for bleeding.	B

Data from Jneid H et al. 2012 ACCF/AHA focused update of the guideline for the management of patients with unstable angina/non-ST-elevation myocardial infarction (updating the 2007 guideline and replacing the 2011 focused update): a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. Circulation 2012;126:875-910; Roffi M et al. 2015 ESC guidelines for the management of acute coronary syndromes in patients presenting without persistent ST-segment elevation: Task Force for the Management of Acute Coronary Syndromes in Patients Presenting without Persistent ST-Segment Elevation of the European Society of Cardiology (ESC). Circulation 2013;127:e362-425; and ESC guidelines for the management of acute myocardial infarction in patients presenting with ST-segment elevation. Eur Heart J 2012;33:2569-619.

Coronary Revascularization

For patients requiring coronary revascularization, patients with diabetes have been among the most controversial population with regard to the merits of PCI versus CABG. The most recent ACCF/AHA/SCAI (Society for Cardiac Angiography and Interventions) guidelines for PCI have only one diabetes-specific graded recommendation—class IIb (B): CABG is probably recommended over PCI to improve survival in patients with multivessel CAD and DM, particularly if a left internal mammary artery graft can be anastomosed to the left anterior descending artery, a position echoed by the European guidelines.[3,23]

Patients with diabetes represent approximately one third of all patients undergoing PCI. For patients undergoing PCI, DM is among the characteristics favoring preferential use of drug-eluting stents (DES) over bare-metal stents (BMS), with no clear evidence favoring any one DES type over others.[23] Even with the use of DES, however, diabetes remains associated with significantly increased risk for in-stent restenosis. In addition, diabetes is identified as a specific risk factor for post-PCI complications, including periprocedural death and development of contrast-induced acute kidney injury, with recommendations for adequate preparatory hydration and minimization of the volume of contrast media used in such patients. In the setting of UA/NSTEMI, diabetes is among the patient characteristics favoring an early invasive management strategy.

Heart Failure

The diagnosis and management of HF generally are the same for patients with and without diabetes. **Table 51G.4** summarizes diabetes-specific recommendations from the most recent updates of the ACCF/AHA and ESC guidelines for the diagnosis and management of HF in adults.[10,11] The staging system for HF

identifies diabetes alone as HF stage A,[9] reflecting the high risk associated with diabetes for the development of HF, with modest incremental risk in men but threefold increased risk in women for developing HF in the setting of diabetes.

TABLE 51G.4

ACCF/AHA Recommendations for the Diagnosis and Management of Heart Failure (HF) in Patients with Diabetes

CLASS	INDICATION	LEVEL OF EVIDENCE
I	For patients with DM (all of whom are at high risk for developing HF), blood sugar should be controlled in accordance with contemporary guidelines.	C
I	Physicians should control systolic and diastolic hypertension and diabetes mellitus in patients with HF in accordance with recommended guidelines.	C
IIa	Empagliflozin should be considered in patients with type 2 DM to prevent or delay the onset of HF and to prolong life.	B
IIa	Treating dysglycemia should be considered to prevent or delay the onset of HF.	C
IIb	ACE inhibitors can be useful to prevent HF in patients with diabetes.	A
IIb	ARBs can be useful to prevent HF in patients with diabetes.	C

Approximately one third of patients with HF have diabetes. The importance of BP control, preferentially with ACE inhibitors or ARBs, is underscored for the prevention of HF in patients with diabetes. Metformin may be used in patients with stable HF with preserved renal function but should be avoided in patients with unstable HF or that necessitating hospitalization.[12] Pioglitazone should not be initiated in patients with NYHA Class III or IV HF, with caution for use in patients with any degree of HF.[12] Based on CV outcomes trial results with empagliflozin, the European Society of Cardiology HF Guidelines specifically endorse consideration for the use of empagliflozin for patients with type 2 DM for the prevention of HF.[11]

Air Pollution and Cardiovascular Disease

Aruni Bhatnagar

Although chemical contamination of the natural environment has been an inevitable consequence of human habitat development and civilization since prehistoric times, the levels of environmental pollutants in the air have increased most significantly since the Industrial Revolution. The accumulation of air pollutants emitted by industrial, traffic, household, and agricultural sources results in adverse effects on the health of exposed populations. The 2010 estimate of the Global Burden of Disease Study indicates that exposure to ambient and household air pollution is a leading cause of death worldwide.[1] Globally, 7 million premature deaths can be attributed to air pollution each year, including 200,000 premature deaths in the United States, 1.6 million death in China, and 1.3 million deaths in India per year. Almost 80% of these deaths are a result of cardiovascular disease (CVD), and more than 60% of these result from indoor air pollution. In its health impact, exposure to air pollution rivals the effects of hypertension, smoking, or physical inactivity.[2] Exposure of polluted air is pervasive, and in some geographic locations, ubiquitous. More than 95% of the urban population currently lives in cities where the levels of air pollution exceed the air quality guidelines of the World Health Organization (WHO).[2] Therefore, even though exposure to

air pollution increases the individual risk of CVD and death only slightly, the overall population health impact of air pollution is substantial.

Composition of Air Pollution

Particulate Matter

Humans living in urban areas are exposed to air pollutants generated by both outdoor and indoor sources. The outdoor sources that generate these pollutants and the type of the pollutants produced vary with geographic location, weather, and local urbanization. Most air pollution consists of aerosols containing a mixture of both particles and gases. Of these, *particulate matter* (PM) suspended in air has received the most attention because it is easily measured and readily relatable to the adverse health effects of polluted air. When analyzed for mass, urban air particle distribution reveals two peaks corresponding to *coarse particles*, approximately 10 to 20 µm, and *fine particles*, varying from 0.1 to 2.5 µm. The fine-particle mode contains one third to two thirds of total PM mass. Within this category, a small fraction consists of *ultrafine particles* (UFP). This fraction, despite its modest contribution to the overall volume of PM, contains the largest number of particles and thus presents the most surface area (**Table 52.1**).

TABLE 52.1

Ambient Air Aerosols and Cardiovascular (CV) Effects

POLLUTANT	U.S. EPA STANDARD	SOURCES	ACUTE CV EFFECTS	CHRONIC CV EFFECTS
PM_{10} (aerodynamic diameter >2.5 microm)	150 µg/m^3 (24 hr)	Windblown soil, agriculture, surface mining, plants	Increased all-cause mortality, CVD mortality, increased BP, exacerbation of asthma, stroke, hospital admissions, suppression of heart rate variability	Exacerbation of ischemic heart disease, congestive heart failure
$PM_{2.5}$ (aerodynamic diameter 0.1 to 2.5 microm)	35 µg/m^3 (24 hr)	Combustion particles, smog, diesel, gasoline	All-cause mortality, CVD mortality, MI, atrial fibrillation, sudden cardiac death, peripheral artery disease exacerbation of heart failure, increased BP, stroke, hospital admission, suppression of heart rate variability	Atherosclerotic lesion formation, increased intima-media thickness, coronary artery calcification
SO_4	75 ppb (1 hr)	Combustion of sulfur-containing fuels: coal and petroleum	All-cause mortality, CVD mortality	—
NO_2	100 ppb (1 hr)	Combustion of fossil fuels, power plants, automobiles	Acute MI	—
Ozone	70 ppb (8 hr)	UV photolysis of NOx and VOCs	All-cause mortality	—

BP, Blood pressure; *CVD,* cardiovascular disease; *EPA,* Environmental Protection Agency; *MI,* myocardial infarction; *NOx,* nitrogen oxides; *PM,* particulate matter; *ppb,* parts per billion; *UV,* ultraviolet: *VOCs,* volatile organic compounds.

Both primary and secondary particles are present in the atmosphere. *Primary particles* are directly emitted into the atmosphere. *Secondary particles* arise from gas-to-particle conversion in the air. *Primary aerosols* are mineral dust, metals, soot, salt particles, pollen, and spores, whereas *secondary aerosols* are generated by sulfates, nitrates, and organic compounds. The formation of secondary aerosols proceeds through the processes of *nucleation,* in which gases transition to liquid or solid phase by condensation or chemical reaction. This leads to the formation of nuclei or particles and is followed by condensation of hot gases and coagulation or agglomeration of particles by turbulence, gravitational sedimentation, and brownian motion to generate secondary particles. The nature, composition, and size distribution of secondary particles is determined by several atmospheric factors, such as humidity, temperature, and sunlight as well as specific gases and primary particles. As a result, PM composition

varies between different locations depending on local emission sources. In most U.S. cities, the current average daily concentration of fine particles ($PM_{2.5}$) varies between 5 and 15 μg/m^3, although episodes of $PM_{2.5}$ levels exceeding 100 μg/m^3 are not uncommon. The $PM_{2.5}$ concentration in cities in the developing countries is much higher; the 24-hour average $PM_{2.5}$ levels in China range from 18 to 116 μg/m^3; with a mean of approximately 60 μg/m^3 (**Table 52.1**).[3,4]

Gaseous Pollutants

In addition to PM, the indoor and the outdoor air also contains a variety of other pollutants. These include gases or vapor-phase compounds such as carbon monoxide (CO), nonmethane hydrocarbons, nitrogen oxides (NOx), sulfur oxides (SOx), ozone (O_3), and volatile organic carbons (VOCs). Most of these gases are present naturally in the atmosphere, but their abundance in the atmosphere increases when they are generated by combustion processes such as burning of fossil fuels or high-temperature industrial processes. These gaseous pollutants could also arise from "fugitive release" by a variety of human activities (e.g., agriculture) or natural phenomena (e.g., erosion, volcanic eruptions). In addition, secondary pollutant gases are generated by atmospheric chemistry-mediated by sunlight, water, and vapor. Such chemistry gives rise to many gases, such as sulfates, nitrates, and ammonia, which are associated with and constitute the organic component of PM. Pollutants such as hydroxyl radical, peroxyacetyl nitrate, nitric acid, formic acid, and acetic acid, as well as formaldehyde and acrolein, arise from such atmospheric reactions. VOCs (e.g., formaldehyde, acrolein, benzene, xylene, 1,4-butadiene) and polycyclic aromatic hydrocarbons (PAHs) partition between particle and gaseous phases and contribute to the formation of O_3. Many VOCs are oxidized in the atmosphere to form semivolatile organic compounds that subsequently partition within particles and contribute to both PM mass and PM composition.

Because of the complex chemistry of gaseous pollutants, their variable condensation reactions, and multiple interactions with airborne particles, the nature of air pollution varies with time, weather, season, and temperature. In urban environments, NOx, CO, and VOCs are coemitted with black carbon and therefore peak during "rush hour" motor vehicle traffic, whereas O_3 and other photochemical oxidants peak in the afternoon, particularly on sunny days. This variability in gaseous co-pollutants contributes to a diversity of exposures across different geographic locations and natural conditions and thus are difficult to characterize and quantify.

Outdoor and Indoor Air Pollution

Outdoor or ambient atmospheres contain PM generated by both natural and anthropomorphic sources. Processes such as volcanic eruptions, spontaneous forest fires, sea sprays, and soil erosion are natural sources that generate atmospheric PM, which can arise also from unpaved roads, traffic, mining, welding, building and other human activities. Most *coarse* PM (PM_{10}) arises from dust and ground materials, endotoxin, pollen grains, fungal spores, vegetation, and debris, whereas *fine* PM ($PM_{2.5}$) is derived mostly from smog, traffic, and combustion. In most urban environments, traffic is the major source of PM; in London, 83% of atmospheric PM_{10} can be attributed to traffic. Generally, combustion of any fossil fuel —wood, gas, diesel, and gasoline—generates PM, particularly fine and ultrafine PM.

In developing countries, most of indoor air pollution arises from biomass fuels, coal, and kerosene burned in open fires for cooking and heating.[5] Cooking, particularly frying, is an important source of

indoor pollution. Most of the particles generated by frying are *ultrafine* particles, and cooking indoors can lead to a 10-fold increase in the number of ultrafine particles. Ultrafine particles are also generated by gas flame and wood smoke. Burning of candles or incense can generate high levels of particulate air pollution. Air fresheners generate xylene, aldehydes, and esters, which can react with O_3 to produce secondary pollutants such as formaldehyde, secondary organic aerosols, and ultrafine particles. In many residential buildings the indoor air contains pollen, dander, toxic molds, and dust, which frequently consists of fungi, endotoxin and bacteria, as well as tobacco smoke. Depending on the construction and use pattern, indoor air may also be polluted by ambient or outdoor pollutants. In developed countries the indoor level of most air pollutants is often lower than, but highly correlated with, their outdoor concentration. There are few indoor sources of $PM_{2.5}$, which comes mostly from outdoor sources and traffic. Therefore, living next to a major street increases the levels of indoor $PM_{2.5}$ and increases exposure to traffic-generated pollutants such as NOx and VOCs.

Air Pollution and Cardiovascular Mortality

Data from the first longitudinal cohort studies showed that the adjusted mortality rate ratio of the most polluted to the least polluted cities was 1.26 (1.08 to 1.47). Air pollution was positively associated with deaths from lung cancer and cardiopulmonary disease. Subsequent work showed that 80% of the excessive deaths attributable to chronic air pollution exposure are caused by CVD, particularly ischemic heart disease, arrhythmias, heart failure, and cardiac arrest. It has been estimated that each $10\mu g/m^3$ increase in $PM_{2.5}$ levels is associated with an 8% to 18% excessive risk of cardiovascular (CV) mortality, with comparable or greater risks for smokers than nonsmokers.[3] The risk persists even at concentrations well below the current regulatory standards, and no threshold has been detected below which air pollution does not affect CV health or mortality. The exposure-response relationship between long-term exposure to $PM_{2.5}$ and the risk of CVD mortality is not linear, but rather steep at low levels of exposure and flattening at high exposure levels, such that most of the risk is imparted at low levels of exposure, with declining marginal effects at higher concentrations. Thus the risk of CVD mortality caused by long-term $PM_{2.5}$ exposure may be comparable in different cities, even with widely different levels of air pollution.

Short-term increases in PM are associated with increased risk of total mortality. For each $10\mu g/m^3$ increase in $PM_{2.5}$, there is a 0.7% to 1.7% increase in all-cause mortality on subsequent days. In Europe, outdoor pollution was found to be responsible for 6% of total mortality, half of which could be attributed to automobile emission. Interestingly, the number of deaths attributable to air pollution exceeded that from motor vehicle crashes. Similar risk estimates have been observed for CV mortality. Short-term elevations in daily PM levels lead to a greater absolute risk for CVD-related mortality than for all other causes. CVD mortality accounts for 69% of the increase in absolute mortality attributable to short-term PM exposure. Consistent associations between CVD mortality and short-term increases in PM levels have been reported from more than 100 cities worldwide. In most studies the relationship between PM exposure and excessive mortality appears to be independent of gaseous co-pollutants; however, CVD mortality has also been associated with episodic increases in ambient levels of NO_2, CO, and O_3 levels. Although PM exposure leads to a population-wide increase the risk of CVD mortality, smokers, elderly persons, and patients with diabetes or heart failure appear to be particularly sensitive to PM exposure.

Like outdoor exposure, indoor exposure to air pollution is also linked to excessive CV mortality. It has

been estimated that indoor air pollution is associated with 1.6 to 3.5 million deaths globally each year. Cumulative health impacts from inhalation in U.S. residences of indoor air pollution ($PM_{2.5}$, acrolein, and formaldehyde, which account for a vast majority of disability-adjusted life-year [DALY] losses) are 400 to 1100 DALYs lost annually per 100,000 persons. This impact is comparable or greater than estimates for secondhand smoke exposure. In Europe, exposure to biomass smoke has been linked to 40,000 premature deaths per year. In developing countries, indoor air pollution caused by biomass burning is associated with 2 million deaths per year; many of these are women who die from CVD. Current epidemiologic evidence indicates that the use of biomass fuels for cooking and heating increases the risk of coronary heart disease (CHD) twofold to fourfold.[5]

Cardiovascular Effects of Air Pollution

Exposure to air pollution has a wide range of acute and chronic CV effects[6] (**Fig. 52.1**). Most such effects have been linked to particulate air pollution, which is a readily measured constituent of air pollution. However, the levels of PM co-vary with other pollutants, and therefore, it is often difficult to rule out the effects of other co-pollutants or the effects of co-pollutants that might act additively or synergistically with PM. Moreover, PM by itself is a heterogeneous collection of particles of varying size and chemical composition, and as a result the biologic effects of PM vary substantially with its composition. It is still unclear which PM constituents are linked with which specific health effects. No specific exposure biomarkers of PM exposure have been identified to date, and therefore, in most epidemiologic studies, exposure misclassification cannot be ruled out. Also, no characteristic pathologic states can be specifically attributed to PM. Exposure to PM affects the final common pathways of CVD. Systemically, PM exposure affects blood pressure, lipids, insulin resistance, coagulation, and organ-specific effects such as neuronal activation, myocardial excitability, oxidative stress, and inflammation. As a result, no specific pathologic feature or clinical state can be directly linked to PM exposure. Nevertheless, the major effects of PM on cardiovascular tissue and function are related to the disease states discussed next.

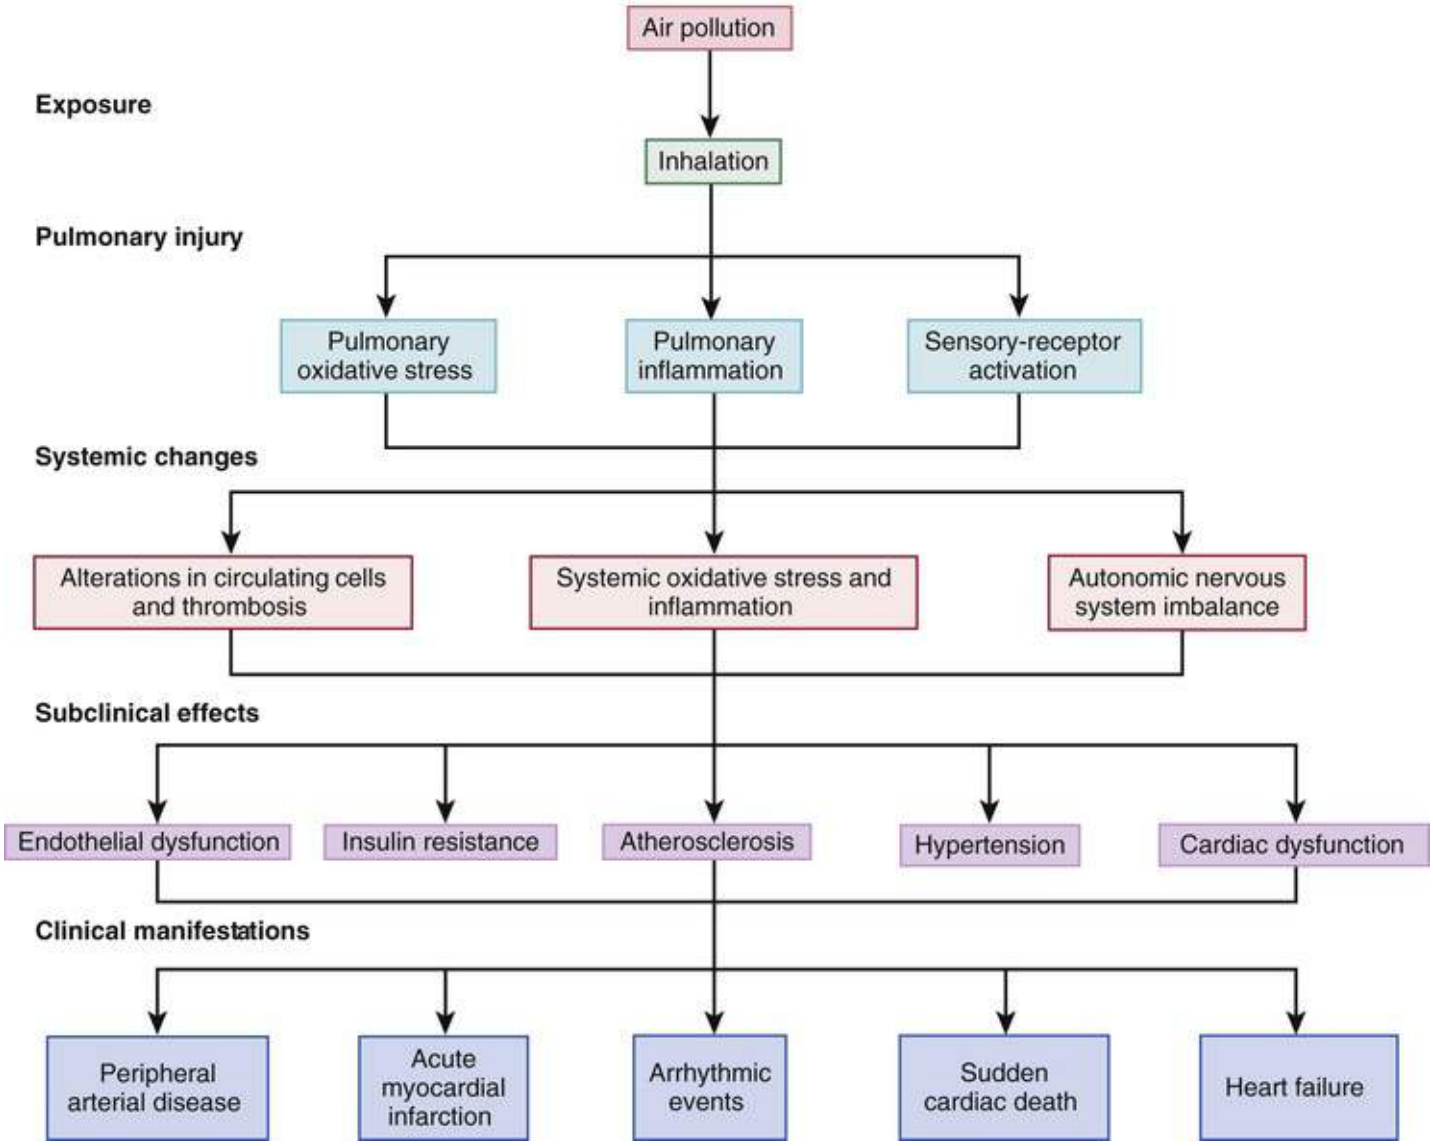

FIGURE 52.1 Cardiovascular effects of exposure to particulate matter (PM). Airborne particles inhaled from the ambient air are deposited in the lung or transported in the circulation, where they induce oxidative stress and establish a state of mild inflammation. Exposure to PM also activates sensory receptors, leading to an imbalance in the autonomic nervous system activity. Systemic oxidative stress and inflammation caused by PM exposures are associated with alterations in the circulating leukocytes and stem cells and subclinical injury to cardiovascular tissues, leading to endothelial dysfunction and exaggeration of insulin resistance, atherogenesis, hypertension, and cardiac dysfunction in susceptible individuals. These alterations manifest as worsening of peripheral artery disease, heart failure, and arrhythmic events and can precipitate acute myocardial infarction or sudden cardiac death.

Myocardial Infarction

Exposure to air pollution significantly increases the risk of acute myocardial infarction (MI) (**see Chapters 58 to 60**). Increased MI risk is associated with exposure to ambient particulate air pollution, gaseous pollutants, household air pollution, and traffic-generated pollutants. Both acute and chronic exposures increase risk. Elevated risk for MI is associated with exposure to elevated PM or traffic exposure over a period as brief as 1, 2, or 6 hours or a few days. The acute risk may remain elevated and may increase even 2 days after exposure. The increase in risk is variable and may range from 10% to 20% increase in risk per 10μg/m^3 increase in $PM_{2.5}$ levels, depending on geographic location, season, and individual vulnerability. The risk is more strongly associated with $PM_{2.5}$ than UFP, PM_{10}, or gaseous co-pollutants. At levels present in most U.S. cities, $PM_{2.5}$ represents an acute threat mostly to elderly

individuals or those who have recognized or unrecognized coronary artery disease (CAD) or structural heart disease. Obese women may be particularly at risk. However, daily $PM_{2.5}$ levels seem to be associated with the risk of ST-segment elevation MI (STEMI) but not non–ST-segment elevation MI (NSTEMI).

Acute exposure to traffic-generated pollution within the hour prior to MI is strongly associated with the onset of MI (odds ratio [OR], 2.9), suggesting that pollutants generated by motor vehicles could trigger acute events. An estimated 7.4% of acute MIs would be prevented if exposure to traffic air pollution did not occur. Long-term exposure to traffic-related air pollution is also associated with a significant increase in acute MI as well as MI recurrence. Similarly, long-term exposure to elevated ambient $PM_{2.5}$ levels also increases the risk of ischemic heart disease death, and each 10μg/m^3 increase in $PM_{2.5}$ levels is associated with a 10% to 30% increase in ischemic cardiac events in those living in areas of high pollution. Significantly higher levels of mortality risk have been seen in those living within 50 m of major roadway with high levels of traffic, and relocation from a less polluted to a more polluted neighborhood increases MI risk in susceptible individuals. Conversely, a decrease in area $PM_{2.5}$ levels reduces ischemic heart disease admissions. In the United States, stronger association of $PM_{2.5}$ levels with CV events has been observed in the Northeast than in other regions, possibly because of differences in the source of air pollution (e.g., greater sulfate-containing pollutants generated by power plants in the East and higher nitrate content of pollutants in the West, generated mainly by transportation sources).

Arrhythmogenesis

Exposure to both ambient air pollution and traffic-related pollutants is associated with cardiac electrical instability, alterations in heart rate, and heart rate variability (**see Chapters 37 to 39**). Similarly, chronic exposure to indoor air pollution can lead to electrical perturbations that may increase arrhythmia risk. Although healthy individuals may be somewhat impervious to the arrhythmogenic effects of air pollution exposure, individuals with preexisting disease are likely to be more sensitive. Exposure to particulate air pollution can affect the autonomic nervous system, often leading to a decrease in parasympathetic tone (**see Chapter 99**). Some studies have reported that even in healthy individuals, long-term exposure to air pollution is associated with QT prolongation (OR, 1.6), intraventricular conduction delay, and dispersion of ventricular repolarization, in part by increasing sympathetic modulation of the heart rate. Ventricular repolarization may also be affected on exposure to household wood smoke. The incremental risk of air pollution in triggering arrhythmias may be higher in elderly persons or individuals who have underlying cardiac disease. The associations with arrhythmias appear to be strongest for PM_{10}, $PM_{2.5}$, and O_3, as well as traffic-generated pollutants. In patients with implantable cardioverter-defibrillators (ICDs; **see Chapter 41**), even moderate increases in air pollution appear to be associated with ventricular arrhythmias within 2 hours of exposure, although the effects may persist over longer durations. Ambient levels of $PM_{2.5}$ within the past 1 to 2 days show a positive dose-dependent relationship with increased risk of out-of-hospital cardiac arrest, particularly in individuals with high CVD risk burden (**see Chapter 42**).

Acute exposure to ambient or traffic-related pollution can increase the risk of atrial fibrillation (AF) as well[7] (**see Chapter 38**). Exposure to $PM_{2.5}$ pollution is associated with prolongation of the PR duration and an increase in the P wave complexity, which are predictors of AF and atrial flutter. In patients with known CVD, for each 6.0μg/m^3 increase in $PM_{2.5}$, the risk of AF increases by 26% within 2 hours of exposure. Exposure to air pollution also leads to a slight increase in the daily maximum heart rate, heart

block frequency, and percentage of time in AF. Episodes of paroxysmal AF detected by ICDs are increased in a few hours after exposure to ambient O_3 levels, although significant associations between AF have also been observed with $PM_{2.5}$, gaseous pollutants, and atmospheric CO. Long-term exposure to traffic-related air pollution in particular is associated with a higher risk of AF and ventricular tachycardia. Independent of other CVD risk factors, living next to major roadways may also increase the risk of sudden cardiac death (SCD) and fatal CHD.[8] A linear 6% increase in the hazard ratio for SCD has been reported for each 100-m increase in residential proximity to a major roadway.

Heart Failure

Although not as strong as that for ischemic heart disease, there is a significant relationship between deaths from heart failure (HF) and exposure to air pollution (**see Chapters 23 and 24**). Short-term changes in PM levels are associated with an increase in daily hospitalization for HF, and a 10μg/m^3 increase in same-day $PM_{2.5}$ is associated with a 1% to 1.5% increase in HF admissions, whereas a reduction in $PM_{2.5}$ reduces HF admissions. In most locations, HF deaths account for 10% of all CVD deaths, but for 30% of CVD deaths related to PM exposure, suggesting that the failing heart may be particularly vulnerable to air pollution. During HF, the heart undergoes adverse remodeling that can compromise cardiac function and electrical conduction. Direct effects of chronic exposure to air pollution on cardiac function and remodeling have been reported in both human and animal studies. Residential proximity to major roadways and higher residential levels of air pollution are associated with increased right and left ventricular mass, even in a cohort free of clinical CVD. Also, exposure to the traffic-generated pollutant NO_2 has been associated with a 5% increase in right ventricular mass, comparable to the increase associated with diabetes or smoking. That HF may be a particularly vulnerable state is supported by a significant association between traffic-related air pollution and increased mortality risk after HF.[2]

Hypertension

Changes in blood pressure (BP) are associated with exposure to both indoor and outdoor air pollution[3] (**see Chapters 46 and 47**). Even modest increases in air pollution are associated acutely with changes in systemic arterial BP (approximately 1 to 4 mm Hg per 10μg/m^3 increase in PM), although the effects may be larger in elderly individuals or those with preexisting CVD. Larger (8 to 9 mm Hg) effects have also been reported 2 to 5 days after exposure to higher levels of $PM_{2.5}$. Chronic exposure to elevated levels of air pollution may lead to the onset of hypertension. Individuals who live near major roadways and are therefore exposed recurrently to traffic-generated pollutants have a higher prevalence of hypertension. Comparing those who live less than 100 m of a major roadway with those who live more than 1000 m, a 9% higher prevalence has been reported. That exposure to air pollution affects BP regulation is supported by data from studies in which healthy young adults were exposed to particulate air pollution. These studies have shown that acute exposure to PM or diesel exhaust could lead to a modest (3 to 4 mm Hg), but rapid increase in systolic BP and a smaller increase in diastolic BP. It is likely that the effect of air pollution on BP may be greater in individuals with CVD, or that the magnitude of the effect may be sufficient to trigger acute events or to induce chronic CV dysfunction. Significantly, antihypertensive drugs appear to mitigate against the effects of air pollution on BP, and therefore appropriate medical management of hypertension could attenuate the impact of air pollution exposure.[2]

In addition to ambient and traffic pollution, indoor air pollution from household biomass burning could

also affect BP and hypertension.[5] In healthy individuals, exposure to $PM_{2.5}$ generated by biomass combustion increases systolic, and to a lesser extent, diastolic BP. The increase is rather small, 2- to 4-mm Hg in systolic and 0.5 to 2 mm Hg for diastolic blood pressure, but may be significant in individuals with preexisting disease. Indoor air pollution due to the use of solid fuels is also associated with increased prevalence of hypertension and an increase in the markers of oxidative stress, inflammation, and cell adhesion; changes that collectively can contribute to the impact of household pollutants on CV health.

Pathophysiology

Inhalation of ambient air particles (<10 μm) results in the deposition of airborne particles in the lung, particularly on bifurcations or angle ramifications of the bronchial tree due to air flow and turbulence, which increases the interaction of PM with the mucous membrane.[9] In humans the median ratio of carinal/tubular deposition of PM is 9 : 1. Within the lung, the coarse (PM_{10}) and fine ($PM_{2.5}$) particles follow different deposition routes, and because they contain different constituents, they elicit different responses. Larger particles are deposited solely in the extrathoracic airways. PM_{10} is preferentially deposited in the bronchial airways, through impaction and sedimentation, and its deposition activates the innate immune response, in part by endotoxin and other bacterial components often associated with aerosolized PM_{10} in ambient atmospheres. However, independent of this biologic material, interactions of PM_{10} with the lung epithelial cells results in the production of interleukin (IL)-8, and the resultant recruitment of neutrophils to the lung leads to airway inflammation. Fine particles are deposited in lung, especially in the alveoli, through sedimentation and brownian diffusion and can also pass into the systemic circulation. These particles carry little or no biologic material and are deposited in the lung in greater quantities than larger particles. In the alveolar spaces, fine particles initially impact the surfactant-rich alveolar lining layer. Interactions between PM and surfactant lipids can lead to physical impairment of lung surface and may be involved in their clearance by macrophages. In addition, impaired surfactant function could lead to chronic lower airway inflammation. The ultrafine particles are mainly deposited in the lung by brownian motion and can pass from the lung to other peripheral organs, including the heart and the brain.

Deposition of PM in the lung leads to the production of reactive oxygen species (ROS) such as the oxygen-centered free radicals superoxide and hydroxyl. The ability of the PM to generate ROS is correlated with its overall metal content. Airborne particles contain a variety of metals (e.g., Fe, V, Cr, Mn, Co, Ni, Cu, Zn, Ti), and these metals catalyze Fenton-type reactions that generate ROS. In addition, PM collected from U.S. cities also contains persistent free radicals derived from redox-active semiquinones. The semiquinone-like radicals are chemisorbed on the particles and provide persistent redox-active surfaces of the particles that, in the presence of oxygen, undergo autocatalysis to generate free radicals such as superoxide. In addition, PAHs present in the particles, which can be metabolically converted to redox-active quinones, may be another source of ROS production. Some investigators suggest that even without ROS on the surface, the carbonaceous core of ultrafine PM can cause oxidative stress merely by presenting a large surface area. PM could also increase ROS production by stimulating an oxidative burst in resting human peripheral blood polymorphonuclear leukocytes (PMNs). Thus, deposition of fine and ultrafine particles could lead to extensive ROS generation in the lung. Data from animal models showing that increased removal of ROS in the lung prevents the vascular effects of PM support the concept that local, pulmonary ROS generation triggers the systemic effects of PM.[10]

Increased ROS production by PM in the lung results in the development of oxidative stress, characterized by depleted antioxidant capacity and accumulation of lipid peroxidation products. This is usually accompanied by a decrease in lung capacity and pulmonary inflammation characterized by the production of several cytokines such IL-8, IL-6, TNF-α, and IL1β. Increased production of cytokines in the lung promotes the accumulation of neutrophils, protein and fibrinogen in the bronchoalveolar fluid. These changes often impair host defense by inducing apoptosis in alveolar macrophages and inhibiting PMN phagocytosis and respiratory bursts. As a result, inhalation of PM induces a state of mild pulmonary inflammation, the systemic consequences of which exacerbate CVD risk. In addition, PM inhalation directly activates sensory receptors.[11] Stimulation of these receptors can cause an imbalance in the autonomic nervous system, which may affect both cardiac rhythm and cardiac conduction, leading to an increase in the risk of arrhythmias and SCD, particularly in vulnerable individuals.

The plausibility of a direct link between PM exposure and adverse CV events is supported by data from studies on humans and animals exposed to PM under well-controlled conditions. For instance, even in normal adult humans, exposure to air pollutants such as diesel exhaust elicits an inflammatory response in the lungs. Similarly, healthy humans respond to concentrated ambient PM with small changes in acute brachial artery vasoconstriction and increased diastolic BP, suggesting that PM exposure acutely affects conduit artery flow. Animal studies have allowed a more detailed evaluation of the CV effects of PM exposure. Exposure to concentrated PM increases vascular inflammation and accelerates atherosclerotic lesion formation in atherosclerosis-prone mice and rabbits, and exposure to diesel exhaust particles results in rapid activation of circulating blood platelets, suggesting that PM exposure increases peripheral thrombosis.[3] The atherogenic effects of air pollution have also been seen in humans. It was recently reported that exposure to increased concentration of $PM_{2.5}$ or traffic-related air pollution is associated with progression of coronary calcification,[12] consistent with acceleration of atherosclerosis, suggesting that exposure to air pollution increases subclinical CVD progression or CVD risk (**see Chapter 44**). Indeed, exposure to high PM levels has been associated with increased platelet activation[13] and increased fibrinogen levels even in healthy adult humans. More recent work has shown that prolonged exposure to concentrated PM exaggerates adipose tissue inflammation and systemic insulin resistance in mouse models of diet-induced obesity. [14] Exposure to PM has also been linked to an increase in insulin resistance, as well as prevalent and incident diabetes in humans.[2] Together, these results provide strong support for the view that PM exposure elicits a range of adverse CV effects, which could explain, at least in part, the positive associations between PM levels and the incidence of CV events and mortality, reported in epidemiologic studies.

Occupational Exposures

In addition to exposures at home, outside, and in traffic, many individuals are exposed to air pollution at work.[6] This may involve exposure to molds, endotoxin, particulates, and gases such as formaldehyde (generated from compressed wood) that might impair CV health and increase CVD risk. Many office buildings contain high levels of indoor particulates and gases, and office equipment such as photocopiers that generate high levels of PM, but mostly these exposures are similar to those at residential locations.

However, workers at plants that generate high levels of PM or gaseous pollutants (e.g., formaldehyde, acrolein, butadiene, benzene) may be particularly at risk, because occupational exposure to these gases has been linked to increased CVD risk. Plant workers involved in the synthesis of aldehydes such as formaldehyde, undertakers, embalmers, and perfumery workers reportedly have a higher risk of

atherosclerotic heart disease, presumably from recurrent exposure to volatile aldehydes. Exposure to 1,3-butadiene, a gas used for the synthesis of rubber, has been associated with an increased incidence of CVD, particularly in African American workers in styrene-butadiene polymer manufacturing plants. Experimental studies with animals have substantiated that exposure to 1,3-butadiene can have atherogenic effects. Chronic occupational exposure to vinyl chloride has also been linked to increased risk of CVD, including hypertension, MI, and other circulatory disorders. Similarly, the use of solvents such as phenol and ethanol is associated with an increase in CVD risk, and carbon disulfide exposure is associated with increased atherosclerosis. Benzene exposure leads to arrhythmogenesis in animals, and workers exposed to benzene show increased prevalence of arterial hypertension, conduction defects, and repolarization disturbances.

Air pollution can also affect workers in occupations that involve frequent exposure to fire and smoke, such as firefighters and military personnel. Firefighters may be particularly at risk.[15] Heart disease accounts for 45% of deaths among U.S. firefighters, and the chances of dying from CHD are 12 to 136 times higher during fire suppression than nonemergency duties. The risk of CV mortality is increased during alarm response (2.8 to 14 times) but is much lower than fighting active fires, suggesting a component of smoke inhalation in triggering CV events. Some studies have suggested that incinerator workers, communities around incinerators, and veterans from the Gulf War have a higher risk of developing CVD because of recurrent exposure to smoke and smoke constituents; however, the evidence is weak and requires additional study.

Management and Intervention

Because it is a community-wide problem, air pollution exposure is difficult to control at an individual level. Clearly, the well-established link between air pollution and heart disease should spur and support regulations limiting industrial emissions and traffic. Indeed, a decrease in air pollution levels in major U.S. cities has resulted in a decrease in CV events and admissions and an increase in life span. Nevertheless, given that 95% of the urban population in major cities is exposed to pollution levels exceeding WHO air quality guidelines, exposure can be reduced by individual choices to diminish the impact of air pollution on CV health. These choices may include avoidance of areas of high pollution, especially traffic pollution, particularly by individuals with high CVD risk. Because residential proximity to major roadways increases exposure to traffic pollutants, avoidance of such exposure may be particularly beneficial for post-MI patients or those with HF.

Individual initiative may be particularly important in minimizing exposure to indoor air pollution. Most indoor pollutants (e.g., molds, endotoxin, bacteria, dust) can be eliminated by maintaining clean living environments, and exposure to large numbers of ultrafine particles can be minimized by avoiding the use of candles, incense, or air fresheners indoors. In developing countries, indoor air pollution can be drastically reduced by discontinuing the use of solid biomass for fuel or by using chimney woodstoves that prevent the accumulation of indoor air particulates. In developed countries, exposure to particles generated by cooking and frying can be minimized by proper ventilation or filtration. Proper indoor air filtration improves endothelial and microvascular function and may decrease systemic inflammation, even in asymptomatic individuals. Gaseous pollutants are difficult to remove, but most airborne particles can be removed by an electrostatic precipitator in a single-pass efficiency of 90% or greater, even for smaller particles. Similarly, in-vehicle air conditioning can reduce exposure to traffic-generated air pollutants. Given the extensive evidence supporting a link between exposure to secondhand tobacco smoke and CVD

risk, eliminating tobacco smoke might have the most robust effect on improving indoor air quality. Lastly, although some dietary interventions have been shown to be marginally effective in decreasing the effects of air pollution, more extensive research is required before such recommendations can be widely advocated or adopted.

Exercise and Sports Cardiology

Paul D. Thompson, Aaron L. Baggish

This chapter presents basic exercise physiology, describes cardiovascular (CV) adaptations to exercise training, and addresses common clinical issues among physically active individuals. The goal is to help clinicians evaluate symptoms produced by exercise, manage questions and clinical problems in athletes and physically active people, and assess the risks and benefits of exercise for individual patients.

Historical Perspective

Debate has long surrounded the cardiovascular risks and benefits of exercise. In 1867 the London surgeon F.C. Sky equated the Oxford-Cambridge crew race to cruelty to animals and opined that such extreme exertion would cause heart disease.[1] Concern about rowers', runners', and bicyclists' hearts emerged in the late 19th century, when these activities migrated from being occupational competitions among only the working classes to being sporting activities for the social elite.[1] The normal CV adaptations to exercise training include resting bradycardia, global cardiac enlargement, and functional pulmonic and aortic valve flow murmurs. Evaluation of these normal adaptations by auscultation and cardiac percussion, the diagnostic tests of the day, led to their interpretation as signs of pathologic conduction disease, dilated cardiomyopathy, and valvular obstruction, respectively.[1] Concerns about the risks associated with prolonged and vigorous exercise were commonplace in the 19th and early 20th centuries. Clarence DeMar, seven-time winner of the Boston Marathon, took a 5-year hiatus from competition during the peak of his competitive years, in part because, according to DeMar, “The frequent warnings of the doctors and fans of the danger to one's heart … had left their impression.”[1] Current concerns about the risks and benefits of exercise include the risk of exercise-related acute cardiac events, the effects of exercise training on cardiac structure, and whether or not long-term endurance exercise training has deleterious CV effects.[2]

Cardiovascular Response to Exercise and Exercise Training

The basic principles of the acute response to exercise[3] and the CV adaptations to exercise training have been summarized elsewhere[4] (**see Chapter 54**). This chapter reiterates relevant essential principles. Physical activity acutely increases systemic oxygen (O_2) demand, which prompts the CV system to increase cardiac output (Q) and the arterial-venous (A-V) O_2 difference. The increase in Q is coupled to the energy required such that there is a 5- to 6-liter increase in Q for each 1-liter increase in oxygen consumption (V_{O_2}). Q is increased by augmentation of both the heart rate (HR) and stroke volume (SV). Several mechanisms increase the A-V O_2 difference. Myocardial oxygen (M_{O_2}) demand depends in part on HR and systolic blood pressure (SBP) and increases with exertion because both HR and SBP increase. This increase in M_{O_2} can produce ischemia in individuals with flow-limiting coronary artery lesions. In addition, the coronary arteries should dilate in response to the myocardial metabolic demands of exertion, but inadequate vasodilation or frank vasoconstriction develops with exercise in some individuals with coronary atherosclerosis because of endothelial dysfunction.[5] Cardiac ischemia, induced by exercise, can contribute to cardiac events during exercise, as discussed later.

The CV response to exercise has both an external and internal work rate.[3] The *external work rate* is the V_{O_2} required by the exercise task and, as mentioned, is a direct determinant of Q. V_{O_2} can also be crudely estimated from treadmill speed and grade or from a stationary bicycle watt requirement. The *internal work rate* refers to the M_{O_2} required for the exercise task and relates directly to increases in HR. In contrast to Q, the HR response to exercise, and therefore the M_{O_2}, is not determined by the external work rate or V_{O_2} but instead by the V_{O_2} required relative to the individual's *maximal exercise capacity*, or V_{O_2}max. Individuals with higher exercise capacity and a greater V_{O_2}max have a larger SV at any given external work rate, such that any exercise task, and V_{O_2} demand, requires a slower HR to generate the

same externally determined Q.

Repetitive aerobic exercise sessions and aerobic exercise training increase maximal exercise capacity, measured physiologically by an increase in V_{O_2}max. This increase in healthy individuals results from increases in both maximal Q and the maximal A-V O_2 difference.[3] Because maximal HR is largely immutable, determined by age, and minimally affected by exercise training, the increase in maximal Q results from an increase in maximal SV. The increase in SV means that performing the same exercise task, which requires the same V_{O_2}, can be performed at a slower HR and a lower MO_2 or internal work rate. The reduction in HR and thereby MO_2 contributes to the increase in exercise capacity in patients with angina pectoris after exercise training (**see Chapter 54**). In addition to the increase in maximal exercise capacity, exercise training also increases *endurance capacity*, the ability to perform submaximal effort for a prolonged period. This effect contributes critically to the exercise training response, because few work and recreational tasks require maximal CV effort.

Intense and prolonged aerobic exercise training produces an array of CV adaptations, commonly referred to as "athlete's heart"[10] (**Fig. 53.1**). Such changes include an increase in resting SV and a decrease in resting HR. The physiologic mediators of training-induced reductions in resting HR are related in part to increased resting vagal tone and reduced resting sympathetic tone. However, the bradycardia persists in trained mice after autonomic blockade or sinus node denervation, suggesting that autonomic changes alone cannot explain the training effect on HR.[6] Indeed, trained mice show widespread remodeling of pacemaker ion channels, including downregulation of the I_f, or funny channel, and blockade of I_f abolished the reduced HR. Highly trained endurance athletes often develop resting bradycardia, which may be associated with marked sinus arrhythmia, first-degree heart block, Mobitz I second-degree atrioventricular (AV) block, or even third-degree AV block during sleep. The reduced AV conduction velocity may make accessory conduction pathways, such as those of Wolff-Parkinson-White syndrome, more apparent. Athletes also have an increased prevalence of an early-repolarization ST-segment pattern and ST-T wave abnormalities, findings also historically attributed to increased vagal tone[7] (**Fig. 53.2**).

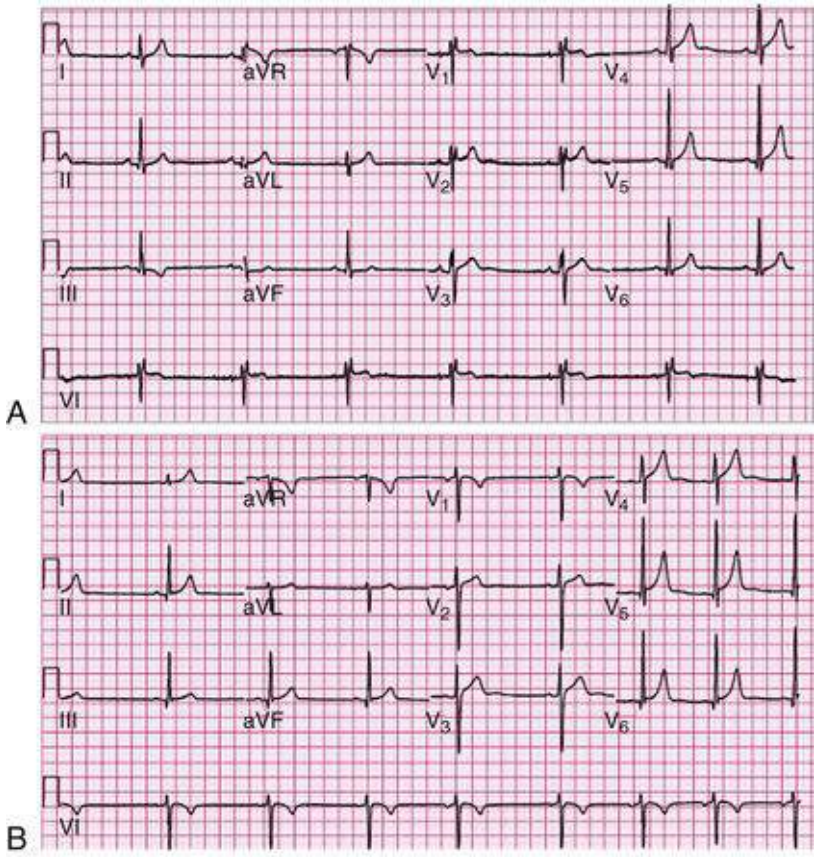

FIGURE 53.1 Twelve-lead ECG tracings from asymptomatic athletes without structural or electrical diseases of the heart demonstrating common findings associated with exercise training. **A,** Sinus bradycardia and an incomplete right bundle branch block resulting from physiologic right ventricular dilation in a 23-year-old male professional hockey player. **B,** Sinus bradycardia with respirophasic sinus arrhythmia, precordial ST-segment elevation characteristic of benign normal early repolarization, and prominent precordial lead QRS voltage, often associated with underlying physiologic left ventricular hypertrophy, in a 19-year-old male distance runner.

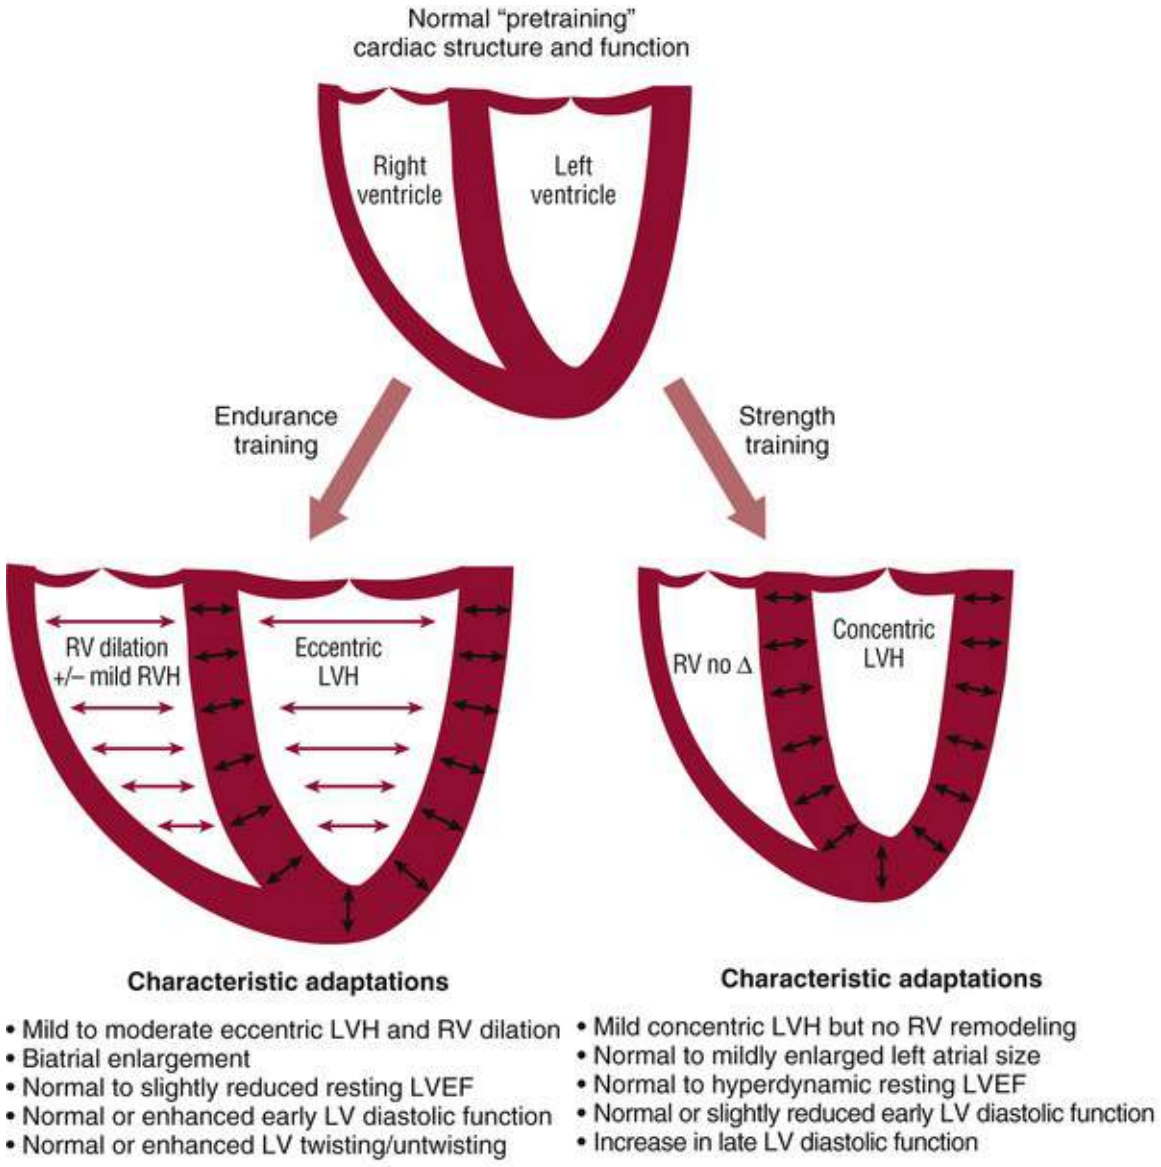

FIGURE 53.2 Summary of the ventricular remodeling that occurs with endurance and resistance exercise training. *LVEF,* Left ventricular ejection fraction; *LVH,* left ventricular hypertrophy; *RV no* Δ, no change in right ventricle; *RVH,* right ventricular hypertrophy. (From Weiner RB, Baggish AL. Exercise-induced cardiac remodeling. Prog Cardiovasc Dis 2012;54:380.)

Four-chamber cardiac enlargement accompanies the increase in SV with training, but left ventricular (LV) wall thickness usually increases only mildly,[4] although chamber dimensions can exceed the standard upper limits of normal (ULN). Small increases in aortic root dimensions also occur, but increases in aortic size greater than expected for body size seldom occur in athletes,[8] even among those playing in the National Basketball Association.[9] In contrast to the extensive cardiac changes reported in endurance-trained athletes, strength exercise training produces modest increases in LV wall thickness with little change in chamber dimensions.[4] Among 1300 elite Italian athletes, 45% exceeded the ULN of 55 mm, with the most marked increases in LV size occurring in the largest athletes and those with the slowest HR.[12] In contrast, LV wall thickness rarely exceeds ULN among trained athletes. For example, among 947 national-caliber and international-caliber Italian athletes, only 16 had LV wall thickness greater than 12 mm.[11] Trained athletes usually have normal resting LV systolic function, most frequently measured as LV ejection fraction (LVEF), but may be near the lower limit of the normal range because large ventricles can meet resting metabolic demands with a lower LVEF.

Cessation of exercise training, or "detraining," may help in clinically differentiating adaptations to

exercise training from hypertrophic cardiomyopathy. Several studies have examined the effect of detraining in endurance athletes with eccentric LV hypertrophy (LVH), a geometric pattern characterized by concomitant LV wall thickening and chamber dilation. Regression of eccentric LVH can occur in highly trained athletes after 6 to 34 weeks (mean, 13 weeks) of abstinence from exercise.[13] A detraining study of 40 Italian male athletes with eccentric LVH and peak fitness LV dimensions (mean ±SD) of 61.2 ±2.9 mm and LV wall thickness of 12.0 ±1.3 mm reported complete normalization of wall thickness and a significant but incomplete reduction in cavity dilation after 5.8 ±3.6 years of detraining[14] (**Figs. 53.3 and 53.4**). Because the LV wall thickening and concentric LVH common in strength-trained athletes can regress partially after 3 months and completely after 6 months of detraining, such diagnostic trials should last 6 months.[15]

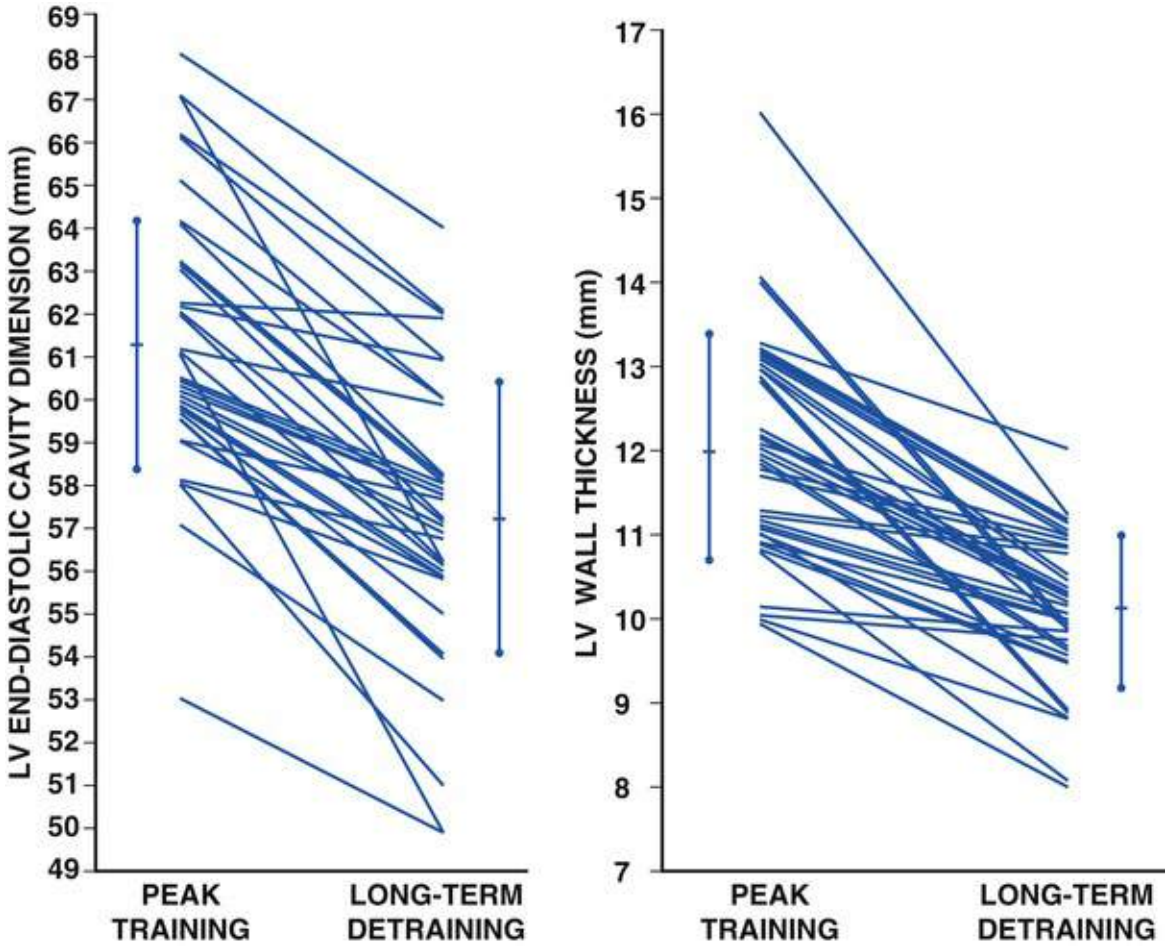

FIGURE 53.3 Echocardiographic measurements of left ventricular (LV) chamber dimensions and LV wall thickness (LVWT) in 40 male Italian athletes measured at their peak of athletic performance (age 24 ±4 years) and after detraining of 1 to 13 years (mean ± SD, 5.6 ± 3.8 years). All had either increased LV chamber enlargement (LVE) of 60 mm or greater or LVWT of 13 mm or greater, or both, at their peak. Nine of the athletes (22%) had persistent LVE greater than 60 mm, but LVWT normalized in all participants. (From Pelliccia A, Maron BJ, Di Paolo FM, et al. Prevalence and clinical significance of left atrial remodeling in competitive athletes. J Am Coll Cardiol 2005;46:690.)

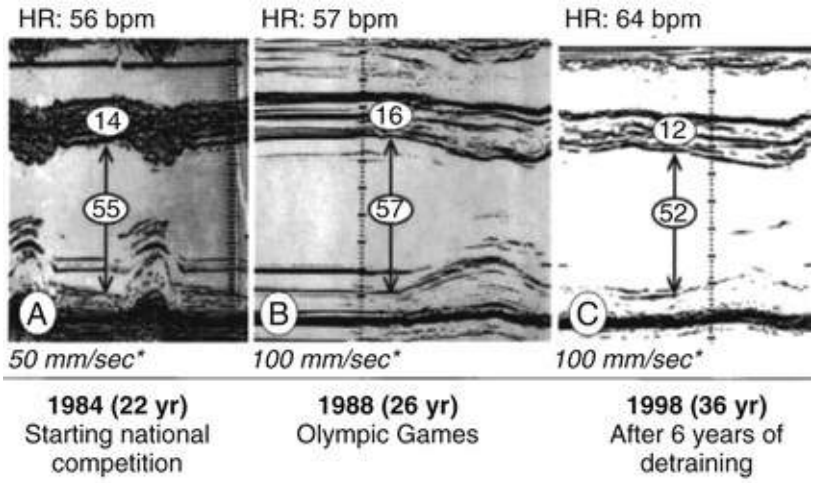

FIGURE 53.4 Serial echocardiograms from an elite canoeist at 22 years of age, when he joined the Italian national team; at 26 years of age, when he competed in the Olympics; and at 36 years of age, after 6 years of detraining; *bpm,* beats per minute; *ovals* show measurements in millimeters. *Paper speed.

Effects of Habitual Physical Activity on Cardiovascular Risk

Multiple epidemiologic, cross-sectional studies examining the frequency of CV events in healthy individuals demonstrate that the more active participants have lower CV risk than their more sedentary counterparts.[16] The reduction in risk in the most active versus the least active individuals is approximately 40%.[16] Even small amounts of physical activity, such as standing, reduce CV risk. CV risk falls progressively with increasing physical activity until approximately 9.1 hours per week of moderate-intensity activity, such as brisk walking.[16] After this level of exertion, there appears to be little additional benefit and, possibly diminution, of the beneficial effects[16] (**Fig. 53.5**) (**see Chapter 45**).

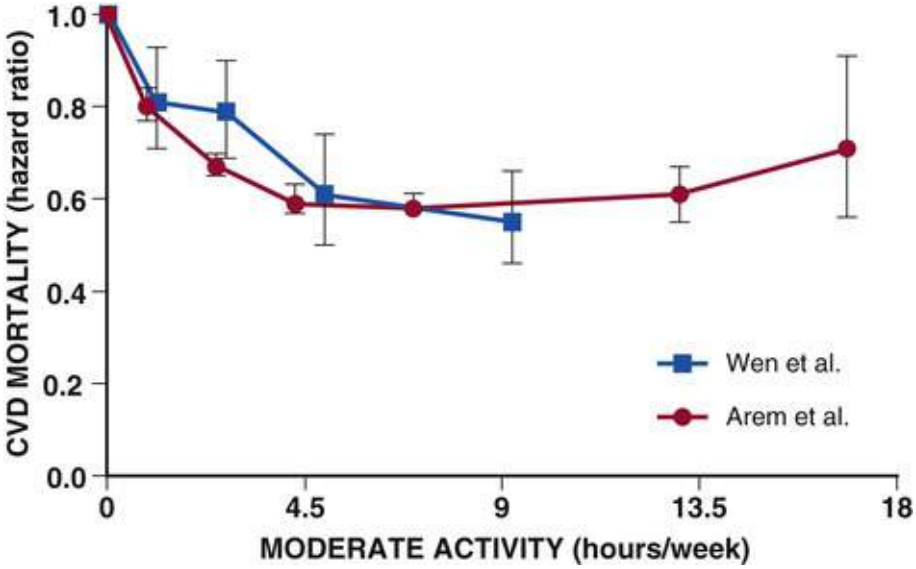

FIGURE 53.5 Relationship between hours of moderate-intensity physical activity and cardiovascular disease (CVD) mortality. (Data from Wen CP et al. Minimum amount of physical activity for reduced mortality and extended life expectancy: a prospective cohort study. Lancet 2011;378:1244–53; and Arem H et al. Leisure time physical activity and mortality: a detailed pooled analysis of the dose-response relationship. JAMA Intern Med 2015;175:959-67. Modified from Eijsvogels TM et al. Exercise at the extremes: the amount of exercise to reduce cardiovascular events. J Am Coll Cardiol 2016;67:316-29.)

Also, as discussed in **Chapter 54**, patients participating in cardiac rehabilitation programs have a reduced risk for recurrent cardiac events. The specific mechanisms that mediate this effect have remain undefined, but habitual physical activity has multiple, potentially beneficial effects on atherosclerotic risk factors. Specifically, habitual physical activity reduces SBP, body weight, blood glucose, and triglycerides and increases high-density lipoprotein cholesterol.[17]

Cross-sectional studies, however, cannot prove that the reductions in CV risk result from physical activity alone. Individuals who engage in physical activity may inherit greater exercise capacity, thereby leading them to select active lifestyles and have lower CV risk. Supporting this possibility, rats selected and bred over multiple generations for superior exercise performance have lower CV "risk" profiles, even though these factors did not enter into the selection process.[18] The same physiologic factors associated with increased exercise capacity may also be associated with reduced CV risk, and individuals choosing an active lifestyle may have lower CV risk independent of their exercise habits. This possibility appears unlikely, however, given the plethora of epidemiologic and experimental evidence linking increased physical activity with lower CV risk, but it remains a possibility that requires consideration.

Cardiovascular Risks of Exercise

Despite the putative benefits of habitual physical activity, convincing evidence has shown that vigorous physical activity, generally defined as 6 or more METS, or metabolic equivalents, of resting energy expenditure (1 MET = 3.5 mL of O_2 per kilogram of body weight per minute), transiently increases the risk for sudden cardiac death (SCD) and acute myocardial infarction (AMI).[19] Most of this evidence derives from studies comparing the hourly cardiac event rate during vigorous exertion with rates during more sedentary activities. The pathologic substrate associated with these acute cardiac events varies by age, primarily because the prevalence of the pathologic cardiac conditions responsible for SCD also varies by age. Exercise-related SCD in young individuals, defined as younger than 30 or 40, has historically been attributed to inherited and congenital conditions, including hypertrophic cardiomyopathy

(HCM) (**see Chapters 42 and 78**) and anomalous origin of the coronary arteries (ACA), although acquired conditions such as myocarditis and cardiomyopathy can also cause exercise-related SCD in young individuals.[20]

Recent studies, however, have noted that up to 40% of SCDs in young athletes remained unexplained even after careful autopsy suggesting that other conditions, such as inherited channelopathies, may be the cause.[21] HCM was responsible for only 6% of deaths.[21] The reasons for this apparent shift in the causes of SCD are not clear but could be related to selected case ascertainment in both the present and the earlier studies or more effective diagnosis and care of athletes with HCM. Atherosclerotic cardiovascular disease (ASCVD) causes most exercise-related AMI and SCD in adults.[19] AMI in previously asymptomatic adults during exercise is usually associated with acute coronary arterial plaque disruption.[22] Several triggering mechanisms for plaque disruption may pertain, including increased flexing and bending of atherosclerotic coronary arteries.[19] Approximately 33% of SCDs in adults caused by ASCVD are associated with clinicopathologic findings of an acute coronary syndrome (ACS), whereas the remainder show evidence of nonacute ASCVD.[23]

The frequency of exercise-related CV events appears to be low, but several factors prevent calculation of a definitive incidence in children or adults. Because of the rarity of exercise-related events, the studies available often include only a small number of participants, so slight changes in the number of cases can greatly affect the incidence. A large population registry could address the paucity of events, but few such registries are available. The lack of systematically collected registries has forced many studies to depend on media reports of CV events, an approach that cannot guarantee total case ascertainment. Furthermore, even if all cases were collected, estimation of the denominator—or the population at risk for an exercise event—is difficult because the number of individuals engaged in vigorous exercise in the study cohort is often unknown. These caveats require consideration when evaluating current estimates. The most consistent estimate is one death per year for every 200,000 high school and college athletes,[24] but the rate may be as high as one death per year for every 5100 Division 1 male National Collegiate Athletic Association (NCAA) basketball players.[25] Estimates for adults suggest that one exercise-related death occurs per year for every 15,000 to 18,000 previously healthy adult men.[19] These estimates are derived largely from studies from the early 1980s and represent overestimates, because overall ASCVD events have now decreased in American adults. The risk for exercise-related AMI may be sevenfold higher than for SCD, so the risk for exercise-related AMI in the exercising population may be as high as 1 per 2000 men per year.[19] All studies suggest that women have a much lower risk for exercise-related events.

Approach to Common Clinical Problems in Sports Cardiology

Athletes and active individuals may seek CV evaluation for a multitude of reasons, but the following section discusses several common clinical complaints in athletic patients and the clinical approach to their management.

Decreased Exercise Capacity

Athletes with decreased exercise capacity are frequently referred to CV specialists for evaluation. SV contributes critically to Q and therefore to exercise capacity, but V_{O_2}max also requires maximal performance from its other CV components, HR and A-V O_2 difference, as well as from the central

nervous system, lungs, and skeletal muscle. Decrements in any of these components can compromise exercise performance. An inappropriately fast HR at low levels of exertion as a result of hyperthyroidism can decrease exercise performance, as can exercise-induced asthma, diseases of skeletal muscle, and reduced O_2-carrying capacity from anemia (often resulting from iron deficiency in female endurance athletes who eat a vegetarian diet). Atrial fibrillation or frequent premature contractions during exercise can reduce exercise capacity. Other conditions not directly related to the CV system, including viral illnesses (e.g., mononucleosis, hepatitis) and autoimmune conditions, can initially be manifest in athletes as decreased exercise capacity or exercise intolerance.

These same issues can reduce exercise performance in older athletes, but occult coronary disease with atypical symptoms always requires consideration first in older patients. Many adult athletes with reduced exercise capacity referred for expert evaluation have LV diastolic dysfunction because prior encounters have eliminated the more obvious diagnoses. This scenario often presents as a lifelong endurance athlete with “borderline hypertension” who somehow avoided antihypertensive treatment. These patients frequently have mild resting hypertension but exhibit an exaggerated blood pressure response to exercise.

Psychological factors and overtraining also can cause decreased exercise capacity in athletes. Psychological issues generally occur in young athletes who have lost their desire to compete before their parents have lost interest in the child's sport. This diagnosis often becomes clear if parents or other key adults are included in the patient's assessment. Some athletes appear to find it easier to use a medical excuse for stopping sports participation than to admit that they have lost interest, want to pursue other interests, or “just aren't good enough” to continue.

Evaluation of athletes complaining of decreased exercise performance requires listening to the athlete's history carefully. Practitioners may dismiss many complaints in athletes because their exercise performance remains superior to that of nonathletes, but important cardiac conditions may present sooner in athletes because of the physical demands of their sport. Evaluating performance times and training diaries in endurance athletes often helps plot the time course of the complaint. The conditions mentioned earlier must be excluded, as must obvious cardiac disease. Exercise testing using protocols designed to mimic the athlete's sport frequently helps document the complaint and its cause. Exercise echocardiography and cardiopulmonary exercise testing with specific attention to the oxygen pulse curve are useful when the history suggests diastolic dysfunction. The oxygen pulse can be calculated by dividing V_{O_2} by HR, and assuming no important change in the A-V O_2 difference, it reflects SV. It can help determine when cardiac performance becomes a limiting factor during exercise. Long-term electrocardiographic monitoring, occasionally performed with implanted monitoring devices, can detect cardiac rhythm disorders in athletes with infrequent symptoms. Psychological and emotional issues should be diagnosed only after the exclusion of other, more medical conditions and require frank discussions with the athlete and family. Depression can frequently cause otherwise unexplained fatigue.

Overtraining is a complex interaction of psychological and physiologic fatigue in athletes that can occur after prolonged high-intensity training. The diagnosis of overtraining is made by careful history since there is no diagnostic test for this condition. Diminished exercise tolerance (sometimes with an elevated resting HR), the sensation of nocturnal fevers, and insomnia all characterize overtraining. The insomnia appears paradoxical because the athletes often experience extreme fatigue but find it difficult to sleep as a result of restlessness and sometimes involuntary muscle contractions. Overtraining should be diagnosed only when other conditions are excluded and frequently requires a therapeutic trial of markedly reduced training to see whether the symptoms resolve and performance improves.

Abnormalities Found on Screening

Many athletes are referred to cardiologists because of CV abnormalities found on preparticipation screening. Both the American Heart Association (AHA) and the American College of Cardiology (ACC),[26] as well as the European Society of Cardiology (ESC),[27] recommend preparticipation screening for athletes. The ESC but not the AHA recommends including a resting electrocardiogram (ECG) in the screening evaluation. The debates on CV screening in general, on screening athletes versus screening all children, and on the role of the ECG exceed the scope of this chapter.[28] One widely cited Italian study suggests that screening greatly reduces cardiac events in athletes,[29] but studies from Minnesota[30] and Israel[31] suggest that screening has no benefit. A U.S. National Institutes of Health consensus conference concluded that the data were insufficient to recommend routine screening of the general population or athletes with an ECG.[32] Regardless of the scientific merit, many young athletes do undergo screening with an ECG, and abnormalities emerge.

Screening athletes with or without an ECG can detect a multitude of CV "problems." Well-trained endurance athletes have a slow HR and large SV, which can produce nonpathologic pulmonic flow murmurs in young athletes, especially if the athlete is examined in the supine position, which expands central blood volume. Pulmonic flow murmurs are soft systolic ejection murmurs heard best in the left second and third intercostal spaces in the supine position. Such murmurs typically diminish or disappear when the athlete assumes a sitting position. Older athletes with hemodynamically insignificant aortic sclerosis may have aortic flow murmurs. Athletes can also have ECG evidence of biatrial hypertrophy, LVH, incomplete or complete right bundle branch block, ST-T wave abnormalities, and conduction abnormalities. Most of these abnormalities occur in endurance athletes undergoing intense training. Such changes in strength-trained athletes or in endurance athletes with low training volumes should raise suspicion of a cardiac problem.

Most CV abnormalities found on screening are variants of normal, and most can be dismissed by a simple clinical examination and review of the ECG, with cardiac imaging procedures used to remove any residual doubt. Some families and athletes have ongoing concern once a screening abnormality is identified, so having the athlete and family return in 3 to 6 months is sometimes useful, even when no abnormalities are found, to provide additional reassurance.

A common problem in athletes with a screening abnormality is "diagnostic creep"—the finding of a minor abnormality on screening such as early ECG repolarization, which prompts a second diagnostic test such as echocardiography, which reveals another borderline finding such as mild LVH, which may prompt another diagnostic test such as cardiac magnetic resonance imaging (MRI). Sometimes, because of the CV adaptations that accompany exercise training, each diagnostic study reveals an additional borderline abnormality, thus making it difficult for a clinician to declare the athlete "normal." Screening abnormalities, especially if borderline abnormal, should be judged with less concern than definite abnormalities found in symptomatic athletes, because the screening abnormalities will most frequently represent normal variants.

Cardiovascular Complaints in Athletes

Athletes are sensitive to changes in their physical being and exercise performance and are more likely to note early CV abnormalities because of the CV demands of exercise training and competition. On the other hand, some athletes are excessively concerned about anything that may affect their performance and may seek evaluation for normal body sensations such as muscular aches produced by new training

regimens. Nevertheless, possible CV complaints in athletes should cause greater concern than borderline abnormalities found on screening, and such complaints require careful evaluation with techniques appropriate for the differential diagnosis.

Chest pain is a common complaint in young and old athletes, possibly because the importance of chest pain in public perception, and because athletes have increasing concerns about the possible risks associated with exercise. Chest discomfort in athletes should never be dismissed summarily. Exertional chest pain may be the first sign of important cardiac diseases, including HCM, ACA, or coronary artery atherosclerosis, but several issues pertain particularly to athletes. Determining the duration of chest pain is important, since many athletes without underlying disease experience momentary chest pain. The sensation of momentary chest pain may accompany premature atrial or ventricular contractions, possibly because contraction against closed AV valves produces a momentary sensation of chest fullness. Fleeting chest pain with movement in athletes may also be related to muscle and joint issues. The relationship between chest pain and recent resistance exercise involving the chest muscles, such as push-ups and bench presses, is also important because such training is a frequent cause of chest discomfort in athletes. Some athletes who have died with ACA had normal exercise stress test results,[33] indicating the importance of pursuing workups that include coronary imaging in athletes if the symptoms are worrisome, even when exercise testing yields normal results. Such an approach differs distinctly from what we advise in asymptomatic athletes with borderline test results.

Well-trained athletes often have *vasovagal syncope*, also known as "neurally mediated syncope," probably because of their resting bradycardia and large venous capacity, which permits sequestration of large amounts of blood when the athlete is upright and motionless.[34] Athletes also often have positive tilt-table tests as a result of the same physiologic changes. Neurally mediated syncope most often occurs in athletes immediately following exercise, particularly with abrupt termination of exercise. This common entity, "postexertional syncope," is benign and can frequently be managed by teaching the athlete avoidance techniques. The most important avoidance technique is for the athlete to keep moving after effort so that the muscle pump in the calf continues to return blood to the systemic circulation. Dietary sodium augmentation, aggressive pre-exercise hydration, and the use of commercially available compression socks may also prove useful. The key issue in evaluating syncope in athletes is to determine whether the syncope occurred during exertion. Syncope at rest or immediately after exercise under conditions consistent with vasovagal syncope or postural syncope is usually caused by these conditions. In contrast, syncope during exercise should prompt a careful search for more serious problems, including HCM, aortic stenosis, cardiac arrhythmia, or ACA.[34]

Determining Athletic Eligibility

The AHA and ACC have developed eligibility and disqualification recommendations for cardiac conditions according to the advice of 15 task forces who created the guidelines based on literature review and expert opinion.[35] Guidelines are necessarily restrictive because they are used by a wide variety of clinicians, many of whom will have no special qualifications or expertise in evaluating athletes. As clinicians gain more experience in evaluating athletes with minor variants of CV disease, many of these guidelines may appear overly restrictive, but they are periodically updated and currently provide the best available consensus opinion on how to advise athletes regarding their risk related to sports participation.

We use these guidelines as the basis for most of our recommendations but alter the final decision depending on multiple factors, including our perception of the athlete's risk given the severity of the lesion

and symptoms, the importance of participation for the athlete's mental health, the danger to others, and the willingness of the athlete and family to share risk in making the decision. The diagnosis, its attendant risk, and the basis for any recommendations also require discussion (if the athlete agrees) with other key individuals, such as parents, school or team administrators, coaches, athletic trainers, and business agents. We use a similar decision-making approach with older athletes, although they usually have a greater ability to understand and assume personal risk.

Advising Adult Athletes with Atherosclerotic Cardiovascular Disease

Vigorous exercise increases the risk for SCD and AMI in adults with occult ASCVD, and individuals with diagnosed disease have greater increased risk with exercise. Many adults with ASCVD want to return to active athletic competition, often in demanding endurance events such as marathon running or long-distance cycling. Imaging techniques such as scanning for coronary artery calcification have expanded the detection of asymptomatic and presymptomatic disease. All athletes with ASCVD require an explanation that vigorous exercise acutely increases their CV risk and that moderate amounts of exercise probably confer as much ASCVD reduction benefit as more intense activity.[16] Despite such discussion, many such athletes want to return to competition or intense exercise training. Plaque stability may increase with decreasing lipid content of the plaque;[36] most plaque regression occurs within 2 years of aggressive lipid lowering.[37,38] Consequently, in athletes strongly wanting to return to competition, we advise a minimum of 2 years of aggressive lipid treatment with the goal of achieving the lowest possible serum lipid levels before returning to competition. We also emphasize the importance of blood pressure (BP) control and tobacco avoidance, as well as the need to report symptoms that may indicate progression of disease. This approach allows the athlete to have the hope of further competition, but it also helps motivate them to adhere to risk reduction strategies.

Adult athletes receiving lipid-lowering or antihypertensive treatment occasionally inquire whether their medications should be stopped before endurance athletic competition. We encourage athletes to continue aspirin and other antiplatelet medications under the assumption that they may help avoid an acute cardiac event if plaque disruption occurs. We continue therapy with a beta blocker to avoid the increase in adrenergic activity that occurs when use of these drugs is stopped abruptly. We generally discontinue other antihypertensive medications on the day of the athletic event because exercise acutely reduces BP, and we want to avoid postexertional hypotension. We routinely discontinue statins for 5 to 7 days before endurance athletic competition because statins magnify the increase in creatine kinase (CK) that occurs with exercise,[39] and the combined effects of statins and exercise could lead to rhabdomyolysis.

Valve Disease

Valvular disease in athletes should be managed according to principles for the nonathletic population and AHA/ACC recommendations,[40] although several issues merit note.[41] Athletes with echocardiographic evidence of critical aortic stenosis (AS) should undergo careful evaluation for symptoms and maximal exercise stress testing that simulates as closely as possible the athlete's typical exercise training and competition.[41] Many adult athletes with critical AS ignore important dyspnea at the start of exercise because it dissipates within 5 to 10 minutes, but this “warm-up dyspnea” frequently indicates clinically important AS.

Athletes generally tolerate aortic regurgitation (AR) well, probably because the increased HR during

exercise decreases diastole and regurgitant flow.[41] Consequently, we rarely restrict athletic competition despite severe AR in the absence of evidence of ventricular deterioration or unexplained symptoms with exertion. We also rarely restrict resistance exercise in this group despite concern that this type of exercise increases AR, because we know of no data that indicate any benefit of such restriction.

Great concern exists regarding exercise and aortic dissection in athletes with a bicuspid aortic valve (BAV), and some clinicians have restricted participation in this group because of concern that athletics will contribute to aortic dilation.[41] Given the prevalence of BAV in approximately 1% of the population and the rarity of aortic dissection in young athletes, we do not restrict activity unless the aortic diameter exceeds 45 mm. The AHA/ACC Aortic Diseases Task Force recommends aortic root measurements biannually for individuals with aortic diameter greater than 40 mm in men and 36 mm in women.[42] Athletes found to have BAV should undergo imaging to determine proximal ascending aortic dimensions at diagnosis and then should be monitored by serial imaging during their years of competitive sport participation.

Elevated "Cardiac Enzymes"

Cardiac troponin T and I (cTnT and cTnI) are used as markers of myocardial necrosis, but athletes have increased cTnT and CTnI levels[43] after prolonged exertion, such as a marathon run,[43] or even after a brief intense treadmill run lasting only 30 minutes[44] (**Fig. 53.6**). Clinicians need to be aware that endurance athletes may have elevated cTn levels after exertion, and that the diagnosis of an acute cardiac event in an athlete requires confirmatory evidence in the form of either symptoms, the ECG, or echocardiographic evidence of myocardial injury.[43]

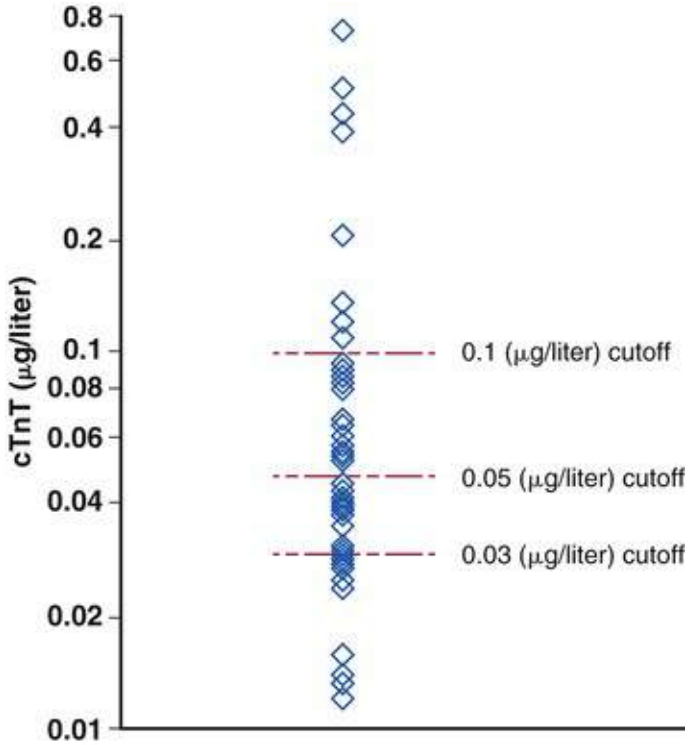

FIGURE 53.6 Cardiac troponin T (cTnT) values obtained 30 minutes after these 72 runners completed the 2002 or 2003 London Marathon (a 42-km footrace). The acute myocardial infarction (AMI) level for this assay was set at greater than 0.05 μg/liter; 36% of the runners exceeded this value. (From Shave RE, Whyte GP, George K, et al. Prolonged exercise should be considered alongside typical symptoms of acute myocardial infarction when evaluating increases in cardiac troponin T. Heart 2005;91:1219.)

Emerging Issues in the Cardiac Care of Athletes

Several emerging concerns suggest that lifelong endurance exercise may have deleterious effect on cardiac function.[2] Although not well documented, clinicians treating athletes should be aware of these concerns.

Atrial Fibrillation

Atrial fibrillation (AF) is epidemic and affects 1% of the U.S. population.[45] Low levels of physical activity and low exercise capacity are both risk factors for AF, and improved physical fitness with exercise training reduces the recurrence of AF independent of weight loss.

In contrast to this reduction in AF with moderate physical activity, the incidence of AF in the Cardiovascular Health Study in those exercising at the highest level was not different from that in inactive subjects.[45] Other studies have demonstrated higher rates of AF among participants in endurance events who ran the most races or had the most years of exercise training. The compendium of results suggests a U-shaped relationship between exercise training and AF, with reductions in AF with moderate amounts of physical activity and an increase with more intense and prolonged activity. Possible mechanisms for this relationship include increased atrial size, changes in autonomic tone, or increased inflammation.[45]

Accelerated Atherosclerosis

Several reports suggest that long-term endurance athletes have increased coronary artery calcification (CAC) scores compared to their sedentary counterparts.[2] We have seen many asymptomatic athletes with remarkably high CAC values despite low ASCVD risk factors. Such increased CAC scores have unclear significance. Increasing CAC scores in the general public are associated with increased ASCVD risk, but the degree to which this relationship applies to athletes is unknown. It is noteworthy that dense CAC portends lower risk,[46] perhaps because densely calcified plaques are less likely to rupture. Our approach is to evaluate the athlete for exercise-induced ischemia, treat ASCVD risk factors aggressively, especially with lipid-lowering agents, and provide reassurance that the significance of this finding is unknown and may be protective rather than deleterious.

Myocardial Fibrosis

At least three studies have detected the presence of late gadolinium enhancement (LGE) with cardiac MRI in 12% to 50% of veteran endurance athletes.[2] Athletes with LGE had exercise-trained for much of their lives and had cardiac dimensions larger than comparison athletes. The LGE volume was small and often located near right ventricular insertion sites, suggesting mechanical stress as the cause. The presence of LGE suggests that prolonged exercise training produces myocardial fibrosis, but this possibility requires more extensive study for confirmation and determination of its significance.

Noncompaction Cardiomyopathy

The left ventricle is highly trabeculated during embryonic cardiac development to increase myocardial surface area and thus facilitate the delivery of oxygen and nutrients from intracavitary blood to the myocardium. These trabeculae regress and the myocardium becomes compacted during normal embryonic

development. The degree of embryonic trabecular regression varies, and many healthy people have some trabecular tissue within the left ventricular (LV) cavity. Noncompaction cardiomyopathy (NCCM) results from an arrest of this process characterized by a hypertrabeculated left ventricle with a thin, subepicardial, compacted layer. First described in 1984 and named in 1990, NCCM is a relatively new entity.[47] NCCM presenting in adults is inherited in an autosomal dominant pattern, but an X-linked pattern is seen in pediatric patents.[47] NCCM can produce myocardial dysfunction, systemic emboli from the deep ventricular pits, and SCD. There are various diagnostic criteria, but a ratio of noncompacted (NC) to compacted (C) myocardium greater than 2 is frequently used.[47] This cut point can be problematic for clinicians treating athletes, especially African American athletes, because 20% of 1146 athletes had increased trabeculations and 8% fulfilled criteria for NCCM,[48] and because African Americans have increased LV trabeculae even in the absence of exercise training. Referrals for possible NCCM in athletes are increasing because of clinicians' growing awareness of the condition, and because the expanded ECG screening of athletes has increased the number of athletes referred for echocardiography. Most of the individuals referred do not have NCCM but rather the benign, mildly trabeculated, normal LV variant previously described. We advise obtaining a careful family history and reviewing the myocardial images, with special attention to LV systolic function and thickness of the compacted layer. Patients with true NCCM should have decreased ventricular function and a thin, compacted layer. The compacted layer is normal and can even be slightly thickened in athletes. (**See also Chapter 75**.)

Exercise in Arrhythmogenic Right Ventricular Cardiomyopathy

Multiple studies since the 1990s have demonstrated that the right ventricle can dilate after prolonged endurance exercise, possibly because the relative increase in right ventricular strain during exercise exceeds that of the left ventricle.[2] Arrhythmogenic right ventricular cardiomyopathy/dysplasia results from defects in the desmosomal proteins that help connect myocytes. Athletes with defects in desmosomal protein genes are more likely to satisfy the diagnostic criteria and to have a worse prognosis than similarly endowed nonathletes.[49] Exercise also accelerates the disease process in animals with genetic desmosomal defects.[50] These results demonstrated that exercise training accelerates the clinical course of right ventricular cardiomyopathy in individuals genetically predisposed to the disease, suggesting that prolonged exercise or exercise training may exacerbate the clinical course of other genetic cardiac diseases.

Conclusion

Cardiovascular clinicians require a working knowledge of exercise physiology, the CV adaptations to exercise training, and the risks and benefits of exercise to advise and evaluate active patients appropriately. Clinicians should avoid overreacting to borderline findings detected on CV screening of asymptomatic athletes, but should also avoid ignoring possible cardiac symptoms in active individuals. Sports cardiology has emerged as a subspecialty of cardiology, but general cardiologists can deal with many of the management issues and queries adequately if they understand the CV adaptations to exercise and the most common pathologic conditions that affect athletic patients.

Exercise-Based, Comprehensive Cardiac Rehabilitation

Paul D. Thompson, Philip A. Ades

Historical Perspective

Until the early 1950s, the standard treatment of myocardial infarction (MI) was several weeks of hospitalization followed by months of restricted physical activity. Exercise-based cardiac rehabilitation (CR) originated to reverse the physical deconditioning produced by this restriction of physical activity. Exercise training was central to this process and was one of the few interventions that reduced exertional angina pectoris in the era before beta-adrenergic blocking agents and coronary artery revascularization procedures.[1]

Shorter hospitalizations, along with effective medications and procedures to treat myocardial ischemia, have changed CR programs. Exercise training is still important, but the rehabilitation effort now includes education and counseling to increase secondary prevention behaviors, improve psychological well-being, and increase adherence to medications and diet as key components.[2] U.S. Centers for Medicare and Medicaid Services (CMS) guidelines reflect these changes and require that CR programs not only provide exercise training but include education and counseling to modify cardiac risk factors. Consequently, CR programs are now often referred to as "cardiac rehabilitation/secondary prevention programs."[2] The American Heart Association (AHA) and American College of Cardiology Foundation (ACCF) strongly recommend comprehensive CR programs (class I indication) for patients who have undergone percutaneous transluminal coronary angioplasty (PTCA) or coronary artery bypass grafting (CABG), who have suffered an acute cardiac syndrome, or who have stable angina pectoris or peripheral vascular disease.[3] This recommendation received the highest level of evidence (A) for all conditions except angina (level B).[3] Exercise training is a class I recommendation for patients with stable chronic systolic heart failure and a left ventricular ejection fraction (LVEF) of 35% or less, whereas CR is a class IIa recommendation.[4] CMS also considers comprehensive CR to be "reasonable and necessary" for patients after valve surgery and heart or heart-lung transplantation.[5] Participation rates in CR have been low, ranging from 19% to 34% nationally,[6] although increased use of electronic medical records may increase referral rates.[7]

Exercise training is central to CR and risk reduction programs because it increases exercise capacity and reduces exercise-induced cardiac ischemia and angina. Meta-analyses of randomized controlled trials (RCTs) of CR have shown benefits of exercise training alone or exercise training combined with comprehensive secondary prevention practices.[8,9] Because risk factor reduction is discussed elsewhere in detail (**see Chapters 45, 47, and 48**), this chapter specifically addresses exercise training in the CR process.

Basic Principles of Exercise Physiology and Training

Maximal Oxygen Uptake

Skeletal muscle contains only small amounts of energy for immediate use. Exercise increases the body's oxygen (O_2) requirements to supply energy to the exercising muscle. The amount of O_2 consumed, referred to as ventilatory oxygen consumption (V_{O_2}), assesses the amount of energy used during effort. Rearranging the Fick equation—cardiac output (Q) = V_{O_2}/arterial-venous O_2 difference (A-V O_2 Δ)—demonstrates that V_{O_2} is the product of Q and A-V O_2 Δ. Thus, the metabolic demands of exercise are met by increasing O_2 delivery through increases in Q, which in turn is the product of heart rate (HR) and

cardiac stroke volume (SV), as well as through increases in A-V O_2 Δ. A-V O_2 Δ increases during exercise by redistribution of blood flow from nonexercising tissue (e.g., kidneys, splanchnic bed) to exercising muscle, by increased O_2 extraction in the exercising muscle, and by hemoconcentration as a result of plasma fluid losses into the interstitial space of exercising muscle. The increase in Q during exercise is tightly linked to the increase in VO_2, such that a 1-liter increase in VO_2 elicits approximately a 6-liter increase in Q. VO_2max—the maximal amount of oxygen that an individual can transport during exercise before being limited by fatigue or dyspnea—measures maximal exercise capacity. VO_2max expressed as either an absolute value (liters per minute) or relative to body weight (milliliters per kilogram per minute) provides a highly stable and reproducible measure of exercise capacity. The maximal increase in A-V O_2 Δ is fixed at approximately 15 to 17 vol-%. Because the exercise work rate determines VO_2, which is the product of Q and A-V O_2 Δ, and because the maximal A-V O_2 Δ is relatively fixed, VO_2max provides an indirect measure of maximal cardiac pump capacity, or maximal Q and SV.

Myocardial Oxygen Uptake

Myocardial oxygen demand (MO_2) can be estimated as the product of HR and systolic blood pressure (SBP)—the so-called double product. Although the absolute exercise work rate determines VO_2 and Q, increases in HR and SBP are determined by the exercise VO_2 requirement as a percentage of VO_2max. Consequently, for any absolute exercise level, an individual with a larger VO_2max uses less maximal capacity and has a lower HR and SBP response to exercise. The key point is that MO_2 is not determined solely by the external exercise work rate, but by the exercise work rate *relative* to maximal exercise capacity.

Ventilatory Threshold

Expired carbon dioxide (VCO_2) also increases as the exercise work rate increases. Increases in VO_2 and VCO_2 are parallel early during exercise, but the rate of CO_2 expiration increases more rapidly, and the coupling of VO_2 and VCO_2 diverge at what is termed the *ventilatory threshold* (VT). This divergence results from the increase in blood lactic acid, buffering of the lactic acid H^+ ions by bicarbonate, and the subsequent exhalation of additional CO_2. VT has also been called the “anaerobic threshold” and OBLA (for “onset of blood lactate accumulation”). Because CO_2 stimulates the respiratory drive, VT is also associated with a nonlinear increase in the respiratory rate and mild dyspnea. VT occurs at approximately 50% of VO_2max in non–exercise-trained individuals but at higher levels of the percentage of VO_2max in exercise-trained subjects. VT is an important measurement of exercise tolerance because it represents the maximal steady work rate that can be maintained during submaximal exercise.

Effect of Cardiac Disease on Exercise Performance

Exercise performance may be normal for age and sex in individuals with cardiac disease. Alternatively, diseases that limit maximal SV, impair the HR response, or cause myocardial ischemia that produces limiting symptoms or a diminished increase in SV may impair exercise capacity. Medications that limit the HR response to exercise (e.g., beta blockers) or restrictions in physical activity that produce a detraining effect may also contribute to reduced exercise tolerance in cardiac patients.

Effect of Exercise Training on Exercise Performance

Either aerobic or strength training increases exercise capacity. Strength training produces an increase muscular size, strength, and endurance of the exercise-trained muscle. Aerobic exercise training principally increases exercise capacity, reflected as an increased V_{O_2}max. This increase in maximal exercise capacity means that any submaximal work rate requires a lower percentage of V_{O_2}max, thereby reducing the HR and SBP response and MO_2 requirements. Endurance exercise training also increases the absolute VT and VT as a percentage of V_{O_2}max. Multiple adaptations contribute to improvement in aerobic exercise tolerance after training, including increases in SV and widening of the A-V O_2 Δ.

The magnitude of the increase in exercise V_{O_2}max with endurance exercise training depends on multiple factors, including the individual's age, baseline fitness level, the intensity and duration of the training regimen, genetic factors, underlying disease states, and whether testing and training use similar exercises, referred to as the “specificity” of training. In general, young persons trained intensively have greater improvement in exercise tolerance. Increases in V_{O_2}max average 11% to 36% in CR patients,[10] although the response varies with the severity of the underlying disease. Individuals with markedly reduced ventricular function, for example, may achieve much of their increase in exercise capacity by widening the A-V O_2 Δ, whereas increases in Q have been documented with 12 months of exercise training in some cardiac patients.[1] In addition to increasing maximal exercise capacity, endurance exercise training—by virtue of its effects on VT—increases endurance capacity. This effect is extremely important because increased submaximal exercise endurance capacity reduces dyspnea at submaximal work rates and facilitates the performance of most daily tasks.

Effects of Cardiac Rehabilitation and Exercise Training on Morbidity and Mortality

Patients with Angina Pectoris

Most patients with angina pectoris currently control their symptoms with medication or eliminate them by undergoing PTCA or CABG. Consequently, with rare exceptions,[11] much of the evidence that exercise training improves effort tolerance in patients with angina pectoris antedates 1990. Exercise training increases exercise time until the onset of angina—or eliminates angina entirely—by at least two mechanisms. First, as discussed earlier, exercise training increases V_{O_2}max, thereby reducing the HR and SBP response to submaximal exercise. This reduction in the double product reduces the MO_2 requirements and delays the onset of angina. Second, exercise training improves endothelial function.[11] With exercise, normal coronary arteries dilate, but atherosclerotic coronary arteries often fail to dilate or vasoconstrict. Exercise training improves endothelial vasodilator function, as measured by quantitative coronary angiography during infusion of acetylcholine.[12] Some patients also demonstrate increases in the rate-pressure product at the onset of angina after only a short period of exercise training,[1] further suggesting improved endothelial function (**Fig. 54.1**).

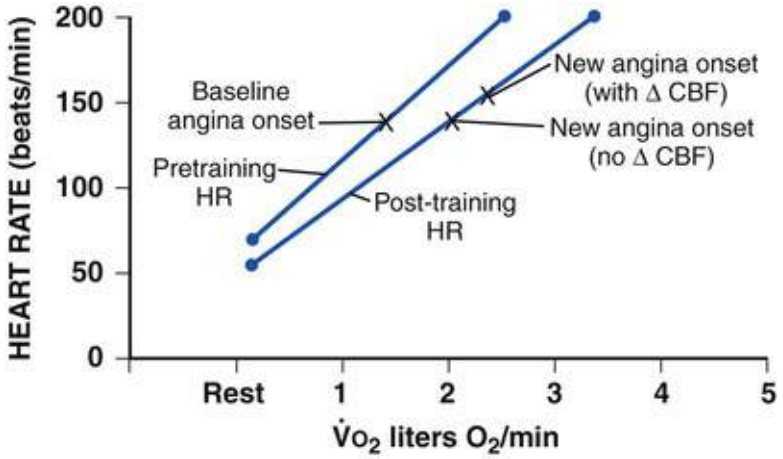

FIGURE 54.1 Changes in exercise tolerance and the onset of angina with exercise training. The heart rate (HR) versus oxygen consumption (VO_2) slope shifts so that any work rate (VO_2) elicits a slower HR response. Angina is delayed but occurs at the same HR if there is no change in coronary blood flow (CBF) (new angina onset [no Δ CBF]). Angina is delayed but occurs at a higher HR if CBF is increased by improved endothelial function. (Reproduced from Thompson PD: Exercise prescription and proscription for patients with coronary artery disease. Circulation 112:2354, 2005.)

Exercise training has particular utility in patients with angina who are not amenable to coronary interventions, but a clinical trial of 101 men age 70 or younger suggested that exercise training is useful in other patients with stable angina.[11] Participants were randomly assigned to 1 year of exercise training or to PTCA. The exercise training consisted primarily of daily 20-minute home bicycle ergometer exercise sessions plus a weekly 60-minute supervised session. Forty-seven participants in each group completed the trial. The exercise level at the onset of ischemia increased 30% in the exercise-trained group and 20% in the PTCA group (P = NS), a nonsignificant difference, but maximal exercise capacity (20% versus 0%) and VO_2max (16% versus 2%) increased significantly more in the exercise-trained group. At 1 year, 88% of the PTCA participants versus only 70% of the exercise-trained participants experienced a major cardiovascular event (P = 0.023) (**Fig. 54.2**). This study predated the widespread use of drug-eluting stents, but only 15% of the PTCA group demonstrated greater than 50% narrowing at the PTCA site, and even assuming no in-stent restenosis, the exercise group would still have had a greater event-free survival rate (88% versus 72%, P = 0.039). The authors noted that angioplasty treats one culprit lesion, whereas exercise training addresses endothelial dysfunction throughout the vascular system. These results may not apply to all individuals with stable angina, but do document the suitability of exercise training for managing select patients with angina.

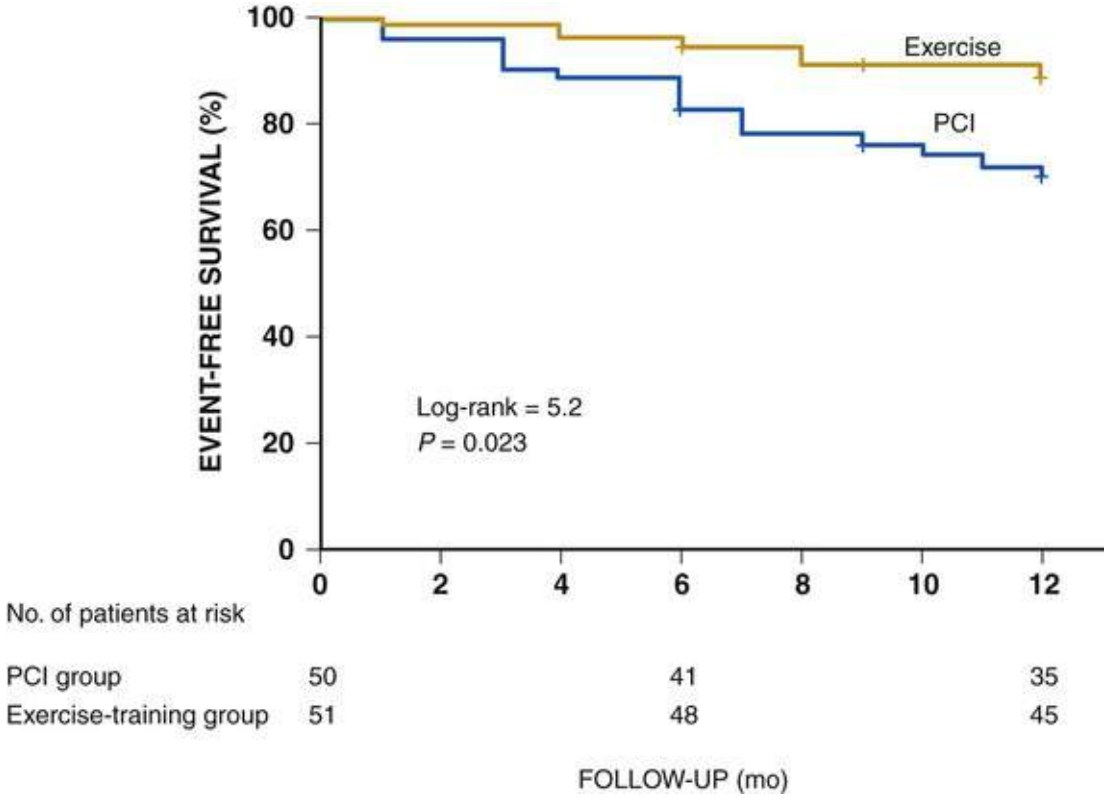

FIGURE 54.2 Event-free survival in 101 carefully selected patients with stable angina randomly assigned to percutaneous coronary intervention (PCI/stent) or to 1 year of exercise training. Numbers at bottom indicate patients free of events. Event-free survival was significantly better in the exercise-training group (88% versus 70%; $P = 0.02$ by log-rank test). (Reproduced from Hambrecht R, Walther C, Mobius-Winkler S, et al. Percutaneous coronary angioplasty compared with exercise training in patients with stable coronary artery disease: a randomized trial. Circulation 2004;109:1371.)

Patients with Coronary Artery Disease

A systematic review identified 47 studies in which 10,794 patients with MI, CABG, PTCA, or angina were randomly assigned to exercise-based CR or to usual care.[8] Total mortality and cardiovascular (CV) mortality were 13% and 26% lower, respectively, at 12 months or more of follow-up, and hospital admissions were 31% lower in the first year of the study ($P < 0.05$ for all). Subsequent MI, CABG, or PTCA did not decrease. The most recent meta-analysis included 63 studies of 14,486 patients with MI, PTCA, CABG, angina, or angiographically defined coronary disease.[9] CV mortality and hospital admissions decreased 26% and 18%, respectively, with CR. Total mortality was 11% lower with CR ($P > 0.05$), but these mortality data were affected by a large study in which the CR intervention was generally only once weekly for 6 to 8 weeks and in which the 1-year data suggested that the controls were doing more exercise than those randomized to CR.[13] CR showed similar benefits regardless of the nature of the program (exercise only versus other).[8,9]

Patients After Percutaneous Transluminal Coronary Angioplasty

Few large trials have examined the effects of exercise-based CR in patients following PTCA. A retrospective analysis of 2395 patients after PTCA noted an approximately 45% reduction in mortality ($P < 0.001$) in the 40% of patients who participated in CR.[14] Rehabilitation did not affect recurrent MI or subsequent revascularization, but the reduction in mortality did not differ by sex, age, or PTCA urgency,

suggesting that CR benefits almost all patients after PTCA. Unfortunately, self-selection bias might contribute to these results, but they agree with the overwhelming theme that CR improves clinical outcomes.

Patients with Heart Failure

Until 2009, meta-analytic data supported a benefit of exercise in patients with heart failure (HF) (**see also Chapter 25**).[15] HF-ACTION (Heart Failure: A Controlled Trial Investigating Outcomes of Exercise Training) was the first large-scale, adequately powered trial to examine the effect of exercise training on CV outcomes in patients with stable HF.[16] HF-ACTION randomly assigned 2331 patients with LVEF of 35% or less to exercise training or a control group. Exercise-training patients were encouraged to participate in 36 supervised exercise sessions over 3 months and were transitioned to home exercise, with the goal of exercising five times weekly for 40 minutes.

The mean duration of follow-up was 3.1 years, with a range of 1 to 4 years. Total mortality (−4%, P = 0.7), CV mortality or CV hospitalization (−8%, P = 0.14), and CV mortality or hospitalization for HF (−13%, P = 0.06) decreased insignificantly more in the exercise-trained group than in the control group. These results were reexamined after adjusting for prespecified confounders, including baseline exercise duration, LVEF, a psychological depression index, and a history of atrial fibrillation or flutter. After this adjustment, total mortality or hospitalization (−11%, P = 0.03), CV mortality or hospitalization (−9%, P = 0.09), and CV mortality or CV hospitalization (−15%, P = 0.03) decreased, suggesting that exercise training had beneficial effects in patients with HF (**Fig. 54.3**).

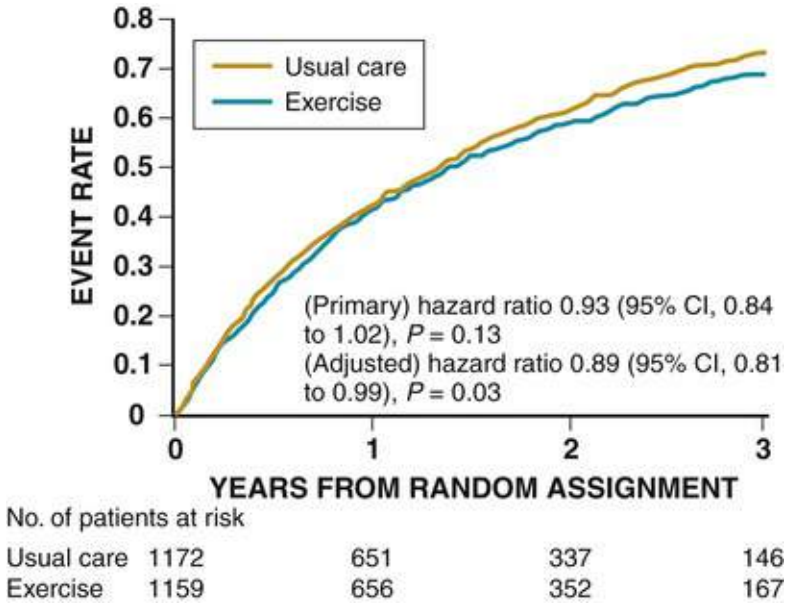

FIGURE 54.3 All-cause mortality or all-cause hospitalization in HF-ACTION. The hazard ratio was not reduced in the unadjusted data but was statistically significant when adjusted for baseline exercise duration, left ventricular ejection fraction, Beck Depression Inventory II score, history of atrial fibrillation or flutter, and cause of heart failure. (Reproduced from O'Connor CM, Whellan DJ, Lee KL, et al. Efficacy and safety of exercise training in patients with chronic heart failure: HF-ACTION randomized controlled trial. JAMA 2009;301:1439.)

The HF-ACTION results were less robust than expected, given a prior meta-analysis suggesting that exercising training reduces overall mortality by 35%,[17] but HF-ACTION may have underestimated the benefits of exercise training in patients with HF. The analysis used an intention-to-treat approach, but the exercise group had poor adherence to exercise training. Only 736 patients (60%) completed the 36

supervised exercise sessions. The poor adherence to exercise is important because exercise volume was a highly significant predictor of CV mortality and HF hospitalization,[18] and even moderate exercise was associated with greater than 30% reductions in subsequent risk.[18] The investigators attempted to enhance long-term exercise adherence by providing home treadmills or exercise cycles, HR monitors, and other adherence optimization strategies.[16] Despite such efforts, peak V_{O_2} increased only 4% in the exercise-training group. This effect was short of the 10% increase projected by the study investigators and well below the 17% increase reported in HF patients exercising in supervised sessions.[15] HF-ACTION employed an exercise-only intervention and did not include the counseling considered a component of comprehensive CR for HF.

In contrast, an Italian study with an 88% adherence to exercise over 10 years suggests that prolonged exercise training can profoundly affect clinical outcomes in patients with HF.[19] This study randomly assigned 123 patients with LVEF lower than 40% to formal exercise-training or to control. Exercise sessions occurred twice weekly, with participants encouraged to exercise a third time on their own. Most of the training was done in a "cardiac club," which also promoted healthy lifestyles. Peak V_{O_2} increased 14.7% in the exercise-training group and decreased 2.5% in the control group after 1 year. At 10 years, peak V_{O_2} was 21.8% higher in the exercise-training group. Remarkably, LVEF increased only in the exercise-training group, and this difference appeared only after 5 years into the study (**Fig. 54.4**). Twelve cardiac events occurred in the exercise-trained group and 35 in the control group, a 45% reduction (95% confidence interval [CI] −28% to −74% reduction; $P < 0.001$) (**Fig. 54.5**). Similarly, four deaths occurred in the exercise-training group and 10 deaths in the control group—a 32% reduction (95% CI −28% to −70% reduction).

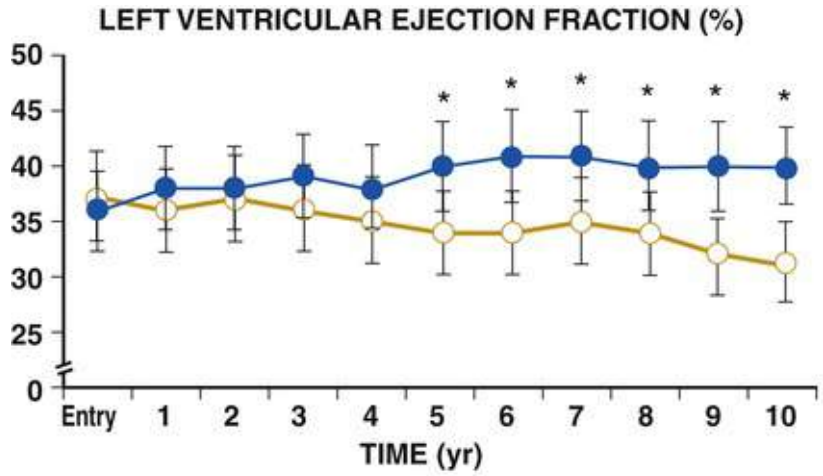

FIGURE 54.4 Left ventricular ejection fraction (LVEF) in exercise-trained (*solid circles*) and non–exercise-trained (*open circles*) patients with heart failure over time. Changes in LVEF were different between the groups over time, but not until 5 years after the start of exercise training. (Reproduced from Belardinelli R, Georgiou D, Cianci G, Purcaro A. 10-Year exercise training in chronic heart failure: a randomized controlled trial. J Am Coll Cardiol 2012;60:1521.)

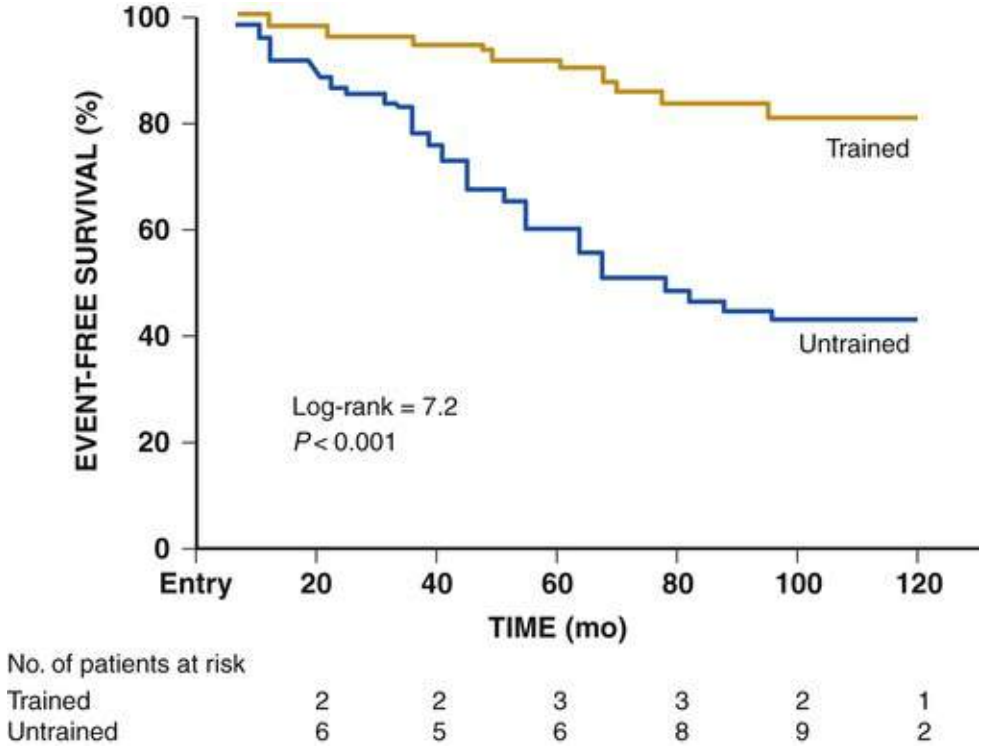

FIGURE 54.5 Event-free survival in exercise-trained and non–exercise-trained patients with heart failure over time. (Reproduced from Belardinelli R, Georgiou D, Cianci G, Purcaro A: 10-year exercise training in chronic heart failure: A randomized controlled trial. J Am Coll Cardiol 60:1521, 2012.)

Practical Aspects of Cardiac Rehabilitation Programs

Program Structure

Cardiac rehabilitation programs involve three phases based on the patient's clinical status. Phase 1 CR refers to inpatient programs started soon after the acute cardiac event or intervention. These programs are uncommon presently because of the brevity of most hospital stays, although some European countries have inpatient rehabilitation programs lasting up to several weeks. Phase 1 programs remain useful in mobilizing elderly patients after complicated cardiac events, as well as for many types of patients after cardiac surgery. In the United States, physical therapy departments or dedicated CR staff often direct these programs. Phase 1 is also an excellent way to introduce patients to the concept of cardiac rehabilitation and to solicit appropriate referrals to phase 2. Separate reimbursement for phase 1 programs in the United States is not available because charges for the acute event include this service, if provided.

Phase 2 CR refers to physician-supervised outpatient programs in the postdischarge period. Patients in these programs usually exercise three times weekly, for a total of 36 sessions over 3 to 4 months. Medical insurance usually covers these programs, although co-pays and deductibles can hinder participation. Other approaches to CR, including simple home-based, self-supervised programs; home-based, visiting nurse–supervised programs; and home-based programs with telephone electrocardiographic (ECG) monitoring, have been examined in research settings and compare favorably with standard facility-based programs.[20] Although most insurance carriers do not cover such alternative programs, these CR programs should be developed because many patients cannot attend the standard, facility-based programs for many reasons, including lack of a local program.[20]

Phase 3 CR refers to non–ECG-monitored long-term maintenance programs. These programs are usually provided by the same facilities providing phase 2 programs, but because phase 3 programs do not

include direct medical supervision, health clubs and fitness facilities may also provide them. In the United States, medical insurance generally does not cover phase 3 programs.

Staff Coverage

The standard CR program has a physician medical director, a staff nurse, and other individuals with training in exercise physiology to design the exercise and educational programs and to supervise the exercise sessions. To qualify for Medicare reimbursement in the United States, phase 2 CR programs must have a physician medical director. This individual must review and approve a treatment plan for each patient every 30 days[21] and must be immediately available during the rehabilitation sessions. Definition of the term “immediately available” is open to interpretation but generally means being in the facility and available within moments for any emergency. All CR staff must be trained in advanced cardiac life support. A nurse must be available during the exercise rehabilitation sessions to handle emergencies and administer medications. Staffing-level recommendations are one staff member per five participants during phase 2 programs and one staff member per 10 to 15 participants during phase 3 sessions.

Design and Implementation of Exercise Training Program

Patients referred to CR should undergo a symptom-limited exercise test before entering the program to identify and evaluate any important symptoms, ischemia, or arrhythmias that might require other interventions before exercise training. The exercise test also establishes baseline exercise capacity and determines the maximum HR to prepare an exercise-training prescription. Tests are usually performed with patients taking their usual medications to mimic the HR response likely to occur during exercise training.

A typical exercise-training session for CR patients consists of 5 minutes of warm-up, followed by 20 to 45 minutes of aerobic exercise training and 5 to 15 minutes of cool-down. The warm-up session consists of stretching and light calisthenics. Some resistance exercise training using light weights or exercise machines should also be performed, often after the aerobic session and as part of an extended cool-down period. The resistance exercises should address most of the major muscle groups to increase patients' ability to perform daily living and work tasks, such as lifting and carrying.

The aerobic exercise–training component is generally performed at 60% to 70% of V_{O_2}max, which corresponds to approximately 70% to 80% of the maximum HR. Some patients require lower training intensities. Although 20 to 45 minutes of exercise training is standard, shorter periods have benefit, and longer sessions almost certainly provide additional benefit. Most CR programs recommend other activities, such as walking or gardening, on days when patients do not attend supervised sessions.

Recent studies have examined the use of high-intensity interval training (HIIT) in CR to accelerate the exercise-training effect.[22,23] A typical protocol starts with a 10-minute walking warm-up followed by four 4-minute intervals of walking at 90% to 95% of maximal HR, followed by 3-minute recovery periods at 50% to 70% of maximal HR. HITT provides enhanced improvements in peak V_{O_2} in patients with systolic HF, after CABG, and after MI compared with continuous moderate-intensity training.[22,23] HITT does not appear to increase cardiac risk, but studies to date are relatively small. Many patients find it less “boring” than standard training.

Exercise testing before starting CR is useful, but not all patients—especially those after recent MI—undergo such testing. Patients who do not undergo exercise testing before starting a CR program can

exercise at a HR 20 beats faster than their resting value. Another approach consists of exercising patients at their resting HR, plus a specified additional percentage of their rest HR. For example, during month 1, a patient might exercise at rest HR plus 20% to 30% of rest HR; month 2, rest HR plus 20% to 40% of rest HR; and month 3, rest HR plus 20% to 50% of rest HR. Alternatively, such patients can exercise to the point of mild dyspnea and maintain that level during the training session. As discussed earlier, the onset of dyspnea approximates VT and indicates adequate intensity for a training stimulus. Finally, patients can exercise to a "somewhat hard" level by using number scales designed to estimate the intensity of exertion, such as the modified Borg Scale of Perceived Exertion.

Unsupervised Exercise Training

Many patients cannot attend supervised exercise training sessions but should be advised to exercise for its CV benefits. Patients without lower limb orthopedic problems should be encouraged to use brisk walking as their exercise-training modality. Patients in unsupervised programs should generally be encouraged to exercise to the onset of mild dyspnea for the reasons mentioned earlier. Such an approach obviates the need for pulse monitoring. Many patients either cannot accurately monitor their HR or become unduly concerned about pulse irregularities caused by premature atrial or ventricular contractions. Patients exercising on their own can also be encouraged to judge their exercise intensity by using the "talk test"—exercising at the fastest rate that still permits comfortable conversation. This work rate corresponds to the exercise-training range recommended for cardiac patients.[1]

Other Components of Comprehensive Cardiac Rehabilitation

Nutritional, psychological, and vocational counseling, as well as serum lipid, blood pressure (BP), and smoking risk factor management, are core components of CR and required by Medicare. Addressing issues such as BP and lipid management and smoking cessation often requires balancing the roles of the CR staff and the primary care physician. CR personnel generally focus on the counseling aspects of risk factor management. They can also interpret laboratory results and physician instructions and act as patient advocates with the primary health care providers. (**See also Chapter 45**.)

Programs differ in how they deliver the counseling and education components. Many programs use the time when the patient is on the exercise apparatus to visit and educate. Some programs simply make printed material available to the participants. Other programs use television monitors and either commercially available or locally prepared video programs to deliver the counseling and risk reduction messages. Some programs have replaced exercise sessions with educational programs. Creatively scheduled classroom activities in addition to the exercise sessions permit participants to craft education programs that best meet their needs.

Approximately 80% of CR patients are overweight or obese.[24] Significant weight loss does not occur with CR exercise alone.[24] CR provides the opportunity for behavioral weight loss counseling combined with an exercise prescription that recommends almost daily, longer-distance walking. Such "high caloric expenditure exercise" programs can achieve a body weight loss of 5% to 10%. This weight loss is associated with improvements in insulin sensitivity, BP, lipids, clotting factors, and endothelial function.[24]

Insurance Coverage

Insurance coverage of CR activities is important for patients to be able to receive these services.[25] Medicare generally provides reimbursement for patients who have stable angina pectoris, have suffered acute MI, or have undergone CABG, cardiac valve repair or replacement, PTCA, or heart or heart-lung transplantation within the previous 12 months. Since 2014, CMS also covers CR for stable systolic HF with LVEF lower than 35% on optimal medical therapy.[26] Many private insurers follow the Medicare reimbursement procedures. Routine coverage includes 36 exercise sessions.

Current Challenges

Exercise-based CR is an AHA guideline class Ia recommendation but is underutilized. Only 14% to 35% of MI survivors and approximately 31% of patients following coronary revascularization participate in CR programs.[20] Women, older patients, minority groups, and low–socioeconomic status patients—the very groups at greatest risk for recurrent events—have especially low referral rates.[20] Simple, available techniques can increase referral. For example, automatic electronic medical-based referral systems can almost triple referral rates,[7] but such approaches see little use. Physician endorsement of CR is one of the most important predictors of participation.[20] Why physicians do not routinely refer patients to rehabilitation is unclear, although physicians' underestimation of the benefits of exercise, lack of knowledge about exercise training, and the absence of exercise advocates similar to pharmaceutical representatives may contribute. Physician referral to cardiac rehabilitation will probably increase when and if referral to such programs becomes a core measure of hospital performance.

Future Perspectives

Use of CR should increase greatly if CMS adopts referral to CR as a core performance measure for the management of patients with coronary disease and after cardiac surgery, as proposed.[26] Furthermore, the ability of CR to reduce cardiac mortality and possibly recurrent cardiac events will probably be a component of any efforts to control medical care costs by accountable care organizations.[20] Cost containment efforts could also result in the wider use of exercise-based CR/secondary prevention as a method to reduce rehospitalization. Furthermore, the role of cardiac rehabilitation with optimal medical therapy to manage stable angina pectoris before proceeding to more costly interventions such as PTCA and CABG requires consideration and more study. Such a change seems unlikely in the present fee-for-service environment but will be more important in a capitated system.

Integrative Approaches to the Management of Patients with Heart Disease

Stephen Devries

Integrative Cardiology

Integrative cardiology is more a philosophy of care than a description of a particular set of practices. Integrative cardiology is focused on the prevention of disease, with an emphasis on maximizing the benefits of nutrition and lifestyle interventions. Completely inclusive of guideline-based medical therapy, integrative cardiology seeks to empower patients to the greatest degree possible with health goals and therapeutic plans developed collaboratively (**Fig. 55.1**).

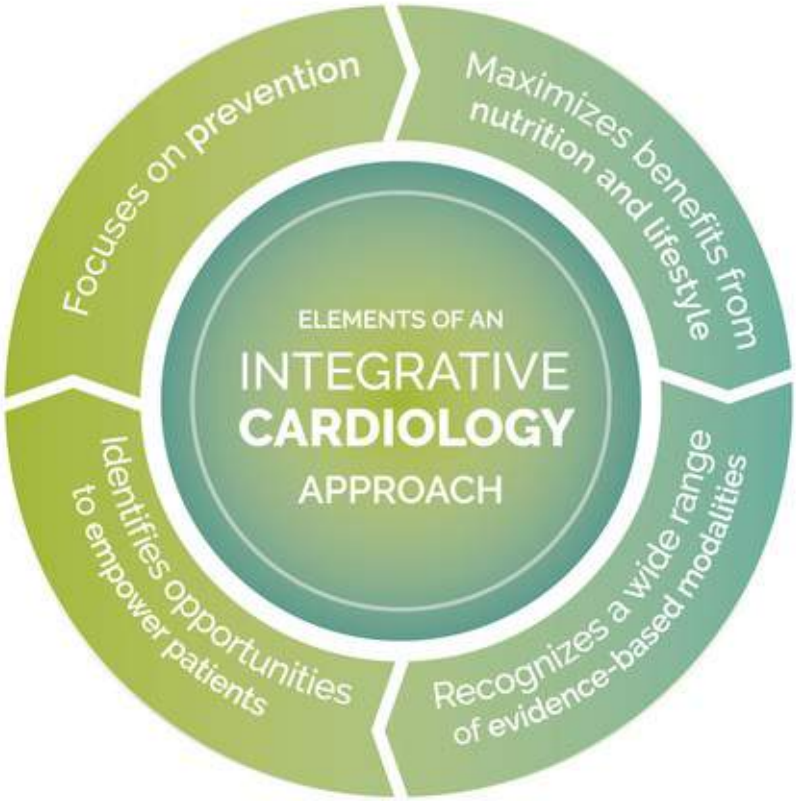

FIGURE 55.1 Key elements of an integrative cardiology approach.

Integrative cardiology is important because it addresses unmet needs in conventional care. Despite the technological advances, a report from the U.S. Centers for Disease Control and Prevention (CDC) describes a recent plateau in the decline of cardiovascular disease (CVD), largely a manifestation of the lifestyle-related problems of obesity and diabetes.[1]

Nutrition and lifestyle are not typically emphasized in the training or practice of cardiology. For example, in the current 38-page document from the Accreditation Council for Graduate Medical Education that details specific requirements for fellowship training in CVD, there is no mention of a requirement for including nutrition in the curriculum.[2] An integrative approach seeks to address this deficiency by highlighting nutrition and lifestyle as integral components of the therapeutic plan.

One of the tenets of integrative cardiology is an emphasis on patient empowerment. The need for greater attention to shared decision making is exemplified by a recent analysis of conversations between cardiologists and patients regarding percutaneous coronary intervention (PCI). In this study, cardiologists inquired about the patient's preferences for treatment in only 54% of discussions and mentioned alternatives to PCI in only 25%.[3]

Most importantly, adoption of an integrative cardiology approach can lead to improved outcomes. An excellent example, as discussed later, is the improved outcome when lifestyle modifications are implemented after an ablation procedure for atrial fibrillation.

Associated Treatment Modalities

Nutrition

Although it can be argued that nutrition is (or should be) part of all medical care, dietary considerations take on an especially prominent role in an integrative model. Nutritional interventions are the foundation of cardiac care for both the prevention and the treatment of CVD.

Mind/Body Therapy

In recognition of the strong influence of thoughts and emotional state on cardiovascular (CV) health, an integrative approach emphasizes the connection between mind and body. In addition to the more traditional approaches with cognitive behavioral therapy and medication, modalities that might be recommended in an integrative model include meditation, breathing exercises, yoga, biofeedback, healing touch, and Reiki.

Acupuncture

Although acupuncture is most often associated with treatment of musculoskeletal pain, emerging data shows promise for acupuncture to be used as adjunctive treatment for a range of CV conditions, including hypertension.

Supplements and Botanicals

It is incumbent on the cardiologist at least to be knowledgeable about the supplements most frequently used by cardiac patients. Also, for some clinicians, review of the evidence may lead them to consider selective use of some over-the-counter (OTC) products (e.g., patient intolerant of prescription statins). Although it is considered good medical practice to document all OTC products taken by patients, this information has limited value if the clinician is unaware of the product and does not know how to obtain credible scientific information about it. Fortunately, several excellent resources are available to help clinicians learn about the science of supplements (**Table 55.1**).

CredibleMeds https://www.crediblemeds.org	OTC and prescription drugs that can prolong the QT interval and lead to arrhythmias (free)

Need for Interprofessional Collaboration

The need for close collaboration between all members of the cardiovascular team is clear, but communication between cardiologists and allied health professionals involved with integrative care has historically been challenging. Regardless of differences in language and perspectives, mutual respect and open communication between all health professionals, conventional and alternative, is essential for optimal patient care.

Integrative Strategies for Specific Cardiac Conditions

The foundation of integrative cardiology begins with guideline-based therapy. This sections describes a select group of evidence-based approaches not often utilized in conventional management. These tools,

added to guideline-based therapy, may extend its benefits and provide additional opportunities to engage and empower patients.

Ischemic Heart Disease

See also Chapter 58.

Nutrition

Perhaps no therapy in clinical medicine is as impactful as nutritional interventions for prevention and treatment of ischemic heart disease. The final report of the Lyon Diet Heart Study, a study of a Mediterranean-style diet in patients with prior myocardial infarction (MI), showed a 72% reduction in cardiac death and recurrent infarction.[4] A Mediterranean-style diet encourages intake of vegetables and fruit, whole grains instead of refined grains, nuts, fish in place of red meat, and olive oil as the predominant cooking oil.

A more recent study of a Mediterranean-style diet in a high-risk primary prevention group, PREDIMED, was terminated prematurely because of early positive results: a 30% reduced risk of major CV events.[5] Interestingly, the primary component that distinguished the intervention and control dietary groups was the source of dietary fats. Both arms of the Mediterranean-style intervention, high consumption of either extra-virgin olive oil or nuts, showed benefit compared to the control diet.

Among the components of a cardioprotective diet, green leafy vegetables, including spinach and kale, appear to be especially beneficial. Combined data from the Nurses' Health Study and Health Professionals Follow-Up Study showed that each daily serving of green leafy vegetables (0.5 cups cooked) reduced the adjusted risk of coronary disease by 23% in women ($P = 0.0004$) and 11% in men ($P = 0.02$).[6]

Anthocyanins are dietary flavonoids that enhance endothelial function and have antioxidant and antihypertensive properties. Anthocyanin-rich foods, especially blueberries and strawberries, are strongly linked to cardiac health. During an 18-year follow-up of the Nurses' Health Study, including 93,600 women, intake of four or more servings of blueberries and strawberries was associated with a 34% decreased risk of MI.[7]

Nut consumption is also strongly associated with reduced risk of heart disease and improved longevity. The health-promoting properties of nuts are likely related to their rich content of magnesium, sterols, vitamin E, alpha-linolenic acid, and monounsaturated fats. In a meta-analysis of 18 prospective studies, the relative risk for ischemic heart disease was reduced by 28% with each daily serving of nuts.[8] In another study, nut intake was associated with a 21% reduced risk of death over a 5-year period in those with the highest versus lowest consumption of nuts ($P < 0.05$).[9]

Mind/Heart Connection

There is no better example of the connection between the mind and heart than takotsubo syndrome, a condition of acute and severe left ventricular failure precipitated by psychological stress.[10] Takotsubo syndrome, quite dramatic in its presentation, is only one of the many manifestations of stress and emotional state on cardiac health.

Meditation

The link between mind and heart can be harnessed for prevention of ischemic heart disease. In a

randomized controlled study of meditation added to conventional cardiac care in 201 individuals with coronary disease, the meditation group experienced a 48% reduced risk of a composite endpoint including all-cause mortality, MI, and stroke ($P = 0.025$).[11] The underlying mechanism of benefit is unclear but likely includes a favorable effect on blood pressure. Mindfulness-based stress reduction has also been linked to an attenuated inflammatory response, another potentially cardioprotective mechanism.[12]

Tai Chi

Tai chi can be described as "meditation in motion" and is practiced as a series of flowing, smoothly executed movements. A regular tai chi practice may favorably alter risk factors associated with atherosclerosis. A study of women with multiple coronary risk factors found that an 8-week program of tai chi was associated with a marked downregulation of proinflammatory cytokines associated with CVD.[13]

Healing Touch

Although unfamiliar to many health professionals, healing touch and Reiki are increasingly popular modalities used for stress management and pain reduction. In both, a practitioner uses light touch and hand motions around the body to redirect "energy." Regardless of the mechanism, many patients report significant relief. In a study of 237 inpatients recovering from coronary bypass surgery, those randomized to receive healing touch had lower anxiety scores, as well as shorter length of stay (6.9 versus 7.2 days; $P = 0.04$).[14]

Environment

The physical environment may influence risk factors that contribute to CVD. Ambulatory heart rate (HR) was monitored in urban settings, with and without greenery. Those who walked in urban green spaces had significantly lower HR then those moving within urban spaces without greenery.[15] A tendency to lower HR while viewing parks and green space may be a reflection of "biophilia," the innate affinity that most people experience to contact with nature.

Supplements

Omega-3 Fatty Acids

Early studies suggested cardiac benefit with omega-3 fatty acids, but more recent publications have not consistently confirmed the preliminary findings. Nevertheless, remaining questions regarding the optimal dose of omega-3 acids, as well as patient selection, make the ultimate role of omega-3 supplements uncertain. Underscoring the possibility that high doses are required, a recent study of post-MI patients showed a favorable effect on left ventricular remodeling with 3.4 g combined docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA), a dose much higher than used in many previous studies.[16]

Currently, a widely supported recommendation is to obtain omega-3 fatty acids from fish, at least 2 servings of omega-3–rich fish per week. Nevertheless, for those who cannot or choose not to eat fish, omega-3 supplements may be particularly beneficial. Several brands of prescription omega-3 fatty acids are now available.

OTC fish oil supplements may also be considered, but dosing requires special attention. Many OTC omega-3 supplements include a front label with total omega-3 content. The amount can be misleading,

however, because accurate dosing depends on DHA and EPA content, which may be only a fraction of the total omega-3 content listed. If, for example, 1000 mg of combined DHA and EPA are prescribed, patients should be advised to review the back label of an OTC omega-3 product and take as many pills as needed to total 1000 mg of combined DHA and EPA. Despite a front label indicating 1000 mg of fish oil per pill, some omega-3 preparations require 2 or 3 pills daily to total 1000 mg of combined DHA and EPA.

Vegans can also enhance their intake of omega-3 fatty acids with algal oil supplements that contain both DHA and EPA. Studies show significant elevation of plasma and erythrocyte DHA levels with consumption of algae-derived DHA supplements.[17]

Multivitamins

Most large trials of multivitamin use for prevention of heart disease have not shown beneficial effects, including a trial limited to men (Physicians' Health Study II)[18] and a large study of women (Women's Health Initiative).[19] However, a more recent analysis of data from the Physicians' Health Study I, involving 18,530 men, found that a duration of multivitamin use of 20 or more years was associated with a 44% lower risk of a major CV event ($P = 0.05$).[20]

Antioxidants

Smaller, early trials of antioxidants showed promising results for prevention of ischemic disease. Nevertheless, more recent, larger studies of vitamins E and C have failed to demonstrate benefit.[21,22] However, most studies of vitamin E evaluated only a single isoform of vitamin E (mostly α-tocopherol), from among the full complement of eight vitamin E isoforms (four tocopherols, four tocotrienols), some of which have opposing effects. Additional studies including varying formulations of vitamin E are needed. In the meantime, it is definitely known that whole-food sources rich in antioxidants, especially vegetables and fruit, are strongly cardioprotective.[23]

Hypertension (see Chapter 47)

Nutrition

DASH Diet and Potassium

Dietary approaches are extremely potent interventions for treatment of hypertension. The best-studied diet for hypertension is DASH (Dietary Approaches to Stop Hypertension). The DASH diet, similar to a Mediterranean-style diet, includes 8 to 10 servings of combined vegetable and fruit in addition to low-fat dairy. Among patients with baseline hypertension, systolic and diastolic blood pressure (BP) were reduced by 11.4 and 5.5 mm Hg, respectively ($P < 0.001$).[24] There is a common misconception that dietary changes require an extended period to realize benefits. To the contrary, the maximal BP-lowering effect of the DASH diet was evident within the first 2 weeks of the trial and was maintained throughout the study period.

The DASH diet was designed to boost potassium intake to approximately the 75th percentile of U.S. consumption. An inverse relationship between potassium and BP reduction is well established.[25] The high-potassium intake in the DASH diet, from increased consumption of potassium-rich fruit and vegetables, was likely responsible for a significant portion of the BP-lowering effect.

The sodium content of both the intervention and the control arm of the original DASH diet were similar, approximately 3 g/day. In a follow-up DASH study, a stepwise reduction of sodium consumption was

superimposed on the original DASH diet. The subset of DASH participants who consumed the lowest versus highest amount of sodium had an additional BP reduction of 3.0 mm Hg systolic and 1.6 mm Hg diastolic.[26]

Dietary Nitrates

Dietary nitrates play a key role in BP reduction through production of the vasodilator nitric oxide. The mechanism by which this occurs is novel. Dietary nitrates are rapidly absorbed into the circulation, where a significant amount is actively taken up and concentrated in the salivary glands, resulting in a salivary nitrate concentration approximately 10-fold that of plasma. Concentrated nitrates in saliva interact with facultative bacteria in the mouth that reduce nitrates to nitrites, the substrate for nitric oxide production.

Beverages made from concentrated preparations of foods rich in dietary nitrates, including arugula, spinach, and beetroot, were associated with BP reductions of 5 to 7 mm Hg within 2.5 hours of consumption.[27] In another study, beetroot juice, consumed daily for 4 weeks, led to a reduction in ambulatory BP of 7.7 mm Hg systolic and 5.2 mm Hg diastolic ($P < 0.001$ for both).[28]

Of note, antiseptic mouthwash can disrupt the bacteria-assisted reduction of nitrates to nitrites in the mouth. Use of an antiseptic mouthwash for 1 week reduced oral nitrite production by 90%, associated with an increase in both systolic and diastolic BP of 2 to 3 mm Hg ($P < 0.001$).[29]

Physical Activity

Aerobic exercise, involving high repetition movement of large muscle groups, is the form of physical activity best studied for BP reduction, with sufficient data to warrant a rating of class I, level of evidence (LOE) A, in an American Heart Association (AHA) scientific statement.[30]

Less well appreciated is the potential for dynamic resistance (class IIa, LOE B) and isometric handgrip exercise (class IIa, LOE C) to aid in BP reduction.[30] Gender appears to be a factor in the response to exercise, with women showing a greater reduction in BP after resistance compared to aerobic exercise. Men have comparable BP-lowering effects with either form of exercise.

Of special note are studies of isometric handgrip exercise. Although the data are limited, available studies demonstrate a particularly strong BP-lowering effect from handgrip exercise. Findings include the observation that handgrip exercise appears to require a relatively short duration for BP lowering, an average of 33 minutes per week.[30]

Mind/Heart Connection

Breathing Exercises

Breathing exercises that include periods of slow, deep breaths are integral to meditation and yoga and help facilitate reflection and relaxation. More recently, device-guided slow-breathing protocols have also been shown to have BP-lowering effects (class IIa, LOE B). A daily device-guided exercise of 7 minutes of slow breathing for 15 minutes has been shown to reduce BP by an average of 4 mm Hg systolic and 3 mm Hg diastolic within 1 to 2 weeks.[30] Although not as well studied, a wide range of instructions for self-directed breathing exercises are widely available, with the advantages of promoting patient empowerment and being free and accessible to all patients.

Biofeedback

Biofeedback (class IIb, LOE B), a technology that permits individuals to visualize their physiologic

responses to breathing and relaxation exercises, has also been shown to be effective for BP management.[30] Biofeedback can be an especially attractive modality for individuals who thrive on quantitative self-monitoring.

Meditation

Transcendental meditation (class IIb, LOE B) has been particularly well studied for treatment of patients with established hypertension, with BP reduction up to 15 mm Hg systolic.[30] The mechanisms are not well defined but likely involve a favorable impact on the autonomic nervous system, resulting in decreased HR and vascular tone. Individuals who are drawn to self-reflection may be especially interested in considering meditation as an adjunctive tool for BP control.

Acupuncture

A randomized controlled study recently evaluated acupuncture performed twice weekly over 8 weeks, with an additional 4-week follow-up. At the end of follow-up, systolic BP was lowered by 9 mm Hg and diastolic by 8 mm Hg.[31] Significant differences were noted in measurements of HR variability between the acupuncture and control groups, consistent with a favorable influence on autonomic function.

Supplements

Magnesium

Several studies have demonstrated an inverse relationship between serum magnesium and BP. In one trial, hypertensive patients treated with magnesium pidolate, 600 mg/day for 12 weeks, had a reduction in BP of 4.3 mm Hg systolic and 1.8 mm Hg diastolic ($P = 0.002$ for both).[32] Magnesium supplements can cause diarrhea and should be avoided in patients with significant renal insufficiency.

Probiotics

Probiotics are supplements containing live microorganisms intended to confer health benefits. A meta-analysis of nine trials of probiotics, with a total of 543 participants, demonstrated a mean reduction in BP of 3.6 mm Hg systolic and 2.4 mm Hg diastolic.[33] Subgroup analysis showed greatest benefit when the dose of probiotics included multiple species with daily consumption of 10^{11} or more colonies for 8 or more weeks.

Environment

Contact with Nature

Physical environment appears to play a role in BP regulation. In an experiment of healthy volunteers with BP measurements during walks in forest and city areas, walks in the forest were associated with lower systolic and diastolic BP, as well as indices of HR variability reflective of lower sympathetic and increased parasympathetic tone.[34]

Environmental Toxin

Bisphenol A (BPA) is a chemical used to coat the inner linings of many canned and plastic products, but not glass. A recent study identified a greater than 1600% increase in urinary BPA level after consuming

two cans of a beverage, with BP increasing 5 mm Hg higher than after drinking the same beverage stored in glass ($P < 0.02$).[35]

Dyslipidemia (see Chapter 48)

Nutrition

Dietary approaches are the foundation of treatment for dyslipidemia. Consistent with the recent AHA/American College of Cardiology (ACC) Guideline on Lifestyle Management to Reduce Cardiovascular Risk, the recommended diet emphasizes vegetables, fruit, nuts, whole grains, and fish and minimizes or avoids intake of sugar-sweetened beverages and red meat.[36] Avoidance of *trans* fats found in some fried foods and bakery items and replacement of saturated fats with polyunsaturated and monounsaturated fats are also key components of a cholesterol-lowering diet.

Physical Activity

Approximately 20% of the reduction in CVD from exercise can be attributed to its beneficial effect on lipids. In adults, aerobic exercise has been shown to reduce low-density lipoprotein cholesterol (LDL-C) by 3 to 6 mg/dL. Resistance training is similarly effective, with an average reduction in LDL-C of 6 to 9 mg/dL when performed 3 or more days a week with three sets of nine exercises.[36]

Statin Intolerance

For those who require cholesterol reduction beyond that achievable with lifestyle measures alone, statins are typically prescribed. Although the majority of statin users experience no significant side effects, a significant number do experience at least mild adverse reactions, most often myalgias. From a survey of 10,138 current or former statin users, 17% recalled experiencing muscular side effects while taking a statin. Among those who discontinued their statin use, 60% reported having experienced muscular side effects.[37]

Many strategies exist to address statin intolerance, including a reduction in daily dose, increasing the interval between doses, and switching brands of statins. For patients in whom these strategies are not successful, and for those who are philosophically opposed to taking prescription statins, OTC supplements may be considered.

Supplements

Dietary Fiber

Water-soluble dietary fiber has long been recognized as helpful in reducing plasma cholesterol levels. Although the mechanisms are not well defined, soluble fiber likely acts as a bile acid sequestrant, in addition to upregulating LDL hepatic receptors. The ideal source of dietary soluble fiber is from whole foods, with fiber from whole-grain sources most closely linked to reduction of CVD risk.[38]

Psyllium is the best studied fiber supplement. In a meta-analysis of eight trials, consumption of 10 g of psyllium (2 tsp)/day, in conjunction with a low-fat diet, reduced LDL-C by 7% ($P < 0.0001$).[39]

Stanols and Sterols

Stanols and sterols are compounds naturally present in all plant-derived foods and are especially

concentrated in seeds, nuts, and grain products. These compounds lower serum cholesterol by competing for cholesterol absorption in the gastrointestinal tract. The average daily intake from food is 200 to 400 mg/day. A meta-analysis of eight studies showed that daily doses of stanols and sterols of up to 3 g reduced LDL-C by 12%.[40] Stanols/sterols can be used as monotherapy for treatment of hypercholesterolemia or in conjunction with statins.

Red Yeast Rice

Red yeast rice is derived from the fermentation of rice with the yeast *Monascus purpureus*, yielding a series of cholesterol-lowering monacolins. The monacolin in highest concentration in red yeast rice is monacolin K, also known as *lovastatin,* the first FDA-approved HMG-CoA reductase inhibitor. Typical dosages of red yeast rice (1200 to 2400 mg/day) result in an average reduction in LDL-C of 27%.[41] This degree of LDL lowering is greater than expected based on the concentration of monacolin K alone, likely because of multiple cholesterol-lowering constituents contained in red yeast rice.

Red yeast rice has been studied as an alternative for patients intolerant of prescription statins. In a randomized study of 62 patients previously statin intolerant, 87% were able to take red yeast rice without adverse reaction. Red yeast rice reduced LDL-C by 26%.[42] In a 5-year study of 4870 patients with prior MI, red yeast rice (compared to placebo) resulted in a 4.7% absolute and 45% relative risk reduction in the primary endpoint of nonfatal MI and cardiac death, as well as a 33% decrease in total mortality.[43]

Brands of red yeast rice differ in both potency and purity. The concentration of total monacolins and monacolin K can vary several-fold between manufacturers. A few brands have been found to contain small amounts of citrinin, a nephrotoxin. Chemical analysis of various red yeast rice formulations, including analysis of monacolin and citrinin concentrations, is available through the independent group ConsumerLabs.com (**see Table 55.1**). Red yeast rice could be considered a therapeutic option for individuals with dyslipidemia who refuse or are intolerant of prescription statins. Because red yeast rice is a form of a statin, patients should be advised of precautions common to all statins and should be monitored by a health care professional.

Coenzyme Q10

Coenzyme Q10 (CoQ10, ubiquinone) is a fat-soluble compound needed for the production of cellular adenosine triphosphate (ATP). Statin therapy has been shown to reduce circulating levels of CoQ10, a finding hypothesized as a possible factor in statin-related adverse reactions, including myalgias. In 120 patients with previous symptoms of statin intolerance studied in an 8-week, randomized, double-blind crossover trial,[44] those receiving 600 mg/day of CoQ10 (ubiquinol) showed no improvement in muscle pain. A meta-analysis of six studies of CoQ10 in 302 patients receiving statin therapy showed a nonsignificant trend toward decreased muscle pain.[45]

Despite the logic implicit in CoQ10 as a therapy for statin-related adverse reactions, the data supporting this use is not strong. However, because the safety profile for CoQ10 is excellent and anecdotal cases have reported benefit, CoQ10 remains a therapeutic option to consider in patients with mild statin-related myalgias.

Probiotics

The effect of probiotics on serum cholesterol was evaluated in a meta-analysis of 11 studies that included fermented milk products and probiotic supplements.[46] On average, the reduction in serum LDL-C associated with probiotic use was 8 mg/dL. The *Lactobacillus acidophilus* strain was especially

effective for LDL-C reduction. No significant impact on HDL-C or triglycerides was noted.

Congestive Heart Failure (see Chapter 23)

Nutrition and Lifestyle

Nutrition and lifestyle are key factors in the development of congestive heart failure (CHF). In a study of 84,537 women from the Women's Health Initiative (WHI), a lifestyle score was developed that included a healthy eating index, physical activity, body mass index, and smoking status.[47] The multivariable-adjusted risk of developing CHF over 11 years had a graded relationship to the ranking of lifestyle measures. Those with the most versus the least favorable lifestyle measures in all four categories, noted in 8% of all patients studied, had a 77% reduced risk of developing CHF.

Once CHF develops, healthy dietary interventions are associated with prolonged survival. In a study of CHF patients in the WHI study, multivariable-adjusted survival improved in a graded manner with level of adherence to a DASH diet.[48] Those with the closest adherence to the DASH diet, compared to the reference group, had a 16% improvement in survival over a follow-up of 4.6 years. Food groups most strongly linked to improved survival included vegetables, whole grains, and nuts.

Mind/Heart Connection

Optimism

The degree to which patients exhibit optimism has been linked to the development of heart failure (HF). In a study of 6808 seniors, adjusted for a wide range of behavioral, biologic, and psychological variables, each standard deviation increase in a measure of optimism was associated with a 26% reduced risk of developing HF.[49] The link between optimism and HF may warrant attempts to help patients cultivate a positive outlook. It is estimated that only 25% of optimism is heritable, with the remainder being shaped by a combination of social factors and learned behavior. Even a short-term intervention of guided imagery, in which patients imagine “a best possible self” for 5 minutes daily, was successful in boosting optimism.[50]

Tai Chi

In a study of patients with HF and preserved ejection fraction (EF), 16 patients were randomized to a 12-week program of tai chi or aerobic exercise, both performed in a group for 1 hour twice a week. At the completion of the study, peak oxygen uptake was similar, but distance on the 6-minute walk test increased more with tai chi, as did a measurement of depression.[51] A similar study of tai chi in patients with HF and EF of 40% or lower also showed no improvement in exercise indices, but did confirm significant improvement in quality-of-life scores and mood.[52]

Acupuncture

Dysregulation of the autonomic nervous system is a hallmark of CHF and a potential target for therapeutic acupuncture. Seventeen stable patients with New York Heart Association (NYHA) Class II or III symptoms and EF less than 40% were randomized to true acupuncture or control acupuncture (blunted, telescopic needle), with sessions twice a week for 10 weeks. No improvement in peak oxygen uptake was observed, but those who received true acupuncture increased their 6-minute walk time by 32 m (P = 0.002).[53]

Supplements

Coenzyme Q10

In patients with CHF, reduced levels of Q10 in the myocardium are linked in a graded manner to both HF symptoms and degree of systolic dysfunction. Accordingly, supplementation with CoQ10 has been studied as an adjunct to treatment of patients with systolic HF. A meta-analysis of CoQ10 supplementation in 13 studies with a total of 395 patients found a mean net change in EF of 3.7% and a decrease in NYHA class of 0.3.[54]

More recently, 420 patients with moderate to severe HF receiving conventional medical therapy were randomized to CoQ10 (300 mg/day) or placebo.[55] No short-term benefits (16 weeks) were observed, but after 2 years, significant improvement was noted in the group receiving CoQ10. NYHA functional class increased by at least 1 grade in 58% receiving CoQ10, compared to 45% in the placebo group (P = 0.028). CV mortality was also lower in the CoQ10 group than in the placebo group (9% versus 16%; P = 0.039).

Although additional research is needed, these preliminary findings hold promise for the use of CoQ10 as adjunctive treatment to improve both symptoms and outcomes of patients with CHF caused by systolic dysfunction. CoQ10 doses of approximately 300 mg have been used most often for this purpose.

Arrhythmias (see Chapter 35)

Comprehensive Lifestyle Approach

There is no better example of the benefits of an integrative approach in cardiology than the data in patients following ablation for atrial fibrillation (AF). Catheter ablation for AF is a highly effective modality, but recurrences are not uncommon. Because many of the risk factors for AF, including hypertension, obesity, and diabetes, are highly modifiable through lifestyle, it was speculated that an aggressive risk factor modification program after ablation might be helpful to reduce recurrent AF. A total of 281 consecutive patients receiving ablation for AF with a body mass index of 27 kg/m^2 or higher and at least one cardiac risk factor were entered into either a risk factor management group or a control group.[56] The risk factor management group received counseling for weight reduction and dietary salt restriction, started an exercise program, and were advised to take home BP measurements. Smokers received behavioral support with the goal of cessation. At the 42-month follow-up, arrhythmia-free survival was 4.8 times as likely ($P < 0.001$) in the risk factor management group than in controls. This finding exemplifies the benefits of a truly integrative approach: the combination of low- and high-tech strategies to achieve optimal results.

Yoga

Yoga combines aspects of both physical activity and meditation, making it a promising candidate for reducing the burden of AF. A group of 52 patients with paroxysmal AF were enrolled in the Yoga My Heart Study.[57] Participants were observed for 3 months, followed by 3 months of an intervention that consisted of twice-weekly yoga sessions. Following 3 months of yoga, symptomatic episodes of AF were reduced by 45% and asymptomatic episodes by 67% ($P < 0.001$ for both).

Conclusion

An integrative approach to heart health seeks to enlarge both the scope of available treatments and the level of patient engagement. An integrative approach opens the door to many low-risk, high-impact interventions that, when added to guideline-based therapy, can make a powerful difference to improve satisfaction, for both patients and physicians, and improve outcomes.

PART VII
Atherosclerotic Cardiovascular Disease

OUTLINE

56

Approach to the Patient with Chest Pain

Marc P. Bonaca, Marc S. Sabatine

Acute chest pain is one of the most common reasons for seeking care in the emergency department (ED), accounting for approximately 10% of all visits or 6 million presentations annually in the United States. Although chest pain raises the possibility of an acute coronary syndrome (ACS), after diagnostic evaluation only 10% to 15% of patients with acute chest pain actually have ACS.[1] The difficulty lies in discriminating patients with ACS or other life-threatening conditions from those with noncardiovascular, non–life-threatening chest pain. The diagnosis of ACS is missed in approximately 2% of patients, which can lead to substantial consequences—for example, the short-term mortality in patients with acute myocardial infarction (AMI) who are mistakenly discharged from the ED increases twofold over that expected for patients who are admitted to the hospital. For patients with a lower risk for complications, however, these concerns must be balanced against the cost and inconvenience of admission and against the risk for complications from tests and procedures with a low probability of improving patient outcomes.

Several recent advances have enhanced the accuracy and efficiency of evaluation of patients with acute chest pain, including better blood markers for myocardial injury,[2] decision aids to stratify patients according to their risk for complications, early exercise testing,[3] radionuclide scanning for lower-risk patient subsets[3] (**see Chapter 16**), multislice computed tomography (CT) for anatomic evaluation of coronary artery disease (CAD), pulmonary embolism (PE), and aortic dissection[4] (**see Chapter 18**), and the use of chest pain units[3] and critical pathways for efficient and rapid evaluation of lower-risk patients.[5]

Causes of Acute Chest Pain

In a typical population of patients undergoing evaluation for acute chest pain in EDs, about 10% to 15% have AMI or unstable angina.[1] A small percentage has other life-threatening problems, such as PE or acute aortic dissection, but most leave the ED without a diagnosis or with a diagnosis of a non–cardiac-related condition.[6] Such noncardiac conditions include musculoskeletal syndromes, disorders of the abdominal viscera (including gastroesophageal reflux disease), and psychological conditions (**Table 56.1**).

TABLE 56.1

Common Causes of Acute Chest Pain

SYSTEM	SYNDROME	CLINICAL DESCRIPTION	KEY DISTINGUISHING FEATURES
Cardiac	Angina	Retrosternal chest pressure, burning, or heaviness; radiating occasionally to the neck, jaw, epigastrium, shoulders, left arm	Precipitated by exercise, cold weather, or emotional stress; duration of 2-10 min
	Rest or unstable angina	Same as angina, but may be more severe	Typically <20 min; lower tolerance for exertion; crescendo pattern
	Acute myocardial infarction	Same as angina, but may be more severe	Sudden onset, usually lasting ≥30 min; often associated with shortness of breath, weakness, nausea, vomiting
	Pericarditis	Sharp, pleuritic pain aggravated by changes in position; highly variable duration	Pericardial friction rub
Vascular	Aortic dissection	Excruciating, ripping pain of sudden onset in either the anterior chest or the back	Marked severity of unrelenting pain; usually occurs in the setting of hypertension or underlying connective tissue disorder such as Marfan syndrome
	Pulmonary embolism	Sudden onset of dyspnea and pain, usually pleuritic with pulmonary infarction	Dyspnea, tachypnea, tachycardia, signs of right-sided heart failure
	Pulmonary hypertension	Substernal chest pressure, exacerbated by exertion	Pain associated with dyspnea and signs of pulmonary hypertension
Pulmonary	Pleuritis and/or pneumonia	Pleuritic pain, usually brief, over the involved area	Pain pleuritic and lateral to the midline, associated with dyspnea
	Tracheobronchitis	Burning discomfort in the midline	Midline location, associated with coughing
	Spontaneous pneumothorax	Sudden onset of unilateral pleuritic pain, with dyspnea	Abrupt onset of dyspnea and pain
Gastrointestinal	Esophageal reflux	Burning substernal and epigastric discomfort, 10-60 min in duration	Aggravated by a large meal and postprandial recumbency; relieved by antacid
	Peptic ulcer	Prolonged epigastric or substernal burning	Relieved by antacid or food
	Gallbladder disease	Prolonged epigastric or right upper quadrant pain	Unprovoked or following a meal
	Pancreatitis	Prolonged, intense epigastric and substernal pain	Risk factors, including alcohol, hypertriglyceridemia, medications
Musculoskeletal	Costochondritis	Sudden onset of intense fleeting pain	May be reproduced by pressure over the affected joint; occasionally, swelling and inflammation over the costochondral joint
	Cervical disc disease	Sudden onset of fleeting pain	May be reproduced with movement of the neck
	Trauma or strain	Constant pain	Reproduced by palpation or movement of the chest wall or arms
Infectious	Herpes zoster	Prolonged burning pain in a dermatomal distribution	Vesicular rash, dermatomal distribution
Psychological	Panic disorder	Chest tightness or aching, often accompanied by dyspnea and lasting ≥30 min, unrelated to exertion or movement	Patient may have other evidence of an emotional disorder

Myocardial Ischemia or Infarction

The most common serious cause of acute chest discomfort is myocardial ischemia or myocardial infarction (MI) (**see Chapter 59**), which occurs when the supply of myocardial oxygen is inadequate for

the demand. Myocardial ischemia usually occurs in the setting of coronary atherosclerosis, but it may also reflect dynamic components of coronary vascular resistance. Coronary spasm can occur in normal coronary arteries or, in patients with CAD, near atherosclerotic plaque and in smaller coronary arteries (**see Chapter 57**). Other, less common causes of impaired coronary blood flow include syndromes that compromise the orifices or lumina of the coronary arteries, such as coronary arteritis, proximal aortitis, spontaneous coronary artery dissection, proximal aortic dissection, coronary emboli from infectious or noninfectious endocarditis or thrombus in the left atrium or left ventricle, myocardial bridge, or a congenital abnormality of the coronary arteries (**see Chapter 20**).

The classic manifestation of ischemia is *angina,* which is usually described as a heavy chest pressure or squeezing, a burning feeling, or difficulty breathing (**see Chapter 10**). The discomfort often radiates to the left shoulder, neck, or arm. It typically builds in intensity over a few minutes. The pain may begin with exercise or psychological stress, but ACS most frequently occurs without obvious precipitating factors.

Atypical descriptions of chest pain reduce the likelihood that the symptoms represent myocardial ischemia or injury. The American College of Cardiology (ACC) and American Heart Association (AHA) guidelines list the following as pain descriptions *uncharacteristic* of myocardial ischemia[5]:

- Pleuritic pain (i.e., sharp or knifelike pain brought on by respiratory movements or coughing)
- Primary or sole location of the discomfort in the middle or lower abdominal region
- Pain that may be localized by the tip of one finger, particularly over the left ventricular apex
- Pain reproduced with movement or palpation of the chest wall or arms
- Constant pain that persists for many hours
- Very brief episodes of pain that last a few seconds or less
- Pain that radiates into the lower extremities

Nevertheless, data from large populations of patients with acute chest pain indicate that ACS occurs in those with atypical symptoms at sufficient frequency that no single factor suffices to exclude the diagnosis of acute ischemic heart disease. Clinicians should be mindful of “angina equivalents” such as jaw or shoulder pain in the absence of chest pain; nausea or vomiting; and diaphoresis. In particular, women, older persons, and individuals with diabetes may be more likely to report atypical symptoms of myocardial ischemia or MI (**see Chapter 89**). Data from the National Registry of Myocardial Infarction demonstrate that among patients hospitalized with MI, women—particularly young women—are significantly less likely than men to manifest chest pain. Not surprisingly, patients without chest pain had higher in-hospital mortality.[7]

Pericardial Disease

The visceral surface of the pericardium is insensitive to pain, as is most of the parietal surface. Therefore, noninfectious causes of pericarditis (e.g., uremia; **see Chapter 83**) usually cause little or no

pain. In contrast, infectious pericarditis almost always involves the surrounding pleura, so patients typically experience pleuritic pain with breathing, coughing, and changes in position. Swallowing may induce the pain because of the proximity of the esophagus to the posterior portion of the heart. Because the central diaphragm receives its sensory supply from the phrenic nerve and the phrenic nerve arises from the third to fifth cervical segments of the spinal cord, pain from infectious pericarditis is frequently felt in the shoulders and neck. Involvement of the diaphragm more laterally can lead to symptoms in the upper part of the abdomen and back, and thus create confusion with pancreatitis or cholecystitis. Pericarditis occasionally causes a steady, crushing substernal pain resembling that of AMI.[8]

Vascular Disease

Acute aortic dissection usually causes a sudden onset of excruciating ripping pain, the location of which reflects the site and progression of the dissection (**see Chapter 63**). *Ascending* aortic dissection tends to manifest as pain in the midline of the anterior aspect of the chest, and *posterior descending* aortic dissection tends to cause pain in the back of the chest. Aortic dissections are rare, with an estimated annual incidence of 3 per 100,000, and usually occur in the presence of risk factors, including Marfan and Ehlers-Danlos syndromes, bicuspid aortic valve, pregnancy (for proximal dissections), and hypertension (for distal dissections).

Pulmonary emboli often cause a sudden onset of dyspnea and pleuritic chest pain, although they may be asymptomatic (**see Chapter 84**). The annual incidence is at least 1 per 1000. Massive pulmonary emboli tend to cause severe and persistent substernal pain, which is attributed to distention of the pulmonary artery. Smaller emboli that lead to pulmonary infarction can cause lateral pleuritic chest pain. Hemodynamically significant pulmonary emboli may cause hypotension, syncope, and signs of right-sided heart failure. Pulmonary hypertension can result in chest pain similar to that of angina pectoris, presumably because of right heart hypertrophy and ischemia (**see Chapter 85**).

Pulmonary Conditions

Pulmonary conditions that cause chest pain generally produce dyspnea and pleuritic symptoms, the location of which reflects the site of pulmonary disease. Tracheobronchitis tends to be associated with a burning midline pain, whereas pneumonia can produce pain over the involved lung. The pain of pneumothorax begins suddenly and is usually associated with dyspnea. Primary pneumothorax typically occurs in tall, thin young men; secondary pneumothorax occurs in the setting of pulmonary disease such as chronic obstructive pulmonary disease (COPD), asthma, or cystic fibrosis. A tension pneumothorax can be life-threatening. Asthma exacerbations can cause chest discomfort, typically characterized as tightness.

Gastrointestinal Conditions

Irritation of the esophagus by acid reflux can produce a burning discomfort that may be exacerbated by alcohol, aspirin, and some foods. Assuming a recumbent position often worsens symptoms, and sitting upright and acid-reducing therapies alleviate them. Esophageal spasm can produce a squeezing chest discomfort similar to that of angina. Mallory-Weiss tears of the esophagus can occur in patients who have had prolonged vomiting episodes. Severe vomiting can also result in esophageal rupture (Boerhaave syndrome) with mediastinitis. Chest pain caused by peptic ulcer disease usually occurs 60 to 90 minutes after meals and typically responds rapidly to acid-reducing therapies. This pain generally localizes in the

epigastrium but can radiate to the chest and shoulders. Cholecystitis produces a wide range of pain syndromes and generally causes right upper quadrant abdominal pain, but chest and back pain caused by this disorder is not unusual. The pain is frequently described as being aching or colicky. Pancreatitis typically causes an intense, aching epigastric pain that may radiate to the back. Relief through acid-reducing therapies is limited.

Musculoskeletal and Other Causes

Chest pain can arise from musculoskeletal disorders involving the chest wall (e.g., costochondritis), by conditions affecting the nerves of the chest wall (e.g., cervical disc disease), by herpes zoster, or following heavy exercise. Chest pain due to musculoskeletal causes is often elicited by direct pressure over the affected area or by movement of the patient's neck. The pain itself can be fleeting, or it can be a dull ache that lasts for hours. Panic syndrome is a major cause of chest discomfort in ED patients. The symptoms typically include chest tightness, often accompanied by shortness of breath and a sense of anxiety, and generally last 30 minutes or longer.

Diagnostic Considerations

See also Chapters 10, 59, and 60 and Fig. 60G.1

Clinical Evaluation

When evaluating patients with acute chest pain, clinicians must address a series of issues related to prognosis and immediate management.[9] Even before trying to arrive at a definite diagnosis, high-priority questions include the following:

- *Clinical stability:* Does the patient need immediate treatment for actual or impending circulatory collapse or respiratory insufficiency?
- *Immediate prognosis:* If the patient is currently clinically stable, what is the risk of a life-threatening condition such as ACS, PE, or aortic dissection?
- *Safety of triage options:* If the risk for a life-threatening condition is low, is it safe to discharge the patient for outpatient management, or should further testing or observation to guide management be undertaken?

Initial Assessment

Evaluation of a patient with acute chest pain can begin before the physician sees the patient, and thus effectiveness may depend on the actions of the office staff and other nonphysician personnel. Guidelines from the ACC and AHA[5] (**see Chapters 59 and 60**, Guidelines sections) emphasize that patients with

symptoms consistent with ACS should not be evaluated solely over the telephone but should be referred to facilities that allow evaluation by a physician and recording of a 12-lead electrocardiogram (ECG).[5,10,11] These guidelines also recommend strong consideration of immediate referral to an ED or a specialized chest pain unit for patients with suspected ACS who experience chest discomfort at rest for longer than 20 minutes, hemodynamic instability, or recent syncope or near-syncope. Transport as a passenger in a private vehicle is considered an acceptable alternative to an emergency vehicle only if the wait would lead to a delay longer than 20 to 30 minutes.

Guidelines[5,10] recommend that patients with the following chief complaints undergo immediate assessment by triage nurses and be referred for further evaluation:

- Chest pain, pressure, tightness, or heaviness; pain that radiates to the neck, jaw, shoulders, back, or one or both arms
- Indigestion or heartburn; nausea and/or vomiting associated with chest discomfort
- Persistent shortness of breath
- Weakness, dizziness, lightheadedness, loss of consciousness

For such patients, initial assessment involves taking a history, performing a physical examination, obtaining an ECG and chest radiograph, and measuring biomarkers of myocardial injury.

History

If the patient does not need immediate intervention because of impending or actual circulatory collapse or respiratory insufficiency, the physician's assessment should begin with a clinical history that captures the characteristics of the patient's pain, including its quality, location, and radiation; the time and tempo (abrupt or gradual) of onset; the duration of symptoms; provoking or palliating activities; and any associated symptoms, particularly those that are pulmonary or gastrointestinal. Patients typically describe ACS discomfort as a diffuse substernal chest pressure that starts gradually, radiates to the jaw or arms, worsens with exertion, and is relieved by rest or nitroglycerin. Because angina tends to be manifested in the same way in a given patient (at least if it is caused by ischemia in the same territory), it is useful to compare the current episode with any previous documented episodes of angina. The response to nitroglycerin may not reliably discriminate cardiac chest pain from non–cardiac-related chest pain.[5] In contrast to the tempo of the chest discomfort in ACS, that of PE, aortic dissection, and pneumothorax is usually sudden and severe in onset. Moreover, pain that is pleuritic or positional in nature suggests PE, pericarditis, pneumonia, or a musculoskeletal condition. A review of the literature yielded eight factors from the chest pain history with a likelihood ratio for ACS significantly greater than 1 and six factors with a likelihood ratio significantly lower than 1 (**Table 56.2**).[5,6]

TABLE 56.2

Value of Elements of the Chest Pain History for the Diagnosis of Acute Coronary Syndrome

PAIN DESCRIPTOR	POSITIVE LIKELIHOOD RATIO (95% CI)
Increased Likelihood of AMI	
Radiation to the right arm or shoulder	4.7 (1.9-12.0)
Radiation to both arms or shoulders	4.1 (2.5-6.5)
Associated with exertion	2.4 (1.5-3.8)
Radiation to the left arm	2.3 (1.7-3.1)
Associated with diaphoresis	2.0 (1.9-2.2)
Associated with nausea or vomiting	1.9 (1.7-2.3)
Worse than previous angina or similar to previous MI	1.8 (1.6-2.0)
Described as pressure	1.3 (1.2-1.5)
Decreased Likelihood of AMI	
Described as pleuritic	0.2 (0.1-0.3)
Described as positional	0.3 (0.2-0.5)
Described as sharp	0.3 (0.2-0.5)
Reproducible with palpation	0.3 (0.2-0.4)
Inframammary location	0.8 (0.7-0.9)
Not associated with exertion	0.8 (0.6-0.9)

AMI, Acute myocardial infarction; *CI,* confidence interval.

Modified from Swap CJ, Nagurney JT. Value and limitations of chest pain history in the evaluation of patients with suspected acute coronary syndromes. JAMA 2005;294:2623.

In addition to the characteristics of the acute episode, the presence of risk factors for atherosclerosis (e.g., advanced age, male sex, diabetes) increases the likelihood that the chest pain results from myocardial ischemia. A history of MI is associated not only with a high risk for obstructive CAD, but also with an increased likelihood of multivessel disease. Younger patients have a lower risk for ACS but should be screened with greater care for a history of recent cocaine use[5,6] (**see Chapter 80**). Although a thorough history is critical, clinician assessment alone does not suffice to rule in or rule out ACS. Combining clinician assessment with physical exam and, more importantly, ECG and biomarkers greatly improves diagnostic assessment.[12]

Physical Examination

The initial examination of patients with acute chest pain should endeavor to identify potential precipitating causes of myocardial ischemia (e.g., uncontrolled hypertension), important comorbid conditions (e.g., COPD), and evidence of hemodynamic complications (e.g., congestive heart failure, new mitral regurgitation, hypotension).[5,6,12] In addition to vital signs, examination of peripheral vessels should include assessment for the presence of bruits or absent pulses, which suggest extracardiac vascular disease (**see Chapter 64**).

For patients whose clinical findings do not suggest myocardial ischemia, the search for noncoronary causes of chest pain should focus first on potentially life-threatening issues (e.g., aortic dissection, PE) and then turn to the possibility of other cardiac diagnoses (e.g., pericarditis) and noncardiac diagnoses (e.g., esophageal discomfort). Aortic dissection may produce blood pressure or pulse disparities or a new murmur of aortic regurgitation accompanied by back or midline anterior chest pain. A friction rub may accompany pericarditis. Differences in breath sounds in the presence of acute dyspnea and pleuritic chest pain suggest pneumothorax. Tachycardia, tachypnea, and an accentuated pulmonic component of the second heart sound (P_2) may be the major manifestations of PE on physical examination.

Electrocardiography

An ECG, a source of decisive data, should be obtained within 10 minutes after arrival for individuals with ongoing chest discomfort and as rapidly as possible in those who have a history of chest discomfort consistent with ACS, but whose discomfort has resolved by the time of evaluation, to identify patients who might benefit from immediate reperfusion therapy (mechanical or pharmacologic)[5,10] (**see Chapter 12**). Obtaining a prehospital ECG decreases the door-to-diagnosis time and, for ST-segment elevation MI (STEMI), the door-to-balloon time. The pre-hospital ECG reduces both scene and transport times for patients with STEMI.[11,13]

The ECG helps to define both diagnosis and prognosis. New persistent or transient ST-segment abnormalities (≥0.05 mV) that develop during a symptomatic episode at rest and resolve when the symptoms resolve strongly suggest acute ischemia and severe CAD. Nonspecific, ST-segment changes or T wave abnormalities of 0.2 mV or less are not as helpful for risk stratification. The likelihood ratios for ACS with various findings on the ECG are shown in **Table 56.3**.[5] A completely normal ECG does not exclude ACS: the risk for AMI is approximately 4% in patients with a history of CAD and 2% in those with no such history.[5,13,14] Patients with normal or near-normal findings on an ECG, however, have a better prognosis than those with abnormal ECG at initial evaluation. Moreover, a normal ECG has a negative predictive value of 80% to 90%, regardless of whether the patient was experiencing chest pain at the time that the ECG was obtained.[5,10,14] Diffuse ST-segment elevation and PR-segment depression suggest pericarditis. Tachycardia with right axis deviation, right bundle branch block, T wave inversions in leads V_1 to V_4, and an S wave in lead I and Q wave and T wave inversions in lead III suggest PE.

TABLE 56.3

Value of Electrocardiographic (ECG) Findings for Diagnosis of Acute Coronary Syndrome (ACS)

ECG FINDING	POSITIVE LIKELIHOOD RATIO (95% CI WHERE AVAILABLE)
New ST-segment elevation ≥1 mm	5.7-53.9
New Q wave	5.3-24.8
Any ST-segment elevation	11.2 (7.1-17.8)
New conduction defect	6.3 (2.5-15.7)
New ST-segment depression	3.0-5.2
Any Q wave	3.9 (2.7-5.7)
Any ST-segment depression	3.2 (2.5-4.1)
T wave peaking and/or inversion ≥1 mm	3.1
New T wave inversion	2.4-2.8
Any conduction defect	2.7 (1.4-5.4)

CI, Confidence interval.

Modified from Panju AA, Hemmelgarn BR, Guyatt GH, Simel DL: Is this patient having a myocardial infarction? JAMA 280:1256, 1998.

The availability of a previous ECG improves diagnostic accuracy and reduces admission rates for patients with abnormal baseline tracings. Serial electrocardiographic tracings improve the clinician's ability to diagnose AMI, especially in the patient remains symptomatic and particularly if combined with serial measurement of cardiac biomarkers. Continuous electrocardiographic monitoring to detect ST-segment shifts makes an uncertain contribution to patient management. Posterior leads can help identify ischemia in the territory supplied by the circumflex coronary artery, an otherwise relatively silent zone on ECGs.

Chest Radiography

All patients with chest pain typically have a chest radiograph. It is usually nondiagnostic in patients with ACS but can show pulmonary edema secondary to ischemia-induced diastolic or systolic dysfunction. It is

more useful for diagnosing or suggesting other disorders; for example, it may show a widened mediastinum or aortic knob in patients with aortic dissection. The chest radiograph generally has normal findings in PE but can show atelectasis, an elevated hemidiaphragm, a pleural effusion, or more rarely a Hampton hump or Westermark sign. The chest radiograph can reveal pneumonia or pneumothorax.

Biomarkers

Patients with chest discomfort possibly consistent with ACS should undergo measurement of biomarkers of myocardial injury (**see Chapters 57 to 59**). The preferred biomarker is cardiac troponin T (cTnT) or I (cTnI); creatine kinase MB isoenzyme (CK-MB) is less sensitive.[5,15]

Diagnostic Performance

Studies of the diagnostic performance of cTnI, cTnT, and CK-MB indicate that when any of these test findings is abnormal, the patient is highly likely to have ACS. These assays aid indispensably the diagnosis of MI and have excellent sensitivity and specificity when viewed as part of all the clinical evidence.

Troponins.

Different genes encode troponins in cardiac muscle, slow skeletal muscle, and fast skeletal muscle; therefore, assays for cardiac troponins are more specific for myocardial injury than assays for CK-MB, and cardiac troponin is the preferred diagnostic biomarker.[15] The high specificity of cardiac troponins for myocardium makes false-positive elevations (i.e., elevation in the absence of myocardial injury) exceedingly rare. Rather, elevations in the absence of other clinical data consistent with ACS usually represent true myocardial damage from causes other than coronary artery thrombosis. Type 2 MIs occur in the setting of stable CAD, from either reduced myocardial oxygen supply (e.g., hypotension, vasospasm, severe anemia) or increased myocardial oxygen demand (e.g., hypertensive crisis, tachycardia, critical aortic stenosis, severe hypertrophic cardiomyopathy, extreme exercise). Myocardial damage may occur with direct forms of myocardial injury, such as in the setting of myocarditis, myocardial contusion, or cardioversion or defibrillation. Conditions that affect the pulmonary circulation, such as in PE or other causes of acute pulmonary hypertension, can also lead to biochemically detectable right ventricular injury. Patients with renal disease may have elevated levels of cardiac troponins.[15] The exact mechanism remains unclear, but in patients with a clinical history suggestive of ACS, an elevated cardiac troponin level conveys a similarly increased risk for ischemic complications in patients across a broad range of renal function.[15] Elevated cTn levels can also occur in patients with severe sepsis. Sex-specific cut points for troponin assays do not appear to offer any practical advantage.[16]

The greater sensitivity of contemporary sensitive cTn assays has allowed the traditional serial biomarker sampling over 24 hours to be shortened considerably. Current U.S. guidelines recommend measurement at presentation and then 3 to 6 hours after symptom onset (with additional measurements if there are electrocardiographic changes or other high-risk features).[5] Such a strategy yields a negative predictive value (NPV) approaching 99%.[17-19]

More recently, high-sensitivity troponin (hsTn) assays now enable even lower limits of detection (e.g., <0.001 ng/mL or <1 pg/mL) and allow at least 50% (some ≥95%) of healthy individuals below the 99th percentile to have a measurable level of troponin.[15,20] These assays can shorten the time interval to the next measurement to 1 to 2 hours and still achieve NPVs ≥99.5%.[21,22] Moreover, such assays may also permit the safe discharge of patients based on a single troponin value at presentation. Using a cutoff well

below the 99th percentile and often the limit of detection, approximately 20% to 25% of patients will have such a low or undetectable level with a corresponding >99% NPV.[23-26] The generalizability of these findings may also depend on the timing and nature of the presenting syndrome, with patients with a very short time from symptom onset to presentation needing serial sampling.[27] Serial sampling with hsTn assays also offers the ability to examine the change in troponin concentration between the two time points, with relative and particularly absolute increases above certain thresholds offering the potential for greater specificity for MI.[2,28-30]

Overall studies evaluating hsTn support the concept of accelerated diagnostic protocols that demonstrate a high NPV of very low concentrations in patients presenting with suspected ACS. However, time from symptom onset and the risk of the population require consideration. In addition, in centers without availability of high-sensitivity assays, serial testing at presentation and after 3 to 6 hours remains the standard of care.[20]

Creatine Kinase MB Isoenzyme.

CK-MB has less specificity than cardiac troponins because of its production by skeletal muscle, tongue, diaphragm, small intestine, uterus, and prostate. Use of the CK-MB relative index (ratio of CK-MB to total CK) partially addresses this limitation for skeletal muscle as a source. The amount of CK-MB in skeletal muscle, however, increases in patients with conditions that cause chronic muscle destruction and regeneration (e.g., muscular dystrophy), those who participate in high-performance athletics (e.g., marathon running), and those with rhabdomyolysis.[31] CK-MB elevations are particularly common in ED patients because they have higher rates of alcohol abuse or trauma history. One advantage of CK-MB is a shorter half-life in the circulation, which makes it useful for gauging the timing of an MI (a normal CK-MB with an elevated troponin level could represent a small MI or an MI that occurred several days ago) and for diagnosing reinfarction in a patient who had an MI in the past week. However, hsTn assays offer similar value.

Other Markers.

(see also **eTable 60.1**). Copeptin is secreted from the pituitary gland early in the course of MI. It has been investigated in combination with troponin in patients presenting with suspected ACS. In the CHOPIN study, both a negative copeptin and a sensitive troponin assay in patients presenting within 6 hours of symptom onset had NPV of 99.2%.[32] However, a study that evaluated the incremental diagnostic contribution of a 1-hour copeptin test when added to hsTn showed no benefit in NPV for MI.[33-35] Myoglobin, heart-type fatty acid–binding protein, and ischemia-modified albumin (IMA) have been studied as diagnostic biomarkers, but none is specific to myocardial tissue. The advent of sensitive and now high-sensitivity troponin assays leaves little room for added value for these assays.[36]

Many patients with ACS, including those without evidence of myocyte necrosis, have elevated concentrations of inflammatory biomarkers such as C-reactive protein, serum amyloid A, myeloperoxidase, or interleukin-6.[37-39] To date, no study has identified exact decision cut points or shown an incremental benefit with an admission or treatment strategy based on these new markers, thus limiting the clinical usefulness of these observations.

D-dimer testing is useful for patients with chest pain to help rule out PE, because a negative enzyme-linked immunosorbent assay (ELISA) has NPV >99% in patients with a low clinical probability (patients with a higher clinical probability should undergo an imaging study).[40] Similarly, a negative D-dimer has NPV of 96% for aortic dissection.[41]

B-type natriuretic peptides (BNP and N-terminal pro-BNP) reflects increased ventricular wall stress. Natriuretic peptides often aid in the diagnosis of heart failure. BNP levels can rise in the setting of transient myocardial ischemia,[42] and the magnitude of elevation in patients with ACS is related to prognosis.[43] Although not specific for ACS, adding natriuretic peptide measurements to the diagnostic algorithm does improve discrimination and results in improved reclassification.[44] Circulating microRNAs have been evaluated in small studies but have not yet been shown to provide incremental diagnostic or prognostic value in patients presenting with suspected AMI.[45]

Testing Strategy

Current practice guidelines recommend measurement of biomarkers of cardiac injury in patients with symptoms that suggest ACS.[5,29] Furthermore, patients with a very low probability of ACS should not undergo measurement of biomarkers because false-positive results could lead to unnecessary hospitalizations, tests, procedures, and complications. The ACC/AHA and European Society of Cardiology (ESC) guidelines recommend cTnI or cTnT as the preferred first-line marker, although CK-MB (by mass assay) is an acceptable alternative. The preference for cardiac troponins reflects the greater specificity of these markers than CK-MB and the prognostic value of troponin elevations in the presence of normal CK-MB levels. If the initial set of markers is negative, another sample should be drawn 3 to 6 hours later; if a high-sensitivity assay is used, a 1-hour algorithm can be considered.[3,5]

Decision Aids

Fig. 56.1 presents an algorithm for the diagnostic evaluation of chest pain. Integration of the history, physical examination, ECG, and biomarkers of myocardial injury allow the clinician to assess the likelihood of ACS and the risk for complications (**Tables 56.4 and 56.5**). Furthermore, prospectively validated multivariable algorithms improve risk stratification in patients with acute chest pain. These algorithms can estimate the probability of AMI, acute ischemic heart disease, or the risk for major cardiac complications in individual patients. They serve mainly to identify patients who are at low risk for complications and who therefore do not require admission to the hospital or coronary care unit.[46] Decision aids also exist for acute PE (**Chapter 84**) and aortic dissection (**Chapter 63**).

ACC/AHA 2007 guidelines for the management of patients with unstable angina/non ST-elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines for the Management of Patients With Unstable Angina/Non ST-Elevation Myocardial Infarction): Developed in collaboration with the American College of Emergency Physicians, the Society for Cardiovascular Angiography and Interventions, and the Society of Thoracic Surgeons: Endorsed by the American Association of Cardiovascular and Pulmonary Rehabilitation and the Society for Academic Emergency Medicine. Circulation 2007;116:e148.

The Thrombolysis in Myocardial Ischemia (TIMI) risk score was derived and validated in patients enrolled in clinical trials with ACS.[5] A care pathway (ADAPT) that allows for the safe disposition of patients integrates this score. A prospective observational study of 2000 patients with suspected ACS evaluated an accelerated protocol including the TIMI risk score and 0- and 2-hour troponin measurements. The NPV for adverse cardiovascular events at 20 days was 99.7%.[47] Using this protocol, the proportion of patients safely discharged within 6 hours increased from 11% to 19%.[48] Limitations of these analyses include their performance at a single center and that they included close follow-up with stress testing within 72 hours for patients discharged early.[19]

The HEART score uses similar components as the TIMI risk score. When combined with serial troponin measurements, it demonstrated the potential to reduce cardiac testing by 82%.[49] A subsequent evaluation of the HEART score and serial hsTn measurements at 0 and 3 hours in patients presenting with suspected ACS (HEART pathway) decreased testing at 30 days by 12.1%, decreased length of stay by 12 hours, and increased early discharge by 21%. At 30 days, no patients identified for early discharge had cardiac events.[50]

Immediate Management

The ACC and AHA guidelines suggest an approach to the immediate management of patients with possible ACS that integrates information from the history, physical examination, 12-lead ECG, and initial cardiac marker tests to assign patients to four categories: non–cardiac-related diagnosis, chronic stable angina, possible ACS, and definite ACS[5] (**Fig. 56.2**). This algorithm triages patients with ST-segment elevations to immediate reperfusion therapy, in accordance with the ACC and AHA guidelines for acute MI. Patients with ACS who have ST-segment or T wave changes, ongoing pain, positive cardiac markers, or hemodynamic abnormalities require hospital admission for the management of acute ischemia. Patients with possible or definite ACS who do not have diagnostic ECGs and with normal initial serum cardiac markers can be observed in a chest pain unit or other non–intensive care facility, with subsequent additional testing (see later).

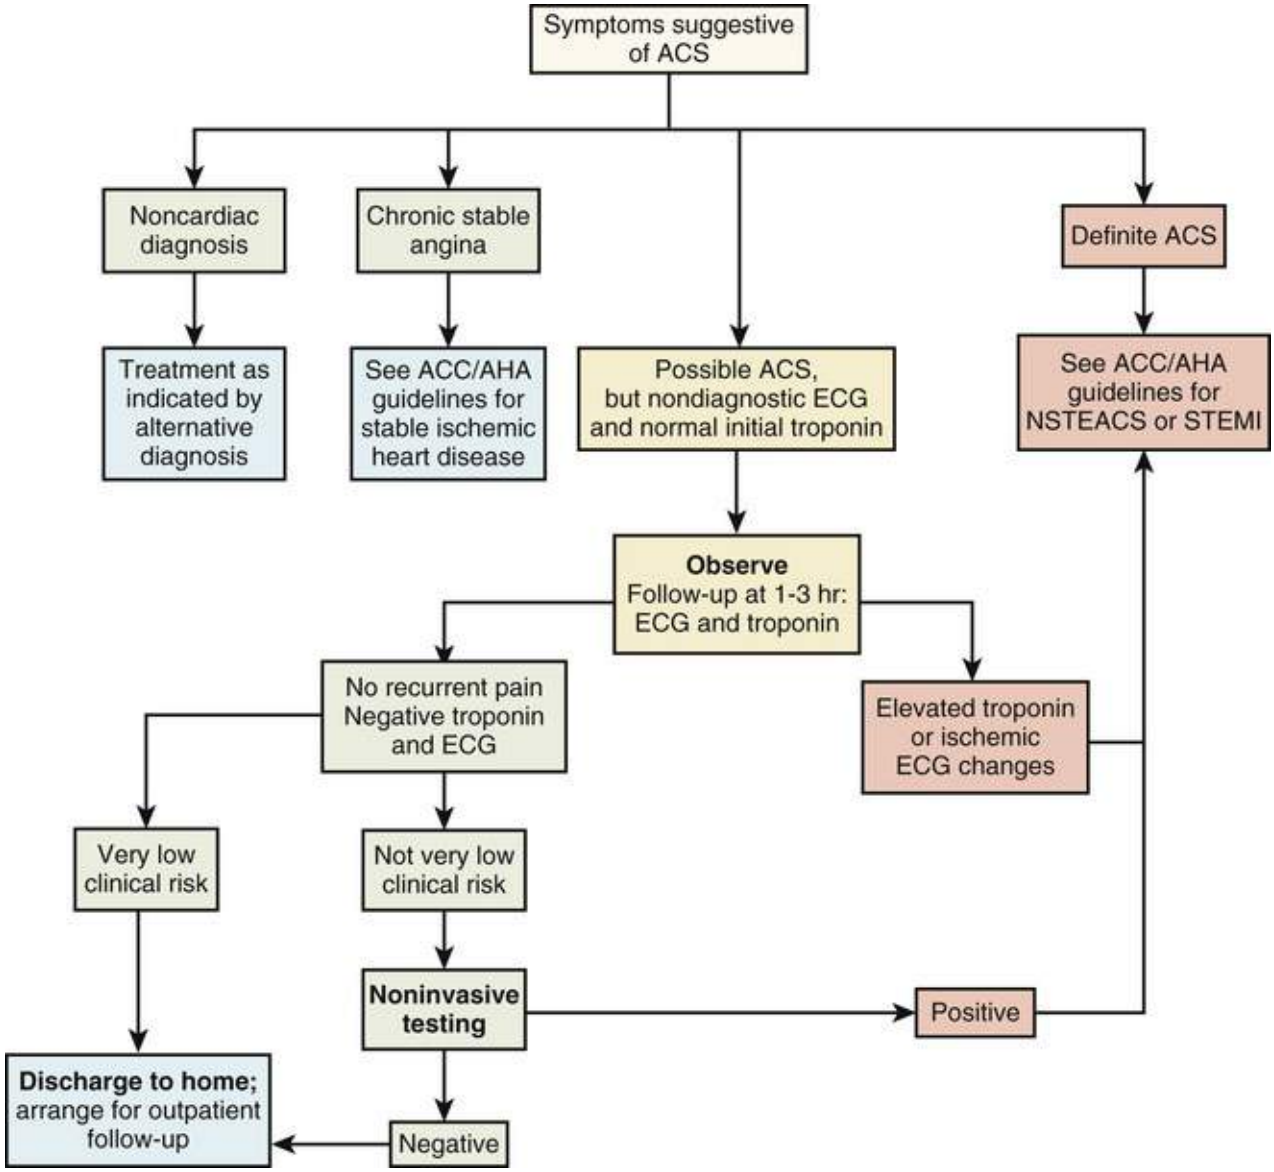

FIGURE 56.2 Algorithm for the evaluation and management of patients suspected of having acute coronary syndrome (ACS). The necessary duration of the observation period (1-3 hours) will depend on the sensitivity of the troponin assay. Key decisions in **bold.** ACC/AHA, American College of Cardiology/American Heart Association; ECG, electrocardiogram; STEMI, ST-segment elevation myocardial infarction; NSTEACS, non–ST-segment elevation acute coronary syndrome. (Adapted from Braunwald E, Antman EM, Beasley JW, et al. ACC/AHA guidelines for the management of patients with unstable angina and non-ST-segment–elevation myocardial infarction: executive summary and recommendations: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on the Management of Patients With Unstable Angina) [published correction appears in Circulation. 2000;102:1739]. Circulation. 2000;102:1193–1209.)

Chest Pain Protocols and Units

A typical chest pain critical pathway includes several main elements (**Fig. 56.2**). According to the ACC and AHA recommendations,[5] patients with a low risk for ACS or associated complications can be observed for several hours while undergoing electrocardiographic monitoring and serial measurement of cardiac markers. Patients in whom evidence of ischemia or other indicators of increased risk develop should be admitted to a cardiology service (step-down or coronary care unit) for further management. Patients in whom recurrent pain or other predictors of increased risk do not develop can either be discharged home if they are very low risk or be scheduled for early noninvasive testing (see later) before or after discharge. Specifically, as previously noted, patients with normal troponin levels, no ECG abnormalities concerning for ischemia, and a TIMI risk score of 0 or a HEART score of ≤3 have extremely low risk of adverse cardiovascular events and can be considered for discharge to home. Patients without biochemical or ECG evidence of ischemia and very low risk can undergo noninvasive testing. Outpatient stress testing is a reasonable option if the patient is at low risk for ACS and if the testing can be accomplished within 72 hours; such a strategy can be safe. Such patients can receive aspirin and possibly beta-adrenergic blocking agents (beta blockers) and sublingual nitroglycerin.

To enhance the efficiency and reliability of implementation of such chest pain protocols, many hospitals triage low-risk patients with chest pain to special chest pain units.[3] These units often localize adjacent to or within EDs. The rate of MI approximates 1% to 2% in most such units, and they have proved safe and cost-saving for care of low-risk patients. Chest pain units are also sometimes used for intermediate-risk patients, such as those with a previous history of CAD but no other high-risk predictors. In one community-based randomized trial, patients with unstable angina and an overall intermediate risk for complications had similar outcomes and lower cost if they received care in a chest pain unit versus conventional hospital management.

Early Noninvasive Testing

Treadmill Electrocardiography

Treadmill exercise electrocardiography is inexpensive and available at many hospitals every day, beyond traditional laboratory hours, and prospective data indicate that early exercise test results provide reliable prognostic information for low-risk patient populations (**see Chapter 13**). Most studies have used the Bruce or modified Bruce treadmill protocol. Multiple studies have demonstrated the safety of exercise testing in low-risk patients, and a negative predictive value of typically greater than 99%, although the positive predictive value is frequently less than 50% (depending on the prevalence of ACS in the tested population).[3]

Patients with low clinical risk for complications can safely undergo exercise testing after their second negative troponin test (typically 3 to 6 hours later) and no other evidence of myocardial ischemia.[3] In general, protocols for early or immediate exercise testing exclude patients with electrocardiographic findings consistent with ischemia not recorded on previous tracings, ongoing chest pain, or evidence of congestive heart failure. Analyses of pooled data have suggested that the prevalence of CAD in populations undergoing early exercise testing averages approximately 5% to 10%, the rate of adverse events is negligible, and fewer than 1% ultimately proceed to angiography and revascularization.[51] The AHA has issued a scientific statement regarding the indications for and contraindications to exercise on electrocardiographic stress testing in the ED (**Table 56.6**).[3] For low-risk patients with no evidence of myocardial ischemia after serial ECGs and biomarkers, outpatient stress testing ideally within 24 hours,

and no later than 72 hours, has proved safe.[3]

TABLE 56.6

Indications and Contraindications for Exercise Electrocardiographic Testing in the Emergency Department (ED)

Requirements before exercise electrocardiographic testing that should be considered in the ED setting:
• Two sets of cardiac enzymes at 4-hour intervals should be normal.
• ECG at arrival and preexercise 12-lead ECG show no significant abnormality.
• Absence of rest electrocardiographic abnormalities that would preclude accurate assessment of the exercise ECG.
• From admission to availability of results from the second set of cardiac enzymes: patient asymptomatic, lessening chest pain symptoms, or persistent atypical symptoms.
• Absence of ischemic chest pain at exercise testing.
Contraindications to exercise electrocardiographic testing in the ED setting:
• New or evolving electrocardiographic abnormalities on the rest tracing.
• Abnormal cardiac biomarker levels.
• Inability to perform exercise.
• Worsening or persistent ischemic chest pain symptoms from admission to exercise testing.
• Clinical risk profiling indicating that imminent coronary angiography is likely.

Imaging Tests

Stress echocardiography and radionuclide scans are the preferred noninvasive testing modalities for patients who cannot undergo treadmill electrocardiographic testing because of physical disability or who have resting ECGs that confound interpretation. Imaging studies are less readily available and more expensive than exercise electrocardiography but have increased sensitivity for the detection of CAD and the ability to quantify the extent of and localize jeopardized myocardium. High-risk rest perfusion scans indicate an increased risk for major cardiac complications, whereas patients with low-risk scans have low 30-day cardiac event rates (<2%).[52-54]

In addition to stress imaging studies to detect provocable ischemia, rest radionuclide scans can also help determine whether a patient's symptoms represent myocardial ischemia.[53] In a multicenter prospective randomized trial of 2475 adult ED patients with ongoing or recently resolved (<3 hours) chest pain or other symptoms suggestive of acute cardiac ischemia and with normal or nondiagnostic initial electrocardiographic results, patients underwent random assignment to a usual evaluation strategy or the usual strategy supplemented with results from acute resting myocardial perfusion imaging. The availability of scan results did not influence the management of patients with acute MI or unstable angina, but it reduced rates of hospitalization for patients without acute cardiac ischemia from 52% to 42%. Rest myocardial perfusion imaging is most sensitive if performed when a patient is experiencing ischemic symptoms, with its sensitivity progressively diminishing thereafter. Imaging should be performed within 2 hours of the resolution of symptoms, although data support its use for up to 4 hours.[53] It should be noted that perfusion defects seen at rest could represent either acute ischemia or previous MI, which can be differentiated on subsequent pain-free rest imaging.

Echocardiography, with and without stress, can detect wall motion abnormalities consistent with myocardial ischemia or MI. The presence of induced or baseline regional wall motion abnormalities is associated with a worse prognosis. The sensitivity of stress echocardiography appears comparable to that of myocardial perfusion imaging (85% to 90%), and its specificity is somewhat better (80% to 95% versus 75% to 90%).[53] As for myocardial perfusion imaging, the results are less interpretable in patients with previous MI, in whom it is difficult to exclude whether the abnormalities are preexisting in the absence of a prior study. Myocardial contrast-enhanced echocardiography using microbubble imaging agents offers reasonable (77%) concordance with radionuclide scanning, and the combination of regional wall motion abnormalities and reduced myocardial perfusion has a sensitivity of 80% to 90% and a

specificity of 60% to 90% for ACS.[53]

Cardiac magnetic resonance imaging (MRI) may also aid the assessment of patients with suspected ACS.[55-57] A study that used cardiac MRI to quantify myocardial perfusion, ventricular function, and hyperenhancement in patients with chest pain showed sensitivity for ACS of 84% and specificity of 85%. The addition of T2-weighted imaging, which can detect myocardial edema and thus help differentiate acute from chronic perfusion defects, improves the specificity to 96% without sacrificing sensitivity.[57] Integration of coronary magnetic resonance angiography is under study.[56] Stress MRI using adenosine, although more labor intensive, also shows excellent sensitivity and specificity.[55] A randomized study of 1202 patients with suspected ACS found that cardiac MRI resulted in a lower probability of unnecessary angiography within 12 months compared to guideline-directed care, with no difference in adverse cardiac outcomes.[58] Resource availability and time requirements may limit common utilization of cardiac MRI in this setting.

In contrast to the functional imaging data from stress testing, coronary computed tomographic angiography (CTA) offers noninvasive anatomic data.[59] Using multidetector CT, coronary CTA has sensitivity of approximately 90% and specificity of 65% to 90% for coronary stenosis greater than 50%. Coronary CTA has been evaluated in patients presenting with suspected ACS. In a randomized trial of 1370 patients presenting with suspected ACS with a TIMI risk score of 0 to 2 (low risk), those receiving coronary CTA had higher rates of ED discharge (49.6% versus 22.7%), shorter length of stay (18.0 hours versus 24.8 hours), and higher rates of CAD detection (9.0% versus 3.5%), with only one adverse event in each group.[60] In a second randomized study, 1000 patients with symptoms suggestive of ACS, a nonischemic ECG, and negative initial troponin were randomized to early coronary CTA or standard care. Overall, the rate of ACS was 8%, and early coronary CTA reduced the mean length of stay by 7.6 hours and resulted in more patients discharged directly from the ED (47% versus 12%). There were no undetected ACS events and no difference in adverse cardiovascular events at 28 days. The coronary CTA group had more downstream testing, higher radiation exposure, and similar cost to standard evaluation.[4] An observational cohort study evaluated the combination of hsTn at presentation and coronary CTA, looking at advanced features of CAD (≥50% stenosis, high-risk plaque features: positive remodeling, low <30-Hounsfield units plaque, napkin-ring sign, spotty calcium), relative to conventional troponin and coronary CTA, looking at traditional features of CAD (no CAD, nonobstructive CAD, ≥50% stenosis), and found greater diagnostic accuracy for ACS using hsTn and advanced CTA assessment.[61] In addition to diagnosis, coronary CTA can provide calcium scores, giving prognostic information and potentially informing the need for additional cardiac testing.[62] The most recent ACC/AHA guidelines acknowledge coronary CTA as a reasonable alternative to stress testing in patients with low to intermediate probability of CAD.[5]

Another advantage of CTA is that it is often the test of choice for PE and for aortic dissection (**see Chapters 63 and 83**), and thus "triple-rule-out CTA" can evaluate for CAD, PE, and aortic dissection.[63-65] Although this approach accurately detects CAD, the low prevalence of PE and aortic dissection and the increased radiation and contrast exposure relative to traditional coronary CTA suggest restricting triple-rule-out scans to patients with a reasonable suspicion for PE or aortic dissection.[66,67] Ultimately, the traditional trifecta of a clinician's careful assessment of the prior probability of a cardiovascular origin for the chest discomfort, the nature of the acute episode, and the physical examination should be coupled with ever more precise objective data, including serial ECGs, rapid biochemical testing, and imaging to help optimize patient triage.

Coronary Blood Flow and Myocardial Ischemia

Dirk J. Duncker, John M. Canty Jr

The coronary circulation is unique in that the heart is responsible for generating the arterial pressure that is required to perfuse the systemic circulation and yet, at the same time, has its own perfusion impeded during the systolic portion of the cardiac cycle. Because myocardial contraction is closely connected to coronary flow and oxygen delivery, the balance between oxygen supply and demand is a critical

determinant of the normal beat-to-beat function of the heart (see Classic References, Feigl). When this relation is acutely disrupted by diseases affecting coronary blood flow, the resulting imbalance can immediately precipitate a vicious cycle whereby ischemia-induced contractile dysfunction precipitates hypotension and further myocardial ischemia. Thus, knowledge of the regulation of coronary blood flow, determinants of myocardial oxygen consumption, and the relation between ischemia and contraction is essential for understanding the pathophysiologic basis and management of many cardiovascular disorders (see Classic References, Hoffman and Spaan).

Control of Coronary Blood Flow

There are pronounced systolic and diastolic coronary flow variations throughout the cardiac cycle, with coronary arterial inflow out of phase with venous outflow (**Fig. 57.1**). Systolic contraction increases tissue pressure, redistributes perfusion from the subendocardial to the subepicardial layers of the heart, and impedes coronary arterial inflow, which reaches a nadir. At the same time, systolic compression reduces the diameter of intramyocardial microcirculatory vessels (arterioles, capillaries, and venules) and increases coronary venous outflow, which peaks during systole. During diastole, coronary arterial inflow increases with a transmural gradient that favors perfusion to the subendocardial vessels. At this time, coronary venous outflow falls.

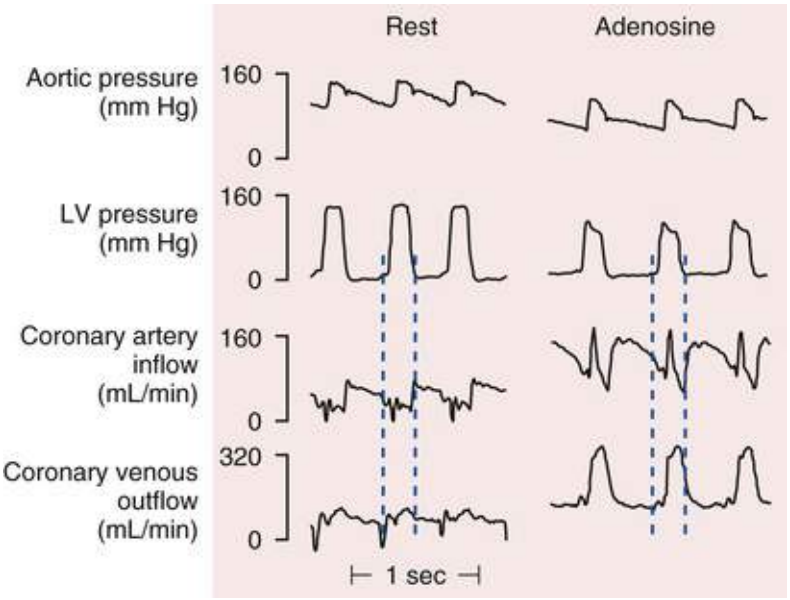

FIGURE 57.1 Phasic coronary arterial inflow and venous outflow at rest and during adenosine vasodilation. Arterial inflow primarily occurs during diastole. During systole (*dotted vertical lines*), arterial inflow declines as venous outflow peaks, reflecting the compression of microcirculatory vessels during systole. After adenosine administration, the phasic variations in venous outflow are more pronounced. LV, Left ventricular. (Modified from Canty JM Jr, Brooks A. Phasic volumetric coronary venous outflow patterns in conscious dogs. Am J Physiol 1990;258:H1457.)

Determinants of Myocardial Oxygen Consumption

In contrast to most other vascular beds, myocardial oxygen extraction is near-maximal at rest, averaging 70% to 80% of arterial oxygen content.[1,2] The ability to increase oxygen extraction as a means to increase oxygen delivery is limited to circumstances associated with sympathetic activation and acute

subendocardial ischemia. Nevertheless, coronary venous oxygen tension (Pv_{O_2}) can only decrease from 25 mm Hg to approximately 15 mm Hg. Because of the high resting oxygen extraction, increases in myocardial oxygen consumption are primarily met by proportional increases in coronary flow and oxygen delivery (**Fig. 57.2**). In addition to coronary flow, oxygen delivery is directly determined by arterial oxygen content (Ca_{O_2}). This is equal to the product of hemoglobin concentration and arterial oxygen saturation plus a small amount of oxygen dissolved in plasma that is directly related to arterial oxygen tension (Pa_{O_2}). Thus, for any given flow level, anemia results in proportional reductions in oxygen delivery, whereas hypoxia, due to the nonlinear oxygen dissociation curve, results in relatively small reductions in oxygen content until Pa_{O_2} falls to the steep portion of the oxygen dissociation curve (below 50 mm Hg).

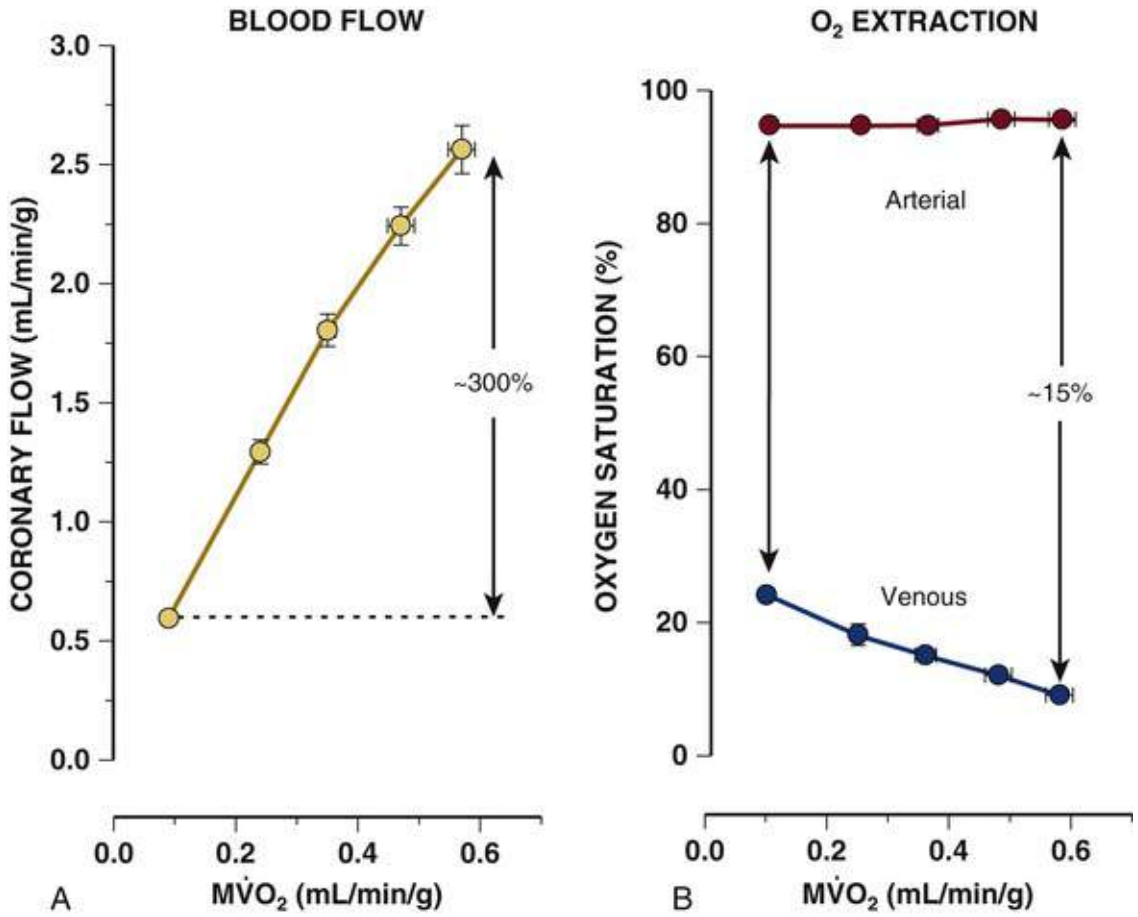

FIGURE 57.2 Tight matching of myocardial oxygen consumption (MVO_2) and coronary blood flow during exercise-induced increases in myocardial oxygen demand. **A,** Increases in MVO_2 are primarily met by increases in coronary flow. **B,** High basal levels of myocardial oxygen extraction allow only modest (approximately 15%) further increases in oxygen extraction during exercise.

The major determinants of myocardial oxygen consumption are heart rate, systolic pressure (or myocardial wall stress), and left ventricular (LV) contractility (**see Chapter 22**). A twofold increase in any of these individual determinants of oxygen consumption requires an approximately 50% increase in coronary flow. Experimentally, the systolic pressure volume area is proportional to myocardial work and linearly related to myocardial oxygen consumption. The basal myocardial oxygen requirements needed to maintain critical membrane function are low (approximately 15% of resting oxygen consumption), and the cost of electrical activation is trivial when mechanical contraction ceases during diastolic arrest (as with cardioplegia) and diminishes during ischemia.

Coronary Autoregulation

Regional coronary blood flow remains constant as coronary artery pressure is reduced below aortic pressure over a wide range when the determinants of myocardial oxygen consumption are kept constant. This phenomenon is termed *autoregulation* (**Fig. 57.3**). When pressure falls to the lower limit of autoregulation, coronary resistance arteries are maximally vasodilated to intrinsic stimuli, and flow becomes pressure-dependent, resulting in the onset of subendocardial ischemia. Resting coronary blood flow under normal hemodynamic conditions averages 0.7 to 1.0 mL/min/g and can increase between four- and fivefold during vasodilation. The ability to increase flow above resting values in response to pharmacologic vasodilation is termed *coronary flow reserve*. Flow in the maximally vasodilated heart is dependent on coronary arterial pressure. Maximum perfusion and coronary flow reserve are reduced when the diastolic time available for subendocardial perfusion is decreased (tachycardia) or the compressive determinants of diastolic perfusion (preload) are increased. Coronary reserve also is diminished by anything that increases resting flow, including increases in the hemodynamic determinants of oxygen consumption (systolic pressure, heart rate, and contractility) and reductions in arterial oxygen supply (anemia and hypoxia). Thus, circumstances can develop that precipitate subendocardial ischemia in the presence of normal coronary arteries (see Classic References, Hoffman and Spaan). Although initial studies suggested that the lower pressure limit of autoregulation is 70 mm Hg, it was later shown that coronary flow can be autoregulated to mean coronary pressures as low as 40 mm Hg (diastolic pressures of 30 mm Hg) in conscious dogs in the basal state (**Fig. 57.4**). These coronary pressure levels are similar to those recorded in humans without symptoms of ischemia, distal to chronic coronary occlusions, using pressure wire micromanometers. The lower autoregulatory pressure limit increases during tachycardia because of an increase in flow requirements, as well as a reduction in the time available for perfusion.

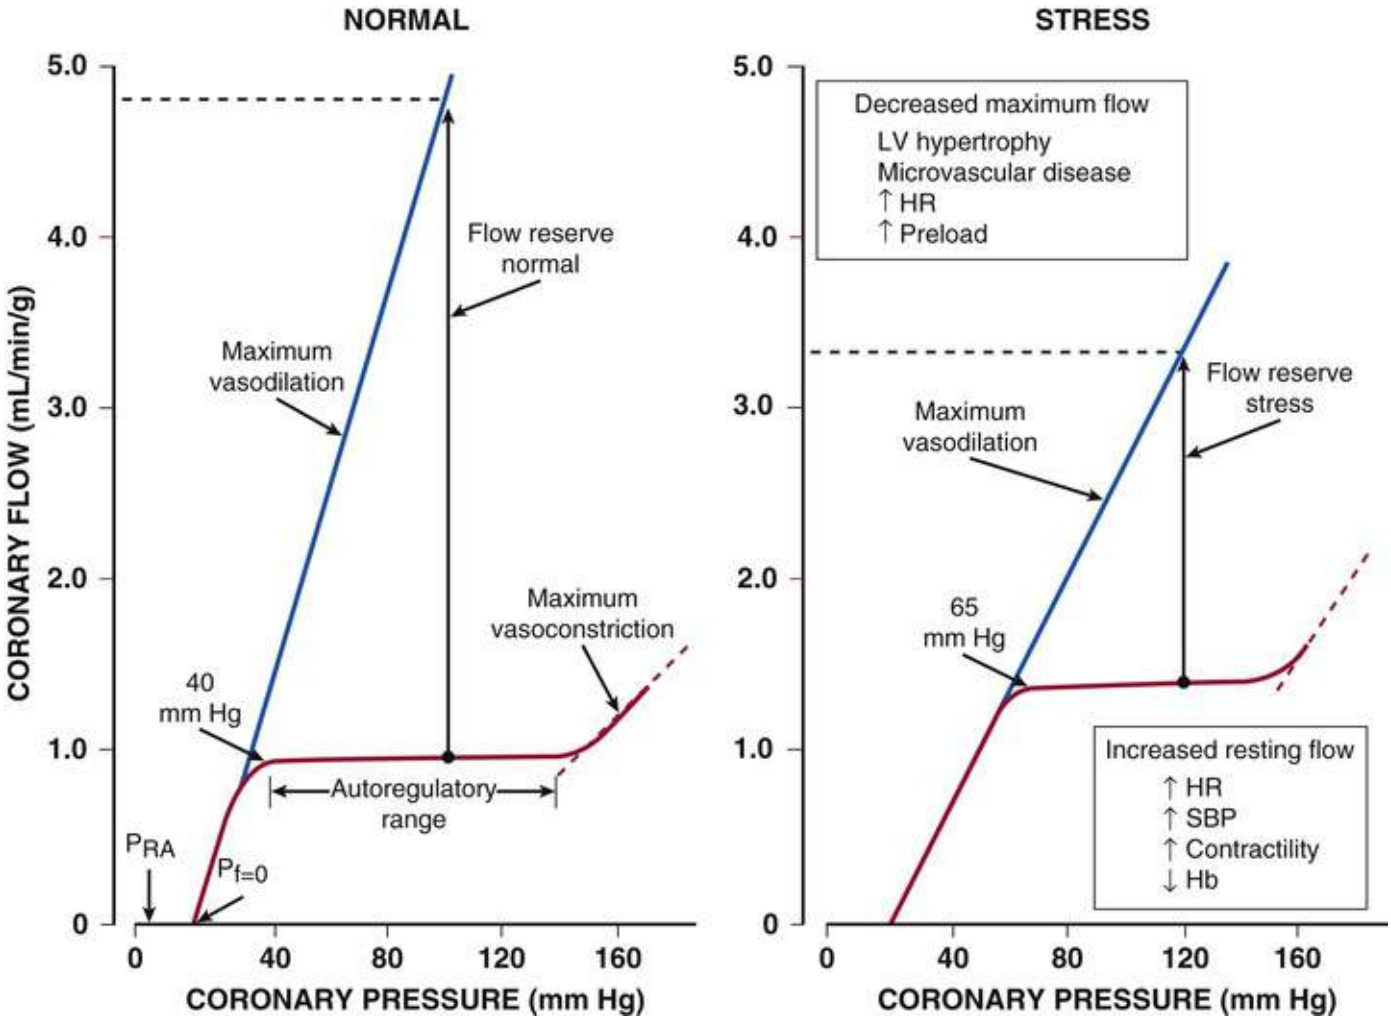

FIGURE 57.3 Autoregulatory relation under basal conditions and after metabolic stress (e.g., tachycardia). **Left**, The normal heart maintains coronary blood flow constant as regional coronary pressure is varied over a wide range when the global determinants of oxygen consumption are kept constant (*red lines*). Below the lower autoregulatory pressure limit (approximately 40 mm Hg), subendocardial vessels are maximally vasodilated and myocardial ischemia develops. During vasodilation (*blue lines*), flow increases four to five times above resting values at a normal arterial pressure. Coronary flow ceases at a pressure higher than right atrial pressure (P_{RA}), called *zero flow pressure* ($P_{f=0}$), which is the effective backpressure to flow in the absence of coronary collaterals. **Right,** After stress, tachycardia increases the compressive determinants of coronary resistance by decreasing the time available for diastolic perfusion and thus reduces maximum vasodilated flow. Left ventricular (LV) hypertrophy and microvascular disease also limit maximal blood flow per gram of myocardium. In addition, increases in myocardial oxygen demand or reductions in arterial oxygen content (e.g., from anemia or hypoxemia) increase resting flow. These changes reduce coronary flow reserve, the ratio between dilated and resting coronary flow, and cause ischemia to develop at higher coronary pressures. Hb, Hemoglobin; HR, heart rate; SBP, systolic blood pressure.

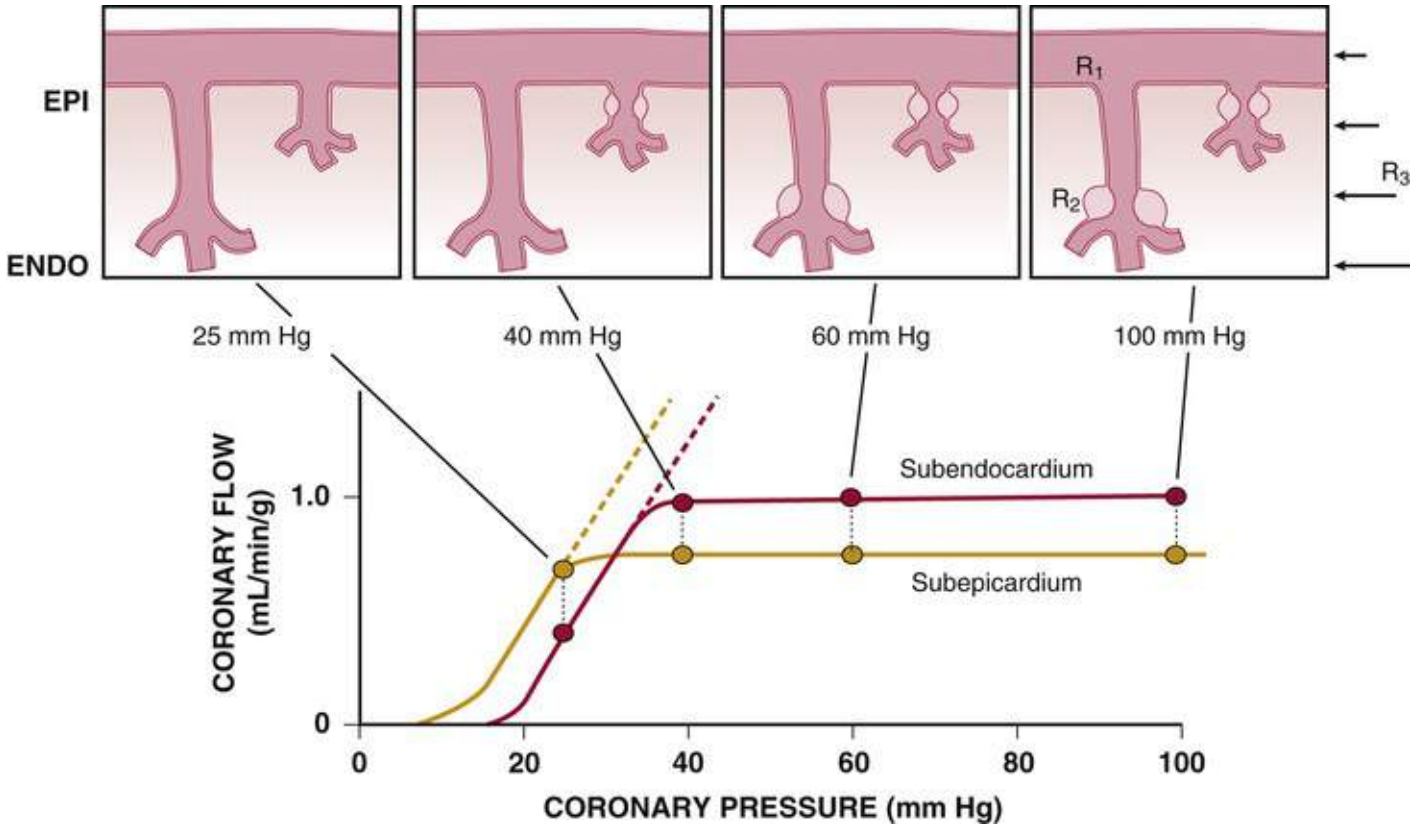

FIGURE 57.4 Transmural variations in coronary autoregulation and myocardial metabolism. Increased vulnerability of the subendocardium (ENDO, *red*) versus subepicardium (EPI, *gold*) to ischemia reflects the fact that autoregulation is exhausted at a higher coronary pressure (40 versus 25 mm Hg). This is the result of increased resting flow and oxygen consumption in the subendocardium and an increased sensitivity to systolic compressive effects, because subendocardial flow only occurs during diastole. Subendocardial vessels become maximally vasodilated before those in the subepicardium as coronary artery pressure is reduced. These transmural differences can be increased further during tachycardia or during conditions with elevated preload, which reduce maximum subendocardial perfusion. (Modified from Canty JM Jr. Coronary pressure-function and steady-state pressure-flow relations during autoregulation in the unanesthetized dog. Circ Res 1988;63:821.)

Fig. 57.4 also illustrates important transmural variations in the lower autoregulatory pressure limit, which result in increased vulnerability of the subendocardium to ischemia. Subendocardial flow occurs primarily in diastole and begins to decrease below a mean coronary pressure of 40 mm Hg. In contrast, subepicardial flow occurs throughout the cardiac cycle and is maintained until coronary pressure falls below 25 mm Hg. This difference arises from increased oxygen consumption in the subendocardium, requiring a higher resting flow level, as well as the more pronounced effects of systolic contraction on subendocardial vasodilator reserve. The transmural difference in the lower autoregulatory pressure limit results in vulnerability of the subendocardium to ischemia in the presence of a coronary stenosis. Although there is no pharmacologically recruitable flow reserve during ischemia in the normal coronary circulation, reductions in coronary flow below the lower limit of autoregulation can occur in the presence of pharmacologically recruitable coronary flow reserve under certain circumstances, e.g. exercise (see Classic References, Duncker and Bache).

Determinants of Coronary Vascular Resistance

The resistance to coronary blood flow can be divided into three major components (**Fig. 57.5**) (see Classic References, Klocke, 1976). Under normal circumstances, there is no measurable pressure drop in the epicardial arteries, indicating negligible conduit resistance (R_1). With the development of hemodynamically significant epicardial artery narrowing (>50% diameter reduction), the fixed conduit

artery resistance begins to contribute an increasing component to total coronary resistance and, when severely narrowed (>90%), may reduce resting flow.

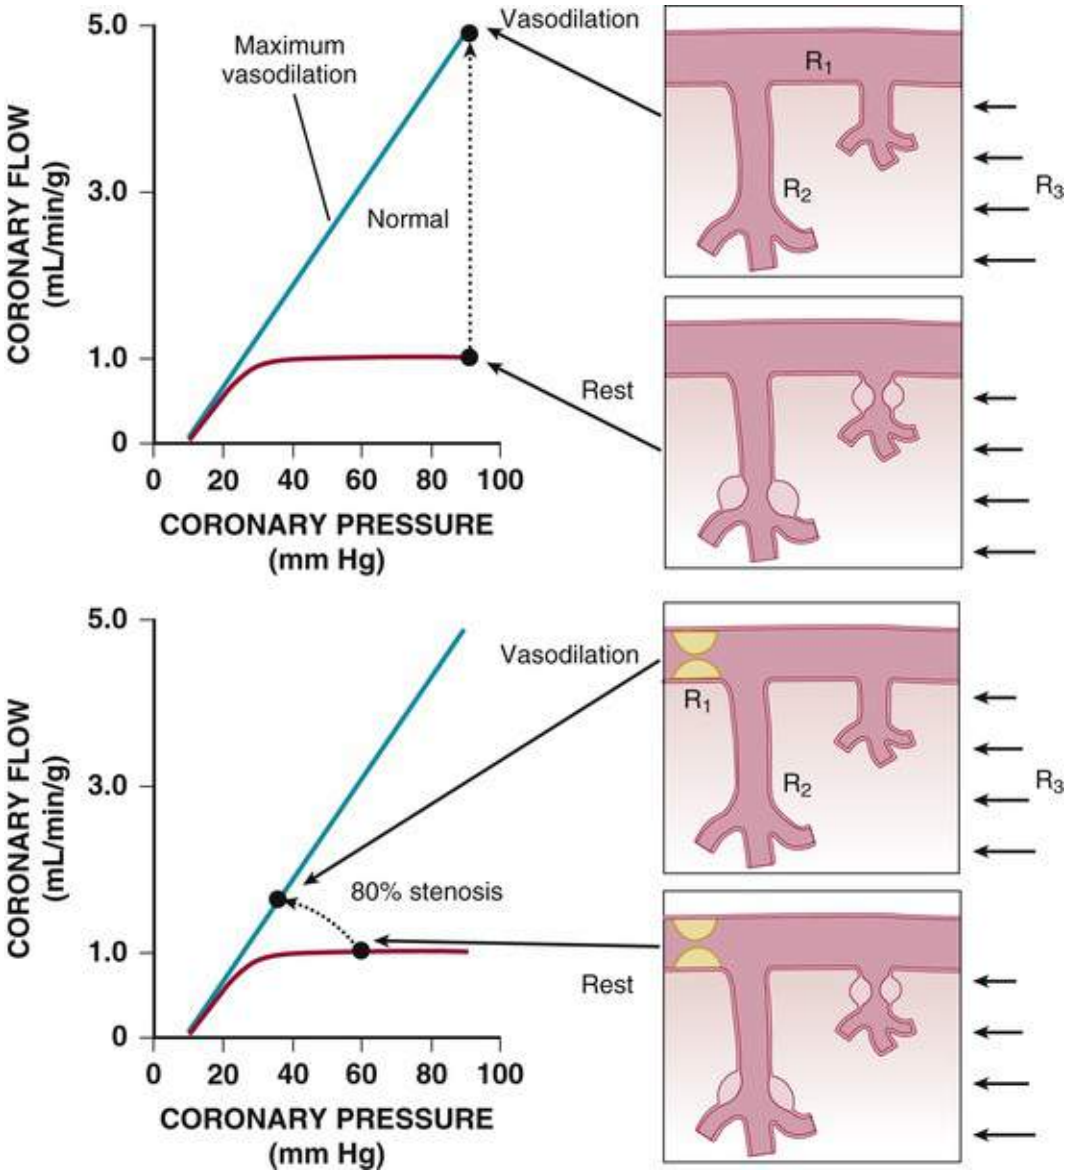

FIGURE 57.5 Schematic of components of coronary vascular resistance with and without a coronary stenosis. R_1 is epicardial conduit artery resistance, which normally is insignificant; R_2 is resistance secondary to metabolic and autoregulatory adjustments in flow and occurs in arterioles and small arteries; and R_3 is the time-varying compressive resistance that is higher in subendocardial than subepicardial layers. In the normal heart **(upper panel),** $R_2 > R_3$ R $_1$. The development of a proximal stenosis or pharmacologic vasodilation reduces arteriolar resistance (R_2). In the presence of a severe epicardial stenosis **(lower panel),** $R_1 > R_3 > R_2$.

The second component of coronary resistance (R_2) is dynamic and arises primarily from microcirculatory resistance arteries and arterioles. This is distributed throughout the myocardium across a broad range of microcirculatory resistance vessel sizes (20 to 400 µm in diameter) and changes in response to physical forces (intraluminal pressure and shear stress), as well as the metabolic needs of the tissue. Normally, little resistance is contributed by coronary venules and capillaries, and their resistance remains fairly constant during changes in vasomotor tone. Even in the maximally vasodilated heart, capillary resistance accounts for no more than 20% of the microvascular resistance.[3] Thus a twofold increase in capillary density would increase maximal myocardial perfusion by only approximately 10%.

Minimal coronary vascular resistance of the microcirculation is primarily determined by the size and density of arterial resistance vessels and results in substantial coronary flow reserve in the normal heart.

Extravascular Compressive Resistance.

The third component, extravascular compressive resistance (R_3), varies with time throughout the cardiac cycle and is related to cardiac contraction and systolic pressure development within the left ventricle. In heart failure, compressive effects from elevated ventricular diastolic pressure also impede perfusion by passive compression of microcirculatory vessels from elevated extravascular tissue pressure during diastole. Increases in preload effectively raise the normal backpressure to coronary flow above coronary venous pressure levels. Compressive effects are most prominent in the subendocardium (see later).

During systole, cardiac contraction raises extravascular tissue pressure to values equal to LV pressure at the subendocardium. This declines to values near pleural pressure at the subepicardium. The increased effective backpressure during systole produces a time-varying reduction in the driving pressure for coronary flow that impedes perfusion to the subendocardium. Although this paradigm can explain variations in systolic coronary inflow, it is not able to account for the increase in coronary venous systolic outflow. To explain both impaired inflow and accelerated venous outflow, some investigators have proposed the concept of the intramyocardial pump (see Classic References, Hoffman and Spaan). In this model, microcirculatory vessels are compressed during systole and produce a capacitive discharge of blood that accelerates flow from the microcirculation to the coronary venous system (**Fig. 57.6**). At the same time, the upstream capacitive discharge impedes systolic coronary arterial inflow. Although this explains the phasic variations in coronary arterial inflow and venous outflow, as well as its transmural distribution in systole, vascular capacitance cannot explain compressive effects related to elevated tissue pressure during diastole. Thus, intramyocardial capacitance, compressive changes in effective coronary backpressure, increases in systolic coronary resistance, and a time-varying driving pressure all contribute to the compressive determinants of phasic systolic coronary blood flow.

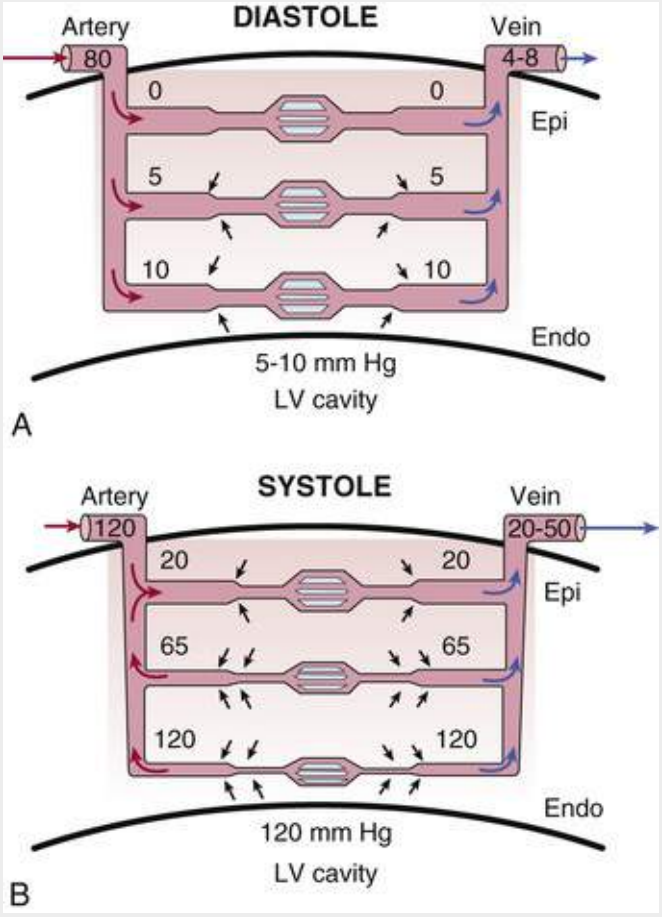

FIGURE 57.6 Effects of extravascular tissue pressure on transmural perfusion. **A,** Compressive effects during diastole are related to tissue pressures that decrease from the subendocardium (*Endo*) to subepicardium (*Epi*). At diastolic left ventricular (LV) pressures greater than 20 mm Hg, preload determines the effective backpressure to coronary diastolic perfusion. **B,** During systole, cardiac contraction increases intramyocardial tissue pressure surrounding compliant arterioles and venules. This produces a concealed arterial "backflow" that reduces systolic epicardial artery inflow, as depicted in **Fig. 57.1**. Compression of venules accelerates venous outflow. (Modified from Hoffman JI, Spaan JA. Pressure-flow relations in the coronary circulation. Physiol Rev 1990;70:331.)

Transmural Variations in Minimum Coronary Resistance (R_2) and Diastolic Driving Pressure.

The subendocardial vulnerability to compressive determinants of vascular resistance is partially compensated by a reduced minimal resistance resulting from an increased arteriolar and capillary density. Because of this vascular gradient, subendocardial flow during maximal pharmacologic vasodilation of the nonbeating heart is greater than subepicardial perfusion. Coronary vascular resistance in the maximally vasodilated heart also is pressure dependent, reflecting passive distention of arterial resistance vessels. Thus the instantaneous vasodilated value of coronary resistance obtained at a normal coronary distending pressure will be lower than that at a reduced pressure.

The precise determinants of the effective driving pressure for diastolic perfusion continue to be controversial. Most experimental studies demonstrate that the effective backpressure to flow in the heart is higher than right atrial pressure. This has been termed *zero flow pressure* ($P_{f=0}$) and its minimum value is approximately 10 mm Hg in the maximally vasodilated heart. This increases to values close to LV diastolic filling pressure when preload is elevated above 20 mm Hg. Elevated preload reduces coronary driving pressure and diminishes subendocardial perfusion. It is particularly important in determining flow when coronary pressure is reduced by a stenosis, as well as in the failing heart.

Endothelium-Dependent Modulation of Coronary Tone

Epicardial conduit arteries do not contribute significantly to coronary vascular resistance, yet arterial diameter is modulated by a wide variety of paracrine factors that can be released from platelets, as well as by circulating neurohormonal agonists, neural tone, and local control through vascular shear stress.[1] **Fig. 57.7 and eTable 57.1** summarize the most common factors related to cardiovascular disease. The net effect of many of these agonists is critically dependent on whether a functional endothelium is present. Furchgott and Zawadzki (see Classic References) originally demonstrated that acetylcholine normally dilates arteries through an endothelium-dependent relaxing factor that was later identified to be nitric oxide (NO). This binds to guanylyl cyclase and increases cyclic guanosine monophosphate (cGMP), resulting in vascular smooth muscle relaxation. When the endothelium is removed, the dilation to acetylcholine is converted to vasoconstriction, reflecting the effect of muscarinic vascular smooth muscle contraction. Subsequent studies have demonstrated that coronary resistance arteries also exhibit endothelial modulation of diameter, and that the response to physical forces such as shear stress, as well as paracrine mediators, vary with resistance vessel size.[3,4] The major endothelium-dependent biochemical pathways involved in regulating coronary epicardial and resistance artery diameter are discussed next.

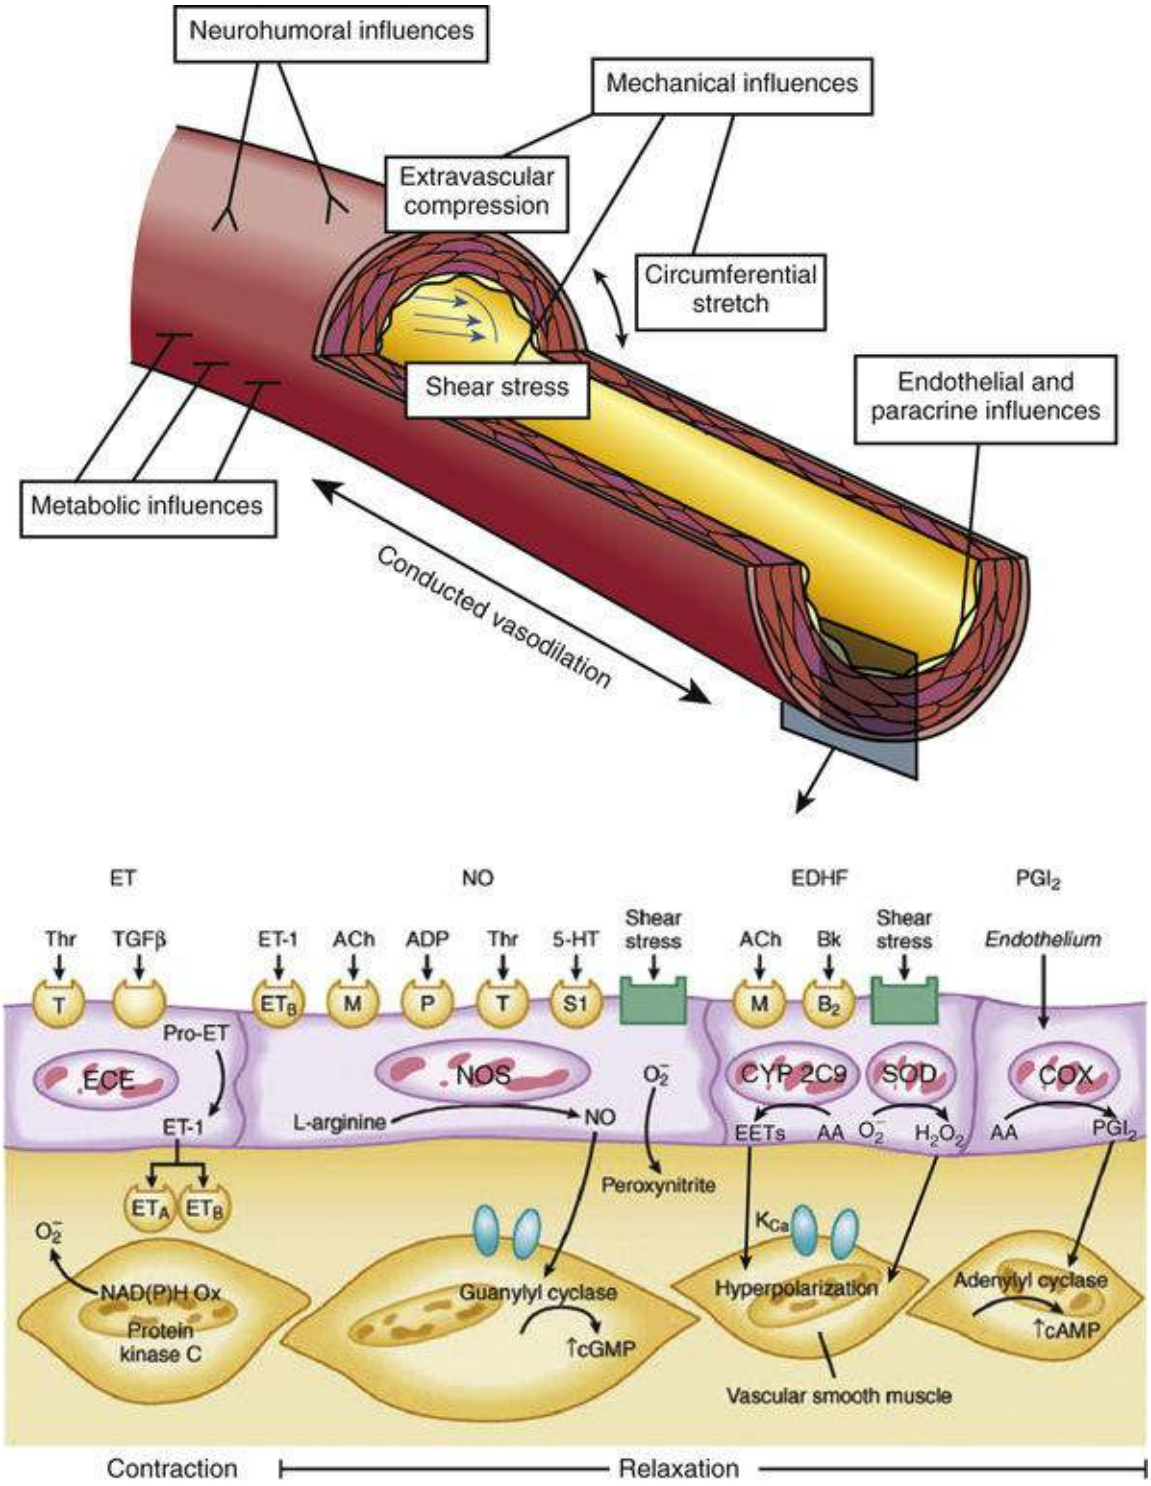

FIGURE 57.7 Endothelium-dependent control of vascular tone. In the normal coronary circulation, endothelium-dependent vasodilation occurs after increases in luminal flow or shear stress, as well as in response to agonists (e.g., released from platelets or cardiac nerves) that bind to receptors on the endothelial surface. These stimulate the production of nitric oxide (*NO*) and endothelium-dependent hyperpolarizing factor (*EDHF*), including epoxyeicosatrienoic acid products (*EETs*) and hydrogen peroxide (H_2O_2) released from mitochondria, which diffuse into vascular smooth muscle and cause relaxation. Prostacyclin, or prostaglandin I_2 (PGI_2), is produced in the coronary endothelium of collateral vessels and causes tonic vasodilation. The endothelium also produces endothelin (*ET*), which activates protein kinase C in vascular smooth muscle to produce coronary constriction and competes with endothelium-derived relaxing factors. Impaired endothelium-dependent vasodilation can result from the lack of production of relaxing factors (e.g., disrupted endothelium) or by inactivation of NO in disease states associated with oxidative stress and superoxide anion production (e.g., NO and O_2^- combining to produce peroxynitrite). In these circumstances, the effect of autacoids on vascular tone can be converted to vasoconstriction because of their direct effects on vascular smooth muscle (*not shown*). *AA,* Arachidonic acid; Ach, acetylcholine; *Bk,* bradykinin; *5-HT,* 5-hydroxytryptamine [serotonin]; K_{Ca}, calcium-activated potassium channel; *TGFβ,* transforming growth factor beta$_1$; *Thr,* thrombin. ETABLE 57.1

Endothelium-Dependent and Net Direct Effects of Neural Stimulation, Autacoids, and Vasodilators on Coronary Tone in Isolated Conduit and Coronary Resistance Arteries

SUBSTANCE	ENDOTHELIUM DEPENDENT	NORMAL RESPONSE	ATHEROSCLEROSIS
Acetylcholine			
Conduit	Nitric oxide	Net dilation	Constriction
Resistance	Nitric oxide, EDHF	Dilation	Attenuated dilation
Norepinephrine			
Conduit			
$Alpha_1$	—	Constriction	Constriction
$Beta_1$ and $Beta_2$	Nitric oxide	Dilation	Attenuated dilation
Resistance			
$Alpha_1$	—	Constriction	Constriction
$Alpha_2$	Nitric oxide	No effect	Constriction
$Beta_2$		Dilation	Dilation
Platelets			
Thrombin	Nitric oxide	Dilation	Constriction
Serotonin			
Conduit	Nitric oxide	Constriction	Constriction
Resistance	Nitric oxide	Dilation	Constriction
Adenosine Diphosphate (ADP)			
	Nitric oxide	Dilation	Attenuated dilation
Thromboxane			
	Endothelin	Constriction	Constriction
Paracrine Agonists			
Bradykinin	Nitric oxide, EDHF	Dilation	Attenuated dilation
Histamine	Nitric oxide	Dilation	Attenuated dilation
Substance P	Nitric oxide	Dilation	Attenuated dilation
Endothelin (ET)			
ET-1	Nitric oxide	Net constriction	Increased constriction

EDHF, Endothelium-dependent hyperpolarizing factor.

Nitric Oxide (Endothelium-Derived Relaxing Factor)

Nitric oxide is produced in endothelial cells by the enzymatic conversion of L-arginine to citrulline via type III nitric oxide synthase (NOS). Endothelial NO diffuses abluminally into vascular smooth muscle, where it binds to guanylyl cyclase, increasing cGMP production and causing relaxation through a reduction in intracellular calcium. NO-mediated vasodilation is enhanced by cyclic or pulsatile changes in coronary shear stress. Chronic upregulation of NOS occurs in response to episodic increases in coronary flow, such as during exercise training, which also potentiates the relaxation to various endothelium-dependent vasodilators. NO-mediated vasodilation is impaired in many disease states and in patients with one or more risk factors for coronary artery disease (CAD). This occurs via inactivation of NO by superoxide anion generated in response to oxidative stress. Such inactivation is the hallmark of impaired NO-mediated vasodilation in atherosclerosis, hypertension, and diabetes.

Endothelium-Dependent Hyperpolarizing Factor

Endothelium-dependent hyperpolarization is an additional endothelium-dependent mechanism for selected agonists (e.g., bradykinin), as well as shear stress–induced vasodilation, in the human coronary microcirculation. Endothelium-dependent hyperpolarizing factor (EDHF), produced by the endothelium, hyperpolarizes vascular smooth muscle and dilates arteries by opening calcium-activated potassium channels (K_{Ca}). The exact biochemical species of EDHF is still unclear, but prominent candidates are

endothelium-derived hydrogen peroxide[4] and epoxyeicosatrienoic acid, a metabolite of arachidonic acid metabolism produced by the cytochrome P-450 epoxygenase pathway.[4,5]

Prostacyclin

Metabolism of arachidonic acid via cyclooxygenase (COX) also can produce prostacyclin, which is a coronary vasodilator when administered exogenously. Although some evidence indicates that prostacyclin contributes to tonic coronary vasodilation, COX inhibitors fail to alter flow during ischemia distal to an acute stenosis or limit oxygen consumption in response to increases in metabolism. This suggests that it is overcome by other compensatory vasodilator pathways.[1,2] In contrast with the coronary resistance vasculature, vasodilator prostaglandins are very important determinants of coronary collateral vessel resistance, and inhibiting COX reduces collateral perfusion in dogs.[6]

Endothelin

The endothelins—ET-1, ET-2, and ET-3—are peptide endothelium-dependent constricting factors. ET-1 is a potent constrictor derived from the enzymatic cleavage of a larger precursor molecule (pre-pro–endothelin) via endothelin-converting enzyme. In contrast with the rapid vascular smooth muscle relaxation and recovery characteristic of endothelium-derived vasodilators (NO, EDHF, and prostacyclin), the constriction to endothelin is prolonged. Changes in endothelin levels are largely mediated through transcriptional control and produce longer-term changes in coronary vasomotor tone. The effects of endothelin are mediated by binding to both ET_A and ET_B receptors. ET_A-mediated constriction is caused by the activation of protein kinase C in vascular smooth muscle. ET_B-mediated constriction is less pronounced and counterbalanced by ET_B-mediated endothelium-dependent NO production and vasodilation. Endothelin is only marginally involved in regulating coronary blood flow in the normal heart but can modulate vascular tone when interstitial and circulating concentrations increase in pathophysiologic states such as heart failure.

Neural Control of Coronary Conduit and Resistance Arteries.

Sympathetic and vagal nerves innervate coronary conduit arteries and segments of the resistance vasculature. Neural stimulation affects tone through mechanisms that alter vascular smooth muscle as well as by stimulating the release of NO from the endothelium. Diametrically opposite effects can occur in the presence of risk factors that impair endothelium-dependent vasodilation. Their actions in normal and pathophysiologic states are summarized in **eTable 57.1**.

Cholinergic Innervation.

Resistance arteries dilate to acetylcholine, resulting in increases in coronary flow. In conduit arteries, acetylcholine normally causes mild coronary vasodilation. This reflects the net action of a direct muscarinic constriction of vascular smooth muscle counterbalanced by an endothelium-dependent vasodilation caused by direct stimulation of NOS and an increased flow-mediated dilation from concomitant resistance vessel vasodilation. The response in humans with atherosclerosis or risk factors for CAD is distinctly different. The resistance vessel dilation to acetylcholine is attenuated and the reduction in flow-mediated NO production leads to net epicardial conduit artery vasoconstriction, which is particularly prominent in stenotic segments (**Fig. 57.8A**).

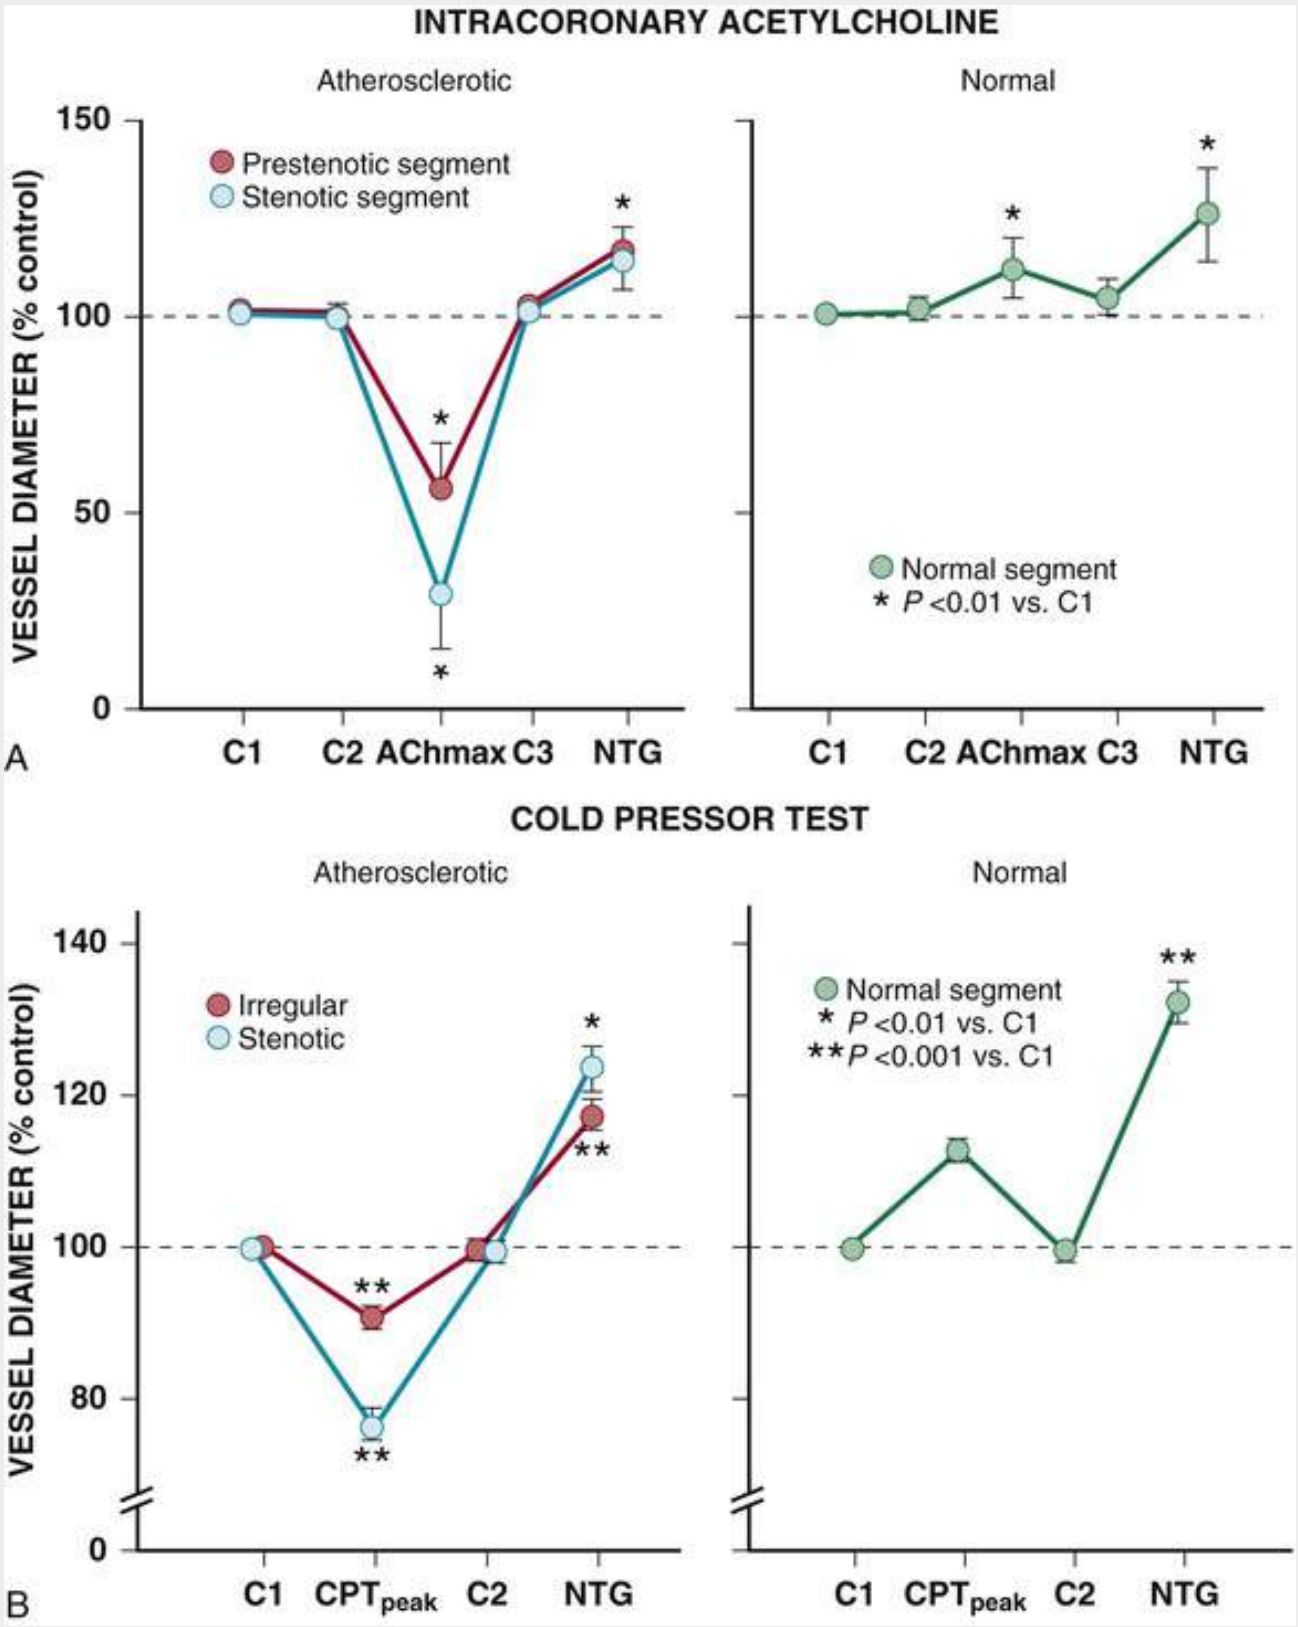

FIGURE 57.8 Differential conduit artery diameter responses in normal and atherosclerotic epicardial arteries. **A,** Acetylcholine. In normal arteries, acetylcholine elicits vasodilation, but there is vasoconstriction in the atherosclerotic artery, which is particularly pronounced in the stenosis. **B,** Cold pressor testing. Activation of sympathetic tone normally leads to net epicardial dilation, but vasoconstriction in irregular and stenotic coronary segments occurs in patients with atherosclerosis. Ach, Acetylcholine; C, control; CPT, cold pressor test [response]; NTG, nitroglycerin. (**A,** Modified from Ludmer PL et al. Paradoxical vasoconstriction induced by acetylcholine in atherosclerotic coronary arteries. N Engl J Med 1986;315:1046; **B,** modified from Nabel EG et al. Dilation of normal and constriction of atherosclerotic coronary arteries caused by the cold pressor test. Circulation 1988;77:43.)

Sympathetic Innervation.

Under basal conditions, there is no resting sympathetic tone in the heart and thus no effect of denervation

on resting perfusion. During sympathetic activation, coronary tone is modulated by norepinephrine released from myocardial sympathetic nerves, as well as by circulating norepinephrine and epinephrine.[1,2] In conduit arteries, sympathetic stimulation leads to $alpha_1$ constriction as well as beta-mediated vasodilation. The net effect is to dilate epicardial coronary arteries. This dilation is potentiated by concomitant flow-mediated vasodilation from metabolic vasodilation of coronary resistance vessels. When NO-mediated vasodilation is impaired, $alpha_1$ constriction predominates and can dynamically increase stenosis severity in asymmetric lesions where the stenosis is compliant. This is one of the mechanisms by which ischemia can be provoked during cold pressor testing (**Fig. 57.8B**).

The effects of sympathetic activation on myocardial perfusion and coronary resistance vessel tone are complex and depend on the net actions of $beta_1$-mediated increases in myocardial oxygen consumption (resulting from increases in the determinants of myocardial oxygen consumption), direct $beta_2$-mediated coronary vasodilation, and $alpha_1$-mediated coronary constriction. Under normal conditions, exercise-induced $beta_2$-adrenergic "feed-forward" dilation predominates, resulting in a higher flow relative to the level of myocardial oxygen consumption.[6] This neural control mechanism produces transient vasodilation before the buildup of local metabolites during exercise and prevents the development of subendocardial ischemia during abrupt changes in demand. After nonselective beta blockade, sympathetic activation unmasks $alpha_1$-mediated coronary artery constriction. Although flow is mildly decreased, oxygen delivery is maintained by increased oxygen extraction and a reduction in coronary venous P_{O_2} at similar levels of cardiac workload. Intense $alpha_1$-adrenergic constriction can overcome intrinsic stimuli for metabolic vasodilation to result in ischemia in the presence of pharmacologic vasodilator reserve.[6] The role of pre- and postsynaptic $alpha_2$ responses is controversial. They appear to have a less significant role in controlling flow. This partly reflects the competing effects of presynaptic $alpha_2$ receptor stimulation, leading to reduced vasoconstriction by inhibiting norepinephrine release.

Paracrine Vasoactive Mediators and Coronary Vasospasm

Many paracrine factors can affect coronary tone in normal and pathophysiologic states that are unrelated to normal coronary circulatory control. The most important of these are summarized in **Fig. 57.7 and eTable 57.1**. Paracrine factors are released from epicardial artery thrombi after activation of the thrombotic cascade initiated by plaque rupture. They can modulate epicardial tone in regions near eccentric ulcerated plaques still responsive to stimuli that alter smooth muscle relaxation and constriction, leading to dynamic changes in the physiologic significance of a stenosis. Paracrine mediators also can have differential effects on downstream vessel vasomotion that depend on vessel size (conduit arteries versus resistance arteries) as well as on the presence of a functionally normal endothelium, because many also stimulate the release of NO and EDHF.

Serotonin released from activated platelets causes vasoconstriction in normal and atherosclerotic conduit arteries and can increase the functional severity of a dynamic coronary stenosis through superimposed vasospasm. By contrast, it dilates coronary arterioles and increases coronary flow through the endothelium-dependent release of NO. In atherosclerosis or circumstances in which NO production is impaired, the direct effects on smooth muscle predominate, and the response of the microcirculation is converted to vasoconstriction. As a result, serotonin release generally exacerbates ischemia in CAD.

Thromboxane A_2 is a potent vasoconstrictor that is a product of endoperoxide metabolism and is released during platelet aggregation. It produces vasoconstriction of conduit arteries as well as isolated

coronary resistance vessels and can accentuate acute myocardial ischemia.

Adenosine diphosphate (ADP) is another platelet-derived vasodilator that relaxes coronary microvessels as well as conduit arteries. It is mediated by NO and abolished by removing the endothelium.

Thrombin normally leads to vasodilation in vitro that is endothelium dependent and mediated by the release of prostacyclin as well as NO. In vivo, thrombin also releases thromboxane A_2, leading to vasoconstriction in epicardial stenoses in which endothelium-dependent vasodilation is impaired. In the coronary resistance vasculature, thrombin acts as an endothelium-dependent vasodilator and increases coronary flow.

Coronary Vasospasm

Coronary spasm results in transient functional occlusion of a coronary artery that is reversible with nitrate vasodilation. It most frequently occurs in the setting of a coronary stenosis, leading to dynamic stenosis behavior that can dissociate the effects on perfusion from anatomic stenosis severity (**see Chapter 20**). In CAD, endothelial disruption probably plays a role in focal vasospasm; the normal vasodilation from autacoids and sympathetic stimulation is converted into a vasoconstrictor response because of the lack of competing endothelium-dependent vasodilation. Nevertheless, although impaired endothelium-dependent vasodilation is a permissive factor for vasospasm, it is not causal, and a trigger is required (e.g., thrombus formation, sympathetic activation).

The mechanisms responsible for variant angina with normal coronary arteries, or Prinzmetal angina, are less clear. Data from animal models have pointed to sensitization of intrinsic vasoconstrictor mechanisms (see Classic References, Konidala and Gutterman). Coronary arteries demonstrate supersensitivity to vasoconstrictor agonists in vivo and in vitro as well as reduced vasodilator responses. Some studies have demonstrated that Rho, a guanosine triphosphate (GTP)–binding protein, can sensitize vascular smooth muscle to calcium by inhibiting myosin phosphatase activity through the effector protein Rho kinase.

Pharmacologic Vasodilation.

The effects of pharmacologic vasodilators on coronary flow reflect direct actions on vascular smooth muscle as well as secondary adjustments in resistance artery tone. Flow-mediated dilation can amplify the vasodilator response, whereas autoregulatory adjustments can overcome vasodilation in a segment of the microcirculation and restore flow to normal. The potent resistance vessel vasodilators are specifically used in assessing coronary stenosis severity.[7]

Nitroglycerin.

Nitroglycerin dilates epicardial conduit arteries and small coronary resistance arteries but does not increase coronary blood flow in the normal heart (see Classic References, Duncker and Bache). The latter observation reflects the fact that transient arteriolar vasodilation is overcome by autoregulatory escape, which returns coronary resistance to control levels.[3,4] Although nitroglycerin does not increase coronary blood flow in the normal heart, it can produce vasodilation of larger coronary resistance arteries that improves the distribution of perfusion to the subendocardium when flow-mediated NO-dependent vasodilation is impaired.[6] It also can improve subendocardial perfusion by reducing LV end-diastolic pressure through systemic venodilation in heart failure. Similarly, coronary collateral vessels dilate in response to nitroglycerin, and the reduction in collateral resistance can improve regional

perfusion in some settings.[6]

Calcium Channel Blockers.

All calcium channel blockers induce vascular smooth muscle relaxation and are, to various degrees, pharmacologic coronary vasodilators. In epicardial arteries the vasodilator response is similar to nitroglycerin and is effective in preventing coronary vasospasm superimposed on a coronary stenosis, as well as in normal arteries of patients with variant angina. Calcium channel blockers also submaximally vasodilate coronary resistance vessels. In this regard, dihydropyridine derivatives such as nifedipine are particularly potent and can sometimes precipitate subendocardial ischemia in the presence of a critical stenosis. This arises from a transmural redistribution of blood flow (coronary steal) as well as the tachycardia and hypotension that transiently occur with short half-life formulations of nifedipine.

Adenosine and A_2 Receptor Agonists.

Adenosine dilates coronary arteries through activation of A_2 receptors on vascular smooth muscle and is independent of the endothelium in coronary arterioles isolated from humans with heart disease.[8] Experimentally, a differential sensitivity of the microcirculation to adenosine is observed, with the direct effects related to resistance vessel size and restricted primarily to vessels smaller than 100 μm.[3,4] Larger upstream resistance arteries dilate through a NO-dependent mechanism from the increase in shear stress. Thus, in states where endothelium-dependent vasodilation is impaired, maximal coronary flow responses to intravenous or intracoronary adenosine may be reduced in the absence of a stenosis[4] and can be increased by interventions that improve NO-mediated vasodilation, such as lowering low-density lipoprotein (LDL) levels. Single-dose adenosine A_2 receptor agonists (e.g., regadenoson) are now more often employed in pharmacologic stress testing and are as effective as adenosine. These agents circumvent the need for continuous infusions during myocardial perfusion imaging[7] (**see Chapter 16**).

Dipyridamole.

Dipyridamole produces vasodilation by inhibiting the myocyte reuptake of adenosine released from cardiac myocytes. It therefore has actions and mechanisms similar to those of adenosine, with the exception that the vasodilation is more prolonged. It can be reversed with the administration of the nonspecific adenosine receptor blocker aminophylline.

Papaverine.

Papaverine is a short-acting coronary vasodilator that was the first agent used for intracoronary vasodilation. It causes vascular smooth muscle relaxation by inhibiting phosphodiesterase and increasing cyclic adenosine monophosphate (cAMP). After bolus injection, it has a rapid onset of action, but the vasodilation is more prolonged than after adenosine (approximately 2 minutes). Its actions are independent of the endothelium.

Structure and Function of the Coronary Microcirculation

The schematics in **Figs. 57.4 and 57.5** suggest a fairly localized site for the control of coronary vascular resistance that is useful for conceptualizing the major determinants of coronary vascular resistance. In fact, individual coronary resistance arteries are a longitudinally distributed network, and in vivo studies of the coronary microcirculation have demonstrated considerable spatial heterogeneity of specific resistance vessel control mechanisms[3,4,6] (**Fig. 57.9**). Each resistance vessel needs to dilate in an orchestrated fashion to meet the needs of the downstream vascular bed, which is frequently removed from the site of metabolic control of coronary resistance. This can be accomplished independently of metabolic signals by sensing physical forces such as intraluminal flow (shear stress–mediated control) or

intraluminal pressure changes (myogenic control). Epicardial arteries (>400 µm in diameter) serve a conduit artery function, with diameter primarily regulated by shear stress, and contribute minimal pressure drop (<5%) over a wide range of coronary flow. Coronary arterial resistance vessels can be divided into small arteries (100 to 400 µm), which regulate their tone in response to local shear stress and luminal pressure changes (myogenic response), and arterioles (<100 µm), which are sensitive to changes in local tissue metabolism and directly control perfusion of the low-resistance coronary capillary bed[3,4] (**Fig. 57.10 and eFig. 57.1**). Capillary density of the myocardium averages 3500/mm^2 (resulting in average intercapillary distance of 17 µm), which is greater in the subendocardium than in the subepicardium.

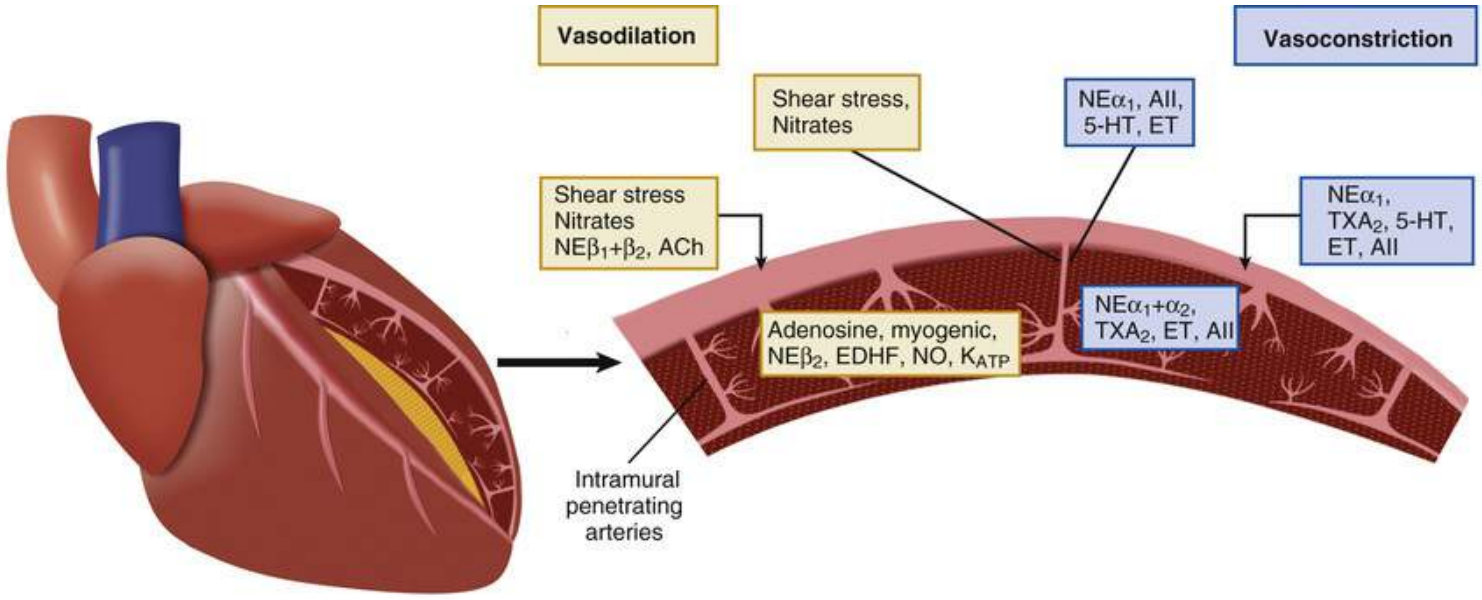

FIGURE 57.9 Transmural distribution of coronary resistance vessels—major vasodilator and vasoconstrictor mechanisms in epicardial conduit arteries and different sites of the microcirculation. The epicardial conduit arteries arborize into subepicardial and subendocardial resistance arteries. Intramural penetrating resistance arteries are unique in that they are removed from subendocardial metabolic stimuli and theoretically are more dependent on regulating their tone in response to shear stress and luminal pressure as mechanisms to produce dilation in response to changes in metabolism of the distal subendocardial arteriolar plexus. See text for further discussion. AII, Angiotensin II; Ach, acetylcholine; EDHF, endothelium-dependent hyperpolarizing factor; ET, endothelin; 5-HT, 5-hydroxytryptamine [serotonin]; K_{ATP}, ATP-dependent potassium channel; $NE\beta_1$, norepinephrine beta$_1$-adrenergic; $NE\alpha_1$, norepinephrine alpha$_1$-adrenergic; TXA_2, thromboxane A_2. FIGURE 57.10 Integrative regulation of coronary flow by ascending, metabolic, myogenic, and shear stress–induced mechanisms in response to metabolic activation. Small distal arterioles immediately before the capillaries are sensitive to tissue metabolites. Upstream intermediate arterioles are pressure sensitive, with myogenic mechanisms predominating. Small resistance arteries are removed from the metabolic milieu and primarily adjust local tone in response to shear stress and flow. Capillary and venular resistances are small and primarily considered to be fixed. (Modified from Davis MJ, Hill MA, Kuo L. Local regulation of microvascular perfusion. In Tuma RF, Duran WN, Ley K, editors. Handbook of Physiology: Microcirculation. San Diego: Academic Press; 2008, p 161.)

EFIGURE 57.1 Microcirculatory pressure profile and local resistance changes to physiologic stimuli in subepicardial microvessels. **A,** Under resting conditions, most of the pressure drop to flow arises from small arteries and arterioles. After dipyridamole vasodilation, a redistribution of microcirculatory resistance

is seen, with a greater pressure drop occurring across small arteries and postcapillary venules that do not alter their resistance. **B,** Heterogeneous arterial microvessel response during autoregulation. A reduction in pressure to 38 mm Hg elicited dilation in arterioles smaller than 100 µm, whereas larger arteries tended to constrict passively from the reduction in distending pressure. **C,** Homogeneous vasodilation of resistance arteries during increases in myocardial oxygen consumption. Dilation occurs in all microvascular resistance arteries, being greatest in vessels smaller than 100 µm. (**A,** Modified from Chilian WM et al. Redistribution of coronary microvascular resistance produced by dipyridamole. Am J Physiol 1989;256:H383; **B,** modified from Kanatsuka H et al. Heterogeneous changes in epimyocardial microvascular size during graded coronary stenosis: evidence of the microvascular site for autoregulation. Circ Res 1990;66:389; **C,** modified from Kanatsuka H et al. Comparison of the effects of increased myocardial oxygen consumption and adenosine on the coronary microvascular resistance. Circ Res 1989;65:1296.)

Under resting conditions, most of the pressure drop in the microcirculation arises in resistance arteries between 50 and 200 µm, with minimal pressure drop occurring across capillaries and venules at normal flow levels[4] (**eFig. 57.1A**). After pharmacologic vasodilation with dipyridamole, resistance artery vasodilation attenuates the precapillary pressure drop in arterial resistance vessels. At the same time, there is an increased pressure drop and redistribution of resistance to venular vessels, in which smooth muscle relaxation is limited and the already low resistance is fairly fixed.

Considerable heterogeneity in microcirculatory vasodilation is evident during physiologic adjustments in flow. For example, as pressure is reduced during autoregulation, dilation is accomplished primarily by arterioles smaller than 100 µm, whereas larger resistance arteries tend to constrict because of the reduction in perfusion pressure[3] (**eFig. 57.1B**). By contrast, metabolic vasodilation results from a more uniform vasodilation of resistance vessels of all sizes[4] (**eFig. 57.1C**). Similar inhomogeneity in resistance vessel dilation occurs in response to endothelium-dependent agonists as well as pharmacologic vasodilators.

A unique component of subendocardial coronary resistance vessels is the transmural penetrating arteries that course from the epicardium to the subendocardial plexus (see Classic References, Duncker and Bache). These vessels not only are less sensitive to metabolic signals but are also removed from the metabolic stimuli that develop when ischemia is confined to the subendocardium. As a result, local control by altered shear stress and myogenic relaxation to local pressure become critical determinants of diameter in this “upstream” resistance segment. Even during maximal vasodilation, this segment creates an additional longitudinal component of coronary vascular resistance that must be traversed before the arteriolar microcirculation is reached. Because of this greater longitudinal pressure drop, the microcirculatory pressures in subendocardial coronary arterioles are lower than in the subepicardial arterioles.[4]

Intraluminal Physical Forces Regulating Coronary Resistance

Because much of the coronary resistance vasculature can be upstream from the effects of metabolic mediators of control, local vascular control mechanisms are critically important in orchestrating adequate regional tissue perfusion to the distal microcirculation. The differential expression of mechanisms that is evident among different sizes and classes of coronary resistance vessels coincides with their function.

Myogenic Regulation

The *myogenic response* refers to the ability of vascular smooth muscle to oppose changes in coronary arterial diameter.[3] Thus, vessels relax when distending pressure is decreased and constrict when distending pressure is elevated (**Fig. 57.11A**). Myogenic tone is a property of vascular smooth muscle and occurs across a large size range of coronary resistance arteries in animals as well as in humans. Although

the cellular mechanism is uncertain, it depends on vascular smooth muscle calcium entry, perhaps through stretch-activated L-type Ca^{2+} channels, eliciting cross-bridge activation. The resistance changes arising from the myogenic response tend to bring local coronary flow back to the original level. Myogenic regulation has been postulated as an important mechanism of the coronary autoregulatory response and in vivo appears to occur primarily in arterioles smaller than 100 µm (e.g., during autoregulation) (**eFig. 57.1B**).

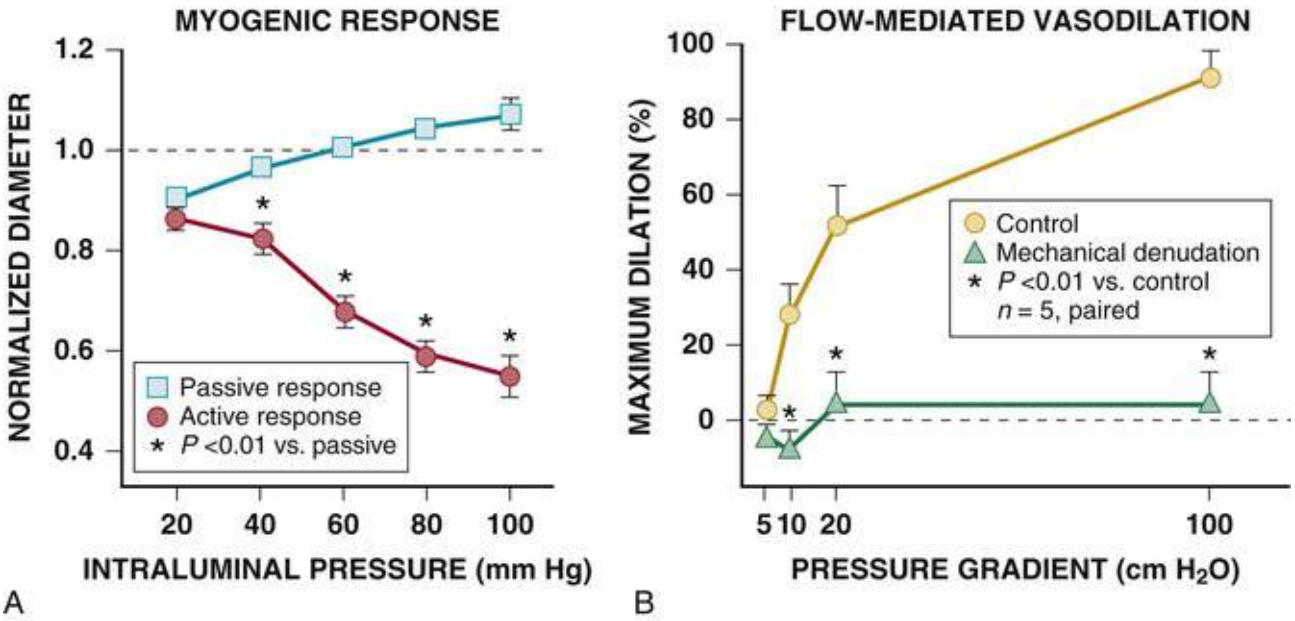

FIGURE 57.11 Effects of physical forces on coronary diameter in isolated human coronary resistance arteries (nominal diameter, 100 µm). **A,** As distending pressure is reduced from 100 mm Hg, progressive vasodilation occurs, consistent with myogenic regulation. Myogenic dilation reaches the maximum passive diameter of the vessel at 20 mm Hg. **B,** Flow-mediated vasodilation in cannulated human resistance arteries. As the pressure gradient across the isolated vessel is increased, intraluminal flow rises, causing progressive dilation that is abolished by removing the endothelium. Similar flow-mediated dilation occurs in most arterial vessels, including the coronary conduit arteries. (**A,** Modified from Miller FJ, Dellsperger KC, Gutterman DD. Myogenic constriction of human coronary arterioles. Am J Physiol 1997;273:H257; **B,** modified from Miura H et al. Flow-induced dilation of human coronary arterioles: important role of Ca^{2+}-activated K^+ channels. Circulation 2001;103:1992.)

Flow-Mediated Resistance Artery Control

Coronary small arteries and arterioles also regulate their diameter in response to changes in local shear stress (**Fig. 57.11B**). Flow-induced dilation in isolated coronary arterioles is endothelium dependent and mediated by NO, because it could be abolished with an L-arginine analogue. By contrast, isolated atrial vessels from patients undergoing cardiac surgery exhibit flow-mediated vasodilation by EDHF. The disparity with animal studies may reflect age or species variability in the relative importance of EDHF versus NO in the coronary circulation. The mechanisms also appear to vary as a function of vessel size, with studies in pigs demonstrating that hyperpolarization regulates epicardial conduit arteries,[8] and NO predominates in the resistance vasculature. Also, EDHF may represent a compensatory pathway that normally is inhibited by NO and becomes upregulated in acquired disease states in which NO-mediated vasodilation is impaired.[8] More recent studies have demonstrated that this factor appears to be hydrogen peroxide.[5,8] Despite the variability in isolated vessels, blocking NOS with an L-arginine analogue in the coronary circulation of humans reduces vasodilation to pharmacologic endothelium-dependent agonists

and attenuates flow increases during metabolic vasodilation. This demonstrates that NO-mediated vasodilation plays a role in determining physiologic vascular tone in some segments of the coronary resistance vasculature.

Metabolic Mediators of Coronary Resistance Vessel Control.

Although increasing knowledge has emerged regarding the distribution of coronary microvascular resistance, there is still no consensus regarding specific mediators of metabolic vasodilation.[1,9] Coronary resistance in any segment of the microcirculation represents the integration of local physical factors (e.g., pressure, flow), vasodilator metabolites (e.g., adenosine, P_{O_2}, pH), autacoids, and neural modulation. Each of these mechanisms contributes to net coronary vascular smooth muscle tone, which may ultimately be controlled by opening and closing vascular smooth muscle adenosine triphosphate (ATP)–sensitive K^+ (K_{ATP}) channels. There is considerable redundancy in the available local control mechanisms.[1,2] Because of this, blocking single mechanisms fails to alter coronary autoregulation or metabolic flow regulation at normal coronary pressures. This redundancy can, however, be unmasked by stressing the heart and evaluating flow regulation at reduced pressures distal to a coronary stenosis at rest or during exercise. Some of the candidates proposed and their role in metabolic resistance control and ischemia-induced vasodilation are summarized here (see Classic References, Feigl and Duncker and Bache).

Adenosine.

There has been a longstanding interest in the role of adenosine as a metabolic mediator of resistance artery control. It is released from cardiac myocytes when the rate of ATP hydrolysis exceeds its synthesis during ischemia. Its production and release also increase with myocardial metabolism. Adenosine has an extremely short half-life (<10 seconds) as a result of its rapid inactivation by adenosine deaminase. It binds to A_2 receptors on vascular smooth muscle, increases cAMP, and opens K_{ATP} and intermediate calcium-activated potassium channels.[6,8] Adenosine has a differential effect on coronary resistance arteries, primarily dilating vessels smaller than 100 μm.[4] Although adenosine has no direct effect on larger resistance arteries and conduit arteries, these dilate through endothelium-dependent vasodilation from the concomitant increases in local shear stress as arteriolar resistance falls.[3] Despite the attractiveness of adenosine as a local metabolic control mechanism, substantial in vivo experimental data now demonstrate convincingly that it is not required for adjusting coronary flow to increases in metabolism or autoregulation.[6] However, adenosine may contribute to vasodilation during hypoxia as well as during acute exercise-induced myocardial ischemia distal to a stenosis.[2]

ATP-Sensitive K^+ Channels.

Coronary vascular smooth muscle K_{ATP} channels are tonically active, contributing to coronary vascular tone under resting conditions. Preventing K_{ATP} channel opening with glibenclamide causes constriction of arterioles smaller than 100 μm, reduces coronary flow, and accentuates myocardial ischemia distal to a coronary stenosis by overcoming intrinsic vasodilator mechanisms.[2] The K_{ATP} channels can modulate both coronary metabolic and autoregulatory responses. It is a potentially attractive mechanism, because many of the other candidates for metabolic flow regulation (e.g., adenosine, NO, $beta_2$-adrenoreceptors, prostacyclin) are ultimately affected by blocking this pathway. K_{ATP} channel opening is likely a common effector rather than sensor of metabolic activity or autoregulatory adjustments in flow. Also, reductions in coronary flow observed after blocking K_{ATP} channel vasodilation may be pharmacologic, caused by vasoconstriction of the microcirculation that overcomes intrinsic vasodilator stimuli, as seen when other

potent vasoconstrictors (e.g., endothelin, vasopressin) are administered at pharmacologic doses.

Oxygen Sensing.

Although a potent coronary vasodilator stimulus, the role of local P_{O_2} in the regulation of arteriolar tone remains unresolved. Coronary flow increases in proportion to reductions in arterial oxygen content (reduced P_{O_2} or anemia), and there is a twofold increase in perfused capillary density in response to hypoxia. The underlying mechanism may involve the release of NO and ATP (which stimulates vascular endothelial P2 receptors to produce NO) from red blood cells, when intravascular P_{O_2} levels drop.[1,2] Studies demonstrating a direct effect of oxygen on metabolic or autoregulatory adjustments are lacking, however, and the vasodilator response to reduced arterial oxygen delivery may simply reflect the close relation between myocardial metabolism and flow.

Acidosis.

Arterial hypercapnia and acidosis are potent stimuli shown to produce coronary vasodilation independent of hypoxia. Whereas their precise role in the local regulation of myocardial perfusion remains unclear,[1] it seems reasonable that some of the vasodilation occurring with increased myocardial metabolism could arise from increased myocardial carbon dioxide (CO_2) production and tissue acidosis in the setting of acute ischemia.

Right Coronary Artery Flow

Although the general concepts of coronary flow regulation developed for the left ventricle apply to the right ventricle, there are differences related to the extent of the right coronary artery supply to the right ventricular (RV) free wall. This has been studied in dogs, in which the right coronary artery (RCA) is a nondominant vessel.[6] In terms of coronary flow reserve, arterial pressure supplying the RCA substantially exceeds RV pressure, minimizing the compressive determinants of coronary reserve. RV oxygen consumption is lower than LV consumption, and coronary venous oxygen saturations are higher than in the left coronary circulation. Because there is considerable oxygen extraction reserve, coronary flow decreases as pressure is reduced and oxygen delivery is maintained by increased extraction. These differences appear specific to the RV free wall. In humans, in whom the RCA is dominant and supplies much of the inferior left ventricle, factors affecting flow regulation to the LV myocardium are likely to predominate.

Physiologic Assessment of Coronary Artery Stenoses

The physiologic assessment of stenosis severity is a critical component of the management of patients with obstructive epicardial CAD[10] (**see Chapter 61**). Epicardial artery stenoses arising from atherosclerosis increase coronary resistance and reduce maximal myocardial perfusion. Abnormalities in coronary microcirculatory control also can contribute to causing myocardial ischemia in many patients. Separating the role of a stenosis from coronary resistance vessels can be accomplished by simultaneously assessing coronary flow and distal coronary pressure using intracoronary transducers currently available for clinical care[11,12] (**see Chapter 62**).

Stenosis Pressure-Flow Relation

The angiographically visible epicardial coronary arteries are normally able to accommodate large increases in coronary flow without producing any significant pressure drop and thus serve a conduit function to the coronary resistance vasculature. This changes dramatically in CAD, in which the epicardial artery resistance becomes dominant. This fixed component of resistance increases with stenosis severity and limits maximal myocardial perfusion.

As a starting point, it is helpful to consider the idealized relation among stenosis severity, pressure drop, and flow, as validated in animals as well as in humans studied under circumstances where diffuse atherosclerosis and risk factors that can impair microcirculatory resistance vessel control are minimized. **Fig. 57.12** summarizes the major determinants of stenosis energy losses. The relation between pressure drop across a stenosis and coronary flow for stenoses between 30% and 90% diameter reduction can be described using the Bernoulli principle. The total pressure drop across a stenosis is governed by three hydrodynamic factors—viscous losses, separation losses, and turbulence—although the last usually is a relatively minor component of pressure loss. The most important determinant of stenosis resistance for any given level of flow is the minimum lesional cross-sectional area within the stenosis (see Classic References, Klocke, 1983). Because resistance is inversely proportional to the square of the cross-sectional area, small dynamic changes in luminal area caused by thrombi or vasomotion in asymmetric lesions (where vascular smooth muscle can relax or constrict in a portion of the stenosis) lead to major changes in the stenosis pressure-flow relation and reduce maximal perfusion during vasodilation. Separation losses determine the curvilinearity or "steepness" of the stenosis pressure-flow relation and become increasingly important as stenosis severity or flow rate increases. Stenosis length and changes in cross-sectional area distal to the stenosis are relatively minor determinants of resistance for most coronary lesions.

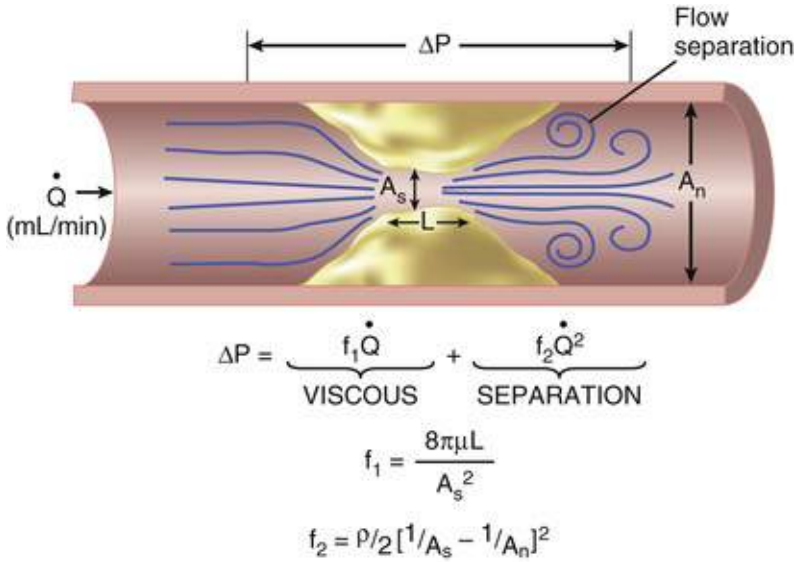

FIGURE 57.12 Fluid mechanics of a stenosis. The pressure drop across a stenosis can be predicted by the Bernoulli equation. It is inversely related to the minimum stenosis cross-sectional area and varies with the square of the flow rate as stenosis severity increases. A_n, Area of the normal segment; A_s, area of the stenosis; f_1, viscous coefficient; f_2, separation coefficient; L, stenosis length; μ, viscosity of blood; ρ, density of blood; ΔP, pressure drop; Q̇, flow.

Diffuse abluminal outward remodeling with thickening of the arterial wall is common in coronary atherosclerosis but does not alter the pressure-flow characteristics of the stenosis for a given intraluminal geometry. By contrast, diffuse inward remodeling effectively reduces minimal lesion area along the length

of the vessel and can lead to underestimation of stenosis severity using relative diameter or area measurements (**see Chapter 20**) and at the same time can contribute to a significant longitudinal pressure drop that also reduces maximum perfusion.[10]

Stenosis pressure drop and resistance increase exponentially as minimum lesional cross-sectional area decreases (**Fig. 57.13A, B**). This reflects that the pressure drop becomes flow dependent and varies with the square of the flow or flow velocity. As a result, the instantaneous stenosis resistance progressively increases during vasodilation. This becomes particularly important in determining the stenosis pressure-flow behavior for severely narrowed arteries, leading to a situation in which small reductions in luminal area result in large reductions in poststenotic coronary pressure that limit maximum coronary perfusion of the distal microcirculation.

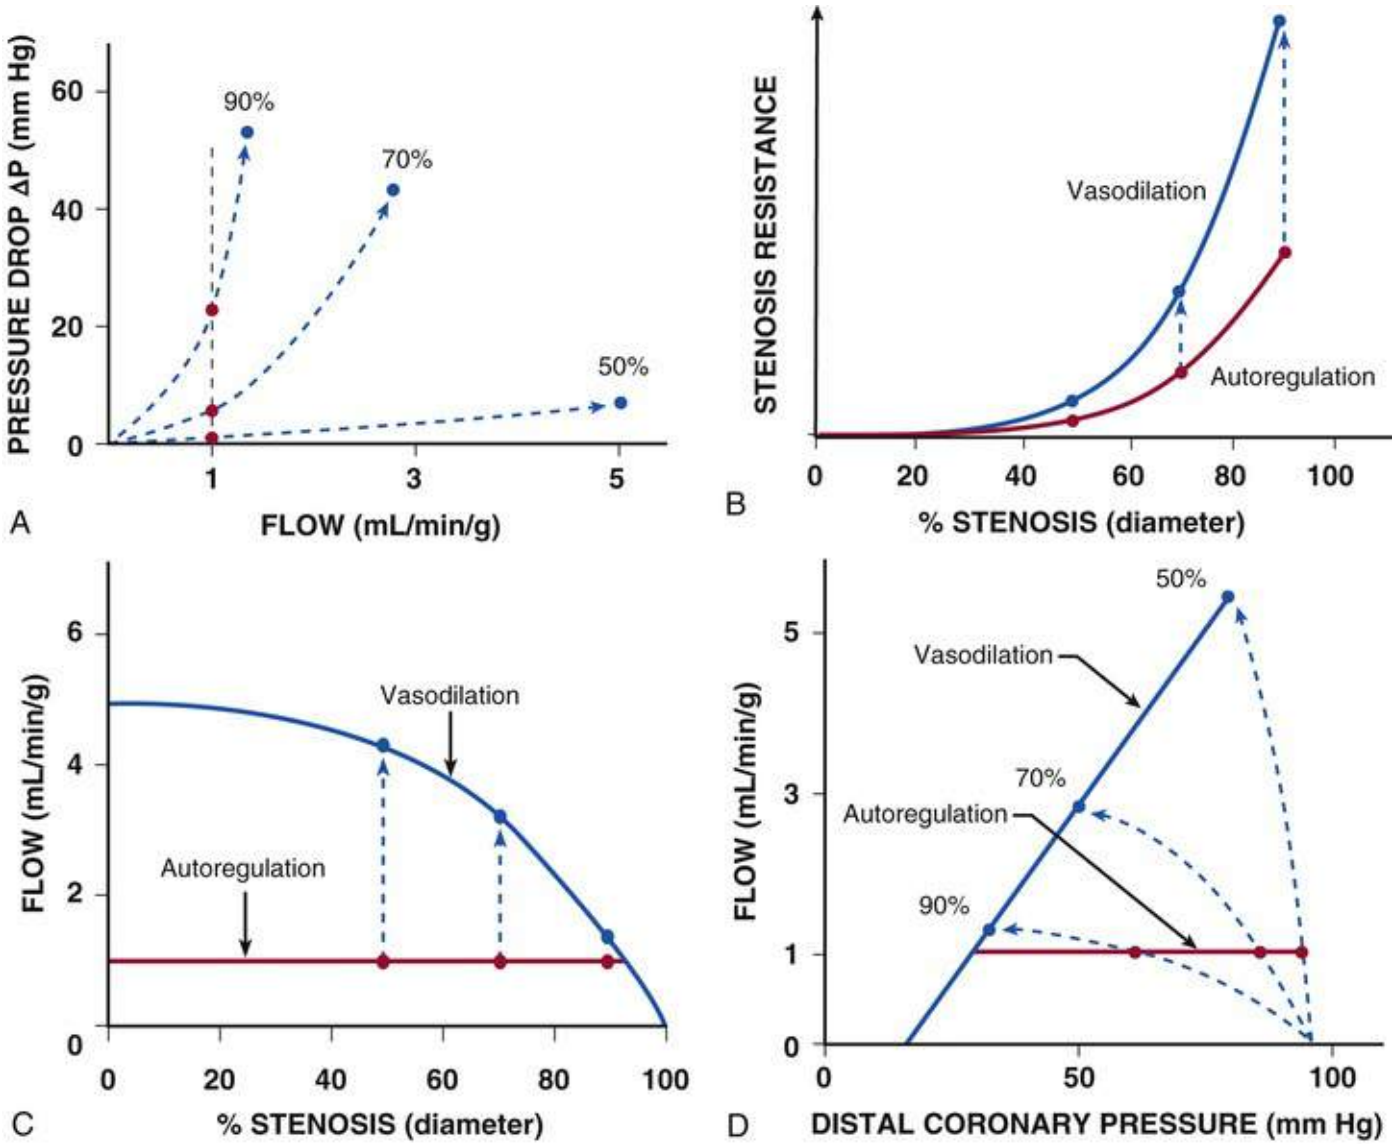

FIGURE 57.13 Interrelation of the epicardial artery stenosis pressure-flow relation **(A)**, stenosis resistance at the autoregulated resting and maximally vasodilated flow **(B)**, absolute coronary flow reserve **(C)**, and the distal coronary pressure-flow relation **(D)**. *Red circles and lines* depict resting flow, and *blue circles and lines* show maximal vasodilation for stenoses of 50%, 70%, and 90% diameter reduction. As shown in **A**, the stenosis pressure-flow relation becomes extremely nonlinear as stenosis severity increases. Thus the instantaneous resistance of the stenosis increases during vasodilation **(B)**. As a result of the nonlinear stenosis pressure-flow behavior, very little pressure drop across a 50% stenosis is seen, and distal coronary pressure and vasodilated flow remain near normal. By contrast, a 90% stenosis critically impairs flow and, because of the steepness of the stenosis pressure-flow relation, causes a marked reduction in distal coronary pressure.

Interrelation of Distal Coronary Pressure, Flow, and Stenosis Severity

Because maximum myocardial perfusion is ultimately determined by the coronary pressure distal to a stenosis, it is helpful to place the epicardial stenosis pressure-flow relation into the context of the coronary autoregulatory and vasodilated coronary pressure-flow relations. **Fig. 57.13C** summarizes the effects of a stenosis on resting and vasodilated flow as a function of percentage diameter reduction, when diffuse intraluminal narrowing is absent and coronary microcirculatory resistance is normal. Because of coronary autoregulation, flow remains constant as stenosis severity increases. Thus imaging resting perfusion cannot identify hemodynamically significant stenoses (**see Chapter 16**). By contrast, the maximally vasodilated pressure-flow relation is much more sensitive to detect increases in stenosis

severity. There is normally substantial coronary flow reserve, and flow can increase approximately five times the resting flow values. As illustrated in **Fig. 57.13D**, there is no significant pressure drop across a stenosis (ΔP) or stenosis-related alteration in maximal myocardial perfusion until stenosis severity exceeds a 50% diameter reduction (cross sectional area reduction of 75%). As stenosis severity exceeds 50%, the curvilinear coronary stenosis pressure-flow relation steepens, and increases in stenosis resistance are accompanied by concomitant increases in ΔP across the stenosis (**Fig. 57.13A**). This reduces distal coronary pressure, the major determinant of perfusion to the microcirculation, and maximum vasodilated flow (and coronary flow reserve) decreases. A critical stenosis, one in which subendocardial flow reserve is completely exhausted at rest, usually develops when stenosis severity exceeds 90%. Under these circumstances, pharmacologic vasodilation of subepicardial resistance vessels results in a reduction in distal coronary pressure that actually redistributes flow away from the subendocardium, leading to a "transmural steal" phenomenon.[6]

Concept of Maximal Perfusion and Coronary Reserve

Gould[10] originally proposed the concept of coronary reserve. With technological advances, it has become possible to characterize this in humans using invasive catheter-based measurements of intracoronary pressure and flow (**Fig. 57.14**) (**see Chapter 62**), as well as with noninvasive imaging of myocardial perfusion with positron emission tomography (PET), single-photon emission tomography (SPECT), and more recently, cardiac magnetic resonance (CMR) (**Chapters 16 and 17**). With physiologically based approaches to quantify perfusion and coronary pressure, it also has become increasingly apparent that abnormalities in coronary microcirculatory control contribute to the functional significance of isolated epicardial artery stenoses in many patients with CAD, as well as leading to impaired coronary flow responses in the presence of normal coronary arteries. Because of these complexities, multiple complementary approaches frequently are required to define limitations in myocardial perfusion that arise from stenosis severity versus abnormalities of the coronary microcirculation. The three major indices currently used to quantify coronary flow reserve are absolute, relative, and fractional flow reserve (**Fig. 57.15**).

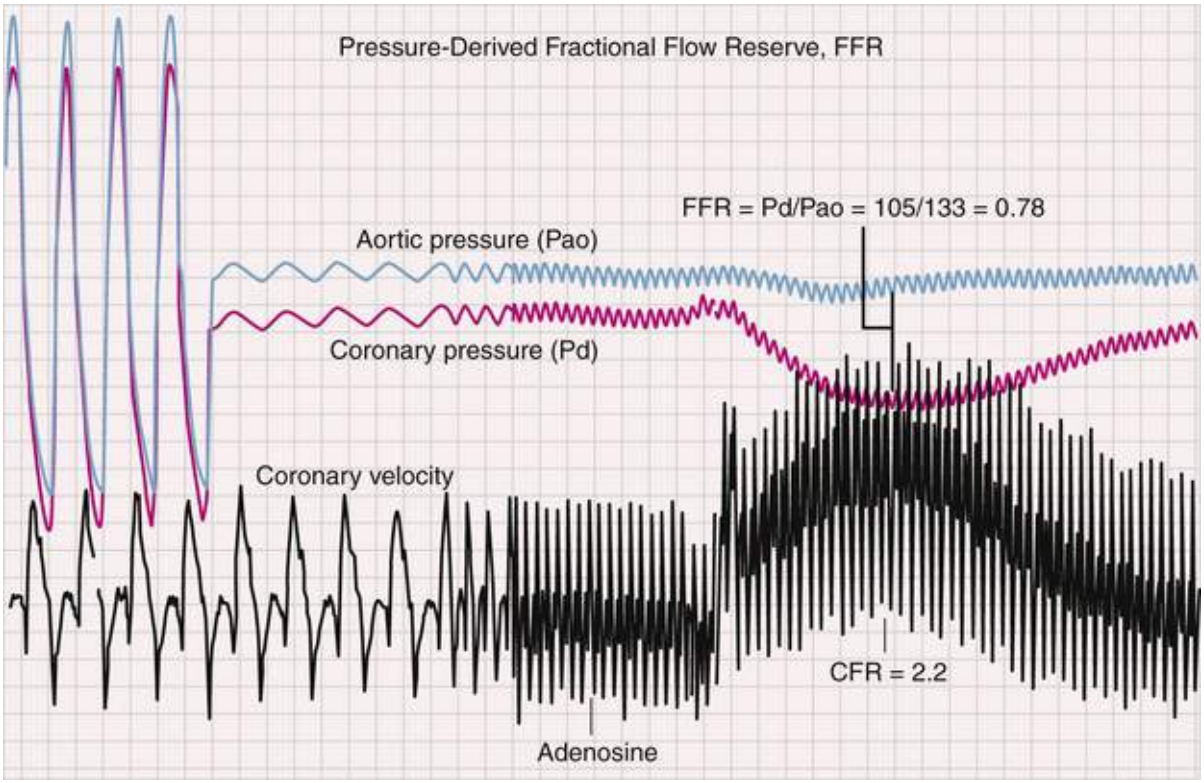

FIGURE 57.14 Coronary pressure and flow velocity tracings in a patient with an intermediate stenosis. After intracoronary adenosine administration, flow velocity transiently increases and mean distal coronary pressure (Pd) falls. Absolute coronary flow reserve (CFR) is the ratio of peak flow to resting flow. FFR is the ratio of Pd/Pao (distal coronary pressure divided by mean aortic pressure).

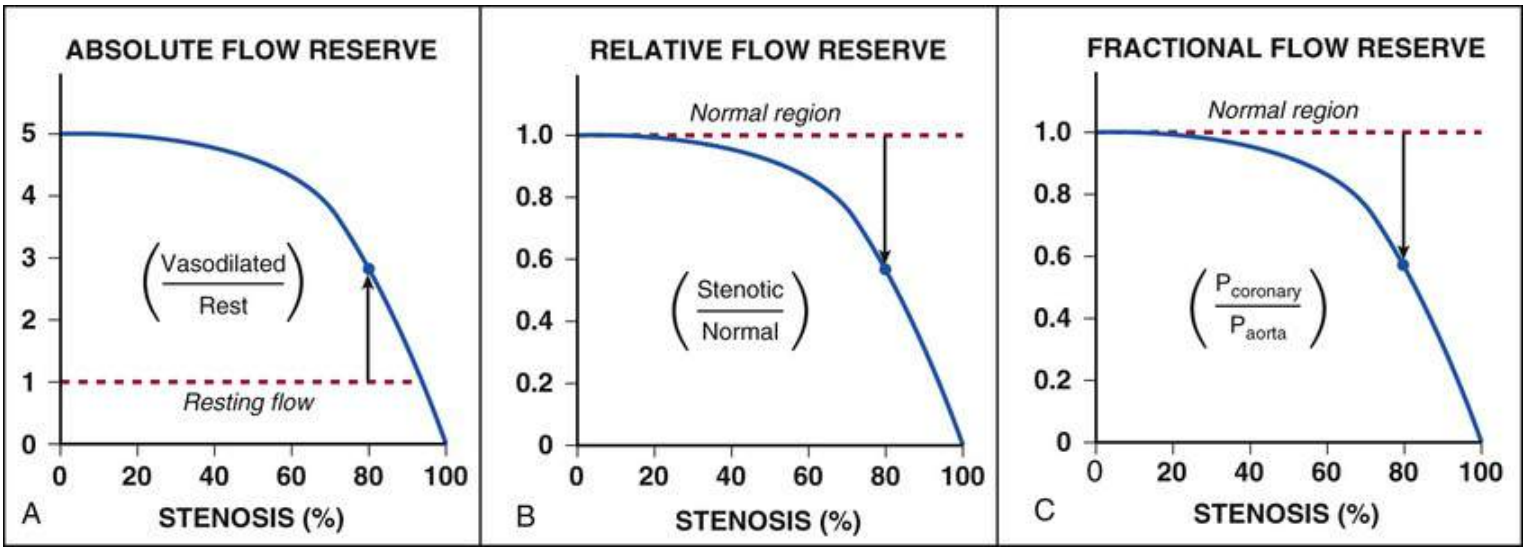

FIGURE 57.15 Interrelation of absolute flow reserve, relative flow reserve, and fractional flow reserve (FFR). **A,** Absolute flow reserve is the ratio of coronary flow during vasodilation to the resting value. It can be obtained with invasive measurements of intracoronary flow velocity or quantitative kinetic perfusion measurements with PET. **B,** Relative flow reserve compares maximal vasodilated flow in a stenotic region with an assumed normal region in the same heart and is most commonly measured with perfusion imaging during stress. **C,** FFR is conceptually similar to relative flow reserve and assesses maximal flow indirectly from coronary pressure measurements distal to a stenosis during vasodilation. Absolute flow reserve reflects the summed effects of a stenosis as well as abnormalities in the coronary microcirculation. By contrast, relative flow reserve and FFR identify the relative effects of a stenosis compared with a normal vessel. They assume maximal vasodilatory responses of coronary resistance vessels and cannot identify the potential contribution of abnormalities in microcirculatory resistance control to the development of myocardial ischemia.

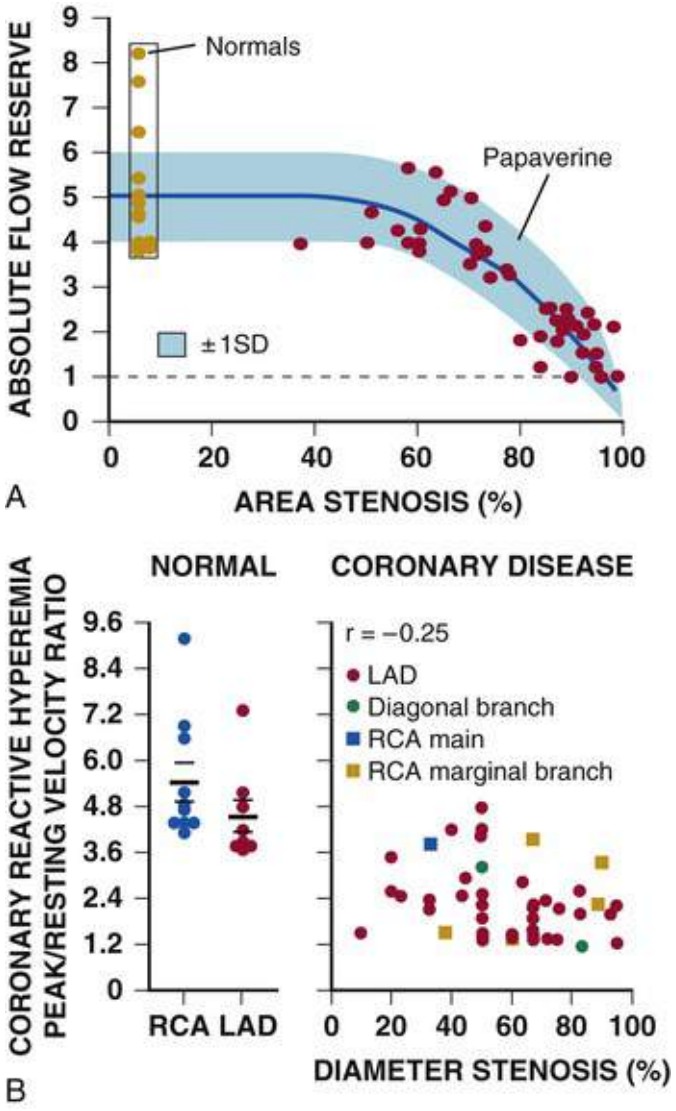
Absolute Flow Reserve

Initial approaches to assess functional stenosis severity focused on assessing the relative increase in flow after ischemic vasodilation (reactive hyperemic response after transient occlusion of the coronary artery) or pharmacologic vasodilation of the microcirculation with intracoronary papaverine, adenosine, or intravenous dipyridamole. Absolute flow reserve can be quantified using intracoronary Doppler velocity or thermodilution flow measurements, as well as by quantitative approaches to image absolute tissue perfusion based on PET and magnetic resonance imaging (MRI). It is expressed as the ratio of maximally vasodilated flow to the corresponding resting flow value in a specific region of the heart and quantifies the ability of flow to increase above the resting value (**Fig. 57.15A**). Clinically important reductions in maximum flow correlating with stress-induced ischemia on SPECT generally are associated with absolute flow reserve values below 2 (**see Chapter 16**). Absolute flow reserve is not only altered by factors that affect maximal coronary flow (e.g., stenosis severity, impaired microcirculatory control, arterial pressure, heart rate) but also by the corresponding resting flow value. As noted previously, resting flow can vary with hemoglobin content, baseline hemodynamics, and the resting oxygen extraction. Reductions in absolute flow reserve, therefore, can arise from inappropriate elevations in resting coronary flow as well as from reductions in maximal perfusion.

In the absence of diffuse atherosclerosis or LV hypertrophy, absolute flow reserve in conscious humans is similar to that measured in animals, with vasodilated flow reaching four to five times the value at rest. Thus, fairly good reduplication of the idealized relation between stenosis severity and absolute flow reserve occurs in patients with isolated one- or two-vessel CAD (**eFig. 57.2A**) with intracoronary papaverine–induced vasodilation. By contrast, abnormalities in the coronary microcirculation as well as uncertainty in stenosis geometry or diffuse atherosclerosis leads to considerably more variability of the observed relation between stenosis severity and absolute flow reserve in patients with more extensive disease (**eFig. 57.2B**). Part of this reflects that patients with risk factors for CAD such as hypercholesterolemia and no significant coronary luminal narrowing have microcirculatory impairment in flow or attenuated vasodilator responsiveness, with absolute flow reserve using PET being lower than in normal individuals. Thus a significant limitation of absolute flow reserve measurements is that the importance of an epicardial stenosis cannot be dissociated from changes caused by functional abnormalities in the microcirculation that are common in patients (e.g., hypertrophy, impaired endothelium-dependent vasodilation). Likewise, recent studies have also identified abnormalities in coronary flow regulation in metabolic syndrome.[13]



EFIGURE 57.2 Absolute coronary flow reserve as a function of stenosis severity in patients. **A,** Measured absolute flow reserve after intracoronary papaverine vasodilation in single-vessel disease without hypertrophy demonstrates a good correlation with values predicted theoretically. **B,** Absolute flow reserve assessed using intraoperative epicardial Doppler flow measurements after onset of reactive hyperemia to a 20-second occlusion in patients with diffuse multivessel coronary artery disease. For all vessels, there is a poor relation with stenosis severity. This reflects variability in stenosis severity with visual interpretation, as well as abnormal microcirculatory responses to ischemia and multiple risk factors for impaired endothelial function. LAD, Left anterior descending artery; RCA, right coronary artery. (**A,** Modified from Wilson RF, Marcus ML, White CW. Prediction of the physiologic significance of coronary arterial lesions by quantitative lesion geometry in patients with limited coronary artery disease. Circulation 1987;75:723; **B,** modified from White CW et al. Does visual interpretation of the coronary arteriogram predict the physiologic importance of a coronary stenosis? N Engl J Med 1984;310:819.)

Relative Flow Reserve

Relative coronary flow reserve measurements are the cornerstone of noninvasive identification of hemodynamically important coronary stenoses using nuclear perfusion imaging (**see Chapter 16**). In this approach, relative differences in regional perfusion (per gram of tissue) are assessed during maximal pharmacologic vasodilation or exercise stress and expressed as a fraction of flow to normal regions of the heart (**see Fig. 57.15B**). This approach compares relative perfusion states under the same hemodynamic conditions and is fairly insensitive to variations in mean arterial pressure, heart rate, and preload. An alternative approach uses invasive absolute flow reserve measurements and derives relative flow reserve by dividing absolute flow reserve in a stenotic vessel by absolute flow reserve in a remote normally perfused territory.[11]

Although widely used to identify hemodynamically significant stenoses, significant limitations arise in using imaging to quantify relative flow reserve. First, conventional SPECT imaging requires a normal reference segment within the left ventricle for comparison. Because of this, relative flow reserve measurements cannot accurately quantify stenosis severity when diffuse abnormalities in flow reserve related to either balanced multivessel CAD or impaired microcirculatory vasodilation are present. Large differences in relative vasodilated flow are required to detect SPECT perfusion differences because nuclear tracers become diffusion limited, and their myocardial uptake fails to increase proportionally with increases in vasodilated flow. As a result, differences in tracer deposition will variably underestimate the actual relative difference in perfusion. This problem can be overcome with use of PET tracers of perfusion and appropriate kinetic modeling to quantify flow. Lastly, although prognostic data related to the perfusion deficit size are available, no imaging studies have been conducted to evaluate the quantitative severity of the stress or vasodilated flow reduction as a continuous outcome measure; conceptually, however, this should be similar to fractional flow reserve.

Fractional Flow Reserve

Considerable focus has turned toward invasive point-of-care approaches that use pressure measurements made distal to a coronary stenosis as an indirect index of stenosis severity[11] (**see Fig. 57.14**). This technique, pioneered by Pijls and Sels,[14] is based on the principle that the distal coronary pressure measured during vasodilation is directly proportional to maximum vasodilated perfusion (**see Fig. 57.15C**). *Fractional flow reserve* (FFR) is an indirect index determined by measuring the driving pressure for microcirculatory flow distal to the stenosis (distal coronary pressure minus coronary venous pressure) relative to the coronary driving pressure available in the absence of a stenosis (mean aortic pressure minus coronary venous pressure). The approach assumes linearity of the vasodilated pressure-flow relation (which is known to be curvilinear at reduced coronary pressure[15]) and usually assumes that coronary venous pressure is zero. This results in the simplified clinical FFR index of mean distal coronary pressure/mean aortic pressure (Pd/Pao). Although derived, the measurements are conceptually similar to those of relative coronary flow reserve because they only rely on minimum mean coronary pressure measurements during intracoronary vasodilation and compare stenotic with normal regions under similar hemodynamic conditions. They are attractive for clinical use in that they can immediately assess the physiologic significance of an intermediate stenosis to help guide decisions regarding the need for percutaneous coronary intervention and are unaffected by alterations in resting flow (**see Chapter 62**). Similarly, because they require only vasodilated coronary pressure determinations, FFR can be used to assess the functional effects of a residual lesion immediately after percutaneous coronary intervention (PCI).

A significant advantage of FFR is the availability of now-considerable prognostic information. The 15-year follow-up of a large prospective randomized study demonstrates that coronary lesions having FFR measurements greater than 0.75 are associated with excellent outcomes with deferred rather than prophylactic intervention in patients with stable ischemic heart disease[16] (**Fig. 57.16**). Physiologically guided PCI using FFR versus angiographic criteria was safe and cost-effective and reduced the number of stents required to treat patients with multivessel CAD. Furthermore, a strategy based on assessing the physiologic severity of stenoses was accompanied by a significant reduction in major adverse cardiac events at 1 year (13.2% using FFR versus 18.3% in angiography-guided treatment)[17] (**eFig. 57.3**). In subsequent trials, the same investigators showed that FFR-guided coronary intervention provided additional benefit over optimal medical therapy alone.[18] Thus, patients with a FFR below 0.80 who underwent a coronary intervention in addition to optimal medical therapy displayed a reduction in major

adverse cardiac events (**Fig. 57.17**), which was principally driven by a lesser need for urgent revascularization triggered by a myocardial infarction (MI) or evidence of ischemia on an electrocardiogram (ECG).[18] Collectively, these studies support the importance of functional stenosis severity in determining prognosis and the use of a physiologic-guided approach to determining the need for PCI in the patient stable ischemic heart disease.

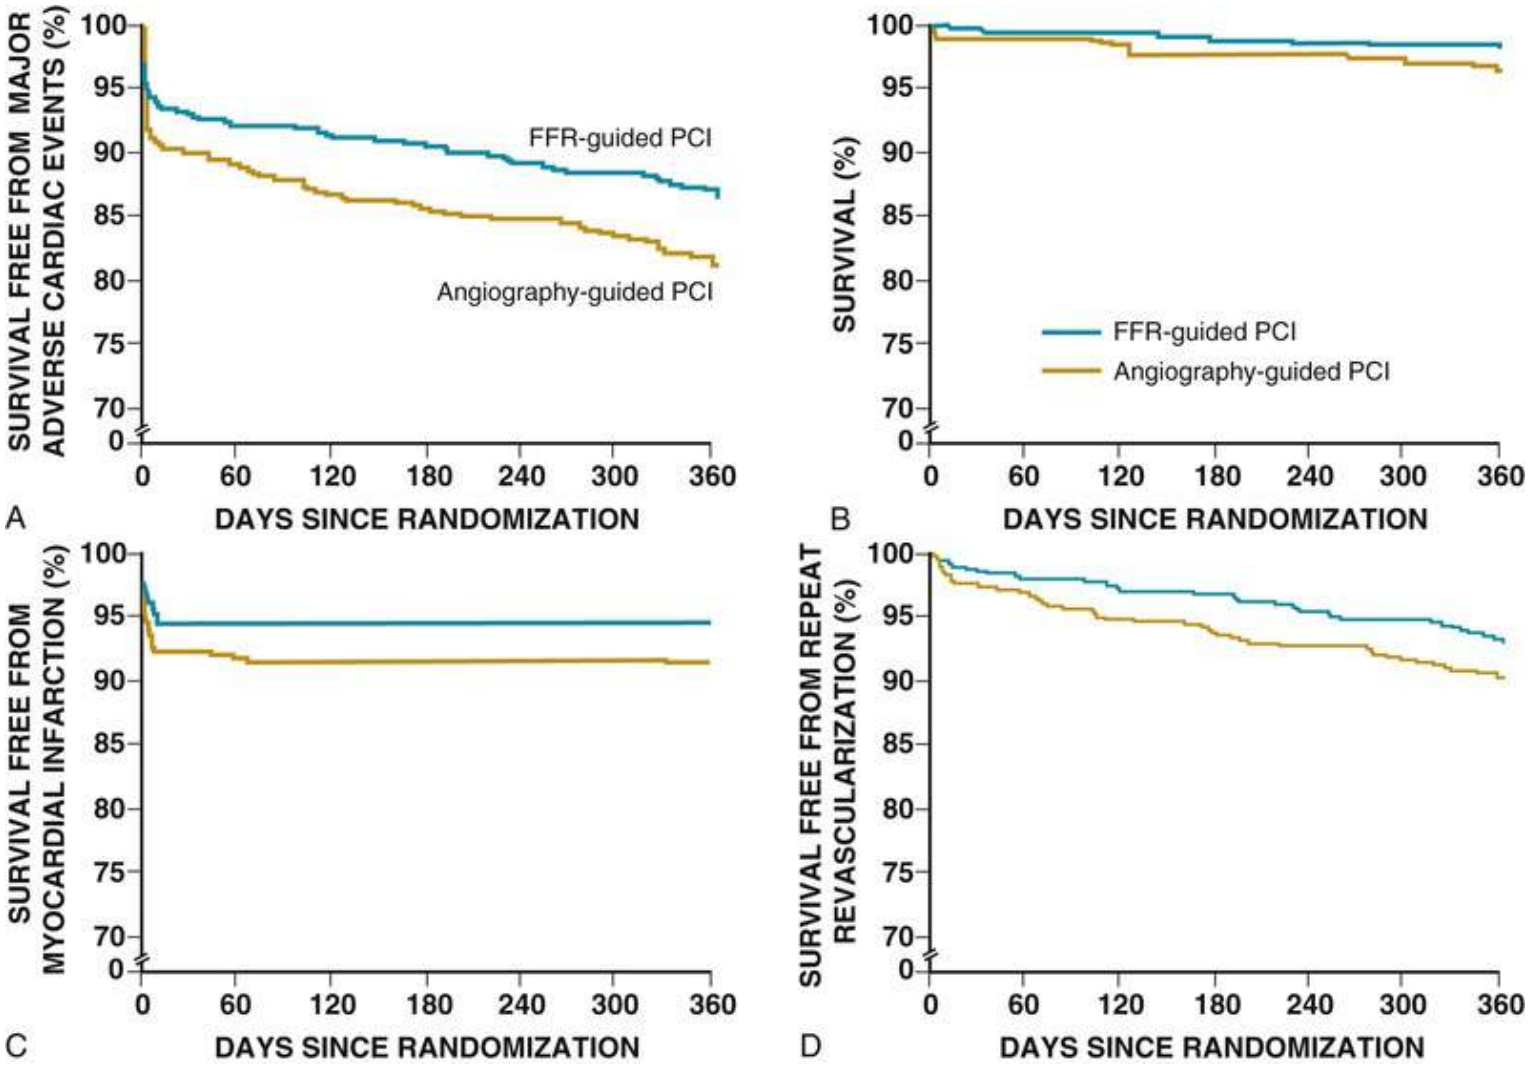
FIGURE 57.17 Patients with stable coronary artery disease with a fractional flow reserve (FFR) value of less than 0.80 randomized to percutaneous coronary intervention (PCI) plus optimal medical therapy (MT) displayed lower rates of the combined endpoint of death, myocardial infarction, and urgent revascularization than patients randomized to optimal medical therapy only. Patients receiving FFR-guided PCI had an event rate similar to those in a registry who had no lesion with FFR less than 0.80 at enrollment. HR, Hazard ratio; CI, confidence interval. (From De Bruyne B, Fearon WF, Pijls NH, et al. Fractional flow reserve–guided PCI for stable coronary artery disease. N Engl J Med 2014;371:1208.)



EFIGURE 57.3 Percutaneous coronary intervention (PCI) guided by assessing the physiologic significance of a coronary stenosis is associated with significant reductions in coronary events. Patients randomly assigned to an angiography-guided strategy based on stenosis severity using fractional flow reserve (FFR) had higher rates of the combined endpoint of death, myocardial infarction, and repeat revascularization than did patients in whom management was guided by a FFR **(A).** Individual endpoint trends showed no difference in mortality **(B)** but higher rates of survival free from myocardial infarction **(C)** and survival free from repeat revascularization **(D)** in patients with the FFR-guided strategy. (From Tonino PA, De Bruyne B, Pijls NH, et al. Fractional flow reserve versus angiography for guiding percutaneous coronary intervention. N Engl J Med 2009;360:213.)

Unfortunately, FFR can assess only the functional significance of epicardial artery stenoses and cannot assess limitations in myocardial perfusion that arise from abnormalities in microcirculatory flow reserve in coronary resistance vessels. While simple, FFR measurements are also critically dependent on achieving maximal pharmacologic vasodilation (underestimating stenosis severity if vasodilation is submaximal at the time of measurement). In addition, ignoring the backpressure to coronary flow by assuming that it is equal to zero and ignoring curvilinearity of the pressure-flow relation will cause the FFR to underestimate the physiologic significance of a stenosis.[15] This is particularly problematic at low coronary pressures and in assessing the functional significance of coronary collaterals, where venous pressure needs to be considered. Lastly, inserting the pressure wire across a stenosis can lead to artifactual overestimation of stenosis severity. This error can be caused by the reduction in effective intralesional area in the presence of diffuse disease or a severe stenosis, as well as placement that results in partial occlusion of small branch vessels. Despite these concerns and its invasive nature, determination of FFR is currently the most direct way to assess the physiologic significance of individual coronary lesions.

Advantages and Limitations of Coronary Flow Reserve Measurements.

Assessing qualitative perfusion differences with noninvasive imaging is useful because relative perfusion deficit size is an important determinant of prognosis. Although the clinical role of invasive measurements that quantify functional stenosis severity continues to evolve, measurement of FFR, available at the point of interventional care, has been demonstrated to affect postprocedural outcomes favorably at reduced cost. The need to use these measurements routinely in decision making for PCI in patients with stable ischemic heart disease may change in future clinical care guidelines.[11,12]

The major assumption common to all flow reserve measurements is that the administered pharmacologic vasodilator consistently achieves maximal vasodilation of the resistance vasculature in normal individuals as well as in patients with atherosclerotic disease and impaired endothelial function. The reductions in absolute flow reserve in humans with microvascular disease and angiographically insignificant stenoses (**eFig. 57.2B**), as well as variability in quantitative perfusion measurements with normal epicardial arteries and coronary risk factors, indicate that this may not always be the case. The extent to which this variability is related to structural (e.g., caused by regional hypertrophy or vascular remodeling) versus functional (e.g., altered microcirculatory vasodilator response versus impaired endothelium-dependent vasodilation) abnormalities in the microcirculation remains unclear (see later). A second limitation is that currently available approaches can measure only coronary flow reserve averaged across the entire wall of the heart. This is because they are based on invasive epicardial coronary measurements (**see Chapter 62**) or, in the case of imaging (e.g., SPECT), have insufficient spatial resolution to assess transmural variations in flow (**Chapter 16**). An imaging technique that could assess the physiologic significance of a stenosis in the subendocardial layers would be a major advance, because this region is most severely affected by an epicardial stenosis. This is now feasible with CMR (**see Chapter 17**).

Pathophysiologic States Affecting Microcirculatory Coronary Flow Reserve

Various pathophysiologic states can accentuate the effects of a fixed-diameter coronary stenosis and may precipitate subendocardial ischemia during stress in the presence of normal coronary arteries.[19] Thus it is important to consider measurements of stenosis severity in the context of coexisting abnormalities of coronary arterial resistance vessel control. In the former case, treatment will be directed at the epicardial stenosis, whereas in the latter, medical therapies designed to improve abnormalities in resistance vessel control will be required. The prognostic importance of abnormalities in coronary resistance vessel control is underscored by emerging data in women evaluated for chest pain thought to be of ischemic origin.[20] Abnormalities in coronary flow reserve and endothelium-dependent vasodilation are common in women with insignificant epicardial coronary disease, produce metabolic evidence of myocardial ischemia as assessed by magnetic resonance spectroscopy (**see Chapter 17**), and negatively affect prognosis.[21] Common factors affecting microcirculatory resistance control independent of coronary stenosis severity in patients are LV hypertrophy, coronary microvascular disease, and impaired NO-mediated resistance vessel vasodilation, which is the result of many of the risk factors for CAD.

Left Ventricular Hypertrophy.

The effects of hypertrophy on coronary flow reserve are complex and must be seen in terms of the absolute flow level (e.g., measured with intracoronary Doppler probe) as well as the flow per gram of myocardial tissue[22] (**Fig. 57.18**). With acquired hypertrophy, resting flow per gram of myocardium remains constant, but the increase in LV mass necessitates an increase in the absolute level of resting flow (mL/min) through the coronary artery (see Classic References, Bache). In terms of maximal perfusion, pathologic hypertrophy does not result in appreciable vascular proliferation (as opposed to physiologic hypertrophy produced by exercise training), and coronary resistance vessels remain essentially unchanged. Since maximum absolute flow (mL/min) during vasodilation remains unchanged, the increase in LV mass in the absence of vascular proliferation reduces the maximum perfusion per gram of myocardium. The net effect of LV hypertrophy is that coronary flow reserve at any given coronary arterial pressure is reduced in a manner that is inversely related to the change in LV mass. For example, in the absence of a change in mean aortic pressure, a twofold increase in LV mass, as with severe LV hypertrophy, can reduce absolute coronary flow reserve in a nonstenotic artery from 4 to 2. This will increase the functional severity of any anatomic degree of coronary artery narrowing and can even precipitate subendocardial ischemia with normal coronary arteries.

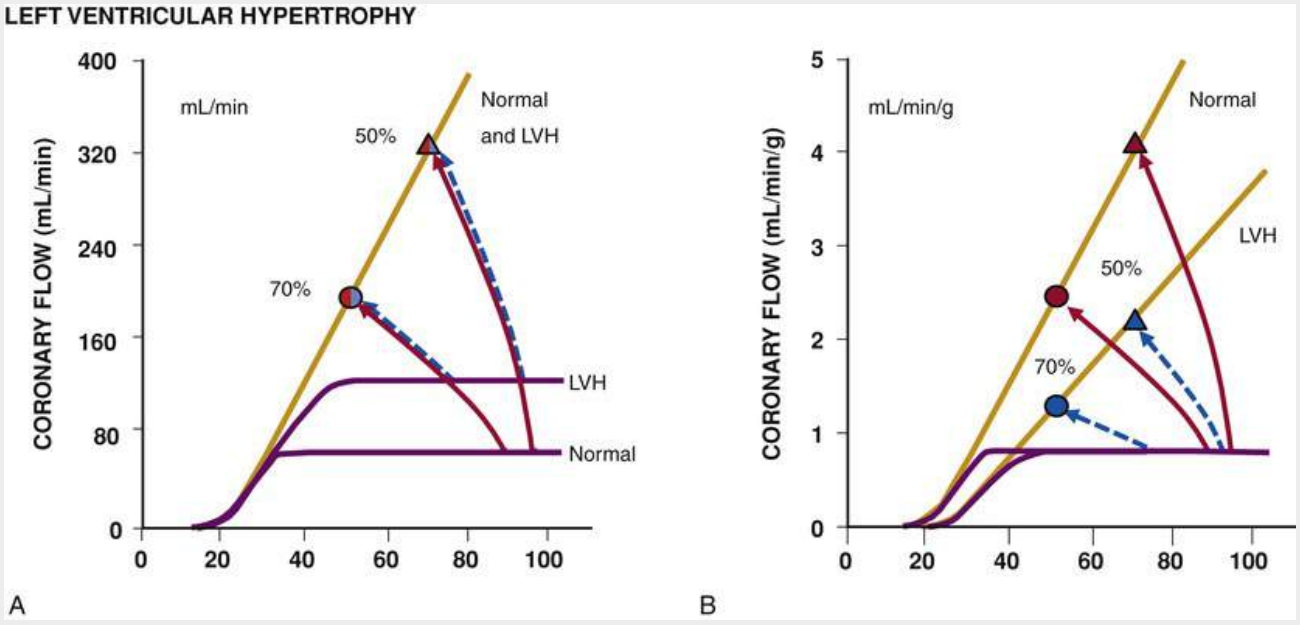


FIGURE 57.18 Effects of hypertrophy on absolute flow (mL/min) and flow per gram of tissue (mL/min/g). With acquired hypertrophy, myocardial mass increases without proliferation of the microcirculatory resistance arteries. **A**, The increase in left ventricular (LV) mass causes a proportional increase in absolute flow at rest (*purple lines*), while the maximum absolute flow per minute during vasodilation (*gold lines*) remains unchanged. **B,** When tissue perfusion is assessed using flow per gram of myocardium (e.g., as obtained using PET), the maximum flow per gram of tissue (*gold lines*) falls inversely with the increase in LV mass. By contrast, the resting flow per gram of myocardium (*purple lines*) remains constant, because the increase in absolute resting flow is proportional to the increase in LV mass. Regardless of whether absolute flow or flow per gram is measured, the net effect of these opposing actions is to decrease coronary flow reserve at any coronary pressure in LV hypertrophy (LVH). As a result of the reduction in microcirculatory reserve in the absence of a coronary stenosis, the functional significance of a 50% stenosis (*triangles*) in the hypertrophied heart could approach a more severe stenosis (in the example, 70%, *circles*) in normal myocardium. This can even lead to ischemia with normal coronary arteries during stress.

Some degree of LV hypertrophy is common in patients with CAD, and it probably contributes to reductions in coronary flow reserve that are independent of stenosis severity. The actual coronary flow reserve in hypertrophy will be critically dependent on the underlying cause of hypertrophy and its effects

on coronary driving pressure. A similar degree of hypertrophy caused by untreated systemic hypertension will be associated with a higher coronary flow reserve than in aortic stenosis, in which mean arterial pressure remains normal. Similarly, when hypertrophy results from systolic hypertension and increased pulse pressure is caused by reduced aortic compliance, the accompanying reduction in diastolic pressure can lower coronary reserve because myocardial perfusion occurs primarily in diastole.

Coronary Microvascular Disease and Dysfunction.

The effects of primary coronary microvascular dysfunction (**Fig. 57.19**) on reducing coronary flow reserve are somewhat similar to those of LV hypertrophy but differ in terms of the effect on maximum coronary flow. As with hypertrophy, flow per gram of myocardium will be normal at rest and reduced during pharmacologic vasodilation. In contrast to hypertrophy, absolute flow remains normal at rest in microvascular disease, and the absolute vasodilated flow is reduced. Because absolute flow across the stenosis during vasodilation is the major determinant of the pressure drop and thus of distal coronary pressure, a similar stenosis will have a smaller pressure gradient and higher distal pressure in a patient with microvascular disease than in a patient with LV hypertrophy. Abnormalities in microvascular vasodilation may be functional rather than structural and, as discussed later, can arise from cumulative coronary risk factors that lead to endothelial dysfunction.

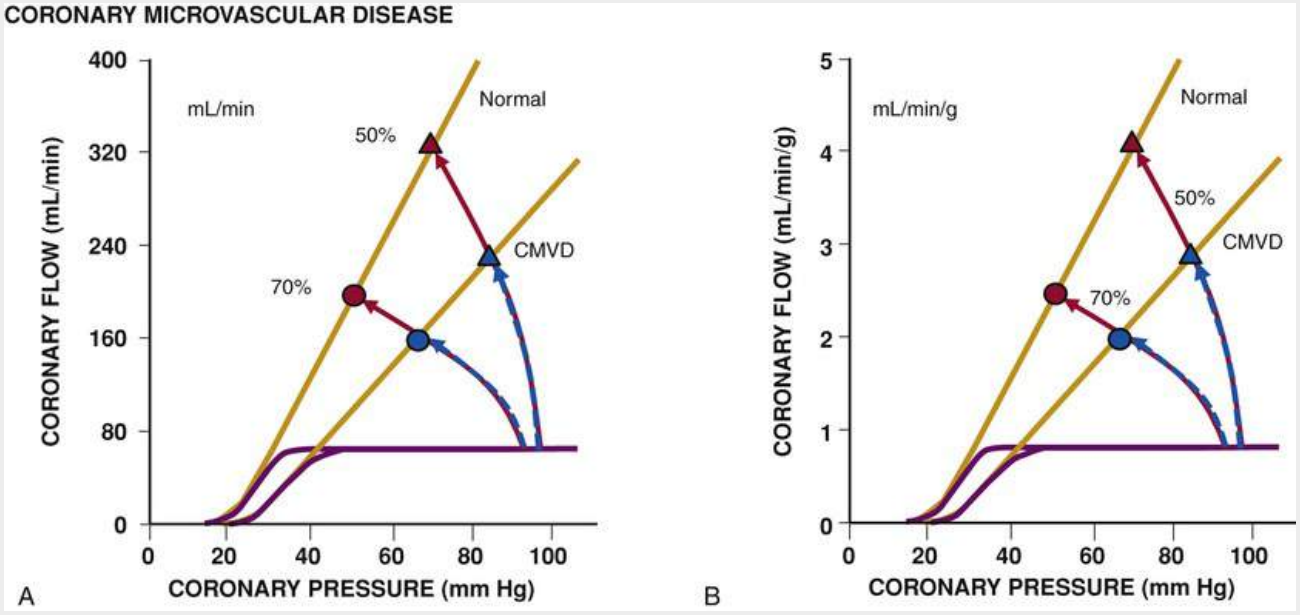

FIGURE 57.19 Effects of microvascular dysfunction on absolute flow (mL/min) and flow per gram of tissue (mL/min/g). In microvascular disease, resting flow and LV mass remain normal. Thus, under resting conditions (*purple lines*), absolute flow and flow per gram of tissue are similar in patients with microvascular disease compared with normal subjects. By contrast, during maximum vasodilation (*gold lines*) absolute flow **(A)** and flow per gram of tissue **(B)** both are reduced in microvascular disease, reflecting a functional or structural abnormality of coronary resistance vessels. CMVD, Coronary microvascular dysfunction.

Impaired Endothelium-Dependent Vasodilation in the Microcirculation.

Measurements of coronary flow reserve in humans with risk factors for atherosclerosis (**see Chapter 45**) are systematically lower than in normal individuals without coronary risk factors, underscoring the importance of functional abnormalities in microvascular control in determining coronary flow reserve.[23,24] Perturbations in microvascular control may arise from abnormal local resistance vessel control through impaired endothelium-dependent vasodilation arising from NO inactivation associated with risk factors for CAD. Experimental hypercholesterolemia markedly attenuates the dilation of

coronary arterioles in response to shear stress as well as pharmacologic agonists that stimulate NOS in the absence of epicardial stenoses (**Fig. 57.20**). This was reversed with L-arginine, suggesting that it reflects impaired NO synthesis or availability. CAD is associated with a shift from NO to the EDHF hydrogen peroxide (H_2O_2), which acts to compensate in part for the loss of NO.[5] This shift appears to be mediated by the sphingolipid ceramide (produced by neutral sphingomyelinase in patients with CAD), resulting in the endothelial production of reactive oxygen species, thereby reducing NO and increasing H_2O_2 levels[8] (**Fig. 57.21**).

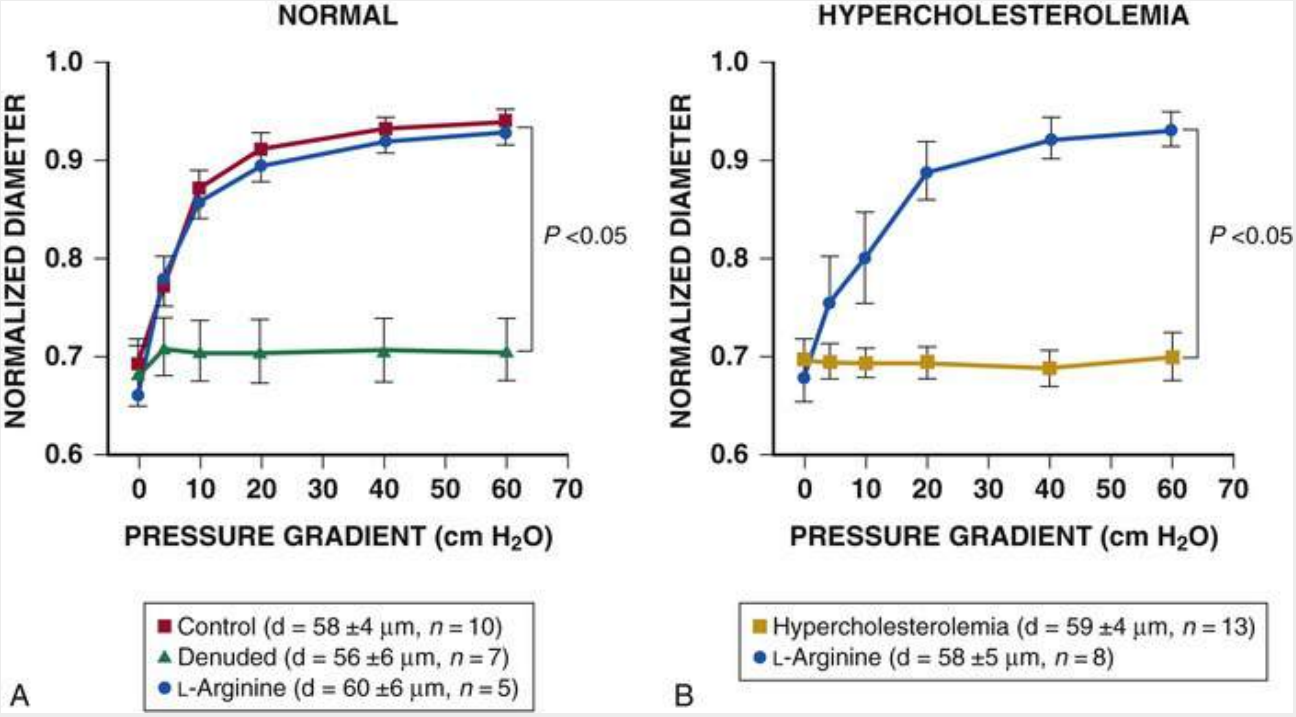

FIGURE 57.20 Flow-mediated vasodilation in coronary resistance arteries is abolished by dietary hypercholesterolemia in swine. **A,** In normal arterioles, increased flow (pressure gradient) elicits vasodilation that, similar to human vessels, is abolished by removing the endothelium (denuded). **B,** In animals with dietary hypercholesterolemia but no significant epicardial stenosis, flow-mediated vasodilation of arterioles is abolished. It was restored by administering L-arginine to increase NO production. Luminal diameters were normalized to the diameter at a luminal pressure of 60 cm H_2O in the presence of nitroprusside (10^{-4} M). Numbers of vessels (*n*) and average luminal diameter (d) with spontaneous tone in physiologic salt solution-albumin at 60 cm H_2O are shown. *Vertical bars* denote mean ±SEM. (Modified from Kuo L, Davis MJ, Cannon MS, et al. Pathophysiological consequences of atherosclerosis extend into the coronary microcirculation: restoration of endothelium-dependent responses by L-arginine. Circ Res 1992;70:465.)

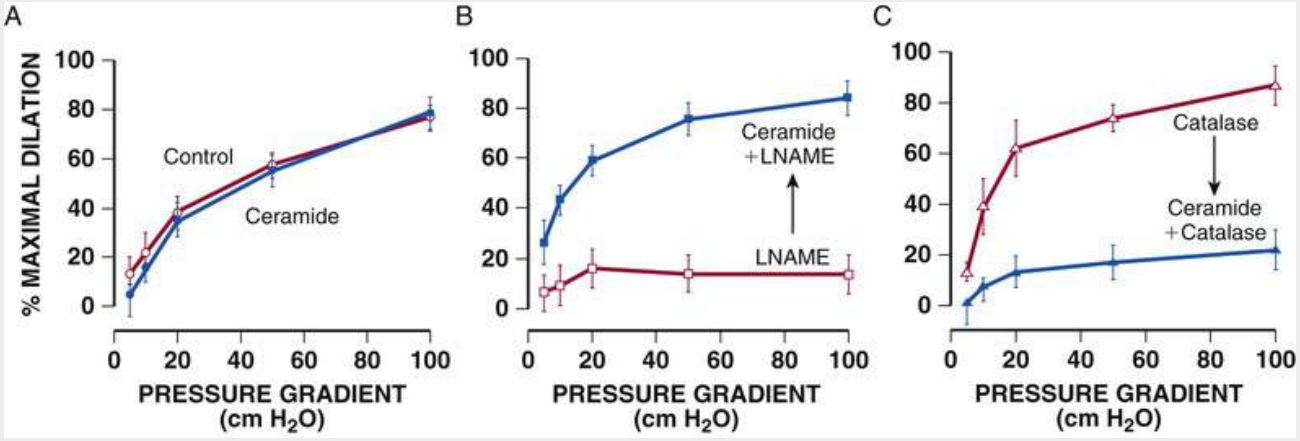

FIGURE 57.21 Effect of ceramide on flow-induced dilation (FID). Ceramide, a risk factor for coronary artery disease (CAD), inhibits neutral sphingomyelinase and increases mitochondrial hydrogen peroxide (H_2O_2) production. **A,** Magnitude of FID is not affected with overnight incubation of ceramide alone compared with vehicle-treated control. **B,** FID in healthy arterioles is reduced in the presence of nitric oxide (NO) synthase inhibition with N^{ω}-nitro-L-arginine methyl ester (LNAME) but is maintained if first preincubated with ceramide. **C,** Breakdown of H_2O_2 with catalase has minimal effect on FID in healthy arterioles but impairs FID in ceramide-treated arterioles. These data suggest that ceramide (which is increased in patients with CAD) may cause the shift in the FID mediator from NO to H_2O_2 in human coronary microvessels. *Vertical bars* denote mean ±SEM. (Modified from American Heart Association; Freed JK, Beyer AM, LoGiudice JA, et al. Ceramide changes the mediator of flow-induced vasodilation from nitric oxide to hydrogen peroxide in the human microcirculation. Circ Res 2014;115:525.)

These in vitro abnormalities in NO-mediated vasodilation can be functionally significant and can impair the ability of the heart to autoregulate coronary blood flow. **Fig. 57.22A** shows the effects of inhibiting NO on the coronary autoregulatory relation in normal dogs. Although resting blood flow is not altered, there is a marked increase in the coronary pressure at which intrinsic autoregulatory adjustments become exhausted, with flow beginning to decrease at a distal coronary pressure of 60 versus 45 mm Hg, approximately similar to the shift occurring in response to a twofold increase in heart rate. In vivo microcirculatory studies have demonstrated that inhibiting NO production prevents resistance arteries from dilating maximally in response to shear stress.[2,4] This limiting effect probably reflects excess resistance in the transmural penetrating arteries, which are upstream of metabolic stimuli for vasodilation and extremely dependent on shear stress as a stimulus for local vasodilation. These functional abnormalities amplify the physiologic effects of a coronary stenosis, resulting in the development of subendocardial ischemia at a lower workload (**Fig. 57.22B**).

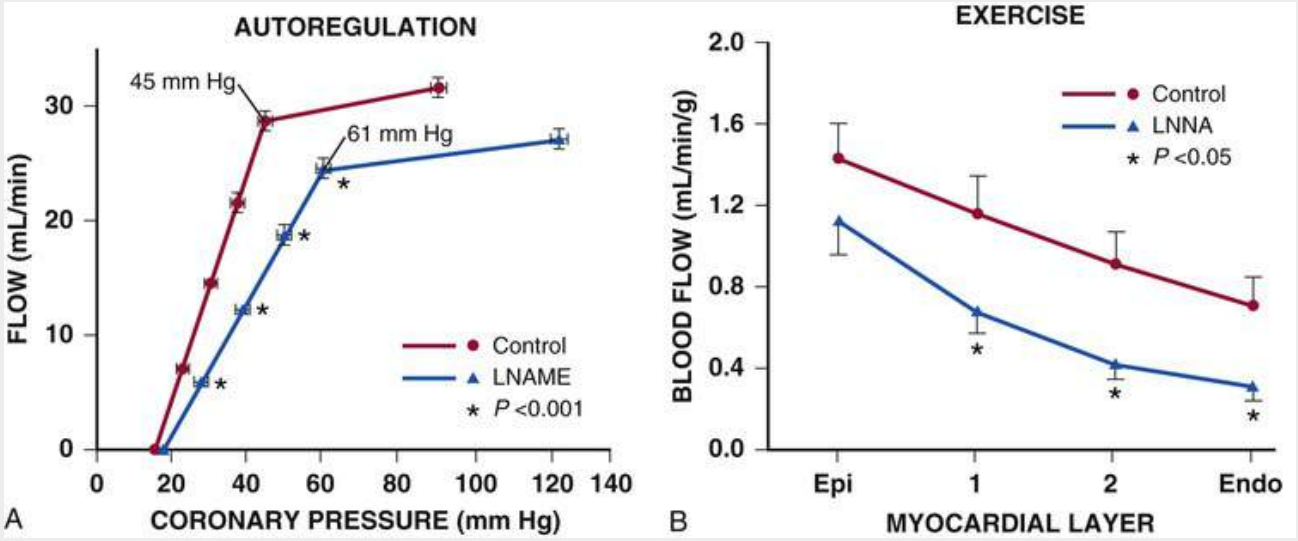

FIGURE 57.22 Impaired microcirculatory control with abnormal NO-mediated endothelium-dependent resistance artery dilation. **A,** Effects of blocking nitric oxide synthase (NOS) with the L-arginine analogue LNAME in chronically instrumented dogs. There is an increase in the lower autoregulatory pressure limit, resulting in the onset of ischemia at a coronary pressure of 61 mm Hg versus 45 mm Hg under normal conditions that occurred without a change in heart rate. **B,** Transmural perfusion before and after blocking NO-mediated dilation with LNNA in exercising dogs subjected to a coronary stenosis. Although coronary pressure and hemodynamics were similar, blood flow was less in each layer of the heart after blocking NOS and was not overcome by metabolic dilator mechanisms during ischemia. Collectively, these experimental data support the notion that abnormalities in endothelium-dependent microvascular vasodilation can amplify the functional effects of a proximal coronary stenosis. Endo, Endocardium; Epi, epicardium; LNAME, N^{ω}-nitro-L-arginine methyl ester; LNNA, N^{ω}-nitro-L-arginine. (**A,** Modified from Smith TP Jr, Canty JM Jr. Modulation of coronary autoregulatory responses by nitric oxide: evidence for flow-dependent resistance adjustments in conscious dogs. Circ Res 1993;73:232; **B,** modified from Duncker DJ, Bache RJ. Inhibition of nitric oxide production aggravates myocardial hypoperfusion during exercise in the presence of a coronary artery stenosis. Circ Res 1994;74:629.)

These observations in normal animals with impaired NO production appear to be relevant to pathophysiologic states associated with impaired endothelium-dependent vasodilation in humans. For example, coronary flow reserve is markedly reduced in the absence of a coronary stenosis in familial hypercholesterolemia, and improving endothelial function by lowering elevated LDL levels with statins produces a delayed improvement in coronary flow reserve in normal and stenotic arteries and also ameliorates clinical signs of myocardial ischemia.[25] Impaired NO-mediated vasodilation probably affects the regulation of myocardial perfusion in other disease states in which endothelium-dependent vasodilation is impaired.

Impact of Microcirculatory Abnormalities on Physiologic Measures of Stenosis Severity

If microcirculatory dysfunction is absent, quantitative measures of stenosis severity during vasodilation that are derived using absolute flow reserve, relative flow reserve, and FFR should all be closely related. Unfortunately, this is the exception rather than the rule, and microvascular dysfunction or variability in the microcirculatory response to pharmacologic vasodilation dissociates the idealized relation between various indices of coronary flow reserve for a given stenosis severity. **Fig. 57.23A** shows the relation between paired invasive measurements of absolute flow reserve versus distal coronary pressure–derived FFR. Hemodynamically insignificant stenoses (FFR >0.8) can have an absolute flow reserve that varies from 1 to more than 5. Although this variability decreases when FFR is less than 0.8, it is still considerable until FFR falls below 0.5.

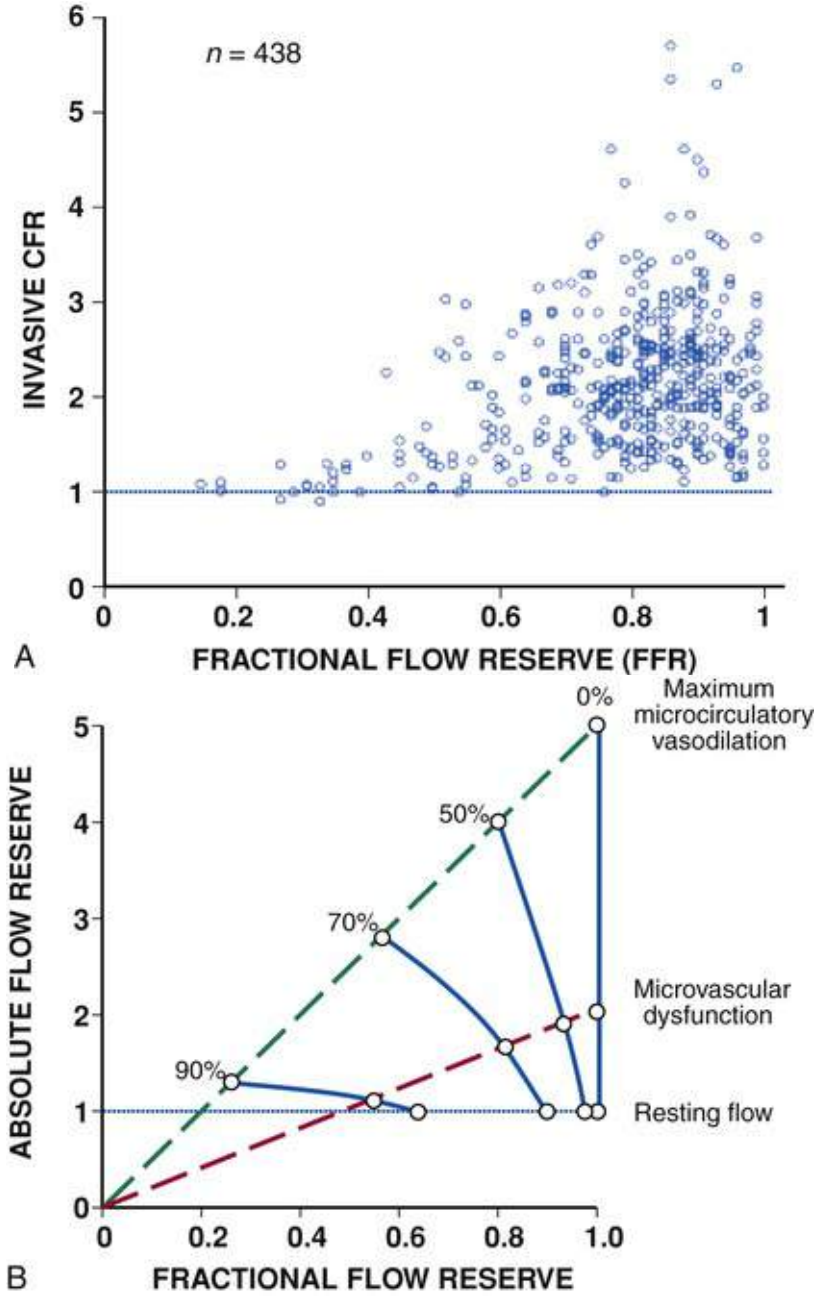

FIGURE 57.23 Wide variation in paired measurements of functional stenosis severity is observed with use of different indices of flow reserve in the same patient, suggesting the presence of coronary microvascular dysfunction. **A,** Simultaneous intracoronary catheter–based measurements of absolute coronary flow reserve (CFR) are compared with FFR. This variability reflects differences in the contribution of the microcirculation and stenosis in individual patients. **B**, Effects of microvascular dysfunction on the stenosis pressure-flow relation and measurements of flow reserve. The *upper green dashed line* shows the idealized linear relation between absolute flow reserve and FFR when the coronary microcirculation is normal and maximally vasodilated. The *lower red dashed line* indicates the relation between absolute flow reserve and FFR when there is microvascular dysfunction. Individual stenoses are illustrated by the *solid blue lines*. The horizontal blue line indicates the resting flow situation (panel **A**) or absolute flow reserve of 1.0 (panel **B**). The presence of microvascular dysfunction will limit vasodilation. Thus, absolute flow reserve will be reduced and will overestimate stenosis severity. By contrast, because distal coronary pressure is higher with submaximal vasodilation, FFR (and relative flow reserve) will underestimate stenosis severity. It is likely that these interactions contribute to the variability demonstrated in panel **A.** (**A,** Modified from Johnson NP, Kirkeeide RL, Gould KL. Is discordance of coronary flow reserve and fractional flow reserve due to methodology or clinically relevant coronary pathophysiology? J Am Coll Cardiol Imaging 2012;5:193.)

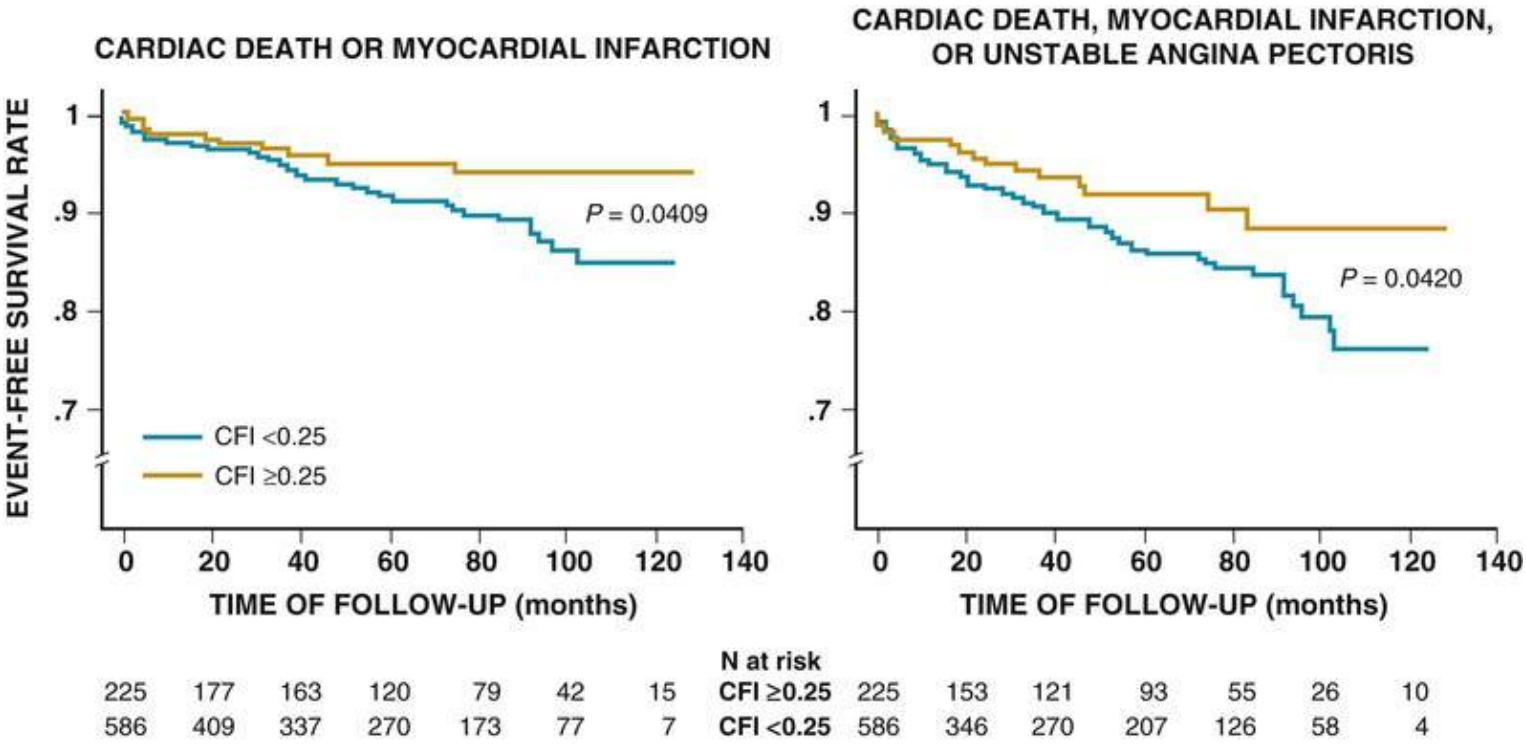
The variability in microvascular dysfunction and submaximal pharmacologic vasodilator responses can have a significant impact on assessing the physiologic significance of a coronary stenosis using FFR (or relative perfusion with imaging). In **Fig. 57.23B**, the two dashed lines show idealized relations between absolute flow reserve and FFR (or relative flow reserve from perfusion imaging). Microvascular

dysfunction in the presence of normal coronary arteries (0% stenosis) *attenuates* coronary flow reserve. Conversely, for any given stenosis, the FFR measured in the presence of microvascular disease will be *higher* than when vasodilator responses are normal. Thus, when maximum vasodilation is not achieved, FFR will underestimate the physiologic severity of the stenosis. This probably contributes to at least some of the discordance between FFR and coronary flow reserve observed in clinical studies, underscoring the importance of combining both pressure- and flow-derived indices to assess vasodilator reserve of the total coronary vascular bed. Indeed, the availability of high-fidelity pressure and flow measurements on a single wire has now facilitated the development of approaches to assess the stenosis pressure-flow relation as well as abnormalities in microcirculatory reserve by determining FFR and absolute coronary flow reserve simultaneously. When assessed together, these measurements have the potential to identify circumstances in which mixed abnormalities from a stenosis and abnormal microcirculation contribute to the functional impact of a coronary stenosis.

Coronary Collateral Circulation

After a total coronary occlusion, residual perfusion to the myocardium persists through native coronary collateral channels that open with development of an intercoronary pressure gradient between the source and recipient vessel. In most animal species, the native collateral flow during occlusion is less than 10% of the resting flow levels and is insufficient to maintain tissue viability for longer than 20 minutes. Tremendous individual variability in the function of coronary collaterals is recognized among patients with chronic stenoses. In humans without coronary collaterals, coronary pressure during balloon angioplasty occlusion falls to approximately 10 mm Hg. In other patients, collaterals proliferate to the point where they are sufficient not only to maintain resting perfusion normal, but also to prevent stress-induced ischemia at submaximal cardiac workloads. Ischemia does not develop during PCI balloon occlusion when FFR (based on coronary wedge pressure during occlusion minus venous pressure) is greater than 0.25.[26] A large observational cross-sectional study has demonstrated that patients with elevated distal coronary pressure arising from recruitable collaterals during transient total balloon occlusion (FFR >0.25) have a lower cardiovascular event rate and improved survival[26] (**eFig. 57.4**).



EFIGURE 57.4 Favorable effect of coronary collaterals on prognosis. Patients with collateral flow index (CFI) of 0.25 or less measured during total occlusion of a coronary artery had a worse prognosis as reflected by the combined endpoint of death or myocardial infarction. These data support the concept that preventing ischemia with physiologically functional collaterals protects the heart from irreversible injury and other coronary events. (From Meier P, Gloeker S, Rainer Z, et al. Beneficial effect of recruitable collaterals: a 10-year follow-up study in patients with stable coronary artery disease undergoing quantitative collateral measurements. Circulation 2007;116:975.)

Arteriogenesis and Angiogenesis

Proliferation of coronary collaterals (**see Chapter 20**) occurs in response to repetitive stress-induced ischemia as well as the development of transient interarterial pressure gradients between the source and recipient vessel through a process termed *arteriogenesis*.[27] Resting distal coronary pressure consistently falls as stenosis severity exceeds 70%, and the resultant interarterial pressure gradient increases endothelial shear stress in preexisting collaterals smaller than 200 μm in diameter. This causes progressive enlargement of collaterals through a process dependent on physical forces and growth factors, particularly vascular endothelial growth factor (VEGF), that is mediated by NOS. Thus, patients with impaired NO-mediated vasodilation caused by coronary risk factors may have a limited ability to develop coronary collaterals in response to a chronic coronary stenosis.

Most functional collateral flow arises from arteriogenesis in existing epicardial anastomoses that enlarge into mature vessels, which can reach 1 to 2 mm in diameter.[27] Collateral perfusion also can originate from de novo vessel growth, or *angiogenesis*, which refers to the sprouting of smaller, capillary-like structures from preexisting blood vessels. These vessels may provide nutritive collateral flow when they develop in the border between ischemic and nonischemic regions. Capillary angiogenesis may also occur within the ischemic region and can reduce the intercapillary distance for oxygen exchange. Nevertheless, because capillary resistance is already a small component of microcirculatory resistance, increases in capillary density in the absence of changes in arteriolar resistance will not significantly increase myocardial perfusion.

Great interest is currently directed toward experimental interventions to improve collateral flow (e.g., recombinant growth factors, in vivo gene transfer, adult progenitor cells) (**see Chapter 30**). Although

many interventions have been demonstrated to cause favorable angiogenesis of capillaries and improve myocardial function, few interventions have increased arteriogenesis in mature collaterals, and randomized human clinical trials have been disappointing.[28,29] Part of this limitation may arise from the fact that no intervention has resulted in measurable increases in maximum vasodilated myocardial perfusion or coronary flow reserve indices, the sine qua non of functional collateral formation. Improvements in myocardial function have been used as an endpoint, but such improvement may occur independent of increased perfusion and may arise from mechanisms that alter cardiac myocyte growth and repair rather than angiogenesis.[30]

Regulation of Collateral Resistance

The control of blood flow to collateral-dependent myocardium is governed by a series resistance arising from interarterial collateral anastomoses, largely epicardial, as well as the native downstream microcirculation. Collateral resistance is therefore the major determinant of perfusion, and coronary pressure distal to a chronic occlusion is already near the lower autoregulatory pressure limit. Consequently, subendocardial perfusion is critically dependent on mean aortic pressure and LV preload, with ischemia easily provoked by systemic hypotension, increases in LV end-diastolic pressure, and tachycardia. As with the distal resistance vessels, collaterals constrict when NO synthesis is blocked, which aggravates myocardial ischemia and can be overcome by nitroglycerin.[6] In contrast with the native coronary circulation, experimental studies have demonstrated that coronary collaterals are under tonic dilation from vasodilator prostaglandins, and blocking COX with aspirin exacerbates myocardial ischemia in dogs.[6] The role of prostanoids in human coronary collateral resistance regulation is unknown.

The distal microcirculatory resistance vasculature in collateral-dependent myocardium appears to be regulated by mechanisms similar to those present in the normal circulation, but it is characterized by impaired endothelium-dependent vasodilation compared with normal vessels.[6] Of interest, the remote normally perfused zone in collateralized hearts also shows alterations in coronary resistance vessel control, suggesting that abnormalities are not restricted to the collateral-dependent region. The extent to which these microcirculatory abnormalities alter the normal metabolic and coronary autoregulatory responses in collateral-dependent and remote myocardial regions is unknown.[6]

Metabolic and Functional Consequences of Ischemia

Because oxygen delivery to the heart is closely related to coronary blood flow, a sudden cessation of regional perfusion after a thrombotic coronary occlusion quickly leads to the cessation of aerobic metabolism, depletion of creatine phosphate, and onset of anaerobic glycolysis. This is followed by the accumulation of tissue lactate, a progressive reduction in tissue ATP levels, and an accumulation of catabolites, including those of the adenine nucleotide pool. As ischemia continues, tissue acidosis develops and there is an efflux of potassium into the extracellular space. Subsequently, ATP levels fall below those required to maintain critical membrane function, resulting in the onset of myocyte death.

Irreversible Injury and Myocyte Death

The temporal evolution and extent of irreversible tissue injury after coronary occlusion are variable and depend on transmural location, residual coronary flow, and the hemodynamic determinants of oxygen

consumption. Irreversible myocardial injury begins after 20 minutes of coronary occlusion in the absence of significant collaterals (see Classic References, Kloner and Jennings, 2001a). Irreversible injury starts in the subendocardium and progresses as a wavefront over time, from the subendocardial layers to the subepicardial layers (**Fig. 57.24**). This reflects the higher oxygen consumption in the subendocardium and the redistribution of collateral flow to the outer layers of the heart by the compressive determinants of flow at reduced coronary pressure. In experimental infarction, the entire subendocardium is irreversibly injured within 1 hour of occlusion, and the transmural progression of infarction is largely completed within 4 to 6 hours after coronary occlusion. Factors that increase myocardial oxygen consumption (e.g., tachycardia) or reduce oxygen delivery (e.g., anemia, arterial hypotension) accelerate the progression of irreversible injury. By contrast, repetitive reversible ischemia or angina occurring before an occlusion can reduce irreversible injury through preconditioning.[31]

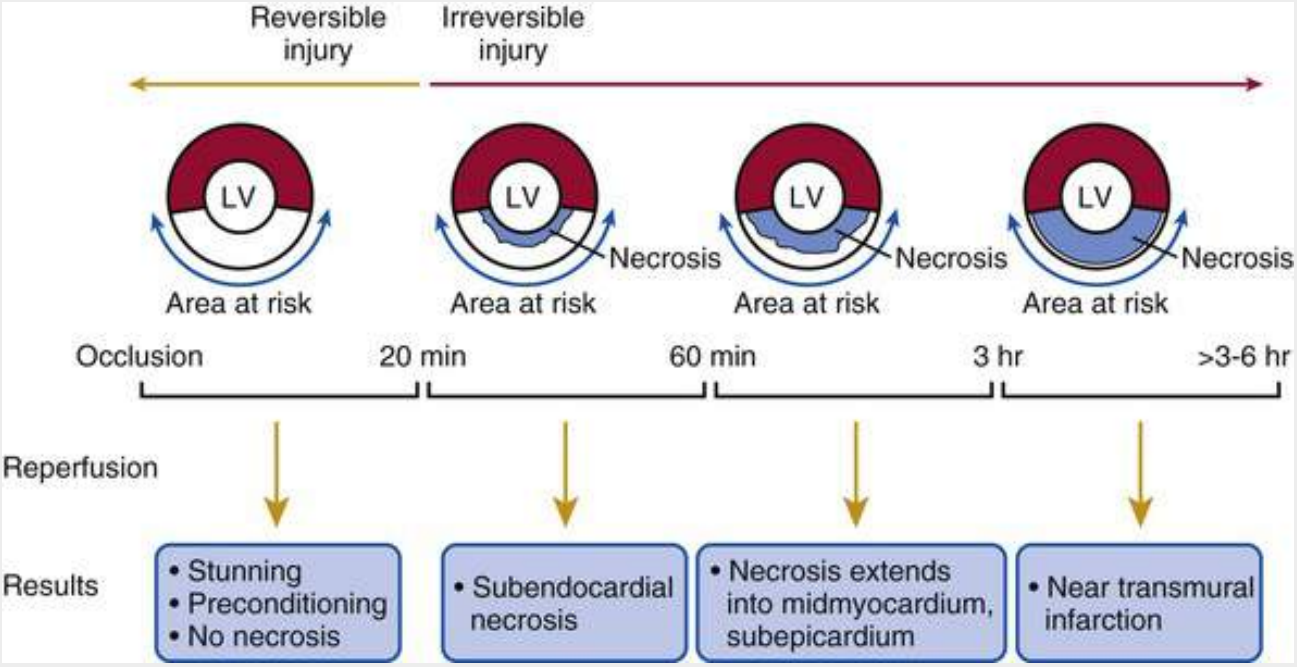


FIGURE 57.24 Wavefront of necrosis in infarction. Total coronary artery occlusions shorter than 20 minutes do not cause irreversible injury but can cause myocardial stunning and also precondition the heart and protect it against recurrent ischemic injury. Irreversible injury begins after 20 minutes and progresses as a wavefront from endocardium to epicardium. After 60 minutes, the inner third of the left ventricle (LV) wall is irreversibly injured. After 3 hours, only a subepicardial rim of tissue remains, with the transmural extent of infarction completed between 3 and 6 hours after occlusion. The most important factor delaying the progression of irreversible injury is the magnitude of collateral flow, which is directed primarily to the outer layers of the heart. (Modified from Kloner RA, Jennings RB. Consequences of brief ischemia: Stunning, preconditioning, and their clinical implications: Part 1. Circulation 2001;104:2981.)

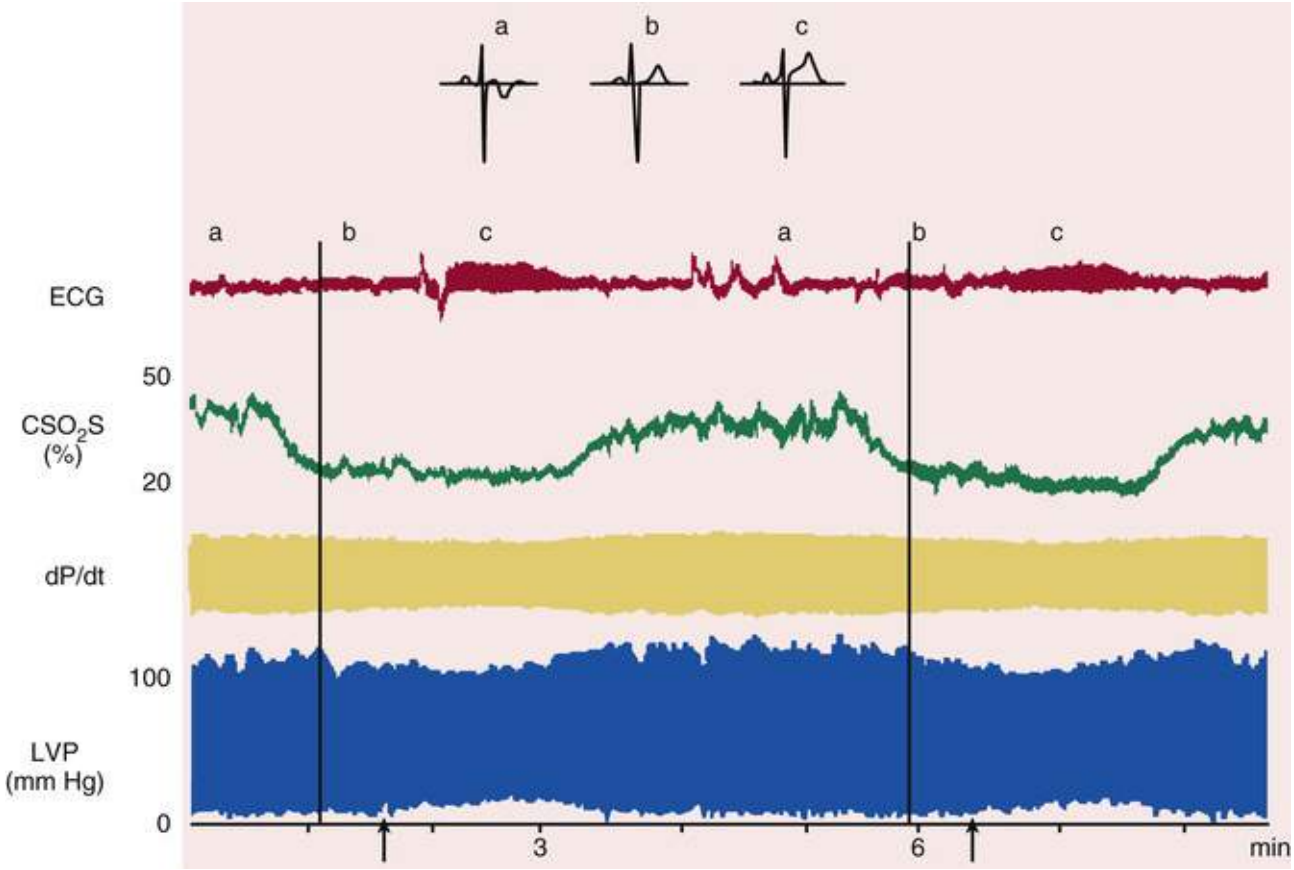
The magnitude of residual coronary flow through collaterals or through a subtotal coronary occlusion is the most important determinant of the actual time course of irreversible injury in patients with chronic CAD. The relation between infarct size and the area at risk of ischemia during a total occlusion is inversely related to collateral flow and likely explains the important role of collateral vessel function in determining prognosis.[26] When subendocardial collateral flow is more than approximately 30% of resting flow values, it prevents infarction after periods of ischemia lasting longer than 1 hour. More moderate subendocardial ischemia from a subtotal occlusion (e.g., flow reduced by no more than 50%) can persist for at least 5 hours without producing significant irreversible injury.[32] This explains why signs and symptoms of ischemia can be present for long periods without producing significant myocardial necrosis.

It also explains the clinical observation that late coronary reperfusion with ongoing ischemia can salvage myocardium beyond the 6-hour time limit predicted from experimental models of MI.[33]

Cell death arises from multiple mechanisms in MI[34] (**see Chapter 58**). Reperfusion immediately causes myocyte necrosis and sarcolemmal disruption, with the leakage of cell contents into the extracellular space. The injury may be further amplified by the reentry of leukocytes into the area of injury. At later time points, myocytes initially salvaged can undergo programmed cell death or apoptosis, which can contribute to further delayed myocardial injury. *Apoptosis* is a coordinated involution of myocytes that circumvents the inflammation associated with necrotic cell death. Because apoptosis is an energy-dependent process, cells can be forced to switch to a necrotic pathway if energy levels are depleted below critical levels. In the setting of more chronic injury, autophagy can contribute to the mechanisms of myocyte death. Because of the temporal complexity of irreversible injury, the relative importance of each mechanism in MI continues to be controversial. Nevertheless, modulating mechanisms contributing to late cell death could prevent deleterious LV remodeling.

Reversible Ischemia and Perfusion-Contraction Matching

Reversible ischemia is considerably more common than irreversible injury. *Supply-induced ischemia* can arise from transient coronary occlusion resulting from coronary vasospasm or transient thrombosis in a critically stenosed coronary artery, producing transmural ischemia similar to that present at the onset of MI. *Demand-induced ischemia* arises from an inability to increase flow in response to increases in myocardial oxygen consumption in which ischemia predominantly affects the subendocardium (**see Chapter 61**). These have fundamentally different effects on myocardial diastolic relaxation, with supply-induced ischemia increasing LV compliance and demand-induced ischemia reducing it. There is a fairly stereotypic sequence of physiologic changes that develop during an episode of spontaneous transmural ischemia (**eFig. 57.5**). Coronary occlusion results in an immediate fall in coronary venous oxygen saturation, with a reduction in ATP production. This causes a decline in regional contraction within several beats, reaching dyskinesis within 1 minute. As regional contraction ceases, concomitant changes include a reduction in global LV contractility (dP/dt), a progressive rise in LV end-diastolic pressure, and a fall in systolic pressure. The magnitude of the systemic hemodynamic changes varies with the severity of ischemia as well as the amount of the left ventricle subjected to ischemia. Significant electrocardiographic ST-segment changes develop within 2 minutes as efflux of potassium into the extracellular space reaches a critical level. Symptoms of chest pain are variable and usually are the last event in the evolution of ischemia. On restoring perfusion, the sequence is reversed, with resolution of chest pain occurring before hemodynamic changes resolve, but regional contraction can remain depressed, reflecting the development of stunned myocardium. A similar temporal sequence of events occurs during exercise-induced ischemia, although the time frame of evolution can be more protracted because ischemia occurs primarily in the subendocardium. Because of the temporal delay in the development of angina and other factors, many episodes of ST-segment depression are symptomatically silent. It is also likely that very brief episodes of ischemia, as reflected by more sensitive indices, such as reduced regional contraction or elevations in end-diastolic pressure, can be electrocardiographically silent.



EFIGURE 57.5 Physiologic changes during two episodes of spontaneous asymptomatic ischemia in a patient with an acute coronary syndrome. High-speed electrocardiographic tracings depict the baseline ECG (a), pseudonormalization of T waves in early ischemia (b), and ST elevation with late ischemia (c). A primary reduction in coronary flow is depicted by the sudden fall in coronary venous oxygen saturation (CSO_2S). Shortly thereafter, left ventricular (LV) dP/dt falls, reflecting regional contractile dysfunction (*solid vertical lines*). Within 1 minute, LV end-diastolic pressure begins to rise (*arrows*) and is associated with a reduction in systolic pressure. Significant ST elevation begins after the rise in LV end-diastolic pressure (c). On spontaneous resolution of ischemia (rise in CSO_2S), the changes resolve. Each episode lasted 2 minutes and was not associated with chest pain. LVP, Left ventricular pressure. (Modified from Chierchia S, Brunelli C, Simonetti I, et al. Sequence of events in angina at rest: primary reduction in coronary flow. Circulation 1980;61:759.)

Acute Perfusion-Contraction Matching During Subendocardial Ischemia

When coronary pressure distal to a stenosis falls below the lower limit of autoregulation, flow reserve is exhausted, resulting in the onset of subendocardial ischemia. In this case, reductions in subendocardial flow are closely related to reductions in regional contractile function of the heart, as measured by sensitive approaches such as regional wall thickening.[32] An approximately linear relation has been shown between relative reductions in subendocardial blood flow and relative reductions in regional wall thickening at rest, during tachycardia, and during exercise-induced dysfunction distal to a critical stenosis[32] (**Fig. 57.25**). This forms the basis for using regional myocardial function as an index of the severity of subendocardial ischemia during stress imaging (**see Chapter 14**).

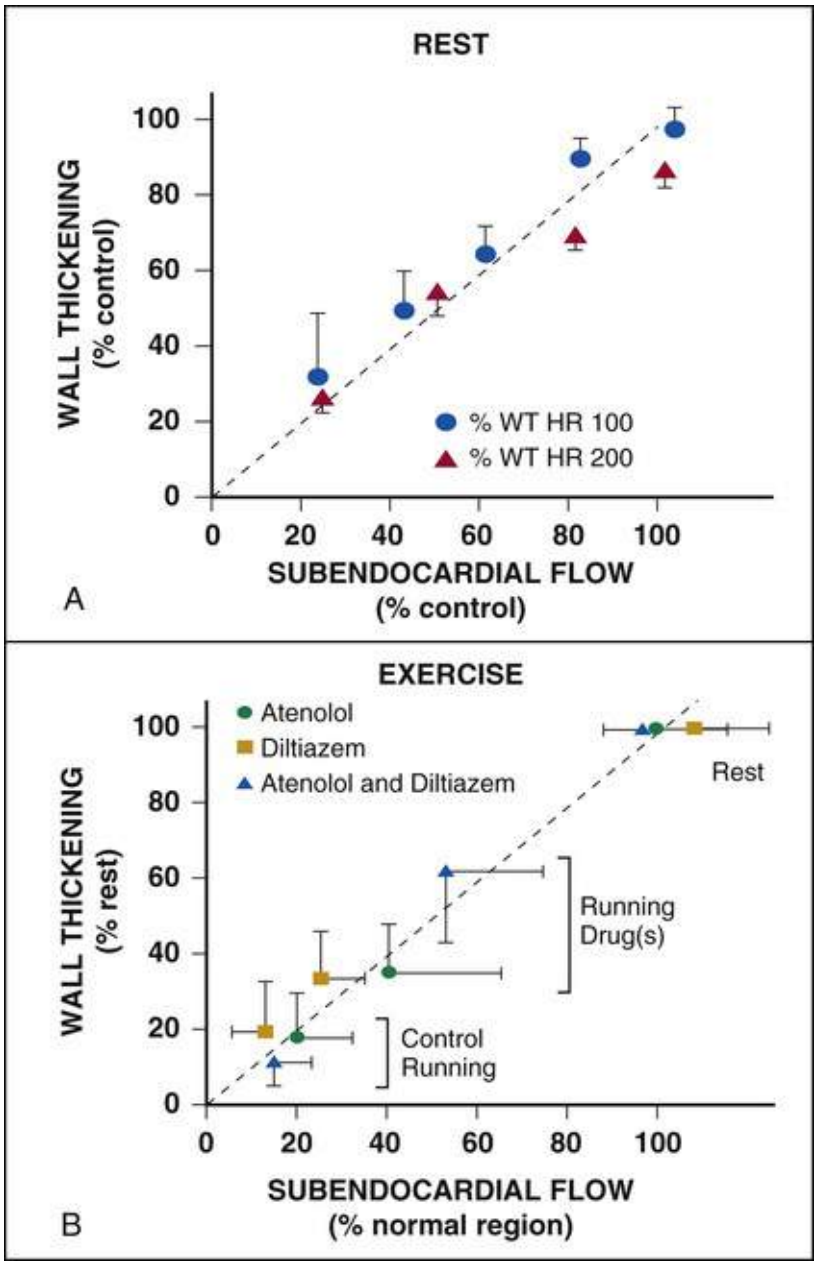


FIGURE 57.25 Perfusion-contraction matching during acute ischemia. Relative reductions in function (regional wall thickening) are proportional to the relative reduction in subendocardial flow measured with microspheres in conscious dogs. This relation is maintained over a wide range of heart rates during autoregulation **(A)** as well as during exercise with a fixed coronary stenosis **(B)**. In the latter case, medical interventions that ameliorate ischemia improve both subendocardial flow and wall thickening (WT) during exercise. HR, Heart rate. (**A,** Modified from Canty JM Jr. Coronary pressure-function and steady-state pressure-flow relations during autoregulation in the unanesthetized dog. Circ Res 1988;63:821; and Canty JM Jr, Giglia J, Kandath D. Effect of tachycardia on regional function and transmural myocardial perfusion during graded coronary pressure reduction in conscious dogs. Circulation 1990;82:1815; **B,** modified from Matsuzaki M et al. Effect of the combination of diltiazem and atenolol on exercise-induced regional myocardial ischemia in conscious dogs. Circulation 1985;72:233.)

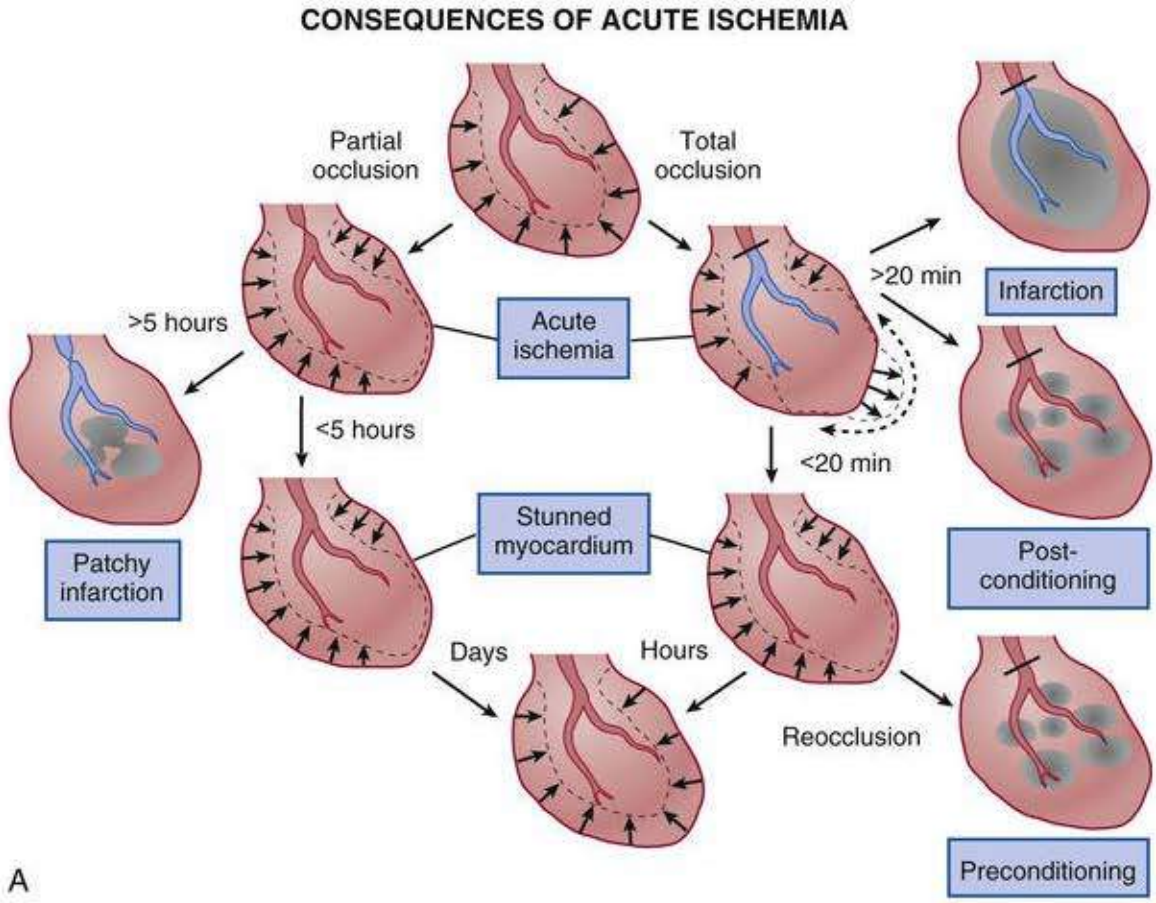
Short-Term Hibernation

In steady-state ischemia, the close matching between perfusion and contraction leads to a reduced regional oxygen consumption and energy utilization, a phenomenon termed *short-term hibernation*.[32] This reestablishes a balance between supply and demand, as reflected by regeneration of creatine phosphate and ATP with the resolution of lactate production, despite persistent hypoperfusion. Short-term hibernation is an extremely tenuous state, and small increases in the determinants of myocardial oxygen demand precipitate further ischemia and a rapid deterioration in function and metabolism (see Classic Reference, Heusch). Thus the ability of short-term hibernation to prevent necrosis is limited by the

severity and duration of ischemia, with irreversible injury developing frequently after periods longer than 12 to 24 hours.[35]

Functional Consequences of Reversible Ischemia

Various late consequences of ischemia have been documented after normal myocardial perfusion is reestablished. These reflect both acute and delayed effects on regional function, as well as protection of the heart from subsequent ischemic episodes. In the most chronic state, they result in hibernating myocardium, characterized by chronic contractile dysfunction and regional cellular mechanisms that downregulate contractile and metabolic function of the heart so as to protect it from irreversible injury. **Fig. 57.26** summarizes the complex interplay among these entities. In clinical practice, it is difficult to separate all the various mechanisms involved in contributing to ischemia-induced viable dysfunctional myocardium, because they all may coexist to some extent in the same heart. They can be separated experimentally, however, and the important features and mechanisms from basic studies are summarized next.



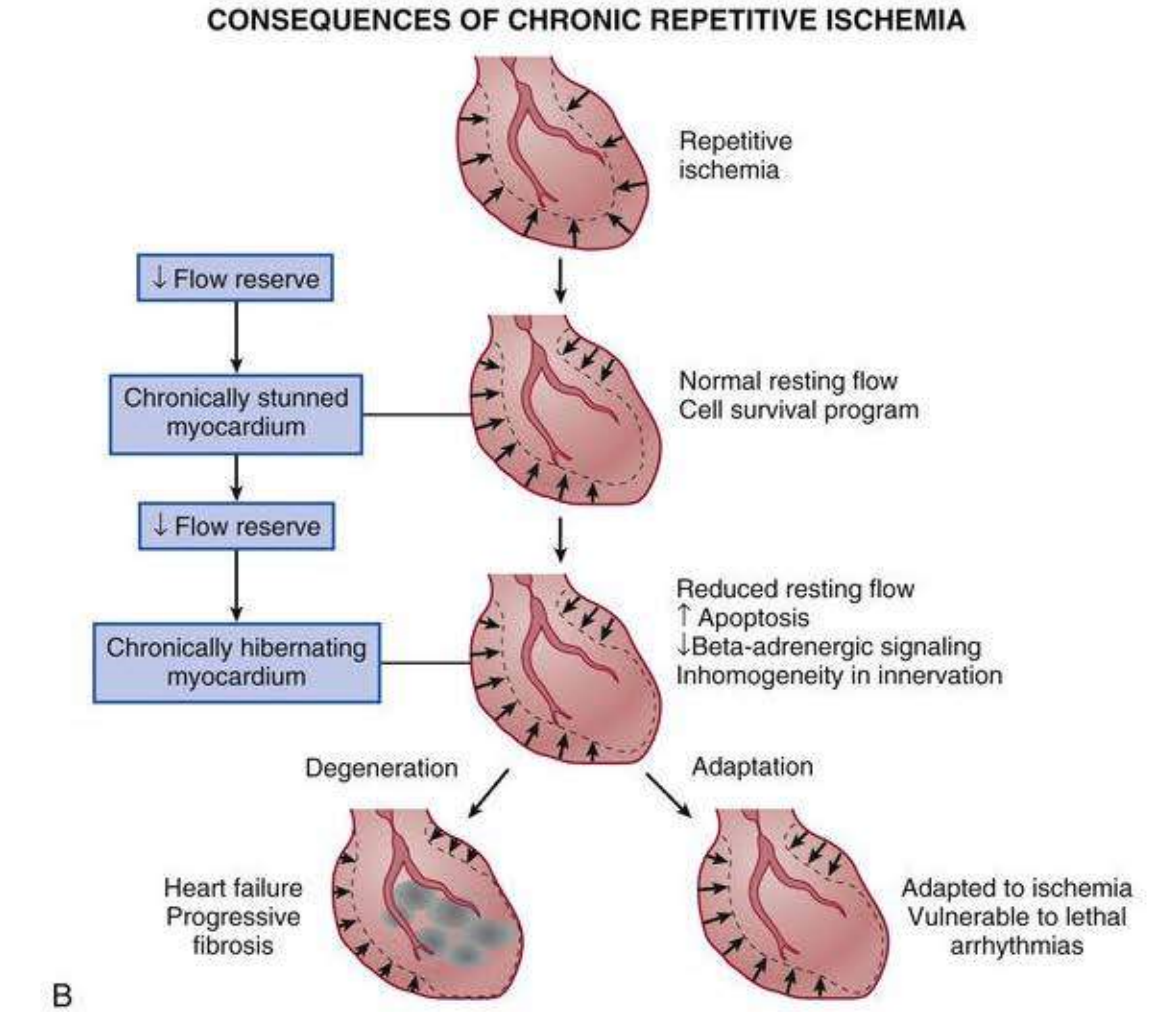


FIGURE 57.26 Effects of ischemia on left ventricular function and irreversible injury. The ventriculograms illustrate contractile dysfunction (*dashed lines* and *arrows*). **A,** Consequences of acute ischemia. A brief total occlusion (*right*) or a prolonged partial occlusion (caused by an acute high-grade stenosis, *left*) leads to acute contractile dysfunction proportional to the reduction in blood flow. Irreversible injury begins after 20

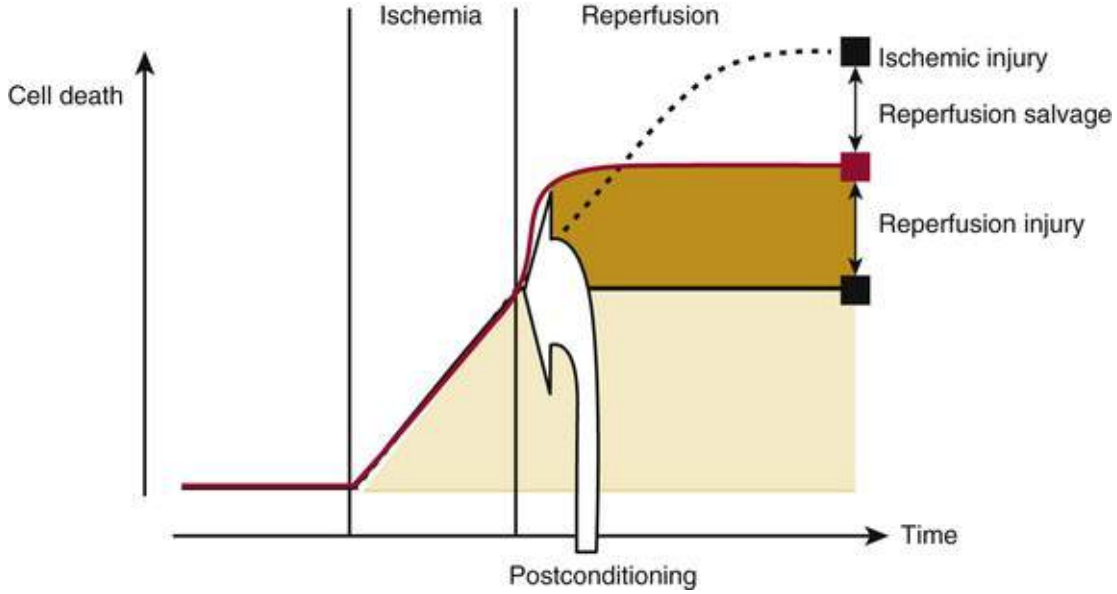
minutes after a total occlusion but is delayed for up to 5 hours after a partial occlusion (or with significant collaterals) caused by short-term hibernation. When reperfusion is established before the onset of irreversible injury, stunned myocardium develops, and the time required for recovery of function is proportional to the duration and severity of ischemia. With prolonged ischemia, stunning in viable myocardium coexists with subendocardial infarction and accounts for a variable amount of irreversible dysfunction. Experimental infarct size can be reduced by cardioprotective mechanisms. Intermittent occlusion at the time of reperfusion (postconditioning) can limit infarct size. Likewise, brief episodes of ischemia preceding prolonged ischemia elicit protection against infarction from prolonged ischemia (preconditioning). **B,** Effects of chronic repetitive ischemia on function distal to a stenosis. As stenosis severity increases, coronary flow reserve decreases and the frequency of reversible ischemia increases. Reversible repetitive ischemia initially leads to chronic preconditioning against infarction and stunning (*not shown*). Subsequently, there is a gradual progression from contractile dysfunction with normal resting flow (chronically stunned myocardium) to contractile dysfunction with depressed resting flow (hibernating myocardium). This transition is related to the physiologic significance of a coronary stenosis and can occur in a time period as short as 1 week or develop chronically in the absence of severe angina. The cellular response during the progression to chronic hibernating myocardium is variable, with some patients exhibiting successful adaptation with little cell death and fibrosis and others developing degenerative changes difficult to distinguish from subendocardial infarction.

Myocardial Preconditioning and Postconditioning

Brief reversible ischemia preceding a prolonged coronary occlusion reduces myocyte necrosis, a phenomenon termed *acute preconditioning*.[31] Because acute MI frequently is preceded by angina, preconditioning is an endogenous mechanism that can delay the evolution of irreversible myocardial injury. Acute preconditioning can be induced pharmacologically using adenosine A_1 receptor stimulation as well as various pharmacologic agonists that stimulate protein kinase C or open mitochondrial K_{ATP} channels. It has been demonstrated in humans during angioplasty with reduced subjective and objective ischemia during successive coronary occlusions as an endpoint. Preconditioning also develops on a chronic basis (*delayed preconditioning*) and, once induced, persists for up to 4 days (see Classic References, Kloner and Jennings, 2001b). It reduces MI size and protects the heart from ischemia-induced stunning. The mechanisms of chronic preconditioning involve protein synthesis, with upregulation of the inducible form of NOS (iNOS), COX-2, and opening of the mitochondrial K_{ATP} channel. A final protective mechanism, *myocardial postconditioning*,[36] refers to the ability to engage cardiac protection by producing intermittent ischemia or administering pharmacologic agonists at reperfusion. It has the great potential to affect irreversible injury because it can be induced after myocardial ischemia is established rather than requiring pretreatment[37] (**eFig. 57.6**). Protection occurs principally through activation of reperfusion injury salvage kinase pathways, thereby limiting opening of the mitochondrial permeability transition pore.[38] A number of small clinical trials, using mechanical or pharmacologic postconditioning, have shown promise.[38-40] However, the first large randomized controlled clinical trial failed to demonstrate a significant reduction by postconditioning in combined all-cause mortality and hospitalization for heart failure.[41] Therefore, the role for these novel approaches as an adjunctive therapy in the setting of reperfusion treatment of acute MI remains to be proven.[40]



EFIGURE 57.6 The concept of lethal reperfusion injury. During ischemia, irreversible cell injury leading to cell death occurs within the ischemic risk zone in a time-dependent manner. In the absence of reperfusion, ischemic injury will progressively kill more and more cells (*dashed line*). Reperfusion stops the process of ischemic cell death but in its early stages imposes injury that results in further cell death. This is beyond the damage that would be produced by ischemia alone and is termed *lethal reperfusion injury*. The net result is that the reperfused tissue still sustains less cell death than would occur in ischemic tissue without reperfusion. Targeting cell death due to reperfusion injury has the potential to maximize cell salvage. Postconditioning applied at the onset of reperfusion limits the extent of reperfusion injury and can potentially maximize myocardial salvage. (Modified from Ovize M, Baxter GF, Di Lisa F, et al. Postconditioning and protection from reperfusion injury: where do we stand? Position paper from the Working Group of Cellular Biology of the Heart of the European Society of Cardiology. Cardiovasc Res 2010;87:406.)

Stunned Myocardium.

Myocardial function normalizes rapidly after single episodes of ischemia lasting less than 2 minutes. As ischemia increases in duration and severity, a temporal delay in the recovery of function occurs despite that blood flow has been restored. Regional myocardial function remains depressed for up to 6 hours after resolution of ischemia following a 15-minute occlusion in the absence of tissue necrosis, a phenomenon called *myocardial stunning* (**Fig. 57.27**). A defining feature of isolated myocardial stunning is that function remains depressed while resting myocardial perfusion is normal.[32] Thus there is a dissociation of the usual close relation between subendocardial flow and function. Stunned myocardium also develops after demand-induced ischemia. For example, exercise-induced ischemia can result in depressed regional function distal to a coronary stenosis for hours after perfusion is restored, and repetitive ischemia can lead to cumulative stunning. Prolonged sublethal ischemia, as seen in short-term hibernation, leads to stunning on restoration of perfusion that may take up to 1 week to resolve in the absence of necrosis. This may be an important cause of reversibly dysfunctional myocardium in the setting of an acute reduction in flow, as in an acute coronary syndrome. Stunned myocardium is also responsible for postoperative pump dysfunction after cardiopulmonary bypass. Further, areas of stunned myocardium can coexist with irreversibly injured myocardium, contributing to time-dependent improvements in function after MI.

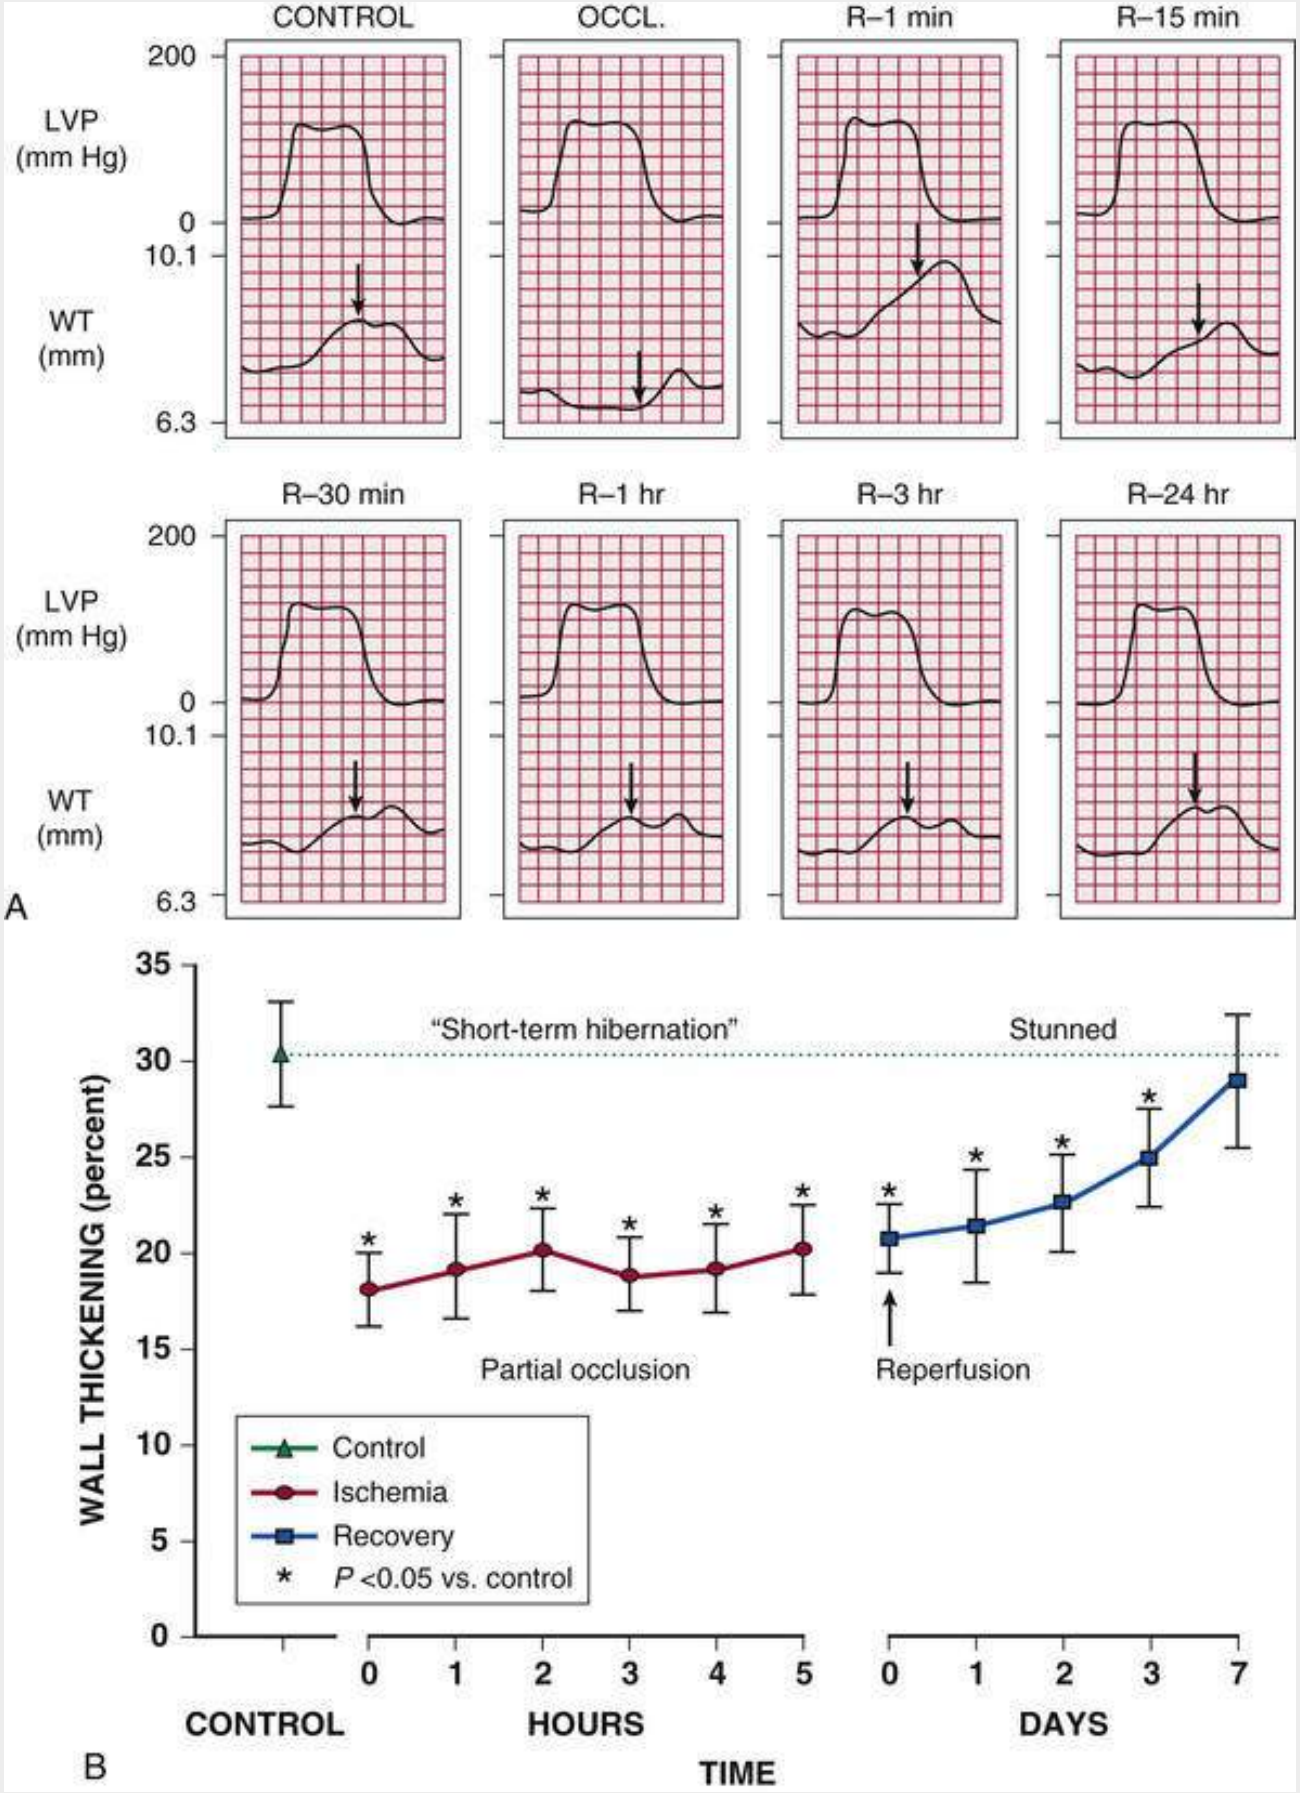


FIGURE 57.27 Stunned myocardium. **A,** Myocardial stunning after a brief total occlusion (OCCL.). Wall thickening (WT) measured by ultrasonic crystals is dyskinetic, with systolic thinning during occlusion. After reperfusion (R), function is completely normal after 24 hours. **B,** Myocardial stunning after a prolonged partial occlusion. During acute ischemia (*red circles*), there is short-term hibernation, reflecting an acute match between reduced flow, wall thickening, and metabolism. With reperfusion (*blue squares*), WT remains depressed and gradually returns to normal after 1 week. LVP, Left ventricular pressure. (**A,** Modified from Heyndrickx GR et al. Depression of regional blood flow and wall thickening after brief coronary occlusions. Am J Physiol 1978;234:H653; **B,** modified from Matsuzaki M et al. Sustained regional dysfunction produced by prolonged coronary stenosis:

gradual recovery after reperfusion. Circulation 1983;68:170.)

Acutely stunned myocardium is clinically important to recognize because contractile function normalizes during stimulation with various inotropic agents, including beta-adrenergic agonists. In contrast with other dysfunctional states, function will spontaneously normalize within 1 week, provided that there is no recurrent ischemia. If repetitive episodes of reversible ischemia develop before function normalizes, they can cause a state of persistent dysfunction or chronic stunning. The cellular mechanism of stunning probably involves free radical–mediated myocardial injury and reduced myofilament calcium sensitivity (see Classic References, Bolli and Marban).

Chronic Hibernating Myocardium

Viable dysfunctional myocardium is defined as any myocardial region in which contractile function improves after coronary revascularization.[37] This broad definition of reversible dyssynergy includes three distinct categories with fairly diverse pathophysiologic mechanisms (**Table 57.1**). Complete normalization of function is the rule after acute ischemia but the exception in chronically dysfunctional myocardium. Brief occlusions or prolonged moderate ischemia (short-term hibernation) will result in postischemic stunning in the absence of infarction, with complete functional recovery occurring rapidly (within 1 week after reperfusion). The time course of improvement is somewhat dependent on the duration and severity of the ischemic episode. Reversible dyssynergy with delayed functional improvement can also arise from structural remodeling of the heart that is independent of ischemia or a coronary stenosis (e.g., remote myocardial remodeling in heart failure, reduced infarct volume over initial weeks after coronary reperfusion). The latter conditions can be readily identified when the clinical setting, coronary anatomy, and assessment of myocardial perfusion are taken into account. Many clinical studies have evaluated the presence of contractile reserve during dobutamine administration as a predictor of functional recovery. Although this identifies the likelihood of functional recovery (**see Chapter 14**), it cannot distinguish the diverse pathophysiologic states underlying reversible dyssynergy. Understanding the cause may be important to the extent that it affects the time course and magnitude of functional recovery after revascularization in patients undergoing revascularization to treat ischemic heart failure.[33]

TABLE 57.1

Viable Dysfunctional Myocardium: Patterns of Contractile Reserve, Resting Perfusion, and Temporal Recovery of Function after Revascularization

PARAMETER	CONTRACTILE RESERVE	RESTING FLOW	EXTENT OF FUNCTIONAL RECOVERY	TIME COURSE OF RECOVERY
Transient Reversible Ischemia				
Postischemic stunning	Present	Normal	Normalizes	<24 hr
Short-term hibernation	Present	Normal	Normalizes	<7 days
Chronic Repetitive Ischemia				
Chronic stunning	Present	Normal	Improves	Days to weeks
Chronic hibernating myocardium	Variable	Reduced	Improves	Up to 12 mo
Structural Remodeling				
Subendocardial infarction	Variable	Reduced	Variable	Weeks
Remodeled, tethered myocardium	Present	Normal	Improves	Months

Chronic segmental dysfunction arising from repetitive episodes of ischemia (frequently clinically silent) is common and present in at least one coronary distribution area in more than 60% of patients with

ischemic cardiomyopathy (**Fig. 57.28**). When resting flow relative to a remote region is normal in dysfunctional myocardium distal to a stenosis, the region is *chronically stunned*. In contrast, when relative resting flow is reduced in the absence of symptoms or signs of ischemia, *hibernating myocardium* is present. It is now clear that both entities can exist in patients and represent extremes in the spectrum of adaptive and maladaptive responses to chronic reversible ischemia. Viability studies are primarily required to distinguish infarction from hibernating myocardium because the myocardium is always viable when the resting flow is normal.[32,35]

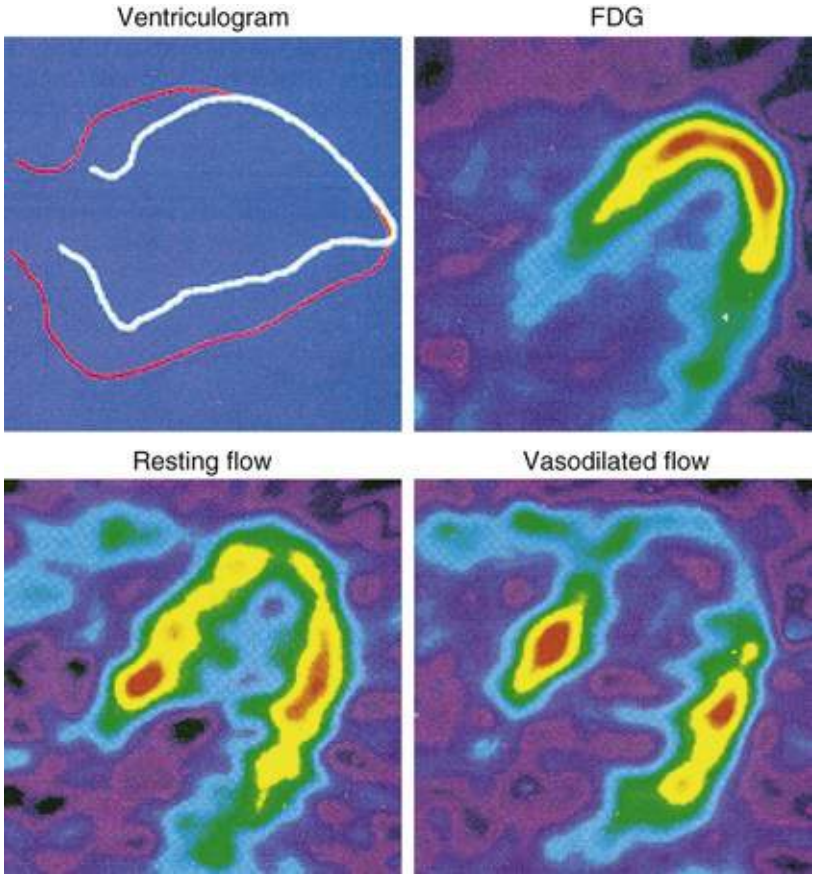

FIGURE 57.28 Hibernating myocardium in humans with a chronic left anterior descending artery (LAD) occlusion and collateral-dependent myocardium. The right anterior oblique (RAO) tracing of the left ventriculogram shows anterior akinesis (*upper left*). Transaxial PET scans illustrate $^{13}NH_3$ flow measurements at rest (*lower left*) and after pharmacologic vasodilation with dipyridamole (*lower right*). Quantitative perfusion measurements showed LAD flow to be critically impaired. Viability (after an oral glucose load) is identified by increased ^{18}F-2-fluoro-2-deoxyglucose (FDG) uptake in the anterior wall (*upper right*). (Modified from Vanoverschelde JL, Wijns W, Depre C, et al. Mechanisms of chronic regional postischemic dysfunction in humans: new insights from the study of noninfarcted collateral-dependent myocardium. Circulation 1993;87:1513.)

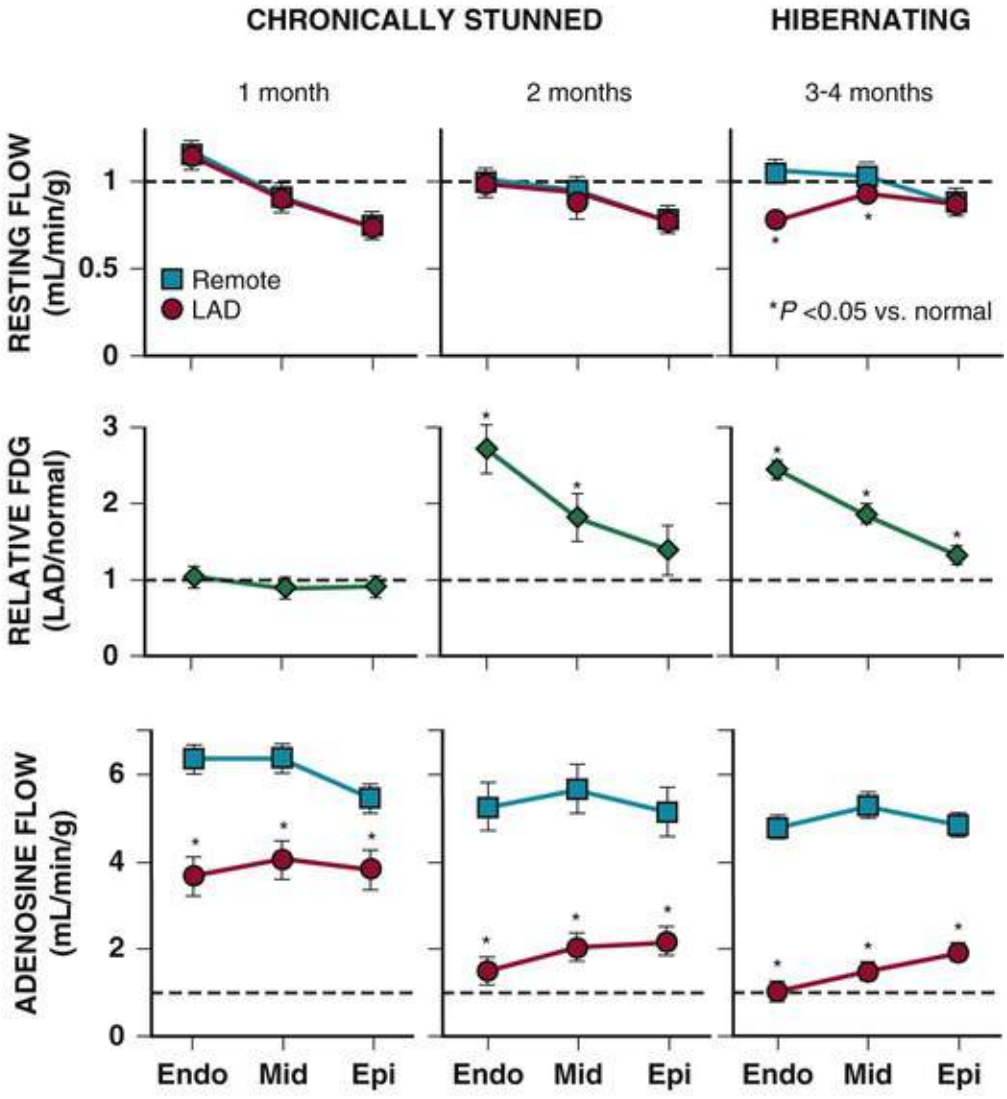
It was originally thought that hibernating myocardium arose from a primary reduction in flow similar to experimental models of prolonged moderate ischemia and short-term hibernation. Whereas this is a plausible mechanism for the development of hibernating myocardium in association with an acute coronary syndrome, experimental studies have subsequently demonstrated that delayed subendocardial infarction is the rule rather than the exception when moderate flow reductions are maintained for more than 24 hours.[32] Many patients with hibernating myocardium present with LV dysfunction rather than symptomatic ischemia. Serial studies in animals (see Classic References, Fallavollita) have now demonstrated that the reductions in relative resting flow are a consequence rather than a cause of the contractile dysfunction.[32] This paradigm, relevant to chronic CAD, was proposed after experimental

studies with a slowly progressive left anterior descending artery (LAD) stenosis demonstrated that dysfunction with normal resting flow, consistent with chronic stunning, precedes the development of hibernating myocardium after 3 months[32,35] (**Fig. 57.29**). The progression from chronically stunned myocardium (with normal resting flow) to hibernating myocardium (with reduced flow) is related to the functional significance of the chronic stenosis supplying the LAD region and is probably a reflection of its propensity to produce repetitive supply- or demand-induced ischemia. This progression can be seen as soon as 1 week after placement of a critical stenosis that exhausts coronary flow reserve.[35] As regional dysfunction progresses from chronically stunned to hibernating myocardium, the myocyte takes on regional characteristics similar to those from an explanted heart with advanced failure. Normally perfused remote-zone cardiac myocytes can be normal or can take on structural alterations similar to the dysfunctional region. Some of the major cellular responses are summarized here.



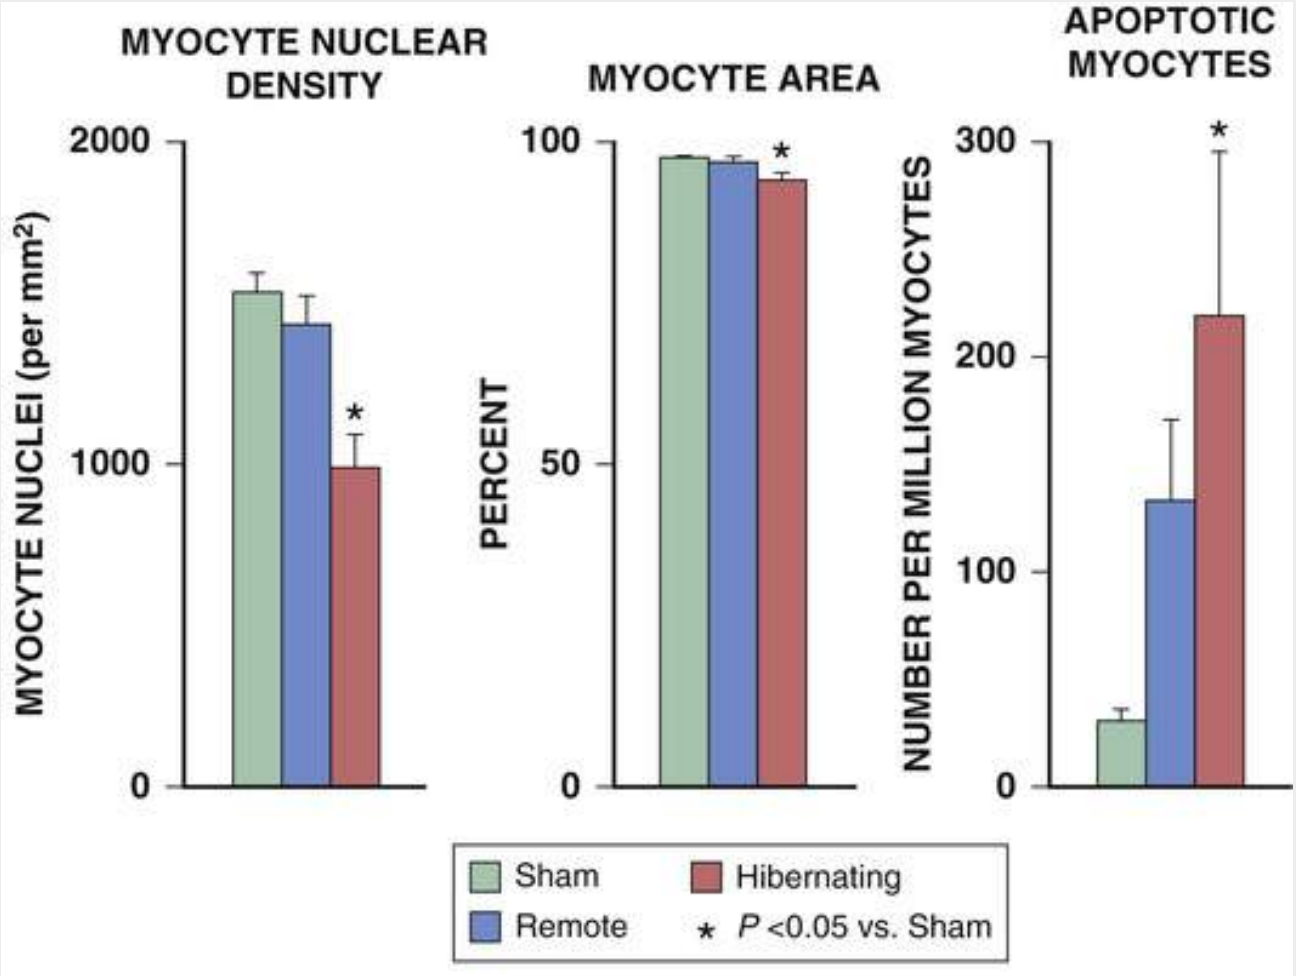
STENOSIS (%)	74 ± 5%	83 ± 6%	97 ± 2% †
ANTERIOR WALL MOTION	2.1 ± 0.1	1.5 ± 0.3	0.7 ± 0.2 †

† *P* <0.05 vs. 1 month

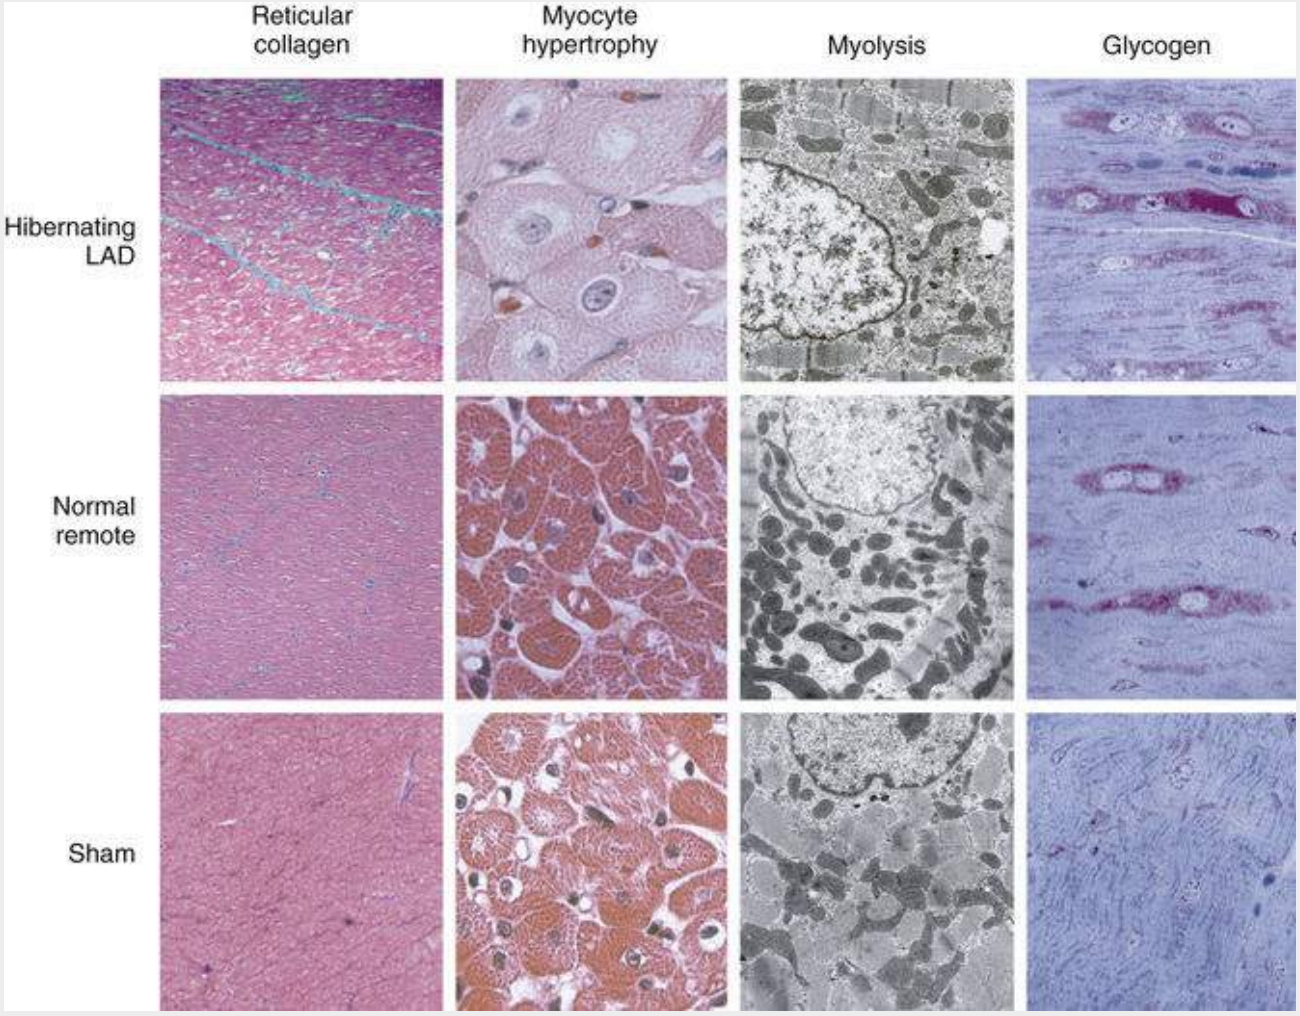
FIGURE 57.29 Progression from chronically stunned to hibernating myocardium as stenosis severity increases in swine with viable dysfunctional myocardium from a chronic left anterior descending artery (LAD) stenosis. Transmural flow measurements (microspheres) at rest and adenosine vasodilation are shown, along with regional ^{18}F-2-fluoro-2-deoxyglucose (FDG) uptake (under fasting conditions). Shown below are the angiographic stenosis severity and anterior wall motion score—3, normal; 2, mild hypokinesis; 1, severe hypokinesis; 0, akinesis. As stenosis severity increases over time, there is a reduction in vasodilated flow (adenosine) to the LAD region. Initially, there is anterior hypokinesis, with normal resting flow consistent with chronically stunned myocardium. After 3 months, the stenosis progresses to occlusion with collateral-dependent myocardium. Subendocardial flow is critically reduced and there is a reduction in resting flow to the inner two thirds of the LAD myocardium. At this time, hibernating myocardium is present, and there is no evidence of infarction. The temporal progression of abnormalities demonstrates that chronic stunning precedes the development of hibernating myocardium. In contrast with short-term hibernation resulting from acute ischemia, the reduction in resting flow is a consequence, rather than a cause, of the contractile dysfunction. Endo, Endocardium; Epi, epicardium. (Modified from Fallavollita JA, Canty JM Jr: Differential ^{18}F-2-deoxyglucose uptake in viable dysfunctional myocardium with normal resting perfusion: Evidence for chronic stunning in pigs. Circulation 99:2798, 1999.)

Apoptosis, Myocyte Loss, and Myofibrillar Loss.

The frequency of focal myocyte death from apoptosis varies during the development of viable dysfunctional myocardium and thus is probably responsible for the variability in the frequency of apoptosis when analyzing biopsies from patients.[35] Experimentally, apoptosis is particularly prominent during the transition from chronically stunned to hibernating myocardium, at which time there is a loss of approximately 30% of the regional myocytes (**eFigs. 57.7 and 57.8**). The myocyte loss results in compensatory regional myocyte hypertrophy to maintain approximately normal wall thickness. Light microscopic and ultrastructural characteristics of hibernating myocardium from transmural biopsy samples are characterized by small increases in interstitial connective tissue, myofibrillar loss (myolysis), increased glycogen deposition, and mini-mitochondria. Experimental animal models of hibernating myocardium also develop these structural changes as quickly as 2 weeks, but they also are present in remote, normally perfused regions of the heart.[32,35] Global cellular changes also have been reported in patients in the absence of a stenosis, suggesting that the structural changes probably are the result of chronically elevated preload. Thus, although cellular dedifferentiation had been emphasized as a mechanism of adaptation, the global ultrastructural changes probably are not causally related to the regional responses to ischemia in hibernating myocardium.[32,35]



EFIGURE 57.7 Progressive myocyte loss and compensatory cellular hypertrophy in hibernating myocardium. Data for hibernating left anterior descending artery (LAD) regions are compared with those for remote regions as well as with those for LAD regions from normal animals. The progression from chronically stunned to hibernating myocardium is accompanied by regional myocyte apoptosis. Although this occurs in only 1 in 5000 myocytes at any instant in time, it is a continuous process that over several months leads to substantial myocyte loss. The result is an approximately 30% reduction in myocyte nuclear number without significant fibrosis, because the myocyte area remains essentially normal. The latter is the result of compensatory myocyte cellular hypertrophy (**see eFig. 57.8**). (From Lim H, Fallavollita JA, Hard R, et al. Profound apoptosis-mediated regional myocyte loss and compensatory hypertrophy in pigs with hibernating myocardium. Circulation 1999;100:2380.)



EFIGURE 57.8 Myocyte cellular changes in hibernating myocardium. The increased myocyte apoptosis results in compensatory myocyte cellular hypertrophy in hibernating myocardium (**see eFig. 57.7**). Although reticular collagen is regionally increased (approximately 2%), there is no evidence of infarction. The electron microscopic characteristics of hibernating myocardium (myolysis, glycogen) demonstrate myofibrillar loss, an increased number of small mitochondria, and increased glycogen content. Although these are markedly different from normal myocardium (sham), biopsy samples from normal remote, nonischemic segments show similar electron microscopic changes, indicating that these ultrastructural abnormalities are not directly related to ischemia, nor are they the cause of regional contractile dysfunction. LAD, Left anterior descending coronary artery region. (From Canty JM, Fallavollita JA. Hibernating myocardium. J Nucl Cardiol 2005;12:104.)

Cell Survival and Antiapoptotic Program in Response to Repetitive Ischemia.

Variability in the regulation of cell survival pathways in response to repetitive ischemia has been well documented. Some studies have demonstrated upregulation of cardioprotective mechanisms in response to repetitive reversible ischemia, which may be operative in minimizing myocyte cell death and fibrosis in the chronic setting. In experimental studies in animals without heart failure, antiapoptotic and stress proteins such as heat shock protein (HSP)-70 have been found to be upregulated,[42] whereas increased proapoptotic proteins and a profile of progressive cell death and fibrosis have been reported in biopsies of patients with hibernating myocardium and heart failure.[35] This variability among reported studies probably reflects the frequency and severity of ischemia, modulation by neurohormonal activation in heart failure, and the complexity of the temporal expression of adaptive and maladaptive responses in myocardium subjected to chronic repetitive ischemia. In this regard, the physiologic significance of a stenosis (i.e., coronary flow reserve) has been shown to be a major determinant of the intrinsic myocardial adaptations to ischemia.[43]

Metabolism and Energetics in Hibernating Myocardium.

Once adapted, the metabolic and contractile response of hibernating myocardium appears to be dissociated from external determinants of workload. As a result, submaximal increases in oxygen consumption can occur without immediately leading to subendocardial ischemia.[35] Experimentally, the hibernating myocardial region appears to operate over a lower range of the normal myocardial supply-demand relation in a manner similar to that for the nonischemic failing heart. Although glycogen content is increased, maximum rates of glucose uptake during insulin stimulation are not altered. Studies of isolated mitochondria from swine with hibernating myocardium have demonstrated alterations in mitochondrial respiration, with downregulation of energy utilization and oxygen consumption.[44] This slows ATP utilization and presumably maintains cell viability during superimposed acute ischemia. Proteomic analysis has demonstrated a reduction in multiple proteins involved in oxidative metabolism and electron transport.[42] Some but not all of the molecular and cellular changes associated with hibernating reverse after revascularization, which can contribute to the failure of contractile function to normalize completely in the absence of MI.[45]

Inhomogeneity in Sympathetic Innervation, Beta-Adrenergic Responses, and Sudden Death.

The contractile response of hibernating myocardium is blunted and partly related to a regional downregulation in beta-adrenergic adenylyl cyclase coupling, similar to that found globally in advanced heart failure.[46] This effect may be related to local norepinephrine overflow and reduced presynaptic uptake of norepinephrine.[46] The resultant inhomogeneity in myocardial sympathetic nerve function may be one of the reasons responsible for the vulnerability of experimental hibernating myocardium to develop lethal ventricular arrhythmias and ventricular fibrillation.[47] Thus, reversing electrical instability as well as improving contractile dysfunction may account for the positive impact of coronary revascularization on survival.[35] Despite this effect, the extent of viable, denervated myocardium remains a strong predictor of arrhythmic death in patients with ischemic cardiomyopathy.[48]

Successful Adaptation versus Degeneration in Hibernating Myocardium.

There is considerable divergence among studies regarding the pathology of reversibly dyssynergic hibernating myocardium. At one extreme, some investigators believe that the myocardium is destined to undergo irreversible myocyte death, which is supported by data showing large amounts of fibrosis (>30% of the tissue) and greatly abnormal high-energy phosphate metabolism, as well as by retrospective analysis suggesting that the degree of fibrosis is related to the duration of hibernating myocardium.[35] At the other extreme, in some circumstances, fibrosis is not a prominent feature with normal myocardial energetics at rest, suggesting that hibernating myocardium can be sustained for long periods without progressive degeneration.[47,48] The factors that promote a path toward progressive degeneration versus adaptation are currently unknown but may be modulated by the superimposed neurohormonal activation and elevation in cytokine levels associated with advanced clinical heart failure, as well as intermittent irreversible injury that arises from intermittent reductions in coronary flow below the threshold required to maintain myocyte viability.

Future Perspectives

The major factors determining myocardial perfusion and oxygen delivery that were established over the last 40 years have been incorporated into the current management of angina and have withstood the test of time. The basic understanding of the fluid mechanical behavior of coronary stenoses also has been translated to the cardiac catheterization laboratory, where measurements of coronary pressure distal to a stenosis and coronary flow are routinely obtained. These physiologic concepts now facilitate routine

clinical decision making in a way that favorably affects outcomes.

Despite progress in advancing our mechanistic understanding of the coronary circulation and myocardial ischemia in health and disease, important gaps remain in basic knowledge as well as in the translation of this knowledge to clinical care. For example, why some patients develop coronary collaterals or intrinsic adaptations to repetitive ischemia whereas others undergo progressive structural degeneration remains unclear. Basic research has identified the importance of physical factors such as shear stress and local coronary pressure in regulating isolated coronary resistance vessels, but how these interact in a complex vascular network to bring about the phenomenon of autoregulation and metabolic coronary vasodilation remains unanswered. Finally, although abnormalities in coronary microcirculatory control may be as important as stenosis severity in determining symptoms of myocardial ischemia and the risk for subsequent coronary events, our understanding of the physiologic and cellular mechanisms responsible for microvascular dysfunction is limited. Continued bench-to-bedside translational investigation in these and other areas is needed to advance our fundamental knowledge of coronary circulatory control and improve the care of patients with chronic ischemic heart disease.

ST-Elevation Myocardial Infarction

Pathophysiology and Clinical Evolution

Benjamin M. Scirica, Peter Libby, David A. Morrow

The pathologic diagnosis of myocardial infarction (MI) requires evidence of myocardial cell death caused by ischemia. Characteristic findings include coagulation necrosis and contraction band necrosis, often with patchy areas of myocytolysis at the periphery of the infarct. During the acute phase of MI, myocytes die in the infarct zone, with subsequent inflammation, clearance of necrotic debris, repair, and eventual scar formation.

Clinical diagnosis of MI requires a syndrome indicative of myocardial ischemia with some combination of myocardial necrosis detected by biochemical, electrocardiographic, or imaging

modalities. The sensitivity and specificity of the clinical tools for diagnosing MI vary considerably depending on the timing of evaluation after the onset of infarction. Cardiac professional societies have jointly established criteria for the diagnosis of MI (**Table 58.1**). The universal definition of *myocardial infarction* classifies MI into five types, depending on the circumstances in which the MI occurs (**Table 58.2**).[1] Successive revisions to the definition of MI and a shift to more sensitive biomarkers of myocardial injury have had important implications for the clinical care of patients, epidemiologic monitoring, public policy, and clinical trials.[2-4]

TABLE 58.1

Third Universal Definition of Myocardial Infarction (MI)

Criteria for Acute Myocardial Infarction

The term *acute MI* should be used when there is evidence of myocardial necrosis in a clinical setting consistent with acute myocardial ischemia. Under these conditions, any of the following criteria meets the diagnosis for MI:
• Detection of a rise and/or fall in cardiac biomarker values (preferably cTn), with at least one value above the 99th percentile URL and with at least one of the following:
  • Symptoms of ischemia
  • New or presumed new significant ST-segment–T wave (ST-T) changes or new LBBB
  • Development of pathologic Q waves on the ECG
  • Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality
  • Identification of an intracoronary thrombus by angiography or autopsy
• Cardiac death with symptoms suggestive of myocardial ischemia and presumed new ischemic changes on the ECG or new LBBB, but death occurred before cardiac biomarkers were determined or before cardiac biomarker values would be increased.
• PCI-related MI is arbitrarily defined by elevation of cTn values (to >5 × 99th percentile URL) in patients with normal baseline values (≤99th percentile URL) or a rise in cTn values >20% if the baseline values are elevated and are stable or falling. In addition, either (1) symptoms suggestive of myocardial ischemia, (2) new ischemic changes on the ECG, (3) angiographic findings consistent with a procedural complication, or (4) imaging demonstration of new loss of viable myocardium or new regional wall motion abnormality is required.
• Stent thrombosis associated with MI when detected by coronary angiography or autopsy in the setting of myocardial ischemia and with a rise and/or fall in cardiac biomarker values and at least one value higher than the 99th percentile URL.
• CABG-related MI is arbitrarily defined by elevation of cardiac biomarker values (to >10 × 99th percentile URL) in patients with normal baseline cTn values (≤99th percentile URL). In addition, either (1) new pathologic Q waves or new LBBB, (2) angiographically documented new graft or new native coronary artery occlusion, or (3) imaging evidence of new loss of viable myocardium or new regional wall motion abnormality is required.

Criteria for Previous Myocardial Infarction
Any of the following criteria meets the diagnosis for prior MI: • Pathologic Q waves with or without symptoms in the absence of nonischemic causes. • Imaging evidence of a region of loss of viable myocardium that is thinned and fails to contract in the absence of a nonischemic cause. • Pathologic findings of previous MI.

From Thygesen K, Alpert JS, White HD, et al. Universal definition of myocardial infarction. J Am Coll Cardiol 2012;60:1581.

TABLE 58.2

Third Universal Myocardial Infarction (MI) Classification of Type

Type 1: Spontaneous Myocardial Infarction

Spontaneous MI related to atherosclerotic plaque rupture, ulceration, fissuring, erosion, or dissection with resulting intraluminal thrombus in one or more of the coronary arteries that leads to decreased myocardial blood flow or distal platelet emboli with ensuing myocyte necrosis. The patient may have underlying severe CAD but on occasion nonobstructive or no CAD.

Type 2: Myocardial Infarction Secondary to Ischemic Imbalance

In cases of myocardial injury with necrosis in which a condition other than CAD contributes to an imbalance between myocardial oxygen supply and/or demand (e.g., coronary endothelial dysfunction, coronary artery spasm, coronary embolism, tachy/bradyarrhythmias, anemia, respiratory failure, hypotension, hypertension ± left ventricular hypertrophy).

Type 3: Myocardial Infarction Resulting in Death When Biomarker Values Are Unavailable

Cardiac death with symptoms suggestive of myocardial ischemia and presumed new ischemic changes on the ECG or new LBBB, but death occurring before blood samples could be obtained, before cardiac biomarkers could rise, or in rare cases, when cardiac biomarkers were not collected.

Type 4a: Myocardial Infarction Related to Percutaneous Coronary Intervention

MI associated with PCI is arbitrarily defined by elevation of cTn values to >5 × the 99th percentile URL in patients with normal baseline values (≤99th percentile URL) or a rise in cTn values >20% if the baseline values are elevated and are stable or falling. In addition, either (1) symptoms suggestive of myocardial ischemia, (2) new ischemic changes on the ECG or new LBBB, (3) angiographic loss of patency of a major coronary artery or a side branch or persistent slow flow or no flow or embolization, or (4) imaging demonstration of new loss of viable myocardium or new regional wall motion abnormality is required.

Type 4b: Myocardial Infarction Related to Stent Thrombosis

MI associated with stent thrombosis is detected by coronary angiography or autopsy in the setting of myocardial ischemia and with a rise and/or fall in cardiac biomarkers values with at least one value above the 99th percentile URL.

Type 5: Myocardial Infarction Related to Coronary Artery Bypass Grafting

MI associated with CABG is arbitrarily defined by elevation of cardiac biomarker values to >10 × the 99th percentile URL in patients with normal baseline cTn values (<99th percentile URL). In addition, either (1) new pathologic Q waves or new LBBB, (2) angiographically documented new graft or new native coronary artery occlusion, or (3) imaging evidence of new loss of viable myocardium or new regional wall motion abnormality is required.

CAD, coronary artery disease; *cTn*, cardiac troponin; *LBBB*, left bundle branch block; *URL*, upper reference limit.

From Thygesen K, Alpert JS, White HD, et al. Universal definition of myocardial infarction. J Am Coll Cardiol 2012;60:1581.

The contemporary approach to patients with new onset or worsening ischemic symptoms is to consider them as having an *acute coronary syndrome* (ACS), which encompasses the diagnoses of unstable angina, non–ST-segment elevation MI (NSTEMI), and ST-segment elevation MI (STEMI) (**Fig. 58.1**). The principal diagnostic tool for patients with suspected ACS is the 12-lead electrocardiogram (ECG), which identifies those with ST-segment elevation, the subject of this chapter and **Chapter 59**, and those without ST-segment elevation, the subject of **Chapter 60**.

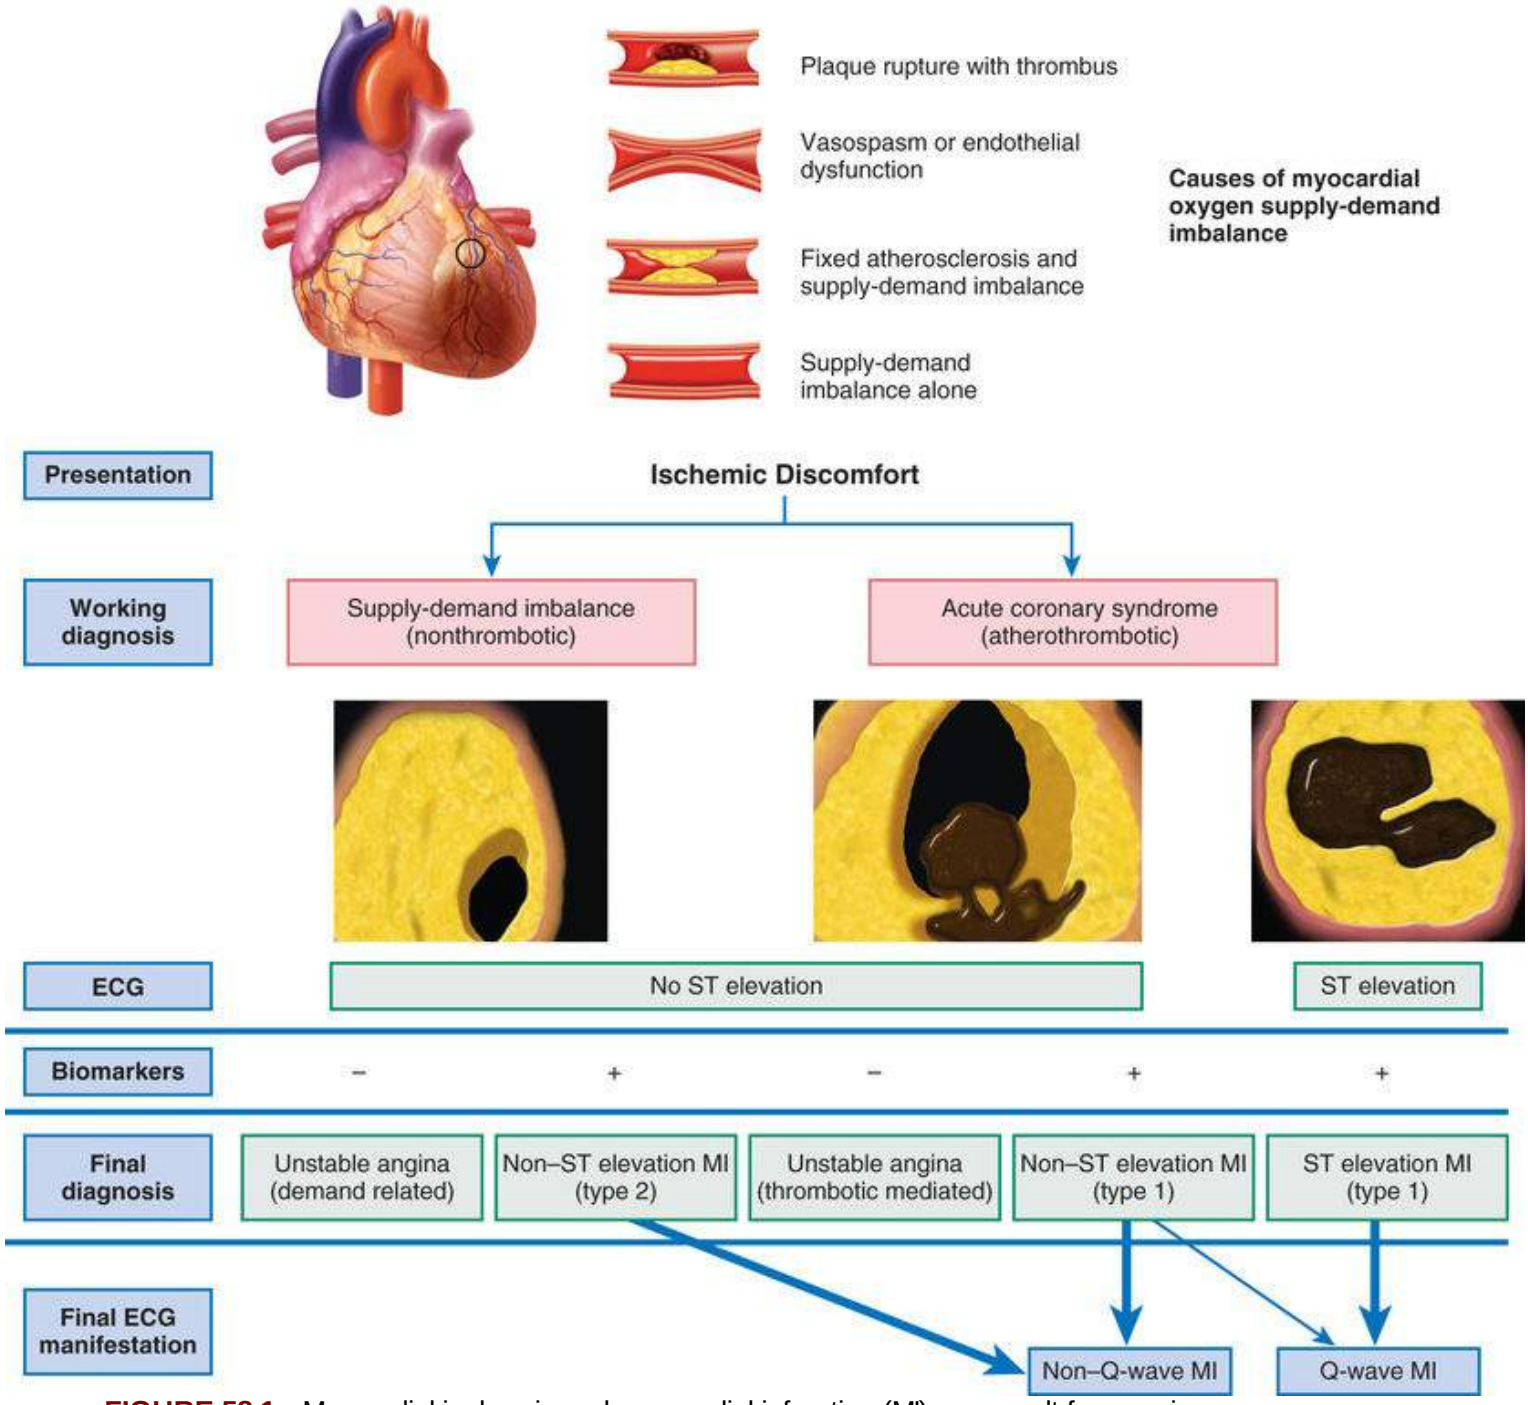

FIGURE 58.1 Myocardial ischemia and myocardial infarction (MI) can result from various coronary disease processes, including vasospasm, increased myocardial demand in the setting of a fixed coronary lesion, and erosion or rupture of vulnerable atherosclerotic plaque leading to acute thrombus formation and subsequent ischemia. All result in myocardial oxygen supply-demand mismatch and can precipitate ischemic symptoms, and all processes, when severe or prolonged, will lead to myocardial necrosis or infarction. Nonthrombotically mediated events (*bottom half, left side*) typically occur without ST-segment elevation (STE) on the ECG but can have elevated levels of cardiac biomarkers if the ischemia is severe and long enough, in which case they are classified as having type 2 MI. The atherothrombotic lesion is the hallmark pathobiologic event of an acute coronary syndrome (ACS). The reduction in flow may be caused by a completely occlusive thrombus (*bottom half, right side*) or by a subtotally occlusive thrombus (*bottom half, middle*). Ischemic discomfort may occur with or without STE on the ECG. Of patients with STE, Q wave MI ultimately develop in most, but not all patients, depending on the duration of ischemia and collateralization. Patients without STE have either unstable angina or non–ST-segment elevation MI (NSTEMI), a distinction that is ultimately made by the presence or absence of a serum or plasma cardiac marker (e.g., cardiac troponin) detected in blood. Non–Q wave MI ultimately develops in most patients with NSTEMI on the ECG; Q wave MI may develop in a few. MI that develops as the result of the atherothrombotic lesion of an ACS is classified as type 1 MI. (Modified from Thygesen K, Alpert JS, Jaffe AS, et al. Third universal definition of myocardial infarction. J Am Coll Cardiol 2012;60:1581.)

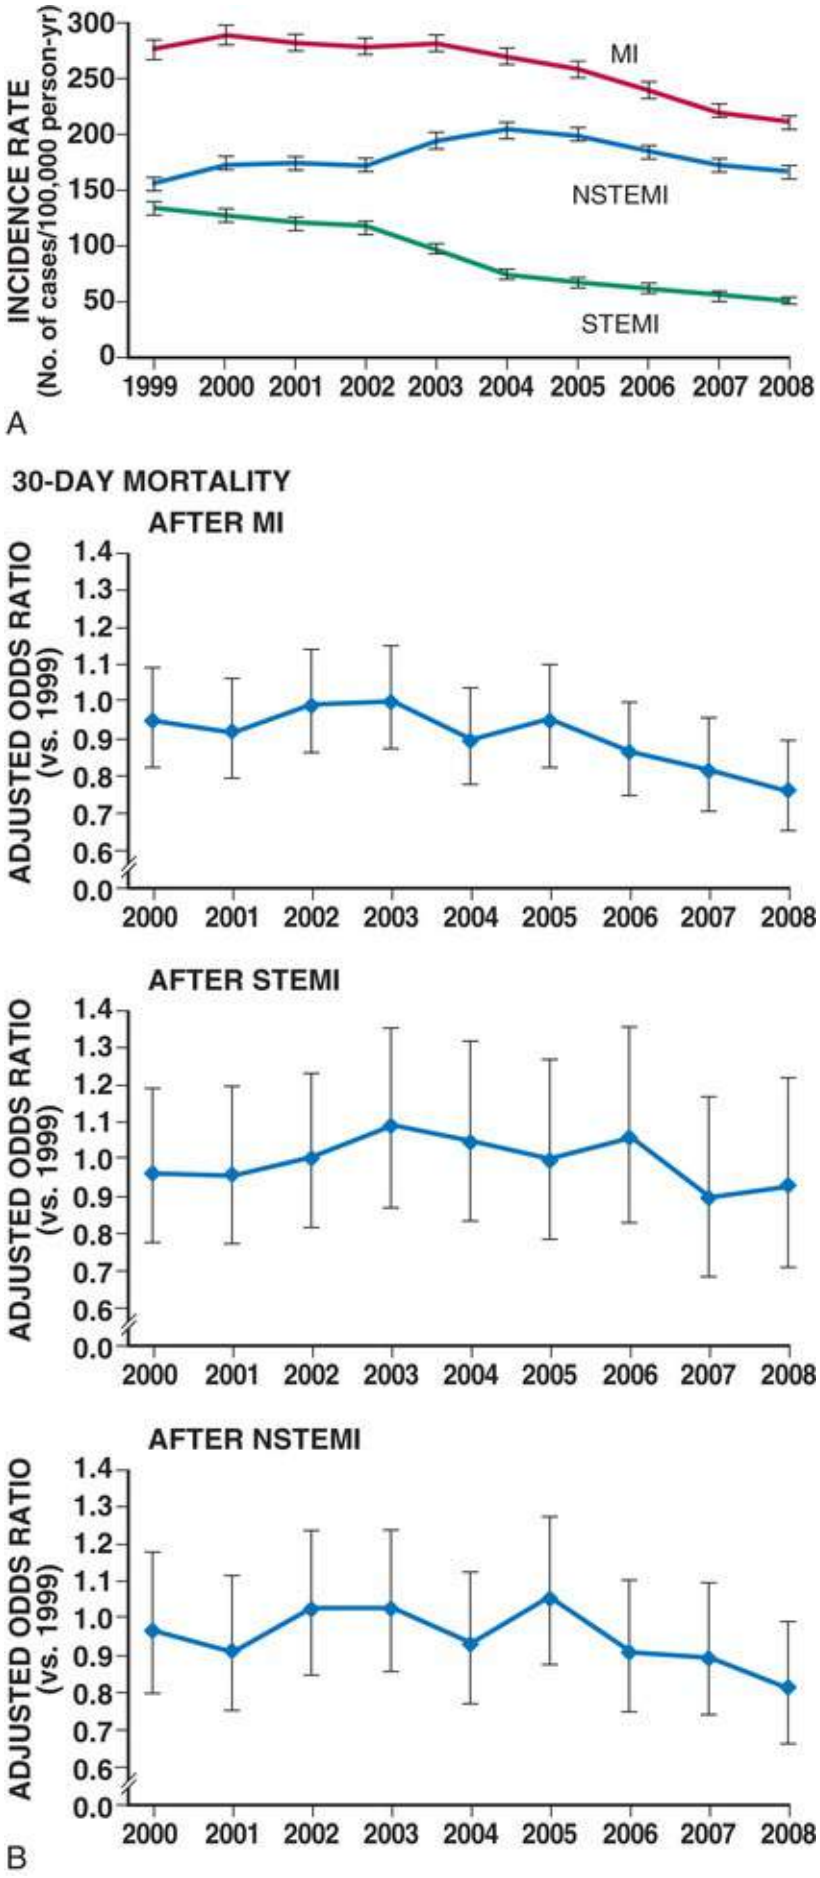
Changing Patterns in Incidence and Care

Despite advances in diagnosis and management, STEMI remains a major public health problem in the industrialized world and is on the rise in developing countries[5] (**see Chapter 1**). Each year in the United States alone, more than 1 million patients will be hospitalized for an MI or coronary heart death.[6] The rate of MI rises sharply in both men and women with increasing age, and racial differences exist, with MI occurring more frequently in black men and women compared to white, regardless of age. The proportion of patients with ACS events who have STEMI varies across observational studies but has declined over the past decade, in part due to the introduction of more sensitive assays of myocardial injury that increase the number of NSTEMI cases relative to STEMI.[6] This estimate does not include "silent" MI, which may not prompt hospitalization. Between 1999 and 2008, the proportion of patients with an ACS and STEMI declined by almost 50% (47.0% to 22.9%)[4] (**eFig. 58.1**). Although hospitalizations for MI have declined for patients older than 55 years old, there has not been a similar decline in the rates for younger patients, in particular in women.[7] Of particular concern from a global perspective, the burden of coronary disease in low- and middle-income countries has reached the rate affecting more affluent countries.[5] The limited resources available to treat STEMI in low- and middle-income countries mandate major international efforts to strengthen primary prevention programs.



EFIGURE 58.1 **A,** Age- and sex-adjusted incidence rates of acute myocardial infarction (MI) from 1999 to 2008. *I bars* represent 95% confidence intervals. **B,** Adjusted odds ratios are shown for 30-day mortality according to year after any MI (*top*), STEMI (*middle*), and NSTEMI (*bottom*). Models were adjusted for patient demographic characteristics, previous cardiovascular disease, cardiovascular risk factors, chronic lung disease, and systemic cancer. The reference year is 1999. (From Yeh RW, Sidney S, Chandra M, et al. Population trends in the incidence and outcomes of acute myocardial infarction. N Engl J Med 2010;362:2155.)

Improvements in Outcome

The overall number of deaths from STEMI has declined steadily over the past 30 years, but it has stabilized over the past decade[8] (**eFig. 58.1**). Both a decreased incidence of STEMI and a decline in the case-fatality rate after STEMI have contributed to this trend.[6] According to estimates from the American Heart Association (AHA), the short-term mortality rate of patients with STEMI ranges from 5% to 6% during the initial hospitalization and from 7% to 18% at 1 year.[8,9] The highest risk of ischemic complications following MI occurs within 180 days, after which the risk becomes fairly linear. This pattern is most evident in patients older than 80 years[10] (**Fig. 58.2**). Mortality rates in clinical trial populations tend to be approximately half of those observed in registries of consecutive patients, most likely because of the exclusion of patients with more extensive comorbidities.

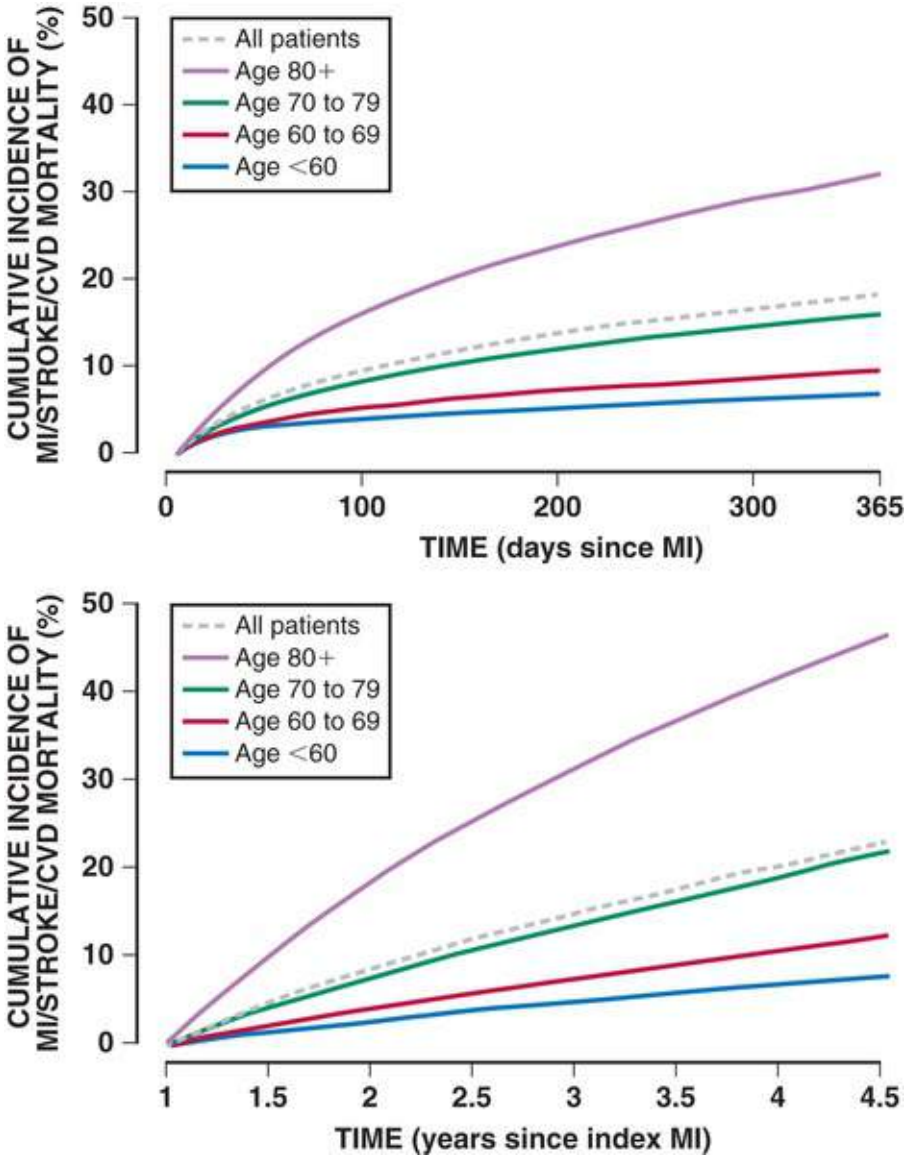


FIGURE 58.2 Cardiovascular risk after myocardial infarction (MI) by age. Kaplan-Meier estimate of the risk of the combined endpoint (MI, ischemic stroke, or cardiovascular disease [CVD] mortality) during the first 365 days after the index MI (*top*) and after 1 year from the initial infarction (*bottom*). (From Jernberg T, Hasvold P, Henriksson M, et al. Cardiovascular risk in post-myocardial infarction patients: nationwide real world data demonstrate the importance of a long-term perspective. Eur Heart J 2015;36:1163-70.)

Improvements in the management of patients with STEMI have occurred in several phases.[11,12] The "clinical observation phase" of coronary care consumed the first half of the 20th century and focused on detailed recording of physical and laboratory findings, with little active treatment of the infarction. The "coronary care unit phase" began in the mid-1960s and emphasized early detection and management of cardiac arrhythmias based on the development of monitoring and cardioversion/defibrillation capabilities. The "high-technology phase," heralded by the introduction of the pulmonary artery balloon flotation catheter, set the stage for bedside hemodynamic monitoring and directed hemodynamic management. The modern "reperfusion era" of STEMI care began with intracoronary and then intravenous fibrinolysis, increased use of aspirin (**see Chapter 59**), and subsequently the development and evolution of primary percutaneous coronary intervention (PCI) (**Chapter 62**).

Contemporary care of patients with STEMI has entered an "evidence-based coronary care phase," driven by professional society guidelines and performance measure benchmarks for clinical practice.[13,14] Implementation of guideline-directed medical treatment (GDMT) and regional quality initiatives has significantly decreased heterogeneity in care, increased compliance with evidence-based therapies, and improved outcomes.[15]

Limitations of Current Therapy

Rates of appropriate initiation of reperfusion therapy vary widely, with up to 30% of patients with STEMI who are eligible to receive reperfusion therapy not receiving this lifesaving treatment in some registries.[16] Care of another substantial proportion of patients does not meet the recommended door-to-reperfusion time.[17] This gap mandates initiatives to increase timely administration of guideline-directed reperfusion therapy[18] (**see Chapter 59**).

Management and outcomes of patients with STEMI appear to vary substantially depending on the volume of such patients cared for within a hospital system.[19] Hospitals with a high clinical volume, a high rate of invasive procedures, and a top ranking in quality reports have lower STEMI mortality rates. Conversely, patients with STEMI not cared for by a cardiovascular specialist have higher mortality rates. Variation also occurs in the treatment patterns of certain population subgroups with STEMI, including elderly, women,[20] blacks, and some high-risk patients (e.g., presenting with cardiogenic shock).

The advent of mandatory reporting for procedural complications and outcomes in STEMI has led to the establishment of benchmarks for procedural success and mortality rates and the ability to compare across different regions and hospitals.[15] However, public reporting of outcomes in STEMI may also have unintentionally led to lower rates of revascularization in the highest-risk patients, who would often benefit most from early revascularization (e.g., cardiogenic shock) because of the concern regarding higher case-fatality rates.[21]

Pathologic Findings

Almost all acute coronary syndromes result from coronary atherosclerosis, generally with superimposed coronary thrombosis caused by rupture or erosion of an atherosclerotic lesion[22] (**see Chapters 44 and 60**). Nonatherogenic forms of coronary artery disease are discussed later in this chapter, and causes of MI without coronary atherosclerosis are presented in **Table 58.3**.

TABLE 58.3

Causes of Myocardial Injury

Injury Related to Primary Myocardial Ischemia
Plaque rupture
Intraluminal coronary artery thrombus formation
Injury Related to the Supply-Demand Imbalance of Myocardial Ischemia
Tachyarrhythmias/bradyarrhythmias
Aortic dissection or severe aortic valve disease
Hypertrophic cardiomyopathy
Cardiogenic, hypovolemic, or septic shock
Severe respiratory failure
Severe anemia
Hypertension with or without left ventricular hypertrophy
Coronary spasm
Coronary embolism or vasculitis
Coronary endothelial dysfunction without significant coronary artery disease
Injury Not Related to Myocardial Ischemia
Cardiac contusion, surgery, ablation, pacing, or defibrillator shocks
Rhabdomyolysis with cardiac involvement
Myocarditis
Cardiotoxic agents (e.g., anthracyclines, trastuzumab [Herceptin])
Multifactorial or Indeterminate Myocardial Injury
Heart failure
Stress (takotsubo) cardiomyopathy
Severe pulmonary embolism or pulmonary hypertension
Sepsis and critically ill patients
Renal failure
Severe acute neurologic diseases (e.g., stroke, subarachnoid hemorrhage)
Infiltrative diseases (e.g., amyloidosis, sarcoidosis)
Strenuous exercise

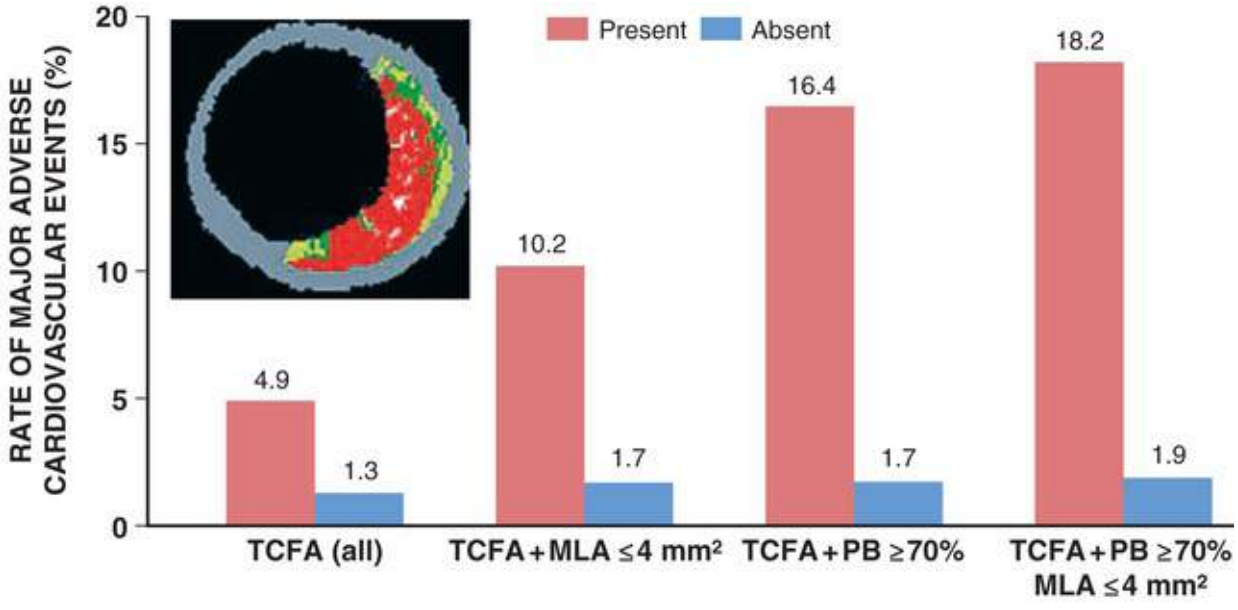
From Thygesen K, Alpert JS, White HD, et al. Universal definition of myocardial infarction. J Am Coll Cardiol 2012;60:1581.

When acute coronary atherothrombosis occurs, the resulting intracoronary thrombus may obstruct partially, which generally leads to myocardial ischemia in the absence of ST elevation, or occlude completely and cause transmural myocardial ischemia and STEMI. Before the fibrinolytic era, clinicians typically divided patients with MI into those in whom a Q wave developed on the ECG and those with non–Q wave MI based on evolution of the ECG pattern over several days. The term *Q wave infarction* was frequently considered to be virtually synonymous with "transmural infarction," whereas *non–Q wave infarctions* were often referred to as "subendocardial infarctions." Contemporary studies using cardiac magnetic resonance imaging (CMR) indicate that the development of a Q wave on the ECG depends more on the size of the infarct than on the depth of mural involvement. Thus the use of *ACS* is the more appropriate, broad conceptual framework as it is anchored by the underlying unifying pathophysiology (**see Fig. 58.1**). Further classification of patients by the presence of ST-segment elevation (STEMI) or by its absence (non–ST-segment elevation ACS), rather than by the evolution of Q waves, permits immediate clinical triage decisions regarding the need for urgent revascularization (**see Chapter 59**).

Plaque Formation and Disruption

Plaques that precipitates ACS usually provoke thrombi caused by fibrous cap rupture, superficial erosion, or occasionally vasospasm or disruption caused by a calcified nodule. Some cases of ACS lack an evident culprit thrombus (**see Chapter 44**). Current clinical data have challenged the simplistic concept of the "vulnerable plaque." In a prospective study of 697 patients with ACS who underwent three-vessel coronary angiography and gray-scale radiofrequency intravascular ultrasonographic imaging after PCI found that less than 5% of plaques with ultrasound characteristics of a thin-capped fibroatheroma actually caused a clinical event during a 3.4-year follow-up[23] (**Fig. 58.3**). Thus, equating the lipid-rich, thin-capped plaque with "vulnerability" is a misnomer. Other morphologic characteristics associated with

rupture-prone plaque include expansive remodeling that minimizes luminal obstruction (mild stenosis by angiography), neovascularization (angiogenesis), plaque hemorrhage, adventitial inflammation, and a "spotty" pattern of calcification.[24]



Lesion hazard ratio (95% CI)	3.90 (2.25–6.76)	6.55 (3.43–12.51)	10.83 (5.55–21.10)	11.05 (4.39–27.82)
P value	<0.001	<0.001	<0.001	<0.001
Prevalence (%)	46.7	15.9	10.1	4.2

FIGURE 58.3 Comparison of cardiovascular event rates for lesions that were and those that were not thin-cap fibrothecomas (TCFAs). This figure shows the event rates associated with 595 nonculprit lesions that were characterized as TCFAs and 2114 that were not, by means of gray-scale radiofrequency intravascular ultrasonographic imaging according to minimal luminal area (MLA) and plaque burden (PB). Lesions that had a larger plaque burden, signifying greater atherosclerotic content, and smaller lumen were at greatest risk for subsequently triggering an acute coronary event. *Insert,* Example of a TCFA imaged by radiofrequency ultrasonography. *Red* indicates necrotic core, *dark green* indicates fibrous tissue, *white* indicates confluent dense calcium, and *light green* indicates fibrofatty tissue. CI, Confidence interval. (From Stone GW, Maehara A, Lansky AJ, et al. A prospective natural-history study of coronary atherosclerosis. N Engl J Med 2011;364:226.)

Acute Coronary Syndromes

Plaque disruption exposes thrombogenic substances that may produce an extensive thrombus in the infarct-related artery (**see Fig. 58.1**). An adequate collateral network that prevents necrosis from occurring can result in clinically silent episodes of coronary occlusion; in addition, many plaque ruptures are asymptomatic if the thrombosis is not occlusive. Characteristically, completely occlusive thrombi lead to extensive injury to the ventricular wall in the myocardial bed subtended by the affected coronary artery (**Fig. 58.4**). Infarction alters the sequence of depolarization ultimately reflected as changes in the QRS complex. The most characteristic change in QRS that develops in most patients with STEMI is the evolution of Q waves in leads overlying the infarct zone. In a minority of patients with ST elevation, no Q waves develop but other abnormalities in the QRS complex occur frequently, such as diminution in R wave height and notching or splintering of the QRS (**see Chapter 12**). Patients who have ischemic symptoms without ST elevation are initially diagnosed as suffering either from unstable angina or, with evidence of myocardial necrosis, from NSTEMI.

The infarct artery can be deduced by identifying the leads that show ST elevation and referencing that polar map format **(D). F,** Identification of the infarct artery from the 12-lead ECG is shown for the arterial supply provided by the LAD, LCX, and RCA. For example, ST elevation seen most prominently in the leads overlying segments 1, 2, 7, 8, 13, 14, and 17 indicates that the LAD is the infarct artery. *D1,* First diagonal; *OM,* obtuse marginal; *PB,* posterobasal; *PD,* posterior descending; *PL,* posterolateral; *S1,* first septal. **G,** Further localization of culprit arteries via differential ECG patterns will depend on the location of lesion (proximal versus distal) and branch artery inclusion. (Modified from Bayes-de-Luna A, Wagner G, Birnbaum Y, et al. A new terminology for the left ventricular walls and location of myocardial infarcts that present Q wave based on the standard of cardiac magnetic resonance imaging. Circulation 2006;114:1755.)

Patients with persistent ST-segment elevation are candidates for reperfusion therapy (either pharmacologic or catheter based) to restore flow in the occluded epicardial infarct-related artery.[13,14] ACS patients without ST-segment elevation are not candidates for pharmacologic reperfusion but should receive anti-ischemic and antithrombotic therapy, followed in most cases by PCI (**see Chapter 60**). Thus

the 12-lead ECG remains at the center of the decision pathway for the management of patients with ACS, to distinguish between those with ST elevation and those without it.[13,14]

Heart Muscle

The cellular effects of ischemia commence within seconds of the onset of hypoxia with the loss of adenosine triphosphate (ATP) production. Myocardial relaxation-contraction is compromised, and irreversible cell injury begins within as early as 20 minutes. Necrosis is usually complete in 6 hours unless reperfusion occurs or an extensive collateral circulation is present (**Fig. 58.5**).

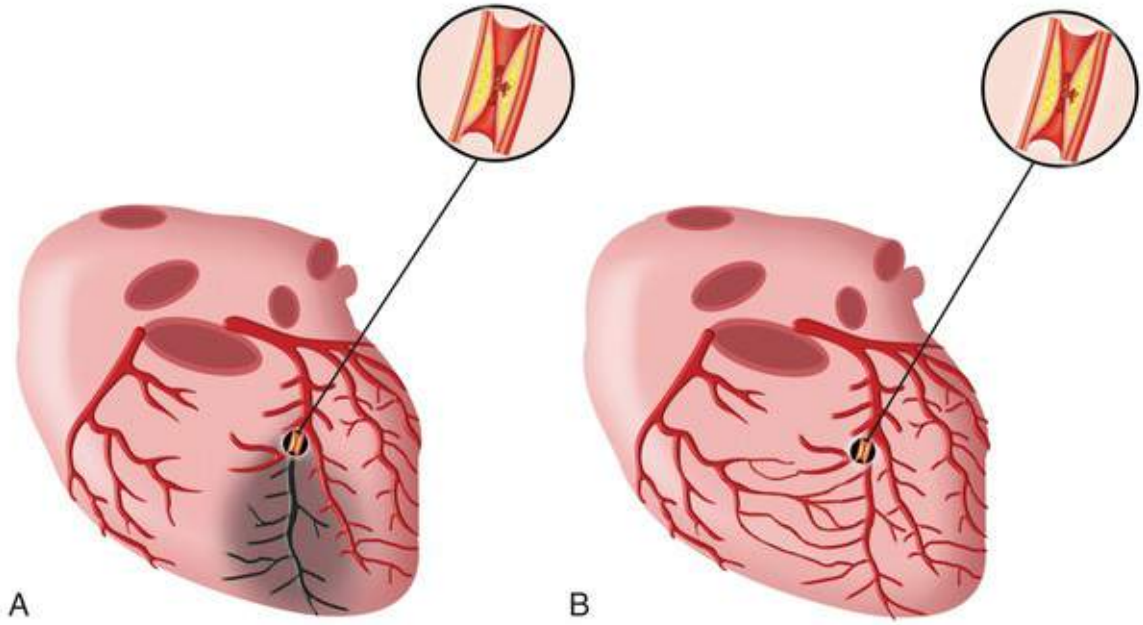

FIGURE 58.5 Schematic drawing of the coronary artery circulation without **(A)** and with **(B)** interarterial anastomoses between the right coronary artery and the occluded left anterior descending artery (LAD) (occluded downstream of the third diagonal branch). **A,** The *gray area* indicates the ischemic area at risk for MI (finally corresponding to infarct size) in the case of LAD occlusion and in the absence of collaterals. **B,** The area at risk for MI is equal to zero because of the extended collaterals. (From Traupe T, Gloekler S, de Marchi SF, et al. Assessment of the human coronary collateral circulation. Circulation 2010;122:1210.)

Gross Pathologic Findings

On gross inspection, MI falls into two major types: *transmural* infarcts, in which myocardial necrosis involves the full thickness (or almost full thickness) of the ventricular wall, and *subendocardial* (nontransmural) infarcts, in which the necrosis involves the subendocardium, the intramural myocardium, or both, without extending all the way through the ventricular wall to the epicardium (**Fig. 58.6**).

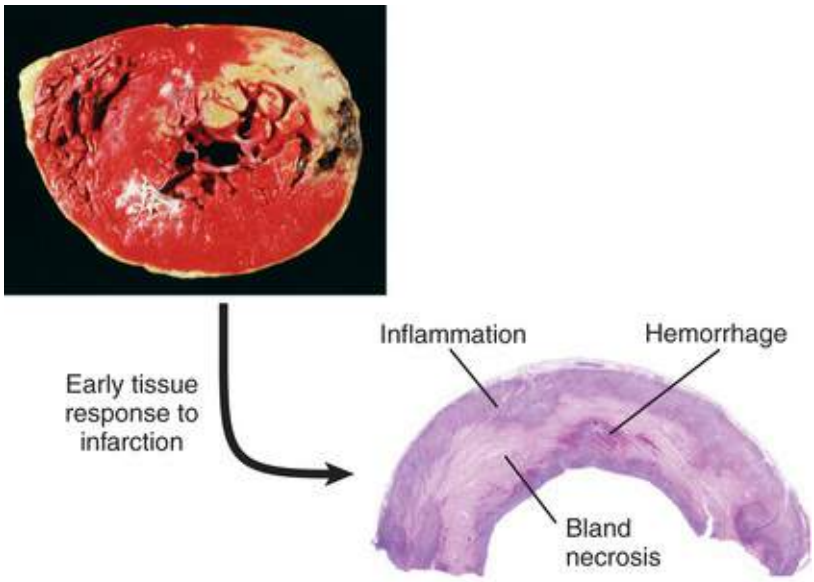

FIGURE 58.6 **Top,** Acute MI, predominantly of the posterolateral left ventricle, demonstrated histochemically by lack of staining with triphenyltetrazolium chloride in areas of necrosis. The staining defect is caused by leakage of the enzyme following cell death. The myocardial hemorrhage at one edge of the infarct was associated with cardiac rupture, and the anterior scar (*lower left*) was indicative of an old infarct. The specimen was oriented with the posterior wall at the top. **Bottom,** The early tissue response to the infarction process involves a mixture of bland necrosis, inflammation, and hemorrhage. (From Schoen FJ. The heart. In Kumar V, Abbas AK, Fausto N, editors. Robbins & Cotran Pathologic Basis of Disease. 8th ed. Philadelphia: Saunders; 2009.)

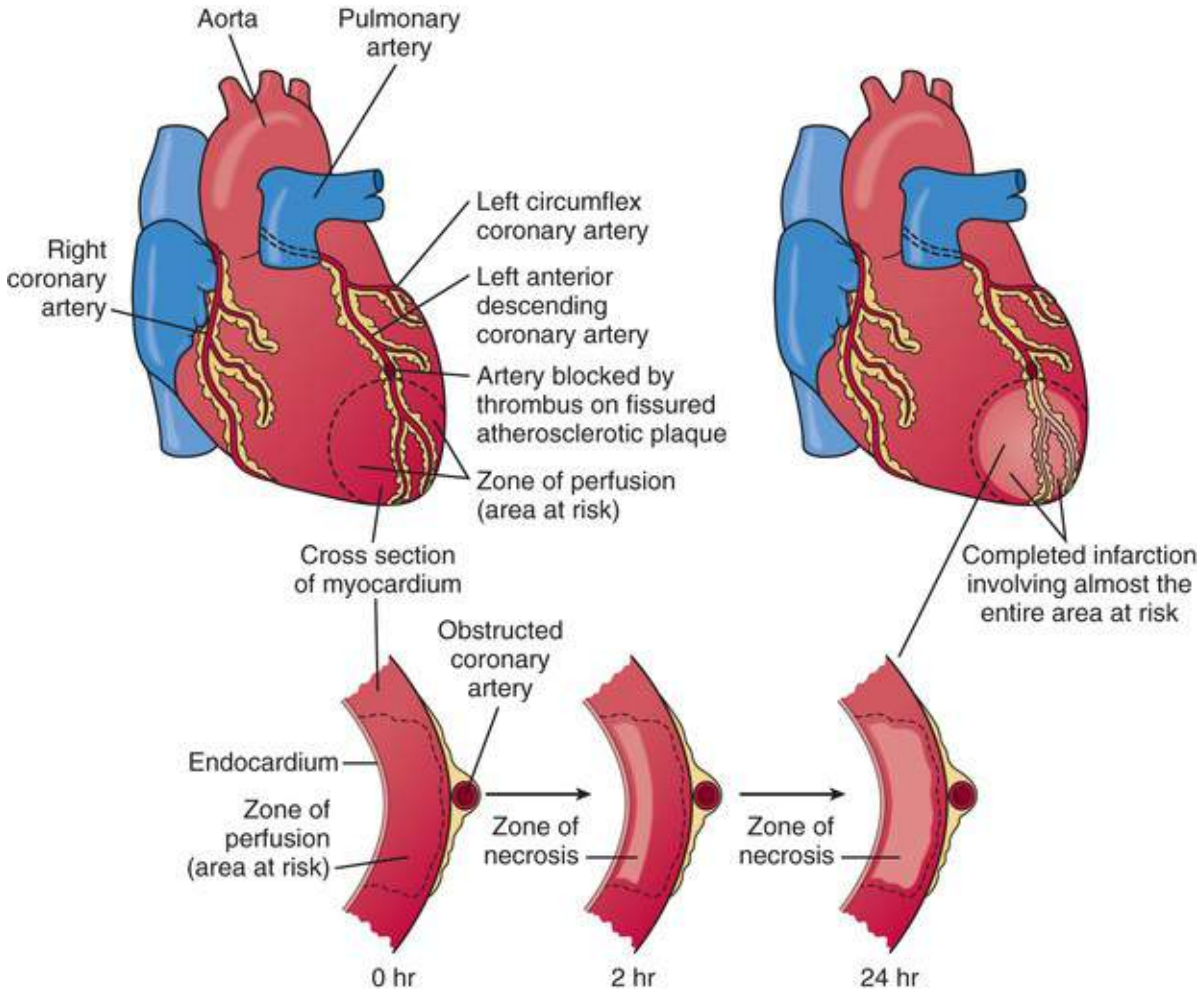
Occlusive coronary thrombosis appears to be much more common when the infarction is transmural and localized to the distribution of a single coronary artery (**see Fig. 58.4**). Nontransmural infarctions, however, frequently occur in the presence of severely narrowed but still patent coronary arteries, or when the infarcted region has sufficient collateral circulation. Patchy nontransmural MI may arise secondary to fibrinolysis or PCI of an originally occlusive thrombus, with restoration of blood flow *before* the wavefront of necrosis has extended from the subendocardium across the full thickness of the ventricular wall (**eFig. 58.2**).



EFIGURE 58.2 Schematic representation of the progression of myocardial necrosis after coronary artery occlusion. Necrosis begins in a small zone of the myocardium beneath the endocardial surface in the center of the ischemic zone. This entire region of myocardium (*dashed outline*) depends on the occluded vessel for perfusion and is the area at risk. A narrow zone of myocardium immediately beneath the endocardium is spared from necrosis because it can be oxygenated by diffusion from the ventricle.
(From Schoen FJ. The heart. In Kumar V, Abbas AK, Fausto N, editors. Robbins & Cotran Pathologic Basis of Disease. 8th ed. Philadelphia: Saunders; 2009.)

Histologic and Ultrastructural Findings

Gross alterations in the myocardium are difficult to identify until at least 6 to 12 hours has elapsed following the onset of necrosis (**Fig. 58.7**), but a variety of histochemical stains can identify zones of necrosis after only 2 to 3 hours. Subsequently, the infarcted myocardium undergoes a sequence of gross pathologic changes (**Fig. 58.8**). Within hours of death from MI, the presence of an infarct can often be detected by immersing slices of myocardium in triphenyltetrazolium chloride (TTC), which turns noninfarcted myocardium a brick-red color while the infarcted area remains unstained (**see Fig. 58.6**).

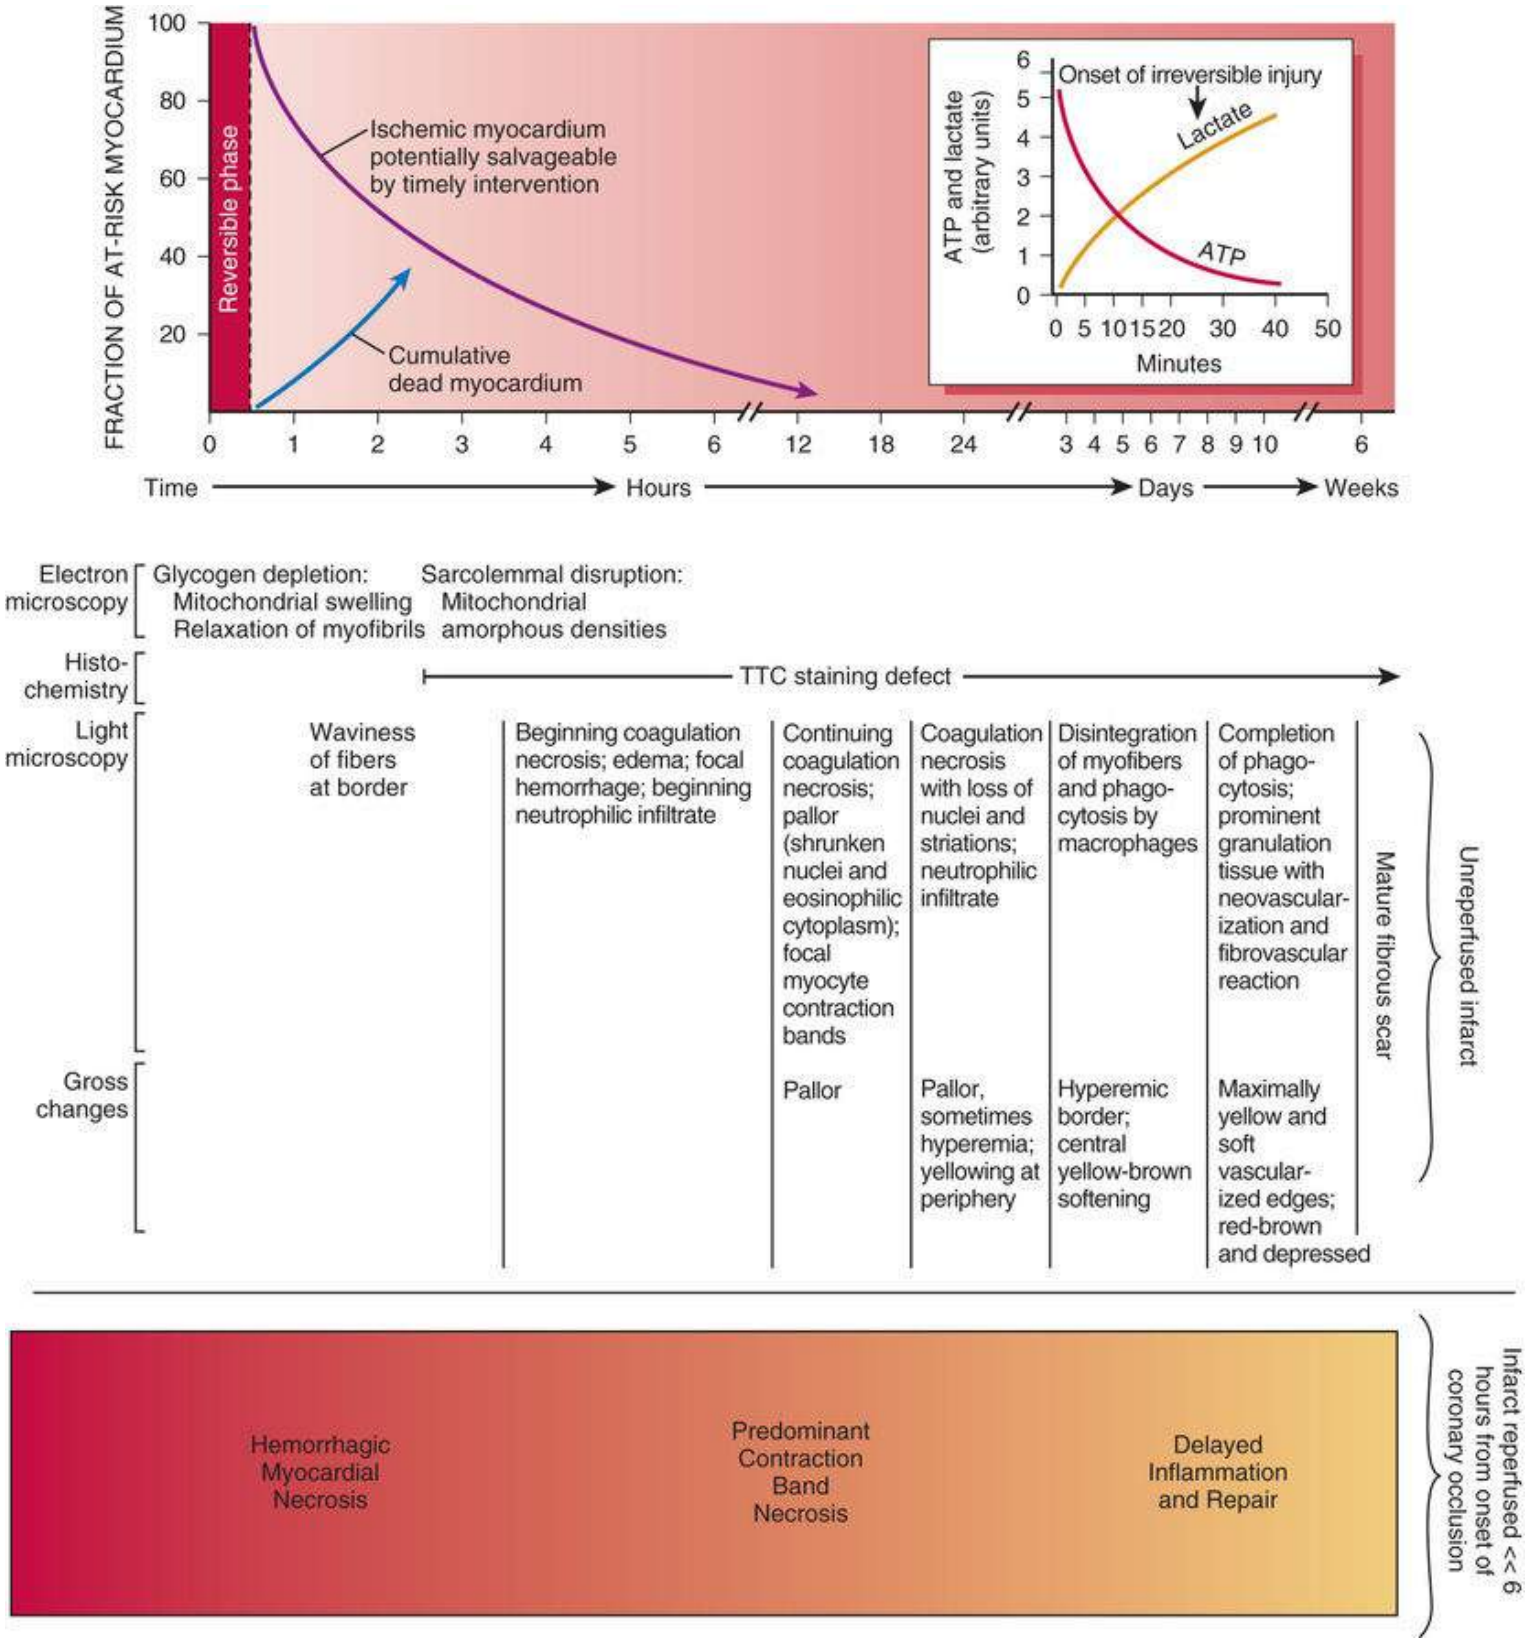


FIGURE 58.7 Temporal sequence of early biochemical, ultrastructural, histochemical, and histologic findings after the onset of myocardial infarction. **Top,** Schematics of the time frames for early and late reperfusion of the myocardium supplied by an occluded coronary artery. For approximately 30 minutes after the onset of even the most severe ischemia, myocardial injury is potentially reversible; after this point, progressive loss of viability occurs and is complete by 6 to 12 hours. The benefits of reperfusion are greatest when it is achieved early, with progressively smaller benefits occurring as reperfusion is delayed. Note the alterations in the temporal sequence in the reperfused infarct. The pattern of pathologic findings following reperfusion varies depending on the timing of reperfusion, previous infarction, and collateral flow. ATP, Adenosine triphosphate; TTC, triphenyltetrazolium chloride. (From Schoen FJ. The heart. In Kumar V, Abbas AK, Fausto N, editors. Robbins & Cotran Pathologic Basis of Disease. 8th ed. Philadelphia: Saunders; 2009.)

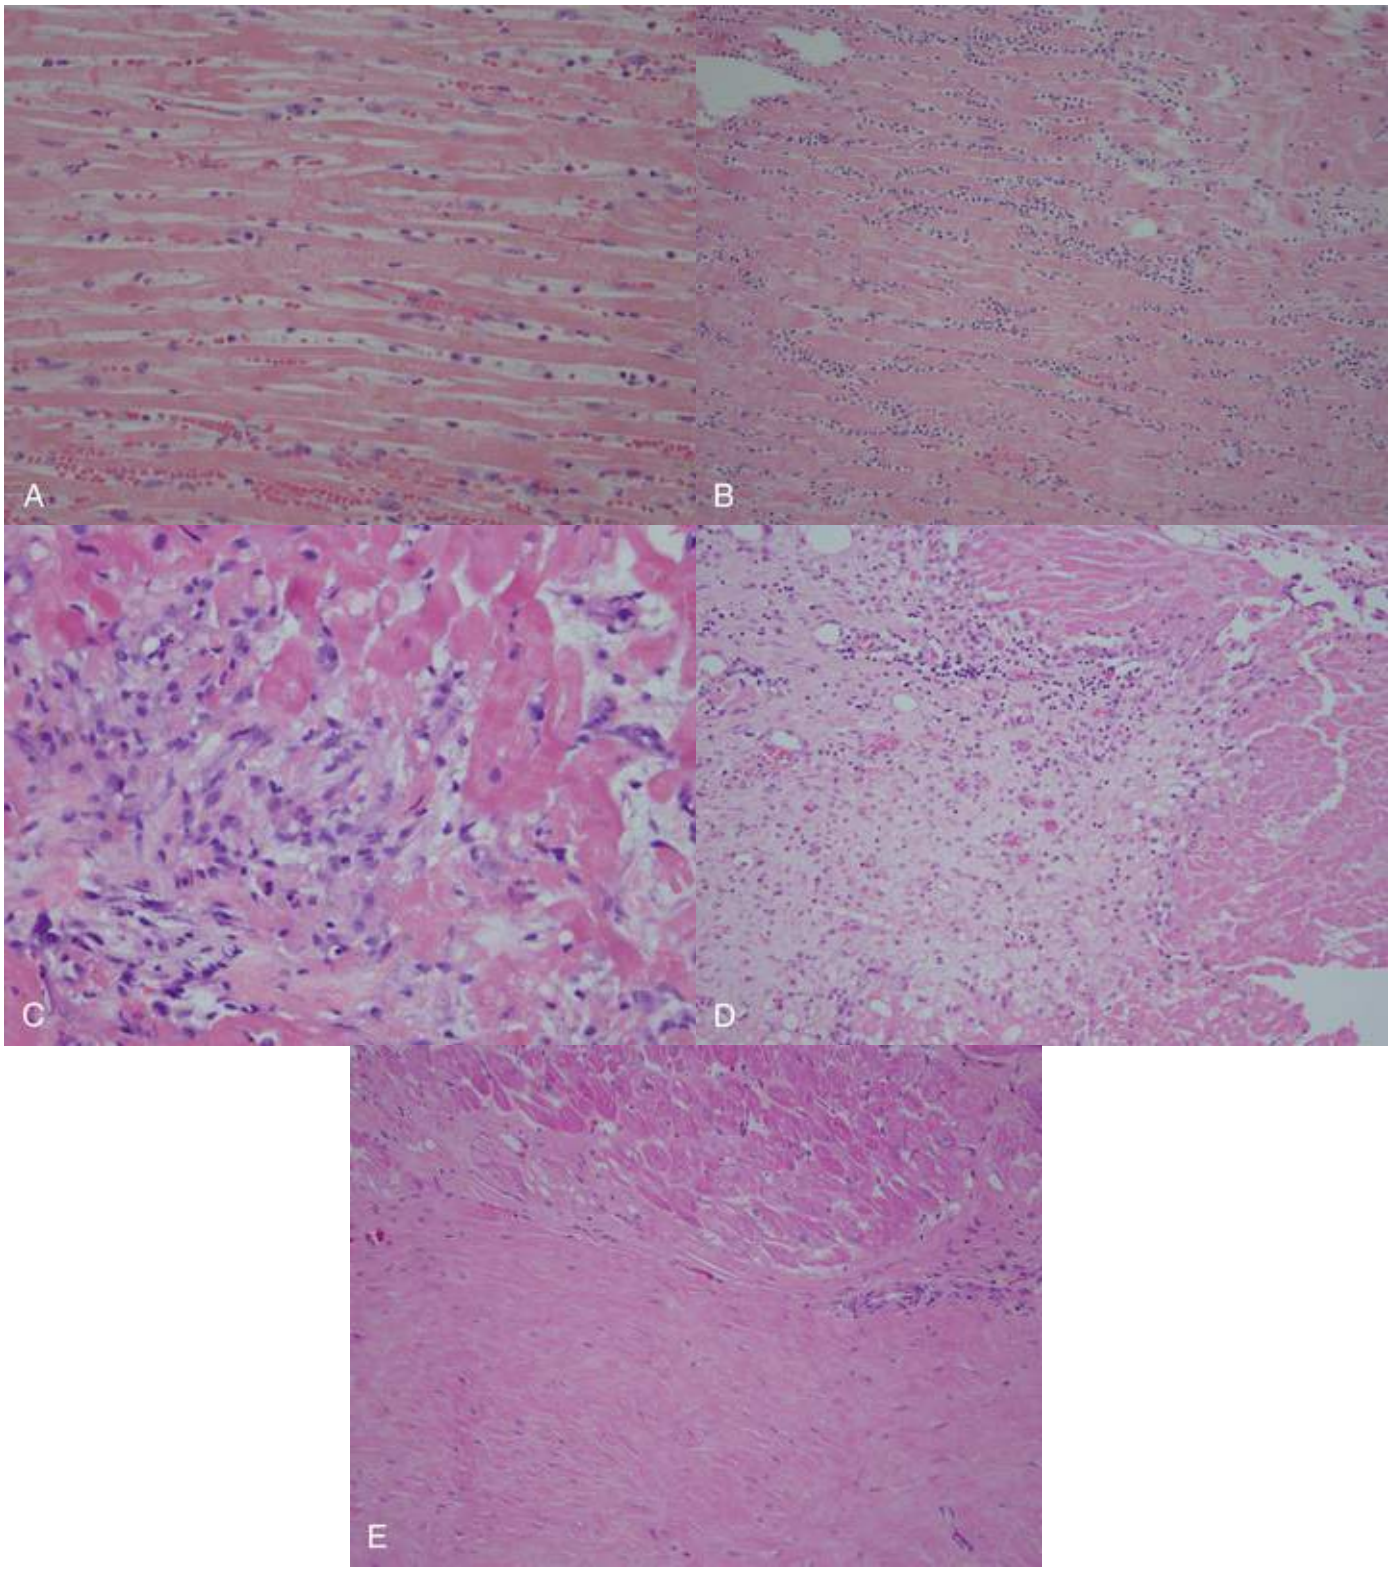

FIGURE 58.8 Microscopic features of myocardial infarction (MI). These histologic sections derived from the heart of a woman who suffered a stuttering reinfarction illustrate the histologic appearance of the injured myocardium and various phases of its healing. Times are estimated based on the clinical history and the typical pathologic findings of myocardial ischemic injury. **A,** At 8 hours post-MI, cross-striations are absent in some cardiac myocytes, and contraction bands are forming. There is myocardial interstitial edema, and leukocytes have begun to appear in the ischemically injured zone. **B,** At 36 hours post-MI, in the center of an ischemic area, most myocytes have lost cross-striations, contraction bands abound, and a predominantly polymorphonuclear leukocytic infiltrate has appeared. **C,** At 5 days post-MI, a few myocytes or fragments of myocytes persist with cross-striations. In the center of this micrograph, a predominantly monocytic leukocyte infiltrate surrounds the debris of dead myocytes. **D,** At 14 days following an acute ischemic insult, an island of granulation tissue has begun to form. There are numerous neovessels in areas of mononuclear cell accumulation. An organized extracellular matrix has begun to form. **E,** At 3 months following the acute ischemic event, an organized scar has formed in the matrix-rich and relatively hypocellular area on the bottom of this micrograph. Some surviving cardiac myocytes remain (*top* of micrograph). (Photomicrographs courtesy Dr. Robert F. Padera, Department of Pathology, Brigham and

Microscopic Findings

Histologic evaluation of MI reveals various stages of the healing process (**see Figs. 58.7 and 58.8**). In experimental infarction, the earliest ultrastructural changes in cardiac muscle after ligation of a coronary artery, noted within 20 minutes, consist of a reduction in the size and number of glycogen granules; intracellular edema; and swelling and distortion of the transverse tubular system, sarcoplasmic reticulum, and mitochondria. These early changes are reversible. Changes after 60 minutes of occlusion include myocyte swelling, swelling and internal disruption of mitochondria, development of amorphous (flocculent) aggregation and margination of nuclear chromatin, and relaxation of myofibrils. After 20 minutes to 2 hours of ischemia, the changes in some cells become irreversible, and progression of these alterations occurs.

Patterns of Myocardial Necrosis

Coagulation Necrosis

Coagulation necrosis results from severe, persistent ischemia and is usually present in the central region of infarcts; it causes arrest of muscle cells in the relaxed state and passive stretching of ischemic muscle cells. The tissue exhibits stretched myofibrils, many cells with pyknotic nuclei, congested microvessels, and phagocytosis of necrotic muscle cells (**see Fig. 58.7**). Mitochondrial damage with prominent amorphous (flocculent) densities occurs, but no calcification is evident.

Necrosis with Contraction Bands

This form of myocardial necrosis, also termed *contraction band necrosis* or *coagulative myocytolysis*, results primarily from severe ischemia followed by reflow. It is characterized by hypercontracted myofibrils with contraction bands and mitochondrial damage, frequently with calcification, marked vascular congestion, and healing by lysis of muscle cells. Necrosis with contraction bands is caused by increased influx of calcium ions (Ca^{2+}) into dying cells, which results in the arrest of cells in the contracted state in the periphery of large infarcts and, to a greater extent, in nontransmural than in transmural infarcts. The entire infarct may show this form of necrosis after reperfusion (**see Figs. 58.7 and 58.8**).

Myocytolysis

Ischemia without necrosis generally causes no acute changes visible on light microscopy, but severe prolonged ischemia can result in myocyte vacuolization, often termed *myocytolysis*. Prolonged severe ischemia, which is potentially reversible, causes cloudy swelling, as well as hydropic, vascular, and fatty degeneration.

Apoptosis

An additional pathway of myocyte death involves apoptosis, or programmed cell death. In contrast to coagulation necrosis, myocytes undergoing apoptosis exhibit shrinkage of cells, fragmentation of DNA, and phagocytosis, but without the usual cellular infiltrate indicative of inflammation. The role of apoptosis in the setting of MI is less well understood than that of classic coagulation necrosis. Apoptosis

may occur shortly after the onset of myocardial ischemia, but its major impact appears to be on late myocyte loss and ventricular remodeling after MI.

Current Concepts of the Cellular Events During Myocardial Infarction and Healing

Classic studies defined the sequence of cellular events that occur during human MI by careful histologic studies.[25] Accumulation of granulocytes characterized the first days following MI, then mononuclear phagocytes accumulated in the infarct in tissue. Granulation tissue characterized by neovascularization and accumulation of extracellular matrix (fibrosis) followed. Recent experimental work in mice has revealed a sequence of accumulation of subpopulations of mononuclear phagocytes.[25] The first wave, occurring about days 1 to 3 after coronary ligation, consists of a proinflammatory subset of monocytes characterized by high proteolytic and phagocytic capacity and elaboration of proinflammatory cytokines. During a later phase (days 3 to 7), less inflammatory monocytes predominate and produce the angiogenic mediator vascular endothelial growth factor (VEGF) and the fibrogenic mediator transforming growth factor beta (TGF-β) (**Fig. 58.9**). This highly orchestrated sequential recruitment of subpopulations of monocytes probably plays an important role in myocardial healing. The granulocytes arriving on the scene of ischemic injury function as “first responders.” They serve to initiate and amplify the acute local inflammatory response. The reactive oxygen species that they elaborate may contribute to endothelial damage, reperfusion injury, and the clinical phenomenon of “no-reflow.” The first wave of proinflammatory and phagocytically active mononuclear cells constitutes a “demolition crew” that can clear necrotic debris and pave the way for the second wave of less inflammatory monocytes, which contribute to healing by promoting the formation of granulation tissue (**Fig. 58.10**). These “repair” monocyte/macrophages elaborate a palette of mediators that stimulate angiogenesis and extracellular matrix production by surviving myocardial stromal cells. New microvessels and fibrosis are key constituents of granulation tissue, and these processes furnish the foundation for myocardial scar formation, ventricular remodeling, and infarct healing.

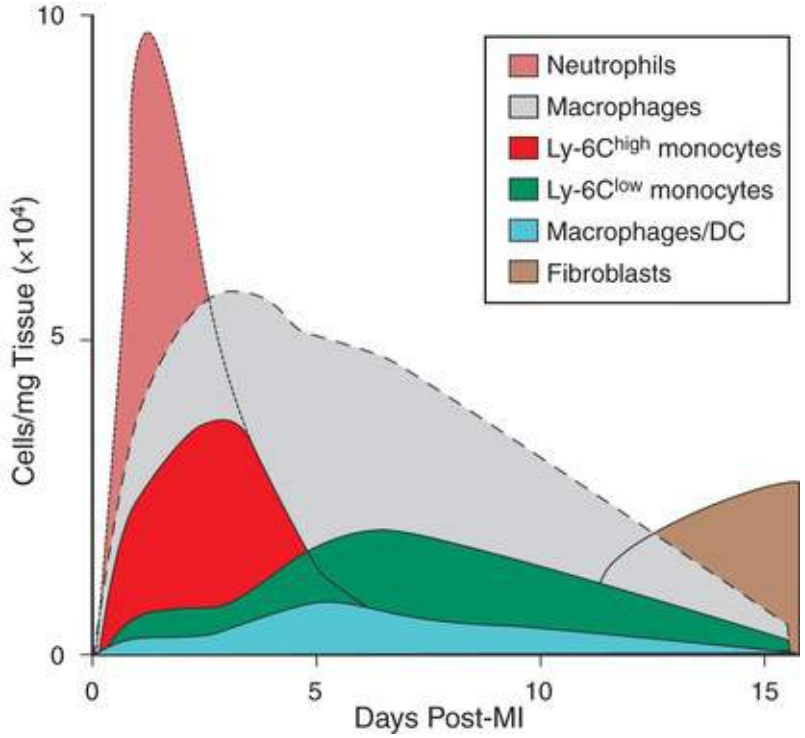

FIGURE 58.9 Sequencing waves of different cell types participate in myocardial infarction (MI) and healing. In the first hours to days following acute myocardial ischemia, neutrophils accumulate in the infarcting myocardium, as shown by the *salmon-colored* peak centered on days 1 and 2. Following this first wave of inflammatory cells, mononuclear phagocytes begin to accumulate in the ischemic tissue. Recent studies in mice have shown that in the early days of this monocytic infiltration, a particularly proinflammatory subset of mononuclear phagocytes characterized by high levels of the surface marker Ly-6C arrive first. In days 5 through 10, a reparative population of monocytes prevails (*green*), marked by low surface expression of Ly-6C. As the accumulation of leukocytes in the injured myocardium wanes, fibroblasts and related mesenchymal cells synthesize extracellular matrix (ECM) macromolecules such as collagen. ECM production contributes to repair and scar formation during healing of the ischemically-injured heart tissue. DC, Dendritic cells. (From Nahrendorf M et al. Mechanisms of myocardial ischemic injury, healing, and remodeling. In Morrow DA, editor. Myocardial Infarction: a Companion to Braunwald's Heart Disease. Philadelphia: Elsevier; 2017.)

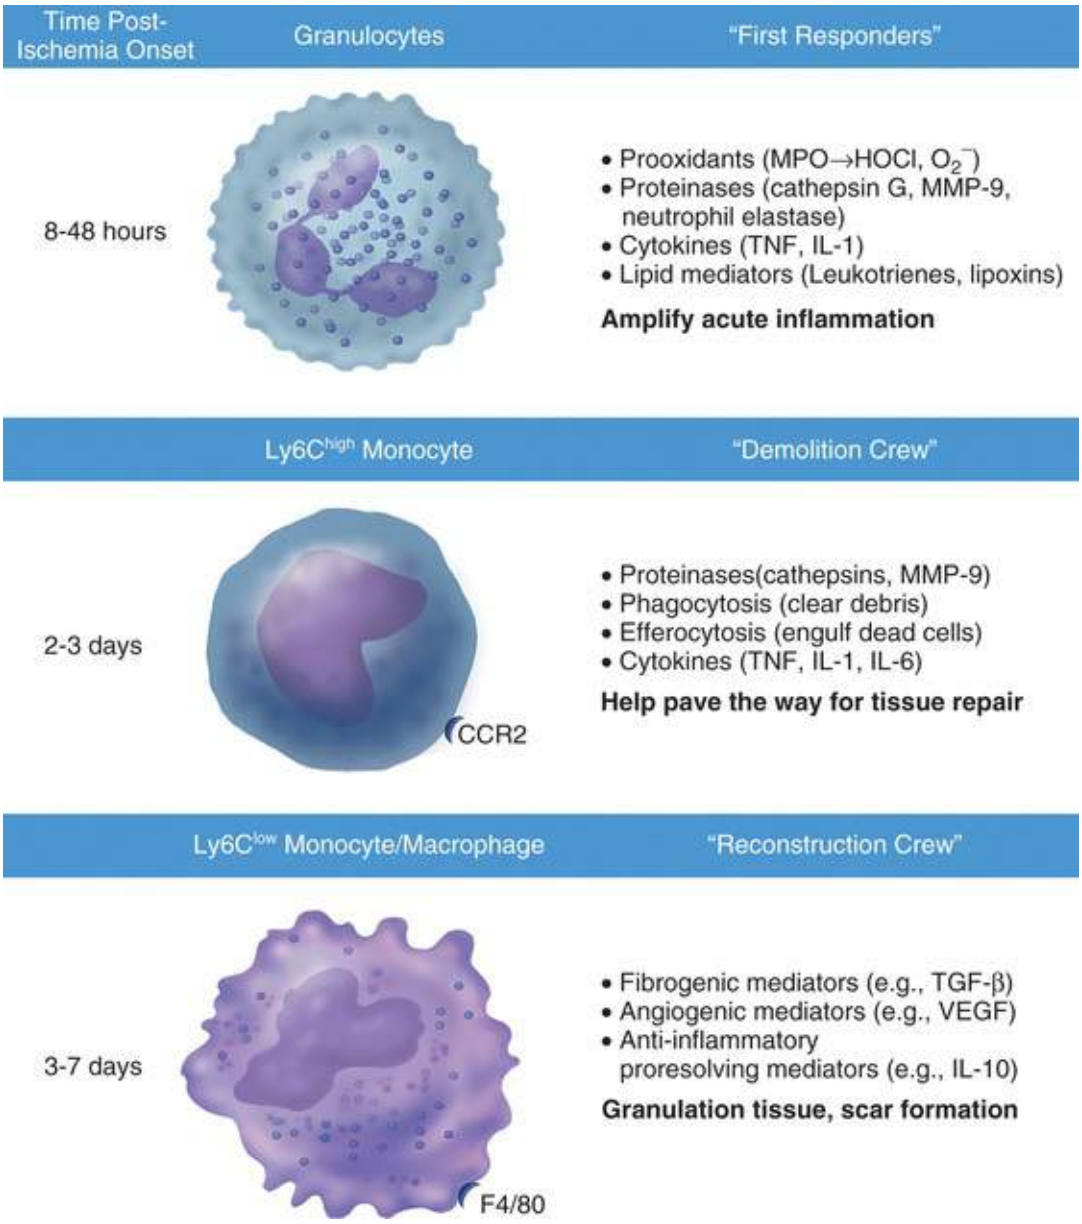

FIGURE 58.10 Temporal sequence and functions of leukocytes localizing in the infarcting myocardium. The leukocytes that predominate sequentially in the evolving myocardial infarct have specific sets of functions that govern the repair of the injured tissue. The granulocytes, "first responders," amplify the acute inflammatory response. The proinflammatory monocyte population functions as a "demolition crew" to pave the way for tissue repair. The reparative monocytes then engage in "reconstruction" to repair the injured tissue. CCR, CC chemokine receptor; HOCl, hypochlorous acid; IL, interleukin; MMP, matrix metalloproteinase; MPO, myeloperoxidase; O_2, superoxide anion; TGF, transforming growth factor; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor. (From Libby P, Nahrendorf M, Swirski FK. Leukocytes link local and systemic inflammation in ischemic cardiovascular disease: an expanded "cardiovascular continuum." J Am Coll Cardiol 2016;67:1091-103.)

The elucidation of this tightly orchestrated response to myocardial ischemic injury provides new perspectives on the pathophysiology of infarction, suggesting novel therapeutic targets to "tune" this local inflammatory response in any way that can favor salutary myocardial healing and prevent the adverse remodeling of the infarcted left ventricle associated with ischemic cardiomyopathy and poor outcomes. Recent experimental work has provided considerable new insight in this regard (**Fig. 58.11**). Sympathetic nervous activation caused by the pain and anxiety associated with the ACS can have far-reaching effects on the inflammatory response in addition to the well-recognized hemodynamic alterations produced by catecholamines. Beta-adrenergic stimulation can mobilize leukocyte progenitor cells from the bone marrow. Some of these cells can feed extra medullary hematopoiesis in the spleen. This "emergency hematopoiesis" can provide the leukocytes that participate in myocardial healing. In mice, mobilization of

a preformed pool of proinflammatory monocytes from the spleen depends in part on the role of angiotensin in signaling. This experimental observation may provide a mechanistic understanding of the ability of angiotensin-converting enzyme (ACE) inhibitors to combat adverse remodeling of the ischemic left ventricular (LV) myocardium. In addition to catecholamines, proinflammatory cytokines released during ACS can promote hematopoiesis and amplify the inflammatory response in the evolving infarct. In mice, interleukin (IL)-1β can stimulate the mobilization of precursors of leukocytes from the bone marrow. Inhibition of this proinflammatory cytokine does not change the size and experimental infarction but limits the decrement in contractile function in the infarcted ventricle.[26] This example illustrates how modulation of the inflammatory response in ischemic myocardium might influence the healing process.

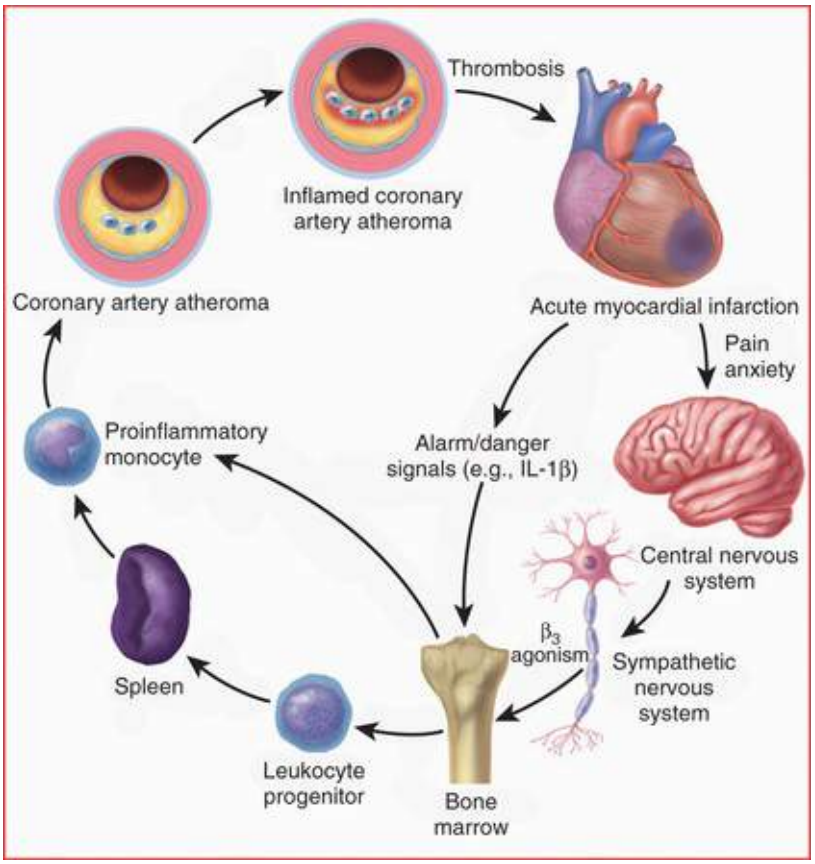

FIGURE 58.11 Leukocytes link local and systemic inflammation in ischemic cardiovascular disease. Myocardial infarction (MI) most often results from a disruption of a coronary artery atheroma that triggers thrombus formation. The sympathetic nervous system discharge in response to the pain and anxiety provoked by the acute MI evokes the mobilization of leukocyte progenitors from the bone marrow. Various humoral mediators, including the proinflammatory cytokine interleukin-1 beta (IL-1β) also help to recruit progenitor cells from the bone marrow. These progenitors can enter the bloodstream and make their way to the spleen, where they may engage in extramedullary leukopoiesis. The circulating proinflammatory monocytes can then home to atheromata that may localize remotely from the culprit lesion of the acute MI, setting the stage for a round of aggravated plaque evolution and recurrent events. This cyclic concept builds on the "cardiovascular continuum" concept promulgated by Dzau and Braunwald in 1991. (From Libby P, Nahrendorf M, Swirski FK. Leukocytes link local and systemic inflammation in ischemic cardiovascular disease: an expanded "cardiovascular continuum." J Am Coll Cardiol 2016;67:1091-103.)

Another insight bolstered by recent experimental work is the concept that inflammation in the myocardium can ignite inflammatory activity in remote atherosclerotic plaques, predisposing them to disrupt and provoke thrombosis. Such "echoes" of myocardial inflammation in plaques themselves may explain some of the early recurrent coronary events in patients with ACS. Moreover, this observation provides some mechanistic understanding of clinical observations that coronary atherosclerotic plaques

remote from the culprit lesion exhibit inflammatory activation not only in the non–infarct-related artery, but also in other arterial beds, such as the carotid circulation.

Although much of the information in **Fig. 58.11** emerged from murine experiments, imaging observations in humans lend credence to their clinical applicability. Uptake of the glucose analogue ^{18}F-deoxyglucose (FDG) monitors metabolic activity. Patients with ACS show increased uptake of FDG in bone marrow and in the spleen compared to stable patients. These observations support the clinical translatability of the mouse experiments that revealed bone marrow activation following coronary artery ligation and boosted inflammatory processes in the spleen. Indeed, those with increased splenic FDG uptake appear to have greater risk for recurrent events.[27] Thus a "cardiosplenic axis" of inflammatory signaling likely operates in humans as well as mice, furnishing new mechanistic insight into the pathogenesis of MI and uncovering novel therapeutic targets.

Modification of Pathologic Changes by Reperfusion

When reperfusion of myocardium undergoing the evolutionary changes from ischemia to infarction occurs sufficiently early (i.e., within 15 to 20 minutes), it can prevent necrosis from developing. Beyond this early stage, the number of salvaged myocytes—and therefore the amount of salvaged myocardial tissue (area of necrosis/area at risk)—is directly related to the duration of coronary artery occlusion, the level of myocardial oxygen consumption, and collateral blood flow (**Fig. 58.12**). Reperfused infarcts typically show a mixture of necrosis, hemorrhage within zones of irreversibly injured myocytes, coagulative necrosis with contraction bands, and distorted architecture of cells in the reperfused zone (**eFig. 58.3**). Reperfusion of infarcted myocardium accelerates the washout of leaked intracellular proteins, thereby producing an exaggerated and early peak value of substances such as the MB fraction of creatine kinase (CK-MB) and cardiac-specific troponin T and I (see later).[1]

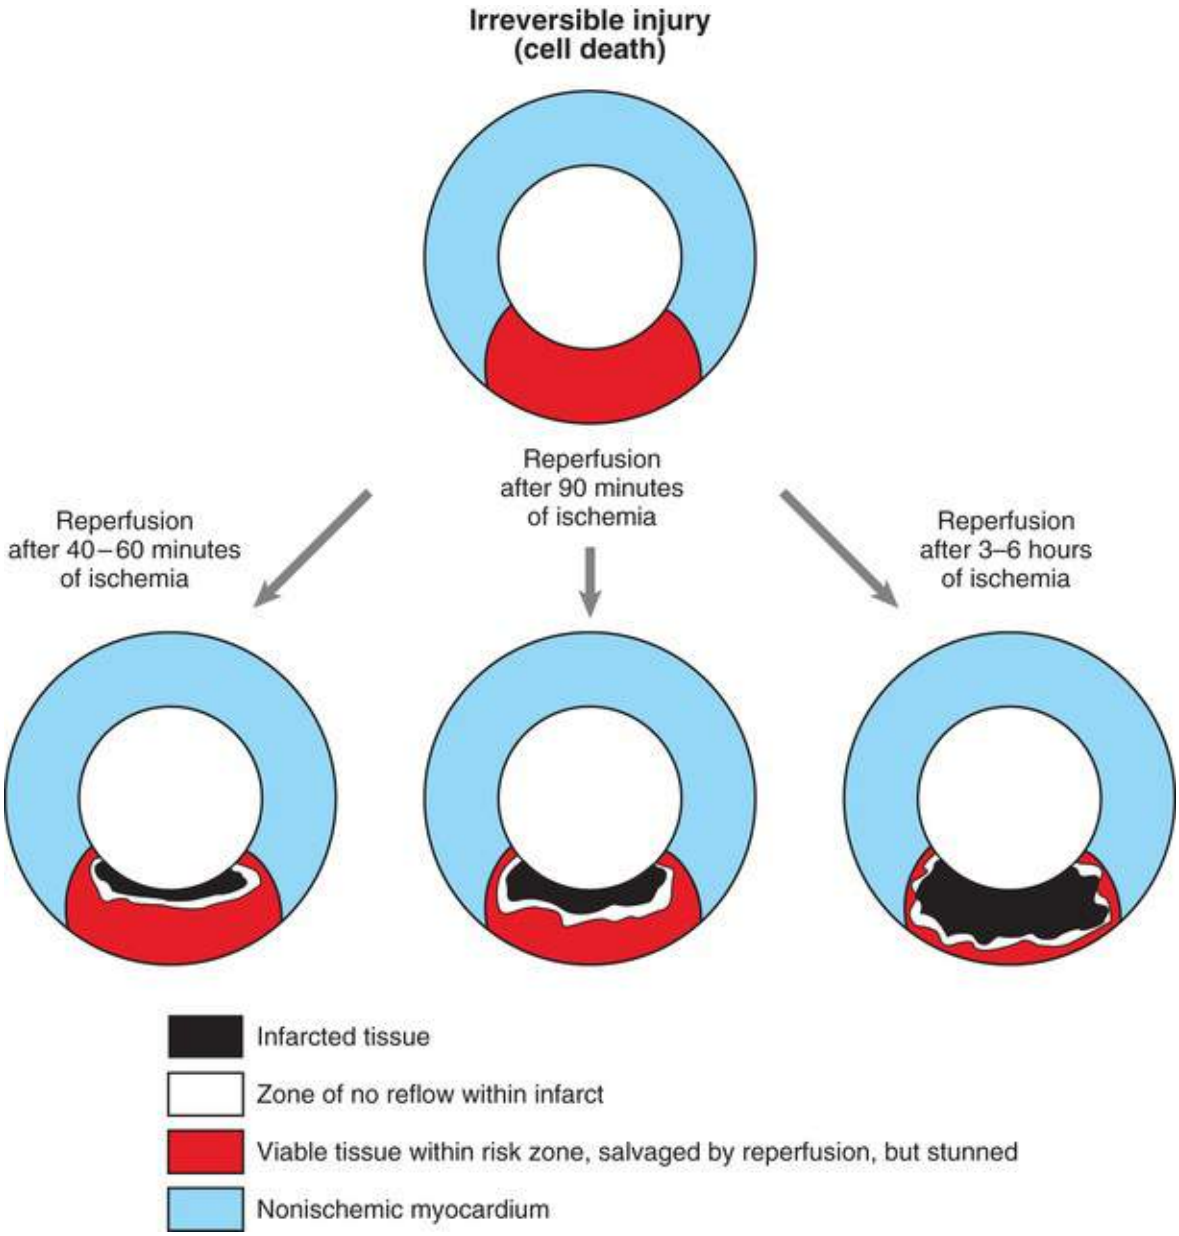

FIGURE 58.12 **Top,** Schematic of a transmural section of the heart after a short period of ischemia (≤20 minutes). Cell death does not occur (reversible injury), but tissue is stunned and reperfusion arrhythmias might ensue. **Middle** and **bottom,** Schematic of a transmural section of the left ventricle derived from studies in the anesthetized canine model of proximal coronary occlusion and reperfusion. After 40 to 60 minutes of ischemia, irreversible cell damage is confined to the subendocardium. A smaller area of no-reflow is present within the necrotic region. If reperfusion is delayed to 90 minutes, the necrotic region expands from the subendocardium to the midmyocardium within the ischemic risk zone, accompanied by an expansion of the no-reflow region. After 3 to 6 hours of ischemia, necrosis becomes nearly transmural, and the no-reflow region, although contained within the necrotic area, becomes larger. (From Kloner RA et al. Reperfusion injury: prevention and management. In Morrow DA, editor. Myocardial Infarction: a Companion to Braunwald's Heart Disease. Philadelphia: Elsevier; 2017.)

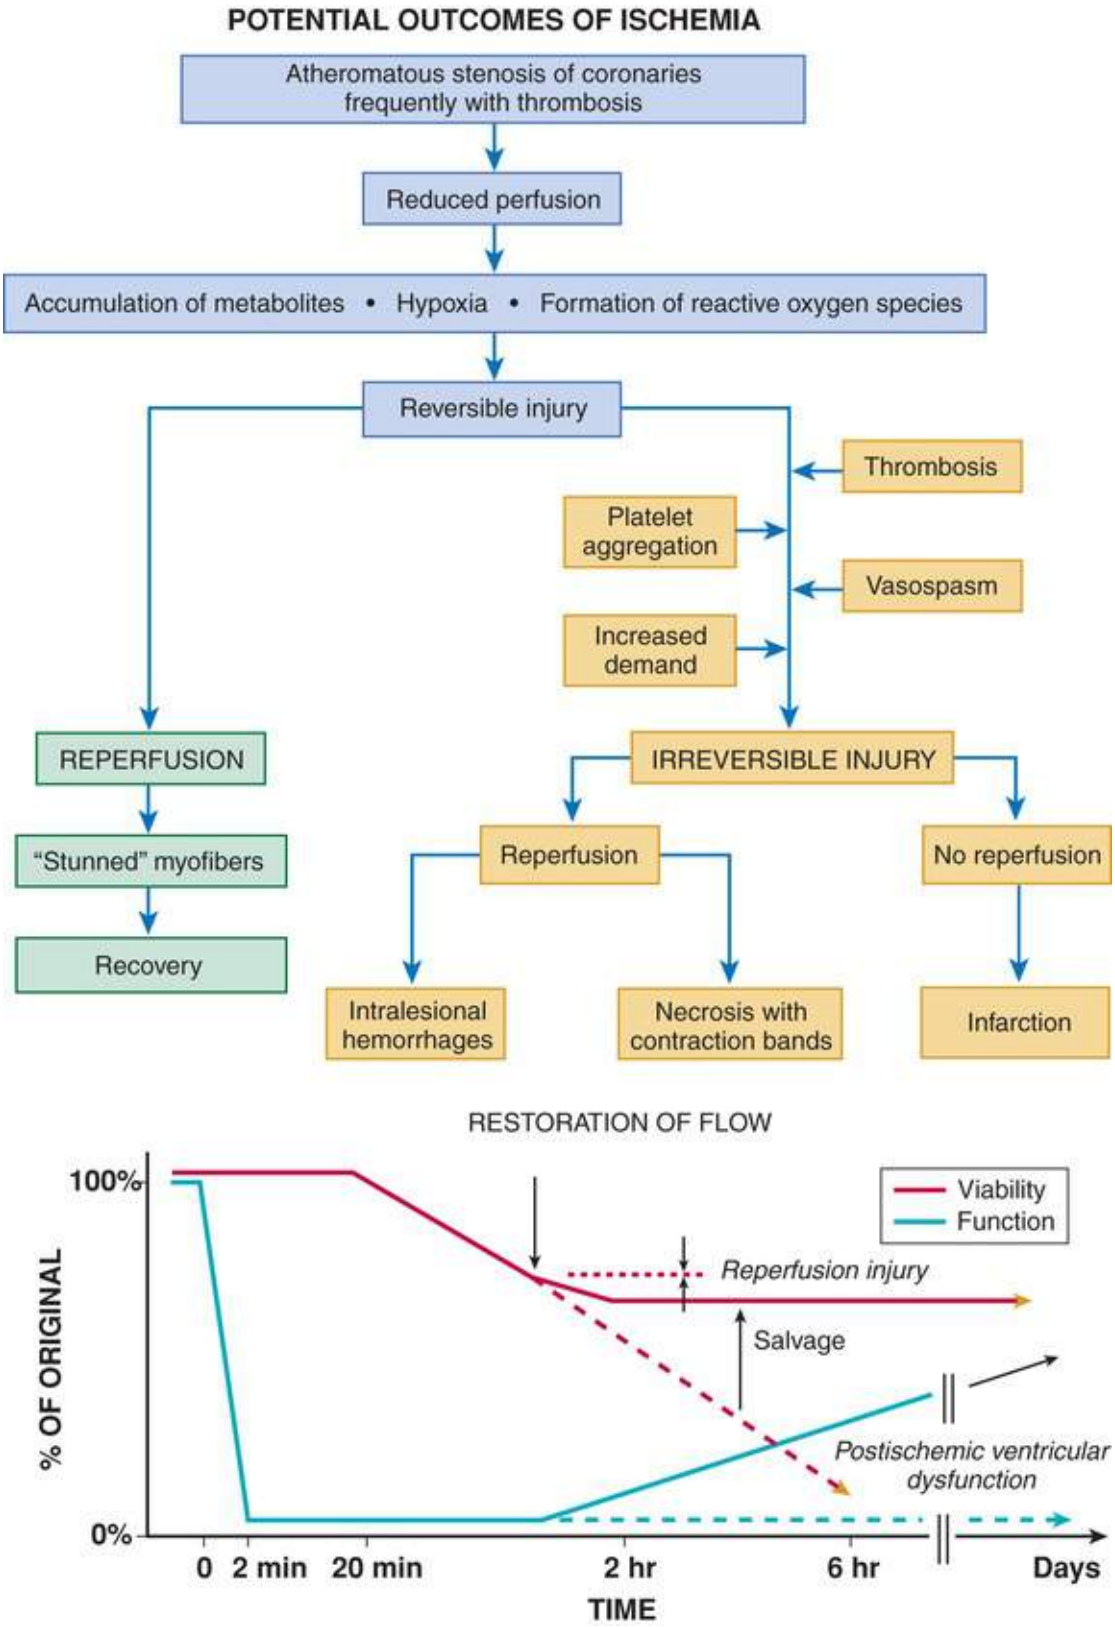

EFIGURE 58.3 Several potential outcomes of reversible and irreversible ischemic injury to the myocardium. The schematic diagram at the *bottom* depicts the timing of changes in function and viability. A key point is that although function drops dramatically after coronary occlusion, the tissue is still viable for a period. This is the basis for early aggressive efforts at reperfusion of patients with STEMI. (From Schoen FJ. The heart. In Kumar V, Abbas AK, Fausto N, editors. Robbins & Cotran Pathologic Basis of Disease. 8th ed. Philadelphia: Saunders; 2009.)

Coronary Anatomy and Location of Infarction

Angiographic studies performed in the earliest hours of STEMI find an approximately 90% incidence of total occlusion of the infarct-related vessel. Spontaneous fibrinolysis of the thrombotic occlusion can

occur in the period following the onset of MI. Pharmacologic fibrinolysis and PCI markedly increase the proportion of patients with a patent infarct-related artery early after STEMI.

A STEMI with transmural necrosis typically occurs distal to an acutely totally occluded coronary artery with thrombus superimposed on an eroded or ruptured plaque (**see Fig. 58.4**). Yet, total occlusion of a coronary artery does not always cause MI. Collateral blood flow and other factors, such as the level of myocardial metabolism, presence and location of stenoses in other coronary arteries, rate of development of the obstruction, and quantity of myocardium supplied by the obstructed vessel, all influence the viability of myocardial cells distal to the occlusion.

Studies of patients in whom STEMI ultimately develops after having undergone coronary angiography at some time before its occurrence have helped clarify the extent of coronary disease before infarction. Although high-grade stenoses more frequently lead to STEMI than do less obstructive lesions, STEMI can result from sudden thrombotic occlusion at the site of disruption of previously noncritically stenosed plaque. When collateral vessels perfuse an area of the ventricle, an infarct may occur at a distance from a coronary occlusion. For example, following gradual obliteration of the lumen of the right coronary artery (RCA), collateral vessels arising from the left anterior descending coronary artery (LAD) can keep the inferior wall of the left ventricle viable. Later, an occlusion of LAD may cause infarction of the distal inferior wall.

Right Ventricular Infarction

Approximately 30% to 50% of patients with inferior infarction have some involvement of the right ventricle.[28,29] RV infarction almost invariably develops in association with a large infarction of the adjacent septum and inferior LV walls, but isolated infarction of the right ventricle is seen in just 3% to 5% of autopsy-proven cases of MI. RV infarction occurs less often than would be anticipated from the frequency of atherosclerotic lesions involving the RCA. The classic presentation of an RV infarct is hypotension, clear lung fields, and elevated jugular venous pressures. Acute management of RV infarction complicated by cardiogenic shock includes judicious volume replacement, early revascularization, maintenance of atrioventricular synchrony, and in refractory cases, mechanical circulatory support (**see Chapter 59**). In contrast to the left ventricle, the right ventricle can sustain long periods of ischemia but still demonstrate excellent recovery of contractile function after reperfusion.

Atrial Infarction

Infarction of the atria occurs in up to 10% of patients with STEMI if PR-segment displacement is used as the criterion. Although isolated atrial infarction is observed in less than 5% of patients with STEMI at autopsy, it often occurs in conjunction with ventricular infarction and can cause rupture of the atrial wall.[30] This type of infarction is more common on the right than the left side, occurs more frequently in the atrial appendages than in the lateral or posterior walls of the atrium, and can result in thrombus formation. Atrial arrhythmias frequently accompany atrial infarction. Reduced secretion of atrial natriuretic peptide may ensue and lead to a low–cardiac output syndrome when RV infarction coexists.

Collateral Circulation in Acute Myocardial Infarction

Patients with occlusive coronary artery disease (CAD) frequently have a particularly well-developed coronary collateral circulation, especially those with reduction of the luminal cross-sectional area by more than 75% in one or more major vessels; patients with chronic hypoxia, as occurs in severe anemia, chronic obstructive pulmonary disease (COPD), and cyanotic congenital heart disease; and those with LV

hypertrophy[31] (**see Fig. 58.5 and Chapter 57**).

The magnitude of coronary collateral flow is a principal determinant of infarct size. Indeed, patients with abundant collateral vessels may have totally occluded coronary arteries without evidence of infarction in the distribution of that artery; thus survival of myocardium distal to such occlusions depends largely on collateral blood flow.[32] Even if the collateral perfusion existing at the time of coronary occlusion does not prevent infarction, it may still exert a beneficial effect by preventing the formation of LV aneurysms. The presence of a high-grade stenosis (90%), possibly with periods of intermittent total occlusion, probably permits the development of collateral vessels that remain only as potential conduits until a total occlusion occurs or recurs. Total occlusion then brings these channels into full operation. Patients with angiographic evidence of collateral formation have improved angiographic and clinical outcomes after MI.

Nonatherosclerotic Causes of Acute Myocardial Infarction

Numerous pathologic processes other than atherosclerosis can involve the coronary arteries and result in STEMI (**see Table 58.3**).[1] For example, coronary arterial occlusions can result from embolization into a coronary artery. The causes of coronary embolism are numerous: infective endocarditis and nonbacterial thrombotic endocarditis (**see Chapter 73**), mural thrombi, prosthetic valves, neoplasms, air introduced at cardiac surgery, and calcium deposits from manipulation of calcified valves at surgery. In situ thrombosis of coronary arteries can occur secondary to chest wall trauma or hypercoagulable states.

Spontaneous coronary artery dissection (SCAD), once thought to be a relatively rare event, is identified more frequently now with greater utilization of intracoronary imaging and may account for 10% to 30% of MIs in women younger than 50. Initial triage and evaluation of patients with suspected SCAD should follow standard ACS algorithms. A clear dissection flap and thrombosis may be visible at angiography, but often there is only an intramural hematoma, which can be mistaken for vasospasm or an atherosclerotic plaque unless intracoronary imaging is used. Revascularization strategies for SCAD diverge from standard ACS recommendations. Conservative management with oral and intravenous (IV) antithrombotic therapy alone is recommended if coronary flow is preserved because of high rates of PCI-related complications. Revascularization with PCI or coronary artery bypass grafting (CABG) should be considered for occlusive lesions, recognizing a higher risk of complications.[33]

Rarer causes include syphilitic aortitis, which can produce marked narrowing or occlusion of one or both coronary ostia, whereas Takayasu arteritis can result in obstruction of the coronary arteries. Necrotizing arteritis, polyarteritis nodosa, mucocutaneous lymph node syndrome (Kawasaki disease), systemic lupus erythematosus (**see Chapter 94**), and giant cell arteritis can cause coronary occlusion. Therapeutic levels of mediastinal radiation can result in coronary arteriosclerosis[34] with subsequent infarction. MI can also result from coronary arterial involvement in patients with amyloidosis (**see Chapter 77**), Hurler syndrome, pseudoxanthoma elasticum, and homocystinuria. Cocaine can cause MI in patients with normal coronary arteries, preexisting MI, documented coronary artery disease, or coronary artery spasm (**see Chapter 80**).

Myocardial Infarction with Nonobstructive Coronary Arteries (MINOCA)

MINOCA is defined as evidence of MI (positive cardiac biomarker and corroborative clinical evidence of infarction) with angiographically normal or near-normal coronary arteries (the absence of obstructive CAD on angiography, [i.e. no coronary artery stenosis ≥50%], in any potential infarct-related artery), and no other explanation for the presentation.[35,35a] Coronary artery spasm, plaque erosion or rupture, and

coronary dissection are common MINOCA etiologies affecting the epicardial arteries, as are plaque erosion and plaque rupture not discerned by standard angiography, whereas the two most common myocardial or microvascular mimickers of MI are acute myocarditis (**see Chapter 79**) and acute stress (takotsubo) cardiomyopathy.

Compared to patients with atherosclerotic-mediated MI, patients with MINOCA tend to be young and more often females, with relatively few coronary risk factors except a history of cigarette smoking. One third of patients with MINOCA present with STEMI.[36] Usually, they have no history of angina pectoris before the infarction. These patients do not generally have a prodrome before infarction, but the clinical, laboratory, and electrocardiographic features of STEMI otherwise resemble those present in the overwhelming majority of patients with STEMI, who have classic obstructive atherosclerotic CAD. Approximately half of patients with MINOCA have smooth vessels on angiography, whereas the other half has some nonobstructive irregularities that may predispose them to vasospasm or plaque erosions.

Additional causes MI in the setting of normal-appearing coronary arteries include (1) coronary emboli, perhaps from a small mural thrombus, prolapsed mitral valve, or myxoma; (2) CAD in vessels too small to be visualized on coronary arteriography or coronary arterial thrombosis with subsequent recanalization; (3) a hematologic disorder (e.g., polycythemia vera, cyanotic heart disease with polycythemia, sickle cell anemia, disseminated intravascular coagulation, thrombocytosis, thrombotic thrombocytopenic purpura) causing in situ thrombosis in the presence of normal coronary arteries; (4) augmented oxygen demand (e.g., thyrotoxicosis, amphetamine use); (5) hypotension secondary to sepsis, blood loss, or pharmacologic agents; and (6) anatomic variations, such as anomalous origin of a coronary artery, coronary arteriovenous fistula, or a myocardial bridge.[35a]

Prognosis in MINOCA

In general, patients who have survived STEMI without evidence of significant CAD have a better long-term outlook than those with atherosclerotic-mediated STEMI; in-hospital mortality is approximately 60% lower, and 1-year mortality, 40% lower.[36] However, the subsequent risk for patients presenting with MINOCA is largely based on the underlying etiology and comorbidities. Cardiac magnetic resonance imaging is recommended to exclude myocarditis in patients without clear cause of MINOCA.[35a]

Stress (Takotsubo) Cardiomyopathy

Acute stress cardiomyopathy, also termed *transient LV apical ballooning syndrome* or takotsubo cardiomyopathy, typically involves transient wall motion abnormalities involving the LV apex and midventricle (**Fig. 58.13**), although other patterns have been reported, including “reverse” takotsubo pattern. This syndrome occurs in the absence of obstructive epicardial CAD and can mimic STEMI.[37] Typically, an episode of physical or psychological stress precedes the development of takotsubo cardiomyopathy; although some cases lack an evident precipitant. More than half of patients presenting with takotsubo cardiomyopathy have an active or history of a neurologic or psychiatric disorder, potentially linking neurologic-mediated vasoconstriction. Initial ECGs demonstrate substantial and often diffuse ST-segment elevation, prompting, when coupled with the typical (frequently severe) chest discomfort, the appropriate immediate referral for coronary angiography. One proposed ECG algorithm for differentiating stress cardiomyopathy from STEMI found that different patterns of ST elevations across the different coronary territories could distinguish stress cardiomyopathy from ACS with excellent specificity. However, this observation requires validation and should not preclude urgent catheterization to exclude acute thrombotic lesions.[38]

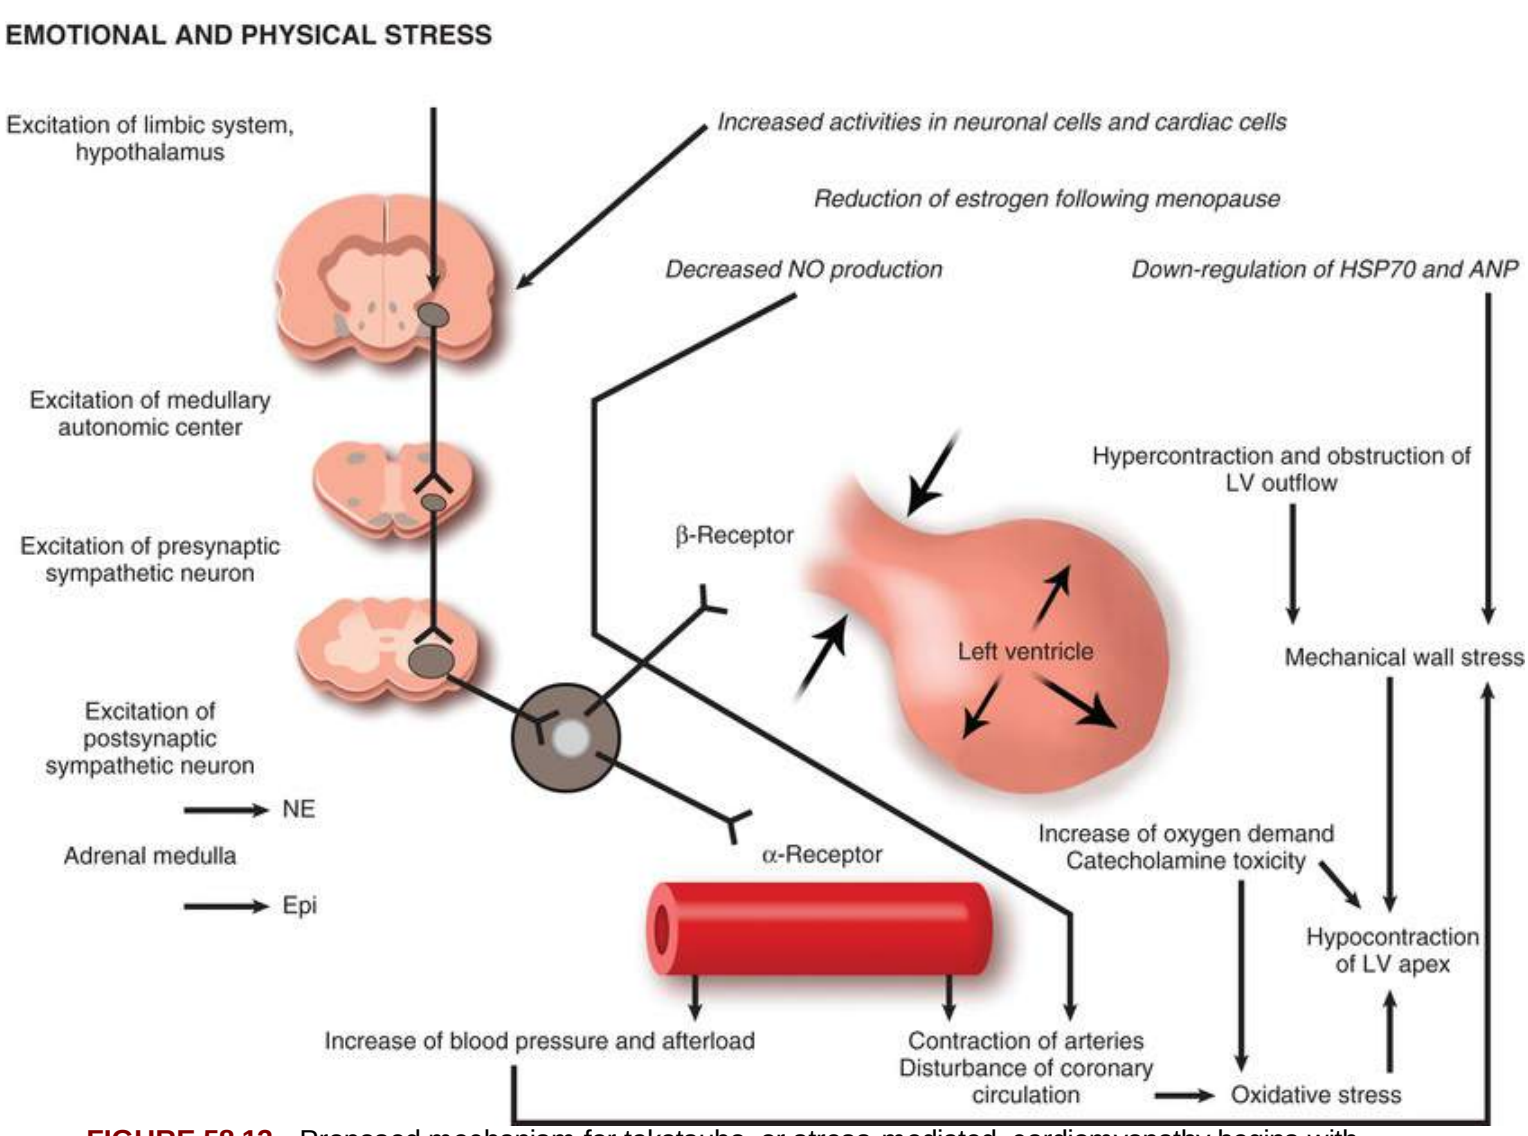

FIGURE 58.13 Proposed mechanism for takotsubo, or stress-mediated, cardiomyopathy begins with sudden and severe emotional stress, which activates central autonomic network neurons expressing estrogen receptors. Simultaneously, sympathetic neuronal and adrenomedullary hormonal outflow increases dramatically and results in release of epinephrine (*Epi*) from the adrenal medulla combined with the release of norepinephrine (*NE*) from cardiac and extracardiac sympathetic nerves, which stimulate adrenoceptors in the blood vessels of the heart. Contraction of resistance vessels rapidly increases systemic blood pressure and cardiac afterload. High circulating levels of NE and Epi can precipitate catecholamine toxicity in cardiomyocytes via occupation of adrenoceptors. The typical hypercontraction of the basal sections of the heart, which leads to functional basal obstruction of left ventricular (*LV*) outflow, further exacerbates LV wall stress and increases end-diastolic pressure. *ANP,* Atrial natriuretic peptide; *HSP70,* heat shock protein 70; *NO,* nitric oxide. (From Akashi YJ, Goldstein DS, Barbaro G, Ueyama T. Takotsubo cardiomyopathy: a new form of acute, reversible heart failure. Circulation 2008;118:2754.)

The etiology of stress-induced cardiomyopathy is not clear, but neurally activated or circulating catecholamine-mediated microvascular dysfunction, as well as myocardial stunning and injury, play important roles. Most patients with takotsubo cardiomyopathy will experience rapid recovery of ventricular function, although more than 20% of patients do suffer in-hospital complications, including heart failure, arrhythmias, and death, and at rates similar to patients with ACS.[37,39]

Pathophysiology

Left Ventricular Function

Systolic Function

On interruption of antegrade flow in an epicardial coronary artery, the zone of myocardium supplied by that vessel immediately loses its ability to shorten and perform contractile work (**Fig. 58.14**). Four abnormal contraction patterns develop in sequence: (1) *dyssynchrony,* or dissociation of the time course of contraction of adjacent segments; (2) *hypokinesis,* or a reduction in the extent of shortening; (3) *akinesis,* or cessation of shortening; and (4) *dyskinesis,* paradoxical expansion, and systolic bulging. Hyperkinesis of the remaining normal myocardium initially accompanies dysfunction of the infarct. The early hyperkinesis of the noninfarcted zones probably results from acute compensation, including increased activity of the sympathetic nervous system and the Frank-Starling mechanism. A portion of this compensatory hyperkinesis is ineffective work because contraction of the noninfarcted segments of myocardium causes dyskinesis of the infarct zone. The increased motion of the noninfarcted region subsides within 2 weeks of infarction, during which some degree of recovery often occurs in the infarct region as well, particularly if reperfusion of the infarcted area occurs and myocardial stunning diminishes.

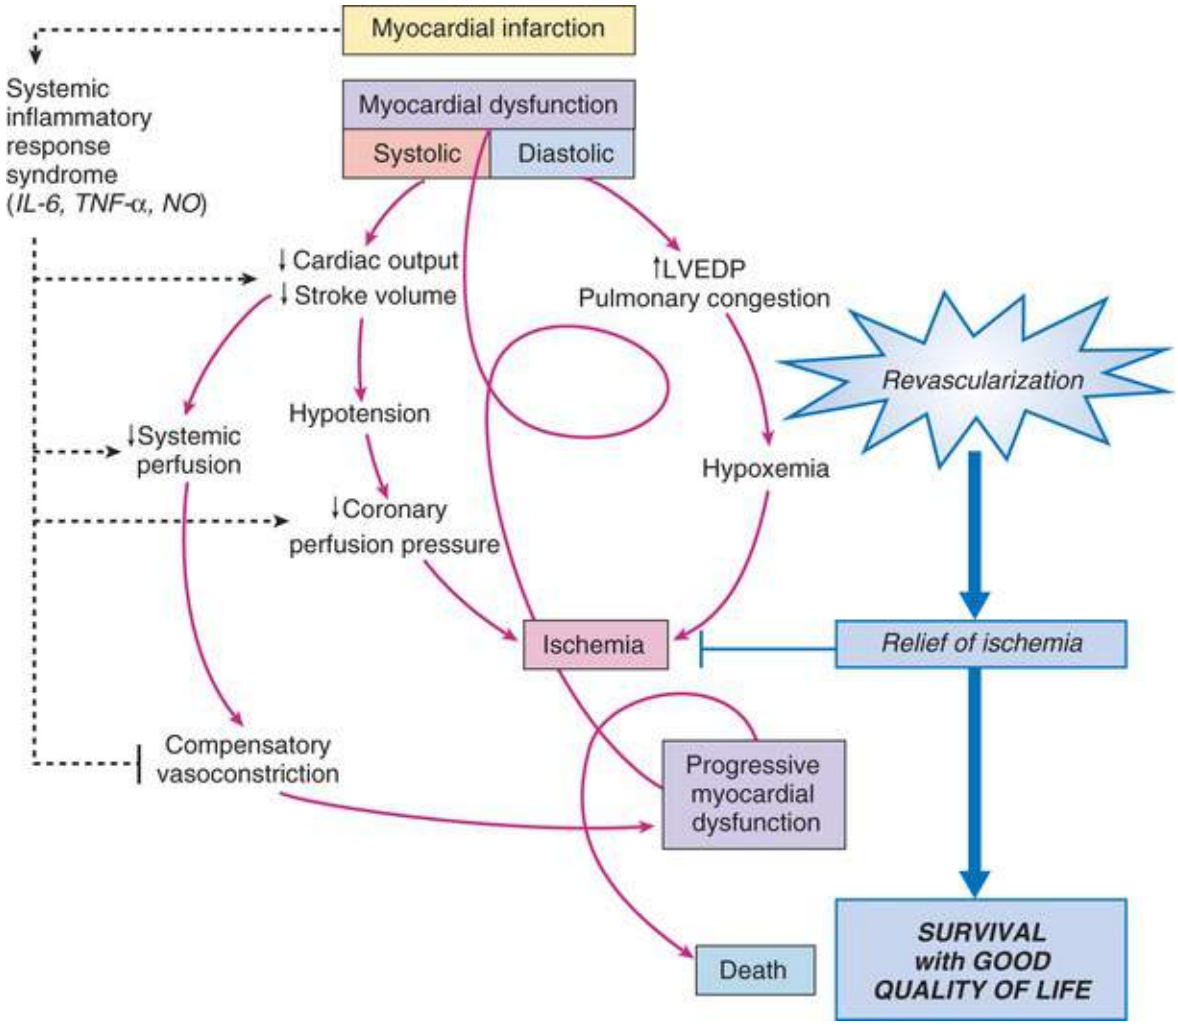

FIGURE 58.14 Pathophysiology of cardiogenic shock. Myocardial injury causes systolic and diastolic dysfunction. A decrease in cardiac output leads to a decrease in systemic and coronary perfusion. The decreased perfusion exacerbates ischemia and causes cell death in the infarct border zone and the remote zone of myocardium. Inadequate systemic perfusion triggers reflex vasoconstriction, which is usually insufficient. Systemic inflammation may play a role in limiting the peripheral vascular compensatory response and may contribute to the myocardial dysfunction. Whether inflammation plays a causal role or is only an epiphenomenon remains unclear. Revascularization leads to relief of ischemia. Demonstration of an increase in cardiac output or the LV ejection fraction as the mechanism of benefit of revascularization has not been possible, but revascularization significantly increases the likelihood of survival with good quality of life. *IL-6,* Interleukin-6; *LVEDP,* left ventricular end-diastolic pressure; *NO,* nitric oxide; *TNF,* tumor necrosis factor. (From Reynolds HR, Hochman JS. Cardiogenic shock: current concepts and improving outcomes. Circulation 2008;117:686, 2008.)

Patients with STEMI may also have reduced myocardial contractile function in noninfarcted zones. This finding may result from previous obstruction of the coronary artery supplying the noninfarcted region of the ventricle and loss of collaterals from the freshly occluded infarct-related vessel, a condition termed *ischemia at a distance*. Conversely, the development of collaterals before STEMI occurs may allow greater preservation of regional systolic function in an area of distribution of the occluded artery and improvement in the LV ejection fraction (EF) early after infarction[31] (**see Fig. 58.5**).

If a sufficient quantity of myocardium undergoes ischemic injury (**see Fig. 58.12**), LV pump function becomes depressed; cardiac output, stroke volume, blood pressure, and peak dP/dt decline; and end-systolic volume increases. The degree to which end-systolic volume increases is perhaps the most powerful hemodynamic predictor of mortality following STEMI.[40] Paradoxical systolic expansion of an area of ventricular myocardium further decreases LV stroke volume.[41] As necrotic myocytes slip past each other, the infarct zone thins and elongates, especially in patients with large anterior infarcts, thereby leading to expansion of the infarct (see later). In some patients a vicious circle of dilation begetting

further dilation ensues. Inhibitors of the renin-angiotensin-aldosterone system (RAAS) can limit the degree of ventricular dilation, which depends closely on infarct size, patency of the infarct-related artery, and RAAS activation, even in the absence of symptomatic LV dysfunction.[42] With time, edema and ultimately fibrosis (via mechanisms previously discussed; **see Fig. 58.9**) increase the stiffness of the infarcted myocardium back to and beyond preinfarct values. Increasing stiffness in the infarcted zone of myocardium improves LV function because it prevents paradoxical systolic wall motion (dyskinesia).

The likelihood of clinical symptoms developing correlates with specific parameters of LV function. The earliest abnormality is ventricular stiffness in diastole (see later), which occurs with infarcts involving only a small portion of the left ventricle. When the abnormally contracting segment exceeds 15% of the myocardium, the EF may decline, and LV end-diastolic pressure and volume may increase. The risk for the development of physical signs and symptoms of LV failure also increases in proportion to increasing areas of abnormal LV wall motion. Clinical heart failure accompanies areas of abnormal contraction exceeding 25%, and loss of more than 40% of the LV myocardium usually leads to cardiogenic shock, often fatal.

Unless extension of the infarct occurs, some improvement in wall motion takes place during the healing phase, with recovery of function occurring in initially reversibly injured (stunned) myocardium (**see Fig. 58.12 and eFig. 58.3**). Regardless of the age of the infarct, patients who continue to demonstrate abnormal wall motion involving 20% to 25% of the left ventricle will probably manifest hemodynamic signs of LV failure, with its attendant poor prognosis for long-term survival.

Diastolic Function

The diastolic properties of the left ventricle change in ischemic and infarcted myocardium (**see Chapters 22, 23, and 26**). These alterations are associated with a decrease in the peak rate of decline in LV pressure (peak—dP/dt), an increase in the time constant of the fall in LV pressure, and an initial rise in LV end-diastolic pressure. Over several weeks, end-diastolic volume increases, and diastolic pressure begins to fall toward normal. As with impairment of systolic function, the magnitude of the diastolic abnormality appears to relate to the size of the infarct.

Circulatory Regulation

Patients with STEMI have an abnormality in circulatory regulation. The process begins with an anatomic or functional obstruction in the coronary vascular bed that results in regional myocardial ischemia and, if the ischemia persists, in MI. If the infarct is of sufficient size, it depresses overall LV function such that LV stroke volume falls and filling pressure rises.[43] A marked depression in LV stroke volume ultimately lowers aortic pressure and, together with increased LV end-diastolic pressure,[44] reduces coronary perfusion pressure. This condition may intensify myocardial ischemia and thereby initiate a vicious cycle (**Fig. 58.14**), leading to cardiogenic shock, which occurs in 5% to 8% of patients with STEMI.[45,46]

Systemic inflammation secondary to myocardial injury leads to the release of cytokines that contribute to the vasodilation and decreased systemic vascular resistance.[47] The inability of the left ventricle to empty normally also increases preload; that is, it dilates the well-perfused, normally functioning portion of the left ventricle. This compensatory mechanism tends to restore stroke volume to normal levels, but at the expense of a reduced EF. Dilation of the left ventricle also elevates ventricular wall tension, because Laplace law dictates that at any given arterial pressure, the dilated ventricle must develop higher wall tension. This increased afterload not only depresses LV stroke volume but also elevates myocardial oxygen consumption, which in turn intensifies the myocardial ischemia. When regional myocardial

dysfunction is limited and the function of the remainder of the left ventricle is normal, compensatory mechanisms—especially hyperkinesis of the nonaffected portion of the ventricle—sustain overall LV function. If a large portion of the left ventricle ceases to function, pump failure ensues.

Ventricular Remodeling

As a consequence of STEMI, the changes in LV size, shape, and thickness involving both the infarcted and the noninfarcted segments of the ventricle described earlier occur and are collectively referred to as *ventricular remodeling*—which in turn can influence ventricular function and prognosis.[48] Changes in LV dilation combined with hypertrophy of residual noninfarcted myocardium cause remodeling. After infarct size, other important factors driving the process of LV dilation are ventricular volume, loading conditions, and infarct artery patency.[41,49] Elevated ventricular pressure contributes to increased wall stress and the risk for infarct expansion, but a patent infarct artery accelerates myocardial scar formation and increases tissue turgor in the infarct zone, thereby reducing the risk for infarct expansion and ventricular dilation. Inflammation, a key component in healing, may also govern the degree of adverse versus appropriate compensatory myocardial remodeling, as discussed.[25] Immediately post-MI, EF correlates only modestly with eventual LV volumes. Many large MIs do not evolve to a poorly remodeled heart, while a subset of patients with relatively smaller infarcts progress to significant adverse remodeling. Genetic or epigenetic differences in the regulation of the healing process resulting from a variable inflammatory response may explain in part the heterogeneous natural history of infarct healing[49] (**Fig. 58.15**). Exaggerated ventricular dilation, for example, may results from an inflammatory process with excessive matrix degradation, whereas greater scar deposition and less dilation may follow an inflammatory process that preferentially stimulates a more profibrotic healing process.[50]

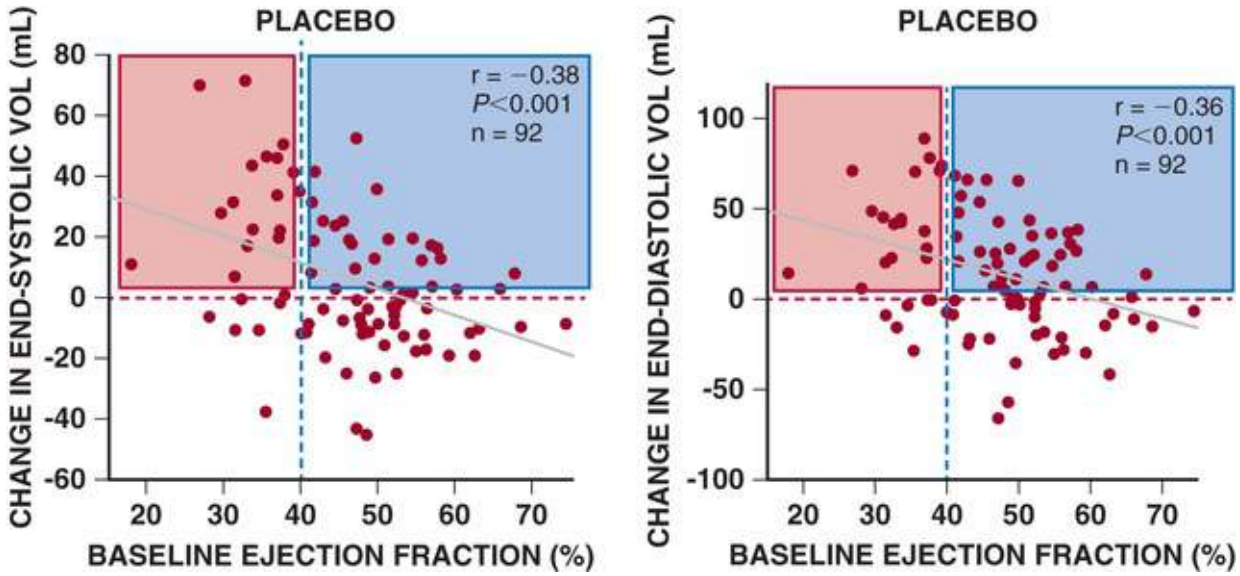

FIGURE 58.15 Relationship between baseline ejection fraction (EF) and subsequent change in left ventricular end-systolic volume (LVESV) and left ventricular end-diastolic volume (LVEDV). LV angiography was performed 4.3 days after percutaneous coronary intervention and was repeated 4 months later. LV remodeling developed over time in both patients with reduced baseline EF (*orange area*) and in patients with normal baseline EF (*blue area*). Although a correlation exists between baseline EF and changes in systolic volumes, a number of patients with preserved EF will progress to ventricular dilation, while some with reduced EF will not. (From Westman PC, Lipinski MJ, Luger D, et al. Inflammation as a driver of adverse left ventricular remodeling after acute myocardial infarction. J Am Coll Cardiol 2016;67:2050-60.)

Infarct Expansion

An increase in the size of the infarcted segment, known as *infarct expansion*, is defined as "acute dilation and thinning of the area of infarction not explained by additional myocardial necrosis." Infarct expansion appears to result from a combination of slippage between muscle bundles, which reduces the number of myocytes across the infarct wall; disruption of normal myocardial cells; and destruction of extracellular matrix within the necrotic zone. Infarct expansion involves thinning and dilation of the infarct zone before the formation of a firm, fibrotic scar. The degree of infarct expansion appears to be related to preinfarction wall thickness, with existing hypertrophy possibly protecting against infarct thinning.

On a cellular level, the degree of expansion and worsening remodeling depends on the intensity of the inflammatory response to the necrotic cells. Suppression of cytokine expression and stimulation may minimize the degree of inflammation and thus final infarct size.[25,26,49,51]

The apex, the thinnest region of the left ventricle, is particularly vulnerable to infarct expansion. Infarction of the apex secondary to LAD occlusion causes the radius of curvature at the apex to increase, thereby exposing this normally thin region to a marked elevation in wall stress.

Infarct expansion associates with both higher mortality and a higher incidence of nonfatal complications, such as heart failure and ventricular aneurysm. Infarct expansion is best recognized as elongation of the noncontractile region of the ventricle on echocardiography or CMR. When the expansion is severe enough to cause symptoms, the most characteristic clinical findings are deterioration of systolic function, new or worsening pulmonary congestion, and development of ventricular arrhythmias.

Ventricular Dilation

Although infarct expansion plays an important role in the ventricular remodeling that occurs early after MI, remodeling is also caused by dilation of the viable portion of the ventricle, which commences immediately after STEMI and progresses for months or years thereafter. A shift of the pressure-volume curve of the left ventricle to the right, which results in a larger LV volume at any given diastolic pressure, may accompany dilation. This dilation of the noninfarcted zone can be viewed as a compensatory mechanism that maintains stroke volume in the presence of a large infarction. This chronic dilation may also be a manifestation of a chronic inflammatory process affecting the myocardium that began at the time of the large infarct, but never fully resolved.[51] Large STEMIs place an extra load on the residual functioning myocardium, a burden that presumably causes the compensatory hypertrophy of the noninfarcted myocardium. This hypertrophy could help compensate for the functional impairment caused by the infarct and may be responsible for some of the hemodynamic improvement seen in some patients in the months after infarction.

Effects of Treatment

Several factors can affect ventricular remodeling after STEMI, notably final infarct size (**see Fig. 58.12 and eFig. 58.3**). Acute reperfusion and other measures to restrict the extent of myocardial necrosis limit the increase in ventricular volume after STEMI. Multiple pharmacologic agents that target reperfusion injury or regenerative therapies aimed at limiting infarct size have undergone evaluation in clinical trials, although few have produced significant results in adequately powered phase III investigations[52] (**see Chapter 59**). Appropriate and timely scar formation in the infarct also affects the degree of LV remodeling post-MI. Glucocorticoids and nonsteroidal anti-inflammatory drugs (NSAIDs) given early after MI can cause scar thinning and greater infarct expansion, whereas RAAS inhibitors attenuate the ventricular enlargement. Additional beneficial consequences of inhibition of angiotensin II that may

contribute to myocardial protection include attenuation of endothelial dysfunction and direct antiatherogenic effects. Inhibition of aldosterone action may limit excessive fibrosis and decrease the development of ventricular arrhythmias.

Pathophysiology of Other Organ Systems

Pulmonary Function.
Increased pulmonary capillary hydrostatic pressure in the setting of STEMI can promote interstitial edema and result in arteriolar and bronchiolar compression that ultimately causes perfusion of poorly ventilated alveoli with resultant hypoxemia. In addition to hypoxemia, diffusion capacity decreases. Hyperventilation often occurs in patients with STEMI and may cause hypocapnia and respiratory alkalosis, particularly in restless, anxious patients with pain. Pulmonary extravascular (interstitial) water content, LV filling pressure, and the clinical signs and symptoms of LV failure are correlated. The increase in pulmonary extravascular water may cause the alterations in pulmonary mechanics observed in patients with STEMI: reduction in airway conductance, pulmonary compliance, forced expiratory volume, and midexpiratory flow rate and an increase in closing volume, presumably related to the widespread closure of small, dependent airways during the first 3 days after STEMI. Ultimately, severe increases in extravascular water may lead to pulmonary edema. Virtually all lung volume indices—total lung capacity, functional residual capacity, and residual volume, as well as vital capacity—fall during STEMI.

Reduction of Affinity of Hemoglobin for Oxygen.
In patients with MI, particularly when complicated by LV failure or cardiogenic shock, the affinity of hemoglobin for oxygen falls (i.e., P50 increases). The increase in P50 results from increased levels of erythrocyte 2,3-diphosphoglycerate, which is an important compensatory mechanism that mediates an estimated 18% increase in release of oxygen from oxyhemoglobin in patients with cardiogenic shock.

Endocrine Function

Glucose Homeostasis
(**see Chapter 51**). Hyperglycemia is common in patients presenting with STEMI and is associated with worse outcomes. Although patients with STEMI often have absolute concentrations of blood insulin in the normal range, these levels are usually inappropriately low for their blood sugar concentration, indicating insulin resistance. Patients with cardiogenic shock frequently have marked hyperglycemia with depressed levels of circulating insulin. Abnormalities in insulin secretion and the resultant impaired glucose tolerance appear to result from a reduction in pancreatic blood flow caused by the splanchnic vasoconstriction accompanying shock. In addition, increased activity of the sympathetic nervous system with augmented circulating catecholamines inhibits insulin secretion and increases glycogenolysis, which also contributes to elevated blood sugar.

Glucose permits the generation of ATP by anaerobic glycolysis, as opposed to free fatty acids (FFAs), which require aerobic conditions to furnish ATP. Because hypoxic heart muscle derives a considerable proportion of its energy from the metabolism of glucose (**see Chapter 22**), and because glucose uptake by the myocardium requires insulin, insulin deficiency can jeopardize the availability of energy. Despite these metabolic considerations, the most contemporary data indicate that maintaining glucose levels below 180 mg/dL, while avoiding hypoglycemia, is the safest post-MI glucose management strategy.[53]

Insulin-glucose infusions confer no benefit for patients with STEMI (**see Chapter 59**).

Adrenal Medulla.

Plasma and urinary catecholamine levels peak in the first 24 hours after onset of chest pain, with the greatest rise in plasma catecholamine secretion occurring during the first hour after onset of STEMI. These high levels of circulating catecholamines in patients with STEMI correlate with the occurrence of serious arrhythmias and result in an increase in myocardial oxygen consumption, both directly and indirectly, because of catecholamine-induced elevation of circulating FFAs. The concentration of circulating catecholamines correlates with the extent of myocardial damage and the incidence of cardiogenic shock, as well as with both early and late mortality.

Circulating catecholamines enhance platelet aggregation; when this occurs in the coronary microcirculation, release of the potent local vasoconstrictor thromboxane A_2 may further impair cardiac perfusion. The marked increase in sympathetic activity immediately following STEMI is both protective and potentially deleterious. Early inhibition of circulating catecholamines with IV beta-adrenergic receptor blockers can diminish cardiac function and worsen outcomes in patients with incipient or frank cardiogenic shock, whereas beta-adrenergic receptor blockade in stable patients and in the convalescent phase is a cornerstone of post-MI care (**see Chapter 59**). Beta blockers may also limit mobilization of leukocytes from the bone marrow and thus exert an anti-inflammatory effect that could benefit infarct healing and limit activation of atheromata.[25,54]

Activation of the Renin-Angiotensin-Aldosterone System

Noninfarcted regions of the myocardium appear to exhibit activation of the tissue RAAS with increased production of angiotensin II. Both locally and systemically generated A II can stimulate the production of various growth factors, such as platelet-derived growth factor and TGF-β, that promote compensatory hypertrophy in the noninfarcted myocardium, as well as control the structure and tone of the infarct-related coronary and other myocardial vessels. Additional potential actions of A II that could aggravate infarction include the release of endothelin, plasminogen activator inhibitor (PAI) 1, and aldosterone, which may cause vasoconstriction, impair fibrinolysis, and increase sodium retention, respectively.[51]

Natriuretic Peptides

The peptides atrial natriuretic peptide (ANP) and B-type natriuretic peptide (BNP) are released from the cardiac atria in response to an elevation in atrial pressure. Atrial and ventricular myocardium secrete B-type natriuretic peptide (BNP) and N-terminal pro-BNP (NT-proBNP). Given the larger mass of ventricular than atrial myocardium, the total amount of mRNA for BNP is higher in the ventricles than in the atria. Natriuretic peptides are released early after STEMI, with a peak at approximately 16 hours. The natriuretic peptides released from the left ventricle during STEMI originate both from the infarcted myocardium and from viable noninfarcted myocardium. The rise in BNP and NT-proBNP after STEMI correlates with infarct size and regional wall motion abnormalities. Measurement of natriuretic peptides can provide useful information both early and late in the course of STEMI.[55,56]

Adrenal Cortex

Plasma and urinary 17-hydroxycorticosteroids and ketosteroids, as well as aldosterone, rise markedly in patients with STEMI. Their concentrations correlate directly with the peak level of serum CK, thus implying an association between the stress imposed by larger infarcts and greater secretion of adrenal

steroids. The magnitude of the elevation in cortisol correlates with infarct size and mortality.

Thyroid Gland

Although patients with STEMI are generally euthyroid clinically, serum triiodothyronine (T_3) levels can decrease transiently, a fall that is most marked on approximately the third day after the infarct. A rise in reverse T_3 usually accompanies this fall in T_3, with variable changes or no change in thyroxine (T_4) and thyroid-stimulating hormone levels.[57] The alteration in peripheral T_4 metabolism appears to correlate with infarct size and may be mediated by the rise in endogenous levels of cortisol that accompanies STEMI.

Renal Function

Both prerenal azotemia and acute renal failure can complicate the marked reduction in cardiac output that occurs in cardiogenic shock.

Hematologic Alterations

Platelets

STEMI generally occurs in the presence of extensive coronary and systemic atherosclerotic plaque, which may serve as the site for the formation of platelet aggregates—a sequence suggested as an early step in the process of coronary thrombosis, coronary occlusion, and subsequent MI. Platelets from patients with STEMI have an increased propensity for aggregation both systemically and locally in the area of disrupted plaque and release vasoactive substances. Thus, platelets are key therapeutic targets for the initial antithrombotic management in STEMI.

Hemostatic Markers

Elevated levels of serum fibrinogen degradation products, an end product of thrombosis, as well as release of distinctive proteins when platelets are activated (e.g., platelet factor 4, beta-thromboglobulin), occur in some patients with STEMI. Fibrinopeptide A (FPA), a protein released from fibrin by thrombin, reflects ongoing thrombosis and increases during the early hours of STEMI. Marked elevation of hemostatic markers such as FPA, thrombin-antithrombin complex, and prothrombin fragment 1.2 is associated with an increased risk for mortality in patients with STEMI. Interpretation of coagulation test results in these patients may be complicated by elevated blood levels of catecholamines, concomitant shock, and venous thrombosis or embolism—conditions that may alter various tests of platelet and coagulation function. Additional factors that affect coagulation test results in patients with STEMI include the type and dosage of antithrombotic agent and reperfusion of the infarct artery.

Leukocytes

Leukocytosis usually accompanies STEMI in proportion to the magnitude of the necrotic process, elevated glucocorticoid levels, and possibly inflammation in the coronary arteries. The magnitude of the elevation in leukocyte count is associated with in-hospital mortality after STEMI. Experimental evidence suggests that the surge in catecholamines after coronary occlusion can mobilize leukocyte progenitors from bone marrow, thereby sustaining the inflammatory response following infarction.[25,54]

Blood Viscosity

Clinical and epidemiologic studies suggest that several hemostatic and hemorrheologic factors (e.g., fibrinogen, factor VII, plasma viscosity, hematocrit, red blood cell aggregation, total white blood cell count) participate in the pathophysiology of atherosclerosis and play an integral role in acute thrombotic events. An increase in blood viscosity also occurs in patients with STEMI and can be attributed to hemoconcentration during the first few days and later to elevated serum concentrations of $alpha_2$-globulin and fibrinogen, components of the acute-phase response to tissue necrosis that also cause the elevated sedimentation rate characteristic of STEMI.

Clinical Features

Predisposing Factors

Up to one third of patients with STEMI have an identifiable precipitating trigger or prodromal symptoms. Unusually heavy exercise (particularly in fatigued or habitually inactive patients), emotional stress, and acute illness are the most frequent triggers.[58,59] Such infarctions could result from marked increases in myocardial oxygen consumption in the presence of severe coronary arterial narrowing (a type 2 MI), or the acute hemodynamic stress on a fragile plaque from a catecholamine or blood pressure surge.

Accelerating angina and rest angina, two patterns of unstable angina, may culminate in STEMI (**see Fig. 58.1**). Noncardiac surgical procedures may also precede STEMI. Perioperative risk stratification and preventive measures may limit STEMI and cardiac-related mortality[60] (**see Chapter 11**). Reduced myocardial perfusion secondary to hypotension (e.g., hemorrhagic or septic shock) and the increased myocardial oxygen demands caused by aortic stenosis, fever, tachycardia, and agitation can also contribute to myocardial necrosis. Other factors reported to predispose to STEMI include respiratory infections, hypoxemia from any cause, pulmonary embolism, hypoglycemia, administration of ergot preparations, cocaine use, sympathomimetics, serum sickness, allergy, and rarely, wasp stings. In patients with Prinzmetal angina (**see Chapter 61**), STEMI may develop in the territory of the coronary artery that undergoes spasm.

Circadian Periodicity

The time of onset of STEMI has a pronounced circadian periodicity, with the peak incidence of events occurring in the morning.[61] Circadian rhythms affect many physiologic and biochemical variables; plasma catecholamines and cortisol and platelet aggregability increase in the early-morning hours. Patients receiving a beta-blocking agent or aspirin do not exhibit this characteristic circadian peak before the development of STEMI, consistent with precipitation by sympathetic stimuli or platelet activation. The concept of “triggering” a STEMI is complex and can involve the superimposition of multiple factors, such as the time of day, season, and the stress of natural disasters.

History

See also Chapters 10, 56, and 60.

Prodromal Symptoms

The patient's history remains crucial to establishing a diagnosis of STEMI. Chest discomfort resembling classic angina pectoris usually characterizes the prodrome, but it occurs at rest or with less activity than

usual. Yet the symptoms are often not disturbing enough to induce patients to seek immediate medical attention. A feeling of general malaise or frank exhaustion frequently accompanies other symptoms preceding STEMI.

Nature of the Pain

Pain in patients with STEMI varies in intensity; in most patients it is severe and in some instances is intolerable. The pain is prolonged—it generally lasts for more than 30 minutes and frequently for several hours if there is no reperfusion. The patient usually describes the discomfort as constricting, crushing, oppressing, or compressing and often complains of a sensation of a heavy weight or a squeezing in the chest. Although patients typically describe the discomfort as a choking, viselike, or heavy pain, it can also be characterized as a stabbing, knifelike, boring, or burning discomfort. The discomfort usually localizes retrosternally and frequently spreads to both sides of the anterior part of the chest, with a predilection for the left side. Often the pain radiates down the ulnar aspect of the left arm and produces a tingling sensation in the left wrist, hand, and fingers. Some patients note only a dull ache or numbness of the wrists in association with severe substernal or precordial discomfort. In some patients, pain from STEMI may begin in the epigastrium and simulate a variety of abdominal disorders, which often causes STEMI to be misdiagnosed as "indigestion." In other patients the discomfort of STEMI radiates to the shoulders, upper extremities, neck, jaw, and interscapular region, again usually favoring the left side. In patients with preexisting angina pectoris, the pain of infarction generally resembles that of angina with respect to location, but it is normally much more severe, lasts longer, and is not relieved by rest or nitroglycerin.

STEMI pain may subside by the time that the physician first encounters the patient (or the patient reaches the hospital), or it may persist for many hours until adequate reperfusion (**see Chapter 59**). Both angina pectoris and STEMI pain likely arise from nerve endings in ischemic or injured, but not necrotic myocardium. Thus, in cases of STEMI, stimulation of nerve fibers in an ischemic zone of myocardium surrounding the necrotic central area of infarction probably gives rise to the pain.

The pain often disappears suddenly and completely following restoration of blood flow to the infarct territory. Recurrent pain after initial reperfusion should prompt immediate evaluation for acute re-occlusion of the culprit lesion. The recognition that pain implies ischemia and not infarction heightens the importance of targeted anti-ischemic therapy and immediate reperfusion (typically by repeat coronary angiography) to relieve the ischemia, for which the pain is a marker. This finding suggests that clinicians should *not* be complacent about ongoing cardiac pain in any circumstances. In some patients—particularly older adults, patients with diabetes, and heart transplant recipients—STEMI can manifest clinically not by chest discomfort but rather by symptoms of acute LV failure and chest tightness or by marked weakness or frank syncope. Diaphoresis, nausea, and vomiting may accompany these symptoms. Women may experience symptoms of STEMI differently than men (**see Chapter 89**), requiring particular awareness and vigilance on the part of the interviewing physician.

Other Symptoms

Nausea and vomiting may occur, presumably because of activation of the vagal reflex or stimulation of LV receptors as part of the Bezold-Jarisch reflex. These symptoms occur more frequently in patients with inferior STEMI than with anterior STEMI. When the pain of STEMI is epigastric in location and associated with nausea and vomiting, the clinical picture can easily be confused with that of acute cholecystitis, gastritis, or peptic ulcer. Other symptoms include feelings of profound weakness, dizziness, palpitations, cold perspiration, and a sense of impending doom. On occasion, symptoms arising from an

episode of cerebral embolism or other systemic arterial embolism can herald STEMI. Chest discomfort may not accompany these symptoms.

Differential Diagnosis

STEMI pain may overlap with that caused by acute pericarditis, acute aortic syndromes, pulmonary, and musculoskeletal discomfort, as discussed in detail in **Chapter 56** (**see Table 56.1**).

Silent ST-Elevation Myocardial Infarction with Atypical Features

Nonfatal STEMI can go unrecognized by the patient and may manifest only on subsequent routine electrocardiographic, imaging, or postmortem examination. Of these unrecognized infarctions, approximately half are truly silent, with patients unable to recall any symptoms. The other portion of patients with so-called silent infarction can recall an event characterized by symptoms compatible with acute MI in response to leading questions after finding ECG or imaging abnormalities. Unrecognized or silent infarction occurs more often in patients without antecedent angina pectoris and in patients with diabetes and hypertension and typically manifests as new wall motion abnormalities, fixed perfusion defects, or pathologic Q waves.[62] Silent ischemia often follows silent STEMI (**see Chapter 61**). The prognosis of patients with silent and symptomatic manifestations of STEMI appear quite similar.[63]

Atypical features of STEMI include the following: (1) heart failure (i.e., dyspnea without pain beginning de novo or worsening of established failure), (2) classic angina pectoris without a particularly severe or prolonged episode, (3) atypical location of the pain, (4) central nervous system manifestations resembling those of stroke secondary to a sharp reduction in cardiac output in a patient with cerebral arteriosclerosis, (5) apprehension and nervousness, (6) sudden mania or psychosis, (7) syncope, (8) overwhelming weakness, (9) acute indigestion, and (10) peripheral embolization. Although women may more likely present with “atypical” features of STEMI than men, recent evidence suggests fewer differences between sexes than previously thought[64] (**see Chapter 89**).

Physical Examination

See also Chapter 10.

General Appearance

Patients suffering from STEMI often appear anxious and in considerable distress. An anguished facial expression is common, and—in contrast to patients with severe angina pectoris, who often lie, sit, or stand still because all forms of activity increase the discomfort—some patients suffering from STEMI may be restless and move about in an effort to find a comfortable position. They often massage or clutch their chests and frequently describe their pain with a clenched fist held against the sternum (Levine sign). In patients with LV failure and sympathetic stimulation, cold perspiration and skin pallor may be evident; they typically sit or are propped up in bed and gasp for breath. Between breaths they may complain of chest discomfort or a feeling of suffocation. Cough producing frothy, pink, or blood-streaked sputum may occur if pulmonary edema is present. Patients in cardiogenic shock often lie listlessly and make few spontaneous movements. Their skin is cool and clammy, with a bluish or mottled color over the extremities, and there is marked facial pallor with severe cyanosis of the lips and nailbeds. Depending on the degree of cerebral perfusion, a patient in shock may converse normally or may be confused.

Heart Rate

The heart rate can vary from marked bradycardia to a rapid regular or irregular tachycardia, depending on the underlying rhythm and degree of LV failure. Typically the pulse is rapid and regular initially (sinus tachycardia at 100 to 110 beats/minute) and slows as the patient's pain and anxiety are relieved; premature ventricular contractions are common. Tachycardia at presentation is associated with a higher risk for fatal complications of MI.

Blood Pressure

Most patients with uncomplicated STEMI are normotensive, although the reduced stroke volume accompanying the tachycardia can cause declines in systolic and pulse pressure and elevation of diastolic blood pressure (BP). In previously normotensive patients, a hypertensive response is occasionally seen during the first few hours, presumably because of adrenergic discharge secondary to pain, anxiety, and agitation. Previously hypertensive patients may become normotensive without treatment after STEMI, although many of them eventually regain their elevated BP levels, generally 3 to 6 months after infarction. In patients with massive infarction, arterial pressure falls acutely because of LV dysfunction and may be exacerbated by morphine and/or nitrates, which cause venous pooling; as recovery occurs, arterial pressure tends to return to preinfarction levels.

Patients in cardiogenic shock by definition have systolic pressure below 90 mm Hg and evidence of end-organ hypoperfusion. Hypotension alone does not necessarily signify cardiogenic shock; some patients with inferior infarction and activation of the Bezold-Jarisch reflex may also transiently have systolic BP below 90 mm Hg. Their hypotension eventually resolves spontaneously, although IV atropine (0.5 to 1 mg) and assumption of the Trendelenburg position can accelerate recovery. Other patients who are initially only slightly hypotensive may demonstrate gradually falling BP with a progressive reduction in cardiac output over several hours or days as cardiogenic shock develops because of increasing ischemia and extension of infarction (**see Fig. 58.14**). Evidence of autonomic hyperactivity is common and varies in type with the location of the infarction. More than half of patients with inferior STEMI have evidence of excess parasympathetic stimulation, with hypotension, bradycardia, or both evident during initial evaluation, whereas approximately half of patients with anterior STEMI show signs of sympathetic excess and have hypertension, tachycardia, or both.

Temperature and Respiration

Fever, a nonspecific response to tissue necrosis, develops in most patients with extensive STEMI within 24 to 48 hours of onset of infarction. Body temperature often begins to rise within 4 to 8 hours after onset of infarction, and rectal temperature may reach 38.3°C to 38.9°C (101°F to 102°F). The fever usually resolves by the fourth or fifth day after MI.

The respiratory rate may rise slightly soon after the development of STEMI; in patients without heart failure (HF), it results from anxiety and pain and returns to normal with treatment of the physical and psychological discomfort. Respiratory rates greater than 20 breaths/min augur heightened risk.[65] In patients with LV failure, respiratory rate correlates with severity of the failure; patients with pulmonary edema may have rates exceeding 40 breaths/min. However, the respiratory rate is not necessarily elevated in patients with cardiogenic shock. Cheyne-Stokes (periodic) respiration may occur in elderly individuals with cardiogenic shock or HF, particularly after opiate therapy or in the presence of cerebrovascular disease.

Jugular Venous Pulse

The jugular venous pulse is usually normal in STEMI involving the left ventricle. The *a* wave may be prominent in patients with pulmonary hypertension secondary to LV failure or reduced compliance. In contrast, RV infarction (regardless of whether it accompanies LV infarction) often results in marked jugular venous distention and, when complicated by necrosis or ischemia of RV papillary muscles, in the tall *c-v* waves of tricuspid regurgitation. Patients with STEMI and cardiogenic shock generally have elevated jugular venous pressure, although in the early phase, if RV function is relatively preserved, right-sided pressures may remain normal. In patients with STEMI, hypotension, and hypoperfusion (findings that may resemble those of patients with cardiogenic shock) without elevated jugular venous pressures, the depression in LV performance probably is related to hypovolemia, at least in part. Assessing LV performance with echocardiography or by measuring LV filling pressure with a pulmonary artery catheter can help determine the cause of hypotension.

Carotid Pulse

Palpation of the carotid arterial pulse provides a clue to LV stroke volume: a small pulse suggests reduced stroke volume, whereas a sharp, brief upstroke often occurs in patients with mitral regurgitation or a ruptured ventricular septum with a left-to-right shunt. Pulsus alternans reflects severe LV dysfunction.

The Chest

Moist rales are audible in patients in whom LV failure or reduction in LV compliance leads to pulmonary edema. Diffuse wheezing can occur in patients with severe LV failure. Cough with hemoptysis, suggesting pulmonary embolism with infarction, can also occur. In 1967, Thomas Killip proposed a prognostic classification scheme on the basis of the presence and severity of rales in patients with STEMI. Class I patients are free of rales and a third heart sound (S_3). Class II patients have rales, but only to a mild to moderate degree (<50% of lung fields), and may or may not have an S_3. Class III patients have rales in more than half of each lung field and frequently have pulmonary edema. Class IV patients have cardiogenic shock. Despite the overall improvement in the mortality rate that applies to each category, the Killip classification still remains useful for prognostication.[66]

Cardiac Examination

Palpation

Palpation of the precordium may yield normal results, but in patients with transmural STEMI, it more often reveals a presystolic pulsation synchronous with an audible fourth heart sound (S_4), a finding reflecting vigorous left atrial contraction filling a ventricle with reduced compliance. Patients with LV systolic dysfunction may have a diffuse or dyskinetic LV impulse, or an outward movement of the left ventricle palpable in early diastole, coincident with an S_3.

Auscultation

Heart Sounds.

The heart sounds, particularly the first sound, are frequently muffled and occasionally inaudible immediately after an infarct, and their intensity increases during convalescence. A soft first heart sound

(S_1) may also reflect prolongation of the PR interval. Patients with marked ventricular dysfunction and/or left bundle branch block (LBBB) may have paradoxical splitting of the second heart sound (S_2). An S_4 is almost universally present in patients in sinus rhythm with STEMI, but it has limited diagnostic value because it is usually audible in most patients with chronic ischemic heart disease and is recordable, although not often audible, in many normal individuals older than 45. An S_3 in patients with STEMI usually reflects severe LV dysfunction with elevated ventricular filling pressure. It reflects rapid deceleration of transmitral blood flow during protodiastolic filling of the left ventricle and is typically heard in patients with large infarctions. S_3 is detected best at the apex with the patient in the left lateral recumbent position. An S_3 may result not only from LV failure but also from increased inflow into the left ventricle, as occurs when mitral regurgitation or a ventricular septal defect complicates STEMI. S_3 and S_4 emanating from the left ventricle are heard best at the apex, and in patients with RV infarcts, can be heard along the left sternal border and increase on inspiration.

Murmurs.

Patients with STEMI typically have systolic murmurs, transient or persistent, that generally result from mitral regurgitation secondary to dysfunction of the mitral valve apparatus (papillary muscle dysfunction, LV dilation). A new, prominent, apical holosystolic murmur accompanied by a thrill may represent rupture of a head of a papillary muscle (**see Chapter 59**). Rupture of the interventricular septum produces similar findings, although the murmur and thrill are usually most prominent along the left sternal border and may be audible at the right sternal border as well. The systolic murmur of tricuspid regurgitation (from RV failure caused by pulmonary hypertension or RV infarction, or from infarction of an RV papillary muscle) is also heard along the left sternal border. It is characteristically intensified by inspiration and is accompanied by a prominent *c-v* wave in the jugular venous pulse and an RV fourth sound.

Friction Rubs.

Patients with STEMI may develop pericardial friction rubs. Rubs are notorious for their evanescence and thus are probably even more common than reported. Although friction rubs can be heard within 24 hours or as late as 2 weeks after onset of infarction, they occur most frequently on the second or third day. Occasionally, patients with extensive infarction can have a loud rub that lasts for many days. Patients with STEMI and a pericardial friction rub may have a pericardial effusion on echocardiographic study, but only rarely the classic ECG changes of pericarditis. Delayed onset of the rub and the associated discomfort of pericarditis (as late as 3 months after infarction) characterizes the now rare post-MI (Dressler) syndrome. Pericardial rubs are most readily audible along the left sternal border or just inside the apical impulse. Loud rubs may be audible over the entire precordium and even over the back. Occasionally, only the systolic portion of a rub is heard, which requires distinction from a systolic murmur, such as might result from rupture of the ventricular septum or mitral regurgitation.

Other Findings

Ocular Fundi

Hypertension, diabetes, and generalized atherosclerosis typically accompany STEMI and can produce characteristic changes in the fundus. A funduscopic (ophthalmoscopic) examination may provide information on the underlying vascular status, which can prove particularly useful in patients unable to provide a detailed history.

Abdomen

Patients often interpret pain in the abdomen associated with nausea, vomiting, restlessness, and even abdominal distention as a sign of "indigestion," leading to self-medication with antacids; it can also suggest an acute abdominal process to the physician. Right-sided HF, characterized by hepatomegaly and a positive abdominojugular reflux, is unusual in patients with acute LV infarction but occurs in patients with severe and prolonged LV failure or RV infarction.

Extremities

Coronary atherosclerosis is often associated with systemic atherosclerosis, and therefore patients with STEMI may have a history of intermittent claudication and may demonstrate the physical findings of peripheral vascular disease (**see Chapter 64**). Thus, patients with CAD may exhibit diminished peripheral arterial pulses, loss of hair, and atrophic skin in the lower extremities. Peripheral edema is a manifestation of RV failure and, as with congestive hepatomegaly, is unusual in patients with acute LV infarction. Cyanosis of the nailbeds is common in patients with severe LV failure and is particularly striking in patients with cardiogenic shock.

Neuropsychiatric Findings

Except for the altered mental status that occurs in patients with STEMI who have greatly reduced cardiac output and cerebral hypoperfusion, findings on neurologic examination are normal unless the patient has sustained a cerebral embolism secondary to mural thrombus. The association between these two conditions can be explained by systemic hypotension from STEMI precipitating a cerebral infarction, and vice versa, as well as by mural emboli from the left ventricle causing cerebral emboli. As discussed in **Chapter 59**, patients with STEMI frequently exhibit alterations in their emotional state, including intense anxiety, denial, and depression.

Laboratory Findings

Serum and Plasma Markers of Cardiac Damage

Proteins released into the blood from damaged myocardial cells can indicate myocardial injury. Even though the availability of serum and plasma cardiac markers with greatly enhanced sensitivity for myocardial injury has enabled clinicians to identify much lower levels of injury, biochemical tests of myocardial injury provide no direct insight into the cause of the damage.[67] MI is the diagnosis given to myocardial injury that results from ischemia[1] (**Fig. 58.16**). Other nonischemic insults, such as myocarditis or direct myocardial toxins, may result in myocardial injury but should not be labeled MI. Moreover, the enhanced ability to detect myocardial damage has increased the number of cases of myocardial injury that result from non–plaque-related clinical events, thus necessitating the establishment of new criteria for MI that place the injury in clinical context[1] (**see Tables 58.1 to 58.3**).

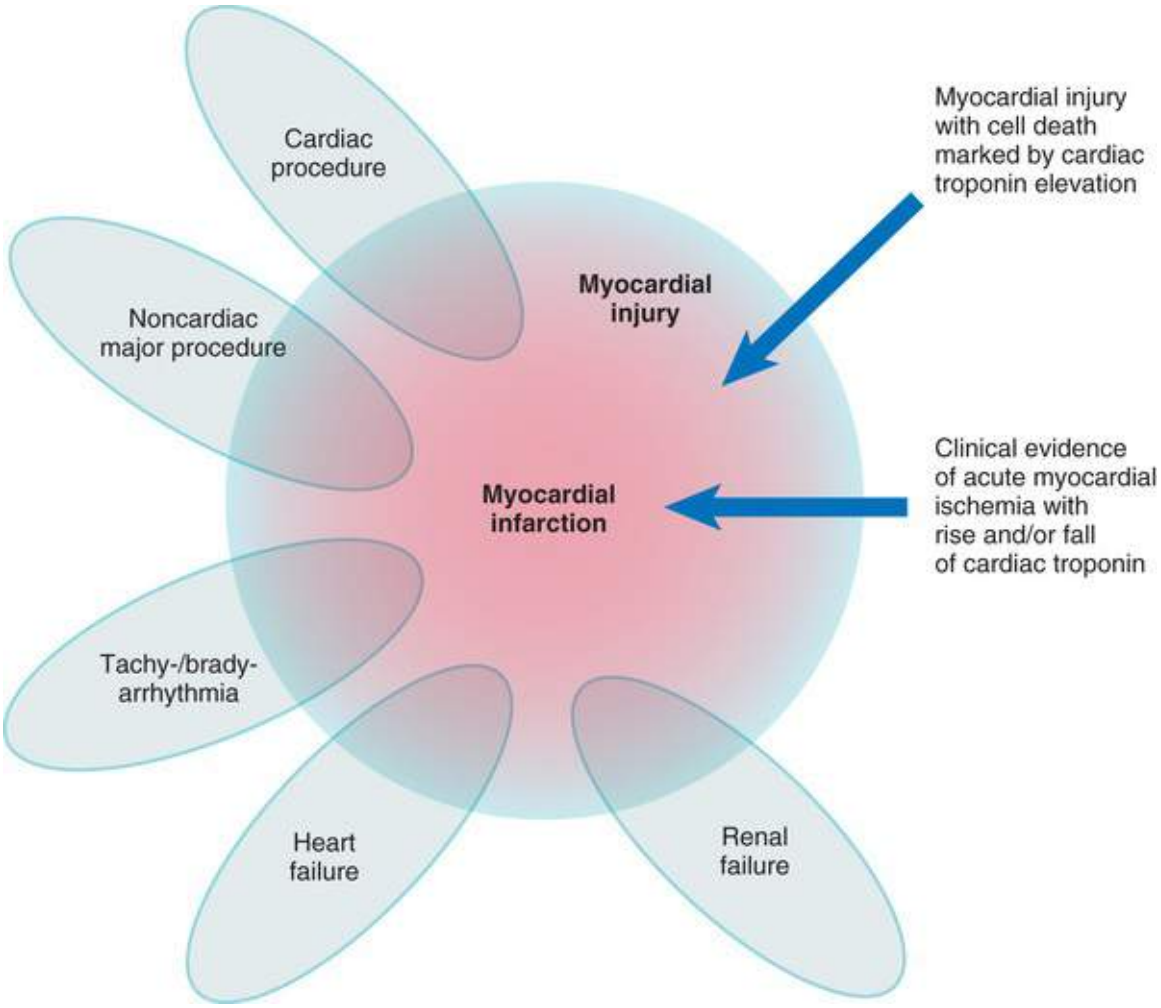

FIGURE 58.16 Myocardial ischemia and subsequent myocardial injury can result from a variety of clinical entities, including renal failure, heart failure, tachyarrhythmia or bradyarrhythmia, and cardiac or noncardiac procedures. Each of these scenarios can result in myocardial injury with cell death marked by the release of detectable circulating levels of cardiac troponin. However, each of these entities can also be associated with myocardial infarction when there is clinical evidence of acute myocardial ischemia with a typical rise and/or fall in cardiac troponin levels. (From Thygesen K, Alpert JS, Jaffe AS, et al. Third universal definition of myocardial infarction. J Am Coll Cardiol 2012;60:1581.)

Although this section applies more to diagnostic decision making for patients with suspected ACS without ST-segment elevation (**see Chapter 60**), this chapter contains a general discussion of cardiac biomarkers because of the overlapping pathophysiologic concepts and methodology regarding the use of biomarkers to evaluate patients with STEMI. Clinicians should *not* wait for the results of biomarker assays to initiate treatment of patients with STEMI. Given the urgency for reperfusion in patients with STEMI, a rapid clinical assessment and the 12-lead ECG should serve to initiate such strategies.

Necrosis compromises the integrity of the sarcolemmal membrane; intracellular macromolecules (serum and plasma cardiac markers) begin to diffuse into the cardiac interstitium and ultimately into the microvasculature and lymphatics in the region of the infarct (**Fig. 58.17; see Table 58.3**). The rate of appearance of these macromolecules in the peripheral circulation depends on several factors, including intracellular location, molecular weight, local blood and lymphatic flow, and the rate of elimination from blood.

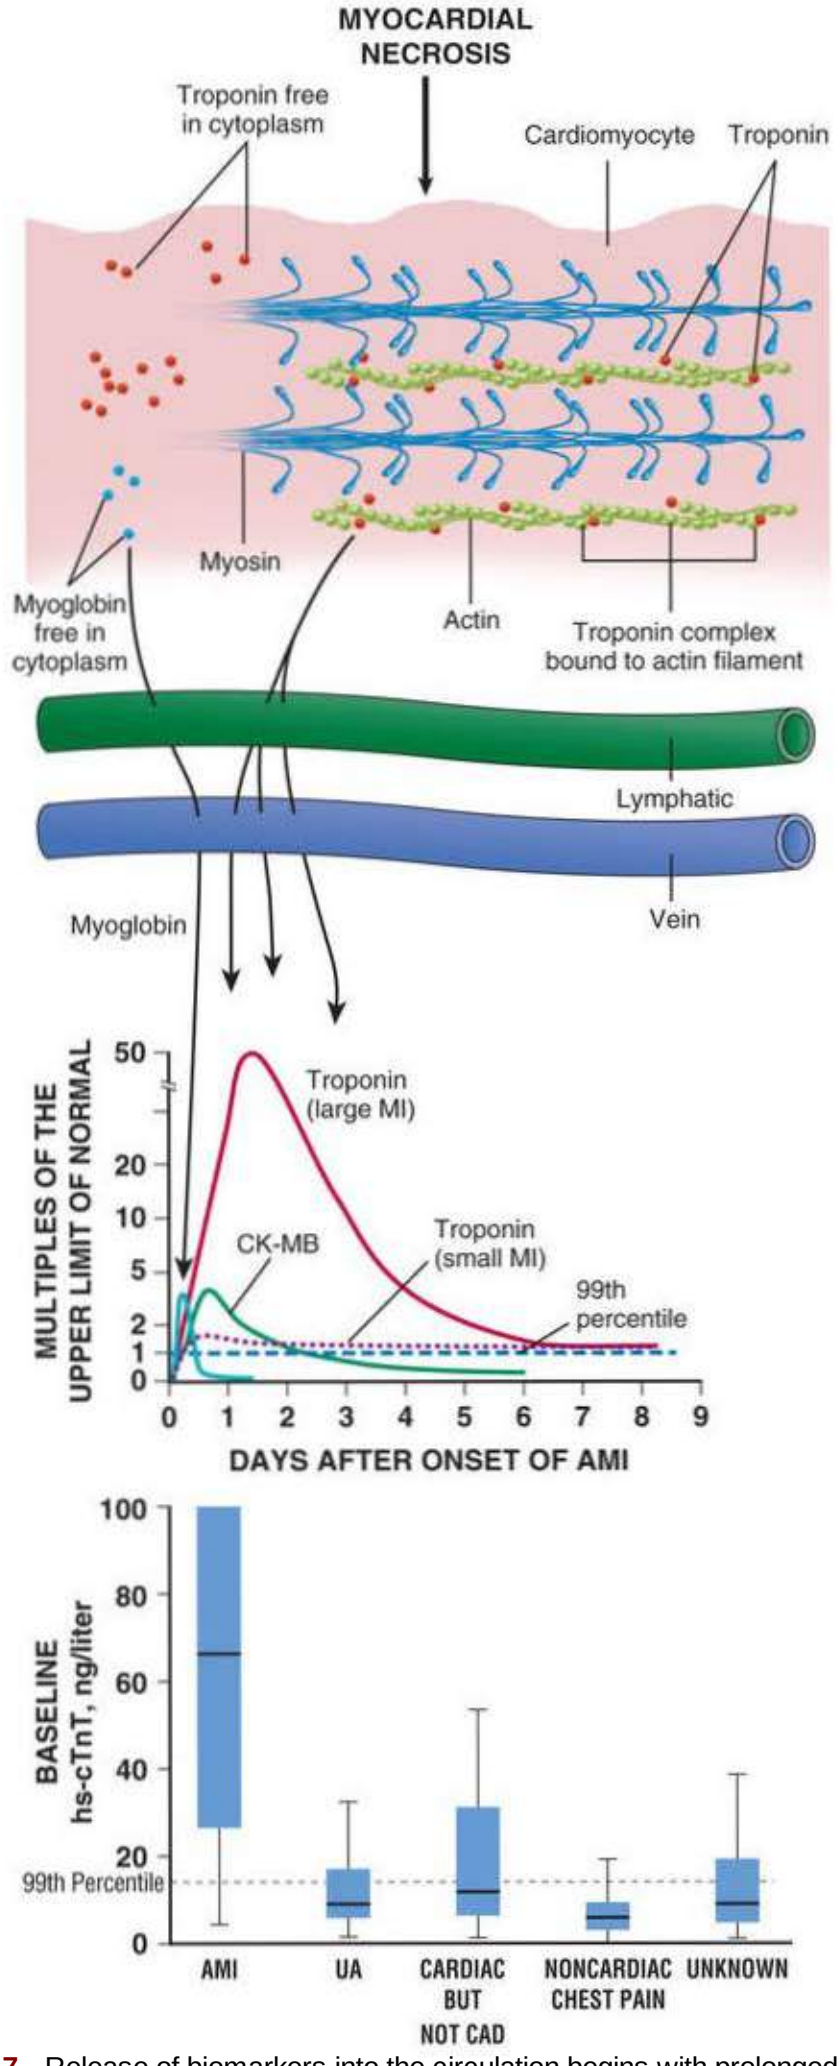

FIGURE 58.17 Release of biomarkers into the circulation begins with prolonged ischemia and

subsequent necrosis that results in loss of integrity of the cellular membranes. After disruption of the sarcolemmal membrane of the cardiomyocyte, the cytoplasmic pool of biomarkers is released first (*leftmost arrow* in **bottom** portion of the top panel). Markers such as myoglobin are released rapidly, and blood levels rise quickly above the cutoff limit. More protracted release of biomarkers from the disintegrating myofilaments follows and may continue for several days *(three-headed arrow).* Cardiac troponin levels rise to substantially higher multiples of the upper reference limit (the 99th percentile of values in a reference control group) compared with CK-MB in patients with acute myocardial infarction (MI) and sustain sufficient myocardial necrosis that results in abnormally elevated levels of CK-MB. Clinicians can now diagnose MI by more sensitive assays that detect even small elevations in cardiac troponin above the upper reference limit, even though levels of CK-MB and troponin determined from older generations of assays may still be below the MI decision limit. Other causes of myocardial injury, such as renal failure or pulmonary embolism, can lead to detectable levels of cardiac troponin even without any coronary artery disease **(lower panel).** AMI, Acute myocardial infarction; CAD, coronary artery disease; UA, unstable angina. (Modified from Antman EM. Decision making with cardiac troponin tests. N Engl J Med 2002;346:2079; Jaffe AS, Babiun L, Apple FS. Biomarkers in acute cardiac disease: the present and the future. J Am Coll Cardiol 2006;48:1; and Reichlin T et al. One-hour rule-out and rule-in of acute myocardial infarction using high-sensitivity cardiac troponin T. Arch Intern Med 2012;172:1211.)

Cardiac-Specific Troponins

The preferred biomarker to detect myocardial injury is cardiac troponin, which consists of three subunits that regulate the calcium-mediated contractile process of striated muscle. These subunits include troponin C, which binds Ca^{2+}; troponin I (TnI), which binds to actin and inhibits actin-myosin interactions; and troponin T (TnT), which binds to tropomyosin, thereby attaching the troponin complex to the thin filament (**Fig. 58.17**). Although most TnT is incorporated in the troponin complex, approximately 6% to 8% is dissolved in the cytosol; in contrast, approximately 2% to 3% of TnI is found in a cytosolic pool. Following myocyte injury, the initial release of cardiac-specific TnT and TnI is from the cytosolic pool, followed subsequently by release of the myofilament-bound protein.[68] Different genes encode TnT and TnI in cardiac and skeletal muscle, thus permitting the production of specific antibodies for the cardiac forms (cTnT and cTnI), which enables quantitative measurement.[69] Detection of a rise and fall in cTnT or cTnI in the appropriate clinical setting is the cornerstone of the diagnostic criteria for MI.[1]

When interpreting the results of assays for cTnT or cTnI, clinicians must recognize several analytic issues. Multiple manufacturers produce cTn assays using different troponin epitopes for detection, which has resulted in varying reference levels.[70] The release pattern of troponin complexes, conformational changes, and degradation into various troponin fragments may differentially affect the results of various commercial assays. Such post-translational modifications may provide insight into the underlying cause and timing of release (e.g., differentiating ischemia from myocarditis), but such applications have not emerged for clinical interpretation.

Cutoff Values.

Variations in the cutoff concentration for abnormal levels of cTn in the clinically available immunoassays result in part from the different specificities of the antibodies used for detecting free and complexed cTn. Thus, clinicians should apply evidence-based cutoff values for the particular assay used in their laboratory, which is defined as a value exceeding that of 99% of a reference control group. Assays that have a level of imprecision (i.e., coefficient of variation) of less than 10% at the specific 99th percentile cutoff are optimal for clinical practice.[1] In patients with MI, concentrations of cTnT and cTnI detected by conventional assays (non–high-sensitivity) can be detected approximately 3 hours after the onset of chest pain.[71] Because of continuous release from a degenerating contractile apparatus in necrotic myocytes, elevations in cTnI may persist for 7 to 10 days after MI; elevations in cTnT may persist for up to 10 to 14

days (**Fig. 58.17**). The prolonged time course of the elevation in cTnT and cTnI is advantageous for the late diagnosis of MI. Patients with STEMI who undergo successful recanalization of the infarct-related artery have a rapid release of cardiac troponins, which can indicate reperfusion (**Fig. 58.18**).

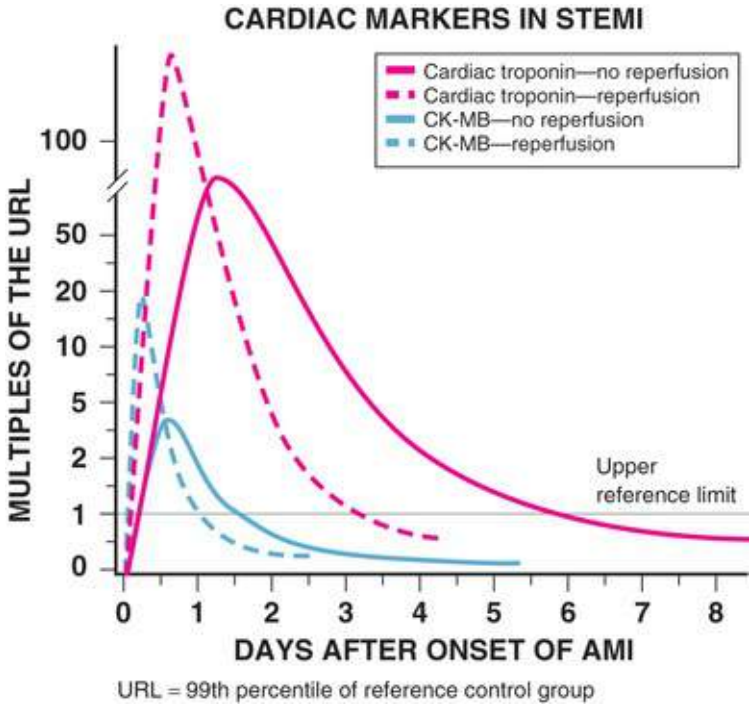

FIGURE 58.18 The kinetics of the release of CK-MB and cardiac troponin in patients who do not undergo reperfusion is shown in the *solid blue* and *red curves* as multiples of the upper reference limit (URL). When patients with STEMI undergo reperfusion, as depicted in the *dashed blue* and *red curves,* the cardiac biomarkers are detected sooner and rise to a higher peak value but decline more rapidly, which results in a smaller area under the curve and limitation of infarct size. AMI, Acute myocardial infarction. (Modified from Antman EM, Anbe DT, Armstrong PW, et al. ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee to Revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction]. Circulation 2004;110:e82.)

High-Sensitivity Cardiac Troponin.

High-sensitivity assays deliver enhanced analytic performance, thus enabling more precise measurement of very low concentrations of cardiac-specific troponin. Experts recommend that the term *high-sensitivity troponin* (hsTn) be reserved for assays that can detect cardiac troponin in more than 50% of an apparently healthy population.[69,70] Such assays have greater sensitivity than previous-generation assays, but also have diminished clinical specificity for MI because they detect true myocardial injury in a variety of other clinical settings. In addition, high-sensitivity assays likely detect troponin release much earlier than older-generation assays. Nevertheless, in multiple studies of patients with nontraumatic chest pain, hsTn assays have improved overall diagnostic accuracy and enabled earlier detection of myocardial injury.[72,73] Moreover, hsTn assays facilitate the adoption of criteria for rapidly changing concentration of troponin over periods as short as 1 to 3 hours that aid in discriminating acute myocardial injury from chronically elevated values caused by underlying structural heart disease (e.g., left ventricular hypertrophy). Use of such “delta” criteria can improve the clinical specificity of diagnostic testing with cardiac troponin as well as permit rapid exclusion of MI in patients without changing values of hsTn.[73]

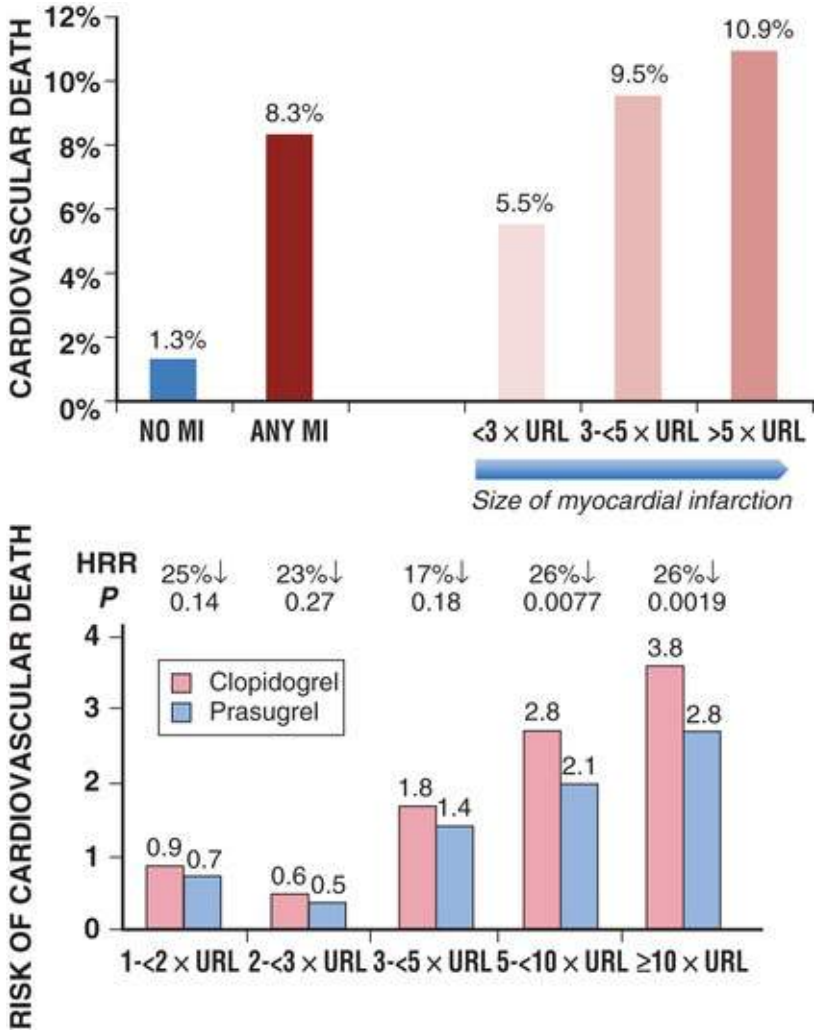
Creatine Kinase MB Isoenzyme

If a cardiac-specific troponin assay is not available, CK-MB measured with a mass assay is the best alternative. Cardiac muscle contains both the MM and the MB isoenzyme of CK. Other tissues can contain small quantities of CK-MB, including the small intestine, tongue, diaphragm, uterus, and prostate. Strenuous exercise, particularly in trained long-distance runners or professional athletes, can elevate both total CK and CK-MB. Because CK-MB can be detected in the blood of healthy persons, the cutoff value for abnormal elevation of CK-MB is usually set a few units above the upper reference limit (URL) for a given laboratory (**see Fig. 58.17**). As with cardiac-specific troponin, the diagnosis of MI requires a maximal concentration of CK-MB exceeding the 99th percentile of values for sex-specific reference levels on two successive samples in a rise-and-fall pattern.[1] CK-MB may rise in circumstances involving severe skeletal muscle injury.

Recommendations for Measurement of Circulating Markers

All patients with suspected MI should undergo measurement of cardiac-specific troponin as soon as possible at the initial encounter. In patients with STEMI, the results of biomarker assessment should not delay interventions to achieve immediate reperfusion. From a cost-effectiveness perspective, measuring both a cardiac-specific troponin and CK-MB is unnecessary.[1] Use of conventional troponin assays permit the routine diagnosis of MI by obtaining measurements at initial evaluation and then 3 to 6 hours later (**see Table 58.1**). The use of high-sensitivity assays can reduce the interval between testing to 1 to 2 hours in patients without diagnostic ECG changes.[73,74] Emerging data suggest that an initial hsTn value below the limit of detection may provide a sufficiently high sensitivity and negative predictive value to enable discharge. Later testing is required only when uncertainty exists regarding the onset of pain or when stuttering symptoms occur. Testing beyond 2 hours from hospital arrival should also be considered for patients who arrive very early (<2 hours) after symptom onset.

The universal definition of MI recommends classifying infarctions into five types (**see Table 58.2**), along with the magnitude of the infarction expressed as the fold elevation in cardiac biomarkers above the 99th percentile URL. For example, a clinical trial that compared prasugrel with clopidogrel as supportive antiplatelet therapy for moderate- to high-risk ACS patients undergoing PCI found benefit across infarct size as determined by biomarker elevation[2] (**eFig. 58.4**).



EFIGURE 58.4 **Top panel,** Risk for cardiovascular death associated with new or recurrent type I myocardial infarction (MI) stratified according to MI size. **Bottom panel,** Event rates with prasugrel versus clopidogrel with respect to the total number of new or recurrent MIs; the incidence of MI (%) is classified by using the biomarker categories recommended by the universal definition of MI (see Table 58.2). The biomarker categories are groupings of fold elevations above the upper reference limit (URL) of normal. The data shown for each *bar* are derived from Kaplan-Meier estimates for the incidence of MI; the percent reductions represent the relative reductions in the hazard ratio (HRR) for the development of an MI in the prasugrel versus clopidogrel groups. (From Morrow DA et al. Effect of the novel thienopyridine prasugrel compared with clopidogrel on spontaneous and procedural myocardial infarction in the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel–Thrombolysis in Myocardial Infarction 38. An application of the classification system from the universal definition of myocardial infarction. Circulation 2009;119:2758; and Bonaca MP et al. American College of Cardiology/American Heart Association/European Society of Cardiology/World Heart Federation universal definition of myocardial infarction classification system and the risk of cardiovascular death: observations from the TRITON-TIMI 38 trial [Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel-Thrombolysis in Myocardial Infarction 38]. Circulation 2012;125:577.)

Other Biomarkers

Other biomarkers may be used noninvasively to assess the potential causes and complications of MI. C-reactive protein (CRP) rises substantially in the setting of STEMI as a result of the inflammatory response to myocyte necrosis and is associated with the subsequent risk for death or HF. Natriuretic peptides reflect the hemodynamic impact of the MI and are associated with prognosis. Although both natriuretic peptides and CRP enhance risk assessment, no clear guidance is available on how to direct specific therapeutic maneuvers in the setting of STEMI based on these biomarkers.[75] Future studies evaluating novel biomarkers should focus on unmet clinical scenarios such as earlier detection of MI, differentiation of type I from type 2 MI, distinguishing the mechanism of thrombosis (e.g., plaque rupture versus erosion;

see Table 60.1), and improved risk stratification.

Other Laboratory Measurements

Serum Lipids

During the first 24 to 48 hours after admission, total cholesterol and high-density lipoprotein (HDL) cholesterol remain at or near baseline values, but they generally fall after that. The fall in HDL cholesterol after STEMI is greater than the fall in total cholesterol; thus the ratio of total cholesterol to HDL cholesterol is no longer useful for risk assessment unless measured early after MI. All patients with STEMI admitted within 24 hours of symptom onset should have a lipid profile,[76] although regardless of lipid levels and unless contraindicated, all patients with STEMI should receive high-intensity statin therapy. Lipid levels may still be clinically useful for patients admitted beyond 24 to 48 hours, but further measurements 4 to 8 weeks after MI provide more informative determination of serum lipid concentrations. Increased triglycerides may offer additional risk stratification beyond LDL and HDL cholesterol levels[77] (**see Chapter 48**).

Hematologic Findings

Elevation of the white blood cell count usually develops within 2 hours after the onset of chest pain, reaches a peak 2 to 4 days after infarction, and returns to normal in 1 week; the peak leukocyte count generally ranges between 12 and 15 × 10^3/mL but occasionally rises to as high as 20 × 10^3/mL in patients with large STEMI. Frequently, there is an increase in the percentage of polymorphonuclear leukocytes and a left shift of the differential count. In epidemiologic studies, higher white blood cell counts at initial evaluation in patients with an ACS are associated with an increased risk for adverse clinical outcomes.[78]

The erythrocyte sedimentation rate (ESR) is usually normal the first couple days after infarction. It then rises to a peak on the fourth or fifth day and may remain elevated for several weeks. The increase in the ESR does not correlate well with the size of the infarction or with prognosis. The hematocrit often increases during the first few days after infarction as a consequence of hemoconcentration. The hemoglobin value at initial evaluation of a patient with STEMI is strongly associated with the risk of recurrent major cardiovascular events following a J-shaped relationship. Cardiovascular mortality increases progressively as the initial hemoglobin value falls below 14 to 15 g/dL; conversely, it also rises as the hemoglobin level increases above 17 g/dL. The increased risk from anemia is probably related to diminished tissue delivery of oxygen, whereas the increased risk with polycythemia may be relates to an increase in blood viscosity.[79]

Electrocardiography

The ECG remains the most important diagnostic test in the evaluation of patients with suspected ischemic symptoms (**see Chapter 12**). Established criteria aid the diagnosis of STEMI in LBBB (**Table 58.4**), evidence of RBBB in setting of acute MI also portends a similar poor prognosis,[80] and should prompt consideration of urgent catheterization in setting of persistent ischemic settings and RBBB.[14] Patients with chest pain and ECG changes consistent with STEMI must be considered for immediate reperfusion.

TABLE 58.4

Electrocardiographic Manifestations of Myocardial Infarction

ELECTROCARDIOGRAPHIC MANIFESTATIONS OF ACUTE MYOCARDIAL ISCHEMIA (IN THE ABSENCE OF LEFT BUNDLE BRANCH BLOCK)	
ST Elevation	

New ST elevation at the J point in two contiguous leads with the following cut points:
• ≥0.1 mV in all leads (except V_2-V_3)
• In leads V_2-V_3 the following cut points apply:
  • ≥0.2 mV in men ≥40 years
  • ≥0.25 mV in men <40 years
  • ≥0.15 mV in women	

ST Depression and T Wave Changes	
• New horizontal or downsloping ST depression ≥0.05 mV in two contiguous leads • T-wave inversion ≥0.1 mV in two contiguous leads with a prominent R wave or R/S ratio >1	
ELECTROCARDIOGRAPHIC MANIFESTATIONS OF ISCHEMIA IN THE SETTING OF LEFT BUNDLE BRANCH BLOCK	
Electrocardiographic Criterion	**Points**
ST-segment elevation ≥1 mm and concordant with the QRS complex	5
ST-segment depression ≥1 mm in lead V_1, V_2, or V_3	3
ST-segment elevation ≥5 mm and discordant with the QRS complex	2
A score of ≥3 had a specificity of 98% for acute MI	
ELECTROCARDIOGRAPHIC CHANGES ASSOCIATED WITH PREVIOUS MYOCARDIAL INFARCTION (IN THE ABSENCE OF LEFT VENTRICULAR HYPERTROPHY AND LEFT BUNDLE BLOCK)	
Any Q wave in leads V_2-V_3 ≥0.02 sec or a QS complex in leads V_2 and V_3	
Q wave ≥0.03 sec and ≥0.1-mV deep or QS complex in leads I, II, aVL, aVF, or V_4-V_6 in any 2 leads of a contiguous lead grouping (I, aVL; V_1-V_6; II, III, aVF)	
R wave ≥0.04 sec in V_1-V_2 and R/S ≥1 with a concordant positive T wave in absence of a conductions defect	

Based on criteria from O'Gara PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2013;61:e78.

Analysis of the constellation of ECG leads showing ST elevation may also be useful for identifying the site of occlusion in the infarct artery[81] (**see Fig. 58.4**). The extent of ST deviation on the ECG, location of the infarction, and the QRS duration correlate with the risk for adverse outcomes. In addition to the diagnostic and prognostic information contained within the 12-lead ECG, the degree of ST-segment resolution provides valuable noninvasive information about the success of reperfusion for STEMI, regardless of whether it was achieved with fibrinolysis or primary coronary intervention[82] (**see Chapter 59**).

Although general agreement exists on electrocardiographic and vector cardiographic criteria for the recognition of infarction of the anterior and inferior myocardial walls, less agreement exists on criteria for lateral and posterior infarcts. Instead of “posterior,” the descriptor “lateral” may be more appropriate given the segmental anatomy of the heart as it sits in the thorax. The most recent universal definition of MI, however, retains the category of posterior MI.[1] Patients with an abnormal R wave in V_1 (0.04 second in duration and/or R/S ratio ≥1 in the absence of preexcitation or RV hypertrophy) and inferior or lateral Q waves have an increased incidence of isolated occlusion of a dominant left circumflex coronary artery without collateral circulation; such patients have a lower EF, increased end-systolic volume, and higher complication rate than do those with inferior infarction because of isolated occlusion of the right coronary artery. ST-segment elevations in aVR, reflecting the basal intraventricular septum, can be observed in up to 30% of STEMIs and identifies patients with a higher likelihood of left main coronary artery or multivessel disease and worse outcomes.[83]

Serial changes on the ECG develop in most patients with STEMI, but many factors limit the usefulness of the ECG in diagnosing and localizing MI: the extent of myocardial injury, age of the infarct, its location, presence of conduction defects, previous infarcts or acute pericarditis, and changes in electrolyte concentrations. Abnormalities in the ST segment and T wave can be quite nonspecific and may occur in a variety of conditions, including stable and unstable angina pectoris, ventricular hypertrophy,

acute and chronic pericarditis, myocarditis, early repolarization, electrolyte imbalance, shock, and metabolic disorders, as well as after administration of digitalis. Serial ECGs help in differentiating these conditions from STEMI, although for early triage decisions, concurrent imaging may help distinguish potential STEMI from other etiologies. Many patients bear the stigmata of a STEMI on the ECG for the rest of their lives, particularly if Q waves evolve, but in a substantial minority the typical changes disappear, the Q waves regress, and findings on the ECG can even return to normal. Conditions that may mimic the electrocardiographic features of MI by producing a pattern of "pseudoinfarction" include ventricular hypertrophy, conduction disturbances, preexcitation, primary myocardial disease, pneumothorax, pulmonary embolism, amyloid heart disease, hypertrophic cardiomyopathy, primary and metastatic tumors of the heart, traumatic heart disease, intracranial hemorrhage, hyperkalemia, pericarditis, early repolarization, forms of muscular dystrophy, and cardiac sarcoidosis.

Q Wave and Non–Q Wave Infarction

The presence or absence of Q waves on the surface ECG does not reliably distinguish between transmural and nontransmural (subendocardial) MI. Q waves on the ECG signify abnormal electrical activity but are not synonymous with irreversible myocardial damage, although Q waves are associated with worse outcomes.[84] Also, the absence of Q waves may simply reflect the insensitivity of the standard 12-lead ECG, especially in zones of the left ventricle supplied by the left circumflex artery (**see Fig. 58.4**).

Ischemia at a Distance

Patients with new Q waves and ST-segment elevation diagnostic of STEMI in one territory often have ST-segment depression in other territories. These additional ST-segment abnormalities, which imply a poor prognosis, result either from ischemia in a territory other than the area of infarction, termed *ischemia at a distance*, or from reciprocal electrical phenomena. ST-segment depression in the anterior leads in the setting of acute inferior STEMI may be caused by concurrent anterior ischemia, inferolateral wall infarction, or true reciprocal changes. Although precordial ST-segment depression is associated more often with extensive infarction of the lateral or inferior septal segments than with anterior wall subendocardial ischemia, imaging techniques such as echocardiography can evaluate the presence of an anterior wall motion abnormality.

Right Ventricular Infarction

ST-segment elevation in the right precordial leads (V_1, V_3R through V_6R) is a relatively sensitive and specific sign of RV infarction.[28,29] Occasionally, ST-segment elevation in V_2 and V_3 results from acute RV infarction; this appears to occur only when injury to the left inferior wall is minimal. Usually, the concurrent inferior wall injury suppresses this anterior ST-segment elevation resulting from RV injury. Similarly, RV infarction appears to reduce the anterior ST-segment depression often observed with inferior wall MI. A QS or QR pattern in V_3R and V_4R also suggests RV myocardial necrosis but has less predictive accuracy than ST-segment elevation in these leads.

Imaging

Noninvasive imaging provides important diagnostic and prognostic information in patients with MI. Most cases of STEMI, unless the ECG is nondiagnostic or the clinical scenario is questionable, do not require imaging for diagnosis. Imaging is key for determining the extent of the infarct, the presence of mechanical

complications, and the overall function of the right and left ventricles.

Radiography

The initial chest radiograph in patients with STEMI is almost invariably a portable film obtained in the emergency department or cardiac intensive care unit (**see Chapter 15**). Chest imaging should not delay primary reperfusion strategies, unless there is a reason to evaluate a particular suspected pulmonary pathology. When present, prominent pulmonary vascular markings on the radiograph reflect elevated LV end-diastolic pressure, but significant temporal discrepancies can occur because of *diagnostic lags* and *post-therapeutic lags*. Up to 12 hours can elapse before pulmonary edema accumulates after ventricular filling pressure has increased. The post-therapeutic phase lag represents a longer interval; up to 2 days is required for pulmonary edema to resolve and the radiographic signs of pulmonary congestion to clear after ventricular filling pressure have returned toward normal. The degree of congestion and the size of the left side of the heart on the chest film are useful for defining groups of patients with STEMI who have an increased risk for fatal complications.

Echocardiography

The relative portability of echocardiographic equipment makes this technique ideal for the assessment of patients with suspected MI[85] (**see Chapter 14**). In patients with active chest pain compatible with ischemia but with a nondiagnostic ECG, the finding on echocardiography of a regional wall motion abnormality supports the diagnosis of myocardial ischemia. Echocardiography can also aid the evaluation of patients with chest pain and a nondiagnostic ECG who are suspected of having aortic dissection. Identification of an intimal flap consistent with aortic dissection is a critical observation because it would drive changes in therapeutic strategy (**see Chapter 63**), but transthoracic echocardiography (TTE) has poor sensitivity for detecting aortic dissection compared with other imaging modalities, such as computed tomography (CT) angiography.

LV function estimated from an echocardiogram correlates well with measurements from angiography and is useful in establishing the prognosis after MI. Furthermore, early use of echocardiography can aid in early detection of potentially viable but stunned myocardium (contractile reserve), residual provocable ischemia, patients at risk for HF after MI, and mechanical complications of MI such as acute mitral or tricuspid regurgitation or ventricular septal defects. Newer techniques also provide information regarding the success of myocardial tissue-level reperfusion.[86] Although TTE is adequate in most patients, some patients have poor echocardiographic windows, especially if they are undergoing mechanical ventilation. In such patients, transesophageal echocardiography (TEE) or CMR can help in evaluating infarct size and location, ventricular septal defects, and papillary muscle dysfunction.

Magnetic Resonance Imaging

Cardiac magnetic resonance imaging (CMR) has limited application during the acute phase because of long scan-times and the need to transport patients with MI to the MRI scanner, but it is a useful imaging technique during the subacute and chronic phases of MI. CMR permits exact localizing and sizing the area of infarction and a quantitative assessment of the severity of the ischemic insult (**see Chapter 17**). This modality is attractive because of its ability to assess perfusion of infarcted and noninfarcted tissue, as well as reperfused myocardium;[87] identify areas of jeopardized but not infarcted myocardium; identify myocardial edema, fibrosis, wall thinning, and hypertrophy; assess ventricular chamber size and segmental wall motion;[88,89] and identify the temporal transition between ischemia and infarction[90] (**Fig.**

58.19). Because of these capabilities, CMR may be particularly useful in the diagnostic assessment of possible MINOCA.

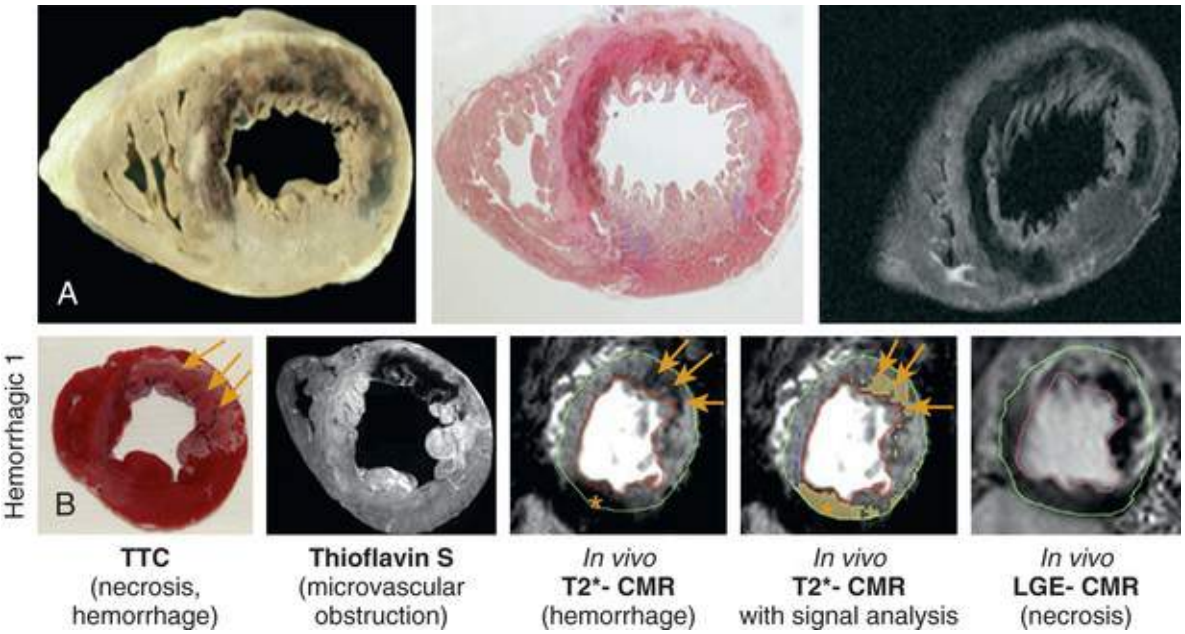


FIGURE 58.19 Cardiac magnetic resonance (CMR) images in myocardial infarction. **A,** *Left to right,* Gross anatomic image obtained at autopsy, histology image after staining with Heidenhain trichrome stain, and ex vivo T2-weighted CMR image from the short-axis slice. **B,** *Left to right,* Images from an experimentally induced MI in a dog. CMR was performed day 3 after reperfusion in which T2*-weighted gradient-echo imaging was performed. Ex vivo, thioflavin S imaging, and triphenyltetrazolium chloride (TTC) staining were performed to assess for microvascular obstruction (MVO), hemorrhage, and myocardial necrosis. LGE, Late gadolinium enhancement. (From Hamirani YS, Wong A, Kramer CM, Salerno M. Effect of microvascular obstruction and intramyocardial hemorrhage by CMR on LV remodeling and outcomes after myocardial infarction: a systematic review and meta-analysis. JACC Cardiovasc Imaging 2014;7:940-52.)

Contrast-enhanced CMR with gadolinium can define areas of myocardial necrosis accurately. The transmural extent of late gadolinium enhancement (LGE) in regions of dysfunctional myocardium accurately predicts the likelihood of recovery of contractile function after successful restoration of coronary flow by mechanical revascularization.[91] Numerous clinical studies have also demonstrated the high sensitivity of LGE ("delayed hyperenhancement") in detecting small amounts of myonecrosis. LGE accurately identifies the infarct zone compared with histologic examination. The best predictor of return to normal ventricular wall thickening is less than 25% transmurality of LGE. LGE is also a sensitive technique for detecting RV infarcts.[92]

In patients with a previous MI, estimation of the size of the peri-infarct zone by CMR with the delayed-enhancement technique provides incremental prognostic value beyond LV volume and EF. Besides detecting infarction, this imaging technique can characterize the presence and size of microvascular obstruction and intramyocardial hemorrhage as a result of infarction, which may be an even poorer prognostic finding than the extent of LGE.[87]

Nuclear Imaging

Radionuclide angiography, perfusion imaging, infarct-avid scintigraphy, and positron emission tomography (PET) can all evaluate patients with suspected ACS but have no role in the acute management of STEMI[85] (**see Chapter 16**). Nuclear cardiac imaging techniques can assess infarct size, collateral flow, and jeopardized myocardium; determine the effects of the infarct on ventricular function; and

establish the prognosis of patients with STEMI. However, echocardiography and CMR provide more relevant information regarding valvular and structural function than nuclear imaging. Stress nuclear imaging may be used to assess for ischemia in patients with residual obstructive CAD after initial reperfusion of the infarct-related artery.

Computed Tomography

CT can provide an assessment of cavity dimensions and wall thickness, can detect LV aneurysms, and—of particular importance in patients with STEMI—can identify intracardiac thrombi (**see Chapter 18**). In the acute setting, contrast-enhanced CT detects focal areas of MI as decreased areas of enhancement. Older infarcts show hyperenhancement.[93] Although cardiac CT is a less convenient technique, it is probably more sensitive than echocardiography for thrombus detection. Coronary CT angiography is sensitive in detecting coronary obstructions, particularly in the proximal third of the coronary anatomy, and may improve the diagnostic evaluation of patients with a low to intermediate probability of ACS, but it does not have a role in the management of suspected STEMI.[85]

Estimation of Infarct Size

Interest in limiting infarct size, largely because of the recognition that the quantity of infarcted myocardium has important prognostic implications, has focused attention on accurate determination of MI size. As reviewed earlier, the relationship between infarct size and subsequent changes in LV volumes and function is not directly linear. Other factors such as residual ischemia, inflammation, and therapy can affect eventual ventricular function and prognosis.[49] However, the degree of infarcted myocardium remains a strong predictor of subsequent outcomes.[94]

Electrocardiography.

The sum of ST-segment elevations measured from multiple precordial leads correlates with the extent of myocardial injury in patients with anterior MI. Moreover, a relationship exists between the number of ECG leads showing ST-segment elevation and the mortality rate: patients with 8 or 9 of 12 leads showing ST-segment elevation have three to four times the mortality of those with ST elevations in only 2 or 3.

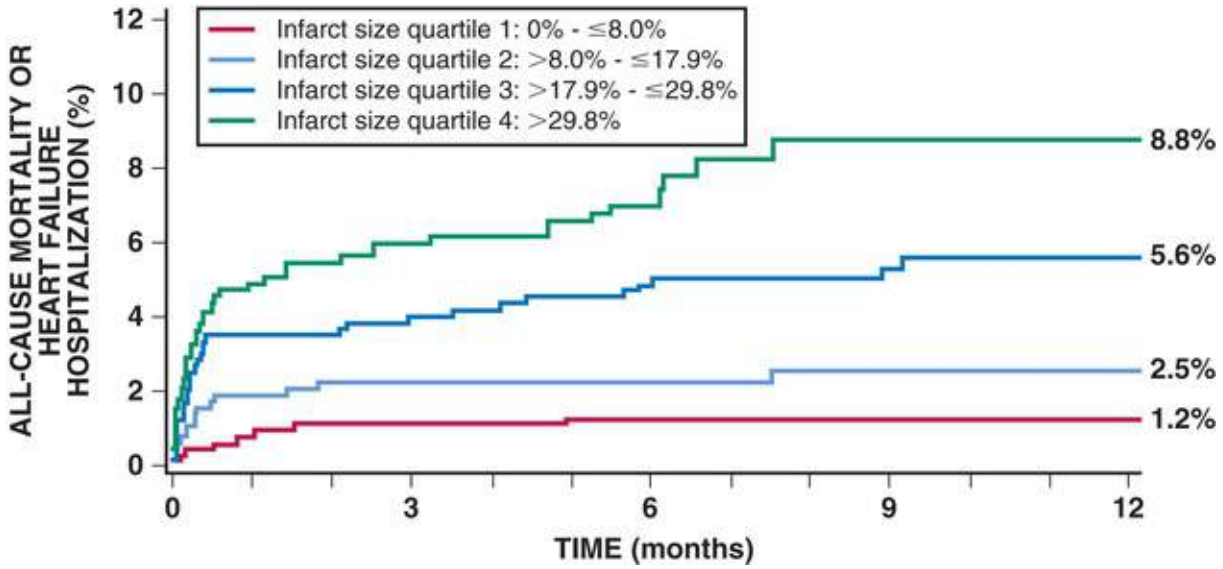
Cardiac Markers.

Estimation of infarct size by analysis of serum or plasma cardiac markers of necrosis requires accounting for the quantity of the marker lost from the myocardium, its volume of distribution, and its release ratio. Serial measurements of proteins released by necrotic myocardium can help to determine MI size. Clinically, the peak CK, CK-MB, or troponin level provides an approximate estimate of infarct size. Coronary artery reperfusion dramatically changes the washout kinetics of necrosis markers from myocardium, thereby resulting in early and exaggerated peak levels (**see Fig. 58.18**). Measuring a cardiac-specific troponin level several days after STEMI, even in cases of successful reperfusion, may provide a reliable estimate of infarct size because such late troponin measurements reflect delayed release from the myofilament-bound pool in damaged myocytes.

Noninvasive Imaging Techniques.

The imaging modalities previously discussed can aid in experimental and clinical assessment of infarct size.[85] Echocardiography remains the most frequently used modality for assessing infarct size and LV function, although contrast-enhanced CMR can detect smaller degrees of ischemia and identify

permanently damaged areas of the myocardium versus “stunned” regions, which may recover. Nuclear imaging and CMR can quantify the extent of infarct size more reliably than echocardiography. Even among patients undergoing primary PCI, the size of infarct is associated strongly with worse outcomes, in particular during the first 6 months[89] (**eFig. 58.5**). CMR can also discern the regional heterogeneity of infarction patterns in patients with persistently occluded infarct arteries or severe microvascular occlusion versus those with a successfully reperfused macrocirculation and microcirculation.



EFIGURE 58.5 Infarct size and outcomes after percutaneous coronary intervention (PCI). All-cause mortality and heart failure according to quartiles of infarct size (IS) assessed by CMR. (From Stone GW, Selker HP, Thiele H, et al. Relationship between infarct size and outcomes following primary pci: patient-level analysis from 10 randomized trials. J Am Coll Cardiol 2016;67:1674-83.)

Future Perspectives

The remarkable advances in understanding the cellular and molecular mechanisms of myocardial ischemic injury, coupled with recent insights into the mechanisms during repair and healing of the infarcted myocardium, have identified potential targets for “tuning” the healing response to optimize the repair process in ischemically injured myocardium and minimize adverse left ventricular remodeling. We still triage patients who present with ACS on the basis of the ECG, but we should strive toward a more mechanistically based categorization of ACS that reflects the underlying biologic basis of the acute ischemic insult. To fill this gap, we need to seek, refine, and validate biomarkers of the different pathologic pathways that provoke acute myocardial ischemia and then apply at point of care, more mechanistically based therapies. Such biomarker-guided personalized therapy would thus achieve more precision in the care of ACS patients. For example, markers that distinguish fibrous cap rupture from superficial erosion as triggers to thrombus formation might inform different management strategies. This hypothesis would require rigorous validation but could lead to a more personalized management strategy.

We understand more clearly the different pathways in formation of coronary thrombi, but not all acute ischemic events result from clot formation. Past research centered on epicardial coronary artery spasm as a contributor to acute ischemic event, but we now recognize that dysfunction of smaller intramyocardial arteries may also provoke ischemia without necessarily causing evident thrombosis.[95] The spectrum of ischemic processes ranging from MINOCA and in the extreme stress (takotsubo) cardiomyopathy highlight

the need for greater investigation into the microvasculature, to understand better the underlying mechanism of these diseases and identify novel therapeutic strategies. Thus, although we have made considerable inroads in understanding and treating ACS in the last decades, the residual risk remains unacceptable. We must strive to expand our mechanistic understanding of the pathophysiology of ACS to address this residual burden and achieve the promise of precision medicine.

ST-Elevation Myocardial Infarction

Management

Erin A. Bohula, David A. Morrow

The care of patients with ST-elevation myocardial infarction (STEMI) has transformed in conjunction with major shifts in the approach to reperfusion therapy from primarily pharmacologic to catheter-based strategies.[1-4] With simultaneous advances in medical therapy, the case-fatality rate for patients with STEMI has continued to decline[4,5] (**Fig. 59.1**). Nevertheless, optimal management of patients at high risk for or with established major complications of STEMI remains critical to the care of this condition. A discussion of the management of STEMI can follow the clinical course of the patient. **Chapter 45** addresses primary and secondary prevention of coronary artery disease (CAD). **Chapter 56** reviews the emergency evaluation of patients with chest pain. This chapter deals with treatment at the time of onset of STEMI (prehospital issues, initial recognition and management in the emergency department, and reperfusion), hospital management (medications, complications, and preparation for discharge), and early secondary prevention after STEMI. **Chapter 62** discusses percutaneous coronary intervention (PCI) in patients with STEMI. **Chapter 41** describes the use of internal and external automated defibrillators for prevention of sudden cardiac death after myocardial infarction (MI). **Chapter 61** discusses the long-term management of the patient with established chronic stable ischemic heart disease, including patients with prior acute MI.

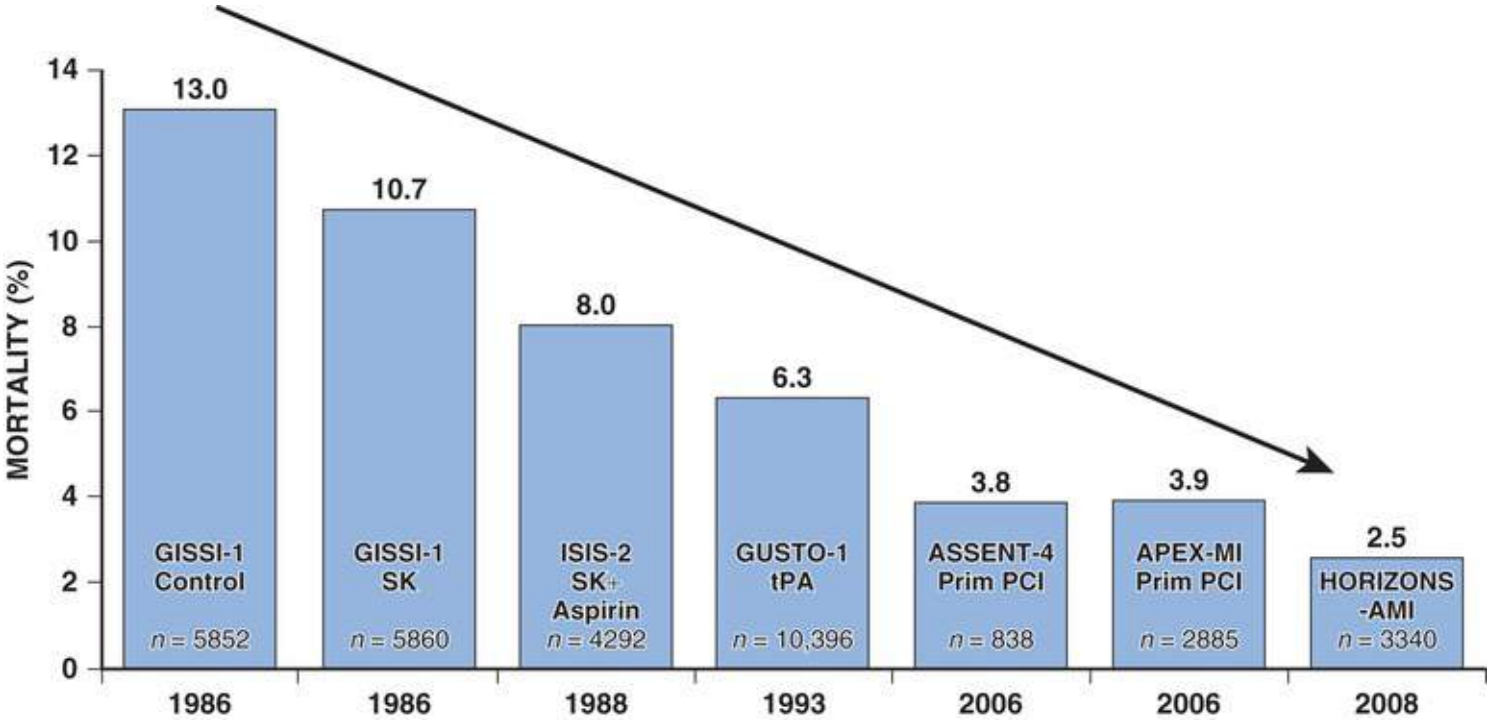

FIGURE 59.1 Early mortality rates have declined in major randomized trials of STEMI patients from 1986 to 2008 with the introduction and improvement in pharmacologic and/or mechanical reperfusion therapy. Prim PCI, Primary percutaneous coronary intervention; SK, streptokinase; tPA, tissue plasminogen activator. (From Van de Werf F. The history of coronary reperfusion. Eur Heart J 2014;35;2510-2515.)

Prehospital Management

Given the progressive loss of functioning myocytes with persistent occlusion of the infarct-related artery in STEMI (**see Chapter 58**), initial management aims to restore blood flow to the infarct zone as rapidly as possible. Primary PCI is generally the preferred option, provided that an experienced operator and team can perform it in timely fashion.[1,4,6] Missed opportunities for improvement in the care of STEMI include failure to deliver any form of reperfusion therapy in approximately 15% of patients and failure to minimize delays in reperfusion because of inefficient systems of care.[5,7,8] The "chain of survival" for STEMI involves a highly integrated strategy beginning with patient education about the symptoms of MI and early contact with the medical system, coordination of destination protocols in emergency medical service (EMS) systems, efficient practices in emergency departments to shorten door-to-reperfusion time, and expeditious implementation of the reperfusion strategy by a trained team.[9,10] The American Heart Association (AHA) launched a national initiative to engineer improved health care delivery for STEMI, including implementation of systems that shorten total ischemic time while emphasizing overall quality of care for STEMI[10] (**Tables 59.1 and 59.2**).

TABLE 59.1

Criteria for a System of Care for ST-Elevation Myocardial Infarction (STEMI)

1. The system should be registered with Mission: Lifeline.
2. Ongoing multidisciplinary team meetings should occur, including EMS, non-PCI hospitals/STEMI referral centers, and PCI hospitals/STEMI receiving centers, to evaluate outcomes and quality improvement data. Operational issues should be reviewed, problems identified, and solutions implemented.
3. Each STEMI system should include a process for prehospital identification and activation, destination protocols to STEMI receiving centers, and transfer for patients who arrive at STEMI referral centers and are primary PCI candidates, are ineligible for fibrinolytic therapy, and/or are in cardiogenic shock.
4. Each system should have a recognized system coordinator, physician champion, and EMS medical director.
5. Each system component (EMS, STEMI referral centers, and STEMI receiving centers) should meet the appropriate criteria.

EMS, Emergency medical services; *PCI,* percutaneous coronary intervention.

TABLE 59.2

Interventions to Improve Door-to-Device Times

1. A prehospital ECG for diagnosing STEMI is used to activate the PCI team while the patient is en route to the hospital.
2. Emergency physicians activate the PCI team.
3. A single call to a central page operator activates the PCI team.
4. A goal is set for the PCI team to arrive at the catheterization laboratory within 20 minutes after being paged.
5. Timely data feedback and analysis are provided to members of the STEMI care team.

From O'Gara PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2013;61:e78.

Prehospital Care

The prehospital care of patients suspected of having STEMI bears directly on the likelihood of survival. Most deaths associated with STEMI occur within the first hour of its onset and usually result from ventricular fibrillation (VF) (**see Chapter 42**). Therefore, immediate implementation of resuscitative efforts and rapid transportation of the patient to a hospital have prime importance. Major components of the time from the onset of ischemic symptoms to reperfusion include (1) the time for the patient to recognize the problem and seek medical attention; (2) prehospital evaluation, treatment, and transportation; (3) the time for diagnostic measures and initiation of treatment in the hospital (e.g., “door-to-needle” time for patients receiving a fibrinolytic agent and “door-to-device” time for patients undergoing a catheter-based reperfusion strategy); and (4) the time from initiation of treatment to restoration of flow.

Patient-related factors that correlate with a longer delay until deciding to seek medical attention include older age; female sex; black race; low socioeconomic or uninsured status; history of angina, diabetes, or both; consulting a spouse or other relative; and consulting a physician.[1,11] Health care professionals should heighten the level of awareness of patients at risk for STEMI (e.g., those with hypertension, diabetes, history of angina pectoris). They should use each patient encounter as a “teachable moment” to review and reinforce with patients and their families the need to seek urgent medical attention for a pattern of symptoms that includes chest discomfort, extreme fatigue, and dyspnea. Patients should also be instructed in the proper use of sublingual nitroglycerin and to call emergency services if the ischemic-type discomfort persists for more than 5 minutes.[1]

Emergency Medical Service Systems

EMS systems have three major components: emergency medical dispatch, first response, and the EMS ambulance response (**see Chapter 56**). The expanded capability to record a prehospital 12-lead

electrocardiogram (ECG) represents a major advance in EMS systems (**Table 59.2**).[12] The ability to transmit such ECGs and to activate the STEMI care team before arrival at the hospital places EMS efforts at the center of the early response to STEMI.[13] Ongoing efforts to shorten the time until treatment of patients with STEMI include improvement in the medical dispatch component by expanding 911 coverage, providing automated external defibrillators to first responders, placing automated external defibrillators in critical public locations, and greater coordination of the EMS ambulance response. Well-equipped ambulances and helicopters staffed by personnel trained in the acute care of patients with STEMI allow definitive therapy to begin during transport to the hospital. Radiotelemetry systems that allow transmission of the electrocardiographic signal to a medical control officer facilitate the triage of patients with STEMI (**Fig. 59.2**).

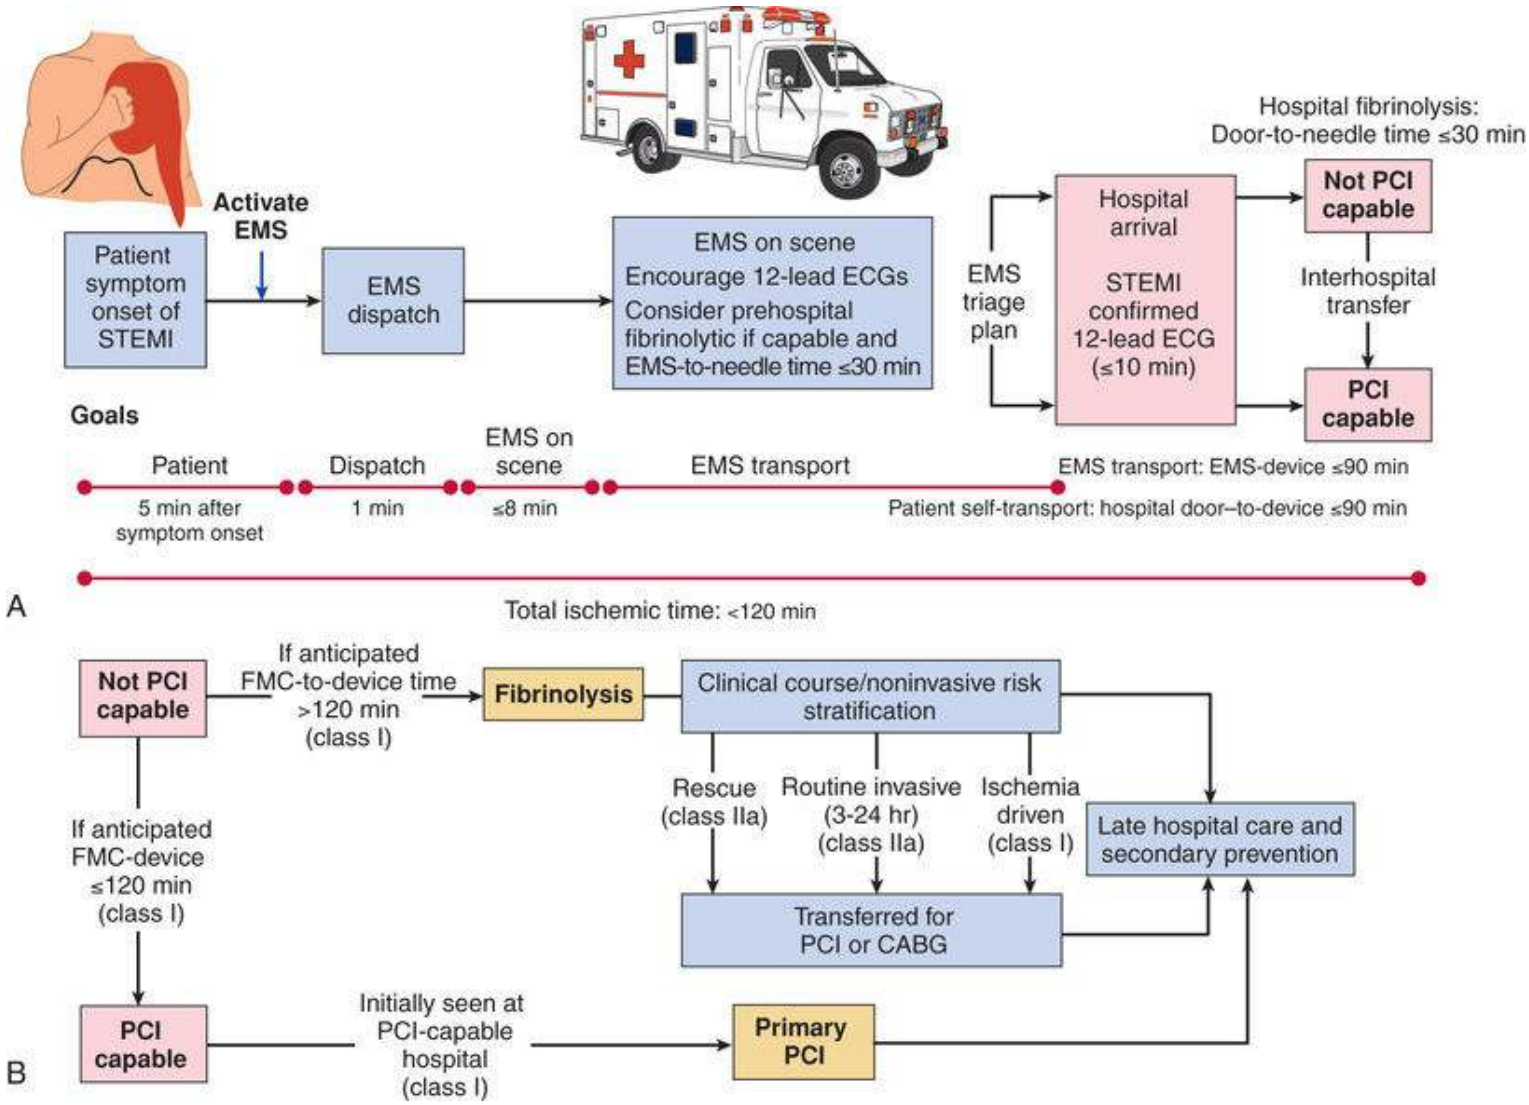

FIGURE 59.2 System goals and initial reperfusion treatment of patients with STEMI. Reperfusion in STEMI patients can be accomplished by pharmacologic (fibrinolysis) or catheter-based (primary PCI) approaches and may involve transfer from a non–PCI-capable to a primary PCI-capable center. **A,** Patient transported by the emergency medical services (EMS). The STEMI systems goal is to maintain a network of transportation and destination hospitals so that the total ischemic time is kept to less than 120 minutes. In addition to this overall goal, three additional time objectives exist. (1) If the EMS has fibrinolytic capability and the patient qualifies for therapy, prehospital fibrinolysis may be considered and, if used, should be started within 30 minutes of arrival of the EMS on scene. (2) For patients transported to a non–PCI-capable hospital where a fibrinolytic is to be administered, the hospital door–to-needle time should be 30 minutes or less. (3) If the patient is transported to a PCI-capable hospital, the time from first medical contact (FMC) to deployment of the first PCI device (FMC-to-device time) should be 90 minutes or less. Patient self-transportation is discouraged. If the patient arrives at a non–PCI-capable hospital and a

fibrinolytic is to be administered, the door-to-needle time should be 30 minutes or less. If the patient arrives at a PCI-capable hospital, the door-to-balloon time should be 90 minutes or less. The treatment options and time recommendations after arrival at the hospital are the same. Consideration of emergency interhospital transfer of the patient to a PCI-capable hospital for mechanical revascularization is also appropriate if use of a fibrinolytic is contraindicated or PCI can be initiated promptly (anticipated FMC-to-device time ≤120 minutes) or if fibrinolysis is unsuccessful (i.e., "rescue PCI"). Secondary nonemergency interhospital transfer can be considered for recurrent ischemia or routine invasive evaluation 3 to 24 hours after fibrinolysis. **B,** Reperfusion strategies for patients with STEMI, regardless of whether they go to a PCI-capable or to a non–PCI-capable hospital. The optimal strategy depends on the timing of the onset of symptoms, the patient's eligibility for fibrinolysis, and the options for timely transfer to a PCI-capable hospital. The denoted class I and class II recommendations are from the ACCF/AHA guidelines for the management of STEMI. For patients who receive fibrinolysis, noninvasive risk stratification is recommended to guide decisions regarding delayed coronary revascularization. CABG, Coronary artery bypass grafting. (Modified from Armstrong PW, Collen D, Antman E. Fibrinolysis for acute myocardial infarction: the future is here and now. Circulation 2003;107:2533; and O'Gara PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2013;61:e78.)

In addition to prompt defibrillation, the efficacy of prehospital care appears to depend on several factors, including early relief of pain with its deleterious physiologic sequelae, reduction of excessive activity of the autonomic nervous system, and treatment of arrhythmias such as ventricular tachycardia (VT)—but these efforts must not delay rapid transfer to the hospital (**Fig. 59.2**).

Prehospital Fibrinolysis

Multiple observational studies and several randomized trials have evaluated the potential benefits of prehospital versus in-hospital fibrinolysis.[1,4] Although none of the individual trials showed a significant reduction in mortality with prehospital-initiated fibrinolytic therapy, earlier treatment generally provides greater benefit, and a meta-analysis of all the available trials demonstrated a 17% reduction in mortality.[1] The CAPTIM (Comparison of Primary Angioplasty and Pre-hospital Fibrinolysis in Acute Myocardial Infarction) trial, for example, reported a trend toward a lower mortality rate in patients with STEMI who received prehospital fibrinolysis compared with patients who received primary PCI, especially if they were treated within 2 hours of the onset of symptoms.[1] In the STREAM (Strategic Reperfusion Early After Myocardial Infarction) trial, prehospital fibrinolysis offered similar efficacy to primary PCI in 1892 patients with STEMI who presented within 3 hours of symptom onset and who could not undergo primary PCI within 1 hour of first medical contact. The primary endpoint of death, shock, heart failure, or reinfarction at 30 days occurred in 12.4% of the fibrinolysis arm and 14.3% in the primary PCI arm (**Fig. 59.3**).[14] Rescue or urgent PCI was required in 36% of patients initially receiving fibrinolysis, with the remainder undergoing coronary angiography per protocol a median of 17 hours after randomization. The rate of intracranial hemorrhage was higher in the fibrinolysis group, but nonintracranial bleeding rates were similar between the treatment groups. Based on these data, prehospital fibrinolysis is reasonable in settings in which substantial time can be saved by prehospital treatment because of long transportation times (60 to 90 minutes or longer), and physicians are present in the ambulance, or there is a well-organized EMS system with full-time paramedics who can obtain and transmit 12-lead ECG recordings from the field to an online medical command able to authorize prehospital fibrinolysis[4] (**see Fig. 59.2**).

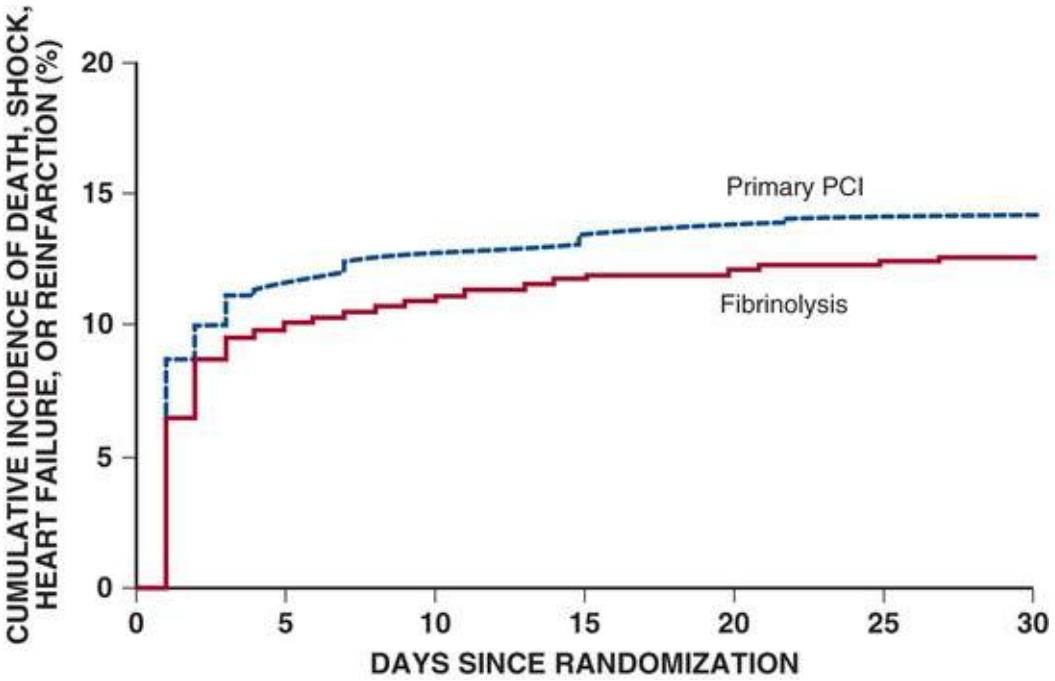

FIGURE 59.3 The STREAM (Strategic Reperfusion Early After Myocardial Infarction) study found that prehospital fibrinolysis offers similar efficacy to primary PCI in 1892 patients with STEMI who presented within 3 hours of symptom onset and who could not undergo primary PCI within 1 hour of FMC, where the primary endpoint of death, shock, heart failure, or reinfarction at 30 days occurred in 12.4% of the fibrinolysis arm and 14.3% in the primary PCI arm (hazard ratio, 0.68; confidence interval, 0.68 to 1.09; *P* = 0.21 by log-rank test). (Modified from Armstrong PW, Gershlick AH, Goldstein P, et al. Fibrinolysis or primary PCI in ST-segment elevation myocardial infarction. N Engl J Med 2013;368(15):1379-87.)

Management in the Emergency Department

When evaluating patients with chest pain in the emergency department (ED), physicians must confront the difficult tasks of rapidly identifying patients who require urgent reperfusion therapy, triaging lower-risk patients to the appropriate setting within the hospital, and not discharging patients inappropriately while avoiding unnecessary admissions. A history of ischemic-type discomfort and the initial 12-lead ECG are the primary tools for screening patients with possible acute coronary syndrome (ACS) for STEMI (**see Chapter 56**). Because the 12-lead ECG is at the center of the decision pathway for initiation of reperfusion therapy, it should be obtained promptly (≤10 minutes after hospital arrival) in patients with suspected ischemic symptoms.[1] More extensive use of prehospital 12-lead ECGs has also facilitated early triage of patients with STEMI.[12] Because lethal arrhythmias can occur suddenly in patients with STEMI, all patients should have bedside monitoring of the ECG and intravenous (IV) access.

The presence of ST-segment elevation on the ECG in a patient with ischemic discomfort highly suggests thrombotic occlusion of an epicardial coronary artery and should trigger a well-rehearsed sequence of rapid assessment of the patient for initiation of a reperfusion strategy.[1] Critical factors that weigh into selection of a reperfusion strategy include the time elapsed since the onset of symptoms, the risk associated with STEMI, the risk related to administering a fibrinolytic, and the time required to initiate an invasive strategy (**see Fig. 59.2**). In non–PCI-capable hospitals, the initial assessment should include evaluation of the contraindications to administration of a fibrinolytic (**Table 59.3**). Patients with an initial ECG that reveals ST-segment depression and/or T wave inversion without ST-segment elevation are not considered candidates for immediate reperfusion therapy unless a posterior injury current is suspected (**see Chapter 12**).

TABLE 59.3

Contraindications to and Cautions in the Use of Fibrinolytics for Treating ST-Elevation Myocardial Infarction*

Absolute Contraindications
Any previous intracranial hemorrhage
Known structural cerebral vascular lesion (e.g., arteriovenous malformation)
Known malignant intracranial neoplasm (primary or metastatic)
Ischemic stroke within 3 months *except* acute ischemic stroke within 4.5 hours
Suspected aortic dissection
Active bleeding or bleeding diathesis (excluding menses)
Significant closed-head or facial trauma within 3 months
Intracranial or intraspinal surgery within 2 months
Severe uncontrolled hypertension (unresponsive to emergency therapy)
For streptokinase, previous treatment within the previous 6 months
Relative Contraindications
History of chronic, severe, poorly controlled hypertension
Significant hypertension at initial evaluation (SBP >180 mm Hg or DBP >110 mm Hg)†
History of previous ischemic stroke >3 months
Dementia
Known intracranial pathology not covered in Absolute Contraindications
Traumatic or prolonged (>10 minutes) cardiopulmonary resuscitation
Major surgery (<3 weeks)
Recent (within 2 to 4 weeks) internal bleeding
Noncompressible vascular punctures
Pregnancy
Active peptic ulcer
Oral anticoagulant therapy

*Viewed as advisory for clinical decision making and may not be all-inclusive or definitive.

†Could be an absolute contraindication in low-risk patients with MI.

DBP, Diastolic blood pressure; *SBP,* systolic blood pressure.

From O' Gara PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2013;61:e78.

Given the importance of time to reperfusion,[4] emphasis has shifted to overall medical system goals, starting at the point of first medical contact with the patient.[1,15] Benchmarks for medical systems to use when assessing the quality of their performance are a door-to-needle time of 30 minutes or less for initiation of fibrinolytic therapy and a door-to-device time of 90 minutes or less for percutaneous coronary perfusion[1,2] (**Fig. 59.2**). In patients with a clinical history suggestive of STEMI (**see Chapter 56**) and an initial nondiagnostic ECG (i.e., no ST-segment deviation or T wave inversion), serial tracings should be obtained during evaluation in the ED. ED staff can seek the sudden development of ST-segment elevation by periodic visual inspection of the bedside electrocardiographic monitor, by continuous ST-segment recording, or by auditory alarms when the ST-segment deviation exceeds programmed limits. Decision aids such as computer-based diagnostic algorithms, identification of high-risk clinical indicators, rapid determination of cardiac biomarkers, echocardiographic evaluation for regional wall motion abnormalities, and myocardial perfusion imaging have greatest clinical usefulness when the findings on the ECG are not diagnostic.

General Treatment Measures

See also **Chapter 60** and **Table 60.5**.

Aspirin

Aspirin is effective across the entire ACS spectrum and is part of the initial management strategy for patients with suspected STEMI. Because low doses take several days to achieve a full antiplatelet effect,

162 to 325 mg should be administered at the first opportunity after initial medical contact.[1] To achieve therapeutic blood levels rapidly, the patient should chew a non–enteric-coated tablet to promote buccal absorption bypassing the gastric mucosa.

Control of Cardiac Pain

Initial management of patients with STEMI should target relief of pain and its associated heightened sympathetic activity. Control of cardiac pain is typically achieved with a combination of analgesics (e.g., morphine) and interventions to favorably improve the balance of myocardial oxygen supply and demand, including oxygen (in the setting of hypoxia), nitrates, and in appropriately selected patients, beta-adrenergic receptor–blocking agents (beta blockers).[1]

Analgesics

Although a wide variety of analgesic agents, including meperidine, pentazocine, and morphine, can treat the pain associated with STEMI, morphine remains the drug of choice, except in patients with well-documented morphine hypersensitivity. Doses of 4 to 8 mg administered intravenously initially, followed by doses of 2 to 8 mg repeated at intervals of 5 to 15 minutes have been recommended until the pain is relieved or side effects emerge—hypotension, depression of respiration, or vomiting.[1] Appropriate dosing of morphine sulfate will vary, however, depending on the patient's age, body size, blood pressure (BP), and heart rate (HR).

Reduction of anxiety with successful analgesia diminishes the patient's restlessness and the activity of the autonomic nervous system, with a consequent reduction in the heart's metabolic demands, and possible favorable effects on myocardial healing (**see Chapter 58**). Morphine has beneficial effects in patients with pulmonary edema as a result of peripheral arterial and venous dilation (particularly in those with excessive sympathoadrenal activity); it reduces the work of breathing and slows the HR secondary to combined withdrawal of sympathetic tone and augmentation of vagal tone. Counterbalancing these potential benefits, observational studies have suggested an association between the administration of morphine and adverse outcomes in patients with ACS, with the putative mechanism being a slowing of antiplatelet agent absorption.[16,17]

Maintaining the patient in a supine position and elevating the lower extremities if BP falls can minimize hypotension following the administration of nitroglycerin and morphine. Such positioning is undesirable in patients with pulmonary edema, but morphine rarely produces hypotension in these circumstances. IV administration of atropine may be helpful in treating excessive vagomimetic effects of morphine.

Nitrates

By virtue of their ability to enhance coronary blood flow by coronary vasodilation and to decrease ventricular preload by increasing venous capacitance, sublingual (SL) nitrates are indicated for most patients with an ACS. At present, the only groups of patients with STEMI in whom SL nitroglycerin should *not* be given are those with suspected right ventricular (RV) infarction[18] or marked hypotension (e.g., systolic BP <90 mm Hg), especially if accompanied by bradycardia.

Once hypotension is excluded, an SL nitroglycerin tablet should be administered and the patient observed for improvement in symptoms or change in hemodynamics. If an initial dose is well tolerated and appears to be beneficial, further nitrates should be administered while monitoring vital signs. Even small doses can produce sudden hypotension and bradycardia, a reaction that can usually be reversed with IV atropine. Long-acting oral nitrate preparations should be avoided in the early course of STEMI

because of the frequently changing hemodynamic status of the patient. In patients with a prolonged period of waxing and waning chest pain, IV nitroglycerin may help control the symptoms and correct the ischemia, but frequent monitoring of BP is required. Initiation of a reperfusion strategy in patients with STEMI should not be delayed while assessing the patient's response to SL or IV nitrates.

Beta-Adrenergic Blocking Agents

Beta blockers aid in the relief of ischemic pain, reduce the need for analgesics in many patients, and reduce infarct size and life-threatening arrhythmias. Avoiding early IV beta blockers in patients with Killip class II or greater is important, however, because of the risk of precipitating cardiogenic shock.[1] Routine use of IV beta blockers is no longer recommended in patients with STEMI, but IV administration of a beta blocker at the initial evaluation of patients with STEMI who are hypertensive and have ongoing ischemia is reasonable.[1]

A practical protocol for use of a beta blocker in this situation follows. First, exclude patients with heart failure (HF), hypotension (systolic BP <90 mm Hg), bradycardia (HR <60 beats/min), or significant atrioventricular (AV) block. Second, administer metoprolol in three 5-mg IV boluses. Third, observe the patient for 2 to 5 minutes after each bolus, and if HR falls below 60 beats/min or systolic BP falls below 100 mm Hg, do not administer any further drug. Fourth, if hemodynamic stability continues 15 minutes after the last IV dose, begin oral metoprolol tartrate, 25 to 50 mg every 6 hours for 2 to 3 days as tolerated, and then switch to 100 mg twice daily.[1] Lower doses may be used in patients who have a partial decline in BP with the initial dosing or who appear to be at higher risk (e.g., larger infarction) for development of HF because of poor left ventricular (LV) performance. Infusion of an extremely short-acting beta blocker, such as esmolol, 50 to 250 µg/kg/min, may be useful in patients with relative contraindications to the administration of a beta blocker and in whom HR slowing is considered highly desirable.[19]

Oxygen

Hypoxemia can occur in patients with STEMI and generally results from ventilation-perfusion abnormalities that are sequelae of LV failure; concomitant intrinsic pulmonary disease may also contribute to hypoxemia in some patients. Treating all patients hospitalized for STEMI with oxygen for at least 24 to 48 hours is common practice based on the empiric assumption of hypoxia and evidence that increased oxygen in the inspired air may protect ischemic myocardium. However, augmentation of the fraction of oxygen in inspired air (FIO_2) does not elevate O_2 delivery significantly in patients who are not hypoxemic. Furthermore, it may increase systemic vascular resistance and arterial pressure, promote coronary vasoconstriction, and result in greater oxidative stress. Moreover, in a randomized trial comparing oxygen (8 L/min) with no supplemental oxygen in 441 patients with STEMI but without hypoxia, compared with the control therapy, supplemental O_2 therapy demonstrated a trend toward increased early myocardial injury measured with cardiac troponin.[20] In a secondary analysis, O_2 supplementation was associated with increased myocardial infarct size assessed by cardiac magnetic resonance imaging (CMR) at 6 months.

In view of these considerations, arterial oxygen saturation (SaO_2)can be estimated by pulse oximetry, and O_2 therapy can be omitted if the oximetric findings are normal. On the other hand, patients with STEMI and arterial hypoxemia (e.g. SaO_2 <90%) should receive oxygen.[1] In patients with severe pulmonary edema, endotracheal intubation and mechanical ventilation may be necessary to correct the hypoxemia and reduce the work of breathing.

Limitation of Infarct Size

Infarct size is an important determinant of prognosis in patients with STEMI. Patients who succumb from cardiogenic shock generally exhibit either a single massive infarct or a moderate infarct superimposed on multiple previous infarctions.[21,22] Survivors with large infarcts frequently exhibit late impairment of ventricular function, and their long-term mortality rate is higher than that of survivors with small infarcts.[22] In view of the prognostic importance of infarct size, the possibility of modifying infarct size has attracted much experimental and clinical attention[4,23] (**see Chapter 58, Fig. 58.12**). Efforts to limit infarct size have used several different (sometimes overlapping) approaches: (1) early reperfusion, (2) reduction of myocardial energy demands, (3) manipulation of energy production sources in the myocardium, and (4) prevention of reperfusion injury.[24]

Dynamic Nature of Infarction

STEMI is a dynamic process that does not occur instantaneously but rather evolves over hours. The fate of jeopardized, ischemic tissue can be favorably affected by interventions that restore myocardial perfusion, reduce microvascular damage in the infarct zone, decrease myocardial oxygen requirements, inhibit accumulation or facilitate washout of noxious metabolites, augment the availability of substrate for anaerobic metabolism, or blunt the effects of mediators of injury that compromise the structure and function of intracellular organelles and constituents of cell membranes. Strong evidence in experimental animals and suggestive evidence in patients indicate that *ischemic preconditioning*, a form of endogenous protection against STEMI, before sustained coronary occlusion decreases infarct size and is associated with a more favorable outcome, along with decreased risk for extension of infarction and recurrent ischemic events. Brief episodes of ischemia in one coronary vascular bed may precondition myocardium in a remote zone and thereby attenuate the size of infarction in the latter when sustained coronary occlusion occurs.[25]

Perfusion of myocardium in the infarct zone appears to fall maximally immediately following coronary occlusion. Spontaneous recanalization of an occluded infarct-related artery occurs in up to one third of patients beginning at 12 to 24 hours. This delayed spontaneous reperfusion may enhance LV function because it improves healing of infarcted tissue, prevents ventricular remodeling, and reperfuses hibernating myocardium. Yet, strategies involving pharmacologically induced and catheter-based reperfusion of the infarct vessel can *maximize* the amount of salvaged myocardium by *accelerating* the process of reperfusion and also implementing it in patients who would otherwise have an occluded infarct-related artery. An overarching concept that applies to all methods of reperfusion is the critical importance of time. The earlier the infarct artery is reperfused, the greater the reduction in mortality[1] (**Fig. 59.4**).

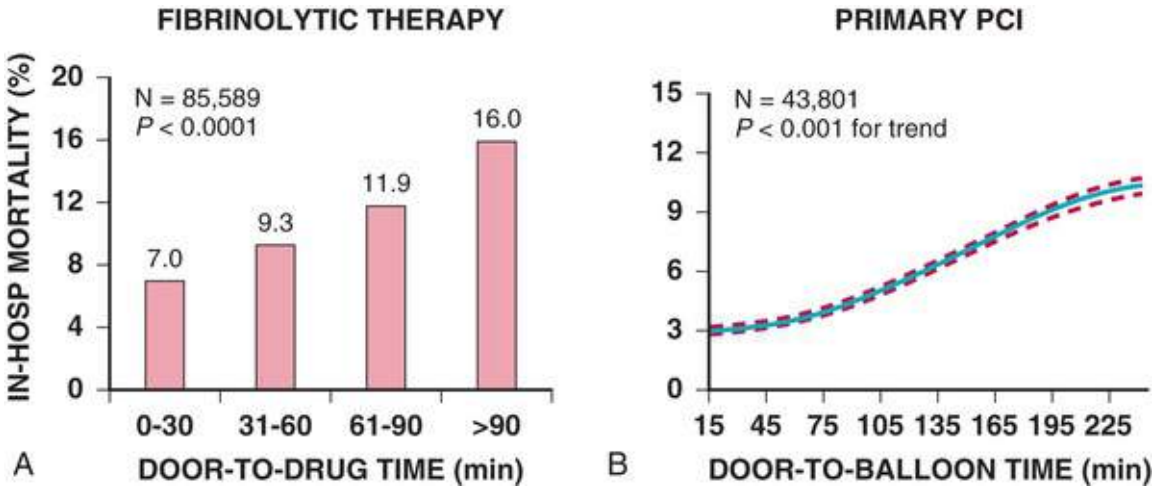

FIGURE 59.4 Importance of time to reperfusion in patients undergoing fibrinolysis **(A)** or primary PCI **(B)** for STEMI. **A,** Graph based on data from 85,589 patients treated with fibrinolysis. A progressive increase in the in-hospital mortality rate occurs for every 30-minute delay. **B,** Based on data from 43,801 patients, this graph depicts the adjusted in-hospital mortality rate as a function of door-to-balloon time. Estimated mortality ranged from 3% with a door-to-balloon time of 30 minutes to 10.3% in patients with a door-to-balloon time of 240 minutes. (Data from Cannon CP et al. Relationship of symptom-onset-to-balloon time and door-to-balloon time with mortality in patients undergoing angioplasty for acute myocardial infarction. JAMA 2000;283:2941; and Rathore SS et al. Association of door-to-balloon time and mortality in patients admitted to hospital with ST elevation myocardial infarction: national cohort study. BMJ 2009;338:b1807.)

Additional factors that may limit infarct size during reperfusion include relief of coronary spasm, prevention of damage to the microvasculature, improved systemic hemodynamics (augmentation of coronary perfusion pressure and reduced LV end-diastolic pressure), and collateral circulation. Prompt implementation of measures designed to protect ischemic myocardium and support myocardial perfusion may provide sufficient time for the development of compensatory mechanisms that limit the ultimate extent of infarction (**see Chapter 58**). Interventions designed to protect ischemic myocardium during the initial event may also reduce the extension of infarction or early reinfarction.

Routine Measures for Limitation of Infarct Size

Although timely reperfusion of ischemic myocardium is the most important technique for limiting infarct size, several routine measures to accomplish this goal apply to all patients with STEMI, regardless of whether they receive reperfusion therapy.[1] The treatment strategies discussed in this section can be initiated at first medical contact and can be continued throughout the hospital phase of care.

Myocardial oxygen consumption should be minimized by maintaining the patient at rest both physically and emotionally and by using mild sedation and a quiet atmosphere—in addition to the interventions already discussed. Administration of adrenergic agonists should be avoided whenever possible. All forms of tachyarrhythmia require prompt treatment because they increase myocardial oxygen needs. HF should also be treated swiftly to minimize increases in adrenergic tone and hypoxemia (see later, Left Ventricular Failure). If ongoing ischemia occurs, severe anemia (hemoglobin <7 g/dL) can be corrected by the cautious administration of packed red blood cells, accompanied by a diuretic if there is any evidence of LV failure. Associated conditions, particularly infections and accompanying tachycardia, fever, and elevated myocardial oxygen needs, require management.

Reperfusion Therapy

General Concepts

Although late spontaneous reperfusion occurs in some patients, thrombotic occlusion persists in most patients with STEMI. Timely reperfusion of jeopardized myocardium is the most effective way of restoring the balance between myocardial oxygen supply and demand.[26] The dependence of myocardial salvage on the time elapsed until treatment pertains to patients treated with either fibrinolysis or PCI[1,27,28] (**Fig. 59.5**). The efficacy of fibrinolytic agents decreases as coronary thrombi mature over time (**see Fig. 59.4**). Analyses adjusted for baseline risk also demonstrate a statistically significant increase in in-hospital and long-term mortality with progressive delays between the onset of symptoms and PCI.[1,28] Each 30-minute delay from symptom onset to PCI increases the relative risk (RR) for 1-year mortality by 8%.

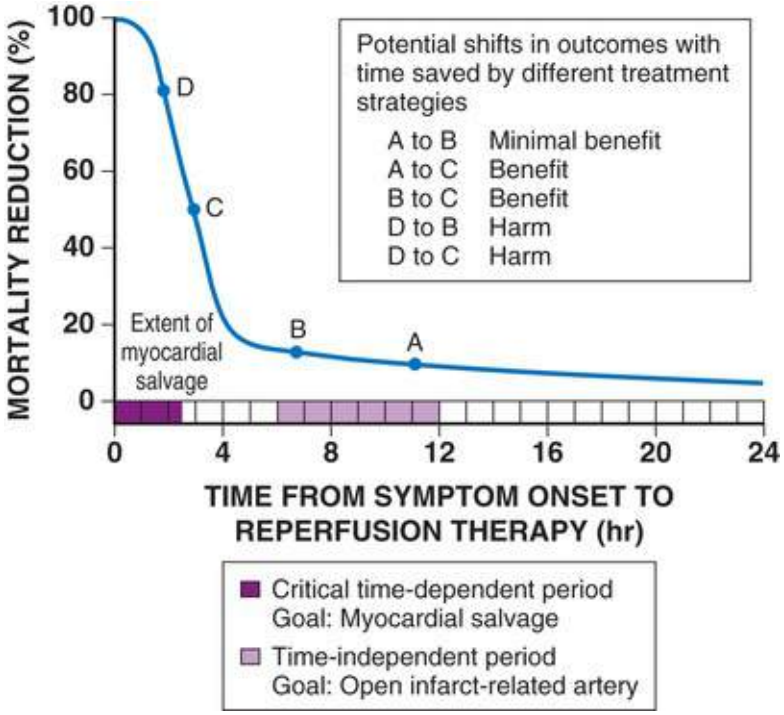

FIGURE 59.5 The reduction in mortality as a benefit of reperfusion therapy is greatest in the first 2 to 3 hours after the onset of symptoms of acute MI, most likely a consequence of myocardial salvage. The exact duration of this critical early period may be modified by several factors, including the presence of functioning collateral coronary arteries, ischemic preconditioning, myocardial oxygen demands, and the duration of sustained ischemia. After this early period, the magnitude of the mortality benefit is much reduced, and as the mortality reduction curve flattens, time to reperfusion therapy is less critical. The magnitude of the benefit depends on how far up the curve the patient can be shifted. The benefit of a shift from point A or B to point C would be substantial, but the benefit of a shift from point A to point B would be small. This schematic illustrates how a treatment strategy that delays therapy during the early critical period, such as transfer of a patient for PCI with a long transportation time, could be harmful (shift from point D to point C or point B). (Modified from Gersh BJ, Stone GW, White HD, Homes DR Jr. Pharmacological facilitation of primary percutaneous coronary intervention for acute myocardial infarction: is the slope of the curve the shape of the future? JAMA 2005;293:979.)

In some patients, particularly those with cardiogenic shock, tissue damage occurs in a “stuttering” manner rather than abruptly. This scenario underscores the need for careful history taking to ascertain whether the patient appears to have had repetitive cycles of spontaneous reperfusion and reocclusion. Determining the precise time of onset of the infarction process in these patients, however, can be difficult and sometimes misleading. In such patients with waxing and waning ischemic discomfort, a rigid time interval from the first episode of pain should not be used when determining whether a patient is “outside the window” for benefit from acute reperfusion therapy.

Pathophysiology of Myocardial Reperfusion

Prevention of cell death by restoration of blood flow depends on the severity and duration of the preexisting ischemia. Substantial experimental and clinical evidence indicates that the earlier blood flow is restored, the more favorable the recovery of LV systolic function, improvement in diastolic function, and reduction in overall mortality.[1] Collateral coronary vessels also appear to influence LV function after reperfusion.[29] They provide sufficient perfusion of myocardium to slow cell death and probably have greater importance in patients undergoing reperfusion later than 1 to 2 hours after coronary occlusion. Even after successful reperfusion and despite the absence of irreversible myocardial damage, a period of postischemic contractile dysfunction can occur—a phenomenon called *myocardial stunning*.[24]

Reperfusion Injury

Reperfusion, although beneficial in terms of myocardial salvage, may cause adverse sequelae described by the term *reperfusion injury*[25] (**see Chapter 58**). Several types of reperfusion injury occur in experimental animals: (1) *lethal* reperfusion injury, which refers to reperfusion-induced death of cells that were still viable at restoration of coronary blood flow; (2) *vascular* reperfusion injury, which is progressive damage to the microvasculature such that there is an expanding area of no-reflow and loss of coronary vasodilatory reserve; (3) *stunned myocardium*, in which salvaged myocytes display a prolonged period of contractile dysfunction after restoration of blood flow because of abnormalities in intracellular metabolism, leading to reduced energy production; and (4) *reperfusion arrhythmias*, which refer to bursts of VT (and occasionally VF) that occur within seconds of reperfusion.[25] Vascular reperfusion injury, stunning, and reperfusion arrhythmias can all occur in patients with STEMI. The concept of lethal reperfusion injury to potentially salvageable myocardium remains controversial, both in animals and in humans.[30-32]

Microvasculature damage in the reperfused myocardium can lead to a hemorrhagic infarct (**see Chapter 58**). Fibrinolytic therapy appears more likely than catheter-based reperfusion to produce hemorrhagic infarction. Although there is concern that this hemorrhage may lead to extension of the infarct, this does not appear to be the case. Histologic study of patients not surviving despite successful reperfusion has revealed hemorrhagic infarcts, but this hemorrhage does not usually extend beyond the area of necrosis.

Protection Against Reperfusion Injury.

A variety of adjunctive therapies have been proposed to mitigate the injury that occurs after reperfusion, including modulators of nitric oxide (NO) and cyclic guanosine monophosphate (cGMP) signaling, such as atrial natriuretic peptide, exenatide, and NO, and inhibitors of mitochondrial permeability and dysfunction, such as cyclosporine A.[25,33] Also, using antiplatelet agents and antithrombins to minimize embolization of atheroembolic debris, and prevention of subsequent inflammatory damage may serve to maintain microvascular integrity (**see Tables 60.4 and 60.5**). The effectiveness of interventions directed against reperfusion injury appears to decline rapidly the later that they are administered after reperfusion. In animals, no beneficial effect is detectable after 45 to 60 minutes of reperfusion has elapsed. Transient ischemia produced in other vascular beds may also reduce reperfusion injury, a concept called *remote ischemic conditioning* (RIC).[25,33] Application of this concept to patients undergoing coronary artery bypass grafting (CABG), using repeated cycles of prolonged BP cuff inflation on the upper extremity, reduced perioperative myocardial injury, but did not improve clinical outcomes in two randomized

trials.[34-36] Several studies have also identified a reduction in MI size in STEMI patients treated with RIC.[33] The ongoing CONDI2/ERIC-PPCI (Effect of Remote Ischaemic Conditioning on Clinical Outcomes in STEMI Patients Undergoing PPCI) trial of 4300 STEMI patients will address whether RIC can improve clinical outcomes.[37]

An alternative experimental approach to protection against reperfusion injury is called *postconditioning*, which involves introducing brief, repetitive episodes of ischemia alternating with reperfusion.[25,33] This appears to activate the cellular protective mechanisms centering around prosurvival kinases.[25] Many of these protective kinases are also activated during ischemic preconditioning. Several clinical studies in patients with STEMI undergoing PCI have provided evidence that postconditioning is associated with reduced infarct size and improvement in myocardial perfusion, but others have failed to show a benefit.[25] A study evaluating clinical outcomes after postconditioning in 1252 patients with STEMI is ongoing.[38]

Reperfusion Arrhythmias

Transient sinus bradycardia occurs in many patients with inferior infarcts at the time of acute reperfusion, often accompanied by some degree of hypotension. This combination of hypotension and bradycardia with a sudden increase in coronary flow may involve activation of the Bezold-Jarisch reflex. Premature ventricular contractions (PVCs), accelerated idioventricular rhythm, and nonsustained VT also usually follow successful reperfusion. Although some investigators have postulated that early afterdepolarizations participate in the genesis of reperfusion-related ventricular arrhythmias, they are present during both ischemia and reperfusion and therefore not likely to be involved in the development of reperfusion-associated VT or VF.

When present, rhythm disturbances may actually indicate successful restoration of coronary flow, but their specificity for successful reperfusion is limited. In general, clinical features are inaccurate markers of reperfusion, with no single clinical finding or constellation of findings being reliably predictive of angiographically demonstrated coronary artery patency.[1] Although reperfusion arrhythmias may show a temporal clustering at restoration of coronary blood flow in patients after successful fibrinolysis, this brief “electrical storm” is generally innocuous and therefore does not warrant prophylactic antiarrhythmic therapy or specific treatment, except in rare cases of symptomatic or hemodynamically significant reperfusion arrhythmias.[1]

Late Establishment of Patency of the Infarct Vessel

The improved survival and ventricular function after successful reperfusion may not result entirely from limitation of infarct size. Poorly contracting or noncontracting myocardium in a zone that is supplied by a stenosed infarct-related artery with slow anterograde perfusion may still contain viable myocytes. PCI can augment flow in the infarct-related artery and thus improve the function of the so-called hibernating myocardium.[39,40]

Fibrinolysis

Fibrinolysis can recanalize the thrombotic occlusion associated with STEMI, and when achieved, restoration of coronary flow reduces infarct size and improves myocardial function and survival over both the short and the long term.[28] Patients treated within the first 1 to 2 hours after the onset of symptoms seem to have the greatest potential for long-term improvement in survival with fibrinolysis.[1]

Assessment of Reperfusion

TIMI Flow Grade.

To provide a level of standardization both for clinical communication and for studies comparing various reperfusion regimens, most clinicians and investigators describe the flow in the infarct vessel according to the TIMI (Thrombolysis In Myocardial Infarction) trial grading system[41] (**Fig. 59.6**). However, an angiographic snapshot in time does not reflect the fluctuating status of flow in the infarct vessel, which may undergo repeated cycles of patency and reocclusion before or during fibrinolysis. When assessed 60 to 90 minutes after the start of fibrinolytic therapy,[1] the finding of TIMI grade 3 flow is far superior to grade 2 in terms of reduction of infarct size and both short-term and long-term mortality benefit. Therefore, TIMI grade 3 flow should be the goal for achieving reperfusion of the epicardial infarct artery (**Fig. 59.6**).

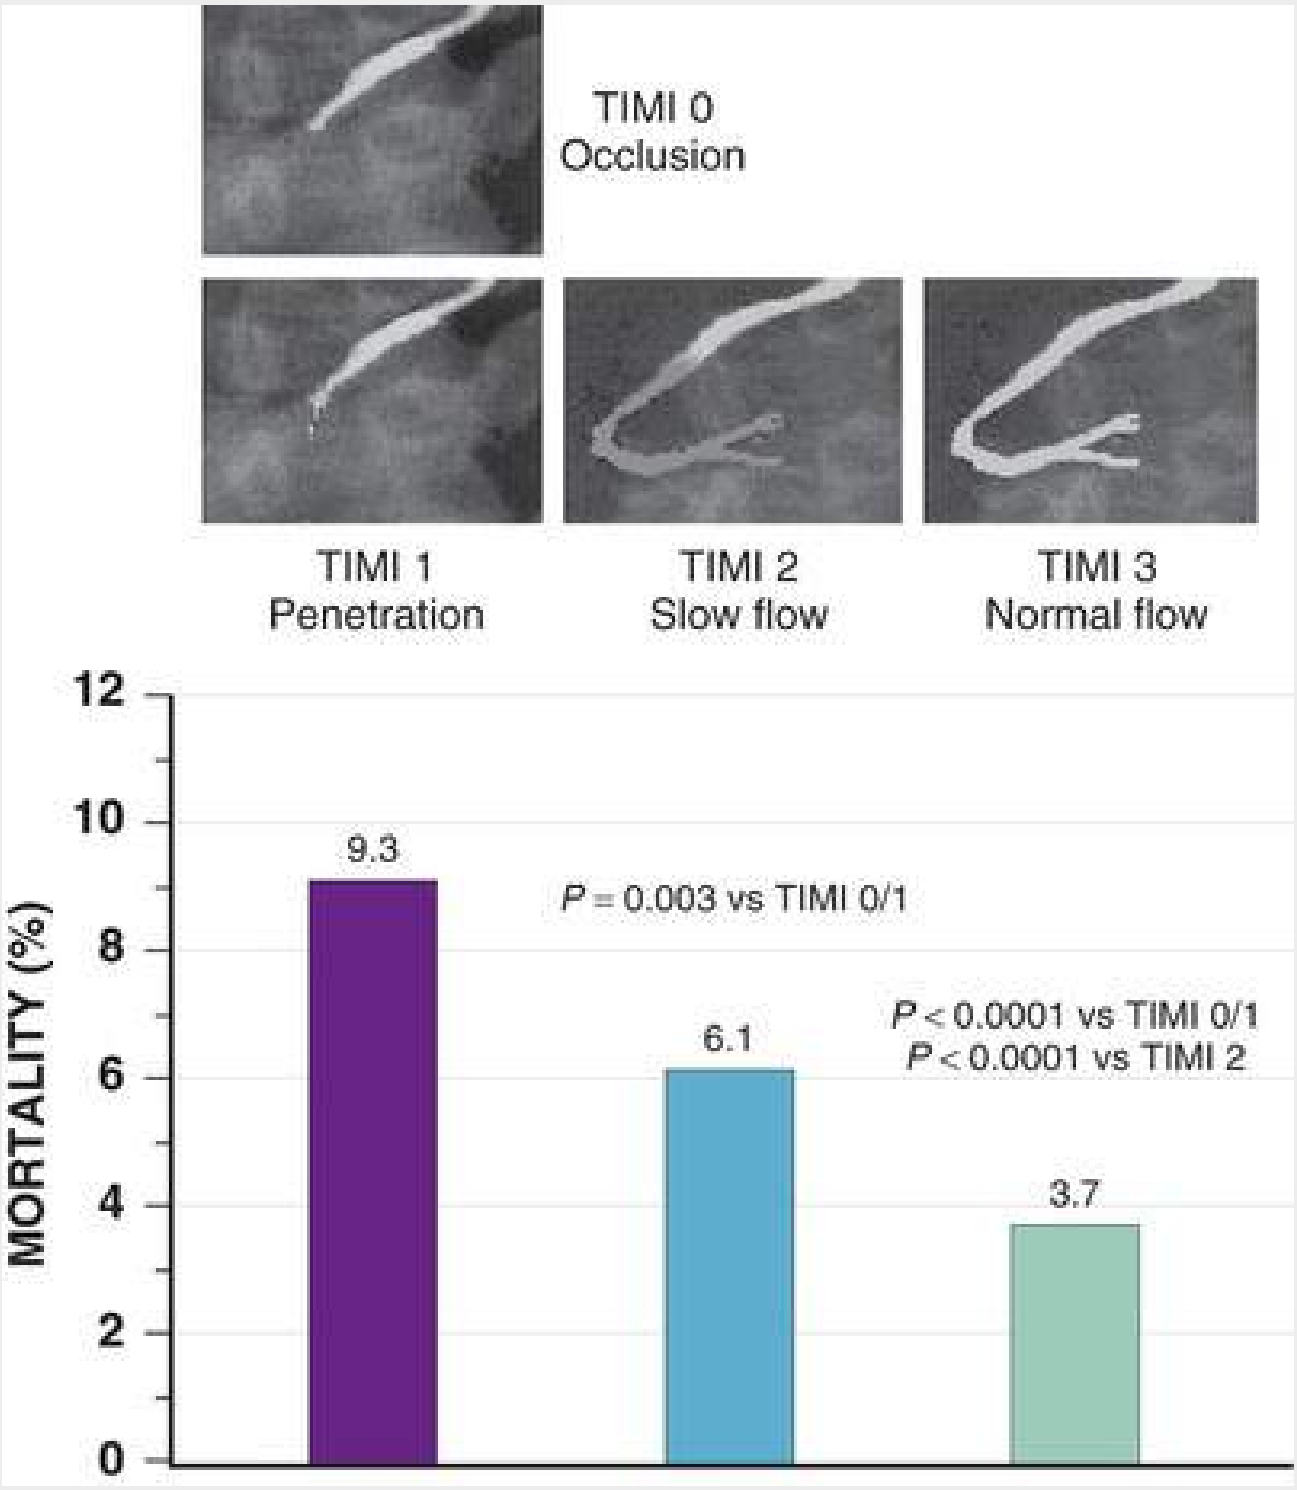

FIGURE 59.6 Correlation of TIMI (thrombolysis in myocardial infarction) flow grade and mortality. A pooled analysis of data from 5498 patients in several angiographic trials of reperfusion for STEMI showed a gradient of mortality when the angiographic findings were stratified by TIMI flow grade. Patients with TIMI 0 or TIMI 1 flow had the highest rate of mortality, TIMI 2 flow associated with an intermediate rate of mortality, and the lowest rate of mortality was observed in patients with TIMI 3 flow. (Courtesy Dr. Michael Gibson, personal communication.)

The TIMI Frame Count.

To provide a more quantitative statement of the briskness of coronary blood flow in the infarct artery and to account for differences in the size and length of vessels (e.g., left anterior descending versus right coronary artery) and interobserver variability, Gibson and coworkers developed the TIMI frame count—a simple count of the number of angiographic frames elapsed until the contrast material arrives in the distal bed of the vessel of interest.[42] This objective and quantitative index of coronary blood flow independently predicts in-hospital mortality from STEMI and also separates patients with TIMI grade 3

flow into low-risk and high-risk groups. The TIMI frame count can also be used to quantitate coronary blood flow (mL/sec), as calculated by:

$$21 \div (\text{Observed TIMI frame count}) \times 1.7$$

based on Doppler velocity wire data showing that normal flow equals 1.7 cm^3/sec, which 21 frames encompass. The calculated coronary perfusion relates to mortality in patients treated with fibrinolytics or primary PCI and can be used to assess various modalities for reperfusion in patients with STEMI.

Myocardial Perfusion.

Even patients with TIMI grade 3 flow in the culprit artery may not always achieve adequate myocardial perfusion (**eFig. 59.1**), especially if the delay between the onset of symptoms and restoration of epicardial flow is long.[42,43] The terms myocardial "no-reflow" and "coronary microvascular obstruction" describe a state of reduced myocardial perfusion after opening of an epicardial infarct-related artery.[42] The four major impediments to normalization of myocardial perfusion are ischemia-related injury, reperfusion-related injury, distal embolization, and individual susceptibility of the microcirculation to injury[42] (**Fig. 59.7**). Obstruction of the distal microvasculature in the downstream bed of the infarct-related artery results from platelet or microparticle microemboli and thrombi. Fibrinolysis may actually exacerbate microembolization of platelet aggregates because of the exposure of clot-bound thrombin, an extremely potent platelet agonist. Spasm can also occur in the microvasculature as a result of the release of substances from activated platelets. Reperfusion injury results in endothelial cell edema, production of reactive oxygen species, and calcium overload. In addition, cytokine activation leads to the accumulation of neutrophils and inflammatory mediators that contribute to tissue injury.[42] Interstitial edema from ischemia and reperfusion injury can compress vasculature, further compromising perfusion. Several techniques can evaluate the adequacy of myocardial perfusion.

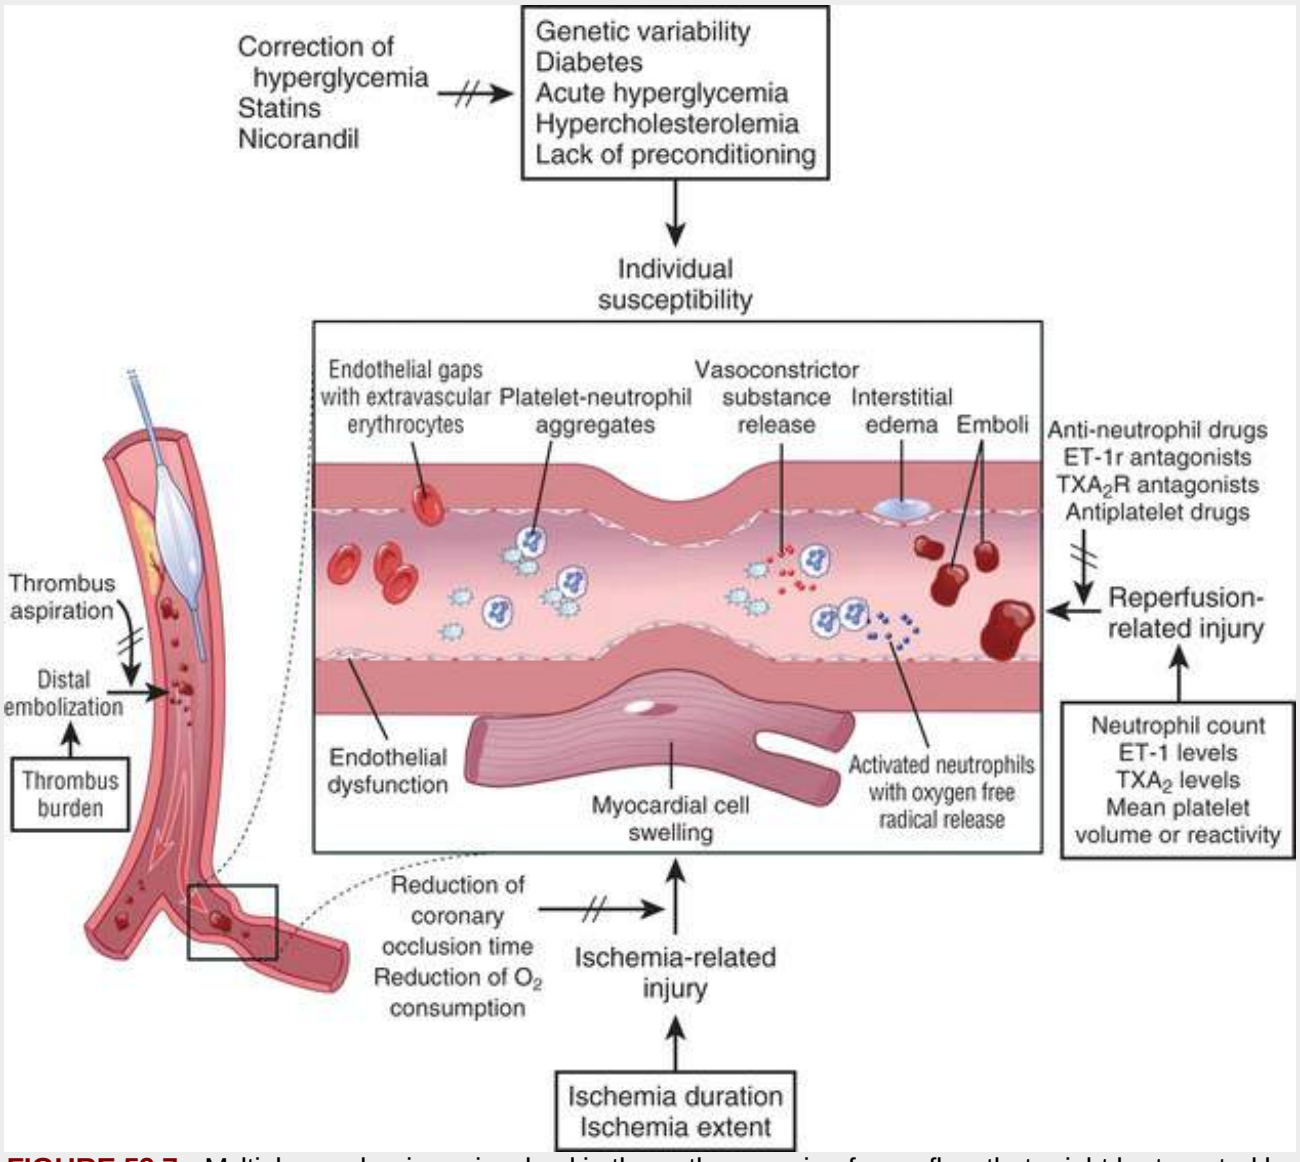

FIGURE 59.7 Multiple mechanisms involved in the pathogenesis of no-reflow that might be targeted by appropriate therapy. ET, Endothelin; TXA_2, thromboxane A_2. (Modified from Niccoli G, Burzotta F, Galiuto L, Crea F: Myocardial no-reflow in humans. J Am Coll Cardiol 2009;54:281.)

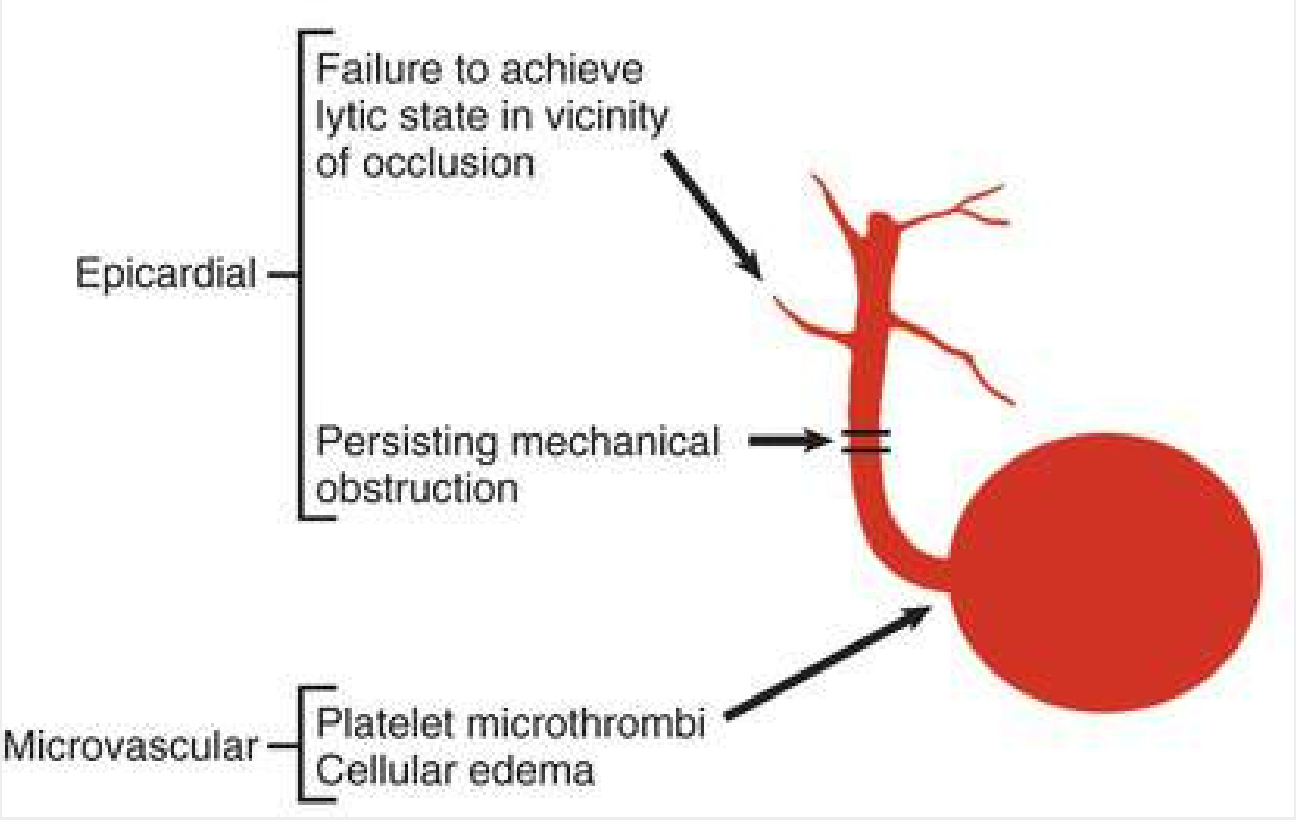


EFIGURE 59.1 Points of possible failure of reperfusion therapy. Complete reperfusion requires successful restoration of normal flow in both the epicardial coronary artery and the distal coronary microvasculature, termed *myocardial tissue–level reperfusion.* Failure of *epicardial* reperfusion can result from failure to induce a lytic state or from persistent mechanical obstruction at the site of occlusion. Failure of *microvascular* reperfusion is caused by a combination of platelet microthrombi followed by endothelial swelling and myocardial edema ("no reflow"). Reperfusion may fail because of persistent occlusion of the epicardial infarct-related artery (TIMI grades 0 and 1), patency of an epicardial artery in the presence of impaired (TIMI grade 2) flow, or microvascular occlusion in the presence of angiographically normal (TIMI grade 3) flow. Successful reperfusion requires a patent artery with an intact microvascular network. (Modified from Davies CH, Ormerod OJ. Failed coronary thrombolysis. Lancet 1998;351:1191.)

Electrocardiography.

Electrocardiographic ST-segment resolution, when present, has a high positive predictive value (PPV) of greater than 90% for infarct artery patency with, but persistent ST-segment elevation (i.e., lack of ST-segment resolution) is a poor predictor of infarct-related artery occlusion, with a negative predictive value (NPV) of approximately 50%. However, the persistence of ST-segment elevation after angiographically successful primary PCI identifies patients with a higher risk for LV dysfunction and mortality, presumably because of microvascular damage in the infarct zone.[44,45] Thus the 12-lead ECG can reflect the biologic integrity of myocytes in the infarct zone and indicate inadequate myocardial perfusion even in the presence of TIMI grade 3 flow.[46] The extent of ST-segment resolution provides powerful prognostic information early in the management of patients with STEMI.[45,47]

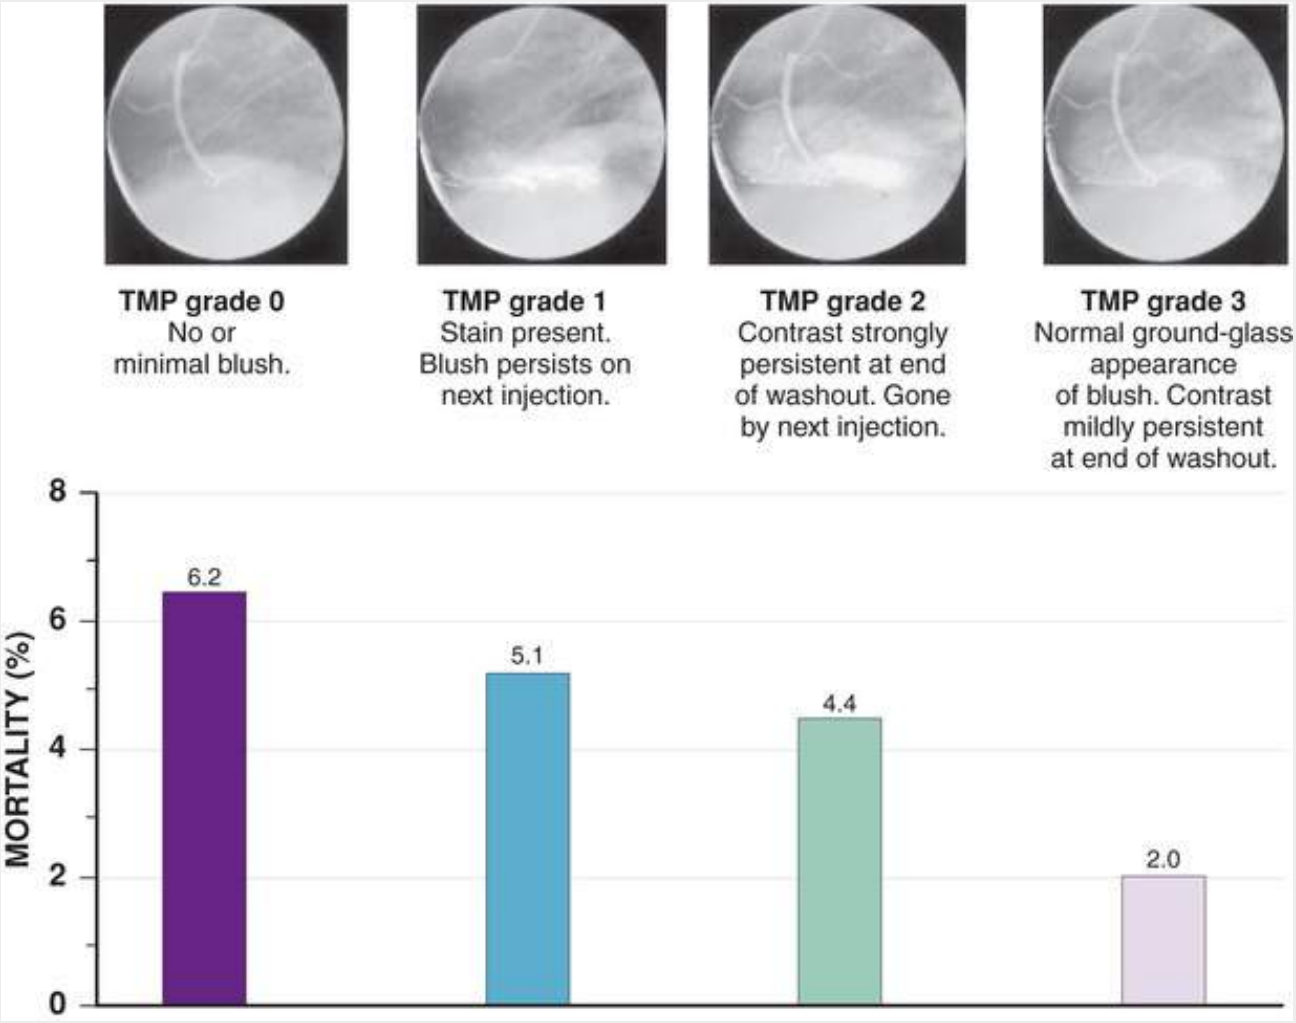
Noninvasive Imaging.

Defects in perfusion patterns seen with myocardial contrast-enhanced echocardiography correlate with regional wall motion abnormalities and lack of myocardial viability on dobutamine stress echocardiography[48] (**see Chapter 14**). Contrast-enhanced CMR can also identify regions of microvascular obstruction, which associate with an adverse long-term prognosis[49] (**see Chapter 17**).

Invasive Assessment.

Doppler flow wire studies can also define abnormalities in myocardial perfusion. In addition, Gibson and colleagues developed an angiographic method for assessing myocardial perfusion: the TIMI

myocardial perfusion (TMP) grade[47,50] (**eFig. 59.2**). Abnormalities associated with increasing myocardial perfusion, as assessed by the TMP grade, correlate with unfavorable ventricular remodeling and risk for mortality, even after adjusting for the presence of TIMI grade 3 flow or a normal TIMI frame count.[43,47]

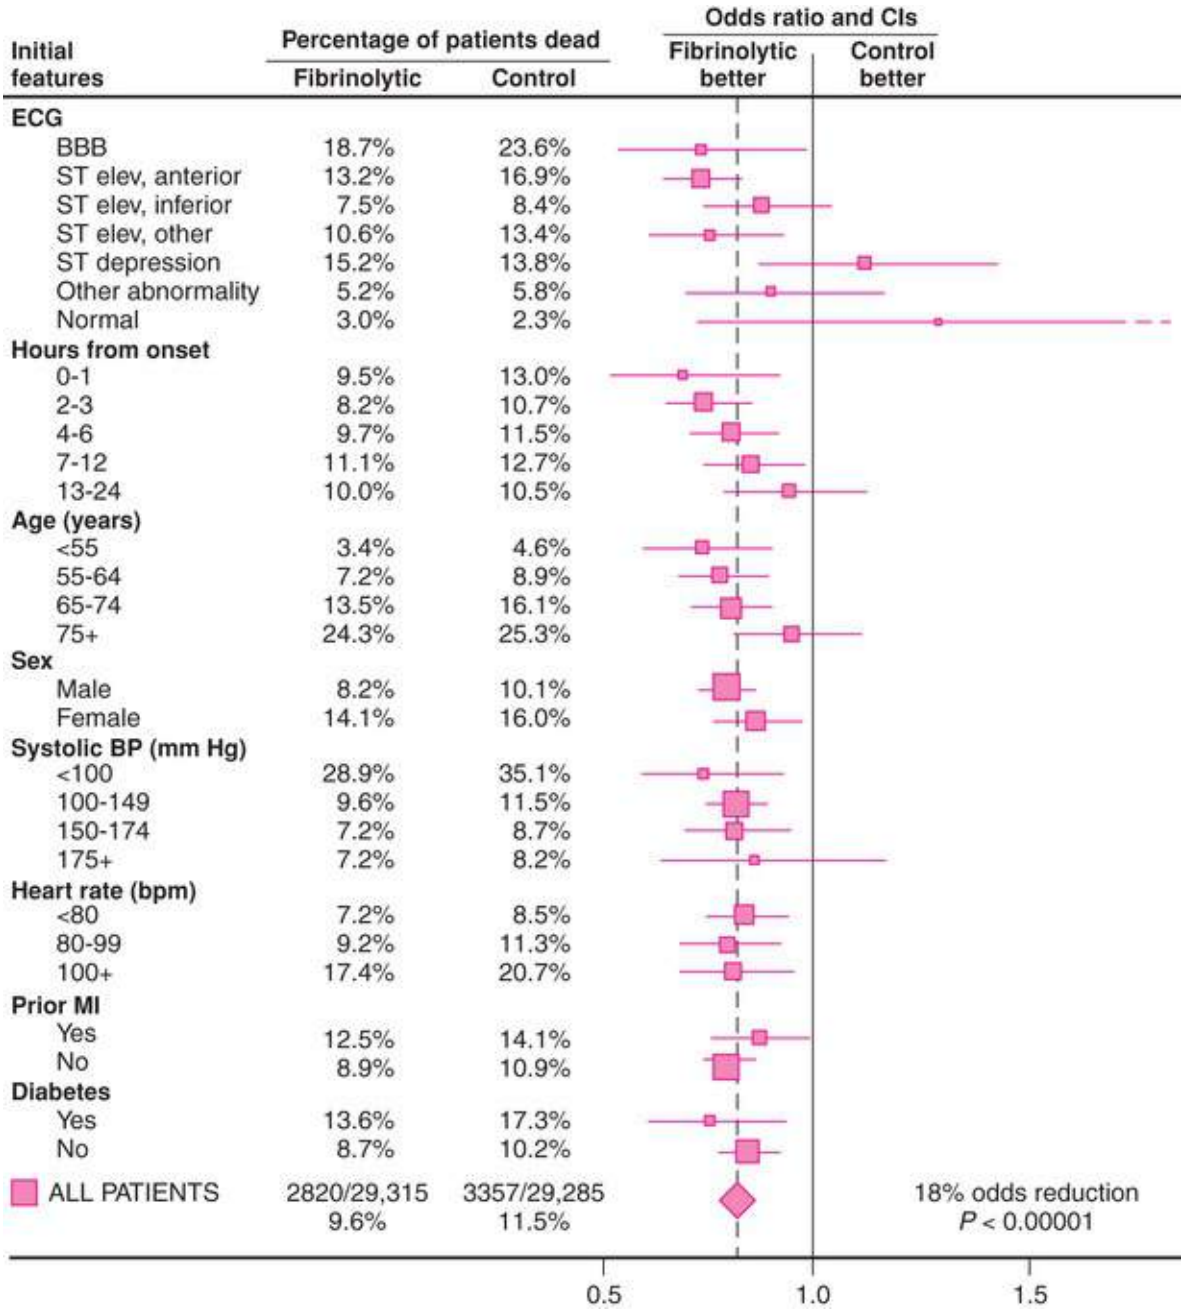


EFIGURE 59.2 Relationship between angiographic assessment of myocardial tissue–level reperfusion categorized by TIMI myocardial perfusion (TMP) grade and mortality. TMP grade 0 or no perfusion of the myocardium is associated with the highest rate of mortality. If a stain of the myocardium is present (grade 1), mortality is also high. A reduction in mortality is seen if the dye enters the microvasculature but is still persistent at the end of the washout phase (grade 2). The lowest mortality rate is observed in patients with normal perfusion (grade 3), with the dye being minimally persistent at the end of the washout phase. (From Gibson CM, Cannon CP, Murphy SA, et al. Relationship of TIMI myocardial perfusion grade to mortality after administration of thrombolytic drugs. Circulation 2000;101:125.)

Effect of Fibrinolytic Therapy on Mortality

Early intravenous fibrinolysis improves survival in patients with STEMI.[1] The Fibrinolytic Therapy Trialists' (FTT) Collaborative Group performed a comprehensive overview of nine trials of fibrinolytic therapy, each of which enrolled more than 1000 patients. The overall results indicated an 18% reduction in short-term mortality, but as much as a 25% reduction in mortality in the subset of 45,000 patients with ST-segment elevation or bundle branch block (**eFig. 59.3**). Two trials, LATE (Late Assessment of Thrombolytic Efficacy) and EMERAS (Estudio Multicéntrico Estreptoquinasa Repúblicas de América del Sur), when viewed together, provide evidence that a reduction in mortality may still be observed in

patients treated with thrombolytic agents between 6 and 12 hours after the onset of ischemic symptoms. Data from the LATE and EMERAS trials and the FTT overview form the basis for extending the window of treatment with fibrinolytics up to 12 hours after the onset of symptoms. As cited in the American College of Cardiology Foundation (ACCF)/AHA guidelines for the management of STEMI, Boersma and colleagues pooled the trials in the FTT overview, two smaller studies with data on time until randomization, and 11 additional trials.[1] Analysis of six time categories from the onset of symptoms to randomization showed a nonlinear relationship of treatment benefit to time, with the best outcome occurring in the first 1 to 2 hours after the onset of symptoms.[1]



EFIGURE 59.3 Differences in mortality during days 0 to 35, subdivided by initial features, in a collaborative overview of results from nine trials of thrombolytic therapy. Absolute mortality rates are shown for the fibrinolytic and control groups in the **center** of the figure for each of the clinical features at initial encounter, listed on the **left side** of the figure. The ratio of the odds of death in the fibrinolytic group to that in the control group is shown for each subdivision *(colored squares),* along with its 99% confidence interval (CI) *(horizontal line).* The summary odds ratio (OR) at the **bottom** of the figure corresponds to an 18% proportional reduction in 35-day mortality and is highly statistically significant. This translates to a reduction of 18 deaths per 1000 patients treated with thrombolytic agents. BBB, Bundle branch block; BP, blood pressure; SD, standard deviation. (From Fibrinolytic Therapy Trialists' [FTT] Collaborative Group. Indications for fibrinolytic therapy in suspected acute myocardial infarction: collaborative overview of mortality and major morbidity results from all randomized trials of more than 1000 patients. Lancet 1994;343:311.)

The effect of fibrinolytic therapy on mortality in elderly patients has been controversial. Although patients older than 75 years were initially excluded from randomized trials of fibrinolytic therapy, they eventually comprised approximately 15% of those studied in trials of fibrinolysis and 35% of those analyzed in registries of patients with STEMI.[51] Barriers to initiation of therapy in older patients with STEMI include a protracted period of delay in seeking medical care, a lower incidence of ischemic discomfort and greater incidence of atypical symptoms and concomitant illnesses, and an increased incidence of nondiagnostic findings on the ECG.[51] Younger patients with STEMI achieve a slightly greater

relative reduction in mortality than elderly patients, but the higher absolute mortality in elderly patients yielded similar absolute reductions in mortality (**eFig. 59.3**).

Several models have integrated the many clinical variables available before the administration of fibrinolytic therapy that affect a patient's risk for death. A convenient, simple, bedside risk-scoring system predicts 30-day mortality at initial evaluation of fibrinolytic-eligible patients with STEMI[52] (**Fig. 59.8**). Modeling of mortality risk cannot cover all clinical scenarios, however, and should supplement clinical judgment in individual cases. For example, patients with inferior STEMI who might otherwise be considered to have a low risk for mortality, and for whom many physicians have questioned the benefits of fibrinolytic therapy, might be in a higher mortality risk subgroup if their inferior infarction is associated with RV infarction, precordial ST-segment depression, or ST-segment elevation in the lateral precordial leads. The short-term survival benefit enjoyed by patients who receive fibrinolytic therapy endures after 1 to 10 years. Advances in adjunctive antiplatelet and antithrombin therapies have led to reductions in the rate of reinfarction after fibrinolysis for STEMI.[4]

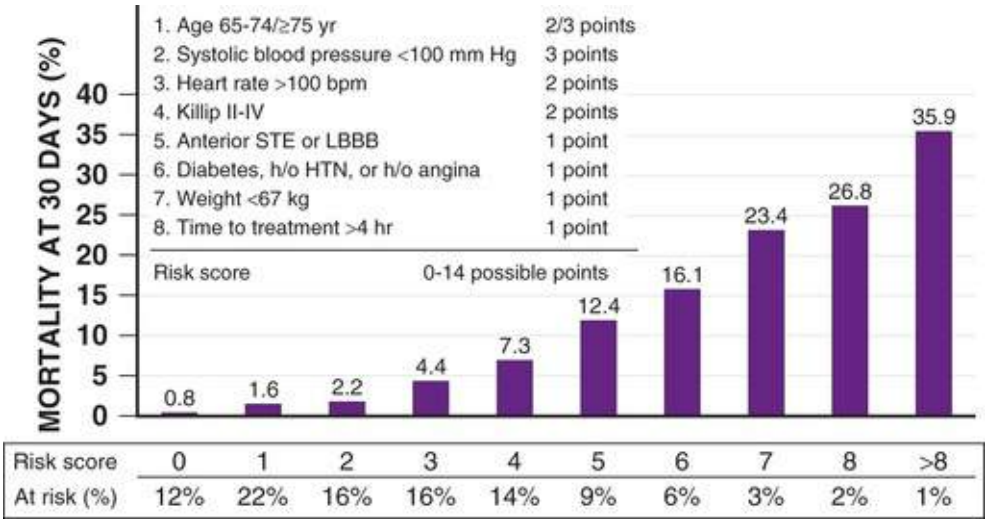


FIGURE 59.8 TIMI risk score for STEMI predicting 30-day mortality. h/o, History of; HTN, hypertension; LBBB, left bundle branch block. (From Morrow DA, Antman EM, Charlesworth A, et al. The TIMI risk score for ST elevation myocardial infarction: a convenient, bedside, clinical score for risk assessment at presentation: An In TIME II substudy. Circulation 2000;102:2031.)

Comparison of Fibrinolytic Agents

Table 59.4 presents the comparative features of the approved fibrinolytic agents for IV therapy. All fibrinolytic agents exert their effect by converting the proenzyme plasminogen to the active enzyme plasmin. The so-called fibrin-specific fibrinolytics are those that are relatively inactive in the absence of fibrin but in its presence substantially increase their activity on plasminogen (**see Chapter 93**).

TABLE 59.4

Comparison of Approved Fibrinolytic Agents

FIBRINOLYTIC AGENT	DOSE	FIBRIN SPECIFICITY*	FIBRINOGEN DEPLETION	ANTIGENIC	PATENCY RATE (90-min TIMI 2 OR 3 FLOW)
Fibrin Specific					
Tenecteplase (TNK)	Single IV weight-based bolus†	++++	Minimal	No	85%
Reteplase (r-PA)	10 units + 10-unit IV boluses given 30 min apart	++	Moderate	No	84%
Alteplase (t-PA)	90-min weight-based infusion‡	++	Mild	No	73-84%
Non–Fibrin Specific					
Streptokinase§	1.5 million units IV given over 30-60 min	No	Marked	Yes¶	60-68%

*Strength of fibrin specificity: ++++ is stronger; ++ is less strong.

†Bolus of 30 mg for weight less than 60 kg, 35 mg for 60 to 69 kg, 40 mg for 70 to 79 kg, 45 mg for 80 to 89 kg, and 50 mg for 90 kg or greater.

‡Bolus of 15 mg, infusion of 0.75 mg/kg for 30 minutes (maximum, 50 mg), then 0.5 mg/kg (maximum, 35 mg) over the next 60 minutes; the total dose not to exceed 100 mg.

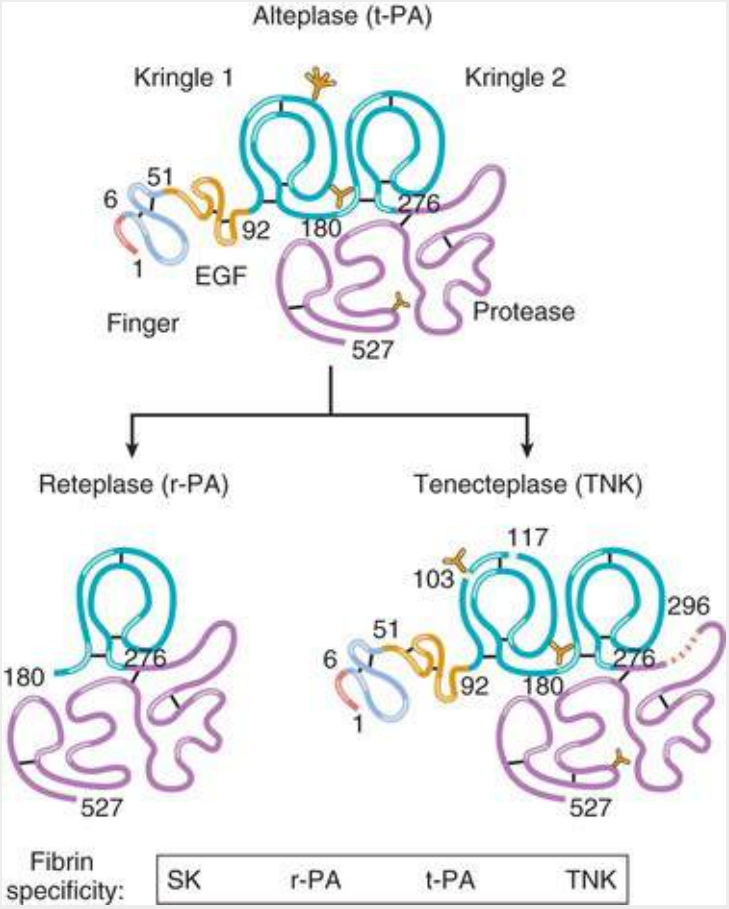
§Streptokinase is no longer marketed in the United States but is available in other countries.

¶Streptokinase is highly antigenic and absolutely contraindicated within 6 months of previous exposure because of the potential for serious allergic reaction.

r-PA, Reteplase plasminogen activator; *t-PA,* tissue plasminogen activator.

From O'Gara PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2013;61:e78.

The tissue plasminogen activator (t-PA) molecule contains five domains[53] (**eFig. 59.4**). In the absence of fibrin, t-PA is a weak plasminogen activator; fibrin provides a scaffold on which t-PA and plasminogen are held in such a way that the catalytic efficiency of t-PA increases many-fold. A dose regimen of t-PA administered over a 90-minute period produces more rapid thrombolysis than a 3-hour fixed-rate infusion. Therefore the recommended dosage for t-PA is the 90-minute “accelerated” regimen.



EFIGURE 59.4 Molecular structure of alteplase (t-PA), reteplase (r-PA), and tenecteplase (TNK). Streptokinase (SK) is the least fibrin-specific thrombolytic agent in clinical use; the progressive increase in relative fibrin specificity for the various thrombolytics is shown at the *bottom.* See also Fig. 93.16. (Modified from Brener SJ, Topol EJ. Third-generation thrombolytic agents for acute myocardial infarction. In Topol EJ, editor. Acute Coronary Syndromes. New York: Marcel Dekker; 1998, p 169.)

Modifications in the native t-PA structure have yielded a group of fibrinolytic agents with prolonged plasma clearance that allows them to be administered as a bolus (**eFig. 59.4 and Table 59.4**) rather than as the bolus and infusion by which accelerated-dose t-PA is administered.[53] Reteplase (double fixed-dose bolus) and tenecteplase (single weight-based bolus) have both been compared with accelerated t-PA. Both these newer agents confer mortality benefits similar to that achieved with accelerated t-PA, but with more convenient dosing. In one large trial, tenecteplase had a lower rate of major bleeding than accelerated t-PA.

Other Fibrinolytic Agents.

Streptokinase, a protein derived from streptococci, binds and activates human plasminogen and is an inexpensive and effective fibrinolytic agent that is still used in some regions of the world. Urokinase is used for STEMI on rare occasions as an intracoronary infusion.

Effect on Left Ventricular Function

As with survival, improvement in global LV function is related to the time of initiation of fibrinolytic treatment, with the greatest improvement occurring with the earliest therapy. Although precise measurements of infarct size would be an ideal endpoint for clinical reperfusion studies, such measures have proved impractical. Attempts to use the LV ejection fraction (EF) as a surrogate for infarct size have not been productive because little difference is seen in EF between treatment groups that show a significant difference in mortality. Methods of assessing LV function, such as end-systolic volume or quantitative echocardiography, are more revealing because patients with smaller volumes and better-

preserved ventricular shape have improved survival. The *myocardial salvage index*, defined as the difference between the initial perfusion defect (e.g., by sestamibi scintigraphy or CMR) and the final perfusion defect, is a useful means for comparing the effectiveness of reperfusion therapies.[49,54] CMR can characterize LV volumes, the extent of scar by gadolinium delayed hyperenhancement, and the presence of ischemia with stress perfusion imaging, providing significant incremental prognostic information over other clinical variables.[49,55]

Complications of Fibrinolytic Therapy

Bleeding complications are most common, and intracranial hemorrhage is the most serious complication of fibrinolytic therapy; its frequency is generally less than 1% but varies with the clinical characteristics of the patient and the fibrinolytic agent used (**Fig. 59.9**).[1] Intracranial bleeding in the setting of fibrinolysis for STEMI is associated with a high case-fatality rate. Nonintracranial bleeding can also increase morbidity, but whether it causes higher overall mortality, after taking into account the higher-risk clinical characteristics that also predispose patients to bleeding during treatment of STEMI, is uncertain.[56,57]

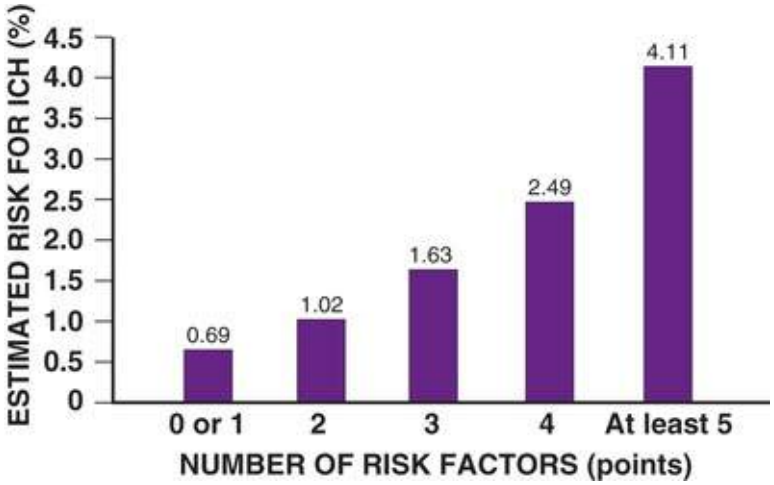


FIGURE 59.9 Estimation of risk for intracranial hemorrhage (ICH) with fibrinolysis. Common risk factors include increased age, low body weight, and hypertension on admission. See reference for further discussion. (Data from Brass LM, Lichtman JH, Wang Y, et al. Intracranial hemorrhage associated with thrombolytic therapy for elderly patients with acute myocardial infarction: results from the Cooperative Cardiovascular Project. Stroke 2000;31:1802.)

Reports have demonstrated an "early hazard" with fibrinolytic therapy—that is, an excess of deaths in the first 24 hours in fibrinolytic-treated patients compared with controls, especially in elderly patients treated more than 12 hours after symptom onset. However, this excess early mortality is more than offset by deaths prevented beyond the first day, with an average 18% (range, 13% to 23%) reduction in mortality by 35 days compared with offering no reperfusion therapy.[1] The mechanisms responsible for this early hazard are not clear but are probably multiple, including an increased risk for myocardial rupture, fatal intracranial hemorrhage, and possibly myocardial reperfusion injury.

Recent exposure to streptococci or streptokinase produces some degree of antibody-mediated resistance to streptokinase (and anistreplase) in most patients. Although such resistance is only rarely of clinical consequence, patients should not receive streptokinase for STEMI if they have been treated with a streptokinase product within the past 6 months.

Recommendations for Fibrinolytic Therapy

As described in the preceding sections, fibrinolytic therapy confers well-established benefits in patients with STEMI, with a time-dependent improvement in survival rates during the initial 12 hours after the onset of symptoms. When a patient arrives at a PCI-capable facility, primary PCI is the preferred mode of reperfusion therapy (see later, Selection of Reperfusion Strategy).[1,2] However, many health care facilities do not have ready access to timely PCI; if the delay from first medical contact to performing primary PCI is anticipated to exceed 120 minutes, administration of a fibrinolytic is indicated for the treatment of STEMI within 12 hours of onset in the absence of contraindications.[1] In addition, even when interhospital transport times are expected to be short, there may be advantages to immediate initiation of fibrinolytic therapy versus incurring any delay until primary PCI in patients with STEMI and low bleeding risk who present very early.[1]

Choice of Agent

The choice of fibrinolytic in hospital systems is generally driven by the desire to establish consistent protocols within the health care system by weighing ease of dosing, cost, and other institutional preferences. In patients seen early with acceptable bleeding risk, a high-intensity fibrin-specific regimen, such as accelerated t-PA, reteplase, or tenecteplase, is usually preferable.[1] In patients whose risk for death is low (e.g., young patient with small inferior MI) and whose risk for intracranial hemorrhage is increased (e.g., acute hypertension), administration of streptokinase is reasonable, but rarely done in the United States. In patients who are to be treated with a fibrin-specific fibrinolytic, we believe that clinicians should use a bolus fibrinolytic such as reteplase or tenecteplase. Bolus fibrinolytics have a lower chance of medication errors and are associated with less noncerebral bleeding—as well as offering the potential for prehospital treatment.[4,53]

Late Therapy

No mortality benefit was demonstrated in the LATE and EMERAS trials when fibrinolytics were routinely administered to patients between 12 and 24 hours, although we believe that it is still reasonable to consider fibrinolytic therapy when PCI is not available, for appropriately selected patients with clinical and electrocardiographic evidence of ongoing ischemia within 12 to 24 hours of symptom onset and a large area of myocardium at risk or hemodynamic instability. Persistent chest pain late after the onset of symptoms correlates with a higher incidence of collateral or anterograde flow in the infarct zone and is therefore a marker for viable myocardium that might be salvaged. Because elderly patients treated with fibrinolytic agents more than 12 hours after the onset of symptoms have an increased risk for cardiac rupture, we believe that restricting late administration of a fibrinolytic to patients younger than 65 years with ongoing ischemia is preferable. An elderly patient with ongoing ischemic symptoms but initially seen late (>12 hours) is better managed with PCI than with fibrinolytic therapy.

Intracoronary Fibrinolysis

In contemporary practice, patients are more likely to be treated with PCI. This evolution has revived the concept of delivering fibrinolytic agents by the intracoronary route, but current efforts are largely restricted to adjunctive use during complicated PCI procedures.

Catheter-Based Reperfusion Strategies

Catheter-based strategies can also achieve reperfusion of the infarct artery. This approach has evolved

from passage of a balloon catheter over a guidewire in the culprit vessel only to now include potent oral antiplatelet therapy, multiple options for anticoagulants, and coronary stents, with the possibility of multivessel revascularization.[1] PCI used as primary reperfusion therapy in patients with STEMI is referred to as direct or primary PCI (**see Fig. 59.2**). If fibrinolysis has failed to reperfuse the infarct vessel, or a severe stenosis is present in the infarct vessel after fibrinolysis, rescue PCI can be performed. A strategy of routine delayed angiography and PCI after successful fibrinolytic therapy may also be considered.[5] Finally, a conservative approach of elective PCI only when spontaneous or exercise-provoked ischemia occurs may be used to manage patients with STEMI, regardless of whether they have received a previous course of fibrinolytic therapy or no initial reperfusion therapy.[1] This chapter discusses decision making regarding the selection of initial reperfusion therapy and referral for PCI in patients who have undergone initial fibrinolysis.

The approach to primary PCI, including device selection, the technical approach to percutaneous revascularization, and decision making regarding non–culprit vessel disease are discussed in **Chapter 62**. As an alternative to pharmacologic reperfusion therapy, primary PCI has evolved significantly. Several randomized trials have suggested that a strategy of multivessel PCI, either at the time of primary PCI or as a planned, staged procedure, may be safe and may improve outcomes in hemodynamically stable patients with STEMI.[58-60] These findings have prompted a change in recommendation from class III to IIb for consideration of multivessel PCI in stable patients with STEMI. Aspiration thrombectomy at primary PCI now has a class III recommendation based on trial data showing no improvement in cardiovascular (CV) outcomes and a possible increase in stroke risk.[6,61] Radial artery access now tends to be favored over femoral artery access in primary PCI based on the MATRIX (Minimizing Adverse Haemorrhagic Events by Transradial Access Site and Systemic Implementation of AngioX) trial, which demonstrated a reduction in bleeding and mortality.[62] Finally, studies suggest that newer-generation drug-eluting stents (DESs) may result in lower rates of repeat revascularization with equivalent rates of stent thrombosis compared to contemporary bare-metal stents (BMSs).[63]

Surgical Reperfusion

Providing surgical reperfusion in a timely fashion is usually not logistically possible. Therefore, patients with STEMI who are candidates for reperfusion should undergo either immediate fibrinolysis or PCI. However, patients with STEMI are currently referred for CABG for persistent or recurrent ischemia despite fibrinolysis or primary PCI with residual coronary disease not amenable to PCI, high-risk coronary anatomy (e.g., left main stenosis) discovered at initial catheterization, or a complication of STEMI such as ventricular septal rupture or severe mitral regurgitation caused by papillary muscle dysfunction. STEMI patients with continued severe ischemic and hemodynamic instability will probably benefit from emergency revascularization.

Patients who successfully undergo fibrinolysis but have important residual stenoses and on anatomic grounds are more suitable for surgical revascularization than for PCI have undergone CABG with quite low rates of mortality (approximately 4%) and morbidity, provided that the procedure is carried out more than 24 hours after STEMI; patients requiring urgent or emergency CABG within 24 to 48 hours of STEMI have mortality rates between 12% and 15%.[1] When surgery is performed under urgent conditions with active and ongoing ischemia or cardiogenic shock, operative mortality rates are higher, in large part reflecting the patient's overall condition that necessitated emergency surgery.

Selection of Reperfusion Strategy

When performed rapidly after arrival at an experienced center, primary PCI is superior to pharmacologic reperfusion therapy.[1,4,64] However, registry and randomized data remind us that very early fibrinolysis may be at least as effective as primary PCI.[14,65] Consequently, decision making for individual patients remains complex regarding the optimum form of reperfusion therapy, especially when a delay until PCI is anticipated.[1] Prehospital fibrinolysis may be as effective as PCI in patients early after symptom onset but requires significant infrastructure, including a trained EMS unit with direct physician support. This infrastructure may not be logistically feasible in many communities, particularly those without the resources to support 24-hour availability of primary PCI. At the same time, improvements in catheterization laboratory facilities, new stents, evolution of adjunctive antithrombotic therapy, and development of collaborative systems for rapid transfer for invasive therapy have improved the efficacy and safety of primary PCI in patients with STEMI, including those being transferred for primary PCI (**see Chapter 62**).[66] Selection of the optimal form of reperfusion therapy therefore involves judgments regarding both system resources and individual patient characteristics.

For patients who arrive at an experienced primary PCI center, primary PCI should be performed in those with STEMI who present within 12 hours of symptom onset and those with later arrival who have ongoing ischemia, HF, or shock. In patients taken to centers that are not PCI capable, the primary consideration is time required for transportation to a PCI-capable center. The greatest operational impediment to routine implementation of a PCI reperfusion strategy is the delay required for transportation to a skilled PCI center (**see Fig. 59.2 and Table 59.1**).[67] Trials conducted in health care systems with extremely short transportation and door-to-balloon times at PCI centers have demonstrated that referral to a PCI center can be superior to fibrinolysis administered at a local hospital.[67] If the delay to implementation of primary PCI is substantial, however, the mortality advantage over administration of a fibrin-specific agent is lost (**Fig. 59.10**). The best estimate of the time delay at which this advantage is lost is 1 to 2 hours, but it may vary depending on the timing of initial evaluation and the extent of myocardium at risk.[67]

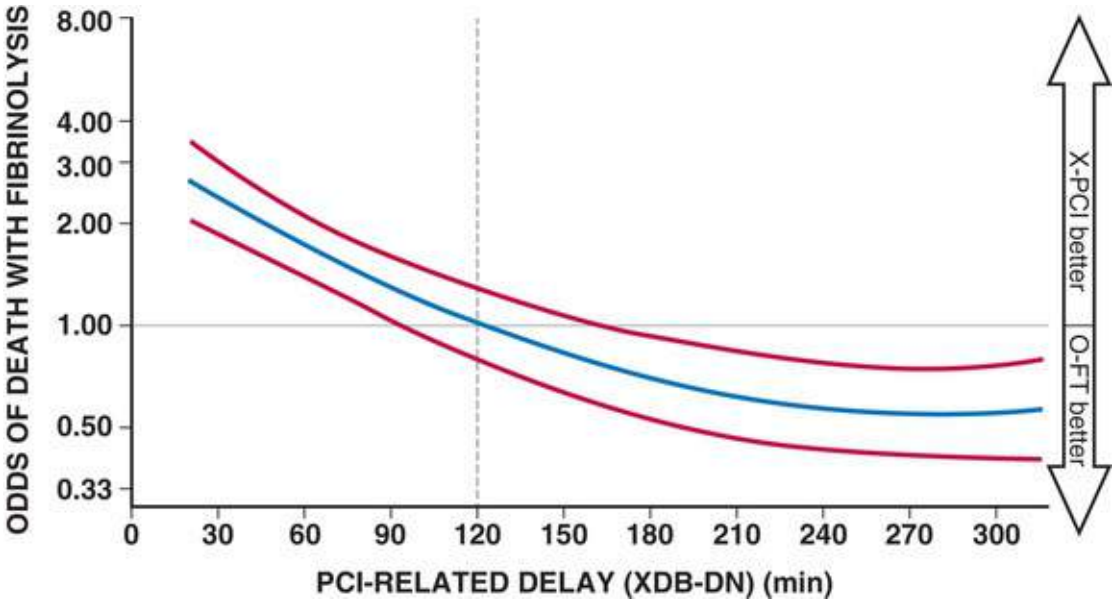

FIGURE 59.10 Relationship between PCI-related delay (minutes) during transfer from a non–PCI-capable hospital to a PCI-capable hospital and in-hospital mortality. The *red lines* represent 95% CIs. XDB-DN indicates transfer delay (transfer door-to-balloon minus door-to-needle time). With delays longer than 120 minutes between administration of a fibrinolytic on-site and balloon (or device) time at a receiving hospital, the on-site fibrinolytic strategy becomes preferable with respect to mortality risk when compared with transfer for PCI. O-FT, On-site fibrinolytic therapy; X-PCI, transfer PCI. (From Pinto DS, Frederick PD, Anjan K, et al. Benefit of transferring ST-segment-elevation myocardial infarction patients for percutaneous coronary intervention compared with administration of onsite fibrinolytic as delays increase. Circulation 2011;124:2518.)

If the time from first medical contact to PCI is expected to be more than 120 minutes, fibrinolysis is recommended in the absence of (1) significant contraindications to fibrinolysis, (2) shock or acute severe heart failure, or (3) late presentation. Otherwise, transfer for primary PCI is generally favored if any of these conditions are present, even if the delay to revascularization will be greater than 120 minutes (**see Fig. 59.2 and Table 59.3**):

1. *High risk for bleeding.* In patients with an increased risk for bleeding, particularly intracranial hemorrhage, therapeutic decision making strongly favors a PCI-based reperfusion strategy. If PCI is unavailable, the benefit of pharmacologic reperfusion should be balanced against the risk for bleeding. A decision analysis suggests that when PCI is not available, fibrinolytic therapy should still be favored over no reperfusion treatment until the risk for life-threatening bleeding exceeds 4%.
2. *Presence of shock or acute severe heart failure.* Patients in cardiogenic shock have improved survival if they are treated with an early revascularization strategy of PCI and/or CABG. Therefore, immediate transfer to a PCI-capable hospital is recommended in patients with shock or acute severe HF regardless of the time delay.[68]
3. *Prolonged time from onset of symptoms to initiation of reperfusion therapy.* PCI is preferable in patients with late arrival, particularly those initially seen 12 to 24 hours after symptom onset. Fibrinolysis can be considered in the 12- to 24-hour window for patients with evidence of ongoing ischemia and where PCI is not available, although the benefit has not been established.[1]

When the diagnosis of STEMI is in doubt, an invasive strategy is clearly the preferred strategy because it not only provides key diagnostic information regarding the patient's symptoms, but does so without the risk for intracranial hemorrhage associated with fibrinolysis.

Referral for Angiography with Intent of Revascularization After Initial Fibrinolysis

Patients with STEMI who are initially managed by fibrinolysis at a non–PCI-capable center should be transferred urgently to a PCI-capable center if the patient develops cardiogenic shock or severe HF or has failed reperfusion with a fibrinolytic. Transfer should also be considered (class IIa) as a part of a pharmacoinvasive strategy in stable patients with the intention of performing angiography, and PCI as necessary, 3 to 24 hours after fibrinolysis[1,69] (**Table 59.5; see Fig. 59.2**).

TABLE 59.5

Indications for Coronary Angiography in Patients Who Were Managed with Fibrinolytic Therapy or Who Did Not Receive Reperfusion Therapy

RECOMMENDATION	COR	LOE
Cardiogenic shock or acute severe heart failure that develops after initial evaluation	I	B
Intermediate- or high-risk findings on predischarge noninvasive ischemia testing	I	B
Spontaneous or easily provoked myocardial ischemia	I	C
Failed reperfusion or reocclusion after fibrinolytic therapy	IIa	B
Stable* patients after successful fibrinolysis—before discharge and ideally between 3 and 24 hours	IIa	B

*Although individual circumstances vary, *clinical stability* is defined as the absence of low output, hypotension, persistent tachycardia, apparent shock, high-grade ventricular or symptomatic supraventricular tachyarrhythmias, and spontaneous recurrent ischemia.

COR, Class of recommendation; *LOE,* level of evidence.

Modified from O'Gara PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2013;61:e78.

Patients undergoing angiography and PCI after suspected failure of reperfusion with fibrinolysis tend to have a lower mortality rate and significantly lower rates of recurrent MI and HF compared with patients who continue medical therapy, including readministration of a fibrinolytic agent. In the REACT (Rapid Early Action for Coronary Treatment) study, patients with suspected failed reperfusion at 90 minutes by electrocardiographic criteria were randomly assigned to one of three treatment arms: rescue PCI, conservative care, or repeated fibrinolytic therapy. The composite of death, reinfarction, stroke, or severe HF at 6 months was significantly lower in patients randomly assigned to rescue PCI than in the two other treatment groups.[1] More minor bleeding, however, occurred in patients randomly assigned to rescue PCI.

The option of administration of a fibrinolytic agent at non–PCI-capable hospitals, followed by routine transfer for angiography and PCI if indicated, has been advanced as an attractive strategy to offer timely reperfusion therapy and arrange a “nonemergency” transfer for subsequent procedures to reduce the risk for subsequent reinfarction. Retrospective analyses of trials of fibrinolytic therapy indirectly support this approach because they suggest a lower risk for recurrent MI and a lower 2-year mortality rate in patients who subsequently undergo early PCI. The limited randomized trials evaluating a strategy of routine catheterization after fibrinolysis have provided mixed results. Nevertheless, overall, these trials have suggested improvement in clinical outcomes in patients transferred for early catheterization, particularly those at higher risk for death and recurrent ischemia (**Fig. 59.11 and eFig. 59.5**).[1] In the largest of these studies, TRANSFER-AMI (Trial of Routine Angioplasty and Stenting after Fibrinolysis to Enhance Reperfusion in Acute Myocardial Infarction; *n* = 1059), immediate transfer for angiography versus conservative care reduced the composite endpoint of death, recurrent MI, recurrent ischemia, new or

worsening HF, or shock at 30 days.[70] In a meta-analysis that included seven randomized trials of early transfer for catheterization, a strategy of routine early catheterization after fibrinolysis yielded a statistically significant 35% reduction in the incidence of death or MI at 30 days (odds ratio [OR], 0.65; 95% confidence interval [CI] 0.49 to 0.88) without an increase in the risk for major bleeding (**Fig. 59.11**).[69]

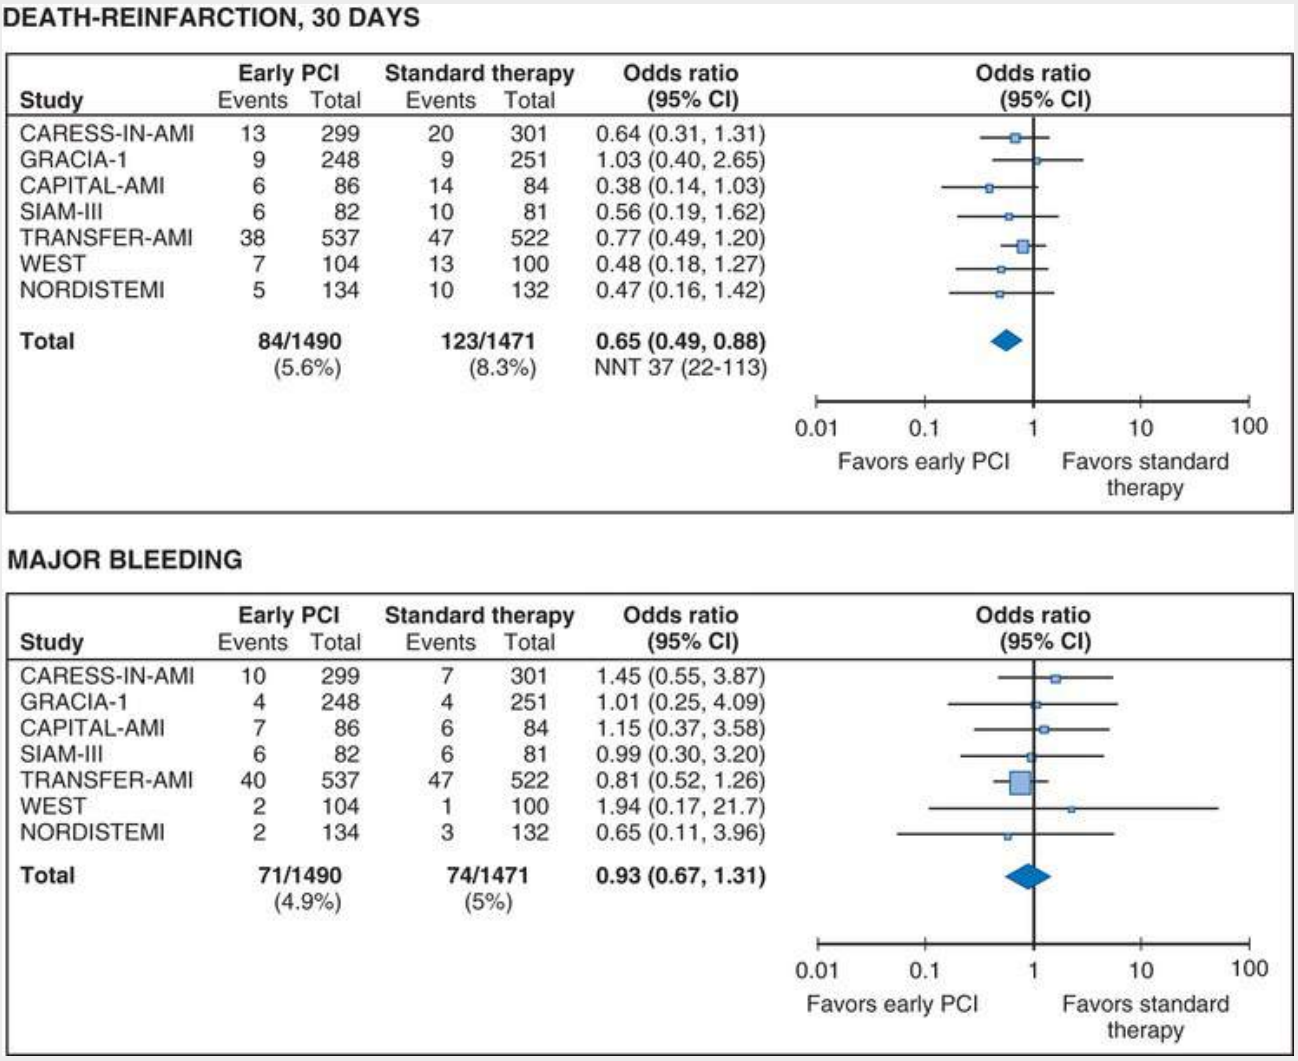

FIGURE 59.11 A meta-analysis of seven randomized trials of early transfer for catheterization, a strategy of routine early catheterization after fibrinolysis, was associated with a statistically significant 35% reduction in the incidence of death or MI at 30 days **(top)** with no increase in major bleeding **(bottom),** for combined death-reinfarction and recurrent ischemia between early PCI and standard therapy. Size of data markers indicates the weight of each trial. (Modified from Borgia, F., Goodman, SG., Halvorsen S, et al. Early routine percutaneous coronary intervention after fibrinolysis vs. standard therapy in ST-segment elevation myocardial infarction: a meta-analysis. Eur Heart J 2010:31(17):2156-69.)

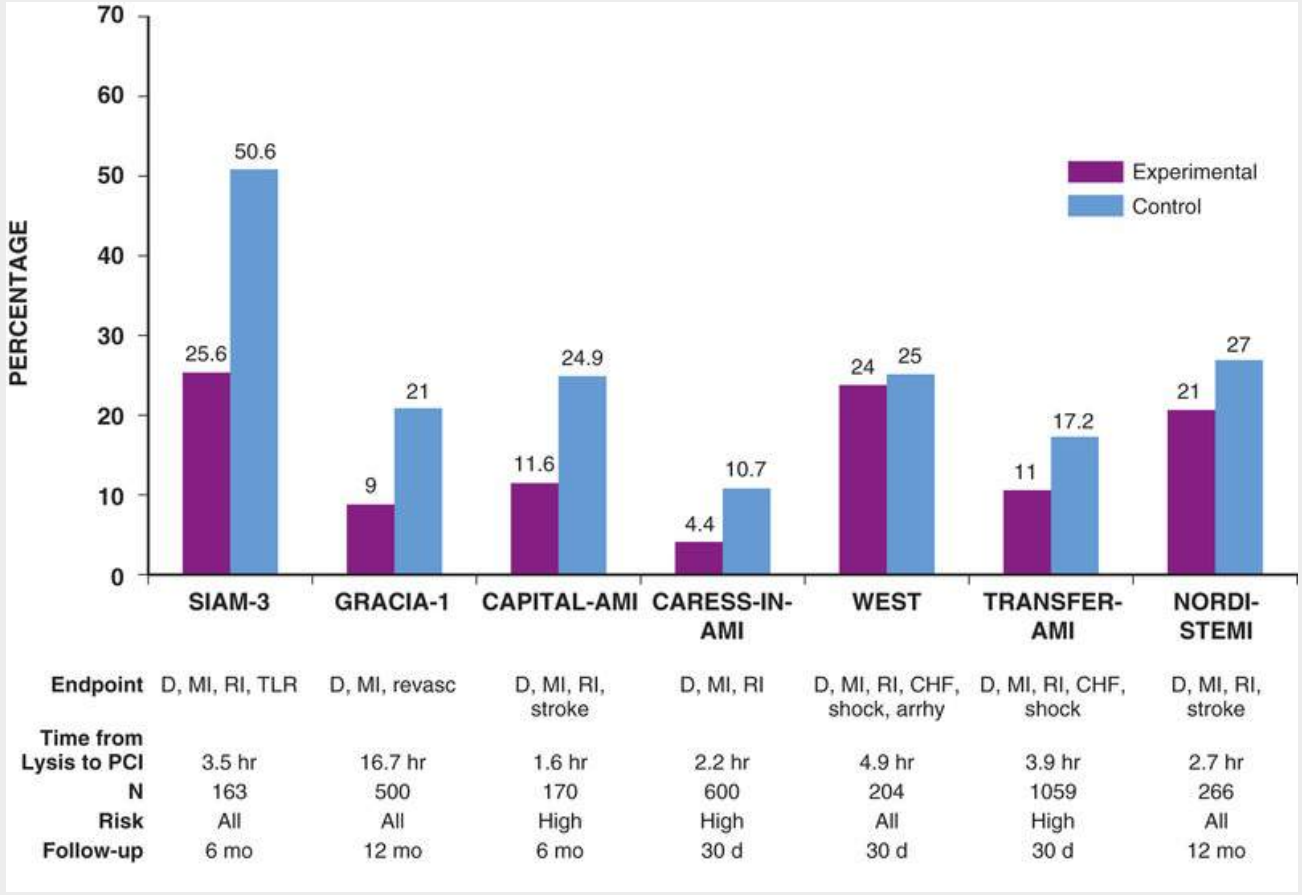


EFIGURE 59.5 Primary outcome of trials of routine versus ischemia-driven (or delayed) catheterization and percutaneous coronary intervention (PCI) after fibrinolytic therapy. Trials comparing routine early catheterization after fibrinolytic therapy with either an ischemia-driven approach or routine delayed catheterization generally showed a consistent pattern of benefit with a strategy of routine transfer for invasive evaluation. The *darker bars* represent patients who underwent routine early catheterization after fibrinolytic therapy. The *lighter bars* represent patients who underwent either an ischemia-guided or routine delayed catheterization approach. arrhy, Arrhythmia; CHF, congestive heart failure; D, death; RI, recurrent ischemia; revasc, ischemia-driven revascularization; TLR, target lesion revascularization. CAPITAL-AMI, Combined Angioplasty and Pharmacological Intervention Versus Thrombolysis Alone in Acute Myocardial Infarction; CARESS-in-AMI, Combined Abciximab Reteplase Stent Study in Acute Myocardial Infarction; GRACIA, Grupo de Análisis de la Cardiopatía Isquémica Aguda; NORDISTEMI, Norwegian Study on District Treatment of ST-Elevation Myocardial Infarction; SIAM-3, Southwest German Interventional Study in Acute Myocardial Infarction; TRANSFER-AMI, Trial of Routine Angioplasty and Stenting after Fibrinolysis to Enhance Reperfusion in Acute Myocardial Infarction; WEST, Which Early ST-Elevated Myocardial Infarction Therapy. (Modified from O'Gara PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHAguideline for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2013;61:e383.)

Notably, the clinical trials that assessed routine invasive evaluation after initial fibrinolysis used a time window of 0 to 24 hours for the “early invasive” strategy, thus supporting earlier transfer after administration of fibrinolytic therapy, even for patients without high-risk features. Although we believe that there will probably be continued benefit even beyond 24 hours in patients with a patent but stenotic infarct artery after initial successful reperfusion, later time windows have not been directly examined. Because of the associated increased bleeding risk, very early (<2 to 3 hours) catheterization after the administration of fibrinolytic therapy with the intent to perform revascularization should be reserved for patients with evidence of failed fibrinolysis and significant myocardial jeopardy, for whom rescue PCI would be appropriate. In addition, when STEMI is suspected to have occurred by a mechanism other than thrombotic occlusion at the site of atherosclerotic plaque, coronary angiography may provide diagnostic information and direct specific therapy.

In summary, delayed coronary angiography with PCI of the infarct artery is indicated in patients initially treated with a noninvasive strategy (i.e., with fibrinolysis or without reperfusion therapy) who become unstable with cardiogenic shock, acute severe HF, or unstable postinfarction angina, provided that invasive management is not considered futile or inappropriate (**Table 59.5**). Delayed PCI also appears to be reasonable in patients with failed fibrinolysis or reocclusion of the infarct artery or in those who demonstrate significant residual ischemia during hospitalization after initial noninvasive management. The benefits of routine (non–ischemia-driven) PCI on an angiographically significant stenosis in a patent infarct artery more than 24 hours after STEMI are less well established, and delayed PCI on a totally occluded infarct artery longer than 24 hours after STEMI should not be undertaken in clinically stable patients without evidence of severe ischemia.[1]

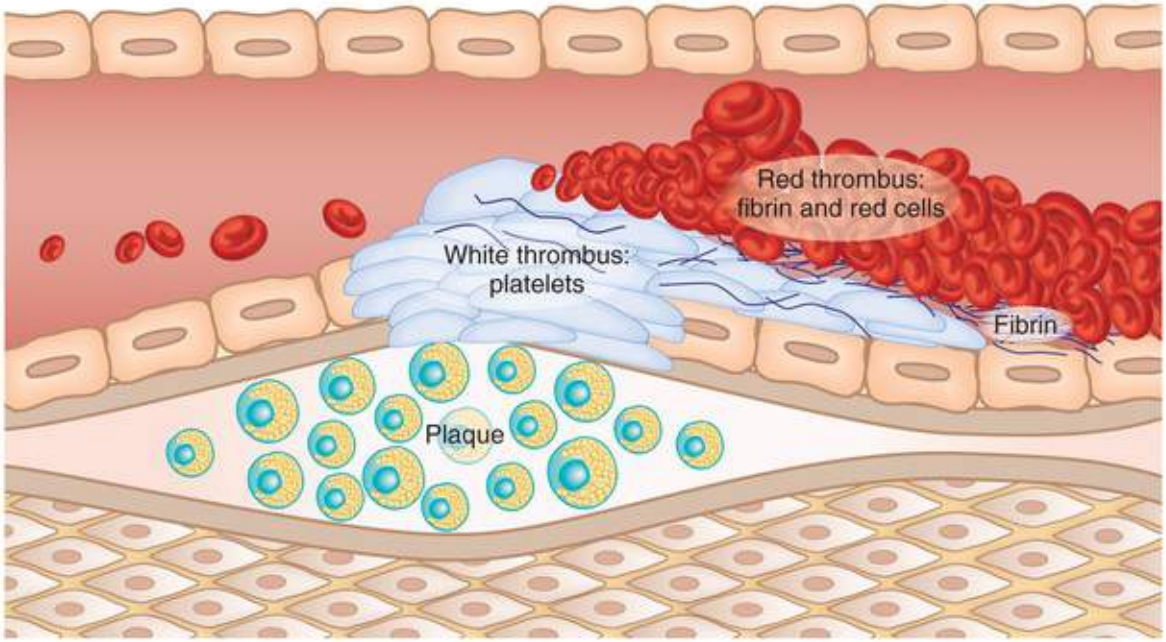
Patients Not Eligible for Reperfusion Therapy

Aspirin and antithrombin therapy can be prescribed for patients who are not candidates for acute reperfusion because of lack of availability of PCI and contraindications to fibrinolysis. In the setting of absolute contraindications to fibrinolysis (**see Table 59.3**) and lack of access to PCI facilities, antithrombotic therapy should be initiated because of the small but finite chance (approximately 10%) of restoring TIMI grade 3 flow in the infarct vessel and decreasing the chance of thrombotic complications of STEMI.

Anticoagulant and Antiplatelet Therapy

Anticoagulant Therapy

The rationale for administering anticoagulant therapy acutely to patients with STEMI includes establishing and maintaining patency of the infarct-related artery, regardless of whether a patient receives fibrinolytic therapy (**eFig. 59.6**), and preventing deep venous thrombosis, pulmonary embolism, ventricular thrombus formation, and cerebral embolization.



EFIGURE 59.6 Targets for therapy during reperfusion of patients with STEMI. This schematic view shows a longitudinal section of an infarct-related artery at the level of the obstructive thrombus. Following rupture of a vulnerable plaque (*bottom center*), the coagulation cascade activates, which ultimately leads to the deposition of fibrin strands; platelets also activate and begin to aggregate. Platelets that aggregate with incorporation of relatively few red cells form a white thrombus. The mesh of fibrin strands and platelet aggregates obstructs flow in the infarct-related artery. Pharmacologic reperfusion is a multipronged approach consisting of fibrinolytic agents that digest fibrin, anticoagulants that prevent the formation of thrombin and inhibit the activity of formed thrombin, and antiplatelet therapy. (Modified from Jackson SP. Arterial thrombosis—insidious, unpredictable, and deadly. Nat Med 2011;17:1423.)

Effect of Heparin on Mortality

Randomized trials of patients with STEMI conducted in the prefibrinolytic era showed a lower risk for reinfarction, pulmonary embolism, and stroke in those who received IV heparin, thus supporting the administration of heparin to STEMI patients not treated with fibrinolytic therapy. With the introduction of the fibrinolytic era and, importantly, after publication of the ISIS-2 (Second International Study of Infarct Survival) trial, the situation became more complicated because of strong evidence of a substantial reduction in mortality with aspirin alone and confusing and conflicting data regarding the risk/benefit ratio of heparin used as an adjunct to aspirin or in combination with aspirin and a fibrinolytic agent.[1] Nevertheless, a meta-analysis of trials in the fibrinolytic era suggested that for every 1000 patients treated with heparin versus aspirin alone, five fewer deaths ($P = 0.03$) and three fewer recurrent infarctions ($P = 0.04$) occur, but at the expense of three more major bleeding episodes ($P = 0.001$).[71]

Other Effects of Heparin.

Several angiographic studies have examined the role of heparin therapy in establishing and maintaining patency of the infarct-related artery in patients with STEMI. Although evidence favoring the use of heparin in conjunction with a fibrin-specific fibrinolytic agent for enhancing patency of the infarct artery is not conclusive, the suggestion of a mortality benefit and amelioration of LV thrombi after STEMI supports the use of heparin for at least 48 hours after fibrinolysis.[1]

The most serious complication of anticoagulant therapy is bleeding (**see Chapter 93**), especially intracranial hemorrhage. Major hemorrhagic events occur more frequently in patients with low body weight, advanced age, female sex, marked prolongation of the activated partial thromboplastin time

(APTT) (>90 to 100 seconds), and performance of invasive procedures.[72] Frequent monitoring of the APTT reduces the risk for major hemorrhagic complications in patients treated with heparin. During the first 12 hours after fibrinolytic therapy, however, the APTT may be elevated as a result of the fibrinolytic agent alone (particularly if streptokinase is administered), thus making it difficult to interpret accurately the effects of a heparin infusion on the patient's coagulation status.

Disadvantages of Heparin.

Potential disadvantages of unfractionated heparin (UFH) include dependency on antithrombin III for inhibition of thrombin activity, sensitivity to platelet factor 4, inability to inhibit clot-bound thrombin, marked interpatient variability in therapeutic response, and the need for frequent monitoring of the APTT. Even with standardized weight-based dosing nomograms, less than 35% of initial APTT measurements are within the therapeutic range.[73] Several alternative anticoagulants can circumvent these disadvantages of UFH.

Hirudin and Bivalirudin

In patients undergoing fibrinolysis, direct thrombin inhibitors such as hirudin or bivalirudin reduce the incidence of recurrent MI by 25% to 30% compared with heparin but have not reduced mortality. In addition, both hirudin and bivalirudin cause higher rates of major bleeding than heparin when used with fibrinolytic agents.[74]

In contrast, when administered for a short period as an adjunct to primary PCI in the HORIZONS-AMI (Harmonizing Outcomes with Revascularization and Stents in Acute Myocardial Infarction) trial, bivalirudin (open label), versus heparin plus glycoprotein (GP) IIb/IIIa inhibitors, reduced the 30-day rate of major bleeding or major adverse CV events, including death, reinfarction, target vessel revascularization for ischemia, and stroke (RR, 0.76; 95% CI 0.63 to 0.92; $P = 0.005$), driven by a significant 40% reduction in major bleeding (**eFig. 59.7**). Treatment with bivalirudin significantly reduced mortality at 30 days and at 1 year, but increased the early risk for stent thrombosis .[72] Similarly, in the EUROMAX (European Ambulance Acute Coronary Syndrome Angiography) trial, when started during transport for primary PCI in STEMI, bivalirudin reduced the primary outcome of death or major bleeding compared to heparin with optional GP IIb/IIIa, with a reduction in major bleeding but increase in stent thrombosis.[75] However, there was no significant difference in mortality. A meta-analysis of 16 randomized controlled trials (RCTs), including four with predominantly STEMI patients, reported an increased risk of major adverse cardiovascular events (MACE) (RR, 1.09; 95% CI 1.01 to 1.17; $P = 0.0204$), primarily from increases in MI, ischemia-driven revascularization, and acute stent thrombosis (**Fig. 59.12**). There was no difference in mortality, and bleeding rates were generally lower with bivalirudin, with the magnitude of the reduction dependent on GP IIb/IIIa co-administration.[76] The findings were consistent in the subset with STEMI.

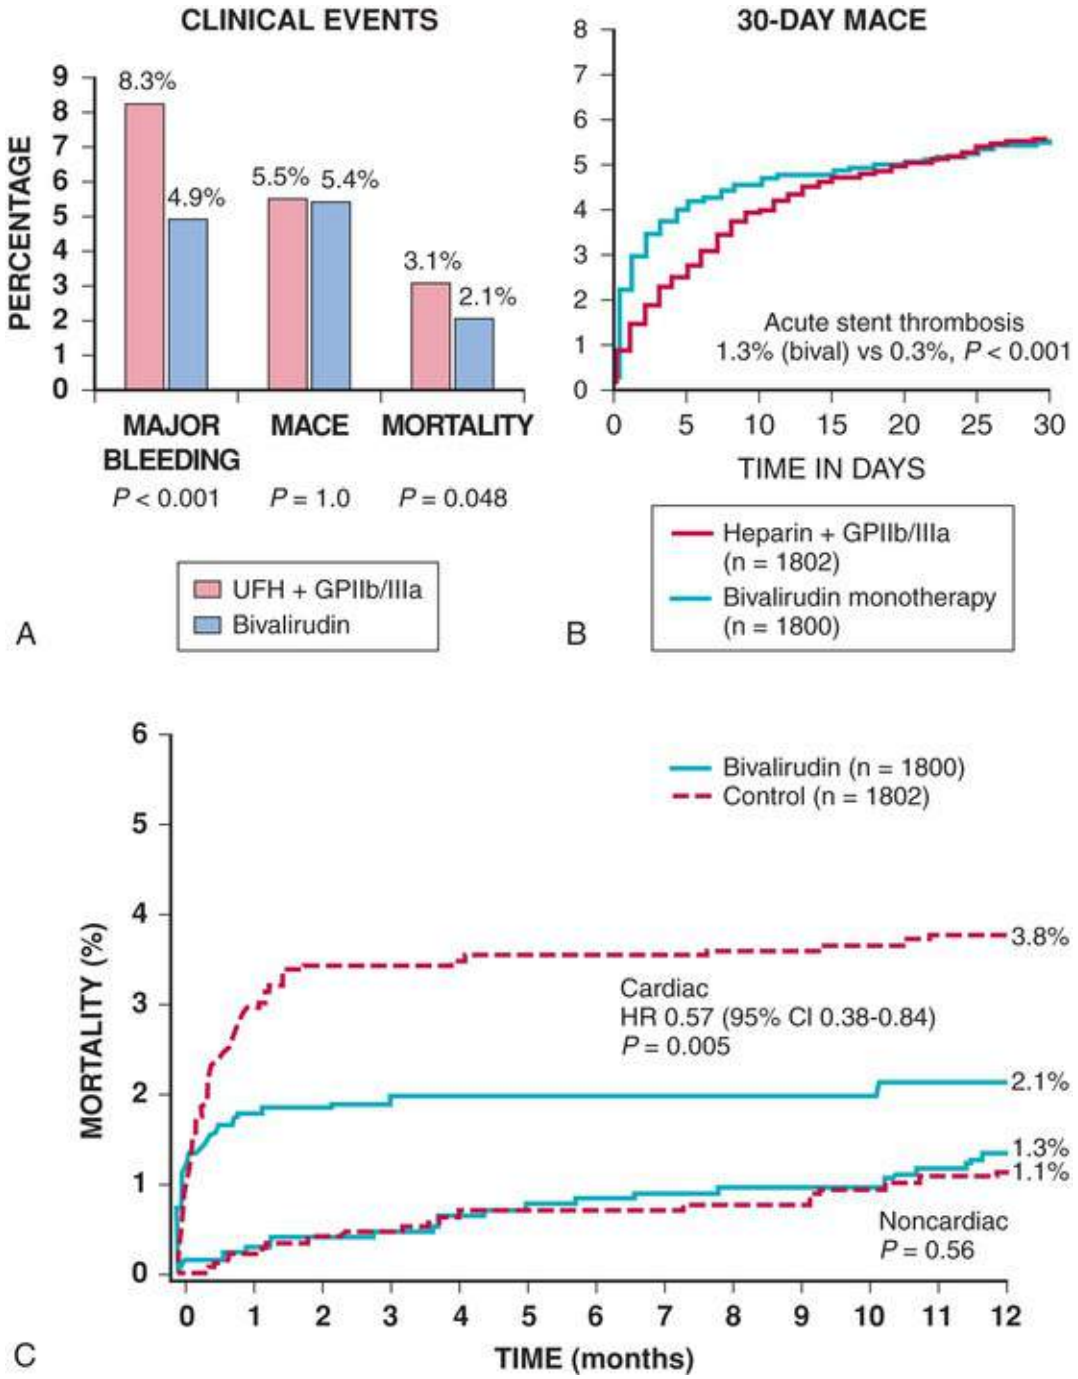
D

FIGURE 59.12 Meta-analysis of 33,958 patients from 16 randomized trials of bivalirudin versus heparin

during PCI. There was an increase in the risk of major adverse cardiac events (MACE) at 30 days with bivalirudin-based regimens compared with heparin-based regimens (risk ratio, 1·09; 95% CI 1·01 to 1·17; *P* = 0·0204) in the overall study population **(A).** While there was no difference in death or ischemia-driven revascularization, there was a significant increase in MI and acute stent thrombosis in the overall study population with bivalirudin-based regimens versus heparin-based regimens. There was a similar 10% increase in MACE **(B)** and numerically larger relative risk of stent thrombosis (risk ratio, 2.25; 95% CI 1.07 to 4.71) **(C)** in the four trials predominantly enrolling STEMI patients. Overall, bivalirudin-based regimens lowered the risk of major bleeding (risk ratio, 0.62; 95% CI 0.49 to 0.78; *P* < 0.0001), but the magnitude of this effect varied depending on whether glycoprotein IIb/IIIa inhibitors (GPI) were used predominantly in the heparin arm only, provisionally in both arms, or planned in both arms **(D).** (Modified from Cavender M, Sabatine MS. Bivalirudin versus heparin in patients planned for percutaneous coronary intervention: a meta-analysis of randomised controlled trials. Lancet. 2014:384(9943):599-606.)



EFIGURE 59.7 Results of an open-label randomized clinical trial comparing bivalirudin to unfractionated heparin (UFH) and a GP IIb/IIIa receptor antagonist as adjunctive medical therapy to support primary PCI in patients with STEMI. **A,** Treatment with bivalirudin was associated with significantly lower rates of major bleeding and mortality at 30 days. **B,** Kaplan-Meier curves of the cumulative incidence of major adverse cardiac events (MACE) did not differ between the two strategies at 30 days. **C,** Acute stent thrombosis during the first 24 hours was higher in patients treated with bivalirudin alone, but cardiovascular mortality was reduced in the bivalirudin group after 1 year of follow-up, thus providing strong evidence for this treatment strategy. (From Stone GW, Witzenbichler B, Guagliumi G, et al. Bivalirudin during primary PCI in acute myocardial infarction. N Engl J Med 2008;358:2218; and Mehran R, Lansky AJ, Witzenbichler B. Bivalirudin in patients undergoing primary angioplasty for acute myocardial infarction (HORIZONS-AMI): 1-year results of a randomized controlled trial. Lancet 2009;374:1149.)

Low-Molecular-Weight Heparins

Advantages of low-molecular-weight heparins (LMWHs) include a stable, reliable anticoagulant effect, high bioavailability permitting administration via the subcutaneous (SC) route, and a high anti-Xa/anti-IIa ratio producing blockade of the coagulation cascade in an upstream location and greatly reducing thrombin generation. The primary role of LMWH for management of STEMI is as an adjunct to

fibrinolytic therapy. Although LMWHs do not improve the rate of early (60 to 90 minutes) reperfusion of the infarct artery, LMWH reduces rates of reocclusion of the infarct artery, reinfarction, or recurrent ischemic events.[77] This effect may underlie the significant reduction in recurrent MI with a strategy of extended anticoagulation with LMWHs, or a factor Xa antagonist versus standard therapy, in patients with STEMI undergoing fibrinolysis.

When compared with placebo, the LMWH reviparin significantly reduced the incidence of death, recurrent MI, or stroke at 30 days in 15,570 patients with STEMI, 73% of whom received a fibrinolytic (predominantly a non–fibrin-specific agent).[78] This important finding demonstrates not only that LMWHs are clinically effective for STEMI, but also that a clinical anticoagulant therapy provides benefit as part of a fibrinolytic reperfusion strategy.

Several trials have compared a LMWH with UFH as part of a pharmacologic reperfusion strategy and demonstrated the LMWH to be superior.[78] In the ASSENT (Assessment of the Safety and Efficacy of a New Thrombolytic) 3 trial, enoxaparin (30-mg IV bolus, followed by SC injections of 1 mg/kg every 12 hours until discharge from the hospital)[79] reduced 30-day mortality, in-hospital reinfarction, or in-hospital refractory ischemia compared with UFH (RR, 0.74; 95% CI 0.63 to 0.87). The rate of intracranial hemorrhage was similar with UFH and enoxaparin (0.93% versus 0.88%; $P = 0.98$). The ExTRACT-TIMI 25 (Enoxaparin and Thrombolysis Reperfusion for Acute Myocardial Infarction Treatment–Thrombolysis in Myocardial Infarction 25) trial tested in a double-blind, double-dummy design the hypothesis that a strategy of enoxaparin (adjusted for age and renal function) administered for the duration of the index hospitalization was superior to the conventional antithrombin strategy of UFH administration for 48 hours after fibrinolysis.[80] The primary endpoint of death or recurrent nonfatal MI through 30 days was reduced by 17% ($P = 0.001$; **Fig. 59.13A**) with enoxaparin compared with UFH, with a 33% reduction ($P = 0.001$) in reinfarction and a nonsignificant favorable trend on overall mortality ($P = 0.11$). This improvement in recurrent MI was balanced by an increase in the incidence of major bleeding (1.4% and 2.1%, $P = 0.001$). In a meta-analysis of trials of LMWH versus UFH, LMWH clearly reduced recurrent MI but with a pattern of increased bleeding (**Fig. 59.13B**).

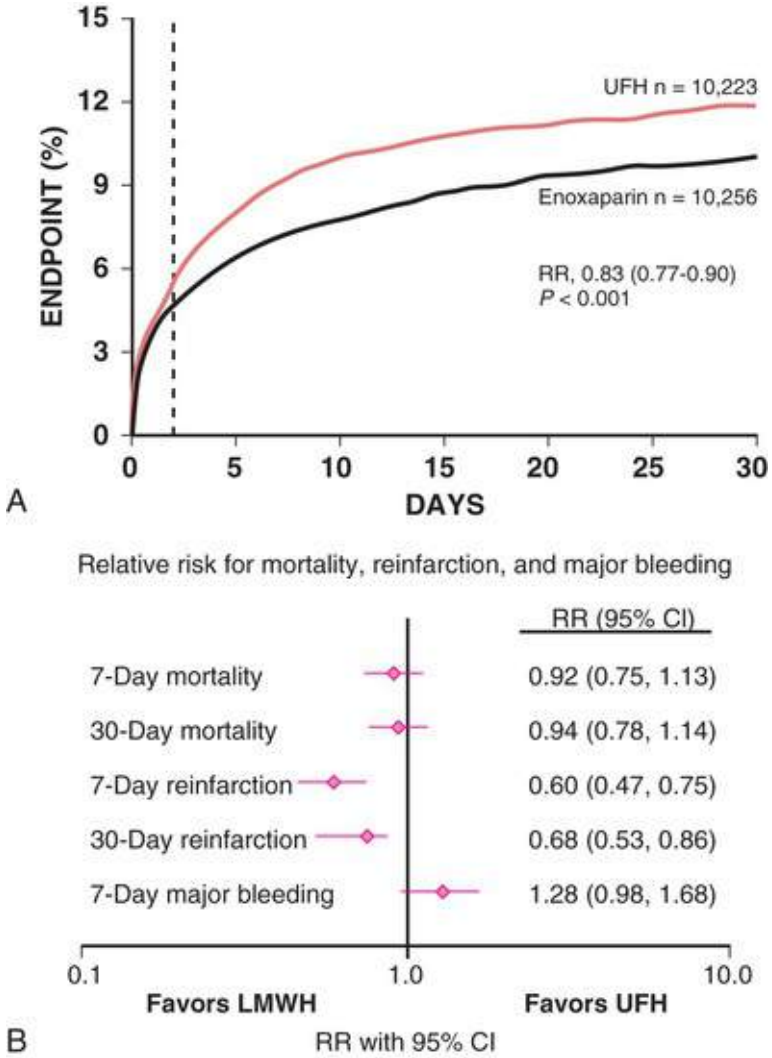


FIGURE 59.13 Comparison of enoxaparin with unfractionated heparin (UFH) as adjunctive therapy in patients with STEMI receiving fibrinolysis. **A,** Primary results from the ExTRACT-TIMI 25 trial showing that the rate of the primary endpoint (death or nonfatal MI) at 30 days was significantly lower in the enoxaparin group than in the UFH group (9.9% versus 12%, *P* <0.001 by log-rank test). The *dashed vertical line* indicates the comparison at day 2 (direct pharmacologic comparison), at which time a trend in favor of enoxaparin was seen. **B,** Results of a meta-analysis of seven randomized controlled clinical trials of low-molecular-weight heparin (LMWH) versus UFH, including 27,577 patents with STEMI. Individual outcomes of all-cause death, reinfarction, and major bleeding through 7 days are shown. (From Antman EM et al. Enoxaparin versus unfractionated heparin with fibrinolysis for ST-elevation myocardial Infarction. N Engl J Med 2006;354:1477; and Singh S et al. Adjunctive low molecular weight heparin during fibrinolytic therapy in acute ST-elevation myocardial infarction: a meta-analysis of randomized control trials. Clin Cardiol 2009;32:358.)

Parenteral Factor Xa Antagonists

The OASIS-6 (Organization for the Assessment of Strategies for Ischemic Syndromes) trial evaluated the specific factor Xa antagonist fondaparinux (2.5 mg subcutaneously) in 12,092 patients with STEMI.[81] The trial design compared fondaparinux given for 8 days with placebo in patients when the treating physician thought that UFH was not indicated (stratum I) and with UFH for 48 hours when the treating physician thought that heparin was indicated (stratum II). Fondaparinux reduced the composite of death or reinfarction in stratum I (hazard ratio [HR], 0.79; 95% CI, 0.68 to 0.92), but not in stratum II (HR, 0.96; 95% CI, 0.81 to 1.13). The outcome of patients in stratum II who underwent PCI tended to be worse with fondaparinux than with UFH, probably because of an increased risk for catheter thrombosis.

Oral Factor IIa and Factor Xa Antagonists

See later section, Secondary Prevention of Acute Myocardial Infarction.

Recommendations for Anticoagulant Therapy

Anticoagulation With Fibrinolysis.

Given the pivotal role of thrombin in the pathogenesis of STEMI (**eFig. 59.6**), antithrombotic therapy remains an important intervention. A regimen of an IV UFH bolus of 60 units/kg to a maximum of 4000 units, followed by an initial infusion at 12 units/kg/hr to a maximum of 1000 units/hr for 48 hours, adjusted to maintain the APTT at 1.5 to 2 times control (approximately 50 to 70 seconds), is effective in patients receiving fibrinolytic therapy.[1]

Both the ExTRACT-TIMI 25 and the OASIS-6 trials indicated that prolonged administration of an anticoagulant for the duration of hospitalization is beneficial compared with the previous practice of administering UFH only for 48 hours unless clear-cut indications for continued anticoagulation were present. Accordingly, patients managed with pharmacologic reperfusion therapy should receive anticoagulant therapy for a minimum of 48 hours and preferably for the duration of hospitalization after STEMI, up to 8 days. Enoxaparin or fondaparinux is preferred when administration of an anticoagulant for longer than 48 hours is planned in patients with STEMI treated with a fibrinolytic.[1] Enoxaparin should be administered according to age, weight, and creatinine clearance and be given as an IV bolus, followed in 15 minutes by SC injection for the duration of the index hospitalization, up to 8 days or until revascularization. Fondaparinux should be administered as an initial IV dose, followed in 24 hours by daily SC injections if the estimated creatinine clearance is higher than 30 mL/min. If PCI is performed in a patient treated with fondaparinux, co-administration of an additional antithrombin agent with anti–factor IIa activity is required to mitigate the risk of catheter-related thrombosis.

In patients with a known history of heparin-induced thrombocytopenia, bivalirudin in conjunction with streptokinase is a useful alternative to heparin.[1] For patients who are referred for CABG, UFH is the preferred antithrombin.

Adjunctive Anticoagulation for Primary PCI (See Chapter 62).

Either UFH or bivalirudin is recommended as an anticoagulant to support primary PCI, with preference for bivalirudin or heparin without a concomitant GP IIb/IIIa inhibitor for patients at high risk for bleeding.[1,76] Fondaparinux is not recommended as the sole anticoagulant in this setting.[1] LMWH has not had sufficient evaluation in primary PCI to formulate recommendations for treatment. Some investigators who have used enoxaparin to support primary PCI for STEMI administer 0.5 mg/kg intravenously at the time of the procedure.

Patients Treated Without Reperfusion Therapy.

Treatment with an anticoagulant is reasonable, and agents shown to be more effective than UFH in other groups with STEMI may be preferable. For example, in patients with STEMI not receiving reperfusion therapy, fondaparinux reduces the composite of death or recurrent MI without an increase in severe bleeding, compared with placebo or UFH.[82]

Antiplatelet Therapy

Platelets play a major role in the response to disruption of coronary artery plaque, especially in the early phase of thrombus formation. Fibrinolysis can activate platelets, and platelet-rich thrombi resist

fibrinolysis more than fibrin and erythrocyte-rich thrombi (**eFig. 59.6**). Thus a sound scientific basis exists for inhibiting platelet aggregation in *all* patients with STEMI, regardless of the reperfusion management strategy. The agent most extensively tested has been aspirin, and treatment with aspirin and a second antiplatelet agent, such as clopidogrel, prasugrel, ticagrelor, or cangrelor, has become the standard of care for patients with STEMI.

Antiplatelet Therapy with Fibrinolysis

The ISIS-2 study was the largest trial of aspirin in patients with STEMI; it provided the single strongest piece of evidence that aspirin reduces mortality in such patients.[83] In contrast to the observations of a time-dependent mortality effect of fibrinolytic therapy, the reduction in mortality with aspirin was similar in patients treated within 4 hours (25% reduction in mortality), between 5 and 12 hours (21% reduction), and between 13 and 24 hours (21% reduction). An overall 23% reduction in mortality with aspirin occurred in ISIS-2 that was largely additive to the 25% reduction in mortality from streptokinase, such that patients receiving both therapies experienced a 42% reduction in mortality. The reduction in mortality was as high as 53% in patients who received both aspirin and streptokinase within 6 hours of symptoms.

Obstructive platelet-rich arterial thrombi resist fibrinolysis and have an increased tendency for reocclusion after initial successful reperfusion in patients with STEMI. Despite inhibition of cyclooxygenase (COX) by aspirin, platelet activation leading to platelet aggregation and increased thrombin formation continues through thromboxane A_2–independent pathways. Adding other antiplatelet agents to aspirin has benefited patients with STEMI.[72] Inhibitors of the $P2Y_{12}$ adenosine diphosphate receptor help prevent the activation and aggregation of platelets. In the CLARITY-TIMI (Clopidogrel as Adjunctive Reperfusion Therapy–Thrombolysis in Myocardial Infarction) 28 trial, addition of the $P2Y_{12}$ inhibitor clopidogrel to background treatment with aspirin in patients with STEMI who were younger than 75 years and received fibrinolytic therapy reduced the risk for clinical events (death, reinfarction, stroke) and reocclusion of a successfully reperfused infarct artery (**Fig. 59.14A**).[72] An ST Resolution (STRes) electrocardiographic substudy from CLARITY-TIMI 28 provided insight into the mechanism of the benefit of clopidogrel in STEMI. No difference was seen in the rate of complete STRes between the clopidogrel and placebo groups at 90 minutes (38.4% versus 36.6%). When patients were stratified by STRes category, treatment with clopidogrel resulted in greater benefit in those with evidence of early STRes, with greater odds of having an open artery at late angiography in patients with partial (OR, 1.4; $P = 0.04$) or complete (OR, 2.0; $P = 0.001$) STRes, but no improvement in those with no STRes evident at 90 minutes (OR, 0.89; $P = 0.48$) (P for interaction = 0.003). Clopidogrel also associated with a significant reduction in the odds for in-hospital death or MI in patients who achieved partial (OR, 0.30; $P = 0.003$) or complete STRes at 90 minutes (OR, 0.49; $P = 0.056$), whereas clinical benefit was not apparent in patients who had no STRes (OR, 0.98; $P = 0.95$) (P for interaction = 0.027). Thus it appears that clopidogrel did not increase the rate of complete opening of occluded infarct arteries when fibrinolysis was administered, but was effective in preventing reocclusion of an initially reperfused infarct artery.

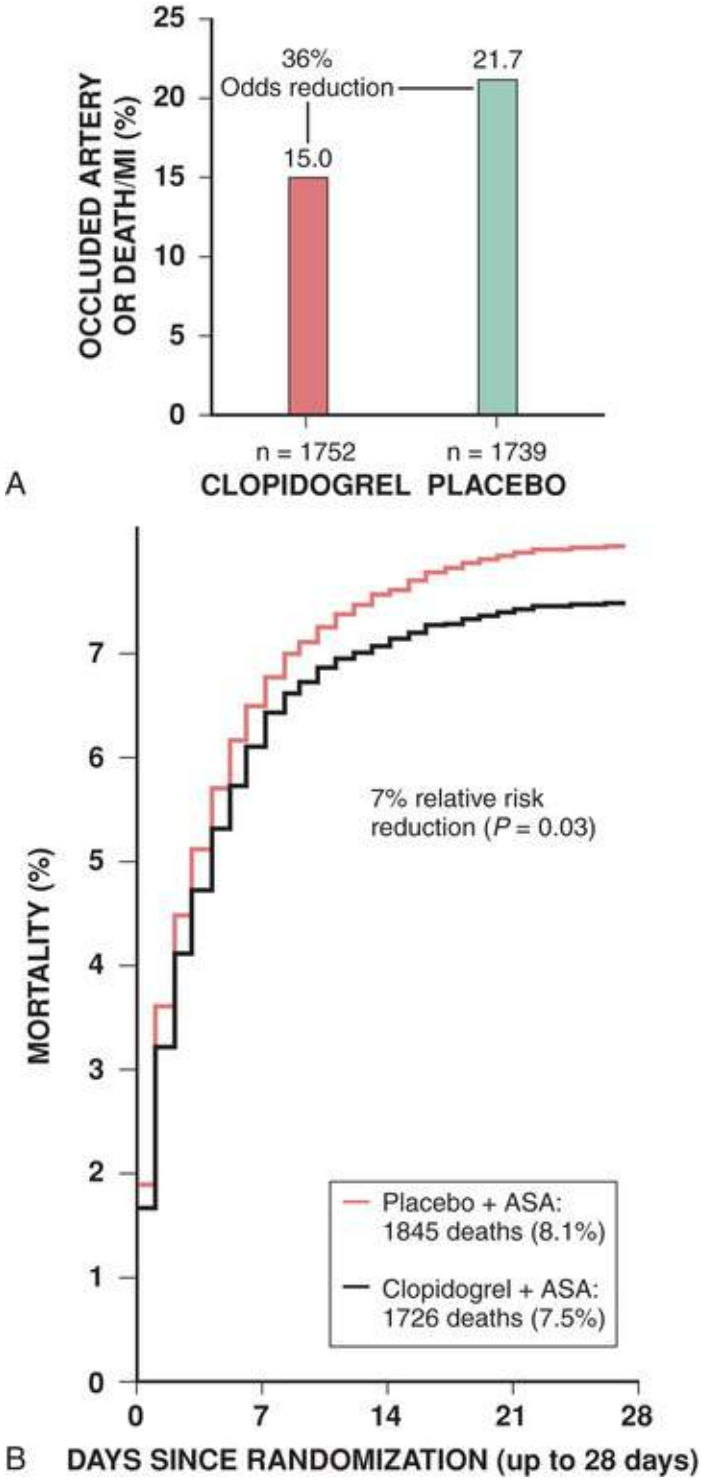

FIGURE 59.14 Impact of the addition of clopidogrel to aspirin (ASA) in patients with STEMI. **A,** Effects of the addition of clopidogrel in patients receiving fibrinolysis for STEMI. Patients in the clopidogrel group (*n* = 1752) had a 36% reduction in the odds of dying, sustaining a recurrent infarction, or having an occluded infarct artery compared with the placebo group (*n* = 1739) in the CLARITY-TIMI 28 trial. **B,** Effect of the addition of clopidogrel on in-hospital mortality after STEMI. These time-to-event curves show a 0.6% reduction in mortality in the group receiving clopidogrel plus aspirin (*n* = 22,961) versus placebo plus aspirin (*n* = 22,891) in the COMMIT trial. (**A,** Modified from Sabatine MS et al. Addition of clopidogrel to aspirin and fibrinolytic therapy for myocardial infarction with ST-segment elevation. N Engl J Med 2005;352:1179; **B,** modified from Chen ZM et al. Addition of clopidogrel to aspirin in 45,852 patients with acute myocardial infarction: randomised placebo-controlled trial. Lancet 2005;366:1607.)

In COMMIT (Clopidogrel and Metoprolol in Myocardial Infarction Trial), 45,852 patients with suspected MI were randomly assigned to clopidogrel, 75 mg/day (without a loading dose), or placebo in addition to aspirin, 162 mg/day[72] (**Fig. 59.14B**). Patients in the clopidogrel group had a lower rate of the composite endpoint of death, reinfarction, or stroke (9.2% versus 10.1%; *P* = 0.002). They also had a

significantly lower rate of death (7.5% versus 8.1%; *P* = 0.03). No excessive bleeding with clopidogrel occurred in this trial.

Combination Pharmacologic Reperfusion

Trials of GP IIb/IIIa inhibitors combined with either full or reduced doses of fibrinolytics showed improvements in reperfusion, including myocardial perfusion as reflected in enhanced STRes and faster angiographic frame counts. However, subsequent large outcomes trials revealed no significant effect on survival, and reductions in reinfarction were outweighed by the increases in bleeding.[79] The combination of a GP IIb/IIIa inhibitor and a fibrinolytic as a pharmacologic reperfusion regimen is therefore not recommended.[1]

Antiplatelet Therapy for PCI in ST-Elevation Myocardial Infarction

All patients with STEMI should receive aspirin as soon as possible after initial encounter in the absence of contraindications. Adding the $P2Y_{12}$ inhibitor clopidogrel to aspirin appears to offer additional benefit in patients undergoing PCI after STEMI. In patients undergoing either primary PCI or delayed PCI after initial therapy for STEMI, the more potent $P2Y_{12}$ inhibitor prasugrel was superior to clopidogrel in reducing the risk for CV death, MI, or stroke.[72] In the subgroup of patients with STEMI enrolled in TRITON-TIMI 38 (Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel–Thrombolysis in Myocardial Infarction; *n* = 3534), the primary endpoint was lowered by 32% at 30 days with prasugrel compared with aspirin (6.5% versus 9.5%; *P* = 0.0017) and by 21% at 15 months (10.0% versus 12.4%; *P* = 0.022) (**Fig. 59.15**).[84] Prasugrel reduced definite or probable stent thrombosis by 42% compared with clopidogrel. Analogously, in the PLATO (Platelet Inhibition and Patient Outcomes) trial, compared with clopidogrel, treatment with the reversible $P2Y_{12}$ inhibitor ticagrelor in patients with STEMI undergoing primary PCI (*n* = 7544) tended to reduce the primary endpoint of CV death, recurrent MI, or stroke by 13%, a magnitude similar to that for the overall trial population (**Fig. 59.15**); there was a 26% reduction in definite or probable stent thrombosis and an 18% reduction in all-cause mortality.[85]

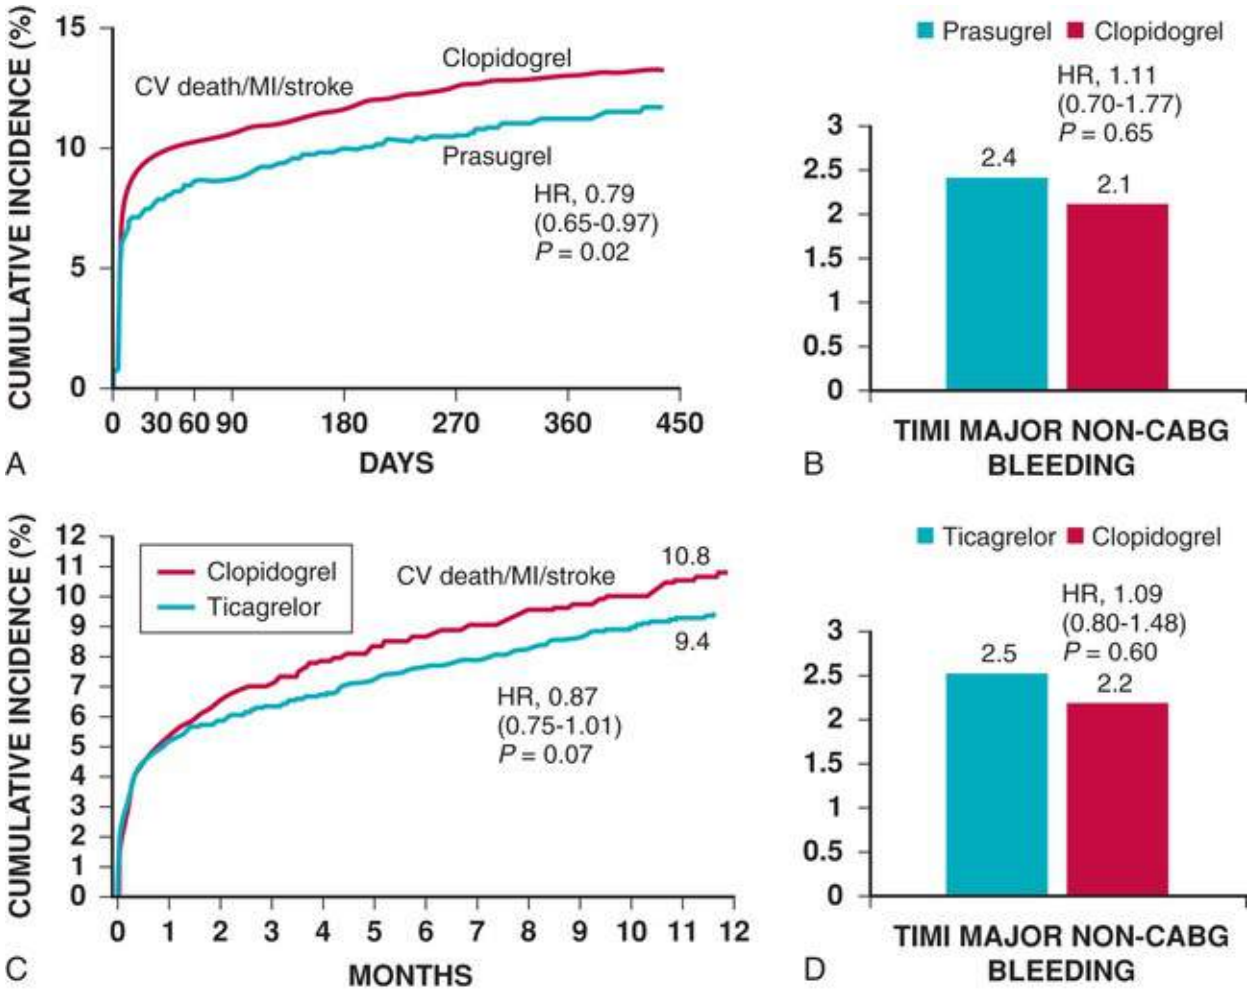

FIGURE 59.15 **A,** Efficacy of prasugrel in the subgroup of patients with STEMI enrolled in a randomized clinical trial of prasugrel versus clopidogrel in patients undergoing PCI after an ACS. Treatment with prasugrel associated with a 21% relative reduction in the risk for cardiovascular (CV) death, MI, or stroke during 15 months of follow-up. **B,** Major bleeding (TIMI non-CABG) increased with prasugrel in the trial overall, but did not reach statistical significance in patients with STEMI. **C,** Efficacy results for ticagrelor (versus clopidogrel) in patients with STEMI enrolled in the PLATO trial. The effect of ticagrelor on the primary endpoint (incidence of MI, stroke, or CV death) was consistent with the superiority of ticagrelor versus clopidogrel in the overall trial. **D,** Rates of major bleeding (TIMI non-CABG) are shown. CABG, Coronary artery bypass grafting. (**A, B,** From Montalescot G et al. Prasugrel compared with clopidogrel in patients undergoing percutaneous coronary intervention for ST-elevation myocardial infarction [TRITON-TIMI 38]: double-blind, randomised controlled trial. Lancet 2009;373:723; **C, D,** from Steg PG et al. Ticagrelor versus clopidogrel in patients with ST-elevation acute coronary syndromes intended for reperfusion with primary percutaneous coronary intervention: a Platelet Inhibition and Patient Outcomes (PLATO) trial subgroup analysis. Circulation 2010;122:2131.)

Evidence regarding the appropriate timing of initiation of $P2Y_{12}$ inhibitor therapy before PCI for STEMI is mixed. As part of the PCI-CLARITY (PCI-Clopidogrel as Adjunctive Reperfusion Therapy) study, the investigators performed a meta-analysis of PCI-CLARITY, PCI-CURE (PCI-Clopidogrel in Unstable angina to prevent Recurrent Events), and CREDO (Clopidogrel for the Reduction of Events During Observation) and found that pretreatment with clopidogrel significantly reduced the risk for 30-day CV death or MI in a population that included both patients with STEMI and non–ST elevation ACS.[1,72] In a subsequent meta-analysis that included data from randomized trials and registries, higher-risk STEMI patients had a lower risk for major coronary events with clopidogrel pretreatment, but not a reduction in mortality or an increase in bleeding.[86] Prehospital administration of ticagrelor did not improve the primary endpoint of coronary reperfusion, but did reduce the secondary endpoint of stent thrombosis without any additional bleeding, compared to in-hospital administration in patients with STEMI undergoing primary PCI in the ATLANTIC trial (Administration of Ticagrelor in the Cath Lab or in the Ambulance for New ST Elevation Myocardial Infarction to Open the Coronary Artery).[87] **Chapter**

62 discusses the use of GP IIb/IIIa inhibitors as part of adjunctive therapy for patients with STEMI undergoing PCI.

Recommendations for Antiplatelet Therapy

Patients who have not taken aspirin before the development of STEMI should chew non–enteric-coated aspirin, and the dose should be 162 to 325 mg initially. During the maintenance phase of antiplatelet therapy following STEMI, the dose of aspirin should be reduced to 75 to 162 mg to minimize the risk for bleeding.[1] Lower doses are preferable because of the increased risk for bleeding with higher doses reported in several studies; the CURRENT-OASIS 7 trial did not find differences in terms of efficacy or safety in STEMI patients randomly assigned to 81 versus 325 mg of aspirin. If true aspirin allergy is present, other antiplatelet agents such as clopidogrel or ticlopidine can be substituted.
