The addition of a $P2Y_{12}$ inhibitor to aspirin is warranted in most patients with STEMI.[1] Based on the results of the COMMIT and CLARITY-TIMI 28 trials, clopidogrel, 75 mg/day orally, is an option for all patients with STEMI regardless of whether they receive fibrinolytic therapy, undergo primary PCI, or do not receive reperfusion therapy. The data available suggest that a loading dose of 300 mg of clopidogrel should be given to patients younger than 75 years who receive fibrinolytic therapy. Data are insufficient in elderly patients to recommend a loading dose in those 75 years or older who receive a fibrinolytic. When primary PCI is the mode of reperfusion therapy, an oral loading dose of 600 mg of clopidogrel before stent implantation is an established treatment, followed by 75 mg daily.[1,88] Interpatient variability in the response to clopidogrel can occur (**see Chapters 8, 60, and 93**), and individuals with lesser degrees of platelet inhibition have increased risk for death and ischemic complications.[89]

Prasugrel and ticagrelor generally achieve greater degrees of platelet inhibition than clopidogrel and can be used to treat patients with STEMI. On the basis of the results of TRITON-TIMI 38, prasugrel administered as an oral loading dose of 60 mg and 10 mg daily thereafter demonstrated benefit in patients with STEMI, but should not be used in patients with a history of cerebrovascular disease or who are at higher risk for life-threatening bleeding.[1] Ticagrelor also reduced CV events compared with clopidogrel, and in PLATO, ticagrelor was administered as an oral loading dose of 180 mg and then 90 mg twice daily.[1,85] When using ticagrelor, the recommended maintenance dose of aspirin is 81 mg daily.[1]

Hospital Management

Coronary Care and Intermediate Care Units

Development of the coronary care unit (CCU) established the practice of continuous monitoring of cardiac rhythm by highly trained nurses with the skills and authority to initiate immediate treatment of arrhythmias in the absence of physicians and with the availability of specialized equipment (defibrillators, pacemakers).[90] The clustering of patients with STEMI in the CCU greatly enhanced efficient use of the trained personnel, facilities, and equipment to improve patient outcomes.[90] These benefits of geographic clustering with specialized nursing contribute to the optimal care of patients with STEMI, and in some hospitals, such care can be provided in “intermediate care” telemetry units with well-trained staff outside the CCU.[91] Such intermediate care units, when equipped with continuous electrocardiographic monitoring and resuscitation equipment, may be appropriate for initial admission of STEMI patients with a low risk for mortality. This strategy has proved cost-effective and may reduce CCU use by one third, shorten hospital stays, and have no deleterious effect on patients' recovery.[1]

With increasing attention directed to limitations on resources and to the economic impact of intensive care, the proportion of appropriately selected patients with STEMI cared for in an intermediate care unit will likely increase. Nevertheless, a dedicated cardiac intensive care unit (CICU) plays a pivotal role in the management of patients with major complications of STEMI, who may require treatment of refractory arrhythmias, use of invasive hemodynamic monitoring, or mechanical circulatory support.[90] In patients with STEMI managed in a CICU, those with an uncomplicated status, such as patients without HF, hypotension, heart block, hemodynamically compromising ventricular arrhythmias, or persistent ischemic-type discomfort, can be safely transferred out of the CICU within 24 to 36 hours. In patients with complicated STEMI, the duration of the CICU stay should be dictated by the need for "intensive" care—that is, hemodynamic monitoring, close nursing supervision, IV vasoactive drugs, and frequent changes in the medical regimen.

General Measures

The managing clinical staff should be sensitive to patient concerns about prognosis and future productivity. A calm, quiet atmosphere can help allay anxiety and reduce adrenergic tone. Use of anxiolytic medications may be appropriate in some cases. To reduce the risk for nausea and vomiting early after infarction and to decrease the risk for aspiration, we find it prudent to limit the patient's diet to either nothing by mouth or clear liquids during the first 4 to 12 hours after admission. Thereafter, dietary intervention is an important component of an overall strategy for secondary prevention (**see Chapters 45 and 49**).

The results of laboratory tests should be scrutinized for any derangements potentially contributing to arrhythmias, such as disturbances in acid-base balance or electrolytes. Delirium can be provoked by medications frequently used in the hospital, including antiarrhythmic drugs, H_2 blockers, narcotics, and beta blockers. Use of potentially offending agents should be discontinued in patients with an abnormal mental status. Haloperidol, a butyrophenone, can be used safely in patients with STEMI. Stool softeners can prevent constipation and straining.

Physical Activity

In the absence of complications, stabilized patients with STEMI need not be confined to bed for more than 12 hours, and unless they are hemodynamically compromised, they may use a bedside commode shortly after admission. Progression of activity should be individualized depending on the patient's clinical status, age, and physical capacity. In patients without hemodynamic compromise, early mobilization (e.g., sitting in chair, standing, walking around bed) does not usually cause important changes in HR, BP, or pulmonary wedge pressure. As long as BP and HR are monitored, early mobilization offers considerable psychological and physical benefit without any clear medical risk.

Pharmacologic Therapy

Beta Blockers

Use of beta blockers for the treatment of patients with STEMI can cause both immediate effects (when the drug is given early in the course of infarction) and long-term effects (secondary prevention). Immediate IV administration of beta blockers reduces the cardiac index, HR, and BP.[92] The net effect is a reduction in myocardial oxygen consumption per minute and per beat. Favorable effects of acute IV administration of beta blockers on the balance of myocardial oxygen supply and demand are reflected in reductions in chest

pain, in the proportion of patients with threatened infarction in whom STEMI actually evolves, and in the development of ventricular arrhythmias. Because beta-adrenergic blockade diminishes circulating levels of free fatty acids (FFAs) by antagonizing the lipolytic effects of catecholamines, and because elevated FFA levels augment myocardial oxygen consumption and probably increase the incidence of arrhythmias, these metabolic actions of beta blockers may also benefit the ischemic heart. As noted earlier, because early administration of IV beta blockers can cause detrimental effects in some patients, the present guidelines omit this therapy for most patients.[1]

More than 52,000 patients have been randomly assigned to treatment in clinical trials studying beta-adrenergic blockade for acute MI.[1] These trials cover a range of beta blockers and timing of administration and were largely conducted in the era before reperfusion strategies were developed for STEMI. Data available in the pre-reperfusion era suggested favorable trends toward a reduction in mortality, reinfarction, and cardiac arrest. In the reperfusion era, adding an IV beta blockers to fibrinolytic therapy was not associated with a reduction in mortality but helped reduce the rate of recurrent ischemic events. Concern arose regarding the potential risk of provoking cardiogenic shock if early IV followed by oral beta-adrenergic blockade was routinely administered to all patients with STEMI. The largest trial of beta blockers in patients with acute MI was COMMIT, which randomly assigned 45,852 patients within 24 hours of MI to metoprolol given as sequential IV boluses of 5 mg up to 15 mg, followed by 200 mg/day orally, or to placebo.[1] The rate of the composite endpoint of death, reinfarction, or cardiac arrest in the metoprolol group (9.4%) did not differ from that in the placebo group (9.9%). Significant reductions occurred in reinfarction and episodes of VF in the metoprolol group, which translated into 5 fewer events for each of these endpoints per 1000 patients treated; yet there were 11 more episodes of cardiogenic shock in the metoprolol group per 1000 patients treated. Risk for the development of cardiogenic shock (recorded as part of COMMIT protocol, in contrast to earlier studies) was greatest in patients with moderate to severe LV dysfunction (Killip class II or greater).

The combined results of the low-risk patients from COMMIT and data from earlier trials provide an overview of the effects of early IV therapy followed by oral therapy with beta blockers (**Fig. 59.16**). A 13% reduction occurred in all-cause mortality (7 lives saved per 1000 patients treated), along with a 22% reduction in reinfarction (5 fewer events per 1000 patients treated) and a 15% reduction in VF or cardiac arrest (5 fewer events per 1000 patients treated). To achieve these benefits safely, early administration of beta blockers to patients with relative contraindications should be avoided (**Table 59.6**).

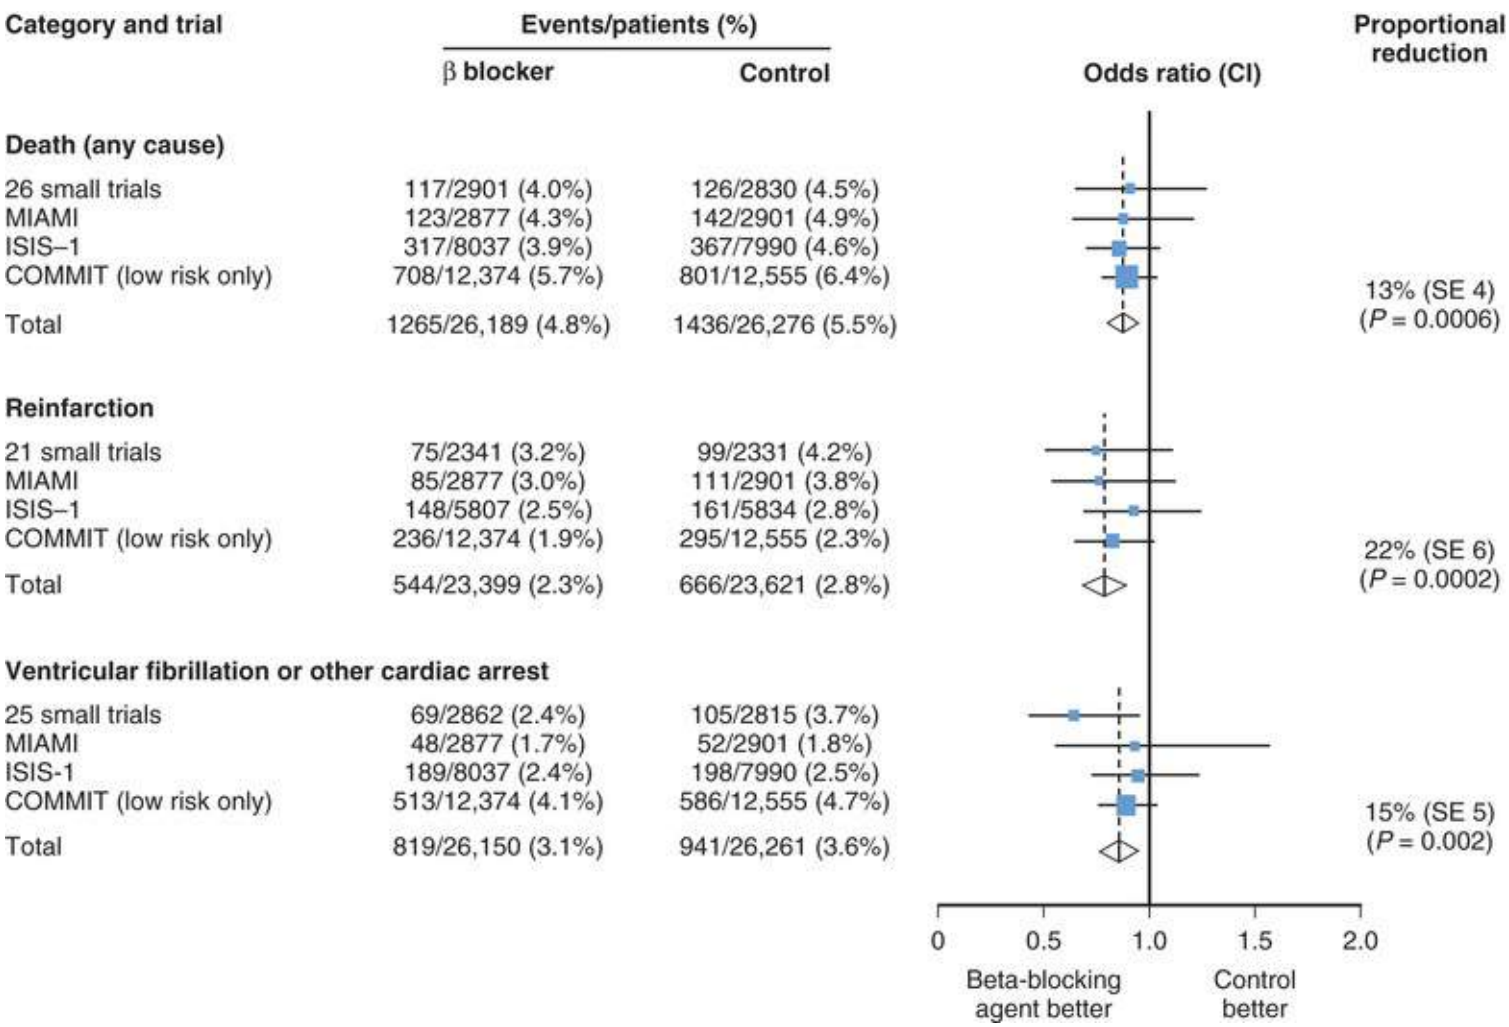

FIGURE 59.16 Meta-analysis of the effects of intravenous and then oral beta (β)-blocker therapy on death, reinfarction, and cardiac arrest during the scheduled treatment periods in 26 small randomized trials, MIAMI, ISIS-1, and the low-risk subset of COMMIT. For COMMIT, data are included only for patients with a systolic blood pressure higher than 105 mm Hg, a heart rate greater than 65 beats/min, and Killip class I (as in MIAMI). Five small trials included in the ISIS-1 report had no data on reinfarction. In the ISIS-1 trial, data on reinfarction in the hospital were available for the last three quarters of the study and involved 11,641 patients. ORs (odd ratios) in each (*blue squares* with the area proportional to the number of events) were determined by comparing outcomes in patients allocated to β-blocker therapy with those in patients allocated to control, along with 99% CIs (confidence intervals) *(horizontal lines).* Overall ORs and 95% CIs are plotted by the *diamonds,* with value and significance given alongside. (From Chen ZM, Pan HC, Chen YP, et al. Early intravenous then oral metoprolol in 45,852 patients with acute myocardial infarction: randomised placebo-controlled trial. Lancet 2005;366:1622.)

TABLE 59.6

Recommendations for Beta-Blocker Therapy for ST-Elevation Myocardial Infarction (STEMI)

RECOMMENDATION	COR	LOE
Oral beta blockers should be initiated in the first 24 hours in patients with STEMI who do not have any of the following: Signs of heart failure or evidence of a low-output state Increased risk for cardiogenic shock*: • Age >70 years • Systolic blood pressure <120 mm Hg • Sinus tachycardia >110 beats/min or heart rate <60 beats/min • Increased time since the onset of symptoms of STEMI Other relative contraindications to use of oral beta blockers: • PR interval longer than 0.24 second • Second- or third-degree heart block • Active asthma or reactive airways disease	I	B
Beta blockers should be continued during and after hospitalization for all patients with STEMI and no contraindications to their use.	I	B
Patients with initial contraindications to the use of beta blockers in the first 24 hours after STEMI should be reevaluated to determine their subsequent eligibility.	I	C
It is reasonable to administer IV beta blockers at initial encounter to patients with STEMI and no contraindications to their use who are hypertensive or have ongoing ischemia.	IIa	B

*The greater the number of risk factors present, the higher the risk for development of cardiogenic shock.

COR, Class of recommendation; *LOE,* level of evidence.

Modified from O'Gara PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2013;61:e78.

Recommendations

Given the evidence of a benefit of early administration of beta blockers for STEMI, patients without a contraindication, regardless of the administration of concomitant fibrinolytic therapy or performance of primary PCI, should receive *oral* beta blockers within the first 24 hours (**Table 59.6**). IV administration of beta-blocking therapy during this period is also reasonable if a tachyarrhythmia or hypertension is present, in the absence of signs of HF/low output, indicators of high risk for the development of shock, or other relative contraindications to beta blockers.[1]

Beta blockers are especially helpful in STEMI patients with significant residual unrevascularized CAD and evidence of recurrent ischemia or tachyarrhythmias early after the onset of infarction.[93] If adverse effects of beta blockers develop or if patients have complications of infarction that are contraindications to these agents, such as HF or heart block, beta blockers should be withheld. Unless there are contraindications (**Table 59.6**), beta blockers probably should be continued in patients in whom STEMI develops. Moreover, patients who initially have contraindications to a beta blockers, such as acute HF, should be reevaluated with respect to their candidacy for such therapy after 24 hours.[1]

Selection of Beta Blockers

Favorable effects have been reported with metoprolol, atenolol, carvedilol, timolol, and alprenolol; these benefits probably occur with propranolol and with esmolol, an ultrashort-acting agent, as well. In the absence of any favorable evidence supporting the benefit of agents with intrinsic sympathomimetic activity, such as pindolol and oxprenolol, and with some unfavorable evidence for these agents in secondary prevention, beta blockers with intrinsic sympathomimetic activity should probably not be chosen for treatment of STEMI. The CAPRICORN (Carvedilol Post Infarction Survival Control in Left Ventricular Dysfunction) trial randomly assigned 1959 patients with MI and systolic dysfunction (EF <40%) to carvedilol or placebo in addition to contemporary pharmacotherapy, including angiotensin-

converting enzyme (ACE) inhibitors in 98% of patients. All-cause mortality was reduced over a mean follow-up of 1.3 years by 23% with carvedilol compared to placebo ($P = 0.031$), with a similar pattern noted during the first 30 days.[22] Thus, CAPRICORN confirmed the benefit of administration of a beta blocker in addition to ACE inhibitor therapy in patients with transient or sustained LV dysfunction after MI.

Occasionally, clinicians may decide to proceed with therapy with a beta blocker even in patients with relative contraindications, such as a history of mild asthma, mild bradycardia, mild HF, or first-degree heart block. In this situation a trial of esmolol may help determine whether the patient can tolerate beta-adrenergic blockade. Because the hemodynamic effects of this drug (half-life of 9 minutes) disappear in less than 30 minutes, it offers an advantage over longer-acting agents when the risk for complications with a beta blocker is relatively high.

Inhibition of the Renin-Angiotensin-Aldosterone System

The rationale for inhibition of the renin-angiotensin-aldosterone system (RAAS) includes experimental and clinical evidence of a favorable impact on ventricular remodeling, improvement in hemodynamics, and a reduction in HF incidence. Unequivocal evidence from RCTs has shown that ACE inhibitors reduce mortality from STEMI.[1] These trials can be grouped into two categories. The first group *selected* MI patients for randomization on the basis of features indicative of increased mortality, such as left ventricular ejection fraction (LVEF) lower than 40%, clinical signs and symptoms of HF, anterior location of infarction, and abnormal wall motion score index (**Fig. 59.17**). The second group consisted of *unselective* trials that randomized all patients with MI provided that they had a minimum systolic BP of approximately 100 mm Hg (ISIS-4, GISSI-3 [Gruppo Italiano per lo Studio della Sopravvivenza nell'infarto Miocardico], CONSENSUS II [Cooperative New Scandinavian Enalapril Survival Study II], and Chinese Captopril Study) (**Fig. 59.18**). With the exception of the SMILE (Survival of Myocardial Infarction Long-Term Evaluation) study, all the selective trials initiated ACE inhibitor therapy between 3 and 16 days after MI and maintained it for 1 to 4 years, whereas the unselective trials all initiated treatment within the first 24 to 36 hours and maintained it for only 4 to 6 weeks.

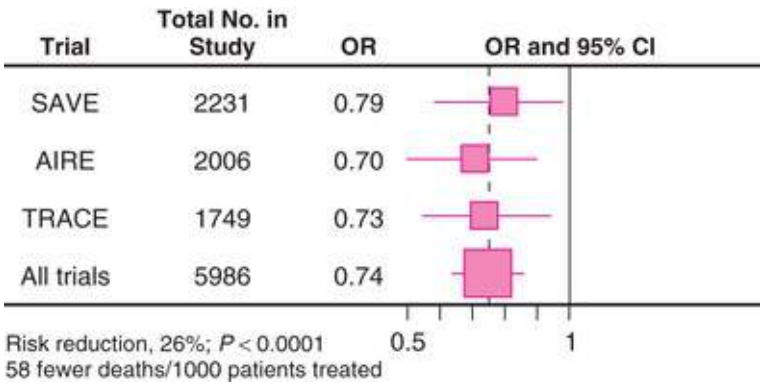

FIGURE 59.17 Effect of ACE inhibitors on mortality after MI—results from long-term trials. (From Gornik H, O'Gara PT. Adjunctive medical therapy. In Manson JE et al, editors. Clinical Trials in Heart Disease: a Companion to Braunwald's Heart Disease. Philadelphia: Saunders; 2004, p 114.)

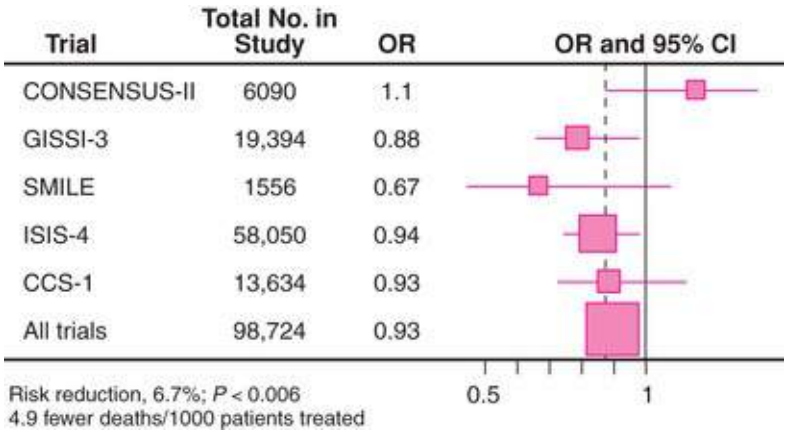

FIGURE 59.18 Effects of ACE inhibitors on mortality after MI—results from short-term trials. (From Gornik H, O'Gara PT. Adjunctive medical therapy. In Manson JE et al, editors. Clinical Trials in Heart Disease: a Companion to Braunwald's Heart Disease. Philadelphia: Saunders; 2004, p 114.)

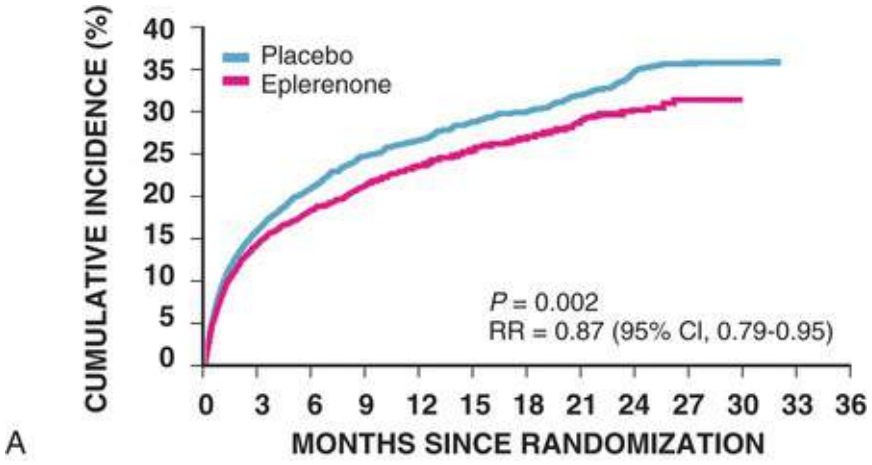
A consistent survival benefit was observed in all the trials already noted, except for CONSENSUS II, the one study that used an IV preparation early in the course of MI. An estimate of the mortality benefit of ACE inhibitors in the unselective trials with a short duration of therapy was 5 lives saved per 1000 patients treated. Analysis of these unselective short-term trials indicates that approximately one third of the lives saved occurred within the first 1 to 2 days. Certain subgroups, such as patients with anterior infarction, showed proportionately greater benefit with the early administration (11 lives saved per 1000) of ACE inhibitors. Not unexpectedly, greater survival benefits of 42 to 76 lives saved per 1000 patients treated were obtained in the selective trials with a long duration of therapy. Of note, a general 20% reduction in the risk for death attributable to ACE inhibitor treatment occurred in the selective trials. The reduction in mortality with ACE inhibitors was accompanied by significant reductions in the development of HF, thus supporting the underlying pathophysiologic rationale for administering this class of drugs to patients with STEMI. In addition, some data suggest that chronic administration of ACE inhibitors after STEMI reduces the incidence of ischemic events, including recurrent MI and the need for coronary revascularization.[26]

The mortality benefits of ACE inhibitors add to those achieved with aspirin and beta blockers. The benefits of ACE inhibition appear to be a class effect because several agents have been associated with reduced mortality and morbidity. To replicate these benefits in clinical practice, however, physicians should select a specific agent and prescribe the drug according to the protocols used in the clinical trials.[94] The major contraindications to ACE inhibitors in patients with STEMI include hypotension in the setting of adequate preload, known hypersensitivity, and pregnancy. Adverse reactions include hypotension, especially after the first dose, and intolerable cough; much less often, angioedema can occur.

An alternative method of pharmacologic inhibition of the RAAS is the administration of angiotensin II receptor–blocking agents (ARBs). The VALIANT (Valsartan in Acute Myocardial Infarction) trial compared the effects of the ARB valsartan, valsartan and captopril, and captopril alone on mortality in patients with acute MI complicated by LV systolic dysfunction and/or HF within 10 days of MI.[26] Mortality rates were similar in the three treatment groups: 19.9% with valsartan, 19.3% with valsartan plus captopril, and 19.5% with captopril alone. The combination of the ACE and the ARB caused more unwanted actions; thus drugs from these classes should not be combined.

Aldosterone blockade is another pharmacologic strategy for inhibition of the RAAS. The EPHESUS (Eplerenone Post-AMI Heart Failure Efficacy and Survival) trial randomly assigned 6642 patients with acute MI *complicated by left ventricular dysfunction and heart failure* to the selective aldosterone-blocking agent eplerenone or placebo in conjunction with contemporary postinfarction

pharmacotherapy.[95,96] During a mean follow-up of 16 months, a 15% reduction occurred in the RR for mortality in favor of eplerenone. Eplerenone also reduced CV mortality or hospitalization for CV events (**Fig. 59.19**). Serious hyperkalemia (serum potassium [K^+] concentration, 6 mmol/L) occurred in 5.5% of patients in the eplerenone group compared with 3.9% in the placebo group ($P = 0.002$). In contrast, in the ALBATROSS (Aldosterone Lethal Effects Blocked in Acute MI Treated with or without Reperfusion to Improve Outcome and Survival at Six Months Follow-up) trial, early mineralocorticoid antagonism versus placebo in an expanded population of patients with MI, *including both STEMI and non–ST elevation MI, and patients without left ventricular function or heart failure*, did not reduce the primary outcome of death, cardiac arrest, ventricular arrhythmia, implantable cardioverter-defibrillator (ICD) placement, or HF.[97] However, an exploratory analysis by MI type found a reduction in all-cause death (HR, 0.20; 95% CI 0.06 to 0.70) in the subgroup of patients with STEMI ($n = 1229$). Further studies are necessary to determine if a mineralocorticoid receptor antagonist (MRA) improves outcomes in all STEMI patients, regardless of HR or LV dysfunction.



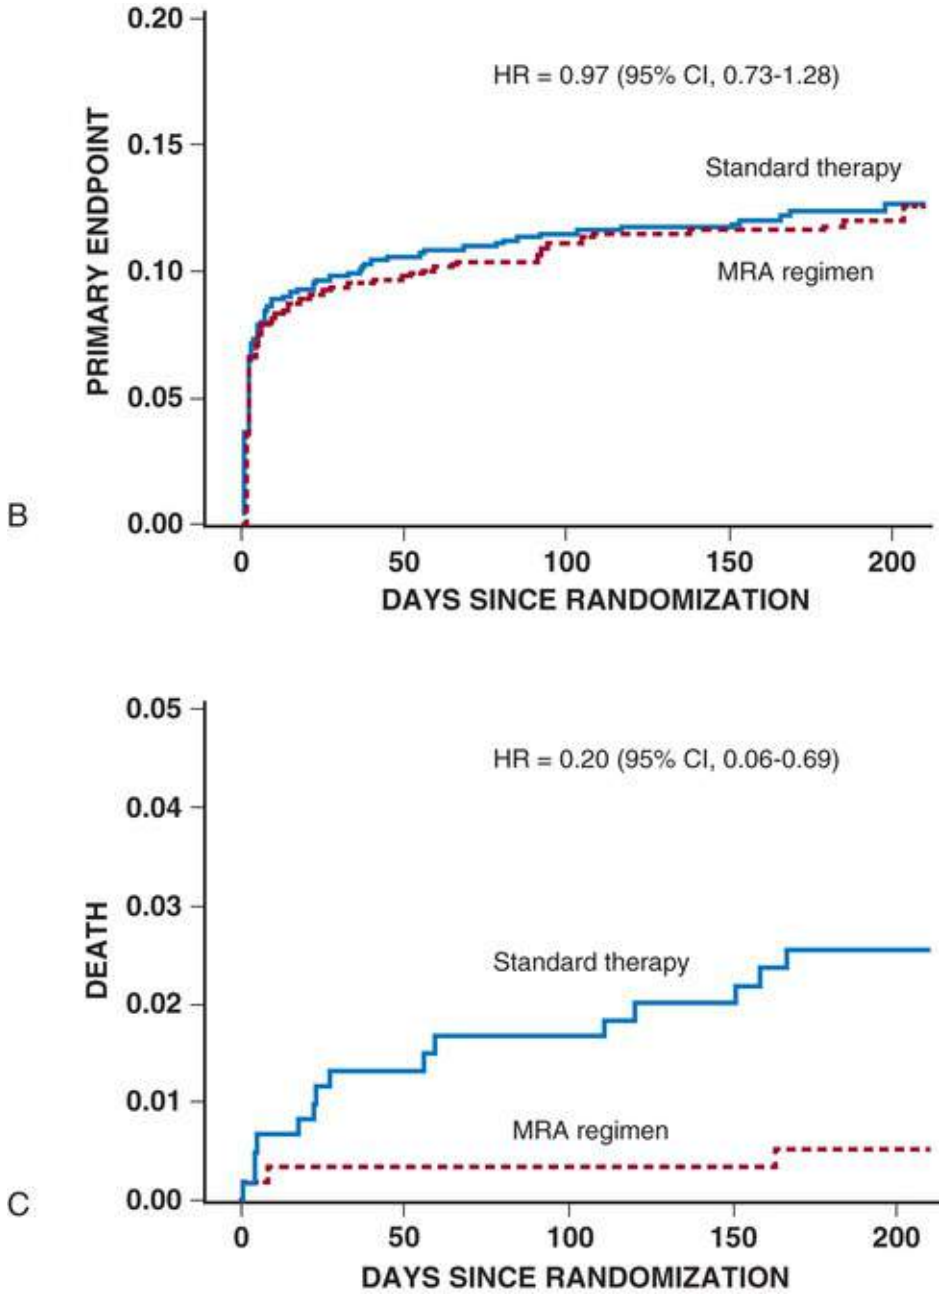


FIGURE 59.19 Mineralocorticoid receptor antagonism (MRA) following MI in patients with and without heart failure or left ventricular dysfunction. **A,** Eplerenone significantly reduced death from cardiovascular causes or hospitalization for cardiovascular events in the EPHESUS (Eplerenone Post-AMI Heart Failure Efficacy and Survival) trial in patients with acute MI *complicated by left ventricular dysfunction and heart failure*. **B,** The ALBATROSS (Aldosterone Lethal Effects Blocked in Acute MI Treated with or without Reperfusion to Improve Outcome and Survival at Six Months Follow-up) trial found no difference in the primary outcome of death, cardiac arrest, ventricular arrhythmia, ICD placement, or heart failure with early MRA versus placebo in acute MI *with or without left ventricular function or heart failure*. **C,** An exploratory subgroup analysis in patients with STEMI identified a reduction in all-cause death. (Modified from Pitt B et al. Eplerenone, a selective aldosterone blocker, in patients with left ventricular dysfunction after myocardial infarction. N Engl J Med 2003;348:14, and Beygui F et al. Early aldosterone blockade in acute myocardial infarction: the ALBATROSS randomized clinical trial. J Am Coll Cardiol 2016;67(16):1917-27.)

Recommendations

After administration of aspirin and initiation of reperfusion strategies and, when appropriate, beta blockers, *all* patients with STEMI should be considered for inhibition of the RAAS. Although few disagree with the recommendation that high-risk STEMI patients (elderly, anterior infarction, previous infarction, Killip class II or greater, and asymptomatic patients with evidence of depressed global ventricular function on imaging) should receive lifelong treatment with ACE inhibitors, some have

proposed short-term (4 to 6 weeks) therapy for a broader group of patients on the basis of the pooled results of the unselective mortality trials.[1]

Considering all the data available, we favor a strategy of an initial trial of oral ACE inhibitors in all patients with STEMI and HF, as well as in hemodynamically stable patients, commencing within the first 24 hours. ACE inhibition therapy should be continued indefinitely in patients with HF, evidence of a reduction in global function, or a large regional wall motion abnormality. In patients without these findings, long-term treatment with ACE inhibitors is based on other considerations related to the potential benefits on secondary prevention. ARBs are a clinically effective alternative to ACE inhibitors. Although not yet studied specifically among patients with acute MI, an angiotensin receptor-neprilysin inhibitor (ARNI) can be considered over an ACE inhibitor or ARB for long-term management in patients with chronic symptomatic HF with reduced EF, including patients with ischemic cardiomyopathy from prior MI.[98] Finally, long-term aldosterone blockade should be instituted in high-risk patients following STEMI (EF <40%, clinical HF, diabetes mellitus) who are already receiving an ACE inhibitor and beta blocker and do not have contraindications. The small but definite increase in the risk for serious hyperkalemia when aldosterone blockade is prescribed, particularly when other measures for RAAS inhibition are used concurrently, warrants periodic monitoring of the serum K^+ level.[96]

Nitrates

The potential for reductions in ventricular filling pressure, wall tension, and cardiac work, coupled with improvement in coronary blood flow, especially in ischemic zones, and antiplatelet effects, makes nitrates a logical and attractive pharmacologic intervention in patients with STEMI.[1] Administration of nitrates reduces pulmonary capillary wedge pressure (PCWP) and systemic arterial pressure, LV chamber volume, infarct size, and the incidence of mechanical complications. Nevertheless, routine administration of nitrates does not alter survival in patients with STEMI. Although a meta-analysis of 10 trials conducted in the prefibrinolytic era showed nitrate therapy to be associated with a reduction in mortality,[71] two megatrials of nitrate therapy (GISSI-3 and ISIS-4) conducted in the reperfusion era demonstrated no benefit on major CV outcomes.[1]

With the aim of controlling hypertension or treating HF, IV nitroglycerin can be administered safely to patients with evolving STEMI as long as the dose is titrated to avoid induction of reflex tachycardia or systemic arterial hypotension. Patients with inferior wall infarction may be sensitive to an excessive fall in preload, particularly with concurrent RV infarction.[1] In such cases, nitrate-induced venodilation could impair cardiac output and reduce coronary blood flow, thus worsening rather than improving myocardial oxygenation.

Clinically significant methemoglobinemia, although rare, can develop when unusually large doses of nitrates are administered. This problem is important not only for its potential to cause symptoms of lethargy and headache, but also because elevated methemoglobin levels can impair the O_2-carrying capacity of blood and potentially exacerbate ischemia. Dilation of the pulmonary vasculature supplying poorly ventilated lung segments may produce a ventilation-perfusion mismatch. Tolerance to IV nitroglycerin (as manifested by increasing nitrate requirements) develops in many patients, often as soon as 12 hours after the infusion is started.

Recommendations

Nitroglycerin is indicated for the relief of persistent pain and as a vasodilator in patients with infarction associated with LV failure or hypertension. In the absence of recurrent angina or HF, we do not routinely

prescribe nitrates for patients with STEMI. Long-term nitrates have no clear benefit in asymptomatic patients, and we therefore do not prescribe them beyond the first 48 hours in patients without angina or LV failure.

Calcium Channel Antagonists

Despite sound experimental and clinical evidence of an anti-ischemic effect, calcium antagonists have not been helpful in the acute phase of STEMI, and several systematic overviews have raised concern about an increased risk for mortality when these agents, particularly short-acting dihydropyridines, are prescribed on a routine basis. Nondihydropyridine calcium channel–blocking agents (verapamil and diltiazem) can be given to slow a rapid ventricular response in atrial fibrillation in patients for whom beta blockers are ineffective. These agents should be avoided in patients with Killip class II or greater.

Other Therapies

Magnesium

A functional deficit in available magnesium may develop in patients with STEMI. Because of the risk for cardiac arrhythmias when electrolytes are deficient in the early phase of infarction, patients with STEMI should have their serum magnesium measured on admission. We advocate repleting magnesium deficits to maintain a serum magnesium level of 2 mEq/L or greater. In the presence of hypokalemia, the serum magnesium level should be rechecked and repleted if necessary because it is often difficult to correct a potassium deficit in the presence of a concurrent magnesium deficit. There is no indication for routine IV administration of magnesium to patients with STEMI.

Glucose Control During ST-Elevation Myocardial Infarction

During the acute phase of STEMI, catecholamine levels increase in both the blood and ischemic myocardium. Insulin levels remain low, whereas cortisol, glucagon, and FFA levels increase. These factors may contribute to an elevation in the blood glucose level, which should be measured routinely on admission. Intensive insulin therapy to control blood glucose strictly is no longer recommended routinely for patients with MI.[99] Blood glucose levels should be maintained below 180 mg/dL, if possible, while avoiding hypoglycemia[1] (**see Chapter 51**).

A series of small trials suggested that infusions of glucose-insulin-potassium (GIK) to patients with STEMI were beneficial, but the CREATE-ECLA (Clinical Trial of Metabolic Modulation in Acute Myocardial Infarction Treatment Evaluation–Estudios Cardiologicos Latinoamerica) investigators randomly assigned 20,201 patients with STEMI (83% of whom received reperfusion therapy) to GIK or placebo and found no impact on mortality (30-day mortality, 9.7% in control and 10% in GIK group).[100,101] In addition, prehospital administration of GIK did not improve the primary endpoint of progression to MI in patients with ACS.[102] Thus, in the contemporary era of management of STEMI in which other effective therapies (reperfusion, aspirin, ACE inhibitors) are administered, routine use of GIK infusions appears to have no benefit.

Other Agents

Multiple adjunctive pharmacotherapies to prevent inflammatory damage in the infarct zone have been investigated but have not shown clinical benefit. For example, *pexelizumab,* a monoclonal antibody against the C5 component of complement, had no effect on infarct size in patients with STEMI treated

with either fibrinolytics or PCI or on mortality in patients treated with primary PCI.[103] The anti-inflammatory agent *losmapimod*, a p38 mitogen-activated protein kinase (MAPK) inhibitor that reduces cytokine amplification in ACS, did not reduce the short-term risk of CV death, MI, or severe recurrent ischemia in 3503 patients with acute MI.[104] Similarly, *darapladib*, an oral, selective inhibitor of the lipoprotein-associated phospholipase A_2 enzyme, did not alter the composite of CV death, MI, or stroke in 13026 patients with acute MI in the SOLID-TIMI 52 (Stabilization of Plaques Using Darapladib) trial.[105]

Hemodynamic Disturbances

Hemodynamic Assessment

Patients with clinically uncomplicated STEMI do not require invasive hemodynamic monitoring because clinical evaluation can assess the status of the circulation. Routine assessments in patients with STEMI should include monitoring of the heart rate and rhythm, repeated measurement of systemic arterial pressure by cuff, repeated auscultation of the lung fields for pulmonary congestion, measurement of urine output, examination of the skin for evidence of the adequacy of perfusion, and monitoring for hypoxemia.

In patients with STEMI who have clinical signs and symptoms of HF, assessment of the degree of hemodynamic compromise is important. Central venous pressure (CVP) reflects right rather than LV function. RV function—and therefore systemic venous pressure—may be normal or almost so in patients with substantial LV failure. Conversely, patients with RV failure caused by RV infarction may exhibit elevated right atrial (RA) pressure and CVP despite normal LV function. Low values for RA pressure and CVP imply hypovolemia, whereas elevated RA pressure usually results from RV failure secondary to LV failure, pulmonary hypertension, RV infarction, or less often, tricuspid regurgitation or pericardial tamponade.

In select patients with complicated STEMI, it may be useful to monitor invasively with an intra-arterial catheter and a pulmonary artery (PA) catheter for measurement of PA, PA occlusive, and RA pressures, as well as estimation of cardiac output. In patients with hypotension, a Foley catheter should be considered for continuous measurement of urine output.

Monitoring of Pulmonary Artery Pressure

Accurate determination of hemodynamics by clinical assessment can be difficult in critically ill patients. Use of a PA catheter thus often leads to important changes in therapy. Before inserting a PA catheter into a patient with STEMI, the physician must believe that the potential benefit of the information that can obtained outweighs any potential risks. Major complications from PA catheters are uncommon, but severe problems can occur, including sepsis, pulmonary infarction, and PA rupture. Minimized duration of catheterization and strict adherence to aseptic technique can diminish the risk. Using antiseptic-impregnated dressings can also reduce catheter-related bloodstream infections.

Accumulating evidence from settings other than STEMI suggests that routine invasive hemodynamic monitoring does not improve outcomes. The Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE) Trial demonstrated no difference in death or hospitalization at 6 months, but increased rates of adverse events (21.9% versus 11.5%; $P = 0.04$) in 433 patients with HF not accompanied by shock randomly assigned to placement of a PA catheter or to noninvasive standard care.[94] A meta-analysis of data for 5051 patients from 13 RCTs of PA

catheterization in patients undergoing surgery admitted to the ICU with advanced HF or diagnosed with acute respiratory distress syndrome (ARDS) or sepsis showed no difference in mortality.[94] Based on these limited data and expert consensus, placement of a PA catheter is recommended in only a subset of patients, including those with presumed cardiogenic shock and need for escalating vasopressor therapy or mechanical circulatory support; those exhibiting clinical decompensation with equivocal findings on assessment of filling pressures, perfusion, and vascular tone (i.e., to assist with determination of shock type); and patients with ongoing significant symptoms or dependence on inotropes despite attempts at noninvasive optimization of recommended therapies (**Table 59.7**). In the setting of STEMI, PA catheterization is reasonable for diagnostic and management purposes in patients with mechanical lesions (or suspected lesions) such as severe mitral regurgitation or a ruptured ventricular septum or RV infarction.[94,106] Noninvasive methods of determination of cardiac output, such as pulse contour analysis and thoracic electrical bioimpedance, are also available.[107]

TABLE 59.7

Indications for Hemodynamic Monitoring in Patients with ST-Elevation Myocardial Infarction

Management of complicated acute myocardial infarction
Shock with unclear clinical assessment of hemodynamics (e.g. filling pressures, vascular tone)
Ventricular septal rupture versus acute mitral regurgitation
Severe cardiogenic shock caused by right or left ventricular failure with a need for escalating vasopressor, inotropic, or mechanical circulatory support
Refractory ventricular tachycardia
Difficulty differentiating severe pulmonary disease from left ventricular failure with available noninvasive data
Assessment of cardiac tamponade

Data from Gore JM, Zwernet PL. Hemodynamic monitoring of acute myocardial infarction. In Francis GS, Alpert JS, editors. Modern Coronary Care. Boston: Little, Brown; 1990, p 138; and Yancy CW et al. 2013 ACCF/AHA guideline for the management of heart failure: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. Circulation 2013;128(16):e240-327.

Hemodynamic Abnormalities

In 1976, Swan, Forrester, and associates measured cardiac output and wedge pressure simultaneously in a large series of patients with acute MI and identified four major hemodynamic subsets of patients (**Table 59.8**): (1) patients with normal systemic perfusion and without pulmonary congestion (normal cardiac output and normal wedge pressure), (2) patients with normal perfusion and pulmonary congestion (normal cardiac output and elevated wedge pressure), (3) patients with decreased perfusion but without pulmonary congestion (reduced cardiac output and normal wedge pressure), and (4) patients with decreased perfusion and pulmonary congestion (reduced cardiac output and elevated wedge pressure). This classification, which overlaps with a crude clinical classification proposed earlier by Killip and Kimball (**Table 59.8**), has proved quite useful, but it should be noted that patients frequently pass from one category to another with therapy and sometimes apparently even spontaneously.

TABLE 59.8

Hemodynamic Classification of Patients with Acute Myocardial Infarction

A. BASED ON CLINICAL EXAMINATION		B. BASED ON INVASIVE MONITORING	
Class	**Definition**	**Subset**	**Definition**
I	Rales and S_3 absent	I	Normal hemodynamics PCWP <18, CI >2.2
II	Crackles, S_3 gallop, elevated jugular venous pressure	II	Pulmonary congestion PCWP >18, CI >2.2
III	Frank pulmonary edema	III	Peripheral hypoperfusion PCWP <18, CI <2.2
IV	Shock	IV	Pulmonary congestion and peripheral hypoperfusion PCWP >18, CI <2.2

CI, Cardiac index; *PCWP,* pulmonary capillary wedge pressure.

Medical therapy of acute myocardial infarction by the application of hemodynamic subsets. N Engl J Med 1976;295:1356.

Hemodynamic Subsets

The hemodynamic groupings shown in **Tables 59.8 and 59.9** allow rational approaches to therapy. The goals of hemodynamic therapy include maintenance of ventricular performance, BP support, and protection of jeopardized myocardium. Because these goals may occasionally be at cross-purposes, recognition of the hemodynamic profile, as assessed clinically or as available from hemodynamic monitoring, may be needed to design an optimal therapeutic management strategy.

TABLE 59.9

Hemodynamic Patterns for Common Clinical Conditions

Cardiac Condition	CHAMBER PRESSURE (mm Hg)				
	RA	**RV**	**PA**	**PCW**	**CI**
Normal	0-6	25/0-6	25/0-12	6-12	≥2.5
AMI without LVF	0-6	25/0-6	30/12-18	≤18	≥2.5
AMI with LVF	0-6	30-40/0-6	30-40/18-25	>18	>2.0
Biventricular failure	>6	50-60/>6	50-60/25	18-25	>2.0
RVMI	12-20	30/12-20	30/12	≤12	<2.0
Cardiac tamponade	12-16	25/12-16	25/12-16	12-16	<2.0
Pulmonary embolism	12-20	50-60/12-20	50-60/12	<12	<2.0

Hypotension in the Prehospital Phase

Hypotension associated with bradycardia often reflects excessive vagotonia. Relative or absolute hypovolemia is often present when hypotension occurs with a normal or rapid HR. Marked diaphoresis, reduction of fluid intake, or vomiting during the period preceding and accompanying the onset of STEMI may contribute to the development of hypovolemia. Even if the effective vascular volume is normal, relative hypovolemia may be present because ventricular compliance is reduced in cases of STEMI, and LV filling pressure as high as 20 mm Hg may be necessary to provide optimal preload.

Management.

In the absence of HF, when hypotension is suspected to result from excessive vagotonia, patients should be placed in the reverse Trendelenburg position. In patients with sinus bradycardia and hypotension, atropine should be administered (0.3 to 0.6 mg intravenously, repeated at 3- to 10-minute intervals up to 2 mg). If these measures do not correct the hypotension, normal saline should be administered intravenously while monitoring for signs of HF. Because of the poor correlation between LV filling pressure and mean RA pressure, assessment of CVP can be of limited value as a guide to fluid therapy. Administration of positive inotropic or vasopressor agents is indicated during the prehospital phase if systemic hypotension persists despite correction of hypovolemia.

The Hyperdynamic State

When infarction is not complicated by hemodynamic impairment, no therapy other than general supportive measures and treatment of arrhythmias is necessary. However, if the hemodynamic profile involves a hyperdynamic state—that is, elevation of the sinus rate, arterial pressure, and CI, occurring singly or together in the presence of a normal or low LV filling pressure—treatment with beta blockers is indicated. Presumably, the increased HR and BP result from inappropriate activation of the sympathetic nervous system, possibly because of augmented release of catecholamines triggered by pain or anxiety.

Left Ventricular Failure

Left ventricular dysfunction is one of the most important predictors of mortality following STEMI[108-112] (**Fig. 59.20**). In patients with STEMI, either systolic dysfunction alone or both systolic and diastolic dysfunction can occur. LV diastolic dysfunction leads to pulmonary venous hypertension and pulmonary congestion. Clinical manifestations of LV failure become more common as the extent of injury to the left ventricle increases. In addition to infarct size, other important predictors of the development of symptomatic LV dysfunction include advanced age and diabetes.[110] Mortality increases in association with the severity of the hemodynamic deficit.[108]

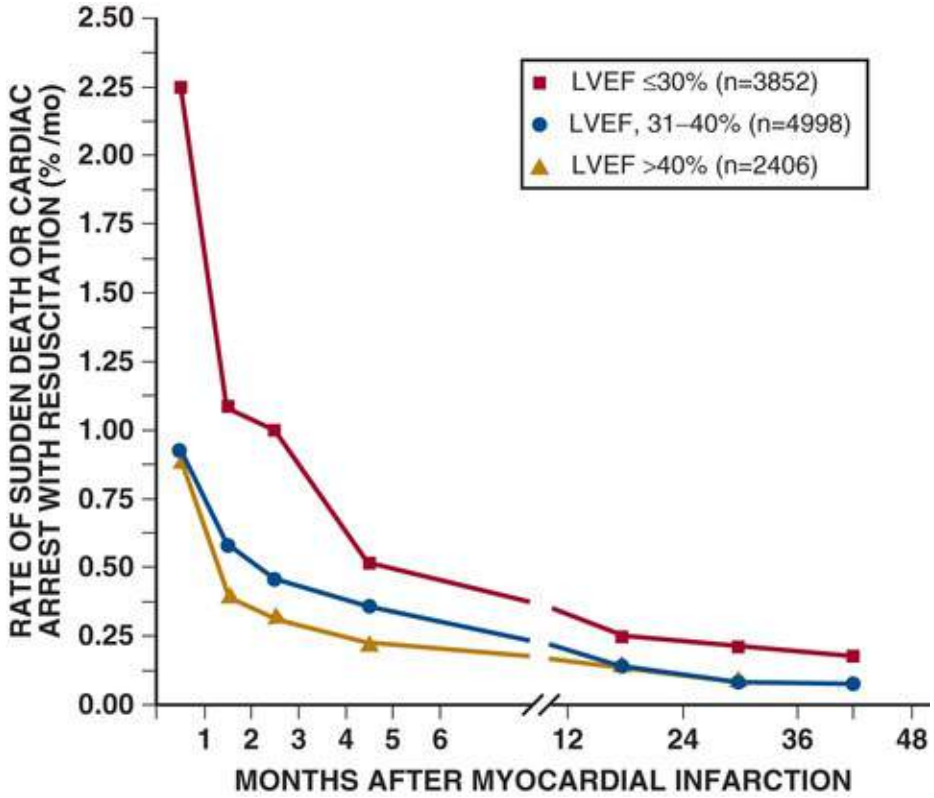

FIGURE 59.20 Rate of sudden death or cardiac arrest with resuscitation stratified by time from MI. The high rate of sudden death or cardiac arrest occurs within the first month after MI in all strata of left ventricular ejection fraction (LVEF) and declines exponentially to a plateau after 12 months. (From Zaman S, Kovoor P. Sudden cardiac death early after myocardial infarction: pathogenesis, risk stratification, and primary prevention. Circulation 2014;129(23):2426-35.)

Therapeutic Implications

Classification of patients with STEMI by hemodynamic subsets has therapeutic relevance. As already noted, patients with low to normal wedge pressure and hypoperfusion may benefit from infusion of fluids because the peak stroke volume value is not usually attained until LV filling pressure reaches 18 to 24 mm Hg. However, a low level of LV filling pressure does not necessarily imply that the LV damage is slight. Such patients may be relatively hypovolemic or may have an RV infarct with or without severe LV damage.

The relationship between ventricular filling pressure and cardiac index when preload is increased by infusion of fluid can provide valuable hemodynamic information in addition to that obtained from baseline measurements. For example, the ventricular function curve rises steeply (marked increase in cardiac index small increase in filling pressure) in patients with normal LV function and hypovolemia, whereas the curve rises gradually or remains flat in patients with a combination of hypovolemia and depressed cardiac function. Invasive hemodynamic monitoring can help guide therapy in patients with severe LV failure (PCWP >18 mm Hg and cardiac index <2.2 liters/min/m^2). Although positive inotropic agents can be useful, they do not represent the initial therapy of choice for patients with STEMI. Instead, HF, in the presence of elevated PCWP, is managed most effectively first by reducing ventricular preload and then, if possible, by lowering afterload. Arrhythmias can contribute to hemodynamic compromise and should be treated promptly in patients with LV failure.

Hypoxemia

In STEMI complicated by HF, a combination of pulmonary vascular engorgement (and in some cases,

pulmonary interstitial edema), diminished vital capacity, and in some patients, contributory respiratory depression from narcotic analgesics may cause hypoxemia. Hypoxemia can impair the function of ischemic tissue at the margin of the infarct and thereby contribute to establishing or perpetuating the vicious cycle. However, augmentation of F_{IO_2} in patients without hypoxemia may increase systemic vascular resistance (SVR) and arterial pressure, promote coronary vasoconstriction, and result in more oxidative stress and greater infarct size.[20] As a result, Sa_{O_2} can be estimated by pulse oximetry, and O_2 therapy can be omitted if the oximetric findings are normal (see earlier, General Treatment Measures).[1] On the other hand, in patients with STEMI and arterial hypoxemia, increasing F_{IO_2} by facemask should be used initially, but if Sa_{O_2} cannot be maintained above 85% to 90% with 100% F_{IO_2}, strong consideration should be given to endotracheal intubation and positive-pressure ventilation. Positive end-expiratory pressure (PEEP) may diminish systemic venous return and reduce effective LV filling pressure. This effect may require reducing the PEEP amount, initiating normal saline infusions to maintain LV filling pressure, or adjusting the rate of infusion of vasodilators (e.g., nitroglycerin). Because myocardial ischemia can occur during the return to unsupported spontaneous breathing, weaning should be accompanied by observation for signs of ischemia.

Diuretics

Mild HF in patients with STEMI frequently responds well to diuretics such as furosemide administered intravenously in doses of 10 to 40 mg, repeated at 3- to 4-hour intervals if necessary. The resultant decrease in PCWP reduces dyspnea, and the lowering of LV wall tension that accompanies the reduction in LV diastolic volume diminishes myocardial oxygen requirements and may lead to improvement in contractility and augmentation of EF, stroke volume, and cardiac output. The reduction in LV filling pressure may also enhance myocardial oxygen delivery by diminishing the impedance to coronary perfusion attributable to the elevated ventricular wall tension. It may also improve arterial oxygenation by reducing pulmonary vascular congestion.

IV furosemide reduces pulmonary vascular congestion and pulmonary venous pressure within 15 minutes, before renal excretion of sodium and water has occurred; presumably this action results from a direct dilating effect of this drug on the systemic venous bed. LV filling pressure generally should not be reduced much below 18 mm Hg, the lower range being associated with optimal LV performance in patients with STEMI, because this may reduce cardiac output further and cause arterial hypotension. Excessive diuresis may also result in hypokalemia and magnesium loss.

Afterload Reduction

Myocardial oxygen requirements depend on LV wall stress, which in turn is proportional to the product of the peak developed LV pressure, volume, and wall thickness. IV vasodilator therapy should be considered in patients with STEMI complicated by (1) HF unresponsive to treatment with diuretics, (2) hypertension, (3) mitral regurgitation (MR), or (4) ventricular septal defect (VSD). In these patients, treatment with vasodilator agents increases stroke volume and may reduce myocardial oxygen requirements and thereby lessens ischemia. Hemodynamic monitoring of systemic arterial pressure and in many cases PCWP and cardiac output in patients treated with these agents is generally indicated. Improvement in cardiac performance and energetics requires three simultaneous effects: (1) reduction of LV afterload, (2) avoidance of excessive systemic arterial hypotension to maintain effective coronary perfusion pressure, and (3) avoidance of excessive reduction of ventricular filling pressure with consequent diminution of cardiac output.

Vasodilator therapy is particularly useful when STEMI is complicated by MR or rupture of the ventricular septum. In such patients, vasodilators alone or in combination with intra-aortic balloon counterpulsation can sometimes provide sufficient hemodynamic stabilization to permit definitive studies, as well as to prepare the patient for early surgical intervention. Because of the precarious state of patients with complicated infarction and the need for meticulous adjustment of dosage, therapy is best initiated with agents that can be administered intravenously and have a short duration of action, such as nitroprusside or nitroglycerin.

Nitroglycerin

Animal experiments have shown this drug to be less likely than nitroprusside to produce "coronary steal" (i.e., diversion of blood flow from the ischemic to the nonischemic zone). Therefore, apart from consideration of its routine use in STEMI patients discussed earlier, it may be a particularly useful vasodilator in patients with STEMI complicated by LV failure. A dosage of 10 to 15 µg/min is infused, and the dose is increased by 10 µg/min every 5 minutes until the desired effect (improvement in hemodynamics or relief of ischemic chest pain) is achieved or a decline in systolic arterial pressure to 90 mm Hg or by more than 15 mm Hg has occurred. Although both nitroglycerin and nitroprusside lower systemic arterial pressure, systemic vascular resistance, and the heart rate–systolic blood pressure product, the reduction in LV filling pressure is more prominent with nitroglycerin because of its relatively greater effect than nitroprusside on venous capacitance vessels. Nevertheless, in patients with severe LV failure, cardiac output often increases despite the reduction in LV filling pressure produced by nitroglycerin.

Oral Vasodilators.

The use of oral vasodilators for the treatment of chronic HF is discussed in **Chapter 25**. Patients with STEMI and persistent HF should receive long-term RAAS inhibition, including an ACE inhibitor or ARB, and an aldosterone antagonist.[1,94,98] Treatment with an ARNI may be indicated in patients with reduced EF who develop chronic HF after MI; however, patients with recent ACS were excluded from the pivotal trial of sacubitril/valsartan.[113] The reduced ventricular load achieved with RAAS inhibition decreases the left ventricle remodeling that typically occurs after STEMI and reduces development of HF and risk for death.[94,98]

Digitalis (see Chapter 25).

Although digitalis increases the contractility and oxygen consumption of normal hearts, when HF is present, the diminution in heart size and wall tension frequently results in a net reduction of myocardial oxygen requirements. In animals, digoxin fails to improve ventricular performance immediately following experimental coronary occlusion, but can prove beneficial when administered several days later. The absence of early beneficial effects may result from the inability of ischemic tissue to respond to digitalis or the already maximal stimulation of contractility of the normal heart by circulating and neuronally released catecholamines.

Although the issue is still controversial, digitalis glycosides may increase the incidence of arrhythmias when given to patients in the first few hours after the onset of STEMI, particularly in the presence of hypokalemia. Administration of digitalis to patients with STEMI in the hospital phase should generally be reserved for the management of supraventricular tachyarrhythmias, such as atrial flutter and fibrillation, in the setting of poor LV function and HF persisting despite treatment with diuretics or

vasodilators.

Vasoactive Medications.

In addition to early coronary reperfusion, preservation of cardiac output, BP, and end-organ perfusion is paramount in patients with acute MI complicated by cardiogenic shock. Inotropes and vasopressors may be administered with the goal of maintaining perfusion so as to preserve end-organ function. To achieve this goal, therapy generally targets support of arterial pressure. Once BP is stabilized with resuscitation and vasopressor therapy, treatment can be tailored to address the underlying pathophysiology (e.g., addition of further inotropic support or vasodilator therapy). In general, the dose of vasopressor and inotropic therapy should be maintained at the minimal dose and duration of therapy necessary to achieve these aims, since these agents can have adverse consequences (e.g., increased myocardial oxygen consumption, arrhythmias).

Beta-Adrenergic Agonists.

When LV failure is severe, as manifested by marked a reduction in the cardiac index (<2.2 liters/min/m^2), and PCWP is at optimal (18 to 24 mm Hg) or excessive (>24 mm Hg) levels despite therapy with diuretics, beta-adrenergic agonists are indicated.[114] Dopamine, norepinephrine and dobutamine can be useful in patients with STEMI and reduced cardiac output, increased LV filling pressure, pulmonary vascular congestion, and hypotension.

Dopamine has dose-dependent stimulation of dopamine, $beta_1$ and $alpha_1$ receptors. At low doses, dopaminergic receptor stimulation predominates; at moderate doses, $beta_1$ activation results in augmentation of cardiac output and HR; at high doses, $alpha_1$ stimulation prevails, manifest as vasoconstriction (**Table 59.10**). Although "renal dosing" of dopamine was believed to improve urine output and renal protection in HF, this effect was not evident in an RCT of patients with acute HF and renal dysfunction.[115] Although dopamine is an important option as a vasopressor, particularly in patients with hypotension, it may cause tachycardia or tachyarrhythmias. Compared with norepinephrine, treatment with dopamine at doses up to 20 µg/kg/min was associated with a higher rate of tachyarrhythmias (24.1% versus 12.4%) among 1679 patients with shock in the SOAP (Sepsis Occurrence in Acutely Ill Patients) II trial. In a subgroup analysis of patients with cardiogenic shock (280, 17% of total trial population), dopamine was not only associated with more arrhythmic events but also with increased mortality (approximately 50% versus 40% at 28 days, log-rank *P* value = 0.03, *P* interaction by shock type = 0.87).[116]

TABLE 59.10

Inotropic and Vasopressor Agents: Indications, Dose Range, Receptor Binding, and Major Clinical Side Effects

			RECEPTOR BINDING*				
Drug	**Clinical Indication**	**Dose Range**	**A1**	**B1**	**B2**	**DA**	**Major Side Effects**
Catecholamines							
Dopamine	Shock (vasodilatory, cardiogenic) Symptomatic bradycardia unresponsive to atropine or pacing	2.0 to 20 (max 50) µg•kg^{-1}•min^{-1}	+++	++++	++	+++++	Severe hypertension (especially in patients taking nonselective beta blockers) Ventricular arrhythmias Cardiac ischemia Tissue ischemia, gangrene (high doses or caused by tissue extravasation)
Dobutamine	Low CO (decompensated HF, cardiogenic shock, sepsis-induced myocardial dysfunction)	2.0 to 20 (max 40) µg•kg^{-1}•min^{-1}	+	+++++	+++	N/A	Tachycardia Increased ventricular response rate in patients

	Symptomatic bradycardia unresponsive to atropine or pacing						with atrial fibrillation Ventricular arrhythmias Cardiac ischemia Hypotension
Norepinephrine	Shock (vasodilatory, cardiogenic)	0.01 to 3 μg•kg^{-1}•min^{-1}	+++++	+++	++	N/A	Arrhythmias Bradycardia Peripheral (digital) ischemia Hypertension (especially nonselective beta-blocker patients)
Epinephrine	Cardiac arrest Anaphylaxis Shock (cardiogenic, vasodilatory)	Infusion: 0.01 to 0.10 μg•kg^{-1}•min^{-1} Bolus: 1 mg IV every 3 to 5 min (max 0.2 mg/kg) IM: (1:1000):0.1 to 0.5 mg (max 1 mg)	+++++	++++	+++	N/A	Ventricular arrhythmias Severe hypertension Cardiac ischemia
Isoproterenol	Bradyarrhythmias (especially torsade des pointes) Brugada syndrome	2 to 10 μg/min	0	+++++	+++++	N/A	Ventricular arrhythmias Cardiac ischemia Hypertension
Phenylephrine	Hypotension (vagally mediated, medication induced) Increase MAP with aortic stenosis and hypotension Decrease left ventricular outflow tract gradient in HCM	Bolus: 0.1 to 0.5 mg IV every 10 to 15 min Infusion: 0.4 to 9.1 μg•kg^{-1}•min^{-1}	+++++	0	0	N/A	Reflex bradycardia Hypertension (especially with nonselective beta blockers) Severe peripheral and visceral vasoconstriction Tissue necrosis with extravasation
Phosphodiesterase Inhibitors (PDEIs)							
Milrinone	Low CO (decompensated HF, after cardiotomy)	Bolus: 50 μg/kg bolus over 10 to 30 min Infusion: 0.375 to 0.75 μg•kg^{-1}•min^{-1} (dose adjustment necessary for renal impairment)	N/A				Ventricular arrhythmias Hypotension Cardiac Ischemia Torsade des pointes
Amrinone	Low CO (refractory HF)	Bolus: 0.75 mg/kg over 2 to 3 min Infusion: 5 to 10 μg•kg^{-1}•min^{-1}	N/A				Arrhythmias; enhanced AV conduction (increased ventricular response rate in atrial fibrillation) Hypotension Thrombocytopenia Hepatotoxicity
Other Agents							
Vasopressin	Shock (vasodilatory, cardiogenic) Cardiac arrest	Infusion: 0.01 to 0.1 U/min (common fixed dose 0.04 U/min) Bolus: 40-U IV bolus	V1 receptors (vascular smooth muscle) V2 receptors (renal collecting duct system)				Arrhythmias Hypertension Decreased CO (at doses >0.4 U/min) Cardiac ischemia Severe peripheral vasoconstriction causing ischemia (especially skin) Splanchnic vasoconstriction
Levosimendan	Decompensated HF	Loading dose: 12 to 24 μg/kg over 10 min Infusion: 0.05 to 0.2 μg•kg^{-1}•min^{-1}	N/A				Tachycardia, enhanced AV conduction Hypotension

Norepinephrine increases myocardial oxygen consumption because of its peripheral vasoconstrictor and positive inotropic actions and thus had previously been avoided in patients with MI and shock (**Table 59.10**). However, based on the findings of SOAP-II, norepinephrine is generally recommended over dopamine, except in cases of relative bradycardia.

Dobutamine has a positive inotropic action comparable to that of dopamine, but a slightly less positive chronotropic effect, and vasodilatory rather than vasoconstrictor activity (**Table 59.10**).[114] As a result, it is useful in select patients whose HF persists despite treatment with diuretics, who are not hypotensive, and who are likely to benefit from both an enhancement in contractility and afterload reduction. As with all vasoactive medications, dobutamine must be given with constant monitoring of the ECG and systemic arterial pressure. In patients with STEMI who develop cardiogenic shock warranting treatment with dobutamine, we also generally place a PA catheter for assessment of PCWP and for frequent measurements of cardiac output. The dose should be reduced if significant tachycardia develops,

if supraventricular or ventricular tachyarrhythmias occur, or if ST-segment deviations increase.

Epinephrine is an activator of alpha- and beta-adrenergic receptors, resulting in increased HR, cardiac output, and vascular tone (**Table 59.10**). It is generally reserved for refractory shock as a second- or third-line agent, for anaphylaxis, or during cardiac arrest. Although epinephrine is recommended during cardiac arrest according to the advanced cardiovascular life support algorithm, studies suggest that those who received epinephrine in the setting of out-of-hospital cardiac arrest had higher rates of return of spontaneous circulation, but equivalent or even worse survival and neurologic function.[117,118]

Other Positive Inotropic Agents.

Milrinone is a noncatecholamine, nonglycoside, phosphodiesterase inhibitor with inotropic and vasodilating actions (**Table 59.10**).[114] Similar to dobutamine, it is useful in patients with cardiogenic shock without significant hypotension. Milrinone has a longer half-life than dobutamine (approximately 2.5 hours versus 2 minutes, with normal renal function) and also tends to correlate with greater pulmonary vasodilatation and fewer arrhythmic events. Calcium-sensitizing agents, such as levosimendan, may have some beneficial effects on CV outcomes, but these medications have shown little incremental value in randomized trials.[119]

Vasopressors.

Vasopressor therapy may be required to stabilize BP in cardiogenic or mixed shock. *Vasopressin,* or antidiuretic hormone (ADH), results in arterial smooth muscle contraction through V1 receptor agonism on the systemic vasculature (**Table 59.10**). Vasopressin is typically used for refractory vasodilatory shock, particularly septic shock. However, we also occasionally use vasopressin as a part of an "adrenergic-sparing" approach in patients with severe HF, particularly in the setting of mixed cardiogenic and vasodilatory shock, based on the hypothesis that endogenous vasopressin may be depleted over time in critically ill patients. Clinical trial data of outcomes are limited with vasopressin use in cardiogenic shock. *Phenylephrine,* a synthetic, selective $alpha_1$ agonist, is rarely used in cardiogenic shock because of potent vasoconstriction.

Cardiogenic Shock

Congestion and inadequate tissue or end-organ perfusion secondary to cardiac insufficiency characterize cardiogenic shock. This reduction in perfusion decreases O_2 and nutrient delivery to tissues, which if severe or protracted, can lead to multiorgan dysfunction and death. Cardiogenic shock complicating MI most often results from LV dysfunction (approximately 80%); the remainder have a mechanical defect (e.g., VSD, papillary muscle rupture) or predominant RV infarction[108,110] (**Fig. 59.21**). Patients with cardiogenic shock complicating STEMI are more likely to be older; to have a history of diabetes mellitus, previous MI, or HF; and to have sustained an anterior infarction at the time of development of shock. In the past, cardiogenic shock occurred in up to 20% of patients with STEMI, but estimates from recent large trials and observational data bases report an incidence rate of 5% to 8%.[120] When shock occurs, the prognosis remains poor, with in-hospital mortality rates of 40% to 60%, and few interventions, with the exception of prompt coronary revascularization, conclusively provide benefit.[108,109]

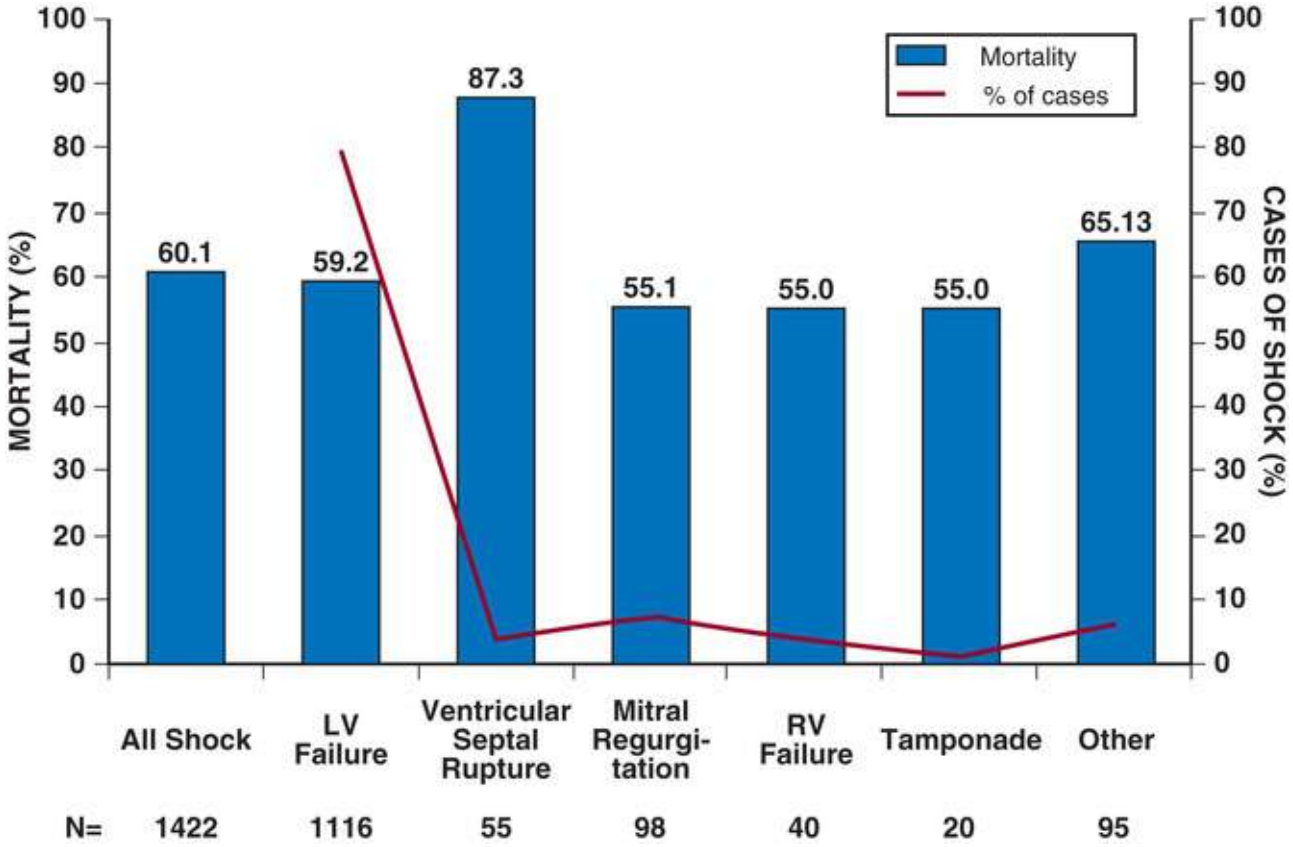

FIGURE 59.21 Mortality by etiology of cardiogenic shock following acute myocardial infarction (AMI). In-hospital mortality rates are shown for various primary etiologic conditions associated with death due to cardiogenic shock after AMI: left ventricular (LV) failure, ventricular septal rupture, acute severe mitral regurgitation, isolated right ventricular (RV) failure, cardiac tamponade/rupture (tamp), and "other" (includes previous severe valvular heart disease and excessive beta or calcium channel blockade). The proportion of patients in each category is shown. (Modified from Hochman JS et al. Cardiogenic shock complicating acute myocardial infarction—etiologies, management and outcome: a report from the SHOCK Trial Registry. Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock? J Am Coll Cardiol 2000;36(3 Suppl A):1063-70.)

Pathologic Findings

At autopsy, more than two thirds of patients with cardiogenic shock demonstrate multivessel coronary disease, usually including the left anterior descending coronary artery (LAD). Almost all patients with cardiogenic shock exhibit thrombotic occlusion of the artery supplying the major region of recent infarction, with loss of 40% or more of LV mass.[108,110] Patients who die of cardiogenic shock often have "piecemeal" necrosis, that is, progressive myocardial necrosis from marginal extension of the infarct into an ischemic zone bordering the infarction. This finding is generally associated with persistent elevation of cardiac biomarkers. Such extensions and focal lesions probably result in part from the shock state itself. Early deterioration of LV function secondary to apparent extension of the infarction in some cases may result from expansion of the necrotic zone of myocardium without actual extension of the necrotic process. The hydrodynamic force that develops during ventricular systole can disrupt necrotic myocardial muscle bundles, with resultant expansion and thinning of the akinetic zone of myocardium, which in turn results in deterioration of overall LV function.

Pathophysiology

The shock state in patients with STEMI appears to be the result of a vicious cycle, as demonstrated in **Fig. 58.14**.

Diagnosis

Generally accepted criteria for cardiogenic shock include (1) frank or relative hypotension, defined by a systolic BP below 80 or 90 mm Hg or a reduction in mean arterial pressure (MAP) of 30 mm Hg; (2) inadequate cardiac index, defined as less than 1.8 liters/min/m^2 without mechanical or pharmacologic support, or less than 2.2 liters/min/m^2 with support; (3) elevated end-diastolic pressures on the right (>10 to 15 mm Hg) and/or left (>18 mm Hg) side of the heart; and (4) evidence of end-organ hypoperfusion.[108,120] End-organ hypoperfusion may manifest as altered mental status, decreased urine output, acute kidney injury, cool or mottled extremities, acute liver injury, or lactic acidosis.

Spurious estimates of LV end-diastolic pressure based on measurements of PA wedge pressure can occur in patients with marked MR, in which the tall *v* wave in the left atrial (and PA wedge) pressure tracing elevates the MAP above LV end-diastolic pressure. Accordingly, MR and other mechanical lesions (e.g., VSD, ventricular aneurysm, pseudoaneurysm) must be excluded before making the diagnosis of cardiogenic shock caused by impairment of ventricular function. Mechanical complications should be suspected in any patient with STEMI in whom circulatory collapse occurs. Patients with cardiogenic shock merit immediate hemodynamic, angiographic, and echocardiographic evaluation. It is important to exclude mechanical complications because primary therapy for such lesions usually requires immediate invasive treatment with intervening mechanical support of the circulation.

Medical Management

In cardiogenic shock caused by impaired ventricular function, inotropic and vasopressor agents can provide pharmacologic support to maintain MAP and augment cardiac output; these agents should be administered at the lowest possible doses. Although inotropes generally improve hemodynamics in these patients, unfortunately they do not appear to improve hospital survival significantly. Similarly, vasodilators may elevate cardiac output and reduce LV filling pressure, but lowering the already markedly reduced coronary perfusion pressure can compromise further myocardial perfusion and accelerate the vicious cycle illustrated in **Fig. 58.14**. Vasodilators may nonetheless be used in conjunction with mechanical circulatory support (see next section) and inotropic agents to increase cardiac output while sustaining or elevating coronary perfusion pressure.

Patients with cardiogenic shock usually have elevated SVR, although cardiogenic shock can be complicated by a systemic inflammatory response syndrome (SIRS) and a vasodilatory state, particularly with shock of longer duration or more profound severity.[108] When SVR is not elevated (i.e., <1800 dynes/sec/cm^5) in patients with cardiogenic shock, *inopressors*, or agents with inotropic and vasopressor properties, can be useful to maintain perfusion through preservation of MAP and augmentation of cardiac output.

Mechanical Circulatory Support

The theoretical benefits of mechanical circulatory support (MCS) include the ability to (1) maintain end-organ perfusion and prevent the progressive shock spiral, (2) reduce intracardiac filling pressures and congestion, (3) reduce LV volumes, wall stress, and myocardial oxygen consumption, (4) augment coronary perfusion, (5) support the circulation during complex coronary interventions, (6) allow time for recovery of stunned or hibernating myocardium, and (7) limit infarct size[121] (**see Chapter 29**). No definitive evidence has yet shown that MCS following MI improves outcomes, and data are lacking to define the optimal strategy for timing and choice of device.[121] As a result, based primarily on expert consensus, early placement of MCS may be considered in those with cardiogenic shock who fail to

stabilize quickly after initial interventions (e.g., reperfusion) and for those undergoing high-risk PCI (e.g., multivessel or unprotected left main) with severe HF or LV dysfunction[121] (**Fig. 59.22**).

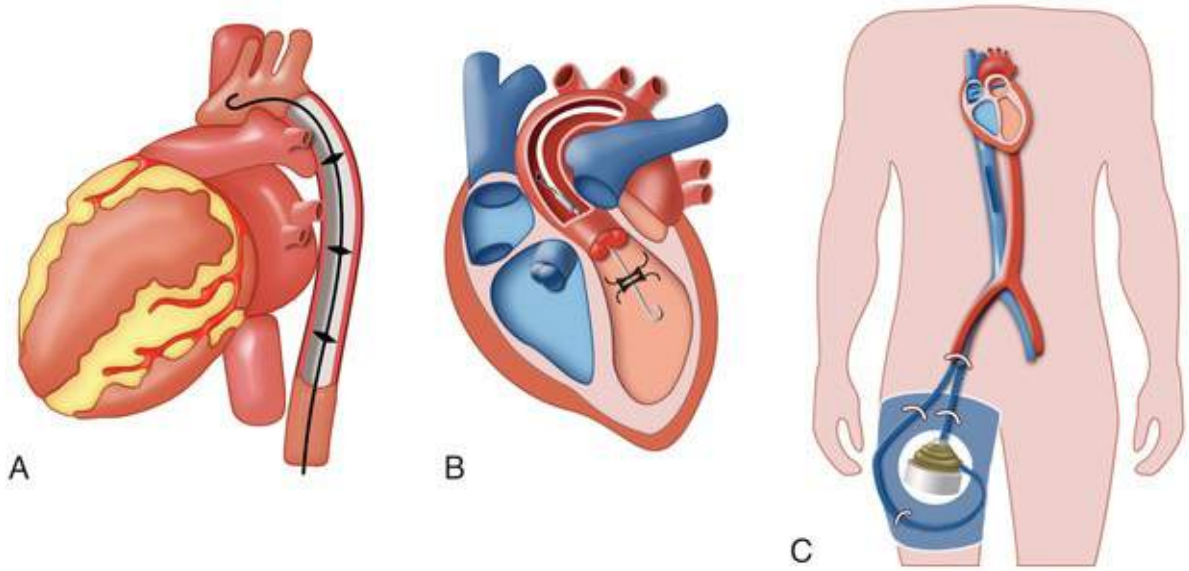

FIGURE 59.22 Schematic representation of examples of major categories of nonsurgical mechanical circulatory support. **A,** Intra-aortic balloon pump inserted into the descending aorta between the arch vessels and renal arteries. **B,** Impella Recover (Abiomed, Aachen, Germany). This rotational flow device is percutaneously inserted through the femoral artery and positioned across the aortic valve, with flow intake in the left ventricle and outflow in the aorta. **C,** TandemHeart (CardiacAssist, Pittsburgh). A cannula is inserted percutaneously through the right femoral vein and advanced toward the right atrium, where it is introduced by transatrial septal perforation, to establish inflow into an external rotational motor. A cannula in either femoral artery then provides the outflow. (Modified from Desai NR, Bhatt DL. Evaluating percutaneous support for cardiogenic shock: data shock and sticker shock. Eur Heart J 2009;30:2073.)

Intra-Aortic Balloon Counterpulsation

Intra-aortic balloon (IAB) counterpulsation continues to be used for the treatment of STEMI in three groups of patients: (1) those with hemodynamic instability who require support of the circulation for the performance of cardiac catheterization and angiography to assess lesions that are potentially correctable surgically or by angioplasty, (2) those with cardiogenic shock that does not respond to medical management, and rarely, (3) those with refractory ischemia that is not alleviated by other treatments, or who await definitive revascularization. In experimental animals, IAB counterpulsation decreases preload, increases coronary blood flow, and improves cardiac performance. Unfortunately, the improvement is often only temporary in patients with cardiogenic shock. Although a response to IAB counterpulsation correlates with better outcomes in observational studies and small randomized trials, in the largest randomized trial conducted to date, counterpulsation alone did not improve overall survival in patients with cardiogenic shock secondary to MI[122] (**Fig. 59.23**). Also, no benefit was observed in any clinically relevant subgroups. Nevertheless, IAB counterpulsation is reasonable in patients with cardiogenic shock whose condition does not stabilize with other interventions, and as a bridge to recovery or more advanced therapies.[1]

LBBB, Left bundle branch block. (From Thiele H, Zeymer U, Neumann FJ, et al. Intraaortic balloon support for myocardial infarction with cardiogenic shock. N Engl J Med 2012;367:1287.)

Percutaneous Left Ventricular Assist Devices

A percutaneous left ventricular assist device (LVAD) may be placed by cannulation of the left femoral vein and advancement to the left atrium by transseptal puncture (**see Fig. 59.22**). Blood from the left atrium returns into the femoral artery via a nonpulsatile motor. This system may provide up to 5 liters/min of flow. Small randomized trials have not revealed any mortality advantage over IAB counterpulsation, but hemodynamic improvement is greater with the percutaneous LVAD.[121] Another percutaneous alternative is a motorized device placed across the aortic valve that delivers continuous flow of blood from the left ventricle into the aorta and provides hemodynamic support superior to that achieved with an IAB in patients with MI.[121,123] Extracorporeal membrane oxygenation (ECMO) is another percutaneous circulatory support option that provides biventricular support as well as oxygenation. The aim of temporary mechanical support with LVADs is to allow time for recovery of stunned or hibernating myocardium or for a bridge to more durable devices. Surgically placed LVADs as a bridge to transplantation or as a destination therapy are discussed in **Chapter 28**.

Complications

Complications of MCS include vascular damage, ischemia distal to the site of insertion for devices requiring femoral arterial cannulation, thrombocytopenia, hemolysis, atheroemboli, infection, mechanical failure, and bleeding in the setting of anticoagulation.

Revascularization

Of the five therapies frequently used to treat patients with cardiogenic shock—inotropes/vasopressors, MCS, fibrinolysis, PCI, and CABG—the first two are useful temporizing maneuvers. Revascularization, however, appears to improve survival.

The SHOCK (Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock?) study evaluated early revascularization for the treatment of patients with MI complicated by cardiogenic shock.[108] Patients with shock caused by LV failure complicating STEMI were randomly assigned to emergency revascularization (n = 152), accomplished by either CABG or angioplasty, or to initial medical stabilization (n = 150). In 86% of patients in both groups, IAB counterpulsation was performed. The primary endpoint was all-cause mortality at 30 days; a secondary endpoint was mortality at 6 months. At 30 days the overall mortality rate was 46.7% in the revascularization group, not significantly different from the 56% mortality observed in the medical therapy group (P = 0.11). Subgroups of patients in the SHOCK study who showed benefit from the early revascularization strategy (i.e., reduced 6-month mortality) were those younger than 75 years, those with a previous MI, and those randomly assigned less than 6 hours from the onset of infarction. Long-term survival improved significantly in patients with cardiogenic shock who underwent early revascularization (**Fig. 59.24**). A subsequent observational study of patients with MI complicated by shock indicated that well-selected elderly patients undergoing PCI had a 1-year survival similar to that in younger patients undergoing early revascularization.[124]

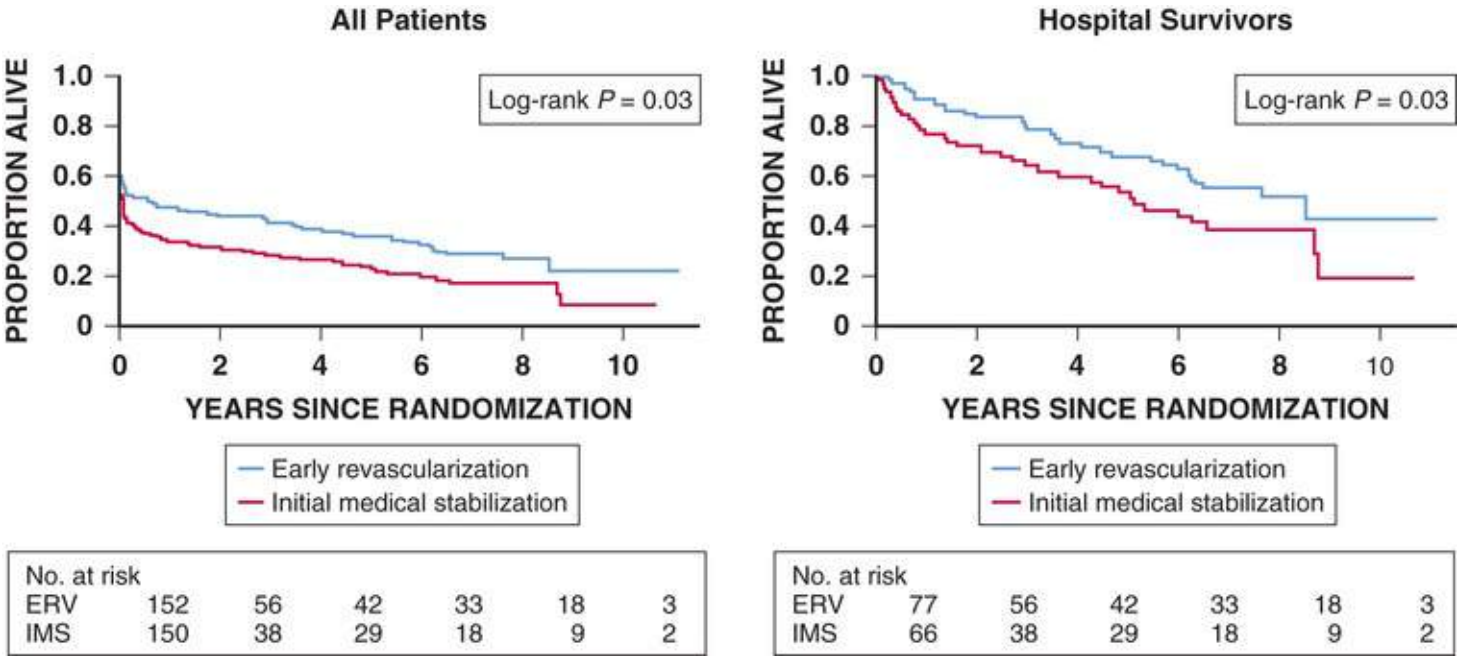

FIGURE 59.24 Impact of revascularization in patients in the SHOCK trial. Among all patients, survival rates in the early revascularization (ERV) and initial medical stabilization (IMS) groups, respectively, were 41.4% and 28.3% at 3 years and 32.8% and 19.6% at 6 years. Among hospital survivors, survival rates in the ERV and IMS groups, respectively, were 78.8% and 64.3% at 3 years and 62.4% and 44.4% at 6 years. (From Hochman JS, Sleeper LA, Webb JG, et al. Early revascularization and long-term survival in cardiogenic shock complicating acute myocardial infarction. JAMA 2006;295:2511.)

Multivessel disease affects 70% to 90% of patients with cardiogenic shock and acute MI, but the optimal extent of the initial revascularization is not yet known.[122] Although multiple recent small studies demonstrated robust reductions in recurrent CV events with multivessel or complete revascularization compared to infarct artery–only revascularization in patients with STEMI, all these studies excluded patients with cardiogenic shock[58-60] (see earlier, Catheter-Based Reperfusion Strategies). In a prospective observational study of 169 participants with resuscitated cardiac arrest and cardiogenic shock, multivessel PCI was associated with decreased mortality compared with culprit vessel–only PCI[125] (**Fig. 59.25**). However, in the substantially larger CULPRIT-SHOCK (Culprit Lesion Only PCI versus Multivessel PCI in Cardiogenic Shock) trial among 706 patients with cardiogenic shock onset within 12 hours in the setting of acute MI (ST- and non–ST-elevation MI) that randomized patients to infarct artery–only or acute multivessel revascularization, patients allocated to infarct artery-only PCI had a lower 30-day rate of death or severe renal failure leading to renal replacement therapy (RR 0.83; 95% CI 0.71 to 0.96; P = 0.01).[1,126,126a] Moreover, the risk of death was lower in patients randomized to culprit-only PCI (P = 0.03).[126a]

Management of cardiogenic shock. Eur Heart J 2015;36:1223-30.)

Recommendations

We recommend individualized assessment of patients to determine their desire for aggressive care and overall candidacy for further treatment (e.g., age, mental status, comorbid conditions). Patients with shock who are potential candidates for revascularization of the culprit artery should be revascularized. Routine revascularization of nonculprit arteries in the same procedure as the primary PCI does not appear indicated and may be associated with worsened outcomes. In patients with STEMI and shock, in whom PCI or CABG is not suitable, fibrinolytic agents can be given unless they have a contraindication.[1] IAB counterpulsation and LVADs may aid patients with refractory shock whose condition does not stabilize with other therapies.

Right Ventricular Infarction

The clinical features of RV infarction range from mild RV dysfunction to cardiogenic shock. Clinically significant RV infarction, which accompanies approximately one third of inferior LV infarctions, produces characteristic electrocardiographic manifestations and hemodynamic patterns (**Fig. 59.26**). Right-sided heart filling pressures (CVP, RA, RV end-diastolic) are elevated, whereas LV filling pressure is normal or only slightly raised; RV systolic and pulse pressures are decreased, and cardiac output is often greatly depressed.

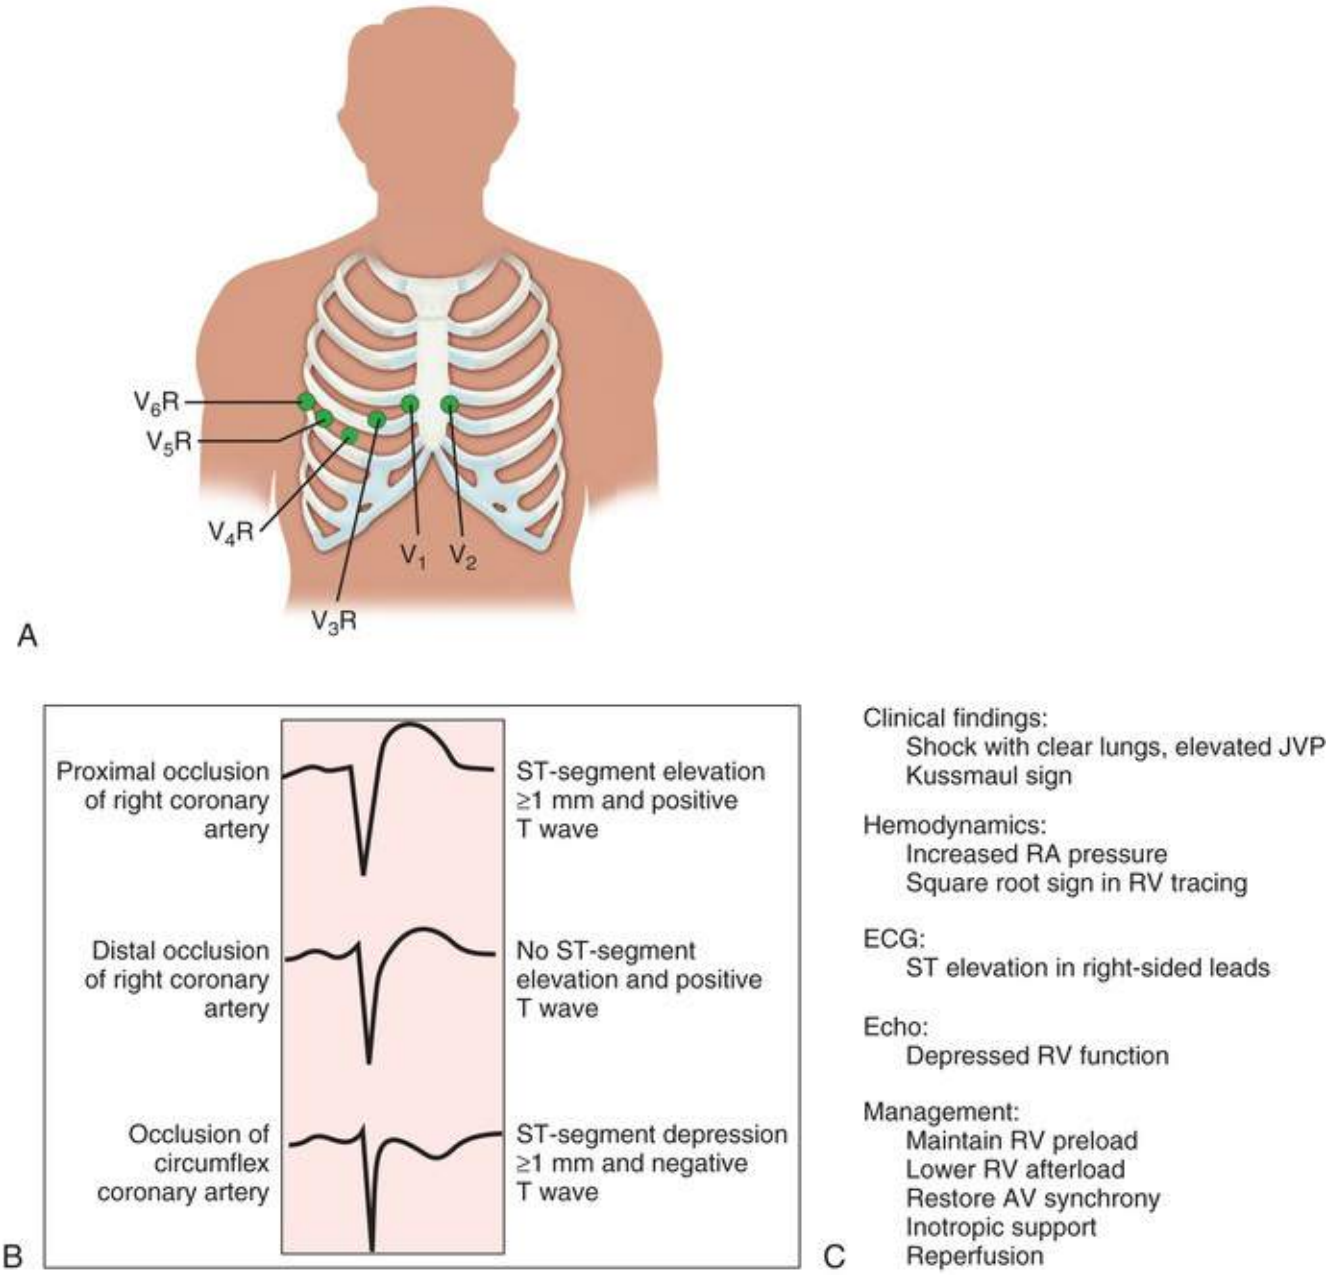

FIGURE 59.26 Right ventricular (RV) infarction: diagnosis, clinical features, and management. **A,** Placement of right-sided leads for electrocardiographic evaluation of RV infarction. **B,** ST elevation is seen in the right-sided ECG leads (e.g., V_4R), with variation in the repolarization pattern depending on the infarct artery and the location of the occlusion. **C,** Patients with hemodynamically significant RV infarction have shock but clear lungs and elevated jugular venous pressure (JVP). Management is directed at maintaining adequate RV preload and lowering pulmonary artery pressure to unload the right ventricle. Inotropic therapy may be necessary in some cases. Echo, Echocardiogram; RA, right atrial. (Modified from Wellens HJ. The value of the right precordial leads of the electrocardiogram. N Engl J Med 1999;340:381; and Antman EM et al. ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee to Revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction]. J Am Coll Cardiol 2004;44(3):e1.)

Diagnosis

Many patients with the combination of a normal LV filling pressure and depressed cardiac index have RV infarcts (with accompanying inferior LV infarcts). The hemodynamic picture may superficially resemble that seen in patients with pericardial disease (**see Chapter 83**) and includes elevated RV filling pressure; a steep, right atrial *y* descent; and an early diastolic drop and plateau (resembling the square root sign) in the RV pressure tracing. Moreover, patients with RV infarction may display the Kussmaul sign (increase

in jugular venous pressure with inspiration) and pulsus paradoxus (decrease in systolic BP >10 mm Hg with inspiration) (**Fig. 59.26C**). In fact, the Kussmaul sign in the setting of inferior STEMI is highly predictive of RV involvement.

The ECG can provide the first clue to RV involvement in patients with inferior STEMI (**Fig. 59.26B**). Most patients with RV infarction have ST-segment elevation in lead V_4R (right precordial lead in the V_4 position).[1] Transient elevation of the ST segment in any of the right precordial leads can occur with RV MI, and the presence of ST-segment elevation of 0.1 mV or greater in any one or a combination of leads V_4R, V_5R, and V_6R in patients with the clinical picture of acute MI points to the diagnosis of RV MI. In addition to noting the presence or absence of convex upward ST elevation in V_4R, clinicians should determine whether the T wave is positive or negative; such distinctions help distinguish proximal versus distal occlusion of the right coronary artery versus occlusion of the left circumflex artery (**Fig. 59.26B**). Elevation of the ST segments in leads V_1 through V_4 caused by RV infarction can be confused with elevation caused by anteroseptal infarction. Although the elevated ST segments orient anteriorly in both cases, the frontal plane can provide important clues: the ST segments orient to the right with RV infarction (e.g., +120 degrees), whereas they orient to the left with anteroseptal infarction (e.g., −30 degrees).

Noninvasive Assessment

Echocardiography helps in the differential diagnosis because in patients with RV infarction, in contrast to pericardial tamponade, little or no pericardial fluid accumulates. The echocardiogram shows abnormal wall motion of the right ventricle, as well as RV dilation and depression of the RV ejection fraction.[127] MRI can also aid in recognition of RV infarction. Impaired RV function delineated by either modality is associated with increased mortality after MI.[127,128] Additionally, shock from isolated RV dysfunction carries almost as high a mortality risk as LV shock; serial studies have shown, however, some degree of ventricular recovery more frequently with RV infarction than with LV infarction.[18]

Treatment

Because of their ability to reduce preload, medications routinely prescribed for LV infarction may produce profound hypotension in patients with RV infarction. Specifically, nitrates, morphine, and diuretics should be avoided. In patients with hypotension caused by RV MI, hemodynamics can improve with a combination of expansion of plasma volume to augment RV preload and cardiac output and, when LV failure is present, arterial vasodilators.[1] If hypotension has not responded to brisk administration of 1 or more liters of fluid, however, consideration should be given to hemodynamic monitoring with a PA catheter because further volume infusion may be of little use and could produce pulmonary congestion. Arterial vasodilators reduce the impedance to LV outflow and, in turn, LV diastolic, left atrial, and pulmonary (arterial) pressure, thereby lowering impedance to RV outflow and enhancing RV output.

Right ventricular infarction is common in patients with inferior LV infarction. Therefore, otherwise unexplained systemic arterial hypotension with diminished cardiac output or marked hypotension in response to small doses of nitroglycerin in patients with inferior infarction should lead to prompt consideration of this diagnosis. In patients requiring pacing, ventricular pacing may fail to increase cardiac output, and AV sequential pacing may be needed. Successful reperfusion of the right coronary artery significantly improves RV mechanical function and lowers in-hospital mortality in patients with RV infarction.[18] Replacement of the tricuspid valve and repair of the valve with annuloplasty rings can treat severe tricuspid regurgitation caused by RV infarction.

Mechanical Causes of Heart Failure

The most dramatic complications of STEMI involve tearing or rupture of acutely infarcted tissue (**Fig. 59.27**). The clinical characteristics of these lesions vary considerably and depend on the site of rupture, which may involve the free wall of either ventricle, the interventricular septum, or the papillary muscles. The overall incidence of these complications, although difficult to assess because clinical and autopsy series differ considerably, appears to have decreased initially with the introduction of reperfusion therapy and subsequently decreased substantially with the widespread adoption of primary PCI.[129] **Table 59.11** shows the comparative clinical profile of these complications, as gathered from different studies.

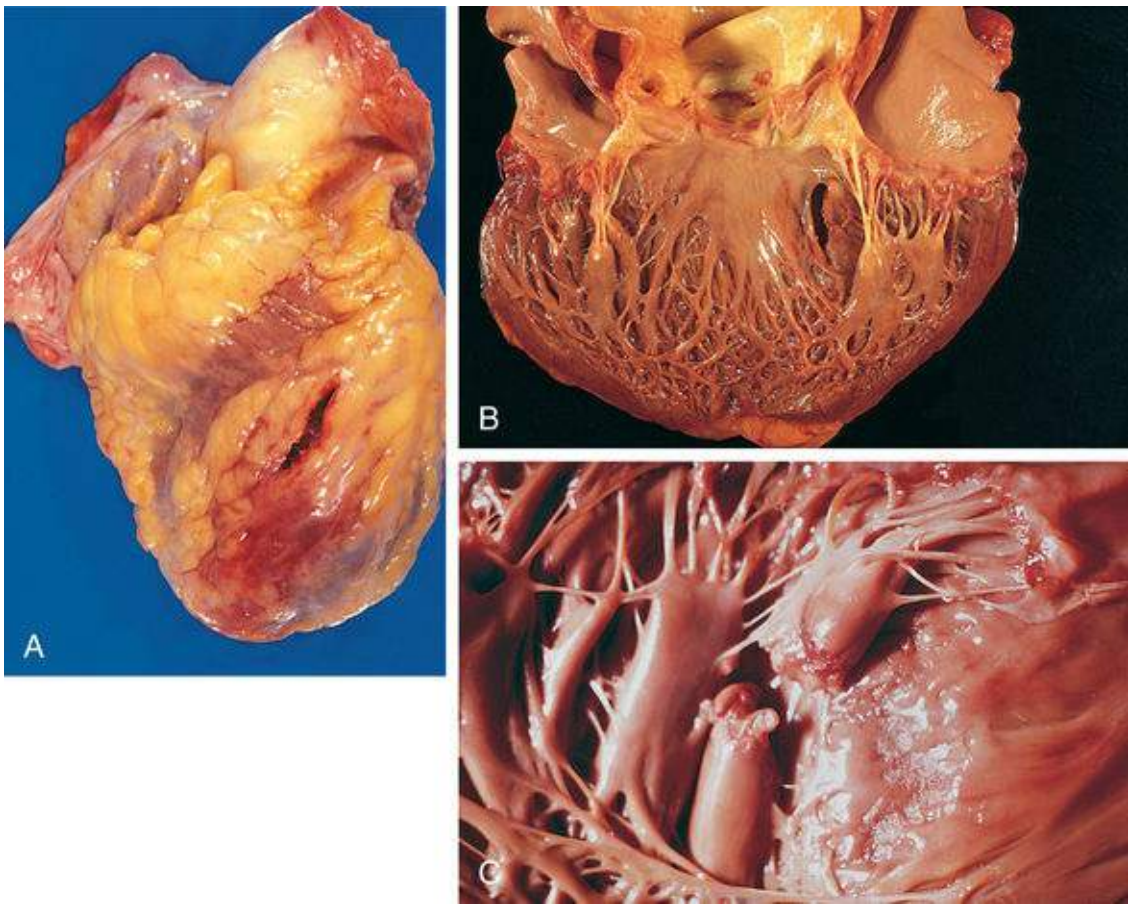

FIGURE 59.27 Cardiac rupture syndromes complicating STEMI. **A,** Anterior myocardial rupture in an acute infarct. **B,** Rupture of the ventricular septum. **C,** Complete rupture of a necrotic papillary muscle.

TABLE 59.11

Characteristics of Ventricular Septal Rupture, Rupture of the Ventricular Free Wall, and Papillary Muscle Rupture

CHARACTERISTIC	VENTRICULAR SEPTAL RUPTURE	RUPTURE OF THE VENTRICULAR FREE WALL	PAPILLARY MUSCLE RUPTURE
Incidence	1-3% without reperfusion therapy, 0.2-0.34% with fibrinolytic therapy, 3.9% in patients with cardiogenic shock	Approximately 1%; fibrinolytic therapy does not reduce risk; primary PCI seems to reduce risk	Approximately 1% (posteromedial more frequent than anterolateral papillary muscle rupture)
Time course	Bimodal peak; within 24 hr and 3-5 days; range, 1-14 days	Bimodal peak; within 24 hr and 3-5 days; range, 1-14 days	Bimodal peak; within 24 hr and 3-5 days; range, 1-14 days
Clinical manifestations	Chest pain, shortness of breath, hypotension	Anginal, pleuritic, or pericardial chest pain; syncope; hypotension; restlessness; sudden death	Abrupt onset of shortness of breath and pulmonary edema; hypotension
Physical findings	Harsh holosystolic murmur, thrill, S_3, accentuated S_2, pulmonary edema, RV and LV failure, cardiogenic shock	Jugular venous distention (29% of patients), pulsus paradoxus (47%), electromechanical dissociation, cardiogenic shock	A soft murmur in some cases, no thrill, variable signs of RV overload, severe pulmonary edema, cardiogenic shock
Echocardiographic findings	Ventricular septal rupture, left-to-right shunt on color flow Doppler echocardiography through the ventricular septum, pattern of RV overload	>5 mm pericardial effusion not visualized in all cases; layered, high-acoustic echoes within the pericardium (blood clot); direct visualization of tear; signs of tamponade	Hypercontractile LV, torn papillary muscle or chordae tendineae, flail leaflet, severe mitral regurgitation on color flow Doppler echocardiography
Right-heart catheterization	Increase in oxygen saturation from the RA to RV, large *v* waves	Ventriculography insensitive, classic signs of tamponade not always present (equalization of diastolic pressures in the cardiac chambers)	No increase in oxygen saturation from the RA to RV, large *v* waves,* very high PCWP

*Large *v* waves are from the pulmonary capillary wedge pressure (PCWP).

Data from Antman EM, Anbe DT, Armstrong PW, et al. ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to Revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction). Circulation 2004;110(9):e82.

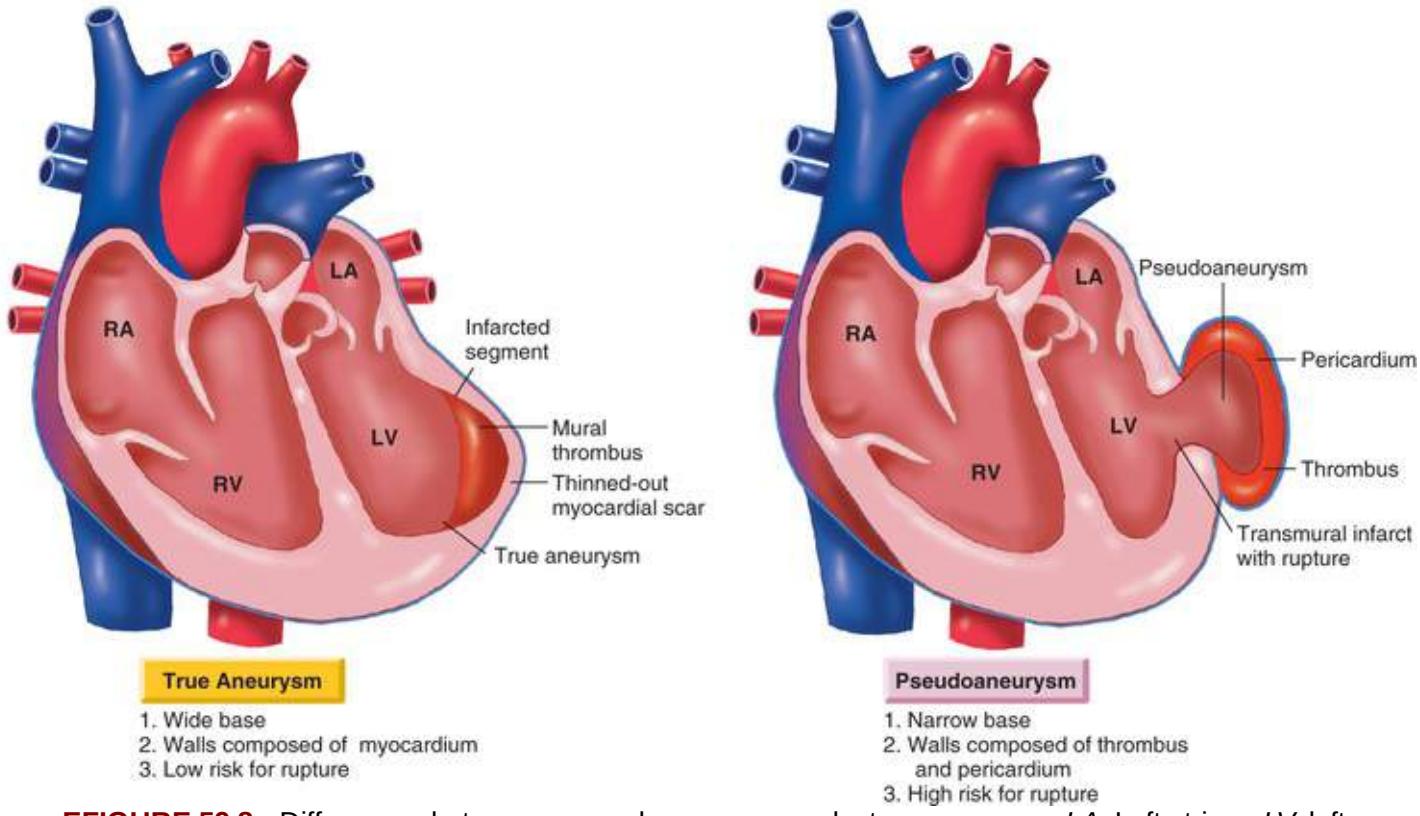
Free Wall Rupture

The clinical course of rupture varies from *catastrophic*, with an acute tear leading to tamponade and immediate death, to *subacute,* with nausea, hypotension, and pericardial discomfort the major clinical clues to its presence (**Fig. 59.27 and Table 59.11**). The tear is usually preceded by a large infarct with subsequent expansion, sometimes with a dissecting hematoma, and occurs near the junction of the infarct and normal muscle. Rupture is more common in the left ventricle (specifically, the anterior or lateral wall) than in the right ventricle and seldom occurs in the atria. Other features associated with rupture include reperfusion with a fibrinolytic agent versus PCI, older age, female sex, hypertension, single-vessel disease without collateral circulation, and an anterior or first MI.[129] Mortality rates can be as high as 75% to 90% following free wall rupture. Survival depends on recognition of this complication, and most importantly, on prompt surgical repair.[1]

Pseudoaneurysm

Incomplete rupture of the heart may occur when organizing thrombus and hematoma, together with pericardium, seal a rupture of the left ventricle and thus prevent the development of hemopericardium (**eFig. 59.8**). With time, this area of organized thrombus and pericardium can become a pseudoaneurysm (false aneurysm) that maintains communication with the cavity of the left ventricle. In contrast to true aneurysms, which always contain some myocardial elements in their walls, the walls of pseudoaneurysms are composed of organized hematoma and pericardium and lack any elements of the original myocardial wall. Pseudoaneurysms can become quite large, even equaling the true ventricular cavity in size, and they communicate with the LV cavity through a narrow neck. Frequently, pseudoaneurysms contain significant quantities of old and recent thrombi, the superficial portions of which can cause arterial emboli.

Pseudoaneurysms can drain off a portion of each ventricular stroke volume, exactly as do true aneurysms. The diagnosis of pseudoaneurysm can usually be made by echocardiography, contrast-enhanced angiography, CMR, or computed tomography (CT), although differentiation between a true aneurysm and a pseudoaneurysm can sometimes be difficult with any imaging technique.[68,127]



EFIGURE 59.8 Differences between a pseudoaneurysm and a true aneurysm. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. (From Shah PK: Complications of acute myocardial infarction. In Parmley W, Chatterjee K, editors. Cardiology. Philadelphia: Lippincott; 1987.)

Diagnosis

Myocardial free wall rupture is usually accompanied by sudden profound shock, often rapidly leading to pulseless electrical activity caused by pericardial tamponade. Immediate pericardiocentesis can confirm the diagnosis. If the patient's condition is sufficiently stable, echocardiography can establish the diagnosis of tamponade.[127]

Treatment

In patients with critically compromised hemodynamics, establishment of the diagnosis should be followed immediately by surgical resection of the necrotic and ruptured myocardium with primary reconstruction. When the rupture is subacute and a pseudoaneurysm is suspected or present, prompt elective surgery is indicated because the risk of rupture approaches 50% in untreated cases.[68]

Rupture of Interventricular Septum

As in rupture of the free wall of the ventricle, transmural infarction underlies rupture of the ventricular septum. The perforation can range in length from one to several centimeters (**Fig. 59.27**). It can be a direct through-and-through opening or more irregular and serpiginous. Rupture of the septum with an anterior

infarction tends to be apical in location, whereas inferior infarctions are associated with perforation of the basal septum and have a worse prognosis than those in an anterior location.

Clinical features associated with increased risk for rupture of the interventricular septum include lack of development of a collateral network, advanced age, female sex, and chronic kidney disease (**Table 59.11**). Because previous ischemia induces myocardial preconditioning, thereby decreasing the likelihood of transmural myocardial necrosis and septal rupture, patients with evidence of hypertension, diabetes mellitus, chronic angina, or previous MI are less likely to experience rupture.[110]

A new, harsh, loud holosystolic murmur heard best at the lower left sternal border, usually accompanied by a thrill, characterizes a ruptured interventricular septum. Biventricular failure generally ensues within hours to days. The defect can also be recognized by echocardiography with color flow Doppler imaging (**Fig. 59.28**) or by insertion of a PA balloon catheter to document the left-to-right shunt. Rupture of the interventricular septum after STEMI carries a poor prognosis, with mortality of 40% to 75%.[129] The likelihood of survival depends on the degree of impairment of ventricular function and the size of the defect, but because the rupture site can expand, prompt repair is necessary even in hemodynamically stable patients.[1] Septal rupture is most often repaired surgically (**Fig. 59.29**), although transcatheter closure may be considered, particularly when the patient is deemed inoperable and the anatomy is amenable to application of a closure device.[130]

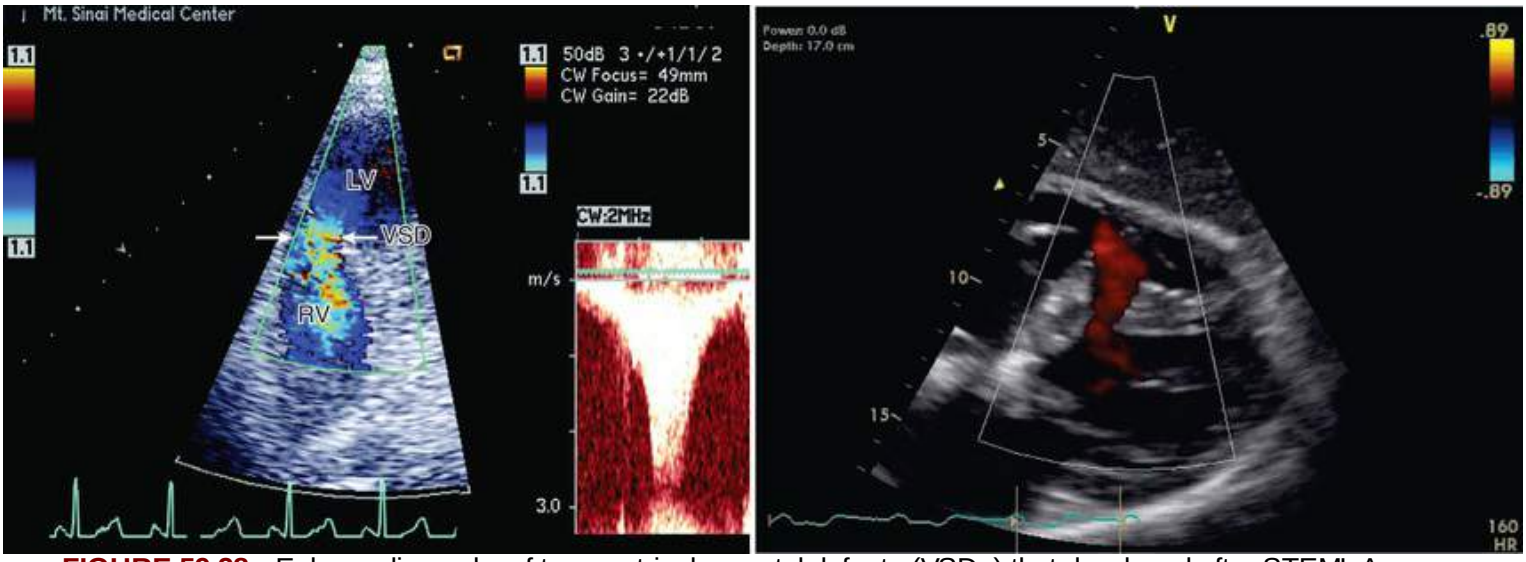


FIGURE 59.28 Echocardiography of two ventricular septal defects (VSDs) that developed after STEMI. A close-up of the ventricular septum demonstrates turbulent systolic color flow Doppler across a VSD (*white arrows*), and continuous-wave Doppler demonstrates systolic flow across a VSD **(left)**. A subcostal view demonstrates color flow Doppler across a VSD **(right)**. *LV,* Left ventricle; *RV,* right ventricle. (**Left,** From Kamran M, Attari M, Webber G. Images in cardiovascular medicine. Ventricular septal defect complicating an acute myocardial infarction. Circulation 2005;112:e337; **Right,** from Brigham and Women's Hospital, 2013.)

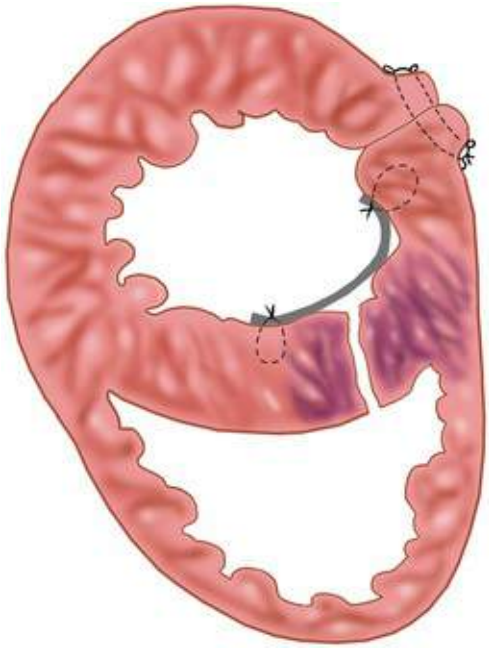

FIGURE 59.29 Repair of an ischemic ventricular septal defect. The infarct typically involves a free wall and septum. Repair of the defect is performed through an incision in the ventricular wall infarct. The septal defect is closed with a prosthetic patch, and a second patch is used to close the incision in the free wall.

Rupture of a Papillary Muscle

Partial or total rupture of a papillary muscle is a rare but often fatal complication of transmural MI[131] (**see Fig. 59.21**). Complete transection of a LV papillary muscle is incompatible with life because the sudden massive MR that develops cannot be tolerated. Rupture of a portion of a papillary muscle, usually the tip or head of the muscle, that results in severe, although not necessarily overwhelming MR, is much more frequent and is not immediately fatal (**Fig. 59.30**). Inferior wall infarction can lead to rupture of the posteromedial papillary muscle, which because of its singular blood supply, occurs more frequently than rupture of the anterolateral muscle, a consequence of anterolateral MI. Unlike rupture of the ventricular septum, which occurs with large infarcts, papillary muscle rupture occurs with a relatively small infarction in approximately half of cases. These patients may have a modest extent of CAD as well. Rupture of a RV papillary muscle is unusual but can cause massive tricuspid regurgitation and RV failure. In a small number of patients, rupture of more than one cardiac structure is noted clinically or at postmortem examination; all possible combinations of rupture of the LV free wall, the interventricular septum, and the papillary muscles can occur.

FIGURE 59.30 Surgical specimen showing a papillary muscle (*top left*), chordae, and anterior mitral leaflet (*bottom right*) from a patient who had a partial rupture of the papillary muscle and underwent mitral valve replacement for severe mitral regurgitation after STEMI. (Courtesy Dr. John Byrne, Brigham and Women's Hospital, Boston.)

As with patients who have a ruptured VSD, those with papillary muscle rupture manifest with increasingly severe HF. These patients may also have a holosystolic murmur, but because of rapid equalization of pressures between the left atrium and ventricle, patients with torrential acute MR may have an unimpressive or absent murmur.[131] In either ventricular or papillary muscle rupture, the murmur may become softer or may disappear as arterial pressure falls. Echocardiography can promptly recognize MR secondary to partial or complete rupture of a papillary muscle and distinguish it from other, generally less severe forms of MR that occur with STEMI. Color flow Doppler imaging is particularly helpful in distinguishing acute MR from VSD in the setting of STEMI (**Table 59.11**).[1] However, acute severe MR may be difficult to diagnose with transthoracic echocardiography (TTE) in cases with narrow eccentric jets with rapid equalization of pressures; therefore, transesophageal echocardiography (TEE) should be employed when suspicion is high because of its greater diagnostic accuracy.

Differentiation Between Ventricular Septal Rupture and Mitral Regurgitation

Distinguishing on clinical grounds between acute MR and rupture of the ventricular septum in patients with STEMI in whom a loud systolic murmur suddenly develops may be difficult. Such differentiation can be made most readily by color flow Doppler echocardiography. In addition, right-heart catheterization can readily distinguish between these two complications. Patients with ventricular septal rupture demonstrate a “step-up” in SaO_2 in blood samples from the right ventricle and PA compared with those from the right atrium. Patients with acute MR lack this step-up; they may demonstrate tall *c-v* waves in both the pulmonary capillary and pulmonary arterial pressure tracings.

Management

We recommend initiation of invasive monitoring in most cases once there is recognition of a major mechanical complication of STEMI. RV and LV filling pressures (RA pressure and PCWP) guide fluid

administration or the use of diuretics, whereas measurements of cardiac output and MAP permit calculation of SVR to direct vasodilator therapy. For acute MR and VSDs, unless systolic BP is below 90 mm Hg, vasodilator therapy, usually nitroglycerin or nitroprusside, should be instituted as soon as possible once hemodynamic monitoring is available. Inotropes may also be needed to support adequate cardiac output. These interventions may be critically important for stabilizing the patient's condition in preparation for further diagnostic studies and repair. If pharmacologic therapy is not tolerated or fails to achieve hemodynamic stability, IAB counterpulsation should be instituted rapidly. IAB counterpulsation as a bridge to definitive repair should be considered for most patients with acute mechanical complications of STEMI.

Operative intervention is most successful in patients with STEMI and circulatory collapse when a surgically correctable mechanical lesion (e.g., VSD, ruptured papillary muscle) can be identified and addressed (**Fig. 59.31**). In most cases, surgery should not be delayed in patients with a correctable lesion who agree to an aggressive management strategy and require pharmacologic and mechanical (counterpulsation) support.[1] In such patients a serious complication frequently develops—infection, ARDS, extension of the infarct, or renal failure—if surgery is delayed. Early surgery, short duration of shock, and mild degrees of RV and LV impairment predict surgical survival.[1] In a subset of patients whose hemodynamic status remains stable, the operation may be postponed for 2 to 4 weeks to allow some healing of the infarct. Such complex decisions regarding the optimal timing of surgery require integration of multiple aspects of the clinical course and anatomy of the mechanical complication by a multidisciplinary “heart” team. These situations also require careful consideration of the goals of care with the patient or proxies to ensure respecting the patient's wishes and values, particularly in cases with a high degree of futility (**see Chapter 31**).

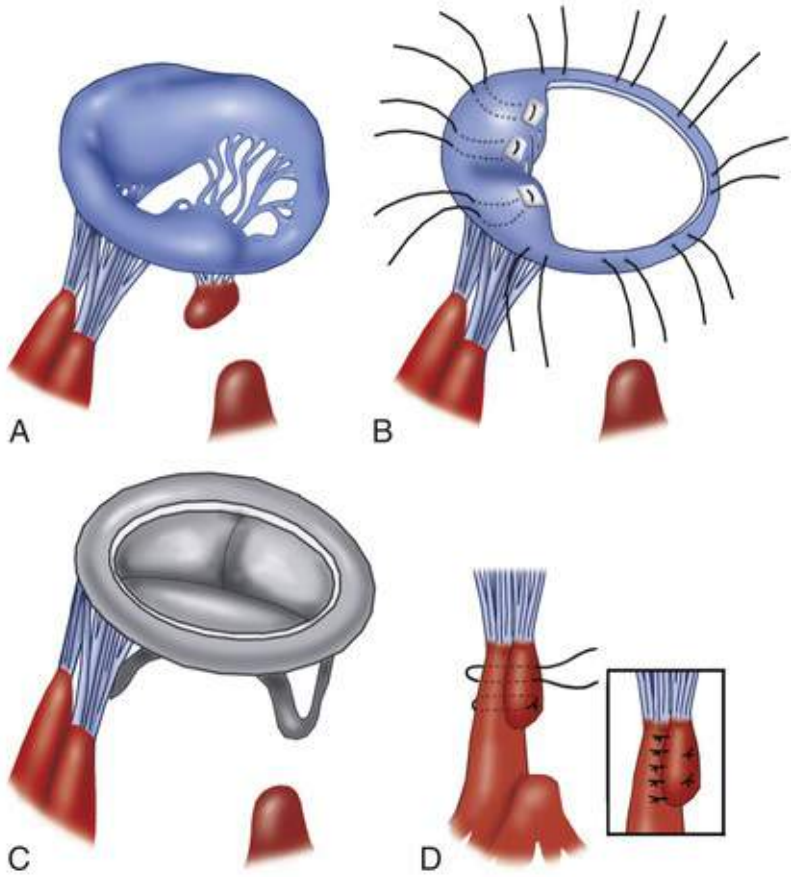

FIGURE 59.31 Surgical management of mitral regurgitation (MR) caused by a ruptured papillary muscle. **A,** Acute papillary muscle rupture results in severe MR as a result of leaflet and commissural prolapse. Mitral valve replacement is usually necessary. **B,** Mitral débridement with retention of the unruptured commissural and leaflet segment is performed to preserve partial continuity of the annular papillary muscle. **C,** Mitral valve replacement is then performed. **D,** Occasionally, mitral valve repair can be performed by transfer of a papillary head to a nonruptured segment. (Courtesy Dr. David Adams, Mt. Sinai Hospital, New York.)

Catheter-based options for VSD repair may be appropriate in patients who are not candidates for early definitive surgical correction.[1,130] We sometimes undertake early catheter-based repair with the aim of temporizing the defect until a later definitive surgical repair, when more infarct healing has occurred. However, because the initial closure of the defect is almost always incomplete, and the device requires time to thrombose and endothelialize, in most patients with hemodynamically significant mechanical complications, surgical management is the best option.[1,130]

Arrhythmias

Arrhythmias can complicate the course of patients with STEMI (**Table 59.12**). Many serious arrhythmias develop before hospitalization, even before the patient is monitored. Some abnormality in cardiac rhythm also occurs in many patients with STEMI treated in the hospital. These arrhythmias can include both tachycardic and bradycardic episodes, either of which can provoke hemodynamic consequences. (See also Part V in this textbook.)

TABLE 59.12

Cardiac Arrhythmias and Management During Acute Myocardial Infarction

CATEGORY	ARRHYTHMIA	OBJECTIVE OF TREATMENT	THERAPEUTIC OPTIONS
1. Electrical instability	Ventricular premature beats	Correction of electrolyte deficits and minimization of sympathetic tone	Potassium and magnesium solutions, beta blocker
	Ventricular tachycardia	Prophylaxis against ventricular fibrillation, restoration of hemodynamic stability	Antiarrhythmic agents, beta blocker; cardioversion/defibrillation; revascularization
	Ventricular fibrillation	Urgent reversion to sinus rhythm	Defibrillation; amiodarone, lidocaine; revascularization
	Accelerated idioventricular rhythm	Observation unless hemodynamic function is compromised	Increase sinus rate (atropine, atrial pacing); antiarrhythmic agents
	Nonparoxysmal atrioventricular junctional tachycardia	Search for precipitating cause (e.g., digitalis intoxication); suppress arrhythmia only if hemodynamic function is compromised	Atrial overdrive pacing; antiarrhythmic agents; cardioversion relatively contraindicated if digitalis intoxication present
2. Pump failure, excessive sympathetic stimulation	Sinus tachycardia	Reduce heart rate to diminish myocardial oxygen demands	Antipyretics; analgesics; consider beta blocker unless heart failure present
	Atrial fibrillation and/or atrial flutter	Reduce ventricular rate; restore sinus rhythm	Verapamil, digitalis glycosides; amiodarone; treat heart failure; cardioversion
	Paroxysmal supraventricular tachycardia	Reduce ventricular rate; restore sinus rhythm	Vagal maneuvers; verapamil, cardiac glycosides, beta blockers; cardioversion
3. Bradyarrhythmias, conduction disturbances	Sinus bradycardia	Acceleration of the heart rate only if hemodynamic function is compromised	Atropine; atrial pacing
	Junctional escape rhythm	Acceleration of the sinus rate only if loss of atrial "kick" causes hemodynamic compromise	Atropine; atrial pacing
	Atrioventricular block, intraventricular block		Insertion of a pacemaker

Hemodynamic Consequences

Patients with LV dysfunction have a relatively fixed stroke volume and depend on changes in HR to alter cardiac output. However, the range of HR with maximal cardiac output is narrow: either faster or slower rates can cause reductions in output. Thus, all forms of tachycardia and bradycardia can depress cardiac output in patients with STEMI. Although optimal cardiac output may require a rate higher than 100 beats/min, because HR is one of the major determinants of myocardial oxygen consumption, more rapid HRs elevate myocardial energy needs to levels that can adversely affect ischemic myocardium. In patients with STEMI, therefore, the optimal rate is usually lower, in the range of 60 to 80 beats/min.

A second factor to consider in assessing the hemodynamic consequences of a particular arrhythmia is loss of the atrial contribution to ventricular preload. Studies of patients without STEMI have demonstrated that loss of atrial transport decreases LV output by 15% to 20%. In patients with reduced diastolic LV compliance of any cause (including STEMI), however, atrial systole is of greater importance for LV filling. In patients with STEMI, atrial systole boosts end-diastolic volume by approximately 15%, end-diastolic pressure by 30%, and stroke volume by 35%.

Ventricular Arrhythmias (See Chapter 39)

Ventricular Premature Depolarizations

Before the widespread use of reperfusion therapy, aspirin, and beta blockers for the management of STEMI, frequent ventricular premature complexes (VPCs) (>5/min), VPCs with a multiform configuration, early coupling ("R-on-T" phenomenon), and repetitive patterns in the form of couplets or salvoes were thought to presage VF. However, as many patients who do not develop fibrillation have such "warning arrhythmias" as those who do. Primary VF (see later) can occur without antecedent warning arrhythmias and may even develop despite their suppression. Both primary VF and VPCs, especially R-on-T beats, occur during the early phase of STEMI, a period of considerable heterogeneity in electrical activity. Although R-on-T beats expose this heterogeneity and can precipitate VF in a small minority of patients, the ubiquitous nature of VPCs in patients with STEMI and the extremely infrequent nature of VF in the current era of STEMI management result in unacceptably low sensitivity and specificity of the electrocardiographic patterns observed on monitoring systems for identifying patients at risk for VF.

Management

The incidence of VF in patients with STEMI seen in CICUs over the past three decades appears to have declined. The previous practice of prophylactic suppression of ventricular premature beats with antiarrhythmic drugs is not indicated and may actually increase the risk for fatal bradycardic and asystolic events.[1] We therefore pursue a conservative course in patients with STEMI with VPCs and do not routinely prescribe antiarrhythmic drugs, other than beta blockers, but instead correct any recurrent ischemia or electrolyte or metabolic disturbances.[1] When VPCs accompany sinus tachycardia at the inception of an infarction, augmented sympathoadrenal stimulation often contributes and can be treated by beta blockers. In fact, early administration of an IV beta blocker effectively reduces the incidence of VF in evolving MI.[132]

Accelerated Idioventricular Rhythm

An accelerated idioventricular rhythm typically occurs during the first 2 days, with about equal frequency in anterior and inferior infarctions. Most episodes are brief. Accelerated idioventricular rhythm often follows when successful reperfusion has been established with fibrinolytic therapy. However, the frequent occurrence of this rhythm in patients without reperfusion limits its reliability as a marker of the restoration of patency of the infarct-related coronary artery and may have different implications following primary PCI.[133] In contrast to rapid VT, accelerated idioventricular rhythm is thought not to affect prognosis, and we do not routinely treat accelerated idioventricular rhythms.

Ventricular Tachycardia and Ventricular Fibrillation

A leading hypothesis for a major mechanism of ventricular arrhythmias in the acute phase of coronary occlusion is reentry caused by inhomogeneity of the electrical characteristics of ischemic myocardium[133] (**Fig. 59.32**). The cellular electrophysiologic mechanisms for reperfusion arrhythmias appear to include washout of various ions such as lactate and potassium and toxic substances that have accumulated in the ischemic zone. VT or VF occurring late in the course of STEMI is more common in patients with transmural infarction and LV dysfunction and is more frequently associated with hemodynamic deterioration.

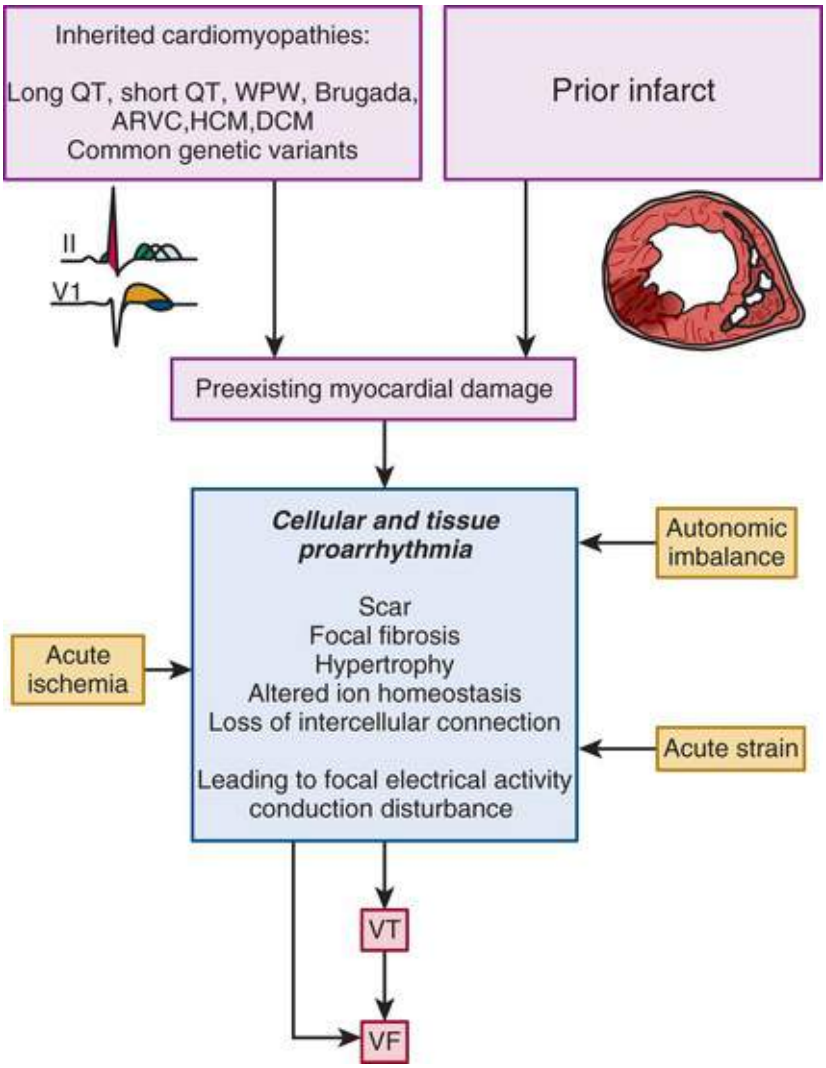

FIGURE 59.32 Drivers of arrhythmias in acute coronary syndromes. A preexisting substrate for ventricular arrhythmias, secondary to prior MI, cardiomyopathy, or a genetic predisposition, together with acute ischemia, autonomic tone, and acute ventricular strain, creates triggered activity and arrhythmias. ARVC, Arrhythmogenic right ventricular cardiomyopathy; DCM, dilated cardiomyopathy; HCM, hypertrophic cardiomyopathy; VF, ventricular fibrillation; VT, ventricular tachycardia; WPW, Wolf-Parkinson-White syndrome. The metamorphosis of myocardial infarction following coronary recanalization. Cardiovasc Pathol 2010;19:22–8.)

Prophylaxis

Because hypokalemia can increase the risk for development of VT, low serum potassium levels require prompt identification and treatment after admission for STEMI.[134] Despite the lack of a consistent relationship between hypomagnesemia and ventricular arrhythmias, magnesium deficits may still link to risk because patients with STEMI have reduced intracellular magnesium levels not adequately reflected by serum measurements. As noted earlier, magnesium should be repleted to achieve a serum level of 2 mEq/L. Early beta-blocker use has reduced VF and can be instituted in patients who lack a contraindication.[1] Lidocaine prophylaxis to prevent primary VF is no longer advised.[1]

Management

Treatment of unstable VT or VF consists of electrical cardioversion implemented as rapidly as possible.[135] IV administration of amiodarone can also facilitate management of unstable ventricular arrhythmias or prevention of refractory recurrent episodes. After reversion to sinus rhythm, every effort

should be made to correct any underlying abnormalities, such as hypoxia, hypotension, acid-base or electrolyte disturbances, or digitalis excess. Urgent revascularization is warranted if ventricular arrhythmias are ongoing and caused by ischemia. The use of extended antiarrhythmic therapy, such as amiodarone or lidocaine, is discussed in **Chapters 36 and 39**. In patients with sustained VT or VF at a time *after* successful reperfusion, we generally continue antiarrhythmic therapy, most often amiodarone, until a defibrillator is placed.

Prognosis

Among patients who underwent fibrinolytic therapy in the GUSTO-I (Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries) study, approximately 10% experienced VT/VF. In the APEX-AMI (Assessment of Pexelizumab in Acute Myocardial Infarction) study, which included patients treated with primary PCI, sustained VT/VF developed in 5.7%. Patients with VT/VF had worse clinical outcomes than those without VT/VF. Additionally, mortality rates were higher in those with late versus early VT/VF; specifically, when compared with patients without VT/VF, the adjusted risk of mortality at 90 days increased twofold or sixfold in patients with early or late VT/VF, respectively.[133] In patients in whom sustained VT/VF develops later in the course after STEMI (e.g., >48 hours) without evidence of a reversible cause, ICD therapy for secondary prevention should be considered before discharge.[1] This situation differs from that in patients with VT/VF *before* reperfusion therapy, in whom antiarrhythmic therapy other than a beta blocker is not indicated. Indications for insertion of an ICD for *primary* prevention in patients with a reduced LVEF after STEMI are discussed later.

Bradyarrhythmias (See Chapters 40 and 41)

Sinus Bradycardia

Sinus bradycardia frequently occurs during the early phases of STEMI, particularly in patients with inferior and posterior infarctions. On the basis of data from experimental infarction and some clinical observations, the increased vagal tone that produces sinus bradycardia during the early phase of STEMI may actually be beneficial, perhaps because it reduces myocardial oxygen demand. Thus the acute mortality rate in patients with sinus bradycardia appears similar to that in those without this arrhythmia.[1]

Management

Isolated sinus bradycardia, unaccompanied by hypotension or ventricular ectopy, should be observed rather than treated. In the first 4 to 6 hours after infarction, if the sinus rate is extremely low (<40 to 50 beats/min) and associated with hypotension, IV atropine in doses of 0.3 to 0.6 mg every 3 to 10 minutes (with total dose not exceeding 3 mg) can be administered to bring the heart rate up to approximately 60 beats/min.

Atrioventricular and Intraventricular Block

Ischemic injury can produce conduction block at any level of the AV or intraventricular conduction system. Such blocks can occur in the AV node and the bundle of His and produce various grades of AV block, in either main bundle branch and produce right or left bundle branch block, and in the anterior and posterior divisions of the left bundle and produce left anterior or left posterior (fascicular) divisional blocks. Conduction disturbances can occur in various combinations. **Table 59.13** summarizes the clinical

features of proximal and distal AV conduction disturbances in patients with STEMI.

TABLE 59.13

Atrioventricular Conduction Disturbances in Acute Myocardial Infarction

	LOCATION OF ATRIOVENTRICULAR (AV) CONDUCTION DISTURBANCE	
	Proximal	**Distal**
Site of block	Intranodal	Infranodal
Site of infarction	Inferoposterior	Anteroseptal
Compromised arterial supply	RCA (90%), LCX (10%)	Septal perforators of LAD
Pathogenesis	Ischemia, necrosis, hydropic cell swelling, excessive parasympathetic activity	Ischemia, necrosis, hydropic cell swelling
Predominant type of AV nodal block	First-degree (PR >200 msec) Mobitz type I second-degree	Mobitz type II second-degree Third-degree
Common premonitory features of third-degree AV block	First- or second-degree AV block Mobitz I pattern	Intraventricular conduction block Mobitz II pattern
Features of escape rhythm following third-degree block		
Location	Proximal conduction system (His bundle)	Distal conduction system (bundle branches)
QRS width	<0.12/sec*	>0.12/sec
Rate	45-60/min but may be as low as 30/min	Often <30/min
Stability of escape rhythm	Rate usually stable; asystole uncommon	Rate often unstable with moderate to high risk for ventricular asystole
Duration of high-grade AV block	Usually transient (2-3 days)	Usually transient but some form of AV conduction disturbance and/or intraventricular defect may persist
Associated mortality rate	Low unless associated with hypotension and/or with power failure or ventricular arrhythmias	High because of extensive infarction associated heart failure
Pacemaker therapy		
Temporary	Rarely required; may be considered for bradycardia associated with left ventricular power failure, syncope, or angina	Should be considered in patients with anteroseptal infarction and acute bifascicular block
Permanent	Almost never indicated because the conduction defect is usually transient	Indicated for patients with high-grade AV block and block in the His-Purkinje system and those with a transient advanced AV block and associated bundle branch block

*Some studies suggest that a wide QRS escape rhythm (>0.12 second) following high-grade AV block in inferior infarction is associated with a worse prognosis.

LAD, Left anterior descending coronary artery; *LCX,* left circumflex coronary artery; *RCA,* right coronary artery.

Modified from Antman EM, Rutherford JD, editors. Coronary Care Medicine: a Practical Approach. Boston: Martinus Nijhoff; 1986; and Dreifus LS et al. Guidelines for implantation of cardiac pacemakers and antiarrhythmia devices. J Am Coll Cardiol 1991;18:1.

First-Degree Atrioventricular Block

A first-degree AV block does not generally require specific treatment. Beta blockers and calcium antagonists (other than dihydropyridines) prolong AV conduction and may be responsible for first-degree AV block as well, but discontinuation of the use of these drugs in the setting of STEMI could increase ischemia and ischemic injury. Therefore, we generally do not decrease the dosage of these drugs unless the PR interval is longer than 0.24 second. These agents should be stopped only if a higher-degree block or hemodynamic impairment occurs. If the block is a manifestation of excessive vagotonia and is associated with sinus bradycardia and hypotension, administration of atropine, as already outlined, may be helpful. Continued electrocardiographic monitoring is important in such patients in view of the possible progression to higher degrees of block.

Second-Degree Atrioventricular Block

First-degree and type I second-degree AV blocks do not appear to affect survival, are most often associated with occlusion of the right coronary artery, and result from ischemia of the AV node (**Table 59.13**). Specific therapy is not required in patients with type I second-degree AV block when the ventricular rate exceeds 50 beats/min and PVCs, HF, and bundle branch block are absent. If these complications develop, however, or if HR falls below approximately 50 beats/min and the patient is

symptomatic, immediate treatment with atropine (0.3 to 0.6 mg) is indicated. Temporary pacing systems are almost never needed in the management of this arrhythmia.

Type II second-degree AV block in the setting of inferior or posterior STEMI is usually temporary and is manifested as a narrow-complex, junctional escape rhythm. These arrhythmias can typically be managed conservatively. With anterior or lateral STEMI, a type II second-degree AV block usually originates from a lesion in the conduction system below the bundle of His (**Table 59.13**). Because of its potential for progression to complete heart block, patients with type II second-degree AV block in this setting should be treated with a temporary external or transvenous demand pacemaker.[1]

Complete (Third-Degree) Atrioventricular Block

Complete AV block can occur in patients with either inferior or anterior infarction, although it is more common in inferior than in anterior MI. Complete heart block in patients with inferior infarction usually develops gradually, often progressing from a first-degree or type I second-degree block.[133] The escape rhythm is typically stable without asystole and often junctional, with a rate exceeding 40 beats/min and a narrow QRS complex in 70% of cases and a slower rate and wide QRS complex in the others. This form of complete AV block is often transient, may respond to pharmacologic antagonism of adenosine with methylxanthines, and resolves in most patients within a few days (**Table 59.13**).

Patients with inferior infarction often have concomitant ischemia or infarction of the AV node secondary to hypoperfusion of the AV node artery, but the His-Purkinje system usually escapes injury. Patients with inferior STEMI and AV block have larger infarcts and more depressed RV and LV function than patients with an inferior infarct and no AV block. As already noted, junctional escape rhythms with narrow QRS complexes occur frequently in this setting.

Pacing is not generally necessary in patients with inferior wall infarction and complete AV block because this is often transient in nature. Pacing is indicated, however, if symptoms related to a ventricular rate emerge, if ventricular arrhythmias or hypotension is present, or if pump failure develops. Atropine rarely proves adequate in these patients. Only when complete heart block develops in less than 6 hours after the onset of symptoms is atropine likely to abolish the AV block or cause acceleration of the escape rhythm. In such cases the AV block is more likely to be transient and related to increases in vagal tone, as opposed to the more persistent block seen later in the course of STEMI, which generally requires cardiac pacing.

In patients with anterior infarction, third-degree AV block can occur suddenly 12 to 24 hours after the onset of infarction, although it is usually preceded by intraventricular block and often a type II (not first-degree or type I) second-degree AV block. Such patients typically have unstable escape rhythms with wide QRS complexes and rates less than 40 beats/min; ventricular asystole may occur quite suddenly. In patients with anterior infarction, AV block generally develops as a result of extensive septal necrosis involving the bundle branches. The high mortality rate in these patients with a slow idioventricular rhythm and wide QRS complex is caused by extensive myocardial necrosis resulting in severe LV failure and frequently shock (**Table 59.13**).

Whether temporary transvenous pacing per se improves survival in patients with anterior STEMI remains controversial. Some physicians contend that ventricular pacing has limited efficacy when used to correct a complete AV block in patients with anterior infarction, in view of the poor prognosis in this group regardless of therapy. However, pacing protects against asystole and may protect against transient hypotension, with its attendant risks of extending the infarction and precipitating malignant ventricular tachyarrhythmias.

Intraventricular Block

The right bundle branch and the left posterior division have a dual blood supply from the left anterior descending and right coronary arteries, whereas the left anterior division is supplied by septal perforators originating from the LAD. Not all conduction blocks in patients with STEMI are complications of infarcts, because almost half are already present at the first ECG recording and may represent antecedent conduction abnormalities. Compared with patients without conduction defects, those with STEMI and bundle branch blocks have higher peak biomarker levels, lower EF, and increased in-hospital and long-term mortality rates.[133,136-138] In the prefibrinolytic era, intraventricular conduction disturbances (i.e., block within one or more of the three subdivisions [fascicles] of the His-Purkinje system: anterior and posterior divisions of the left bundle and the right bundle) occurred in 5% to 10% of patients with STEMI. More recent series in the reperfusion era suggest that intraventricular blocks occur in approximately 2% to 5% of patients with MI.[1]

Isolated Fascicular Blocks

An isolated left anterior divisional block is unlikely to progress to a complete AV block. Mortality is increased in these patients, although not as much as in those with other forms of conduction block. The posterior fascicle is larger than the anterior fascicle, and in general, a larger infarct is required to block it. As a consequence, mortality is markedly increased. Complete AV block is an uncommon complication of either form of isolated divisional block.

Right Bundle Branch Block

Right bundle branch block (RBBB) alone can lead to AV block because it is often a new lesion associated with anteroseptal infarction. Isolated RBBB is associated with increased mortality risk in patients with anterior STEMI, even if complete AV block does not occur, but this appears to be the case only if accompanied by HF.[136,137]

Bifascicular Block, Including Left Bundle Branch Block

The combination of RBBB with either left anterior or left posterior divisional block or the combination of left anterior and posterior divisional blocks (i.e., LBBB) is known as *bidivisional* or *bifascicular block*. If a new block occurs in two of the three divisions of the conduction system, the risk for development of a complete AV block is quite high. Mortality is also high because of the occurrence of severe pump failure secondary to the extensive myocardial necrosis required to produce such an extensive intraventricular block.[1]

Preexisting bundle branch block or divisional block is less often associated with the development of complete AV block in patients with STEMI than conduction defects acquired during the course of the infarct. Bidivisional block in the presence of prolongation of the PR interval (first-degree AV block) may indicate disease of the third subdivision rather than disease of the AV node and entails a greater risk for complete heart block than if first-degree AV block is absent.

Complete bundle branch block (either left or right), the combination of RBBB and left anterior divisional (fascicular) block, and any of the various forms of trifascicular block are all associated more often with anterior than with inferoposterior infarction. All these forms are more common with large infarcts and in older patients and have a higher incidence of other accompanying arrhythmias than seen in patients without bundle branch block.

Use of Pacemakers in Patients with Acute Myocardial Infarction (See Chapter 41)

Temporary Pacing

As with complete AV block, transvenous ventricular pacing has not resulted in a statistically demonstrable improvement in prognosis in STEMI patients who develop intraventricular conduction defects. Temporary pacing is advisable in some patients, however, because of the high risk for complete AV block. This category includes patients with new bilateral (bifascicular) bundle branch block (i.e., RBBB with left anterior or posterior divisional block and alternating right and left BBB); first-degree AV block adds to this risk. An isolated new block in only one of the three fascicles, even with PR prolongation and preexisting bifascicular block and a normal PR interval, poses somewhat less risk; these patients should be monitored closely, with insertion of a temporary pacemaker deferred unless a higher-degree AV block occurs.

Asystole

The presence of apparent ventricular asystole on monitor displays of continuously recorded ECGs may be misleading because the rhythm may actually be fine VF. The predominance of VF as the cause of cardiac arrest in this setting suggests electrical countershock as initial therapy, even if definitive electrocardiographic documentation of this arrhythmia is not available.

Permanent Pacing

The advisability of permanent pacemaker insertion is complicated because not all sudden deaths in patients with STEMI and conduction defects result from high-grade AV block. A high incidence of late VF occurs in survivors with anterior STEMI complicated by either RBBB or LBBB. Therefore, rather than asystole caused by failure of AV conduction and infranodal pacemakers, VF could be responsible for late sudden death.

Long-term pacing may be indicated when complete heart block persists throughout the hospital phase in a patient with STEMI, when sinus node function is greatly impaired, or when type II second-degree or third-degree block occurs intermittently.[139] High-grade AV block associated with newly acquired BBB or other criteria for conduction system impairment may justify prophylactic long-term pacing as well. Additional considerations that drive the decision to insert a permanent pacemaker include whether the patient is a candidate for an ICD or has severe HF that might be improved with biventricular pacing (**see Chapters 25 and 39**).

Supraventricular Tachyarrhythmias (See Chapters 37 and 38)

Sinus Tachycardia

Sinus tachycardia is typically associated with augmented sympathetic activity and may provoke transient hypertension or hypotension. Common causes are anxiety, persistent pain, LV failure, fever, pericarditis, hypovolemia, pulmonary embolism, and drugs (e.g., epinephrine, dopamine); rarely, it occurs in patients with atrial infarction. Sinus tachycardia is particularly common in patients with anterior infarction, especially in those with significant accompanying LV dysfunction. It is an undesirable rhythm in patients with STEMI because it augments myocardial oxygen consumption and reduces the time in diastole

available for coronary perfusion, thereby intensifying the myocardial ischemia and external myocardial necrosis. Persistent sinus tachycardia can signify persistent HF and, in these circumstances, connotes a poor prognosis and excess mortality. An underlying cause should be sought and appropriate treatment instituted, such as analgesics for pain; diuretics for HF; oxygen, beta blockers, and nitroglycerin for ischemia; and aspirin for fever or pericarditis. Treating sinus tachycardia caused by pain, anxiety, or fever with beta blockers is reasonable, but these agents are contraindicated in patients who are tachycardic because of pump failure.

Atrial Flutter and Fibrillation

Atrial flutter and atrial fibrillation (AF) are usually transient in patients with STEMI; these arrhythmias typically result from augmented sympathetic stimulation of the atria and often occur in patients with LV failure, pulmonary emboli, or atrial infarction and aggravate the hemodynamic deterioration in these states (**see Table 59.11**). The increased ventricular rate and loss of the atrial contribution to LV filling can reduce cardiac output considerably. AF during STEMI is associated with increased mortality and stroke, particularly in patients with anterior infarction.[140-143] Because it is more common in patients with clinical and hemodynamic manifestations of extensive infarction and a poor prognosis, AF is probably a marker of a poor prognosis, and several studies have found at least a small, independent contribution to increased mortality.[141-143]

Management

Atrial flutter and AF in patients with STEMI are treated as in other settings (**see Chapter 38**). If the arrhythmia causes ongoing hypotension, ischemia, or HF, cardioversion should be considered. In stabilized patients and in the absence of contraindications, a beta blocker should be administered after STEMI; in addition to several other benefits, these agents help slow the ventricular rate should AF recur. Digitalis may also help slow the ventricular rate when AF develops after STEMI in the setting of ventricular dysfunction. In addition, amiodarone may aid management. Patients with recurrent episodes of AF should be treated with oral anticoagulants (to reduce the risk for stroke), even if sinus rhythm is present at hospital discharge, because no antiarrhythmic regimen can completely suppress AF.

Other Complications

Recurrent Chest Discomfort

Evaluation of postinfarction chest discomfort may be complicated by previous abnormalities on the ECG and a vague description of the discomfort by the patient, who either may be exquisitely sensitive to fleeting discomfort or may deny a potential recrudescence of symptoms. Clinicians face the critical task of distinguishing recurrent angina or infarction from nonischemic causes of discomfort that might result from infarct expansion, pericarditis, pulmonary embolism, and non–cardiac-related conditions. Ischemic causes to consider include acute reocclusion of an initially recanalized or stented vessel, mechanical or thrombotic occlusion of a side branch or distal vessel during an initial PCI, new ischemia in a non–infarct-related coronary artery that was also stenosed but not occluded, and coronary spasm. Important diagnostic maneuvers include repeated physical examination, repeated ECG, and assessment of the response to SL nitroglycerin. (The use of noninvasive diagnostic evaluation for recurrent ischemia in patients whose symptoms appear only with moderate or higher levels of exertion is also discussed later in

this chapter.)

Recurrent Ischemia and Reinfarction

Patients undergoing primary PCI for STEMI versus fibrinolysis have less postinfarction angina and reinfarction. Additionally, in high-risk patients with STEMI who were treated with fibrinolysis, transfer for PCI within 6 hours after fibrinolysis is also associated with significantly fewer ischemic complications than treatment with fibrinolysis alone.[69] More effective antiplatelet and antithrombin therapies have also reduced the rate of recurrent ischemic events following STEMI.[1] Consequently, the incidence of early recurrent ischemic events in STEMI patients treated by immediate or delayed PCI now is less than 5%.[4,69]

Diagnosis

Extension of the original zone of necrosis or reinfarction into a separate myocardial zone can be a difficult diagnosis, especially within the first 24 hours after the index event. Diagnostic criteria have been established,[144] but discrimination of a new MI discrete from the initial STEMI is often challenging, because cardiac markers may remain elevated as a result of the initial infarction, and distinguishing changes of the normal evolution after the index infarction from those caused by recurrent infarction may not be possible on the ECG. Recurrent infarction should be strongly considered, however, with dynamic recurrence of ST-segment elevation.

Pericarditis should also be considered in such patients. The presence of a rub and lack of responsiveness to nitroglycerin may be useful in distinguishing pericardial discomfort, but doing so on clinical grounds is frequently challenging, and diagnostic coronary angiography may be necessary to exclude acute native vessel or stent thrombosis. The predominant angiographic predictors of reinfarction in patients undergoing primary PCI include a final coronary stenosis greater than 30%, post-PCI coronary dissection, and post-PCI intracoronary thrombus, multivessel disease, and greater total stent length.[145,146]

Prognosis

Regardless of whether postinfarction angina is persistent or limited, its presence is important because of the associated higher short-term morbidity rate. Reinfarction links to higher rates of in-hospital complications (e.g., HF, AV block) and early and long-term mortality.[145]

Management

Patients with repeat ST-segment elevation and the appropriate clinical findings should undergo urgent catheterization and PCI (**see Fig. 59.2**), unless pericarditis or other post-MI complications are the cause; repeated fibrinolysis can be considered if PCI is not available. In patients believed to have recurrent ischemia in the absence of ST elevation concerning for ongoing injury and who do not have evidence of hemodynamic compromise, an attempt should be made to control symptoms with SL or IV nitroglycerin and IV beta blocker to slow HR to 60 beats/min. Hypotension, HF, or ventricular arrhythmias developing during recurrent ischemia usually warrant urgent catheterization and revascularization.

High-risk patients with STEMI who undergo fibrinolysis may benefit from a strategy of routine referral for catheterization and revascularization (3 to 24 hours; **see eFig. 52.5**).[69] Trials that compared primary PCI with PCI performed as soon as possible after establishing a preparatory pharmacologic regimen, however, have not shown such a facilitated-PCI approach to be more effective than primary PCI, and mortality may even increase because of excessive bleeding in the facilitated-PCI group.[1]

Finally, with increasing use of PCI for the management of patients with STEMI, clinicians should be alert to the problem of stent thrombosis as a cause of recurrent ischemia. Stent thrombosis can occur acutely (hours to days after stent deployment) or late (many months after stent deployment) (**see Chapter 62**).

Pericardial Effusion and Pericarditis (See Chapter 83)

Pericardial Effusion

Effusions are generally detected echocardiographically, and their incidence varies with imaging modality and technique, criteria, and laboratory expertise. Effusions are more common in patients with anterior or lateral STEMI, larger infarcts, more microvascular obstruction, greater LV dysfunction, no reperfusion, and higher rates of HF.[147-149] Most pericardial effusions after STEMI do not cause hemodynamic compromise. The reabsorption rate of a postinfarction pericardial effusion is slow, with resolution often taking several months. An effusion does not necessarily indicate pericarditis; although they may coexist, most effusions develop without other evidence of pericarditis. When tamponade does occur, it is usually caused by ventricular rupture or hemorrhagic pericarditis.[150]

Pericarditis

Pericarditis can produce pain as early as the first day and as late as 8 weeks after STEMI. The pain of pericarditis may be confused with that resulting from postinfarction angina, recurrent infarction, or both. An important distinguishing feature is radiation of the pain to either trapezius ridge, a finding that is almost pathognomonic of pericarditis and rarely seen with ischemic discomfort. Additionally, the discomfort of pericarditis usually worsens during a deep inspiration but can be relieved or diminished by sitting up and leaning forward.

Transmural MI, by definition, extends to the epicardial surface and can cause local pericardial inflammation. An acute fibrinous pericarditis, *pericarditis epistenocardica,* occurs frequently after transmural infarction, but most patients do not report any symptoms from this process. Although transient pericardial friction rubs are relatively common within the first 48 hours in patients with transmural infarction, pain or electrocardiographic changes occur much less often. The development of a pericardial rub, however, appears to correlate with a larger infarct and greater hemodynamic compromise.

Although anticoagulation clearly increases the risk for hemorrhagic pericarditis early after STEMI, this complication does not occur with sufficient frequency during heparinization or after fibrinolytic therapy to warrant absolute prohibition of such agents when a rub is present. Nevertheless, detection of a significant (≥1 cm) or enlarging pericardial effusion usually should indicate discontinuation of anticoagulation. Patients in whom continuation or initiation of anticoagulant therapy is strongly indicated (e.g., during cardiac catheterization) should have heightened monitoring of clotting parameters and observation for clinical signs of possible tamponade. Late pericardial constriction caused by anticoagulant-induced hemopericardium has been reported.

Treatment of pericardial discomfort consists of aspirin, but usually in doses higher than prescribed routinely following infarction—doses of 650 mg orally as often as every 4 hours may be necessary. Nonsteroidal anti-inflammatory drugs (NSAIDs) and steroids should be avoided because they may interfere with myocardial scar formation.[151]

Dressler Syndrome

Also known as *post–myocardial infarction syndrome*, Dressler syndrome usually occurs 1 to 8 weeks after infarction. Dressler cited an incidence of 3% to 4% of all patients with MI in 1957, but the incidence has decreased dramatically since that time. Clinically, patients with Dressler syndrome have malaise, fever, pericardial discomfort, leukocytosis, an elevated erythrocyte sedimentation rate (ESR), and a pericardial effusion. At autopsy, individuals with this syndrome usually demonstrate localized fibrinous pericarditis containing polymorphonuclear leukocytes (PMNs). The cause of post-MI syndrome is not clearly established, although detection of antibodies to cardiac tissue suggests an immunopathologic process. Treatment is with aspirin, 650 mg as often as every 4 hours, may be effective.[151] Glucocorticosteroids and NSAIDs are best avoided in patients with Dressler syndrome within 4 weeks of STEMI because of their potential to impair infarct healing, cause ventricular rupture, and increase coronary vascular resistance.[151]

Venous Thrombosis and Pulmonary Embolism

Almost all peri-MI pulmonary emboli originate from thrombi in the veins of the lower extremities; much less frequently, they originate from mural thrombi overlying an area of RV infarction. Bed rest and HF predispose to venous thrombosis and subsequent pulmonary embolism (PE), and both these conditions often occur in patients with STEMI, particularly in those with large infarcts. At a time when patients with STEMI were routinely subjected to prolonged bed rest, more than 20% examined at autopsy had PE, and massive PE accounted for 10% of deaths from MI. In contemporary practice, with early mobilization and the widespread use of low-dose anticoagulant prophylaxis, PE has become an uncommon cause of death in patients with STEMI. When PE does occur in patients with STEMI, management is generally similar to that for patients without infarction (**see Chapter 84**).

Left Ventricular Aneurysm

The term *left ventricular aneurysm* (often called *true aneurysm*) is generally reserved for a discrete, dyskinetic area of the LV wall with a broad neck (to differentiate it from a pseudoaneurysm caused by a contained myocardial rupture) (**eFig. 59.8**). Dyskinetic or akinetic areas of the left ventricle are much more common than true aneurysms after STEMI. True LV aneurysms probably develop in less than 5% of all patients with STEMI.[1] The wall of a true aneurysm is thinner than that of the rest of the left ventricle (**eFig. 59.8**), and it is usually composed of fibrous tissue, as well as necrotic muscle occasionally mixed with viable myocardium.

Pathogenesis

Aneurysm formation presumably occurs when intraventricular tension stretches the noncontracting infarcted heart muscle and thus produces expansion of the infarct, a relatively weak, thin layer of necrotic muscle, and fibrous tissue that bulges with each cardiac contraction. With the passage of time, the wall of the aneurysm becomes more densely fibrotic, but it continues to bulge with systole and renders some of the LV stroke volume during each systole ineffective.

Total occlusion of a poorly collateralized LAD is associated with aneurysm formation after anterior STEMI. An aneurysm rarely occurs with multivessel disease when either extensive collaterals or a patent LAD. Aneurysms occur approximately four times more often at the apex and in the anterior wall than in the inferoposterior wall. The overlying pericardium generally adheres densely to the wall of the aneurysm, which may even become partially calcified after several years. True LV aneurysms (in contrast

to pseudoaneurysms) rarely rupture.

Diagnosis

The presence of persistent ST-segment elevation in an electrocardiographic area of infarction, classically thought to suggest aneurysm formation, indicates a large infarct with a regional wall motion abnormality but does not necessarily imply an aneurysm. The diagnosis of aneurysm is best made by echocardiography, CMR, CT, or left ventriculography at cardiac catheterization.

Prognosis and Treatment

A LV aneurysm increases the risk for mortality, even compared with that in patients with a comparable LVEF. Death in these patients is frequently sudden and presumably related to the relatively high incidence of ventricular tachyarrhythmias that occur with aneurysms.[152] With loss of shortening from the area of the aneurysm, the remainder of the ventricle may become hyperkinetic to compensate, but with relatively large aneurysms, complete compensation is impossible. Stroke volume falls, or if maintained, it is at the expense of an increase in end-diastolic volume, which in turn leads to increased wall tension and myocardial oxygen demand. Heart failure may ensue, and angina may appear or worsen.

Aggressive management of STEMI, including prompt reperfusion, may diminish the incidence of ventricular aneurysms. Surgical aneurysmectomy generally succeeds only if contractile performance in the nonaneurysmal portion of the left ventricle is relatively preserved. In such circumstances, when the operation is performed for worsening HF or angina, operative mortality is relatively low, and clinical improvement can be expected.[94] Compared with CABG alone, adding surgical ventricular reconstruction for patients with LVEF of 35% or less reduced LV volume but did not improve symptoms, exercise tolerance, or the endpoint of death or hospitalization for cardiac causes.[153] A transcatheter approach for aneurysm exclusion is currently under investigation; to date, device implantation has been generally successful, but outcome data are limited.[154,155] Because of the risk for mural thrombosis and systemic embolization, patients with a residual LV aneurysm after STEMI may warrant long-term oral anticoagulation.

Left Ventricular Thrombus and Arterial Embolism

Endocardial inflammation and the relative stasis of blood during the acute phase of infarction probably provide a thrombogenic surface for clots to form in the left ventricle. With extensive transmural infarction of the septum, however, mural thrombi may overlie infarcted myocardium in both ventricles. The incidence of LV thrombus formation after STEMI appears to have dropped from approximately 20% to 5% with more aggressive use of antithrombotic strategies, but variation in imaging techniques will influence detection rates.[156] Prospective studies have suggested that patients in whom a mural thrombus develops early (within 48 to 72 hours of infarction) have an extremely poor early prognosis, with a high rate of mortality from the complications of a large infarction (shock, reinfarction, rupture, and ventricular tachyarrhythmia), rather than emboli from the LV thrombus.

Even though a mural thrombus adheres to the endocardium overlying the infarcted myocardium, superficial portions can become detached and embolize systemically. Although estimates vary because of patient selection, approximately 10% of mural thrombi result in systemic embolization.[156] Echocardiographic risk factors for thrombus embolization include increased mobility and protrusion into the ventricular chamber, visualization on multiple views, and contiguous zones of akinesis and

hyperkinesis. CMR techniques can also characterize LV thrombi and assist in prediction of the risk for embolism.

Management

Data from previous trials with limited sample sizes suggested that anticoagulation (IV heparin or high-dose SC heparin) reduces the development of LV thrombi by 50%. However, because of a low event rate, precluded demonstrating reduced systemic embolism.[156] Fibrinolysis reduces the rate of thrombus formation. However, antithrombotic therapy with heparin cloud the interpretation of data from fibrinolytic trials. Recommendations for anticoagulation vary considerably, and fibrinolysis has precipitated fatal embolization. Moreover, few data from the era of dual-antiplatelet therapy after primary PCI are available to guide decisions. Nevertheless, anticoagulation for 3 to 6 months with warfarin is reasonable for many patients with demonstrable mural thrombi. Patients with STEMI and anterior apical akinesis or severe dyskinesis may also merit a limited course of anticoagulant therapy.[1]

Convalescence, Discharge, and Post–Myocardial Infarction Care

The transition to outpatient care after STEMI is a critical one. Posthospital systems of care designed to reduce hospital readmissions can facilitate coordinated, evidence-based outpatient care for all patients with STEMI.[1] (**See also Chapter 54**.)

Timing of Hospital Discharge

In practice, the timing of discharge from the hospital is variable. Patients with STEMI have risk for late in-hospital mortality from recurrent ischemia or infarction, hemodynamically significant ventricular arrhythmias, and severe HF. Risk indicators for mortality in the hospital include clinical HF, as evidenced by persistent sinus tachycardia and pulmonary congestion, recurrent VT and VF, new AF or atrial flutter, intraventricular conduction delays or heart block, anterior location of infarction, and recurrent episodes of angina with marked ST-segment abnormalities at low activity levels (see later, Risk Stratification after ST-Elevation Myocardial Infarction).

Aggressive reperfusion protocols with PCI or fibrinolytics can reduce the length of hospital stay without compromising mortality after discharge.[157,158] In patients with apparently successful reperfusion, absence of early sustained ventricular tachyarrhythmias, hypotension, or HF, coupled with a well-preserved LVEF, predicts a low risk for late complications in the hospital. Such patients appear to be suitable candidates for hospital discharge less than 5 days from the onset of symptoms; current practice in U.S. hospitals is discharge in 3 days or less for many patients who have undergone successful primary PCI.[158] Most complications that would preclude early discharge occur within the first 3 days of admission, permitting identification of patients suitable for expedited discharge early during the hospitalization. Several controlled trials and many uncontrolled trials of early discharge after STEMI have shown no increase in risk in patients appropriately selected for early discharge.[157,158]

Following STEMI, patients are often eager for information, anxious, in need of reassurance, confused by misinformation and previous impressions, and capable of counterproductive denial. The hospitalization after STEMI provides ample opportunities to begin the rehabilitation process. The decision regarding timing of discharge for patients with uncomplicated STEMI should consider the

patient's psychological state after STEMI, the adequacy of dose titration for essential drugs such as beta blockers and RAAS inhibitors, and the availability and timing of follow-up with visiting nurses and the primary care physician. In patients who have experienced a complication, discharge is deferred until their condition has been stable for several days and they clearly have responded appropriately to any interventions.

Counseling

Before discharge from the hospital, all patients should receive detailed instruction concerning physical activity. Initially, this should consist of walking at home but avoidance of isometric exercise such as lifting. The patient should be given fresh nitroglycerin tablets and instructed in their use (**see Chapter 61**). The patient should also be educated regarding all other medications prescribed. Graded resumption of activity should be encouraged, ideally as part of a monitored cardiac rehabilitation program (**see Chapter 54**). Many approaches have been used, ranging from formal rigid guidelines to general advice advocating moderation and avoidance of any activity that evokes symptoms. Sexual activity counseling, often overlooked during recovery from STEMI, should be included in the educational process.[159] In addition, physicians should explicitly discuss the risk associated with continued smoking and offer assistance in cessation, along with nicotine replacement therapy in appropriate patients.[1,160]

Some evidence indicates that behavioral alteration is possible after recovery from STEMI and may improve the prognosis. Patients with STEMI should be referred to a postdischarge cardiac rehabilitation program with supervised physical exercise and an educational component.[161] Given the relationship between depression and STEMI, psychosocial intervention programs can decrease symptoms of depression and are a useful adjunct to standard cardiac rehabilitation programs after STEMI[162] (**see Chapters 54 and 96**).

Risk Stratification after ST-Elevation Myocardial Infarction

The process of risk stratification following STEMI occurs in several stages: initial findings, in-hospital course, and at hospital discharge. The tools used to form an integrated and dynamic assessment of the patient consist of baseline demographic information; serial ECGs and serum and plasma cardiac biomarker measurements; hemodynamic monitoring data; a variety of noninvasive tests; and if performed, the findings at cardiac catheterization. These findings, integrated with the occurrence of in-hospital complications, can provide information regarding survival.

Initial Findings.

Certain demographic and historical factors portend a worse prognosis in patients with STEMI, including age older than 65, history of diabetes mellitus, previous angina pectoris, and previous MI (**eFig. 59.3**). Diabetes mellitus in particular appears to confer a more than 40% increase in adjusted risk for death by 30 days[163] (**see Chapter 51**). Surviving diabetic patients also experience a more complicated post-MI course, including a greater incidence of postinfarction angina, infarct extension, and HF. These higher rates of complications are probably related to the extensive accelerated atherosclerosis and higher risk for thrombosis and HF associated with diabetes mellitus.

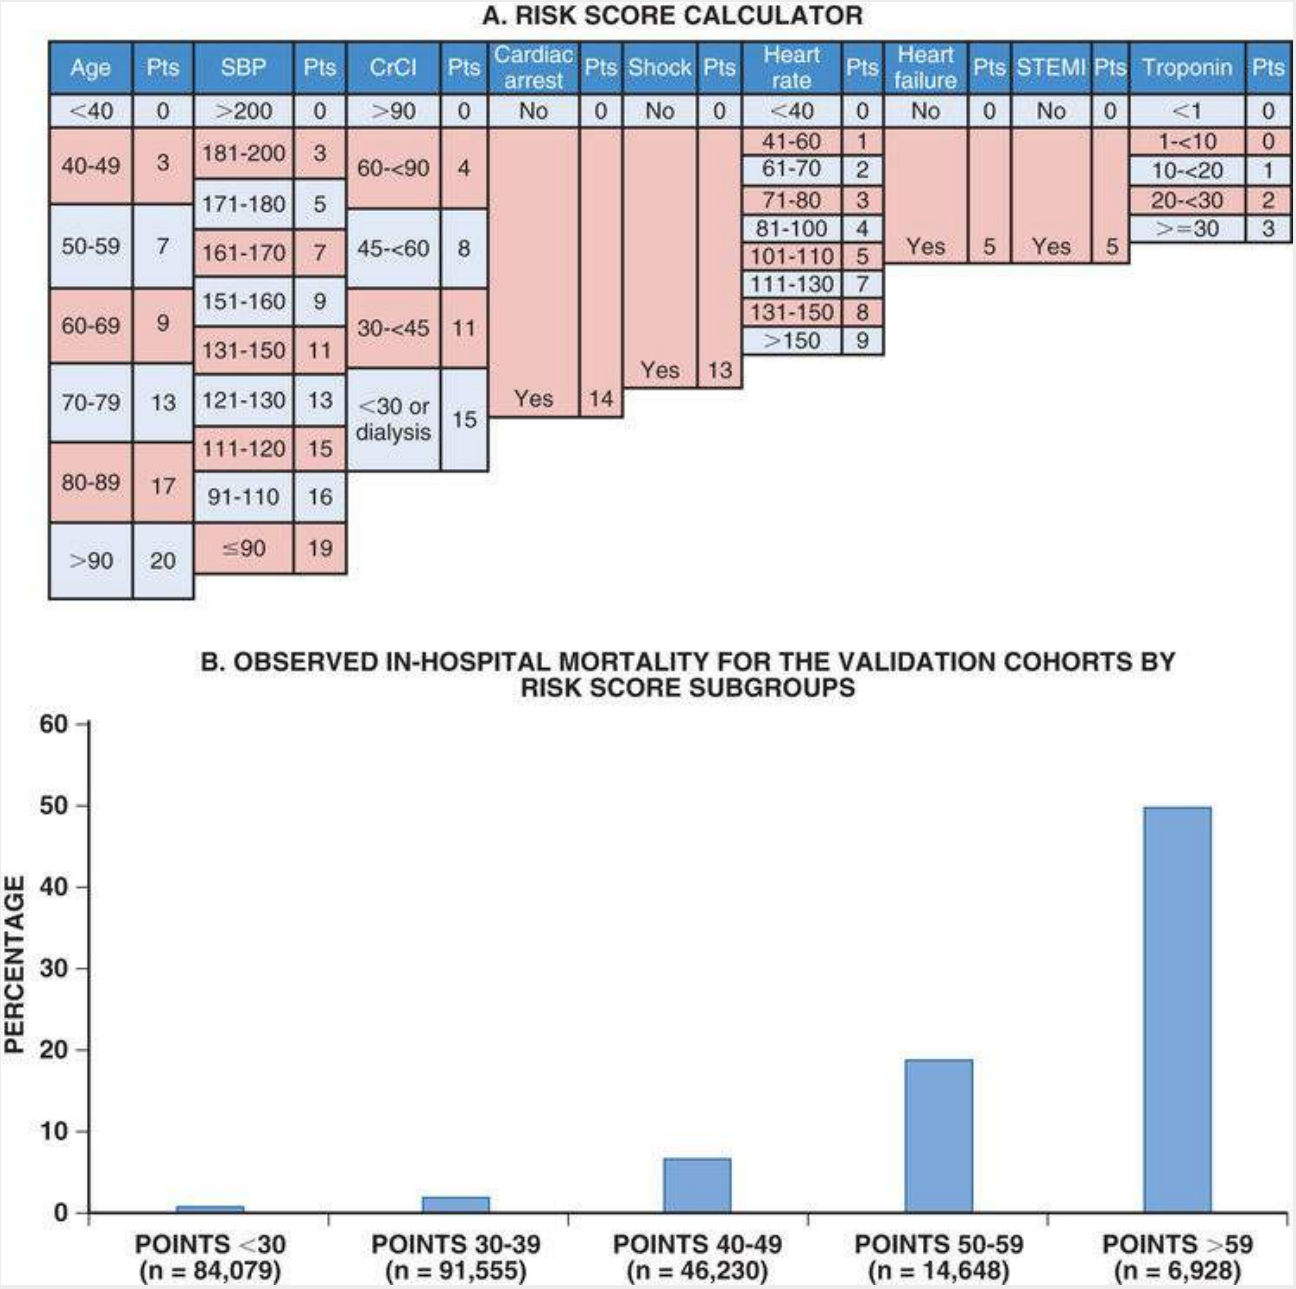
In addition to playing a central role in the decision pathway for the management of patients with ACS based on the presence or absence of ST-segment elevation, the 12-lead ECG provides important prognostic information.[52] Mortality is greater in patients experiencing anterior wall STEMI than in those with inferior STEMI, even when corrected for infarct size. Patients with RV infarction complicating

inferior infarction, as suggested by ST-segment elevation in V_4R, have higher mortality than patients sustaining an inferior infarction without RV involvement. Patients with multiple leads showing ST elevation and a high sum of ST-segment elevation have increased mortality, especially if their infarct is anterior. Patients whose ECGs demonstrate persistent advanced heart block (e.g., type II second-degree or third-degree AV block) or new intraventricular conduction abnormalities (bifascicular or trifascicular) in the course of STEMI have a worse prognosis than patients without these abnormalities (see earlier, Atrioventricular and Intraventricular Block). The influence of high degrees of heart block has particular importance in patients with RV infarction because such patients have a greatly increased mortality risk.[52] Other electrocardiographic findings that augur poorly are persistent horizontal or downsloping ST-segment depression, Q waves in multiple leads, ST-segment depression in anterior leads in patients with inferior infarction, and atrial arrhythmias, especially AF.

Several validated clinical risk stratification tools may be used at initial evaluation to assess the short-term and long-term risk for death after MI.[52] In addition to the patient's age and historical factors such as diabetes and previous MI, clinical signs of HF, including tachycardia and hypotension, are common in many of these clinical risk assessment scores.

Hospital Course.

Hospital mortality from STEMI depends directly on the severity of LV dysfunction. Risk stratification incorporating abnormalities of vital signs (e.g. HR, systolic BP); presence of HF, shock, or cardiac arrest; estimation of infarct size; and in appropriate patients, invasive hemodynamic monitoring provides an assessment of the likelihood of a complicated hospital course and may also identify important abnormalities, such as hemodynamically significant mitral regurgitation, that convey an adverse long-term prognosis[164] (**see Table 59.8 and eFig. 59.9**). In particular, the development of HF and LV dysfunction after MI entails a higher risk for sudden cardiac death.[112] Recurrent infarction and new stroke during hospitalization for STEMI also, not surprisingly, confer a higher risk for death.



EFIGURE 59.9 Using contemporary patient-level data from a large database of 243,440 patients (ACTION [Acute Coronary Treatment and Intervention Outcomes Network] Registry–GWTG [Get with the Guidelines]), a multivariate hierarchical logistic regression model was developed to predict in-hospital mortality in patients presenting with acute myocardial infarction (AMI) using demographic, clinical, and laboratory parameters **(A).** Observed in-hospital mortality rates for the validation cohort varied substantially by risk score **(B),** ranging from as low as 0.4% in the lowest-risk group (score <30) to 49.5% in the highest-risk group (score >59). CrCl, Creatinine clearance; Pts, points; SBP, systolic blood pressure; STEMI, ST-segment elevation myocardial infarction. (From McNamara RL et al. Predicting in-hospital mortality in patients with acute myocardial infarction. J Am Coll Cardiol 2016;68(6):626-35.)

Assessment at Hospital Discharge

Both short-term and long-term survival after STEMI depend on three major factors: resting LV function, residual potentially ischemic myocardium, and susceptibility to serious ventricular arrhythmias. The most important of these factors is the state of LV function[52] (**see Fig. 59.20**). The second most important factor is how the severity and extent of the obstructive lesions in the coronary vascular bed perfusing residual viable myocardium affect the risk for recurrent infarction and serious ventricular arrhythmias. Thus, survival is related to the quantity of myocardium that has become necrotic and the portion remaining in ischemic jeopardy. The third risk factor, susceptibility to serious arrhythmias, is reflected in ventricular

ectopic activity and other indicators of electrical instability, such as reduced HR variability or baroreflex sensitivity and abnormal findings on a signal-averaged ECG.[52] All these factors identify patients at increased risk for death.

Assessment of Left Ventricular Function

The left ventricular ejection fraction (LVEF), a readily assessed measurement of LV function, is extremely useful for risk stratification. However, imaging of the left ventricle at rest may not adequately distinguish among infarcted, irreversibly damaged, and stunned or hibernating myocardium. To circumvent this difficulty, various techniques have been investigated to assess the extent of residual viable myocardium and degree of microvascular obstruction, including exercise and pharmacologic stress echocardiography, stress radionuclide perfusion imaging, positron emission tomography, and gadolinium-enhanced CMR.[127,165,166] All these techniques can be performed safely in postinfarction patients. Because no study has clearly shown one imaging modality to be superior to the others, clinicians should be guided in their selection of ventricular imaging technique by the availability and level of expertise with a given modality at their local institution.[166]

Assessment of Myocardial Ischemia

Because of the adverse consequences of recurrent MI after STEMI, assessing a patient's risk for future ischemia and infarction is important. Noninvasive testing for ischemia, usually before discharge, provides valuable information about the presence of residual ischemia in patients who have not undergone coronary angiography during the initial management of STEMI. It may also be useful in assessing the functional significance of any coronary stenoses identified at angiography but not revascularized (**see Table 59.5**). In the latter case, stress imaging to localize ischemia may be useful.

Exercise Testing.

An exercise test also offers an opportunity to formulate a more precise exercise prescription and helps boost patients' confidence in their ability to conduct their daily activities after discharge. Patients who are unable to exercise can be evaluated by a pharmacologic stress protocol with echocardiography or perfusion imaging. Treadmill exercise testing after STEMI has traditionally used a submaximal protocol that requires the patient to exercise until symptoms of angina appear, electrocardiographic evidence of ischemia is seen, or a target workload (5 metabolic equivalents) has been reached, whichever comes first (**see Chapters 13 and 54**). Symptom-limited exercise tests can be performed safely before discharge in patients with an uncomplicated course after infarction. Variables derived from exercise tests after STEMI that have been evaluated for their ability to predict the occurrence of death or recurrent nonfatal infarction include the development and magnitude of ST-segment depression, the development of angina, exercise capacity, and the systolic BP response during exercise.[52]

Assessment for Electrical Instability

After STEMI, patients have the greatest risk for development of sudden cardiac death (SCD) from malignant ventricular arrhythmias in the first 1 to 2 years.[52] Multiple techniques may stratify patients into those who are at increased risk for SCD after STEMI. These include measurement of QT dispersion (variability in QT intervals between ECG leads), ambulatory ECGs for detection of ventricular arrhythmias (Holter monitoring), invasive electrophysiologic testing, recording of a signal-averaged ECG (a measure of delayed, fragmented conduction in the infarct zone), and measurement of HR variability

(beat-to-beat variability in R-R intervals) or baroreflex sensitivity (slope of a line relating beat-to-beat change in the sinus rate in response to alteration of blood pressure). However, none of these approaches has proved sufficiently useful for routine practice.[52]

Despite the increased risk for arrhythmic events following STEMI in patients who have abnormal results on one or more of the noninvasive tests described, several points merit emphasis. The low positive predictive value (<30%) of the noninvasive screening tests limits their usefulness when viewed in isolation. Although the predictive value of screening tests can be improved by combining several tests, the therapeutic implications of an increased risk profile for arrhythmic events have not been established. The reductions in mortality achievable with the general use of beta blockers, ACE inhibitors, aspirin, and revascularization, when appropriate after infarction, coupled with concerns about the efficacy and safety of antiarrhythmic drugs and the cost of implanted defibrillators, leave considerable uncertainty about the therapeutic implications of an abnormal noninvasive test result for electrical instability in an asymptomatic patient. Action by clinicians on the results of an abnormal finding in asymptomatic patients should await additional data on patient outcomes. Management of patients with sustained, hemodynamically compromising arrhythmias is discussed in Part V.

Prophylactic Antiarrhythmic Therapy

Although antiarrhythmic therapy can control atrial and ventricular arrhythmias effectively in many patients, routine use of prophylactic antiarrhythmic drug therapy, with the exception of beta blockers, does not improve outcome and, with some agents, increases the risk for death.[1] The most notable postinfarction trial in this area was CAST (Cardiac Arrhythmia Suppression Trial), which tested whether encainide, flecainide, or moricizine for suppression of ventricular arrhythmias detected on ambulatory electrocardiographic monitoring would reduce the risk for cardiac arrest and death; however, CAST was stopped prematurely because of increased mortality in the active treatment groups. The SWORD (Survival with Oral D-Sotalol) trial was similarly stopped prematurely because of increased mortality in the active treatment group. In contrast, CAMIAT (Canadian Amiodarone Myocardial Infarction Trial) showed that amiodarone reduces the frequency of ventricular premature depolarization in patients with recent MI, and that this reduction correlated with lowering of arrhythmic death or resuscitation from VF. However, 42% of patients discontinued use of amiodarone during maintenance therapy in CAMIAT because of intolerable side effects. EMIAT (European Amiodarone Myocardial Infarction Trial) showed a reduction in arrhythmic death after MI in patients with depressed LV function, but total mortality and other CV-related mortality did not decrease.

The routine use of antiarrhythmic agents (including amiodarone) therefore cannot be recommended. Although trials that included post-STEMI patients in the study population have shown significant reductions in mortality in those randomly assigned to ICD implantation versus conventional medical therapy (**see Chapter 41**), early implantation of an ICD in the first few weeks after MI has not shown benefit.[167] Routine risk stratification to guide ICD placement early after STEMI is therefore not recommended; reassessment of LV function 40 days or longer after STEMI can guide consideration of an ICD for primary prevention of SCD[167] (**Fig. 59.33**). Trials of strategies for prevention and treatment of arrhythmias, including the use of wearable external defibrillators,[168] during the early period after STEMI are ongoing. Wearable cardiac defibrillators can be considered in the immediate post-MI period (e.g., 40 days) in patients with LV dysfunction based on small studies demonstrating efficacy for detection and termination of VT/VF, but without proven survival benefit.[169]

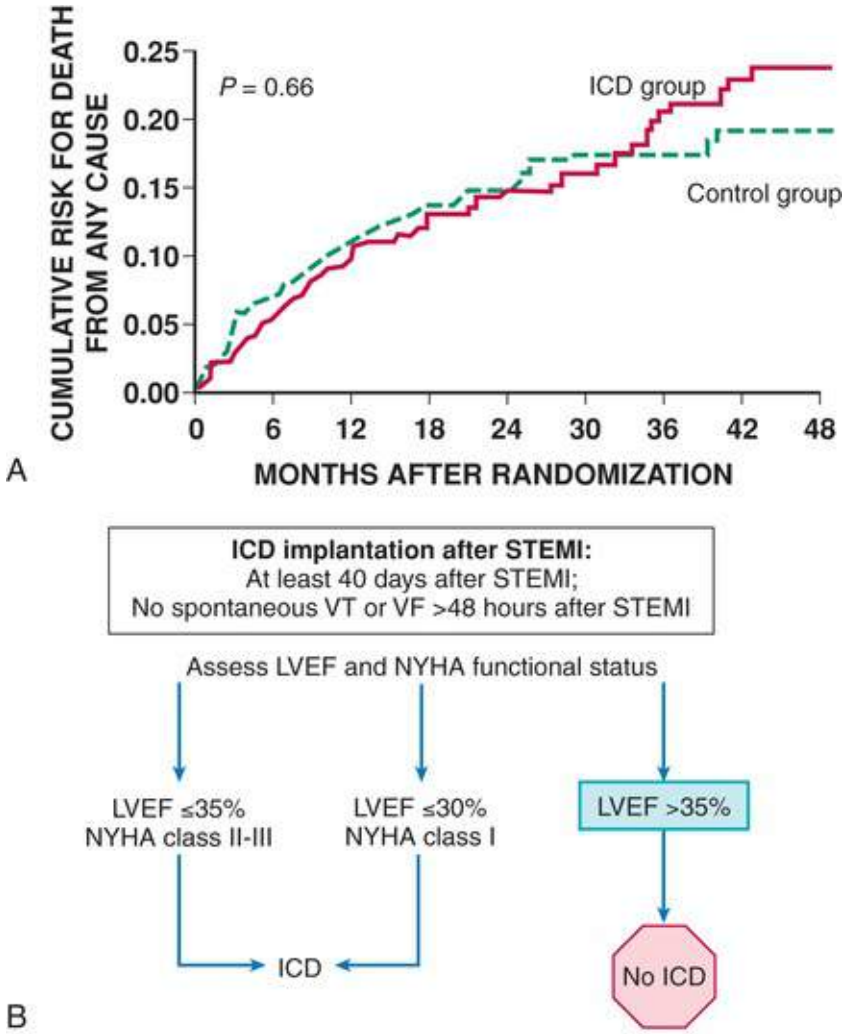


FIGURE 59.33 **A,** DINAMIT trial and algorithm for placement of an implantable cardioverter-defibrillator (ICD) in patients with STEMI but without ventricular fibrillation (VF) or sustained ventricular tachycardia (VT) more than 48 hours after STEMI. DINAMIT, a randomized, open-label study, compared ICD with no ICD therapy 6 to 40 days after an MI in 674 patients who also had a left ventricular ejection fraction (LVEF) of 35% or less and impaired cardiac autonomic function. The study concluded that ICD therapy reduced the rate of death from arrhythmias but that this advantage was offset by an increase in deaths from other causes. **B,** The appropriate management path is based on measurement of LVEF; measurements obtained 3 days or less after STEMI should be repeated before proceeding with the algorithm. Patients with LVEF less than 35% at least 40 days after STEMI are referred for insertion of an ICD if they are in New York Heart Association (NYHA) Class II or III. Patients with a more depressed LVEF less than 30% are referred for ICD implantation even if they are NYHA Class I because of their increased risk for sudden cardiac death. Patients with LVEF less than 40% who have nonsustained VT and inducible VT on electrophysiological study are discussed in Chapter 42. Patients with preserved left ventricular function (LVEF >40%) do not receive an ICD and are treated with medical therapy after STEMI. (**A,** From Hohnloser SH et al. Prophylactic use of an implantable cardioverter-defibrillator after acute myocardial infarction. N Engl J Med 2004;351:2481; **B,** modified from Al-Khatib SM, Stevenson WG, Ackerman MJ, et al. 2017 AHA/ACC/HRS guideline for management of patients with ventricular arrhythmias and the prevention of sudden cardiac death: a report of the ACCF/AHA Task Force on Clinical Practice Guidelines and the Heart Rhythm Society. *Circulation.* 2017.

Secondary Prevention After Acute Myocardial Infarction

Patients who survive the initial course of STEMI still have considerable risk for recurrent events, thus rendering preventive efforts imperative. (See also Part VI.)

Cardiac Rehabilitation (See Chapter 54)

Contemporary exercise-based cardiac rehabilitation after STEMI aims to increase functional capacity,

reducing disability, improving quality of life, modifying coronary risk factors, and limit morbidity and mortality.[161,170] The key components of cardiac rehabilitation include patient assessment; ongoing medical surveillance; nutritional counseling; management of hypertension, lipids, and diabetes mellitus; cessation of smoking; psychosocial counseling; physical activity counseling; exercise training; and pharmacologic treatment, as appropriate. When compared with usual care, cardiac rehabilitation is associated with lower total and cardiac mortality, but despite these outcomes, cardiac rehabilitation services remain vastly underused.[171]

Lifestyle Modification (See Chapter 45)

Efforts to improve survival and quality of life after MI are related to lifestyle modification of known risk factors. Of these, cessation of smoking and control of hypertension are probably the most important. Use of hospital-based smoking cessation programs and referral to cardiac rehabilitation programs have led to successful smoking cessation.[1]

Depression (See Chapter 96)

Physicians caring for patients following STEMI need to acknowledge the prevalence of major depression after infarction. This problem is associated independently with higher mortality. In addition, lack of an emotionally supportive network in the patient's environment after discharge increases risk for recurrent cardiac events. The precise mechanisms relating depression and lack of social support to a worse prognosis after STEMI are not clear, but one possibility is lack of adherence to prescribed treatments, a behavior associated with increased risk for post-MI mortality. Therefore, a comprehensive cardiac rehabilitation program that includes primary health care personnel who counsel patients and make home visits can reduce the rate of rehospitalization for recurrent ischemia and infarction.[171]

Modification of Lipid Profile (See Chapters 45 and 48)

Obtaining a lipid profile on admission is reasonable in all patients admitted with acute MI. Total cholesterol levels may fall 24 to 48 hours after infarction. We continue to ascribe to a long-term target low-density lipoprotein (LDL) cholesterol level of less than 70 mg/dL for patients who experience an ACS, as recommended in many guidelines.[172] High-intensity statin therapy should be initiated or continued in all patients with STEMI and no contraindications to its use.[1] Ezetimibe, a nonstatin lipid-lowering agent, may be added during hospitalization for STEMI based on IMPROVE-IT (Improved Reduction of Outcome: Vytorin Efficacy International Trial), which demonstrated a reduction in recurrent CV events when added to statin therapy.[172,173] Proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors result in decreased LDL receptor degradation and can be considered for chronic lipid-lowering therapy as an adjunct to statin therapy, based on proven efficacy for event reduction.[172,173a] CV outcomes trials with PCSK9 inhibitors are ongoing, and their place in therapy is not yet well defined.[174]

Antiplatelet Agents (See Chapter 93)

On the basis of compelling data from the Antiplatelet Trialists' Collaboration of a 22% reduction in the risk for recurrent infarction, stroke, or vascular death in high-risk vascular patients receiving prolonged antiplatelet therapy, all patients with STEMI without contraindications should receive 75 to 325 mg of aspirin daily indefinitely, with 81 mg the preferred maintenance dose.[1] Additional benefits of long-term aspirin therapy that can accrue in patients with STEMI include an increased likelihood of patency of the infarct artery and smaller infarcts if MI recurs. Patients with true aspirin allergy can receive clopidogrel

(75 mg once daily). In the absence of contraindications, all patients after STEMI should receive a platelet inhibitor in addition to aspirin for 12 months according to one of the following regimens: clopidogrel (75 mg/day) in patients with STEMI treated with medical therapy alone, lytic therapy, or PCI; prasugrel (10 mg/day) in patients treated with PCI; or ticagrelor (90 mg twice daily) in patients treated with medical therapy alone or PCI[1,175] (**Fig. 59.34**). *Cangrelor,* a potent, fast-acting reversible, IV $P2Y_{12}$ inhibitor, can be used during PCI in patients who have not received a $P2Y_{12}$ inhibitor before PCI, based on CHAMPION-PHOENIX (A Clinical Trial Comparing Cangrelor to Clopidogrel Standard Therapy in Subjects Who Require Percutaneous Coronary Intervention) findings demonstrating a lower rate of death, MI, revascularization, or stent thrombosis, compared with clopidogrel, in patients undergoing PCI, including primary PCI for STEMI.[176]

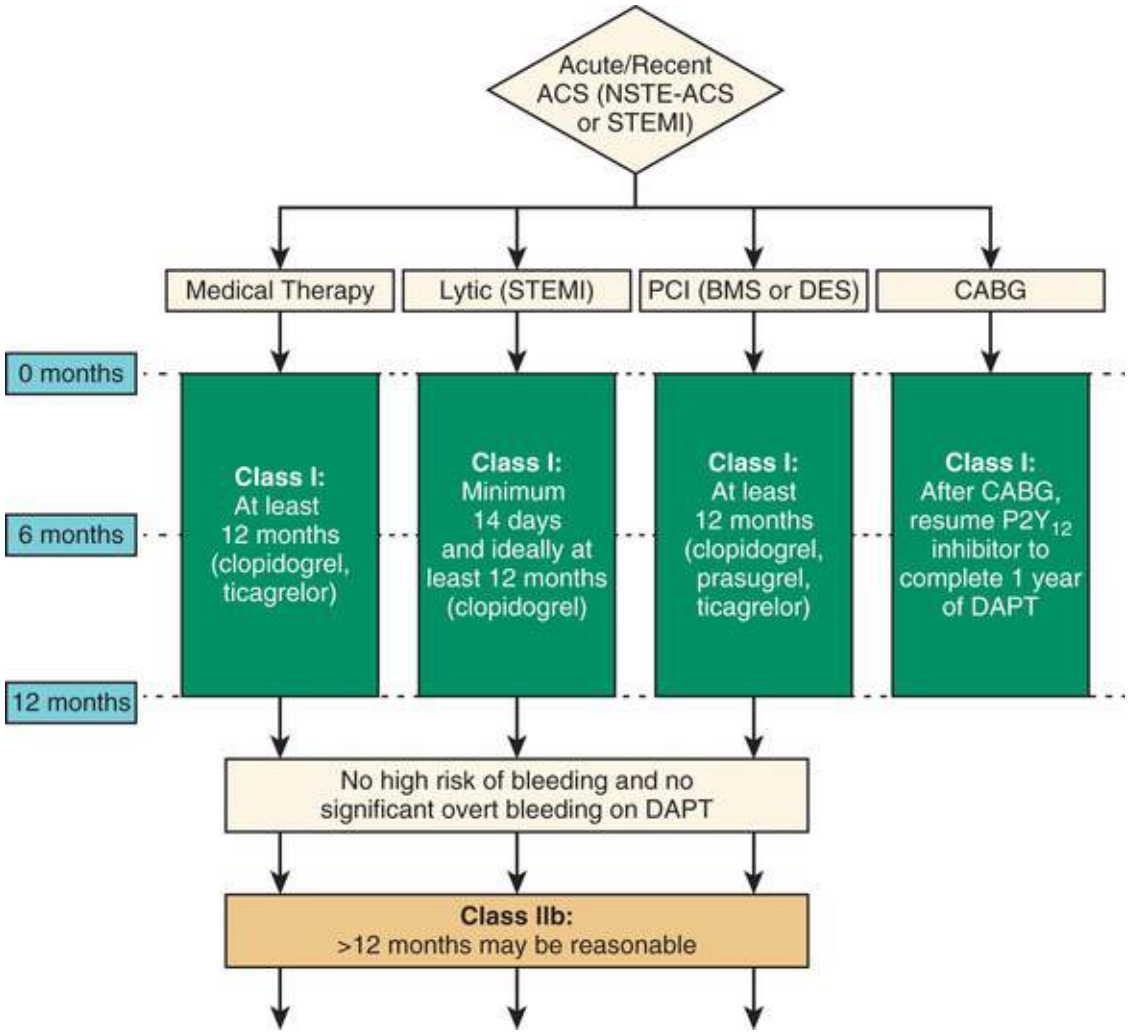

FIGURE 59.34 ACC/AHA guideline recommendation for duration and choice of antiplatelet agent in patients with recent acute coronary syndrome (ACS), including STEMI. Aspirin therapy is generally continued indefinitely post-ACS. In patients treated with dual-antiplatelet therapy (DAPT) after DES implantation who have a high risk of bleeding (e.g. use of oral anticoagulant therapy, major intracranial surgery) or develop significant overt bleeding, discontinuation of P2Y12 inhibitor therapy after 6 months for ACS may be reasonable. The optimal duration of prolonged DAPT is not established. BMS, Bare-metal stent; CABG, coronary artery bypass grafting; CAD, coronary artery disease; DES, drug-eluting stent; Hx, history; lytic, fibrinolytic therapy; NSTE-ACS, non–ST-elevation acute coronary syndrome; PCI, percutaneous coronary intervention. (Modified from Levine GN et al. 2016 ACC/AHA guideline focused update on duration of dual antiplatelet therapy in patients with coronary artery disease. J Am Coll Cardiol 2016;68(10):1082-115.)

Aspirin therapy should be maintained indefinitely. In the absence of significant overt bleeding or risk factors for bleeding, it is reasonable to continue dual-antiplatelet therapy for more than 12 months based

on the DAPT (Dual Antiplatelet Therapy) and PEGASUS-TIMI 54 (Prevention of Cardiovascular Events in Patients with Prior Heart Attack Using Ticagrelor Compared to Placebo on a Background of Aspirin) trials.[177,178] The PEGASUS-TIMI 54 study, which randomized 21,162 patients with MI in the preceding 1 to 3 years to ticagrelor versus placebo, demonstrated a reduction in the composite of CV death, MI, or stroke at the cost of increased bleeding.[178] The DAPT study demonstrated a reduction in death, MI, and stroke as well as stent thrombosis with continuation of a thienopyridine (clopidogrel or prasugrel) on background therapy with aspirin for 30 months versus 12 months in patients undergoing drug-eluting stent (DES) placement, including 1045 STEMI patients.[177] A large RCT of the thrombin receptor antagonist *vorapaxar* in stable patients with prior MI, ischemic stroke, or symptomatic peripheral artery disease provided additional evidence for a benefit of more potent oral antiplatelet therapy than aspirin alone for long-term secondary prevention.[179] In particular, among patients with prior MI, the addition of vorapaxar to standard antiplatelet therapy reduced the risk of CV death, MI, or stroke by a relative 20% (HR, 0.80; 95% CI 0.72 to 0.89; $P < 0.001$).[180] This benefit was counterbalanced by an increased risk of bleeding with the addition of vorapaxar. A similar reduction in major atherothrombotic events with oral anticoagulants lend additional support to the concept of expanded antithrombotic therapy for long-term secondary prevention (see Anticoagulants). Risk stratification can aid in personalization of antiplatelet therapy in patients with stable ischemic heart disease based on balancing the risk of recurrent atherothrombotic events with the risk of bleeding.[181,182]

In patients treated with PCI, prasugrel and ticagrelor have proved superior to clopidogrel and are recommended as preferred in some guidelines.[2,175] However, in some practice environments, economic or formulary barriers may render access to prasugrel or ticagrelor difficult for some patients. Given the critical importance of dual-antiplatelet therapy in patients who have received DESs, access to a $P2Y_{12}$ inhibitor must be ensured.

Inhibition of the Renin-Angiotensin-Aldosterone System

To prevent late remodeling of the left ventricle and to decrease the likelihood of recurrent ischemic events, we advocate indefinite therapy with an ACE inhibitor in patients with HF, a moderate decrease in global EF, or a large regional wall motion abnormality, even in the presence of a normal global EF. (See earlier, Pharmacologic Therapy, Inhibition of the Renin-Angiotensin-Aldosterone System.)

Beta-Adrenergic Blocking Agents

Meta-analyses of trials from the prethrombolytic era involving more than 24,000 patients who received beta blockers in the convalescent phase of STEMI have shown a 23% reduction in long-term mortality. In most patients who have beta blockade initiated during the convalescent phase of STEMI, the reduction in long-term mortality probably results from the combination of an antiarrhythmic effect (prevention of SCD) and prevention of reinfarction.

Despite the well-documented benefits of therapy with a beta blocker, this treatment continues to be underused, especially in high-risk groups such as older adults. Patients with a relative contraindication to beta blockers (e.g., bradyarrhythmias) should undergo a monitored trial of therapy in the hospital. The dosage should be sufficient to blunt the HR response to stress or exercise. Much of the impact of beta blockers in preventing mortality occurs in the first weeks; consequently, treatment should commence as soon as possible. Programs that provide physician feedback to improve adherence to guidelines should be used.

Some controversy exists regarding how long patients should be treated. The collective data from five

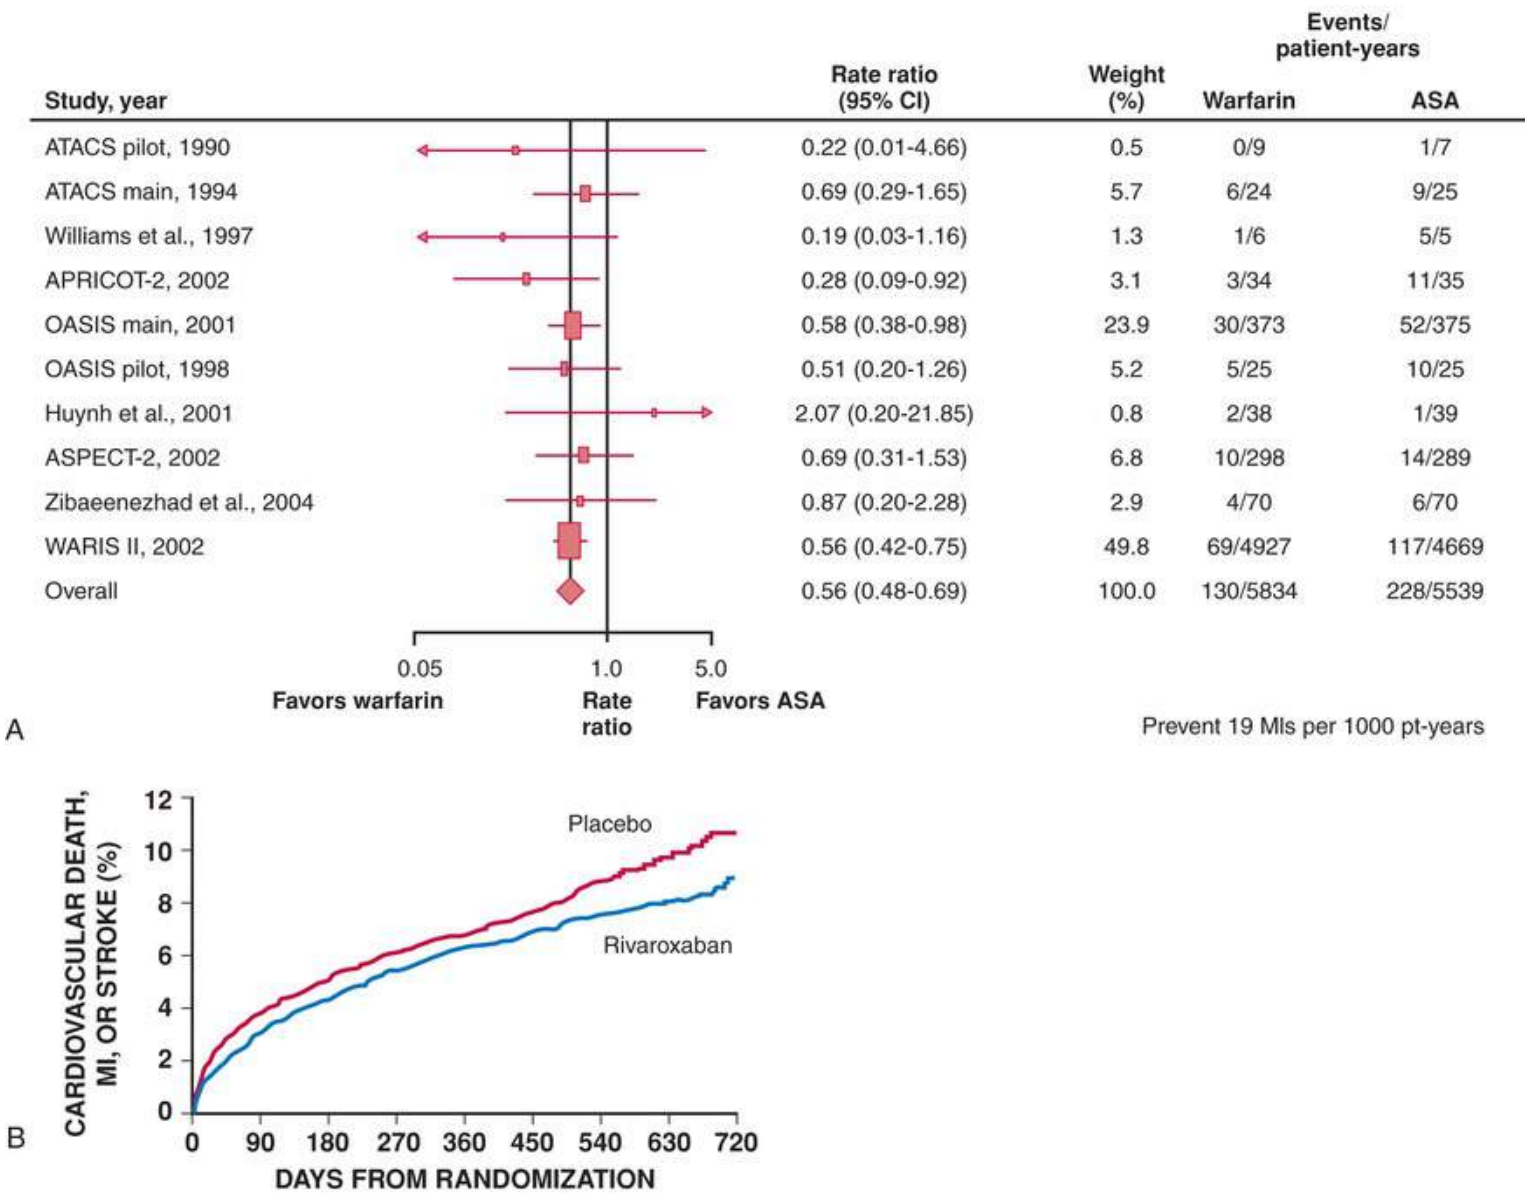
trials on long-term follow-up of patients treated with beta blockers after infarction suggest that therapy should be continued for at least 2 to 3 years. At that time, if the beta blocker is well tolerated and there is no reason to discontinue therapy, such therapy probably should be continued in most patients (**see Chapter 61**).

Nitrates

Although nitrates are suitable for the management of specific conditions after STEMI (e.g., recurrent angina) or as part of a treatment regimen for HF, little evidence indicates that nitrates reduce mortality over the long term when prescribed on a routine basis to all MI patients.

Anticoagulants (See Chapter 93)

After several decades of evaluation, the weight of evidence now suggests that anticoagulants have a favorable effect on late mortality, stroke, and reinfarction in patients hospitalized with STEMI (**eFig. 59.10**). Nevertheless, given the multiple alternatives for antithrombotic therapy for long-term secondary prevention, clinicians must weigh the potential benefits of treatment with an OAC based on established indications for anticoagulation, the use of other antithrombotic therapies, including long-term DAPT, and the risk for bleeding.



EFIGURE 59.10 Outcomes with extended oral anticoagulant therapy for secondary prevention in patients with STEMI. **A,** Meta-analysis of trials of warfarin versus placebo with respect to the outcome of recurrent MI showing the potential to prevent 19 MIs per 1000 patients treated. **B,** Primary result of the ATLAS ACS 2–TIMI 51 trial, in which 15,526 patients with acute coronary syndrome (ACS) were randomly assigned to one of two doses of the oral factor Xa inhibitor rivaroxaban or placebo for a mean of 13 months. Rivaroxaban lowered the rate of cardiovascular death, MI, or stroke by 16%. This benefit was present in patients with STEMI (*n* = 7727), who showed a 15% reduction in the primary endpoint. ASA, Acetylsalicylic acid.

At least three theoretical reasons exist for anticipating that anticoagulants might be beneficial in the long-term management of patients after STEMI. First, because the coronary occlusion responsible for STEMI is often caused by a thrombus, anticoagulants might be expected to halt progression, slow progression, or prevent the development of new thrombi elsewhere in the coronary arterial tree. Second, anticoagulants might be expected to diminish the formation of mural thrombi and resultant systemic embolization. Third, anticoagulants might reduce the incidence of venous thrombosis and pulmonary embolization.

Alternative OACs to warfarin that have the advantage of more predictable anticoagulation with stable oral dosing, such as the oral factor Xa inhibitors, have undergone evaluation in patients with ACS, including STEMI. The ATLAS ACS 2-TIMI 51 (Anti-Xa Therapy to Lower Cardiovascular Events in

Addition to Standard Therapy in Subjects with Acute Coronary Syndrome–Thrombolysis in Myocardial Infarction) trial tested two low doses of the oral factor Xa inhibitor *rivaroxaban* versus placebo. Rivaroxaban at doses of both 2.5 and 5 mg twice daily significantly reduced CV death, MI, or stroke compared to placebo (8.9% versus 10.7%; $P = 0.008$; **eFig. 59.10**).[183] Both doses also reduced stent thrombosis. The group receiving the 2.5-mg dose demonstrated a significant reduction in CV mortality (2.7% versus 4.1%; $P = 0.002$) compared with placebo, which was not seen with 5 mg. Rivaroxaban resulted in an increase in major bleeding (2.1% versus 0.6%; $P < 0.001$) without a significant increase in fatal bleeding.

The risk-benefit profile of low dose oral anticoagulant therapy with rivaroxaban for secondary prevention after STEMI has been supplemented by the results of a large trial of secondary prevention in patients with stable atherosclerosis, including prior MI. In the COMPASS (Cardiovascular OutcoMes for People Using Anticoagulation StrategieS) trial, 27,2395 patients with established stable CAD or peripheral artery disease were randomized to treatment with rivaroxaban (2.5 mg twice daily) plus aspirin (100 mg once daily), rivaroxaban (5 mg twice daily), or aspirin (100 mg once daily).[183a] Patients with CAD qualified for participation with either a history of MI in the past 20 years or multivessel CAD. Compared with aspirin alone, rivaroxaban 2.5 mg twice daily plus aspirin reduced the risk of CV death, MI, or stroke by 24% (HR 0.76; 95% CI, 0.66 to 0.86; P < 0.001). Major bleeding was increased by the addition of rivaroxaban from 1.9% to 3.1% (HR 1.70; 95% CI, 1.40 to 2.05; P < 0.001). However, there were fewer deaths overall in the rivaroxaban 2.5 mg twice daily plus aspirin group compared with aspirin alone (HR 0.82; 95% CI, 0.71 to 0.96; nominal P = 0.01). Rivaroxaban 5 mg twice daily without aspirin did not significantly reduce the primary endpoint compared with aspirin alone. COMPASS did not study patients receiving an ADP antagonist in any treatment arm. The role of the available options for long-term antithrombotic therapy in addition to aspirin (e.g. ticagrelor, rivaroxaban, or vorapaxar) are likely to be refined with clinical experience, additional research, and review by professional society guidelines committees.

Despite similar findings in the ACS phase II studies with rivaroxaban (ATLAS ACS-TIMI 46) and with another oral factor Xa inhibitor, *apixaban* (APPRAISE, Apixaban for Prevention of Acute Ischemic Events), the phase III APPRAISE-2 study, which tested apixaban versus placebo in patients following an ACS, was terminated early because of an increase in major bleeding without a significant improvement in efficacy.[72,184] The divergent results of the ATLAS ACS 2-TIMI 51 and APPRAISE-2 studies may be related to a higher baseline risk of the patients and concordant competing risks, the inclusion of patients with previous stroke or transient ischemic attack, and higher degrees of anticoagulation in APPRAISE-2.

Calcium Channel Antagonists.

We do *not* recommend the routine use of calcium antagonists for secondary prevention of MI. A possible exception is a patient who cannot tolerate a beta blocker because of adverse effects on bronchospastic lung disease but who has well-preserved LV function. Such patients may be candidates for a rate-slowing calcium antagonist such as diltiazem or verapamil.

Hormone Therapy (See Chapters 45 and 89).

The decision to prescribe hormone therapy is often complex and involves the desire to suppress postmenopausal symptoms versus the risk for breast and endometrial cancer and vascular events. At present, we recommend that hormone therapy with estrogen plus progestin should *not* be started after STEMI and should be discontinued in postmenopausal women after STEMI.

Antioxidants (See Chapter 45).

Dietary supplementation with omega-3 polyunsaturated fatty acids has associated with a reduction in

coronary death and reinfarction after MI. Contemporary randomized studies, however, have shown no convincing benefit in the context of guideline-based medical therapy.[185,186] Current data therefore do not support the use of antioxidant therapy for secondary prevention after STEMI.

Nonsteroidal Anti-Inflammatory Drugs

Evidence has emerged that COX-2–selective drugs and NSAIDs with varying COX-1/COX-2 inhibitory ratios promote a prothrombotic state, and that their use is associated with an increased risk for atherothrombotic events.[1] Given the desire not to interfere with the beneficial pharmacologic actions of low-dose aspirin after STEMI, and reports of increased mortality and reinfarction when NSAIDs are used after MI, clinicians should avoid prescribing NSAIDs to patients recovering from STEMI.[1] If NSAIDs must be prescribed for relief of pain, the lowest dose required to control symptoms should be administered for the shortest time required.

Future Perspectives and Emerging Therapies

Although the case-fatality rate of patients with STEMI has declined substantially, considerable opportunities for improvement remain. Of these, we emphasize three major directions: (1) mitigation of reperfusion injury and impaired myocardial tissue perfusion, (2) management of cardiogenic shock after STEMI, and (3) amelioration of the adverse remodeling.

Although PCI usually restores flow through epicardial arteries, many patients do not achieve adequate nutrient flow at the myocardial level in the infarct zone because of impaired microvascular flow (**see Fig. 59.7 and eFig. 59.1**). Despite effective restoration of flow in the culprit epicardial artery, patients with impaired microvascular reperfusion have reduced survival.[42] Identification of therapies that reliably improve microvascular perfusion in the setting of primary PCI and pharmacologic reperfusion has proved challenging. For example, although thrombus aspiration was hypothesized to improve outcomes through a reduction in microvascular obstruction due to distal embolization, improvements in ST-segment resolution did not translate to a reduction in recurrent CV events.[61,187,188]

Reperfusion injury to the microvasculature can also extend myocardial injury beyond the initial ischemic zone. To date, multiple candidate interventions to reduce reperfusion injury that appeared promising in initial studies have failed in definitive randomized trials. Amelioration of the reperfusion injury that contributes to long-term myocardial dysfunction remains an unmet clinical need. Therefore, therapies that target microvascular obstruction and reperfusion injury merit ongoing investigation.[25,42]

Even if reperfusion were achieved in timely fashion and microvascular obstruction were minimized, patients with STEMI inevitably lose some myocytes. When ventricular failure or severe mechanical disruption results, cardiogenic shock may ensue. Mortality from cardiogenic shock remains in excess of 40%. Improvement in the outcomes of patients in whom shock develops after STEMI remains a vexing clinical challenge.[108] The disappointing results of trials of percutaneous mechanical support have challenged common clinical assumptions.[122,189,190] Novel therapies and strategies for the management of shock are an area of unmet clinical need.

In addition to the early risk for ventricular failure because of acute myocardial injury, secondary damage to the left ventricle can also occur in the long term as a result of ventricular remodeling after STEMI. Treatments to minimize ventricular remodeling include the standard approaches to disruption of the RAAS and potential new therapies such as ARNIs, reducing the amount of central nervous system generation of aldosterone, enhancing the synthesis of endothelial nitric oxide synthase, modulating beta-

adrenergic signaling, and minimizing the processes that lead to cardiac apoptosis.[191] Novel approaches using biologic and mechanical interventions to improve ventricular structure are under investigation.[192,193] Moreover, myocytes are capable of entering the cell cycle and dividing[194] (**see Chapter 30**). Cardiac regenerative measures merit rigorous evaluation regarding efficacy in ameliorating the adverse ventricular remodeling or myocardial repair by use of either endogenous or exogenous sources of cells that give rise to myocytes (**Fig. 59.35**).[195]

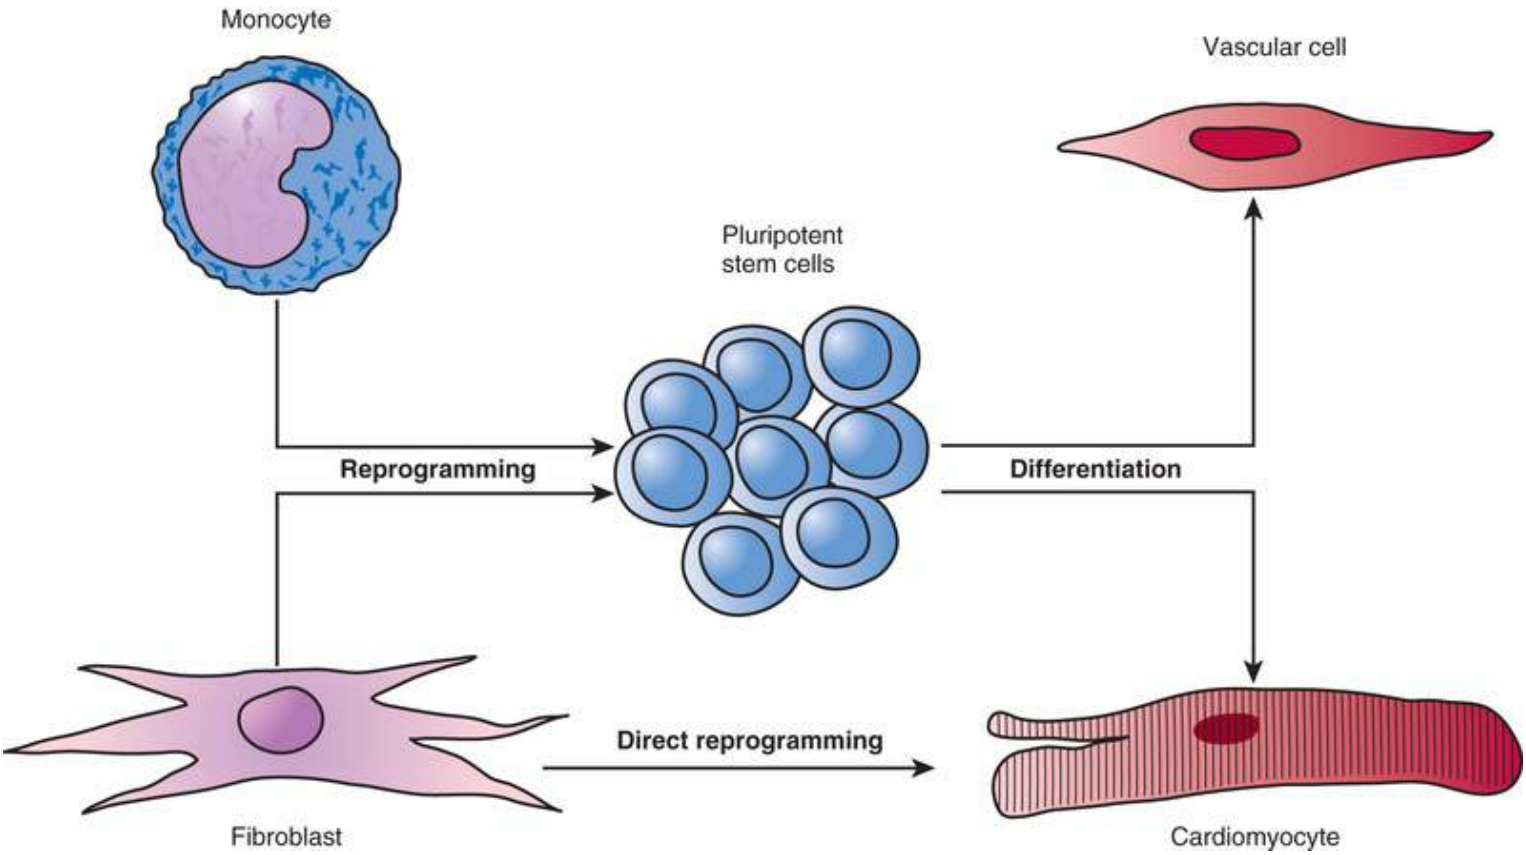


FIGURE 59.35 Not only can embryonic stem cells give rise to multiple cell types, but cells such as monocytes and fibroblasts can undergo reprogramming to differentiate into cardiovascular cells. Guidelines

Management of Patients with ST-Elevation Myocardial Infarction

Stephen D. Wiviott

The American College of Cardiology Foundation/American Heart Association (ACCF/AHA) updated guidelines for the diagnosis and management of patients with ST-elevation myocardial infarction (STEMI) in 2013.[1] This guideline has not been updated *in full* since this publication, but two other documents provide substantial additional information to guide management of patients with STEMI: the 2015 Focused update on Primary Percutaneous Coronary Intervention[2] and the 2016 Guideline Focused Update on Duration of Dual Antiplatelet Therapy in Patients with Coronary Artery Disease.[3] As with other ACCF/AHA guidelines, these documents place recommendations into the customary four classes and ratings for the level of evidence (LOE.)

Definition and Diagnosis

STEMI is defined by symptoms of myocardial ischemia associated with persistent electrocardiographic evidence of ST elevation and subsequent elevation of biologic markers of myocardial necrosis. According to the universal definition of myocardial infarction (MI), ST elevation in the absence of either left bundle branch block (LBBB) or left ventricular (LV) hypertrophy is defined as new ST elevation of at least 2 mm in men or 1.5 mm in women in at least two contiguous leads.[4] New or presumably new LBBB at initial evaluation should not be considered diagnostic of MI. Interpretation of the electrocardiogram (ECG) may be obscured by previous LBBB, paced rhythm, LV hypertrophy, or Brugada syndrome.

Onset of Myocardial Infarction

Time until treatment is paramount in the management of STEMI, and early recognition, transport, and treatment can improve outcomes in patients with this syndrome.

Patient-Related Delays and Initial Treatment

Time delays in seeking care tend to be longer in women, blacks, and older adults. Delays may result from failure to recognize symptoms, uncertainty of the severity of symptoms, and lack of understanding of the importance of rapid treatment. The STEMI guidelines emphasize the importance of anticipatory planning, including the need to activate the emergency medical service (EMS) system and early aspirin treatment. Patients should learn warning signs, develop a survival plan, and discuss risk reduction with their physicians.

Mode of Transport to the Hospital

Patients with ischemic symptoms should be transported to the hospital by ambulance rather than by friends or family. Ambulance transport associates with earlier recognition of STEMI, faster reperfusion, and lower mortality. The benefits of ambulance transport are increased by prehospital communication of the diagnosis of STEMI and by transfer to hospitals capable of performing prompt percutaneous coronary intervention (PCI).

Community Preparedness and Systems Goals for Reperfusion Therapy

Time until appropriate reperfusion therapy is one key to the treatment of STEMI. Community-based systems designed for the rapid management of patients with STEMI should facilitate rapid reperfusion. **Fig. 59G.1** outlines the major strategies and decision points for the management of patients with STEMI.

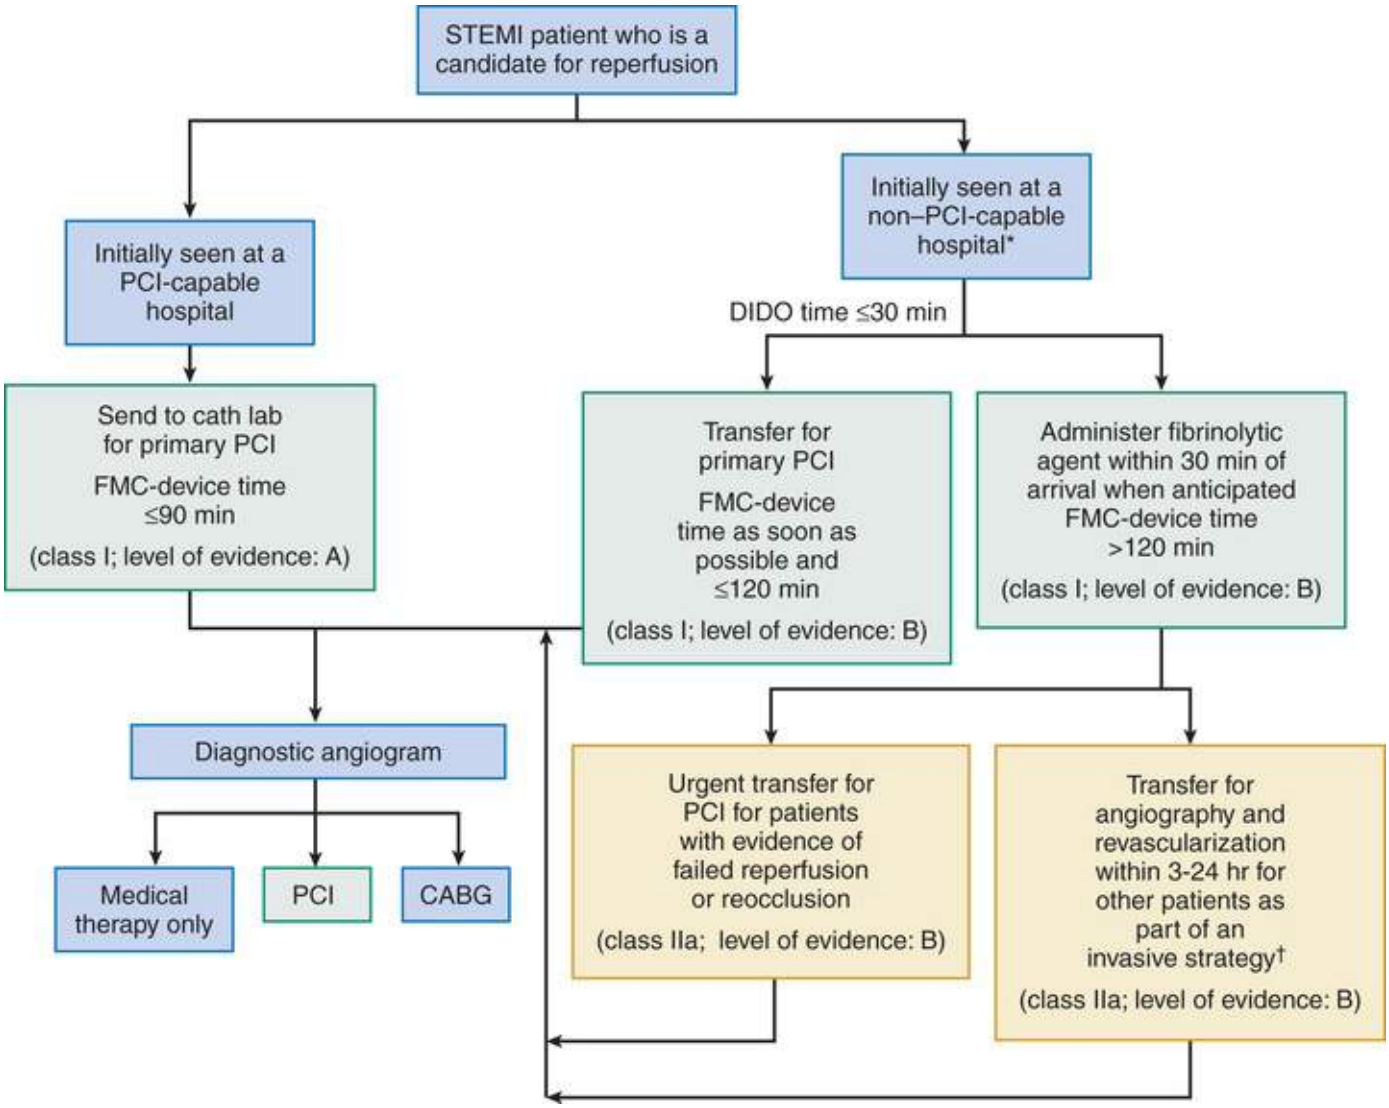

FIGURE 59G.1 Reperfusion therapy for patients with ST-segment elevation myocardial infarction (STEMI). The *bold arrows* and *boxes* are the preferred strategies. Performance of percutaneous coronary intervention (PCI) is dictated by an anatomically appropriate culprit stenosis. *Patients with cardiogenic shock or severe heart failure initially seen at a non–PCI-capable hospital should be transferred for cardiac catheterization and revascularization as soon as possible, irrespective of the delay in time after the onset of MI (class I; LOE: B). †Angiography and revascularization should not be performed within the first 2 to 3 hours after the administration of fibrinolytic therapy. *CABG,* Coronary artery bypass graft surgery; *DIDO,* door in–door out; *FMC,* first medical contact. (Modified from O'Gara PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2013;61(4):e78.)

Class I recommendations include the following:

- Communities should create and maintain regional systems of STEMI care that includes assessment and quality improvement of EMS and hospital-based activities (LOE: B).
- A 12-lead ECG should be performed by EMS personnel at the site of first medical contact (FMC) in patients with symptoms consistent with STEMI (LOE: B).
- Reperfusion therapy should be administered to all eligible patients

with STEMI in whom the onset of symptoms began within the previous 12 hours (LOE: A).
• Primary PCI is the recommended method of reperfusion when experienced operators can perform it within timely fashion (LOE: A).
• EMS transport directly to a PCI-capable hospital for primary PCI is the recommended triage strategy for patients with STEMI, with an ideal FMC-to-device time goal of 90 minutes or less (LOE: B).
• Immediate transfer to a PCI-capable hospital for primary PCI is the recommended triage strategy for patients with STEMI who initially arrive at or are transported to a non–PCI-capable hospital, with an FMC-to-device time goal of 12 minutes or less (LOE: B).
• Without contraindications, fibrinolytic therapy should be administered to patients with STEMI at non–PCI-capable hospitals when the anticipated FMC-to-device time at a PCI-capable hospital exceeds 120 minutes because of unavoidable delays (LOE: B).
• When fibrinolytic therapy is indicated or chosen as the primary reperfusion strategy, it should be administered within 30 minutes of hospital arrival (LOE: B).

When selecting reperfusion therapy, the provider must consider several features in relation to these recommendations, including time from the onset of symptoms, risk for STEMI-related complications, risk for bleeding, presence of heart failure or shock, and time required for the administration of fibrinolytics versus the time needed for transfer to a PCI-capable hospital. Patients best suited for transfer to PCI-capable hospitals include those with congestive heart failure (CHF) or shock, high bleeding risk, longer than 3 to 4 hours after onset of symptoms, and short transfer times to PCI-capable hospitals. Those best suited for initial fibrinolytic therapy include patients with low bleeding risk, very early after the onset of symptoms, and longer delays until the performance of PCI.

Relationship Between Sudden Cardiac Death and ST-Elevation Myocardial Infarction

STEMI is inexorably linked to sudden cardiac death: approximately 70% of deaths attributable to coronary heart disease occur with out-of-hospital arrest. The STEMI guidelines offer some key recommendations for the evaluation and management of patients with STEMI and out-of-hospital cardiac arrest, including the following class I recommendations:

• Therapeutic hypothermia should be started as soon as possible in comatose patients with STEMI and out-of-hospital cardiac arrest

caused by ventricular fibrillation or pulseless ventricular tachycardia, including patients who undergo primary PCI (LOE: B).

• Immediate angiography and PCI, when indicated, should be performed in resuscitated patients with out-of-hospital cardiac arrest whose initial ECG shows STEMI (LOE: B).

Reperfusion at a Hospital Capable of Performing Percutaneous Coronary Interventions

The 2013 STEMI guidelines are divided into sections describing appropriate care at PCI-capable hospitals versus non–PCI-capable hospitals.[1]

Primary Percutaneous Coronary Intervention (Table 59G.1)

Primary PCI is generally preferable to fibrinolytic therapy when time until treatment is short and the patient arrives at a high-volume, well-equipped center with experienced operators and support staff. When compared with fibrinolysis, primary PCI produces higher rates of TIMI (thrombolysis in myocardial infarction) grade 3 flow and patent infarct-related arteries and lower rates of recurrent ischemia, urgent revascularization, recurrent MI, and death. Primary PCI, when successful, can also enable early hospital discharge and return to activities. Such improvements are less or absent in low-volume centers or with low-volume operators.

PCI on a noninfarct artery at the time of primary PCI in patients without hemodynamic compromise	III: Harm	B

COR, Class of recommendation; *FMC,* first medical contact; *LOE,* level of evidence.

Modified from O'Gara PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2013;61(4):e78.

Procedural Considerations

The 2013 STEMI guidelines offered a class IIa recommendation for manual aspiration thrombectomy in patients undergoing primary PCI, although subsequent trial data do not show that this procedure reduces 30-day mortality in patients with STEMI.[5] The 2015 focused update on primary PCI changed this recommendation to class III (LOE: A) as a routine strategy and class IIb for selective bailout in the setting of unsatisfactory results.

The 2013 guidelines listed non–culprit vessel PCI in hemodynamically stable patients with multivessel CAD at the time of primary PCI as class III (LOE B), discouraging such procedures. The results of subsequent randomized controlled trials (RCTs) suggesting benefit in certain circumstances led to an

upgraded recommendation of class IIb (LOE B).

Class I indications are given for the use of intracoronary stents at primary PCI (LOE: A). Either drug-eluting stents (DESs) or bare-metal stents (BMSs) can be used, but when patients are anticipated to be at high bleeding risk or are probably not compliant with dual-antiplatelet therapy (DAPT) for other reasons, a class I indication is given for the use of BMSs and a class III indication for DESs—because of the risk for delayed stent thrombosis in DESs with premature discontinuation of DAPT. **Table 59G.2** summarizes the adjunctive antithrombotic therapy for primary PCI, including antiplatelet therapy and anticoagulant therapy.

TABLE 59G.2

Adjunctive Antithrombotic Therapy to Support Reperfusion with Primary Percutaneous Coronary Intervention (PCI)

	COR	LOE
Antiplatelet Therapy		
Aspirin		
• 162- to 325-mg loading dose before the procedure	I	B
• 81- to 325-mg daily maintenance dose (indefinite)*	I	A
• 81 mg daily is the preferred maintenance dose*	IIa	B
$P2Y_{12}$ Inhibitors		
Loading Doses		
• Clopidogrel: 600 mg as early as possible or at the time of PCI	I	B
• Prasugrel: 60 mg as early as possible or at the time of PCI	I	B
• Ticagrelor: 180 mg as early as possible or at the time of PCI	I	B
Maintenance Doses		
Drug-eluting stents (DESs) placed: continue therapy for 1 yr with:		
• Clopidogrel: 75 mg daily	I	B
• Prasugrel: 10 mg daily	I	B
• Ticagrelor: 90 mg twice a day	I	B
Bare-metal stents (BMSs)† placed: continue therapy for 1 yr with:		
• Clopidogrel: 75 mg daily	I	B
• Prasugrel: 10 mg daily	I	B
• Ticagrelor: 90 mg twice a day	I	B
DESs placed		
• Patients with STEMI and previous stroke or TIA: prasugrel	III: Harm	B
Intravenous Glycoprotein IIb/IIIa Receptor Antagonists in Conjunction with Unfractionated Heparin or Bivalirudin in Selected Patients		
• Abciximab: 0.25-mg/kg IV bolus, then 0.125 µg/kg/min (maximum, 10 µg/min)	IIa	A
• Tirofiban (high bolus dose): 25-µg/kg IV bolus, then 0.15 µg/kg/min	IIa	B
• In patients with CrCl <30 mL/min, reduce the infusion by 50%		
• Eptifibatide (double bolus): 180-µg/kg IV bolus, then 2 µg/kg/min; a second 180-µg/kg bolus is administered 10 min after the first bolus	IIa	B
• In patients with CrCl <50 mL/min, reduce the infusion by 50%		
• Avoid in patients on hemodialysis		
• Pre–catheterization laboratory administration of IV GP IIb/IIIa receptor antagonist	IIb	B
• Intracoronary abciximab: 0.25-mg/kg bolus	IIb	B
Anticoagulant Therapy		
• Unfractionated heparin (UFH)		
• With a GP IIb/IIIa receptor antagonist planned: 50- to 70-unit/kg IV bolus to achieve therapeutic ACT‡	I	C
• With no GP IIb/IIIa receptor antagonist planned: 70- to 100-unit/kg bolus to achieve a therapeutic ACT§	I	C
• Bivalirudin: 0.75-mg/kg IV bolus, then 1.75-mg/kg/hr infusion with or without previous treatment with UFH. An additional bolus of 0.3 mg/kg may be given if needed	I	B
• Reduce the infusion to 1 mg/kg/hr with estimated an CrCl <30 mL/min		
• Preferred over UFH with a GP IIb/IIIa receptor antagonist in patients at high risk for bleeding	IIa	B
• Fondaparinux: not recommended as the sole anticoagulant for primary PCI	III: Harm	B

*The recommended maintenance dose of aspirin to be used with ticagrelor is 81 mg daily.

†Balloon angioplasty without stent placement may be used in selected patients. It might be reasonable to provide $P2Y_{12}$ inhibitor therapy to patients with STEMI undergoing balloon angioplasty alone according to the recommendations listed for BMSs (LOE: C).

‡The recommended ACT with planned GP IIb/IIIa receptor antagonist treatment is 200 to 250 seconds.

§The recommended ACT with no planned GP IIb/IIIa receptor antagonist treatment is 250 to 300 seconds (HemoTec device) or 300 to 350 seconds (Hemochron device).

ACT, Activated clotting time; *CrCl,* creatinine clearance; *COR,* class of recommendation; *GP,* glycoprotein; *IV,* intravenous; *LOE,* level of evidence; *STEMI,* ST-elevation myocardial infarction.

Modified from O'Gara PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2013;61(4):e78.

For antiplatelet therapy, class I recommendations include aspirin and $P2Y_{12}$ receptor antagonists.

Aspirin

• Aspirin (162 to 325 mg) should be given before primary PCI (LOE: B).
• After PCI, aspirin should be continued indefinitely (LOE: B). *Note:* An 81-mg dose of aspirin is recommended for maintenance (class IIa; LOE: B) instead of higher doses.

$P2Y_{12}$ Antagonists

• A loading dose of a $P2Y_{12}$ receptor inhibitor should be given as early as possible or at the time of primary PCI in patients with STEMI (LOE: B), with options including clopidogrel, 600 mg (LOE: B); prasugrel, 60 mg (LOE: B); or ticagrelor, 180 mg (LOE: B).
• Patients with STEMI who receive a stent should receive a $P2Y_{12}$ antagonist. Options include clopidogrel, 75 mg daily (LOE: B); prasugrel, 10 mg daily (LOE: B); or ticagrelor, 90 mg twice daily (LOE: B). The 2016 focused update on duration of DAPT indicates that it is reasonable to use ticagrelor (class IIa, LOE: B) or prasugrel (class IIa, LOE: B) in preference to clopidogrel. *Note:* Prasugrel should not be used (class III, LOE: B) in patients with high bleeding risk or a history of transient ischemic attack (TIA) or stroke.

Anticoagulant Therapy

For anticoagulant therapy, key recommendations include supportive anticoagulation with unfractionated heparin (UFH), with dosing based on the activated clotting time (ACT: class I, LOE: C), or with bivalirudin in patients who have not been treated previously with UFH (class I, LOE: B). In patients with a high risk for bleeding, bivalirudin is generally recommended instead of heparin plus a glycoprotein IIb/IIIa receptor antagonist (class IIa, LOE: B), and fondaparinux should *not* be used as the sole anticoagulant (class III, LOE: B).

Reperfusion at a Hospital Not Capable of Performing Percutaneous Coronary Interventions

The guidelines categorize the management of patients at a non–PCI-capable hospital into three phases: fibrinolytic therapy, assessment of patency, and transfer to a PCI-capable hospital.

Fibrinolytic Therapy When the Delay Anticipated Is Within 120 Minutes

Table 59G.3 summarizes the key recommendations for the indications for fibrinolytic therapy with a

delay of longer than 120 minutes from FMC to primary PCI. The 2013 STEMI guidelines recommend fibrin-specific agents over non–fibrin-specific agents when available.[1] Fibrin-specific regimens include single-bolus tenecteplase (TNK tissue plasminogen activator [t-PA]), double-bolus reteplase (r-PA), or infusion of alteplase (t-PA). Streptokinase administered over a 30- to 60-minute period is the only nonspecific agent recommended. The choice of fibrinolytic agent depends on a risk-benefit analysis that integrates time from the onset of symptoms, clinical features, comorbid conditions, delay until performance of PCI, and potential contraindications (**Table 59G.4**). **Table 59G.5** summarizes antithrombotic therapy for STEMI treated with fibrinolytic therapy.

TABLE 59G.3

Indications for Fibrinolytic Therapy When the Delay from First Medical Contact to Primary Percutaneous Intervention Is Longer than 120 Minutes

	COR	LOE
Ischemic symptoms <12 hr	I	A
Evidence of ongoing ischemia 12-24 hr after the onset of symptoms and a large area of myocardium at risk or hemodynamic instability	IIa	C

TABLE 59G.4

Contraindications to Fibrinolytic Therapy for ST-Elevation Myocardial Infarction

Absolute Contraindications
Any previous intracranial hemorrhage
Known structural cerebral vascular lesion
Known malignant intracranial neoplasm
Ischemic stroke within 3 months (except ischemic stroke within 4.5 hours)
Suspected aortic dissection
Active bleeding or bleeding diathesis
Significant closed-head or facial trauma within 3 months
Intracranial or intraspinal surgery within 2 months
Severe uncontrolled hypertension (not responsive to emergency therapy)
For streptokinase, previous treatment within 6 months
Relative Contraindications
History of chronic, severe, poorly controlled hypertension
Significant hypertension at initial evaluation (SBP, >180 mm Hg, DBP >110 mm Hg)
History of ischemic stroke >3 months
Dementia
Known intracranial pathology not covered in Absolute Contraindications
Traumatic or prolonged cardiopulmonary resuscitation (>10 minutes)
Major surgery within 3 weeks
Recent internal bleeding (within 2-4 weeks)
Noncompressible vascular puncture
Pregnancy
Active peptic ulcer
Oral anticoagulant therapy

DBP, Diastolic blood pressure; *SBP,* systolic blood pressure.

TABLE 59G.5

Adjunctive Antithrombotic Therapy to Support Reperfusion with Fibrinolytic Therapy

	COR	LOE
Antiplatelet Therapy		
Aspirin		
• 162- to 325-mg loading dose	I	A
• 81- to 325-mg daily maintenance dose (indefinite)	I	A
• 81 mg daily is the preferred maintenance dose	IIa	B
P2Y$_{12}$ Receptor Inhibitors		
• Clopidogrel:	I	A
• Age ≤75 yr: 300-mg loading dose		
• Followed by 75 mg daily for at least 14 days	I	A
• Age >75 yr: no loading dose, give 75 mg	I	A
• Followed by 75 mg daily for at least 14 days	I	A (14 days)
Anticoagulant Therapy		
• Unfractionated heparin (UFH):	I	C
• Weight-based IV bolus and infusion adjusted to obtain an APTT of 1.5-2.0 times control for 48 hr or until revascularization. IV bolus of 60 units/kg (maximum, 4000 units) followed by an infusion of 12 units/kg/hr (maximum, 1000 units) initially, adjusted to maintain the APTT at 1.5-2.0 times control (≈50-70 sec) for 48 hr or until revascularization		
• Enoxaparin:	I	A
• If age <75 yr: 30-mg IV bolus, followed in 15 min by 1 mg/kg subcutaneously every 12 hr (maximum, 100 mg for the first 2 doses)		
• If age ≥75 yr: no bolus, 0.75 mg/kg subcutaneously every 12 hr (maximum, 75 mg for the first 2 doses)		
• Regardless of age, if CrCl <30 mL/min, 1 mg/kg subcutaneously every 24 hr		
• Duration: For the index hospitalization, up to 8 days or until revascularization		
• Fondaparinux:	I	B
• Initial dose of 2.5 mg IV, then 2.5 mg subcutaneously daily starting the following day, for the index hospitalization up to 8 days or until revascularization		
• Contraindicated if CrCl <30 mL/min		

APTT, Activated partial thromboplastin time; *COR,* class of recommendation; *CrCl,* creatinine clearance; *LOE,* level of evidence.

Antiplatelet Therapy

- A loading dose of aspirin (162 to 325 mg) and clopidogrel (300 mg in patients ≤75 years of age; 75 mg in patients >75 years of age) should be administered with fibrinolytic therapy (class I, LOE: A).
- Aspirin should be continued indefinitely at 81 to 100 mg, and clopidogrel should be continued at 75 mg. *Note:* A dose of 81 mg of aspirin is preferred instead of higher maintenance dosing (class IIa, LOE: B).

Anticoagulant Therapy

Patients with STEMI treated with fibrinolytic therapy for reperfusion should receive anticoagulant therapy for a minimum of 48 hours and preferably for the duration of hospitalization, up to 8 days or until revascularization is performed (class I, LOE: A). Acceptable regimens include UFH for up to 48 hours (LOE: C), enoxaparin for up to 8 days (LOE: A), or fondaparinux for up to 8 days (LOE: B).

Transfer to a Hospital Capable of Performing PCI after Fibrinolytic Therapy

Table 59G.6 summarizes key recommendations for transfer to a PCI-capable hospital for angiography. The only class I indication for immediate transfer in the 2013 STEMI guidelines is for patients with severe heart failure or cardiogenic shock, but the general recommendation is for all patients who have failed reperfusion or suffered reocclusion (class IIa, LOE: B) to be transferred urgently and for stable patients to be transferred routinely (class IIa, LOE: B).

TABLE 59G.6

Indications for Transfer for Angiography after Fibrinolytic Therapy

	COR	LOE
Cardiogenic shock or acute severe heart failure that develops after initial evaluation	I	B
Intermediate- or high-risk findings on predischarge noninvasive ischemia testing	I	B
Spontaneous or easily provoked myocardial ischemia	I	C
Failed reperfusion or reocclusion after fibrinolytic therapy	IIa	B
Stable* patients after successful fibrinolysis, before discharge and ideally between 3 and 24 hr	IIa	B

*Although individual circumstances vary, *clinical stability* is defined by the absence of low output, hypotension, persistent tachycardia, apparent shock, high-grade ventricular or symptomatic supraventricular tachyarrhythmias, and spontaneous recurrent ischemia.

COR, Class of recommendation; *LOE,* level of evidence.

Modified from O'Gara PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2013;61(4):e78.

Delayed Invasive Management

Coronary Angiography and PCI in Patients Initially Managed with Fibrinolytic Therapy or in Those with No Reperfusion (Table 59G.7)

PCI should be performed when angiography identifies significant stenosis in the infarct-related arteries. Class I indications relate to high-risk clinical features (cardiogenic shock, severe CHF), recurrent spontaneous or provoked ischemia, or high-risk features on noninvasive testing. PCI on non–infarct-related arteries should be based on spontaneous symptoms (class I, LOE: C) or high-risk features on noninvasive testing (class IIa, LOE: B) suggestive of ischemia in the territory of the non-infarct–related artery. One study published after the guidelines suggested a benefit of PCI on non–infarct-related arteries.[6]

TABLE 59G.7

Indications for Percutaneous Coronary Intervention (PCI) on an Infarct Artery in Patients Who Were Managed with Fibrinolytic Therapy or Who Did Not Receive Reperfusion Therapy

	COR	LOE
Cardiogenic shock or acute severe heart failure	I	B
Intermediate- or high-risk findings on predischarge noninvasive ischemia testing	I	C
Spontaneous or easily provoked myocardial ischemia	I	C
Patients with evidence of failed reperfusion or with reocclusion after fibrinolytic therapy (as soon as possible)	IIa	B
Stable* patients after successful fibrinolysis, ideally between 3 and 24 hr	IIa	B
Stable* patients >24 hr after successful fibrinolysis	IIb	B
Delayed PCI on a totally occluded infarct artery >24 hr after STEMI in stable patients	III: No benefit	B

*Although individual circumstances vary, *clinical stability* is defined by the absence of low output, hypotension, persistent tachycardia, apparent shock, high-grade ventricular or symptomatic supraventricular tachyarrhythmias, and spontaneous recurrent ischemia.

COR, Class of recommendation; *LOE,* level of evidence; *STEMI,* ST-elevation myocardial infarction.

Modified from O'Gara PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2013;61(4):e78.

Adjunctive Antithrombotic Agents to Support Delayed PCI

Table 59G.8 summarizes adjunctive antiplatelet therapy and anticoagulant therapy to support delayed PCI. Antiplatelet and anticoagulant therapies in patients in whom PCI is delayed are similar to those in patients who undergo PCI early, but the timing and dosing of $P2Y_{12}$ antagonists differ depending on the time interval and type of fibrinolytic agent given. Notably, a loading dose of 300 mg of clopidogrel should be administered (if not already given with fibrinolysis) for PCI performed within 24 hours, and for PCI performed after 24 hours, a 600-mg loading dose. Prasugrel should be used at standard dosing, but not within 48 hours of fibrinolytic therapy. Anticoagulant therapy can consist of UFH (class I, LOE: C) or enoxaparin (class I, LOE: B), but fondaparinux should *not* be used as a stand-alone anticoagulant (class III, LOE: B).

TABLE 59G.8

Adjunctive Antithrombotic Therapy to Support Percutaneous Intervention (PCI) after Fibrinolytic Therapy

	COR	LOE
Antiplatelet Therapy		
Aspirin		
• 162- to 325-mg loading dose given with a fibrinolytic agent (before PCI)	I	A
• 81- to 325-mg daily maintenance dose after PCI (indefinite)	I	A
• 81 mg daily is the preferred daily maintenance dose	IIa	B
$P2Y_{12}$ Receptor Inhibitors		
Loading Doses		
For patients who received a loading dose of clopidogrel with fibrinolytic therapy:		
• Continue clopidogrel, 75 mg daily, without an additional loading dose	I	C
For patients who have not received a loading dose of clopidogrel:		
• If PCI is performed ≤24 hr after fibrinolytic therapy: clopidogrel, 300-mg loading dose before or at the time of PCI	I	C
• If PCI is performed >24 hr after fibrinolytic therapy: clopidogrel, 600-mg loading dose before or at the time of PCI	I	C
• If PCI is performed >24 hr after treatment with a fibrin-specific agent or >48 hr after a non–fibrin-specific agent: prasugrel, 60 mg at the time of PCI	IIa	B
For patients with previous stroke/TIA: prasugrel	III: Harm	B
Maintenance Doses		
Drug-eluting stents (DESs) placed: continue therapy for at least 1 yr with:		
• Clopidogrel: 75 mg daily	I	C
• Prasugrel: 10 mg daily	IIa	B
Bare-metal stents (BMSs) placed: continue therapy for at least 30 days and up to 1 yr with:*		
• Clopidogrel: 75 mg daily	I	C
• Prasugrel: 10 mg daily	IIa	B
Anticoagulant Therapy		
• Continue UFH throughout PCI while administering additional IV boluses as needed to maintain a therapeutic ACT, depending on use of a GP IIb/IIIa receptor antagonist†	I	C
• Continue enoxaparin throughout PCI: • No additional drug if the last dose was given within the previous 8 hr • 0.3-mg/kg IV bolus if the last dose was given 8-12 hr earlier	I	B
• Fondaparinux: • As sole anticoagulant for PCI	III: Harm	C

*Balloon angioplasty without stent placement may be used in selected patients. It might be reasonable to provide $P2Y_{12}$ inhibitor therapy to patients with STEMI undergoing balloon angioplasty after fibrinolysis alone according to the recommendations listed for BMSs (LOE: C).

†The recommended ACT with no planned GP IIb/IIIa receptor antagonist treatment is 250 to 300 seconds (HemoTec device) or 300 to 350 seconds (Hemochron device).

ACT, Activated clotting time; *COR,* class of recommendation; *IV,* intravenous; *LOE,* level of evidence.

Modified from O'Gara PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2013;61(4):e78.

Coronary Artery Bypass Graft Surgery

The 2013 STEMI guidelines accord coronary artery bypass grafting (CABG) a relatively limited role in the management of patients with STEMI. The only class I indications for CABG in patients with STEMI include the management of those whose coronary anatomy is not amenable to PCI; those who have ongoing or recurrent ischemia, shock, severe heart failure, or other high-risk features (LOE: B); and patients at the time of operative repair of mechanical defects, such as a ventricular septal defect (LOE: B).

In general, aspirin should be continued throughout the pre-CABG and peri-CABG periods. With the understanding that CABG is often urgent in the setting of STEMI, clopidogrel or ticagrelor should be discontinued for at least 24 hours when possible. In stable settings, clopidogrel and ticagrelor should be stopped for 5 days and prasugrel stopped for 7 days before CABG, but earlier surgery may be considered if the benefits outweigh the risks (class IIb).

Duration of Dual-Antiplatelet Therapy

The focused update on dual-antiplatelet therapy provides guidance on duration of therapy in patients with acute coronary syndrome (ACS), including both STEMI and non-STEMI (**Fig. 59G.2**). In this guideline, aspirin, in the absence of any contraindication, is continued indefinitely at a maintenance dose of 75 to 100 mg.

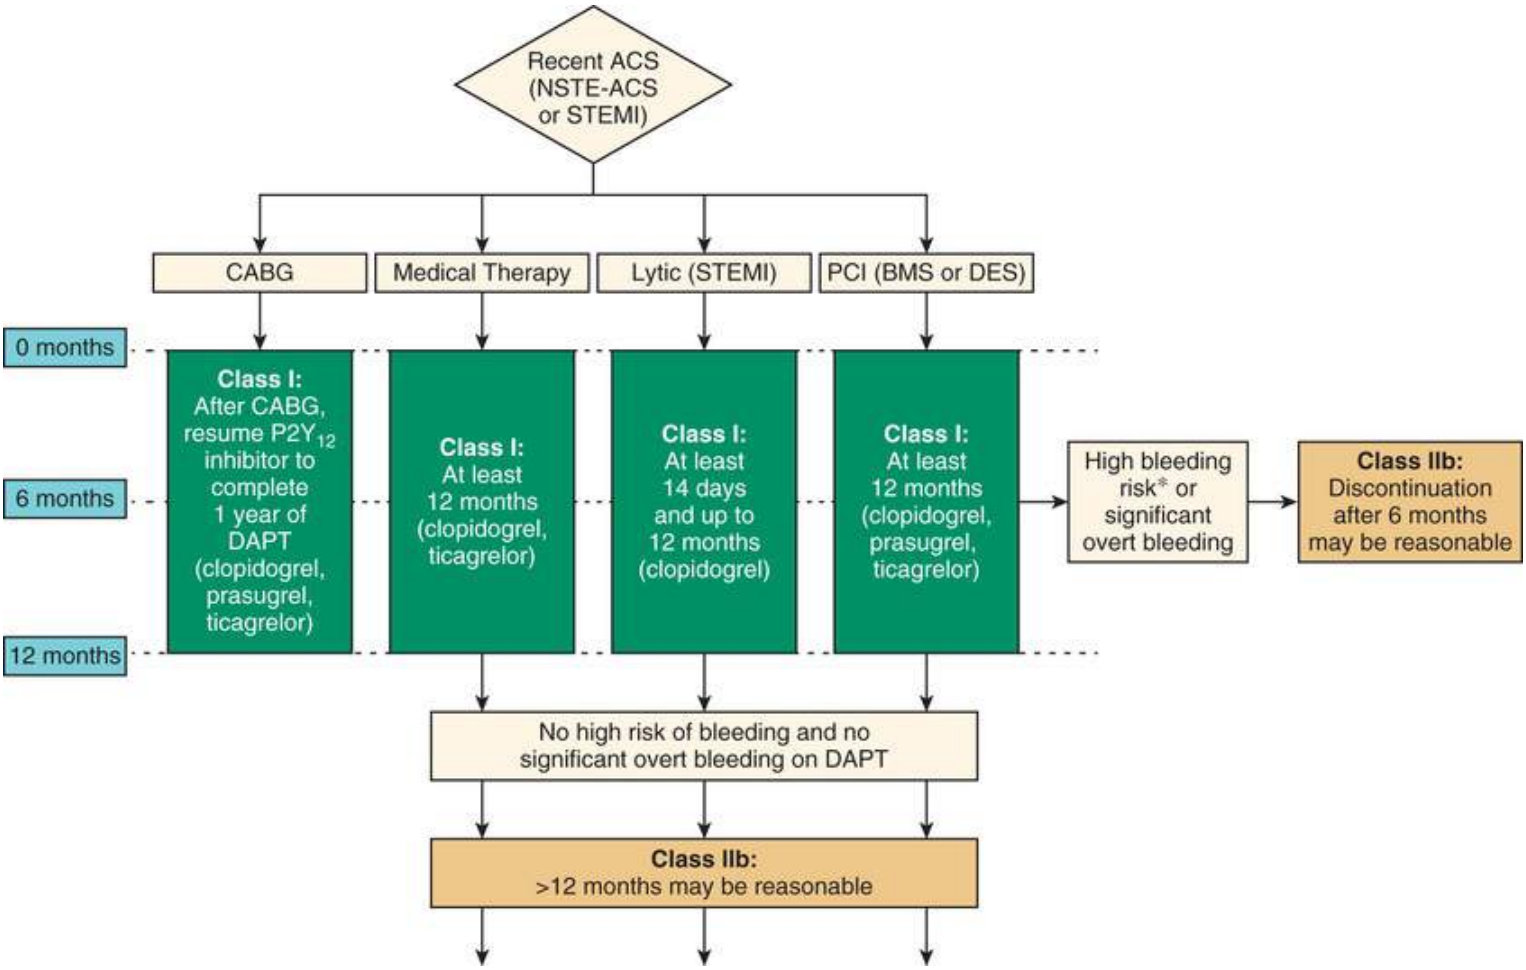

FIGURE 59G.2 Treatment algorithm for duration of $P2Y_{12}$ inhibitor therapy in patients with recent acute coronary syndrome (NSTE-ACS or STEMI). Colors correspond to class of recommendation in Table 59G.1. *Arrows* at the **bottom** of the figure denote that the optimal duration of prolonged DAPT is not established. Aspirin therapy is almost always continued indefinitely in patients with coronary artery disease. *High bleeding risk denotes those who have or develop a high risk of bleeding (e.g., treatment with oral anticoagulant therapy) or are at increased risk of severe bleeding complication (e.g., major intracranial surgery). *BMS,* Bare-metal stent; *CABG,* coronary artery bypass graft surgery; *DAPT,* dual-antiplatelet therapy; *DES,* drug-eluting stent; *lytic,* fibrinolytic therapy; *NSTE-ACS,* non–ST-elevation acute coronary syndrome; *PCI,* percutaneous coronary intervention; *STEMI,* ST-segment elevation myocardial infarction. (From Levine GN, Bates ER, Bittl JA, et al. 2016 ACC/AHA guideline focused update on duration of dual antiplatelet therapy in patients with coronary artery disease: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. Circulation 2016;134(10):e141.)

• For patients with ACS treated with PCI (either primary or delayed), in general, treatment with clopidogrel, prasugrel, or ticagrelor should be given for at least 12 months (class I, LOE: B). In those who have

tolerated 12 months of treatment without a bleeding complication and who are not at high risk for bleeding (e.g., coagulopathy, oral anticoagulant use) longer durations of DAPT may be reasonable (class IIb, LOE: A). In contrast, discontinuation of DAPT at 6 months, even in patients with DESs, may be reasonable if patients develop overt bleeding or are at high risk for severe bleeding (class IIb, LOE: C).

- In patients treated with fibrinolytic therapy clopidogrel should be continued for a minimum of 14 days (class I, LOE: A) and ideally at least 12 months (class I, LOE: C). In such patients who have tolerated 12 months of treatment without bleeding complication and who are not at high risk for bleeding, DAPT for longer than 12 months may be reasonable (class IIb; LOE: A).
- In patients with ACS treated with CABG, DAPT should be resumed following CABG to complete 12 months of therapy (class I, LOE: C).
- In patients with ACS treated with medical therapy alone (without fibrinolytic or revascularization), clopidogrel or ticagrelor should be continued for at least 12 months (class I, LOE B). It is reasonable to use ticagrelor in preference to clopidogrel (class IIa, LOE: B). In such patients who have tolerated 12 months of treatment without bleeding complication and who are not at high risk for bleeding, DAPT for longer than 12 months may be reasonable (class IIb, LOE: A).

Routine Medical Therapies

Pharmacologic management of STEMI is covered in this chapter. **Table 59G.9** summarizes the indications and cautions for routine medical therapies in patients following STEMI, as based on the 2013 guidelines.

TABLE 59G.9

Indications and Cautions for Adjunctive Medical Therapies for Patients with ST-Elevation Myocardial Infarction

THERAPY	INDICATIONS	CAUTIONS
Beta-adrenergic receptor–blocking agents	Oral: All patients without contraindication IV: Patients with refractory hypertension or ongoing ischemia without contraindication	Signs of congestive heart failure Low-output state Increased risk for cardiogenic shock Prolonged first-degree or high-grade atrioventricular block Reactive airways disease
Angiotensin-converting enzyme (ACE) inhibitors	Anterior myocardial infarction and LVEF ≤0.40 or congestive heart failure All patients without contraindication	Hypotension Renal failure Hyperkalemia
Angiotensin receptor–blocking agents (ARBs)	Intolerant of ACE inhibitors	Hypotension Renal failure Hyperkalemia
Statins	All patients without contraindications	With drugs metabolized via CYP3A4, fibrates Monitor for myopathy, hepatotoxicity Adjust dose for lipid targets
Nitroglycerin	Ongoing chest pain Hypertension and congestive heart failure	Suspected right ventricular infarction SBP <90 (or 30 mm Hg below baseline) Recent use of a type 5 PDE inhibitor
Oxygen	Clinically significant hypoxemia (SpO_2 <90) Congestive heart failure Dyspnea	Chronic obstructive pulmonary disease and CO_2 retention
Morphine	Pain Anxiety Pulmonary edema	Lethargic or moribund patient Hypotension Bradycardia Known hypersensitivity

IV, Intravenous; *LVEF,* left ventricular ejection fraction; *PDE,* phosphodiesterase; *SBP,* systolic blood pressure.

Risk Assessment after ST-Elevation Myocardial Infarction

Post-STEMI risk assessment allows the clinician's initial impression to be updated based on data occurring during the hospital stay, such as successful reperfusion, angiographic parameters, clinical heart failure or arrhythmia, and ventricular function; noninvasive testing may be helpful. Testing for the presence of residual ischemia may be helpful in patients following STEMI. The only class I recommendation is to use noninvasive testing for ischemia before discharge in patients who did not undergo angiography and who did not have high-risk features for which coronary angiography would be warranted. (LOE: B.)

Because LV function strongly predicts outcome in patients with STEMI, a class I indication recommends that all patients with STEMI undergo measurement of their LV ejection fraction (LVEF). Echocardiography is the most commonly used modality and can assess mechanical complications, in addition to ventricular function. Patients with significant ventricular dysfunction should have a repeat examination more than 40 days after MI to evaluate the potential need for an implantable cardioverter-defibrillator (ICD).

In the absence of a reversible cause, late (defined as >48 hours after MI) in-hospital sustained ventricular tachycardia or ventricular fibrillation is an indication (class I; LOE: B) for ICD therapy. In patients who do not have an indication for ICD therapy based on late life-threatening arrhythmias, evaluation of LVEF to determine the need for an ICD for primary prevention of sudden cardiac death should be performed with sufficient time to allow any LV stunning to resolve. Based on the 2013 STEMI guidelines, patients with an LVEF of 0.40 or lower should have echocardiography repeated more than 40 days after MI. If the LVEF remains 0.35 or lower and the patient has a Class II or III New York Heart Association classification of CHF or an LVEF of 0.30 or lower independent of symptoms, an ICD is indicated.

Posthospitalization Plan of Care

Transition from hospital to outpatient care requires a careful discharge and follow-up plan. Class I indications for posthospital care planning include the following:

- Posthospital care systems should be used to facilitate the transition to effective, coordinated outpatient care for all patients with STEMI. (LOE: B.)
- Exercise-based cardiac rehabilitation/secondary prevention programs are recommended for patients with STEMI. (LOE: B.)
- A clear, detailed, evidence-based plan of care that promotes adherence to medication, timely follow-up with the health care team, appropriate dietary and physical activities, and compliance with interventions for secondary prevention should be provided to patients with STEMI. (LOE: C.)
- Encouragement and advice to stop smoking and to avoid secondhand smoke should be provided to patients with STEMI. (LOE: A.)

Key components in the plan of care should include medications, physical activity/rehabilitation, risk factor modification, lifestyle interventions, attention to management of comorbid conditions and psychosocial factors, provider follow-up, patient and family education, and socioeconomic factors.

Non–ST Elevation Acute Coronary Syndromes

Robert P. Giugliano, Eugene Braunwald

Ischemic heart disease may manifest clinically as either chronic stable angina (**see Chapter 61**) or an acute coronary syndrome (ACS).[1] The spectrum of ACS includes ST-segment elevation myocardial infarction (STEMI) (**see Chapter 58 and 59**), and the non–ST elevation acute coronary syndromes (NSTE-ACS). The latter consist of non–ST elevation myocardial infarction (NSTEMI), and unstable angina (UA) (**Fig. 60.1**), which have indistinguishable clinical presentations at the initial evaluation.

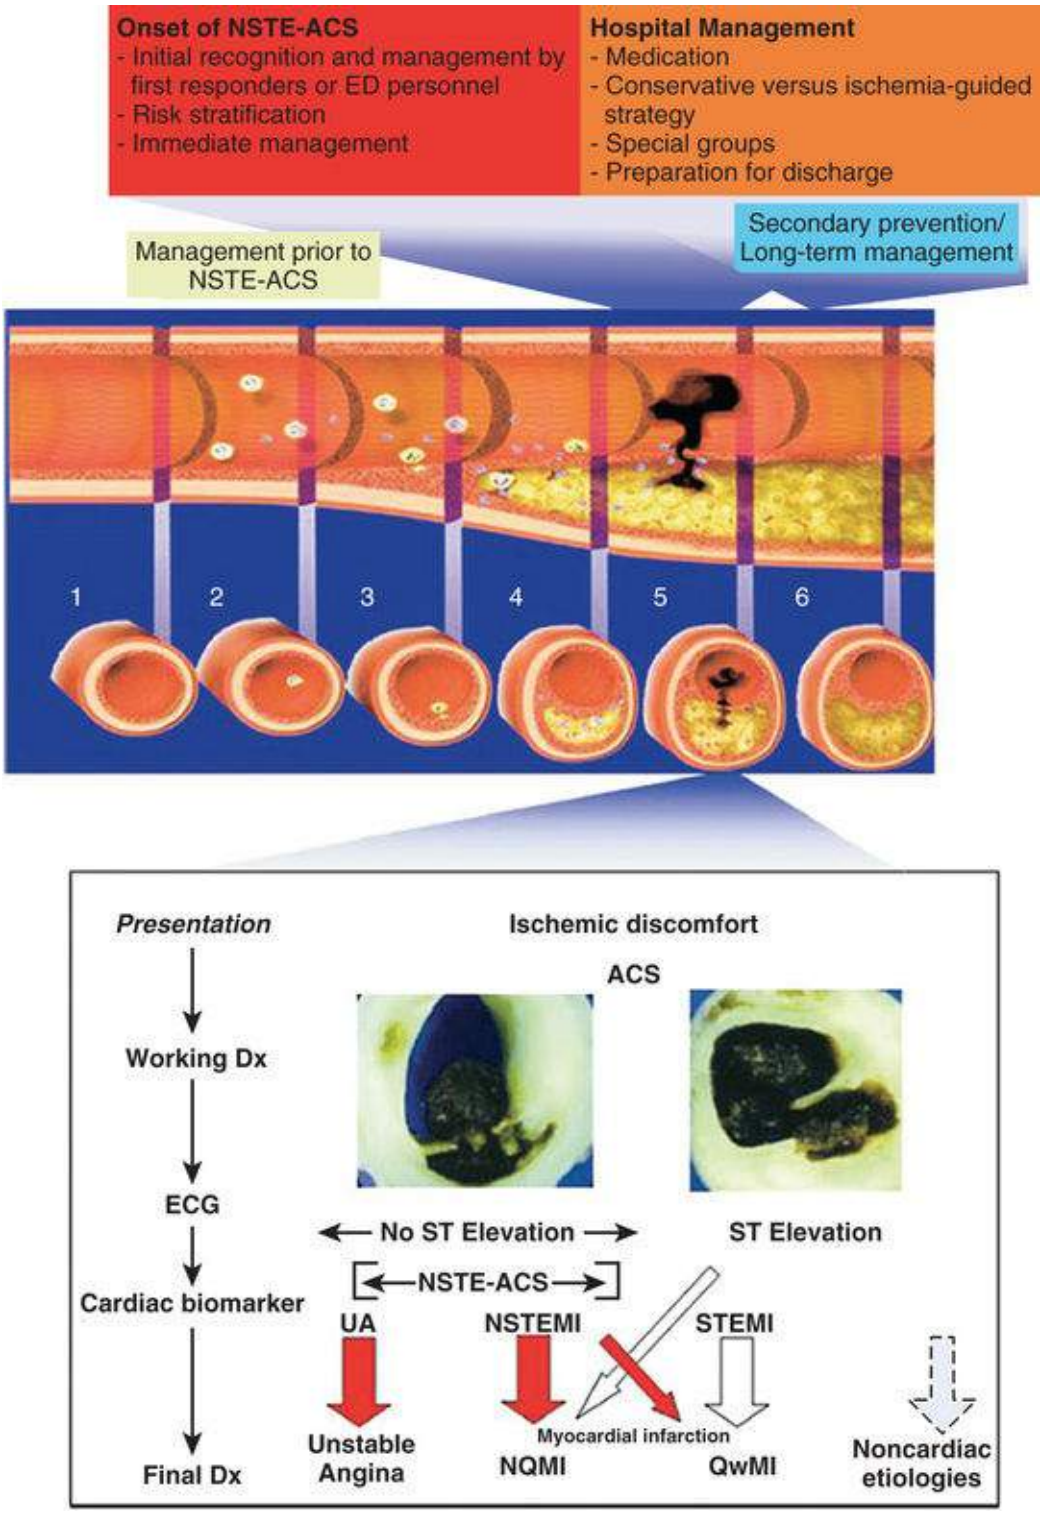

FIGURE 60.1 Acute coronary syndrome (ACS). The **top** half of the figure illustrates the progression of plaque formation and onset and complications of non–ST elevation (NSTE)-ACS, with management at each stage. The numbered section of an artery depicts the process of atherogenesis from (*1*) normal artery to (*2*) extracellular lipid in the suboptimal to (*3*) fibrofatty stage to (*4*) procoagulant expression and weakening of the fibrous cap. ACS develops with (*5*) disruption of the fibrous cap, which is the stimulus for thrombogenesis. (*6*) Thrombus resorption may be followed by collagen accumulation and smooth muscle cell growth. Thrombus formation and possible coronary vasospasm reduce blood flow in the affected coronary artery and cause ischemic chest pain. The **bottom** half of the figure illustrates the clinical, pathologic, electrocardiographic, and biomarker correlates in ACS and the general approach to management. Flow reduction may be related to a completely occlusive thrombus (*right side*) or subtotally occlusive thrombus (*left side*). Most patients with ST-segment elevation (*thick white arrow*) develop QwMI, and a few (*thin white arrow*) develop NQMI. Those without ST-elevation have either UA or NSTEMI (*thick red arrows*), a distinction based on cardiac biomarkers. Most patients presenting with NSTEMI develop NQMI; a few may develop QwMI. The spectrum of clinical presentations including UA, NSTEMI, and STEMI is referred to as ACS. This NSTE-ACS CPG includes sections on initial management before NSTE-ACS, at the onset of NSTE-ACS, and during the hospital phase. Secondary prevention and plans for long-term management begin early during the hospital phase. Patients with noncardiac etiologies make up the

largest group presenting to the ED with chest pain (*dashed arrow*). *CPG,* Clinical practice guideline; *Dx,* diagnosis; *ECG,* electrocardiogram; *ED,* emergency department; *MI,* myocardial infarction; *NQMI,* non–Q wave myocardial infarction; *NSTEMI,* non–ST elevation myocardial infarction; *QwMI,* Q wave myocardial infarction; *STEMI,* ST-elevation myocardial infarction; *UA,* unstable angina. (From Amsterdam EA et al. 2014 ACC/AHA non-ST-segment elevation ACS guideline. J Am Coll Cardiol 2014;64(24):e139-228; and Libby P et al. Current concepts of the pathogenesis of the acute coronary syndromes. Circulation 2001;104:365-72.)

Several features help to differentiate ACS from chronic stable angina, including (1) sudden onset of symptoms at rest (or with minimal exertion) that last at least 10 minutes unless treated promptly; (2) severe pain, pressure, or discomfort in the chest; and (3) an accelerating pattern of angina that develops more frequently, with greater severity, or that awakens the patient from sleep. The 12-lead electrocardiogram (ECG) and markers of myocardial necrosis are essential tools in distinguishing between the three types of ACS. Patients with typical symptoms (**see Chapter 56**) *without* persistent (>20 minutes continuously) ST-segment elevation in at least two contiguous electrocardiographic leads, but with elevation of myocardial biomarkers >99% percentile of normal, are classified as having NSTEMI. Patients without typical symptoms and serial negative markers of myocardial necrosis are classified as having UA, a diagnosis that carries a better prognosis.

Epidemiology

Despite the decline in cardiovascular disease (CVD) mortality over the past three decades,[2,3] cardiovascular and circulatory diseases remain the leading causes of death in the world, responsible for more than 54 million deaths in 2013.[4] In 2016 in the United States, it is estimated that more than 1.1 million patients will experience an ACS event, of whom 72% will have a myocardial infarction (MI).[5] The fraction of ACS attributed to NSTEMI continues to increase, while that for STEMI is declining, for several reasons: (1) wider use of preventive measures such as aspirin, statins, and smoking cessation; (2) aging of the population, with greater prevalence of diabetes and chronic kidney disease (CKD) and lower rates of smoking; and (3) broader use of troponin assays with higher sensitivity for myocardial necrosis, which shifts the diagnosis from UA to NSTEMI.[6]

Pathophysiology

The pathogenesis of NSTE-ACS involves four processes operating singly or in various combinations: (1) disruption of an unstable atheromatous plaque, which may be driven at least in part by inflammation[1] (**Fig. 60.2**); (2) coronary arterial vasoconstriction; (3) gradual intraluminal narrowing of an epicardial coronary artery caused by progressive atherosclerosis or restenosis after stenting; and (4) oxygen supply-demand mismatch (**see Chapter 57**). Our understanding of the complex interactions between these pathways continues to evolve. For example, recent studies have identified increased levels of proprotein convertase subtilisin/kexin type 9 (PCSK9) as a risk factor for more severe atherosclerosis, a marker for vulnerable plaques, and a contributor to plaque destabilization resulting in ACS.[7,8] (**See also Chapters 44 and 58**.)

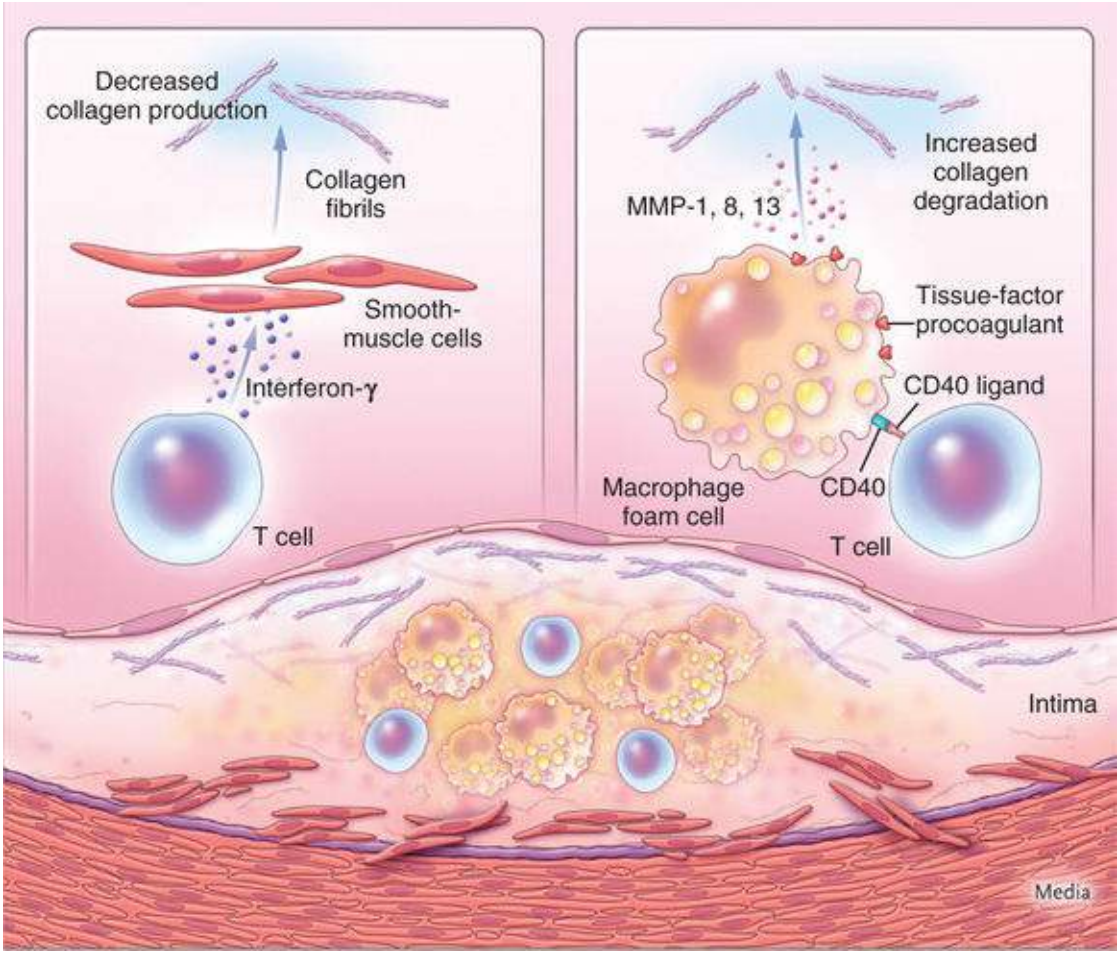

FIGURE 60.2 Inflammatory pathways predisposing coronary arteries to rupture and thrombosis. A cross section of an atheromatous plaque at the **bottom** of the figure shows the central lipid core containing macrophage foam cells (*yellow*) and T cells (*blue*). Arterial smooth muscle cells (*red*) present in the intima and media are the source of arterial collagen (triple helical structures). Activated T cells secrete cytokine interferon-gamma, which inhibits the production of the new, interstitial collagen required to repair and maintain the plaque's protective fibrous cap **(top left).** T cells may also activate macrophages in the intima by expressing CD40 ligand, which engages the CD40 receptor on the phagocyte. This inflammatory signaling causes overproduction of matrix metalloproteinases (*MMP*) 1, 8, and 13, which catalyze the initial rate-limiting step in collagen breakdown **(top right).** CD40 ligand also causes macrophages to overproduce tissue-factor procoagulant. These multiple consequences of inflammatory signaling each contribute to the instability of the plaque's fibrous cap. (From Libby P. Mechanisms of acute coronary syndromes and their implications for therapy. N Engl J Med 2013;368:2004-13.)

Three forms of disruptions of coronary artery plaques can precipitate thrombosis: plaque rupture, plaque erosion, and disruptive nodular calcification protruding into the lumen (**Fig. 60.3**).[9] Plaque rupture remains the most common, but plaque erosion has become responsible for an increasing proportion of ACS events.[10] **Table 60.1** summarizes differences in the main characteristics between plaque rupture and superficial erosion as the causes of ACS. Vasoconstriction causing dynamic obstruction of coronary arterial flow may result from spasm of the epicardial coronary arteries (Prinzmetal angina) or from constriction of small, intramural muscular coronary arteries. The latter may result from vasoconstrictors released by platelets, from endothelial dysfunction (cardiac syndrome X; **see Chapter 89**), adrenergic stimuli, cold, cocaine, or amphetamines (**Chapter 80**). More than one of these mechanisms may operate simultaneously.

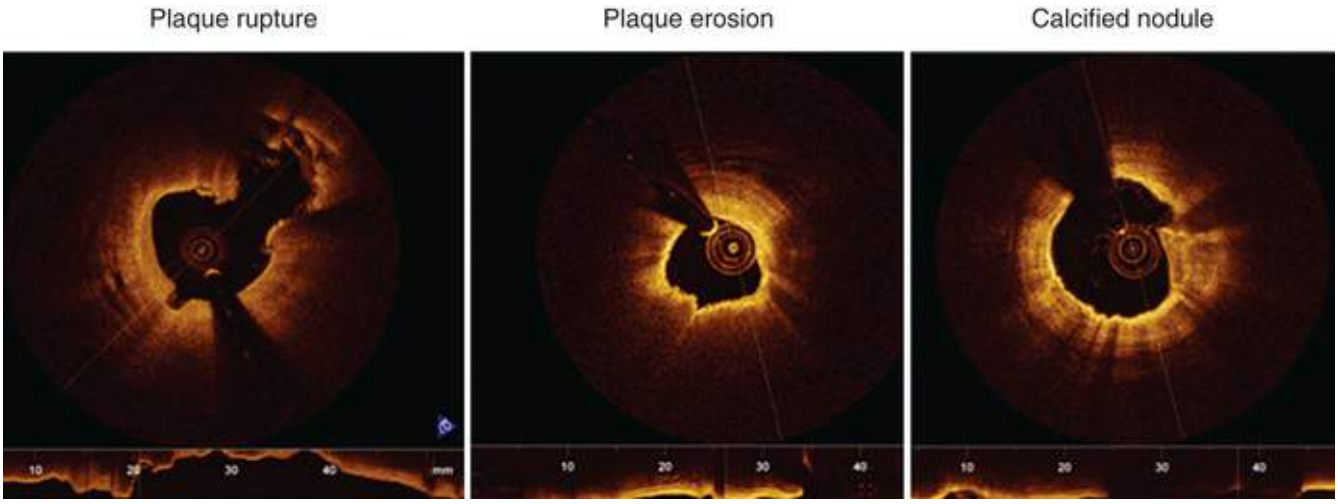

FIGURE 60.3 Representative optical coherence tomography images of underlying plaque morphologies. **Left,** Plaque rupture of a necrotic core with an overlying thin ruptured cap represents the most frequent pathophysiologic process leading to an acute coronary syndrome. **Center,** Plaque erosion with a thrombus in direct contact with an intimal plaque that is rich in smooth muscle cells and proteoglycan matrix. **Right,** The least common plaque morphology resulting in an acute coronary syndrome (ACS) is the calcified nodule, a heavy calcified plaque with a surrounding area of fibrosis. There are breaks in the calcified plate of the plaque with bone formation and interspersed fibrin, with a disrupted fibrous cap and overlying thrombus. A calcified nodule as the basis of ACS is more common in older men than in women or younger patients. (From Eisen A, Giugliano RP, Braunwald E. Update on acute coronary syndrome. JAMA Cardiol 2016;1(6):718-30.)

TABLE 60.1

Main Characteristics of Plaque Rupture and Superficial Erosion

PLAQUE RUPTURE	PLAQUE EROSION
Lipid rich	Lipid poor
Collagen poor, thin fibrous cap	Proteoglycan and glycosaminoglycan rich
Interstitial collagen breakdown	Nonfibrillar collagen breakdown
Abundant inflammation	Few inflammatory cells
Smooth muscle cell apoptosis	Endothelial cell apoptosis
Macrophage predominance	Secondary neutrophil involvement
Male predominance	Female predominance
High level of low-density lipoprotein cholesterol	High level of triglycerides

Modified from Libby P, Pasterkamp G. Requiem for the "vulnerable plaque." Eur Heart J 2015;36:2984-87.

Activation of the coagulation cascade and platelets play central roles in the formation of thrombus following plaque disruption (**see Chapter 93**). The first step in thrombus formation is vascular injury that causes *adhesion* of platelets to the arterial wall via binding of platelet glycoprotein (GP) Ib to subendothelial von Willebrand factor. Exposure of platelets to subendothelial collagen and/or circulating thrombin causes platelet *activation*, which induces platelets to change shape and results in their degranulation with release of adenosine diphosphate (ADP) and thromboxane A_2 (TxA_2), which in turn cause further platelet activation and expression of platelet GP IIb/IIIa. In parallel, tissue factor expressed within the lipid-rich core of atherosclerotic plaque, when exposed to circulating blood, activates the *coagulation cascade*. A complex of tissue factor and coagulation factors VIIa and Va leads to the formation of activated factor X (factor Xa), which in turn amplifies the production of activated factor IIa (thrombin). This cascade proceeds with thrombin-induced conversion of fibrinogen to fibrin. The platelet and coagulation systems converge as thrombin also potently activates platelets. Platelet GP IIb/IIIa binds circulating fibrinogen, thereby causing platelet aggregation and ultimately producing a platelet-fibrin thrombus, portions of which may embolize distally and cause myocardial necrosis.

Four observations support the central role of coronary artery thrombosis in the pathogenesis of NSTE-ACS: (1) autopsy findings of thrombi in the coronary arteries typically localized to a ruptured or eroded atherosclerotic plaque, (2) visualization by optical coherence tomography (**Fig. 60.3**) or computed tomographic angiography (CTA) of plaque ulceration and/or irregularities in the fibrous cap of atherosclerotic plaque, consistent with plaque rupture and thrombus formation; (3) elevation of serum markers of platelet activity, thrombin generation, and fibrin formation; and (4) improvement in clinical outcome with antiplatelet and anticoagulant therapies.

Clinical Assessment

History

NSTE-ACS resulting from atherosclerosis is relatively uncommon in men younger than 40 and women younger than 50 in the absence of genetic disorders such as familial hypercholesterolemia, but the incidence rises steadily thereafter. Patients with ACS frequently have traditional risk factors for coronary heart disease (CHD) (**see Chapter 45**). However, while coronary risk factors reliably assess risk in populations, they are less helpful in the assessment of individual patients.

The initial symptom of NSTE-ACS is typically described as retrosternal pressure, heaviness, or frank pain (**see Chapter 56**), and although it resembles stable exertional angina, it is usually more intense and lasts longer (>10 minutes). Radiation to the ulnar aspect of the upper left arm, either shoulder, the neck, or the jaw is common, but symptoms may localize anywhere between the ear and epigastrium.[11] Symptoms such as diaphoresis, nausea, abdominal pain, dyspnea, and syncope may accompany the discomfort. Features that support the diagnosis include exacerbation of symptoms by physical exertion; precipitation by severe anemia, infection, inflammation, fever, or metabolic or endocrinologic (e.g., thyroid) disorders. Atypical manifestations, such as dyspnea without chest discomfort, pain limited to the epigastrium, or indigestion, represent “anginal equivalents.” These atypical findings are more prevalent in women, older adults, and patients with diabetes, CKD, or dementia and can lead to underrecognition, undertreatment, and worse outcomes. Chest pain that is pleuritic, positional, or described as “stabbing” is generally not caused by myocardial ischemia. The clinical manifestations may appear suddenly, with severe, new-onset symptoms occurring during minimal exertion (Canadian Cardiovascular Society Class [CCSC] III) or at rest (CCSC IV), an accelerating pattern of angina (more frequent, more intense, longer lasting), or angina occurring shortly after a completed MI.[12]

Physical Examination

Findings on physical examination may be normal, although patients with large territories of myocardial ischemia may have audible third and/or fourth heart sounds or pulmonary rales. Rarely, hypotension, pale cool skin, sinus tachycardia, or frank cardiogenic shock can occur; these findings are much more common with STEMI than with NSTE-ACS. Potential precipitating causes of ACS, such as fever, resistant hypertension, tachycardia, profound bradycardia, thyroid disease, and gastrointestinal (GI) bleeding, can sometimes be identified. Findings such as pulse deficits, tachypnea, and tachycardia in the presence of clear lung fields and pulsus paradoxus with jugular venous distention may lead to alternative life-threatening diagnoses, such as aortic dissection, pulmonary embolism, or cardiac tamponade.

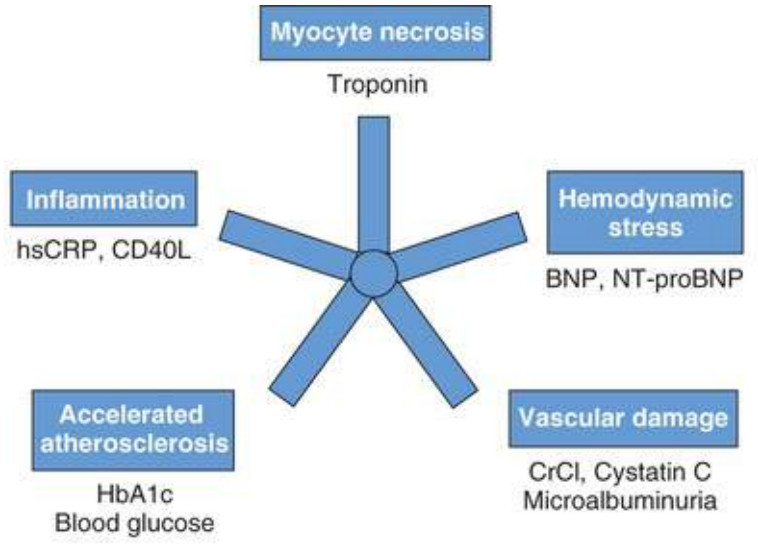
Electrocardiography

The most common abnormalities on the 12-lead ECG are ST-segment depression and T wave inversion, which are more likely to be present while the patient is symptomatic. Comparison with a recent ECG is important because dynamic ST-segment depressions as little as 0.05 mV are a sensitive (but not specific) marker for NSTE-ACS. Greater degrees of ST-segment depression predict poorer outcomes. Transient ST-segment elevation lasting less than 20 minutes occurs in up to 10% of patients and suggests either UA or coronary vasospasm. Deep (>0.2 mV) T wave inversions are compatible with, but not necessarily diagnostic of, NSTE-ACS, whereas isolated T wave inversions of lesser magnitude are not particularly helpful given their low specificity. More than half of patients with definite NSTE-ACS may have normal or nondiagnostic ECGs. Because ischemia may occur in a territory that is not well represented on the standard 12-lead ECG (see later), or because the patient may have episodic ischemia that is missed on the initial ECG, tracings should be repeated every 20 to 30 minutes until the symptoms resolve, or the diagnosis of MI is established or excluded.

Coronary angiography identifies a culprit lesion in the circumflex coronary artery in one third of patients with high-risk NSTE-ACS.[13] Because the standard 12-lead ECG does not represent this territory well, assessment of posterior leads V_7 through V_9 (with the gain increased to 20 mm/mV) should be considered in patients with a history suggestive of ACS and a nondiagnostic initial ECG. Similarly, ACS caused by isolated involvement of an acute marginal branch of the right coronary artery is often not apparent on the standard 12-lead ECG but may be suspected from leads V_3R and V_4R. Therefore, it is useful to obtain these extra leads in patients suspected of having ACS but with normal findings on a 12-lead ECG. Continuous monitoring of the ECG in the days following NSTE-ACS can identify patients at higher risk for recurrent events. ST-segment depressions noted on such monitoring within the first week after NSTE-ACS are associated with an increased risk for reinfarction and death.

Laboratory Testing: Biomarkers

A number of biomarkers reflecting the diverse causes of NSTE-ACS are useful for prognostication. These include markers of myocyte necrosis, hemodynamic stress, vascular damage (particularly renovascular), acceleration of atherosclerosis, and inflammation (**Fig. 60.4**). Cardiac-specific troponins I (cTnI) and T (cTnT) are the biomarkers of choice to identify myocardial necrosis, thus distinguishing between NSTE-ACS and UA. Since the sensitivities of different troponin assays in clinical practice vary, the consensus recommendation is to define MI by an elevation in cTnI or cTnT >99th percentile of the normal range of the specific assay used,[14] with a typical temporal rise and fall occurring in a patient with a clinical presentation consistent with ACS. However, although troponin elevation in the presence of ischemic discomfort often signifies myocardial necrosis, there are numerous other mechanisms of troponin release, including apoptosis, cellular release of proteolytic degradation products of troponin, increased cellular wall permeability, and normal myocyte turnover.[15] Furthermore, a wide variety of clinical conditions can be associated with troponin elevation that are not MI (**Table 60.2**). Even with less sensitive troponin assays, 60% to 70% of persons with chest discomfort seen in the emergency department (ED) will have detectable cTn, but only a minority are diagnosed with acute MI.[16] As high-sensitivity troponin (hsTn) assays[17] that can detect ultralow concentrations of troponin in approximately 90% of healthy individuals become increasingly available, consideration of the clinical context of a troponin elevation will become even more important in avoiding misdiagnosis and improper triage in management of patients. (**See also Chapters 56 and 58**.)



Biomarker	Independent predictor of risk	Useful as a component in a multimarker strategy	Therapeutic implication
Troponin	+++	++	+++
BNP	+++	++	0
Renal dysfunction	++	+	+
Glucose metabolism*	+	0	+
CRP	++	++	++

FIGURE 60.4 Multimarker approach for risk stratification in ACS. *Glucose metabolism** = Hyperglycemia or elevated glycated hemoglobin (HbA1c); BNP, brain natriuretic peptide; CD40L, CD40 ligand; CrCl, creatinine clearance; hsCRP, high-sensitivity C-reactive protein; NT-proBNP, N-terminal pro-BNP. (Modified from Morrow DA, Braunwald E. Future of biomarkers in acute coronary syndromes: moving toward a multimarker strategy. Circulation 2003;108:250.)

TABLE 60.2

Causes of Elevated Troponin Reflecting Direct Myocardial Damage Other Than Spontaneous Myocardial Infarction (Type 1)

CARDIAC	NONCARDIAC OR SYSTEMIC
Tachyarrhythmias	Pulmonary embolism, pulmonary hypertension
Congestive heart failure	Trauma (e.g., electrical shock, burns, blunt chest wall)
Hypertensive emergencies	Hypo- or hyperthyroidism
Infection, inflammation (e.g., myocarditis, pericarditis)	Toxicity (e.g., anthracyclines, snake venom)
Stress cardiomyopathy (takotsubo cardiomyopathy)	Renal failure
Structural heart disease (e.g., aortic stenosis)	Sepsis, shock
Aortic dissection	Stroke or other acute neurologic event
Coronary spasm	Extreme endurance efforts (e.g., ultramarathon)
Cardiac procedures (endomyocardial biopsy, ablation, coronary artery bypass grafting, percutaneous coronary intervention)	Rhabdomyolysis
Infiltrative diseases (e.g., amyloidosis, hemochromatosis, malignancy)	

Modified from Newby LK et al. JACC 2012;60:2427-63 and Roffi M et al. 2015 ESC guidelines for the management of acute coronary syndromes in patients presenting without persistent st-segment elevation. Task Force for the Management of Acute Coronary Syndromes in Patients Presenting without Persistent ST-Segment Elevation of the European Society of Cardiology. Eur Heart J 2016;37:267-315.

Fourth-generation cTn assays currently used in the United States are less sensitive than hsTn assays available in some European countries. Thus, two negative cTn assays at least 6 hours apart are needed to exclude MI with these less sensitive assays. However, with newer hsTn assays (approved in the United States in 2017), it is possible with a single measurement at presentation of less than 5 ng/L to classify almost two thirds of patients presenting to the ED with suspected ACS as “very low risk” for MI or cardiac death in the next 30 days (negative predictive value [NPV], 99.6%).[18] Absolute changes in hsTn greater than 9.2 ng/L are even more predictive of acute MI than a single measure or relative changes

between two measurements.[19] Use of absolute changes in hsTn allow for rapid protocols as brief as 1 hour to rule in or rule out MI in up to 77% of unselected patients presenting to the ED with acute chest pain,[20,21] with results comparable to a 3-hour approach.[22] In addition to their utility in early diagnosis and prognostication, cTn levels following ACS aid intermediate-term risk stratification over the subsequent 6 months. When hsTn assays are not available, the 2015 European Society of Cardiology (ESC) guidelines[23] recommend assessment of *copeptin*, the C-terminal part of the vasopressin prohormone, to improve the sensitivity in diagnosing acute MI.[24]

Several other biomarkers may be useful to determine prognosis and help guide care. Of these, the natriuretic peptides (i.e., brain natriuretic peptide [BNP] and N-terminal pro-BNP) have been most widely used in patients with NSTE-ACS. Natriuretic peptides (NPs) rise in proportion to the degree of ventricular distention (strain) and correlate with the risk of adverse events, including death, heart failure (HF), and MI, in a graded fashion. More importantly, elevation of a baseline NP identifies patients who are more likely to benefit from more intensive anti-ischemic and lipid-lowering regimens and early coronary revascularization. Similarly, C-reactive protein (CRP), a marker of inflammation, is elevated following NSTE-ACS, and the degree of elevation correlates with long-term cardiovascular (CV) outcomes. In addition, CRP may identify patients with NSTE-ACS who require more intensive management of risk factors, including lipids, glucose, blood pressure, and weight. Other promising novel biomarkers in ACS are summarized in **eTable 60.1**.

ETABLE 60.1

Novel Biomarkers in Acute Coronary Syndromes (ACS)

BIOMARKER	DESCRIPTION
Markers Predicting Death and/or Ischemic Events	
Chemokine ligand-5 and ligand-18	Mediators of monocyte recruitment induced by ischemia[a]
Interleukin-6	Stimulator of hepatic synthesis of C-reactive protein[b]
Interleukin-17 (IL-17)	Produced by CD4+ T cells, IL-17 plays a role in host immunity and development of an unstable plaque[c]
Growth differentiation factor-15	Member of the transforming growth factor-beta cytokine superfamily that is released from cardiomyocytes after ischemia and reperfusion injury[d]
Heart-type fatty acid–binding protein	Cytoplasmic protein involved in intracellular uptake and buffering of free fatty acids in the myocardium[e]
Membrane attack complex	Ischemia leads to changes in myocardial cell surface molecule expression, rendering the cell membrane a target for the complement system, ultimately leading to cell lysis[f]
Myeloperoxidase	Hemeprotein released during degranulation of neutrophils and some monocytes[g]
Pentraxin 3	Inflammatory marker associated with thin-cap vulnerable plaques[h]
Pregnancy-associated plasma protein A	Zinc-binding metalloproteinase found in vulnerable plaques that cause destabilization of the fibrous plaque[i]
Placental growth factor	Member of the vascular endothelial growth factor family that is strongly upregulated in atherosclerotic lesions and acts as a primary inflammatory instigator of atherosclerotic plaque instability [j]
Secretory phospholipase A_2	Hydrolyzes phospholipids to generate lysophospholipids and fatty acids, thereby enhancing susceptibility of the vessel atherosclerosis[k]
Markers Predicting Heart Failure	
Copeptin	Peptide fragment of provasopressin[l]
Midregional proadrenomedullin	Peptide fragment of the vasodilatory peptide adrenomedullin[l]
Midregional proatrial natriuretic peptide	Peptide fragment of atrial natriuretic peptide[l]
Neopterin	Marker of monocyte activation[m]
Osteoprotegerin	Modulator of immune function and inflammation[n]

Multimarker approaches (e.g., simultaneous assessment of cTn, hs-CRP, and BNP) can further improve risk stratification of patients with NSTE-ACS.[25] While lipid measurements are less helpful for individual prognostication, assessment of the low-density lipoprotein cholesterol (LDL-C) and triglycerides, along with glucose or hemoglobin (Hb) A_{1c} can identify uncontrolled risk factors that with proper management, could reduce the risk of future CV events (**see Chapter 45**). Likewise, routine assessments of arterial oxygenation, hematocrit, and thyroid function may identify treatable conditions that can cause secondary ACS.[26]

Noninvasive Testing

Noninvasive testing in patients with established or suspected NSTE-ACS plays a number of important roles: (1) establishing the presence (or absence) of significant CHD; (2) diagnosing CHD as the cause of cTn elevation in patients who may have other explanations (see earlier); (3) evaluating the extent of residual ischemia after initiation of medical therapy, helping to guide future management; (4) localizing the territory of ischemia before revascularization in a patient with multivessel disease; and (5) assessing left ventricular (LV) function.

The safety of early stress testing in patients with NSTE-ACS has been debated, but symptom-limited or pharmacologic stress testing appear to be safe after at least 24 hours of stabilization without symptoms of

active ischemia or other signs of hemodynamic or electrical instability. The merits of various modalities of stress testing have been compared (**see Chapter 13**). Exercise stress myocardial perfusion imaging with nuclear isotopes and stress echocardiography with dobutamine have greater sensitivity than electrocardiographic exercise stress testing without imaging (**see Chapters 14 and 16**). A practical approach is to select the modality of stress testing based on individual patient characteristics and preferences, as well as local availability and expertise. For most patients, electrocardiographic exercise stress testing is recommended if the ECG at rest lacks significant baseline abnormalities (e.g., ST depressions, bundle-branch block, electronic pacing). If significant baseline ECG abnormalities are present, stress perfusion or echocardiographic imaging should be performed before and immediately after exercise. In patients who cannot achieve a significant workload during exercise, pharmacologic stress testing with imaging is recommended. High-risk findings on the stress test (e.g., severe ischemia as reflected by ST-segment depression ≥0.2 mV before stage 3, hypotension with exercise, ventricular tachyarrhythmia, new or worsening LV dysfunction) are indications to proceed rapidly with coronary angiography with the intent to perform coronary revascularization, if possible.

Echocardiography is useful in the assessment of LV systolic and diastolic function and can also identify left atrial dilation, functional mitral regurgitation, tricuspid annular plane systolic excursion, diastolic dysfunction, ventricular mechanical dyssynchrony, and ultrasound “lung comets” (extravascular lung fluid observed on thoracic ultrasound scanning). Each of these is associated with an adverse prognosis in patients with NSTE-ACS.

Contrast-enhanced coronary CTA (CCTA) in patients with or suspected of having NSTE-ACS can help: (1) recognize or exclude the presence of epicardial CHD, (2) identify which vessel(s) have coronary atherosclerosis, (3) assist in risk stratification and prognosis (**see Chapter 18**). Three large randomized trials have shown that CCTA compared to standard evaluation expedites the triage of patients presenting with chest discomfort in the ED, thereby shortening length of stay.[27-29] Additional benefits include reductions in costs,[30,31] and of return visits to the ED.[31] A randomized trial comparing standard of care with versus without CCTA in 4146 patients with suspected angina demonstrated that CCTA better clarified the diagnosis of angina due to CHD, reduced the need for stress testing, but increased the use of coronary angiography.[32] These studies and others led the American College of Radiology and the American College of Cardiology to recommend use of CCTA in the ED in patients with chest discomfort and suspected ACS who are at low risk at presentation[33,34] (**Table 60.3**).

TABLE 60.3

Appropriateness of Coronary Computed Tomographic Angiography (CTA) in Patients with Acute Chest Pain Syndromes

Appropriate Indications
Electrocardiogram negative or indeterminate for myocardial ischemia
Low-intermediate pretest likelihood by risk stratification tools
TIMI risk score of 0-2 (low risk) ideal or TIMI score of 3-4 (intermediate) in some cases
HEART score <3
≥1 Negative troponin value, including point-of-care assays
Equivocal or inadequate previous functional testing during index ED or within previous 6 months
Equivocal Indications
High clinical likelihood of ACS by clinical assessment and standard risk criteria (e.g., TIMI score >4)
Previously known coronary artery disease
Known calcium score ≥400
Relative Contraindications
History of allergic reaction to iodinated contrast
Estimated glomerular filtration rate (eGFR) 30 to <60 mL/min/1.73 m^2
Factors likely to lead to nondiagnostic scans; specific will vary with scanner technology and site capabilities
Heart rate greater than site maximum for reliably diagnostic scans after beta blockers (usually 70-80 bpm)
Contraindications to beta blockers and heart rate not controlled
Atrial fibrillation or other markedly irregular rhythm
Body mass index >39 kg/m^2
Absolute Contraindications
Known acute coronary syndromes
eGFR <30 unless on long-term dialysis
Previous anaphylaxis after iodinated contrast administration
Previous episode of contrast allergy after adequate steroid/antihistamine preparation
Pregnancy or uncertain pregnancy status in premenopausal women

ACS, Acute coronary syndrome; *ED,* emergency department; *eGFR,* estimated glomerular filtration rate; *TIMI,* Thrombolysis in Myocardial Infarction.

Modified from Hollander JE, Than M, Mueller C. State-of-the-art evaluation of emergency department patients presenting with potential acute coronary syndromes. Circulation 2016;134:547-64.

In hospitals that have hsTn assays available, the benefit of CCTA is less clear,[35] although some studies suggest CCTA may improve risk stratification in patients in whom hsTn levels do not conclusively rule in or rule out MI.[36,37] The benefits of CCTA may extend beyond the ED, permitting more rapid and accurate identification of high-risk patients who may benefit from early, intensive therapies.[32,38]

Cardiac magnetic resonance imaging (CMR) using a rapid-scan protocol can provide precise measurements of ventricular volumes and function, evaluate ventricular wall edema, identify areas of infarcted versus hibernating myocardium, establish the presence of myocardial perfusion, quantify wall motion, and identify myocardium at risk in patients with NSTE-ACS.[39] These detailed assessments can help guide coronary revascularization in several common clinical scenarios, as when the stenosis is of borderline significance, the culprit lesion is uncertain because of multivessel disease, or myocardial viability in a territory at risk is in question (**see Chapter 17**).

Invasive Imaging

Invasive coronary angiography has been the standard technique for imaging the coronary arterial tree for nearly six decades. The culprit lesion in NSTE-ACS typically exhibits an eccentric stenosis with scalloped or overhanging edges and a narrow neck (**see Chapter 20**). These angiographic findings may represent disrupted atherosclerotic plaque or thrombus. Features suggesting thrombus include globular intraluminal masses with a rounded or polypoid shape; “haziness” of a lesion suggests the presence of thrombus, but this finding is not specific.

Approximately 85% of patients with a clinical diagnosis of NSTE-ACS have significant coronary obstruction (i.e., >50% stenosis of luminal diameter, in at least one major coronary artery). Most have

obstructive disease, including multiple epicardial arteries—approximately 10% with left main coronary artery disease, 35% with three-vessel disease, and 20% with two-vessel disease—whereas only approximately 20% have single-vessel disease. The remaining 15% have no significant coronary obstruction, a finding that is more common in women and minorities. In such patients, NSTE-ACS may be related to microvascular coronary obstruction, endothelial dysfunction, or coronary artery spasm and may have a more favorable prognosis. In 37,101 patients enrolled in eight clinical trials of NSTE-ACS, the 30-day rate of death or MI was 2.2% in those with no obstructive coronary artery disease (CAD) compared to 13.3% in patients with obstructive disease.[40]

Intravascular ultrasound (IVUS) and optical coherence tomography (OCT) are two invasive cross-sectional imaging techniques that can provide details regarding plaque morphology (**see Fig. 60.3**). In the clinical setting, IVUS and OCT are used most commonly to guide coronary stent placement (**see Chapter 20**). These techniques and others (e.g., near-infrared spectroscopy, intravascular magnetic resonance imaging, angioscopy) can provide detailed plaque morphology and establish the pathophysiologic etiology of ACS, although the clinical utility of such additional information is uncertain.

Risk Assessment

Residual Risk

The risk for recurrent ischemic events following an episode of ACS depends as much on the presence and stability of multifocal lesions as on the culprit lesion responsible for the initial event.[41] Aggressive medical management of the remaining plaques and prevention of new ones is required to prevent recurrent events.[41] The percentage of patients with more than one active plaque on angiography correlates with the level of high-sensitivity (hs) CRP. These findings provide an important pathophysiologic link among inflammation, more diffuse active CAD, and recurrent cardiac events in the months to years following a clinical ACS event.

Natural History

Patients with UA have lower short-term mortality (<2.0% at 30 days) than do those with NSTEMI or STEMI. However, with the increasing use of hsTn, the fraction of patients with NSTE-ACS diagnosed with UA is declining.[6]

The early mortality risk with NSTEMI is related to the extent of myocardial damage and resulting hemodynamic compromise and is lower than in patients with STEMI, who usually have larger infarcts.[42] In contrast, long-term outcomes with respect to both mortality and nonfatal events are worse in patients with NSTE-ACS. This finding probably results from the greater age, extent of CAD, previous MI, comorbid condition (e.g., diabetes, impaired renal function), and likelihood of recurrence of ACS in patients with NSTE-ACS than in those with STEMI.

Risk Assessment Scores

Several risk scores that integrate clinical variables and findings on the ECG and from serum biomarkers have been developed for patients with NSTE-ACS.[43-45] The TIMI (Thrombolysis in Myocardial Ischemia) risk score for UA/NSTEMI identifies seven independent risk factors; their sum correlates directly with death or recurrent ischemic events[43] (**Fig. 60.5**). This simple, rapid assessment at the initial evaluation identifies high-risk patients who can derive benefit from an early invasive strategy and more intensive antithrombotic therapy. The GRACE (Global Registry of Acute Coronary Events) risk score[45] uses a

larger number of weighted risk factors to predict mortality after NSTE-ACS; however, it is more complex than the TIMI risk score and is not easily calculated by hand. For longer-term prognostication in patients after ACS, a risk score based on nine independent clinical predictors identifies a gradient of risk for recurrent atherothrombotic events, the TIMI stable ischemic CAD risk score (**Fig. 60.6**). It distinguishes patients with greater absolute benefit with more intensive antithrombotic and lipid-lowering therapies.[46,47]

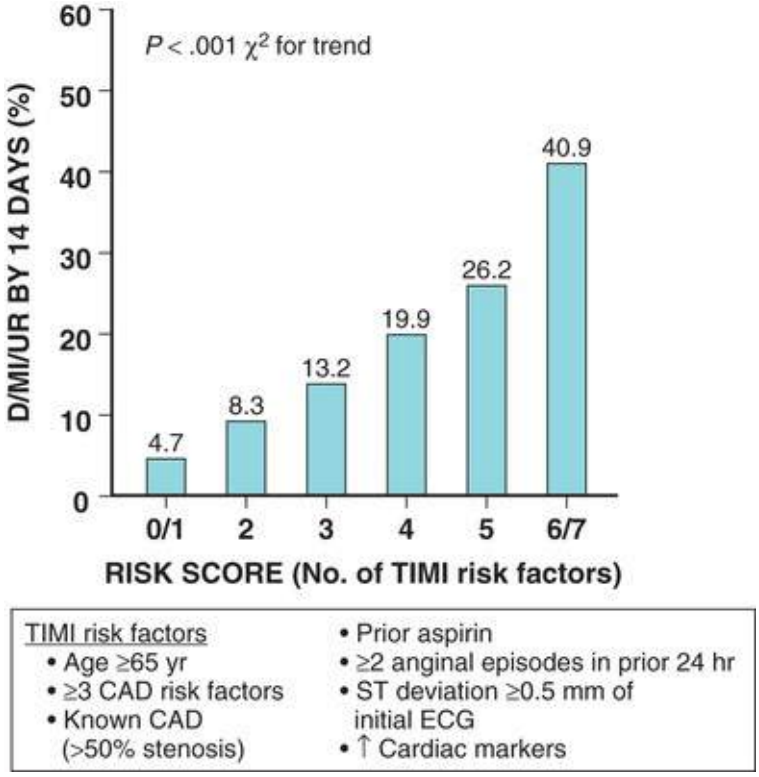

FIGURE 60.5 Thrombolysis in Myocardial Infarction (TIMI) risk score for UA/NSTE-MI (NSTE-ACS). The number of risk factors present is counted. CAD, Coronary artery disease; D/MI/UR, death, myocardial infarction, or urgent revascularization. (Modified from Antman EM, Cohen M, Bernink PJ, et al: The TIMI risk score for unstable angina/non-ST elevation MI: a method for prognostication and therapeutic decision making. JAMA 2000;284:835.)

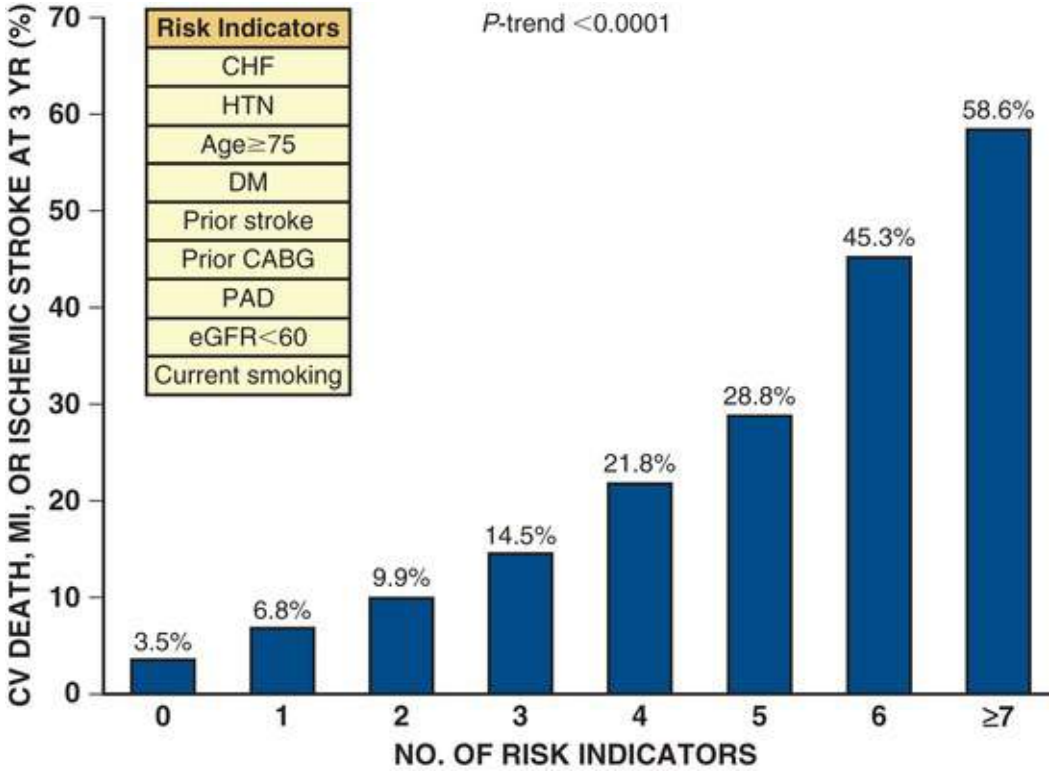

FIGURE 60.6 Long-term risk stratification after myocardial infarction using the TIMI Stable Ischemic CAD Risk Score. Nine independent factors, when combined in a simple long-term risk score, can identify a broad range of future risk of the composite of cardiovascular (CV) death, myocardial infarction (MI), or ischemic stroke. CABG, Coronary artery bypass grafting; CHF, coronary heart disease; DM, diabetes mellitus; eGFR, estimated glomerular filtration rate; HTN, hypertension; PAD, peripheral artery disease.

Management

Management of patients with NSTE-ACS consists of an acute phase focused on the clinical symptoms and stabilization of the culprit lesion(s) and a longer-term phase that involves therapies directed at the prevention of disease progression and future plaque rupture/erosion. Retrospective angiographic studies[48] and a prospective natural history study of patients with NSTE-ACS managed with PCI[41] have shown that plaques that cause more severe stenosis have a higher risk of rupture leading to an ACS event. However, since plaques with less severe stenosis are more prevalent, these less obstructive lesions are responsible for about half of the future ACS events.

General Measures

Patients with new or worsening chest discomfort or an anginal equivalent symptom suggestive of ACS should be transported rapidly to the ED by ambulance, if possible, and evaluated immediately.[49] The initial evaluation should include a directed history and physical examination and ECG performed within 10 minutes of arrival.[23] If possible, the ECG should be obtained in the ambulance. Blood specimens for cTn or, if possible, hsTn assay should be obtained with expedited assessment via either a point-of-care device or laboratory measurement that can provide results within 60 minutes. Additional laboratory studies, such as natriuretic peptide, a complete blood count, serum electrolytes, creatinine, and glucose, can help guide early management treatments and strategy.

Patients with elevated cTn or new ST-segment abnormalities or deemed to be at moderate or high risk

based on a validated risk score should be admitted to a specialized cardiovascular intensive care unit (ICU). Patients with UA but without elevated cTn and ischemic electrocardiographic changes should be admitted to a monitored bed, preferably in a CV step-down unit.[11] In these settings, continuous electrocardiographic monitoring with telemetry detects tachyarrhythmias, alterations in atrioventricular (AV) and intraventricular conduction, and changes in ST-segment deviation. Patients should be placed on bed rest and inhaled oxygen provided to patients with arterial oxygen saturation (SaO_2) less than 90% and those with HF and pulmonary rales. Ambulation, as tolerated, is permitted if the patient has been stable without recurrent chest discomfort or ECG changes for at least 12 to 24 hours. Patients with atypical symptoms and low risk or those who have symptoms more consistent with another noncardiac cause may be observed in the ED or a short-stay unit. A second cTn assay should be performed 3 to 6 hours after the first, and further assessment with noninvasive imaging or stress testing may be considered to permit rapid exclusion of ACS.

Anti-Ischemic Therapy

Guidelines emphasize the early use of anti-ischemic therapies to improve the balance between oxygen supply and demand.[11,23] The goals of anti-ischemic therapy include relief of symptoms and prevention of early sequelae of ACS, including recurrent MI, HF, arrhythmias, and death. **Table 60.4** summarizes traditional and newer/experimental pharmacologic anti-ischemic therapies.

TABLE 60.4

Pharmacologic Anti-Ischemic Therapies in Non–ST Elevation Acute Coronary Syndromes (NSTE-ACS)

CLASS OF MEDICATION	MECHANISM OF ACTION	CLINICAL EFFECTS IN NSTE-ACS
Traditional Therapies		
Beta blockers	Decrease heart rate, blood pressure, and contractility through antagonism of $beta_1$ receptors	Decrease mortality[51]
Nitrates	Decrease preload through venodilation; vasodilate coronary arteries	No benefit on mortality
Calcium channel blockers	May vasodilate, reduce heart rate, or decrease contractility depending on specific drug	No clear benefit on mortality or reinfarction Increased reinfarction rate when short-acting nifedipine is used alone
Newer and Experimental Therapies		
Ranolazine	Inhibits late inward sodium current	Decreases recurrent ischemia and arrhythmias
Trimetazidine	Shifts myocardial metabolism from fatty acid to glucose use	Decreases short-term mortality
Nicorandil	Activates ATP-sensitive K^+ channels and dilates arterioles; may have ischemic precondition-like effect	Decreases arrhythmias and transient ischemia
Cyclosporine	Inhibitor of the mitochondrial permeability transition pore involved in reperfusion injury	Reduces infarct size in small studies;* larger clinical trial in progress

*Mewton N, Croisille P, Gahide G, et al. Effect of cyclosporine on left ventricular remodeling after reperfused myocardial infarction. J Am Coll Cardiol 2010;55(12):1200-5.

From American Heart Association; Soukouli V, Boden WE, Smith SC Jr, O'Gara PT. Nonantithrombotic medical options in acute coronary syndromes: old agents and new lines on the horizon. Circ Res 2014;114:1944-58.

Nitrates

Nitrates are vasodilators that increase myocardial blood flow (coronary vasodilation of atherosclerotic and normal vessels), reduce myocardial oxygen requirements by lowering cardiac preload (systemic venodilation), reduce cardiac afterload (systemic arterial dilation) thereby diminishing ventricular wall stress, and may have a mild antiplatelet effect. Reflex increases in heart rate (HR) and contractility that increase myocardial oxygen demand can be mitigated by concomitant use of a beta blocker. Well-

controlled clinical trials have not shown a reduction in cardiac events with nitrates; however, the rationale for nitrate use in NSTE-ACS is extrapolated from pathophysiologic principles and extensive clinical observations demonstrating their clinical effectiveness in relief of pain or other discomfort caused by myocardial ischemia.

In symptomatic patients without hypotension, the initial administration of rapidly acting nitroglycerin (sublingual or buccal, 0.3 to 0.6 mg at 5-minute intervals) is recommended, beginning before hospital arrival whenever possible. Intravenous (IV) nitroglycerin (5 to 10 µg/min, titrated to a maximum of 200 µg/min as needed) should be initiated in patients with hypertension and in patients with persistent or recurrent ischemic symptoms or HF, provided the systolic blood pressure (SBP) is at least 90 to 100 mm Hg. Tolerance to nitrates may develop within 12 to 24 hours and can be mitigated by nitrate-free intervals (if symptoms permit) or increasing the dose (if symptoms persist). Abrupt discontinuation of high doses of IV nitrates is not advised because this may precipitate recurrent ischemia and/or rebound hypertension; instead, IV nitrates should be weaned over several hours.

Important contraindications to nitrates include hypotension and recent use of a phosphodiesterase type 5 (PDE-5) inhibitor, sildenafil or vardenafil (within 24 hours), or tadalafil (within 48 hours). Since the catalytic site of PDE-5 normally degrades cyclic guanosine monophosphate, inhibitors of PDE-5 potentiate the endogenous levels of cGMP, possibly resulting in exaggerated, prolonged, and dangerous vasodilatory effects of nitrates. Relative contraindications to nitrates include hypotension (SBP <90 mm Hg), severe obstruction to LV outflow, large right ventricular infarction, or hemodynamically significant pulmonary embolism. In such patients, nitrates should be used with caution, if at all.

Beta-Adrenergic Receptor–Blocking Agents

Beta blockers competitively inhibit the myocardial effects of neuronally released and circulating catecholamines and reduce myocardial oxygen consumption by lowering HR, BP, and myocardial contractility. The evidence supporting beta blockers derives largely from older studies of patients with acute MI (generally STEMI) or new left bundle branch block (LBBB), before the current era of reperfusion therapy. In clinical trials of patients with acute MI, beta blockers reduce reinfarction, ventricular arrhythmias, and death. The findings from these trials, some of which included patients without ST elevation, have been extrapolated to patients with UA and NSTEMI.

A systematic review that pooled data on approximately 4700 patients with UA from five trials performed before 1986 showed that beta blockers reduced the risk for progression to MI.[50] Whether beta blockers would have similar efficacy in the modern era of intensive pharmacologic management with an early invasive strategy is unclear. Two more recent nonrandomized analyses from large registries of patients with NSTE-ACS demonstrated risk-adjusted decreases in predischarge[51] and longer-term[52] survival among patients treated with a beta blocker.

Oral beta blockers in doses used for chronic stable angina (**see Chapter 61**) should be initiated within the first 24 hours[11,23] with the following exceptions: (1) acute or severe HF; (2) low cardiac output; (3) hypotension; and (4) contraindications to beta-blocker therapy (e.g., high-degree AV block, active bronchospasm). Patients with initial contraindications to beta blockers should be reevaluated to determine subsequent eligibility to receive one of these agents. If ischemia persists despite IV nitrate therapy, IV beta blockers (5 mg over 1 to 2 min, repeated every 5 min for a total initial dose of 15 mg) may be used cautiously, generally following initial oral administration. IV beta blockers should be avoided in hypotensive patients.[53] Beta blockers should be avoided in patients with coronary vasospasm or acute intoxication with cocaine or methamphetamine because unopposed alpha-mediated coronary vasoconstriction may occur, worsening coronary spasm. Beta blockers with intrinsic sympathomimetic

activity (e.g., acebutolol, pindolol) should generally be avoided because they may increase the risk of ventricular tachycardia (VT) and fibrillation (VF).

Morphine

In the absence of contraindications (e.g., hypotension, allergy), it is reasonable to administer IV morphine (1 to 5 mg) if there is ongoing ischemic discomfort or pain despite treatment with maximally tolerated anti-ischemic medications (nitrates, beta blockers), with the caveat that morphine may slow intestinal absorption of oral platelet inhibitors. The morphine dose may be repeated every 5 to 30 minutes to relieve symptoms and maintain the patient's comfort. Morphine may act as both an analgesic and an anxiolytic; its venodilator effects may be beneficial by reducing preload (particularly in patients with acute pulmonary edema), and mildly reduces HR and BP by increasing vagal tone. Morphine may cause hypotension; supine positioning and IV saline may be used to restore BP. Naloxone (0.4 to 2.0 mg IV) may be administered for morphine overdose with respiratory or circulatory depression. In patients with morphine allergy, meperidine can be substituted.

Calcium Channel Blockers

Calcium channel blockers (CCBs) have vasodilatory effects and reduce arterial pressure. Some CCBs, such as verapamil and diltiazem, also slow HR, reduce myocardial contractility, and thereby reduce myocardial oxygen requirements. CCBs have been effective in reducing ischemia in patients with NSTE-ACS and persistent ischemia despite treatment with full-dose nitrates and beta blockers, as well as in patients with contraindications to beta blockers and in those with hypertension.[10,25] Such patients should receive nondihydropyridine CCBs that lower HR. The short-acting formulation of the dihydropyridine nifedipine, which accelerates HR, can cause harm in patients with ACS when not co-administered with a beta blocker. No harm has been observed with long-term treatment with the long-acting dihydropyridines—amlodipine and felodipine—in patients with documented LV dysfunction and CAD, suggesting that these agents may be safe in patients with NSTE-ACS and LV dysfunction. In patients with suspected/confirmed vasospastic angina (see later), CCBs and nitrates should be considered and beta blockers avoided. Contraindications to nondihydropyridine CCBs include significant LV dysfunction, increased risk for cardiogenic shock, PR interval longer than 0.24 second, and high-degree AV block.

Antiplatelet Therapy

See **Fig. 60.7** and **Table 60.5**.

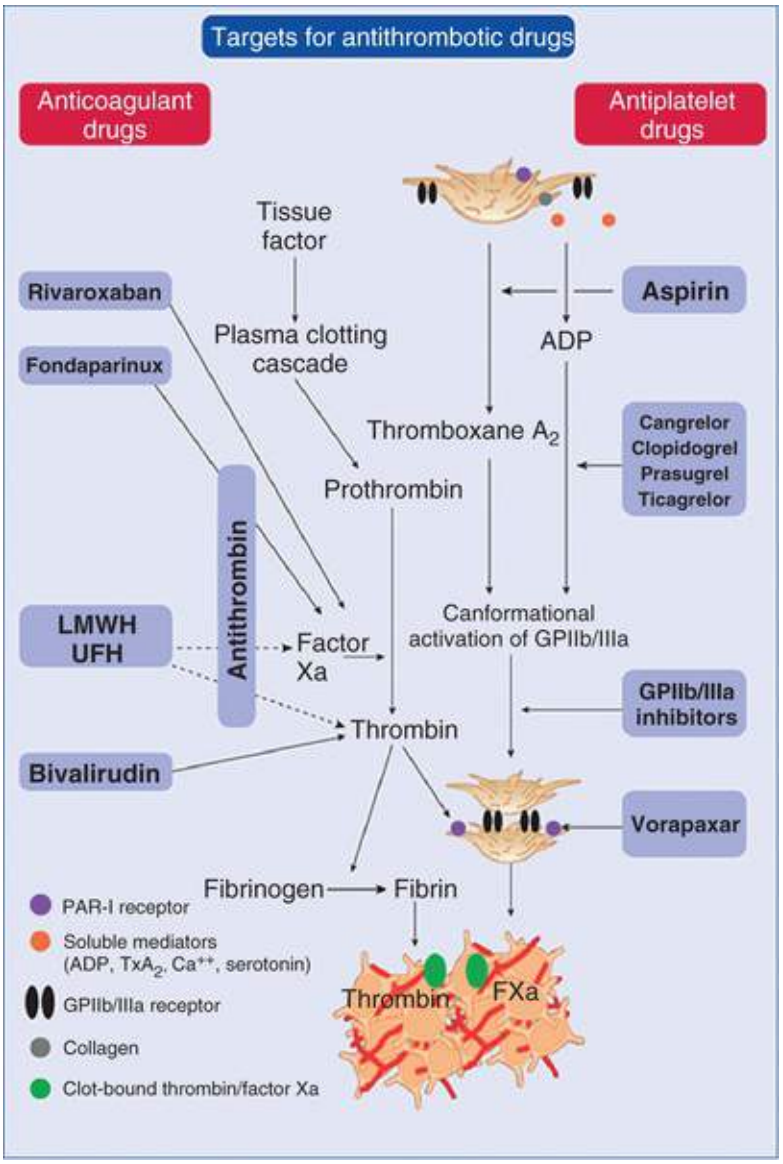

FIGURE 60.7 Targets of available antithrombotic drugs for NSTE-ACS can be used to inhibit blood coagulation and platelet aggregation during and after thrombus formation. *ADP,* Adenosine diphosphate; *GP,* glycoprotein; *LMWH,* low-molecular-weight heparin; *Tx,* thromboxane; *UFH,* unfractionated heparin; *vorapaxar* is a protease-activated receptor 1 (*PAR-1*) blocker. TABLE 60.5

2014 Guideline Recommendations for Antithrombotic Agents in Patients with Non–ST Elevation Acute Coronary Syndromes

Antiplatelet Therapy
Non–enteric-coated, chewable aspirin (162 to 325 mg) should be given to all patients without contraindications on presentation, and a maintenance dose of aspirin (81 to 325 mg/day) continued indefinitely.
In patients who are unable to take aspirin because of hypersensitivity or major gastrointestinal intolerance, a loading dose of clopidogrel (300 or 600 mg) followed by a daily maintenance dose of 75 mg should be substituted.
Either clopidogrel or ticagrelor can be used initially with either an early invasive or ischemic guided strategy (COR I, LOE: B).
Ticagrelor may be preferred over clopidogrel as the initial treatment (COR IIa, LOE: B).
In patients treated with ticagrelor, the preferred aspirin maintenance dose is 81 mg/day.
Use prasugrel only in patients receiving coronary stents (COR I, LOE: B).
The use of glycoprotein IIb/IIIa receptor inhibitors is reserved mainly to the time of PCI in high-risk patients who were not adequately pretreated with $P2Y_{12}$ inhibitors (COR I, LOE: A) or in those patients who were adequately pretreated with $P2Y_{12}$ inhibitors but have a high-risk profile (COR IIa, LOE: B).
Clopidogrel and ticagrelor should be discontinued at least 5 days (COR I, LOE: B) and prasugrel at least 7 days (COR I, LOE: C) before major surgery.
Anticoagulant Therapy
Enoxaparin is recommended at presentation (COR I, LOE: A); other option include unfractionated heparin (UFH) (COR I, B) and fondaparinux (COR I, LOE: B). If an early invasive strategy is planned, bivalirudin (COR I, LOE: B) is also an option.
If fondaparinux is used initially, add UFH or bivalirudin just before or during PCI to prevent catheter-related thrombosis (COR I, LOE: B).
Bivalirudin is preferred over UFH plus GP IIb/IIIa inhibitor in patients undergoing PCI who are at high risk of bleeding (COR IIa, LOE: B).
It is reasonable to use enoxaparin during PCI if it was used as the initial anticoagulant (COR IIb, LOE: B).

COR, Class of recommendation; *LOE,* level of evidence; *PCI,* percutaneous coronary intervention.

Modified from Eisen A, Giugliano RP. Antiplatelet and anticoagulation treatment in patients with non-ST-segment elevation acute coronary syndrome: comparison of the updated North American and European guidelines. Cardiol Rev 2016;24:170-6; and Amsterdam EA, Wenger NK, Brindis RG, et al. 2014 AHA/ACC guideline for the management of patients with non-ST-elevation acute coronary syndromes: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2014;64: e139-228.

Oral Antiplatelet Drugs

Aspirin (Acetylsalicylic Acid, ASA)

ASA acetylates platelet cyclooxygenase 1 (COX-1), thereby blocking the synthesis and release of thromboxane A_2 (TxA_2), a platelet activator, and decreasing platelet aggregation and arterial thrombus formation. Because the inhibition of COX-1 by ASA is irreversible, the antiplatelet effects last for the lifetime of the platelets, approximately 7 to 10 days. Several placebo-controlled trials have demonstrated the benefit of ASA in patients with NSTE-ACS.[54] In addition to reducing adverse clinical events early in treatment, ASA also reduces the frequency of ischemic events in secondary prevention. It is a cornerstone of antiplatelet therapy in patients with all forms of ACS, as well as those with chronic CHD.[11]

Even though doses of ASA have ranged from 50 to 1300 mg/day in randomized trials, there does not appear to be a dose-response effect on efficacy, but GI bleeding is increased at higher doses.[54] The CURRENT OASIS-7 (Clopidogrel and Aspirin Optimal Dose Usage to Reduce Recurrent Events–Seventh Organization to Assess Strategies in Ischemic Symptoms)[55] trial randomly assigned 25,086 patients with ACS to receive high-dose (300 to 325 mg/day) or low-dose (75 to 100 mg/day) ASA for 30 days (and to high-dose versus regular-dose clopidogrel; see later). No difference in the risk for CV death, MI, or stroke was observed between the two doses of ASA, but GI bleeding increased with the higher dose. Guidelines recommend that in patients with NSTE-ACS who have not been taking ASA, the initial loading dose should be 162 to 325 mg of non–enteric-coated ASA, followed by a maintenance dose of 75 to 100 mg daily.[11] Enteric-coated ASA should be avoided initially because it delays and reduces absorption.[56] Data from PLATO (Study of Platelet Inhibition and Patient Outcomes), a large trial of ticagrelor, an oral antiplatelet agent that inhibits the receptor $P2Y_{12}$, provides another reason to favor low-dose ASA.[57] High-dose (≥160 mg) aspirin was associated with increased GI bleeding risk in the

absence of improved outcomes, compared to low-dose (<160 mg) aspirin.[58] Most nonsteroidal anti-inflammatory drugs (NSAIDs) bind reversibly to COX-1, preventing this enzyme's inhibition by aspirin, and may cause prothrombotic effects; thus NSAIDs should be avoided.

So-called ASA resistance may occur during chronic therapy, with 2% to 8% of patients exhibiting a limited antiplatelet effect (i.e., minimal change in inhibition of platelet aggregation). These patients tend to have a greater risk for recurrent cardiac events. Causes of ASA resistance are varied and include poor compliance (pseudoresistance), reduced absorption, interaction with ibuprofen or other NSAIDs, overexpression of COX-2 mRNA, and use of enteric-coated forms. Rarely, a genetic or other intrinsic reason for minimal response to ASA is present. No evidence supports the routine monitoring of antiplatelet effects with adjustment of the ASA dose.[59]

Contraindications to ASA include documented allergy (e.g., ASA-induced asthma), nasal polyps, active bleeding, or a known platelet disorder. Dyspepsia or other GI symptoms with long-term ASA therapy (i.e., ASA intolerance) do not usually preclude therapy in the short term. In patients who have an allergy to ASA, desensitization or substituting clopidogrel, prasugrel, or ticagrelor is recommended.[11] Clopidogrel may be substituted in place of ASA in patients who cannot tolerate ASA because of GI bleeding.

$P2Y_{12}$ Inhibitors

Management of ACS now routinely includes dual-antiplatelet therapy (DAPT) consisting of both ASA and a $P2Y_{12}$ inhibitor (**Table 60.5**). The latter includes the oral thienopyridines (ticlopidine, clopidogrel, prasugrel), which irreversibly block ADP binding to the surface of the platelet $P2Y_{12}$ receptor, as well as a cyclopentyltriazolopyrimidine (ticagrelor), which is a reversible ADP inhibitor. Thienopyridines are prodrugs that require oxidation by the hepatic cytochrome P-450 (CYP) system to form the active metabolites. Thus drugs that inhibit the CYP system reduce the formation of the active form of thienopyridines, unlike ticagrelor, which does not depend on the CYP system. In addition to inhibition of platelet activation and aggregation, thienopyridines also reduce fibrinogen, blood viscosity, and erythrocyte deformability and aggregability through mechanisms that appear to be independent of ADP.

Clopidogrel

Clopidogrel largely avoids the hematologic complications (neutropenia and, rarely, thrombotic thrombocytopenic purpura) associated with ticlopidine, the first widely used thienopyridine. When clopidogrel is absorbed, approximately 85% is hydrolyzed by circulating esterases and thus rendered inactive. The remaining clopidogrel must be oxidized by the hepatic CYP system to generate the active metabolites that inhibit the $P2Y_{12}$ receptor.

The addition of clopidogrel to ASA was studied in the CURE (Clopidogrel in Unstable Angina to Prevent Recurrent Events) trial of 12,562 patients with NSTE-ACS who were treated with ASA, unfractionated heparin (UFH), or low-molecular-weight heparin (LMWH), and other standard therapies and randomly assigned to receive either a 300-mg loading dose of clopidogrel followed by 75 mg daily or a placebo.[60] The addition of clopidogrel to ASA reduced CV death, MI, or stroke by 20% in both low- and high-risk patients with NSTE-ACS, regardless of whether they were managed with medical therapy, PCI, or coronary artery bypass grafting (CABG) (**Fig. 60.8**). Benefit was seen as early as 24 hours, with Kaplan-Meier curves beginning to diverge after just 2 hours.[61] Moreover, the reduction in MI or CV death was similar before and after PCI, through a mean follow-up of 8 months.[62] Addition of clopidogrel results in a small increase in bleeding, including a nonsignificant increase in both life-threatening and fatal

bleeding.[60]

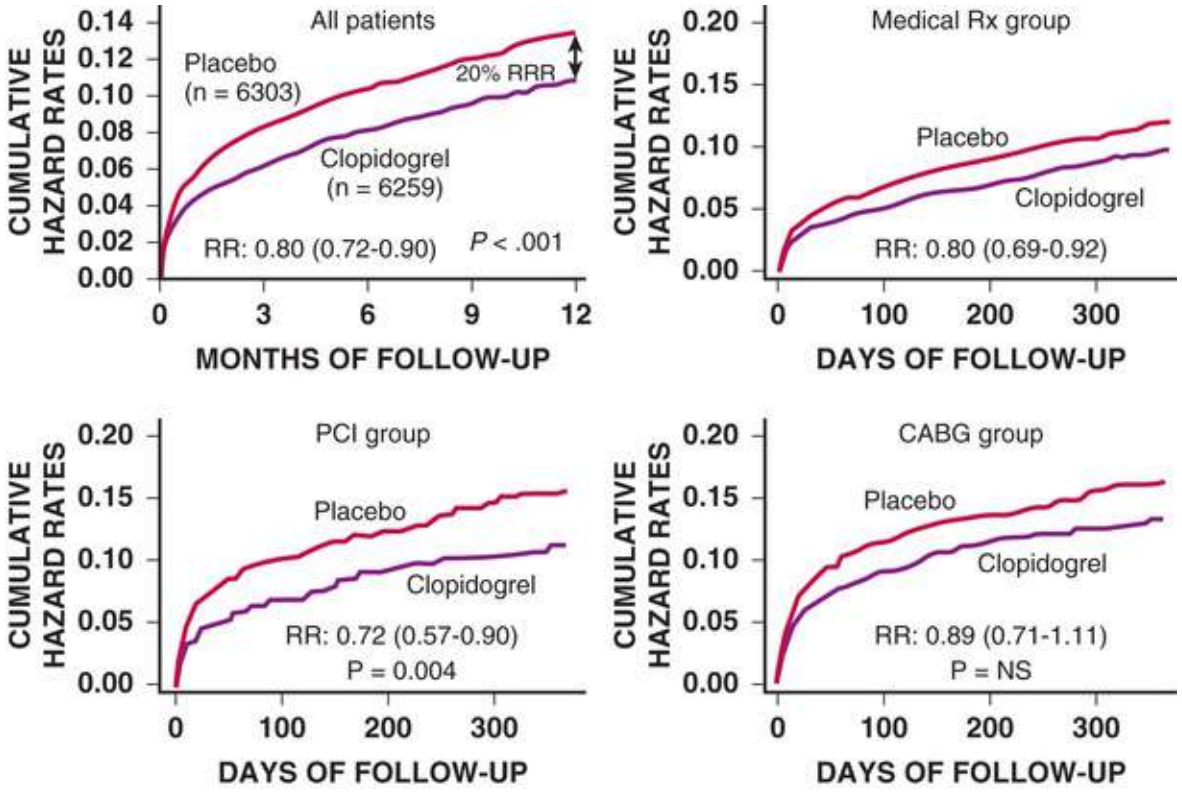

FIGURE 60.8 Benefit of clopidogrel in reducing cardiovascular death, MI, or stroke in patients with NSTE-ACS in the CURE trial and in patients managed medically or with percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG). P-value or interaction among strata 0.53. RR, relative risk; RRR, relative risk ratio; Rx, drug. (From Yusuf Set al. Effects of clopidogrel in addition to aspirin in patients with acute coronary syndromes without ST-segment elevation. N Engl J Med 2001;345:494; and Fox KAet al. Benefits and risks of the combination of clopidogrel and aspirin in patients undergoing surgical revascularization for non-ST-elevation acute coronary syndrome. The Clopidogrel in Unstable Angina to Prevent Recurrent Ischemic Events (CURE) trial. Circulation 2004;110:1202.)

These and similar findings in other trials led to a class I recommendation in both North American[11] and European[63] guidelines to administer clopidogrel prior to PCI. In patients undergoing CABG, those who had received clopidogrel within 5 days of surgery had an increased risk for major bleeding and the need for reoperation, which led to the recommendation that clopidogrel be discontinued at least 5 days before major surgery, if possible.[11,63]

In NSTE-ACS patients the initial loading dose of 300 to 600 mg clopidogrel should be followed by a maintenance dose of 75 mg daily. Use of a 600-mg loading dose achieves a steady-state level of platelet inhibition after just 2 hours, more rapidly than the 300-mg dose. Thus, 600-mg clopidogrel is the preferred loading dose for patients with NSTE-ACS undergoing PCI.[11,23] Two strategies for initiating clopidogrel therapy in patients with NSTE-ACS have evolved: (1) starting clopidogrel at arrival or hospital admission or (2) delaying treatment with clopidogrel until after coronary angiography and then administering the drug on the catheterization table if PCI is performed. The early treatment strategy is preferred because it affords the benefits of reducing early ischemic events, but at the cost of an increase in bleeding in the minority of patients who undergo CABG instead of or immediately after PCI.

Although DAPT reduces recurrent ischemic events in patients with NSTE-ACS compared to ASA alone,

up to 10% of patients treated with ASA plus clopidogrel have events within the first year of ACS, including definite stent thrombosis in up to 2% of patients at 1 year.[64] As with ASA, hyporesponders to clopidogrel have been identified and are at higher risk for recurrent cardiac events, including stent thrombosis, MI, and death.[59] The incidence of patients not achieving the expected pharmacologic response to clopidogrel ranges from 5% to 30%, depending on the population and the definition used to assess response.[59] Hyporesponsiveness to clopidogrel is more common in patients with diabetes, as well as in those with obesity, advanced age, and with certain genetic polymorphisms of the CYP system. Patients with a minimal antiplatelet response to clopidogrel have lower concentrations of the active metabolite, thus indicating failure of this necessary conversion.

Several polymorphisms of the gene encoding for the CYP2C19 enzyme have been associated with reduced production of the active metabolite of clopidogrel (**see Chapter 8**). These polymorphisms (especially the reduced-function *C2 allele) occur in approximately one third of white individuals and up to half of Asians and have been associated with increased adverse clinical outcomes in patients treated with clopidogrel. In other studies, reduced-function alleles are associated with increased stent thrombosis. Testing for these polymorphisms in patients who are candidates for thienopyridine treatment can identify those who are likely to be unresponsive or hyporesponsive to the standard dose of clopidogrel and are candidates for alternative antiplatelet regimens. Three randomized trials that evaluated more aggressive antiplatelet regimens in patients with high platelet reactivity after standard dose of ASA and clopidogrel, however, did not show a significant reduction in clinical CV events with higher doses of antiplatelet drugs versus standard doses.[65-67] Data from a study of patients with UA undergoing PCI showed that a daily maintenance dose of 225 mg or more of clopidogrel (at least three times the standard dose) is necessary in heterozygote carriers of the CYP2C19*2 allele to achieve the same level of platelet inhibition as that in noncarriers who receive 75 mg daily.[68] Thus the three aforementioned trials may have failed to show clinical benefit with more intensive antiplatelet regimens in patients with high platelet reactivity, in part because of insufficiently high clopidogrel doses. Proton pump inhibitors (PPIs) modestly reduce the antiplatelet effect of clopidogrel when assessed by platelet function assays[69] because of competition for metabolism by the CYP3A4 enzyme. However, a randomized, double-blind trial[70] indicated that a clinically significant interaction between clopidogrel and PPIs is unlikely.

Prasugrel

Similar to clopidogrel, prasugrel is a prodrug requiring hepatic oxidation to form an active metabolite that irreversibly inhibits the platelet $P2Y_{12}$ receptor. However, unlike clopidogrel, formation of the active metabolite of prasugrel requires only one step and is generated within 30 minutes of ingestion. While the active metabolites of clopidogrel and prasugrel exert equal antiplatelet effects in vitro, the generation of the prasugrel metabolite is approximately 10 times as great as the clopidogrel metabolite, which results in approximately a 10-fold greater potency.

Prasugrel (60-mg loading dose, 10-mg daily maintenance dose) was compared to clopidogrel (300-mg loading dose, 75-mg daily maintenance dose) in 10,074 patients with NSTE-ACS with known anatomy coronary anatomy in the TRITON-TIMI 38 (Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel-Thrombolysis in Myocardial Infarction 38) trial.[71] The primary composite of CV death, MI, or stroke was reduced by 19% in the patients randomized to prasugrel through 15 months of follow-up.(**Fig. 60.9A**) The benefit driven by a significant 24% reduction in MI and was particularly striking in patients with diabetes (30% reduction).[72] In addition, prasugrel

markedly reduced the rate of definite or probable stent thrombosis (by 52%), particularly in patients with drug-eluting stents (64%)[73]; thus prasugrel should be considered in patients who present with stent thrombosis despite compliance with clopidogrel therapy.[23]

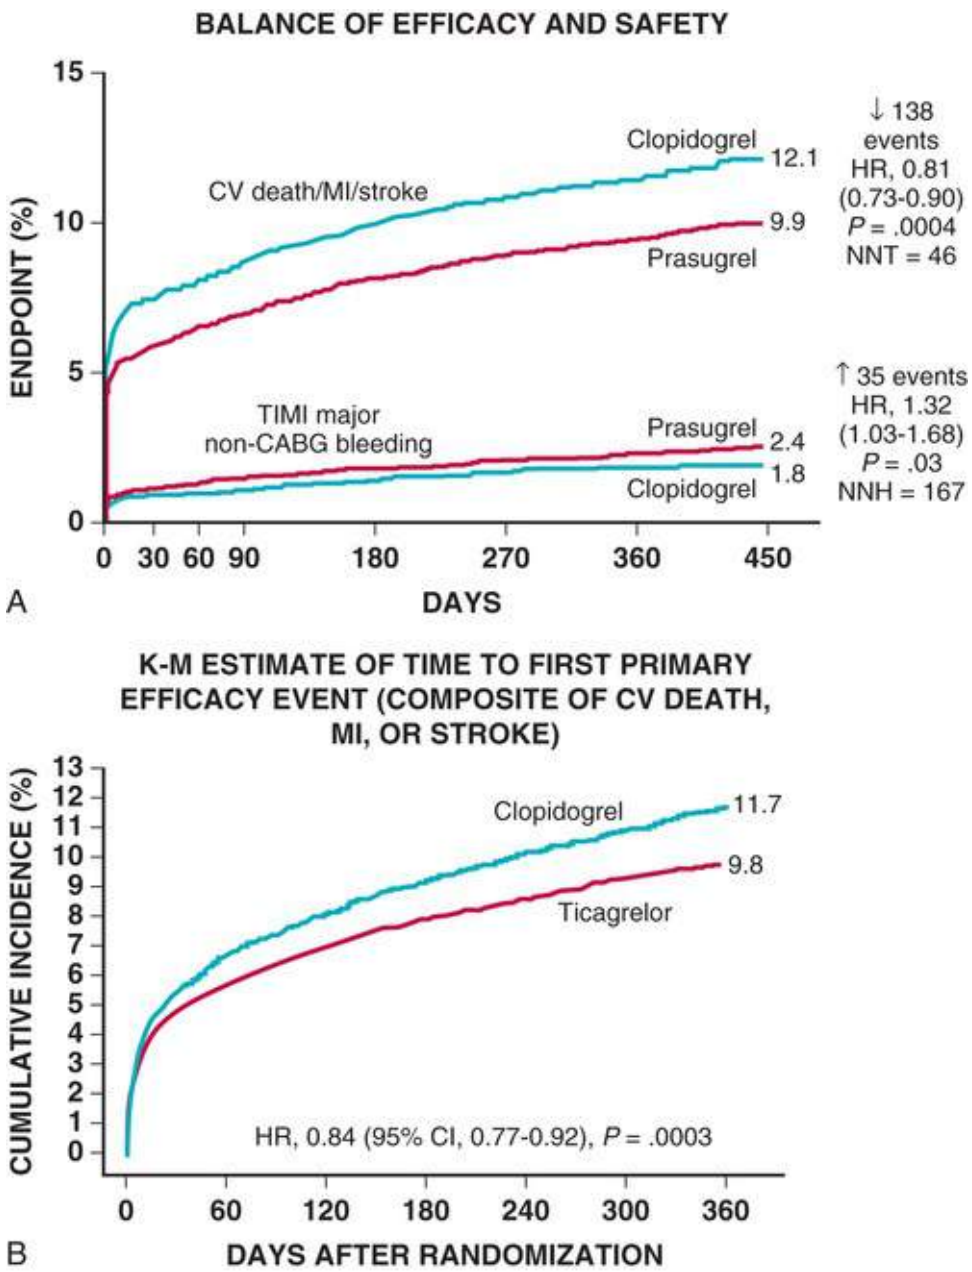

FIGURE 60.9 Comparison of more potent adenosine diphosphate (ADP) inhibitors versus clopidogrel. **A,** Comparison of the efficacy and safety of prasugrel versus clopidogrel in the TRITON-TIMI 38 trial in patients with ACS undergoing PCI. HR, Hazard ratio; NNT, number of patients needed to prevent one primary endpoint event; NNH, number of patients needed to be treated to cause harm (TIMI major bleeding). **B,** The primary endpoint of the PLATO trial—a composite of death from vascular causes, myocardial infarction (MI), or stroke—occurred significantly less often in the ticagrelor group than in the clopidogrel group. CV, Cardiovascular; K-M, Kaplan-Meier curve. (**A,** From Wiviott SD et al. Prasugrel versus clopidogrel in patients with acute coronary syndromes. N Engl J Med 2007;347:2001; **B,** from Wallentin L et al. Ticagrelor versus clopidogrel in patients with acute coronary syndromes. N Engl J Med 2009;361:1045.)

Severe bleeding complications were more common with prasugrel, including non-CABG major (**Fig. 60.9A**), spontaneous, and fatal bleeding events. Prasugrel is contraindicated in patients with prior stroke or transient ischemic attack (TIA) due to evidence of net harm in this group in TRITON-TIMI 38. Bleeding rates were especially high in elderly patients (≥75 years) and those with reduced body weight

(<60 kg [132 lb]). Thus, prasugrel should be avoided in such patients unless they are at high risk for thrombosis, in which case a 5-mg maintenance dose is preferred. In patients younger than 75 who weighed at least 60 kg and had no prior stroke or TIA—the "core" group of patients for whom the U.S. Food and Drug Administration (FDA) approved its use—prasugrel was associated with a 26% reduction in the primary endpoint.[74] Prasugrel should be discontinued at least 7 days before cardiac surgery whenever possible.[11]

Prasugrel (10 mg daily) was compared to clopidogrel (75 mg daily) on a background of ASA and other standard therapies in 7243 patients under age 75 with NSTE-ACS managed with an ischemia-guided strategy in the TRILOGY ACS (Targeted Platelet Inhibition to Clarify the Optimal Strategy to Medically Manage Acute Coronary Syndromes) randomized trial.[75] There was no benefit of treatment with prasugrel over clopidogrel, and bleeding rates were similar. The ACCOAST (A Comparison of Prasugrel at the Time of Percutaneous Coronary Intervention or as Pretreatment at the Time of Diagnosis in Patients with Non–ST-Elevation Myocardial Infarction) trial of high-risk patients with NSTE-ACS managed with an early invasive strategy randomized to prasugrel versus clopidogrel *prior to angiography*.[76] There was no significant difference in the composite primary efficacy endpoint, but prasugrel did increase bleeding compared to clopidogrel. Given the totality of the evidence from these three randomized trials, prasugrel is most suitable in patients younger than 75 years without a prior stroke or TIA who have had coronary angiogram and in whom PCI is planned. Prasugrel is not recommended for use in patients with NSTE-ACS before angiography.[10,25]

Ticagrelor

Ticagrelor is the first nonthienopyridine ADP blocker approved for use. It is a *reversible* inhibitor (half-life approximately 12 hours) of the $P2Y_{12}$ platelet receptor, in contrast to the oral thienopyridines, which are irreversible inhibitors. Both the parent drug and its metabolite are active and have similar potency; thus, similar to prasugrel, inhibition of $P2Y_{12}$-mediated platelet aggregation is nearly complete and more rapid than with clopidogrel. Since ticagrelor does not require metabolism via the CYP2C19 pathway to generate its active metabolite, the variability of antiplatelet activity described with clopidogrel in patients does not apply to ticagrelor.

The phase 3 PLATO trial compared ticagrelor (180-mg loading dose, 90-mg twice-daily maintenance dose) with clopidogrel (300- or 600-mg loading dose, 75-mg daily maintenance dose) on a background of ASA. In PLATO, 11,067 (59%) of the 18,624 patients had NSTE-ACS.[77] Ticagrelor significantly reduced the primary endpoint (CV death, MI, or stroke) by 16% (**Fig. 60.9B**) and also reduced stent thrombosis by 33%, CV death by 21%, and total mortality by 22%. A broad array of subgroups demonstrated consistent benefit with ticagrelor over clopidogrel, including patients age 75 or older, weight less than 60 kg, with a prior history of stroke or TIA, and those managed with a noninvasive strategy. However, there was no benefit of ticagrelor in patients enrolled in the United States, in whom the dose of ASA was higher on average than in other countries.[57] Whether this finding is related to chance, more frequent use of higher-dose ASA (e.g. 325 mg daily), or some other aspect of care that differed in the United States remains uncertain. Nevertheless, the FDA has recommended that low-dose ASA (75 to 100 mg daily) be used in combination with ticagrelor.

Safety events were similar between ticagrelor and clopidogrel, with three important exceptions that were more common with ticagrelor: non–CABG-related major bleeding (4.5% versus 3.8%; $P = 0.03$), dyspnea (13.8% versus 7.8%; $P < 0.001$), and pauses in sinus rates in the first week lasting longer than 3 seconds (5.8% versus 3.6%; $P = 0.01$).[77] Although a reversible $P2Y_{12}$ inhibitor with a shorter effective

half-life than clopidogrel, ticagrelor achieves a higher level of platelet inhibition and thus should be discontinued at least 5 days before major surgery.[11]

Long-term use of ticagrelor with ASA in patients who had experienced MI 1 to 3 years earlier was evaluated in the PEGASUS-TIMI 54 trial.[78] Compared to placebo, both the standard maintenance dose of ticagrelor (90 mg twice daily) and a lower dose (60 mg twice daily) reduced the rate of the primary composite endpoint (CV death, MI, or stroke) by 15% and 16%, respectively. Although the rates of TIMI major bleeding were higher with ticagrelor, rates of intracranial and fatal bleeding were not increased. Major bleeding rates were lower and tolerability better with the 60-mg twice-daily dose,[79] which was FDA approved for the prevention of CV death, MI, and stroke in stable patients with a history of stroke.

Protease-Activated Receptor-1 Antagonists

The oral protease-activated receptor-1 (PAR-1) antagonist *vorapaxar*, which inhibits thrombin-mediated platelet activation, was not effective in patients with NSTE-ACS.[80] In the TRA-2P-TIMI 50 (Thrombin Receptor Antagonist in Secondary Prevention of Atherothrombotic Ischemic Events–TIMI) trial of 26,449 stable patients with a history of MI, ischemic stroke, or peripheral vascular disease, the addition of vorapaxar to standard therapies reduced ischemic events while increasing bleeding compared to placebo.[81] Patients enrolled 2 weeks to 1 year after MI had a 20% reduction in CV death, MI, or stroke. The efficacy and safety profile of vorapaxar were similar whether patients were or were not taking a concomitant thienopyridine.[82] This PAR-1 antagonist may play a role in secondary prevention in stable patients following an NSTEMI.

Intravenous Antiplatelet Agents

Glycoprotein IIb/IIIa Inhibitors

The glycoprotein (GP) IIb/IIIa inhibitors block the final common pathway of platelet aggregation—fibrinogen-mediated cross-linkage of platelets—caused by a variety of stimuli (e.g., thrombin, ADP, collagen, serotonin) (**see Fig. 60.7**) and were more frequently used in the era before the introduction of potent oral and IV $P2Y_{12}$ inhibitors. Three agents in this class are available: abciximab, a monoclonal antibody approved only in patients undergoing PCI, and eptifibatide and tirofiban, both of which are reversible small-molecule inhibitors approved for use in patients with ACS and in those undergoing PCI (**see Table 98.4**).

Several trials, mostly on a background of ASA without $P2Y_{12}$ inhibitor, have shown benefit of GP IIb/IIIa inhibition in the management of patients with NSTE-ACS, with an overall small (9%) but statistically significant relative reduction in death or MI at 30 days in a large meta-analysis,[83] with greater benefit in high-risk patients with ST-segment changes and/or elevated troponin concentration or diabetes.[83,84] However, the rates of major hemorrhage were significantly higher in patients treated with GP IIb/IIIa inhibitors, occurring in 2.4% compared to 1.4% of those given placebo, and severe thrombocytopenia (<50,000/mm^3) was also increased.[85] Two large trials have examined routine early administration at initial evaluation versus delayed provisional use of GP IIb/IIIa inhibitors just before PCI in patients who also received a $P2Y_{12}$ inhibitor (most commonly pre-PCI) and found no significant benefit with an increased risk of bleeding.[86,87] Based on the totality of the evidence, the routine administration of GP IIb/IIIa inhibitors to patients with NSTE-ACS who receive DAPT with ASA and a $P2Y_{12}$ inhibitor (i.e., triple-antiplatelet therapy) is not recommended. However, selective use in patients at high risk for ischemic complications, such as those with diabetes or angiographic evidence of thrombus, and at low

risk for bleeding who are to undergo PCI, or in the management of thrombotic complications during PCI, appears more prudent.

Cangrelor

Cangrelor is an IV direct-acting $P2Y_{12}$ inhibitor that blocks ADP-induced platelet activation and aggregation. The parent compound exhibits an almost immediate onset of action and short half-life of 3 to 6 minutes.[88] Three large outcome studies have evaluated cangrelor in more than 25,000 patients undergoing PCI across a broad spectrum of clinical presentations (stable angina, UA, NSTEMI, STEMI). In a patient-level meta-analysis, cangrelor reduced the risk of the primary composite outcome of death, MI, ischemia-driven revascularization, and stent thrombosis at 48 hours by 18% (2.9 versus 3.5%; P = 0.04) relative to control among the 14,282 patients who underwent PCI after NSTE-ACS.[89] There was an excess of 3 per 1000 non-CABG bleeds with cangrelor (1.0 versus 0.7%).

Since cangrelor is administered intravenously and has a rapid onset and offset of action, it has the potential to overcome several practical limitations of oral $P2Y_{12}$ inhibitors in patients with NSTE-ACS undergoing PCI. These limitations include (1) a slower onset action of oral delivery; (2) delayed absorption of oral agents in patients who have decreased GI perfusion, nausea, or receive opiates; and (3) the need to postpone CABG for 5 to 7 days after an oral $P2Y_{12}$ inhibitor to reduce the risk of bleeding. Cangrelor was approved in the United States and Europe in 2015 as an adjunct to PCI for reducing the risk of periprocedural MI, repeat coronary revascularization, and stent thrombosis in patients in who have not been treated with a $P2Y_{12}$ platelet inhibitor and who are not being given a GP IIb/III inhibitor.

Anticoagulant Therapy

Once the diagnosis of NSTE-ACS has been made, a parenteral anticoagulant should be initiated in addition to DAPT, unless the patient has an absolute contraindication (e.g., uncontrolled bleeding) (**see Fig. 60.7**).

Heparin

Unfractionated heparin is a mixture of polysaccharide chains of different lengths that prevent coagulation by blocking thrombin (factor IIa) and factor Xa. UFH also binds to circulating plasma proteins, acute-phase reactants, and endothelial cells and thus has an unpredictable anticoagulant effect. Because of its short half-life, UFH must be administered as an IV infusion to ensure a stable level of anticoagulation.

A meta-analysis of 1353 patients in six trials showed a 33% reduction in death or MI with UFH plus ASA versus ASA alone.[90] Daily monitoring of the anticoagulant response via the activated partial thromboplastin time (APTT) is recommended, with titrations made according to a standardized nomogram to achieve an APTT of 50 to 70 seconds or 1.5 to 2.5 times control.[23] The ACC/AHA guidelines recommend a weight-adjusted dose of UFH (60-unit/kg bolus and 12-unit/kg/hr infusion), as well as frequent monitoring of the APTT (every 6 hours until the target range is reached and every 12 to 24 hours thereafter) and adjustment of the dose if necessary.[11] Adverse effects include bleeding, especially when the APTT is excessively elevated. Immunogenic heparin-induced thrombocytopenia (HIT) is an infrequent but serious complication that can cause thrombosis and bleeding and may even be fatal. In patients with HIT, a direct thrombin inhibitor (e.g., argatroban, 2-μg/kg/min infusion to achieve APTT 1.5 to 3 times control[91]) or fondaparinux (see later) should be substituted.

Heparin Reversal

Protamine sulfate binds heparin to form a stable salt, thus quickly reversing the anticoagulant effect of UFH. Because the half-life of UFH is approximately 1 to 1.5 hours, the dose of protamine necessary to reverse an infusion of UFH should be based on the total UFH dose administered in the previous 2 to 3 hours. Approximately 1 mg neutralizes 100 units of UFH. A slow IV infusion is recommended to avoid hypotension or bradycardia. Protamine reverses approximately 60% of the anticoagulant effect of LMWH but does not completely neutralize its anti-Xa activity.

Low-Molecular-Weight Heparin

The low-molecular-weight forms of heparin are enriched with shorter polysaccharide chains, which results in a more predictable anticoagulant effect than with UFH. LMWH has several potential advantages over UFH: (1) its greater anti–factor Xa activity (relative to factor IIa) inhibits thrombin generation more effectively; (2) LMWH induces greater release of tissue factor pathway inhibitor than UFH, and it is not neutralized by platelet factor 4; (3) LMWH less frequently causes HIT; (4) the high and consistent bioavailability of LMWH allows subcutaneous (SC) administration; (5) monitoring of the anticoagulation level is not necessary; and (6) LMWH binds less avidly to plasma proteins than UFH and therefore has a more consistent anticoagulant effect.

Although several LMWHs have been approved, the weight of evidence supports the choice of *enoxaparin.*[11,23] The standard dose of enoxaparin is 1 mg/kg subcutaneously every 12 hours, with dosing only once daily for patients with a creatinine clearance (CrCl) less than 30 mL/min. Administration of enoxaparin for up to 8 days (or until hospital discharge) was found effective in patients with ACS, whereas extending therapy to 6 weeks did not reduce ischemic events further in patients with NSTE-ACS.[92] In the event of bleeding, the anticoagulant effect of LMWH can be reversed partially with protamine. LMWH should not be used in patients with a history of HIT. In patients with NSTE-ACS treated with ASA, LMWH reduced the incidence of death or MI by 66% compared with placebo. In a meta-analysis of 21,945 patients from six trials of patients with NSTE-ACS in which enoxaparin was compared with UFH, new or recurrent MI occurred less frequently with enoxaparin, whereas the rate of major bleeding was similar between the drugs.[93]

Direct Thrombin Inhibitors

The direct thrombin inhibitors have a potential advantage over indirect thrombin inhibitors such as UFH or LMWH in that they do not require antithrombin and can inhibit clot-bound thrombin. Direct thrombin inhibitors do not interact with plasma proteins, provide a very stable level of anticoagulation, and do not cause thrombocytopenia, thus making them an excellent choice for anticoagulation in patients with a history of HIT.

Bivalirudin, the drug in this class most widely used in patients with ACS or undergoing PCI, binds reversibly to thrombin and has a half-life of approximately 25 minutes. In the ACUITY (Acute Catheterization and Urgent Intervention Triage Strategy) trial,[94] patients with NSTE-ACS randomized to bivalirudin without a GP IIb/IIIa inhibitor experienced less bleeding in comparison to the combination of a GP IIb/IIIa inhibitor with either UFH or enoxaparin. However, there were no differences in major bleeding between anticoagulants (UFH or enoxaparin versus bivalirudin) in patients taking a GP IIb/IIIa inhibitor, and there were no differences in ischemic events between the three treatment arms.[94] A meta-analysis of four trials enrolling predominantly patients with NSTE-ACS showed that heparin-based regimens slightly reduced major adverse cardiovascular events (MACE) compared to bivalirudin-based

regimens (relative risk [RR], 1.10; 95% confidence interval [CI] 0.99 to 1.23).[95]

Subsequently, in the Minimizing Adverse Hemorrhagic Events by Transradial Access Site and Systemic Implementation of Angiomax (MATRIX) study,[96] 7213 patients with ACS (44% with high-risk NSTE-ACS) in whom PCI was planned were randomized to either bivalirudin or UFH in an open-label fashion. Rates of MACE (death, MI, stroke), net adverse clinical events (MACE or major bleeding), and mortality did not differ between the treatment groups in the entire population or among the 3203 patients with NSTE-ACS. Major bleeding was reduced significantly in the bivalirudin group by almost 50% among patients with NSTE-ACS. However, use of GP IIb/IIIa inhibitors in the study was more frequent in the UFH group (26% versus 5%), as designated by the trial design, and likely contributed to the increased bleeding in the UFH group.

The use of bivalirudin monotherapy (with ASA and a $P2Y_{12}$ inhibitor but without a GP IIb/IIIa inhibitor) is now considered an acceptable alternative to heparin-based regimens in patients with NSTE-ACS managed with an early invasive strategy and may be preferred in patients with increased risk for bleeding who are undergoing PCI.[11] In patients with NSTE-ACS before angiography, the recommended dose of bivalirudin is a 0.10-mg/kg IV bolus followed by an infusion of 0.25 mg/kg/hr. If started during the procedure, a 0.75-mg/kg bolus dose of bivalirudin should be administered, followed by an infusion at 1.75 mg/kg/hr during PCI.[11] It may be discontinued shortly after PCI to permit removal of arterial access sheaths. In patients with renal dysfunction and a CrCl less than 30 mL/min, the infusion rate should be reduced to 1 mg/kg/hr.

Factor Xa Inhibitors

Both parenteral and oral factor Xa inhibitors have been studied in patients with NSTE-ACS.

Fondaparinux

This synthetic pentasaccharide indirectly inhibits factor Xa and requires the presence of antithrombin for its action. The OASIS-5 trial compared daily SC fondaparinux (2.5 mg) with standard-dose enoxaparin in 20,078 patients with high-risk NSTE-ACS.[97] No difference was found in the primary ischemic composite through 9 days, although fondaparinux did reduce major bleeding by nearly half, and mortality at 30 days tended to be lower with fondaparinux. In patients undergoing PCI, however, fondaparinux was associated with a greater than threefold increased risk for catheter-related thrombi. Supplemental UFH at catheterization (85 units/kg if no GP IIb/IIIa inhibitor was used; 60 units/kg with concomitant GP IIb/IIIa inhibitor) appeared to minimize the risk of this problem with fondaparinux.[98] Thus, fondaparinux is an alternative for patients with NSTE-ACS managed noninvasively, particularly in patients at high risk for bleeding.[11,23]

Oral Factor Xa Inhibitors

Two oral direct factor Xa inhibitors, *rivaroxaban* and *apixaban,* have been studied in phase 3 trials of patients with ACS. In the ATLAS ACS 2-TIMI 51 (Anti-Xa Therapy to Lower Cardiovascular Events in Addition to Standard Therapy in Subjects with Acute Coronary syndrome–Thrombolysis in Myocardial Infarction) trial, low-dose rivaroxaban (5 mg twice daily) and very-low-dose rivaroxaban (2.5 mg twice daily) reduced the primary composite (death, MI, or stroke) significantly by 16% compared to placebo on a background of DAPT.[99] Bleeding, including intracranial hemorrhage, was significantly increased with the addition of rivaroxaban to DAPT. Because the 2.5-mg twice-daily dose had a more favorable safety profile and also significantly reduced death, it was approved by the European Medicines Agency in 2013

for the prevention of atherothrombotic events in post–acute MI patients. However, rivaroxaban has not been approved for use after ACS by the FDA. Studies with apixaban in combination wtih antiplatelet agents demonstrated increased bleeding without a reduction in ischemic events; thus this indication was not pursued further.

Longer-Term Oral Anticoagulant and Antiplatelet Therapy

Approximately 10% of patients presenting with NSTE-ACS have an indication for ongoing oral anticoagulation, such as atrial fibrillation (AF), mechanical heart valves, or recent venous thromboembolism. Since the combination of oral anticoagulation with DAPT is associated with a threefold to fourfold increase in bleeding requiring hospitalization[100] the management of such patients is complicated and remains controversial. Current consensus statements provide variable recommendations ranging from 1 to 12 months for the duration of triple therapy (ASA, ADP inhibitor, and anticoagulant), depending on the bleeding and thromboembolic risk and type of coronary stent.[101] The desire to avoid prolonged interruptions in oral anticoagulation needs to be balanced by the increased risk of bleeding when patients with NSTE-ACS require coronary angiography and revascularization.[102]

In patients with NSTE-ACS receiving DAPT who had been receiving prior oral anticoagulation, it is reasonable to transition to a parenteral anticoagulant at or shortly after presentation (i.e., once therapeutic anticoagulation has waned). If immediate angiography is required, radial access is the preferred choice because it may reduce the risk of access site bleeding. After the procedure the duration of triple therapy should be minimized. Since most of the available data with triple therapy are in patients who have received ASA, clopidogrel, and a vitamin K antagonist (VKA), current guidelines[11,23] favor low-dose ASA (75 to 100 mg daily), clopidogrel, and VKA targeting an international normalized ratio (INR) of 2.0 to 2.5, although ongoing studies are evaluating different combinations of ADP inhibitors and oral anticoagulants (warfarin and non–vitamin K antagonist oral anticoagulants [NOACs]), with and without ASA. Use of bare-metal stents (which require a shorter duration of DAPT than drug-eluting stents) should be considered, and gastric protective agents[103] are recommended to reduce the risk of bleeding. An approach to antithrombotic therapy in patients with AF and NSTE-ACS minimizes bleeding while providing protection from thrombosis and ischemia (**Fig. 60.10**).

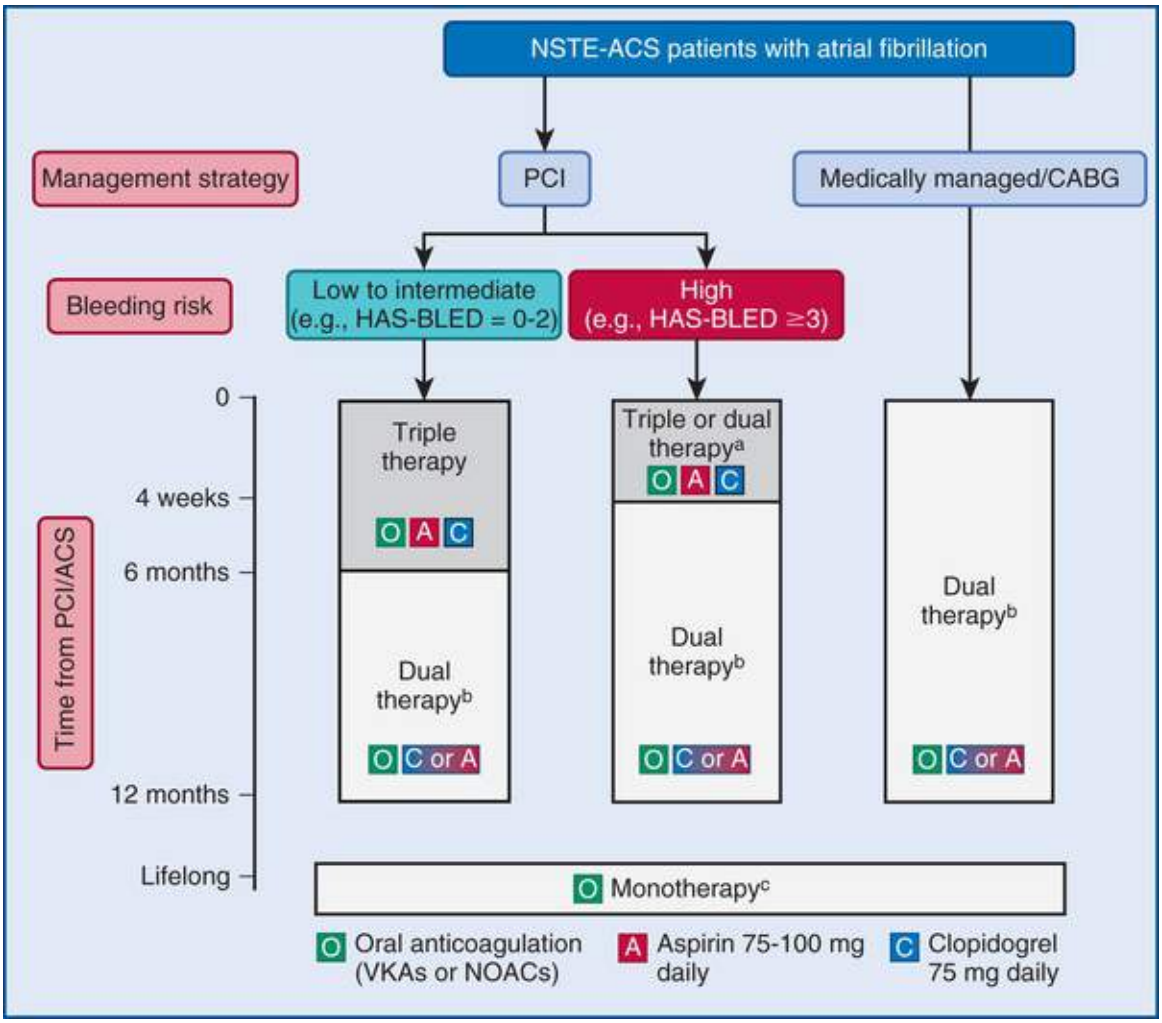

FIGURE 60.10 Antithrombotic strategies in patients with non–ST elevation acute coronary syndrome (NSTE-ACS) and nonvalvular atrial fibrillation (AF). CABG, Coronary artery bypass graft; CHA_2DS_2-VASc, congestive heart failure, hypertension, age ≥75 years (2 points), diabetes, stroke, or systemic arterial embolism (2 points)–vascular disease, age 65-74, sex category; DAPT, dual-antiplatelet therapy; NOACs, non–vitamin K antagonist oral anticoagulants; PCI, percutaneous coronary intervention; VKAs, vitamin K antagonists. [a]Dual therapy with oral anticoagulation and clopidogrel may be considered in select patients (low ischemic risk). [b]Aspirin as an alternative to clopidogrel may be considered in patients on dual therapy (i.e., oral anticoagulation plus single antiplatelet); triple therapy may be considered up to 12 months in very select patients at high risk of ischemic events (e.g., prior stent thrombosis on adequate antiplatelet therapy, stenting in the left main or last remaining patent coronary artery, multiple stenting in proximal coronary segments, two stents bifurcation treatment, or diffuse multivessel disease, especially in diabetic patients). [c]Dual therapy with oral anticoagulation and an antiplatelet agent (aspirin or clopidogrel) beyond 1 year may be considered in patients at very high risk of coronary events. In patients undergoing coronary stenting, dual-antiplatelet therapy may be an alternative to triple or a combination of anticoagulants and single-antiplatelet therapy if the CHA_2DS_2-VASc score is 1 (males) or 2 (females). (Modified from Lip GY, Windecker S, Huber K, et al. Management of antithrombotic therapy in atrial fibrillation patients presenting with acute coronary syndrome and/or undergoing percutaneous coronary or valve interventions. Eur Heart J 2014;35:3155-79.)

Subsequent to the release of the previous guidelines, the results of a trial[104] in 2124 patients with AF undergoing coronary stenting randomized to low-dose rivaroxaban (15 mg once daily) plus a P_2Y_{12} inhibitor for 12 months, very-low-dose rivaroxaban (2.5 mg twice daily) plus DAPT for 1, 6, or 12 months, or dose-adjusted VKA (once daily) plus DAPT for 1, 6, or 12 months were reported. The rates of clinically significant bleeding were approximately 40% lower in the two groups receiving rivaroxaban than in the group receiving VKA plus DAPT. The rates of death from CV causes, MI, or stroke were similar in the three groups, although events were infrequent and confidence intervals broad. Both rivaroxaban-based regimens were associated with fewer deaths and less hospitalization for adverse events compared to the group randomized to VKA plus DAPT.[105]

Bleeding: Risk Assessment, Prevention, and Treatment

Severe bleeding is the most common complication of antithrombotic therapy and is associated with poorer outcomes in patients with ACS undergoing PCI,[102] although the magnitude of the independent contribution to mortality that can be attributed to bleeding remains controversial.[106] Regardless, efforts to minimize the risk of bleeding are recommended and include (1) assessment of bleeding (and ischemic) risk using an established risk score, such as the HAS-BLED score;[23] (2) dose adjustment of antithrombotic drugs according to body weight and renal function (**see Table 98.5**); (3) selection of anticoagulants (e.g., fondaparinux in medically managed patients or bivalirudin without a GP IIb/IIIa inhibitor in patients managed invasively) and antiplatelet (e.g., low-dose ASA + clopidogrel) regimens with a lower-risk bleeding profile;[107] (4) avoidance of other therapies that increase the risk for bleeding (e.g., NSAIDs); (5) use of radial arterial access,[96] smaller sheath sizes, timely removal of arterial sheaths, and femoral closure devices;[108] (6) use of bare-metal stents to permit a shorter duration (1 month) of DAPT; and (7) prophylactic administration of gastroprotective agents, in particular PPIs,[103] in patients at increased risk of upper GI bleeding.

Decisions regarding the number and duration of antithrombotic agents after NSTE-ACS are complex and require individual assessment of risk and benefit. Use of a clinical prediction rule to estimate the benefit and harm of DAPT beyond 12 months after PCI may help to identify which patients should continue long-term DAPT.[109] Patients receiving an oral anticoagulant who present with NSTE-ACS represent a particularly high-risk group who require careful management of the antithrombotic regimen. The following steps are recommended[23]: 1) do not use heparin in patients with INR greater than 2.5 taking a VKA; (2) in patients taking a NOAC, use reduced-dose parenteral anticoagulant (e.g., UFH, 60 U/kg, or enoxaparin, 0.5 mg/kg) periprocedurally; (3) avoid pretreatment with a $P2Y_{12}$ inhibitor; and (4) limit use of GP IIb/IIIa inhibitors to only periprocedural complications.

In case of major bleeding, the European Society of Cardiology (ESC) provides the following recommendations[23]: (1) interrupt both anticoagulant and antiplatelet therapies, unless bleeding can be adequately controlled by specific hemostatic measures; (2) neutralize anticoagulant therapy; (3) consider platelet transfusion to neutralize antiplatelet agents; (4) since blood transfusions may have deleterious effects on outcome, individual assessment of the risk/benefit ratio is recommended, and transfusions should be withheld in hemodynamically stable patients with hemoglobin above 7 g/dL; (5) erythropoietin is not indicated as a treatment for acute anemia or blood loss, because it may increase the risk of arterial or venous thromboembolism; and (6) minor bleeding should be managed without interruption of antithrombotic therapies.

Invasive Versus Conservative Management

Two general approaches to cardiac catheterization and revascularization can be used to manage patients with NSTE-ACS: (1) an early invasive strategy involving routine early (within 48 hours of initial evaluation) cardiac catheterization, followed by PCI, CABG, or continuing medical therapy, depending on the coronary anatomy, and (2) an ischemia-guided (or selective invasive) approach, with initial medical management and catheterization being reserved for patients with hemodynamic instability or recurrent ischemia, either at rest or on a noninvasive stress test, followed by revascularization if the anatomy is suitable. An early invasive strategy is *not* recommended in patients with extensive comorbidities in whom the risks of revascularization outweigh the potential benefits, or in patients with acute chest pain with low clinical likelihood of ACS and a negative troponin assay.[11]

A meta-analysis of seven trials confirmed an overall significant 25% reduction in mortality and a 17% reduction in nonfatal MI after 2 years of follow-up in patients managed with an early invasive strategy.[110] Similar findings were reported in an individual patient-level meta-analysis from three contemporary randomized trials involving 5467 patients who were followed for 5 years.[111] The benefit of an early invasive strategy also applied to key subgroups who traditionally were less likely to undergo early angiography, including older adults,[112] patients with CKD,[113] and women,[114] although one analysis in women did not show benefit.[115] A sex-specific meta-analysis demonstrated benefit of an invasive strategy in all men and in high-risk women but not in low-risk women.

Thus, an early invasive strategy, in the absence of contraindication, is recommended in patients with NSTE-ACS who have ST-segment changes and/or positive troponin assay on admission, or in whom these high-risk features develop over the subsequent 24 hours. Other high-risk indicators, such as recurrent ischemia or evidence of congestive heart failure, also indicate an early invasive strategy.[11,23] An early invasive strategy is also advised in patients with NSTE-ACS previously treated with CABG[11] and in patients who have had NSTE-ACS within 6 months of a previous PCI and in whom restenosis may be the cause.[23] Indications for an initial conservative strategy include patients with life-threatening comorbid conditions or in whom the risks outweigh the potential benefits, and in low-risk patients without recurrent symptoms.[11,23]

Timing of an Invasive Approach

A meta-analysis of four trials involving 4013 patients with NSTE-ACS compared an early invasive strategy (time to angiography, 1.2 to 14 hours following hospital presentation) with a delayed invasive strategy (time to angiography, 21 to 86 hours). Mortality and MI rates in the two strategies did not differ,[116] but the early invasive approach was associated with significant reductions in recurrent ischemia (41%) and duration of hospital stay (28%) and with favorable trends with respect to bleeding and the composite of CV death, MI, or stroke. These findings were confirmed in a more recent study of NSTEMI patients in whom randomization to a strategy of immediate angiography (median, 1.4 hours from admission) followed by PCI, when appropriate, significantly reduced death or MI at 30 days (4.3 versus 13.0%; $P = 0.008$) compared to a delayed invasive strategy (median, 61 hours).[117] Although relatively uncommon (<3% incidence), patients who develop cardiogenic shock post-NSTEMI represent a particularly high-risk subgroup, with an in-hospital mortality of 35% in a U.S. national database of over 2.2 million patients admitted with NSTEMI.[118] The risk-adjusted mortality was reduced by more than 50% with an invasive strategy in these patients.

Predischarge Risk Stratification in Patients Managed With an Ischemia-Guided Strategy

In stable patients managed with an ischemia-guided strategy, noninvasive stress testing is recommended after at least 12 to 24 hours following the most recent symptoms.[11] Options include exercise testing (in patients without resting ST-segment abnormalities), exercise testing with imaging modalities in patients with ST-segment changes, or pharmacologic stress testing in patients unable to exercise. An additional benefit of imaging studies is the assessment of LV function, which should be ascertained in all patients with definite ACS.[11]

Percutaneous Coronary Intervention (See also Chapter 62)

Angiographic success (TIMI epicardial grade 2 or 3 flow) can be achieved in a large majority (95%) of

patients with NSTE-ACS who undergo PCI, even in those considered to be at high risk.[119] However, the development of intraprocedural complications, such as transient or sustained loss of a side branch, abrupt closure, distal embolization, or development of the no-reflow phenomenon, may entail a four- to fivefold increase in the risk for ischemic complications and death over the next 30 days.[119] Although use of drug-eluting stents (DESs) reduces the risk for restenosis, there is a risk for late stent thrombosis following DES implantation, especially when DAPT (i.e., ASA and $P2Y_{12}$ inhibitor) is discontinued. This serious complication can be reduced in the long term in patients with DESs, by continuing DAPT beyond 12 months after stenting.[109]

The newer stents coated with everolimus have demonstrated consistent benefits compared to earlier-generation stents coated with sirolimus or paclitaxel[120,121] and to bare-metal stents (BMSs).[122] Given reductions in stent thrombosis, restenosis, and other ischemic events following placement of an everolimus-eluting stent, the need for prolonged (≥12 months) DAPT is less clear, and shorter durations of DAPT may be possible. Ongoing innovation in stent technology (e.g., polymer-free drug-coated stents[123]) to reduce the risk of stent failure (e.g., bioabsorbable polymer-coated stents)[124] and the need for prolonged DAPT are being developed, but have not yet been tested in large numbers of patients with NSTE-ACS. Radial arterial access reduces bleeding compared to femoral access, achieves similar procedural and clinical success,[96] and should become the standard of care for patients with ACS undergoing coronary angiography.

Percutaneous Coronary Intervention Versus Coronary Artery Bypass Grafting

Several trials have compared PCI and CABG in patients with stable CHD, but no large studies have randomized patients with NSTE-ACS to different modes of revascularization. Based on the results from patients with stable CHD, CABG is recommended in patients with disease of the left main coronary artery (LMA), as well as for those with multivessel disease (involving all three major epicardial vessels or the proximal left anterior descending artery [LAD] plus a second artery) and an LV ejection fraction (EF) less than 40% and/or diabetes mellitus (DM). In a study of 1900 patients with DM and multivessel CAD (27% of whom had NSTE-ACS), when compared to PCI, CABG significantly reduced the composite endpoint of death, MI, or stroke.[125] However, as experience with multivessel and LMA PCI grows, an increasing number of nondiabetic patients with this more complex coronary anatomy may also be suitable for PCI. For other patients with less severe CAD, and with suitable coronary anatomy, although PCI is associated with slightly lower initial morbidity and mortality and lower rates of stroke than CABG,[125] it is associated with a higher need for repeat PCI[125-127] and somewhat less relief of angina.[128]

Both North American[11] and European[23] guidelines recommend using a “heart team” approach to guide decisions regarding revascularization that includes input from interventional cardiologists and cardiothoracic surgeon in patients with lLMA and complex CAD. Factors that favor CABG include multiple and complex coronary lesions, presence of DM, LV systolic dysfunction, and DAPT intolerance. Factors favoring PCI include high risk of operative mortality, prior thoracotomy, and advanced CKD.[11]

Lipid-Lowering Therapy (See Also Chapters 45 and 48)

In a meta-analysis of 13 randomized controlled trials (RCTs) involving 17,963 patients with ACS (a mixture of STEMI and NSTE-ACS), early (on average 4 days after admission), intensive statin therapy compared to control, usually placebo, decreased the rate of death and CV events over 2 years of follow-

up by 19%.[129] The benefit began to emerge between 4 and 12 months, achieving statistical significance by 12 months. The prespecified subgroup of 3260 patients with UA in the LIPID (Long-Term Intervention with Pravastatin in Ischemic Disease) trial experienced a 26% reduction in total mortality with pravastatin compared to placebo.[130] However, intensive statin (atorvastatin, 80 mg) was even more effective than pravastatin (40 mg) in the 2724 patients post-NSTE-ACS enrolled in the PROVE IT-TIMI 22 (Pravastatin or Atorvastatin Evaluation and Infection Therapy-Thrombolysis in Myocardial Infarction 22) trial,[131] reducing the composite of CV death, MACE, or stroke by 20% relative (5% absolute) over an average of 2 years of follow-up. Atorvastatin (80 mg) not only achieved a lower on-treatment LDL than pravastatin (40 mg) (mean, 62 versus 95 mg/dL), but was also more effective in reducing hsCRP (median, 1.3 versus 2.1 mg/dL), which may have also contributed to the early divergence of the event curves beginning at 2 weeks after randomization.[132]

More recently IMPROVE-IT (Improved Reduction of Outcomes: Vytorin Efficacy International Trial) for the first time demonstrated the added clinical benefit of adding a nonstatin therapy (*ezetimibe,* a cholesterol absorption inhibitor) to background statin therapy. In the overall trial population of 18,144 patients with ACS (71% of whom had NSTE-ACS), ezetimibe significantly reduced the risk of CV death, MACE, or stroke by 6.4% relative (2% absolute) at 7 years.[133] MI and stroke fell significantly by 13% and 21%, respectively. Specifically, in the 12,941 patients with NSTE-ACS at presentation, there was the same 2% absolute reduction in events with ezetimibe (36.6% versus 34.4%; number needed to treat [NNT] = 50).[133] Despite a low time-weighted average LDL-C during the trial (54 mg/dL with ezetimibe + simvastatin versus 70 mg/dL with placebo + simvastatin), ezetimibe was well tolerated with no increase in serious side effects.[133] On the basis of the IMPROVE-IT results, a recent Expert Consensus Decision Pathway[134] has recommended the use of ezetimibe in patients with ACS who (1) have a recurrent CV event despite maximally tolerated statin, (2) have an inadequate response to maximally tolerated statin, or (3) are intolerant of several statins. The benefits of ezetimibe were most prominent in post-ACS patients at high risk of MACE, including patients with DM and those older than 75 years.[133] An especially high-risk group were patients who developed an ACS despite having previously undergone CABG. In these patients, treatment patients managed with the standard of care, including simvastatin (40 to 80 mg), had a 60% rate of MACE or stroke at a median of 6 years, despite achieving an average LDL-C less than 70 mg/dL.[47] However, addition of ezetimibe (which reduced the LDL-C to 54 mg/dL on average) resulted in a 20% relative reduction in MACE (NNT = 11) (**Fig. 60.11**).

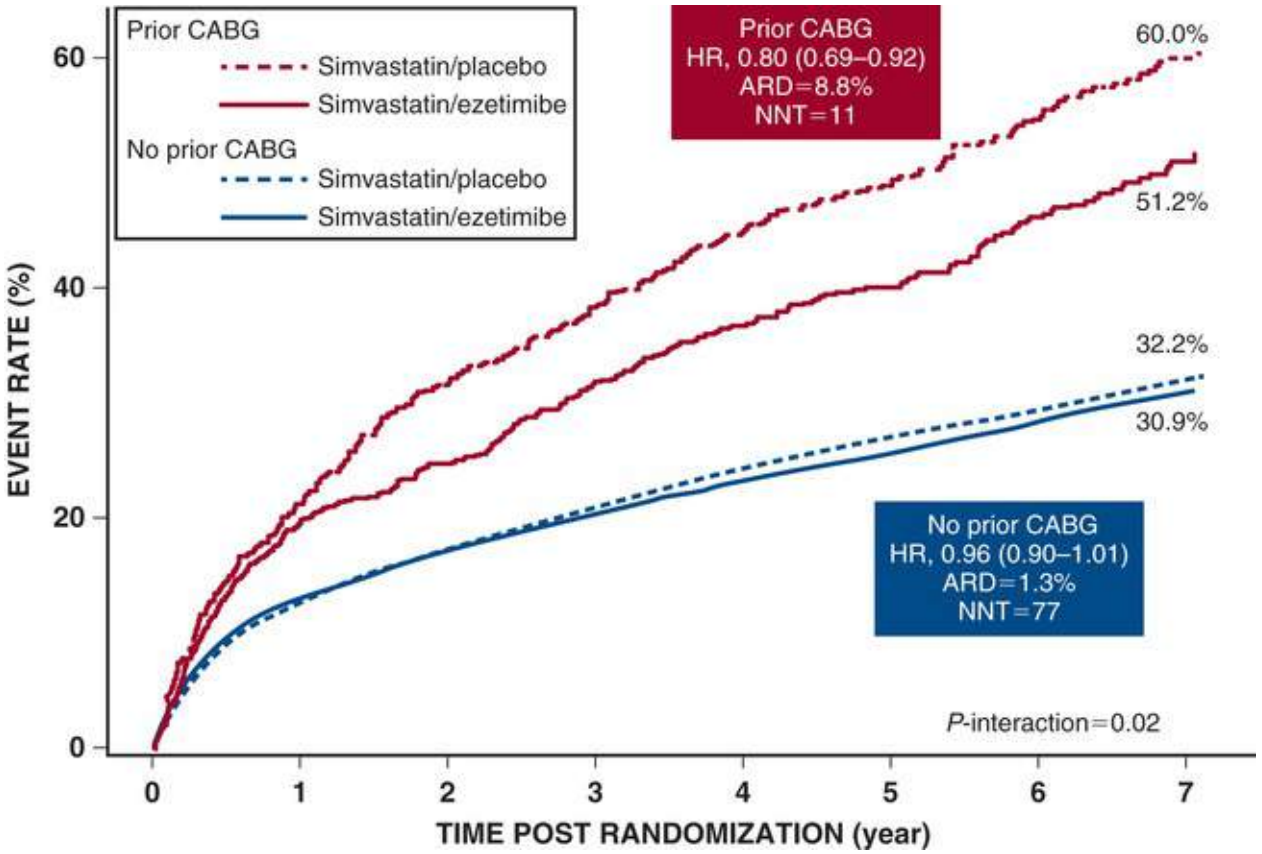

FIGURE 60.11 Benefit of ezetimibe in addition to statin in patients with acute coronary syndrome (ACS) and prior coronary artery bypass graft surgery (CABG). Shown are the cumulative event rates for the primary composite endpoint of death from cardiovascular (CV) disease, a major coronary event (nonfatal myocardial infarction, documented unstable angina requiring hospital admission, or coronary revascularization occurring at least 30 days after randomization), or nonfatal stroke in the intention-to-treat population during the overall study period in IMPROVE-IT. Patients with prior CABG are shown in *red* and those without prior CABG are in *blue*. Among patients with a prior CABG, ezetimibe reduced the primary CV composite endpoint by 20% relative to placebo. ARD, Absolute risk differences; HR, hazard ratio; NNT, number needed to treat. (From Eisen A, Cannon CP, Blazing MA, et al. The benefit of adding ezetimibe to statin therapy in patients with prior coronary artery bypass graft surgery and acute coronary syndrome in IMPROVE-IT. Eur Heart J 2016;37(48):3576-84.)

These findings underscore the importance of initiating intensive lipid-lowering therapy as soon as possible after admission with NSTE-ACS to achieve a 50% reduction in LDL-C.[23] Given the ongoing benefit seen during follow-up in the ACS trials as well as later divergence of the curves in patients with stable CHD, lipid-lowering therapy should be continued indefinitely, without reducing the dose in patients who are tolerating the therapy regardless of how low the LDL-C falls.[134a] An additional potential benefit of early high-intensity statin in patients with NSTE-ACS is protection from contrast-induced nephropathy. In 504 statin-naive patients with NSTE-ACS managed with an early invasive strategy, patients randomized to rosuvastatin (40 mg) at admission followed by 20 mg daily had a 62% relative reduction in contrast-induced acute kidney injury (6.7% versus 15.1%; $P = 0.003$) and fewer than half the number of adverse CV and renal events (3.6 versus 7.9%; $P = 0.04$) compared to placebo.[135]

Discharge and Posthospital Care

The time of hospital discharge following ACS affords a “teachable moment” for the patient, when the physician and staff can review and optimize the medical regimen for long-term treatment. Patients with NSTE-ACS and those with STEMI should receive secondary prevention approaches (**see Chapters 45, 54, and 59**).

Subgroups of Special Interest

Older Adults (See Also Chapter 88)

Patients age 75 or older have a higher incidence, prevalence, and rates of adverse outcomes of NSTE-ACS.[5,136,137] Advanced age is accompanied by a greater degree of comorbidity; age- and disease-related changes in physiology can affect pharmacokinetics/dynamics, volume of distribution, drug sensitivity; and polypharmacy (increasing the risk of drug-drug interactions), each of which poses additional challenges to the management of NSTE-ACS. Elderly patients are more likely to present with atypical symptoms (e.g., dyspnea rather than chest pain or discomfort), and with ECG abnormalities that are less diagnostic than those seen in younger patients.[138] Nevertheless, elderly patients with NSTE-ACS derive similar or even greater benefit from guideline-directed therapy than younger patients, yet, paradoxically, they are less likely to receive such proven therapies. Among the guideline therapies, several practical suggestions can reduce the risk of bleeding in the elderly patient, including (1) exclusive use of low-dose maintenance ASA, 75 to 100-mg; (2) selection of an ADP inhibitor other than prasugrel; (3) use of bivalirudin rather than UFH plus GP IIb/IIIa inhibitor; and (4) avoidance of abciximab if a GP IIb/IIIa inhibitor is needed to manage a peri-PCI thrombotic complication.[139]

In addition, it is critically important to dose-adjust therapies according to body weight and renal function to avoid excess dosing of antithrombotics in older patients, which can lead to excess bleeding.[23,140] Reliance on the serum creatinine alone may underestimate the true extent of renal dysfunction, since age contributes importantly to determining creatinine clearance. Guidelines recommend assessment of renal function in all patients at the time of ACS and during long-term follow-up at an interval in months equal to the CrCl (in mL/min) divided by 10 (e.g., for a CrCl of 30 mg/dL, reassess renal function in 30/10 = 3 months).[141]

Since older patients are more likely to have more severe and extensive CAD, they are more likely to have coronary anatomy amenable to revascularization than younger patients with NSTE-ACS. However, since elderly patients are at higher risk for procedural complications and bleeding, patients and physicians often exercise more caution regarding invasive procedures, resulting in lower rates of revascularization. A meta-analysis[142] of three randomized trials demonstrated a 29% reduction (HR, 0.71; 95% CI 0.55 to 0.91) in death or MI at 5 years in patients age 75 or older with an early invasive strategy. More recently, a randomized trial of 457 patients 80 or older (median 85) demonstrated a 47% reduction (HR, 0.53; 95% CI 0.41 to 0.69) in the composite of MI, need for urgent revascularization, stroke, and death over a median follow-up of 1.5 years with an early invasive strategy versus a conservative strategy (optimum medical treatment alone).[143] Barring comorbidities that prove to be contraindications, advanced age should not deter otherwise-indicated comprehensive treatment of NSTE-ACS, including the use of an early invasive strategy and revascularization.[11] An approach in the elderly patient that carefully considers the potential risks and benefits, estimated life expectancy, comorbidities, quality of life, frailty, and patient values and preferences is recommended.[23]

Women (See Also Chapter 89)

Cardiovascular disease is the leading cause of death in women in the United States[5] and worldwide.[4] Since 1984, the annual mortality rate for CVD has been higher for women than men, yet CVD remains understudied, underdiagnosed, and undertreated in women.[144] Similar to older patients with NSTE-ACS, when compared to men, women are more likely to present with atypical symptoms[137] and to have more

comorbidities,[114,145] and are less likely to be referred for cardiac testing, including coronary angiography.[137,145] However, younger women, in contrast to men and older women, are more likely to have nonatherosclerotic causes of angina, such as microvascular dysfunction and abnormal vascular reactivity. In addition, the biochemical profile of women with NSTE-ACS differs from men in that women are more likely to have abnormal BNP and hsCRP levels and less likely to have an elevated troponin assay. Nevertheless, women with NSTE-ACS should receive the same pharmacologic therapy as men in both the acute care and the secondary prevention phase, and women with NSTE-ACS with high-risk features should undergo an early invasive strategy.[11] In contrast, low-risk women with NSTE-ACS should not routinely undergo an early invasive strategy because of the lack of benefit and potential for harm. In a pooled analysis of 3550 patients with NSTE-ACS from eight trials, women are more likely than men to have nonobstructive CAD on coronary angiography.[40] Although rates of MACE are lower in patients with nonobstructive disease compared to those with obstructive CAD, they are not negligible (16% at 5 years in women participating in the WISE registry[146]), and therefore secondary preventive measures should not be withheld in either women or men with nonobstructive CHD.

Because women on average have lower body weight and are older than their male counterparts, they are more likely to have impaired renal function and are at greater risk for excess dosing of antithrombotic therapies that require renal dose adjustment. Although older studies showed that women had higher rates of contrast-induced nephropathy (CIN) and vascular complications than men, recent data from the MATRIX study demonstrated a similar advantage of radial over femoral arterial access in women as in men.[96] Furthermore, analyses from ACS registries suggest that the poorer early outcomes in women were associated with lower rates of evidence-based care than men.[136] Women are also more likely to experience adverse cardiovascular outcomes after discharge and to experience higher rates of readmission for angina.[147] This may in part be explained by the lower rates of evidence-based therapies (beta blockers, statins, ACE inhibitors) in women, particularly women younger than 55.[148] Thus, strategies to promote guideline adherence and greater awareness of the similar CV risk in patients with NSTE-ACS, regardless of sex, are needed.[144]

Diabetes Mellitus and Glucose Intolerance (See Also Chapter 51)

More than 30 million Americans live with DM, and another 84 million have prediabetes.[149] The prevalence of diagnosed DM in adults age 65 and older was 26% in 2012, and an additional 51% (>20 million) had prediabetes based on fasting glucose, oral glucose tolerance testing (OGTT), or HbA_{1c}. CHD causes 75% of deaths in patients with DM.

Since more than 30% of patients with NSTE-ACS have DM and such patients have higher rates of adverse CV outcomes,[150] all patients presenting with NSTE-ACS should be screened for DM during hospitalization. Patients with known DM or glucose intolerance should receive the medical therapies established in those with normal glucose metabolism, and in addition, should have frequent glucose monitoring through discharge. Glucose-lowering therapies should be considered in most patients with blood glucose greater than 180 mg/dL, while avoiding hypoglycemia (<90 mg/dL), because there is a U-shaped relationship between glucose levels and outcomes in patients with DM and ACS. Patients with DM have a blunted response to standard antiplatelet regimens, including clopidogrel and ASA.[151] Subgroup analyses comparing outcomes in patients with and without DM have suggested incrementally greater benefit of some more potent antiplatelet agents, including prasugrel[72] and GP IIb/IIIa inhibitors, in

patients with DM.

With regard to revascularization, the ESC NSTE-ACS guidelines[23] recommend an early invasive strategy and a preference for CABG over PCI in patients with DM and complex (e.g., multivessel or LMA) CAD.[125] When PCI is selected, a newer-generation DES should be employed.[63] Renal function should be closely monitored for 2 to 3 days after coronary angiography or PCI in patients with renal dysfunction or who are treated with metformin. If renal function deteriorates, metformin should be held for at least 48 hours until renal function improves.

A pooled analysis of 15,459 patients with NSTE-ACS enrolled in 11 TIMI trials demonstrated that DM is associated independently with higher risk of mortality at 30 days (HR, 1.78; 95% CI 1.24 to 2.56) and at 1 year (HR, 1.65; 95% CI 1.30 to 2.10).[152] This increased risk also extended to patients with undiagnosed DM and those with newly identified glucose intolerance.[153] Despite poorer outcomes, patients with DM and NSTE-ACS are less likely to receive guideline-directed therapies and revascularization.[150]

Chronic Kidney Disease (See Also Chapter 98)

In 2017, the prevalence of CKD had increased to 15% (>30 million) of the adults in the United States.[154] Patients with impaired renal function and NSTE-ACS are older on average and more likely to have additional comorbid conditions, including DM, peripheral arterial disease (PAD), and HF. Thus, they have increased risk for recurrent ischemic events,[155] including stent thrombosis and post-PCI ischemic events,[156] and for treatment complications;[157] are underrepresented in clinical trials; and are often undertreated in clinical practice.[155,157,158] All patients admitted with NSTE-ACS should have renal function measured at presentation to permit informed decisions regarding management and proper dosing of antithrombotic agents.

Data on patients with advanced CKD (stages IV or V) and ACS are limited as most randomized trials excluded patients with CrCl less than 30 mL/min or estimated glomerular filtration rate (eGFR) less than 30 mL/min/1.73 m^2. A meta-analysis of five trials of 1453 patients with NSTE-ACS and CKD (all with eGFR <60 mL/min/1.73 m^2) demonstrated favorable trends in all-cause mortality, the composite of death or nonfatal MI, and rehospitalization with an early invasive strategy compared to conservative management.[113] Thus, coronary angiography should be considered in patients with CKD, and the benefits of prompt revascularization should be weighed against the risks of bleeding and CIN. In patients with CKD undergoing PCI, newer-generation DESs are preferred over BMSs.[23] In patients with multivessel CHD, acceptable surgical risk, and life expectancy longer than 1 year, CABG is preferred over PCI, whereas in patients with high surgical risk or shorter life expectancy, PCI is recommended.[23]

Patients with CKD have a greater risk of bleeding because of impaired platelet function and excess dosing with antithrombotic therapy[159] (**Table 98.5**). In patients with CKD, the dosage of renally cleared medications requires adjustment; such medications include enoxaparin, bivalirudin, eptifibatide, and tirofiban. In addition, patients with CKD have increased risk for CIN following angiography and revascularization. Current guidelines recommend that the risk for CIN be assessed by measurement of the ratio of contrast volume to eGFR and that this ratio not exceed 3.7.[63] Adequate hydration with isotonic saline from 12 hours before to 24 hours after dye exposure is essential.

Heart Failure

Both the AHA/ACC[11] and ESC[23] guidelines provide specific new recommendations regarding patients

with NSTE-ACS complicated by heart failure (HF). An early invasive approach is recommended if possible because these patients are at increased risk of major morbidity and death, and revascularization, particularly CABG, improves outcomes.[160,161] Echocardiography is recommended prior to coronary angiography to evaluate LV systolic function, extent and degree of wall motion abnormalities, and associated valvular dysfunction and to identify possible mechanical complications. The revascularization strategy should be determined by coronary anatomy, degree of LV and valvular dysfunction, comorbidities, and surgical risk. In patients with prior CABG or anatomy not suitable for CABG, PCI may be considered. If there is a large territory of myocardial ischemia and severe LV systolic dysfunction, LV support (e.g., percutaneous ventricular assist devices) may be necessary for hemodynamic support peri-PCI.[162]

Although cardiogenic shock is less common in patients with NSTEMI-ACS than in STEMI patients, in NSTEMI the shock tends to occur later in the hospitalization and in patients with more comorbidities, extensive CAD, and recurrent ischemia/infarction. When possible, early revascularization with PCI is recommended to improve chances of survival; emergency CABG is recommended if the coronary anatomy is not suitable for PCI. Short-term use of mechanical circulatory support should be considered in patients with hemodynamic instability caused by mechanical complications. However, routine use of intra-aortic balloon counterpulsation in patients without mechanical complications is not recommended, given the lack of proven benefit.[163] A percutaneous LV assist device (LVAD) may be considered in select patients as a bridge to cardiac transplantation or to an implanted LVAD.[164] Patients who emerge from the acute episode stable, but with persistent LV systolic dysfunction, should receive management as outlined in **Chapter 25**.

Prinzmetal Variant Angina

In 1959, Prinzmetal and colleagues described a syndrome of ischemic pain that occurred at rest, accompanied by ST-segment elevation.[165] Prinzmetal variant angina (PVA) may be associated with acute MI, VT or VF, and sudden cardiac death (SCD). Spasm of a proximal coronary artery with resultant transmural ischemia and abnormalities in LV function are the diagnostic hallmarks of PVA. Patients with PVA tend to be younger than those with NSTE-ACS attributable to coronary atherosclerosis, and many do not exhibit the classic coronary risk factors, except they are frequently heavy cigarette smokers. Angina is often extremely severe, tends to cluster between midnight and 8 AM, and may be accompanied by syncope related to AV block,[166] asystole, or ventricular tachyarrhythmia.[167] Increased QT dispersion appears to be a risk marker for SCD in these patients.

Approximately one third of patients with PVA also exhibit severe fixed coronary obstruction and may have a combination of exertion-induced angina with ST-segment depression and episodes of angina at rest with ST-segment elevation.[168] Rarely, PVA appears to be a manifestation of a generalized vasospastic disorder associated with migraine and/or Raynaud phenomenon. PVA can also develop in association with aspirin-induced asthma and administration of 5-fluorouracil and cyclophosphamide. The ergot derivatives used to treat migraine headache and serotonin antagonists used to treat depression can precipitate episodes of PVA. The incidence of PVA has always been greater in Japan than in Western countries, but across the world, the incidence appears to have fallen markedly over the past three decades, possibly related in part to the widespread use of calcium antagonists.

The key to diagnosis of PVA lies in the detection of episodic ST-segment elevation, often accompanied by severe chest pain, usually occurring at rest. Multiple asymptomatic episodes of (silent) ST-segment elevation occur in many patients. ST-segment deviations may be present in any leads, depending on the artery involved. Patients with no or mild fixed coronary obstruction tend to experience a more benign course than do patients with PVA and associated severe obstructive lesions.[167]

Three provocative tests for coronary spasm can be performed at coronary angiography—hyperventilation, intracoronary acetylcholine, and intracoronary ergonovine—although the third test is no longer available in the United States. Acetylcholine, according to a fixed protocol, is now most widely used.[169] These provocative maneuvers should be used only in patients without obstructive CHD and in whom PVA is suspected, but not yet confirmed. Their use has been declining over the past three decades, in part related to the induction of rare but sometimes fatal arrhythmias.

Management.

Patients with PVA should be strongly urged to discontinue smoking. The mainstay of therapy is a calcium antagonist, alone or preferably in combination with a long-acting nitrate. Sublingual or IV nitroglycerin often abolishes attacks of PVA promptly, while the long-acting nitrates are useful in preventing attacks. The response to beta blockade in patients with PVA is variable. Some patients, particularly those with associated fixed obstructions, show a reduction in the frequency of exertion-induced angina caused primarily by augmentation of myocardial oxygen requirements. In others, however, nonselective beta-blocking agents may actually be detrimental because blockade of $beta_2$ receptors, which mediate coronary dilation, may allow unopposed alpha receptor–mediated coronary vasoconstriction. In a study of 640 Japanese patients with vasospastic angina confirmed by acetylcholine provocation testing and no significant coronary stenosis, statin therapy significantly reduced the risk of MACE.[170] Prevention of plaque formation or progression may explain part of the benefit of statins, but the pleiotropic effects of statins, such as the amelioration of endothelial dysfunction, suppression of inflammation, and inhibition of the Rho A/Rho-kinase pathway, may also pertain.

PCI and occasionally CABG may be indicated in patients with PVA associated with discrete, proximal, fixed obstructive lesions, but revascularization is contraindicated in patients with isolated coronary artery spasm without accompanying fixed obstructive disease. Patients who have experienced ischemia-associated VF and continue to manifest ischemic episodes despite maximal medical treatment should receive an implantable cardioverter-defibrillator (ICD).

Many patients with PVA pass through an acute, active phase, with frequent episodes of angina and cardiac events occurring during the first 6 months after diagnosis. The extent and severity of the underlying CAD and the tempo of the syndrome have a major effect on the incidence of late mortality and MI. Remission occurs more frequently in patients without significant fixed coronary artery stenoses and in those who have discontinued smoking. For unclear reasons, some patients, after a relatively quiescent period of months or even years, experience a recrudescence of vasospastic activity with frequent and severe episodes of ischemia. Fortunately, these patients generally respond to retreatment with calcium antagonists and nitrates. Clinical outcomes are excellent in patients with isolated coronary spasm and no underlying CAD, with no cardiac death or MI occurring in 76 patients monitored for 3 years in the CASPAR (Coronary Artery Spasm in Patients with Acute Coronary Syndrome) study, although about half these patients experienced angina frequently.[171]

Cardiac Syndrome X (See Also Chapter 89)

Approximately 15% of patients with NSTE-ACS have no obstructive epicardial coronary artery disease,

although they may have electrocardiographic evidence of myocardial ischemia. This condition is sometimes still referred to as “cardiac syndrome X.” It must be distinguished from metabolic syndrome (**see Chapter 45**).

Cocaine and Amphetamines (See Also Chapter 80)

Cocaine use causes a marked increase in sympathetic tone by blocking the reuptake of norepinephrine from synapses by preganglionic neurons, thereby resulting in increased myocardial oxygen demand and decreased supply. This may cause acute myocardial ischemia and may manifest as ACS. This condition, which has similar findings as amphetamine abuse, occurs more frequently in younger persons and should be especially considered in males younger than 30 years.[172] The use of psychoactive “street” drugs known as “bath salts” that contain synthetic cathinones with cocaine-like actions may also cause CV complications, including ACS.[173]

Patients with NSTE-ACS and a recent history of cocaine or methamphetamine use should be treated similar to those without recent stimulant use, except that patients with signs of acute intoxication (e.g., euphoria, tachycardia, hypertension) should not receive beta blockers because of the risk of coronary spasm.[11] Vasodilators and CCBs are preferred agents, and benzodiazepines alone or in combination with nitroglycerin may also be used to manage hypertension.

Future Perspectives

NSTE-ACS is a heterogeneous syndrome, not a specific disease. Subgroups of patients who respond to specific therapies should be identified. Specifically, there is considerable variation in the responses to antiplatelet agents and anticoagulants, in terms of both efficacy and safety. Efforts should be elevated to identify predictors of responses to these agents. In addition to phenotypic subgroups of patients with NSTE-ACS, the “omics” technologies, especially genomics, proteomics, and metabolomics, will play critically important roles in this effort. For example, the inflammatory biomarker hsCRP is used to identify patients with NSTE-ACS with active or persistent inflammation. These patients are at substantially high risk of recurrent ACS and should receive intensive secondary prevention. Since inflammation appears to play a key role in the development of unstable atherosclerotic plaques, the use of potent anti-inflammatory agents that can be administered safely over prolonged periods in patients at high risk of plaque disruption should be considered. Two large trials of anti-inflammatory drugs—canakinumab, which blocks interleukin-1,[174] a proinflammatory cytokine, and methotrexate[175]—are now underway. Colchicine is another anti-inflammatory drug that is useful in the treatment of acute pericarditis and should also be tested in NSTE-ACS. **Table 60.6** summarizes important additional unanswered questions regarding NSTE-ACS.

TABLE 60.6

Key Unanswered Questions in Non–ST Elevation Acute Coronary Syndromes (NSTE-ACS)

Pathophysiology
• Will superficial plaque erosion continue to rise to become the dominant pathophysiology? • Should patients be treated differently based on their underlying pathophysiology? • What are the critical determinants that cause one vulnerable plaque to cause a clinical event but another vulnerable plaque to be silent and heal?
Diagnosis
• What will be the role of concomitant use of coronary computed tomographic angiography and high-sensitivity troponin (hsTn) assays in evaluating patients with suspected ACS? • Will shorter rule-out algorithms with hsTn assays improve patient outcomes? • What will be the role of genetic testing to individualize treatment and improve patient outcomes?
Acute Treatment
• What is the preferred antithrombotic regimen peri-PCI? • What is the optimal combination of and timing for administering high-potency lipid-lowering therapies? • What is the optimal timing and dosing for administering beta blockers? • What is the optimal timing of oral antiplatelet administration in patients undergoing an early invasive strategy? • What are the indications for and timing of revascularization of obstructed nonculprit lesions? • What is the role of FFR-guided PCI? • What are the contemporary benefits of CABG versus PCI in patients with multivessel disease? • Will novel pharmacologic and mechanical circulatory support strategies improve survival in patients with cardiogenic shock? • What is the desired hemoglobin level, and what is the optimal timing for blood transfusion?
Chronic Treatment
• What is the optimal duration and regimen of antiplatelet therapy, and how does this differ if an oral anticoagulant is needed? • Will newer-generation stents allow shortening of the duration of antiplatelet therapy? • Can dual-antiplatelet therapy be replaced by a single potent $P2Y_{12}$ inhibitor? • What is the role of PCSK9 inhibitors in patients admitted with ACS?
Prognosis and Secondary Prevention
• Can we improve prediction of the risk of sudden cardiac death and identify who might benefit more from prevention strategies? • How can the rate of recurrent ischemic cardiovascular events be further reduced? • What is the role of cardiac regenerative medicine in patients with left ventricular dysfunction after MI?

Guidelines

Non–ST Elevation Acute Coronary Syndromes

Robert P. Giugliano and Eugene Braunwald

In 2014 the American Heart Association (AHA) and American College of Cardiology (ACC) issued a new guideline on the Management of Patients with Non–ST Elevation Acute Coronary Syndromes (NSTE-ACS).[1] The European Society of Cardiology (ESC) guideline on the same topic followed in 2015.[2] These guidelines cover the entire spectrum of issues related to management of patients with NSTE-ACS, including definitions, pathophysiology, epidemiology, diagnosis, risk assessment, biomarkers, treatment, and quality of care. New to this pair of guidelines are sections on additional high-risk groups, performance measures, registries, and gaps in evidence. This chapter uses the standard system—class of recommendation (COR) I to III, level of evidence (LOE): A to C—to summarize the key recommendations for the management of patients with NSTE-ACS from the 2014 AHA/ACC 2014 guideline.[1]

Initial Evaluation

The initial evaluation of patients with suspected ACS should incorporate features of the patient's history, risk factors, symptoms, electrocardiographic findings, and troponin to identify the likelihood of ACS and help guide the diagnosis (**Fig. 60G.1**).

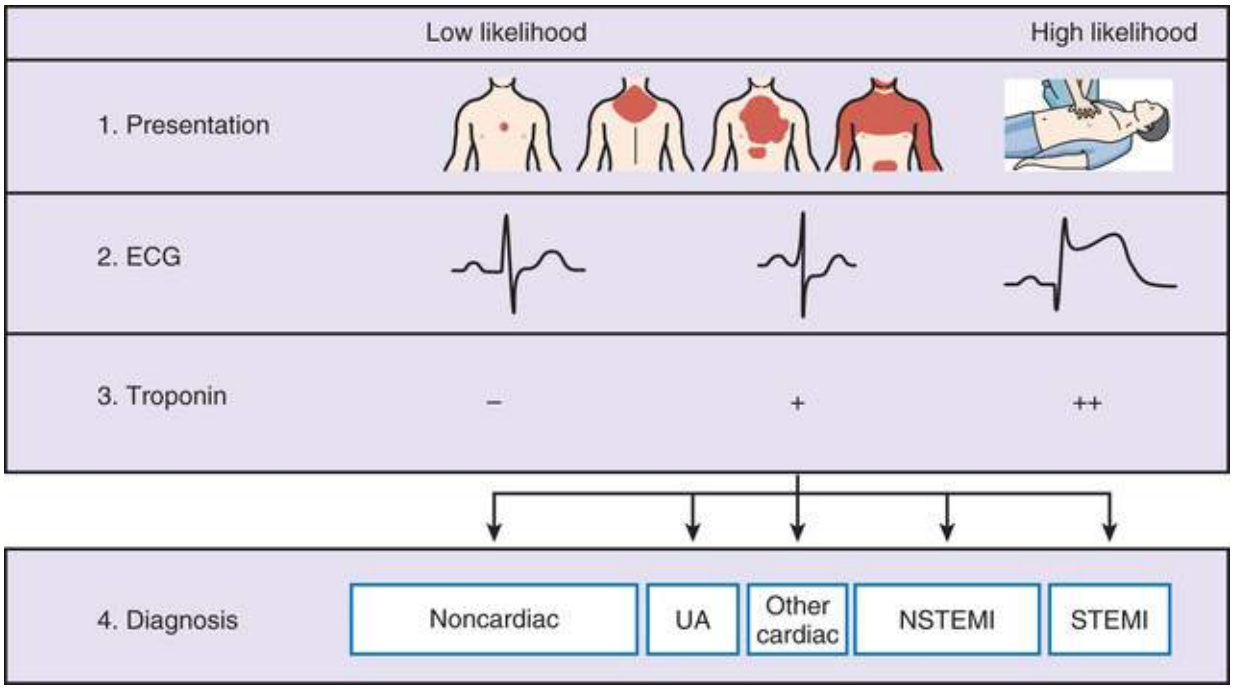

FIGURE 60G.1 Initial assessment of patients with suspected acute coronary syndrome (ACS). The initial assessment is based on the integration of low-likelihood and/or high-likelihood features derived from the clinical presentation (i.e., symptoms, vital signs), 12-lead ECG, and cardiac troponin. The proportion of the final diagnoses derived from the integration of these parameters is visualized by the size of the respective boxes. "Other cardiac" includes myocarditis, takotsubo cardiomyopathy, tachyarrhythmias, and a variety of addition noncoronary cardiac diagnoses (**see Table 60.2**). "Noncardiac" refers to thoracic diseases such as pneumonia or pneumothorax. Cardiac troponin should be interpreted as a quantitative marker; the higher the level, the higher the likelihood for the presence of myocardial infarction. In patients presenting with cardiac arrest or hemodynamic instability of presumed cardiovascular origin, echocardiography should be performed and interpreted by trained physicians immediately following a 12-lead ECG. If the initial evaluation suggests aortic dissection[11] or pulmonary embolism,[12] other diagnostic studies (e.g., computed tomographic angiography) are recommended. STEMI, ST-elevation myocardial infarction; NSTEMI, non–ST elevation myocardial infarction; UA, unstable angina. (From Roffi M, Patrono C, Collet JP, et al. 2015 ESC guidelines for the management of acute coronary syndromes in patients presenting without persistent ST-segment elevation. Task Force for the Management of Acute Coronary Syndromes in Patients Presenting without Persistent ST-Segment Elevation of the European Society of Cardiology. Eur Heart J 2016;37:267-315.)

Early Risk Stratification

AHA/ACC Class I Recommendations[1]

1. In patients with chest pain or other symptoms suggestive of ACS, a 12-lead ECG should be performed and evaluated for ischemic changes within 10 minutes of the patient's arrival at an emergency facility (LOE: C).
2. If the initial ECG is not diagnostic but the patient remains symptomatic and there is a high clinical suspicion for ACS, serial ECGs (e.g., 15- to 30-minute intervals during the first hour) should be performed to detect ischemic changes (LOE: C).
3. Serial cardiac troponin I or T levels (when a contemporary assay is used) should be obtained at presentation and 3 to 6 hours (1 to 3 hours if hsTn) after symptom onset in all patients who present with symptoms consistent with ACS, to identify a rising and/or falling pattern of values (LOE: A).
4. Additional troponin levels should be obtained beyond 6 hours after symptom onset in patients with normal troponin levels on serial examination when changes on ECG and/or clinical

presentation confer an intermediate or high index of suspicion for ACS (LOE: A).

5. The presence and magnitude of troponin elevations are useful for short- and long-term prognosis (LOE: B).
6. Risk scores should be used to assess prognosis in patients with NSTE-ACS (LOE: A).

Early Hospital Care

The key recommendations from the AHA/ACC[1] for standard medical therapies during the early hospital care phase are summarized in **Table 60G.1**. These therapies include oxygen, nitrates, morphine, antithrombotic therapy, beta blockers, calcium channel blockers (CCBs), and high-intensity statins.

TABLE 60G.1

Summary of Recommendations for Standard Medical Therapy in the Early Hospital Care Phase of Management of Patients with Non–ST Elevation Acute Coronary Syndromes (NSTE-ACS)

RECOMMENDATIONS	COR	LOE
Oxygen		
Administer supplemental oxygen only with oxygen saturation <90%, respiratory distress, or other high-risk features for hypoxemia.	I	C
Nitrates		
Administer sublingual NTG every 5 min × 3 for continuing ischemic pain and then assess need for IV NTG.	I	C
Administer IV NTG for persistent ischemia, HF, or hypertension.	I	B
Nitrates are contraindicated with recent use of a phosphodiesterase inhibitor.	III: Harm	B
Analgesic Therapy		
IV morphine sulfate may be reasonable for continued ischemic chest pain despite maximally tolerated anti-ischemic medications.	IIb	B
NSAIDs (except aspirin) should not be initiated and should be discontinued during hospitalization for NSTE-ACS because of the increased risk of MACE associated with their use.	III: Harm	B
Beta-Adrenergic Blockers		
Initiate oral beta blockers within the first 24 hr in the absence of HF, low-output state, risk for cardiogenic shock, or other contraindications to beta blockade.	I	A
Use of sustained-release metoprolol succinate, carvedilol, or bisoprolol is recommended for beta-blocker therapy with concomitant NSTE-ACS, *stabilized* HF, and reduced systolic function.	I	C
Reevaluate to determine subsequent eligibility in patients with initial contraindications to beta blockers.	I	C
It is reasonable to continue beta-blocker therapy in patients with normal LV function with NSTE-ACS.	IIa	C
IV beta blockers are potentially harmful when risk factors for shock are present.	III: Harm	B
Calcium Channel Blockers (CCBs)		
Administer initial therapy with nondihydropyridine CCBs with recurrent ischemia and contraindications to beta blockers in the absence of LV dysfunction, increased risk for cardiogenic shock, PR interval >0.24 sec, or second- or third-degree atrioventricular block without a cardiac pacemaker.	I	B
Administer oral nondihydropyridine calcium antagonists with recurrent ischemia after use of beta blocker and nitrates in the absence of contraindications.	I	C
CCBs are recommended for ischemic symptoms when beta blockers are not successful, are contraindicated, or cause unacceptable side effects.*	I	C
Long-acting CCBs and nitrates are recommended for patients with coronary artery spasm.	I	C
Immediate-release nifedipine is contraindicated in the absence of a beta blocker.	III: Harm	B
Cholesterol Management		
Initiate or continue high-intensity statin therapy in patients with no contraindications.	I	A
Obtain a fasting lipid profile, preferably within 24 hr.	IIa	C

*Short-acting dihydropyridine calcium channel antagonists should be avoided.

COR, Class of recommendation; *HF,* heart failure; *IV,* intravenous; *LOE,* level of evidence; *LV,* left ventricular; *MACE,* major adverse cardiovascular events; *N/A,* not available; *NSAIDs,* nonsteroidal anti-inflammatory drugs; *NTG,* nitroglycerin.

Initial Antithrombotic Therapy

Once the diagnosis of ACS has been established, patients should be promptly treated with an anticoagulant, aspirin, and in the majority of patients, a $P2Y_{12}$ inhibitor (**Table 60G.2**). Important

differences exist between clopidogrel and the newer $P2Y_{12}$ inhibitors, prasugrel and ticagrelor (**Table 60G.3**). Cangrelor is an intravenous $P2Y_{12}$ inhibitor with rapid onset and offset now approved for use in patients undergoing PCI.

TABLE 60G.2

Summary of Recommendations for Antithrombotic Therapy

RECOMMENDATIONS	DOSING, SPECIAL CONSIDERATIONS	COR	LOE
Aspirin			
Non–enteric-coated aspirin to all patients promptly after presentation	162-325 mg	I	A
Aspirin maintenance dose continued indefinitely	81-325 mg/day*	I	A
$P2Y_{12}$ Inhibitors			
Clopidogrel loading dose followed by daily maintenance dose in patients unable to take aspirin	75 mg	I	B
$P2Y_{12}$ inhibitor, in addition to aspirin, for up to 12 mo for patients treated initially with either an early invasive or initial ischemia-guided strategy:		I	B
• Clopidogrel	300- or 600-mg loading dose, then 75 mg/day		
• Ticagrelor	180-mg loading dose, then 90 mg twice daily		
$P2Y_{12}$ inhibitor therapy (clopidogrel, prasugrel, or ticagrelor) continued for at least 12 mo in post-PCI patients treated with coronary stents	N/A	I	B
Ticagrelor in preference to clopidogrel for patients treated with an early invasive or ischemia-guided strategy	N/A	IIa	B
Glycoprotein (GP) IIb/IIIa Inhibitors			
GP IIb/IIIa inhibitor in patients treated with an early invasive strategy and DAPT with intermediate/high-risk features (e.g., positive troponin)	Preferred options are eptifibatide or tirofiban	IIb	B
Parenteral Anticoagulant and Fibrinolytic Therapy			
SC enoxaparin for duration of hospitalization or until PCI is performed	1 mg/kg SC every 12 hr (reduce dose to 1 mg/kg/day SC in patients with CrCl <30 mL/min) Initial 30-mg IV loading dose in select patients	I	A
Bivalirudin until diagnostic angiography or PCI is performed in patients with early invasive strategy only	Loading dose 0.10 mg/kg loading dose followed by 0.25 mg/kg/hr Only provisional use of GP IIb/IIIa inhibitor in patients also treated with DAPT	I	B
SC fondaparinux for the duration of hospitalization or until PCI is performed	2.5 mg SC daily	I	B
Administer additional anticoagulant with anti-IIa activity if PCI is performed while patient is on fondaparinux	N/A	I	B
IV UFH for 48 hr or until PCI is performed	Initial loading dose 60 IU/kg (max 4000 IU) with initial infusion 12 IU/kg/hr (max 1000 IU/hr) Adjusted to therapeutic APTT range	I	B
IV fibrinolytic treatment not recommended in patients with NSTE-ACS	N/A	III: Harm	A

*The recommended maintenance dose of aspirin to be used with ticagrelor is 81 mg daily.[10]

Administration	Oral	Oral	Oral	Intravenous
Dose	300-600 mg orally, then 75 mg/day	60 mg orally, then 10 mg/day	180 mg orally, then 90 mg twice daily	30-μg/kg bolus and 4-μg/kg/min infusion
Dosing in chronic kidney disease (CKD)				
• Stage 3 (eGFR 30-59)	No dose adjustment	No dose adjustment	No dose adjustment	No dose adjustment
• Stage 4 (eGFR 15-29)	No dose adjustment	No dose adjustment	No dose adjustment	No dose adjustment
• Stage 5 (eGFR <15)	Use only for selected indications (e.g., stent thrombosis prevention)	Not recommended	Not recommended	No dose adjustment
Binding reversibility	Irreversible	Irreversible	Reversible	Reversible
Activation	Prodrug, with variable liver metabolism	Prodrug, with predictable liver metabolism	Active drug with additional active metabolite	Active drug
Onset of loading dose effect[a]	2-6 hr[b]	30 min[b]	30 min[b]	2 min
Duration of effect	3-10 days	7-10 days	3-5 days	1-2 hr
Withdrawal before surgery	5 days[c]	7 days[c]	5 days[e]	1 hr
Plasma half-life of active $P2Y_{12}$ inhibitor[d]	30-60 min	30-60 min[e]	6-12 hr	5-10 min
Inhibition of adenosine reuptake	No	No	Yes	Yes ("inactive" metabolite only)

[a]50% inhibition of ADP-induced platelet aggregation.

[b]Onset of effect may be delayed if intestinal absorption is delayed (e.g., by opiates).

[c]Shortening may be considered if indicated by platelet function tests and low bleeding risk.

[d]Affecting the response to platelet transfusion.

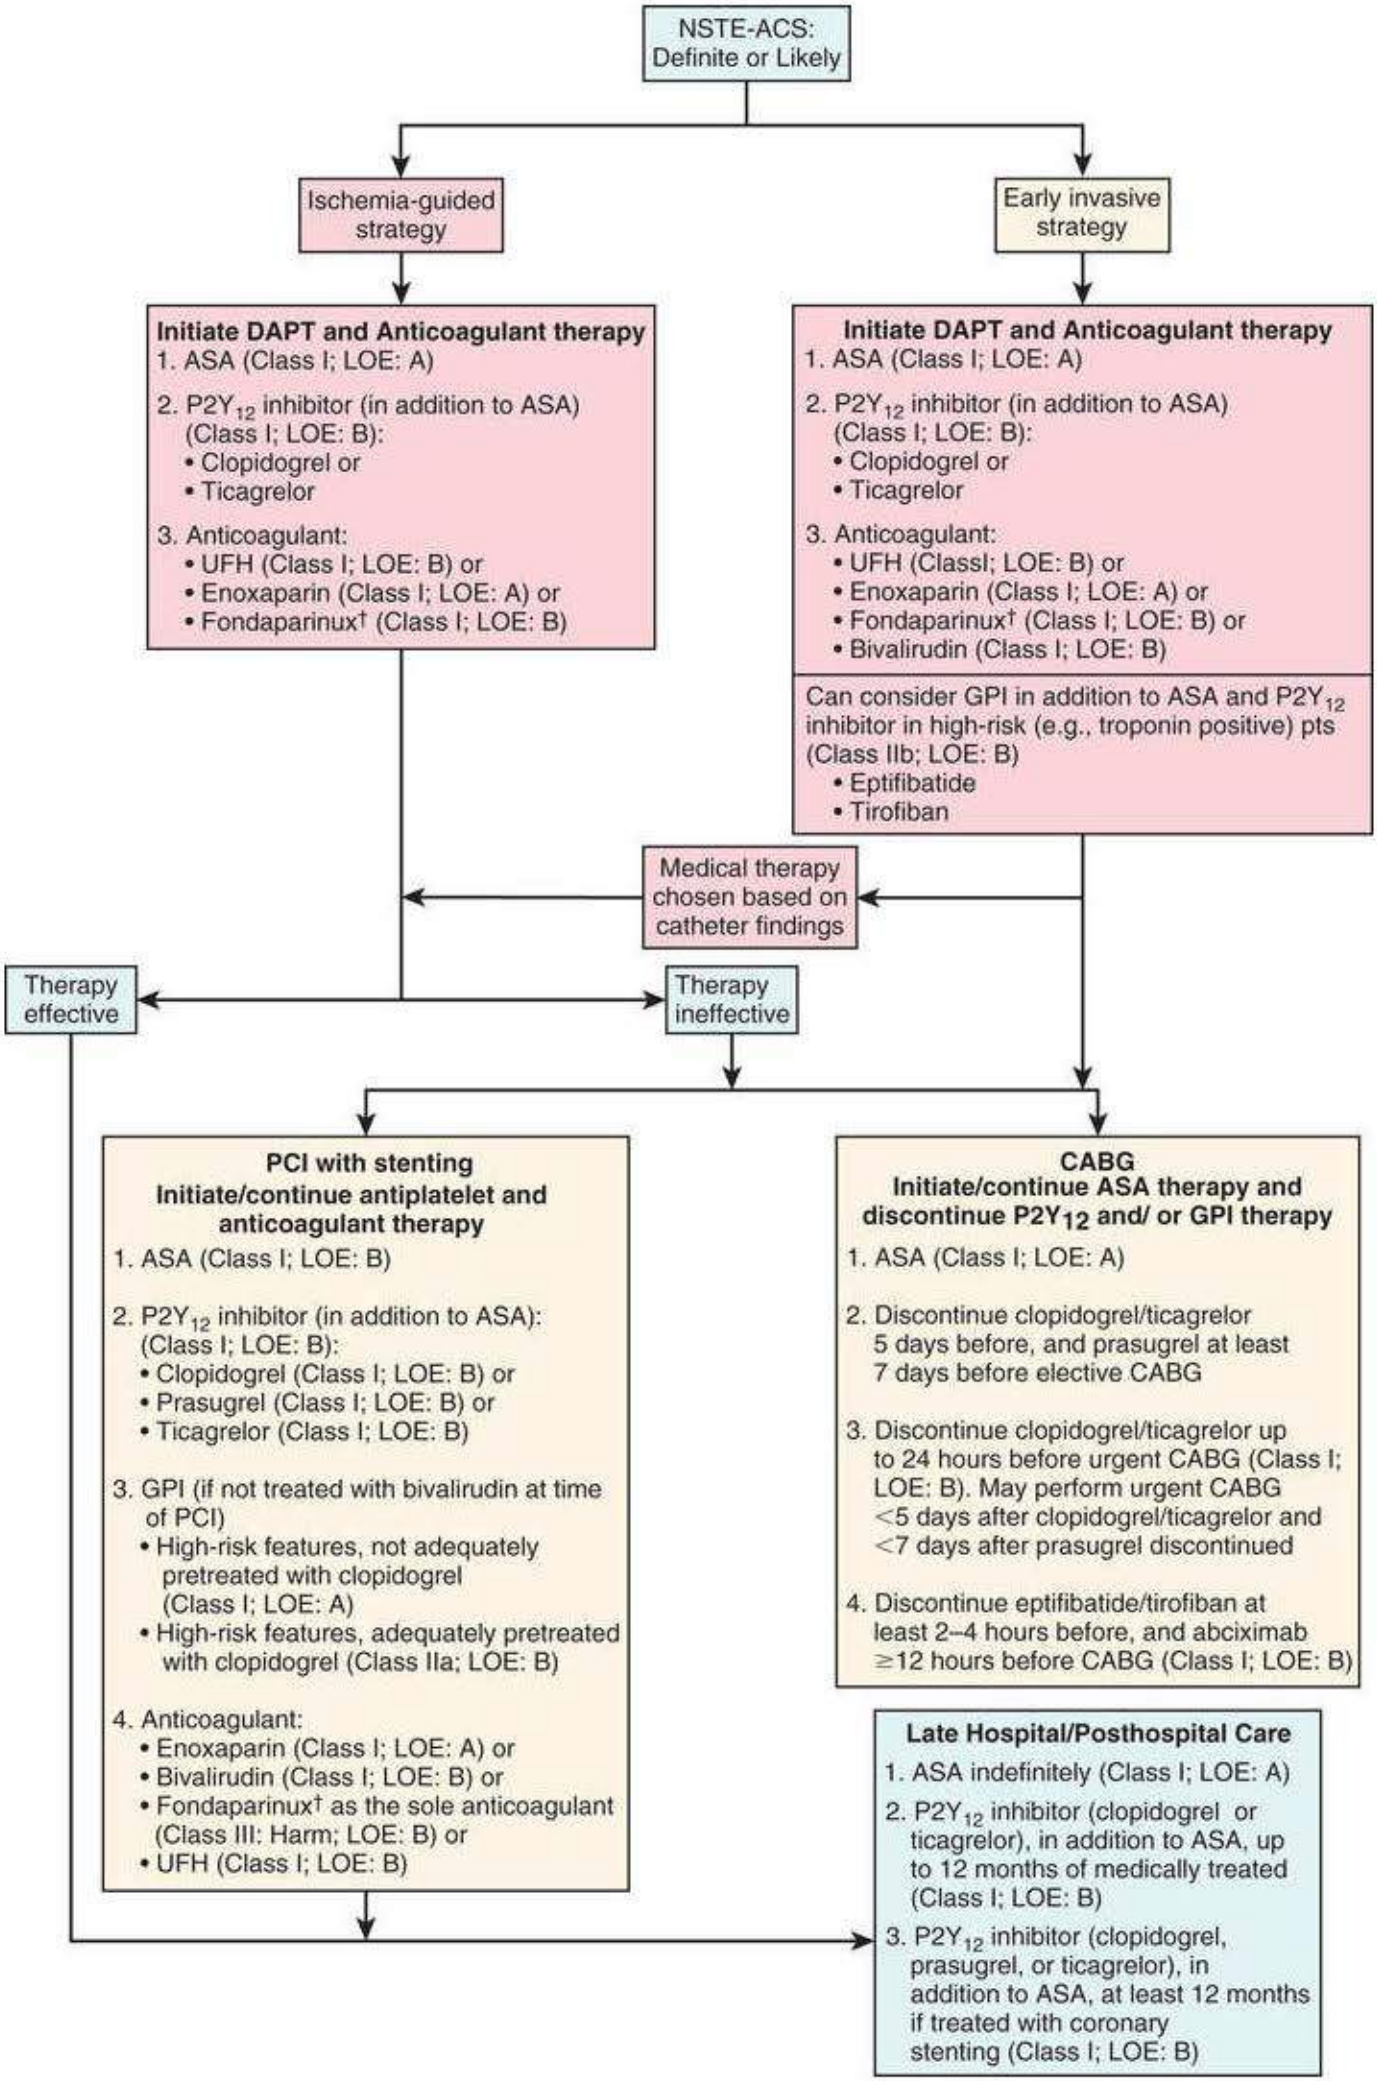
[e]The distribution phase half-life is reported since it most likely reflects duration of clinically relevant plasma levels, whereas the corresponding elimination-phase half-life is approximately 7 hours.

ADP, Adenosine diphosphate; *ATP,* adenosine triphosphate; *eGFR,* estimated glomerular filtration rate (in mL/min/1.73 m^2).

Modified from Roffi M, Patrono C, Collet JP, et al. 2015 ESC guidelines for the management of acute coronary syndromes in patients presenting without persistent ST-segment elevation. Task Force for the Management of Acute Coronary Syndromes in Patients Presenting without Persistent ST-Segment Elevation of the European Society of Cardiology. Eur Heart J 2016;37:267-315.

Ischemia-Guided Strategy Versus Early Invasive Strategies

The two treatment strategies have emerged for managing patients with NSTE-ACS (**Fig. 60G.2**). In both strategies, patients should receive optimal medical therapy, as previously described (**Tables 60G.1 to 60G.3**). On presentation, patients who are very-high risk, such as those with hemodynamic instability (**Table 60G.4**), should be referred for an immediate (within 2 hours of presentation) invasive coronary angiogram. At the other extreme, patients without recurrent symptoms and who are deemed to be at low risk for subsequent ischemic events may be managed with an ischemia-guided strategy, including a noninvasive stress test (preferably with imaging) to assess for inducible ischemia. In particular, patients with acute chest pain and a low likelihood of ACS who are troponin negative (LOE: C), especially women (LOE: B), should preferentially be managed with an ischemia-guided strategy.



NSTE-ACS: Definite or Likely
Ischemia-guided strategy
Early invasive strategy
Initiate DAPT and Anticoagulant therapy
1. ASA (Class I; LOE: A)
2. P2Y12 inhibitor (in addition to ASA) (Class I; LOE: B):
• Clopidogrel or
• Ticagrelor
3. Anticoagulant:
• UFH (Class I; LOE: B) or
• Enoxaparin (Class I; LOE: A) or
• Fondaparinux† (Class I; LOE: B)
Initiate DAPT and Anticoagulant therapy
1. ASA (Class I; LOE: A)
2. P2Y12 inhibitor (in addition to ASA) (Class I; LOE: B):
• Clopidogrel or
• Ticagrelor
3. Anticoagulant:
• UFH (ClassI; LOE: B) or
• Enoxaparin (Class I; LOE: A) or
• Fondaparinux† (Class I; LOE: B) or
• Bivalirudin (Class I; LOE: B)
Can consider GPI in addition to ASA and P2Y12 inhibitor in high-risk (e.g., troponin positive) pts (Class IIb; LOE: B)
• Eptifibatide
• Tirofiban
Medical therapy chosen based on catheter findings
Therapy effective
Therapy ineffective
PCI with stenting
Initiate/continue antiplatelet and anticoagulant therapy
1. ASA (Class I; LOE: B)
2. P2Y12 inhibitor (in addition to ASA): (Class I; LOE: B):
• Clopidogrel (Class I; LOE: B) or
• Prasugrel (Class I; LOE: B) or
• Ticagrelor (Class I; LOE: B)
3. GPI (if not treated with bivalirudin at time of PCI)
• High-risk features, not adequately pretreated with clopidogrel (Class I; LOE: A)
• High-risk features, adequately pretreated with clopidogrel (Class IIa; LOE: B)
4. Anticoagulant:
• Enoxaparin (Class I; LOE: A) or
• Bivalirudin (Class I; LOE: B) or
• Fondaparinux† as the sole anticoagulant (Class III: Harm; LOE: B) or
• UFH (Class I; LOE: B)
CABG
Initiate/continue ASA therapy and discontinue P2Y12 and/ or GPI therapy
1. ASA (Class I; LOE: A)
2. Discontinue clopidogrel/ticagrelor 5 days before, and prasugrel at least 7 days before elective CABG
3. Discontinue clopidogrel/ticagrelor up to 24 hours before urgent CABG (Class I; LOE: B). May perform urgent CABG <5 days after clopidogrel/ticagrelor and <7 days after prasugrel discontinued
4. Discontinue eptifibatide/tirofiban at least 2–4 hours before, and abciximab ≥12 hours before CABG (Class I; LOE: B)
Late Hospital/Posthospital Care
1. ASA indefinitely (Class I; LOE: A)
2. P2Y12 inhibitor (clopidogrel or ticagrelor), in addition to ASA, up to 12 months of medically treated (Class I; LOE: B)
3. P2Y12 inhibitor (clopidogrel, prasugrel, or ticagrelor), in addition to ASA, at least 12 months if treated with coronary stenting (Class I; LOE: B)

FIGURE 60G.2 Algorithm for management of patients with definite of likely non-ST-elevation acute coronary syndromes (NSTE-ACS). See text and **Table 60G.2** for selecting between the two management strategies (ischemia-guided and early invasive). †In patients who have been treated with fondaparinux (as upfront therapy) who undergo percutaneous coronary intervention (PCI), an additional anticoagulant with anti-IIa activity should be administered at the time of PCI because of the risk of catheter thrombosis. ASA, Acetylsalicylic acid (aspirin); CABG, coronary artery bypass grafting; DAPT, dual-antiplatelet therapy; GPI, glycoprotein inhibitor; LOE, level of evidence; UFH, unfractionated heparin. (From Amsterdam EA, Wenger NK, Brindis RG, et al. 2014 AHA/ACC guideline for the management of patients with non-ST-elevation acute coronary syndromes: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2014;64:e139-228.)

TABLE 60G.4
Risk Criteria in Patients with NSTE-ACS

Very-High-Risk Criteria
• Hemodynamic instability or cardiogenic shock • Recurrent or ongoing chest discomfort refractory to optimal medical therapy • Life-threatening arrhythmias or cardiac arrest • Mechanical complications of MI • Acute heart failure • Recurrent dynamic ST-T wave changes, particularly with intermittent ST-elevation
High-Risk Criteria
• Rise and fall in cardiac troponin compatible with MI • Dynamic ST-T wave changes without symptoms (silent) • Elevated TIMI (>4) or GRACE (>140) risk score
Intermediate-Risk Criteria
• Diabetes mellitus • Renal insufficiency (eGFR <60 mL/min/173 m^2) • LVEF <40% or congestive heart failure • Early post-MI angina • Prior PCI • Prior CABG • TIMI (2-3) or GRACE (109-140) risk score
Low-Risk Criteria
• None of the characteristics mentioned above

CABG, Coronary artery bypass graft; *eGFR,* estimated glomerular filtration rate; *GRACE,* Global Registry of Acute Coronary Events; *LVEF,* left ventricular ejection fraction; *PCI,* percutaneous coronary intervention; *MI,* myocardial infarction; *TIMI,* thrombolysis in myocardial infarction.

Modified from Roffi M, Patrono C, Collet JP, et al. 2015 ESC guidelines for the management of acute coronary syndromes in patients presenting without persistent ST-segment elevation. Task Force for the Management of Acute Coronary Syndromes in Patients Presenting without Persistent ST-Segment Elevation of the European Society of Cardiology. Eur Heart J 2016;37:267-315.

If any of the following occur, the patient is considered to have failed initial ischemia-guided strategy and should be referred for invasive angiography: (1) refractory angina at rest or with minimal exertion despite optimal medical therapy, (2) objective evidence of ischemia (e.g., dynamic ST-segment changes on ECG, ischemia demonstrated on noninvasive stress imaging study), or (3) very high prognostic risk score.

Coronary Revascularization

See **Chapter 62**.

Late Hospital Care, Hospital Discharge, and Posthospital Care

Goals of care in the phase of the management of patients with NSTE-ACS include prevention of recurrent ACS, late complications of infarction, and progression of atherosclerosis with lifestyle and aggressive

risk modification, as well as restoring the patient to normal activities.

AHA/ACC Class I Recommendations[1]

Anti-Ischemic Therapies

1. Medications required in the hospital to control ischemia (e.g., beta blockers, CCBs, nitrates) should be continued after hospital discharge in patients with NSTE-ACS who do not undergo coronary revascularization, patients with incomplete or unsuccessful revascularization, and patients with recurrent symptoms after revascularization. Titration of the doses may be required. (LOE: C.)
2. All patients who are post–NSTE-ACS should be given sublingual (SL) or spray nitroglycerin with oral and written instructions for its use (LOE: C). For patients who are post–NSTE-ACS and have initial angina lasting more than 1 minute, nitroglycerin (1 dose SL or spray) is recommended if angina does not subside within 3 to 5 minutes; call emergency medical services (EMS) immediately (LOE: C).

Antiplatelet Therapy

1. Aspirin should be continued indefinitely. The maintenance dose should be 81 mg daily (although up to 325 mg daily maybe used in special circumstances). (LOE: A.)
2. In addition to aspirin, a $P2Y_{12}$ inhibitor should be continued for up to 12 months in all patients with NSTE-ACS without contraindications. Options include:
    - Clopidogrel: 75 mg daily (LOE: B) *or*
    - Ticagrelor: 90 mg twice daily (LOE: B) *or*
    - Prasugrel 10 mg daily (LOE: B), only if coronary stenting was performed

Combined Postdischarge Oral Anticoagulant and Antiplatelet Therapy

1. The duration of triple-antithrombotic therapy with a vitamin K antagonist (VKA), aspirin, and a $P2Y_{12}$ receptor inhibitor in patients with NSTE-ACS should be minimized to the extent possible to limit the risk of bleeding (LOE: C).
2. Proton pump inhibitors (PPIs) should be prescribed in patients with NSTE-ACS with a history of gastrointestinal bleeding who require triple-antithrombotic therapy with a VKA, aspirin, and a $P2Y_{12}$ receptor inhibitor[3] (LOE: C).

Renin-Angiotensin-Aldosterone Inhibitors

1. Angiotensin-converting enzyme inhibitors (ACEIs) should be started and continued indefinitely in all patients with left ventricular ejection fraction (LVEF) less than 40% and in those with diabetes mellitus (DM), hypertension, or stable chronic kidney disease (CKD), unless contraindicated (LOE: A). Angiotensin receptor blockers (ARBs) are recommended in who are ACEI intolerant (LOE: A).

2. Aldosterone blockade is recommended in patients after MI without significant renal dysfunction (creatinine >2.5 mg/dL in men or >2.0 mg/dL in women) or hyperkalemia (>5.0 mEq/L) who are receiving therapeutic doses of ACEI and beta blocker and have an LVEF of 40% or less, DM, or heart failure (LOE: A).

Education

1. Before hospital discharge, patients with NSTE-ACS should be informed about symptoms of worsening myocardial ischemia and MI and should be given oral and written instructions about how and when to seek emergency care for such symptoms (LOE: C).
2. Before hospital discharge, patients who are post–NSTE-ACS and/or designated responsible caregivers should be provided with easily understood and culturally sensitive verbal and written instructions about medication type, purpose, dose, frequency, side effects, and duration of use (LOE: C).
3. If the pattern or severity of angina changes, suggesting worsening myocardial ischemia (e.g., pain is more frequent or severe or is precipitated by less effort or occurs at rest), patients should contact their clinician without delay to assess the need for additional treatment or testing (LOE: C).
4. Before discharge, patients should be educated about modification of cardiovascular risk factors (LOE: C).

Risk Factor Modification

1. All eligible patients with NSTE-ACS should be referred to a comprehensive cardiovascular rehabilitation program either before hospital discharge or during the first outpatient visit (LOE: B). Patients who have undergone PCI or CABG derive benefit from risk factor modification and should receive counseling that revascularization does not obviate the need for lifestyle changes (LOE: C).
2. Patients should be educated about appropriate cholesterol management, blood pressure (BP), smoking cessation, and lifestyle management[4,5] (LOE: C).
3. The pneumococcal vaccine is recommended for patients age 65 and older and in high-risk patients with cardiovascular disease[6] (LOE: B).

In addition, NSAIDs and hormones should be avoided because of the potential for harm, and there is no proven benefit for antioxidant vitamins or folic acid for secondary prevention of ACS.

Special Patient Groups

The AHA/ACC provide the following class I recommendations for select special patient groups.

Older Patients

1. Patients ≥75 years of age should be treated with guideline-directed medical therapy, an early invasive strategy, and revascularization as appropriate[7] (LOE: A).

2. Pharmacotherapy should be individualized and dose adjusted by weight and/or creatinine clearance to reduce adverse events caused by age-related changes in pharmacokinetics/dynamics, volume of distribution, comorbidities, drug interactions, and increased drug sensitivity (LOE: A).
3. Management decisions should be patient centered and should consider patient preferences/goals, comorbidities, functional and cognitive status, and life expectancy[8] (LOE: B).

Women

1. Women with NSTE-ACS should be managed with the same pharmacologic therapy as men for acute care and for secondary prevention, with attention to weight and renally calculated doses of antiplatelet and anticoagulant agents to reduce bleeding risk (LOE: B).
2. Women with NSTE-ACS and high-risk features (e.g., troponin elevation) should undergo an early invasive strategy (LOE: A).
3. Women with low-risk features should not undergo early invasive treatment because of lack of benefit and the possibility of harm (COR III, LOE: B).

Patients with Heart Failure

1. Patients with a history of heart failure (HF) and NSTE-ACS should be treated according to the same risk stratification guidelines and recommendations for patients without HF[9] (LOE: B).
2. Selection of a specific revascularization strategy should be based on the degree, severity, and extent of coronary artery disease (CAD); associated cardiac lesions; extent of LV dysfunction; and history of prior revascularization procedures[9] (LOE: B).
3. Early revascularization is recommended in suitable patients with cardiogenic shock caused by cardiac pump failure after NSTE-ACS (LOE: B).

Diabetes Mellitus

Medical treatment in the acute phase of NSTE-ACS and decisions to perform stress testing, angiography, and revascularization should be similar in patients with and without DM (LOE: A).

Post–Coronary Artery Bypass Graft Surgery

Patients with prior CABG and NSTE-ACS should receive antiplatelet and anticoagulant therapy according to guideline-directed medical therapy and should be strongly considered for early invasive strategy because of their increased risk (LOE: B).

Chronic Kidney Disease

1. The creatinine clearance should be estimated in patients with NSTE-ACS at the time of presentation, and doses of renally cleared medications should be adjusted according to the pharmacokinetic data for specific medications (LOE: B).
2. Patients undergoing coronary and left ventricular angiography should receive adequate hydration

(LOE: C).

Use of Performance Measures and Registries

Participation in a standardized quality-of-care data registry designed to track and measure outcomes, complications, and performance measures can be beneficial in improving the quality of NSTE-ACS care (LOE: B). National systems for ACS and standardization of quality-of-care data registries are critical to permit assessment of care and quality improvement. **Table 60G.5** lists 10 performance measures from the ESC[2] that are useful for monitoring and improving the standards of care in NSTE-ACS.

TABLE 60G.5

Ten Performance Measures in Patients with NSTE-ACS

1. Use of aspirin
2. Use of an oral $P2Y_{12}$ inhibitor
3. Use of fondaparinux, bivalirudin, UFH, or enoxaparin
4. Use of beta blocker at discharge for patients with LV dysfunction
5. Use of statins
6. Use of ACEI or ARB in patients with systolic LV dysfunction or heart failure, hypertension, or diabetes
7. Use of early invasive procedures in intermediate- to high-risk patients
8. Smoking cessation advice/counseling
9. Enrollment in a secondary prevention or cardiac rehabilitation program
10. Development of regional and/or national programs to measure performance indicators systematically and provide feedback to individual hospitals

ACE, Angiotensin-converting-enzyme inhibitor; ARB, angiotensin receptor blocker; *LV,* left ventricular; *UFH,* unfractionated heparin.

Modified from Roffi M, Patrono C, Collet JP, et al. 2015 ESC guidelines for the management of acute coronary syndromes in patients presenting without persistent ST-segment elevation. Task Force for the Management of Acute Coronary Syndromes in Patients Presenting without Persistent ST-Segment Elevation of the European Society of Cardiology. Eur Heart J 2016;37:267-315.

Evidence Gaps

Despite decades of high-quality clinical trials, data from well-conducted registries, and other controlled studies that provide the large body of evidence supporting guideline-directed management of NSTE-ACS, challenges and gaps in optimal care remain. Optimal medical therapy remains underutilized, particularly in high-risk subgroups. Comparative effectiveness studies lag behind the landmark trials establishing the efficacy and safety of novel therapies.

The paradox of newer and more potent antithrombotic and anticoagulant drugs that reduce major adverse cardiac outcomes but increase bleeding risk represents a particularly difficult challenge for patients at increased risk for bleeding (e.g., elderly, CKD) and those receiving oral anticoagulation. An unmet need is to distinguish which higher-risk patients are candidates for an ischemia-guided strategy compared with an early invasive management strategy, since these patients were typically underrepresented in the landmark clinical trials.

At the extreme, a sizable minority of patients (more often women than men) with NSTE-ACS have nonobstructive CAD, yet the prognosis is not benign. There appear to be multiple mechanisms of ACS postulated, and rigorous evaluation of treatment for this condition is lacking. **See Table 60.6** for additional unanswered questions.

Stable Ischemic Heart Disease

David A. Morrow, James A. de Lemos

The spectrum of stable ischemic heart disease (SIHD) is broad and includes individuals with chronic stable angina, asymptomatic ischemia, prior myocardial infarction, prior coronary revascularization, as well as individuals with nonobstructive coronary atherosclerosis. SIHD is most frequently caused by

atheromatous plaque that obstructs or gradually narrows the epicardial coronary arteries. The pathogenesis of atherosclerosis is described in **Chapter 44**. However, other contributors, such as endothelial dysfunction, microvascular disease, and vasospasm, may also exist alone or in combination with coronary atherosclerosis and may be the dominant cause of myocardial ischemia in some patients (**Fig. 61.1**). Thus, the concept that ischemic heart disease (IHD) is synonymous with "obstructive coronary atherosclerosis" is an overly simplified view.[1-3]

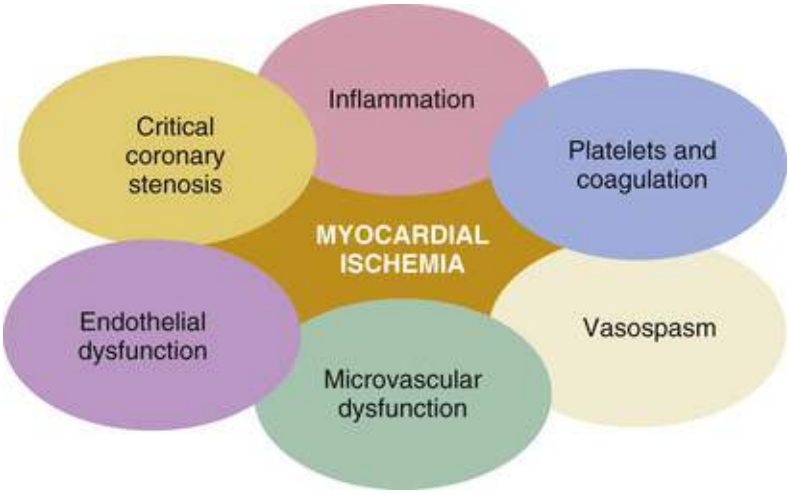

FIGURE 61.1 Pathophysiology of ischemic heart disease (IHD). The idea that IHD is synonymous with critical stenoses of epicardial coronary arteries is an oversimplification. The potential contributors to IHD are multiple. (Modified from Marzilli M, Bairey Merz CN, Boden WE, et al. Obstructive coronary atherosclerosis and ischemic heart disease: an elusive link. J Am Coll Cardiol 2012;60:951.)

Factors that predispose to coronary atherosclerosis are discussed in **Chapter 45**, control of coronary blood flow in **Chapter 57**, percutaneous coronary revascularization in **Chapter 62**, ST-segment elevation myocardial infarction (MI) in **Chapters 58 and 59**, non–ST-segment elevation acute coronary syndrome (ACS) in **Chapter 60**, and sudden cardiac death, another significant consequence of IHD, in **Chapter 42**.

The presenting symptoms in patients with IHD are highly variable. Chest discomfort is usually the predominant symptom in chronic (stable) angina, unstable angina, Prinzmetal (variant) angina, microvascular angina, and acute MI. However, manifestations of IHD also occur in which chest discomfort is absent or not prominent, such as asymptomatic (silent) myocardial ischemia, heart failure, cardiac arrhythmias, and sudden death. Notably, IHD may also present with atypical angina or anginal equivalents, such as midepigastric discomfort, dyspnea, effort intolerance, and excessive fatigue, which are observed more frequently in women, older adults, and individuals with diabetes.

Coronary arteries may also become obstructed by nonatherosclerotic mechanisms, including extrinsic compression, myocardial bridging, coronary arteritis in association with systemic vasculitis, and radiation-induced coronary artery disease (CAD). Myocardial ischemia and angina pectoris may also occur in the setting of extreme myocardial oxygen (O_2) demand with or without underlying obstructive CAD, as in the case of aortic valve disease (**see Chapter 68**), hypertrophic cardiomyopathy (**Chapter 78**), dilated nonischemic cardiomyopathies (**Chapter 77**), or pulmonary hypertension (**Chapter 85**).

Magnitude of the Problem

The importance of IHD in contemporary society is attested to by the large number of persons afflicted

(**see Chapter 1**). It is estimated that 15,400,000 Americans have IHD, 7,800,000 of whom have angina pectoris and 7,600,000 have had MI.[4] Based on data from the Framingham Heart Study, the lifetime risk for IHD among individuals with an optimal risk factor profile is 3.6% for men and less than 1% for women; whereas among individuals with two or more major risk factors, the lifetime risk is 37.5% for men and 18.3% for women. In 2013, IHD accounted for 46% of all deaths caused by cardiovascular disease (CVD) and was the single most frequent cause of death in American men and women, resulting in more than one in seven deaths in the United States. The economic cost of IHD is formidable, estimated to be $207.3 billion in the United States in 2011 to 2012.

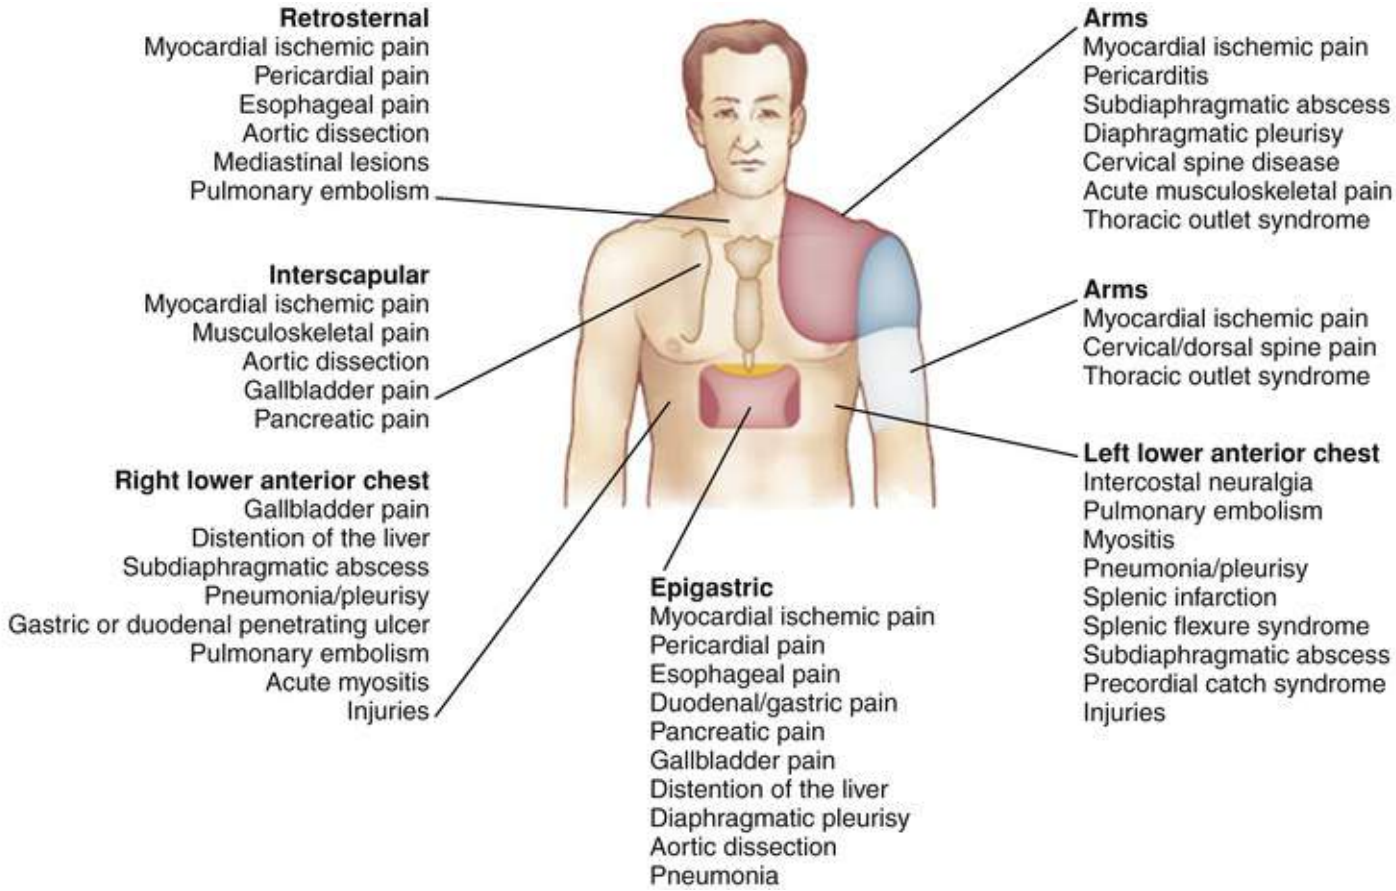
Despite a steady decline in age-specific mortality from CAD over the past several decades, IHD is the leading cause of death worldwide, and it is expected that the rate of CAD will only accelerate in the coming decades. Moreover, with a decline in case-fatality rate of MI, the prevalence of survivors with SIHD has increased despite a relatively stable rate of incident MI. At the same time, the burden of IHD is shifting progressively to lower socioeconomic groups with contributory factors that include aging of the population, increases in the worldwide prevalence of obesity and type 2 diabetes, and a rise in cardiovascular risk factors in younger generations. The World Health Organization (WHO) has estimated that by 2030, the global number of deaths from IHD will have risen from 7.4 million in 2012 to 9.2 million.

Stable Angina Pectoris

Clinical Manifestations

Characteristics of Angina (See Chapter 56)

Angina pectoris is a discomfort in the chest or adjacent areas caused by myocardial ischemia. It is usually precipitated by exertion but may also be initiated by emotional distress. Angina that is prolonged, occurs at rest, or occurs in an accelerating pattern of increasing frequency and tempo is indicative of unstable IHD, including unstable angina and acute MI (**see Chapters 58 and 60**). Heberden's initial description of angina as conveying a sense of “strangling and anxiety” is still remarkably pertinent. Other adjectives frequently used to describe this distress include constricting, suffocating, crushing, heavy, and squeezing. In other patients the quality of the sensation can be vague and described as a mild pressure-like discomfort, tightness, an uncomfortable numbness, or a burning sensation. The site of the discomfort is usually retrosternal, but radiation is common and generally occurs down the ulnar surface of the left arm; the right arm and the outer surfaces of both arms may also be involved (**eFig. 61.1**). Epigastric discomfort alone or in association with chest pressure may occur and can masquerade as indigestion. Anginal discomfort above the mandible or below the epigastrium is rare. Anginal equivalents (i.e., symptoms of myocardial ischemia other than angina), such as dyspnea, faintness, fatigue, and frequent belching, are more commonly seen in women and older adults. A history of abnormal exertional dyspnea may be an indicator of IHD even when angina is absent. Nocturnal angina may be a manifestation of unstable angina but should also raise suspicion of sleep apnea (**see Chapter 87**). Postprandial angina, presumably caused by redistribution of coronary blood flow to the splanchnic circulation, may be a marker of severe IHD.



EFIGURE 61.1 Location of discomfort and cause of chest symptoms. The location of angina is usually retrosternal, but radiation is common. An epigastric location of angina may also occur.

The typical episode of angina pectoris usually begins gradually and reaches its maximum intensity over a period of minutes before dissipating. It is unusual for angina pectoris to reach its maximum severity within seconds, and it is characteristic that patients with angina generally prefer to rest, sit, or stop walking during episodes. Chest discomfort while walking in the cold or uphill is suggestive of angina. Features suggesting the absence of angina pectoris include pain that is pleuritic, sharp or stabbing in quality, or reproduced by movement or palpation of the chest wall or arms (**eFig. 61.1**). Constant pain lasting many hours or, alternatively, very brief episodes of pain lasting seconds are also unlikely to result from angina. Typical angina pectoris is relieved within minutes by rest or the use of short-acting nitroglycerin. Response to the latter is often a useful diagnostic tool, although it should be remembered that esophageal pain may also respond to nitroglycerin. A delay of more than 5 to 10 minutes before relief is obtained with rest and nitroglycerin suggests that the symptoms are either not caused by ischemia or are caused by severe ischemia, as with acute MI or unstable angina. The phenomenon of *warm-up angina* is used to describe the ability of some patients in whom angina develops with exertion to continue subsequently at the same or even greater level of exertion without symptoms after an intervening period of rest. This attenuation of myocardial ischemia observed with repeated exertion has been postulated to be caused by ischemic preconditioning (**see Chapter 57**).

Assessment and Classification of Angina Pectoris

A system of grading the severity of angina pectoris proposed by the Canadian Cardiovascular Society (CCS) is widely used. The system is a modification of the New York Heart Association (NYHA) functional classification and allows patients to be categorized in more specific terms. Other grading systems include a specific activity scale developed by Goldman and associates that is based on the metabolic cost of specific activities. A limitation of all these grading systems is their dependence on

accurate reporting by patients in the context of patients' widely varying tolerance of symptoms. Functional estimates based on the CCS criteria have shown a reproducibility that is only moderate and that do not correlate well with objective measures of exercise performance.

More recent developments incorporate measures of the impact of angina on quality of life, which can be assessed using general instruments such as the Medical Outcomes Study 36-Item Short Form Health Survey (SF-36) or the disease-specific Seattle Angina Questionnaire (SAQ). Although these objective measurements have typically only been used in the research setting, a short, seven-question version of the SAQ may be more practical for the clinical setting. In the future, embedding simple, objective, patient-centered disease measurements into the clinical encounter is likely to become increasingly important for chronic diseases such as SIHD.

Mechanisms of Anginal Pain.

The mechanisms of cardiac pain and the neural pathways involved are poorly understood. It is presumed that angina pectoris results from ischemic episodes that excite chemosensitive and mechanosensitive receptors in the heart. Stimulation of these receptors results in the release of adenosine, bradykinin, and other substances that excite the sensory ends of sympathetic and vagal afferent fibers. The afferent fibers traverse the nerves that connect to the upper five thoracic sympathetic ganglia and the upper five distal thoracic roots of the spinal cord. Impulses are transmitted by the spinal cord to the thalamus and then to the neocortex. Data from animal studies have identified the vanilloid receptor-1 (VR1), also known as the transient receptor potential vanilloid-1 receptor (TRPV1) receptor, an important sensor for somatic nociception, to be present on sensory nerve endings in the heart and have suggested that VR1 functions as a transducer of myocardial tissue ischemia and may play a role in ischemic preconditioning.

Within the spinal cord, cardiac sympathetic afferent impulses may converge with impulses from somatic thoracic structures, which may be the basis for referred cardiac pain, such as to the chest. In comparison, cardiac vagal afferent fibers synapse in the nucleus tractus solitarius of the medulla and then descend to excite the upper cervical spinothalamic tract cells, which may contribute to the anginal pain experienced in the neck and jaw. Moreover, vagal input in the nucleus tractus solitarius may lead to stimulation of efferent impulses in the autonomic system that contribute to nausea and emesis. Positron emission tomography (PET) of the brain in persons with silent ischemia suggests that failed transmission of signals from the thalamus to the frontal cortex may contribute to this phenomenon, along with impaired afferent signaling, such as that caused by autonomic neuropathy. Silent ischemia in diabetic patients, for example, has been proposed to be related to failed development of the cardiac sensory system because of reduced nerve growth factor.

Differential Diagnosis of Chest Pain

Esophageal Disorders

Common disorders that may simulate or coexist with angina pectoris are gastroesophageal reflux and disorders of esophageal motility, including diffuse spasm. To compound the difficulty in distinguishing between angina and esophageal pain, both may be relieved by nitroglycerin. However, esophageal pain is often relieved by milk, antacids, foods, or occasionally, warm liquids.

Esophageal Motility Disorders

Esophageal motility disorders are not uncommon in patients with retrosternal chest pain of unclear cause. In addition to chest pain, most such patients have dysphagia. Both IHD and esophageal disease are common clinical entities that may coexist. Diagnostic evaluation for an esophageal disorder may be indicated in patients with IHD who have a poor symptomatic response to antianginal therapy in the absence of documented ischemia.

Biliary Colic

Although visceral symptoms are often associated with myocardial ischemia (particularly acute inferior MI; **see Chapter 56**), biliary colic and related hepatobiliary disorders may also mimic ischemia and should always be considered in patients with atypical chest discomfort, particularly in patients with diabetes. The pain is steady, usually lasts 2 to 4 hours, and subsides spontaneously, without any symptoms between attacks. It is generally most intense in the right upper abdominal area but may also be felt in the epigastrium or precordium. This discomfort is often referred to the scapula, may radiate around the costal margin to the back, or in rare cases may be felt in the shoulder and may suggest diaphragmatic irritation.

Costochondritis

In 1921, Tietze first described a syndrome of local pain and tenderness, generally limited to the anterior chest wall and associated with swelling of costal cartilage. The full-blown Tietze syndrome (i.e., pain associated with tender swelling of the costochondral junctions) is uncommon, whereas costochondritis causing tenderness of the costochondral junctions (without swelling) is relatively common. Pain on palpation of these joints is usually well localized and is a useful clinical sign, although deep palpation may elicit pain in the absence of costochondritis. Although palpation of the chest wall often reproduces pain in patients with various musculoskeletal conditions, it should be appreciated that chest wall tenderness does not exclude symptomatic CAD.

Other Neurologic and Musculoskeletal Disorders

Cervical radiculitis may be confused with angina. This condition may occur as a constant ache and sometimes results in a sensory deficit. The pain may be related to motion of the neck, just as motion of the shoulder triggers attacks of pain from bursitis. Occasionally, pain mimicking angina can be caused by compression of the brachial plexus by the cervical ribs, and tendinitis or bursitis involving the left shoulder may also cause angina-like pain. Physical examination may also detect pain triggered by movement of an arthritic shoulder or a calcified shoulder tendon. Herpes zoster, caused by recrudescence of the varicella-zoster virus, can manifest as pain across the chest and should be recognized by its dermatomal distribution and associated blistering or crusting rash. The pain of zoster (shingles) may begin several days before a rash is apparent. Postherpetic neuralgia may persist in the absence of a rash.

Other Causes of Angina-Like Pain

Severe pulmonary hypertension may be associated with exertional chest pain with the characteristics of angina pectoris, and indeed, this pain is thought to be caused by right ventricular (RV) ischemia that develops during exertion (**see Chapter 85**). Other associated symptoms include exertional dyspnea, dizziness, and syncope. Related findings on physical examination, such as a parasternal lift, a palpable and loud pulmonary component of the second sound, and RV hypertrophy on the electrocardiogram (ECG), are usually readily recognized.

Pulmonary embolism is initially characterized by dyspnea as the cardinal symptom, but chest pain may

also be present (**see Chapter 84**). Pleuritic pain suggests pulmonary infarction, and a history of exacerbation of the pain with inspiration, along with a pleural friction rub, if present, helps distinguish it from angina pectoris.

The pain of acute pericarditis may at times be difficult to distinguish from angina pectoris (**see Chapter 83**). However, pericarditis tends to occur in younger patients, and the diagnosis depends on the combination of chest pain not relieved by rest or nitroglycerin, exacerbation by movement or deep inspiration, and lying flat; a pericardial friction rub, which may be evanescent; and changes on the ECG, notably PR-segment depression and/or diffuse ST elevation.

The classic symptom of aortic dissection is a severe, often sharp pain that radiates to the back (**see Chapter 63**).

Physical Examination

Most patients with SIHD have normal findings on cardiac examination, and thus the single best clue to the diagnosis of angina is the clinical history. Nonetheless, careful examination can exclude other conditions that mimic angina and may reveal atherosclerosis in noncoronary vascular territories, evidence of risk factors for coronary atherosclerosis (e.g., acanthosis nigricans, tendon xanthomas), or the consequences of myocardial ischemia (**see Chapter 10**).

Pathophysiology

Angina pectoris results from myocardial ischemia, which is caused by an imbalance between myocardial O_2 requirements and myocardial O_2 supply. The former may be elevated by increases in heart rate (HR), left ventricular (LV) wall stress, and contractility (**see Chapter 22**); the latter is determined by coronary blood flow and coronary arterial O_2 content (**Fig. 61.2**). The clinical precipitants and manifestations of supply-demand imbalance are discussed in this section. The pathobiology of atherosclerosis is discussed in **Chapter 44**. See Chest Pain with a Normal Coronary Arteriogram later in this chapter and **Chapter 57** for discussion of other abnormalities in coronary function and contributors to myocardial ischemia in the absence of critical coronary obstruction.

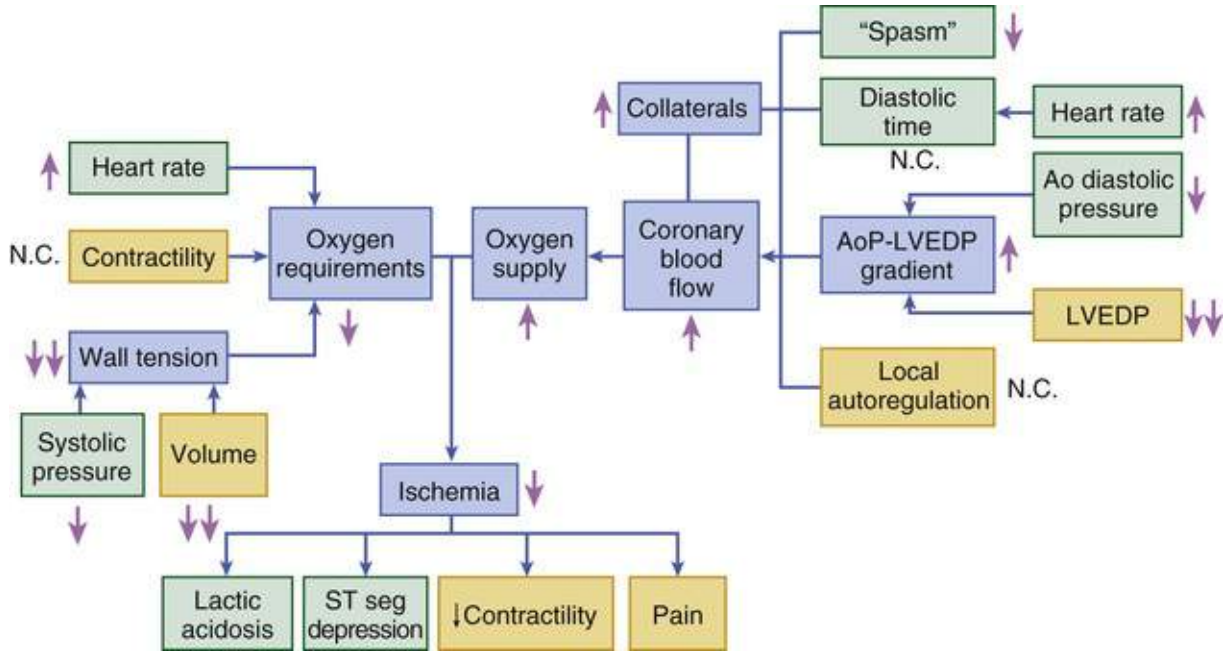


FIGURE 61.2 Factors influencing the balance between myocardial O_2 requirement (*left*) and supply (*right*). *Arrows* indicate effects of nitrates. In relieving angina pectoris, nitrates exert favorable effects by reducing O_2 requirements and increasing supply. Although a reflex increase in heart rate would tend to reduce the time for coronary flow, dilation of collaterals and enhancement of the pressure gradient for flow to occur as left ventricular end-diastolic pressure (LVEDP) falls tend to increase coronary flow. AoP-LVEDP, Aortic pressure minus LVEDP; N.C., no change. (From Frishman WH: Pharmacology of the nitrates in angina pectoris. Am J Cardiol 1985;56:8I.)

Angina Caused by Increased Myocardial Oxygen Requirements

In this condition, sometimes termed *demand angina*, the myocardial O_2 requirement increases in the presence of a constant and usually restricted O_2 supply. The increased O_2 requirement usually results from a physiologic response to exertion, emotional duress, or mental stress. Of great importance to the myocardial O_2 requirement is the rate and intensity at which any physical task is carried out. Mental and emotional stress may precipitate angina, presumably by increased hemodynamic and catecholamine responses to stress, increased adrenergic tone, and reduced vagal activity. The combination of physical exertion and emotion in association with sexual activity may precipitate angina. Other precipitants of angina include physical exertion after a heavy meal and the excessive metabolic demands imposed by chills, fever, thyrotoxicosis, tachycardia from any cause, uncontrolled hypertension, exposure to the cold, and hypoglycemia.

Angina Caused by Transiently Decreased Oxygen Supply

As with unstable angina, chronic stable angina may be caused by transient reductions in O_2 supply, a condition sometimes termed *supply angina*, as a consequence of coronary vasoconstriction that results in dynamic stenosis. In the presence of atherosclerotic stenoses, platelet thrombi and leukocytes may elaborate vasoconstrictor substances such as serotonin and thromboxane A_2. In addition, endothelial damage in atherosclerotic coronary arteries decreases production of vasodilator substances, resulting in an abnormal vasoconstrictor response to exercise and other stimuli. A variable threshold of myocardial ischemia in patients with chronic stable angina may be caused by dynamic changes in smooth muscle tone and also by constriction of arteries distal to the stenosis. Patients with resulting "variable-threshold angina" may have good days, when they are capable of substantial physical activity, as well as bad days,

when even minimal activity can cause clinical and/or electrocardiographic evidence of myocardial ischemia or angina at rest. They often complain of a circadian variation in angina that is more common in the morning. Angina on exertion and sometimes even at rest may be precipitated by cold temperature, emotion, and mental stress.

In rare instances, severe dynamic obstruction may develop alone in patients without organic obstructing lesions and can cause myocardial ischemia and angina at rest (see later, Prinzmetal Variant Angina; **see also Chapters 57 and 60**). On the other hand, in patients with severe fixed obstruction in one or more epicardial coronary arteries, only a minor increase in dynamic obstruction is necessary for coronary blood flow to fall below a critical level and cause myocardial ischemia.

Importance of Pathophysiologic Considerations in Configuring Therapy

The pathophysiologic and clinical correlations of ischemia in patients with SIHD may have important implications for the selection of anti-ischemic agents, as well as for their timing. The greater the contribution from increased myocardial O_2 demand associated with tachycardia or increased contractility, the greater is the likelihood that beta-blocking agents will be effective; nitrates and calcium channel–blocking agents, at least hypothetically, are more likely to be effective in episodes caused primarily by coronary vasoconstriction. The finding that an increase in myocardial O_2 requirement precedes episodes of ischemia in most patients with chronic stable angina—that is, that they have demand angina—argues in favor of controlling the HR and blood pressure (BP) as a primary therapeutic approach.

Evaluation and Management

Biochemical Tests

In patients with SIHD, metabolic abnormalities that are risk factors for the development of CAD are frequently detected. Such abnormalities include dyslipidemia (**see Chapter 48**) and insulin resistance. Moreover, chronic kidney disease is strongly associated with risk for atherosclerotic vascular disease (**see Chapter 98**). All patients with established or suspected CAD warrant evaluation of total cholesterol, low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol, triglycerides, serum creatinine (leading to estimation of glomerular filtration rate [eGFR]), fasting blood glucose levels, and measurement of hemoglobin (Hb) A_{1c}.

Measurement of other lipid elements that are particularly atherogenic, such as apolipoprotein B and small dense LDL, appears to add prognostic information to the measurement of total cholesterol and LDL and may be considered a secondary target for therapy in patients who have achieved therapeutic targets for LDL.[5,6] However, no consensus has been reached regarding routine measurement, and a simple approach based on calculation of non-HDL cholesterol (particularly in patients with triglyceride levels >200 mg/dL) may capture most of the important information related to other atherogenic lipid particles. Similarly, lipoprotein-associated phospholipase A_2 (Lp-PLA_2) is associated with risk for coronary heart disease (CHD), as well as for recurrent events, independent of traditional risk factors. However, despite this association, inhibitors of Lp-PLA_2 have not proved useful for the treatment of IHD.[7,8] Present prevention guidelines do not recommend Lp-PLA_2 for routine risk assessment. Lipoprotein (a) [Lp(a)] is a highly heritable lipid-related risk factor that should be considered for measurement in selected individuals with premature CAD, as well as those with recurrent ischemic events despite standard preventive therapies, particularly if a strong family history of CAD is present. After decades of study, large genetic studies have now clearly established Lp(a) as a causal risk factor for CAD. Although niacin is the only widely available treatment shown to lower Lp(a), proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors also lower Lp(a) and may emerge as a therapeutic option.[9]

Although homocysteine has also been linked to atherogenesis, prospective studies suggest, at most, a modest increase in risk associated with elevated homocysteine levels and have not consistently demonstrated a relationship independent of traditional risk factors or other biochemical markers.[10] Moreover, placebo-controlled trials have failed to demonstrate clinical benefit associated with folate and B vitamin replacement therapies as an intervention to mitigate the adverse effects of increased homocysteine levels.[11] Therefore, general screening for elevated homocysteine levels is not recommended.

Biomarkers of Myocyte Injury, Ischemia, and Hemodynamic Stress

Blood levels of cardiac troponins T and I are typically used to differentiate patients with acute MI from those with SIHD. However, with the development of high-sensitivity assays, low levels of circulating troponins are now detectable in most patients with SIHD and demonstrate a graded relationship with the subsequent risk for cardiovascular (CV) mortality and heart failure.[12,13] Moreover, patients with SIHD who have small increases in high-sensitivity troponin (hsTn) levels over time are at increased risk for adverse outcomes, even in the absence of an evident change in clinical status (**Fig. 61.3**). Potential emerging applications of cardiac troponin in SIHD are reviewed in depth elsewhere.[14]

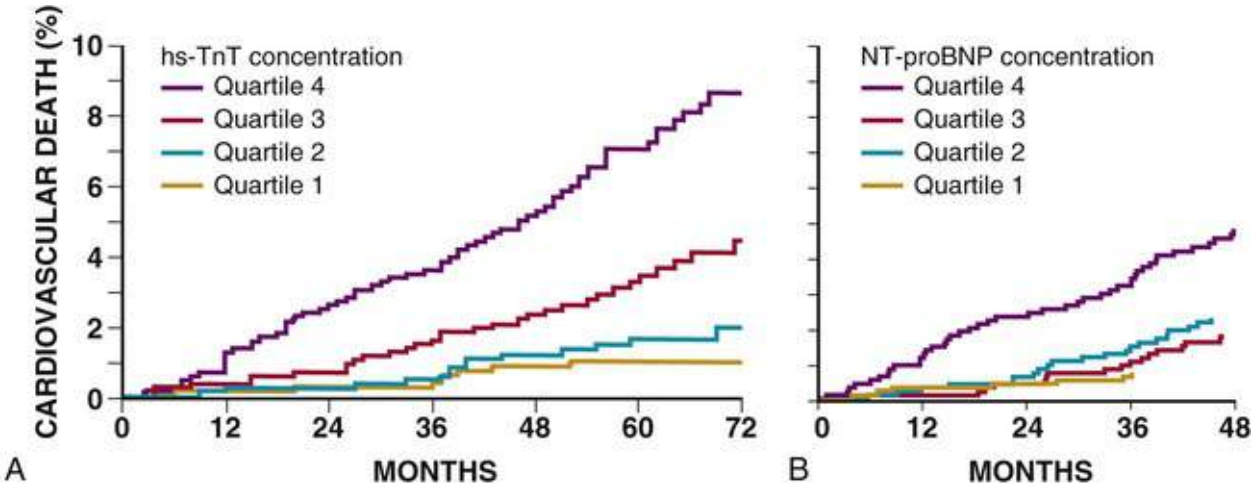

FIGURE 61.3 Incidence of cardiovascular (CV) death according to the concentration of high-sensitivity troponin T (hs-TnT) **(A)** and N-terminal pro–B-type natriuretic peptide (NT-proBNP) **(B)** in patients with stable coronary artery disease (CAD) subgrouped by quartiles of biomarker concentration. **A,** Circulating cardiac troponin T was detected in 97.7% of individuals by hs-TnT assay, with 11.1% having a concentration that exceeded the 99th percentile reference limit. During a median follow-up of 5.2 years, the incidence of CV death was associated with the baseline concentration of hs-TnT. This relationship was apparent at concentrations of hs-TnT below the 99th percentile reference limit (0.013 µg/L). **B,** The NT-proBNP concentration was also strongly associated with risk for CV mortality; prognostic accuracy improved when NT-proBNP was considered alongside traditional clinical risk indicators. (**A,** From Omland T et al. A sensitive cardiac troponin T assay in stable coronary artery disease. N Engl J Med 2009;361:2538; **B,** from Omland T et al. Prognostic value of B-type natriuretic peptides in patients with stable coronary artery disease. J Am Coll Cardiol 2007;50:201.)

Biomarkers of neurohormonal activation have also been extensively studied in patients with SIHD. For example, the plasma concentration of brain (B-type) natriuretic peptide (BNP) increases in response to spontaneous or provoked ischemia. Although BNP and N-terminal pro-BNP (NT-proBNP) do not have sufficient specificity to aid in the diagnosis of SIHD, higher concentrations of these peptides are strongly associated with risk for CV events in those at risk for and with established CAD. As has been shown with hsTn, serial measurements of natriuretic peptides also provide incremental prognostic information in patients with SIHD, suggesting a potential future role of outpatient monitoring with these tests.[14] Despite the promising results of studies to date, routine measurement of troponins and natriuretic peptides is not yet warranted in patients with SIHD, because the optimal strategies to reduce levels of these biomarkers, or to lower risk for patients with elevated levels, have not been determined. However, intensive secondary preventive therapies, such as treatment with high-intensity statin regimens, reduce risk in those with elevated troponin, with absolute risk reductions that are heightened given the high risk status of these patients.[15-17]

Growth differentiation factor-15,[18] ST2, fibroblast growth factor-23,[19] and galectin-3[20] are also biomarkers that may putatively reflect myocardial ischemia or its consequences and have been associated with CV outcomes in clinical studies of patients with SIHD. Other novel biomarkers of hemodynamic stress, such as midregional proadrenomedullin (MR-proADM) and midregional pro–atrial natriuretic peptide (MR-proANP), can also provide information regarding the risk for CV death in patients with SIHD.[21] However, insufficient information is available to demonstrate that these measurements provide robust incremental information beyond natriuretic peptide and hsTn measurements, which have emerged as the strongest candidate biomarkers for clinical application in patients with SIHD.

Inflammatory Biomarkers

Advances in understanding of the pathobiology of atherothrombosis have generated interest in

inflammatory biomarkers as noninvasive indicators of underlying atherosclerosis and CV risk (**see Chapter 44**). Measurement of the acute-phase protein high-sensitivity C-reactive protein (hsCRP) has shown a consistent relationship to risk for incident CV events. (**see Chapter 45**). The prognostic value of hsCRP is additive to traditional risk factors, including lipids; however, its incremental clinical value for screening among individuals without known vascular disease continues to be debated.[22] The role of hsCRP testing among individuals with SIHD has also been extensively studied, with multiple studies confirming independent associations of hsCRP with adverse cardiac events. Also, two studies have shown that hsCRP may be an important biomarker reflecting residual risk among patients following ACS who are treated to low LDL goals with statin therapy. Patients who achieved low LDL cholesterol levels (<70 mg/dL) but with hsCRP levels above 2 mg/L were at higher risk for subsequent ischemic events than patients with low levels of both LDL and hsCRP. Moreover, hsCRP has been used to select potential candidates for antiinflammatory pharmacotherapy.[22a] In head-to-head comparison studies, the strength of the association of hsCRP with outcomes has been less than that seen with natriuretic peptides and cardiac troponins.

Although other biomarkers of inflammation, such as interleukin-6, myeloperoxidase, growth factors, cytokines, and metalloproteinases, remain under study as potential biomarkers reflecting inflammatory pathways contributing to atherosclerosis,[23] given their lack of cardiac specificity, they are unlikely to emerge as clinically useful biomarkers.

Genetic and Transcriptomic Biomarkers

Large-scale genetic mapping programs, utilizing genome-wide association studies (GWASs) and more recently next-generation genome sequencing have identified more than 50 unique genetic variants contributing to IHD (**see Chapter 7**). These studies have contributed to the identification of many new potential pathogenic targets and have also allowed testing for large numbers of genetic variations simultaneously at relatively low cost. Because the genes contributing to IHD individually explain only a small amount of the variation in disease, combining multiple variants in genetic risk scores is presently thought to be the only viable strategy by which genetic risk prediction could enter clinical practice. However, the genetic risk scores have only marginally improved risk prediction in individuals without known IHD and did not improve risk prediction in patients with previous CAD.[24] Larger genetic risk scores, incorporating additional variants identified with finer gene-mapping strategies, may improve performance in the future. It is more likely that genetic testing will enter routine practice as a tool to guide therapeutic drug selection (pharmacogenomics; **see Chapter 6**). Two studies have demonstrated that individuals with high genetic risk scores, identifying a genetic predisposition to IHD, derive greater reduction in risk with statin therapy than do individuals with low genetic risk scores.[25]

It is now also possible to study multigene expression from peripheral blood cells, so called transcriptomics.[26] For example, a peripheral blood gene expression score based on expression values for 23 genes from peripheral blood cells has been developed and validated to assess the risk for obstructive CAD; a high negative predictive value (NPV) with a very low rate of major adverse cardiac events (MACE) over a 1-year period was demonstrated in patients with a low gene expression score.[26]

Noninvasive Testing

Resting Electrocardiogram

Findings on the resting ECG are normal in approximately half of patients with SIHD, and even patients

with severe CAD may have a normal tracing at rest (**see Chapter 12**). A normal resting ECG suggests the presence of normal resting LV function and is an unusual finding in a patient with an extensive previous MI. The most common abnormalities on the ECG in patients with SIHD are nonspecific ST-T wave changes with or without abnormal Q waves. In patients with known CAD, however, the occurrence of ST-T wave abnormalities on the resting ECG (particularly if obtained during an episode of angina) can correlate with the severity of the underlying heart disease. This correlation explains the adverse association of ST-T wave changes with prognosis in these patients. In contrast, a normal resting ECG is a more favorable long-term prognostic sign in patients with suspected or definite CAD.

Interval ECGs may reveal the development of Q wave MIs that have gone unrecognized clinically. Various conduction disturbances, most frequently left bundle branch block (LBBB) and left anterior fascicular block, may occur in patients with SIHD. They are often associated with impairment of LV function, reflect multivessel CAD, and are an indicator of a relatively poor prognosis. Various arrhythmias, especially premature ventricular contractions (PVCs), may be present on the ECG, but these also have low sensitivity and specificity for accurately detecting CAD. LV hypertrophy on the ECG is associated with a worse prognosis in patients with chronic stable angina. This finding implies the presence of underlying hypertension, aortic stenosis, hypertrophic cardiomyopathy, or previous MI with remodeling and warrants further evaluation, such as echocardiography to assess LV size, wall thickness, and function.

During an episode of angina pectoris, ECG findings become abnormal in 50% or more of patients with normal resting ECGs. The most common finding is ST-segment depression, although ST-segment elevation and normalization of previous resting ST-T wave depression or inversion (pseudonormalization) may develop. Ambulatory ECG monitoring (see later, Silent Myocardial Ischemia) provides a quantitative estimate of the frequency and duration of ischemic episodes during routine activities; however, its sensitivity for detecting CAD is less than that of exercise electrocardiography.

Resting Echocardiogram

Assessment of global LV function is one of the most valuable aspects of echocardiography. Identification of regional wall motion abnormalities may be suggestive of CAD, whereas other findings such as valvular stenosis or pulmonary hypertension may suggest alternative diagnoses. U.S. and European guidelines differ notably regarding recommendations for routine echocardiography in patients with SIHD. European Society of Cardiology (ESC) guidelines recommend routine echocardiography (class I, level of evidence [LOE]: B) for patients with SIHD,[27] whereas American College of Cardiology/American Heart Association (ACC/AHA) guidelines do not recommend routine echocardiography for all patients with angina pectoris (class III, LOE: C); rather, echocardiography is recommended for patients with a history of MI, ST-T wave abnormalities, or conduction defects or Q waves on the ECG (class I, LOE: B).[28] We also believe echocardiography is appropriate for patients with persistent elevation in cardiac biomarkers such as BNP (or NT-proBNP) or cardiac troponin (cTn).

Chest Radiograph (See Chapter 15)

The chest roentgenogram is generally within normal limits in patients with SIHD, particularly if they have normal findings on the resting ECG and have not experienced MI. If present, cardiomegaly is indicative of severe CAD with previous MI, preexisting hypertension, or an associated nonischemic condition such as concomitant valvular heart disease or cardiomyopathy.

Stress Testing (See Chapters 13, 14, and 16)

Noninvasive stress testing can provide useful and often indispensable information to establish the diagnosis and estimate the prognosis in patients with suspected stable angina. However, indiscriminate use of such tests yields limited incremental information beyond that provided by the physician's detailed and thoughtful clinical assessment. Appropriate application of noninvasive tests requires consideration of bayesian principles, which state that the negative and positive predictive values of any test are defined not only by its sensitivity and specificity but also by the prevalence of disease (or pretest probability) in the population under study. Noninvasive testing should be performed only if the incremental information provided by a test is likely to alter the planned management strategy. The value of noninvasive stress testing is greatest when the pretest likelihood is intermediate because the test result is likely to have the greatest effect on the post-test probability of CAD and thus on clinical decision making.

Traditionally, the pretest probability of CAD has been estimated using a classification scheme developed by Diamond and Forrester over 40 years ago that incorporates age, sex, and whether symptoms are typical, atypical, or nonanginal. However, the performance of this classification scheme has been diminished by changing risk factor profiles, leading to substantial overestimation of the probability of obstructive CAD in contemporary cohorts.[29,30] Two newer algorithms for predicting CAD have been developed by a European consortium and calibrated in more modern cohorts. These two CAD consortium scores—a basic score (**Table 61.1**) and a more detailed clinical score—are now recommended in the ESC guidelines on the management of SIHD.[27] A head-to-head comparison of the Diamond-Forrester and CAD consortium scores demonstrated substantial improvement in the prediction of obstructive CAD with the two newer scores, suggesting that use of these scores could reduce unnecessary referrals for diagnostic testing.[31]

TABLE 61.1

Pretest Likelihood of Coronary Artery Disease (CAD) in Symptomatic Patients According to Age, Sex, and Symptom Quality

AGE (yr)	NONANGINAL PAIN		ATYPICAL ANGINA		TYPICAL ANGINA	
	Women (%)	Men (%)	Women (%)	Men (%)	Women (%)	Men (%)
30-39	5	18	10	29	28	59
40-49	8	25	14	38	37	69
50-59	12	34	20	49	47	77
60-69	17	44	28	59	58	84
70-79	24	54	37	69	68	89
>80	32	65	47	78	76	93

Modified from Genders TS et al. A clinical prediction rule for the diagnosis of coronary artery disease: validation, updating, and extension. Eur Heart J 2011;32(11):1316-30.

Exercise Electrocardiogram (See Chapter 13)

Diagnosis of Coronary Artery Disease.

The exercise ECG is particularly helpful in patients with chest pain syndromes who are considered to have a moderate probability of CAD and in whom the resting ECG is normal, provided that they are capable of achieving an adequate workload.[32] Although the incremental diagnostic value of exercise testing is limited in patients in whom the estimated prevalence of CAD is high or low, the test provides useful additional information about the degree of functional limitation in both groups of patients and

about the severity of ischemia and prognosis in patients with a high pretest probability of CAD. Interpretation of the exercise test should include consideration of the patient's exercise capacity (duration and metabolic equivalents) and clinical, hemodynamic, and electrocardiographic responses.

Asymptomatic Persons.

Exercise testing in asymptomatic individuals without known CAD is not usually recommended. Exercise testing may be appropriate for asymptomatic individuals at high cardiac risk who plan to begin vigorous exercise, those with high-risk professions (e.g., airline pilots), and those with evidence of extensive atherosclerosis on other noninvasive testing, such as severe coronary calcifications on cardiac computed tomography (CT).

Risk Stratification.

One of the most important and consistent prognostic markers is maximal exercise capacity, regardless of whether it is measured by exercise duration or by workload achieved or whether the test was terminated because of dyspnea, fatigue, or angina.[23] After adjustment for age, the peak exercise capacity measured in metabolic equivalents is among the strongest predictors of mortality in patients with CVD. Other factors identified with exercise treadmill testing associated with a poor prognosis in patients with SIHD include the presence and magnitude of ST depression, and abnormal HR and BP response.

Regardless of the severity of symptoms, patients with high-risk stress test results have a high likelihood of CAD and, if they have no obvious contraindications to revascularization, should undergo coronary arteriography.[33] Such patients, even if asymptomatic, are at risk for left main or triple-vessel CAD, and many have impaired LV function. By contrast, patients with clearly negative exercise test results, regardless of symptoms, have an excellent prognosis that cannot usually be improved by revascularization. If they do not have other high-risk features or refractory symptoms, coronary arteriography is not generally indicated. Similarly, patients in whom objective evidence of mild ischemia (e.g., 1-mm ST-segment depression) develops at a high workload (e.g., >9 to 10 minutes on a Bruce protocol) may not necessarily warrant coronary arteriography before an adequate trial of medical therapy is first administered.

Influence of Antianginal Therapy.

Antianginal therapy may reduce the sensitivity of exercise testing as a screening tool. If the purpose of the exercise test is to *diagnose* ischemia, it should be performed, if possible, in the absence of antianginal medications, particularly long-acting beta-blocking agents, which should be omitted for 2 to 3 days before testing. For long-acting nitrates, calcium antagonists, and short-acting beta blockers, discontinuing use of the medications the day before testing usually suffices. If the test is being performed for *risk stratification* in a patient with known CAD, discontinuation of medications is not necessary.

Controversy Regarding the Routine Use of Adjunctive Imaging *(see later, **Nuclear Cardiology Techniques** and **Stress Echocardiography**)*.

Important differences exist between U.S. and European guidelines regarding the routine addition of adjunctive imaging to exercise stress testing. In the U.S. guidelines, a regular exercise ECG is recommended to be considered first in patients with chest pain and a normal resting ECG for screening and detection of CAD, whereas in the European guidelines, stress imaging is recommended as the initial test option if local expertise and availability permit.[27] These differences reflect differing interpretations of exercise-ECG studies and their limitations, as well as the cost-effectiveness of routine imaging. The European guideline authors highlight the problem of verification bias, by which the sensitivity of exercise ECG may be artificially inflated and specificity decreased when only patients with positive exercise tests are referred for coronary angiography. When studies with verification bias are not included

(including those using CT angiography), the sensitivity and specificity of exercise ECG change from approximately 70% to 75% sensitivity and specificity to 50% sensitivity and 90% specificity (**Table 61.2**).

TABLE 61.2

ACC/AHA 2012 and ESC 2013 Guidelines: Selected Sensitivity and Specificity of Noninvasive Tests for Detection of Coronary Artery Disease (CAD)

	SENSITIVITY		SPECIFICITY	
	ACC/AHA 2012	ESC 2013	ACC/AHA 2012	ESC 2013

American College of Cardiology/American Heart Association (ACC/AHA) 2012 estimates modified from Garber and Solomon, 1999.

European Society of Cardiology (ESC) 2013 estimates were collated from multiple studies and modified from Montalescot G, Sechtem U, Achenbach S, et al. 2013 ESC guidelines on the management of stable coronary artery disease: the Task Force on the Management of Stable Coronary Artery Disease of the European Society of Cardiology. Eur Heart J 2013;34:2949-3003.

Sex Differences in Exercise Testing for Diagnosis of CAD *(see Chapters 13 and 89)*.

On the basis of earlier studies that indicated a much higher frequency of false-positive stress test results in women than in men, it is generally accepted that electrocardiographic stress testing is not as reliable in women.[32,34] However, the prevalence of CAD in women in the patient populations under study was low, and the lower positive predictive value (PPV) of an exercise ECG in women can be accounted for, in large part, on the basis of bayesian principles (**see Table 61.1**). Once men and women are stratified appropriately according to the pretest prevalence of disease, the results of stress testing are similar, although the specificity is probably slightly less in women. Exercise imaging modalities have greater diagnostic accuracy than exercise electrocardiography in men and women.[35] Nevertheless, the standard exercise stress test is recommended by the ACC/AHA as the initial stress test of choice in most patients who can exercise, including women. Again, the ESC guidelines favor use of adjunctive cardiac imaging. In support of the U.S. recommended approach, a trial of symptomatic women randomly assigned to exercise ECG or single-photon emission computed tomography (SPECT) perfusion imaging demonstrated no difference in the 2-year rate of MACE but significantly lower costs with the exercise ECG strategy.[36]

Nuclear Cardiology Techniques (See Chapter 16)

Stress Myocardial Perfusion Imaging.

Exercise myocardial perfusion imaging (MPI) with simultaneous ECG recording is generally considered to be superior to an exercise ECG alone in detecting CAD, in identifying multivessel CAD, in localizing

diseased vessels, and in determining the magnitude of ischemic and infarcted myocardium. Exercise SPECT yields higher sensitivity and specificity than exercise electrocardiography alone (**see Table 61.2**).[37]

Stress MPI is particularly helpful in the diagnosis of CAD in patients with abnormal resting ECGs and in those in whom ST-segment responses cannot be interpreted accurately, such as patients with repolarization abnormalities caused by LV hypertrophy and those receiving digitalis. Because stress MPI is a relatively expensive test (three to four times the cost of an exercise ECG) and is associated with radiation exposure, stress MPI should *not* be used as a screening test in patients in whom the prevalence of CAD is low.[38]

MPI with Pharmacologic Vasodilator Stress.

For patients unable to exercise adequately, pharmacologic vasodilator stress with adenosine derivatives (and rarely dipyridamole) may be used. As a general rule, a patient should be able to walk up two flights of stairs without stopping in order to complete a standard exercise stress test. The need for pharmacologic stress should be considered for patients who are older or have claudication, pulmonary disease, orthopedic problems, or severe obesity. In most nuclear cardiology laboratories, vasodilator studies account for approximately 40% to 50% of those referred for perfusion imaging. Although the diagnostic accuracy of pharmacologic vasodilator stress perfusion imaging is comparable to that achieved with exercise perfusion imaging (**see Table 61.2**), treadmill testing is preferred for patients who are capable of exercising because the exercise component of the test provides additional diagnostic and prognostic information, including ST-segment changes, effort tolerance, symptomatic response, and HR and BP response (**Table 61.3**). For patients unable to tolerate adenosine or regadenoson, dobutamine MPI can be performed.

TABLE 61.3

Risk Stratification Based on Noninvasive Testing

High Risk (>3% Annual Risk for Death or Myocardial Infarction)
1. Severe resting left ventricular dysfunction (LVEF <35%) not readily explained by noncoronary causes
2. Resting perfusion abnormalities involving ≥10% of the myocardium without previous known MI
3. High-risk stress findings on the ECG, including • ≥2-mm ST-segment depression at low workload or persisting into recovery • Exercise-induced ST-segment elevation • Exercise-induced VT/VF
4. Severe stress-induced LV dysfunction (peak exercise LVEF <45% or drop in LVEF with stress ≥10%)
5. Stress-induced perfusion abnormalities encumbering ≥10% of the myocardium or stress segmental scores indicating multiple vascular territories with abnormalities
6. Stress-induced LV dilation
7. Inducible wall motion abnormality (involving >2 segments or 2 coronary beds)
8. Wall motion abnormality developing at a low dose of dobutamine (≤10 mg/kg/min) or at a low heart rate (<120 beats/min)
9. Multivessel obstructive CAD (≥70% stenosis) or left main stenosis (≥50% stenosis) on CCTA
Intermediate Risk (1-3% Annual Risk for Death or Myocardial Infarction)
1. Mild to moderate resting LV dysfunction (LVEF of 35% to 49%) not readily explained by noncoronary causes
2. Resting perfusion abnormalities involving 5-9.9% of the myocardium in patients without a history or previous evidence of MI
3. ≥1-mm ST-segment depression occurring with exertional symptoms
4. Stress-induced perfusion abnormalities encumbering 5-9.9% of the myocardium or stress segmental scores indicating 1 vascular territory with abnormalities but without LV dilation
5. Small wall motion abnormality involving 1-2 segments and only 1 coronary bed
6. 1-vessel CAD with ≥70% stenosis or moderate CAD stenosis (50-69% stenosis) in ≥2 arteries on CCTA
Low Risk (<1% Annual Risk for Death or Myocardial Infarction)
1. Low-risk treadmill score (score ≥5) or no new ST-segment changes or exercise-induced chest pain symptoms when achieving maximal levels of exercise
2. Normal or small myocardial perfusion defect at rest or with stress encumbering <5% of the myocardium*
3. Normal stress or no change in limited resting wall motion abnormalities during stress
4. No coronary stenosis >50% on CCTA

*Although the published data are limited, patients with these findings will probably not be at low risk in the presence of either a high-risk treadmill score or severe resting LV dysfunction (LVEF <35%).

CCTA, Cardiac computed tomography angiography; *LVEF,* left ventricular ejection fraction; *VF,* ventricular fibrillation; *VT,* ventricular tachycardia.

Assessment of coronary artery calcium (CAC) can also be used to contribute to risk assessment.

Modified from Fihn SD, Gardin JM, Abrams J, ACCF/AHA/ACP/AATS/PCNA/SCAI/STS guideline for the diagnosis and management of patients with stable ischemic heart disease: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, and the American College of Physicians, American Association for Thoracic Surgery, Preventive Cardiovascular Nurses Association, Society for Cardiovascular Angiography and Interventions, and Society of Thoracic Surgeons. Circulation 2012;126:e354.

Vasodilator stress agents are also used with positron emission tomography (PET) to diagnose CAD and determine its severity (**see Chapter 16**). PET is associated with improved diagnostic accuracy compared with SPECT (**see Table 61.2**),[39] as well as lower radiation dose because of the shorter half-life of the radiotracers typically used. However, PET is less widely available. Both SPECT and PET are valuable for assessing myocardial viability in patients with regional or global LV dysfunction and thus may be useful to help identify candidates with ischemic cardiomyopathy who will most benefit from revascularization (see later, Myocardial Hibernation).

High-Risk Findings on MPI.

The prognostic value of stress MPI is now well established. In particular, the ability of MPI to identify patients at low (<1% with a normal MPI study), intermediate (1% to 5%), or high (>5%) risk for future cardiac events is valuable in patient management decisions (**Table 61.3**). The prognostic data obtained from MPI, including LV ejection fraction (EF) as well as the size and distribution of perfusion abnormalities, are incremental to clinical and treadmill exercise data in predicting future cardiac events.[37]

Stress Echocardiography (See Chapter 14).

Two-dimensional echocardiography is useful for the evaluation of patients with chronic CAD because it can be used to assess global and regional LV function under basal conditions and during ischemia, as

well as to detect LV hypertrophy and associated valve disease. Stress echocardiography may be performed with exercise or pharmacologic stress and allows detection of regional ischemia by identifying wall motion abnormalities induced by ischemia. Adequate images can be obtained in more than 85% of patients, and the test is highly reproducible in expert centers. Numerous studies have shown that exercise echocardiography can detect the presence of CAD with an accuracy similar to that of stress MPI and is superior to exercise electrocardiography alone (**see Table 61.2**).[40] Stress echocardiography is also valuable in localizing and quantifying ischemic myocardium. Limitations imposed by poor visualization of endocardial borders in a sizable subset of patients have been reduced by use of myocardial contrast agents, three-dimensional imaging, and strain-rate echocardiography (**see Chapter 14**). Although less expensive than nuclear perfusion imaging, stress echocardiography is more expensive than and not as widely available as exercise electrocardiography. Pharmacologic stress with dobutamine is an effective alternative for patients unable to exercise.

As with perfusion imaging, stress echocardiography also provides important prognostic information about patients with known or suspected CAD. The presence or absence of inducible regional wall motion abnormalities and the response of the EF to exercise or pharmacologic stress provide incremental prognostic information to that provided by the resting echocardiogram. Moreover, a negative stress echocardiographic result portends a low risk for future events (<1% per person-year; **see Table 61.3**).

Computed Tomography (See Chapter 18)

Cardiac CT has made substantial advances as a noninvasive approach to imaging atherosclerosis and its consequences.[41,42] In addition to being a highly sensitive method for detecting coronary calcification, which is a good marker of the total coronary atherosclerotic burden, cardiac CT can also provide angiography of the coronary arterial tree and quantification of ventricular function. Emerging applications allow assessment of myocardial perfusion and even functional assessment of the hemodynamic significance of coronary stenoses (fractional flow reserve).[43,44]

Coronary artery calcification (CAC) can be detected with a rapid noncontrast CT that utilizes only low doses of ionizing radiation. CAC screening does not have a role in the diagnosis of obstructive CAD in symptomatic patients with a high pretest probability of CAD. However, screening of *asymptomatic* individuals at intermediate risk for CAD events may be reasonable in selected individuals, because a high calcium score may reclassify an individual as being at higher risk and thereby lead to more intense risk factor modification.[43] Routine CAC screening in low-risk individuals is not recommended.

As an alternative to noncontrast CT to identify coronary calcification, coronary computed tomographic angiography (CCTA) can be used to diagnosis CAD in patients with an indication for diagnostic testing.[45] CT technology has progressed such that in select individuals, high-quality images of the coronary arteries may be obtained at relatively low overall radiation exposure. Consequently, CCTA may be reasonable in symptomatic patients at intermediate risk for CAD after initial evaluation, in particular, those with indeterminate results of stress testing.[46] The accuracy of CCTA for estimating the severity of luminal stenosis is limited in patients with tachycardia unable to be controlled adequately with beta blockers, heavy coronary calcification, or in the region of previously placed coronary stents. Sensitivity and specificity of CCTA compare favorably to other noninvasive techniques (**see Table 61.2**).

In a randomized trial of 10,003 symptomatic patients without known CAD, CCTA was compared with functional testing as an initial evaluation strategy. Clinical outcomes and costs were similar in the CCTA and functional testing arms over a median follow-up of 2 years (**Fig. 61.4**). Patients randomized to CCTA underwent more cardiac catheterizations but were less likely to be found to have no obstructive disease

on invasive angiography.[30] An important finding from this study was the low rate of CV events in both treatment arms, highlighting the possibility that deferral of all testing may be reasonable for many lower-risk individuals.

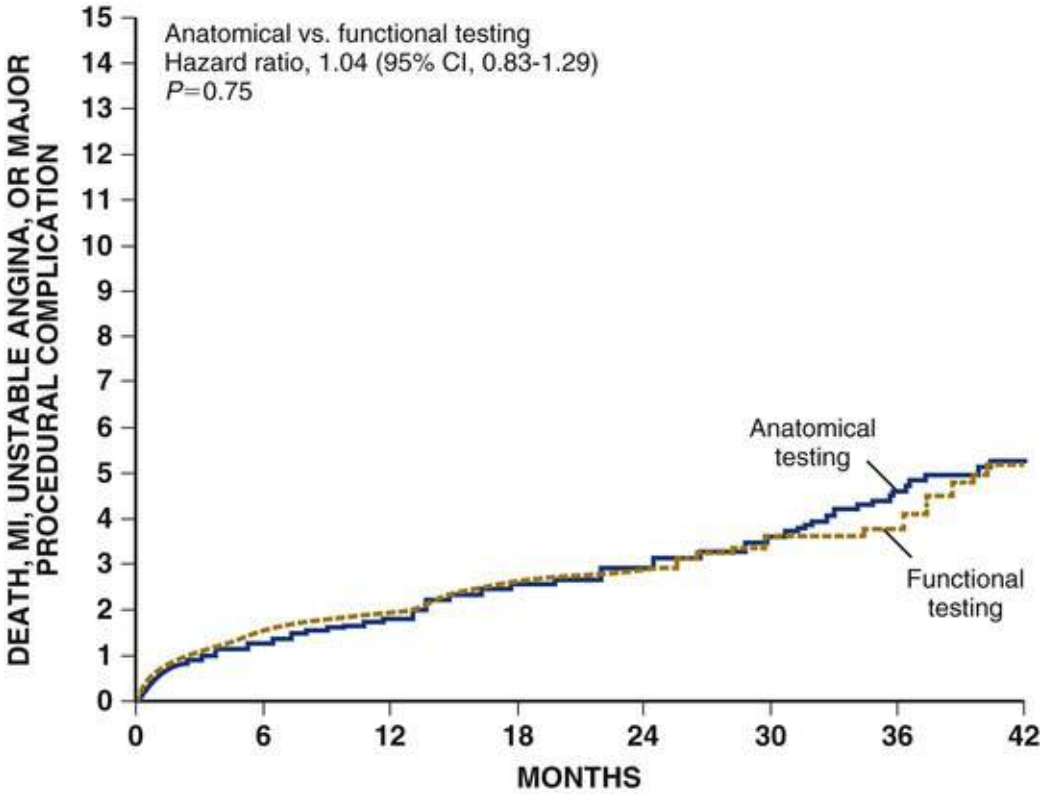

FIGURE 61.4 Outcome of patients with symptoms suggestive of coronary artery disease undergoing initial anatomic versus functional testing. Among 10,003 patients randomized to a strategy of anatomic testing (coronary computed tomographic angiography) or to functional testing (exercise electrocardiography, nuclear stress testing, or stress echocardiography), the composite primary end point of death, myocardial infarction (MI), hospitalization for unstable angina, or major procedural complication did not differ between the two diagnostic strategies (Modified from Douglas PS, Hoffman U, Patel MR et al. Outcomes of anatomical versus functional testing for coronary artery disease. N Engl J Med 2015;372:1298.)

Stress myocardial CT perfusion imaging is an emerging technique that provides both anatomic and physiologic information that can be combined with CCTA in a single protocol with a radiation dose similar to that of nuclear perfusion imaging.[47,48] In a study of 381 patients across 16 centers, CT perfusion imaging sensitivity and specificity for the diagnosis of CAD (≥50% stenosis) were 88% and 55%, respectively, compared with 62% and 67% for SPECT, with overall superior accuracy for CT (0.74 versus 0.64; $P = 0.001$).[45]

In experienced centers with advanced technology, CT has also been used to characterize plaque composition and, when paired with PET in a hybrid PET/CT scanner, can offer an assessment of coronary anatomy concurrent with information regarding myocardial blood flow and metabolism.[49] Nevertheless, the capacity of CT for determination of plaque composition is currently not sufficient for routine application.[50,51] Fractional flow reserve (FFR) can also now be estimated from CT angiogram images using complex computational algorithms (CTA-FFR), but these currently require off-line processing using proprietary software. The PLATFORM study compared patient care guided by CTA plus CTA-FFR versus usual care and reported a reduction in the probability of finding no obstructive CAD in the group who underwent CTA-FFR before angiography.[44] Further technological enhancements will be required before CTA-FFR is suitable for routine clinical use.

Currently, the clinical strength of CCTA remains its ability to exclude significant CAD with a high NPV. The rapid pace of innovation and clinical investigation of cardiac CT is likely to lead to further evolution of its role and integration into the assessment and management of SIHD.[44]

Cardiac Magnetic Resonance Imaging (See Chapter 17)

CMR is established as a valuable clinical tool for imaging the aorta and cerebral and peripheral arterial vasculature and is evolving as a versatile noninvasive cardiac imaging modality that has multiple applications in patients with SIHD. Clinical use of CMR for assessment of myocardial viability has grown because of evidence demonstrating its ability to predict functional recovery after percutaneous or surgical revascularization and its very good correlation with PET. Pharmacologic stress perfusion imaging with CMR compares favorably with SPECT (**Table 61.2**) and also offers accurate characterization of LV function, as well as delineation of patterns of myocardial disease that are often useful in discriminating ischemic from nonischemic myocardial dysfunction.[52]

Because of its ability to visualize arteries in three dimensions and differentiate tissue constituents, CMR has received interest as a method to characterize arterial atheroma and assess vulnerability to rupture on the basis of compositional analysis. Characterization of arterial plaque has been achieved in the aorta and carotid arteries in humans and has been shown to be predictive of subsequent vascular events.[53] Moreover, CMR coronary angiography is established as a modality to characterize congenital coronary anomalies (**see Chapter 75**) and has shown promise in detecting stenoses in the proximal and middle segments of major epicardial vessels or surgical bypass grafts.

Invasive Assessment

Catheterization, Angiography, and Coronary Arteriography

The clinical examination and noninvasive techniques described earlier are extremely valuable in establishing the diagnosis of CAD and are indispensable to the overall assessment of patients with this condition. Currently, however, precise assessment of the anatomic severity of CAD still requires invasive coronary arteriography (**see Chapters 19 and 20**). Nevertheless, it should be remembered that myocardial ischemia may occur in the absence of epicardial CAD (see later, Chest Pain with a Normal Coronary Arteriogram).[1,2] In patients with chronic stable angina referred for coronary arteriography, older series suggested that approximately 25% each had single-, double-, or triple-vessel anatomically significant CAD (i.e., >70% luminal diameter narrowing). From 5% to 10% had obstruction of the left main coronary artery, and in approximately 15%, no critical obstruction was detectable. In a contemporary report from the National Cardiovascular Data Registry (NCDR) that included almost 400,000 patients without known CAD, the proportion of individuals who reported angina but had no obstructive disease on coronary angiography was much higher, approaching 50%.[54]

LV function can be assessed by contrast ventriculography (**see Chapter 19**). Global abnormalities in LV systolic function are reflected by elevations in LV end-diastolic and end-systolic volume and depression of the EF. These changes are nonspecific, however, and can occur in many forms of heart disease. Abnormalities in regional wall motion (e.g., hypokinesis, akinesis, dyskinesis) are more characteristic of CAD.

High-Risk Findings from Coronary Angiography.

The independent impact of multivessel CAD and LV dysfunction and their interaction on the prognosis of patients with CAD is well established (**Fig. 61.5**).

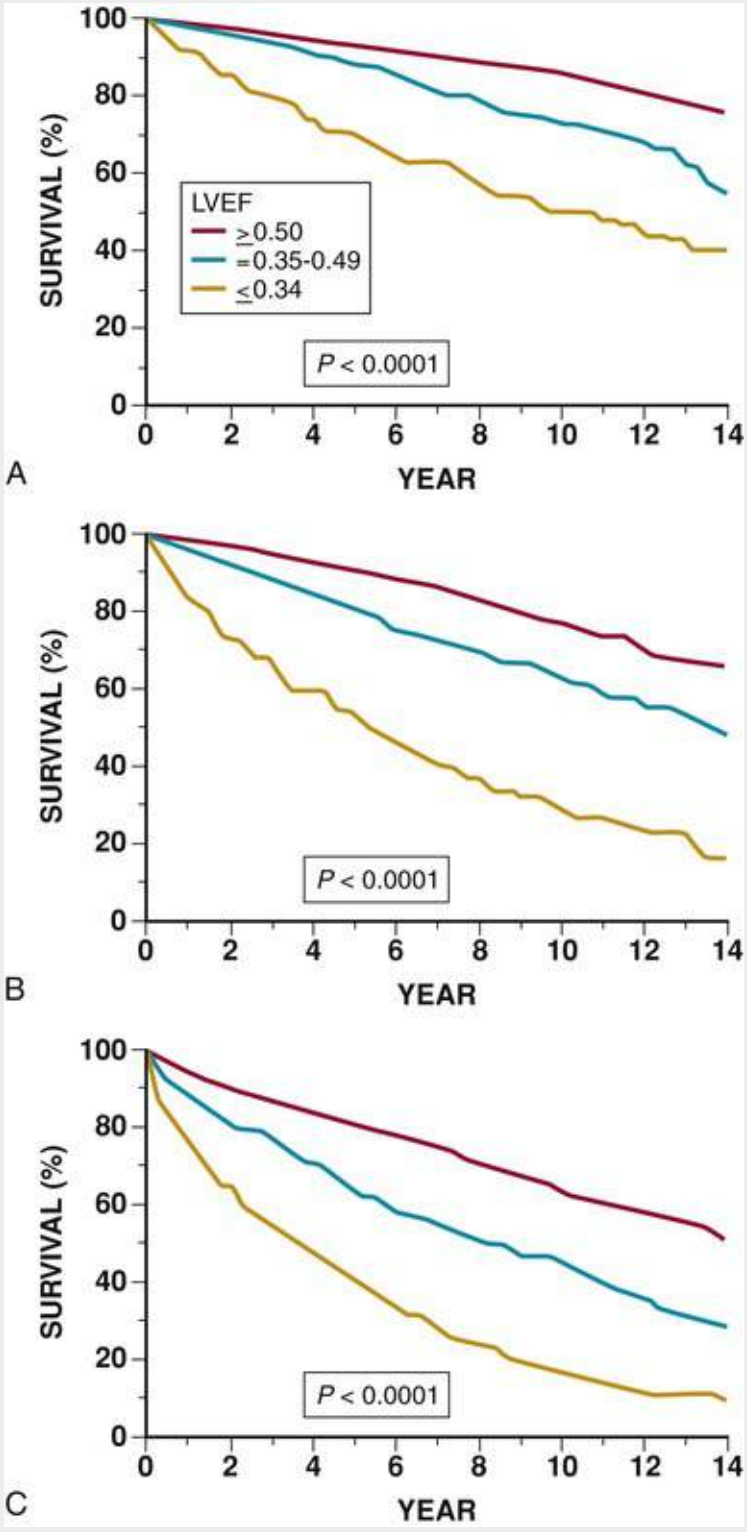

FIGURE 61.5 Graphs showing survival of medically treated patients in CASS stratified by normal, moderately, or severely reduced left ventricular ejection fraction (LVEF). **A,** Patients with single-vessel coronary disease. **B,** Patients with double-vessel coronary disease. **C,** Patients with triple-vessel coronary disease. (From Emond M, Mock MB, Davis KB, et al. Long-term survival of medically treated patients in the Coronary Artery Surgery Study [CASS] Registry. Circulation 1994;90:2651.)

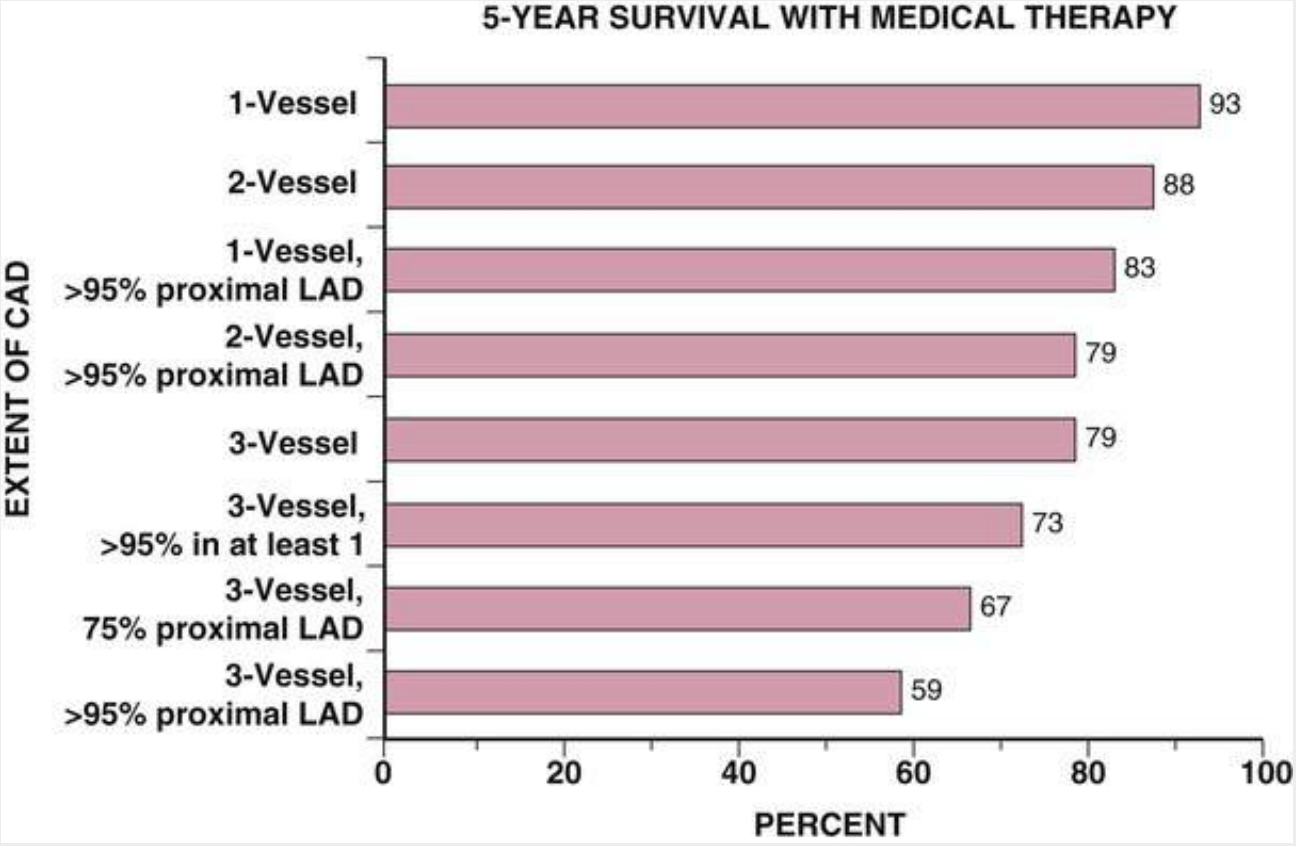
Extent of Coronary Artery Disease.

Although several indices have been used to quantify the extent or severity of CAD, the simple

classification of disease into single-, double-, or triple-vessel or left main CAD is the most widely used and is effective. Additional prognostic information is provided by the severity of the obstruction and its location, whether proximal or distal. The concept of the gradient of risk is illustrated in **eFig. 61.2**. The importance to survival of the quantity of myocardium that is jeopardized is reflected in the observation that an obstructive lesion proximal to the first septal perforating branch of the left anterior descending (LAD) coronary artery was associated with a 5-year survival rate of 90%, versus 98% in patients with more distal lesions. More sophisticated scoring systems, such as the SYNTAX (Synergy between PCI with Taxus and Cardiac Surgery) score, capture a more detailed assessment of the full extent and severity of epicardial CAD.[55]



EFIGURE 61.2 Angiographic extent of coronary artery disease (CAD) and subsequent survival with medical therapy. A gradient of mortality risk is established based on the number of diseased vessels and the presence and severity of disease of the proximal left anterior descending (LAD) coronary artery. (Data from Califf RM, Armstrong PW, Carver JR, et al. Task Force 5. Stratification of patients into high-, medium-, and low-risk subgroups for purposes of risk factor management. J Am Coll Cardiol 1996;27:964.)

High-grade lesions of the left main coronary artery or its equivalent, as defined by severe proximal LAD and proximal left circumflex CAD, are particularly life threatening. In natural history studies before the era of aggressive coronary revascularization, mortality in medically treated patients with severe left main CAD was reported to be 29%, with a 3-year mortality rate as high as 59% in patients with left main stenosis greater than 70%.

Limitations of Angiography.

Coronary angiography provides information principally about the degree of luminal stenosis of the coronary arteries. However, the pathophysiologic significance of coronary stenoses lies in their impact on resting and exercise-induced blood flow and their potential for plaque rupture with superimposed thrombotic occlusion. Coronary angiography is not a reliable indicator of the functional significance of

stenosis. Furthermore, coronary angiographic determinants of the severity of stenosis are based on a decrease in the caliber of the lumen at the site of the lesion relative to adjacent reference segments, which are considered, often erroneously, to be relatively free of disease. This approach may lead to significant underestimation of the severity and extent of atherosclerosis. The recent evolution in invasive diagnostics that frequently include measurement of FFR to assess the functional severity of lesions and to guide revascularization is an important step addressing this limitation of coronary angiography.

The most serious limitation to the routine use of coronary angiography for prognosis in patients with SIHD is its inability to identify which coronary lesions can be considered to be at high risk, or vulnerable, for future events, such as MI or sudden cardiac death (SCD). Although it is widely accepted that MI is the result of thrombotic occlusion at the site of plaque rupture or erosion (**see Chapter 58**), it is clear that it is not necessarily the plaque causing the most severe stenosis that subsequently ruptures. Lesions causing mild obstruction can rupture, thrombose, and occlude, thereby leading to MI and SCD. In fact, two thirds to three quarters of all acute MIs emanate from antecedent coronary stenoses that involve less than 50% of the luminal diameter. Approaches to quantifying the extent of CAD, inclusive of nonobstructive lesions, appear to offer additional prognostic information.

In summary, angiographic documentation of the extent of CAD provides useful information for assessment of the patient's risk for death and future ischemic events and is an indispensable step in the selection of patients for coronary revascularization, particularly if the interaction among the anatomic extent of disease, LV function, and severity of ischemia is taken into account. However, angiography often underestimates the burden of coronary atherosclerosis and is not helpful in predicting sites of subsequent plaque rupture or erosion that can precipitate MI or SCD. Additional tools that improve structural and functional assessment of coronary stenoses are discussed next.

Advanced Structural Coronary Imaging

Advanced invasive imaging techniques such as intravascular ultrasonography (IVUS) provide a more comprehensive evaluation of the coronary wall and have substantially enhanced the detection and quantification of coronary atherosclerosis, as well helping to characterize the vulnerability of coronary atheroma to rupture[56,57] (**see Chapter 20**). Studies incorporating both coronary angiography and IVUS have demonstrated that IVUS detects the presence of atherosclerosis missed by angiography alone. Although clinical use of IVUS for assessment of borderline stenoses has been largely supplanted by FFR measurement, IVUS continues to have a role in assessing left main coronary stenoses and bifurcation lesions and in optimizing stent deployment.[58] Virtual-histology (VH) IVUS uses ultrasound backscatter data to identify plaque components, including calcification, fibrous, and fibrofatty tissue. In several studies, VH-IVUS–defined thin-capped fibroatheroma (VH-TCFA) was associated with future MACE.[59,60]

Intravascular optical coherence tomography (OCT) is a light-based technology that provides much higher-resolution images of the coronary atheroma (10 to 15 μ versus 100 to 150 μ with IVUS), but penetration is limited to 1 to 3 mm in depth. OCT is particularly useful for measuring fibrous cap thickness and assessing coronary dissections and endothelial coverage of stent struts. Coronary angioscopy and thermography are exclusively research tools that have not emerged as clinically useful.[23,61,62]

Functional Assessment

Fractional flow reserve has emerged as the most important invasive tool to complement coronary angiography, providing a functional assessment of the hemodynamic impact of a coronary stenosis. The

measurement is simple to perform and highly reproducible. The primary role of FFR is in guiding decisions regarding percutaneous coronary intervention (PCI) for stenoses that appear intermediate in severity on angiography. FFR is determined as the ratio of pressure distal to a stenosis to pressure before the stenosis under conditions of maximal hyperemia, which is usually achieved with adenosine (**see Fig. 62.1**). For practical purposes, the proximal pressure measurement is performed in the aorta using a guiding catheter. A stenosis with FFR values less than 0.75 is highly likely to be associated with ischemia on nuclear perfusion imaging, whereas stenoses with FFR greater than 0.8 are rarely associated with ischemia. FFR of 0.75 to 0.8 represents a "gray zone." Recently a new measurement, the instantaneous wave free ratio (iFR), has been developed that allows characterization of the hemodynamic significance of coronary stenoses without administration of adenosine. This technique measures the gradient across a coronary stenosis at a point in diastole when microvascular resistance is minimal and stable.[62a]

Additional options for functional assessment include measurement of *coronary flow reserve* (maximum flow divided by resting flow) and endothelial function. These measurements frequently produce abnormal results in patients with CAD and play an important role in detecting microvascular dysfunction, particularly in those without obstructive epicardial disease.[63-65] The *index of microcirculatory resistance* (IMR) is a newer tool to interrogate the coronary microcirculation.[66,67] IMR incorporates the measured pressure gradient divided by coronary flow, is easier to perform than coronary flow reserve, and can be performed simultaneously with FFR using the same equipment. (See later, Patient Selection for Revascularization, and **Chapters 57 and 62**.)

Other Angiographic Findings

Coronary Artery Ectasia and Aneurysms.

Patulous aneurysmal dilation involving most of the length of a major epicardial coronary artery is present in approximately 1% to 3% of patients with obstructive CAD at autopsy or angiography. Most coronary artery ectasia and aneurysms are caused by coronary atherosclerosis (50%), and the rest are caused by congenital anomalies and inflammatory conditions such as Kawasaki disease.[68] Despite the absence of overt obstruction, 70% of patients with multivessel fusiform coronary artery ectasia or aneurysms have demonstrated evidence of cardiac ischemia.

Coronary ectasia should be distinguished from discrete coronary artery aneurysms, which are almost never found in arteries without severe stenosis, are most common in the LAD coronary artery, and are usually associated with extensive CAD. These discrete atherosclerotic coronary artery aneurysms do not appear to rupture and do not warrant resection.

Coronary Collateral Vessels *(see Chapter 20)*.

Provided that they are of adequate size, collateral vessels may protect against MI when total occlusion occurs. In patients with abundant collateral vessels, MI size is smaller than in patients without collaterals, and total occlusion of a major epicardial artery may not lead to LV dysfunction. In patients with chronic occlusion of a major coronary artery but without MI, collateral-dependent myocardial segments show almost normal baseline blood flow and O_2 consumption but severely limited flow reserve. This finding helps explain the ability of collateral vessels to protect against resting ischemia but not against exercise-induced angina.

Myocardial Bridging.

Bridging of coronary arteries is observed during coronary angiography at a rate of less than 5% in otherwise angiographically normal coronary arteries and ordinarily does not constitute a hazard.

Occasionally, compression of a portion of a coronary artery by a myocardial bridge can be associated with clinical manifestations of myocardial ischemia during strenuous physical activity and may even result in MI or initiate malignant ventricular arrhythmias. In an autopsy study, increased myocardial bridge thickness and length, as well as proximal vessel location, correlated with increased risk for MI, proposed to result from promotion of proximal atherosclerosis.[69] The functional consequences of myocardial bridging may be characterized with intracoronary Doppler measurements or MPI (**see Chapter 20**).

Natural History and Risk Stratification

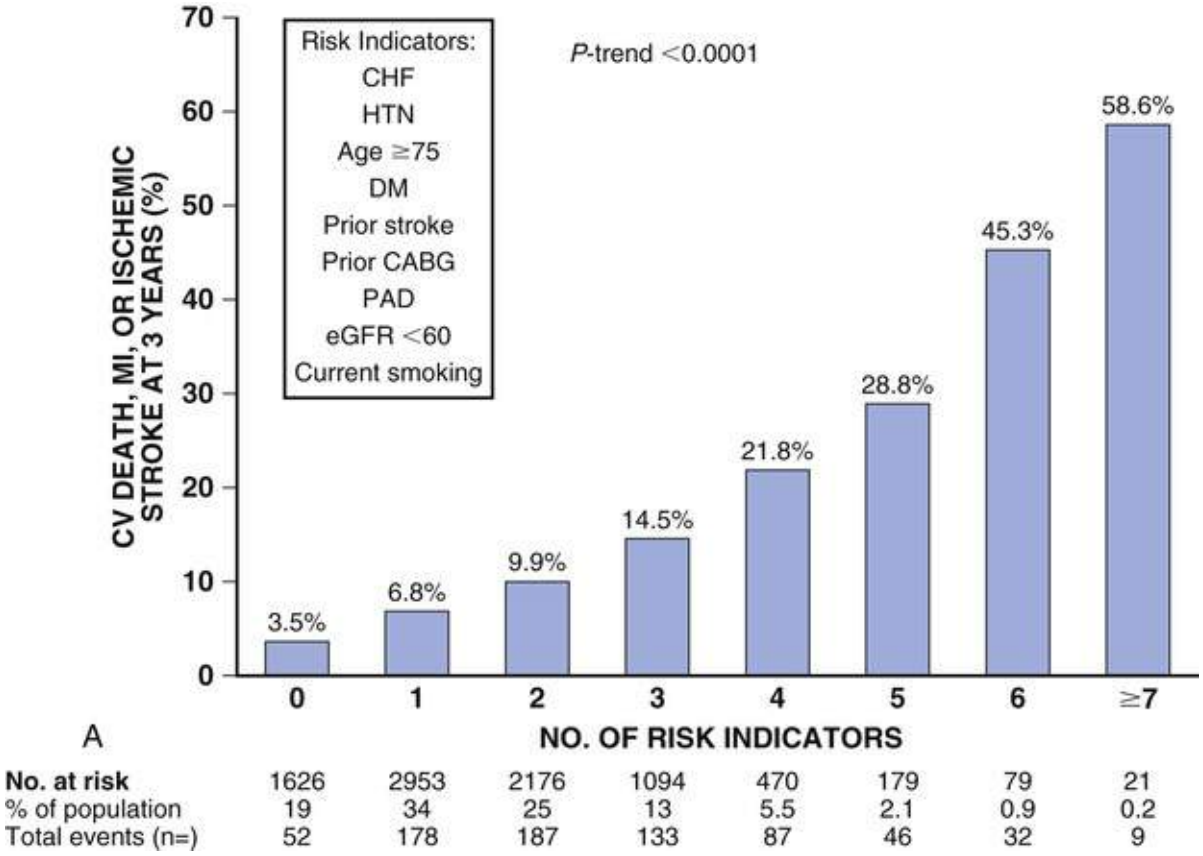
Up to 30% of patients with a history of stable angina experience angina one or more times per week. Stable angina is associated with physical limitation and worse quality of life. The frequency of reported angina varies substantially between providers, suggesting significant heterogeneity in identifying, characterizing, and managing angina.[70] Women have a similar incidence of stable angina as men, and angina in both sexes is associated with higher risk for mortality than is seen in the general population. Data from the Framingham Study, obtained before the widespread use of aspirin, beta-blocking agents, and aggressive modification of risk factors, revealed an average annual mortality rate of 4% in patients with SIHD. The combination of these treatments has improved the prognosis, with a current annual mortality rate of 1% to 3% and a rate of major ischemic events of 1% to 2%. For example, among 38,602 outpatients with SIHD enrolled in the REACH Registry, the 1-year rate of CV death was 1.9% (95% confidence interval [CI] 1.7% to 2.1%), that of all-cause mortality was 2.9% (95% CI 2.6% to 3.2%), and that of CV death, MI, or stroke was 4.5% (95% CI 4.2% to 4.8%).[71,72] Clinical, noninvasive, and invasive tools are useful for refining the estimated risk in individual patients with SIHD. Moreover, noninvasively acquired information is valuable in identifying patients who are candidates for invasive evaluation with cardiac catheterization.

Risk Stratification and Risk Models

Risk stratification is an integral component of the assessment and management of patients with SIHD. Risk assessment should be considered an iterative process, by which the estimation of risk is continually updated as new clinical or test information becomes available or symptoms change. Clinical characteristics, including older age, male sex, diabetes mellitus (DM), previous MI, and the presence of symptoms typical of angina, are predictive of the presence of CAD and associated with a higher risk of MACE in patients with SIHD.[23] A number of studies have attested to the adverse prognostic implications of heart failure (HF) in patients with SIHD. The severity of angina, especially the tempo of intensification, and the presence of dyspnea are also important predictors of outcome. Each of the noninvasive and invasive tests that assesses the extent of CAD, burden of ischemia, and LV function also provides powerful prognostic information (see later).

Several risk scores that integrate widely available clinical risk indicators have been developed to aid in prognostication with the aim of directing follow-up and therapeutic decision making. Patients with SIHD and prior MI vary in their risk for recurrent CV events. The Thrombolysis in Myocardial Ischemia (TIMI) Risk Score for Secondary Prevention (TRS 2°P) is a pragmatic integer score based on nine routinely assessed clinical characteristics—age, DM, hypertension, smoking, peripheral arterial disease (PAD), prior stroke, prior coronary artery bypass grafting (CABG), history of HF, and renal dysfunction—that exhibited a clear graded relationship with the risk for CV death, MI, or ischemic stroke in a population of 8598 patients with established coronary or peripheral atherosclerosis (**Fig. 61.6A**).[73] Also,

this risk score identified a pattern of increasing absolute benefit from treatment with the novel platelet inhibitor vorapaxar. In a second validation cohort in the IMPROVE IT trial of ezetimibe, the TRS 2°P performed similarly for risk stratification and also identified patients with a significantly greater absolute and relative risk reduction with the addition of ezetimibe to simvastatin (**Fig. 61.6B**).[74] Although the discriminatory capacity of the TRS 2°P was only moderate (C-statistic, 0.68) in both datasets, the demonstrated role for estimating benefit from more than one specific therapy lends clinical relevance.



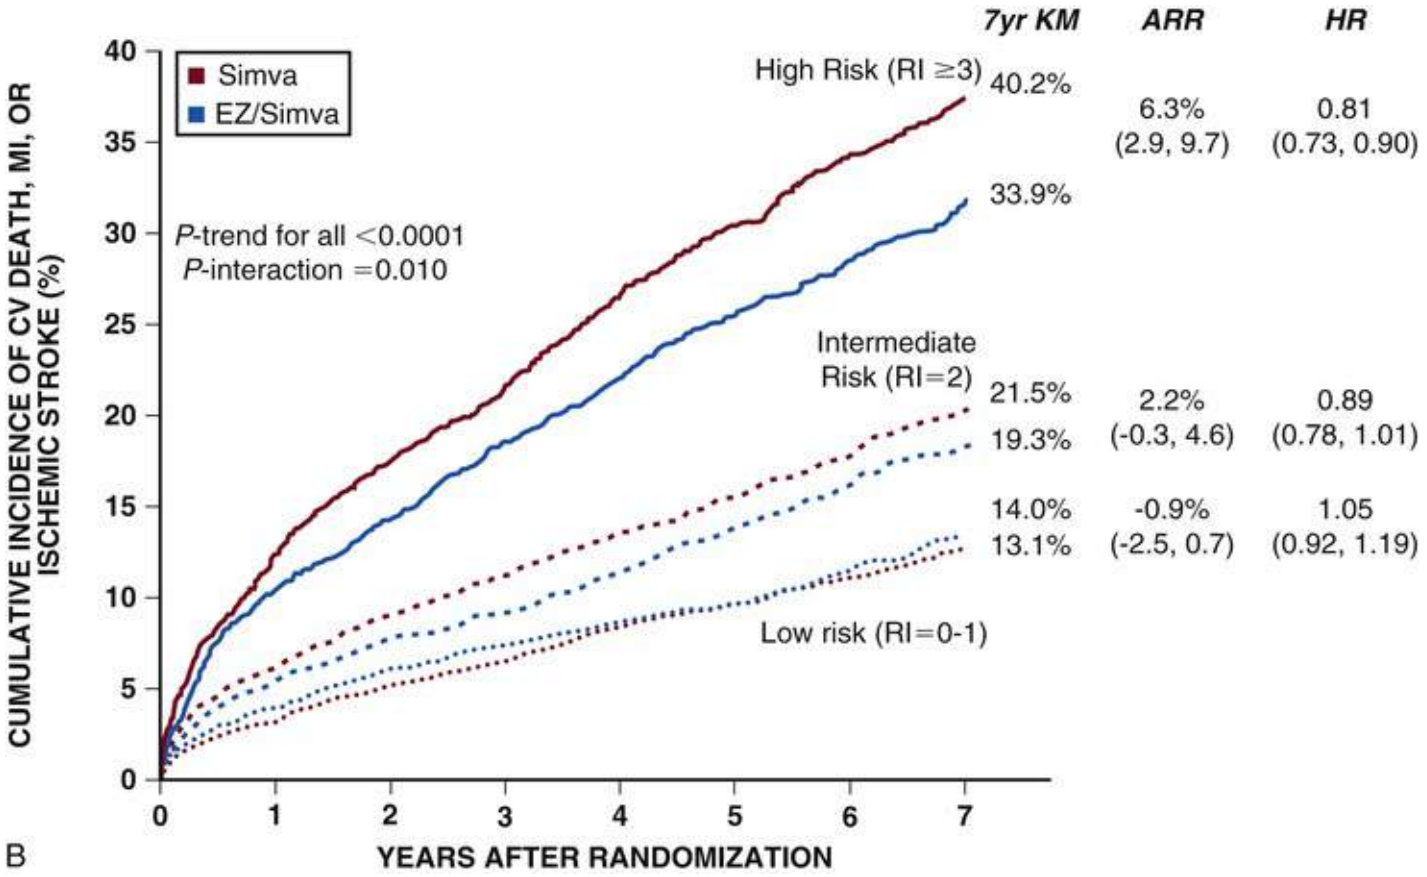


FIGURE 61.6 The TIMI Risk Score for Secondary Prevention. This risk score (http://www.timi.org/index.php?page=trs2p) was developed as a pragmatic nine-variable risk stratification tool among 8589 stable patients with a history of prior myocardial infarction (MI), prior stroke, or symptomatic peripheral artery disease (PAD). **A,** The 3-year risk of cardiovascular (CV) death, MI, or ischemic stroke is shown by risk score group along with the proportion of the development population that fell within each group. CABG, Coronary artery bypass grafting; CHF, Coronary heart disease; DM, diabetes mellitus; eGFR, estimated glomerular filtration rate; HTN, hypertension. **B**, The risk score was applied prospectively to 17,717 patients stabilized after an acute coronary syndrome and randomized to ezetimibe/simvastatin (EZ/Simva) or simvastatin (simva) alone. The cumulative incidence of CV death, MI, or ischemic stroke is shown by risk category and treatment group, demonstrating a pattern of increasing benefit of ezetimibe with higher risk categories defined by the score. ARR, absolute risk reduction; HR, hazard ratio; KM, Kaplan-Meier event rate; RI, risk index. (**A,** From Bohula EA et al. Atherothrombotic risk stratification and the efficacy and safety of vorapaxar in patients with stable ischemic heart disease and previous myocardial infarction. Circulation 2016;134:304-13; **B,** from Bohula EA et al. Atherothrombotic risk stratification and ezetimibe use in IMPROVE-IT. J Am Coll Cardiol 2016;67:2129.)

In addition, two risk scores have been developed for patients who have undergone PCI to aid in decision making regarding the use of dual-antiplatelet therapy (DAPT).[75,76] The DAPT risk score estimates net clinical outcome (balancing reductions in ischemia with increases in bleeding) with extending the duration of DAPT from 12 to 30 months after stenting.[76] The PARIS risk score was developed as a weighted integer score to predict new coronary thrombotic events (MI or stent thrombosis) in patients who had undergone PCI. The PARIS risk variables are consistent with the TRS 2°P, including PCI for ACS, revascularization before the qualifying PCI, DM, renal dysfunction, and current smoking. Patients are stratified into three bins of coronary thrombotic risk ranging from 1.8% to 10% at 2 years.[75]

Medical Management

Comprehensive management of SIHD has five aspects: (1) identification and treatment of associated diseases that can precipitate or worsen angina and ischemia, (2) reduction of coronary risk factors, (3)

application of pharmacologic and nonpharmacologic interventions for secondary prevention, (4) pharmacologic management of angina, and (5) revascularization by PCI or CABG, when indicated. Although discussed individually in this chapter, all five of these approaches must be considered, often simultaneously, in each patient. Of the medical therapies, aspirin, statins, and angiotensin-converting enzyme (ACE) inhibitors have been shown to reduce mortality and morbidity in patients with SIHD. Other therapies, such as nitrates, beta blockers, calcium antagonists, and ranolazine, have been shown to improve symptoms and exercise performance, but their effect, if any, on survival in patients with SIHD has not been demonstrated.[77]

In stable patients with LV dysfunction following MI, ACE inhibitors and beta-blocking agents reduce both mortality and the risk for repeat MI, and these agents are recommended in all such patients, with or without chronic angina, along with aspirin, statins, and in select individuals, aldosterone antagonists.

Treatment of Associated Diseases

Several common medical conditions that can increase myocardial O_2 demand or reduce O_2 delivery may contribute to the onset of new angina pectoris or exacerbation of previously stable angina. Such conditions include anemia, occult thyrotoxicosis, fever, infections, and tachycardia. Cocaine can cause acute coronary spasm and MI. In patients with CAD, by causing cardiac dilation, HF, increases in filling pressures, or tachyarrhythmias, including sinus tachycardia, can increase myocardial O_2 need and increase the frequency and severity of angina. Identification and treatment of these conditions are critical to the management of SIHD.

Reduction of Coronary Risk Factors

Hypertension (See Chapters 46 and 47)

Epidemiologic links between increased blood pressure and CAD severity and mortality are well established. For individuals 40 to 70 years of age, risk for IHD doubles for each 20–mm Hg increment in systolic BP across the entire range of 115 to 185 mm Hg.[78] Hypertension predisposes to vascular injury, accelerates the development of atherosclerosis, increases myocardial O_2 demand, and intensifies ischemia in patients with preexisting obstructive CAD. Although the relationship between hypertension and CAD is linear, LV hypertrophy is a stronger predictor of MI and CAD death than is the actual degree of BP increase. A meta-analysis of clinical trials of treatment of mild to moderate hypertension has shown a statistically significant 16% reduction in CAD events and mortality in patients receiving antihypertensive therapy. This treatment effect is almost twice as great in older as in younger persons. It is logical to extend these observations about the benefits of antihypertensive therapy to patients with established CAD. Moreover, the number of individuals treated to avoid one death is lower in patients with established CV disease. Therefore, BP control is an essential component of the management of patients with SIHD, with a goal of less than 140/90 mm Hg.[78-80] However, there is also evidence for a “J” shaped risk relationship, reflecting adverse outcomes in patients who achieve a very low BP on therapy. Therefore, in patients who have CAD with evidence of myocardial ischemia, the BP should be lowered slowly and, given concern of an increase risk at low ranges of diastolic BP, it is recommended to avoid diastolic BP below 60 mm Hg in elderly patients. Newer and emerging options for the treatment of hypertension are discussed in **Chapter 47**.[81]

Although there has been an assumed incremental risk for increased CV events in hypertensive patients with SIHD and a belief that more intensive BP lowering would reduce clinical events, the data from

randomized trials examining systolic BP targets below 140 mm Hg have had mixed results. Among patients with SIHD and DM, the ACCORD-BP study did not reveal an additional benefit of lowering systolic BP below 120 mm Hg in type 2 DM patients compared with lowering BP to less than 140 mm Hg.[5,82] However, in a trial of 9361 patients with hypertension and a high risk indicator other than DM, patients randomized to a systolic BP target of less than 120 mm Hg compared with below 140 mm Hg had a significantly reduced rate of the primary endpoint of ACS, stroke, HF, or death (1.65%/yr versus 2.19%/yr; hazard ratio [HR], 0.75; 95% CI 0.64 to 0.89) as well as all-cause mortality (HR, 0.73; 95% CI 0.60 to 0.90).[83]

Cigarette Smoking

Smoking remains one of the most powerful risk factors for the development of CAD in all age-groups (**see Chapter 45**). In patients with CAD, cigarette smokers have a higher 5-year risk for SCD, MI, and all-cause mortality than do those who have stopped smoking. Cigarette smoking may be responsible for aggravating angina other than through the progression of atherosclerosis. It may increase myocardial O_2 demand and reduce coronary blood flow by means of an alpha-adrenergically mediated increase in coronary artery tone and thereby cause acute ischemia. Moreover, passive exposure to cigarette smoke has adverse CV effects that are almost as great as those of active smoking. Smoking cessation lessens the risk for MACE in patients with established CAD and is one of the most effective and cost-saving approaches to prevention of disease progression.[79,84] Strategies for smoking cessation are discussed in **Chapter 45**.[85] Studies of nicotine medications and smokeless tobacco suggest that the risks of nicotine without tobacco combustion products are low compared with cigarette smoking, but are still of concern in people with CVD. The health implications of electronic cigarette use are as yet incompletely understood.[86]

Management of Dyslipidemia (See Chapter 48)

Clinical trials in patients with established atherosclerotic vascular disease have demonstrated a significant reduction in subsequent CV events in patients with a wide range of serum cholesterol and LDL cholesterol levels treated with statins. In the aggregate, angiographic trials of cholesterol lowering in patients with chronic CAD have shown that its effects on coronary obstruction are modest in comparison to the substantive reduction in CV events, thus suggesting that regression of atherosclerosis is not the primary mechanism of benefit. Nonetheless, in angiographic trials using IVUS, intensive statin therapy has led to regression of coronary atherosclerotic burden. Furthermore, several, but not all, studies have shown that statins significantly improve endothelium-mediated responses in the coronary and systemic arteries of patients with hypercholesterolemia or known atherosclerosis.

Lipid lowering with statins has been shown to reduce circulating levels of hsCRP, decrease thrombogenicity, and favorably alter the collagen and inflammatory components of arterial atheroma; these effects do not appear to correlate well with the change in serum LDL cholesterol level and suggest anti-atherothrombotic properties of statins. These pleiotropic properties may contribute to plaque stabilization, improvement in blood flow, reduction of inducible myocardial ischemia, and a decrease in coronary events in patients treated with statins.

Results from secondary prevention trials of patients with a history of SIHD, unstable angina, or previous MI have provided convincing evidence that effective lipid-lowering therapy significantly improves overall survival and reduces CV mortality in patients with CAD, regardless of baseline cholesterol levels. Moreover, trials in patients with established IHD have provided evidence of greater

reduction in MACE with intensive-dose compared with moderate-dose statin therapy. The 2013 ACC/AHA guidelines for cholesterol management advocate high-intensity statin therapy in all patients with established IHD who are younger than 75 years, in the absence of contraindications, with less emphasis on specific LDL target goals than in prior cholesterol guidelines.[87-89]

Since these 2013 guidelines were published, several additional studies of LDL-lowering agents other than statins have been completed. Among 18,144 patients stabilized after an ACS and who had a baseline LDL cholesterol (LDL-C) level between 50 to 100 mg/dL and were randomized to simvastatin (40 mg) plus ezetimibe or simvastatin (40 mg) alone, the addition of ezetimibe lowered the composite of CV death, MI, unstable angina requiring hospitalization, or coronary revascularization by a relative 6.4% (2% absolute difference at 7 years; $P = 0.016$).[90] In addition, combined analyses of multiple small trials of PCSK9 inhibitors with lipid lowering as the primary endpoint suggested that this class of agents that potently lowers LDL-C improved CV outcomes.[91,92] Subsequently, a randomized placebo-controlled trial of the PCSK9 inhibitor evolocumab in 27,564 patients with established atherosclerotic vascular disease demonstrated a 15% reduction in the composite of CV death, MI, stroke, hospitalization for unstable angina, or coronary revascularization (3yr rate, 12.6% vs. 14.6%; P < 000.1).[92a] A decision pathway developed by the ACC recognizes that if a patient with known atherosclerotic vascular disease treated with a statin has a less-than-anticipated response (i.e., <50% reduction in LDL-C or on-treatment LDL-C ≥100 mg/dL, or LDL-C ≥70 mg/dL for those with additional risk indicators), additional clinical approaches are warranted. In our practice, we also continue to view achieving an LDL-C less than 70 mg/dL as optimal in patients with established IHD. After addressing adherence to a high-intensity statin regimen, the clinician should consider the addition of a nonstatin medication to the current regimen, weighing risks, benefits, costs, and preferences with the individual patient.[93]

Low High-Density Lipoprotein Cholesterol.

Patients with established CAD and low levels of HDL cholesterol (HDL-C) represent a subgroup at considerable risk for future coronary events, even when LDL-C is low.[94,95] Low HDL levels are often associated with obesity, hypertriglyceridemia, insulin resistance, and hypertension. The constellation of these findings—often referred to as metabolic syndrome—typically signifies the presence of small lipoprotein remnants and small, dense, LDL particles, which are thought to be particularly atherogenic (**see Chapter 48**). Therapies to raise HDL have focused on diet and exercise, as well as smoking cessation. Whether HDL itself should be a target for pharmacologic therapies remains a controversial question.[96] Data on fibric acid derivatives, which lower triglycerides and raise HDL, have provided conflicting results, and no benefit was seen in the most contemporary trial that combined fenofibrate with statin therapy.[97,98] Moreover, two randomized trials of extended-release niacin failed to show benefit when niacin was added to contemporary therapy, despite marked increases in HDL-C among niacin-treated patients.[99,100] A trial of extended-release niacin versus placebo in 3414 patients with atherosclerotic vascular disease who had low baseline levels of HDL (<40 mg/dL for men; <50 mg/dL for women) and well-controlled LDL-C values (<70 mg/dL) while taking a statin, with or without ezetimibe, found no incremental clinical benefit of the addition of niacin to statin therapy during a mean 3-year follow-up.[99] In addition, a secondary prevention trial involving 25,673 IHD patients (Heart Protection Study 2–Treatment of HDL to Reduce the Incidence of Vascular Events) reported no significant reduction in a composite of major vascular events during a mean 4 years of treatment with simvastatin combined with extended-release niacin and laropiprant, a prostaglandin D_2 receptor-1 antagonist used to retard cutaneous flushing during niacin therapy, compared with statin-based therapy alone.[100]

Inhibitors of cholesterol ester transport protein (CETP) have also been disappointing. In two large

randomized trials, torcetrapib, a CETP inhibitor, increased HDL-C by 61% and reduced LDL-C by 20% but did not decrease progression of atherosclerosis and was associated with an increase in ischemic events, which may be explained by increased BP with torcetrapib.[101] In addition, a large outcomes trial of the CETP inhibitor dalcetrapib was stopped early because of a lack of clinically meaningful efficacy, and a multinational randomized trial of evacetrapib among 12,092 patients at high vascular risk demonstrated no effect on MACE compared with placebo.[102,103] In the last of this series of large outcomes trials with CETP inhibitors, among 30,449 patients with atherosclerosis followed for a median of 4.1 years, anacetrapib increased HDL by 104% and lowered LDL by 18% with a 1% absolute reduction in the risk of a major coronary event commensurate with the effect of lowering LDL without an additional benefit of raising HDL.[103a] Even though CETP inhibitors may raise plasma levels of HDL significantly, these agents can produce qualitatively dysfunctional, large HDL particles that may not be associated with a reduction in cardiac events. These trials have raised questions regarding the treatment of HDL-C as a target for secondary prevention.

Management of Diabetes Mellitus (See Chapter 51).

Patients with DM are at significantly higher risk for atherosclerotic vascular disease. Although a favorable impact of control of glycemia on microvascular complications of diabetes has been established, the effect on macrovascular complications (including CAD) is unclear. During a mean follow-up of 17 years in participants in the Diabetes Control and Complications Trial, patients with type 1 DM assigned to intensive glycemic therapy were at lower risk for CV complications. However, the results of studies of glycemic therapy with a shorter duration of follow-up, principally in patients with type 2 DM, are mixed.[104] Several large trials evaluating the effects of oral hypoglycemic agents on CV outcomes have shown no reduction in MACE.[105,106] Moreover, three large randomized trials comparing tight versus standard glucose control strategies failed to demonstrate benefit of more aggressive treatment. One of the trials, ACCORD (Action to Control Cardiovascular Risk in Diabetes) was stopped prematurely due to excess mortality in the group randomized to tight glucose control.[107] Thus, although a near-normal HbA_{1c} level (i.e., <7% [53 mmol/L]) is optimal to minimize microvascular complications, for older patients and those with preexisting CVD, a less stringent HbA_{1c} target of 8% or lower is recommended[108] Weight management, physical activity, BP control, and lipid management are recommended for all patients with SIHD and diabetes.[28,79]

Given reported CV risks of some oral hypoglycemic agents, the CV safety and efficacy of pharmacologic approaches to lowering blood glucose have garnered substantial attention from clinicians and researchers, particularly as new agents have become available. Guidance from U.S. and European regulatory authorities has required that large outcomes trials be performed to establish the CV safety of these new agents. Thus, new data are becoming available on the CV effects of these drugs, several of which have recently shown improvements in CV outcomes. The EMPA-REG Outcomes trial compared two doses of empagliflozin versus placebo in 7020 patients with type 2 DM and established CVD.[109] Empagliflozin is an inhibitor of sodium-glucose transporter 2 (SGLT2) that lowers blood glucose by promoting glucosuria; it also has diuretic and natriuretic effects. The primary endpoint of CV death, MI, or stroke was reduced by 14% in the combined empagliflozin groups, a finding driven by a 38% reduction in CV death (HR, 0.62; 95% CI 0.49 to 0.78; $P < 0.001$). Significant reductions were also seen in all-cause mortality (5.7 versus 8.3%; HR, 0.68; 95% CI 0.57 to 0.82) and HF hospitalization (HR, 0.65; 95% CI 0.50 to 0.85; $P < 0.001$). Similarly, canagliflozin lowered the rate of CV death, MI, or

stroke by 14% among 10,142 patients with diabetes and high cardiovascular risk.[109a] CV benefits have also emerged with the glucagon-like peptide-1 (GLP-1) GLP-1 agonist liraglutide. In the Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results–A Long Term Evaluation (LEADER) trial, liraglutide reduced MACE by a relative 13% (HR, 0.87; 95% CI 0.78 to 0.97; $P < 0.001$) and CV death by 22% (HR, 0.78; 95% CI 0.66 to 0.93; $P = 0.007$) among 9340 patients with type 2 DM and elevated CV risk.[110] Semaglutide, a once-weekly administered GLP-1 agonist, was also shown to reduce the rates of CV death, MI, and stroke compared with placebo (HR, 0.74; 95% CI, .58 to 0.95; $P < 0.02$).[110a] Multiple other large cardiovascular outcomes studies are ongoing evaluating novel therapies for type 2 DM.

Estrogen Replacement.

In view of the collective data from randomized clinical trials, it is *not* advised that hormone replacement therapy be initiated or continued for secondary CV prevention in women with CAD (**see Chapter 89**).[28,79]

Exercise (see Chapter 54)

The conditioning effect of exercise on skeletal muscles allows a greater workload at any level of total-body O_2 consumption. By decreasing the HR at any level of exertion, higher cardiac output can be achieved at any level of myocardial O_2 consumption. The combination of these two effects of exercise conditioning permits patients with chronic stable angina to increase physical performance substantially following institution of a continuing exercise program.[111]

Most of the information about the physiologic effects of exercise and their effect on prognosis in patients with IHD has come from studies on patients entered into cardiac rehabilitation programs, many of whom previously sustained an MI. Less information is available on the benefits of exercise in patients with SIHD without a previous MI. Collectively, small randomized trials evaluating exercise training in patients with SIHD indicate improved effort tolerance, O_2 consumption, and quality of life and reduced evidence of ischemia on MPI.[111] In addition, exercise training reduced hospitalizations and revascularization procedures and was associated with favorable changes in inflammatory and hemostatic mediators of CV risk in proportion to the intensity of exercise. Whether exercise accelerates the development of collateral vessels in patients with chronic CAD is unclear.

Exercise is safe if increased gradually, and if survivors of MI can be used as a yardstick, it is probably cost-effective.[112] The psychological benefits of exercise are difficult to evaluate. However, a single nonrandomized study demonstrated significant improvement in well-being scores and positive affect scores, as well as a reduction in disability scores, in patients in a structured exercise program. Patients who are involved in exercise programs are also more likely to be health conscious, to pay attention to diet and weight, and to discontinue cigarette smoking. For all these reasons, patients should be urged to participate in regular exercise programs, usually walking, in conjunction with their drug therapy.[79,112]

Obesity (See Chapters 50 and 51)

Obesity is both an independent contributor to the risk for IHD and is associated with a constellation of other risk factors, including hypertension, dyslipidemia, and abnormal glucose metabolism. Weight loss can improve or prevent many of the metabolic consequences of obesity.[113,114] However, the association of obesity with outcomes among patients with established SIHD is complex, with the most favorable outcomes consistently seen among individuals with overweight or mild-moderate obesity, and worse

outcomes among normal-weight individuals and those with extreme obesity (body mass index [BMI] ≥40 kg/m^2).[115] The explanation for the "obesity paradox" by which mild-moderate obesity appears protective in observational studies has not been fully elucidated.

Inflammation (See Chapters 44 and 45)

Atherothrombosis has been recognized as an inflammatory disease.[116,117] Markers of systemic inflammation, of which hsCRP is the most extensively studied, identify patients with established vascular disease who are at higher risk for death and future ischemic events. Moreover, the lower levels of hsCRP achieved with statin therapy in patients with established IHD are associated with a better long-term prognosis.[118] Targeting of inflammation as a potential objective for therapeutic intervention in patients with IHD is discussed in **Chapter 48**. Additional research is ongoing to clarify whether inflammation should be a target for routine strategies of risk reduction or novel therapeutic agents in patients with atherosclerosis.[119] At least one adequately sized outcomes trial has demonstrated the potential for an agent specifically targeting inflammation for secondary prevention. In the randomized placebo-controlled Canakinumab Antiinflammatory Thrombosis Outcome Study (CANTOS), canakinumab, a monoclonal antibody targeting interleukin-1β, reduced the composite of CV death, MI, or stroke at the cost of an increased rate of fatal infections (**see Chapter 48**).[22a]

Pharmacotherapy for Secondary Prevention

Aspirin *(see Chapters 45, 59, and 93)*.

Aspirin reduces the incidence of MACE in men and women with previous MI or stroke, and after CABG. Moreover, small studies have supported the benefit of aspirin in patients with chronic stable angina but without a history of MI.[28] Therefore administration of aspirin daily is advisable in patients with SIHD and no contraindications to this drug. Dosing at 75 to 162 mg daily appears to have comparable effects on secondary prevention as dosing at 160 to 325 mg daily and is associated with lower bleeding risk. Even among patients with intracoronary stenting, low-dose aspirin has been shown to be preferable to higher-dose aspirin. Thus, aspirin, 75 to 162 mg daily, is preferred for secondary prevention.[28]

Other Oral Platelet Inhibitors.

Other orally acting antiplatelet agents have been studied in patients with SIHD, including patients with or without a prior MI and patients managed with or without prior coronary stenting. Clopidogrel, a thienopyridine derivative, may be substituted for aspirin in patients with aspirin hypersensitivity or in those who cannot tolerate aspirin (**see Chapter 93**).[28] In a randomized comparison between clopidogrel and aspirin in patients with established atherosclerotic vascular disease (the Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events [CAPRIE] trial), treatment with clopidogrel resulted in a modest 8.7% relative reduction in the risk for vascular death, ischemic stroke, or MI ($P = 0.043$) over 2 years. Studies evaluating the addition of adenosine diphosphate (ADP) receptor antagonists such as clopidogrel, prasugrel, and ticagrelor to aspirin in patients with ACS or after PCI have demonstrated important risk reductions. Therefore, DAPT combining aspirin with one of these agents is routine in patients with ACS. In contrast, the treatment of patients with SIHD with DAPT should be more individualized because the clinical data suggest important risk/benefit trade-offs.[120]

When studied in a population that included patients with clinically evident CVD ($n = 12,153$) or asymptomatic individuals with multiple risk factors ($n = 3284$) enrolled in the CHARISMA (Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization Management and Avoidance) trial, the

addition of clopidogrel to aspirin showed no significant benefit with respect to the primary endpoint of CV death, MI, or stroke over a median of 28 months. However, in the large subgroup of those with established vascular disease, the addition of clopidogrel was associated with a 1% absolute reduction in these events (6.9% versus 7.9%; $P = 0.046$), thus supporting the hypothesis of a potential benefit from clopidogrel in patients with SIHD taking aspirin. In a subsequent study, patients were who had received a coronary stent were randomized to discontinuation of thienopyridine therapy at 12 months or continuation of DAPT through 30 months. Studied in this manner, continuation of long-term DAPT reduced the risk of death, MI, or stroke by 13% (absolute difference 1.6%) and stent thrombosis by 72% (absolute 1%) at the cost of a significant increase in bleeding (0.9%).[121] The balance of ischemia reduction and bleeding was more favorable among individuals in this trial who underwent PCI for an ACS event than those who underwent elective PCI.[122]

In a multinational randomized placebo-controlled trial (RCT) of ticagrelor in patients 1 to 3 years after a prior MI, whether managed medically or with revascularization, the addition of ticagrelor to aspirin reduced the rate of CV death, MI, or stroke, balanced against an increased rate of bleeding.[123] A combined analysis of these and other trials of long-term DAPT, predominantly in patients with prior ACS, revealed a significant reduction in CV mortality.[124] As such, treatment with long-term DAPT may be reasonable for patients at high risk of recurrent thrombosis, particularly those with a prior ACS event, provided they have an acceptable risk of bleeding.[120]

Importantly, patients at lower risk for ischemic events, including most patients undergoing PCI for SIHD symptoms who have not had a prior ACS, may not have a favorable balance of risk/benefit with extending the duration of DAPT. Indeed, some studies evaluating optimal DAPT duration for elective stenting for SIHD have suggested that *shorter* durations than 1 year are associated with similar ischemic outcomes along with expectedly lower rates of bleeding than longer durations of treatment.[125] As such, the most recent DAPT guideline from ACC/AHA recommends that the standard duration of DAPT be at least 6 months for most patients receiving stents for SIHD.[120] Risk scores weighing these competing risks for ischemic events and bleeding may be useful in decision making. Patients who are at higher risk of atherothrombotic events with acceptable bleeding risk may be considered for DAPT longer than 6 to 12 months.[73,75,76]

A large study of the oral platelet inhibitor vorapaxar has provided additional support that more potent antiplatelet therapy than aspirin alone reduces recurrent atherothrombosis in patients with SIHD who have had a prior MI. In a randomized, double-blinded, placebo-controlled trial of vorapaxar, an antagonist of the platelet-activating action of thrombin, vorapaxar reduced the risk for recurrent MACE in the overall trial; driven by a large subgroup of 17,779 patients enrolled with MI in the prior year.[126,127] However, a significant increase in the risk for bleeding with vorapaxar underscores the need for tailoring treatment to the individual patient based on the competing risks for increased thrombotic events versus increased bleeding.

Low-Dose Oral Anticoagulation.

When studied as therapy for secondary prevention in IHD, vitamin K antagonists reduced the risk of recurrent atherothrombotic events at a cost of significantly increased risk of bleeding. As a result of this risk and the challenges of long-term administration, vitamin K antagonists have not been routinely used for secondary prevention in SIHD. Direct oral anticoagulants offer the potential for a more favorable balance of efficacy and safety. In the Cardiovascular Outcomes for People Using Anticoagulation Strategies (COMPASS) trial, 27,2395 patients with established stable CAD or peripheral artery disease were randomized to treatment with rivaroxaban (2.5 mg twice daily) plus aspirin (100 mg once daily), rivaroxaban (5 mg twice daily), or aspirin (100 mg once daily). Patients with CAD qualified for

participation with either a history of MI in the past 20 years or multivessel CAD. Patients with CAD who were <65 years of age were also required to have documentation of atherosclerosis involving at least two vascular beds or to have at least two additional risk factors (current smoking, diabetes mellitus, an estimated glomerular filtration rate <60 mL/min, heart failure, or nonlacunar ischemic stroke ≥1 month earlier). Patients with peripheral artery disease qualified with either prior lower extremity artery revascularization, symptomatic claudication with an abnormal diagnostic test for PAD, or documented carotid artery disease. Compared with aspirin alone, rivaroxaban 2.5 mg twice daily plus aspirin reduced the risk of CV death, MI, or stroke by 24% (HR, 0.76; 95% CI, 0.66 to 0.86; $P < 0.001$). Major bleeding was increased by the addition of rivaroxaban from 1.9% to 3.1% (HR, 1.70; 95% CI, 1.40 to 2.05; $P < 0.001$). However, there were fewer deaths overall in the rivaroxaban 2.5 mg twice daily plus aspirin group compared with aspirin alone (HR, 0.82; 95% CI, 0.71 to 0.96; nominal $P = 0.01$). Rivaroxaban 5 mg twice daily without aspirin did not significantly reduce the primary endpoint compared with aspirin alone. This result provides a clear demonstration of the benefit of low-dose anticoagulation with rivaroxaban as an option for secondary prevention in SIHD. However, COMPASS did not study patients receiving an ADP antagonist in any treatment arm. The roles of the available options for long-term antithrombotic therapy in addition to aspirin (e.g. ticagrelor, rivaroxaban, or vorapaxar) are likely to be refined with clinical experience, additional research, and review by professional society guidelines committees.[127a]

Patients with Other Indications for Chronic Oral Anticoagulation.

Patients with SIHD who have indications for treatment with oral anticoagulation (OAC), because of atrial fibrillation (AF), venous thromboembolic disease, or mechanical heart valves, present challenging decisions regarding management (**see Chapter 93**). As a result of prior ACS or coronary stenting, such patients usually have indications for one or two antiplatelet agents in addition to OAC. However, the addition of even a single antiplatelet agent increases major bleeding rates by more than 50%, whereas bleeding is more than doubled among those requiring “triple therapy” with OAC, aspirin, and clopidogrel.[128]

For patients with strong indications for OAC who are at relatively low ischemic risk (i.e., no recent MI or stent), it may be reasonable to omit antiplatelet therapy altogether, particularly if bleeding risk is increased.

For patients with AF, reassessment of the risks and benefits of OAC should be performed after considering the increased bleeding risk associated with combination therapy. For example, among patients at lower stroke risk, it may be preferable to defer OAC after MI and/or stenting and reinitiate OAC once the patient can safely be withdrawn from DAPT. When triple therapy is necessary, recommendations include (1) limiting exposure to triple therapy to the shortest possible duration, (2) targeting the lower range of international normalized ratio (INR) for warfarin, (3) avoiding the more potent $P2Y_{12}$ antagonism of prasugrel and ticagrelor (i.e., clopidogrel is preferred in combination with OAC), and (4) routinely administering proton pump inhibitors (PPIs) to prevent gastrointestinal (GI) bleeding.[129] In addition, a small trial has shown that withdrawing aspirin after coronary stenting is associated with favorable bleeding and efficacy compared with triple therapy.[130]

Two subsequent trials have further advanced this strategy using reduced dose direct oral anticoagulants. In the PIONEER AF-PCI trial, reduced dose rivaroxaban (15 mg) plus P2Y12 inhibitor, without aspirin, was associated with markedly lower major bleeding rates at 1 year than standard triple therapy with warfarin, aspirin, and P2Y12 inhibitor (16.8 vs 26.7%, $P < 0.001$).[130a] Similarly, in the RE-DUAL PCI trial, reduced dose daibigatran plus P2Y12 inhibitor (without aspirin) resulted in similar bleeding reduction at 1 year compared to the triple-therapy regimen with warfarin (15.4% vs 26.9%, $P <$

0.001).[130b] No differences in ischemic outcomes or stroke were observed for either of the less-intensive regimens. These findings suggest that for patients with atrial fibrillation undergoing PCI, dual therapy with an oral anticoagulant (preferably a reduced dose of a direct oral anticoagulant) and clopidogrel, without aspirin, provides the best balance of safety and efficacy.

Beta-Blocking Agents.

The value of beta adrenoceptor–blocking drugs (beta-blocking agents) in reducing death and recurrent MI in patients who have experienced MI is well established (**see Chapters 59 and 60**), as is their usefulness in the treatment of angina. However, the optimal duration of treatment after MI is not clear, particularly for patients without LV dysfunction. Moreover, whether these drugs are also of value in preventing MI and SCD in patients with SIHD without previous MI is less certain, and there have been no prospective controlled trials involving placebo.[131] Findings from observational studies are mixed, with one of the largest studies reporting no reduction in mortality in patients with SIHD receiving beta-blocking agents[132] (**Fig. 61.7**). However, such observational studies are limited by the high potential for uncontrolled confounding. Moreover, the favorable effects of beta blockers on ischemia and arrhythmias evident in randomized trials among patients with prior MI or reduced LVEF may extend to other patients with SIHD. Therefore, although the use of beta blockers as first-line therapy for uncomplicated hypertension has been questioned, it is sensible to use these drugs when angina, hypertension, or both are present in patients with SIHD and when these drugs are well tolerated.[28]

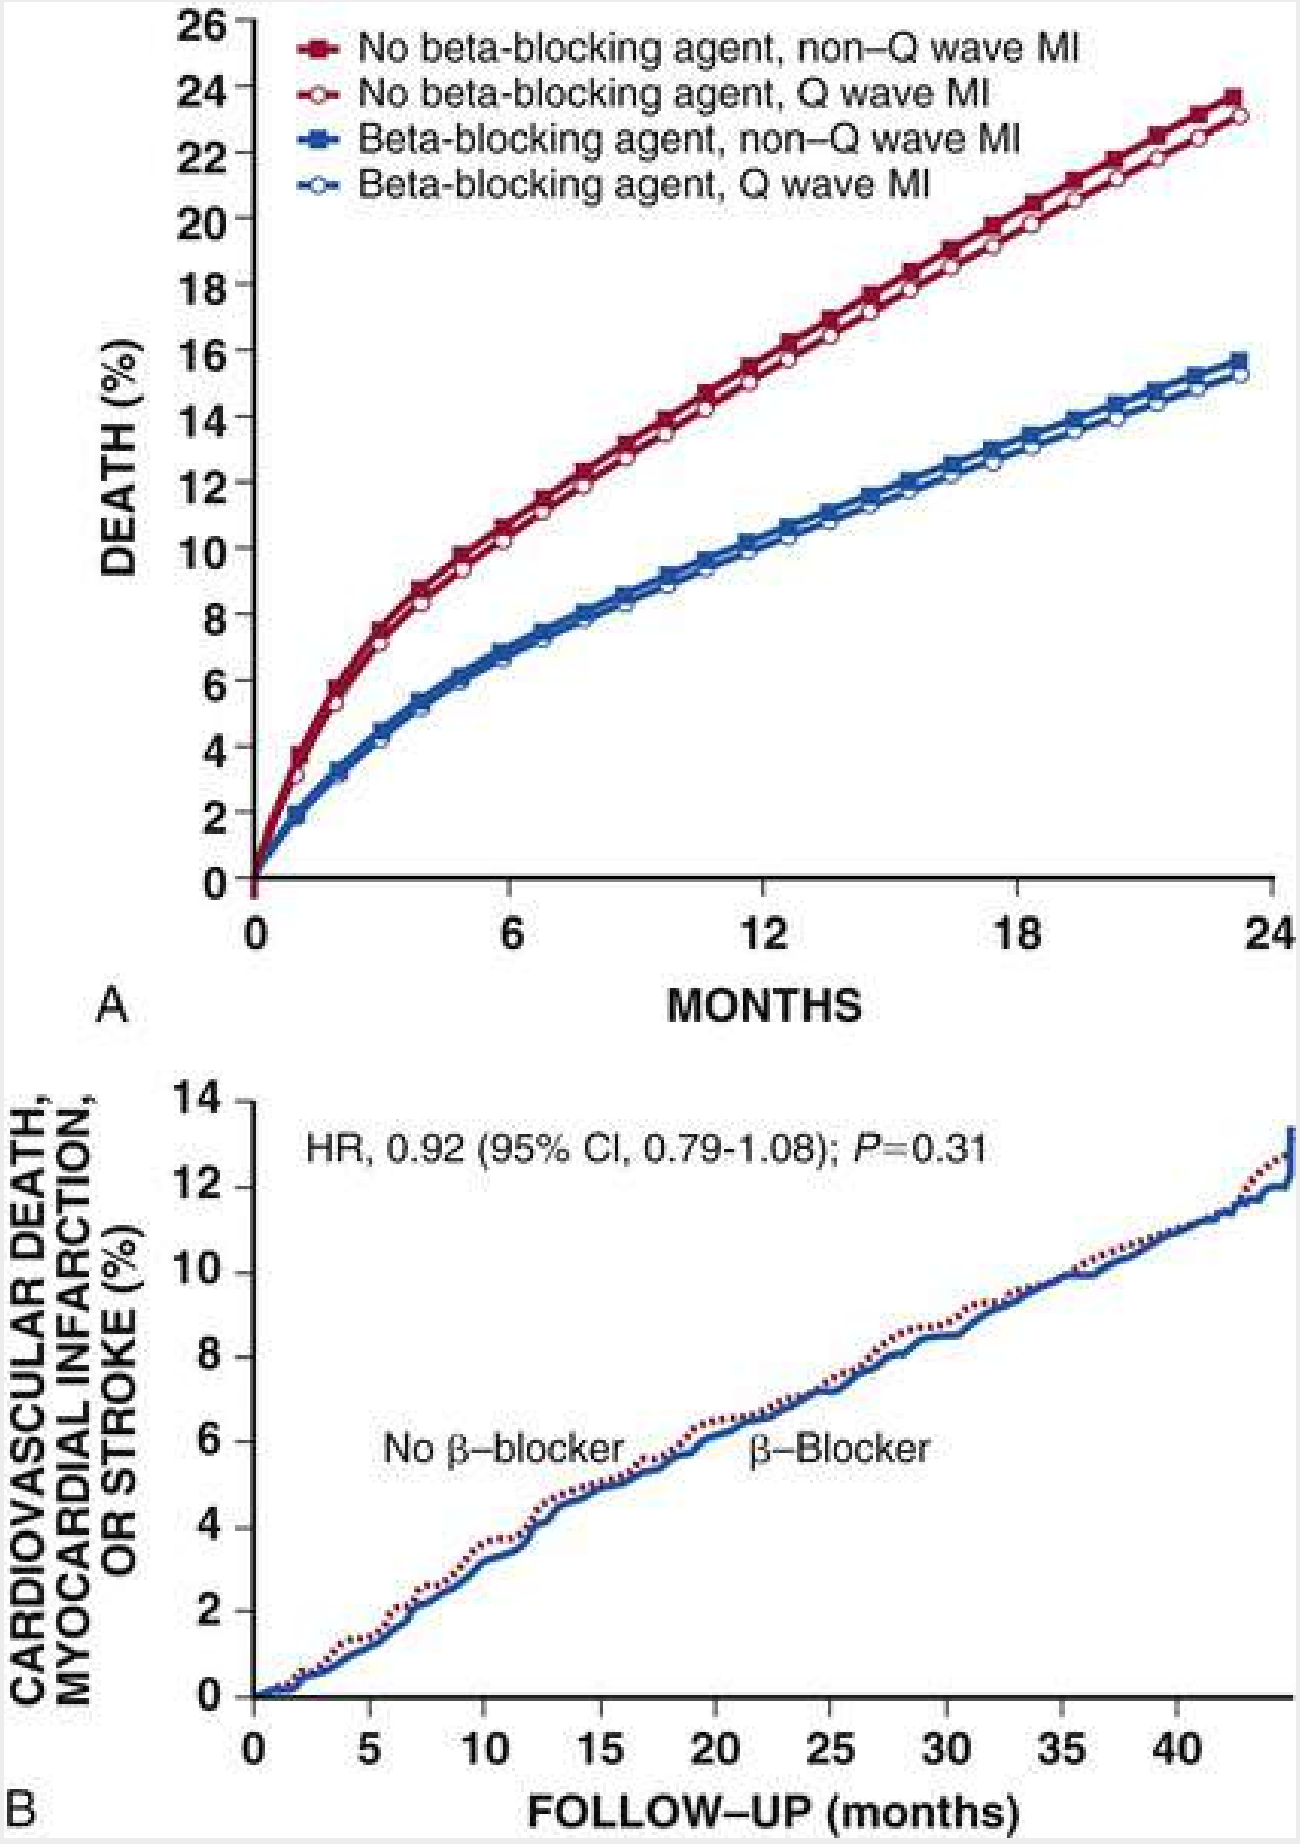

FIGURE 61.7 **A,** Assessment of the association between administration of a beta-blocking agent and the mortality rate in 201,752 individuals with previous myocardial infarction (MI) followed in a Medicare-based registry of patients discharged in 1994 to 1995 after MI. In patients with uncomplicated MI, prescription of a beta blocker was associated with a 40% relatively lower mortality rate. **B,** Longitudinal, observational study of patients in the REACH (Reduction of Atherothrombosis for Continued Health) registry in which a subgroup of 12,012 patients with known coronary artery disease (CAD) and no previous MI were monitored. In a propensity-matched analysis, the rate of cardiovascular death, MI, or stroke did not differ

between those treated with or without a beta blocker (*n* = 3599) in each matched group; hazard ratio (HR), 0.92; 95% CI 0.79 to 1.08; *P* = 0.31. (**A,** From Gottlieb SS, McCarter RJ, Vogel RA. Effect of beta-blockade on mortality among high-risk and low-risk patients after myocardial infarction. N Engl J 1998;Med 339:493; **B,** from Bangalore S et al. Beta-blocker use and clinical outcomes in stable outpatients with and without coronary artery disease. JAMA2012;308:1340.)

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers.

Although inhibitors of the renin-angiotensin-aldosterone system (RAAS) are not indicated for the treatment of angina, these drugs appear to have important benefits in reducing the risk for future ischemic events in some patients with CVD.[28] Potentially beneficial effects of ACE inhibitors include reductions in LV hypertrophy, vascular hypertrophy, progression of atherosclerosis, plaque rupture, and thrombosis, in addition to a potentially favorable influence on myocardial O_2 supply-and-demand relationships, cardiac hemodynamics, sympathetic activity, and coronary endothelial vasomotor function. Furthermore, in vitro experiments have shown that angiotensin II induces inflammatory changes in human vascular smooth muscle cells and that treatment with ACE inhibitors can reduce signs of inflammation in animal models of atherosclerosis.

Two trials have provided strong evidence supporting the therapeutic benefit of ACE inhibitors in patients with normal LV function and absence of HF (**Fig. 61.8**). In the HOPE (Heart Outcomes Protection Evaluation) study, ramipril significantly decreased the risk for major vascular events by a relative 22% in 9297 patients with atherosclerotic vascular disease or DM. EUROPA (European Trial on Reduction of Cardiac Events with Perindopril in Stable CAD) similarly showed a 20% relative reduction in the risk for CV death, MI, or cardiac arrest in 13,655 patients with stable CAD in the absence of HF. In contrast, in the PEACE (Prevention of Events with Angiotensin Converting Enzyme Inhibition) trial, trandolapril showed no effect on the risk for CV death, MI, or coronary revascularization in 8290 patients with stable CAD and preserved LV function who were receiving intensive preventive therapy (**Fig. 61.8**).[28] ACE inhibitors are recommended for all patients with CAD and LV dysfunction and for those with hypertension, DM, or chronic kidney disease. ACE inhibitors may be considered for optional use in all other patients with SIHD, including those with a normal LVEF, well-controlled CV risk factors in whom revascularization has been performed.[28] Investigation to identify reliable indicators of which patients with SIHD will derive particular benefit from treatment is ongoing; such indicators include renal dysfunction, biomarkers of myocardial stress, and genetic polymorphisms.[21,133]

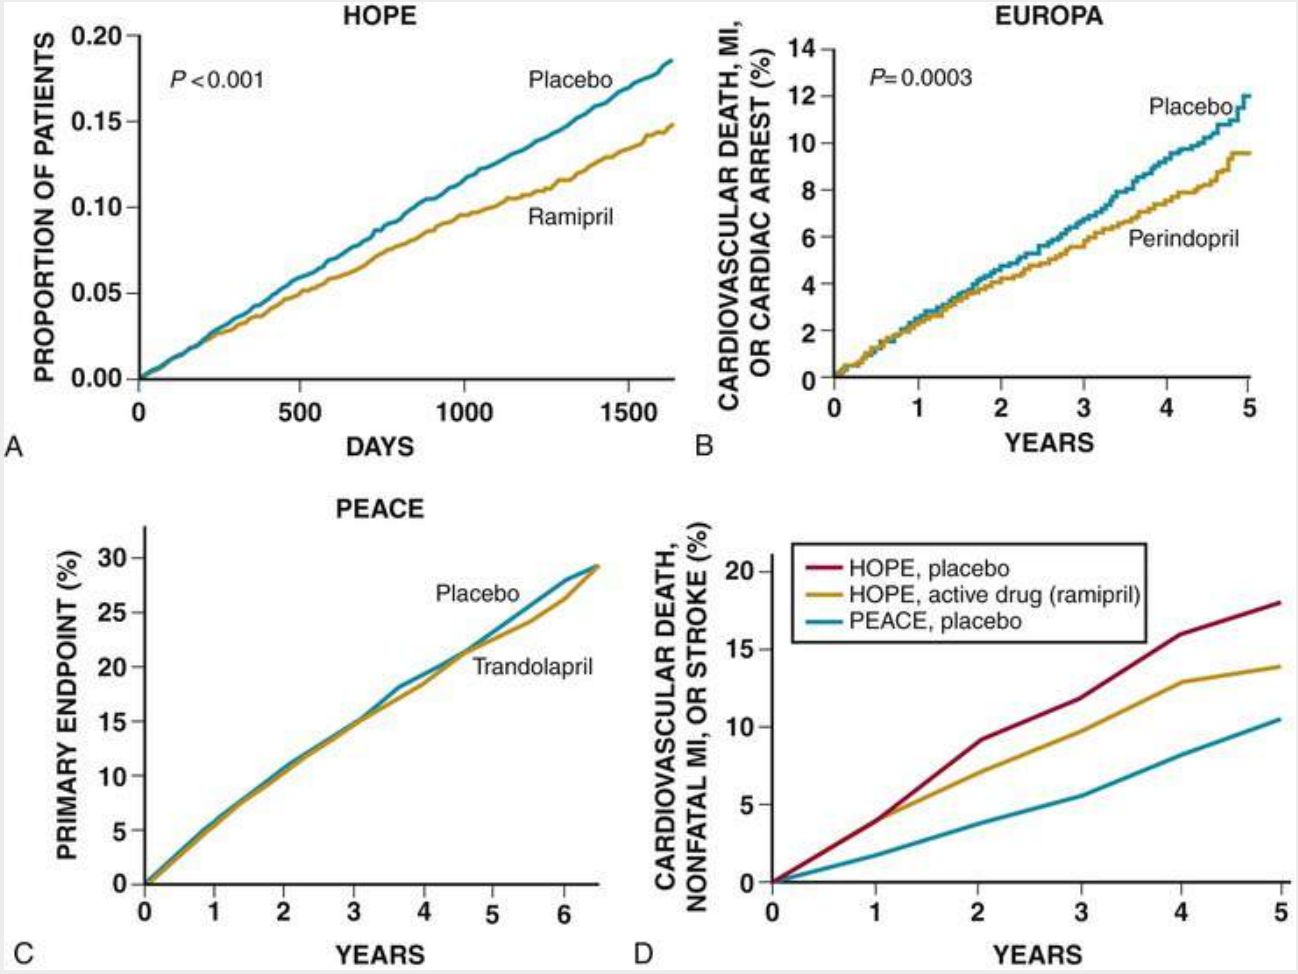

FIGURE 61.8 Kaplan-Meier time-to-event curves for the primary endpoint of three large randomized, placebo-controlled trials of angiotensin-converting enzyme (ACE) inhibitors for patients at high risk for or with established cardiovascular (CV) disease without heart failure. **A,** Cumulative incidence of CV death, MI, or stroke with ramipril versus placebo in patients in the HOPE trial. **B,** Cumulative incidence of CV death, MI, or cardiac arrest with perindopril or placebo in EUROPA. **C,** Cumulative incidence of CV death, MI, or coronary revascularization with trandolapril or placebo in the PEACE trial. **D,** Comparison of CV death, MI, or stroke in the HOPE and PEACE trials. The cumulative incidence of major CV events was lower in patients treated with placebo in the PEACE trial than in patients treated with ramipril in the HOPE trial. (**A,** From HOPE Study Investigators. Effects of an angiotensin-converting enzyme inhibitor, ramipril, on cardiovascular events in high risk patients. N Engl J Med 2000;342:145; **B,** from EUROPA Investigators. Efficacy of perindopril in reduction of cardiovascular events among patients with stable coronary artery disease: randomized double-blind, placebo-controlled, multicenter trial [the EUROPA study]. Lancet 2003;363:782; and **C,** From PEACE Trial Investigators. Angiotensin-converting enzyme inhibition in stable coronary artery disease. N Engl J Med 2004;351:2058.)

In patients with established vascular disease or high-risk diabetes, angiotensin receptor blockers (ARBs) appear to provide similar secondary prevention benefits as ACE inhibitors and thus are suitable alternatives for patients intolerant of ACE inhibitors. However, ARBs should generally not be used in combination with ACE inhibitors because the combination provides no additional benefit over the individual agents and results in an increased rate of complications.[134]

Antioxidants and Vitamins *(see Chapter 44)*.

Oxidized LDL particles are strongly linked to the pathophysiology of atherogenesis, and observational studies have suggested that high dietary intake of antioxidant vitamins (A, C, and beta-carotene) and flavonoids (polyphenolic antioxidants), naturally present in vegetables, fruits, tea, and wine, is associated with a decrease in CAD events. However, in multiple large randomized trials of antioxidant supplements, including vitamin E, vitamin C, beta-carotene, folic acid, and vitamins B_6 and B_{12}, the risk for MACE was not reduced. Similarly, despite multiple observational studies suggesting that low levels of vitamin D are associated with increased CV risk, several randomized trials have failed to show

reduction in CV risk factors or subclinical disease with vitamin D supplementation.[135] Several additional large randomized trials are ongoing that should provide a clearer picture of the risks and benefits of vitamin D supplementation (www.clinicaltrials.gov; NCT01169259, NCT00736632). Thus, according to current evidence, there is no basis for recommending that individuals with IHD take supplemental folate, vitamin E, vitamins C, D, or E, or beta-carotene for the purpose of improving CV outcomes.[28]

Counseling and Changes in Lifestyle

The psychosocial issues faced by patients in whom stable angina develops are similar to, although usually less intense than, those experienced by patients with acute MI. Depressive symptoms are strongly associated with health status as reported by the patient, including the burden of symptoms and overall quality of life, independent of LV function and the presence of ischemia.[136] In addition, the association between depressive symptoms and IHD may reflect a causal relationship between the former and atherothrombosis inasmuch as depressive symptoms are associated with higher levels of circulating biomarkers of inflammation.[137] In conjunction with counseling, treatment with a selective serotonin reuptake inhibitor (SSRI) appears to be safe and effective in managing depression in patients with IHD.[138] Thus, efforts to evaluate and treat depression in patients with CAD are an important element of the overall management of such patients. Moreover, psychosocial stress at work, home, or both is associated with an increased risk for MI and may be a target for preventive interventions.[139] In a small RCT, physical exercise complemented antidepressant pharmacotherapy in reducing depressive symptoms.[140]

An important aspect of the physician's role is to counsel patients with respect to dietary habits, goals for physical activity, the types of work that they can do, and their leisure activities.[141] Certain changes in lifestyle may be helpful, such as modifying strenuous activities if they consistently and repeatedly produce angina. A history of CAD and stable angina is not inconsistent with the ability for physical exertion, which is important not only in regard to recreational activities and lifestyle, but also when some physical exertion is required in the patient's employment. However, isometric activities such as weightlifting and other activities such as snow shoveling, which involves an energy expenditure of 60% to 65% of peak O_2 consumption, and cross-country skiing may be undesirable. In addition, these latter activities expose the individual to the detrimental effects of cold on the O_2 demand-and-supply relationship.

Eliminating or reducing the factors that precipitate anginal episodes is of obvious importance. Patients learn their usual threshold by trial and error. Patients should avoid sudden bursts of activity, particularly after long periods of rest or inactivity, after meals, and in cold weather. Both chronic angina and unstable angina exhibit a circadian rhythm characterized by a lower angina threshold shortly after arising. The stress of sexual intercourse is approximately equal to that of climbing one flight of stairs at a normal pace or any activity that induces an HR of approximately 120 beats/min. Most patients with stable angina are able to continue satisfactory sexual activity. Patients with SIHD may use sildenafil and other phosphodiesterase inhibitors to treat impotence, but these agents cannot be used in conjunction with nitrates, since this combination may promote life-threatening hypotension.[142]

Although from a perspective of both quality of life and avoiding prolonged ischemia, it is desirable to minimize the number of bouts of angina, occasional angina is not to be feared. Indeed, unless patients occasionally reach their angina threshold, they may not appreciate the extent of their exercise capacity. An important dimension to effective angina control relates to the benefits of prophylactic use of short-acting nitrates (either sublingual nitroglycerin or nitrolingual pump spray). If there is a clear pattern of effort angina, prophylactic use of short-acting nitrates several minutes before engaging in the offending activity may provide sufficient vasodilation to prevent an anginal episode.

Pharmacologic Management of Angina

Beta Adrenoceptor–Blocking Agents

Beta-blocking agents constitute a cornerstone of therapy for angina.[143] In addition to their anti-ischemic properties, beta-blocking agents are modestly effective antihypertensives (**see Chapter 47**) and antiarrhythmics (**Chapter 36**). They have also been shown to reduce mortality and reinfarction in patients after MI (**Chapter 59**) and to reduce mortality in patients with HF with reduced EF (**Chapter 25**). Beta blockers reduce the frequency of anginal episodes and raise the anginal threshold, both when given alone and when added to other antianginal agents. This combination of actions makes them extremely useful in the management of SIHD.

The beneficial actions of these drugs depend on their ability to competitively inhibit the effects of neuronally released and circulating catecholamines on beta adrenoceptors (**Tables 61.4 and 61.5**). Beta blockade reduces myocardial O_2 requirements, primarily by slowing the HR; the slower HR in turn increases the fraction of the cardiac cycle occupied by diastole, with a corresponding increase in the time available for coronary perfusion (**Fig. 61.9; see also Table 61.4**). In addition, these drugs reduce exercise-induced increases in BP and limit exercise-induced increases in contractility. Thus, beta-blocking agents reduce myocardial O_2 demand primarily during activity or excitement, when surges of increased sympathetic activity occur. In the presence of impaired myocardial perfusion, the effects of beta blockers on myocardial O_2 demand may critically and favorably alter the imbalance between supply and demand and thereby mitigate ischemia.

TABLE 61.4

Effects of Antianginal Agents on Indices of Myocardial Oxygen Supply and Demand

From Abrams J. Medical therapy of stable angina pectoris. In Beller G, Braunwald E, editors. Chronic Ischemic Heart Disease. Atlas of Heart Disease. Vol 5. Philadelphia: Saunders; 1995, p 7.19.

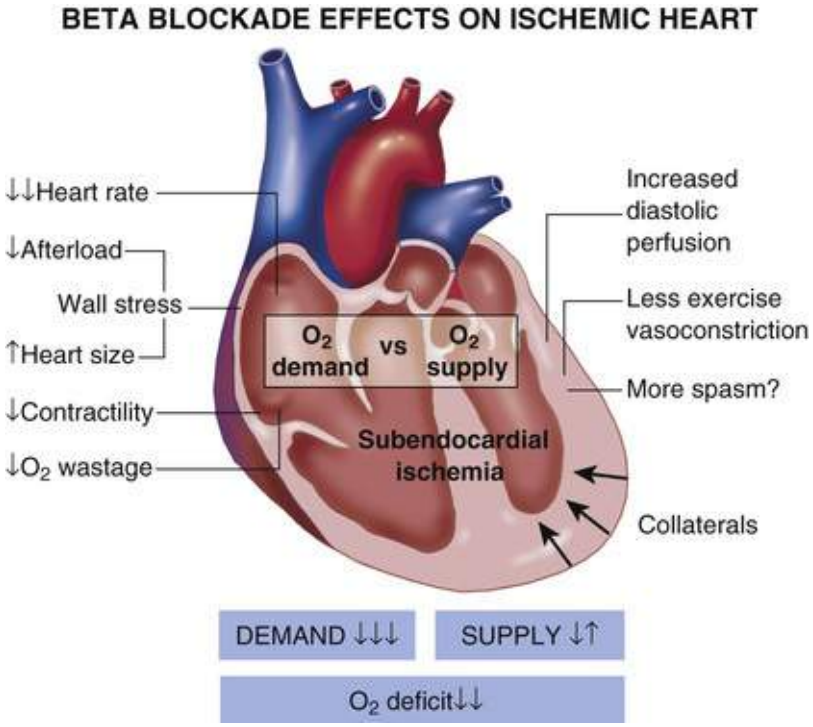

FIGURE 61.9 Effects of beta blockade on an ischemic heart. Beta blockade has a beneficial effect on ischemic myocardium unless (1) the preload rises substantially, as in left-sided heart failure, or (2) vasospastic angina is present, in which case spasm may be promoted in some patients. Note the suggestion that beta blockade diminishes exercise-induced vasoconstriction. (Modified from Opie LH: Drugs for the Heart. 4th ed. Philadelphia: Saunders; 1995, p 6.)

Beta-blocking agents may reduce blood flow to most organs by means of the combination of unopposed alpha-adrenergic vasoconstriction and $beta_2$ receptor blockade (**Table 61.5**). Complications are relatively minor, but in patients with peripheral vascular disease, the reduction in blood flow to skeletal muscles with the use of nonselective beta-blocking agents may decrease maximal exercise capacity. In patients with preexisting LV dysfunction, beta blockade may increase LV volume and thereby enhance O_2 demand.

Characteristics of Different Beta-Blocking Agents

Selectivity.

Two major subtypes of beta receptors, designated $beta_1$ and $beta_2$, are present in different proportions in different tissues. $Beta_1$ receptors predominate in the heart, and stimulation of these receptors leads to an increase in HR, atrioventricular (AV) conduction, and contractility; release of renin from juxtaglomerular cells in the kidneys; and lipolysis in adipocytes. $Beta_2$ stimulation causes bronchodilation, vasodilation, and glycogenolysis. Nonselective beta-blocking drugs (e.g., propranolol, nadolol, penbutolol, pindolol, sotalol, timolol, carteolol) block both $beta_1$ and $beta_2$ receptors, whereas cardioselective beta-blocking agents (e.g., acebutolol, atenolol, betaxolol, bisoprolol, esmolol, metoprolol, nebivolol) block $beta_1$ receptors while having less effect on $beta_2$ receptors. Thus, cardioselective beta blockers reduce myocardial O_2 requirements while tending not to block bronchodilation, vasodilation, or glycogenolysis. However, as the doses of these drugs are increased, this cardioselectivity diminishes. Because cardioselectivity is only relative, the use of cardioselective beta blockers in doses sufficient to control angina may still cause bronchoconstriction in some susceptible patients. Nevertheless, beta blockers are relatively well tolerated by most patients with obstructive pulmonary disease.

Some beta-blocking agents also cause vasodilation. Such drugs include labetalol (an alpha-adrenergic–blocking agent and $beta_2$-agonist; **see Chapter 47**), carvedilol (with alpha- and $beta_1$-blocking activity), bucindolol (a nonselective beta blocker that causes direct [non–alpha-adrenergic–mediated] vasodilation), and nebivolol (a cardioselective beta blocker with a direct stimulatory effect on endothelial nitric oxide synthase [eNOS]).

Intrinsic Sympathomimetic Activity.

Beta-blocking agents with intrinsic sympathomimetic activity (ISA), such as acebutolol, bucindolol, carteolol, celiprolol, penbutolol, and pindolol, are partial beta-agonists that also produce blockade by shielding beta receptors from more potent beta-agonists. Pindolol and acebutolol produce low-grade beta stimulation when sympathetic activity is low (at rest), whereas these partial agonists behave more as conventional beta blockers when sympathetic activity is high. Agents with ISA may not be as effective as those without this property in reducing HR or the frequency, duration, and magnitude of ambulatory ST-segment changes or increasing the duration of exercise in patients with severe angina.

Potency.

Potency can be measured by the ability of beta blockers to inhibit the tachycardia produced by isoproterenol. All drugs are considered in reference to propranolol, which is given a value of 1.0 (**Table 61.6**). Timolol and pindolol are the most potent agents, and acebutolol and labetalol are the least potent.

TABLE 61.6

Pharmacokinetics and Pharmacology of Some Beta Adrenoceptor–Blocking Agents

CHARACTERISTIC	ATENOLOL	METOPROLOL/XL	NADOLOL	PINDOLOL	PROPRANOLOL/LA	TIMOLOL	ACEBUTOLOL	LA

*Determined by the distribution ratio between octanol and water.

†The half-life of the active metabolite diacetolol is 12 to 15 hours.

‡Acebutolol is eliminated mainly by the liver, but its major metabolite diacetolol is excreted by the kidney.

§Rapid metabolism by esterases in the cytosol of red blood cells.

‖Beta$_1$ selectivity is maintained at lower doses, but beta$_2$ receptors are inhibited at higher doses.

FDA, U.S. Food and Drug Administration; *HM,* hepatic metabolism; *MI,* myocardial infarction; *RE,* renal excretion.

Lipid Solubility.

The hydrophilicity or lipid solubility of beta-blocking agents is a major determinant of their absorption and metabolism (**Table 61.6**). The lipid-soluble (lipophilic) beta blockers propranolol, metoprolol, and pindolol are readily absorbed from the GI tract and metabolized predominantly by the liver. Water-soluble beta blockers, such as atenolol, are usually eliminated unchanged by the kidneys. Lipid-soluble agents are often preferable in patients with significant renal dysfunction, for whom clearance of water-soluble agents is reduced. Greater lipid solubility is associated with greater penetration into the central nervous system (CNS) and may contribute to the side effects (e.g., lethargy, depression, hallucinations) that are not clearly related to beta-blocking activity.

Alpha Adrenoceptor–Blocking Activity.

The alpha-blocking potency of oral labetalol (approximately 10% that of phentolamine) is approximately 20% of its beta-blocking potency (**Table 61.6**). Labetalol's combined alpha- and beta-blocking effects make it a particularly useful antihypertensive agent (**see Chapter 47**), and it is especially useful in patients with hypertension and angina. The major side effects of labetalol are postural hypotension and retrograde ejaculation. Carvedilol also possesses alpha-adrenergic–blocking activity with an alpha$_1$-to-

beta–blocking ratio of approximately 1:10, and thus may be preferable to other beta blockers when additional BP lowering is desired.

Genetic Polymorphisms.

The metabolism of metoprolol, carvedilol, and propranolol may be influenced by genetic polymorphisms or other medications that influence hepatic metabolism. Oxidative metabolism of metoprolol occurs primarily through the cytochrome P-450 enzyme CYP2D6 and exhibits the debrisoquin type of genetic polymorphism; poor hydroxylators or metabolizers (≤10% of white individuals) have significant prolongation of the elimination half-life of the drug in comparison to extensive hydroxylators or metabolizers. Thus, angina might be controlled by a single daily dose of metoprolol in poor metabolizers, whereas extensive metabolizers require the same dose two or three times daily. If a patient exhibits an exaggerated clinical response (e.g., extreme bradycardia) after the administration of metoprolol, propranolol, or other lipid-soluble beta blockers, it may be the result of prolongation of the elimination half-life because of slow oxidative metabolism. Metabolism of metoprolol may also be altered by drugs that interact with CYP2D6. Preliminary evidence suggests differences in survival in patients with unstable IHD and provoked ischemia in those with SIHD treated with beta-blocking agents based on polymorphisms of the $beta_2$-adrenergic receptor (*ADRB1* and *ADRB2*).[144,145]

Effects on Serum Lipid Levels.

Therapy with beta blockers (those lacking ISA) usually causes no significant changes in total or LDL-C levels but increases triglyceride and reduces HDL-C levels. The most studied drug has been propranolol, which can increase plasma triglyceride concentrations by 20% to 50% and reduce HDL-C levels by 10% to 20%. Increasing $beta_1$ selectivity is associated with lesser effects on lipid levels. Adverse effects on the lipid profile may be more common with nonselective than with $beta_1$-selective–blocking agents.

Adverse Effects and Contraindications

Most of the adverse effects of beta-blocking agents occur as a consequence of the known properties of these drugs and include cardiac effects (e.g., severe sinus bradycardia, sinus arrest, AV block, reduced LV contractility), bronchoconstriction, fatigue, mental depression, nightmares, GI upset, sexual dysfunction, intensification of insulin-induced hypoglycemia, and cutaneous reactions (**Table 61.7; see also Table 61.5**). Lethargy, weakness, and fatigue may be caused by reduced cardiac output or may arise from a direct effect on the CNS. In patients who already have impaired LV function, HF may be exacerbated (**see Chapter 25**). Pindolol, because of its ISA activity, may be preferable in patients with sinus node dysfunction. Carvedilol has been shown to exhibit modest insulin-sensitizing properties and can relieve some manifestations of metabolic syndrome.[146] Blockade of $beta_2$ receptors also inhibits the vasodilating effects of catecholamines in peripheral blood vessels and leaves the constrictor (alpha-adrenergic) receptors unopposed, thereby enhancing vasoconstriction. Noncardioselective beta blockers may precipitate episodes of Raynaud phenomenon in patients with this condition. Reduced flow to the limbs may also occur in patients with peripheral vascular disease.

TABLE 61.7

Candidates for Use of Beta-Blocking Agents for Angina

Ideal Candidates
Prominent relationship of physical activity to attacks of angina
Coexistent hypertension
History of supraventricular or ventricular arrhythmias
Previous myocardial infarction
LV systolic dysfunction
Mild to moderate heart failure symptoms (NYHA Functional Class II and III)
Prominent anxiety state
Poor Candidates
Asthma or reversible airway component in patients with chronic lung disease
Severe LV dysfunction with severe heart failure symptoms (NYHA Functional Class IV)
History of severe depression
Raynaud phenomenon
Symptomatic peripheral artery disease
Severe bradycardia or heart block
Diabetes with frequent hypoglycemic episodes

LV, Left ventricular; *NYHA,* New York Heart Association.

Modified from Abrams JA. Medical therapy of stable angina pectoris. In Beller G, Braunwald E, editors. Chronic Ischemic Heart Disease. Atlas of Heart Disease. Vol 5. Philadelphia: Saunders; 1995, p 7.22.

Abrupt withdrawal of beta blocker after prolonged administration can result in increased total ischemic activity in patients with chronic stable angina. Chronic beta-blocker therapy can be safely discontinued by slowly withdrawing the drug in a stepwise manner over 2 to 3 weeks. If abrupt withdrawal of beta blockers is required, patients should be instructed to reduce exertion and manage angina episodes with sublingual nitroglycerin and/or substitute a calcium antagonist.

Calcium Antagonists

The critical role of calcium ions (Ca^{2+}) in the normal contraction of cardiac and vascular smooth muscle is discussed in **Chapters 22 and 57**. The calcium antagonists (**see Chapter 47**) are a heterogeneous group of compounds that inhibit movement of Ca^{2+} through slow channels in cardiac and smooth muscle membranes by noncompetitive blockade of voltage-sensitive L-type calcium channels. The three major classes of calcium antagonists are the dihydropyridines (nifedipine is the prototype), the phenylalkylamines (verapamil is the prototype), and the modified benzothiazepines (diltiazem is the prototype). Amlodipine and felodipine are additional dihydropyridines that are among the most commonly used calcium antagonists in the United States. The two predominant effects of calcium antagonists result from blocking the entry of Ca^{2+} and slowing recovery of the channel. Phenylalkylamines have a marked effect on recovery of the channel and thereby exert depressant effects on cardiac pacemakers and conduction, whereas dihydropyridines, which do not impair channel recovery, have little effect on the conduction system.

Mechanism of Action.

The efficacy of calcium antagonists in patients with angina pectoris is related to the reduction in myocardial O_2 demand and the increase in O_2 supply (**see Table 61.4**). The latter effect is particularly important in patients with conditions in which a prominent vasospastic or vasoconstrictor component may be present, such as Prinzmetal variant angina (**see Chapters 57 and 60**). Calcium antagonists may be effective on their own or in combination with beta-blocking agents and nitrates in patients with chronic stable angina. Several calcium antagonists are effective for the treatment of angina pectoris

(**Table 61.8**). Each relaxes vascular smooth muscle in the systemic arterial and coronary arterial beds. In addition, blockade of the entry of calcium into myocytes results in a negative inotropic effect, which is counteracted to some extent by peripheral vascular dilation and by activation of the sympathetic nervous system in response to drug-induced hypotension. However, the negative inotropic effect must be taken into consideration in patients with significant LV dysfunction.

Potential Antiatherogenic Actions.

Hyperlipidemia-induced changes in the permeability of smooth muscle cells to calcium may play a role in atherogenesis. Experimental work with calcium channel–blocking drugs, in particular, work with more lipophilic second-generation agents such as amlodipine, has demonstrated improved endothelial function and inhibition of smooth muscle cell proliferation and migration, in addition to ameliorating unfavorable membrane alterations. Although data from small randomized trials suggested reduced progression of coronary atherosclerosis and improved coronary endothelial function with amlodipine and nifedipine, several larger trials have failed to confirm an effect of calcium antagonists on atherosclerosis burden. Thus the hypothesis that calcium antagonists might inhibit atherogenesis has been explored since the 1970s but has not yet been definitively answered.[147]

First-Generation Calcium Antagonists

Nifedipine.

Nifedipine, a dihydropyridine, is a particularly effective dilator of vascular smooth muscle and is a more potent vasodilator than diltiazem or verapamil. The beneficial effects of nifedipine in the treatment of angina result from its capacity to reduce myocardial O_2 requirements because of its afterload-reducing effect and to increase myocardial O_2 delivery as a result of its dilating action on the coronary vascular bed (**see Table 61.4**). Because immediate-release formulations can precipitate hypotension and adverse events, an extended-release formulation should be used when nifedipine is administered. A meta-analysis of 15 studies of long-acting calcium channel antagonists, including nifedipine, in patients with CAD demonstrated significant reductions in angina, stroke, and HF, with no improvement in other CV outcomes. Long-acting nifedipine should be considered an effective and safe antianginal drug for the treatment of symptomatic patients with angina who are already receiving beta-blocking agents, with or without nitrates.

Adverse Effects.

These occur in 15% to 20% of patients and require discontinuation of medication in approximately 5%. Most adverse effects are related to systemic vasodilation and include headache, dizziness, palpitations, flushing, hypotension, and leg edema (unrelated to HF). In rare cases in patients with extremely severe, fixed coronary obstructions, nifedipine aggravates angina, presumably by lowering arterial pressure excessively with subsequent reflex tachycardia. For this reason, combined treatment of angina with nifedipine and a beta-blocking agent is particularly effective and superior to nifedipine alone. Nifedipine has been reported to worsen HF in patients with preexisting chronic HF and is contraindicated in patients who are hypotensive or have severe aortic valve stenosis.

Verapamil.

Verapamil dilates systemic and coronary resistance vessels and large coronary conductance vessels. It slows the HR and reduces myocardial contractility. This combination of actions results in a reduction in the myocardial O_2 requirement, which is the basis for the drug's efficacy in the management of chronic stable angina (**Table 61.8**). When evaluated in INVEST (International Verapamil-Trandolapril Study), a strategy combining sustained-release verapamil and trandolapril versus atenolol and a diuretic for the treatment of patients with hypertension and CAD, including those with previous MI, showed equivalent outcomes with respect to death, MI, or stroke.[147]

In patients with cardiac dysfunction, verapamil may reduce cardiac output, increase LV filling pressure, and cause clinical HF. Verapamil slows the HR and AV conduction. Therefore, it is contraindicated in patients with preexisting AV nodal disease or sick sinus syndrome, HF, and suspected digitalis or quinidine toxicity. Verapamil should generally not be used together with a beta-blocking agent due to the risk for bradycardia or heart block. The bioavailability of verapamil is increased by cimetidine and carbamazepine, whereas verapamil may increase plasma levels of cyclosporine and digoxin.

Adverse effects of verapamil are noted in approximately 10% of patients and are related to systemic vasodilation (hypotension and facial flushing), GI symptoms (constipation, nausea), and CNS reactions such as headache and dizziness. A rare side effect is gingival hyperplasia, which appears after 1 to 9 months of therapy.

Diltiazem.

The actions of diltiazem are intermediate between those of nifedipine and verapamil. In clinically useful doses, diltiazem's vasodilator effects are less profound than those of nifedipine, and its cardiac depressant action on the sinoatrial and AV nodes and myocardium is less than that of verapamil. This profile may explain the remarkably low incidence of adverse effects of diltiazem. Diltiazem is a systemic vasodilator that lowers arterial pressure at rest and during exertion and increases the workload required to produce myocardial ischemia, but it may also increase myocardial O_2 delivery. Although it causes little vasodilation of epicardial coronary arteries under basal conditions, diltiazem may enhance perfusion of the subendocardium distal to a flow-limiting coronary stenosis; it also blocks exercise-induced coronary vasoconstriction.

Major side effects of diltiazem are similar to those of the other calcium channel–blocking agents and are related to vasodilation, but they are relatively infrequent, particularly if the dosage does not exceed 240 mg daily. As with verapamil, diltiazem should be prescribed with caution for patients with sick sinus syndrome or AV block. In patients with preexisting LV dysfunction, diltiazem may exacerbate or precipitate HF.

Diltiazem interacts with other drugs, including beta-blocking agents (causing enhanced negative inotropic, chronotropic, and dromotropic effects), flecainide, and cimetidine (which increases the bioavailability of diltiazem). Diltiazem has been associated with increased plasma levels of substrates of CYP3A4, including apixaban, atorvastatin, simvastatin, cilostazol, dofetilide, ivabradine, and ranolazine, as well as non-CYP3A4 substrates, including carbamazepine and cyclosporine. Diltiazem may cause excessive sinus node depression if administered with disopyramide and may reduce digoxin clearance, especially in patients with renal failure.

Second-Generation Calcium Antagonists

The second-generation calcium antagonists (e.g., nicardipine, isradipine, amlodipine, felodipine) are mainly dihydropyridine derivatives, with nifedipine being the prototypic agent. Experience has also accumulated with nimodipine, nisoldipine, and nitrendipine. These agents differ in potency, tissue specificity, and pharmacokinetics and generally are potent vasodilators because of the greater vascular selectivity than seen with the first-generation antagonists (e.g., verapamil, nifedipine, diltiazem).

Amlodipine.

Less lipid soluble than nifedipine, amlodipine has a slow, smooth onset and ultralong duration of action (plasma half-life of 36 hours). It causes marked coronary and peripheral dilation and may be useful in the treatment of patients with angina accompanied by hypertension. It may be used as a once-daily hypotensive or antianginal agent. In a series of randomized placebo-controlled studies in patients with stable exercise-induced angina pectoris, amlodipine was shown to be effective and well tolerated. In two trials involving patients with established CAD, amlodipine reduced the risk for MACE. Amlodipine has little if any negative inotropic action and may be especially useful in patients with chronic angina and LV dysfunction.

The usual dosage of amlodipine is 5 to 10 mg once daily. Downward adjustment of the starting dose is appropriate for patients with liver disease and elderly patients. Significant changes in BP are typically not evident until 24 to 48 hours after initiation. Steady-state serum levels are achieved at 7 to 8 days. Amlodipine should not be co-administered with simvastatin because it increases drug levels of this statin and may increase risk for myopathy.

Nicardipine.

Although it has a half-life similar to that of nifedipine (2 to 4 hours), nicardipine appears to have greater vascular selectivity. Nicardipine may be used as an antianginal and antihypertensive agent and requires administration three times daily, although a sustained-release formulation is available for twice-daily dosing in patients with hypertension. For chronic stable angina pectoris, nicardipine appears to be as effective as verapamil or diltiazem, and its efficacy is enhanced when combined with a beta-blocking agent.

Felodipine and Isradipine.

In the United States, both these drugs are approved by the U.S. Food and Drug Administration (FDA) for the treatment of hypertension, but not for angina pectoris. One study has documented similar efficacy between felodipine and nifedipine in patients with chronic stable angina. Felodipine has also been reported to be more vascular selective than nifedipine and to have a mild positive inotropic effect as a result of calcium channel agonist properties. Isradipine has a longer half-life than nifedipine and demonstrates greater vascular sensitivity.

Nitrates

Mechanism of Action

The action of nitrates is to relax vascular smooth muscle. The vasodilator effects of nitrates are evident in systemic (including coronary) arteries and veins, but they appear to be predominant in the venous circulation. The venodilator effect reduces ventricular preload, which in turn reduces myocardial wall tension and O_2 requirements. The action of nitrates in reducing preload and afterload makes them useful in the treatment of HF (**see Fig. 61.2**), as well as angina. By reducing the heart's mechanical activity, volume, and O_2 consumption, nitrates increase exercise capacity in patients with IHD, thereby allowing greater total-body workload to be achieved before the angina threshold is reached. Thus, in patients with stable angina, nitrates improve exercise tolerance and time to ST-segment depression during treadmill exercise tests. When used in combination with calcium channel–blocking agents and/or beta-blocking agents, the antianginal effects appear to be greater.[28]

Effects on the Coronary Circulation (See Table 61.4).

Nitroglycerin causes dilation of epicardial stenoses. Even a small increase in a narrowed arterial lumen can produce a significant reduction in resistance to blood flow across obstructed segments. Nitrates may also exert a beneficial effect in patients with impaired coronary flow reserve by alleviating the vasoconstriction caused by endothelial dysfunction of resistance vessels.

Redistribution of Blood Flow.

Nitroglycerin causes blood flow to be redistributed from normally perfused segments to ischemic areas, particularly in the subendocardium. This redistribution may be mediated in part by an increase in collateral blood flow and in part by lowering of LV diastolic pressure, thereby reducing subendocardial compression. Nitroglycerin appears to reduce coronary vascular resistance preferentially in viable myocardium with ischemia, as detected by SPECT. Nitroglycerin alters myocardial perfusion by preferentially increasing flow to areas of reduced perfusion, with little or no change in global myocardial

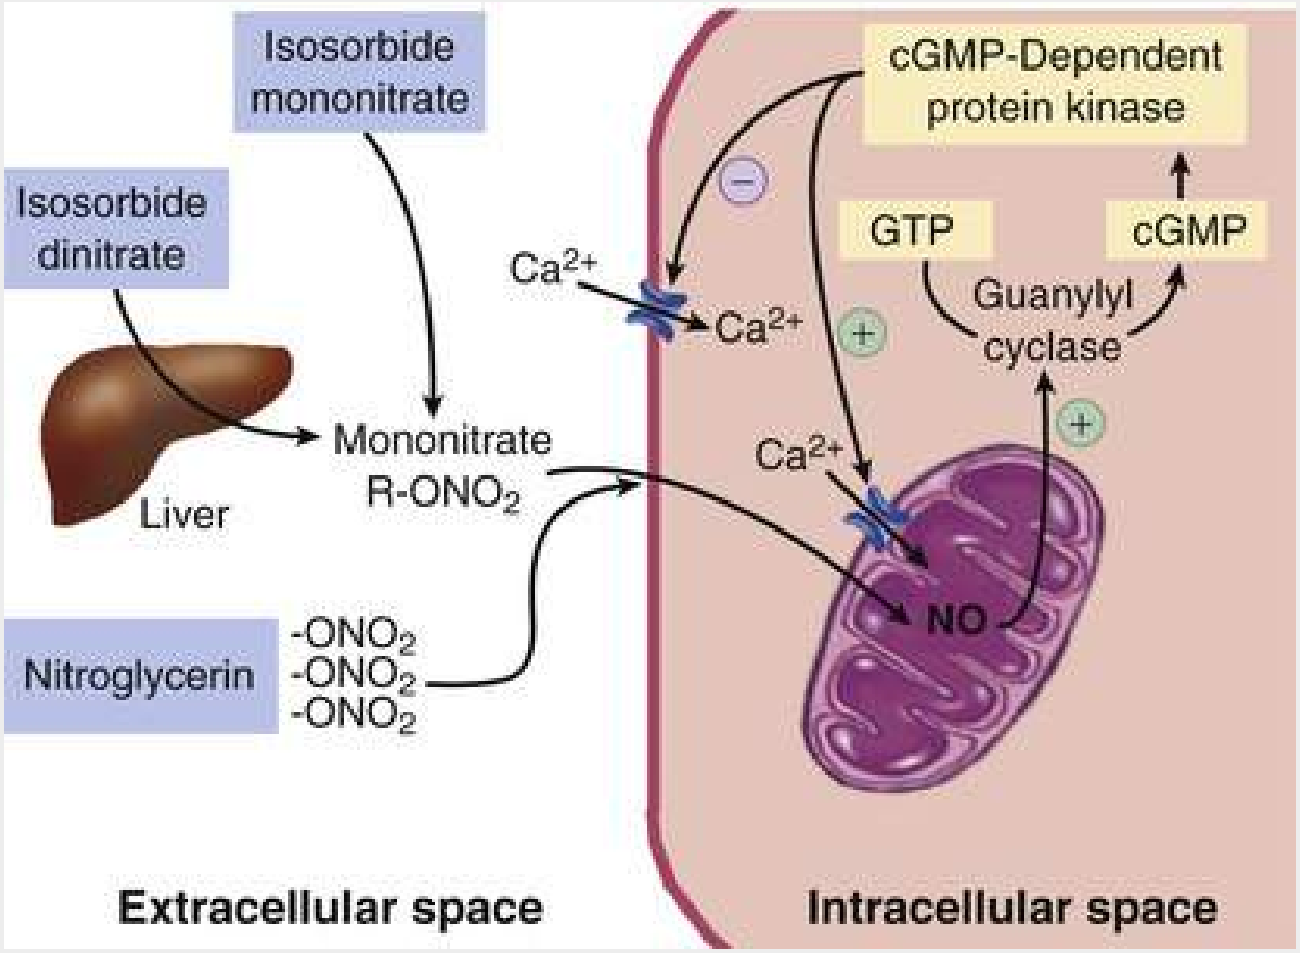
perfusion.

Antithrombotic Effects.

Stimulation of guanylate cyclase by nitric oxide (NO) results in inhibitory action on platelets in addition to vasodilation. Although antithrombotic effects of intravenous (IV) nitroglycerin have been demonstrated in patients with unstable angina and in those with SIHD, the clinical significance of these actions is not clear as nitrates have not been shown to lower the rate of MI.

Cellular Mechanism of Action.

Nitrates have the ability to cause vasodilation, regardless of whether the endothelium is intact. After entering the vascular smooth muscle cell, nitrates are converted to reactive NO or *S*-nitrosothiols, which activate intracellular guanylate cyclase to produce cyclic guanosine monophosphate (cGMP), which in turn triggers smooth muscle relaxation and antiplatelet aggregator effects (**eFig. 61.3**). Evidence now exists that biotransformation of nitroglycerin occurs via mitochondrial aldehyde dehydrogenase and that inhibition of this enzyme may contribute to the development of tolerance.[148] Subsequent studies have also shown cytosolic bioactivation by aldehydrogenase-2. Although the aggregate evidence supports release of NO as the major cellular mechanism of action of oral nitrates, experimental data have challenged this conclusion. In particular, the arterial vasodilatory effects of nitroglycerin in vitro depend, at least in part, on endothelial calcium-activated potassium channels.



EFIGURE 61.3 Mechanism of action of nitrates. Evidence exists that biotransformation of mononitrates occurs through the action of mitochondrial aldehyde reductase in producing nitric oxide (NO). NO activates soluble guanylyl cyclase, which results in increased production of cyclic guanosine monophosphate (cGMP). The second messenger cGMP reduces cytoplasmic calcium (Ca^{2+}) by inhibiting inflow and stimulating mitochondrial uptake of calcium, thus mediating the relaxation of smooth muscle cells and causing vasodilation. Isosorbide dinitrate is metabolized by the liver, whereas the liver is bypassed by mononitrates. GTP, Guanosine triphosphate. R-ONO_2, mononitrate. (Modified from Gori T, Parker JD. Nitrate tolerance: a unifying hypothesis. Circulation 2002;106:2510; and Opie LH. Drugs for the Heart. 4th ed. Philadelphia: Saunders; 1995, p 33.)

Potential for Adverse Effects During Long-Term Administration.

Experimental data have raised questions regarding the potentially competing long-term effects of oral nitrates.[148] Multiple animal experiments and at least one human study have demonstrated that extended exposure to nitrates can impair endothelial-dependent vasodilation through increases in endothelin-1 and the generation of free radical species.[149] This effect appears to be reversed by antioxidant therapy. Long-term studies in humans are necessary to determine the clinical relevance of these findings.

Types of Preparations and Routes of Administration

Short-acting nitroglycerin administered sublingually (either by tablet or spray) remains the drug of choice for the treatment of acute angina episodes (**Table 61.9**). Because sublingual (SL) administration avoids first-pass hepatic metabolism, a transient but effective concentration of the drug rapidly appears in the circulation. Within 30 to 60 minutes, hepatic breakdown has abolished the hemodynamic and clinical effects. SL nitroglycerin is also useful when taken prophylactically shortly before undertaking physical activities that are likely to cause angina. When used for this purpose, it may prevent angina for up to 40 minutes.

TABLE 61.9

Recommended Dosing Regimens for Long-Term Nitrate Therapy

PREPARATION OF AGENT	DOSE	SCHEDULE
Nitroglycerin*		
Ointment	0.5-2 inches	2 or 3 times daily
Transdermal patch	0.2-0.8 mg/hr	Every 24 hr; remove at bedtime for 12-14 hr
Sublingual tablet	0.3-0.6 mg	As needed, up to 3 doses 5 min apart
Spray	1 or 2 sprays	As needed, up to 3 doses 5 min apart
Isosorbide Dinitrate*		
Oral	10-40 mg	2 or 3 times daily
Oral sustained release	80-120 mg	Once or twice daily (eccentric schedule)
Isosorbide 5-Mononitrate		
Oral	20 mg	Twice daily (given 7-8 hr apart)
Oral sustained release	30-240 mg	Once daily

*A 10- to 12-hour nitrate-free interval is recommended.

Adverse Reactions.

Adverse reactions are common and include headache, flushing, and hypotension. The last is rarely severe, but in some patients with volume depletion and in an upright posture, nitrate-induced hypotension is accompanied by a paradoxical bradycardia, consistent with a vasovagal or vasodepressor response. This reaction is more common in older adults, who are less able to tolerate hypovolemia, and may be magnified in hot weather. Methemoglobinemia is a rare complication of very large doses of nitrates; commonly used doses of nitrates cause small elevations in methemoglobin levels that are probably not of clinical significance.

Short-Acting Nitroglycerin (Nitroglycerin Tablets and Oral Spray).

Nitrate preparations are available in SL, buccal, oral, spray, and ointment forms (**Table 61.9**). An oral nitroglycerin spray that dispenses metered, aerosolized doses of 0.4 mg may be better absorbed than the SL form in patients with dry mucosal membranes. It can also be quickly sprayed onto or under the tongue. For prophylaxis, the spray should be used 5 to 10 minutes before angina-provoking activities. An additional advantage of the pump spray preparation is a longer shelf life (up to 2 years) than that of SL nitroglycerin (which is approximately 6 months).

Isosorbide Dinitrate.

This drug is available in tablets for SL use, in chewable form, in tablets for oral use, and in sustained-release (SR) capsules. Partial or complete nitrate tolerance (see later) develops with regimens of isosorbide dinitrate administered as 30 mg three or four times daily. A dosage schedule should be adopted that allows a 12-hour or longer nitrate-free interval. If the drug is administered on a three-times-daily schedule (e.g., at 8 AM, 1 PM, and 6 PM), the antianginal benefit lasts for approximately 6 hours, and the magnitude of the antianginal benefit decreases with each successive dose.

Isosorbide 5-Mononitrate.

Plasma levels of isosorbide 5-mononitrate reach their peak between 30 minutes and 2 hours after ingestion, and the drug has a plasma half-life of 4 to 6 hours. A single 20-mg tablet still exhibits activity 8 hours after administration. Tolerance has not been demonstrated with once-daily or eccentric dosing intervals but does occur with a twice-daily dosing regimen at 12-hour intervals. The only SR preparation of isosorbide 5-mononitrate is Imdur, which is given once daily at 30 to 240 mg. Presumably, this

preparation avoids tolerance by providing a sufficiently low nitrate level or a duration of action of 12 hours or less. Once-daily dosing of oral nitrates improves compliance and may offer better efficacy in reducing angina.

Topical Nitroglycerin.

Nitroglycerin may be applied as a transdermal patch. Application of a silicone gel or polymer matrix impregnated with nitroglycerin results in absorption for 24 to 48 hours at a rate determined by various methods of preparation of the patch. Transdermal nitroglycerin therapy has been shown to increase exercise duration and maintain its anti-ischemic effects for 12 hours after patch application throughout 30 days of therapy, without significant evidence of nitrate tolerance or rebound phenomena, provided that the patch is not applied for more than 12 of 24 hours.

Nitrate Tolerance.

A major problem with the use of nitrates is the development of nitrate tolerance, which has been demonstrated with all forms of nitrate administration that deliver continuous, relatively stable blood levels of the drug. Although nitrate tolerance is rapid in onset, renewed responsiveness is easily established after a short, nitrate-free interval. The problem of tolerance applies to most nitrate preparations. Nitrate tolerance appears to be limited to capacitance and resistance vessels and has not been noted in large conductance vessels, including the epicardial coronary arteries and radial arteries, despite continuous administration of nitroglycerin for 48 hours.

Mechanisms.

Several mechanisms of nitrate tolerance have been proposed. Evidence has supported the hypothesis that increased generation of vascular superoxide anion (O_2^-) is central to the process.[148,150] There are multiple possible contributors to the generation of oxygen free radicals, including the effects of nitroglycerin on eNOS uncoupling and counterregulatory neurohormonal activation. The increased O_2^- formation has a number of consequences, including plausible links to many of the proposed mechanisms of nitrate tolerance: (1) plasma volume expansion and neurohormonal activation, (2) impaired biotransformation of nitrates to NO, and (3) decreased end-organ responsiveness to NO.

Management.

The primary strategy for managing nitrate tolerance is to prevent it by providing a nitrate-free interval. The optimal interval is unknown, but with patches or ointment or preparations of isosorbide dinitrate or isosorbide 5-mononitrate, a 12-hour off-period is recommended. Experimental data suggest that nitrate-induced oxidative stress, nitrate tolerance, and endothelial dysfunction may be mitigated by an ARB.[151] In addition, pentaerythrityl tetranitrate is an organic nitrate that may have lesser detrimental effects on mitochondrial aldehyde dehydrogenase.[152]

Nitrate Withdrawal.

A common form of nitrate withdrawal (rebound) is observed in patients whose angina is intensified after discontinuation of large doses of long-acting nitrates. In this situation, patients may also have heightened sensitivity to constrictor stimuli. The potential for rebound can be modified by adjusting the dose and timing of administration, in addition to the use of other antianginal drugs.

Interaction With Cyclic Guanosine Monophosphate–Specific Phosphodiesterase Type 5 Inhibitors.

The combination of nitrates and phosphodiesterase type 5 (PDE5) inhibitors (sildenafil, tadalafil, and

vardenafil) may cause serious, prolonged, and potentially life-threatening hypotension.[142] Nitrate therapy is an absolute contraindication to the use of these agents, and vice versa. Patients who want to take a PDE5 inhibitor should be aware of the serious nature of this adverse drug interaction and be warned about taking any of these agents within 24 hours of any nitrate preparation, including short-acting SL nitroglycerin tablets.

Other Pharmacologic Agents

Ranolazine

Ranolazine is a piperazine derivative that was approved in 2006 in the United States for use in patients with chronic stable angina.[153] Ranolazine is unique among currently approved antianginals in that its anti-ischemic effects are achieved without a clinically meaningful change in HR or BP. When studied at high concentrations with in vitro experiments, ranolazine was shown to shift myocardial substrate uptake from fatty acid to glucose and thus was considered to be a potential myocardial metabolic modulator. However, subsequent studies at concentrations of ranolazine consistent with doses tested in clinical trials have indicated that ranolazine exerts favorable effects on ischemia through a reduction in calcium overload in ischemic myocytes via inhibition of the late inward sodium current (I_{Na}).[154] In animal models of ischemia and reperfusion, ranolazine preserves tissue levels of adenosine triphosphate (ATP) and improves myocardial contractile function.

An SR formulation of ranolazine has been studied in four RCTs and improved exercise performance and increased the time to ischemia during exercise treadmill testing when used as monotherapy or in combination with the most frequently used doses of atenolol, amlodipine, or diltiazem. Ranolazine also decreases angina frequency and nitroglycerin use when used in conjunction with a beta-blocking agent or calcium channel–blocking agent, and in patients with DM.[153,155]

Despite the favorable effect of ranolazine on ischemic symptoms, in two multinational outcomes RCTs, ranolazine has not reduced major CV events. When studied in 6560 patients with non–ST-segment elevation ACS, ranolazine, administered for an average of approximately 1 year, did not add to standard therapy in secondary prevention of MACE. However, ranolazine reduced the incidence of recurrent ischemia, in particular, worsening angina, in a more diverse population with CAD than studied previously (**Fig. 61.10**). Consistent with previous studies, the reduction in angina and improvement in exercise performance were evident only in patients with a history of chronic angina and was no less in women than in men.[156] When studied in 2651 patients with incomplete revascularization after PCI, ranolazine had no demonstrable effect on ischemia-driven revascularization or hospitalization (HR, 0.95; 95% CI 0.82 to 1.10; $P = 0.48$)[157] or on quality of life.[158]

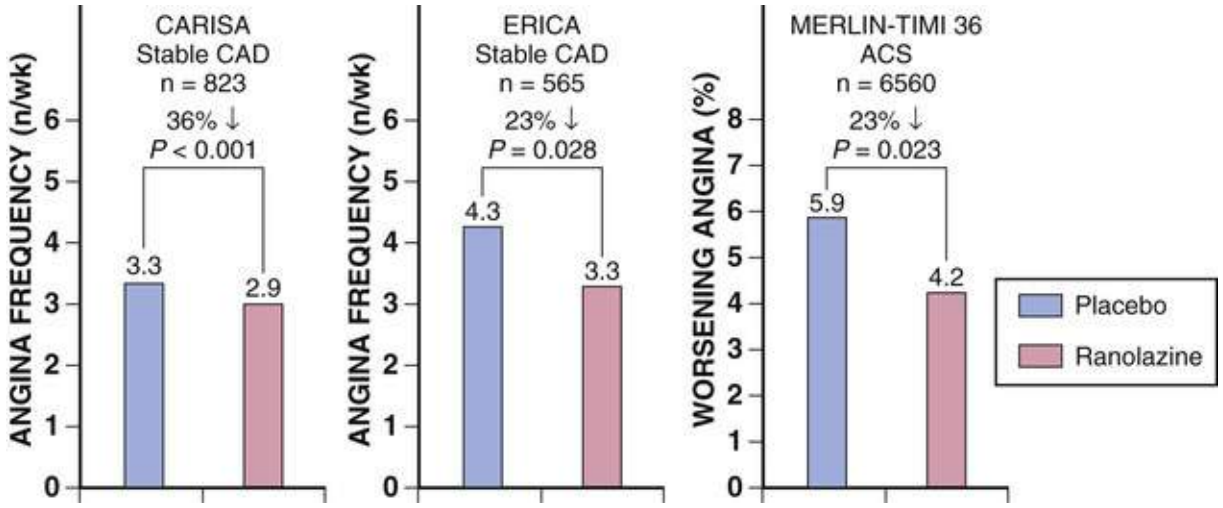


FIGURE 61.10 Reduction in the frequency of angina in three randomized, double-blind, placebo-controlled trials of ranolazine in patients with established coronary artery disease (CAD). Patients with stable CAD and early positive stress testing treated with standard doses of atenolol, amlodipine, or diltiazem were studied in the CARISA (Combination Assessment of Ranolazine in Stable Angina) trial. Patients with stable CAD and at least three episodes of angina per week despite amlodipine, 10 mg daily, were studied in the ERICA (Efficacy of Ranolazine in Chronic Angina) trial. After the diagnosis of non–ST-elevation ACS, patients were studied for an average of 12 months in the MERLIN (Metabolic Efficiency with Ranolazine for Less Ischemia in Non–ST-Elevation Acute Coronary Syndromes) trial. In each trial, ranolazine reduced the frequency of angina. (Data from Chaitman BR et al. Effects of ranolazine with atenolol, amlodipine, or diltiazem on exercise tolerance and angina frequency in patients with severe chronic angina: a randomized controlled trial. JAMA 2004;291:309; Stone PS et al. Antianginal efficacy of ranolazine when added to treatment with amlodipine. J Am Coll Cardiol 2006;48:566; and Morrow DA et al. Effects of ranolazine on recurrent cardiovascular events in patients with non–ST-elevation acute coronary syndromes: the MERLIN-TIMI 36 randomized trial. JAMA 2007;297:1775.)

Because of its proposed mechanism of action on cardiac myocytes rather than modulation of the HR or BP, ranolazine has been studied in patients with angina and ischemia without obstructive epicardial CAD. In a pilot study of 20 women with angina and no obstructive CAD but with impaired coronary flow reserve on CMR, ranolazine reduced symptoms, with evidence of an improved myocardial perfusion reserve index.[159] However, a subsequent study in 128 women with evidence of microvascular dysfunction in the absence of obstructive CAD showed no benefit of ranolazine with respect to symptoms or myocardial perfusion abnormalities.[160]

The half-life of the SR formulation of ranolazine is approximately 7 hours. A steady state is generally achieved within 3 days of twice-daily dosing. Ranolazine is metabolized primarily through the CYP3A4 pathway, and thus the plasma concentration is increased if administered in combination with moderate (e.g., diltiazem) or strong (e.g., ketoconazole, macrolide antibiotic) inhibitors of this system. Verapamil increases the absorption of ranolazine by inhibition of P-glycoprotein. Plasma concentrations of simvastatin are increased approximately twofold after the administration of ranolazine, and it should not be co-administered with ranolazine in doses greater than 20 mg daily.

Ranolazine should be started at 500 mg twice daily and may be increased to a maximum of 1000 mg twice daily in patients with persistent angina. The most commonly reported adverse effects in clinical studies are nausea, generalized weakness, and constipation. Dizziness has also been reported, as has a small, dose-related increase in the corrected QT (QTc) interval, an average of 2 to 5 milliseconds in the dosage range of 500 to 1000 mg twice daily. In contrast to beta blockers and calcium antagonists, ranolazine does not have adverse effects on LV contractility.

The electrophysiologic effects of ranolazine include inhibition of the delayed rectifier current and inhibition of I_{Na}; the net effect is to shorten the action potential duration and suppress early afterdepolarizations.[161,162] Thus, ranolazine does not have the electrophysiologic profile observed with

QT-prolonging drugs associated with torsades de pointes. Rather, ranolazine appears to have favorable electrophysiologic effects on ventricular and atrial arrhythmias. For example, in patients with recent ACS, ranolazine reduced the incidence of arrhythmias detected on ambulatory electrocardiographic monitoring compared with placebo. Subsequent experimental and small human studies have revealed possible favorable effects on AF, suppression of torsades de pointes, and recurrence of internal defibrillator discharges. Ranolazine has been investigated for its potential clinical antiarrhythmic effects alone and in combination with other agents.[163,164] Nevertheless, because of its effect on the QT interval, ranolazine is contraindicated in patients with preexisting QT prolongation, in patients receiving other QT-prolonging medications, or in those with hepatic impairment, which has been associated with a steeper relationship between ranolazine and the QTc.

In addition to these electrophysiologic effects, ranolazine also appears to have favorable glycometabolic effects, including a modest reduction in HbA_{1c}.[165,166]

Ivabradine.

Ivabradine is a specific and selective inhibitor of the I_f ion channel, the principal determinant of the sinoatrial (SA) node pacemaker current.[167,168] Ivabradine reduces the spontaneous firing rate of SA pacemaker cells and thus slows HR through a mechanism not associated with negative inotropic effects. Although approved for use in the United States and Europe for patients with chronic HF with an HR not optimally controlled on maximally tolerated beta-blocker therapy,[168] ivabradine does not currently have a role in patients with SIHD.

Ivabradine reduces the peak HR during exercise, increases the time to limiting angina compared with placebo, and is equivalent to atenolol with respect to exercise performance and time to ischemic ST-segment depression in patients with stable angina undergoing exercise testing. Ivabradine has also been shown to reduce the HR without any effect on ventilatory parameters in patients with obstructive pulmonary disease and to be tolerated in patients with CAD and LV dysfunction. Ivabradine reduced CV death or hospitalization for worsening HF in patients with chronic HF, reduced EF, and HR of 70 beats/min or higher (**see Chapter 25**).[169] However, in a randomized trial of 10,917 patients with CAD and decreased LV function, ivabradine did not reduce the primary endpoint of CV death, hospitalization for MI, or hospitalization for HF. Moreover, in a subsequent trial in 19,102 patients who had SIHD without clinical HF and an HR of 70 beats/min or higher, ivabradine did not reduce the rate of CV death or MI or its components in the overall population or in prespecified subgroups.[170] Rather, there was a possible adverse effect of ivabradine on the incidence of CV death or MI in the subgroup of patients with a history of activity-limiting angina.[170]

Nicorandil.

Nicorandil is a nicotinamide ester that dilates peripheral and coronary resistance vessels via action on ATP-sensitive potassium channels and possesses a nitrate moiety that promotes systemic venous and coronary vasodilation.[171] As a result of these dual actions, nicorandil reduces preload and afterload and results in an increase in coronary blood flow. In addition to these effects, nicorandil may have cardioprotective actions mediated through the activation of potassium channels. Nicorandil has also been studied as a coronary vasodilator for hyperemic testing and for renal protection during PCI. Nicorandil has been associated with ulcerations of the GI tract.[172]

Nicorandil has antianginal efficacy similar to that of beta-blocking agents, nitrates, and calcium channel–blocking agents. In a randomized clinical trial (n = 5126), nicorandil reduced the risk for

cardiac death, MI, or hospital admission for angina (HR, 0.83; $P = 0.014$) in comparison to placebo when added to standard antianginal therapy. Nicorandil is not approved for use in the United States.

Metabolic Agents.

Agents aimed at increasing the metabolic efficiency of cardiac myocytes have also been studied in patients with chronic stable angina. Partial inhibitors of fatty acid oxidation appear to shift myocardial metabolism to more oxygen-efficient pathways. Trimetazidine and perhexiline are drugs that have been shown to inhibit fatty acid metabolism and reduce the frequency of angina without hemodynamic effects in patients with chronic stable angina.[173] These agents are not available for clinical use in the United States but are prescribed in other regions of the world.[174]

Other Considerations of Medical Management of Angina Pectoris

Choice of Initial Therapy

Selection of initial therapy for angina pectoris is reasonably based on an individualized approach to each patient that considers other CV conditions such as hypertension, tachyarrhythmias, conduction system disease, PAD, and LV dysfunction, as well as other non–cardiac-related medical conditions such as severe reactive airways disease, DM, or depression. Comparative studies of antianginal agents have not shown any meaningful difference in efficacy to differentiate one specific class of agents from another for patients with SIHD and no previous MI. Rather, selection of the optimal agent is usually based on overall consideration of the management of coexisting conditions, tolerability, and cost. For most patients, beta-blocking agents or calcium channel antagonists, which are effective and low cost, remain the first line of therapy.

Relative Advantages of Beta-Blocking Agents and Calcium Antagonists

The choice between a beta-blocking agent and a calcium channel antagonist as initial therapy in patients with chronic stable angina is controversial because both classes of agents are effective in relieving symptoms and reducing ischemia[28] (**Table 61.10**). Trials comparing beta blockers and calcium antagonists have not shown any difference in the rate of death or MI,[70] although in some studies, beta blockers appeared to have greater clinical efficacy and less frequent discontinuation because of side effects. Because long-term administration of beta blockers has been demonstrated to prolong life in patients after acute MI (**see Fig. 61.7A**), it is reasonable to consider beta blockers over calcium antagonists as the agents of choice in treating patients with SIHD.[28] Nevertheless, as highlighted by a large observational study, definitive evidence to support this preference is not available (**see Fig. 61.7B**).[132] In addition, these drugs may produce fatigue, depression, and sexual dysfunction. In contrast, although calcium antagonists do not show these adverse effects, their long-term administration has *not* been shown to improve long-term survival after acute MI.

TABLE 61.10

Recommended Use of Beta-Blocking Agents or Calcium Antagonists in Patients Who Have Angina in Conjunction with Other Medical Conditions

CLINICAL CONDITION	RECOMMENDED DRUG
Cardiac Arrhythmia or Conduction Disturbance	
Sinus bradycardia	Nifedipine, amlodipine
Sinus tachycardia (not caused by cardiac failure)	Beta-blocking agent
Supraventricular tachycardia	Beta-blocking agent, verapamil, or diltiazem
AV block	Nifedipine or amlodipine
Rapid atrial fibrillation	Beta-blocking agent, verapamil, or diltiazem
Ventricular arrhythmia	Beta-blocking agent
Left Ventricular Dysfunction	
Heart failure	Beta-blocking agent
Miscellaneous Medical Conditions	
Systemic hypertension	Beta-blocking agent or calcium antagonist
Severe preexisting migraine headaches	Beta-blocking agent, verapamil or diltiazem
COPD with bronchospasm or asthma	Nifedipine, amlodipine, verapamil, or diltiazem
Hyperthyroidism	Beta-blocking agent
Raynaud syndrome	Nifedipine or amlodipine
Claudication	Calcium antagonist
Severe depression	Calcium antagonist

COPD, Chronic obstructive pulmonary disease.

Selection of Therapy

The choice of drug with which to initiate therapy for management of angina is influenced by a number of clinical factors[28] (**Table 61.10**):

1. In patients with a history of asthma or chronic obstructive lung disease with wheezing on clinical examination, in whom beta-blocking agents, even relatively selective agents, may not be tolerated, calcium antagonists or nitrates are preferred, and ranolazine is an option. A trial of a beta blocker should be considered if the patient has a history of previous MI or LV dysfunction.
2. Nifedipine (long acting), amlodipine, and nicardipine are the calcium antagonists of choice in patients with chronic stable angina and sick sinus syndrome, sinus bradycardia, or significant AV conduction disturbances, whereas beta blockers and verapamil should be used only with great caution in such patients. In patients with symptomatic conduction disease, neither a beta blocker nor a heart rate–lowering calcium antagonist should be used unless a pacemaker is in place. If a beta blocker is required in patients with asymptomatic evidence of conduction disease, pindolol, which has the greatest ISA, is useful. In the case of calcium channel–blocking agents in patients with conduction system disease, amlodipine, nifedipine or nicardipine are preferable to verapamil and diltiazem. Nitrates and ranolazine are alternatives.
3. Calcium antagonists or long-acting nitrates are preferred for patients with suspected Prinzmetal variant angina; beta blockers may even aggravate angina under these circumstances.
4. Calcium antagonists may be preferred over beta blockers in patients with significant, symptomatic peripheral artery disease because the latter may cause peripheral vasoconstriction.
5. Beta-blocking agents should usually be avoided in patients with a history of significant depressive illness and should be avoided or monitored for exacerbation of symptoms in patients with sexual dysfunction, sleep disturbance, nightmares, fatigue, or lethargy.
6. The beneficial effects of beta blockers on survival in patients with LV dysfunction after MI, coupled with their beneficial effects on survival and LV performance in patients with heart failure, have established beta-blocking agents as the drug class of choice for the treatment of

angina in patients with LV dysfunction, with or without symptoms of HF, together with ACE inhibitors or ARBs. If a beta blocker is not tolerated or angina persists despite beta blockade and nitrates, amlodipine can be administered. Ranolazine is also an option for such patients. In countries where it is available, ivabradine may be considered in patients with angina in conjunction with LV dysfunction and HR above 70 beats/min who are receiving beta-blocker therapy. Verapamil, nifedipine, and diltiazem should be avoided.

7. Hypertensive patients with angina pectoris do well with either beta blockers or calcium antagonists because both have antihypertensive effects, and an ACE inhibitor should strongly be considered for all patients with CAD and hypertension. Although less effective as antihypertensive agents, present professional society guidelines favor use of beta blockers in patients with angina and hypertension, with nondihydropyridine calcium channel blockers as an alternative if symptom relief or control of hypertension is inadequate with the beta blocker. Carvedilol has a more robust effect than metoprolol on BP and is better tolerated than labetalol, so carvedilol may be the preferred beta blocker for patients with angina and hypertension.

Combination Therapy

A combination of multiple agents is widely used for the management of chronic stable angina, with options that include a beta blocker, calcium antagonist, long-acting nitrate, or ranolazine, which may be particularly useful when the HR, BP, or LV dysfunction limits escalation of other therapy. In patients with moderate or severe LV dysfunction, sinus bradycardia, or AV conduction disturbances, combination therapy with nondihydropyridine calcium antagonists and beta blockers should be avoided or should be initiated with caution. The negative inotropic effects of calcium antagonists are not usually a problem in combined therapy with low doses of beta blockers but can become significant with higher doses. With such doses, amlodipine is the calcium antagonist of choice, but it should be used cautiously. Ranolazine may be useful in such patients who do not tolerate other agents.

Synthesis of Integrated Approach to Management of Patients with Chronic Angina

1. Identify and treat precipitating factors, such as anemia, uncontrolled hypertension, thyrotoxicosis, tachyarrhythmias, uncontrolled heart failure, and concomitant valvular heart disease.
2. Initiate risk factor modification, physical exercise, diet, and lifestyle counseling. Commence therapy with a high-intensity statin regimen.
3. Begin pharmacotherapy with aspirin and a beta blocker or calcium antagonist. Initiate an ACE inhibitor in all patients with an LV ejection fraction of 0.40 or lower and in those with hypertension, diabetes, or chronic kidney disease. In addition, an ACE inhibitor should be considered for all other patients.
4. Use sublingual nitroglycerin for alleviation of anginal symptoms and for prophylaxis, if needed.
5. If angina persists, the next step is usually the addition of a second agent: a calcium antagonist or beta blocker, or long-acting nitrate with dosing schedules that prevent nitrate tolerance. The need to treat concomitant hypertension or the presence of LV dysfunction and symptoms of HF may be an indication for the use of one of these agents, even in patients in whom episodes of symptomatic angina are infrequent. Ranolazine is an alternative for some patients, particularly those in whom initiation or titration of other agents is limited by low HR or BP.

6. If angina persists despite two antianginal agents (usually a beta blocker with a long-acting nitrate preparation or a calcium antagonist), add a third antianginal agent. Selection of the agent will be guided by potential side effects and the presence or absence of concomitant hypertension, relative hypotension, conduction system disease, tachyarrhythmias, or LV dysfunction.
7. Coronary angiography, with a view to considering coronary revascularization, is indicated in patients with refractory symptoms or ischemia despite guideline-directed medical therapy. Coronary angiography should also be carried out in patients with high-risk noninvasive test results (**see Table 61.3**) and in those whose occupation or lifestyle requires a more aggressive approach.

Nonpharmacologic Treatment Approaches.

These therapies are generally considered only for patients who have refractory ischemic symptoms after failing medical therapy with multiple agents and coronary revascularization (see later, Revascularization Approaches in Stable Ischemic Heart Disease).

Enhanced External Counterpulsation.

The use of enhanced external counterpulsation (EECP) is another alternative treatment of refractory angina.[175] EECP is generally administered as 35 1-hour treatments over 7 weeks. Observational data have suggested that EECP reduces frequency of angina and use of nitroglycerin and improves exercise tolerance and quality of life, and responses can last for up to 2 years. In a randomized, double-blind, sham-controlled study of EECP for patients with chronic stable angina, active counterpulsation was associated with an increase in time to ST-segment depression during exercise testing and a reduction in angina, as well as an improvement in health-related quality of life that extended to at least 1 year. There are no definitive data that EECP reduces the extent of ischemia as determined by MPI.

The mechanisms underlying the effects of EECP are poorly understood. Possible mechanisms include (1) durable hemodynamic changes that reduce myocardial O_2 demand; (2) improvement in myocardial perfusion caused by the capacity of increased transmyocardial pressure to open collaterals; and (3) elaboration of various substances that improve endothelial function and vascular remodeling caused by augmented flow through the arterial vascular bed, thereby resulting in an improvement in systemic arterial compliance.[176] Finally, the possibility of placebo effects should be recognized; most of the evidence demonstrating favorable effects of EECP is derived from uncontrolled studies, and data from sham-controlled studies are few.

Spinal Cord Stimulation.

An option for patients with refractory angina who are not candidates for coronary revascularization is spinal cord stimulation using a specially designed electrode inserted into the epidural space.[177] The beneficial effects of neuromodulation on pain with this technique are based on the gate theory, in which stimulation of axons in the spinal cord that do not transmit pain to the brain will reduce input to the brain from axons that do transmit pain. Regardless of the mechanism, several observational studies have reported success rates of up to 80% in terms of reducing the frequency and severity of angina. Small randomized trials, including one sham-controlled study, have indicated improvements in symptoms and functional status.[178] Less easily explained is an apparent anti-ischemic effect of this technique.[179] This approach should be reserved for patients in whom all other treatment options have been exhausted.

Transmyocardial Revascularization.

Revascularization Approaches in Stable Ischemic Heart Disease (See Chapter 62)

Approach to Decision Making Regarding Revascularization

Ischemic heart disease represents as a dynamic continuum of disease with a variable natural history that may, over decades, encompass many phases of clinical expression ranging from asymptomatic periods, development of chronic exertional angina, subsequent quiescent periods, progression to accelerating angina, and culmination in unstable angina, acute MI, HF, or SCD (**see Chapters 23, 42, 58, and 60**). Therefore, the approach to treatment should be tailored to the individual patient's clinical status. Atherosclerosis is typically a diffuse or multifocal process that requires a comprehensive, systemic approach to management. Moreover, myocardial ischemia may also occur in the absence of obstructive CAD. In general, the principles guiding patient management are predicated on addressing two simultaneous goals, if possible: (1) use of disease-modifying therapies or approaches to prolong life and reduce major adverse cardiovascular events (MACE) such as acute MI, hospitalization for ACS, or HF, and (2) optimization of the patient's health status, quality of life, and functional capacity such that angina or ischemia do not have an adverse impact on activities of daily living (ADLs).[28]

The benefits of revascularization on the natural history of SIHD are proportional to the patient's underlying risk, which makes it essential to quantify the patient's prognosis as accurately as possible (**see Table 61.3**). In addition to the patient's MACE risk, sociodemographic factors such as age, physical capacity, ability to adhere to prescribed treatments and lifestyle interventions, overall quality of life, other medical conditions, and patient preferences should be considered. Each of these aspects should be integrated in considering how best to achieve these two fundamental goals of therapy for patients with SIHD. Revascularization approaches are an integral component of an overall management strategy to improve outcomes and are used when needed in addition to guideline-directed medical therapy (GDMT). The success of catheter-based or surgical treatment is predicated on the overall success of GDMT and lifestyle intervention as a platform for the management of all patients with SIHD. Decisions regarding the best mode of revascularization (catheter based or surgical) should follow a thoughtful assessment of whether and when revascularization is necessary to achieve these goals of therapy and are best made by a multidisciplinary heart team that includes a noninterventional cardiologist, an interventional cardiologist, and a cardiac surgeon. Patients are also critical participants in decision making in terms of their preferences.[180]

Patient Selection for Revascularization

Each of the following considerations may be used to guide decisions regarding the indications for, as well as the approach to, revascularization: (1) the presence and severity of symptoms, (2) physiologic significance of the coronary lesions and other anatomic considerations, (3) extent of myocardial ischemia and presence of LV dysfunction, and (4) other medical conditions that influence the risks associated with percutaneous or surgical revascularization and longevity after revascularization.

Presence and Severity of Symptoms

A goal of therapy is complete elimination of angina and resumption of full physical function to the extent

possible.[28] Coronary revascularization (catheter based or surgical) should be considered if ischemic symptoms persist after intensification of medical therapy, or if unacceptable side effects or the patient's therapeutic preferences limit antianginal therapy (see earlier, Assessment and Classification of Angina Pectoris).

Significance of Coronary Lesions (and Other Anatomic Considerations)

Seventy percent or greater stenosis of an epicardial coronary artery is considered to be anatomically significant (≥50% for left main coronary stenosis). Thus the professional guidelines that have influenced clinical practice regarding revascularization have been framed principally around these anatomic criteria —number of diseased vessels and extent and severity of anatomic disease—together with integration of functional considerations: magnitude and distribution of ischemia and amount of threatened myocardium.[28] Data from the large, prospective Clinical Outcomes Utilization Revascularization and Aggressive Drug Evaluation (COURAGE) randomized trial of PCI versus medical therapy examined the relationship between the severity of stenosis and the extent of angiographic CAD by using quantitative coronary angiography in a core laboratory, and contrary to conventional wisdom, no anatomic subset of CAD stenosis severity (including patients with 70% to 90% narrowing and >90% narrowing of LAD) was found to benefit from PCI versus medical therapy with respect to long-term clinical events.[28]

Moreover, clinicians also face clinical uncertainty regarding the potential significance of “borderline” visual coronary stenoses, nominally defined as lesions in the 50% to 70% range. It is widely acknowledged that angiographically determined stenosis severity expressed as the percentage of luminal narrowing is often an inaccurate measure of a lesion's functional significance.[2,3,65,181] Even though cardiac surgeons have considered 50% or greater stenosis as the criterion for “significant,” many factors other than visual stenosis severity (e.g., lesion eccentricity, tortuosity, presence of plaque rupture or asymmetric luminal filling defects, presence of additional serial lesions) can potentially render a 50% to 70% stenosis “functionally or hemodynamically significant.” Multiple additional techniques, such as IVUS, OCT, and coronary pressure/flow measurements (see earlier, Invasive Assessment, and **Chapter 20**), provide enhanced assessment of the anatomic and functional significance of specific coronary lesions and may complement stress testing to aid in decision-making judgments on the potential benefits of revascularization.

Other anatomic features, in addition to lesion severity, also influence the likelihood of success and the approach to revascularization for a given patient.[33] Such features include vessel size, extent of calcification, tortuosity, and relationships to side branches (**see Chapter 62**). Patients with diffuse severe disease of the distal coronary arteries may be poor candidates for any revascularization procedure.

Fractional Flow Reserve

Measurement of FFR is extremely useful for guiding appropriate decisions regarding revascularization of intermediate stenoses[65,182] (see earlier, Invasive Assessment, and **Chapters 57 and 62**). In a study of 325 patients with an intermediate stenosis scheduled for PCI, patients with an FFR higher than 0.75 (56%) were randomly assigned to PCI or medical therapy. Patients managed medically had a risk for cardiac death or MI that was less than 1% per year over the first 5 years and was not increased relative to the group who underwent stenting through 15-years of follow-up.[183] Subsequently, FFR was evaluated in the FAME (Fractional Flow Reserve versus Angiography for Multivessel Evaluation) trial, in which patients were randomly assigned to conventional PCI, guided by visual assessment of the angiogram, or FFR-guided PCI (with PCI performed only in lesions with FFR ≤0.8). The results showed a lower 2-year rate

of death or MI with the FFR-guided strategy. From 2 to 5 years, the risks with the two strategies were similar. Therefore, at 5 years, outcomes in the two treatment groups were also similar; however, the FFR-guided group had a lower number of stented arteries and less resource use.[184] Nonetheless, the FAME trial did not include a comparison group that received GDMT without revascularization. The FAME 2 trial did include a comparison group receiving GDMT without revascularization[64] (see later, Comparisons between Percutaneous Coronary Intervention and Medical Therapy). The FAME 3 trial is testing use of FFR to guide multivessel PCI and is comparing FFR-guided PCI with contemporary drug-eluting stents to CABG in patients with three-vessel disease.[185]

Extent of Ischemia and Presence of Left Ventricular Dysfunction

The three major determinants of risk in patients with CAD are the extent of ischemia, the number of vessels diseased, and LV function.[23] The extent of ischemia on noninvasive testing is an important predictor of subsequent adverse outcomes and identifies patients in whom revascularization may provide clinical benefit over that of medical therapy beyond the relief of symptoms. The magnitude of the benefit with revascularization versus medical therapy is enhanced in the setting of LV dysfunction. Moreover, the greatest survival benefits of CABG, as well as symptomatic and functional improvements, are evident in patients with impaired LV function (generally defined as LVEF <0.40) (**Tables 61.11 and 61.12**).

TABLE 61.11

Impact of Coronary Artery Bypass Surgery Versus Medical Therapy on Survival*

CATEGORY OF RISK	NUMBER OF VESSELS DISEASED	SEVERITY OF ISCHEMIA	EJECTION FRACTION	RESULTS OF SURGERY ON SURVIVAL

*Systematic overview of the effect of CABG versus medical therapy on survival based on data from seven randomized trials comparing a strategy of initial CABG with one of initial medical therapy. Subgroup results at 5 years are shown.

From Yusuf S, Zucker D, Peduzzi P, et al. Effect of coronary artery bypass surgery on survival: overview of 10-year results from randomized trials by the Coronary Artery Bypass Surgery Trialists Collaboration. Lancet 1994;344:563.

Risks Associated with the Procedure

Patients with SIHD may have other medical conditions, such as renal dysfunction, peripheral atherosclerosis, or pulmonary disease, that may influence the patient's suitability for surgical or percutaneous revascularization. For example, in a patient with a history of GI bleeding, the potential need for long-term DAPT after a procedure should be considered. Moreover, a patient with three-vessel CAD and impaired LV function who might derive a more durable survival benefit from CABG may be too high risk clinically to undergo surgery and might be a better candidate for multivessel PCI.

In addition, the following general principles regarding the choice of treatment in patients with SIHD should be considered:

1. For most patients with stable angina, revascularization should not constitute the initial management strategy before evidence-based medical therapy (pharmacologic antianginal therapy, disease-modifying treatments, and therapeutic lifestyle intervention) is initiated and optimized.[28]
2. When improvement in survival is not a relevant consideration, the severity of angina or impairment in health status should play a significant role in determining whether revascularization is appropriate to enhance quality of life (i.e., limiting angina while undergoing GDMT is a more compelling indication than episodic, exertional angina occurring on minimal medical therapy).
3. The patient's treatment preferences should always be a primary consideration in guiding which

treatment strategy should be used.

4. In certain clinical circumstances, it may be difficult to reliably ascertain whether anginal symptoms or anginal equivalents such as exertional dyspnea or fatigue are a direct manifestation of underlying CAD, especially in patients with significant obesity, those who are sedentary, or those who may have coexisting chronic obstructive pulmonary disease. In such settings, symptoms that are either atypical for or nondiagnostic of obstructive CAD may not necessarily improve with revascularization, even when such symptoms coexist with physiologically significant CAD.
5. The decision to proceed with coronary revascularization in a patient with SIHD should entail a thoughtful, transparent discussion of all potential treatment options, with full disclosure of the anticipated benefits and potential risks associated with PCI or CABG relative to GDMT. In an elective setting where urgent/emergency PCI is not being contemplated to reduce the possibility of death or MI, use of a “heart team,” as cited earlier, is both prudent and clinically appropriate. Although ad hoc PCI is typically done once the patient's coronary anatomy is defined in the catheterization laboratory, it is frequently difficult to have the type of discussion that would involve a complete review of the potential risks and benefits of all treatment options by the heart team in this setting.
6. In summary, treatment decisions must be individualized according to the specific clinical features and personal preferences of a given patient (often in collaboration with family members and referring physician), along with informed discussion about the potential risks and benefits of all three therapeutic options.

Percutaneous Coronary Intervention

PCI, which includes percutaneous transluminal coronary angioplasty (PTCA), intracoronary stenting, and related techniques, has continued to evolve significantly over the past three decades. PTCA has been largely supplanted by stenting with the advent of bare-metal stents (BMSs) in the mid-1990s, followed by the introduction of drug-eluting stents (DESs) in 2003 and subsequent evolutions in stent design to include thinner struts and improved drug-eluting platforms and delivery systems to minimize both restenosis and acute, subacute, and late/very late stent thrombosis. Moreover, the practice of interventional cardiology has evolved significantly with improved adjunctive pharmacotherapy and advances in technology other than stenting, such as devices directed at specific technical issues (e.g., rotablation and atherectomy catheters).[186,187] PCI is an important treatment modality in patients with SIHD, particularly in those with chronic angina who remain symptomatic despite optimal GDMT.

Chapter 62 discusses the technical aspects, early outcomes, and long-term outcomes of PCI. This section focuses on comparisons of PCI with medical therapy and when to select PCI as part of a therapeutic strategy.

Among the many desirable features of PCI is the fact that it can be performed during the same clinical encounter as diagnostic angiography. Stable patients can often be discharged on the same or next day, and clinical recovery is usually complete within 1 week. In many patients, relief of symptoms may be immediate and dramatic. Such attributes can motivate some patients to elect to undergo PCI even when medical therapy alone may lower overall risk with equivalent long-term outcomes.

Early Outcome.

Continued improvement in the technical aspects of PCI (predominantly coronary stenting), as well as increasing operator experience, has had a favorable impact on the rate of primary success and the rate of reductions in complications. The ACC National Cardiovascular Data Registry (ACC-NCDR) has reported an angiographic success rate of 96% and a procedural success rate (angiographic success without death, heart attack, or emergency revascularization) of 93% in patients undergoing PCI. The incidence of death before hospital discharge is less than 1%, and emergency CABG is required in 0.3% of cases. The ACC-NCDR has also reported a periprocedural MI rate of 1%. Although studies using routine assessment of cardiac biomarkers have reported higher rates, the significance of increases in these periprocedural biomarkers is debated.[188] With modern-generation DESs, the rate of restenosis is now less than 10%, with a corresponding approximately 20% decrease in the need for repeat revascularization procedures relative to the era of BMSs. Outcomes in specific challenging subgroups of patients, such as those with chronic total occlusions or left main coronary stenosis, are discussed in **Chapter 62**. Advances in technology have improved success rates in both these anatomic settings; for example, technical success rates greater than 70% have been reported for PCI of chronic total occlusions, supporting this approach as a reasonable alternative (class IIa) in patients with appropriate clinical indications and suitable anatomy when performed by operators with appropriate experience.[189]

Long-Term Outcome

Stenting versus Angioplasty.

Compared with balloon angioplasty, coronary stenting reduces MACE by approximately 40% as a result of reduced repeat revascularization, without a detectable decrease in mortality or rate of MI.[33]

Restenosis and Late Stent Thrombosis.

See Chapter 62.

Comparisons Between Percutaneous Coronary Intervention and Medical Therapy

Studies comparing balloon angioplasty with medical therapy in the present era are of uncertain clinical relevance today because both PCI and medical treatments have undergone profound changes over the past two decades. Moreover, randomized clinical trials comparing PCI with medical therapy are few in number and have involved fewer than 9000 patients (in total). Most have enrolled patients with predominantly single-vessel disease and were completed before the routine use of coronary stenting and enhanced adjunctive pharmacotherapy. In aggregate, the results of these 16 trials have supported better control of angina, improved exercise capacity, and improved quality of life in patients treated with angioplasty versus medical therapy.[28,190] However, a meta-analysis of eight trials of stenting versus medical therapy indicated that the initial improvement in relief of angina with PCI over medical therapy is not sustained in the era of contemporary medical therapy[28,190] (**Fig. 61.11**). In addition, no randomized trial or meta-analysis has demonstrated a reduction in death or MI with PCI versus medical therapy for patients with SIHD.

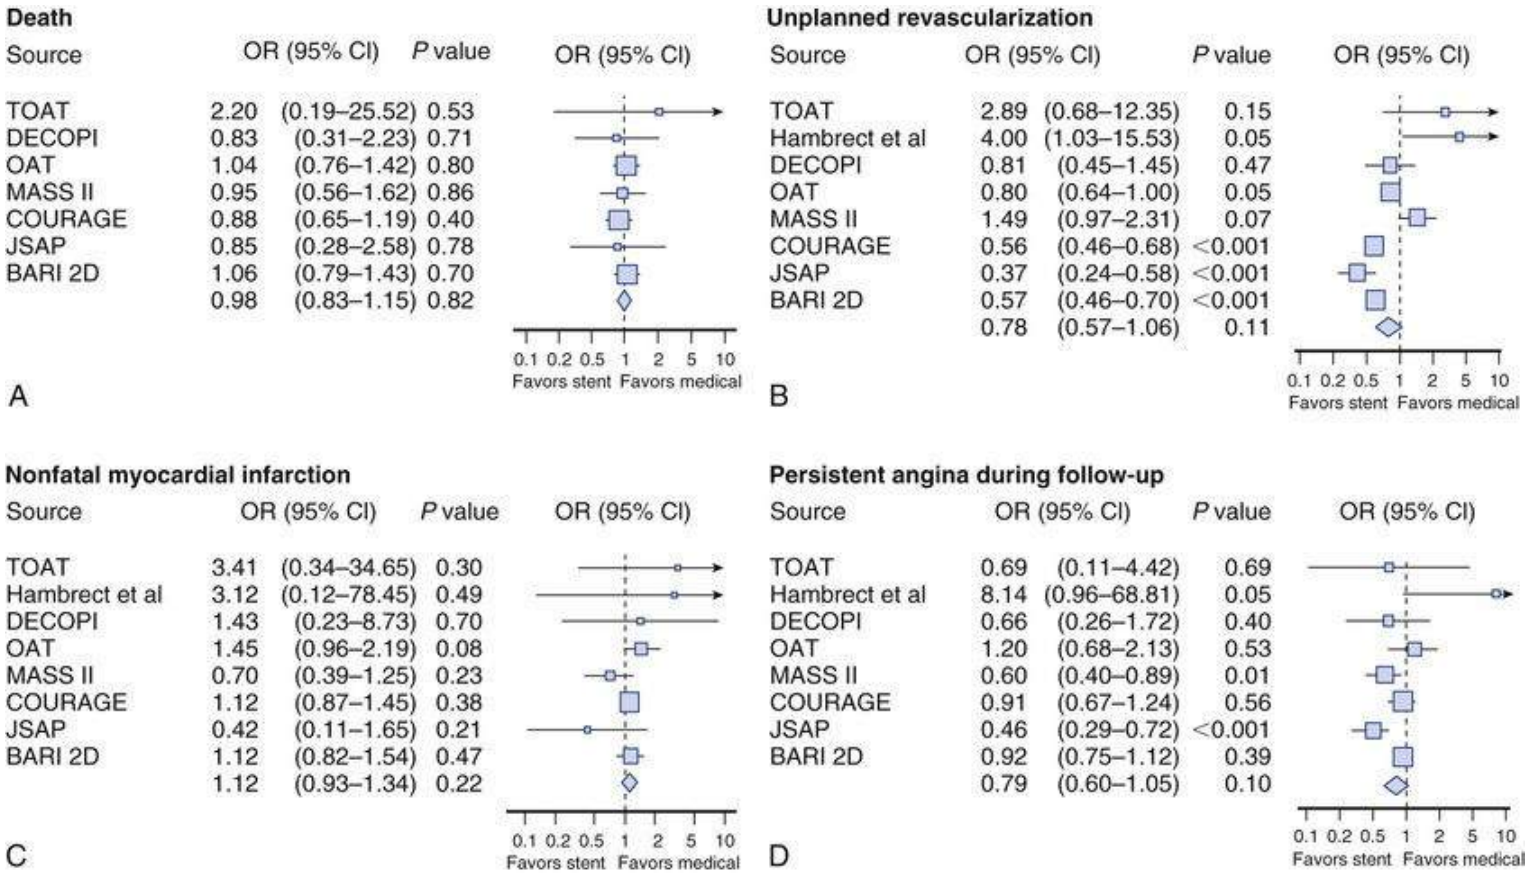

FIGURE 61.11 Meta-analysis of coronary stent implantation versus medical therapy. Data are developed in eight trials enrolling 7229 patients, including three trials of stable patients after myocardial infarction (MI), and five studies enrolled patients with stable angina and/or ischemia on stress testing. Mean weighted follow-up was 4.3 years. There was no evidence of benefit of initial coronary stenting compared with initial medical therapy for prevention of death **(A),** unplanned revascularization **(B),** nonfatal MI **(C),** or persistent angina **(D).** OR, Odds ratio. (Modified from Stergiopoulos K, Brown DL. Initial coronary stent implantation with medical therapy vs medical therapy alone for stable coronary artery disease: meta-analysis of randomized controlled trials. Arch Intern Med 2012;172:312-9.)

Between 1999 and 2004, 2287 patients with objective evidence of ischemia and proximal angiographic CAD (≥70% visual stenosis) were randomized to GDMT with or without PCI in the COURAGE trial.[28] Its goal was to test a strategy of routine, anatomically driven PCI plus GDMT versus a strategy of PCI, if needed, for failure of initial GDMT. During a median follow-up of 4.6 years, death or MI occurred with similar frequency in both arms (HR for PCI + GDMT versus GDMT, 1.05; 95% CI 0.87 to 1.27; P = 0.62) (**Fig. 61.12**). Thus the main study findings indicated that as an initial management strategy in patients with SIHD, PCI did not reduce death, MI, or other MACE when added to GDMT. Patients initially treated with PCI had less angina at 1 and 3 years, but not at 5 years, than did patients initially treated without initial PCI. As expected, in patients who received GDMT initially, subsequent PCI was performed more frequently than in those initially treated with PCI, although only 16.5% of GDMT patients required revascularization during the first year of follow-up, whereas the remaining 16.1% of patients crossed over to revascularization between years 1 and 7.

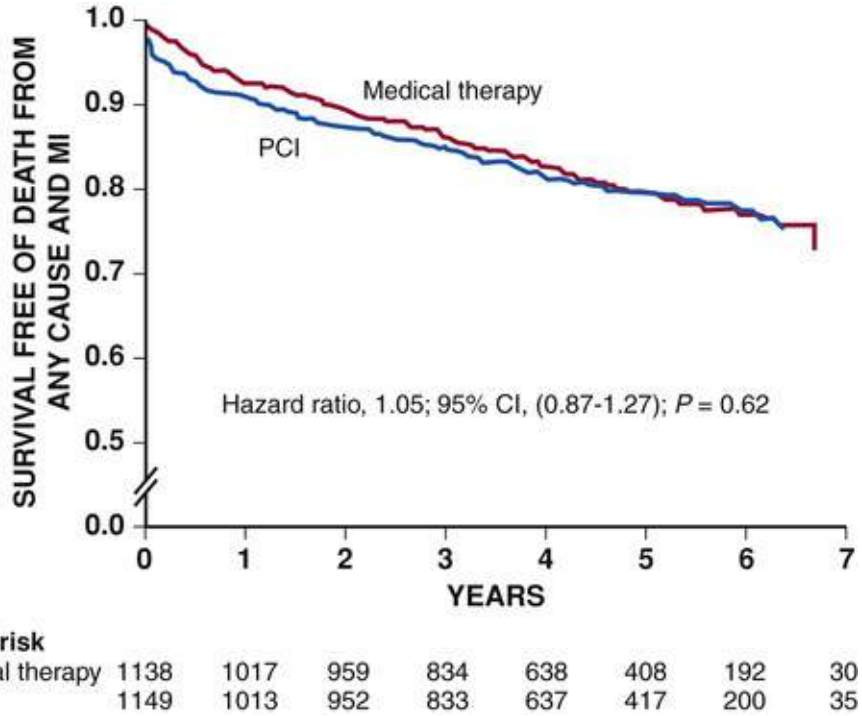

FIGURE 61.12 Outcome in 2287 patients with objective evidence of myocardial infarction (MI) and significant coronary artery disease enrolled in the COURAGE trial and randomly assigned to percutaneous coronary intervention (PCI) and optimal medical therapy (OMT) or to OMT alone. No difference in the primary endpoint of death from any cause or MI was observed between the two treatment groups. (From Boden WE, O'Rourke RA, Teo KK, et al. Optimal medical therapy with or without PCI for stable coronary disease. N Engl J Med 2007;356:1503.)

Subgroup analyses of the COURAGE trial revealed consistency among clinically relevant special populations: no difference between PCI plus OMT versus GDMT in patients with multivessel CAD, low LVEF, CCS class II or III angina, or diabetes. The primary endpoint (death or MI) was similar in the two treatment groups for the subsets with either no to mild ischemia (18% and 19%, respectively, $P = 0.92$) or moderate to severe ischemia (19% and 22%, respectively; $P = 0.53$; interaction P value = 0.65). Moreover, there was no graded increase in events for the overall cohort based on the extent of ischemia. Thus the premise that severe ischemia may identify an important subset of patients with SIHD who may derive clinical benefit from PCI remains unproven.

Although it is plausible results would be different with newer-generation DESs, which are both safer (less stent thrombosis) and more effective (reduced restenosis) than PCI techniques used in COURAGE, no RCTs are yet available comparing newer-generation DESs with GDMT.

Fractional Flow Reserve Strategy

An FFR-guided PCI strategy plus the best available medical therapy was compared with best available medical therapy alone in the FAME 2 trial.[64,182] In this trial, patients who had lesions with an FFR of 0.8 or less in one or more visually stenotic coronary arteries (≥50% stenosis) were randomly assigned to medical therapy alone or PCI plus medical therapy. The plan was to enroll 1632 patients in the study with a projected minimum 2-year follow-up; however, the trial was terminated prematurely after enrollment of 888 patients with a mean follow-up of 7 months, at the recommendation of the data monitoring committee because of a highly significant reduction in the composite primary endpoint of death, MI, or urgent revascularization. The final analysis revealed a 68% relative risk reduction in the primary endpoint from 12.7% in the medical therapy group to 4.3% in the PCI group (HR, 0.32; 95% CI, 0.19 to 0.53; $P < 0.001$). Notably, the difference in this open-label trial was driven solely by a lower rate of urgent revascularization in the PCI group than in the medical therapy group (1.6% versus 11.1%; HR, 0.13; 95%

CI 0.06 to 0.30; $P < 0.001$), with no significant difference in death or MI[182] (**Fig. 61.13**).

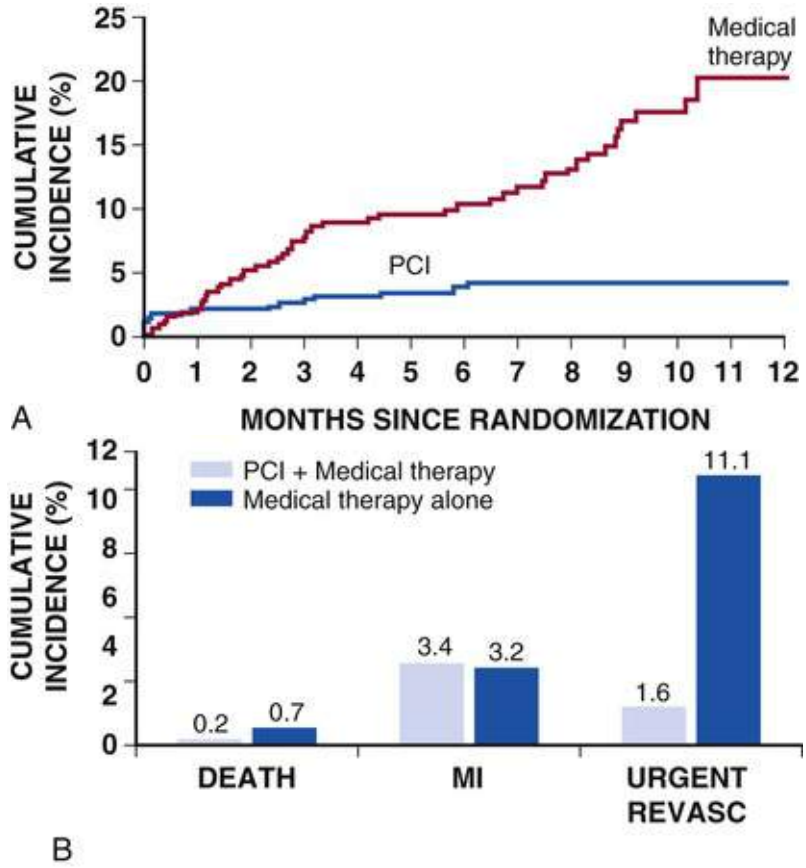

FIGURE 61.13 Outcome of death, myocardial infarction (MI), or urgent revascularization in 888 patients with stable coronary artery disease (CAD) for whom percutaneous coronary intervention (PCI) was being considered. The patients underwent assessment of all stenoses by fractional flow reserve (FFR) and were randomly assigned to FFR-guided PCI plus best available medical therapy or the best available medical therapy alone. **A,** Enrollment was halted prematurely because of a significant reduction in the primary endpoint in patients treated with an FFR-guided revascularization strategy: 4.3% in the PCI group and 12.7% in the medical therapy group (HR with PCI, 0.32; 95% CI 0.19 to 0.53; $P < 0.001$). **B,** However, this effect on the primary endpoint was driven entirely by a reduction in unplanned revascularization (Revasc) rather than by death or MI. (Modified from De Bruyne B, Piljs NH, Kalesan B et al. Fractional flow reserve–guided PCI versus medical therapy in stable coronary disease. N Engl J Med 2012;367:998.)

Findings from both the COURAGE and FAME 2 studies show that PCI reduces ischemic symptoms and the need for future revascularization. Neither the FAME 2 trial (with a mean 7 months of follow-up) nor the COURAGE trial (with a mean 55 months of follow-up) showed a reduction in the rate of death or MI with PCI versus GDMT. Although FAME 2 did not test use of FFR versus not used, the findings lend indirect support to current guidelines for the selective use of FFR to guide PCI decision making for borderline visual lesions (50% to 70% stenosis).[182]

Recently two randomized controlled trials compared PCI guided by the newer instantaneous wave-free ratio (iFR) vs. PCI guided by FFR. Randomization to iFR, which allows assessment of the hemodynamic consequences of a stenosis without the use of adenosine vasodilation, was associated with similar major adverse cardiac event rates, but fewer side effects and shorter procedure times.[182a,182b]

In summary, to date, meta-analyses of randomized trials of PCI versus medical therapy for SIHD have demonstrated that mortality, MI, severity and extent of ischemia, and long-term angina do not differ between these two strategies.[28] Nevertheless, the question of whether PCI can reduce the risk for CV death or MI in select patients at higher risk for ischemia remains under investigation. ISCHEMIA

(International Study of Comparative Health Effectiveness with Medical and Invasive Approaches; ClinicalTrials.gov, NCT01471522), funded by the National Heart, Lung and Blood Institute (NHLBI), is presently underway and is designed to evaluate whether revascularization plus GDMT is superior to GDMT alone with respect to CV death or MI in patients with SIHD and documented moderate to severe myocardial ischemia.[191]

At present, based on the best available data from randomized trials, it appears reasonable to pursue a strategy of initial medical therapy for most patients with SIHD and CCS class I or II symptoms and to reserve revascularization for those with persistent and/or more severe symptoms despite GDMT or those with high-risk criteria on noninvasive testing, such as inducible ischemia involving a moderate or large territory of myocardium.[28]

Selection of Percutaneous Coronary Intervention for Revascularization

In addition to general considerations regarding the indications and approach to revascularization (see earlier, Approach to Decision Making Regarding Revascularization), additional factors that need to be weighed in selecting PCI as an option for therapy include the following:

1. The likelihood of successful catheter-based revascularization based on the angiographic characteristics of the lesion.
2. The ability to achieve complete revascularization based on the extent of CAD and the volume of myocardium and the severity of ischemia in the distribution of the artery or arteries amenable to PCI.
3. Although advances in technology have significantly reduced the rates of both acute failure of PCI and target lesion restenosis, consideration of these risks and their potential consequences remain relevant to decision making regarding PCI. The percentage of viable myocardium at risk, the presence of impaired LV function, and the diffuseness and anatomic complexity of CAD, including specific angiographic factors such as small vessel diameter, long lesion length, total occlusion, and saphenous vein graft disease, may be relevant to the potential risks and benefit of PCI.

Percutaneous Coronary Intervention in Specific Subgroups of Patients with Stable Ischemic Heart Disease

Diabetes Mellitus.

Patients with DM are at substantially higher risk for complications after PCI (**see Chapter 51**). Possible explanations for the higher rate of adverse outcomes include a greater burden of coronary atherosclerosis, an altered vascular biologic response to balloon and stent injury, rapid progression of disease in nonrevascularized segments, and higher platelet reactivity. The diabetic atherosclerotic milieu is characterized by a procoagulant state, decreased fibrinolytic activity, increased proliferation, and inflammation. Restenosis is more frequent in patients with diabetes, as is disease progression. For this reason, CABG, which bypasses most of the vessel instead of a specific lesion, may offer a better intermediate- to long-term outcome for patients with multivessel CAD. The optimal strategy for revascularization in patients with DM is discussed later. A strategy of initial GDMT appears to be reasonable for most patients with diabetes and SIHD.[192]

Left Ventricular Dysfunction.

Despite advances in interventional cardiology, LV dysfunction remains independently associated with higher in-hospital and long-term mortality after PCI. Specifically, in patients with stable CAD and estimated EF of 40% or less, 41% to 49%, and 50% or higher in the NHLBI Dynamic Registry, mortality at 1 year after PCI was 11.0%, 4.5%, and 1.9%, respectively. Contemporary trials of PCI versus medical therapy have included too few patients with impaired LV function to guide therapeutic decision making in this important subset of patients.

Women and Older Patients.

Specific issues related to PCI in women and older adults are discussed in **Chapters 88 and 89**. Observational studies have shown higher rates of complications, particularly bleeding, among women compared with men undergoing invasive management. A post hoc study from the COURAGE trial showed that the 40% of the patients 65 years or older had a twofold higher rate of death or MI than younger patients, although no age-related differences in clinical outcomes were noted in patients randomly assigned to PCI or GDMT. Of note, despite the potential increased risk for complications in older patients undergoing PCI, no such increased rate of comorbid conditions (e.g., local vascular complications, worsening renal function, bleeding) was observed.[193]

Renal Dysfunction.

Patients with impaired renal function (generally those with an eGFR <60 mL/min), particularly those with diabetes, are at increased risk for worsening azotemia (**see Chapter 98**), and this is often an important consideration in the physician's decision of whether to proceed with coronary angiography and PCI in such patients. A post hoc analysis from the COURAGE trial showed that patients with decreased renal function had a significantly higher long-term rate of CV events than did those whose eGFR was 60 mL/min or higher, but there was neither evidence of clinical benefit nor harm in patients with reduced renal function who underwent PCI versus GDMT, thus suggesting that treatment decisions in such patients should be appropriately individualized on the basis of anticipated benefits and risks.

Previous Coronary Bypass Grafting.

CABG and PCI are often considered competitive procedures, but it is more appropriate to view them as complementary. An increasing number of patients who have treated with CABG and later have recurrent ischemia undergo revascularization with PCI. The technical aspects and procedural outcomes of PCI in patients with venous bypass grafts are discussed in **Chapter 62**.

Coronary Artery Bypass Grafting

In 1964, Garrett, Dennis, and DeBakey first used CABG as a “bailout” procedure. Widespread use of the technique by Favoloro and Johnson and their respective collaborators followed in the late 1960s. Use of an internal mammary artery (IMA) graft was pioneered by Kolessov in 1967 and by Green and colleagues in 1970. CABG evolved over the next five decades and currently remains an important treatment modality for many patients with SIHD. Most bypass operations continue to be performed through a median sternotomy using cardiopulmonary bypass (CPB) and cardioplegic cardiac arrest, with a smaller number performed without bypass on a beating heart. Less invasive approaches have been developed for select patients who may be appropriate candidates for more limited coronary revascularization, including anterior and lateral thoracotomies, partial sternotomies, and epigastric incisions. The technical goal of bypass surgery is to achieve, whenever possible, complete revascularization by grafting all coronary arteries of sufficient caliber that have physiologically significant proximal stenoses. CABG has been documented to prolong survival, relieve angina, and improve quality of life in specific subgroups of patients with CAD.[194-196]

The annual number of CABG operations in the United States rose steadily over the first three decades, with a peak in the late 1990s. Since then, however, rates of CABG have steadily declined, which is probably related to growth of the use of PCI, particularly in patients with multivessel CAD.[4] CABG provides excellent short- and intermediate-term results in the management of SIHD; its long-term results are affected by failure of venous grafts. Long-term data with totally arterial surgical revascularization (i.e., using bilateral IMA grafts) are few.

Minimally Invasive Coronary Artery Bypass Surgery.

Less invasive or minimally invasive approaches may be divided into four major categories based on the approach and use of CPB.[194] *Port-access* CABG is performed through limited incisions with femoral-femoral CPB and cardioplegic arrest. Port-access technology has also now enabled *totally endoscopic, robotically assisted* CABG (TECAB) surgery to be performed on the arrested heart.[197] *Off-pump* CABG (OPCAB) is performed by using a standard median sternotomy, with generally small skin incisions, and stabilization devices to reduce motion of the target vessels while anastomoses are performed without CPB.[198-200] Finally, *minimally invasive direct coronary artery bypass* (MIDCAB) is performed through a left anterior thoracotomy without CPB. Thus, off-pump approaches to CABG include both OPCAB and MIDCAB techniques.

Potential advantages of the minimally invasive approaches include less postoperative patient discomfort, reduced risk for wound infection, and shorter recovery times. Avoidance of CPB may mitigate the risk for bleeding, systemic thromboembolism, renal insufficiency, myocardial stunning, and stroke. Also, the damaging neurologic effects of CABG may result in cognitive impairment, particularly in older adults and those with heavily calcified aortas. Amelioration of the systemic inflammatory response that occurs after CPB is viewed as an additional advantage that may affect these clinical outcomes.

Initial short-term clinical and angiographic outcomes studies suggested that the less invasive techniques could achieve results comparable to those of traditional CABG.[201,202] In 2009, however, a comparative trial of OPCAB versus CABG plus CPB in 2203 patients revealed no difference in death or complications at 30 days (7.0% versus 5.6%, respectively; $P = 0.19$) but a significantly worse 1-year composite outcome of all-cause mortality, nonfatal MI, and need for repeat revascularization in off-pump versus on-pump procedures (9.9% versus 7.4%, respectively; $P = 0.04$). Additionally, in patients undergoing follow-up angiography, the graft patency rate was significantly lower in OPCAB recipients, with no treatment-based differences in neuropsychological outcomes or short-term resource use. Thirty-day outcomes of off-pump versus on-pump CABG in CORONARY (CABG Off or On Pump Revascularization Study) had similar results in 4752 patients randomly assigned to OPCAB versus traditional CABG. Although the duration of the operation and subsequent mechanical ventilation were both reduced, as was the incidence of postoperative bleeding and acute kidney injury, the primary composite outcome of death, MI, stroke, or renal failure requiring dialysis did not differ between groups (9.8% versus 10.3%; HR, 0.95; 95% CI 0.79 to 1.14; $P = 0.59$), but the need for early revascularization was increased.[203] In addition, data on long-term outcomes after OPCAB are conflicting,[202] with concern remaining that poorer graft patency and incomplete revascularization may contribute to a hazard associated with OPCAB. Therefore, although most datasets support reductions in blood loss and transfusion requirements, fewer wound infections, less postoperative AF, lower indices of myocardial injury, shorter duration of mechanical ventilation, and earlier hospital discharge with OPCAB, long-term outcome studies are concerning, and additional data on long-term survival and neurocognitive function are needed to assess the comparative effectiveness of these two approaches.[200]

Novel approaches to coronary revascularization combine a minimally invasive surgical CABG

procedure on the LAD coronary artery (i.e., a left IMA implant to the proximal LAD using OPCAB) with PCI on the remaining vessels.[204] Additional experience with these so-called hybrid revascularization procedures is needed to further clarify appropriate selection criteria and to determine whether this strategy offers important advantages over multivessel CABG alone. Despite initial enthusiasm for TECAB, robotic-assisted CABG remains less than 1% of total CABG volume.[197]

Arterial and Venous Conduits.

The current standard for bypass grafting advocates routine use of an IMA for grafting the LAD and supplemental saphenous vein grafts to other vessels.[205,206] Although the benefits of a single IMA graft over a saphenous vein graft alone are not in dispute, the superiority of bilateral IMA grafts over a single IMA graft is less well accepted. Initial enthusiasm for the use of bilateral IMA grafts was tempered by a higher rate of postoperative complications, including bleeding, wound infection, and prolonged ventilatory support. Wound infection, most notably deep sternal wound infection, has been of particular concern but remains modest in frequency (<3%), except in patients who are obese or have diabetes or those who require prolonged ventilatory support. In a randomized trial of 3102 patients undergoing CABG, the use of bilateral IMA grafts conferred similar CV outcomes at 30 days, 1 year, and 5 years as the use of a single IMA graft, but higher rates of sternal complications.[207] Current professional society guidelines recommend use of bilateral IMA grafts as reasonable (class IIa) in younger patients in the absence of excessive risk of sternal complications.[206,208] Nevertheless, given the increased technical demands and longer operative times of bilateral IMA grafting, it has not been adopted widely. Studies attempting to differentiate patency and outcomes with radial artery grafts versus the right IMA have been inconclusive, and thus either approach is a reasonable option as a second arterial conduit to native arteries with severe stenoses. The uncertainty may be reflected in the variable strength of recommendation from professional societies ranging from class IIb[196] to class I,[208] with a class IIa recommendation in 2015 guidelines from the Society of Thoracic Surgeons.[206]

Patency of Venous and Arterial Grafts.

Early occlusion (before hospital discharge) occurs in 8% to 12% of venous grafts, and by 1 year, 15% to 30% have become occluded. After the first year the annual occlusion rate is 2% and rises to approximately 4% annually between years 6 and 10. Patency rates with IMA grafts are superior. Data regarding patency of radial artery grafts are mixed; although, a network meta-analysis of trials with a minimum of 4 years of follow-up indicates improved patency compared with venous grafts.[209] Arterial grafts are more susceptible to failure because of competitive flow from native blood vessels than saphenous vein grafts (SVGs); thus, arterial grafts should not be used to revascularize borderline stenoses without clear evidence of flow limitation.

Distal Vasculature.

The state of the distal coronary vasculature is important for the fate of bypass grafts. Late patency of grafts is related to coronary arterial runoff, as determined by the diameter of the coronary artery into which the graft is inserted, the size of the distal vascular bed, and the severity of coronary atherosclerosis distal to the site of insertion of the graft. The highest graft patency rates are found when the lumina of vessels distal to the graft insertion are larger than 1.5 mm in diameter, perfuse a large vascular bed, and are free of atheroma obstructing more than 25% of the vessel lumen. For saphenous veins, optimal patency rates are achieved with a lumen of 2.0 mm or larger.

Progression of Disease in Native Arteries.

The rate of disease progression appears to be highest in arterial segments already showing evidence of disease, and it is between three and six times higher in grafted native coronary arteries than in nongrafted

native vessels. These data suggest that bypassing an artery with minimal disease, even if initially successful, may ultimately be harmful to patients, who incur both a risk for graft closure and an increased risk for accelerated obstruction of native vessels. Lesions in the native vessel that are long (>10 mm) and greater than 70% in diameter are at increased risk for progressing to total occlusion.

Effects of Therapy on Vein Graft Occlusion and Native Vessel Progression.

Measures aimed at enhancing long-term patency are generally directed at delaying the overall process of atherosclerosis and thus may have several additional benefits.[210] Secondary preventive therapy, in particular aspirin and lipid-lowering treatment, is important in reducing the risk for failure of venous grafts. Chronic anticoagulant therapy has not been convincingly shown to alter outcomes.

Antiplatelet Therapy.

Several trials have demonstrated the efficacy of aspirin therapy for maintaining early graft patency when started within 24 hours preoperatively, but the benefit is lost when aspirin is started more than 48 hours postoperatively. Aspirin, 75 to 325 mg daily, should be continued indefinitely for long-term secondary prevention. Although the addition of clopidogrel to aspirin is indicated after CABG for patients with ACS, in a trial of 113 patients with SIHD, the addition of clopidogrel to aspirin did not influence the progression of SVG intimal hyperplasia.[211] Thus, routine DAPT after CABG in patients with SIHD (without ACS) is not recommended. Clopidogrel monotherapy should be used for patients who have an allergy or are intolerant to aspirin.

Lipid-Lowering Therapy.

Three randomized trials of lipid-lowering therapy have shown a favorable impact on the development of graft disease. High-intensity statin therapy is indicated for post-CABG patients, since clinical trials comparing intensive versus moderate statin doses confirm similar relative benefit in subgroups with prior CABG.

Patient Selection

Indications for CABG are centered on evidence demonstrating improvement in the quality and duration of life.[194,196,212] The decision to perform revascularization with PCI or CABG is determined largely from the coronary anatomy, LV function, comorbidities that may affect the patient's risk associated with either revascularization procedure, and patient preference (see earlier). CABG is indicated, regardless of symptoms, for patients with CAD in whom survival is likely to be prolonged and for those with multivessel CAD in whom noninvasive testing suggests high risk (**see Table 61.11**). Patients with more extensive and severe CAD have an increasing magnitude of benefit from CABG over medical therapy (**Fig. 61.14 and eFig. 61.4; see also Table 61.12**). Patients with left main and/or three-vessel CAD and, in particular, those with multivessel CAD and LV systolic dysfunction should be considered candidates for CABG to prolong life, whereas similar data support the benefits of CABG in diabetic patients with multivessel CAD if revascularization is needed. Other factors that must always be considered in the decision are general health and non–coronary-related comorbid conditions that influence both the risks associated with surgery and the likelihood of durable functional benefit.

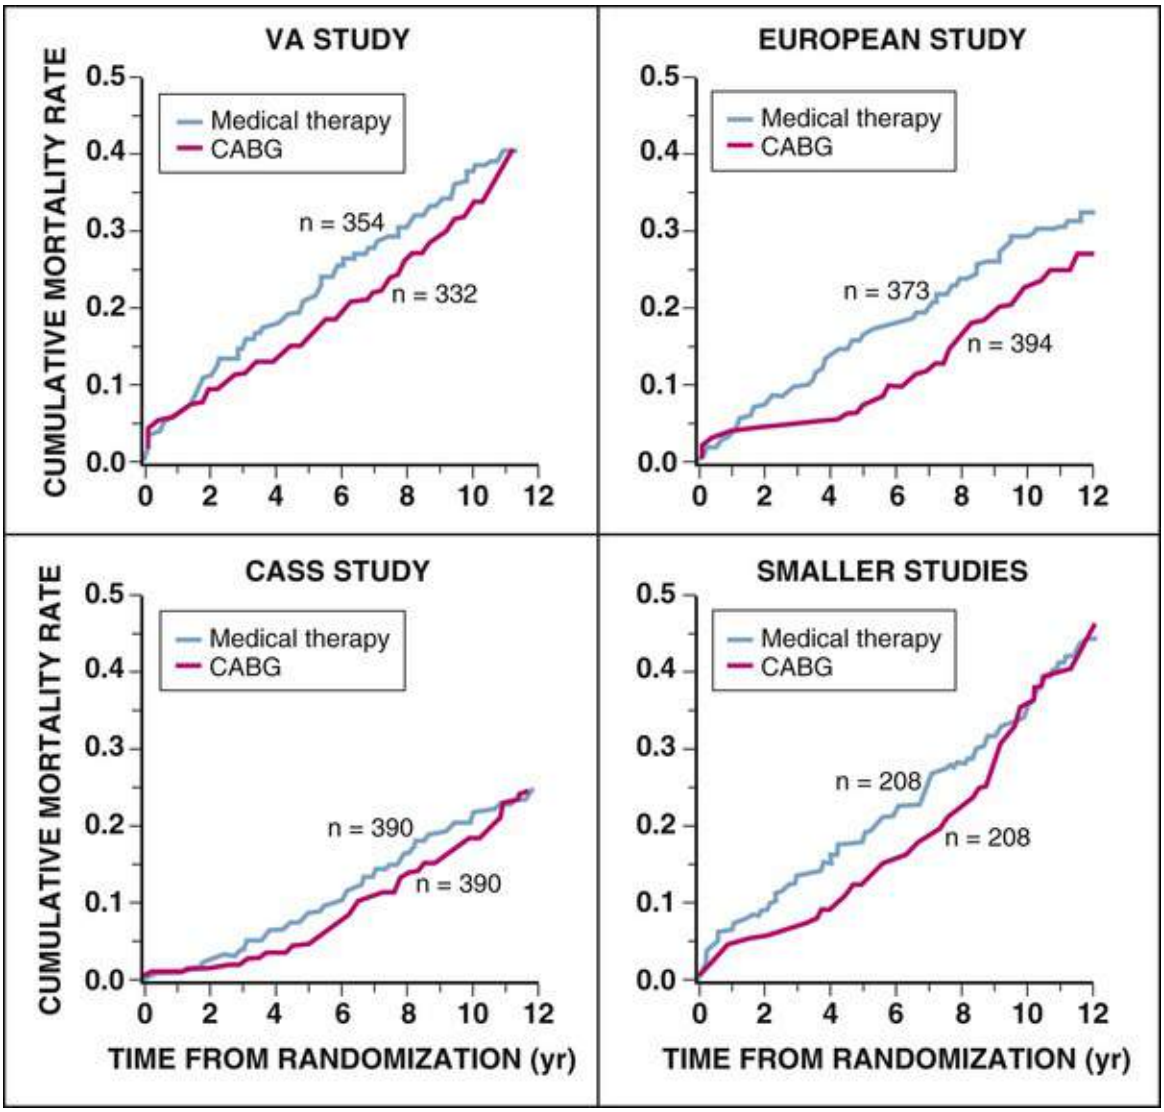

FIGURE 61.14 Survival curves of three large randomized trials of medical therapy versus coronary artery bypass grafting (CABG) and four smaller studies combined. (From Eagle KA, Guyton RA, Davidoff R, et al. ACC/AHA guidelines for coronary artery bypass graft surgery: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee to Revise the 1991 Guidelines for Coronary Artery Bypass Graft Surgery]. J Am Coll Cardiol 1999;34:1262.)

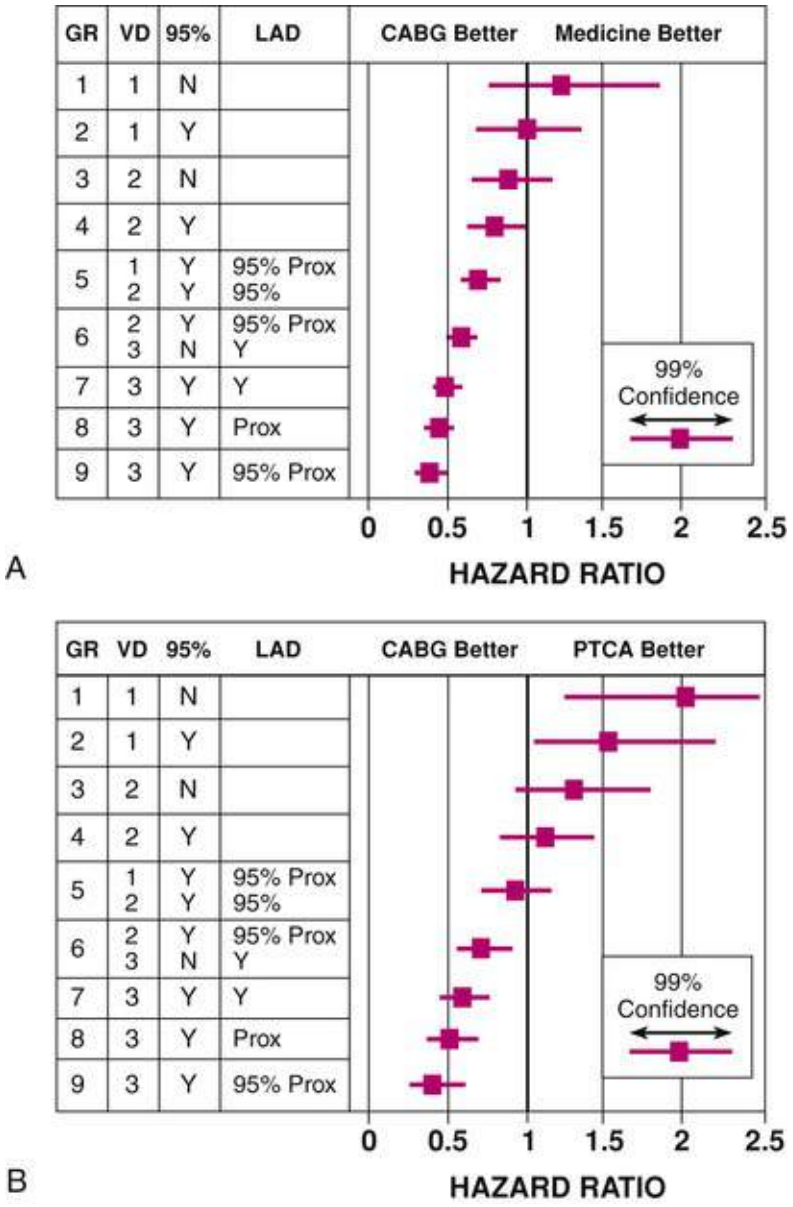

EFIGURE 61.4 **A,** Adjusted hazard (mortality) ratios comparing CABG surgery and medical therapy for nine coronary anatomy severity groups (GR) according to the number of vessels diseased (VD), the presence or absence of a 95% proximal stenosis, and involvement of the left anterior descending (LAD) coronary artery. **B,** Adjusted hazard (mortality) ratios comparing coronary artery bypass graft (CABG) surgery and percutaneous transluminal coronary angioplasty (PTCA) for nine coronary anatomy groups according to the number of vessels diseased, the presence or absence of a 95% proximal stenosis, and LAD involvement. In patients with the least severe categories of disease, 5-year survival appears to be better with PTCA (single-vessel disease without proximal stenosis and without LAD involvement), whereas for patients with triple-vessel disease and higher grade, more complex double-vessel disease, a survival benefit is noted with surgery. For other subsets of patients with double-vessel disease, no difference in survival was seen in those treated with CABG surgery or PTCA, and many of these patients are probably similar to those included in the randomized trials. (From Jones RH, Kesler K, Phillips HR III, et al. Long-term survival benefits of coronary artery bypass grafting and percutaneous transluminal angioplasty in patients with coronary artery disease. J Thorac Cardiovasc Surg 1996;111:1013.)

Surgical Outcomes and Long-Term Results

The patient population undergoing CABG has been changing over time, particularly with the wider use of PCI. Compared with the 1970s, patients undergoing CABG at present are older, include a higher percentage of women, and are sicker in that a greater proportion have unstable angina, three-vessel CAD, previous coronary revascularization with either CABG or PCI, LV dysfunction, and comorbidities, including hypertension, diabetes, and peripheral vascular disease. Despite the increasing risk profile of

this population, outcomes with CABG have generally remained stable or have improved.

Operative Mortality

Robust multivariable models have been developed and refined with the objective of predicting perioperative mortality. In particular, the Society of Thoracic Surgeons (STS) risk estimator (riskcalc.sts.org) and the European System for Cardiac Operative Risk Evaluation (EuroSCORE, www.euroscore.org) are well-validated risk estimation tools that are available with convenient on-line calculators. Risk indicators for death following CABG that are shared across the available risk tools include (1) preoperative CV factors, including the number of coronary vessels diseased, presence of left main CAD, recent acute MI or ACS event, prior CABG, hemodynamic instability, LV dysfunction, concomitant valvular heart disease, pulmonary hypertension with or without right-sided heart failure, and associated carotid or peripheral vascular disease; (2) preoperative noncardiac comorbid conditions and demographic factors such as older age at surgery, female sex, DM, and pulmonary and renal disease, as well as overall frailty; and (3) intraoperative factors such as ischemic damage and failure to use IMA grafts.

The cumulative mortality in almost 1.6 million isolated CABG operations recorded in the STS database declined from 3.05% between 1997 and 1999 to approximately 2% in 2008 and has remained at that rate through 2015.[213] Moreover, CABG-related mortality has declined substantially over the past two decades when adjusted for changes in clinical risk profile.

Perioperative Complications.

Perioperative morbidity has increased because of a larger fraction of higher-risk patients. The rates of major morbidity in the 144,940 CABG-only operations recorded in the STS database in 2014 were 1.3% for stroke, 2.0% for renal failure, 0.3% for mediastinitis, and 23.4% for AF. Approximately 10% of patients required rehospitalization within 30 days.[213]

Myocardial Infarction.

Perioperative MI, particularly if associated with hemodynamic or arrhythmic complications or with preexisting LV dysfunction, has a major adverse effect on early and late prognosis. The reported incidence varies widely (0% to >10%), in large part because of heterogeneous diagnostic criteria, with a median of 2.9%. The diagnostic criteria for MI in the setting of CABG have been revised and are now based on elevation of cardiac troponin (cTn) or a myocardial creatine kinase (CK) MB isoenzyme level more than 10 times the upper limit of normal in association with objective evidence of new myocardial dysfunction or graft occlusion based on noninvasive imaging or angiography.[214]

Cerebrovascular Complications.

Neurologic abnormalities following cardiac surgery are dreaded complications and are associated with higher long-term mortality.[215,216] Postulated mechanisms include emboli from atherosclerosis of the aorta or other large arteries (potentially precipitated by aortic cross-clamping), emboli from the CPB machine circuit and its tubing, and intraoperative hypotension, particularly in patients with preexisting hypertension.[215] Type I injury is associated with major neurologic deficits, stupor, and coma, and type II injury is characterized by deterioration in intellectual function and memory. The incidence of neurologic abnormalities is variably estimated, depending on how the deficits are defined. Findings of perioperative silent brain injury detected by magnetic resonance imaging (MRI) are present in 25% to 50% of patients after CABG.[217] The incidence of stroke reported in the Northern New England Cardiovascular Disease

Study Group database between 1992 to 2001 was 1.6%, with a higher rate documented in prospective studies (1.5% to 5%). Studies aimed at careful evaluation of neurologic deficits report more frequent neurologic sequelae; type I deficits have been documented in 6% of patients early after CABG, with short-term cognitive decline occurring in 33% to 83%. A prospective long-term study using sophisticated neurocognitive testing revealed cognitive decline in 53% of patients at the time of hospital discharge, in 36% at 6 weeks, and in 24% at 6 months. Older age, in addition to other comorbidities (particularly diabetes), and intraoperative manipulation of the aorta are powerful predictors of the neurologic sequelae of CPB, including stroke, delirium, and neurocognitive dysfunction.[215] In most but not all studies, atherosclerosis of the proximal aorta has also been a strong predictor of stroke, as has use of an intra-aortic balloon pump (IABP). CABG performed without CPB may be associated with reduced risk for stroke.

Atrial Fibrillation.

This arrhythmia is one of the most frequent complications of CABG.[218,219] AF occurs in up to 40% of patients, primarily within 2 to 3 days. In the early postoperative period, rapid ventricular rates and loss of atrial transport may compromise systemic hemodynamics, increase the risk for embolization, and lead to a significant increase in the duration and cost of the hospital stay. AF is associated with a twofold to threefold increase in postoperative stroke. Older age, hypertension, previous AF, and HF are associated with a higher risk for AF after cardiac surgery. Statin therapy may be accompanied by less frequent postoperative AF.[220] Off-pump techniques may be associated with less frequent postoperative AF.

Prophylactic use of beta-blocking agents reduces the frequency of postoperative AF; such drugs should be administered routinely before and after CABG to patients without contraindications. Amiodarone is also effective in prophylaxis against postoperative AF and may be considered in patients at high risk for its development (**see Chapter 38**). However, when the rhythm occurs perioperatively, a strategy of rhythm control is not superior compared to one of rate control with respect to days of hospitalization, complications, or AF rates at 60 days.[218] Up to 80% of patients spontaneously revert to sinus rhythm within 24 hours without treatment other than agents used for controlling the ventricular rate. At 60 days, 94% of the patients in the rate-control group and 98% of those in the rhythm-control group had had a stable heart rhythm without AF for the previous 30 days ($P = 0.02$).[218]

Renal Dysfunction.

The incidence of renal failure requiring dialysis after CABG remains low (0.5% to 1.0%) but is associated with significantly greater morbidity and mortality[221,222] (**see Chapter 98**). Less severe postoperative renal dysfunction is much more common, particularly in patients with advanced age, DM, preexisting renal dysfunction, and HF. Patients with preoperative renal dysfunction and a serum creatinine level that rises to above 2.5 mg/dL appear to be at increased risk for the need for hemodialysis and may be candidates for alternative approaches to revascularization. *N*-acetylcysteine does not appear to prevent the development of renal dysfunction in patients undergoing cardiac surgery. Other interventions proposed to reduce postoperative renal dysfunction, such as treatment with fenoldopam or high-dose statin therapy have also failed.[200,223,224]

Relief of Angina

All the major randomized trials have demonstrated greater relief of angina, better exercise performance, and a lower requirement for antianginal medications at 5 years in surgically treated than in medically treated patients. Independent predictors of recurrence of angina include female sex, obesity, and lack of use of the IMA as a conduit. In patients with three-vessel CAD undergoing CABG, the completeness of

revascularization is a significant determinant of the relief of symptoms at 1 year and over a 5-year period. After 5 years, approximately 75% of surgically treated patients can be predicted to be free of an ischemic event, SCD, occurrence of MI, or recurrence of angina; approximately 50% remain free for approximately 10 years and 15% for 15 or more years.

Effects on Survival

Clinical practice has been shaped by three major randomized trials of CABG versus medical therapy in which patients were enrolled between 1972 and 1984: the VA (Veterans Affairs) trial, the European Cardiac Society Study (ECSS), and the NHLBI-supported CASS[194,196] (**see Fig. 61.14**). The evidence base consists of data from 2649 patients participating in these and several smaller trials and has important limitations with respect to application to current practice because the risk profile of patients referred for surgery, as well as the available surgical and medical interventions, have evolved substantially since these trials were conducted. In particular, these trials antedated the widespread use of IMAs and the disease-modifying therapies (e.g., aspirin, statins, RAS inhibitors) that currently comprise GDMT.

Nevertheless, major points guiding clinical practice have been drawn from a meta-analysis of these trials. In each of the trials, a survival benefit of CABG emerged during midterm follow-up (2 to 6 years), an advantage that eroded during long-term follow-up. Considered together, the results of these trials supported a reduction in long-term mortality (10 years), an absolute 4.1% lowering of mortality rates at the time, with CABG compared with medical therapy ($P = 0.03$). Subgroup analyses revealed several high-risk criteria that identify patients who are likely to sustain a more substantial survival benefit: (1) left main CAD, (2) single- or double-vessel CAD with proximal LAD disease, (3) LV systolic dysfunction, and (4) a composite evaluation that indicates high risk, including severity of symptoms, high-risk exercise tolerance test, history of previous MI, and presence of ST depression on resting ECG.

The combined results of all the trials and registries indicate that the sicker the patient—based on the severity of symptoms or ischemia, presence of DM, number of vessels diseased, and presence of LV dysfunction—the greater the benefit of surgical over medical therapy on survival (**see Table 61.12 and eFig. 61.4**). CABG prolongs survival compared with medical therapy alone in patients with significant left main CAD regardless of symptoms and in patients with three-vessel CAD that includes the proximal LAD irrespective of LV function. The preponderance of evidence indicates that surgical therapy prolongs life in patients with three- and two-vessel CAD with impaired LV function, particularly those with proximal narrowing of one or more coronary arteries and severe angina. Patients with angina or evidence of ischemia at a low or moderate level of exercise, especially those with obstruction of the proximal LAD, may benefit from coronary revascularization by PCI or CABG.

Patients with Depressed Left Ventricular Function (See Chapter 57).

Depressed LV function is one of the most powerful predictors of perioperative and late mortality. In the New York State CABG registry, an EF of 25% or less was associated with 6.5% in-hospital mortality, compared with 1.4% in those with EF greater than 40%.[196] As the population ages and the proportion undergoing reoperation increases, the number of patients with preoperative LV dysfunction and clinical HF will increase. In the CABG Patch trial confined to patients with EF of 35% or less, perioperative mortality was 3.5% for patients without clinical signs of HF versus 7.7% for those with NYHA Classes I to IV HF.[196]

Although the effect of a reduced EF on operative mortality cannot be eliminated, careful attention to

intraoperative metabolic, inotropic, and mechanical support, including preoperative intra-aortic balloon counterpulsation in some patients, may decrease perioperative mortality compared to the mortality rates expected from prediction models. Thus, in experienced centers, in-hospital mortality for patients with severe LV dysfunction is less than 4% to 5%.[225]

The powerful association between preoperative EF and late survival emphasizes that currently the presence of LV dysfunction has changed from a relative contraindication to CABG to a potential indication.[196,226] This shift in perspective occurred in concert with the recognition that viable dysfunctional myocardium may improve after coronary revascularization. Indeed, in the largest meta-analysis of randomized trials of CABG versus medical therapy, the most striking survival benefits of CABG, as well as symptomatic and functional improvements, were shown by patients with impaired LV function, in whom the prognosis with medical therapy is poor.[196]

This conclusion is also supported by large contemporary registries and long-term follow-up of patients with LV dysfunction randomized to CABG plus medical therapy versus medical therapy alone. In a propensity-adjusted observational analysis comparing survival with CABG versus medical therapy in patients with an LVEF less than 35% and no left main stenosis greater than 50%, a survival advantage was observed through 10 years of follow-up.[227] In the randomized STICH (Surgical Treatment for Ischemic Heart Failure) trial of predominantly on-pump CABG versus medical therapy in 1212 patients with CAD amenable to revascularization and EF of 35% or less in the absence of left main CAD or severe (class III) angina, the rate of death from any cause at an average of 56 months after randomization was 36% in patients assigned to CABG and 41% in those assigned to medical therapy (HR, 0.86; 95% CI 0.72 to 1.04; $P = 0.12$). However, the combined endpoint of death or hospitalization for CV causes was significantly lower (58%) in the CABG group than in the medical therapy group (68%; HR, 0.74; 95% CI 0.64 to 0.85; $P < 0.001$; **eFig. 61.5**).[228] Moreover, in the STITCH Extension Study (STICHES), in which follow-up was extended to 10 years, a significant mortality difference emerged favoring the CABG arm (58.9% versus 66.1%; HR, 0.84; 95% CI 0.73 to 0.97; $P = 0.02$ (**Fig. 61.15**).[229]

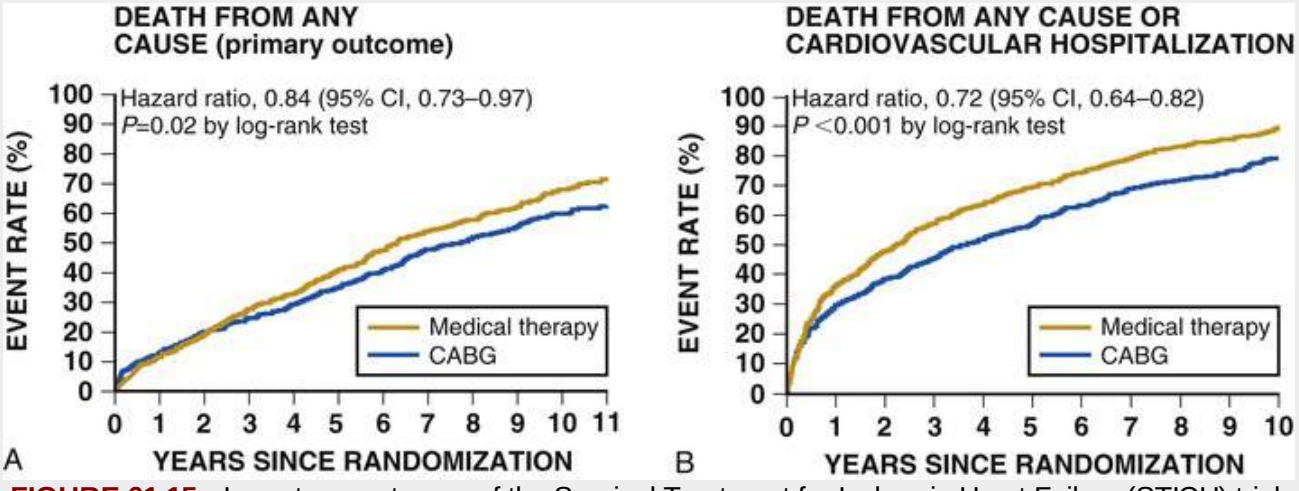

FIGURE 61.15 Long-term outcome of the Surgical Treatment for Ischemic Heart Failure (STICH) trial. The STICH trial included a 1212 patients with an ejection fraction of 35% or less and coronary artery disease amenable to coronary artery bypass grafting (CABG) who were randomly assigned to undergo CABG plus medical therapy or medical therapy alone and followed for 10-years. **A,** Death from any cause occurred in 58.9% of the CABG group and 66.1% in the medical-therapy group (HR, 0.84; 95% CI 0.73 to 0.97; $P = 0.02$ by log-rank test). **B,** Death from any cause or cardiovascular hospitalization was similarly reduced by CABG compared with medical therapy alone. (Modified from Velazquez EJ, Lee KL, Jones RH, et al. Coronary-artery bypass surgery in patients with ischemic cardiomyopathy. N Engl J Med 2016;374:1511-20.)

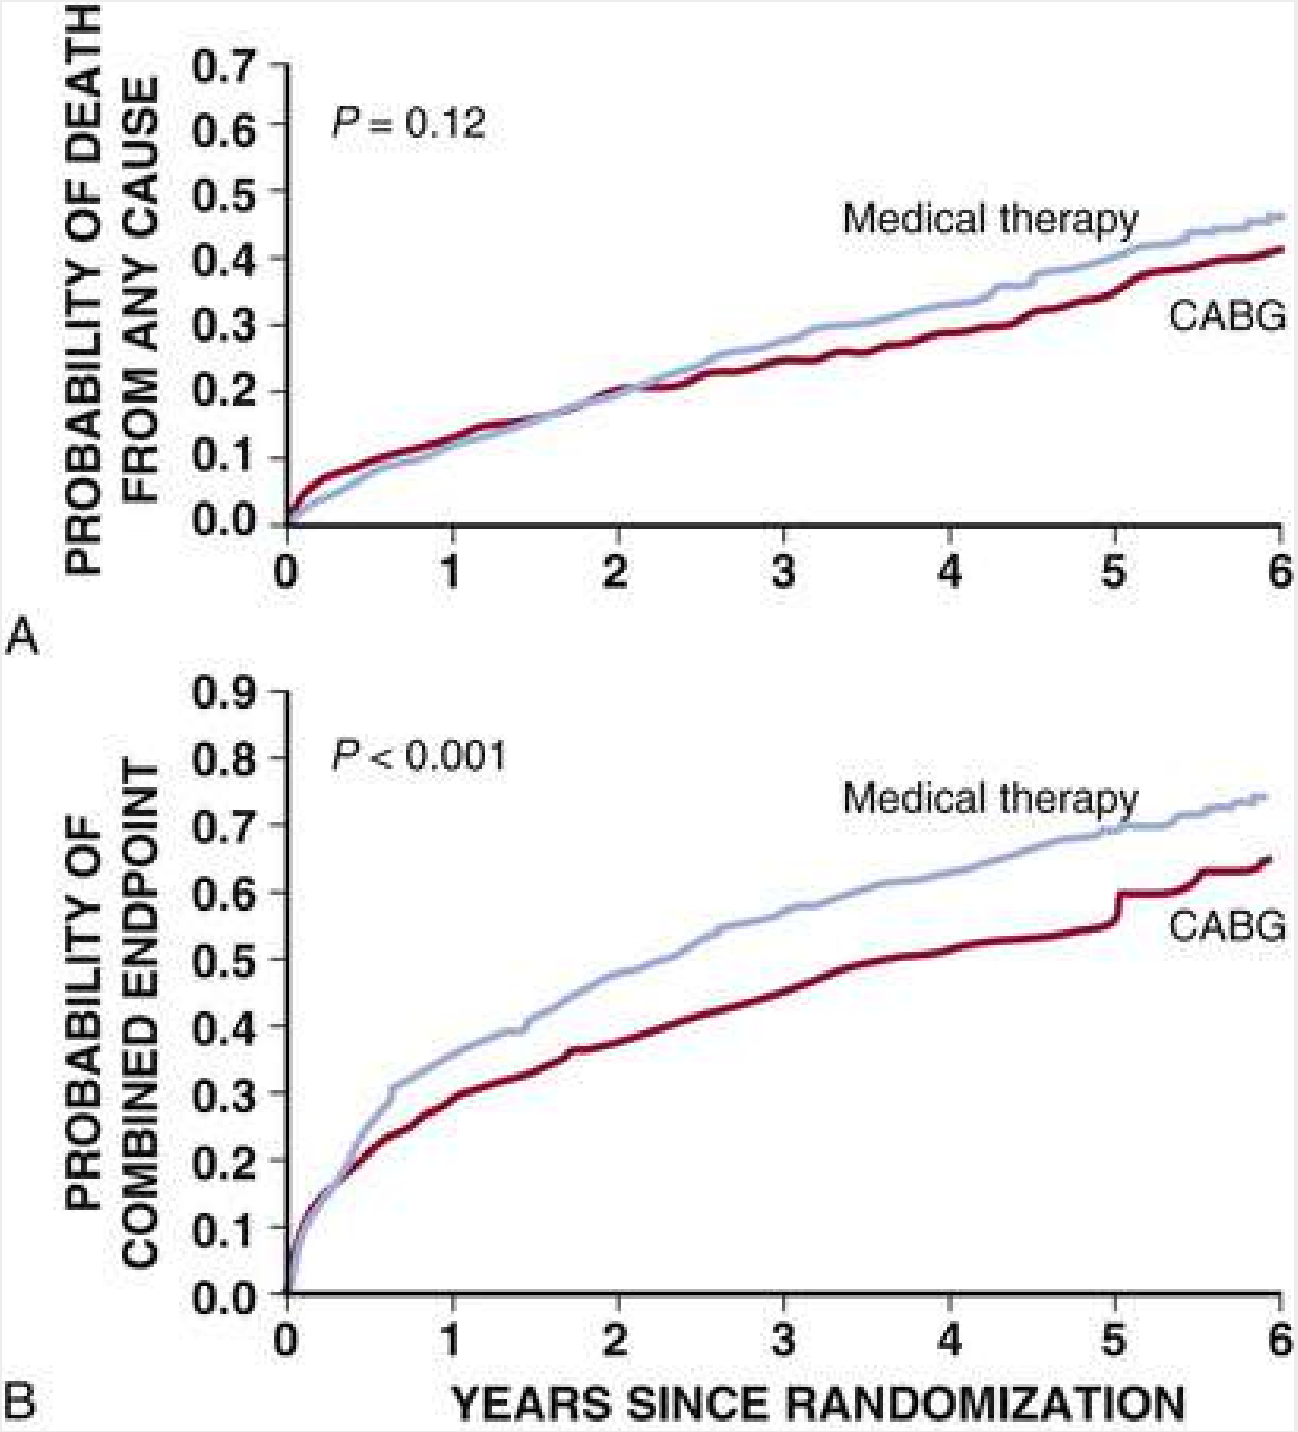


EFIGURE 61.5 Patients (*n* = 1212) with CAD amenable to coronary artery bypass grafting (CABG) and an ejection fraction of 0.35 or less were randomly assigned to medical therapy alone or medical therapy plus CABG. **A,** There was no significant difference in the rate of death from any cause, which occurred in 41% of the medical therapy group and 36% in the CABG group (HR, 0.86; 95% CI, 0.72 to 1.04; *P* = 0.12). **B,** The secondary combined endpoint of death from any cause or hospitalization for cardiovascular causes was lower in the CABG group (58% versus 68%; HR with CABG, 0.74; 95% CI, 0.64 to 0.85; *P* < 0.001). (Modified from Velazquez E, Lee KL, Deja MA, et al. Coronary-artery bypass surgery in patients with left ventricular dysfunction. N Engl J Med 2012;364:1607.)

Although preoperative LV dysfunction creates the potential for significant benefit, the perioperative risk must be considered and weighed in shared decision making with the patient,[226] Despite the absence of a clear impact of myocardial viability on outcomes with CABG in the STICH trial,[230] selective evaluation of patients for viable myocardium may be a reasonable strategy when considering CABG for high-risk patients with severe LV dysfunction.[225]

Myocardial Hibernation (see Chapter 57).

Successful reperfusion of viable but noncontractile or poorly contracting myocardium is a goal of

coronary revascularization in patients with LV dysfunction.[225] Two related pathophysiologic conditions have been described to explain the reversible ischemic contractile dysfunction: (1) *myocardial stunning*, which describes prolonged but temporary postischemic LV dysfunction without myocardial necrosis, and (2) *myocardial hibernation*, or persistent LV dysfunction when myocardial perfusion is chronically reduced (or repetitively stunned) but sufficient to maintain the viability of tissue. The reduction in myocardial contractility in hibernating myocardium conserves metabolic demands and may be protective, but more prolonged and severe hibernation may lead to severe ultrastructural abnormalities, irreversible loss of contractile units, and apoptosis.

Hibernating myocardium can cause abnormal systolic or diastolic LV function, or both. Studies involving PET, thallium-201, and dobutamine echocardiography have demonstrated that patients with LV dysfunction and evidence of hibernating myocardium have a high mortality rate when treated with medical therapy alone. The predominant clinical feature of myocardial ischemia in these patients may not be angina but dyspnea secondary to increased LV end-diastolic pressure. Symptoms of HF resulting from chronic LV dysfunction may be inappropriately ascribed to myocardial necrosis and scarring when the symptoms may in fact be reversible if the chronic ischemia is relieved by coronary revascularization.

Detection of Hibernating Myocardium.

Several clinical and imaging markers may be used to determine the likelihood that a dysfunctional myocardial segment is viable or nonviable (**Table 61.13**). The presence of angina and the absence of Q waves on the ECG and a history of previous MI are useful clues. A severe reduction in the diastolic wall thickness of dysfunctional LV segments is indicative of scarring. On the other hand, akinetic or dyskinetic segments with preserved diastolic wall thickness may represent a mixture of scarred and viable myocardium. Imaging tools that may be used for this assessment (dobutamine echocardiography, PET, contrast-enhanced CMR, CT, thallium rest-redistribution imaging) are discussed in **Chapters 14, 16, and 17**.

TABLE 61.13

Markers of Viable Myocardium

CLINICAL INDICATOR	FEATURE SUGGESTING VIABILITY/NONVIABILITY	DIAGNOSTIC TEST	ALTERNATIVE TEST
Diastolic wall thickness	Wall thickness <6 mm is highly suggestive of nonviable scar.	Standard Echo	CT, CMR
Regional wall motion	Improved wall motion after stimulation with low-dose dobutamine (i.e., contractile reserve) suggests viability.	Low-dose dobutamine Echo	CT, CMR, gated SPECT
Regional blood flow	Late redistribution or redistribution with second tracer injection suggests viability.	SPECT	PET, CMR
Myocardial metabolism	Mismatch between flow (low) and metabolism (active) suggests viability.	PET	SPECT
Myocardial fibrosis	Scar limited to subendocardium suggests viability, whereas transmural or near-transmural scar indicates nonviability.	CMR	CT

CMR, Cardiac magnetic resonance imaging; *CT,* computed tomography; *Echo,* echocardiography; *PET,* positron emission tomography; *SPECT,* single-photon emission computed tomography.

Surgical Treatment in Special Groups

Women (See Chapter 89)

Women are less likely than men to be referred for coronary angiography and subsequent revascularization.[231] In some studies, sex-based differences in referral for revascularization are explained fully by clinical factors. Moreover, it has not been established whether sex-based differences represent underuse of CABG in women, overuse in men, or both. Compared with men, women who undergo CABG

are sicker, as defined by age, comorbid conditions, severity of angina, and history of HF. In-hospital mortality and perioperative morbidity after CABG have remained, on average, 1.5 to 2 times higher in women than in men. However, when adjusted for the greater risk profile of women referred for CABG, short-term mortality rates, as well as long-term outcomes, are similar to those for men in most but not all studies, with similar advantages of CABG over multivessel PCI.[232] With generally similar long-term outcomes after surgical revascularization with risk adjustment, female sex should not be a significant factor in decisions regarding whether to offer CABG.

Older Patients (see Chapter 88)

The aging of the population, in combination with marked improvement in perioperative care and in the outcomes of CABG has resulted in a burgeoning population of elderly patients with extensive CAD undergoing such surgery.[233] The number of individuals older than 75 years in the United States is expected to quadruple in the next 50 years, with CVD the leading cause of morbidity and mortality in this population. Many such individuals are likely to become candidates for CABG.

Older patients are sicker than their younger counterparts in that they have a greater frequency of comorbidities, including peripheral vascular and cerebrovascular disease; more extensive triple-vessel and left main CAD; and a higher frequency of LV dysfunction and history of HF.[196] Not unexpectedly, these differences translate into higher perioperative mortality and complication rates, with a sharp increase in the slope of the curve relating mortality to age in patients older than 70 years. Despite these differences, in-hospital mortality for older adults has declined over time to 7% to 9% in those undergoing CABG only and has been reported as low as 3% to 4% in the subgroup of octogenarians without significant medical comorbid conditions. However, elderly patients with high indices of frailty and disability are at significantly higher risk for major morbidity and mortality during CABG.[234] Given the marked variation in outcomes in older patients undergoing revascularization, decisions should be based on individual risk and needs assessment.

Renal Disease

Cardiovascular disease is the major cause of mortality in patients with end-stage renal disease (ESRD) and accounts for 54% of deaths (**see Chapter 98**). Patients with ESRD, as well as those with less severe renal insufficiency, have numerous risk factors that not only accelerate the development of CAD but also complicate its medical management. These risk factors include diabetes, hypertension with LV hypertrophy, systolic and diastolic dysfunction, abnormal lipid metabolism, anemia, and increased homocysteine levels. Therefore, mild or more severe renal dysfunction is prevalent in as many as 50% of patients undergoing CABG. Coronary revascularization with PCI or CABG is frequently performed in patients with ESRD, but mortality and complication rates are increased. Patients with milder degrees of renal insufficiency who are not dependent on dialysis are also at higher risk for major perioperative complications, longer recovery times, and lower rates of short-term and midterm survival. Observational data have suggested that in patients undergoing chronic dialysis, CABG is the preferred strategy for revascularization over PCI for patients with multivessel CAD.[235-237] However, randomized data are few, and 30-day mortality in patients with ESRD undergoing CABG ranges from 9% to as high as 20%.

Patients with Diabetes (see Chapter 51)

Diabetes is an important independent predictor of mortality in patients undergoing surgical revascularization. Patients with DM have smaller distal vessels, which are deemed to be poorer targets

for bypass grafting. Nevertheless, the patency of arterial and venous grafts appears to be similar in diabetic and nondiabetic patients. Despite these higher risks with operative intervention, because of the potential long-term benefits of CABG in patients with DM and severe CAD, such patients should be considered candidates for CABG[238,239] (see later, Comparisons between Percutaneous Coronary Intervention and Coronary Artery Bypass Surgery).

Coronary Bypass Surgery in Patients with Associated Vascular Disease.

Management of patients with combined CAD and peripheral vascular disease involving the carotid arteries, the abdominal aorta, or vessels of the lower extremities presents many challenges (**see Chapter 64**).

Impact of Combined Coronary Artery Disease and Peripheral Artery Disease.

Clinically apparent CAD occurs frequently in patients with peripheral artery disease (PAD). In patients undergoing peripheral vascular surgery, late outcomes are dominated by cardiac causes of morbidity and mortality. Conversely, in patients with CAD, presence of PAD, even if asymptomatic, is associated with an adverse prognosis, presumably because of the greater total atherosclerotic burden borne by these patients.[240]

Because patients with CAD and peripheral atherosclerosis tend to be older and have more widespread vascular disease and end-organ damage than patients without peripheral atherosclerosis, the perioperative mortality and morbidity consequent to CABG are high and the late outcome is not as favorable. In the Northern New England Cardiovascular database, in-hospital and long-term mortality after CABG were 2- to 2.5-fold greater in patients with peripheral vascular disease than in those without it, with augmented risk for those with lower extremity disease. Diffuse atheroembolism is a particularly serious complication of CABG in patients with aortic atherosclerosis. It is a major cause of perioperative death, stroke, neurocognitive dysfunction, and multiorgan dysfunction after CABG. Nevertheless, given the diffuse nature of CAD in patients with peripheral vascular disease, CABG may have advantages over PCI in many such patients.

Carotid Artery Disease.

In patients with stable CAD and carotid artery disease in whom carotid endarterectomy or stenting is planned, consideration of coronary revascularization can usually be performed after the carotid surgery. The prevalence of significant carotid disease in an increasingly older population being considered for CABG is high; approximately 20% have 50% or greater stenosis, 6% to 12% have 80% or greater stenosis, and the percentage is higher in patients with left main CAD. In patients for whom surgical treatment is being considered for both carotid artery disease and CAD, the merits of a combined versus a staged approach have been debated.[241] Moreover, it remains uncertain whether asymptomatic carotid disease significantly increases the risk for stroke during CABG. Neither the combined nor staged approaches has been demonstrated to be unequivocally superior to the other, and an individualized approach, depending on the patient's initial condition, severity of symptoms, anatomy of the coronary and carotid vessels, and individual institutional experience, is most appropriate. Preoperative or simultaneous carotid stenting is under investigation as an alternative approach to combined carotid endarterectomy and CABG.[242]

Management of Patients with Associated Vascular Disease *(see **Chapter 64**)*.

Patients with severe or unstable CAD requiring revascularization can be categorized into two groups according to the severity and instability of the accompanying vascular disease. When the noncoronary

vascular procedures are elective, they can generally be postponed until the cardiac symptoms have stabilized, either by intensive medical therapy or by revascularization. A combined procedure is necessary in patients with both unstable CAD and an unstable vascular condition, such as frequent recurrent transient ischemic attacks or a rapidly expanding abdominal aortic aneurysm. In some patients in this category, PCI offers the potential for stabilizing the patient's cardiac condition before proceeding with a definitive vascular repair. A problem is posed by the use of clopidogrel after stenting; this will increase bleeding unless surgery is performed at least 5 days after discontinuation of clopidogrel.

Patients Requiring Reoperation

In some centers, as many as 20% of isolated CABG surgeries are cardiac reoperations,[243] with the major indication for reoperation being late disease of SVGs. An added factor underlying recurrent symptoms is progression of disease in native vessels between the first and second operations. Several series have emphasized the sicker preoperative status of patients undergoing reoperation, including older age, more serious comorbid conditions, associated valvular heart disease, and a greater prevalence of LV dysfunction and greater extent of ischemic jeopardized myocardium.

Not unexpectedly, the mortality associated with reoperation is significantly higher than that of initial CABG procedures. At a time when mortality in STS risk estimates was 2.6% for urgent and 6% for emergency first CABG operations, the corresponding rates were 7.4% and 13.5% in patients undergoing repeated CABG. As a result of the higher risk and operative complexity of redo CABG, PCI is increasingly being considered as the first-line option in patients with SVG failure. In such cases, PCI of the native coronary vessels is preferred to SVG PCI because of lower complication rates and better long-term patency. When the native coronary artery has a chronic total occlusion (CTO), revascularization decisions can be challenging. Many CTOs, which previously required redo CABG, can now be successfully revascularized by expert PCI operators in specialized referral centers. However, it has not been demonstrated that CTO PCI improves clinical outcomes.

Comparisons Between Percutaneous Coronary Intervention and Coronary Artery Bypass Surgery

Observational Studies

In observational studies of CABG versus balloon angioplasty, over 1 to 5 years of follow-up, rates of mortality and MI were not significantly different between treatment strategies. However, recurrent events, including angina and the need for repeat revascularization procedures, were significantly more frequent in the PTCA than in the CABG group, largely because of incomplete revascularization and restenosis. More recent studies have compared CABG with coronary stenting. In an analysis of approximately 60,000 patients with multivessel CAD treated with coronary stenting or CABG and recorded in the New York State Registry between 1997 and 2000, CABG was found to be associated with higher survival after adjustment for medical comorbidities in patients with two or more diseased vessels, with or without involvement of the LAD.[196] Results were similar among more than 100,000 propensity-matched Medicare beneficiaries who underwent CABG or multivessel PCI between 1992 and 2008.[244] Similarly, in an analysis of approximately 600,000 patients with multivessel CAD enrolled in the ACC-NCDR and STS databases, the observed 1-year mortality rates were similar between patients who underwent CABG and those who underwent PCI. However, 4-year mortality was significantly lower in the CABG group in multiple sensitivity analyses of potential confounders.[245] A propensity-matched analysis of approximately

18,000 patients who underwent PCI with second-generation DESs (everolimus) or CABG for multivessel CAD showed similar risk of death in the two groups but a higher risk of MI and need for repeat revascularization among patients treated with PCI.[246] The similarity of the rates of survival highlights the role of clinical judgment in selecting the optimal therapy for the individual patient and the ability to achieve good outcomes in appropriately selected patients with multivessel CAD, particularly those without involvement of the proximal LAD coronary artery.

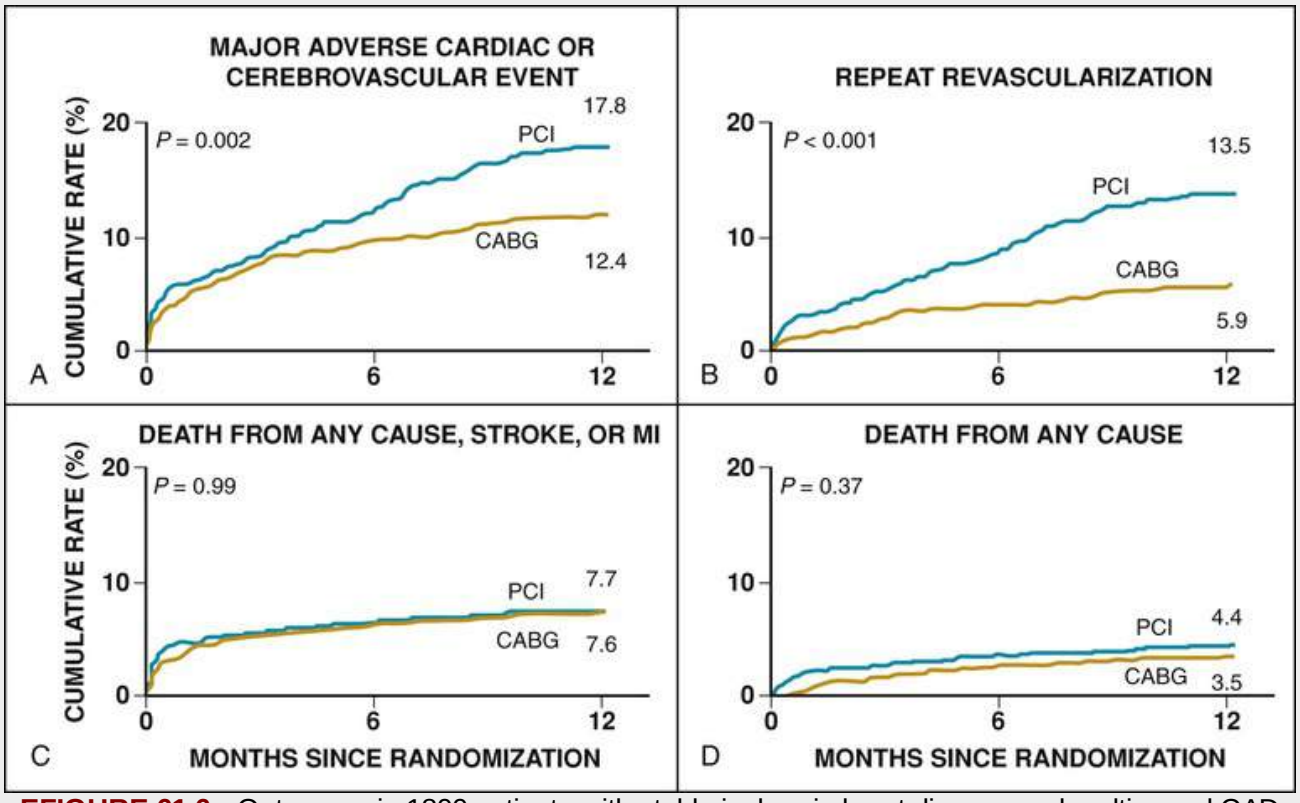
Randomized Trials

Overall, the findings from randomized trials indicate that in selected patients with multivessel CAD and preserved ejection fraction, CABG results in fewer repeat revascularizations and fewer symptoms without a significant difference in survival when compared with multivessel PCI.

Percutaneous Coronary Intervention Versus Coronary Artery Bypass Surgery in Patients with Multivessel Disease.

At least 10 published randomized studies have compared PCI with CABG in patients with multivessel CAD. Despite the heterogeneity of the trials in regard to design, methods, and the patient population enrolled, the results are generally comparable and provide a consistent perspective of CABG and PCI in select patients with multivessel CAD. Nevertheless, limitations should be recognized. Conducted over several decades, the trials evolved substantially with respect to the technology used for both procedures and disease-modifying preventive therapy. Moreover, most patients entered into the trials had preserved LV function. Therefore, patients enrolled in these trials were at relatively low risk, with predominantly double-vessel CAD and a normal LVEF—that is, a high proportion of patients in whom CABG had not previously been shown to be superior to medical therapy in regard to survival. Thus, one would not expect a significant mortality difference between PCI and CABG.[28]

With progressive improvements in stent technology, patients with higher-risk coronary anatomy have been enrolled in trials. In the Synergy between PCI with Taxus and Cardiac Surgery (SYNTAX) trial conducted between 2005 and 2007, 1800 patients with three-vessel or left main CAD were randomly assigned to undergo CABG or PCI after a "multidisciplinary team" consisting of a local cardiac surgeon and interventional cardiologist determined that equivalent anatomic revascularization could be achieved with either treatment.[247] The primary outcome measure was a noninferiority comparison of the two groups for major adverse cardiac or cerebrovascular events (MACCE; i.e., death from any cause, stroke, MI, or repeat revascularization) during the 12-month period after randomization. Rates of MACCE at 12 months were significantly higher in the PCI group (17.8% versus 12.4% for CABG; $P = 0.002$) (**eFig. 61.6**), in large part because of an increased rate of repeat revascularization (13.5% versus 5.9%; $P < 0.001$); thus the criterion for noninferiority was not met. At 12 months the rates of death and MI were similar between the two groups. However, stroke was significantly more likely to occur with CABG (2.2% versus 0.6% with PCI; $P = 0.003$). With longer follow-up in this trial, MACCE rates were lower in CABG-treated patients than those treated with PCI, both at 3 years (20.2% with CABG versus 28.0% with PCI; $P < 0.001$) and at 5 years (26.9% with CABG versus 37.3% with PCI; $P < 0.001$).[248] At 5 years, rates for MI (3.8% with CABG versus 9.7% with PCI; $P < 0.0001$) and repeat revascularization (13.7% with CABG versus 25.9% with PCI; $P < 0.0001$) were significantly lower in the CABG group, whereas rates of all-cause mortality (11.4% with CABG versus 13.9% with PCI; $P = 0.10$) and stroke (3.7% with CABG versus 2.4% with PCI; $P = 0.09$) did not significantly differ between groups.



EFIGURE 61.6 Outcomes in 1800 patients with stable ischemic heart disease and multivessel CAD randomly assigned to coronary artery bypass grafting (CABG) or percutaneous coronary intervention (PCI). **A,** CABG was superior to PCI at 1 year with respect to the primary outcome measure of death from any cause, myocardial infarction (MI), stroke, or repeat revascularization. **B,** This result was driven by the need for repeat revascularization, which was reduced significantly in the CABG group. **C, D,** There was no difference in the rate of death, MI, or stroke or death from any cause in the two treatment groups. (Modified from Serruys PW, Morice MC, Kappetein AP, et al. Percutaneous coronary intervention versus coronary-artery bypass grafting for severe coronary artery disease. N Engl J Med 2009;360:961.)

The comparative effectiveness of CABG versus PCI differs based on the anatomic complexity and severity of the CAD, as determined by the SYNTAX score. This score considers the number, location, and complexity of the coronary stenoses. Among patients with intermediate or high SYNTAX scores, CABG was clearly superior to PCI for major CV events, but among those with low scores, outcomes were similar (**Fig. 61.16**). Therefore, CABG should remain the standard of care for patients with complex coronary lesions (high or intermediate SYNTAX scores), whereas for patients with less complex CAD (low SYNTAX scores) or left main CAD (with low or intermediate SYNTAX scores), PCI remains an acceptable alternative. In a meta-analysis of 10 randomized trials, long-term mortality was similar after CABG or PCI in most subgroups with multivessel CAD. However, CABG appears to be better in patients with diabetes or older age, in whom mortality was more favorable in the CABG group.[196,247,249,250] Moreover, patients with diabetes with multivessel disease and low surgical risk may be appropriate candidates for CABG with increasing benefit with longer follow-up time[251] (**eFig. 61.7**). In-hospital costs are lower for patients undergoing PCI, but need for recurrent hospitalization and repeat revascularization procedures over the long term contributes to an increase in postdischarge cost in patients treated with PCI, which resulted in similar overall cost over 3 to 5 years.

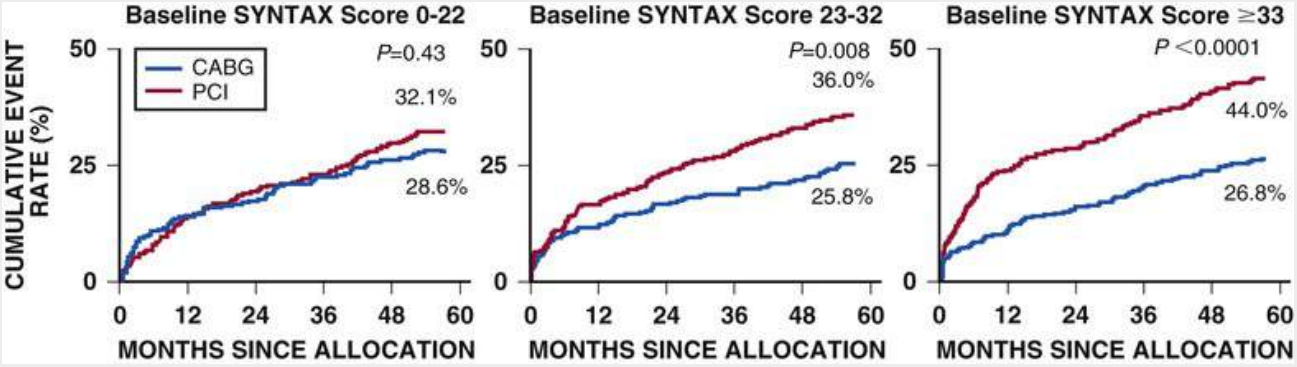


FIGURE 61.16 Major adverse cardiac and cerebral events at 5 years follow-up in the SYNTAX (Synergy Between Percutaneous Coronary Intervention with Taxus and Cardiac Surgery) trial. Patients are stratified by baseline SYNTAX score tertiles. The SYNTAX trial compared coronary artery bypass graft (CABG) surgery with percutaneous coronary intervention (PCI) in patient with left main or three-vessel coronary artery disease (CAD). The SYNTAX score describes the location, extent, and complexity of angiographic CAD, with low scores reflecting less complex disease and high scores more complex disease. CABG and PCI yielded similar outcomes among individuals in the lowest SYNTAX score tertile, but CABG was superior among individuals in the upper two tertiles, with the largest difference favoring CABG seen among patients with the most complex disease. (Modified from Mohr FW, Morice M-C, Kapetein AP, et al. Coronary artery bypass graft surgery versus percutaneous coronary intervention in patients with three-vessel disease and left main coronary disease: 5-year follow-up of the randomised, clinical SYNTAX trial. Lancet 2013;381:629-38.)

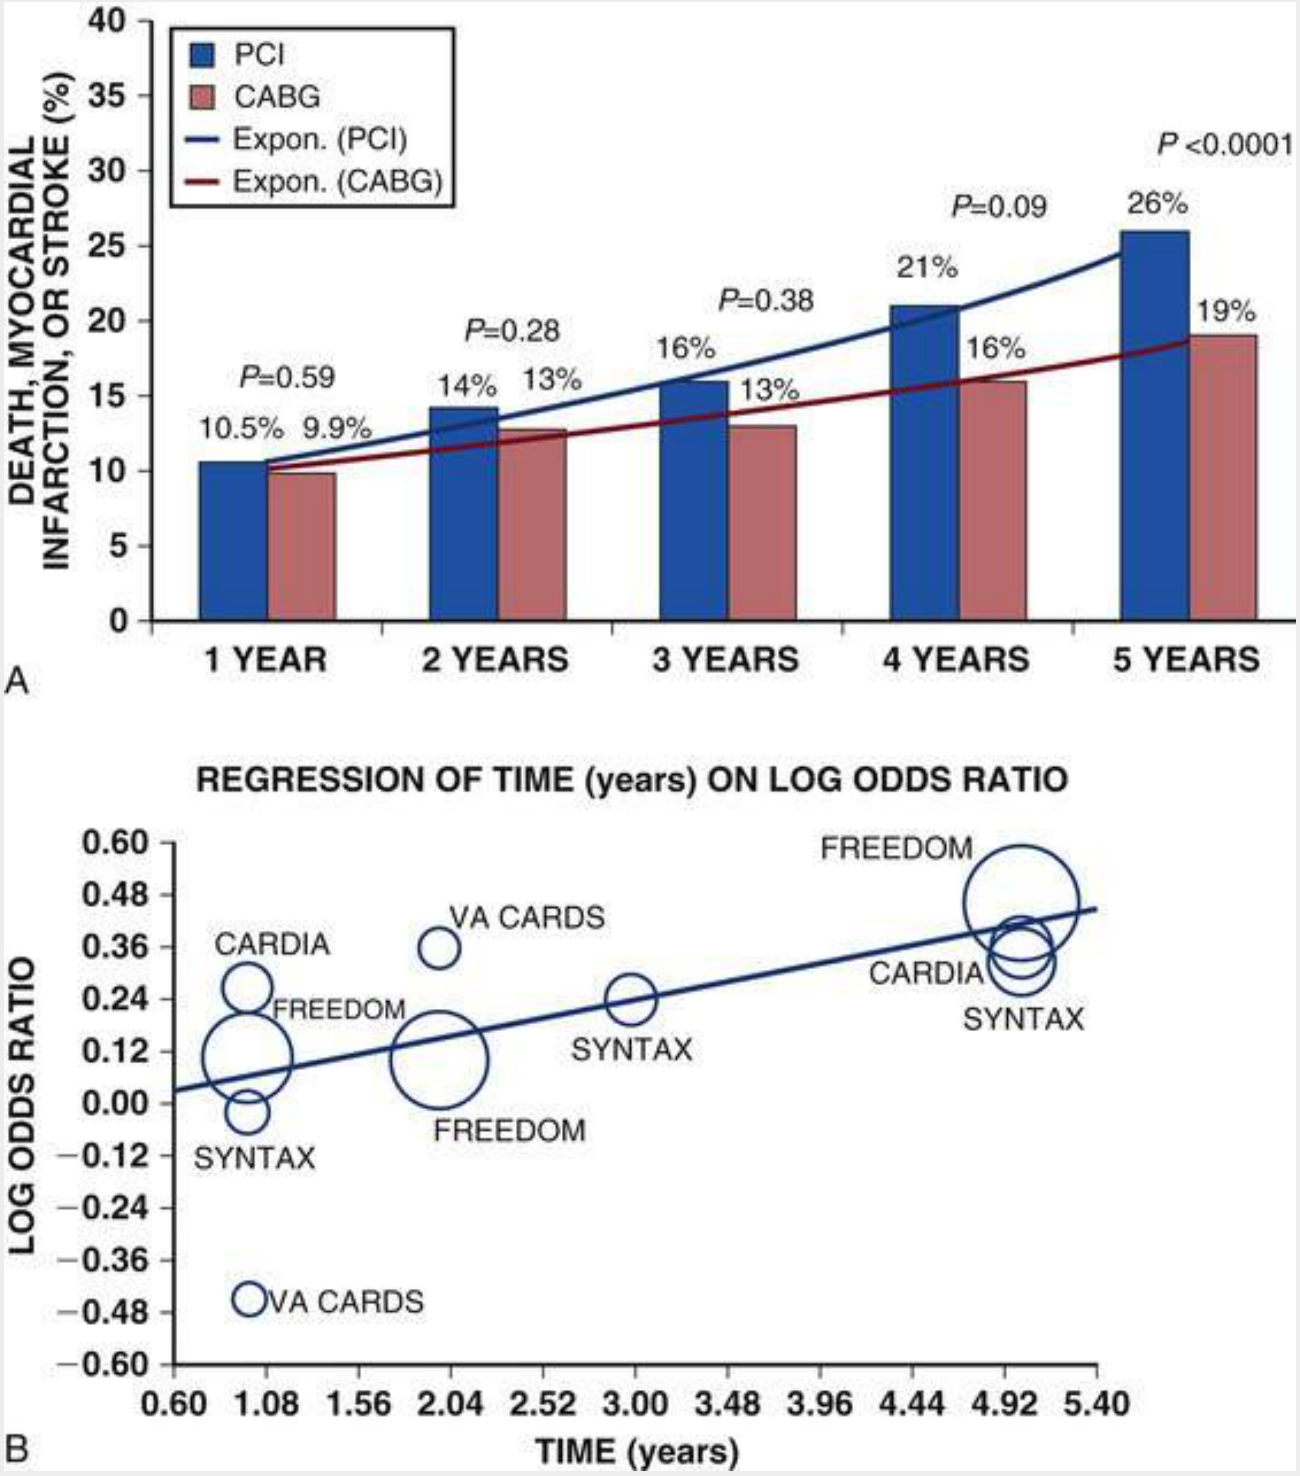


EFIGURE 61.7 Meta-analysis of four randomized trials (*n* = 3052) comparing percutaneous coronary intervention (PCI) with drug-eluting stents versus coronary artery bypass grafting (CABG) in diabetic patients with multivessel CAD. The primary endpoint (major adverse cardiac events) was a composite of death, myocardial infarction (MI), and stroke at a mean follow-up of 4 years. **A,** Display of the pooled rate of the primary endpoint across the duration of follow-up by CABG or PCI, demonstrating an increasing advantage of CABG with longer duration of follow-up. **B,** Metaregression plot for log odds ratio of the primary endpoint for PCI versus CABG as a function of time (in years). Markers above the regression line favor CABG and below the line favor PCI. The size of the data markers represents the weight of each trial. (Hakeem A, Garg N, Bhatti S, et al. Effectiveness of percutaneous coronary intervention with drug-eluting stents compared with bypass surgery in diabetics with multivessel coronary disease: comprehensive systematic review and meta-analysis of randomized clinical data. J Am Heart Assoc 2013;2:e000354.)

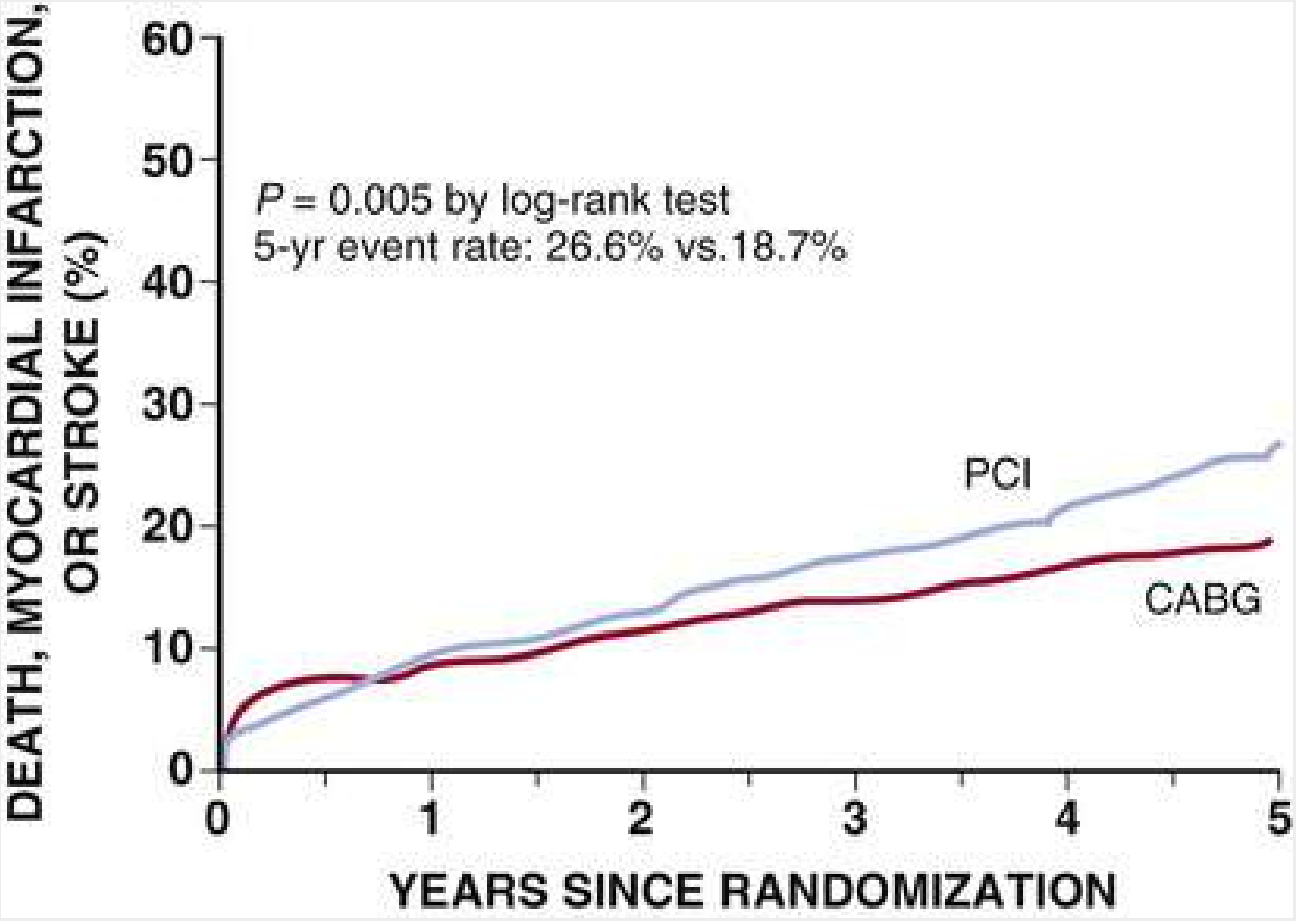
Patients with Diabetes (see Chapter 51).

An initially unexpected finding in the BARI (Bypass Angioplasty Revascularization Investigation) trial was that patients with previously treated DM who underwent PTCA had a 5-year mortality of 34.5% versus 19.4% for those who underwent CABG (P = 0.003). This advantage of CABG over PTCA for

patients with DM became more robust by 10 years of follow-up in the BARI trial and was supported in other studies. More rapid progression of atherosclerosis and high rates of restenosis in patients undergoing PCI were plausibly major contributors to this difference. In a collaborative meta-analysis of individual patient data from 7812 patients in 10 trials of PCI versus CABG, total mortality was significantly reduced by 30% with CABG in the subset of 1233 diabetic patients—findings that persisted even after exclusion of the BARI trial.[196,252]

The findings of the BARI-2D trial did not directly compare PCI and CABG but provide additional information and indirect comparisons for revascularization in patients with DM.[196] In the BARI-2D trial, 2368 patients with established diabetes and CAD were randomly assigned to prompt revascularization (PCI or CABG) versus delayed/no revascularization and OMT. A notable feature of the prompt-revascularization strategy was prespecification to PCI or CABG before randomization, with patients who had more severe CAD being allocated to CABG. Approximately two thirds of patients in BARI-2D were assigned to PCI, with the remainder who displayed more extensive CAD undergoing CABG based on "heart team" consensus decision making. At the 5-year follow-up, all-cause mortality did not differ between these two treatment groups. However, two prespecified analyses of a secondary composite endpoint (death, MI, or stroke) provide important insight: (1) compared with GDMT without revascularization, the CABG cohort had a significantly lower rate of death, MI, or stroke driven mainly by a reduction in nonfatal MI but also accompanied by a nonsignificant 16% relative decrease in mortality, and (2) in contrast to CABG, there was no difference in either the primary survival or secondary composite endpoints in patients treated with PCI or GDMT. Of note, in BARI-2D, only 35% of patients received a DES.[196]

Subsequently, the FREEDOM (Future Revascularization Evaluation in Patients with Diabetes Mellitus: Optimal Management of Multivessel Disease) trial of 1900 patients with multivessel CAD who were randomly assigned to either DES treatment or CABG showed a convincing clinical benefit in diabetic patients who underwent CABG. In particular, the trial findings showed significant reductions in all-cause mortality and the composite of death or MI in CABG-treated diabetic patients[253] (**eFig. 61.8**). The results of the FREEDOM trial add to the growing body of scientific information that patients with SIHD and diabetes, especially those with 3-vessel CAD, have better long-term clinical outcomes with CABG than with PCI, even when using DESs. A potential advantage of CABG over PCI is that bypass grafts to the mid–coronary vessel both treat the culprit lesion (regardless of anatomic complexity) and may afford prophylaxis against new proximal disease progression, whereas stents treat only suitable stenotic segments with no benefit against the development of new disease.[194]



EFIGURE 61.8 Patients (*n* = 1900) with diabetes and multivessel CAD suitable for revascularization either by percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG) were randomly assigned to undergo either PCI with drug-eluting stents or CABG and monitored for a minimum of 2 years. The primary endpoint of death, MI, or stroke was significantly lower in the CABG group than in those randomly assigned to PCI (18.7% versus 26.6% at 5 years, *P* = 0.005). Both myocardial infarction and death were significantly reduced with the CABG strategy. However, stroke was more frequent in the CABG group. (From Farkouh ME, Domanski M, Sleeper LA, et al. Strategies for multivessel revascularization in patients with diabetes. N Engl J Med 2012;20:367.)

Choosing Among Percutaneous Coronary Intervention, Coronary Artery Bypass Surgery, and Medical Therapy

Optimal medical therapy for SIHD involves a reduction in reversible risk factors, counseling in lifestyle alteration, treatment of conditions that intensify angina, and pharmacologic management of ischemia. Unlike the situation in ACS patients,[33] revascularization has not been shown to reduce the rate of death or MI when used in patients with SIHD (with the exception of CABG in patients meeting specific anatomic criteria). Recommendations for either PCI or CABG should be based on both the extent and the severity of ischemia (by noninvasive stress testing or invasive assessment of the hemodynamic significance of anatomic stenosis) and the severity of anginal symptoms or functional impairment. When an unacceptable level of angina persists despite medical management, the patient has troubling side effects from the anti-ischemic drugs, or the patient exhibits a high-risk result on noninvasive testing, the coronary anatomy should be defined to allow selection of the appropriate technique for revascularization. When one method of revascularization is preferred over the other for improved survival, this consideration generally takes precedence over improved symptoms. The patient should understand when the procedure is being performed in an attempt to improve symptoms, survival, or both. After elucidation of the coronary anatomy, selection of the technique of revascularization should be made as described next[33,196] (**Table**

61.14; see also eFig. 61.4).

TABLE 61.14

Comparison of Revascularization Strategies in Multivessel Disease

ADVANTAGES	DISADVANTAGES
Percutaneous Coronary Intervention	
Less invasive Shorter hospital stay Lower initial cost Easily repeated Effective in relieving symptoms	Restenosis High incidence of incomplete revascularization Understudied in patients with severe LV dysfunction Less favorable outcome in diabetic persons Limited to specific anatomic subsets Requires adherence with long-term DAPT
Coronary Artery Bypass Graft Surgery	
Effective in relieving symptoms Improved survival in certain subsets Ability to achieve complete revascularization Wider applicability (anatomic subsets)	Cost Morbidity Higher periprocedural mortality Higher risk for stroke and neurocognitive complications

DAPT, Dual-antiplatelet therapy; *LV,* left ventricular.

Modified from Faxon DP. Coronary angioplasty for stable angina pectoris. In Beller G, Braunwald E, editors. Chronic Ischemic Heart Disease. Atlas of Heart Disease. Vol 5. Philadelphia: Saunders; 1995, p 9.15.

Single-Vessel Disease

In patients with single-vessel disease in whom revascularization is deemed necessary and the lesion is anatomically suitable, PCI is almost always preferred over CABG.

Multivessel Disease

The first step is to assess the extent of CAD and its complexity while considering whether the patient falls into a subset of patients for whom surgical revascularization may confer a survival benefit. Most of the patients included in randomized trials comparing PCI to CABG were at lower risk, as defined by double-vessel CAD and well-preserved LV function. Moreover, several trials required that equivalent degrees of revascularization be achievable by both techniques. Most patients with chronically occluded coronary arteries were excluded, and of those who were clinically eligible, approximately two thirds were excluded for angiographic reasons. Although there was no significant difference in mortality at 5 years between PCI- and CABG-treated patients with left main and/or multivessel CAD in the SYNTAX trial, rates of both MI and repeat revascularization were significantly higher in patients who underwent PCI.

For patients who either refuse surgery or are not deemed suitable candidates for CABG, PCI remains a reasonable treatment option over medical therapy, provided that the patient accepts the possibility of symptom recurrence and the need for repeat revascularization. Patients with focal stenoses in each affected vessel (i.e., low SYNTAX score) and preserved LV function generally fare best with PCI. Additional anatomic factors, such as the presence of severe proximal LAD disease, should also be considered and weigh in favor of surgery (**see eFig. 61.4**). For patients with left main CAD or severe three-vessel CAD and LV dysfunction, CABG is generally the best approach and is recommended (class I) in professional society guidelines.[28,194,248] However, in selected patients with left main CAD, excellent technical and clinical results can still be obtained with PCI, but with a greater need for repeated revascularization procedures than with CABG. With newer-generation DES, outcomes for left main PCI have improved, and PCI now represents a suitable alternative to CABG if anatomic features are favorable (i.e., disease does not involve the bifurcation, and diffuse CAD is not present). PCI for unprotected left main disease is reasonable (class IIa) in patients whose coronary anatomy is consistent with a low risk of

PCI procedural complications and a high likelihood of good long-term outcome (i.e., low SYNTAX score of ≤22, ostial or trunk left main CAD), particularly if the risk of adverse surgical outcomes is high (e.g., STS-predicted risk of operative mortality ≥5%).[28] In general, for all patients with complex multivessel CAD for whom revascularization is being contemplated, there should be a thorough review and discussion of treatment options with the patient by a team that includes a cardiac surgeon and interventional cardiologist to reach a consensus on which approach is best suited for a particular patient.

Need for Complete Revascularization

Complete revascularization is an important goal in patients with LV dysfunction and/or multivessel CAD. The major advantage of CABG over PCI is its greater ability to achieve complete revascularization, particularly in patients with triple-vessel CAD, in addition to providing a conduit to the distal native vessel downstream of future de novo coronary stenoses. In patients with borderline LV function (EF of 0.40 to 0.50) and milder degrees of ischemia, PCI may provide adequate revascularization, even if it is not complete anatomically.

In many patients, either method of revascularization is suitable. Other factors to consider include the following:

1. Access to a high-quality team and operator (surgeon or interventional cardiologist).
2. Patient preference. Some patients are reluctant to remain at risk for recurrence of symptoms and reintervention; such patients are better candidates for surgical treatment. Other patients are attracted by the less invasive nature and more rapid recovery from PCI; these patients prefer to have PCI as their initial revascularization, with the plan of undergoing CABG if the symptoms persist and/or excellent revascularization has not been achieved.
3. Advanced patient age and comorbidity. Frail, very elderly patients and those with comorbid conditions are often better candidates for PCI.
4. Need for chronic oral anticoagulation. CABG may be preferable in patients with higher bleeding risk to avoid the risks of triple therapy with aspirin, clopidogrel, and an oral anticoagulant.

Patients with Diabetes (see Chapter 51)

The BARI-2D trial results reinforced the principal finding of the COURAGE trial that an initial strategy of PCI provides no incremental clinical benefit over GDMT, even in patients with diabetes.[238,239] However, in patients who remain symptomatic despite GDMT or when significant ischemia or extensive CAD is demonstrated, a revascularization strategy is warranted. Either PCI or CABG may be reasonable choices, depending on the anatomic complexity of the disease. However, based on the findings of BARI-2D, FREEDOM, and recent meta-analyses, CABG is regarded as the preferred revascularization approach in patients with multivessel CAD and DM when reduction of clinical events is the principal goal of treatment[238] (**Fig. 61.17**).

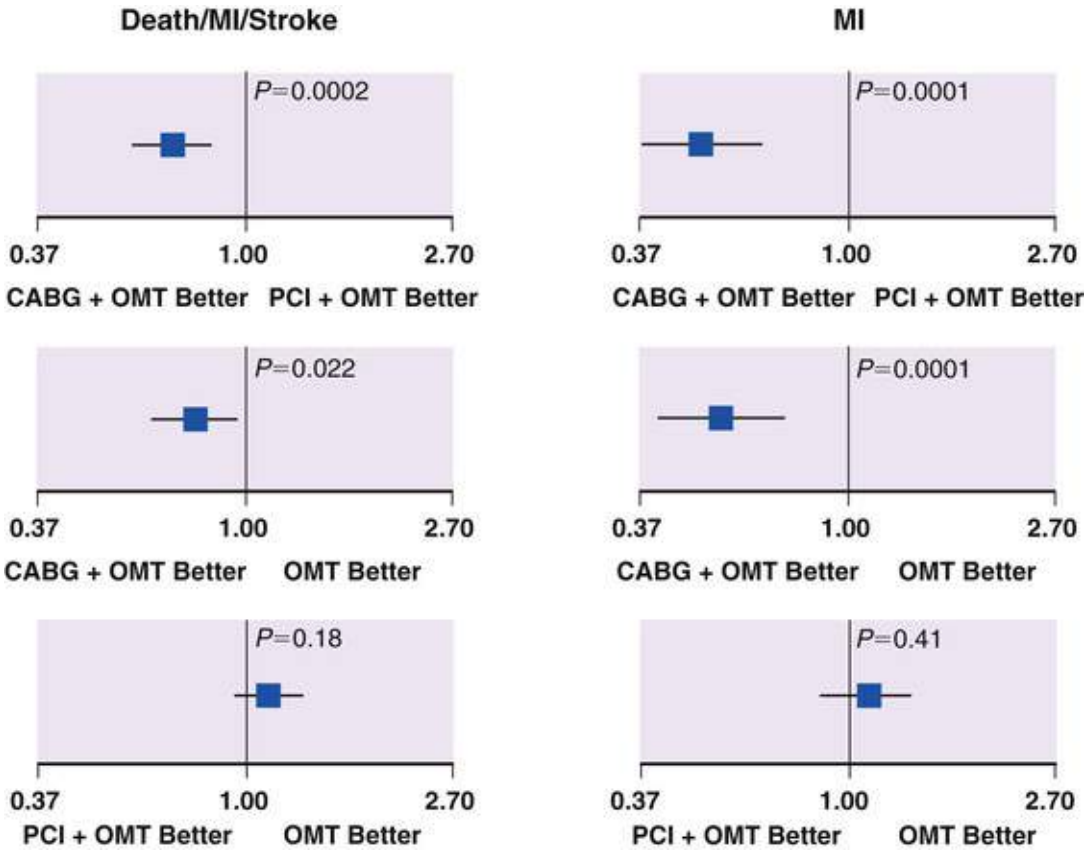


FIGURE 61.17 Meta-analysis of randomized trials comparing different revascularization strategies for patients with coronary artery disease and type 2 diabetes mellitus. Trial-adjusted hazard ratios are reported for comparisons of coronary artery bypass graft (CABG) surgery versus percutaneous coronary intervention (PCI), CABG versus optimal medical therapy (OMT), and PCI versus OMT. CABG was superior to PCI and to OMT for both the composite outcome as well as the individual MI endpoint. In contrast, PCI was not superior to OMT for either outcome. (From Mancini GB, Farkouh ME, Brooks MM, et al. Medical Treatment and Revascularization Options in Patients With Type 2 Diabetes and Coronary Disease. J Am Coll Cardiol 2016;68:985-95.)

Summary of Indications for Coronary Revascularization

1. Certain anatomic subsets of patients are candidates for CABG, regardless of the severity of symptoms or LV dysfunction. Such patients include those with significant left main CAD and most patients with three-vessel CAD that includes the proximal LAD, especially those with LV dysfunction (EF <50%). Patients with chronic stable angina and two-vessel CAD with significant proximal disease of the LAD and either LV dysfunction or high-risk findings on noninvasive testing may also be best considered for CABG.[28]
2. The results of the long-term extension (STICHES) of the STICH trial[229] as well as other aggregate data support the benefits of CABG in patients with LV dysfunction and multivessel CAD, regardless of symptoms, provided that they do not have other conditions likely to reduce life expectancy. In patients whose dominant symptom is HF without severe angina, the benefits of coronary revascularization are less well defined, but this approach should be considered in those who also have evidence of severe ischemia (regardless of angina symptoms), particularly in the presence of a significant extent of potentially viable dysfunctional (hibernating) myocardium.[196]
3. The primary objective of coronary revascularization in patients with single-vessel disease is relief of significant symptoms or objective evidence of severe ischemia. For most of these patients, PCI is the revascularization modality of choice.

4. In patients with angina who are not considered to be at high risk, survival is similar with surgery, PCI, and medical management.
5. All the indications discussed earlier relate to the potential benefits of CABG over medical therapy on survival. Coronary revascularization with PCI or CABG is highly efficacious in relieving symptoms and may be considered for patients with moderate to severe ischemic symptoms whose condition is not controlled by and/or who are dissatisfied with medical therapy, even if they are not in a high-risk subset. For such patients, the optimal method of revascularization is selected on the basis of LV function and arteriographic findings and the likelihood of technical success.

Transmyocardial Laser Revascularization

Transmyocardial laser revascularization (TMLR) is performed by placing a laser on the epicardial surface of the left ventricle, exposed through a lateral thoracotomy, and creating small channels from the epicardial to the endocardial surfaces. Failure of two sham-controlled trials of percutaneous laser myocardial revascularization to show any benefit has diminished interest in TMLR. However, the potential to enhance stem cell engraftment has led to investigation of TMLR in conjunction with stem cell therapy.[254]

Other Manifestations of Coronary Artery Disease

Prinzmetal Variant Angina

See Chapters 57 and 60.

Chest Pain with a Normal Coronary Arteriogram

The syndrome of angina or angina-like chest discomfort with normal findings on coronary arteriography, previously termed *syndrome X* (to be differentiated from "metabolic syndrome X") (**see Chapter 45**), is an important clinical entity that is often associated with clinical and electrocardiographic evidence of myocardial ischemia and has previously been underrecognized. Better described as "angina without flow-limiting epicardial coronary stenosis," this syndrome was generally regarded as having a benign long-term prognosis but is now recognized to be associated with an increased risk for adverse outcomes in certain subsets of patients.[1,2,181] For decades, angina with normal findings on coronary arteriography in the absence of underlying conditions such as severe aortic stenosis or hypertrophic cardiomyopathy was largely viewed by clinicians as unrelated to true myocardial ischemia, but rather a manifestation of undetected noncardiac reasons. Potential explanations for angina in the absence of flow-limiting CAD offered historically include vasospastic angina, misinterpreted coronary angiogram, potential misdiagnosis of flush (or stump) coronary occlusions at sites of major arterial bifurcations, increased subendocardial pressure leading to coronary artery compression, and hyperdynamic ventricular contraction with an elevated EF resulting in a supply-demand imbalance. In some patients, particularly premenopausal women, when exercise-induced ST-segment depression during treadmill exercise triggered referral for diagnostic coronary angiography that resulted in normal angiographic findings, these abnormal noninvasive test results were dismissed as being "false positives." However, steady accumulation of experimental and clinical data has provided a sound scientific basis for recognizing that

myocardial ischemia may occur without critical coronary stenosis and may be explained by overlapping effects of concealed diffuse coronary atherosclerosis revealed by FFR or IVUS, endothelial dysfunction, microvascular dysfunction, coronary spasm, and in some cases myocardial bridging.[2,181,255,256]

Patients with chest pain and normal findings on coronary arteriography may represent as many as 10% to 30% of those undergoing coronary arteriography because of clinical suspicion of angina.[181] This proportion may be substantially higher in women. For example, in the initial WISE (Women's Ischemic Syndrome Evaluation) study, approximately two thirds of women with chest pain and other findings suggestive of SIHD had no critical coronary stenoses detected with angiography.[256] Data from 388 U.S. hospitals participating in the ACC-NCDR revealed that at least 50% of women and 30% of men referred for coronary angiography had no obstructive CAD.[256] True myocardial ischemia, as reflected by the production of lactate by the myocardium during exercise or pacing, is present in some of these patients. In addition, coronary artery reactivity testing demonstrates evidence of endothelial and microvascular dysfunction in a substantial proportion of such individuals.[257] The incidence of coronary calcification on CT is significantly higher than that in normal controls (53% versus 20%) but lower than that in patients with angina secondary to obstructive CAD (96%). Moreover, observational data have established that their outcome is not as uniformly excellent as suggested by early cohort studies.[34,258] In addition, abnormal measures of endothelial and microvascular function in these patients are associated with a higher risk for death, MI, or hospitalization for HF.

The causes of the syndrome are probably multiple and not homogeneous across individuals.[3] Vascular (endothelial and microvascular) dysfunction, coronary vasospasm, and myocardial metabolic abnormalities, as previously noted, have each been implicated. Included in this syndrome are patients in whom angina may be the direct consequence of subendocardial ischemia as a result of abnormalities in the coronary microvasculature (or arteriolar resistance vessels), the small caliber of which would be beyond the resolution of coronary angiography. This condition is frequently termed *microvascular angina.* Alternatively, in some individuals, chest discomfort without ischemia may be caused by abnormal pain perception or sensitivity. Furthermore, IVUS studies have demonstrated anatomic and physiologic heterogeneity in such patients, with a spectrum ranging from completely normal epicardial coronary arteries to vessels with intimal thickening and atheromatous plaque and non–flow-limiting obstructions (10% to 30% diameter reductions)—insufficient to cause angina on the basis of coronary luminal narrowing alone, but in the setting of superimposed dynamic coronary vasomotor tone, such ischemic symptoms could readily occur. Lastly, it may be difficult to distinguish patients with angina and normal findings on coronary arteriography in whom chest pain is caused by ischemia from patients with noncardiac pain. However, an approach of assuming a favorable prognosis and dismissing symptoms in all such patients is clearly not justified by the evidence.

Microvascular Dysfunction (Impaired Coronary Flow Reserve).

Many patients with evidence of myocardial ischemia do not have visible coronary atherosclerosis at angiography, and conversely, some patients with severe coronary atherosclerotic obstructions neither experience chest discomfort nor have any objective findings of myocardial ischemia.[35,259] Atherosclerosis is just one element of a complex myriad of potential impediments to coronary flow that includes inflammation, microvascular coronary dysfunction, endothelial dysfunction, and thrombosis. Accordingly, patients with chest pain, angiographically normal coronary arteries, and no evidence of large-vessel spasm, even after an acetylcholine challenge, may demonstrate an abnormally decreased capacity to

reduce coronary resistance and increase coronary flow in response to stimuli such as exercise, adenosine, dipyridamole, and atrial pacing. Discordance between epicardial coronary function (by FFR) and microvascular function (by coronary flow reserve [CFR] or the index of microcirculatory resistance [IMR]) can provide insight into coronary microvascular function. The finding of a normal FFR, indicating no obstructive epicardial stenosis, but reduced CFR or IMR, indicating predominant microvascular disease, is associated with a particularly unfavorable prognosis.[260] As such, coronary flow evaluation may be useful in the investigation of the functional severity of coronary pathology.[3,181]

Patients with microvascular angina also have an exaggerated response of small coronary vessels to vasoconstrictor stimuli and an impaired response to intracoronary vasodilators. Abnormal endothelium-dependent vasoreactivity has been associated with regional myocardial perfusion defects on SPECT, PET, and CMR.[261] It has been reported that patients with angina and angiographically normal coronary anatomy also have impaired vasodilator reserve in forearm vessels and airway hyperresponsiveness, which suggests that the smooth muscle of systemic arteries and other organs may be affected in addition to that of the coronary circulation.

Endothelial dysfunction and endothelial cell activation, reported in patients with microvascular angina, may participate in the release of cellular adhesion molecules, proinflammatory cytokines, and constricting mediators that induce changes in the arterial wall and result in microvascular coronary dysfunction and higher risk for the future development of obstructive CAD.

Evidence of Ischemia.

Despite the general acceptance that microvascular or endothelial dysfunction is present in many patients with angina and normal findings on coronary arteriography, whether ischemia is in fact the putative cause of the symptoms in all patients is not clear. For this reason, studies of transmyocardial production of lactate have generated mixed results. The development of LV dysfunction and electrocardiographic or scintigraphic abnormalities during exercise in some of these patients supports an ischemic cause. Moreover, stress echocardiography with dobutamine detects regional contraction abnormalities consistent with ischemia in a subset of patients. More sensitive techniques, such as perfusion analysis with CMR, have demonstrated that subendocardial perfusion abnormalities, in particular, may be associated with angina with normal angiographic findings.

Abnormal Pain Perception.

The lack of definitive evidence of ischemia in many patients with angina and normal coronary angiographic findings has focused attention on alternative nonischemic causes of cardiac-related pain, including a decreased threshold for pain perception. This hypersensitivity may result in an awareness of chest pain in response to stimuli such as arterial stretch or changes in heart rate, rhythm, or contractility. A sympathovagal imbalance with sympathetic predominance in some of these patients has also been postulated. At cardiac catheterization, some patients with angina are unusually sensitive to intracardiac instrumentation, with the typical chest pain being consistently produced by direct right atrial stimulation and saline infusion. Measurements of regional cerebral blood flow at rest and during chest pain have suggested differential handling of afferent stimuli between such patients and those with obstructive CAD.

Clinical Features

The syndrome of angina or angina-like chest pain with no obstructive disease of the epicardial arteries occurs more frequently in women (**see Chapter 89**), many of whom are premenopausal, whereas obstructive CAD is found more often in men and postmenopausal women (**Fig. 61.18**). Similarly to women with critical epicardial CAD, many women with microvascular angina will experience dyspnea

or fatigue or may have a preponderance of symptoms such as nausea, and midepigastric pain. Although the features are frequently atypical, the chest pain may nonetheless be severe and disabling. Angina in the absence of obstructive CAD may have markedly adverse effects on quality of life, employment, and use of health care resources.

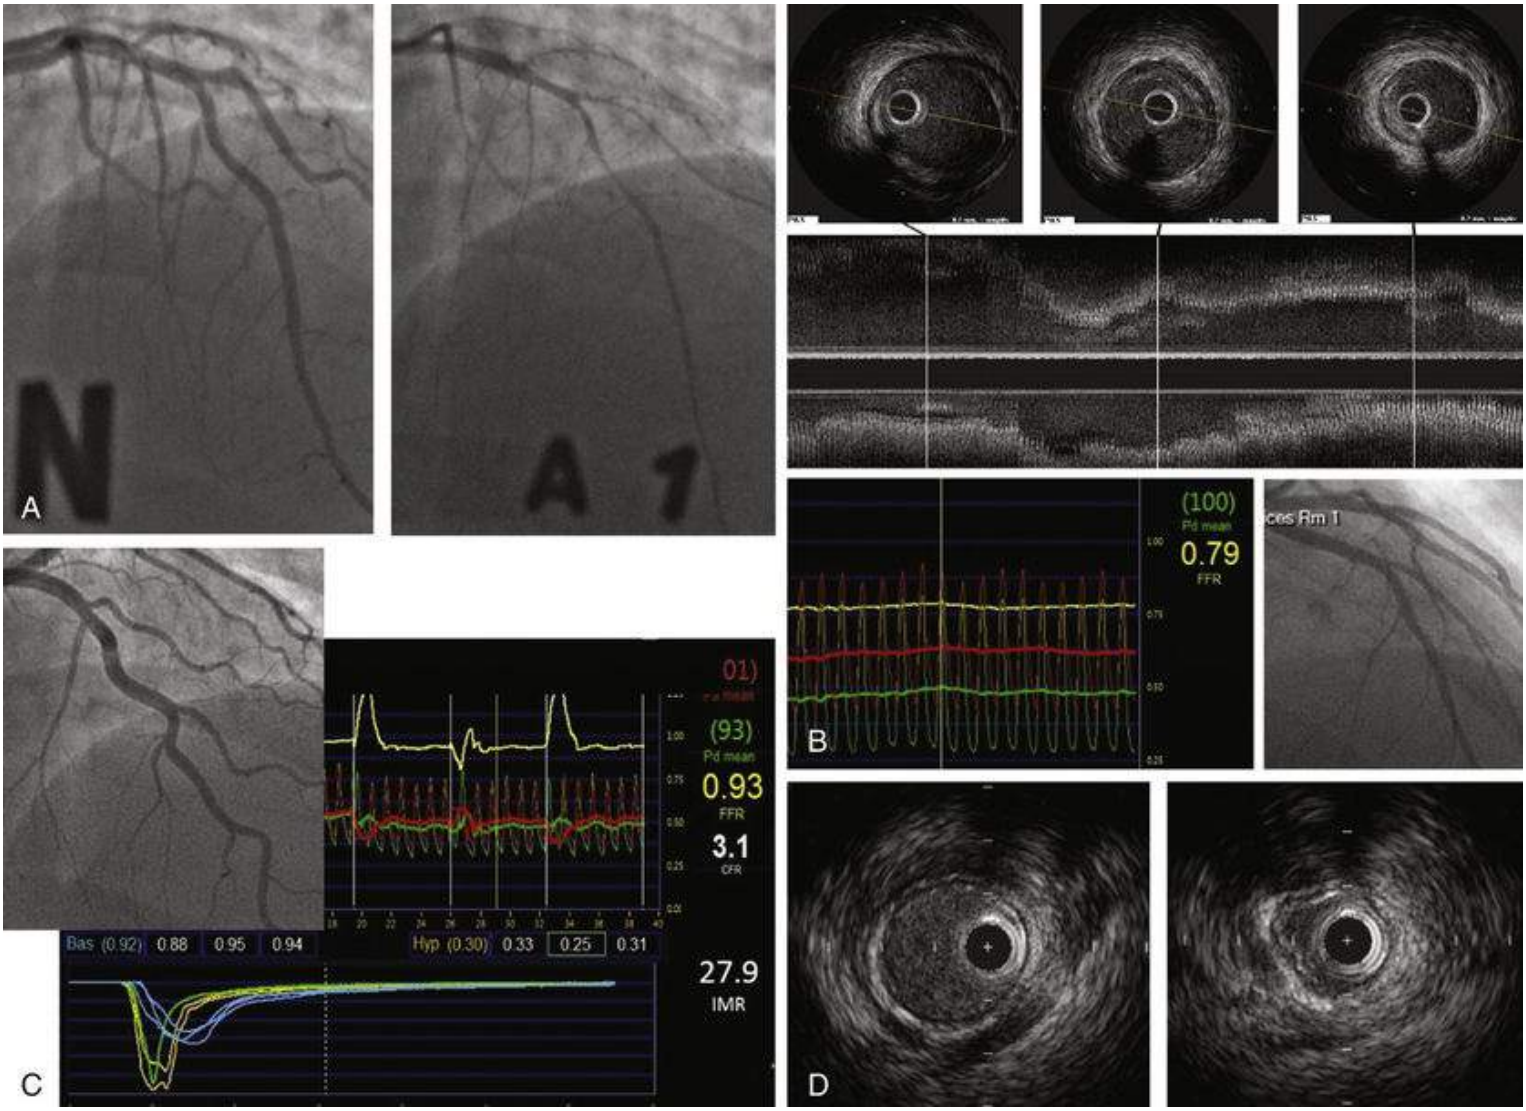

FIGURE 61.18 Evaluation of patients with chest pain in the absence of coronary artery obstruction. **A,** Baseline coronary angiogram and subsequent angiogram after intracoronary acetylcholine, demonstrating diffuse endothelial dysfunction with vasoconstriction. **B,** Cross-sectional and longitudinal intravascular ultrasound images demonstrating diffuse atherosclerosis, and coronary pressure tracing revealing an abnormal fractional flow reserve in a normal-appearing left anterior descending coronary artery (LAD) on angiography. **C,** Coronary angiogram revealing a normal LAD with a pressure tracing showing an abnormal index of microcirculatory resistance. **D,** Cross-sectional intravascular ultrasound images of a myocardial bridge segment. (With permission from Lee BK, Lim HS, Fearon WF, et al. Invasive evaluation of patients with angina in the absence of obstructive coronary artery disease. Circulation 2015;131:1054-60.)

Clinical and Diagnostic Assessment

Abnormal physical findings reflecting ischemia are uncommon in these patients. The resting ECG may be normal, but nonspecific ST-T wave abnormalities are often observed, sometimes occurring in association with the chest pain. Approximately 20% to 30% of patients with chest pain and normal coronary angiographic findings have positive exercise test results. However, many patients with this syndrome do not complete the exercise test because of fatigue or mild chest discomfort. LV function is usually normal at

rest and during stress, unlike the situation in obstructive CAD, in which function often becomes impaired during stress.

Comprehensive invasive assessment of patients with evidence of myocardial ischemia on noninvasive testing can provide diagnostic information in more than 75% of those without obstructive CAD. Such a comprehensive invasive assessment may include FFR to evaluate epicardial obstructive disease that was not apparent from the angiogram, endothelial function testing with acetylcholine, IMR with adenosine, and IVUS to assess for diffuse structural abnormalities and myocardial bridging. In some series, IVUS revealed diffuse coronary atherosclerosis in all such patients evaluated.[3] Such findings may be useful to guide management.

Prognosis

Accumulating data suggest that the prognosis in patients with chest pain without obstructive CAD is more heterogeneous than once thought. In patients with EF of 50% or greater in the CASS registry, the 7-year survival rate was 96% for those with normal arteriographic findings and 92% for those whose arteriographic study revealed mild CAD (50% luminal stenosis). However, subsequent studies have shown that the prognosis is not as favorable in some groups of patients.[1,2,181] For example, an ischemic response to exercise is associated with increased mortality. Moreover, in women with angina and no obstructive CAD enrolled in the WISE investigations, persistence of symptoms was associated with more than a twofold higher risk for CV events. Such patients may be appropriate candidates for formal studies of vascular function and aggressive risk factor modification (**see Chapter 89**).

Management

No specific guideline-recommended therapy is available for patients with signs and symptoms of IHD who do not have obstructive CAD (**see Fig. 61.18**). Risk factors for atherosclerotic vascular disease should be managed, and for those with established atherosclerosis, even if nonobstructive, GDMT should be instituted.[181] For those with ischemic symptoms, a trial of anti-ischemic therapy with nitrates, calcium antagonists, and beta blockers is logical, but the response to this therapy is variable. Perhaps because of the heterogeneity of this population, studies testing these antianginal therapies have produced conflicting results. For example, beta blockers may be most effective in such patients who also have evidence of a hyperadrenergic state characterized by increased sympathetic nervous system activity (e.g., hypertension, tachycardia, reduced HR variability). SL nitroglycerin has shown paradoxical effects on blood flow and exercise tolerance in some studies and beneficial effects in others. Observational studies of calcium antagonists have in general resulted in disappointing outcomes with respect to amelioration of symptoms. Although a small pilot study of women with well-documented microvascular angina and myocardial ischemia treated with ranolazine showed an improvement in functional status and quality of life,[159] no benefit from ranolazine was seen in a subsequent placebo-controlled trial performed in patients with angina and MR evidence of impaired CFR.[160]

ACE inhibitors have favorable effects on endothelial function, vascular remodeling, and sympathetic tone that may be relevant to the pathophysiology of the underlying myocardial ischemia in some of these patients. Preliminary data on ACE inhibitors in this population are promising. Similarly, *estrogen* has been shown to attenuate the normal coronary vasomotor responses to acetylcholine, increase coronary blood flow, and potentiate endothelium-dependent vasodilation in postmenopausal women. Studies of estrogen replacement in postmenopausal women with angina but without critical epicardial CAD have demonstrated improvement in symptoms and exercise performance; however, the role of exogenous

estrogen in treatment of this group remains in question. Treatment with imipramine (50 mg daily) and structured psychological intervention targeted to the altered somatic and visceral pain perception of certain patients have been reported to be helpful.

Silent Myocardial Ischemia

Epidemiologic studies of sudden cardiac death (SCD), as well as clinical and postmortem studies of patients with silent MI, have suggested that many patients with severe IHD never experience angina pectoris (**see Chapter 42**). These patients may be considered to have a defective anginal warning system in that they may not be subjectively aware of myocardial ischemia when it is present. In addition, up to one third of patients with chronic stable angina also exhibit episodes of silent (asymptomatic) ischemia. The total ischemic burden in these patients refers to the total period of ischemia, both symptomatic and asymptomatic.

Analysis of ambulatory electrocardiographic recordings in patients with CAD who had both symptomatic and silent myocardial ischemia has shown that 85% of ambulant ischemic episodes occur without chest pain, and 66% of angina reports were unaccompanied by ST-segment depression. Their frequency suggests that overt angina pectoris is merely the "tip of the ischemic iceberg." Episodes of silent ischemia may be present in approximately one third of all treated patients with angina, although a higher prevalence has been reported in diabetic persons (**see Chapter 51**).

Mechanisms.
Differences in both peripheral and central neural processing of pain have been proposed as important factors underlying silent ischemia. PET of cerebral blood flow during painful versus silent ischemia indicates differences in the CNS handling of afferent signals. Specifically, overactive gating of afferent signals in the thalamus may reduce the cortical activation necessary for perception of pain from the heart. *Autonomic neuropathy* has also been implicated in the reduced sensation of pain during ischemia, supporting the belief that diabetic patients with dysautonomia may manifest myocardial ischemia without anginal symptoms more often than nondiabetic persons.

Prognosis.
Although some controversy remains, ample evidence has supported the view that episodes of myocardial ischemia, regardless of whether they are symptomatic or asymptomatic, are of prognostic importance in patients with CAD.[262] In asymptomatic patients, the presence of exercise-induced ST-segment depression has been shown to predict a four- to fivefold higher cardiac mortality compared to patients without this finding. Similarly, in patients with stable angina or previous MI, the presence of inducible ischemia, evident by ST depression or reversible myocardial perfusion abnormalities during exercise testing, is associated with unfavorable outcomes regardless of whether symptoms are present. The strength of this association is greatest when the ischemia is found to occur at a low workload. A study of stress nuclear imaging revealed that a threshold of ischemia in 7.5% or greater of the myocardium was associated with a higher risk for cardiac death or MI in asymptomatic patients without known CAD.

Detection and Management.
Ambulatory ECG monitoring, while feasible, is not justified as a widespread screening tool for silent ischemia. The exercise ECG can be used to identify most patients likely to have significant ischemia during their daily activities (**see Chapter 13**). In addition, silent ischemia may be discovered by a

positive scintigraphic perfusion scan undertaken in patients with known angiographic CAD, or in asymptomatic individuals with suspected high-risk CAD. However, we emphasize that routine stress testing or nuclear perfusion studies are not indicated for patients with SIHD in the absence of a change in clinical status. Noninvasive studies have been overused in some countries, despite the lack of evidence to support benefit.[263]

In such patients with a defective anginal warning system, it is reasonable to assume that *asymptomatic* ischemia has a prognostic significance similar to that of symptomatic ischemia, and that their management is similar with respect to disease-modifying preventive therapy. Studies evaluating revascularization for silent ischemia have yielded conflicting results. A post hoc analysis of the COURAGE trial evaluated clinical outcomes in patients with silent myocardial ischemia and in those with symptomatic ischemia during a 5-year follow-up.[264] A total of 283 patients with SIHD qualified for enrollment on the basis of objective baseline findings of inducible ischemia and significant flow-limiting coronary stenoses (>70%) but who lacked anginal symptoms. No overall differences were detected in patients with silent ischemia between those randomly assigned to PCI or medical therapy for the endpoints of death or MI.[264] When these results were combined with the ACIP (Asymptomatic Cardiac Ischemia Pilot) trial and the earlier SWISSI-II study, the pooled analysis of 1042 patients with silent ischemia revealed a statistically significant 64% reduction in the composite endpoint of death or MI in PCI-treated patients and a significant 56% reduction in death alone. In contrast, in a propensity-adjusted analysis of patients undergoing repeated revascularization in the setting of asymptomatic ischemia noted on MPI, all-cause mortality was not improved during a mean 5.7-year follow-up.[265] A nuclear substudy from the COURAGE trial was undertaken in 1381 randomly assigned patients (GDMT alone = 699 patients; PCI + GDMT = 682 patients) who underwent stress myocardial perfusion SPECT at baseline only (with or without a repeated follow-up scan), with the results interpreted locally by the on-site investigators. At baseline, moderate to severe ischemia was present in one third of patients (n = 468), and the incidence was comparable in both treatment groups (P = 0.36). The primary endpoint (death or MI) was similar in the two treatment groups for the subsets with either no to mild ischemia (18% and 19%, respectively; P = 0.92) or moderate to severe ischemia (19% and 22%, respectively; P = 0.53; interaction P value = 0.65).[266]

In summary, although suppression of ischemia in asymptomatic patients with SIHD appears to be a worthwhile objective, at present it is not clear whether treatment should be guided by symptoms or by ischemia as determined by noninvasive testing. Nevertheless, it seems reasonable to use anti-ischemic and disease-modifying pharmacologic therapy in patients with well-documented myocardial ischemia, even if symptoms are lacking. Whether revascularization improves outcomes among patients with large ischemic burden, with or without symptoms, absent other indications for revascularization, remains to be determined. The NHLBI-sponsored ISCHEMIA is currently randomizing 8000 patients with SIHD and moderate to severe ischemia to either optimal medical therapy or OMT plus revascularization. This trial should provide further insights into the role of ischemia (and ischemia monitoring) for targeting coronary revascularization in patients with SIHD.

Heart Failure in Ischemic Heart Disease (See Chapter 23)

Currently, the leading cause of HF in developed countries is CAD. In the United States, CAD and its complications account for two thirds to three fourths of all cases of HF. In many patients the progressive nature of HF reflects the advancing nature of the underlying CAD.

Ischemic Cardiomyopathy

In 1970, Burch and colleagues first used the term *ischemic cardiomyopathy* to describe the condition in which CAD results in severe myocardial dysfunction, with clinical manifestations often being indistinguishable from those of primary dilated cardiomyopathy (**see Chapter 77**). Symptoms of HF caused by ischemic myocardial dysfunction and hibernation, diffuse fibrosis, or multiple MIs, alone or in combination, may dominate the clinical picture of CAD. In some patients with chronic CAD, angina may be the principal clinical manifestation at one time, but later this symptom diminishes or even disappears as HF becomes more prominent. Other patients with ischemic cardiomyopathy have no history of angina or MI, and it is in this subgroup that ischemic cardiomyopathy is most often confused with dilated cardiomyopathy. When angina coexists with ischemic cardiomyopathy, outcomes appear particularly poor.[267]

It is important to recognize hibernating myocardium in patients with ischemic cardiomyopathy because symptoms resulting from chronic LV dysfunction may be incorrectly thought to result from necrotic and scarred myocardium rather than from a reversible ischemic process[268] (see earlier, Myocardial Hibernation). Hibernating myocardium may be present in patients with known or suspected CAD and a degree of cardiac dysfunction or HF not readily accounted for by previous MIs.

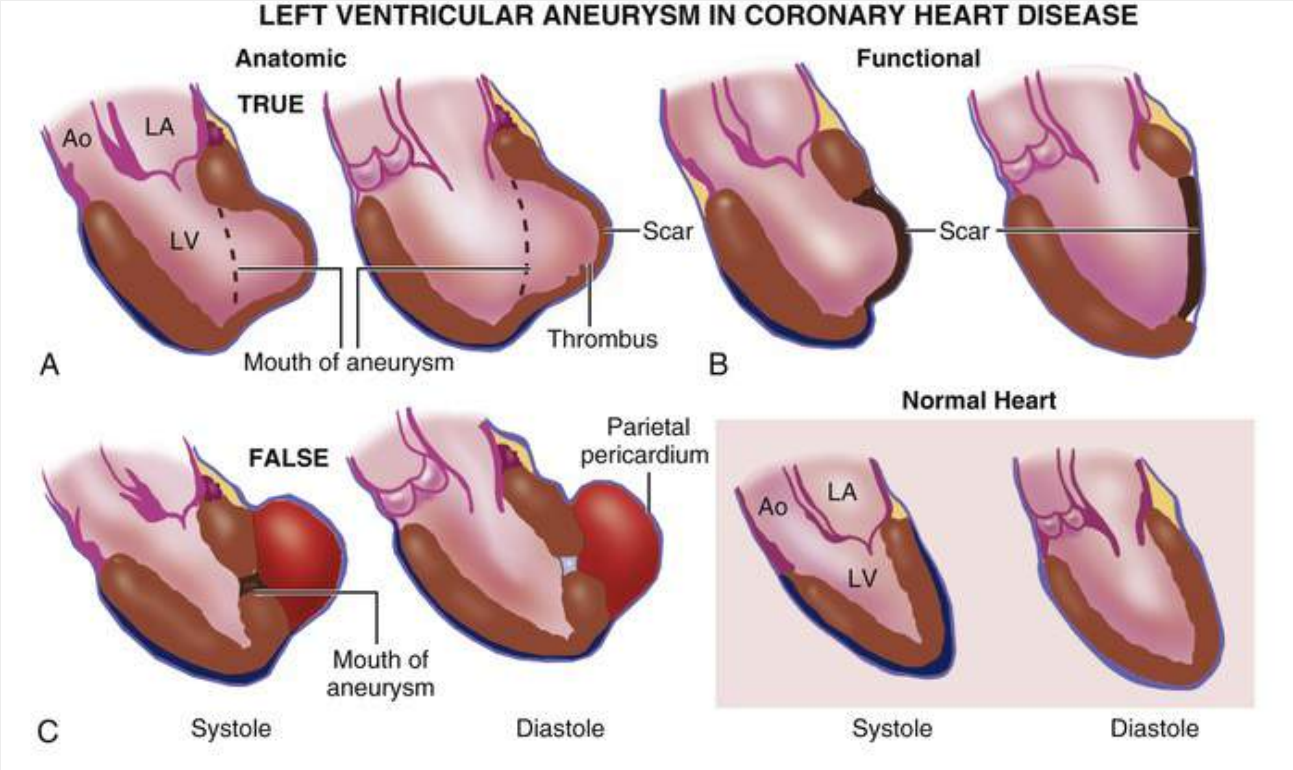
The outlook for patients with ischemic cardiomyopathy treated medically is poor, and revascularization or cardiac transplantation may be considered.[230] The prognosis is particularly poor for patients in whom ischemic cardiomyopathy is caused by multiple MIs, in those with associated ventricular arrhythmias, and in those with an extensive amount of hibernating myocardium. However, this last group of patients, whose HF, even if severe, is caused by large segments of reversibly dysfunctional but viable myocardium, may have a better prognosis and relief of HF symptoms after revascularization. Thus the key to management of patients with ischemic cardiomyopathy, in addition to providing evidence-based medical therapy for HF, is careful selection of patients who may be appropriate candidates for revascularization[269] (see earlier, Coronary Artery Bypass Grafting, Patients with Depressed Left Ventricular Function).

Although seemingly of intuitive value, the role of viability testing to guide revascularization decisions in patients with ischemic cardiomyopathy is not clear. Observational studies have suggested that patients with ischemic cardiomyopathy who have extensive multivessel CAD and viable myocardium may derive a survival advantage with CABG, whereas those with little or no viable myocardium should usually be managed similar to those with dilated cardiomyopathy (**see Chapters 25 and 77**). Nonetheless, in the randomized STICH trial, viability testing did not appear to identify patients in whom CABG provided incremental survival benefit.[230] Similarly, the small PARR-2 (PET and Recovery Following Revascularization-2) study of 430 patients randomly assigned to PET-guided management versus standard care did not demonstrate an advantage of revascularization when viability testing was used as a guide.[225] Additional, rigorous, adequately sized observational studies and RCTs are needed to define the role of viability testing.

Left Ventricular Aneurysm.

LV aneurysm is usually defined as a segment of the ventricular wall that exhibits paradoxical (dyskinetic) systolic expansion. Chronic fibrous aneurysms interfere with LV performance principally through loss of contractile tissue. Aneurysms made up largely of a mixture of scar tissue and viable myocardium or of thin scar tissue also impair LV function by a combination of paradoxical expansion and loss of effective contraction. False aneurysms (pseudoaneurysms) represent localized myocardial rupture in which the

hemorrhage is limited by pericardial adhesions, and they have a mouth that is considerably smaller than the maximal diameter (**eFig. 61.9**). True and false aneurysms may coexist, although the combination is extremely rare.



EFIGURE 61.9 Hearts in systole and diastole with true and false anatomic and functional left ventricular (LV) aneurysms and healed MI. A normal heart in systole and diastole is shown for comparison **(inset). A,** True anatomic LV aneurysm protrudes during both systole and diastole, has a mouth that is as wide as or wider than the maximal diameter, has a wall that was formerly the wall of the left ventricle, and is composed of fibrous tissue with or without residual myocardial fibers. A true aneurysm may or may not contain thrombus and very rarely ruptures once the wall is healed. **B,** A functional LV aneurysm protrudes during ventricular systole but not during diastole and consists of fibrous tissue with or without myocardial fibers. **C,** False anatomic LV aneurysm protrudes during both systole and diastole, has a mouth that is considerably smaller than the maximal diameter of the aneurysm and represents a myocardial rupture site, has a wall made up of parietal pericardium, almost always contains thrombus, and often ruptures. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle. (From Cabin HS, Roberts WC. Left ventricular aneurysm, intra-aneurysmal thrombus, and systemic embolus in coronary heart disease. Chest 1980;77:586.)

The frequency of LV aneurysms depends on the incidence of transmural MI and HF in the population studied. LV aneurysms and the need for aneurysmectomy have declined dramatically during the past 5 to 10 years in concert with the expanded use of acute reperfusion therapy for evolving MI (**see Chapter 59**). More than 80% of LV aneurysms are located anterolaterally near the apex. They are often associated with total occlusion of the LAD coronary artery and poor collateral blood supply. Approximately 5% to 10% of aneurysms are located posteriorly. Three fourths of patients with LV aneurysms have multivessel CAD.

Approximately 50% of patients with moderate or large aneurysms have symptoms of HF, with or without associated angina; 33% have severe angina alone; and 15% have symptomatic ventricular arrhythmias that may be intractable and life threatening. Mural thrombi are found in almost half of patients with chronic LV aneurysms and can be detected by angiography and two-dimensional echocardiography (**see Chapter 14**). Systemic embolic events in patients with thrombi and an LV aneurysm tend to occur early after MI. In patients with a chronic LV aneurysm (documented at least 1

month after MI), subsequent systemic emboli were extremely uncommon (0.35 per 100 patient-years in those not receiving anticoagulants).

Detection.

Clues to the presence of an aneurysm include persistent ST-segment elevations on the resting ECG (in the absence of chest pain) and a characteristic bulge of the silhouette of the left ventricle on a chest radiograph. Marked calcification of the LV silhouette may be present. These findings, when clear-cut, are relatively specific, but they have limited sensitivity. Two-dimensional echocardiography can readily demonstrate LV aneurysms and is helpful in distinguishing between true and false aneurysms based on the demonstration of a narrow neck in relation to cavity size in false aneurysm. Color flow echocardiographic imaging is useful in establishing the diagnosis because flow “in and out” of the aneurysm, as well as abnormal flow within the aneurysm, can be detected, and pulsed Doppler imaging can reveal a “to-and-fro” pattern with characteristic respiratory variation in the peak systolic velocity. CMR may be emerging as the preferred noninvasive technique for the preoperative assessment of LV shape, thinning, and resectability.

Left Ventricular Aneurysmectomy.

True LV aneurysms do not rupture, and operative excision is carried out to improve the clinical manifestations, most often HF but sometimes also angina, embolization, and life-threatening tachyarrhythmias.[269,270] CABG is frequently performed along with aneurysmectomy, especially in patients with angina accompanying HF.

A large LV aneurysm in a patient with HF symptoms, particularly if angina pectoris is also present, is a possible indication for surgery. The operative mortality rate for LV aneurysmectomy is approximately 8% (range, 2% to 19%), with rates as low as 3% being reported in more recent series. Improvement in LV function has been reported in survivors of resection of LV aneurysms. Anterior ventricular restoration has the potential to reverse the adverse remodeling, realign contractile fibers, and decrease LV wall stress and thus has been of interest as a possible intervention to mitigate the progression of ischemic cardiomyopathy. Small, unblinded series have suggested that surgical ventricular restoration (SVR) could result in improvement in both LV function and quality of life.[270] The value of SVR for patients with ischemic cardiomyopathy who do not have frank LV aneurysms was tested in the STICH trial and shown not to improve rates of death or cardiac hospitalization: 56% for CABG and 57% for CABG plus SVR. Thus, in the absence of new data, use of SVR remains an unproven strategy in the management of HF patients.[270,271]

Mitral Regurgitation Secondary to Coronary Artery Disease

Mitral regurgitation (MR) is an important cause of HF in some patients with CAD. Rupture of a papillary muscle or the head of a papillary muscle usually causes severe acute MR in the course of acute MI (**see Chapters 58 and 69**). The cause of chronic MR in patients with CAD is multifactorial, and the geometric determinants are complex; these include papillary muscle dysfunction from ischemia and fibrosis, in conjunction with a wall motion abnormality and changes in LV shape in the region of the papillary muscle and/or dilation of the mitral annulus. Enlargement of the mitral annulus at end-systole is asymmetric, with lengthening primarily involving the posterior annular segments and leading to prolapse of leaflet tissue tethered by the posterior papillary muscle and restriction of leaflet tissue attached to the anterior leaflet. Most patients with chronic CAD and MR previously had an MI. Clinical features that help identify MR secondary to papillary muscle dysfunction as the cause of acute pulmonary edema or milder symptoms of left-sided HF include a loud systolic murmur and demonstration of a flail mitral valve leaflet on

echocardiography. In some patients with severe MR into a small, noncompliant left atrium, the murmur may be unimpressive or inaudible. Doppler echocardiography is helpful in assessing the severity of the regurgitation (**see Chapter 14**). As in MR of other causes, the left atrium is not usually greatly enlarged unless MR has been present for more than 6 months. The ECG is nonspecific, and most patients have angiographic evidence of multivessel CAD.

Management

In patients with severe MR, the indications for surgical correction, usually in association with CABG, are fairly clear-cut.[272] Because of progression of underlying LV dysfunction and resultant structural abnormalities, mitral valve (MV) repair is not always durable. In a randomized trial from the NHLBI Cardiothoracic Surgery Network (CTSN), MV replacement was equivalent to repair in producing reverse LV remodeling and resulted in more durable correction.[273] The decision for MV surgery is based on the anatomic characteristics of the structures forming the MV apparatus, the urgency of the need for surgery, and the severity of LV dysfunction.

A more complex and frequently encountered problem has involved the indications for MV surgery in patients undergoing a CABG procedure in whom the severity of MR is moderate. In a trial comparing CABG alone with CABG plus MV repair in 301 patients with moderate ischemic MR, MV repair reduced the 2-year rate of moderate or severe residual MR (11.2% versus 32.3%; $P < 0.001$) but did not result in a significant difference in the left ventricular end-systolic volume index (LVESVI) or survival at 1 year or 2 years of follow-up[274] (**Fig. 61.19**). Individual treatment decisions require balancing the risks of an increased rate of adverse perioperative events with combined surgery against uncertain benefits of a lower incidence of postoperative moderate or severe MR (**see Chapter 69**).

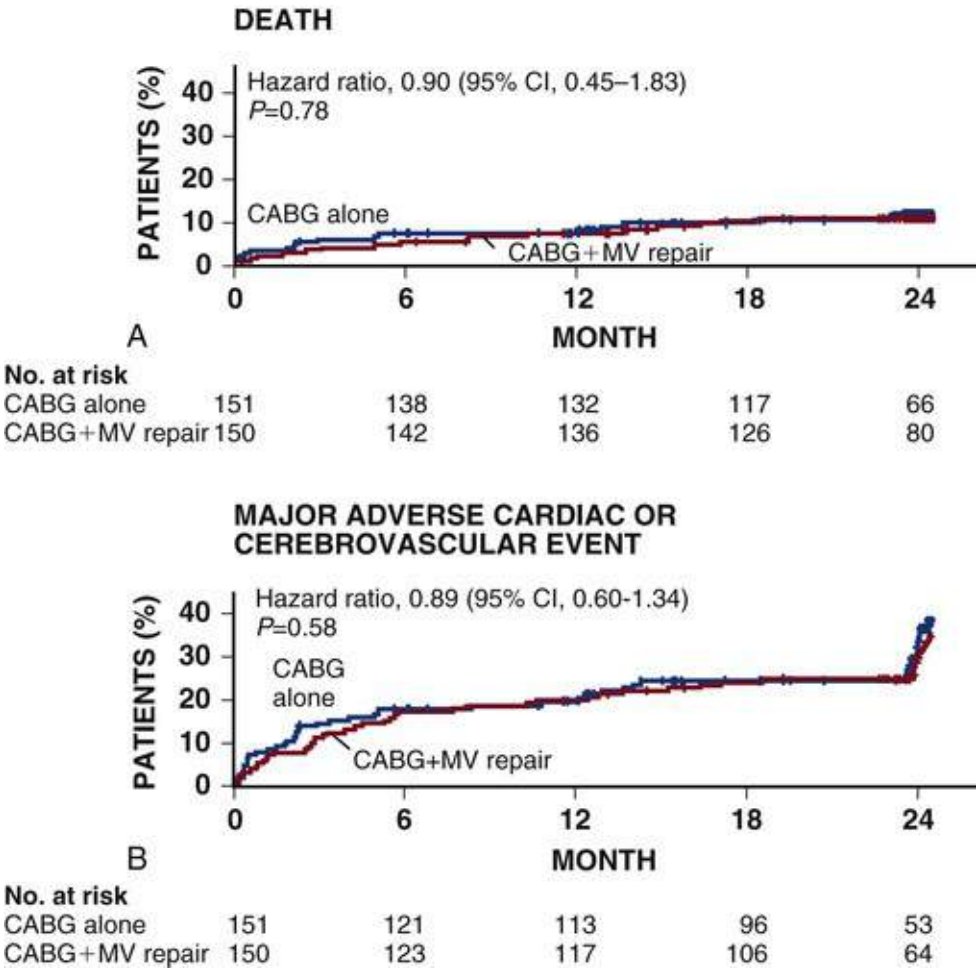


FIGURE 61.19 Outcomes after surgery in patients with moderate ischemic mitral regurgitation (MR). In a randomized trial, 301 patients with moderate ischemic MR undergoing planned coronary-artery bypass grafting (CABG) were allocated to either CABG alone or CABG plus mitral valve (MV) repair. Over 2 years of follow-up, MV repair provided a more durable correction of MR but did not significantly improve survival or reduce major adverse cardiac or cerebrovascular events. (From Michler RE, Smith PK, Parides MK, et al. Two-year outcomes of surgical treatment of moderate ischemic mitral regurgitation. N Engl J Med 2016;374:1932-41.)

In 2015, mortality associated with combined CABG and MV repair was less than 6%.[213] Predictors of early mortality include the need for replacement versus repair (in some but not all series) but also may include other variables, such as age, comorbid conditions, the urgency of surgery, and LV function. Late results are strongly influenced by the pathophysiologic mechanisms underlying MR and are poorer in patients with regurgitation resulting from annular dilation or restrictive leaflet motion than in patients with chordal or papillary muscle rupture. It is encouraging that despite the relatively high operative mortality, long-term outcomes of hospital survivors are excellent. In patients with very poor LV function and dilation of the mitral annulus, MR can intensify the severity of LV failure. In such patients the risk associated with surgery is high and the long-term benefit not established, and a trial of intensive medical therapy, including afterload reduction, beta blockade, and biventricular pacing may be worthwhile (**see Chapters 25 and 27**), because favorable remodeling may reduce the severity of MR without the need for surgery. For patients undergoing CABG, the procedural risks associated with combined CABG and MV repair may outweigh the benefit of reduced MR in those at highest perioperative risk.[272]

Cardiac Arrhythmias.

In some patients with CAD, cardiac arrhythmias are the dominant clinical manifestation of the disease. Various degrees and forms of ventricular ectopic activity are the most common arrhythmias in patients

with CAD, but serious ventricular arrhythmias may be a major component of the clinical findings in other subgroups. The clinical features of arrhythmias and their management in patients with CAD are discussed in **Chapters 35 and 36**.

Nonatheromatous Coronary Artery Disease.

Although atherosclerosis is by far the most common cause of CAD, other conditions may also be responsible. These include congenital abnormalities in the origin or distribution of the coronary arteries (**see Chapters 20 and 75**), the most important of which are anomalous origin of a coronary artery (usually the left) from the pulmonary artery, origin of both coronary arteries from either the right or the left sinus of Valsalva, and coronary arteriovenous fistula.[275] An anomalous origin of the left main coronary artery or right coronary artery from the aorta, with subsequent coursing between the aorta and pulmonary trunk, is a rare and sometimes fatal coronary arterial anomaly. Coronary anomalies are reported to cause between 12% and 19% of sports-related deaths in U.S. high school and college athletes and account for one third of cardiac anomalies in military recruits with nontraumatic sudden death.

Myocardial Bridging.

This cause of systolic compression of the LAD coronary artery is a well-recognized angiographic phenomenon of questionable clinical significance.[276]

Connective Tissue Disorders.

Several inherited connective tissue disorders are associated with myocardial ischemia (**see Chapter 7**), including Marfan syndrome (causing aortic and coronary artery dissection), Hurler syndrome (causing coronary obstruction), Ehlers-Danlos syndrome (causing coronary artery dissection), and pseudoxanthoma elasticum (causing accelerated CAD).

Spontaneous Coronary Artery Dissection.

This is a rare cause of MI and SCD that is much more common in women than men and is often unrecognized or misdiagnosed.[277] Chronic dissection manifesting as HF has been described. Some cases are associated with atherosclerosis. Emerging data suggest that fibromuscular dysplasia may be an important cause of this syndrome, and screening of the renal arteries with angiography or CCTA is recommended. Other contributing factors include estrogen use and hypertension. In the acute phase, a conservative strategy is recommended because PCI failure rates are high, iatrogenic dissection is common, and complete healing may lead to a favorable outcome without intervention.[277] In survivors of spontaneous coronary artery dissection, the subsequent 3-year mortality is approximately 20%, and 10% to 15% of patients have a recurrent dissection.

Coronary Vasculitis and Vasculopathy.

Connective tissue diseases or autoimmune forms of vasculitis, including polyarteritis nodosa, giant cell (temporal) arteritis, or vasculopathy (e.g., scleroderma), can involve the coronary arteries (**see Chapter 94**). Kawasaki disease, a mucocutaneous lymph node syndrome, may cause coronary artery aneurysms and ischemic heart disease in children. Coronary arteritis is seen at autopsy in approximately 20% of patients with rheumatoid arthritis but is rarely associated with clinical manifestations. The incidence of CAD is increased in women with systemic lupus erythematosus (SLE). In patients with SLE, CAD has been attributed to vasculitis, immune complex–mediated endothelial damage, and coronary thrombosis from antiphospholipid antibodies, as well as accelerated atherosclerosis. Antiphospholipid syndrome, characterized by arterial and venous thrombosis and the presence of antiphospholipid antibodies, may be associated with MI, angina, and diffuse LV dysfunction. Luetic (syphilitic) aortitis may also produce myocardial ischemia by causing coronary ostial obstruction.

Takayasu Arteritis.

In rare cases, Takayasu arteritis is associated with angina, MI, and cardiac failure in patients younger than 40 years (**see Chapter 94**). Coronary blood flow may be decreased by involvement of the ostia or proximal segments of the coronary arteries, but disease in distal coronary segments is rare. The average age at the onset of symptoms is 24 years, and the event-free survival rate 10 years after diagnosis is approximately 60%. CCTA has been shown to be useful in detecting involvement of the coronary arteries in Takayasu arteritis.

Postmediastinal Irradiation.

The occurrence of CAD and morbid cardiac events in young individuals after mediastinal irradiation is highly suggestive of a cause-and-effect relationship.[278] Pathologic changes include adventitial scarring and medial hypertrophy with severe intimal atherosclerotic disease. Radiation injury may be latent and may not manifest clinically for many years after therapy. Contributory factors include higher doses than those currently administered and the presence of cardiac risk factors. In patients without risk factors who receive an intermediate total dose of 30 to 40 Gy, the risk for cardiac death and MI is low.

Cardiac Transplantation–Associated Coronary Arteriopathy

See Chapters 28 and 44.

Future Perspectives

Despite Heberden aptly describing “angina” almost two and a half centuries ago, our understanding of the syndrome, its causes, and optimal management continues to evolve. Three major areas are in need of continued investigation. First, the complex and probably heterogeneous causes of myocardial ischemia in the absence of obstructive epicardial coronary disease require continued exploration. Substantial data challenge the paradigm that ischemic heart disease requires critical epicardial coronary atherosclerosis or other structural heart disease that results in dramatically increased myocardial oxygen demand. Preclinical, translational, and clinical epidemiologic data have all demonstrated abnormalities in coronary artery function that may result in myocardial ischemia in the absence of atherosclerotic obstruction. As yet, however, therapies proposed to address this important syndrome appear to be insufficient. Additional insight into the pathobiology of ischemia in these circumstances may lead to new therapeutic directions. Second, although it is clear that an initial approach of guideline-directed medical therapy is the best approach for most patients with SIHD, clinical equipoise remains regarding whether patients with moderate or severe ischemia on noninvasive testing should routinely undergo coronary revascularization in the absence of symptoms that are refractory to medical therapy. Moreover, the role of invasive functional testing of coronary blood flow in decision making regarding coronary revascularization will no doubt continue to evolve. Third, definitive evidence regarding the value of using viability and ischemia assessments to guide the management of patients with SIHD and concomitant severe LV dysfunction remains elusive. Despite our wealth of experience with stable ischemic heart disease, important questions remain unanswered.

Guidelines

Stable Ischemic Heart Disease

David A. Morrow and James A. de Lemos

The American College of Cardiology Foundation and the American Heart Association (ACCF/AHA) published updated guidelines for the diagnosis and management of patients with stable ischemic heart disease (SIHD) in 2012 and a focused update of this guideline in 2014.[1,2] In addition, a new ACCF/AHA guidelines document was published in 2016 providing new recommendations for the duration of dual-antiplatelet therapy (DAPT) for patients with SIHD undergoing percutaneous coronary intervention (PCI).[3] The European Society of Cardiology (ESC) published guidelines for management of stable coronary artery disease in 2013.[4] We refer to the ACCF/AHA guidelines except in cases where the U.S. and European guidelines disagree. The tables and figures reflect only the ACCF/AHA guidelines.

Populations addressed include patients with "ischemic equivalents" such as dyspnea or arm pain with exertion and patients with IHD who have become asymptomatic. Patients with unstable ischemic syndromes are not included in these guidelines (see guidelines summarized in **Chapter 60**).

Overview

The ACCF/AHA guidelines emphasize the importance of a detailed symptom history, focused physical examination, and directed risk factor assessment for patients with chest pain to estimate the probability of IHD before additional testing. For patients without symptoms or findings suggestive of high risk, noninvasive evaluation rather than invasive coronary angiography is recommended (**Fig. 61G.1**). For patients with an intermediate probability of coronary artery disease (CAD), noninvasive testing should be considered to refine the diagnostic assessment of patients. Noninvasive testing is also indicated to inform risk stratification in patients with a high probability of or established SIHD (**Fig. 61G.2**).

J Am Coll Cardiol 2012;60:2564.)

The treatment algorithm recommended by the ACCF/AHA guidelines emphasizes the importance of patient education about CAD, prevention of progression of atherosclerosis through risk factor management, and improvement in health status by treatment of ischemic symptoms (**Fig. 61G.3**). In particular, the patient should be included in decision making such that choices about diagnostic and

therapeutic options are made through a process of shared decision making, with discussion of risks, benefits, and costs to the patient.

Diagnosis

Noninvasive Studies

Resting Electrocardiography

A resting electrocardiogram (ECG) is recommended in patients undergoing evaluation for symptoms who do not have an obvious, noncardiac cause of chest pain. Any of the following abnormalities on the ECG are associated with a poorer prognosis: evidence of previous myocardial infarction (MI); persistent ST-segment depression or T wave inversion (especially in leads V_1 to V_3); left bundle branch block (LBBB), bifascicular block, or high-degree atrioventricular (AV) block; or left ventricular (LV) hypertrophy.[1,2]

Exercise Electrocardiography

Exercise testing is considered most valuable for diagnosis in patients with an intermediate probability of CAD. The ACCF/AHA guidelines recommend exercise ECGs unless the baseline ECG shows abnormalities likely to render the exercise tracing uninterpretable or patients are unable to exercise (**see Fig. 61G.1**). Exercise ECG is also reasonable in patients with a low pretest probability of obstructive CAD who do require testing (**Table 61G.1**). In contrast, the ESC guidelines recommend routine addition of adjunctive imaging if such testing is available with local expertise, regardless of baseline ECG findings. This important difference in guidelines reflects a differing interpretation of the guideline committees regarding the influence of test verification bias on the sensitivity and specificity of the exercise ECG.

Stress Imaging Studies

The ACCF/AHA guidelines recommend stress imaging (exercise or pharmacologic) as opposed to an exercise ECG when the ECG is uninterpretable, such as in (1) patients who have complete LBBB, electronically paced ventricular rhythm, preexcitation syndrome, and other conduction abnormalities; (2) patients who have more than 1 mm of ST-segment depression at rest, including those with LV hypertrophy or taking drugs such as digitalis; and (3) patients who are unable to exercise to a sufficient level for meaningful exercise ECG results. Stress imaging is also reasonable in patients with CAD who have undergone previous revascularization, for whom localizing ischemia is important. It is reasonable also in patients with an intermediate to high pretest probability of obstructive CAD, even those with an interpretable ECG and moderate or better physical functioning (**Table 61G.1**). As previously noted, the ESC guideline recommends more broad use of stress imaging even among patients with interpretable baseline ECGs.

The guidelines specify that exercise stress is preferable to pharmacologic stress when the patient can exercise adequately. **Table 61G.1** summarizes the appropriate indications for stress imaging in patients who are and who are not able to exercise. As with the exercise ECG, these tests are considered most useful for diagnosis in patients with an intermediate probability of disease.

Coronary Computed Tomography Angiography

The ACCF/AHA guidelines indicate that coronary computed tomographic angiography (CCTA; **see Chapter 18**) is reasonable (class IIa) for patients with a low to intermediate pretest probability of CAD who are incapable of exercising or have persistent symptoms after other testing has provided normal or inconclusive results (**Table 61G.1**). CCTA may be reasonable (class IIb) for patients with an intermediate pretest probability of CAD who are capable of exercising. A recent large comparative effectiveness trial demonstrating generally equivalent outcomes for CCTA versus standard stress testing[5] may lead to a stronger recommendation for CCTA in the next update to the SIHD guidelines.

Specific Patient Subsets

Although treadmill ECG testing is less accurate for diagnosis in women than in men, the ACCF/AHA guidelines note that “there currently are insufficient data to justify replacing standard exercise testing with stress imaging in the initial evaluation of women.” In contrast, the ESC guidelines recommend routine adjunctive imaging in women, provided testing is available with local expertise.

Coronary Angiography

In the 2012 ACCF/AHA guidelines, invasive coronary angiography plays a very limited role in the diagnosis of CAD. The guidelines do support coronary angiography for diagnosis in patients with suspected SIHD who (1) have survived sudden death or serious ventricular arrhythmias or (2) have symptoms or findings that suggest high-risk coronary lesions (**see Fig. 61G.1**). Use of invasive coronary angiography for risk assessment and to enable coronary revascularization is discussed next.

Risk Stratification

The ACCF/AHA guidelines emphasize the following four factors that predict survival for patients with CAD: (1) LV function, (2) anatomic extent and severity of coronary atherosclerosis, (3) presence of recent plaque rupture, and (4) the patient's general health and noncoronary comorbidity.

Assessment of Left Ventricular Function and Other Structural Heart Disease

The guidelines consider echocardiographic assessment of LV function and evaluation for myocardial, valvular, or pericardial abnormalities (class I) appropriate in patients with known or suspected IHD and symptoms or signs of heart failure (HF), a history of previous MI, pathologic Q waves on the ECG, complex ventricular arrhythmias, or an undiagnosed heart murmur. Echocardiography may be considered (class IIb) for patients with hypertension or diabetes mellitus (DM) and abnormal findings on an ECG. In contrast, the ESC guidelines recommend routine resting echocardiography in *all* patients (class I) to exclude alternative causes of angina, assess regional wall motion abnormalities, measure LV ejection fraction (EF), and assess diastolic function.

Noninvasive Tests for Ischemia

Noninvasive testing provides valuable information regarding ischemic burden and prognosis and helps identify candidates for coronary revascularization. Standard treadmill exercise testing is recommended in the ACCF/AHA guidelines for assessment of prognosis in all patients who are able to exercise, except those with an uninterpretable ECG (**Table 61G.2**), in whom nuclear myocardial perfusion imaging (MPI) or echocardiography is indicated. Pharmacologic stress imaging is discouraged in patients who are able to exercise.

TABLE 61G.2

Coronary Angiography

In the ACCF/AHA guidelines the decision to proceed to coronary angiography should be based on

symptomatic status and risk estimation derived from clinical data and noninvasive test results. Coronary angiography is a necessary step for the management of patients in whom coronary revascularization is likely to be beneficial because of a high risk for complications with medical therapy alone. Thus the guidelines support coronary angiography in patients with suspected SIHD who (1) have survived sudden death, (2) have signs or symptoms of HF, (3) have a high likelihood of severe IHD and the potential benefits are deemed to exceed the risk, or (4) have persistent symptoms despite an adequate trial of guideline-directed medical therapy (GDMT) (**Table 61G.3; see also Fig. 61G.3**).

TABLE 61G.3

ACCF/AHA Guidelines for Coronary Angiography to Assess Risk in Patients with Known or Suspected Stable Ischemic Heart Disease (SIHD)

COR	INDICATION	LOE
I (indicated)	1. Patients with SIHD who have survived sudden cardiac death or potentially life-threatening ventricular arrhythmia should undergo coronary angiography to assess cardiac risk.	B
	2. Patients with SIHD in whom symptoms and signs of heart failure develop should be evaluated to determine whether coronary angiography should be performed for risk assessment.	B
	3. Coronary angiography is recommended for patients with SIHD whose clinical characteristics and results of noninvasive testing indicate a high likelihood of severe IHD and when the benefits are deemed to exceed risk.	C
IIa (good supportive evidence)	1. Coronary angiography is reasonable to further assess risk in patients with SIHD who have depressed LV function (EF <50%) and moderate-risk criteria on noninvasive testing with demonstrable ischemia.	C
	2. Coronary angiography is reasonable to further assess risk in patients with SIHD and inconclusive prognostic information after noninvasive testing or in patients for whom noninvasive testing is contraindicated or inadequate.	C
	3. Coronary angiography for risk assessment is reasonable for patients with SIHD who have unsatisfactory quality of life because of angina, have preserved LV function (EF >50%), and have intermediate-risk criteria on noninvasive testing.	C
III (no benefit)	1. Coronary angiography for risk assessment is not recommended in patients with SIHD who elect not to undergo revascularization or who are not candidates for revascularization because of comorbid conditions or individual preferences.	B
	2. Coronary angiography is not recommended to further assess risk in patients with SIHD who have preserved LV function (EF >50%) and low-risk criteria on noninvasive testing.	B
	3. Coronary angiography is not recommended to assess risk in patients who are at low risk according to clinical criteria and who have not undergone noninvasive risk testing.	C
	4. Coronary angiography is not recommended to assess risk in asymptomatic patients with no evidence of ischemia on noninvasive testing.	C

COR, Class of recommendation; *LOE,* level of evidence; *EF,* ejection fraction; *LV,* left ventricular.

The ACCF/AHA guidelines conclude that there is no benefit of coronary angiography in patients who are at low risk according to clinical criteria and have not undergone or have no evidence of ischemia on noninvasive testing.

Treatment

The ACCF/AHA guidelines for medical therapy in patients with SIHD are oriented toward preventing death while maximizing health and function. More specific objectives are shown in **Table 61G.4**. Coronary revascularization is recommended in specific patient subsets in whom it has been shown to extend life, but in many settings there are a variety of reasonable options, including GDMT, PCI (**see Chapter 62**), and coronary artery bypass grafting (CABG) (**Fig. 61G.3**). Cost-effectiveness and patient preference are considered important components in decision making.

TABLE 61G.4

ACCF/AHA Goals for Management of Stable Ischemic Heart Disease (SIHD)

1. Reduce premature cardiovascular death.
2. Prevent complications of SIHD that directly or indirectly impair patients' functional well-being, including nonfatal acute myocardial infarction and heart failure.
3. Maintain or restore a level of activity, functional capacity, and quality of life that are satisfactory to the patient.
4. Completely or almost completely eliminate ischemic symptoms.
5. Minimize the cost of health care, in particular by eliminating avoidable adverse effects of tests and treatments and by preventing hospital admissions.

The guidelines identify five complementary strategies: (1) educate patients about the cause, manifestations, and treatment options for IHD; (2) identify and treat conditions that contribute to, worsen, or complicate IHD; (3) modify risk factors for IHD (see next); (4) use evidence-based pharmacologic treatments to improve health status and survival; and (5) use coronary revascularization when there is clear evidence of the potential to improve health status and survival.

Risk Factor Modification

The ACCF/AHA guidelines support lifestyle modifications, including daily physical activity and weight management, for all patients with SIHD (**Table 61G.5**) and also recommend intensive management of risk factors, including hypertension (target blood pressure <140/90 mm Hg), cigarette smoking, diabetes, low-density lipoprotein (LDL) cholesterol, and obesity (**Table 61G.6; see also Table 61G.5**). The 2013 ACCF/AHA cholesterol guidelines[6] support dietary therapy for all patients and high-intensity statin therapy in the absence of contraindications or documented adverse effects for all patients with established coronary heart disease (CHD). For elderly patients age 75 or older, moderate rather than high-dose statin therapy is a reasonable option.

TABLE 61G.5

ACCF/AHA Guidelines for Risk Factor Modification for Patients with Stable Ischemic Heart Disease (SIHD)

COR	INDICATION	LOE
Lipid Management		
I (indicated)	1. Lifestyle modifications, including daily physical activity and weight management, are strongly recommended for all patients with SIHD.	B
	2. Dietary therapy for all patients should include reduced intake of saturated fats (to <7% of total calories), trans fatty acids (to <1% of total calories), and cholesterol (to <200 mg/day).	B
	3. In addition to therapeutic lifestyle changes, high-intensity statin therapy should be prescribed in the absence of contraindications or documented adverse effects. For patients older than 75 years, moderate-intensity statin therapy may be considered.	A
IIa (good supportive evidence)	For patients who do not tolerate statins, LDL cholesterol–lowering therapy with bile acid sequestrants, niacin, or both is reasonable. Ezetimibe or PCSK9 inhibitors are also alternatives.	B
Blood Pressure (BP) Management		
I (indicated)	1. All patients should be counseled about the need for lifestyle modification: weight control, increased physical activity, alcohol moderation, sodium reduction, and emphasis on increased consumption of fresh fruits, vegetables, and low-fat dairy products.	B
	2. In patients with SIHD and a BP of 140/90 mm Hg or higher, antihypertensive drug therapy should be instituted in addition to or after a trial of lifestyle modifications.	A
	3. The specific medications used for the treatment of high BP should be based on specific patient characteristics and may include ACE inhibitors and/or beta-blocking agents, as well as the addition of other drugs such as thiazide diuretics or calcium channel blocking agents if needed to achieve a goal BP of less than 140/90 mm Hg.	B
Physical Activity		
I (indicated)	1. For all patients, clinicians should encourage 30 to 60 minutes of moderate-intensity aerobic activity at least 5 days and preferably 7 days per week, supplemented by an increase in daily lifestyle activities (e.g., walking breaks at work, gardening, household work) to improve cardiorespiratory fitness and move patients out of the least-fit, least-active, high-risk cohort (bottom 20%).	B
	2. For all patients, risk assessment with a physical activity history and/or an exercise test is recommended to guide prognosis and prescription.	B
	3. Medically supervised programs (cardiac rehabilitation) and physician-directed, home-based programs are recommended for at-risk patients at first diagnosis.	A
IIa (good supportive evidence)	It is reasonable for clinicians to recommend complementary resistance training at least 2 days per week.	C
Weight Management		
I (indicated)	1. BMI and/or waist circumference should be assessed at every visit, and clinicians should consistently encourage weight maintenance or reduction through an appropriate balance of lifestyle physical activity, structured exercise, caloric regulation, and formal behavioral programs	B
	2. The initial goal of weight loss therapy should be to reduce body weight by approximately 5% to 10% from baseline. With success, further weight loss can be attempted if indicated.	C
Smoking Cessation		
I (indicated)	Smoking cessation and avoidance of exposure to environmental tobacco smoke at work and home should be encouraged for all patients with SIHD. Follow-up, referral to special programs, and pharmacotherapy are recommended, as is a stepwise strategy for smoking cessation (Ask, Advise, Assess, Assist, Arrange, Avoid).	B
Management of Psychological Factors		
IIa (good supportive evidence)	It is reasonable to consider screening patients with SIHD for depression and to refer or treat when indicated.	B
IIb (weak supportive evidence)	Treatment of depression has not been shown to improve cardiovascular disease outcomes but might be reasonable for its other clinical benefits.	C
Alcohol Consumption		
IIb (weak supportive evidence)	In patients with SIHD who drink alcohol, it might be reasonable for nonpregnant women to have 1 drink (4 oz of wine, 12 oz of beer, or 1 oz of spirits) a day and for men to have 1 or 2 drinks a day unless alcohol is contraindicated (e.g., patients with history of alcohol abuse or dependence, patients with liver disease).	C
Exposure to Air Pollution		
IIa (good supportive evidence)	It is reasonable for patients with SIHD to avoid exposure to increased air pollution to reduce their risk for cardiovascular events.	C

The management of diabetes mellitus in patients with established atherosclerosis is discussed in **Chapter 51**.

TABLE 61G.6

ACCF/AHA Guidelines for Medical Therapy to Prevent Myocardial Infarction (MI) and Death

COR	INDICATION	LOE
Antiplatelet Therapy		
I (indicated)	1. Treatment with aspirin, 75 to 162 mg daily, should be continued indefinitely in the absence of contraindications in patients with SIHD.	A
	2. Treatment with clopidogrel is reasonable when aspirin is contraindicated in patients with SIHD.	B
IIb (weak supportive evidence)	3. Treatment with aspirin, 75 to 162 mg daily, and clopidogrel, 75 mg daily, might be reasonable in certain high-risk patients with SIHD.	B
Beta-Blocking Therapy		
I (indicated)	1. Beta-blocking therapy should be started and continued for 3 years in all patients with normal LV function after MI or ACS.	B
	2. Beta-blocking therapy should be used in all patients with LV systolic dysfunction (EF <40%) and heart failure or previous MI unless contraindicated. (Use should be limited to carvedilol, metoprolol succinate, or bisoprolol, which have been shown to reduce the risk for death.)	A
IIb (weak supportive evidence)	Beta-blocking agents may be considered as chronic therapy for all other patients with coronary or other vascular disease.	C
Renin-Angiotensin-Aldosterone Blocker Therapy		
I (indicated)	1. ACE inhibitors should be prescribed in all patients with SIHD who also have hypertension, diabetes mellitus, LVEF of 40% or less, or CKD unless contraindicated.	A
	2. ARBs are recommended for patients with SIHD who have hypertension, diabetes mellitus, LV systolic dysfunction, or CKD who are intolerant of ACE inhibitors.	A
IIa (good supportive evidence)	1. Treatment with an ACE inhibitor is reasonable in patients with both SIHD and other vascular disease.	B
	2. It is reasonable to use ARBs in other patients who are intolerant of ACE inhibitors.	C
Other Therapies		
III (not indicated)	1. Estrogen therapy is not recommended in postmenopausal women with SIHD with the intent of reducing cardiovascular risk or improving clinical outcomes.	A
	2. Vitamin C, vitamin E, and beta-carotene supplementation is not recommended with the intent of reducing cardiovascular risk or improving clinical outcomes in patients with SIHD.	A
	3. Treatment of elevated homocysteine with folate or vitamins B_6 and B_{12} is not recommended with the intent of reducing cardiovascular risk or improving clinical outcomes in patients with SIHD.	A

COR, Class of recommendation; *LOE,* level of evidence; *ACE,* angiotensin-converting enzyme; *ACS,* acute coronary syndrome; *ARB,* angiotensin receptor blocker; *CKD,* chronic kidney disease; *EF,* ejection fraction; *LV,* left ventricular; *SIHD,* stable ischemic heart disease.

Pharmacologic Therapy

The guidelines emphasize the importance of low-dose aspirin (75 to 162 mg) for patients with SIHD in the absence of contraindications (class I, level of evidence [LOE]: A) (**Table 61G.6**). In the absence of contraindications, beta-blocking agents are recommended for 3 years in all patients after an acute coronary syndrome (ACS) who have normal LV function and indefinitely in all patients with SIHD and LV systolic dysfunction. The evidence for beta blockers as chronic therapy in other patients with SIHD is weaker (class IIb, LOE: C). Absolute contraindications to beta blockers include severe bradycardia, preexisting high degree of AV block, sick sinus syndrome, and decompensated LV failure; relative contraindications include asthma and bronchospastic disease, severe depression, and peripheral vascular disease.

Angiotensin-converting enzyme (ACE) inhibitors are recommended (class I; **Table 61G.6**) for patients with SIHD who also have diabetes, hypertension, chronic kidney disease, and/or LV systolic dysfunction and may be considered in other patients with CAD (class IIa).

The AHA/ACC guidelines recommend beta-blocking agents as initial therapy for relief of symptoms of myocardial ischemia in patients with SIHD (**Table 61G.7**). Long-acting nitrates and/or calcium antagonists (class I) or ranolazine (class IIa) should be used (or added) for symptom control when beta blockers are contraindicated, not tolerated, or ineffective. The ESC guidelines provide different recommendations for antianginal drug selection, recommending beta blockers and/or calcium antagonists as first-line therapy (class I), with long-acting nitrates, ivabradine, or ranolazine (class IIa) or

trimetazidine (class IIb) considered as second-line additions. Annual influenza vaccination is recommended for patients with SIHD.

TABLE 61G.7

ACCF/AHA Guidelines for Medical Therapy for Relief of Symptoms

COR	INDICATION	LOE
I (indicated)	1. Beta-adrenergic blocking agents (beta blockers) should be prescribed as initial therapy for relief of symptoms in patients with SIHD.	B
	2. Calcium channel–blocking agents* or long-acting nitrates should be prescribed for relief of symptoms when beta blockers are contraindicated or cause unacceptable side effects in patients with SIHD.	B
	3. Calcium channel–blocking agents* or long-acting nitrates, in combination with beta blockers, should be prescribed for relief of symptoms when initial treatment with beta blockers is unsuccessful in patients with SIHD.	B
	4. Sublingual nitroglycerin or nitroglycerin spray is recommended for immediate relief of angina in patients with SIHD.	B
IIa (good supportive evidence)	1. Treatment with a long-acting nondihydropyridine calcium channel blocker (verapamil or diltiazem) instead of a beta blocker as initial therapy for relief of symptoms is reasonable in patients with SIHD.	B
	2. Ranolazine can be useful when prescribed as a substitute for a beta blocker for relief of symptoms in patients with SIHD if initial treatment with beta blockers leads to unacceptable side effects or is ineffective or if initial treatment with beta blockers is contraindicated.	B
	3. Ranolazine in combination with beta blockers can be useful when prescribed for relief of symptoms when initial treatment with beta blockers is not successful in patients with SIHD.	A
IIb weak supportive evidence)	1. Enhanced external counterpulsation may be considered for relief of refractory angina in patients with SIHD.	B
	2. Spinal cord stimulation may be considered for relief of refractory angina in patients with SIHD.	C
III (not indicated)	Acupuncture should not be used for the purpose of improving symptoms or reducing cardiovascular risk in patients with SIHD.	C

*Short-acting dihydropyridine calcium antagonists should be avoided.

COR, Class of recommendation; *LOE,* level of evidence.

Revascularization

The ACCF/AHA guidelines for revascularization focus on improvement of survival in patients with SIHD and high clinical risk for mortality with GDMT (**Fig. 61G.4 and Table 61G.8**) and in those who have inadequate control of symptoms and quality of life despite GDMT (**Table 61G.9; see also Fig. 61G.4**). Recommendations include CABG for patients with significant left main CAD, triple-vessel CAD, or CAD involving the proximal left anterior descending (LAD) plus one other major coronary artery. CABG is reasonable (class IIa) for patients with double-vessel CAD who have evidence of severe or extensive myocardial ischemia or mild to moderate LV systolic dysfunction with viable myocardium in the region of intended revascularization. CABG is given preference over PCI (class IIa) in patients with complex three-vessel disease and those with DM.

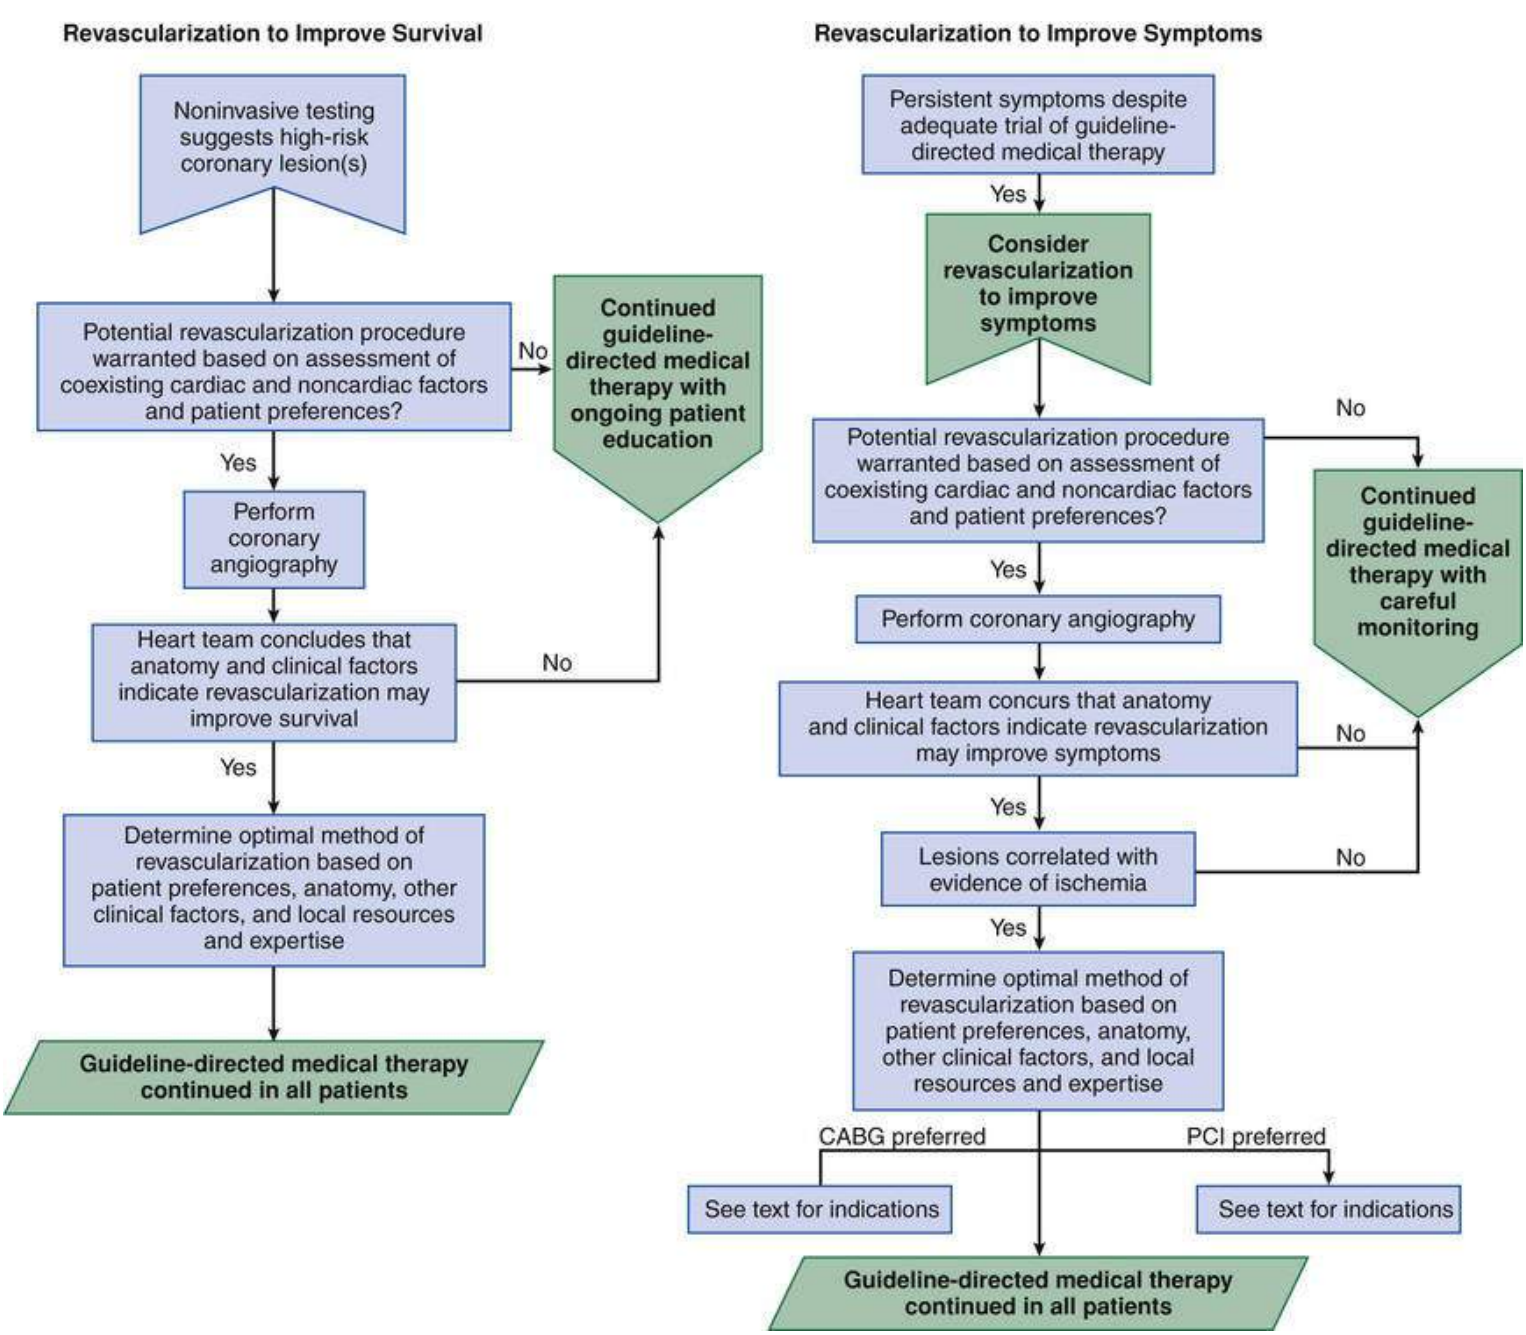

FIGURE 61G.4 Algorithm for revascularization to improve survival (*left*) and symptoms (*right*) in patients with stable ischemic heart disease. The algorithms do not represent a comprehensive list of recommendations (see full guideline text for all recommendations. CABG, Coronary artery bypass graft surgery; PCI, percutaneous coronary intervention. (From Fihn SD, Gardin JM, Abrams J, et al. 2012 ACCF/AHA/ACP/AATS/PCNA/SCAI/STS guideline for the diagnosis and management of patients with stable ischemic heart disease. A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, and the American College of Physicians, American Association for Thoracic Surgery, Preventive Cardiovascular Nurses Association, Society for Cardiovascular Angiography and Interventions, and Society of Thoracic Surgeons. J Am Coll Cardiol 2012;60:2564.)

TABLE 61G.8

ACCF/AHA Guidelines for Revascularization to Improve Survival Versus Medical Therapy in Patients with Stable Ischemic Heart Disease (SIHD)

ANATOMIC SETTING	COR	RECOMMENDATION	LOE
Unprotected Left Main or Complex Coronary Artery Disease (CAD)			
CABG and PCI	I	Heart team approach	C
CABG and PCI	IIa	Calculation of STS and SYNTAX Scores	B
Unprotected Left Main			
CABG	I		B
PCI	IIa	For SIHD when both the following are present: 1. Anatomic conditions associated with a low risk for PCI procedural complications and a high likelihood of a good long-term outcome 2. Clinical characteristics that predict a significantly increased risk for adverse surgical outcomes	B
	IIb	For SIHD when both the following are present: 1. Anatomic conditions associated with a low to intermediate risk for PCI procedural complications and an intermediate to high likelihood of a good long-term outcome 2. Clinical characteristics that predict increased risk for adverse surgical outcomes (e.g., STS-predicted operative mortality >2%)	B
	III	For SIHD in patients (versus performing CABG) with unfavorable anatomy for PCI and who are good candidates for CABG	B
Three-Vessel CAD with or Without Proximal Left Anterior Descending CAD			
CABG	I		B
	I	CABG is generally recommended in preference to PCI to improve survival in patients with diabetes mellitus and three-vessel CAD, particularly if a LIMA graft can be anastomosed to the LAD, provided the patient is a good candidate for surgery.	
	IIa	It is reasonable to choose CABG over PCI in patients with complex three-vessel CAD (e.g., SYNTAX score ≥22) who are good candidates for CABG.	B
PCI	IIb		B
Two-Vessel CAD with Proximal Left Anterior Descending CAD			
CABG	I		B
CABG	I	CABG is generally recommended in preference to PCI to improve survival in patients with diabetes mellitus and complex two-vessel CAD with proximal LAD involvement, particularly if a LIMA graft can be anastomosed to the LAD, provided the patient is a good candidate for surgery.	B
PCI	IIb		B
Two-Vessel CAD Without Proximal Left Anterior Descending CAD			
CABG	IIa	With extensive ischemia	B
	IIb	Without extensive ischemia	C
PCI	IIb		B
One-Vessel Proximal Left Anterior Descending CAD			
CABG	IIa	With LIMA	B
PCI	IIb		B
One-Vessel CAD Without Proximal Left Anterior Descending CAD			
CABG	III	Harm	B
PCI	III	Harm	B
Left Ventricular Dysfunction			
CABG	IIa	EF of 35% to 50%	B
CABG	IIb	EF <35% without significant left main disease	B
PCI	N/A	Insufficient data	
Survivors of Sudden Cardiac Death with Presumed Ischemia-Mediated Ventricular Tachycardia			
CABG	I		B
PCI	I		C
No Anatomic or Physiologic Criteria for Revascularization			
CABG	III	Harm	B
PCI	III	Harm	B

COR, Class of recommendation; *LOE,* level of evidence; *CABG,* coronary artery bypass grafting; *EF,* ejection fraction; *LAD,* left anterior descending coronary artery; *LIMA,* left internal mammary artery; *N/A,* not applicable; *PCI,* percutaneous coronary intervention; *STS,* Society of Thoracic Surgeons; *SYNTAX,* Synergy between PCI with Taxus and Cardiac Surgery.

TABLE 61G.9

ACCF/AHA Guidelines for Revascularization to Improve Symptoms in Patients with Significant Anatomic (>50% Left Main or >70% Non–Left Main Coronary Artery Disease) or Physiologic (Fractional Flow Reserve <0.80) Coronary Artery Stenoses

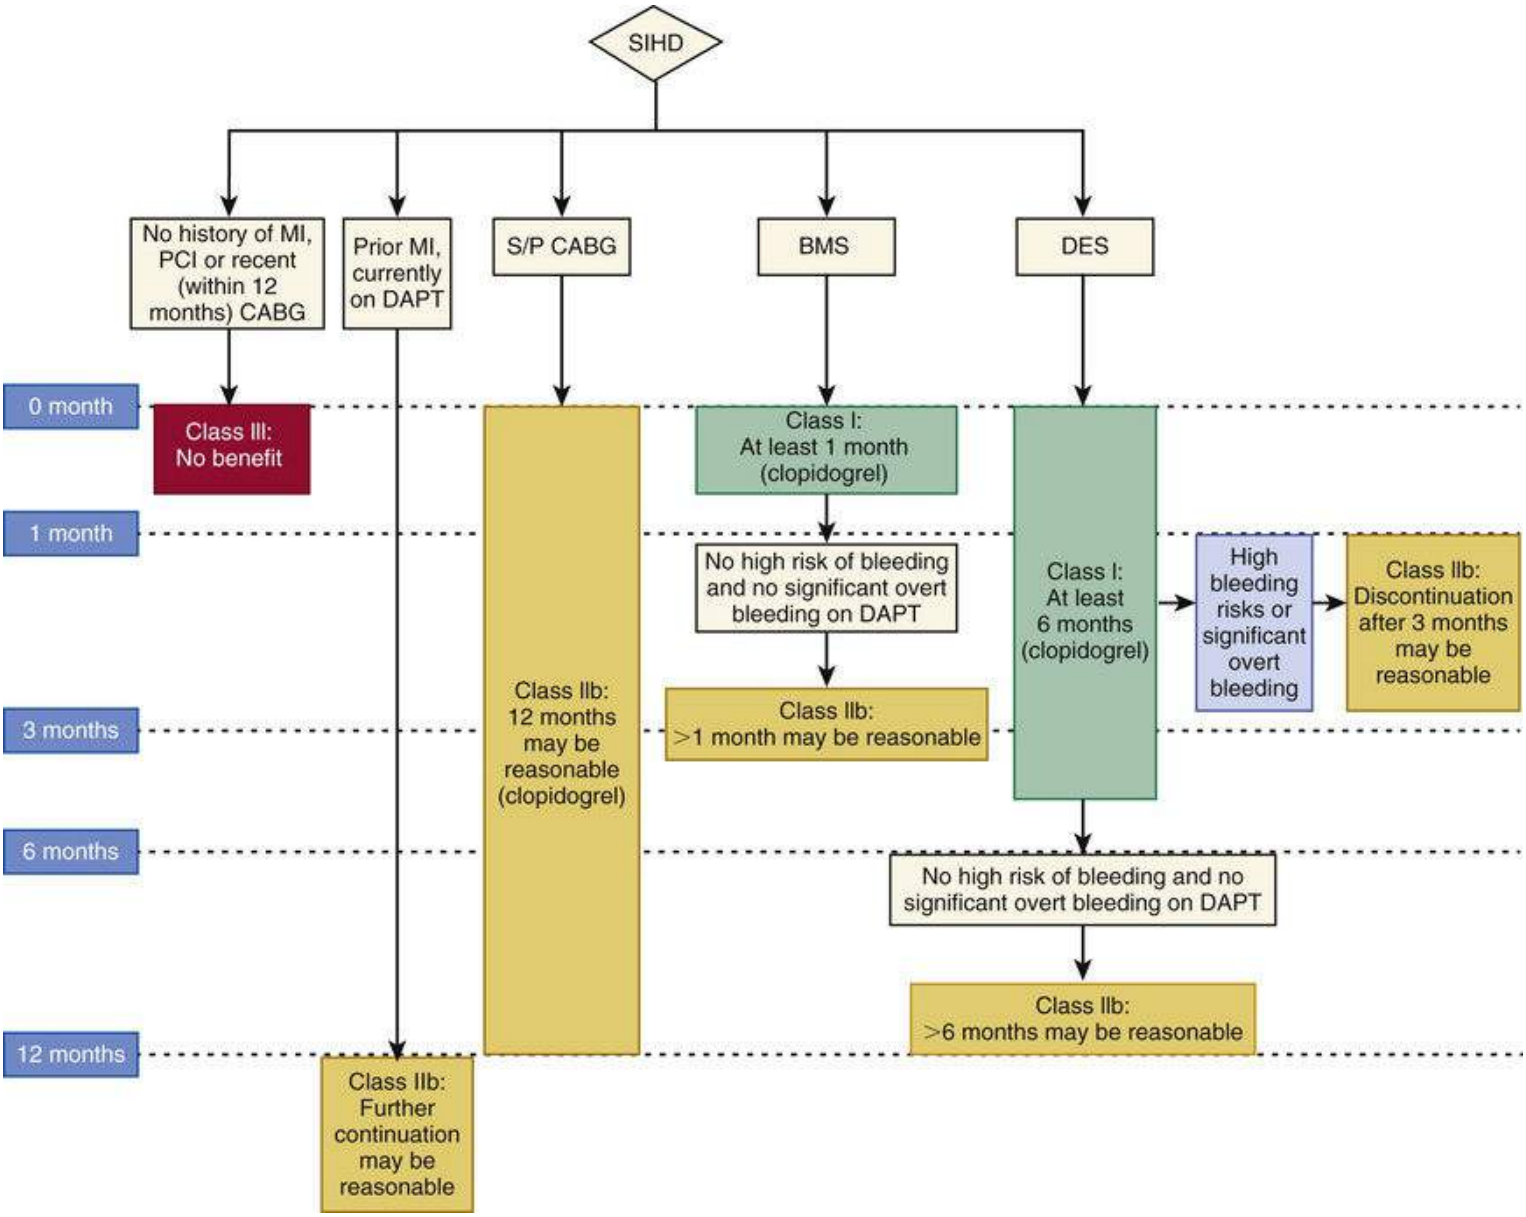
CLINICAL SETTING	RECOMMENDATION		LOE
≥1 significant stenosis amenable to revascularization and unacceptable angina despite GDMT	I	CABG or PCI	A
≥1 significant stenoses and unacceptable angina in whom GDMT cannot be implemented because of medication contraindications, adverse effects, or patient preferences	IIa	CABG or PCI	C
Previous CABG with ≥1 significant stenosis associated with ischemia and unacceptable angina despite GDMT	IIa	PCI	C
	IIb	CABG	C
Complex three-vessel CAD (e.g., SYNTAX score ≥22) with or without involvement of the proximal left anterior descending coronary artery and a good candidate for CABG	IIa	CABG preferred over PCI	B
No anatomic or physiologic criteria for revascularization	III	Neither CABG nor PCI	C

LOE, Level of evidence; *CABG,* coronary artery bypass grafting; *GDMT,* guideline-directed medical therapy; *PCI,* percutaneous coronary intervention; *SYNTAX,* Synergy between PCI with Taxus and Cardiac Surgery.

The ACCF/AHA guidelines discourage the use of PCI or CABG for single- or double-vessel CAD without significant involvement of the proximal LAD artery unless lifestyle limiting angina remains after an adequate trial of GDMT, particularly if noninvasive testing data indicate that they have only a small area of viable myocardium or do not have extensive ischemia or reduced LVEF (**Tables 61G.8 and 61G.9**).

Dual-Antiplatelet Therapy After PCI for SIHD

The 2016 ACCF/AHA guideline update on DAPT for patients with CAD[3] represents a substantial change from previous guidelines, in that different durations of DAPT are now recommended for patients undergoing PCI for SIHD than for those undergoing PCI for ACS. For SIHD treated with drug-eluting stents (DES), the recommended duration of therapy has been shortened to at least 6 months (class I), with even shorter durations (a least 3 months) reasonable for patients at high bleeding risk (class IIb) and longer durations (>6 months) reasonable for selected patients at low bleeding risk who have done well for the initial 6-month period (class IIb) (**eFig. 61G.1**). For patients receiving bare metal stents (BMS), the recommended duration of therapy is at least 1 month (class I), with longer durations reasonable for patients at low bleeding risk (class IIb). For patients with ACS, the recommended duration of DAPT remains at least 12 months (class I) in the absence of high bleeding risk. Also, a class IIb recommendation supports extending the duration of DAPT beyond 12 months from PCI for ACS patients at low risk for bleeding who had no overt bleeding during the initial 12-month course of DAPT.



EFIGURE 61G.1 Treatment algorithm for duration of P2Y12 inhibitor therapy in patients with stable ischemic heart disease (SIHD), without acute coronary syndrome (ACS) within the past several years. Colors correspond to class of recommendation. Patients with a history of ACS >1 year prior who have since remained free of recurrent ACS are considered to have transitioned to SIHD. Clopidogrel is the only currently used $P2Y_{12}$ inhibitor studied in patients with SIHD undergoing percutaneous coronary intervention (PCI). Aspirin therapy is almost always continued indefinitely in patients with coronary artery disease. High bleeding risk denotes those who have or develop a high risk of bleeding (e.g., treatment with oral anticoagulant therapy) or are at increased risk of severe bleeding complication (e.g., major intracranial surgery). BMS, Bare metal stent; CABG, coronary artery bypass graft surgery; DES, drug-eluting stent; Hx, history; MI, myocardial infarction; S/P, status post. (From Levine GN, Bates ER, Bittl JA, et al. 2016 ACC/AHA guideline focused update on duration of dual antiplatelet therapy in patients with coronary artery disease. A report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. An update of the 2011 ACCF/AHA/SCAI guideline for percutaneous coronary intervention, 2011 ACCF/AHA guideline for coronary artery bypass graft surgery, 2012 ACC/AHA/ACP/AATS/PCNA/SCAI/STS guideline for the diagnosis and management of patients with stable ischemic heart disease, 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction, 2014 AHA/ACC guideline for the management of patients with non-ST-elevation acute coronary syndromes, and 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery. Circulation 2016;134:e123-55.)

Patient Follow-Up

The ACCF/AHA guidelines recommend that patients with SIHD have follow-up evaluations at least annually for assessment of symptoms and clinical function, surveillance of complications of SIHD,

monitoring of cardiac risk factors, and assessment of the adequacy of and adherence to lifestyle interventions and GDMT (**Table 61G.10**). Assessment of LVEF is recommended for patients with SIHD and new or worsening HF or evidence of intervening MI. The guidelines urge restraint in the use of routine testing in the follow-up of patients with SIHD if they have not had a change in clinical status (**Table 61G.11**).

Percutaneous Coronary Intervention

Laura Mauri, Deepak L. Bhatt

The use of percutaneous coronary intervention (PCI) to treat ischemic coronary artery disease (CAD) has expanded dramatically over the past three decades. In the absence of left main or complex multivessel CAD, PCI is the preferred method of revascularization in the United States for most patients with ischemic CAD. The estimated 600,000 PCI procedures performed annually in the United States exceed the number of coronary artery bypass graft (CABG) procedures.[1] Over the past several years, however, the growth of PCI has slowed because of the effectiveness of risk factor modification, prevention of restenosis with drug-eluting stents, and a better understanding of the patients who will benefit from revascularization.[2] The number of PCIs is expected to grow modestly (1% to 5%) over the next decade as a result of the aging U.S. population and an increased frequency of obesity and diabetes. Other key enablers of the expanded use of PCI in patients with complex CAD include improvements in equipment design (e.g., catheters with lower profile and enhanced deliverability), development of adjunctive pharmacologic strategies (e.g., adenosine diphosphate [ADP] receptor antagonists and direct thrombin inhibitors) to improve safety, and better hemodynamic support devices in “ultrahigh”-risk patients. Additionally, some types of CAD previously difficult to treat with PCI (e.g., left main disease, chronic total occlusions) have benefited from advances in technology and clinical studies that demonstrate good safety and efficacy in select patients.

This chapter reviews the indications and clinical considerations for the selection of patients for PCI; discusses the current array of coronary devices, antithrombotic therapy, vascular access approaches, and vascular closure devices used for PCI; details the short- and long-term outcomes of PCI; and summarizes the requirements for operator and institutional proficiency.

Coronary balloon angioplasty, or percutaneous transluminal coronary angioplasty (PTCA), was first performed by Andreas Gruentzig in 1977 with a fixed-wire balloon catheter. The procedure was initially limited to the fewer than 10% of patients with symptomatic CAD who had a single, focal, noncalcified lesion in a proximal coronary vessel. As equipment design and operator experience evolved over the next decade, the use of PCI expanded to encompass an increasing spectrum of coronary anatomy, including multivessel CAD, total occlusions, diseased saphenous vein grafts, and acute ST-segment elevation myocardial infarction (STEMI) (**see Chapter 59**). Two limitations prevented the widespread use of balloon angioplasty for CAD: abrupt closure of the treated vessel occurred in 5% to 8% of cases and required emergency CABG in 3% to 5%, and restenosis resulted in recurrence of symptoms in 30% of patients within the following year.

New coronary devices were developed in the late 1980s to overcome the limitations associated with balloon angioplasty. Coronary stents act as a scaffold on the inner arterial wall to prevent early and late vascular remodeling. Rotational atherectomy ablates calcific atherosclerotic plaque and was developed as stand-alone therapy for nondilatable coronary stenoses or for use in combination with coronary stents following the ablation of calcific plaque. By the early 2000s, several devices had been developed to protect the distal circulation from atherothrombotic embolization (i.e., embolic protection devices). Aspiration and thrombectomy catheters were developed to remove medium and large thrombi from within the coronary artery, thereby preventing distal embolization. The term *percutaneous coronary intervention* now encompasses the broad array of balloons, stents, and adjunctive devices required to perform safe and effective percutaneous revascularization in complex coronary artery lesions.

Indications

Clinical Presentations

The major value of percutaneous or surgical coronary revascularization is relief of the symptoms and signs of ischemic CAD (**see Chapters 59 and 61** and PCI Guidelines at the end of this chapter). PCI reduces the risk for mortality and subsequent myocardial infarction (MI) compared with medical therapy in patients with acute coronary syndromes (ACS). Optimal medical therapy (OMT) appears to be as effective as PCI in reducing death and MI in patients with stable angina, although relief of symptoms and improvement of ischemia are better with PCI. Greater than 5% improvement in the ischemic burden is achieved more often with PCI, and the magnitude of the residual ischemia correlates with less frequent death and MI. Further studies comparing the use of coronary arteriography and PCI in patients with moderate degrees of myocardial ischemia are ongoing (e.g., ISCHEMIA, International Study of Comparative Health Effectiveness with Medical and Invasive Approaches),[3] and recent randomized trials requiring physiologic evidence of ischemia, as measured by fractional flow reserve (FFR), have identified a benefit of PCI over medical therapy in preventing urgent revascularization.[4] Irrespective of the indication for revascularization, PCI should be coupled with OMT after the procedure, such as control of hypertension and diabetes, exercise, and smoking cessation (**see Chapter 45**). Lipid management, particularly statin use, is also an important component of OMT.

Compared with PCI alone, CABG is associated with a late mortality benefit in certain high-risk medical and anatomic subsets, such as patients with left main disease, three-vessel CAD, and extensive markers of higher anatomic risk for PCI, such as determined by a SYNTAX (Synergy Between PCI with TAXUS and Cardiac Surgery) score,[5] or patients with diabetes and significant multivessel disease.[6] These benefits are manifested beyond 1 year after treatment and for up to 5 years of follow-up, but the early periprocedural risks, particularly for stroke, are higher with CABG, and patients have a longer in-hospital recovery period. The risks and benefits associated with coronary revascularization therefore need careful review with the patient and family, and the relative options of PCI, CABG, or OMT should be discussed before performing these procedures. Patients with left main or multivessel disease benefit from joint consultation with a cardiac surgeon, an interventional cardiologist, and the referring cardiologist, and consideration of patient preferences in weighing diverse factors is valuable. A task force of the American College of Cardiology (ACC) and American Heart Association (AHA) has published guidelines for the performance of PCI and CABG procedures,[7-9] and a multispecialty writing committee has developed appropriate use criteria for revascularization in several clinical and lesion-specific subsets (see later, PCI Guidelines).[10,11]

Asymptomatic or Minimally Symptomatic Patients.
Asymptomatic patients or those who have only mild symptoms are generally best treated with medical therapy unless one or more high-grade lesions subtend a moderate to large area of viable myocardium, the patient prefers to maintain a very active lifestyle or has a high-risk occupation, and the procedure can be performed with a high chance of success and low likelihood of complications.[11] Patients who are minimally symptomatic or asymptomatic should not undergo coronary revascularization if only a small area of myocardium is at risk, if no objective evidence of ischemia can be detected, or if the likelihood of success is low or the chance of complications is high.[10]

Patients with Moderate to Severe Angina (see Chapter 61).
Patients with Canadian Cardiovascular Society (CCS) class III angina, particularly those who are refractory to medical therapy, can benefit from coronary revascularization, provided that the lesion subtends a moderate to large area of viable myocardium, as determined by noninvasive testing.[8] Patients with recurrent symptoms while receiving medical therapy are candidates for revascularization even if they have a higher risk for an adverse outcome with revascularization. Patients with class III symptoms should not undergo revascularization without noninvasive evidence of myocardial ischemia or a trial of medical therapy, particularly if only a small region of myocardium is at risk, the likelihood of success is low, or the chance of complications is high.[10]

Patients with Unstable Angina, NSTEMI, and STEMI (see Chapters 59 and 60).
Cardiac catheterization and coronary revascularization in moderate- to high-risk patients with unstable angina (UA) or non–ST-segment elevation MI (NSTEMI) may improve mortality and reduce the rate of reinfarction.[12] In a meta-analysis of seven trials with 8375 patients monitored for up to 2 years, the all-cause mortality rate was 4.9% in the early invasive group versus 6.5% in the conservative group (risk ratio [RR], 0.75; $P = 0.001$). The 2-year incidence of nonfatal MI was 7.6% in the invasive group and 9.1% in the conservative group (RR, 0.83; $P = 0.012$). At a mean of 13 months of follow-up, rehospitalization for UA was reduced as well (RR, 0.69; $P < 0.0001$). Current guidelines suggest that an early invasive strategy should be pursued in patients with recurrent ischemia despite therapy, elevated troponin levels, new ST-segment depression, new or worsening symptoms of heart failure (HF), depressed left ventricular (LV) function, hemodynamic instability, sustained ventricular tachycardia (VT), or a recent PCI or CABG procedure.[12]

Specific clinical recommendations pertain to patients with STEMI, including primary PCI, rescue PCI, facilitated PCI, and PCI following successful thrombolysis[13] (see Guidelines). Timely PCI in patients with STEMI improves survival over that achieved with medical therapy, provided that it is performed by a physician who routinely performs PCI, and that the hospital has sufficient PCI volume to support its proficiency. Patients with cardiogenic shock or severe HF also benefit from primary PCI, regardless of their age at initial evaluation.

Left Main and Three-Vessel Coronary Artery Disease

The SYNTAX trial randomly assigned 1800 patients with multivessel disease ($n = 1709$) or left main disease to PCI with a drug-eluting stent (DES) versus CABG.[2] Complete revascularization was the goal for both study groups, and the average number of treated vessels and stents in patients undergoing PCI for left main or multivessel disease was 3.6 lesions and 4.6 stents. One-year outcomes did not differ between the PCI and CABG groups in all-cause mortality or MI. However, rates of major adverse cardiovascular or cerebrovascular events (MACCE) were significantly higher with PCI, mainly attributable to the significantly higher rates of target lesion revascularization in the PCI group. Five-year outcomes were similar to these findings, with no significant difference in all-cause mortality, but a persistently elevated rate of target lesion revascularization was associated with PCI, as was MI.[5] These findings were based on the SYNTAX score, an angiographic grading system to quantify the complexity of PCI (**see Chapter 20**). With low scores (≤22), there was no significant difference in the primary outcome between PCI and CABG patients, but with intermediate or with high scores (>33), MACCE rates were lower with CABG.

Patients with Diabetes Mellitus

The largest trial to date devoted to studying outcomes after revascularization in patients with diabetes

mellitus (DM) and multivessel disease is FREEDOM (Future Revascularization Evaluation in Patients with Diabetes Mellitus: Optimal Management of Multivessel Disease), a randomized controlled trial (RCT) that compared the outcomes of PCI and CABG in patients with DM and multivessel disease.[6] In this trial, diabetic patients requiring revascularization with angiographically proven multivessel disease and lesions amenable to either PCI or CABG were randomly assigned to complete coronary revascularization with one of these techniques. The primary outcome (all-cause mortality, nonfatal MI, or nonfatal stroke) at 5 years was worse in patients treated with PCI than in those who underwent CABG (26.6% versus 18.7%; $P = 0.005$). Considering individual components of the primary outcome, there was a significantly increased long-term risk for all-cause mortality and nonfatal MI with PCI as opposed to CABG. CABG, however, was associated with an increased risk for nonfatal stroke, and the severity of strokes in the CABG group was twice as likely to disable a patient severely as were strokes occurring in the PCI group.

The results of the FREEDOM trial have largely validated smaller studies, subgroup analyses, and meta-analyses attempting to compare methods of revascularization in diabetic patients with multivessel disease. The CARDia (Coronary Artery Revascularization in Diabetes) randomized trial compared PCI with CABG; although smaller in size, it was dedicated to patients with DM, and a significant fraction had multivessel disease.[14] The trial lacked sufficient power to compare mortality. As in the FREEDOM trial, however, CARDia revealed an increased risk for stroke in the CABG group. Similarly, even though most patients were treated with DESs in this trial, the need for repeated revascularization procedures was significantly increased with PCI.

Patients Without Options for Revascularization

Patients with substantial angina but who are poor candidates for conventional revascularization have limited therapeutic options. These patients generally either have occlusion of a single proximal vessel that subtends a large amount of myocardium or have undergone one or more previous CABG operations with stenoses or occlusions of the saphenous vein grafts (SVGs), which are poorly suited for conventional repeated revascularization. “Limited-option” patients account for approximately 4% to 12% of those undergoing coronary angiography; a larger group (20% to 30%) of patients have incomplete revascularization because the coronary anatomy is unsuitable for surgical or percutaneous techniques. Better techniques and equipment for crossing chronic total occlusions have helped some of these patients (see later). Antianginal medications such as ranolazine may also be particularly useful in this subset (**see Chapter 61**).

Patient-Specific Considerations

Assessment of the potential risks and benefits of PCI must address five fundamental patient-specific risk factors: extent of jeopardized myocardium, baseline lesion morphology, underlying cardiac function (e.g., LV function, rhythm stability, coexisting valvular heart disease), presence of renal dysfunction, and preexisting medical comorbid conditions that may place the patient at higher risk for PCI. Each of these factors contributes independently to the risks and benefits attributable to PCI. Proper planning for a PCI procedure requires careful attention to each of these factors.

Extent of Jeopardized Myocardium

The proportion of viable myocardium subtended by the treated coronary artery is the principal

consideration in assessing the acute risk associated with the PCI procedure. PCI interrupts coronary blood flow for a period of seconds to minutes, and the ability of patients to hemodynamically tolerate a sustained coronary occlusion depends on both the extent of "downstream" viable myocardium and the presence and grade of collaterals to the ischemic region. Although the risk for abrupt closure has been reduced substantially with the availability of coronary stents, when other procedural complications develop—such as a large side branch occlusion, distal embolization, perforation, or no-reflow—rapid clinical deterioration may occur that is proportionate to the extent of jeopardized myocardium. In the unlikely event that out-of-hospital stent thrombosis develops, the clinical sequelae of the episode are related to the extent of myocardium subtended by the occluded stent. Predictors of cardiovascular collapse with a failed PCI include the magnitude of myocardium at risk, the severity of the baseline stenosis, multivessel CAD, and the presence of diffuse disease.

Complete Versus Ischemia-Targeted Intervention for Multivessel Disease

The treatment approaches for PCI and CABG compared in randomized trials have essentially all focused on the strategy of complete revascularization. Data supporting complete revascularization of all angiographic lesions during treatment of multivessel disease with PCI or CABG have been observational (nonrandomized) and thus limited by selection bias in that patients in whom full revascularization is feasible are also those who are at lower risk for procedural and future adverse events. The concept of targeted treatment of vessels with only physiologically significant—not just angiographically significant—stenosis may be one that allows improved outcomes in patients with multivessel disease being treated with either PCI or CABG.

The FFR technique involves placement of a pressure wire across a potentially significant lesion, and under conditions of maximal coronary blood flow, the ratio of pressure distal to versus proximal to a lesion or series of sequential lesions is measured in a given artery (**Fig. 62.1**) (**see Chapters 57 and 61**). In contrast to traditional angiography, which can provide only an anatomic evaluation, FFR provides a functional assessment of the presence of a reduction in flow that correlates well with ischemia as detected by nuclear scintigraphy. The FAME (Fractional Flow Reserve versus Angiography for Multivessel Evaluation) trial compared angiography with FFR guidance for selection of lesions during DES PCI in more than 1000 patients.[15] Only lesions with an FFR of 0.8 or less were considered to warrant PCI in the FFR arm. FFR guidance resulted in fewer overall stented lesions, and a 2-year analysis revealed significantly reduced mortality or MI with the use of FFR versus pure angiographic guidance, thus corroborating not only the simple procedural benefit of FFR but also the morbidity and mortality advantages of stenting across physiologically relevant lesions.[16]

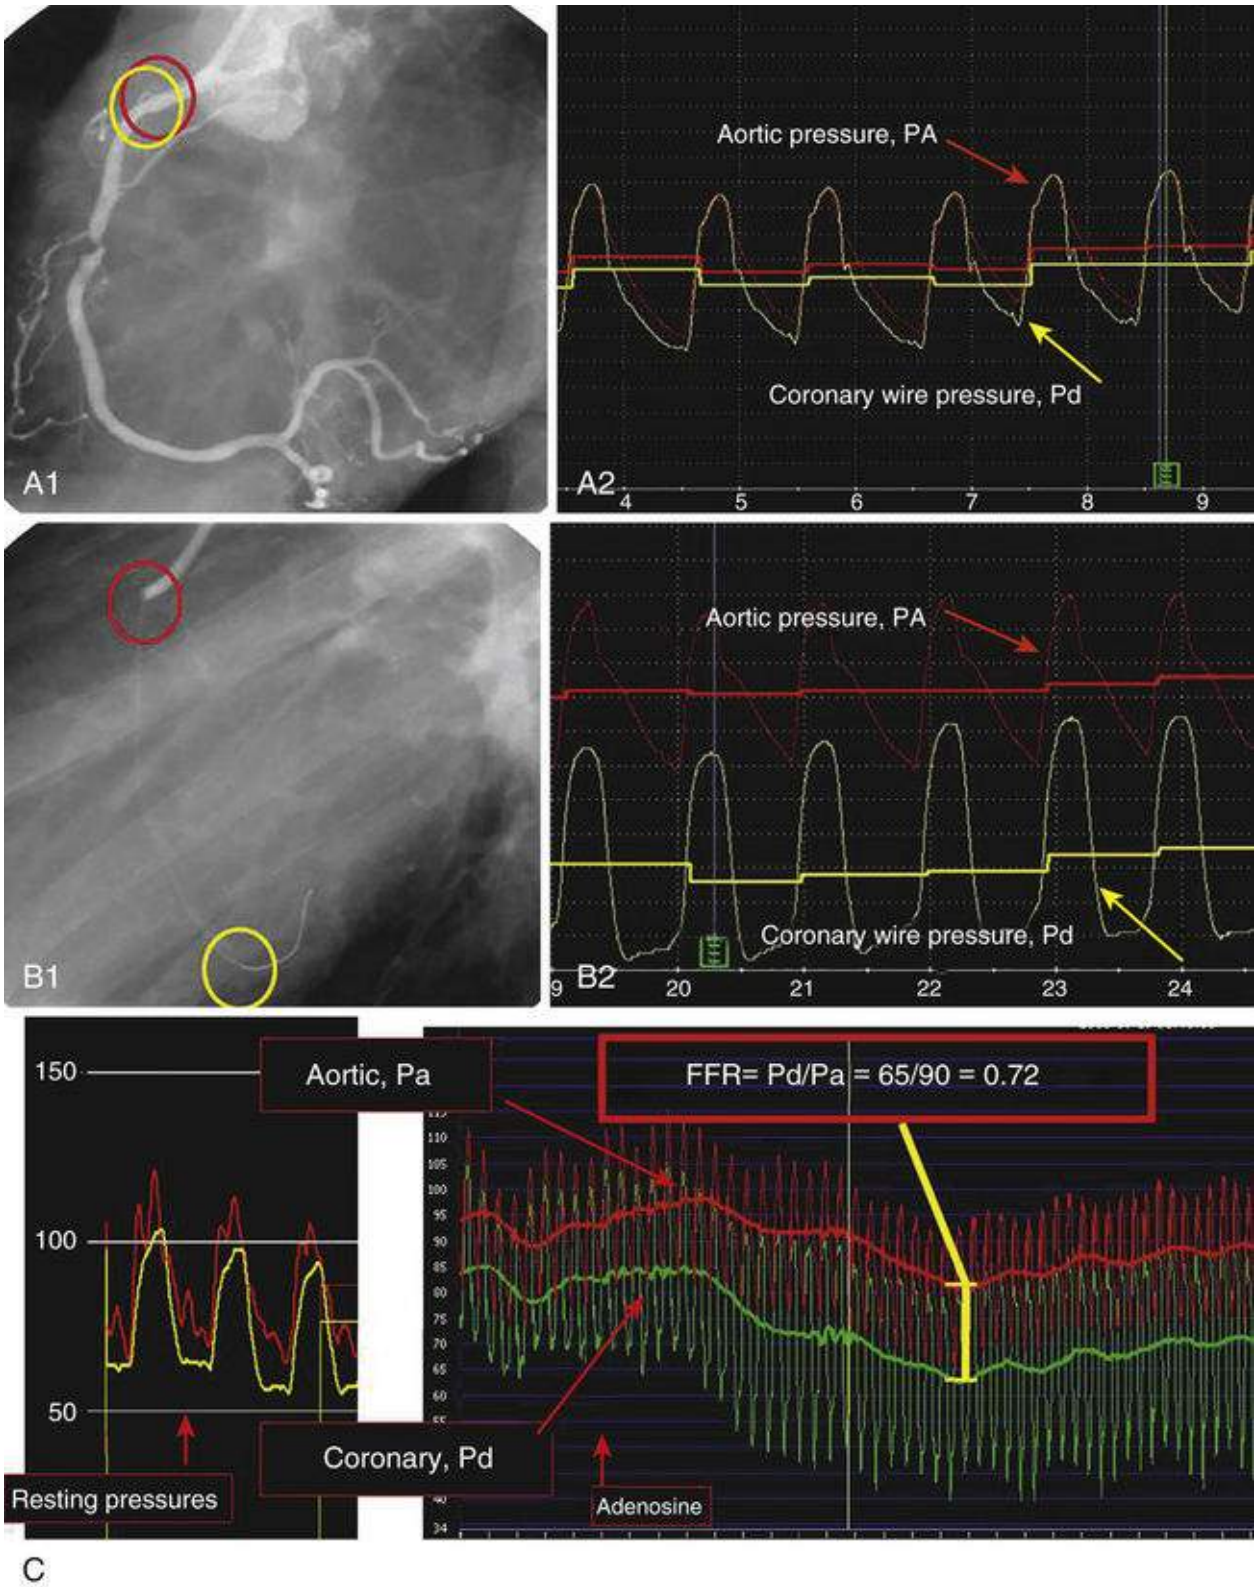

FIGURE 62.1 Method of fractional flow reserve (FFR) measurement. The first step is always to advance the pressure wire up to the tip of the catheter **(A1)** to be absolutely sure that the pressures are superimposed **(A2).** Then, the wire is advanced across the stenosis **(B1)** and obtains a corresponding FFR **(B2). C**, Mild resting gradient **(left panel)** becomes larger with hyperemia **(right panel).** FFR is calculated as Pd/Pa at the nadir of distal pressure presumed to be the point of maximal hyperemia. In this example, FFR = 0.72. (From Kern, MJ. Fractional flow reserve. In Bhatt DL, editor. Cardiovascular Intervention: A Companion to Braunwald's Heart Disease. Philadelphia: Elsevier; 2016.)

In patients with STEMI, revascularization of only the culprit infarct–related artery has generally been recommended,[10] unless there is ongoing cardiogenic shock because of jeopardized myocardium in other regions. However, recent guideline changes now suggest that PCI of a noninfarct artery may be considered in select patients with STEMI and multivessel disease who are hemodynamically stable.[17] Recent trials of

modest size have suggested that there may be reduction in future need for revascularization, and potentially even "hard" outcomes, with a strategy of complete revascularization[18] (**Fig. 62.2**). A larger trial is underway to determine whether nonculprit severe lesions should be treated even in the absence of shock.

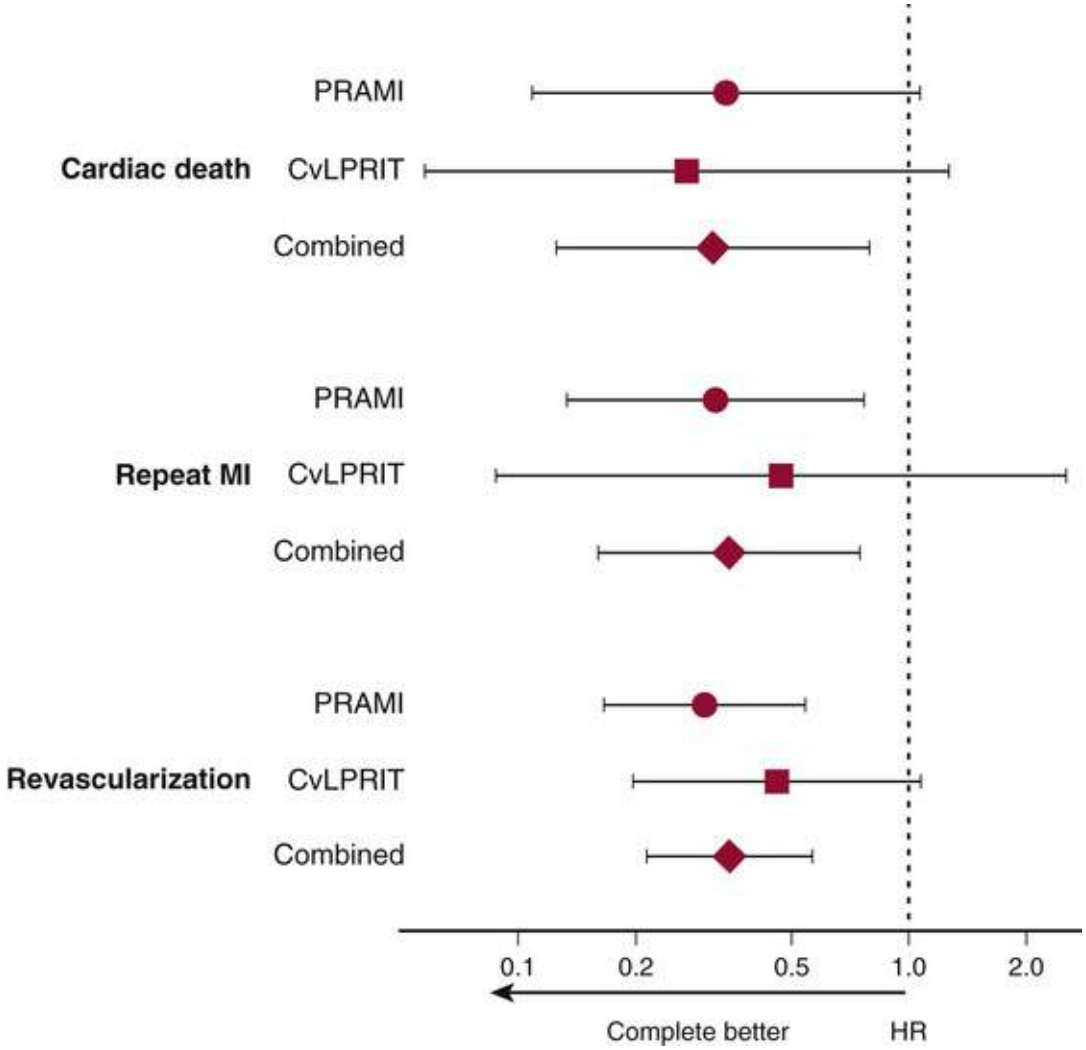

FIGURE 62.2 Reduction in the need for future revascularization and possibly "hard" events with a strategy of complete revascularization versus culprit-only revascularization in primary percutaneous coronary intervention for ST-elevation myocardial infarction. *CvLPRIT,* Complete versus Lesion-only Primary PCI Trial; *HR,* Hazard ratio; *MI,* myocardial infarction; *PRAMI,* Preventive Angioplasty in Acute Myocardial Infarction. (From Bhatt DL. Do we really know the CvLPRIT in myocardial infarction? Or just stent all lesions? J Am Coll Cardiol 2015;65:973-5.)

Baseline Lesion Morphology.

Several angiographic findings increase the technical complexity of PCI and elevate the risk for acute and long-term complications. The initial ACC/AHA lesion classification system has been refined with use of the Society for Cardiovascular Angiography and Interventions (SCAI) risk system, which further characterizes risk by the presence or absence of total occlusion. Although coronary stents have reduced the need for emergency CABG from 3% to 8% with balloon angioplasty to less than 1% with the availability of coronary stents, they have not eliminated the risk for periprocedural MI, stent thrombosis, or distal embolization and "no reflow." Vessel patency and lesion complexity remain important

predictors of outcome in patients undergoing coronary stent placement. Reviews of registry data have confirmed the impact of high-risk lesion features on procedural success rates and the risk for short- and long-term complications. Most recently, the SYNTAX angiographic scoring system, when combined with clinical factors, has become a method of deciding between complex PCI and CABG.[19] An online calculator is available (www.syntaxscore.com).

Chronic Total Occlusions.

Chronic coronary occlusions occur in many patients with severe (>70% stenosis) CAD and are the most important factor leading to referral for CABG procedures rather than PCI. The inability of guidewires to recanalize total coronary occlusions is related to duration of the occlusion, presence of bridging collaterals, occlusion length greater than 15 mm, and absence of a "beak" to assist in guidewire advancement. Although approaches such as retrograde crossing via collaterals and newer guidance technologies have been used to recanalize refractory occlusions, better guidewires and wire techniques have accounted for much of the improvement in successfully crossing occlusions over recent years.[20] Once the chronic total occlusion (CTO) has been crossed, DESs may be used to reduce late clinical recurrence.

Saphenous Vein Grafts.

SVG interventions account for approximately 8% of PCI procedures and pose an increased risk for postprocedural MI as a result of the atheroembolization that occurs during PCI. When no-reflow occurs, administration of arterial vasodilators (e.g., nitroprusside, verapamil, adenosine) into the SVG may improve flow into the distal native circulation, but the risk for death or MI is still substantially increased. More extensive SVG degeneration and bulkier lesions are associated with higher complication rates than are SVGs that have less extensive disease. In the setting of "high-risk" SVG anatomy, alternative approaches using the native coronary artery should be pursued whenever possible. Lower rates of restenosis in SVG lesions occur after coronary stent placement than after balloon angioplasty. Although DESs provide lower restenosis rates in SVGs that are 4.0 mm or less, they are currently not available for SVGs larger than 4.5 mm in diameter, and bare-metal stents (BMSs) are reasonable in this setting. Embolic protection devices are strongly recommended in patients treated for SVG stenoses to lessen the risk for distal embolization of atherothrombotic debris.

Bifurcation Lesions.

Optimal management of lesions involving both branches of a coronary bifurcation remains controversial. "Snowplowing" of plaque into the adjacent parent vessel or side branch is a major limitation of conventional balloon angioplasty. Atheroablative procedures such as rotational atherectomy have not reduced this risk. Risk stratification for bifurcation PCI includes assessment of the extent of atherosclerotic disease in both vessels, estimation of relative vessel size and distribution in the parent vessel and side branch, and determination of the orientation of the vessels to one another. Side branch compromise may also occur in up to 30% of bifurcation lesions without apparent branch vessel disease.

Stent placement in one vessel rather than in both parent vessel and side branch is generally preferred. In a meta-analysis of six randomized trials that included 1642 patients with coronary bifurcation lesions who were randomly selected to undergo PCI involving either double or single stenting, the risk for MI increased with double stenting (RR, 1.78; $P = 0.001$).[21]

When extensive disease occurs in both vessels, various strategies have been used, including simultaneous "kissing" stents (**Fig. 62.3**) and "crush," culotte, T stenting, and TAP ("T and small protrusion") techniques. Irrespective of the bifurcation stenting strategy used, a final kissing balloon inflation in the parent vessel and side branch should generally be performed. DESs appear to have lower

restenosis rates than BMSs do, but when recurrence develops in patients treated with a DES, it generally occurs at the origin of the side branch. New dedicated bifurcation stents and side branch access main vessel stents are in development. Determination of the FFR of an angiographically narrowed side branch can be useful if it demonstrates no significant impairment of flow and therefore no need to place a stent.

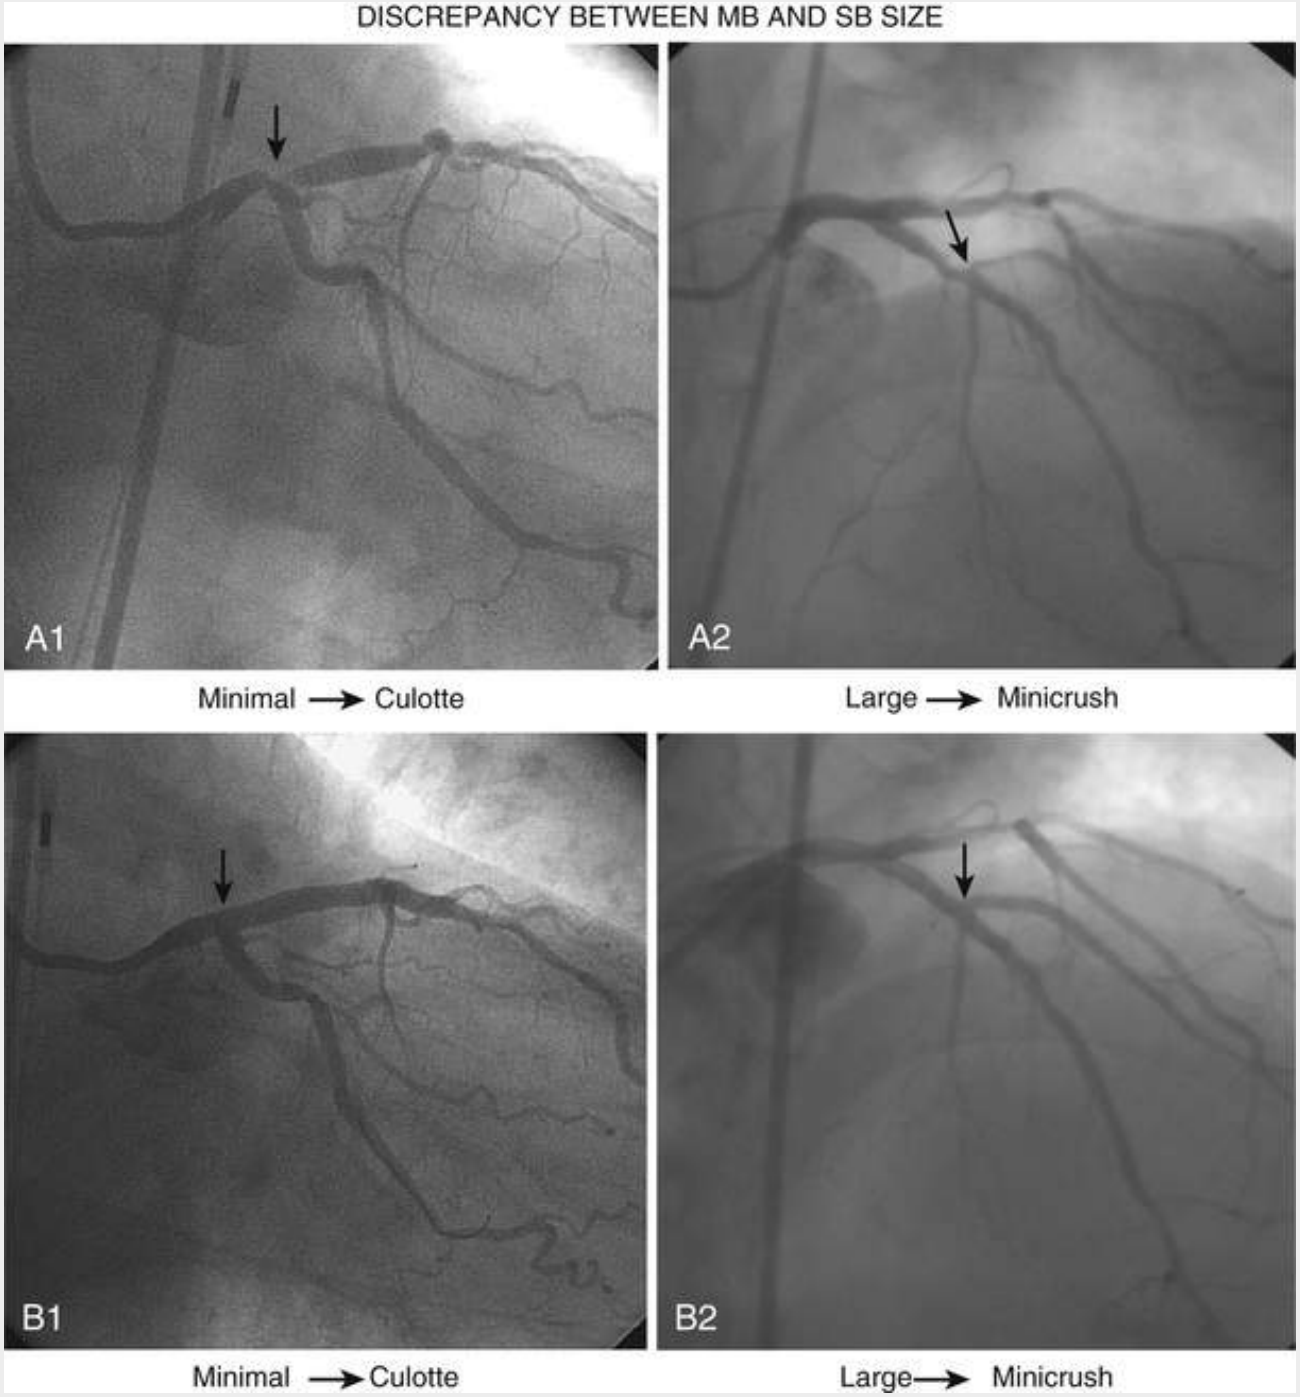

FIGURE 62.3 Angiography demonstrating a left main coronary artery bifurcation with minimal discrepancy between distal left main and circumflex size **(A1)** that would be suitable for culotte stenting **(B1)** compared with an left anterior descending coronary artery (LAD)–diagonal bifurcation with a large discrepancy between LAD and diagonal **(A2)** that would not be suitable for culotte stenting but should rather be treated with a minicrush technique **(B2).** *MB,* main branch; *SB,* side branch. (From Colombo A, Latib A. Bifurcations. In Bhatt DL, editor. Cardiovascular Intervention: A Companion to Braunwald's Heart Disease. Philadelphia: Elsevier; 2016.)

Lesion Calcification.

The presence of extensive coronary calcification poses unique challenges for PCI because calcium in the

vessel wall leads to irregular and inflexible lumens, thus making delivery of guidewires, balloons, and stents much more challenging. Extensive coronary calcification also renders the vessel wall rigid, which necessitates higher balloon inflation pressure to achieve complete stent expansion and, on occasion, leads to “undilatable” lesions that resist any balloon expansion pressure that can be achieved. Rotational atherectomy effectively ablates the vessel wall calcification and facilitates stent delivery and complete stent expansion (**Fig. 62.4**).

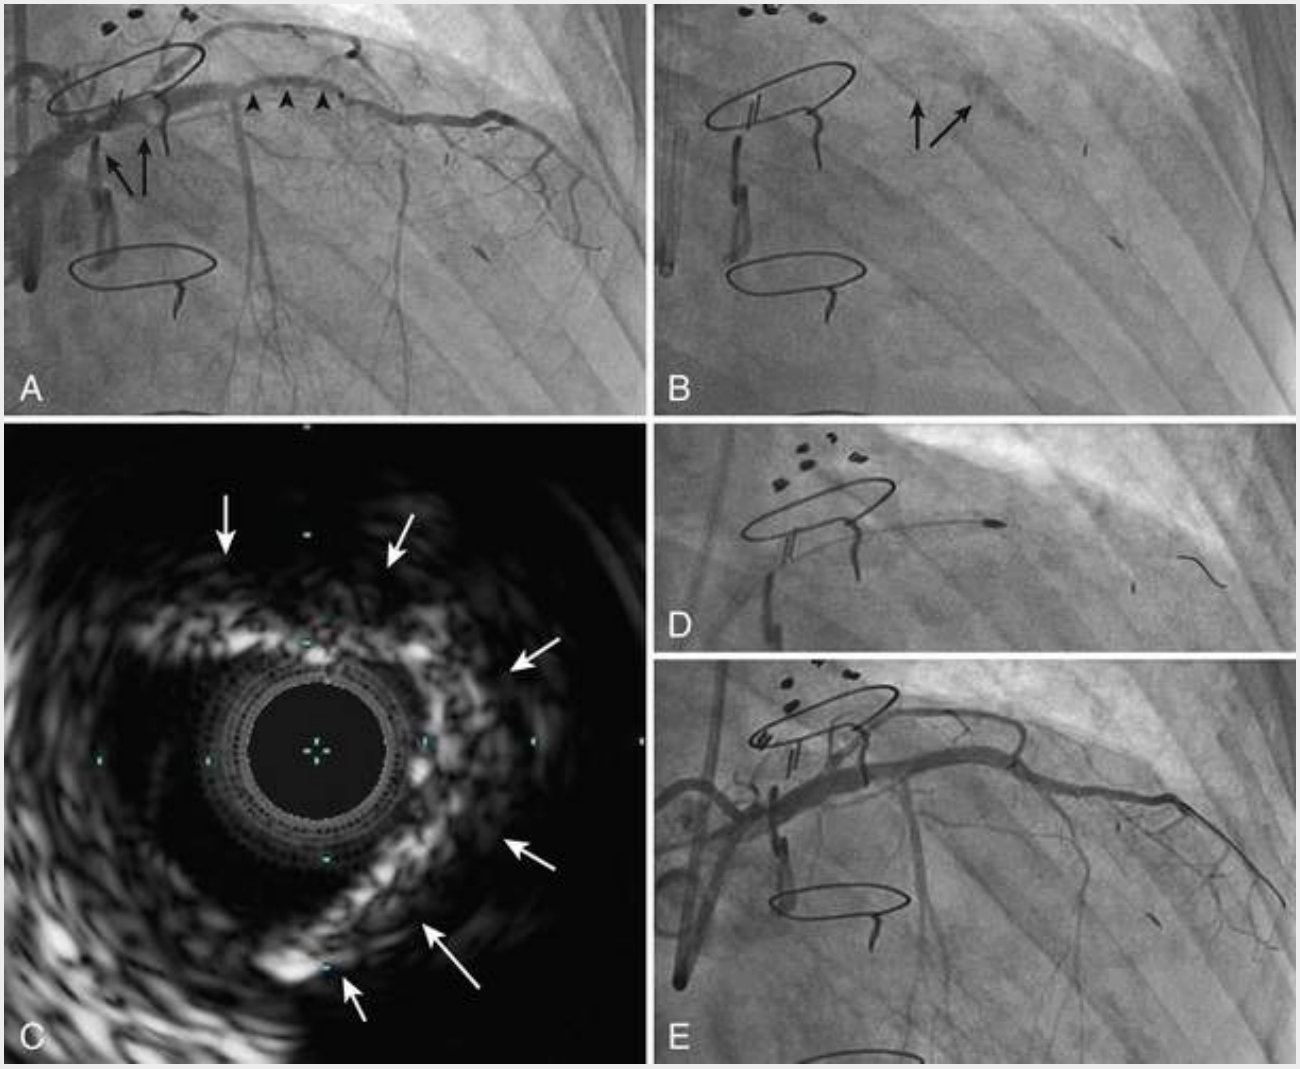

FIGURE 62.4 Rotational atherectomy of the left anterior descending coronary artery (LAD)/diagonal. **A,** Initial angiogram demonstrates severe calcified stenosis in the proximal (*arrow*) and mid-LAD (*arrowheads*) extending to the diagonal. **B,** Fluoroscopy alone shows the severe calcification (*arrows*). **C,** Intravascular ultrasound demonstrates 270-degree calcification (*arrows*) with echo dropout behind the calcium. **D,** Rotaburr in the mid-LAD. **E,** Final angiogram after stent placement. (From Krishnaswamy A, Whitlow PL. Calcified lesions. In Bhatt DL, editor. Cardiovascular Intervention: A Companion to Braunwald's Heart Disease. Philadelphia: Elsevier; 2016.)

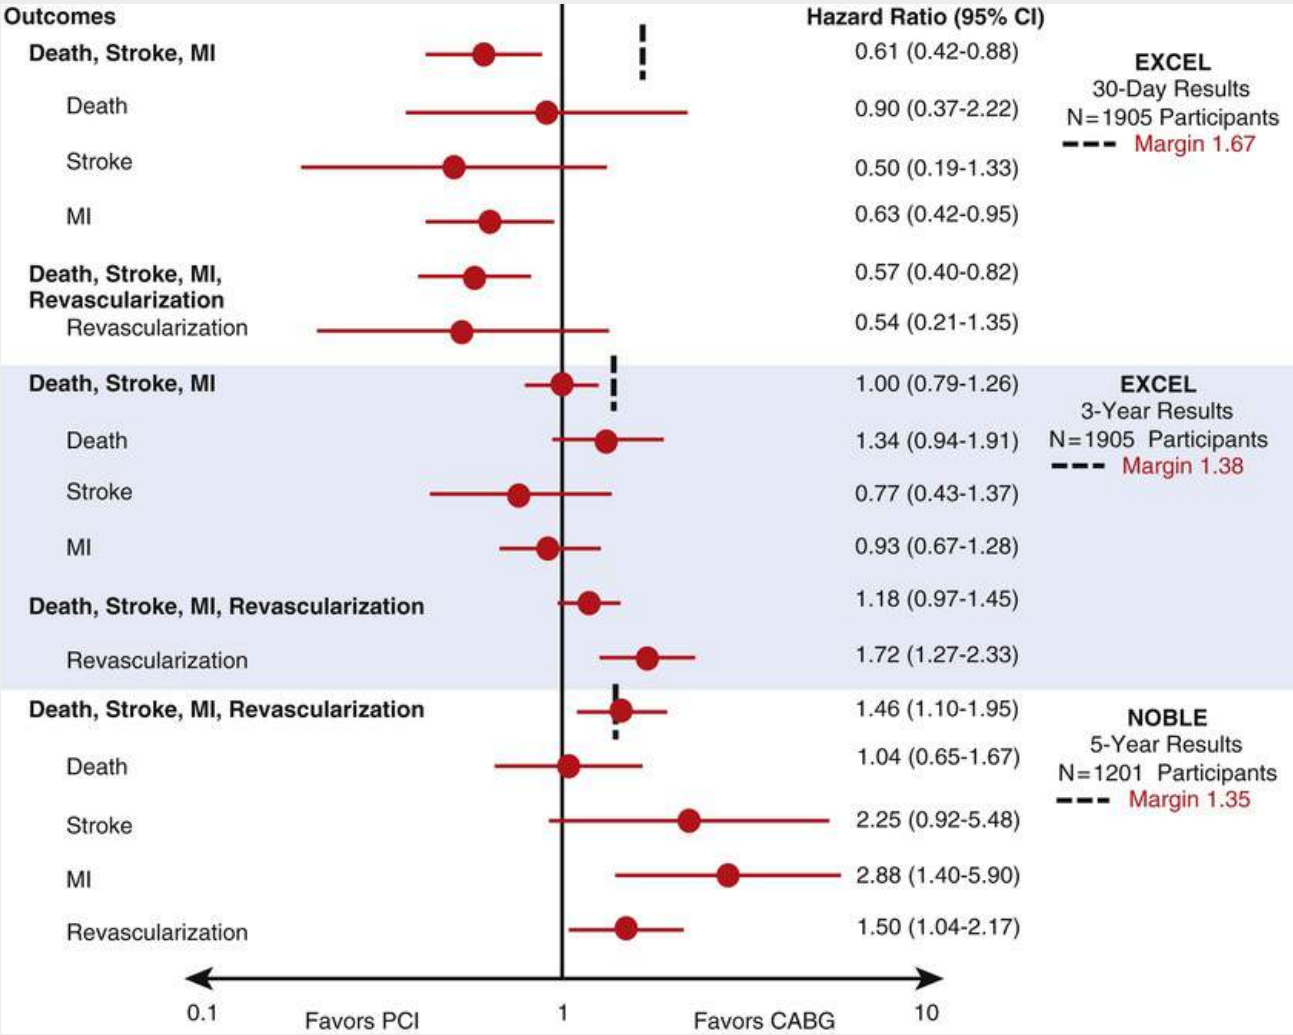
Thrombus.

Conventional angiography has poor sensitivity for the detection of coronary thrombus, but the presence of a large, angiographically apparent coronary thrombus heightens the risk for procedural complications. Large coronary thrombi may fragment and embolize during PCI or may extrude through gaps between stent struts placed in the vessel, thereby risking lumen compromise or thrombus propagation and acute thrombosis of the treated vessel. In addition, large coronary thrombi can embolize to other coronary branches or vessels or dislodge and compromise the cerebral or other vascular beds. In the setting of

contemporary primary PCI for STEMI, routine manual catheter aspiration of thrombus appears to have no significant effect on mortality and may increase the risk of stroke,[22] but it may be helpful in select patients with visible thrombus.[3]

Left Main Coronary Artery Disease.

The presence of left main CAD has been an accepted indication for CABG because of the potential for hemodynamic collapse in the setting of acute complications, stent thrombosis, or restenosis involving the body of the left main coronary artery or its extension into the left anterior descending or left circumflex coronary artery. Registry and randomized studies have suggested that rates of death or MI are similar in patients undergoing CABG or PCI,[3,23,24] although the need for repeated revascularization is higher in patients treated with PCI with additional vessel disease.[3,25] The use of PCI for left main CAD has been elevated to a class IIb indication (see PCI Guidelines at the end of this chapter). The Evaluation of XIENCE versus Coronary Artery Bypass Surgery for Effectiveness of Left Main Revascularization (EXCEL) and Nordic-Baltic-British Left Main Revascularization (NOBLE) trials each evaluated the noninferiority of PCI versus CABG for left main coronary artery stenosis (**eFig. 62.1**).[25a,25b] EXCEL, which had a composite primary endpoint of death, stroke, or myocardial infarction, concluded noninferiority of PCI at a median follow-up of 3 years.[25a] NOBLE, which had a composite primary endpoint of death, stroke, myocardial infarction, or revascularization, assessed at 5 years, did not conclude that PCI was noninferior and did conclude that CABG was superior.[25b] The additional endpoint component included in the NOBLE trial resulted in the differing conclusions, indicating that close inspection of the details and timing of the assessment are critical for study interpretation, as well as consideration of the balance of risk and benefit in patients with left main stenosis.[25c]



EFIGURE 62.1 Two noninferiority trials comparing percutaneous coronary intervention (PCI) with coronary artery bypass grafting (CABG). The EXCEL trial (Evaluation of XIENCE versus Coronary Artery Bypass Surgery for Effectiveness of Left Main Revascularization) primary composite endpoint was death, stroke, or myocardial infarction at 3 years. The NOBLE trial (Nordic–Baltic–British Left Main Revascularization) composite primary endpoint was death from any cause, nonprocedural myocardial infarction, any coronary revascularization, or stroke. Although the noninferiority margins were roughly similar in the two trials, the EXCEL results led to the conclusion that PCI was superior to CABG at 30 days and was noninferior at 3 years, and the NOBLE findings, based on longer follow-up and a more inclusive primary endpoint, led to the conclusion that CABG was superior at 5 years. In the EXCEL trial, the early benefit of PCI was due to avoidance of periprocedural infarction. The late benefit of CABG, on the basis of extended follow-up, was largely due to lower rates of spontaneous myocardial infarction (not shown: 4.3% with PCI vs. 2.7% with CABG; hazard ratio [HR] with PCI, 1.60; 95% confidence interval [CI], 0.95 to 2.70; P = 0.07 for the superiority of CABG) and revascularization (12.9% vs. 7.6%; HR, 1.72; 95% CI, 1.27 to 2.33; P < 0.001 for the superiority of CABG). Similarly, the NOBLE trial showed that PCI, as compared with CABG, was associated with higher rates of nonprocedural myocardial infarction (7% vs. 2%; HR, 2.88; 95% CI, 1.40 to 5.90; P = 0.004 for the superiority of CABG) and revascularization (16% vs. 10%; HR, 1.50; 95% CI, 1.04 to 2.17; P = 0.03 for the superiority of CABG) at 5 years, leading to the conclusion that CABG was superior (rate of major adverse cardiovascular and cerebrovascular events, 29% with PCI vs. 19% with CABG; HR, 1.48; 95% CI, 1.11 to 1.96; P = 0.007 for the superiority of CABG). (Modified from Mauri L, D'Agostino RB. Challenges in the design and interpretation of noninferiority trials. N Engl J Med 2017;377:1357-67.)

Underlying Cardiac Function

Left ventricular function is an important predictor of outcome during PCI. For each 10% decrement in resting LV ejection fraction (EF), the risk for in-hospital mortality following PCI increases approximately twofold. Associated valvular disease or ventricular arrhythmia further increases the risk associated with PCI in the setting of LV dysfunction. Intra-aortic balloon pump (IABP) support may be useful when LV

function is severely compromised (i.e., EF <35%) or when the PCI target lesion supplies a substantial portion of viable myocardium. Routine use of IABPs has limited benefit in patients with STEMI,[26] although they are recommended for patients in cardiogenic shock. Other percutaneous cardiopulmonary support devices that do not effectively reduce LV pressure have been replaced by percutaneous LV assist devices that are positioned in the left atrium (e.g., TandemHeart, CardiacAssist, Pittsburgh, Pa)[27,28] or directly in the left ventricle (Impella, Abiomed, Danvers, Mass)[29-31] (**Fig. 62.5**). These devices may permit very-high-risk PCI with less chance of hemodynamic collapse during the procedure, although current data do not show them to be superior to IABPs.[32] Peripheral extracorporeal membrane oxygenation (ECMO) support through large-bore arterial and venous access may be useful in cases of cardiovascular collapse.

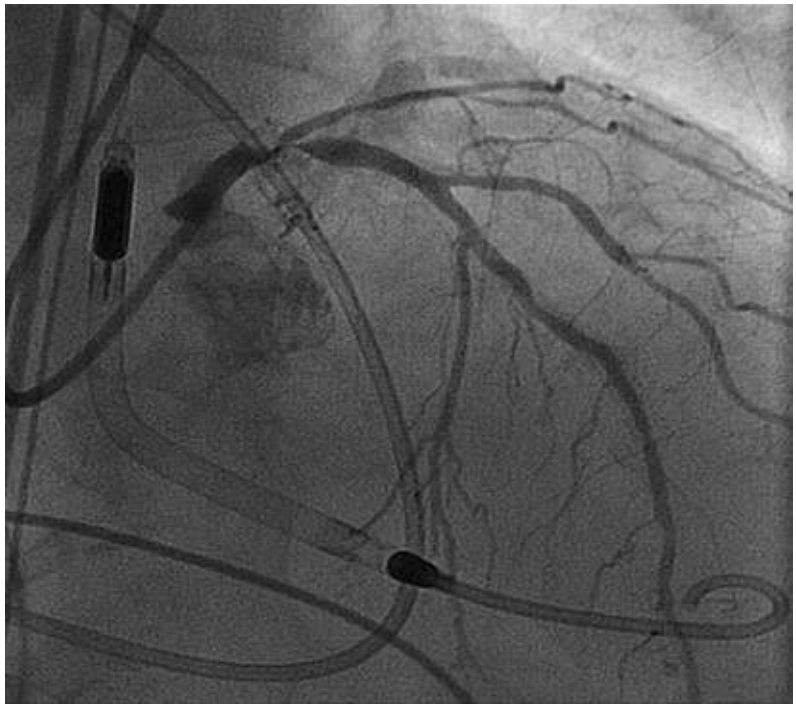


FIGURE 62.5 Position of the Impella device in the left ventricle before left main coronary intervention in a sole remaining artery.

Renal Insufficiency

The morbidity and mortality associated with PCI are directly related to the extent of baseline renal disease (**see also Chapter 98**). Patients with evidence of mild renal dysfunction have a 20% higher risk for death at 1 year following PCI than do those with preserved renal function. Renal dysfunction following the administration of contrast material during angiography may be related to contrast-induced nephropathy (**see Chapter 19**), to cholesterol embolization syndrome (**see Chapter 64**), or to both. The risk for nephropathy is dependent on the dose of the contrast agents used, hydration status at the time of the procedure, preexisting renal function of the patient, age, hemodynamic stability, anemia, and diabetes. The risk for cholesterol embolization syndrome is related to manipulation of the catheter in an ascending or descending atherosclerotic aorta from which cholesterol crystals are released. Although the risk associated with hemodialysis is less than 3% in cases of uncomplicated contrast-induced nephropathy, in-hospital mortality in the setting of hemodialysis exceeds 30%. Mild renal dysfunction is associated with an up to fourfold increased risk for death at 1 year after PCI compared with patients with preserved renal

function, although this association is probably not causal.

Associated Medical Comorbid Conditions

A bleeding diathesis or need for chronic warfarin therapy may preclude patients from tolerating long-term combination aspirin and clopidogrel therapy after placement of a DES, thereby placing them at higher risk for stent thrombosis. The need for discontinuation of dual-antiplatelet therapy (DAPT) before impending non–cardiac-related surgery soon after stent implantation may also predispose to stent thrombosis. In each of these circumstances, BMS placement may be the preferred approach, particularly if the surgery can be deferred for approximately 6 weeks after placement of the stent[33,34] (**Fig. 62.6**).

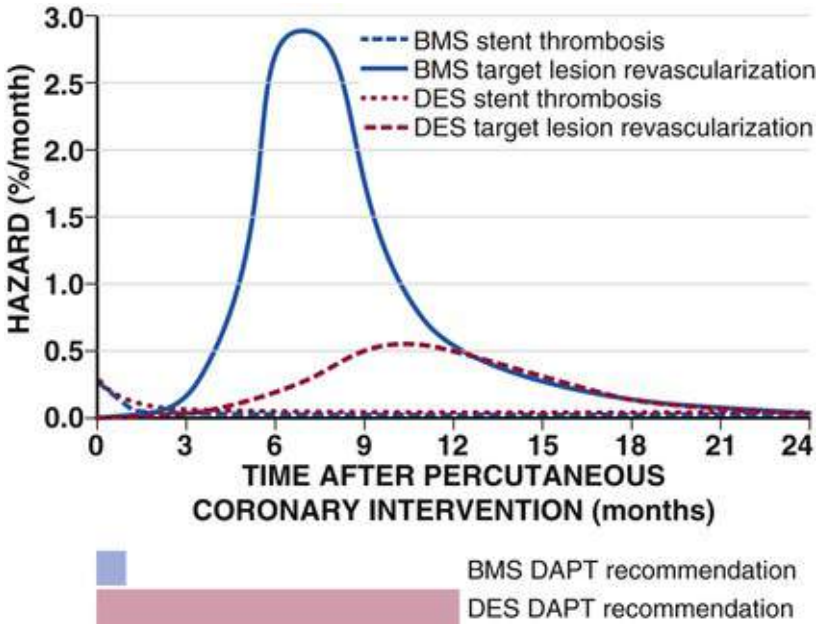

FIGURE 62.6 Hazard of stent thrombosis and target lesion revascularization over time according to the type of stent. BMS, Bare-metal stent; DAPT, dual-antiplatelet therapy; DES, drug-eluting stent. (From Matteau A, Mauri L. Optimal timing of noncardiac surgery after stents. Circulation 2012;126:1322.)

Vascular Access

The most frequently used vascular access sites for PCI include the common femoral artery, the brachial artery, and increasingly, the radial artery (**see Chapters 19 and 20**). The *femoral approach* (either right or left sided) is the most commonly used vascular access site in the United States and provides the advantages of large vessel size (typically 6 to 8 mm in diameter) and the ability to accommodate larger (>6 French [F]) sheath sizes, including IABPs. In addition, because of the typically straight path from the femoral artery to the ascending aorta, the femoral approach provides excellent guide catheter support and manipulability and access to the venous system through the adjacent femoral vein. The presence of severe peripheral arterial disease or peripheral vascular bypass grafts and the requirement for immobilization after the procedure limit use of the femoral approach in some patients.

The *brachial approach* was historically used as the principal alternative to femoral access, but because the brachial artery provides the only circulation to the forearm and hand (i.e., it is a functional end-artery), any compromise of the brachial artery can lead to severe ischemic complications in the hand.

The *radial approach* has gained in popularity as an alternative to femoral access in patients with

significant peripheral vascular disease, particularly in obese patients, in whom direct compression of the radial artery reduces bleeding complications.[35,36] The radial approach provides direct access to the ascending aorta and has the unique advantage of allowing immediate mobilization following PCI. An Allen test may be useful to assess flow to the hand before radial artery cannulation. Tortuosity of the brachiocephalic trunk may limit use of the radial approach in 2% to 3% of patients. The small size of the radial artery limits the size of guiding catheters that can be used during PCI (typically 5F or 6F for women and 7F for men, although larger, sheathless guides are entering practice). Transradial access is associated with a generally lower rate (2%) of vascular complications.[37] A meta-analysis suggested that radial access reduced major bleeding in comparison to femoral access.[38] In the RIVAL (Radial vs Femoral Access for Coronary Intervention) trial, which randomly assigned patients to either femoral or radial access, no significant difference was found in the primary endpoint of major ischemic events or bleeding[39] (**Table 62.1**), but the rate of vascular complications was significantly reduced with the radial approach.

TABLE 62.1

Outcomes in Radial Versus Femoral Access in RIVAL Trial

OUTCOME	FEMORAL (*n* = 3514)	RADIAL (*n* = 3507)	*P* VALUE
Composite of death, myocardial infarction, stroke, or non-CABG–related major bleeding at 30 days*	4.0%	3.7%	0.50
Death at 30 days	1.5%	1.3%	0.47
Myocardial infarction at 30 days	1.9%	1.7%	0.65
Stroke at 30 days	0.4%	0.6%	0.30
Percutaneous coronary intervention success	95.2%	95.4%	0.83
Access site crossover	2.0%	7.6%	<0.0001
Major vascular complications	3.7%	1.4%	<0.0001
Access site major bleeding	0.3%	0.2%	Not provided
Symptomatic radial occlusion	NA	0.2%	NA
Procedure time (min)	35	34	0.62
Fluoroscopy time (min)	8.0	9.3	<0.0001
Contrast volume (mL)	180	181	0.87
Patient prefers radial access for next procedure	50.7%	90.2%	<0.0001

Complications

Vascular access site complications occur after 3% to 7% of femoral PCIs and lead to significantly increased length of hospital stay, total cost, and morbidity and mortality. Complications range from relatively minor access site hematomas, to life-threatening retroperitoneal bleeding requiring emergency blood transfusion, to damage to the vasculature necessitating prompt surgical intervention. Factors predisposing patients to increased risk for serious vascular complications after PCI include older age, female sex, larger vascular sheath size, low body mass index, renal insufficiency, and degree of anticoagulation during the procedure. The location of the entry point for transfemoral access predicts the risk and type of vascular complication (**see Chapter 19**). If the access site is above the level of the inguinal ligament, the risk for retroperitoneal hemorrhage increases substantially. If the access site is distal to the femoral bifurcation, pseudoaneurysms (0.4%) and arteriovenous fistulas (0.2%) may occur. Major vascular complications of the femoral approach include limb-threatening ischemia (0.1%) and retroperitoneal hemorrhage (0.4%), which are associated with a 2- to 10-fold increased risk for death in

the first 30 days after PCI.

Vascular Closure Devices

Vascular access closure devices were introduced in the mid-1990s as a new way of managing access sites following femoral access procedures. Vascular closure devices reduce the time to ambulation, increase patient comfort after PCI, and facilitate efficient case flow in the catheterization laboratory.

Currently approved vascular closure devices fall into three categories: (1) sealant devices, including collagen-based and thrombin-based systems, which leave no mechanical anchor inside or outside the vessel; (2) mechanical closure devices, including suture-mediated and nitinol clip–based systems, which provide immediate secure closure to the vessel; and (3) hybrid closure devices, such as the dissolvable AngioSeal device (St. Jude Medical, Minneapolis), which use a combination of collagen sealant and internal mechanical closure to induce rapid hemostasis.[40] Although each device has proved to be relatively safe and effective, a lack of comparative data prohibits evaluation of the relative risks and benefits associated with each device. Meta-analyses have concluded that vascular closure devices do not lower the risk for vascular complications compared with manual hemostasis, but infections may occur more often with suture-based closure devices, and occlusions are found more often with hybrid devices. Registry analyses have suggested that closure devices reduce bleeding complications in select patients,[41] but randomized clinical trials are necessary to validate this finding.

Coronary Devices

Over the past three decades, steady improvements in the equipment used for coronary revascularization (e.g., reductions in device profile and improvements in catheter flexibility) have been supplemented by the introduction of periodic "transformational technology," such as coronary stents and, more recently, drug-eluting stents, which have extended the scope and breadth of clinical practice. The type of lesions amenable to PCI has become progressively more complex over this period, and the outcomes associated with the use of these devices have progressively improved. A brief overview of currently available coronary devices follows.

Balloon Angioplasty

Balloon angioplasty expands the coronary lumen by stretching and tearing the atherosclerotic plaque and vessel wall and, to a lesser extent, by redistributing atherosclerotic plaque along its longitudinal axis. Elastic recoil of the stretched vessel wall generally leaves a 30% to 35% residual diameter stenosis, and the vessel expansion can result in propagation of coronary dissections and lead to abrupt vessel closure in 5% to 8% of patients. Although stand-alone balloon angioplasty is rarely used other than for very small (<2.25 mm) vessels, balloon angioplasty remains integral to PCI for predilating lesions before stent placement, deploying coronary stents, and further expanding stents after deployment.

Most enhancements in balloon technology are related to the development of *low-profile* (deflated diameter = 0.7 mm) balloons that can be tracked more readily through tortuous anatomy and *noncompliant* balloons that can be inflated to pressures in excess of 20 atm without overexpansion or rupture. A modification of balloon angioplasty includes a focused-force dilation in which a scoring blade or guidewire external to the balloon concentrates the dilating force and resists balloon slippage during inflation. The Cutting Balloon (Boston Scientific, Natick, Mass) and the AngioScore catheter (AngioScore, Fremont, Calif) are focused-force balloon angioplasty systems that are currently used in a

small minority (<5%) of PCIs. They are sometimes useful in restenotic stent lesions to prevent slippage of the balloon during inflation.

Coronary Atherectomy

Atherectomy refers to removal (rather than simple displacement) of the obstructing atherosclerotic plaque. By removing plaque or improving lesion wall compliance in calcified or fibrotic lesions, atherectomy can provide a larger final minimal lumen diameter than can be achieved by balloon angioplasty alone. Atherectomy was performed in 30% of interventional procedures between 1992 and 1994, but its use fell dramatically with the availability of coronary stents. Fewer than 5% of current procedures involve the use of atherectomy, most often rotational atherectomy in combination with coronary stents.

The Rotablator Rotational Atherectomy System (Boston Scientific) is the most commonly used atherectomy device and removes atheromatous plaque by abrasion of the inelastic calcified plaque with microscopic (20 to 50 µm) diamond chips embedded on the surface of a rapidly rotating (160,000 rpm) olive-shaped atherectomy burr. Such abrasion generates 2- to 5-µm microparticles that pass through the coronary microcirculation for removal by the reticuloendothelial system. The burrs travel over a specialized 0.009-inch guidewire and are available in diameters ranging from 1.25 to 2.50 mm. In the setting of severe calcification, smaller-diameter (1.25 mm) burrs can be used initially, followed by larger burrs in 0.25- to 0.50-mm increments up to 70% of the reference vessel diameter. Aggressive rotational atherectomy techniques do not provide a restenosis advantage over more conservative methods and tend to increase acute procedural complications such as distal embolization or coronary perforation. Rotational atherectomy does not appear to reduce restenosis in noncalcified vessels any more than balloon angioplasty does. Rotational atherectomy is currently reserved for ostial and heavily calcified lesions that cannot be dilated with balloon angioplasty or those that prevent the delivery of coronary stents. Rotational atherectomy is generally limited to abrasion of superficial calcification with a single 1.5- or 1.75-mm burr to improve lesion compliance (plaque modification) before the lesion is treated definitively by balloon dilation and stent placement. Rotational atherectomy is presently used in fewer than 5% of PCI procedures (**Fig. 62.7**). Orbital atherectomy is a variant of rotational atherectomy that has recently been introduced into coronary and peripheral intervention.

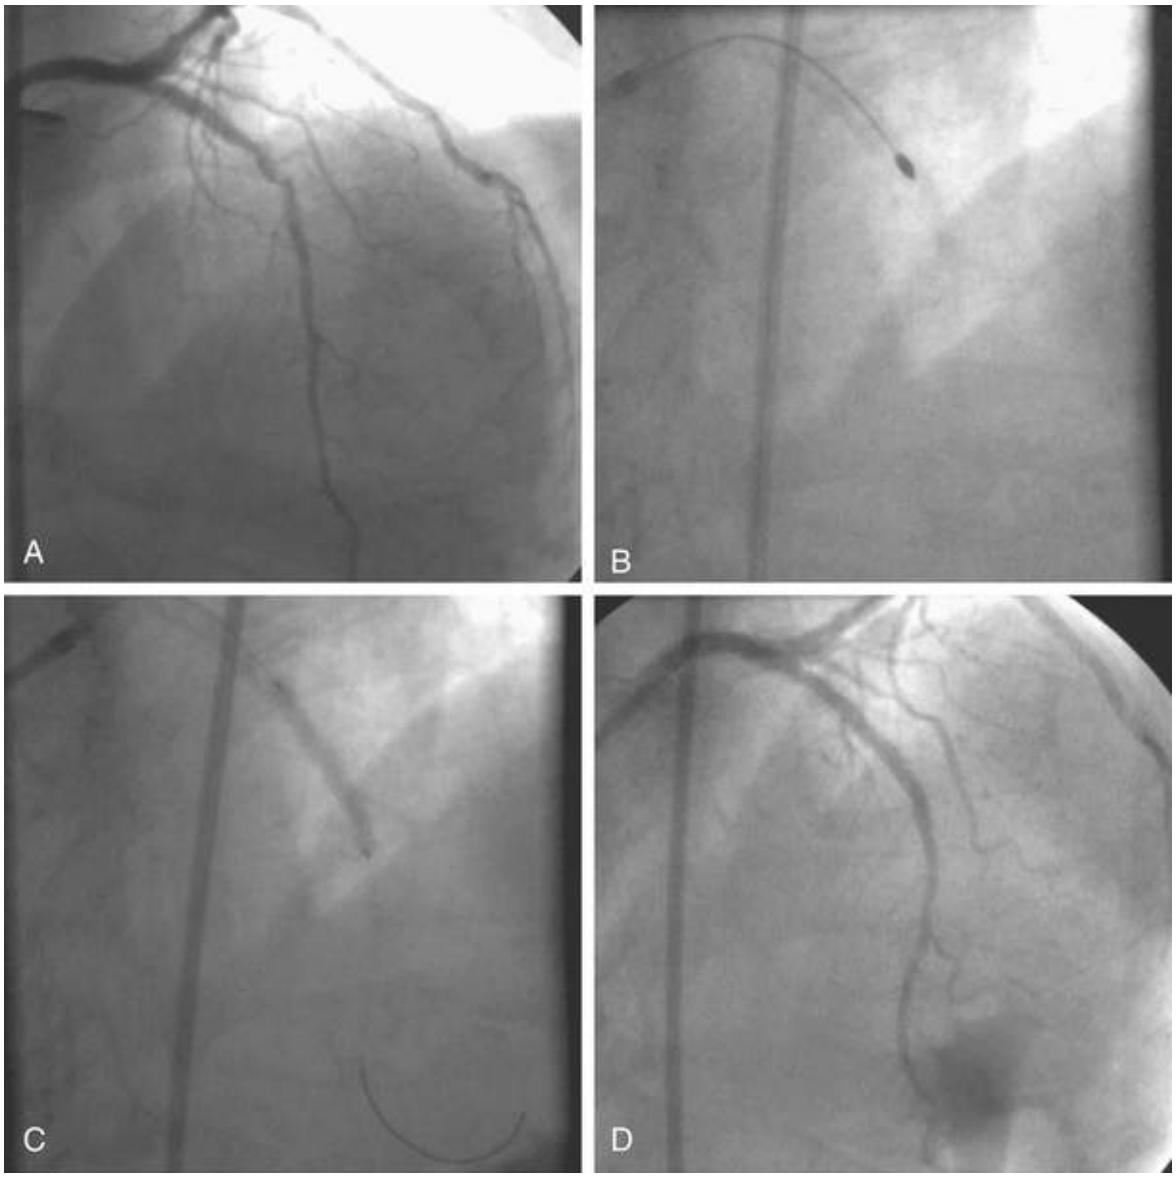

FIGURE 62.7 Rotational atherectomy of an undilatable left anterior descending coronary artery (LAD). **A,** Heavily calcified diffuse lesion in LAD is generally considered undilatable with conventional balloon techniques. **B,** A 1.5-mm rotational atherectomy burr revolving at 160,000 rpm is advanced to ablate the calcified lesion. **C,** A 3-mm × 28-mm stent can then be advanced across the blockage and inflated to 16 atm. Full stent expansion is unlikely to occur without pretreatment with rotational atherectomy. **D,** Final angiographic result shows no residual stenosis and normal flow into the distal vessel.

Thrombectomy and Aspiration Devices

The AngioJet rheolytic thrombectomy catheter (Possis Medical, Minneapolis) was introduced as a dedicated device for thrombus removal through dissolution and aspiration of the thrombus. High-speed saline jets within the tip of the catheter create intense local suction by the Venturi effect; surrounding blood, thrombus, and saline are pulled into the lumen of the catheter opening, and the debris is propelled proximally through the catheter lumen. Rheolytic thrombectomy was superior to a prolonged intraluminal urokinase infusion in patients with a large thrombus, but its routine use in patients with STEMI was not associated with improvement in infarct size on single-photon emission computed tomography (SPECT) imaging and may have caused more complications. Rheolytic thrombectomy may still be useful in clinical practice when a large angiographic thrombus is located in a native vessel or SVG.

Newer, aspiration catheters that use 6F guiding catheters have been developed as alternatives to rheolytic thrombectomy in patients with thrombus-containing lesions. Although simpler to use, these

techniques may be slightly less effective (particularly with partially organized thrombus) than rheolytic thrombectomy. In a multicenter study of 1071 patients with STEMI who were randomly assigned to a thrombus aspiration group or a conventional PCI group, a myocardial blush grade of 0 or 1 occurred in 17.1% of the patients in the thrombus aspiration group and in 26.3% of those in the conventional PCI group ($P < 0.001$). At 30 days the rate of death in patients with a myocardial blush grade of 0 or 1, 2, and 3 was 5.2%, 2.9%, and 1.0%, respectively ($P = 0.003$), and the rate of adverse events was 14.1%, 8.8%, and 4.2%, respectively ($P < 0.001$).[42] Meta-analysis of older data had suggested that simple manual thrombus aspiration before PCI reduced mortality in patients undergoing primary PCI, but larger randomized clinical trials in the present era demonstrated no significant reduction.[22]

Embolic Protection Devices

The advent of embolic protection systems has reduced the risk for postprocedural adverse events following SVG PCI. Although embolization of atherosclerotic debris was not considered a major complication during the early years of native coronary balloon angioplasty, it is now recognized as a potential cause of distal myocardial necrosis after PCI, particularly in friable SVG lesions. Distal embolization causes postprocedural elevation of cardiac enzymes in almost 20% of patients after SVG PCI, and this enzyme elevation is associated with substantial morbidity and mortality. Numerous additional occlusive and filter-based distal protection systems, as well as proximal occlusion devices, have undergone evaluation for use in SVG interventions,[43] but currently the filter devices are most commonly available. Despite their potential benefit in preventing thromboembolization in patients with STEMI, none of the embolic protection devices has reduced MI size with primary intervention.

Distal Embolic Filters.

Distal filters are advanced across the target lesion in their smaller collapsed state, and withdrawal of the retaining sheath allows the filters to open and expand against the vessel wall. The filters then remain in place to catch any liberated embolic material larger than the pore size (usually 120 to 150 μm) of the filter during intervention. At the end of the intervention the filters are collapsed by using a sheath, and the captured embolic material is removed from the body. This type of device has the advantage of maintaining anterograde flow during the procedure and allowing intermittent injection of contrast material to visualize the underlying anatomy, but it has the potential disadvantage of allowing debris with a diameter smaller than the pore size of the filter to pass (**Fig. 62.8**).

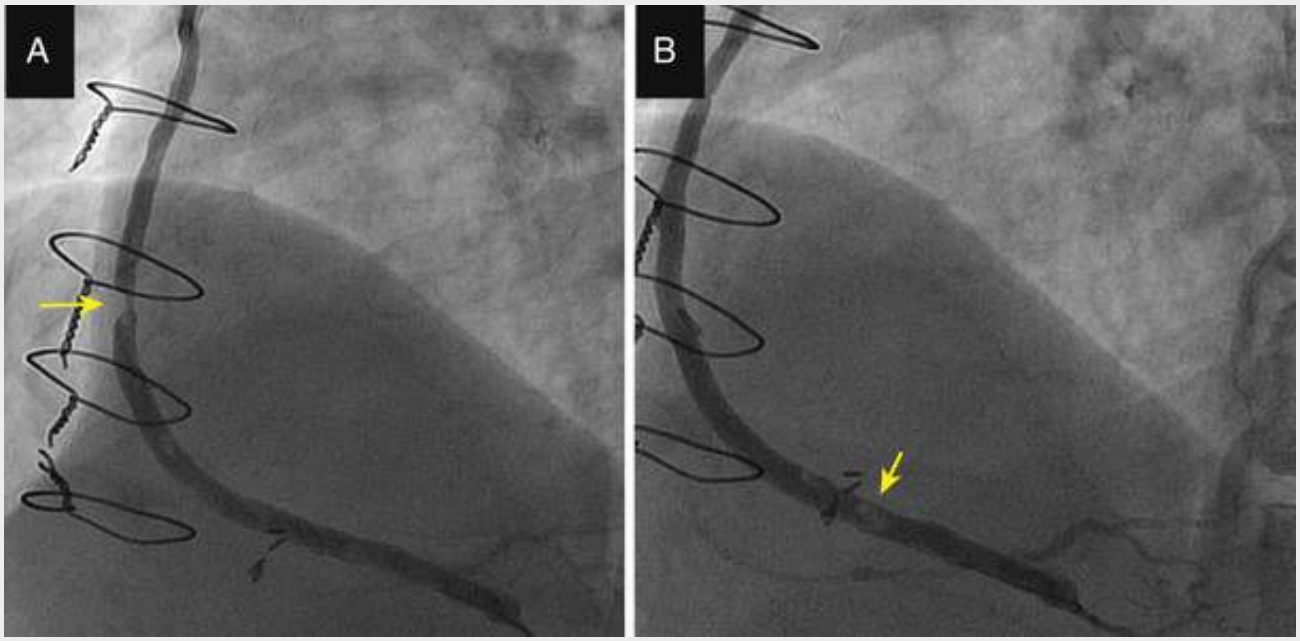

FIGURE 62.8 Examples of debris capture by a filter. **A,** FilterWire placed distally to eccentric saphenous vein graft body lesion. **B,** During PCI, debris embolized distally and was captured within the filter. (From Brilakis ES, Banerjee S. Bypass graft interventions. In Bhatt DL (ed.): Cardiovascular Intervention: A Companion to Braunwald's Heart Disease. Philadelphia, Elsevier, 2016.)

Coronary Stents

Coronary stents have emerged as the predominant form of PCI and are currently used in more than 90% of PCI procedures worldwide. Coronary stents act as scaffolds for arterial dissection flaps, thereby lowering the incidence of vessel closure and need for emergency CABG; they also lessen the frequency of restenosis because of their effect in preventing arterial recoil, which is the primary mechanism of restenosis with balloon angioplasty. Despite the late clinical improvement in comparison to balloon angioplasty, restenosis after coronary stent placement occurs in some patients as a result of excessive intimal hyperplasia within the stent. Second-generation balloon-expandable stents introduced between 1997 and 2003 vary in metallic composition (i.e., cobalt chromium or layered metals versus solid 316 L stainless steel), strut design, stent length, delivery and deployment system, and arterial surface coverage. These modifications enhanced flexibility and ease of delivery of the stent while also improving vessel scaffolding and side branch access.

The early use of coronary stents was limited by high (3% to 5%) subacute thrombosis rates despite aggressive antithrombotic therapy with aspirin, dipyridamole, periprocedural low-molecular-weight dextran, and an uninterrupted transition from intravenous (IV) heparin to oral warfarin. Subacute thrombosis produced profound clinical consequences that resulted in an untoward outcome (e.g., death, MI, or emergency revascularization) in virtually every such patient. Lower frequencies of subacute stent thrombosis (approximately 0.5% to 1.0%) have resulted from the use of high-pressure stent deployment and with a drug regimen that includes aspirin and an ADP receptor antagonist (clopidogrel, prasugrel, or ticagrelor, and/or IV cangrelor) started just before or after stent placement (**see Chapter 93**).

Even though coronary BMSs reduce the incidence of angiographic and clinical restenosis compared with balloon angioplasty, angiographic restenosis (follow-up diameter stenosis >50%) still occurs in 20% to 30% of patients, and clinical restenosis (recurrent angina caused by restenosis in the treated segment) develops in 10% to 15% of patients in the first year after treatment. Restenosis with BMSs occurs more often in patients with small vessels, long lesions, and DM, among other factors. Adjunctive

pharmacologic therapy has not prevented restenosis after stent placement.

Mechanical treatments of in-stent restenosis have included balloon redilation, removal of in-stent hyperplasia by means of atherectomy, and repeated BMS placement. Brachytherapy using beta or gamma sources modestly improved this outcome for in-stent restenosis, but brachytherapy has several limitations, including the requirement for a radiation therapist, a tendency for late "catch-up" restenosis, and inhibition of endothelialization, which greatly increases the risk for thrombosis if another stent is implanted in the same vessel segment. Brachytherapy was found to be inferior to DES placement for treating restenosis in two randomized studies.[44,45]

BMSs are currently used in 10% to 20% of patients undergoing PCI, most often because of an inability to take long-term DAPT. However, the data actually suggest superiority of current-generation DESs over BMSs even in patients at high risk of bleeding.[46]

Drug-Eluting Stents

DESs were developed in the early 2000s to provide sustained local delivery of an antiproliferative agent at the site of vessel wall injury. The three components of current DESs are a balloon-expandable stent, a durable or resorbable polymer coating that provides sustained drug delivery, and the pharmacologic agent used to limit intimal hyperplasia.

DESs have proven efficacy in patients with focal, de novo, and "workhorse" lesions that include reference vessel diameters of 2.5 to 3.5 mm and lesion lengths of 15 to 30 mm. Additional randomized trials and registries have also demonstrated the benefit of DESs in patients with long (>30 mm in length) and small (<2.5 mm) vessels, CTOs, SVG and internal mammary artery disease, in-stent restenosis, and STEMI.[47] Current DESs show lower risk of stent thrombosis than the first DESs[48,49] and consistent prevention of restenosis compared with BMSs, as well as improved deliverability because of lower-profile materials. Stent thrombosis is now rare compared with risk of MI unrelated to prior stents. Recent randomized comparisons of current DESs to BMSs indicate similar or lower rates of stent thrombosis with DESs, both early[48] and beyond 1 year.[49]

With current DESs, guidelines now recommend 6 months or longer of DAPT in patients without ACS who are not at high risk of bleeding and who tolerated DAPT without a bleeding complication.[50] Guidelines have also been updated regarding longer-duration DAPT based on recently published trials and indicate that 12 months or longer may be reasonable for patients who do not have a high risk of bleeding and who have tolerated DAPT without a bleeding complication.[51] Although low stent thrombosis risks with DESs are further reduced with extended therapy, the recommendations are largely based on reduction in the risk of late MI unrelated to the stent, rather than stent thrombosis.[52-54]

Sirolimus-Eluting Stents

The CYPHER stent (Cordis, Warren, NJ) contains sirolimus, a naturally occurring immunosuppressive agent that causes cytostatic inhibition of cell proliferation. Sirolimus is released from a biostable polymer over 30 days. The pivotal SIRIUS (Sirolimus-Eluting Stent in De-Novo Native Coronary Lesions) trial included 1058 patients with workhorse lesions who were randomly assigned to treatment with a sirolimus-eluting stent or a BMS. The primary clinical endpoint of 8-month target vessel failure, which included target-vessel revascularization, death, or MI, was reduced from 21% in patients treated with BMSs to 8.6% in patients treated with sirolimus-eluting stents ($P < 0.001$). The rate of target-vessel revascularization was reduced from 16.6% in BMSs to 4.1% in sirolimus-eluting stents at 1 year ($P < 0.001$) and was sustained at 5 years.[55,56] The cumulative incidence of MI or revascularization attributed to

remote segments of the target vessel did not differ between the two groups. Even though manufacture of the CYPHER stent ceased in 2011, other sirolimus-eluting stents continue to be manufactured and sold outside the United States.

Paclitaxel-Eluting Stents

The TAXUS stent (Boston Scientific) is composed of a stainless steel stent platform, a polyolefin polymer derivative, and the microtubular stabilizing agent paclitaxel, which has anti-inflammatory effects while also inhibiting both cell migration and division. Release of paclitaxel is completed within 30 days of implantation, although a substantial portion (>90%) of the paclitaxel remains within the polymer indefinitely. The pivotal TAXUS-IV trial randomly assigned 1314 patients with single de novo coronary lesions to either a TAXUS stent or an identical-appearing BMS. The rate of ischemia-driven target-vessel revascularization at 9 months was reduced from 11.3% to 3% and remained significantly reduced at 12 months (from 17.1% to 7.1%) in patients with paclitaxel-eluting stents ($P < 0.001$). The TAXUS stent is no longer manufactured.

Zotarolimus-Eluting Stents

Zotarolimus (also known as ABT-578) is another rapamycin analogue released from a phosphorylcholine (PC)-coated stent that has been evaluated in the Endeavor stent (Medtronic Vascular, Santa Rosa, Calif). In the ENDEAVOR-II trial, 1197 patients were assigned to treatment with the Endeavor zotarolimus-eluting PC polymer–coated stent or with the same BMS without the drug or the polymer coating.[57] The 9-month primary endpoint of target-vessel failure was reduced from 15.1% with the BMS to 7.9% with the Endeavor stent ($P < 0.0001$).[57] The ENDEAVOR-IV trial was a prospective, randomized, single-blind, controlled trial in which the safety and efficacy of the zotarolimus-eluting stent was compared with that of the paclitaxel-eluting stent in 1548 patients with single de novo coronary lesions. The primary endpoint was a composite of cardiac death, MI, or target-vessel revascularization, and the Endeavor stent was noninferior to the TAXUS stent. In addition, fewer periprocedural MIs occurred with zotarolimus-eluting stents (0.5% versus 2.2%; $P = 0.007$) because of less side branch occlusion in patients with these stents.[58] A large randomized trial compared stent thrombosis between the Endeavor and Cypher stents and showed no difference at the primary endpoint of definite or probable stent thrombosis at 3 years,[59] but did show a difference at 4 years (1.6% vs. 2.6%, $P = 0.003$).[60] The Endeavor stent is currently being manufactured but less widely available than the more recently approved Resolute zotarolimus-eluting stent. In the RESOLUTE All Comers Trial of 2,292 patients, the Resolute zotarolimus-eluting stent was found to be noninferior to the everolimus-eluting stent (8.2% versus 8.3%, respectively; $P < 0.001$ for noninferiority) with respect to the primary endpoint of target-lesion failure.[61] At 5 years of follow-up, there were no significant differences between stents in target-lesion failure, its components, or stent thrombosis.[62]

Everolimus-Eluting Stents

The XIENCE stent (Abbott Vascular) uses the cobalt chromium Vision stent, a durable fluoropolymer, and everolimus, a rapamycin analogue that has both immunosuppressive and antiproliferative effects. Based on initial studies in which the use of an absorbable poly-L-lactic acid (PLA) polymer was evaluated, the SPIRIT program has shown a reduction in late lumen loss comparable to that achieved with the CYPHER stent. SPIRIT III was a prospective, single-blind RCT that enrolled 1002 patients undergoing PCI for lesions 28 mm or less in length and with a reference vessel diameter of between 2.5 and 3.75 mm.[63] Angiographic in-segment late loss was significantly less in the everolimus-eluting stent group than in the

paclitaxel group (0.14 versus 0.28 mm; $P \leq 0.004$).[63] The everolimus stent was noninferior to the paclitaxel stent in terms of the rate of target-vessel failure at 9 months (7.2% versus 9.0%, respectively; $P < 0.001$ for noninferiority). The everolimus stent was associated with significant reductions in composite major adverse cardiac events (MACE) at 9 months compared with the paclitaxel stent (4.6% versus 8.1%; $P = 0.03$) and at 1 year (6.0% versus 10.3%; $P = 0.02$) because of fewer MIs and target-lesion revascularization procedures.[63] SPIRIT IV, a larger randomized comparison of the everolimus and paclitaxel stents in 3687 patients, found similar benefits of the everolimus stent, with significantly lower rates of target-lesion failure, MI, stent thrombosis, and ischemia-driven target-lesion revascularization at 2 years.[64] At 3 years of follow-up, similar results were found in a meta-analysis of the SPIRIT II, III, and IV trials (target-lesion failure, 8.9% versus 12.5%; $P = 0.0002$; MI, 3.2% versus 5.1%; $P = 0.002$; stent thrombosis, 0.7% versus 1.7%; $P = 0.003$; ischemia-driven target-lesion revascularization, 6.0% versus 8.2%; $P = 0.004$).[65]

Bioabsorbable Polymers and Drug-Eluting Stents

Bioabsorbable polymers have the potential benefit of no polymer remaining after the period required for drug suppression of neointimal hyperplasia, therefore limiting possible vascular reaction and toxicity. These polymers have been used on conventional metal stents to elute drug,[66,67] as well as in combination with fully bioabsorbable scaffolds.[68,69] The EVOLVE II trial found that the SYNERGY stent, which contains an bioabsorbable everolimus-eluting polymer on a cobalt chromium stent, was noninferior to a durable polymer everolimus-eluting stent in target-lesion failure at 12 months (6.7% versus 6.5%, respectively; P for noninferiority = 0.0005) in 1687 patients.[70] Clinical studies are underway to determine whether shorter durations of DAPT may be reasonable in patients at higher bleeding risk treated with this stent, since the drug and polymer are resorbed within 3 to 4 months after stent implantation.[71]

DESs that are completely bioabsorbable several years after implantation are now available.[72] In the ABSORB III trial, the primary endpoint of target-lesion failure at 1 year occurred in 7.8% of patients treated with an everolimus-eluting bioabsorbable scaffold (ABSORB) and in 6.1% of patients treated with a durable polymer everolimus-eluting stent (noninferiority $P = 0.007$; difference $P = 0.16$).[73] In a meta-analysis of six randomized trials with 3738 patients, ABSORB was associated with a greater risk of definite/probable thrombosis than the durable polymer everolimus-eluting stent (odds ratio, 1.99; 95% confidence interval [CI] 1.00 to 3.98; $P = 0.05$).[73] Currently, these stents are being considered primarily for proximal, simple large-vessel stenoses, to avoid higher risks of scaffold thrombosis in smaller or more complex lesions.

Antiplatelet Agents

See also Chapter 93.

Aspirin

Aspirin irreversibly inhibits cyclooxygenase (COX) and thus blocks the synthesis of thromboxane A_2 (TxA_2), a vasoconstriction agent that promotes platelet aggregation.[74] Aspirin substantially reduces periprocedural MI caused by thrombotic occlusions compared with placebo and is standard for all patients undergoing PCI. The inhibitory effect of aspirin occurs within 60 minutes, and its effect on platelets lasts for up to 7 days after discontinuation. Although the minimum effective aspirin dosage in the

setting of PCI remains uncertain, patients maintained on a regimen of daily chronic aspirin therapy should receive 81 to 325 mg of aspirin before PCI. Patients not already taking daily long-term aspirin therapy should be given 325 mg of aspirin at least 2 hours and preferably 24 hours before PCI is performed. After PCI, aspirin should be continued indefinitely in patients without allergy, and a lower dose (e.g., 81 mg) may be preferable to decrease the risk for gastrointestinal bleeding risk (see Guidelines).

Adenosine Diphosphate Receptor Antagonists

Thienopyridine derivatives cause irreversible platelet inhibition through their effects on the $P2Y_{12}$ ADP receptor, which can activate the glycoprotein (GP) IIb/IIIa complex. Because aspirin and the thienopyridines have distinct mechanisms of action, their combination inhibits platelet aggregation to a greater extent than either agent alone. Use of the combination of aspirin and clopidogrel (or previously, ticlopidine) for 14 to 28 days was essential to prevent stent thrombosis after BMS placement. The combination of aspirin and clopidogrel was also found to reduce death, MI, and urgent revascularization within 12 months in patients undergoing PCI in the setting of NSTEMI and UA and in those undergoing elective PCI. Recent studies suggest that a loading dose of 600 mg of clopidogrel rather than 300 mg results in more rapid (<2 hours) platelet inhibition and improved clinical outcomes, including lower rates of stent thrombosis. Additional clopidogrel loading with 300 or 600 mg may also be used in patients being treated with chronic maintenance clopidogrel therapy, although whether this actually improves clinical outcomes is unclear.[75] The need for pretreatment with clopidogrel is more controversial in that the improved clinical outcomes need to be balanced against the potential risk for bleeding should CABG be necessary. Current guidelines recommend that a 600-mg loading dose of clopidogrel be administered before or during PCI. All post-PCI patients treated with a DES should receive clopidogrel (75 mg daily) for at least 6 months if they do not have a high risk for bleeding. For post-PCI patients receiving a BMS, current guidelines recommend clopidogrel for a minimum of 1 month and ideally up to 12 months (unless the patient has an increased risk for bleeding, in whom it should be given for a minimum of 2 weeks). However, recent studies comparing BMSs to current DESs do not indicate greater safety with BMS, with similar or higher risks of stent thrombosis and higher risks of repeat revascularization within 12 months.[76,77]

Prasugrel, a thienopyridine, is a more potent $P2Y_{12}$ ADP receptor inhibitor with a more rapid onset of action and higher levels of platelet inhibition than higher-dose clopidogrel.[78] In a study of 13,608 patients with moderate- to high-risk ACS undergoing scheduled PCI and randomly assigned to receive prasugrel (60-mg loading dose and 10-mg daily maintenance dose) or clopidogrel (300-mg loading dose and 75-mg daily maintenance dose) for 6 to 15 months, the primary efficacy endpoint—a composite of death from cardiovascular causes, nonfatal MI, or nonfatal stroke—occurred in 12.1% of patients receiving clopidogrel and in 9.9% of those receiving prasugrel ($P < 0.001$).[79] Prasugrel was also associated with significant reductions in rates of MI (9.7% for clopidogrel versus 7.4% for prasugrel; $P < 0.001$), urgent target-vessel revascularization (3.7% versus 2.5%; $P < 0.001$), and stent thrombosis (2.4% versus 1.1%; $P < 0.001$).[79] On the other hand, major bleeding was observed in 2.4% of patients receiving prasugrel and in 1.8% of patients receiving clopidogrel ($P = 0.03$), with more frequent rates of life-threatening bleeding occurring in the prasugrel group (1.4% versus 0.9% with clopidogrel; $P = 0.01$), including fatal bleeding (0.4% versus 0.1%, respectively; $P = 0.002$).[79,80] Among patients treated with clopidogrel, carriers of reduced-function *CYP2C19* alleles had significantly lower levels of active metabolite, diminished platelet inhibition, and higher rates of adverse cardiovascular events.[81] Such a relationship was not found in patients treated with prasugrel. Further research will be necessary to determine whether point-of-care

platelet assays or determination of genetic polymorphisms can help in allocating therapy, although to date this type of testing does not appear to be clinically useful.[82] In patients with an ACS undergoing PCI who are at low bleeding risk, prasugrel may be given in a 60-mg loading dose as soon as possible after definition of the coronary anatomy, with 10 mg daily continued for 12 months after stent placement.

Ticagrelor, a reversible oral $P2Y_{12}$ receptor antagonist, provides faster, greater, and more consistent ADP receptor inhibition than clopidogrel.[83] In a multicenter double-blind trial, 18,624 patients with ACS, with or without ST-segment elevation, were randomly assigned to treatment with ticagrelor (180-mg loading dose, then 90 mg twice daily) or clopidogrel (300- to 600-mg loading dose, then 75 mg daily) for 12 months. The primary endpoint—a composite of death from vascular causes, MI, or stroke at 12 months—occurred in 9.8% of patients receiving ticagrelor and in 11.7% of those receiving clopidogrel (hazard ratio, 0.84; $P < 0.001$).[84] Ticagrelor was also associated with significant reductions in MI alone (5.8% versus 6.9% in clopidogrel group; $P = 0.005$) and in death from vascular causes (4.0% versus 5.1%, respectively; $P = 0.001$).[84] No significant difference in overall rates of major bleeding was observed between the ticagrelor and clopidogrel groups (11.6% and 11.2%, respectively; $P = 0.43$), but ticagrelor was associated with a higher rate of major bleeding not related to CABG (4.5% versus 3.8%; $P = 0.03$).[84]

Current evidence suggests that in the absence of risk factors for bleeding, DAPT should continue for at least 12 months after stent placement.[51] The DAPT score was developed to help further refine individualized treatment by determining which patients are most likely to benefit from or be harmed by continuation of DAPT beyond 12 months.[85] Prolonged ADP receptor antagonist therapy not only reduces late stent thrombosis but also prevents MI remote from the initial intervention. Nonetheless, in patients with elevated bleeding risk, it may be reasonable to consider shorter durations of therapy (6 months) with current DES. Indefinite aspirin and clopidogrel therapy is recommended in patients undergoing brachytherapy, and long-term higher doses (150 mg daily) of clopidogrel, or alternatively, prasugrel or ticagrelor, may be considered in patients in whom stent thrombosis may be catastrophic, such as those with unprotected left main coronary artery stenting or with stenting of the last remaining vessel.[10] It is important to note that the patients in these trials did not receive anticoagulant therapy, and that there are multiple ongoing trials examining antiplatelet therapy in conjunction with warfarin or novel anticoagulants for patients with atrial fibrillation undergoing coronary stent treatment.[86,87] IV cangrelor is now approved for use in elective and urgent PCI and is an attractive option for patients who have not been pretreated with oral ADP receptor antagonists.[88,89]

Glycoprotein IIB/IIIA Inhibitors

Thrombin and collagen are potent platelet agonists that can cause release of ADP and serotonin and activate GP IIb/IIIa receptors on the platelet surface (**see Chapter 93**). Functionally active GP IIb/IIIa has a role in the "final common pathway" of platelet aggregation by binding fibrinogen and other adhesive proteins that bridge adjacent platelets. Three intravenous GP IIb/IIIa inhibitors are approved for clinical use. Studies supporting the use of these agents during PCI were performed before the widespread use of DAPT, however, and use of these agents has been reevaluated in this context.

Abciximab is a chimeric human-murine monoclonal antibody that irreversibly binds to the platelet GP IIb/IIIa receptor on human platelets. It also binds to the vitronectin ($\alpha_v\beta_3$) receptor found on platelets and to vessel wall endothelial and smooth muscle cells. The recommended dosage of abciximab is a 0.25 mg/kg by IV bolus, followed by a continuous IV infusion of 0.125 µg/kg/min (to a maximum of 10 µg/min) for 12 hours. Abciximab can be administered safely in patients with renal insufficiency, and

platelet infusions can reverse the effect of this agent (although repeated transfusions may be necessary).

Eptifibatide is a cyclic peptide derivative that reversibly binds GP IIb/IIIa. The double eptifibatide bolus (180-µg/kg boluses 10 minutes apart) and infusion dose (2.0 µg/kg/min for 18 to 24 hours) result in sufficient platelet inhibition to prevent ischemic events in patients undergoing PCI. Addition of eptifibatide to a 600-mg loading dose of clopidogrel also causes incremental platelet inhibition. The eptifibatide infusion must be reduced to 1 µg/kg/min in patients with a creatinine clearance lower than 50 mL/min. Platelet transfusions do not reverse the platelet inhibition with eptifibatide, although by 4 hours after cessation of the infusion, patients have safely undergone CABG.

Tirofiban, a small peptidomimetic molecule, has also undergone evaluation for its adjunctive benefit during urgent PCI but was found to be inferior to abciximab for prevention of ischemic events during PCI. The recommended dosage of tirofiban is an initial rate of 0.4 µg/kg/min for 30 minutes and then continued at 0.1 µg/kg/min. Patients with severe renal insufficiency (creatinine clearance <30 mL/min) should receive half the usual rate of infusion. Subsequent studies have suggested that the tirofiban bolus dose given in the initial PCI studies may not have produced an optimal antiplatelet effect during PCI, and that larger bolus doses can improve the inhibition of platelet aggregation.

The GP IIb/IIIa inhibitors have demonstrated improvement in clinical outcomes within the first 30 days after PCI, primarily by reducing ischemic complications, including periprocedural MI and recurrent ischemia. They are particularly useful in patients with troponin-positive ACS but have no consistent effect in reducing late restenosis. Although GP IIb/IIIa inhibitors differ in their structure, reversibility, and duration, two meta-analyses found no difference between their clinical effects in patients undergoing primary PCI.[90,91] Bleeding is the major risk associated with GP IIb/IIIa inhibitors, and therefore downward adjustment of the unfractionated heparin dose has been recommended. GP IIb/IIIa inhibitors are recommended in patients with NSTEMI and UA who are *not* pretreated with clopidogrel, and it is reasonable to administer them to patients with troponin-positive ACS who have also been pretreated with clopidogrel.[92,93]

Antithrombin Agents

Unfractionated heparin (UFH) is the most commonly used thrombin inhibitor during PCI. Point-of-care activated clotting time (ACT) monitoring has facilitated heparin dose titration during PCI, and retrospective studies on balloon angioplasty have related the ACT value to clinical outcome after PCI. An ACT in the range of 350 to 375 seconds provided the lowest composite ischemic event rate, although any level of ACT longer than 250 seconds was not associated with any further reductions in ischemic complications with the concomitant use of GP IIb/IIIa inhibitors. More recent studies in the thienopyridine era have failed to correlate ischemic outcomes with the level of anticoagulation achieved with UFH during coronary stent placement. Weight-adjusted heparin dosing regimens of 50 to 70 IU/kg help avoid "overshooting" the ACT. Sufficient UFH should be administered during PCI to achieve an ACT longer than 250 to 300 seconds if no GP IIb/IIIa inhibitor is given, and longer than 200 to 250 seconds if a GP IIb/IIIa inhibitor is given. Routine use of IV heparin after PCI is no longer indicated. If no closure device has been used, early sheath removal is encouraged when the ACT falls to less than 150 to 180 seconds. (**See also Chapter 93**.)

Low-Molecular-Weight Heparin

Enoxaparin is considered a reasonable alternative to UFH in patients with non–ST-segment elevation

ACS undergoing PCI (**see Chapter 60**), but difficulty monitoring the levels of anticoagulation in the event that PCI is performed has limited its clinical use at many centers.[94] The SYNERGY (Superior Yield of the New Strategy of Enoxaparin, Revascularization and Glycoprotein IIb/IIIa Inhibitors) trial prospectively randomly assigned 10,027 high-risk patients with non–ST-elevation ACS with an intended early invasive strategy to treatment with subcutaneous enoxaparin or to IV UFH. The 30-day primary efficacy outcome, a composite clinical endpoint of all-cause death or nonfatal MI occurred in 14% of the enoxaparin patients and in 14.5% of the UFH patients. More TIMI (thrombolysis in myocardial infarction) major bleeding was observed in patients treated with enoxaparin (9.1% versus 7.6%; $P = 0.008$). Risk for bleeding was highest in patients who received "crossover" therapy with UFH and enoxaparin. When enoxaparin is given before PCI, empiric dose algorithms have been designed to guide additional anticoagulation therapy during PCI. If the last dose of enoxaparin was administered less than 8 hours before PCI, no additional antithrombin is needed. If the last dose of enoxaparin was given between 8 and 12 hours, a 0.3-mg/kg bolus of IV enoxaparin should be administered. If the dose was administrated more than 12 hours before PCI, conventional anticoagulation therapy is indicated.

Bivalirudin

Bivalirudin is a direct thrombin inhibitor that has been used as an alternative to UFH in patients undergoing PCI. Bivalirudin generally causes fewer bleeding complications than UFH because of its shorter half-life (25 minutes) and more predictable bioavailability. Bivalirudin is also accessible to clot-bound thrombin, because its anticoagulant effect does not depend on binding with antithrombin. Bivalirudin was not inferior to the combination of UFH and GP IIb/IIIa inhibitor in 6010 "low-risk" patients in the REPLACE-2 (Second Randomized Evaluation in PCI Linking Angiomax to Reduced Clinical Events) trial. In a larger study of 13,819 patients with UA and NSTEMI, bivalirudin alone was compared with bivalirudin plus a GP IIb/IIIa inhibitor and with heparin plus a GP IIb/IIIa inhibitor. Using a composite ischemia endpoint of death, MI, or unplanned revascularization for ischemia and major bleeding to determine the net clinical benefit, bivalirudin alone, versus heparin plus a GP IIb/IIIa inhibitor, showed noninferiority in the composite ischemia endpoint (7.8% and 7.3%, respectively) and significantly reduced rates of major bleeding (3.0% versus 5.7%; $P < 0.001$), which resulted in a better net clinical outcome (10.1% versus 11.7%; $P = 0.02$). Bivalirudin is considered a reasonable alternative to UFH in low-risk patients undergoing PCI and may reduce bleeding complications in higher-risk patients with UA and NSTEMI. Bivalirudin may be safely substituted for UFH in patients with ACS[95] and is a cost-effective alternative to UFH plus a GP IIb/IIIa inhibitor. In a randomized study of 3602 patients with STEMI undergoing primary PCI, anticoagulation with bivalirudin alone, versus heparin plus GP IIb/IIIa inhibitors, resulted in significantly reduced 30-day rates of major bleeding and net adverse clinical events, including a lower rate of mortality.[93] Adjunctive oral ADP-blocking agents should be given as soon as possible before PCI in patients with ACS.

Factor Xa Inhibitors

Fondaparinux is a pentasaccharide that has anti–factor Xa activity without effects on factor IIa and may cause less bleeding when used to treat patients with ACS.[96] The OASIS-5 (Fifth Organization to Assess Strategies in Acute Ischemic Syndromes) trial randomly assigned 20,078 patients with ACS to receive either fondaparinux (2.5 mg daily) or enoxaparin (1 mg/kg of body weight twice daily) for a mean of 6 days. Occurrence of the 9-day primary study endpoint (death, MI, or refractory ischemia) was similar in

the two groups (5.8% with fondaparinux and 5.7% with enoxaparin), although the risk for major bleeding at 9 days was markedly lower with fondaparinux than with enoxaparin (2.2% versus 4.1%; $P < 0.001$). This reduction in bleeding was accompanied by an improvement in late mortality in patients treated with fondaparinux. Potential limitations of this approach are the relatively long half-life of fondaparinux and the need for adjunctive anticoagulation with heparin during PCI to avoid the development of catheter thrombi. Fondaparinux was not effective in reducing ischemic events in patients undergoing primary PCI for STEMI.

Outcomes After Percutaneous Coronary Intervention

Procedural success and complication rates are used to measure outcomes after PCI. Early (<30 day) success (e.g., relief of angina; freedom from death, MI, urgent revascularization) is generally related to the safety and effectiveness of the initial procedure, whereas late (30 days to 1 year) success (e.g., freedom from angina recurrence, target-vessel revascularization, MI, death) depends on both clinical restenosis and progressive atherosclerosis at remote sites. Substantial improvements in coronary devices (e.g., DESs), in the adjunctive antithrombotics used during PCI (e.g., ADP antagonists, GP IIb/IIIa inhibitors, direct thrombin inhibitors), and in secondary prevention after PCI (e.g., therapy with lipid-lowering agents, beta-adrenergic blockers, antiplatelet drugs; **see Chapter 45**) have greatly improved early and late clinical outcomes after PCI.

Early Clinical Outcomes

Anatomic (or angiographic) *success* after PCI is defined as attainment of a residual diameter stenosis of less than 50%, which is generally associated with at least a 20% improvement in diameter stenosis and relief of ischemia. With the widespread use of coronary stents, the angiographic criterion for success is 20% stenosis or less when stents are used. Procedural success is defined as angiographic success without the occurrence of major complications (death, MI, or CABG) within 30 days of the procedure. *Clinical success* is defined as procedural success without the need for urgent repeated PCI or surgical revascularization within the first 30 days of the procedure. Several clinical, angiographic, and technical variables can be used to predict the risk for procedural failure in patients undergoing PCI. Major complications include death, MI, or stroke, and minor complications include transient ischemic attacks, vascular complications, contrast-induced nephropathy, and angiographic complications.

Mortality

Although mortality after PCI is rare (<1%), it is higher in the setting of STEMI, in cardiogenic shock, and in patients with previously poor LV function in whom an occlusion develops. Several risk factors for early mortality after PCI have been identified.[97,98]

Myocardial Infarction

Periprocedural MI is one of the most common complications of PCI.[99] Two classification systems were previously used to classify MI after PCI: the World Health Organization (WHO) classification system, which defines MI as an elevation in total creatine kinase (CK) more than two times normal in association with elevation of the CK-myocardial band (MB) isoform, and a second system, more frequently used for evaluation of adjunctive pharmacologic agents by the U.S. Food and Drug Administration (FDA), in

which MI is defined as an elevation in CK-MB three times normal or higher after the procedure. A consensus definition of periprocedural MI now uses a troponin level elevated more than five times normal when it occurs in conjunction with clinical evidence of MI with symptoms, changes on the electrocardiogram (ECG), angiographic findings, or a new imaging abnormality.[100] In clinical practice, asymptomatic CK-MB elevation (<5 times upper limit of normal) occurs after 3% to 11% of technically successful PCIs and has little apparent clinical consequence. Larger degrees of myonecrosis (CK-MB 5 to 8 times upper limit of normal) are associated with higher 1-year mortality rates and should be considered a periprocedural MI. Many of these clinically silent infarcts may reflect a higher atherosclerotic burden in patients with such events and may not be truly causal. Troponin T and I elevations occur more often than CK-MB elevations, but their prognostic significance over that of CK-MB elevation is not as well established. Spontaneous MI after PCI has much more prognostic importance than periprocedural enzyme elevation.[101]

Urgent Revascularization

Emergency or urgent CABG following PCI is now uncommon and, in the era of coronary stents, results from catastrophic complications during PCI, such as coronary perforation or severe dissection and abrupt closure. Chest pain after PCI is relatively common, and evaluation requires an immediate 12-lead ECG. Recurrent ischemia after PCI, as manifested by chest pain, ECG abnormalities, and elevated levels of cardiac biomarkers, may result from acute or subacute stent thrombosis, residual dissections, plaque prolapse, side branch occlusion, or thrombus at the treatment site or may be related to residual disease not treated during the initial procedure. In the presence of suspected recurrent ischemia, coronary arteriography is the most expeditious way to identify the cause of the residual ischemia.

Angiographic Complications

Complications that occur during PCI, depending on their severity and duration, may result in periprocedural MI (Videos 62.1 and 62.2). If coronary dissections that extend deeper into the media or adventitia begin to compromise the true lumen of the vessel, clinical ischemia may develop. Even though most intraprocedural dissections can be treated promptly by stenting, significant residual dissections of the treated artery occur in 1.7% of patients. These residual dissections increase the risk for postprocedural MI, need for emergency CABG, and the incidence of stent thrombosis and increase mortality threefold.[102] In addition to barotrauma-induced dissections, dissections attributable to the guiding catheter represent another mechanism for disrupting the coronary vessel and compromising distal flow.

Coronary perforation develops in 0.2% to 0.5% of patients undergoing PCI and is more common with atheroablative devices and hydrophilic wires than with balloon angioplasty or conventional guidewires. Depending on the rate of flow through the vessel perforation, cardiac tamponade and hemodynamic collapse can occur within minutes, thus requiring immediate recognition and treatment of the perforation. Strategies for controlling coronary perforations include reversal of intraprocedural anticoagulation and prolonged inflation (at least 10 minutes) of an oversized balloon at low pressure at the site of the perforation to encourage sealing of the tear in the vessel. Management strategies for perforations include the use of perfusion balloons, which provide a small amount of distal perfusion, and the use of polytetrafluoroethylene (PTFE)-covered stents, which may control free perforations, in addition to decompression of pericardial pressure with prompt pericardiocentesis. Approximately one third of patients with PCI-associated coronary artery perforation require emergency cardiac surgery.

No-reflow is defined as reduced anterograde perfusion in the absence of a flow-limiting stenosis and occurs in up to 2% to 3% of PCI procedures, typically during interventions on degenerated SVGs, during rotational atherectomy, and during acute MI interventions. No-reflow is probably caused by distal embolization of atheromatous and thrombotic debris dislodged by balloon inflation, atherectomy, or stent implantation. Once it occurs, no-reflow can cause severe short- and long-term consequences, including a fivefold increased risk for periprocedural MI and a threefold increased risk for death. Although numerous pharmacologic strategies (e.g., intracoronary sodium nitroprusside) have been used to treat no-reflow, their efficacy in reducing the frequency of subsequent adverse events is still debated.

Stent Thrombosis.

With the routine use of a high-pressure stent after dilation and DAPT after stent implantation, the rate of stent thrombosis has declined to approximately 1% within the first year after stenting, although it can be higher in patients with STEMI or after complex PCI. Certain clinical, angiographic, and procedural factors predispose to its development. Lesion-specific factors that increase the likelihood of stent thrombosis include a residual dissection at the margin of the stent, impaired flow into or out of the stent, small stent diameter (<3 mm), long stent length, and treatment of acute MI. Patient noncompliance with DAPT, resistance to the antiplatelet effects of aspirin and clopidogrel, and hypercoagulability may also play important roles in the development of stent thrombosis (**Table 62.2**).

TABLE 62.2

Variables Associated with Stent Thrombosis

Clinical Variables
Acute myocardial infarction
Clopidogrel noncompliance and discontinuation
Clopidogrel bioavailability
Diabetes mellitus
Renal failure
Congestive heart failure
Previous brachytherapy
Anatomic Variables
Long lesions
Smaller vessels
Multivessel disease
Acute myocardial infarction
Bifurcation lesions
Procedural Factors
Stent underexpansion
Incomplete wall apposition
Residual inflow and outflow disease
Margin dissections
Crush technique
Overlapping stent
Polymer materials

The timing of stent thrombosis is defined as acute (<24 hours), subacute (24 hours to 30 days), late (30 days to 1 year), and very late (>1 year). Traditional definitions of stent thrombosis have included only episodes associated with an ACS and angiographic or pathologic demonstration of thrombosis within the stent or its margins. The Academic Research Consortium has proposed criteria for documentation of all possible stent thrombosis in clinical studies, including the categories of definite, probable, and possible.

Early reports suggested an incremental risk (0.2% to 0.5% per year) for very late stent thrombosis occurring 1 year or longer after DES implantation.[103] Inhibition of endothelialization caused by the potent antiproliferative effect of the drugs delivered by DESs may significantly prolong the period of risk for

the development of stent thrombosis. Although concerning, these events have not yet been shown to cause a significant increase in late morbidity or mortality, probably because of the benefits of DESs in reducing the need for repeated revascularization procedures and avoidance of the complications associated with the development of in-stent restenosis.[1,104-106] Ongoing evaluation of the long-term safety of DESs has engendered intense investigation, with efforts focused on determining whether patient- and lesion-specific risk factors, such as insensitivity to aspirin or clopidogrel, may contribute; whether these risks are device-specific or drug-specific phenomena; and whether prolonged DAPT may ameliorate these risks. Preliminary data suggest that second-generation DESs have lower rates of stent thrombosis than first-generation DESs. IV antiplatelet agents, such as the ADP receptor antagonist cangrelor, have the potential to further reduce the rate of periprocedural stent thrombosis.[107]

The not-infrequent scenario of a patient requiring noncardiac surgery in the weeks following PCI can markedly increase the risk for stent thrombosis. Studies of outcomes in patients undergoing noncardiac surgery soon after BMS PCI have documented stent thrombosis occurring in up to 8% in the first 2 weeks after PCI, with risks declining to baseline rates by 8 weeks. This increased risk probably results from the frequent cessation of ADP receptor antagonist treatment before surgery, as well as the hypercoagulable state in the perioperative period.

Late Clinical Outcomes

Ischemic events within the first year after PCI result from one of three processes. *Lumen renarrowing* requiring repeated target-lesion revascularization occurs in 20% to 30% of patients undergoing balloon angioplasty because of reparative arterial constriction, also known as “negative remodeling.” *Clinical restenosis* after stent implantation is less common (10% to 20%) and attributable to intimal hyperplasia within the stent. *Clinical recurrence* caused by restenosis is least common (3% to 5%) after DES placement because of focal tissue growth within the stent or at its margins. Yet another cause of clinical events after PCI is progression of coronary atherosclerosis at a site remote from that treated earlier by PCI. Death and MI can also result from sudden rupture of a plaque that is remote from the site of the initial intervention.

These processes can be partially distinguished by the timing of their occurrence. Clinical restenosis resulting from lumen renarrowing at the site of PCI generally develops within the first 6 to 9 months after PCI, whereas death and MI because of plaque instability may occur at any point after PCI at a low but constant rate (1% to 2% risk per year). Predictors of higher risk for all-cause late mortality include advanced age, reduced LV function, congestive heart failure, DM, a higher number of diseased vessels, inoperable disease, or severe comorbid conditions. A 95% 10-year survival rate can be expected in patients with single-vessel CAD, and an 80% survival rate after PCI can be achieved in those with multivessel CAD. In a 5-year follow-up study of patients treated with the TAXUS stent, target-vessel revascularization during the first year was driven by target-lesion revascularization, and target-vessel revascularization after 1 year involved similar numbers of target-lesion and non–target-lesion revascularization events, primarily as a result of progression of atherosclerotic disease. The annualized hazard ratio for non–target-lesion revascularization and other major adverse events (including death, MI, and stent thrombosis) was relatively constant beyond 1 year and not significantly different between paclitaxel-eluting stents and BMSs.[108]

Outcomes Benchmarking and Procedural Volumes

Along with CABG, PCI ranks among the most studied of all procedures in the United States. National structured outcomes registries, such as the National Heart, Lung and Blood Institute (NHLBI) Dynamic Registry and the ACC National Cardiovascular Data Repository (NCDR), have been examined.[9,109-111] The NCDR CathPCI registry also provides contemporary risk-adjusted outcomes benchmarked to hundreds of participating institutions. Participants in such national, regional, or statewide outcomes-reporting initiatives can compare their risk-adjusted clinical outcomes with those at institutions with similar patient mix and size. The detailed nature of these datasets, in which the data collected span the range of patient clinical characteristics, lesion descriptors, and device-level information, provides centers with a comprehensive comparison of their practice patterns and outcomes with those at peer institutions. More than 50% of U.S. hospitals participate in the NCDR CathPCI registry. Participation in a prospective quality assessment and outcomes registry is recommended for centers performing PCI.

Guidelines recommend that physicians undergo a 3-year comprehensive cardiac training program with 12 months of training in diagnostic catheterization, during which the trainee performs 300 diagnostic catheterizations, including 200 as the primary operator. Interventional training requires a fourth year of training, including more than 250 interventional procedures, a level that is also required for physicians to be eligible for the American Board of Internal Medicine certifying examination in interventional cardiology.

The guidelines favor performance of PCI by higher-volume operators, defined as those performing more than 75 procedures per year at high-volume centers (those in which more than 400 procedures are performed each year). These recommendations are based on the dated observations that higher-volume operators have lower adverse event rates than do lower-volume operators.[112] In one analysis of 1338 PCIs performed in the United States and Canada, operators with fewer than 100 cases per year had higher rates of 30-day death, MI, or target-vessel revascularization (13.2% versus 8.7%; $P = 0.18$) and large MI (7.7% versus 3.3%; $P = 0.06$) than did those with 100 or more cases per year.[112] However, a more contemporary analysis of primary PCI found no relationship between hospital PCI volume and mortality in hospitals participating in a quality improvement initiative.[113]

Although PCI has traditionally been performed at centers that offer on-site surgical backup, more recent analyses have shown that PCI for STEMI and elective PCI can be performed safely, provided that PCI is performed by high-volume operators with minimal institutional volume requirements.[9,114-116] Off-site PCI is best suited for underserved areas that are geographically far removed from major centers.

Institutions must have a system for quality measurement and improvement that includes valid peer review. The guidelines recommend that quality assessment reviews take into consideration risk adjustment, statistical power, and national benchmark statistics. They should also include tabulation of adverse event rates for comparison with benchmark values, as well as case review of complicated procedures and some uncomplicated procedures.

Future Perspectives

After three decades of rapid growth and dissemination of coronary interventional techniques and the associated dramatic refinement in the devices used for revascularization, many challenges still remain for the percutaneous treatment of CAD. Ongoing large-scale multicenter randomized trials will assess the safety and efficacy of PCI with DESs in patients with unprotected left main coronary artery stenosis. Additional technologies are currently in clinical testing for the treatment of complex bifurcation stenosis with dedicated bifurcation stent systems. Better techniques to treat chronic total occlusions are being

developed.

DES design is continually evolving in an attempt to optimize effective early endothelialization of the stented segment without sacrificing the long-term benefits of DESs in reducing target-lesion revascularization. Theoretically, advances in stent, polymer, and drug design could lead to improvements in restenosis and thrombosis rates, which in turn may reduce rates of MI and even death (**Fig. 62.9**). Of course, this concept would need to be tested prospectively in adequately powered trials of sufficient duration, but it could lead to reexamination of the relative merits of PCI versus medical therapy or CABG in a variety of settings.

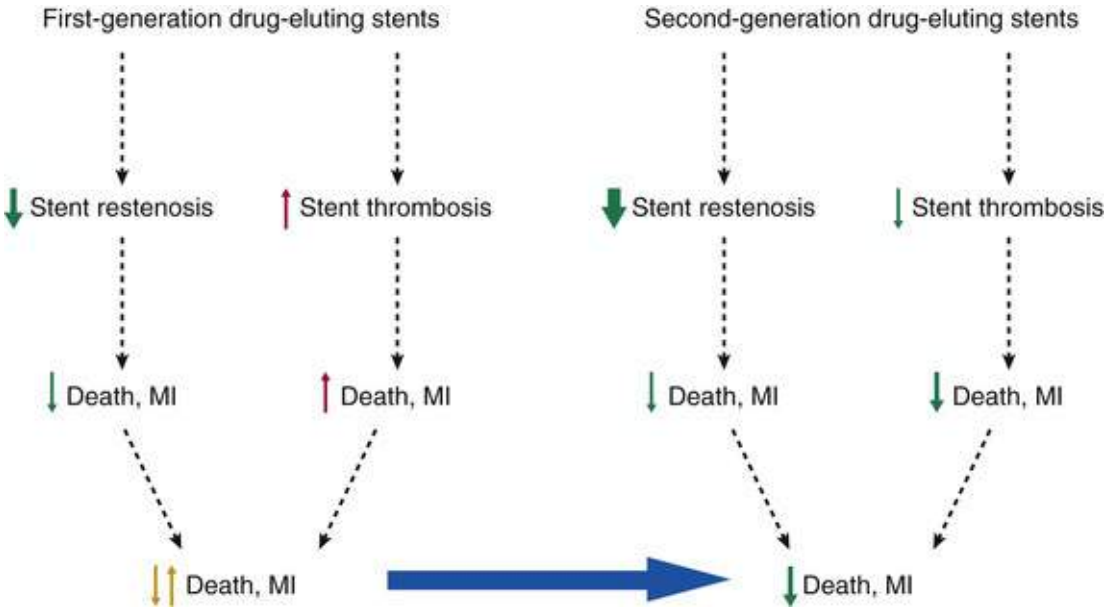

FIGURE 62.9 Theoretical framework by which second-generation drug-eluting stents (DESs) might decrease the risk for myocardial infarction (MI) and cardiovascular death in comparison to bare-metal stents, even though first-generation DESs did not. (From Bhatt DL. Examination of new drug-eluting stents—top of the class! Lancet 2012;380:1453.)

Determination of the optimal duration of antiplatelet therapy following DES deployment requires ongoing study. Bioabsorbable stents, produced from bioerodible polymers or magnesium alloys, show promise as a mechanism of providing short-term scaffolding to prevent abrupt closure of the vessel while leaving nothing permanent in the vessel wall after several months, thereby potentially reducing the risk for very late stent thrombosis, although this has not been proved to date.

Early investigations of myocardial regeneration following acute MI by percutaneous delivery of autologous stem cell or progenitor cell lines have generated great interest in the potential of such therapies to improve myocardial recovery (**see Chapter 30**), but more clinical data are needed. Continued refinement of ventricular support devices offers hope for myocardial recovery in the patient with severe myocardial dysfunction.

Guidelines

Percutaneous Coronary Intervention

Laura Mauri and Deepak L. Bhatt

The American College of Cardiology/American Heart Association (ACC/AHA) published their initial guidelines for the performance of percutaneous coronary intervention (PCI) in 2001 and have since provided a series of focused updates that revised selected recommendations based on the ever-expanding clinical evidence base and evolving practice patterns.[1-3] In aggregate, these guidelines have provided clinicians with the tools required to enhance clinical decision making for patients undergoing percutaneous revascularization.

As with other ACC/AHA guidelines, they use the standard ACC/AHA classification system for indications (class of recommendation, COR):

I: Conditions for which there is evidence and/or general agreement that the test is useful and effective.
II: Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness or efficacy of performing the test.
IIa: Weight of evidence or opinion is in favor of usefulness or efficacy.
IIb: Usefulness or efficacy is less well established by evidence and/or opinion.
III: Conditions for which there is evidence and/or general agreement that the test is not useful or effective and in some cases may be harmful.

Three levels are used to rate the level of evidence (LOE) on which recommendations have been based:

A: Recommendations are derived from data from multiple randomized clinical trials.
B: Recommendations are derived from a single randomized trial or nonrandomized studies.
C: Recommendations are based on the consensus opinion of experts.

Clinical Features

Guidelines relevant to the use of PCI to improve survival over that achieved with medical therapy (**Table 62G.1**) and to improve symptoms in patients with significant anatomic or physiologic coronary artery stenoses (**Table 62G.2**) and ST-elevation myocardial infarction (STEMI) (**Table 62G.3**) are provided.

TABLE 62G.1

ACC/AHA Recommendations for Percutaneous Coronary Intervention (PCI) to Improve Survival Over That Achieved with Medical Therapy[3]

ANATOMIC SETTING	COR	RECOMMENDATION	LOE
Unprotected left main or complex CAD	I	Heart team approach recommended	C
	IIa	Calculation of STS and SYNTAX scores	B
Unprotected left main	IIa	PCI for SIHD when both the following are present: anatomic conditions associated with a low risk for procedural complications (e.g., low SYNTAX score of ≤22, ostial or trunk left main CAD) *and* clinical characteristics that predict a significantly increased risk for adverse surgical outcomes, such as an STS-predicted risk for operative mortality ≥5%	C
	IIa	PCI for UA/NSTEMI if not a CABG candidate	B
	IIa	PCI for STEMI when distal coronary flow is TIMI flow grade <3 and PCI can be performed more rapidly and safely than CABG	C
	IIb	PCI for SIHD when both the following are present: anatomic conditions associated with a low to intermediate risk for procedural complications and an intermediate to high likelihood of good long-term outcome (e.g., low to intermediate SYNTAX score of <33, bifurcation left main CAD) *and* clinical characteristics that predict an increased risk for adverse surgical outcomes, such as moderate to severe COPD and disability from previous stroke or previous cardiac surgery, as well as an STS-predicted risk for operative mortality >2%	B
Three-vessel disease	IIb	PCI of uncertain benefit relative to CABG	B

COR, Class of recommendation; *LOE,* level of evidence; *CABG,* coronary artery bypass grafting; *CAD,* coronary artery disease; *COPD,* chronic obstructive pulmonary disease; *NSTEMI,* non–ST-segment elevation myocardial infarction; *SIHD,* stable ischemic heart disease; *STEMI,* ST-segment elevation myocardial infarction; *STS,* Society of Thoracic Surgeons; *SYNTAX,* Synergy Between PCI with TAXUS and Cardiac Surgery; *TIMI,* Thrombolysis in Myocardial Infarction; *UA,* unstable angina.

TABLE 62G.2

ACC/AHA Recommendations for Percutaneous Coronary Intervention (PCI) to Improve Symptoms in Patients with Significant Anatomic or Physiologic Coronary Artery Stenosis[3]

ANATOMIC SETTING	COR	RECOMMENDATION	LOE
≥1 significant stenosis and unacceptable angina despite GDMT	I	PCI or CABG	A
≥1 significant stenosis and unacceptable angina in patients in whom GDMT cannot be implemented	IIa	PCI or CABG	C
Previous CABG with ≥1 significant stenosis associated with ischemia and unacceptable angina despite GDMT	IIa	PCI	C
Complex three-vessel CAD (e.g., SYNTAX score >22) and a good candidate for CABG	IIa	CABG preferred over PCI	B

COR, Class of recommendation; *LOE,* level of evidence; *CABG,* coronary artery bypass grafting; *CAD,* coronary artery disease; *GDMT,* guideline-directed medical therapy.

TABLE 62G.3

ACC/AHA Recommendations for Percutaneous Coronary Intervention (PCI) in Patients with ST-Segment Elevation Myocardial Infarction (STEMI)[2,3]

INDICATION	COR	RECOMMENDATION	LOE
Primary PCI	I	STEMI symptoms within 12 hours	A
		Severe heart failure or cardiogenic shock	B
		Contraindications to fibrinolytic therapy with ischemic symptoms <12 hours	B
	IIa	Clinical and/or electrocardiographic evidence of ongoing ischemia between 12 and 24 hours after symptom onset	B
	IIb	PCI of noninfarct artery may be considered in selected patients with STEMI and multivessel disease who are hemodynamically stable, either at the time of primary PCI or as a planned staged procedure	B-R
Delayed or elective PCI	IIa	Clinical evidence of fibrinolytic failure or infarct artery reocclusion	B
		Ischemia on noninvasive testing	B
	IIb	Hemodynamically significant stenosis in a patent infarct artery >24 hours after STEMI	B
	III (no benefit)	Totally occluded infarct artery >24 hours after STEMI in a hemodynamically stable asymptomatic patient without evidence of severe ischemia	B

COR, Class of recommendation; *LOE,* level of evidence.

Adjunctive Pharmacotherapy

Guidelines for duration of antiplatelet therapy after PCI have recently been updated, based on data from randomized clinical trials assessing the duration of dual-antiplatelet therapy (DAPT) with aspirin plus a $P2Y_{12}$ inhibitor (**Table 62G.4**). Overall, extended-duration DAPT is associated with lower risks of myocardial infarction (MI) and stent thrombosis and a higher risk of nonfatal bleeding. Balancing the benefits of reduced ischemic events with the risks of increased bleeding events is recommended for individual patients when determining the duration of treatment (**Table 62G.5**). The expanding number of antiplatelet and antithrombin agents available for use during PCI has provided clinicians with a number of competing therapeutic options. Guidelines for antiplatelet therapy and antithrombin therapy during PCI have been provided (**Table 62G.6**). Guidelines for antiplatelet therapy after PCI have also been provided (**Table 62G.7**). In addition, there is increasing awareness that providing optimal medical therapy following PCI is mandatory, including secondary risk factor modifications such as lipid-lowering therapy (**see Chapter 45**).

TABLE 62G.4

ACC/AHA Recommendations on Duration of Dual-Antiplatelet Therapy (DAPT) for Patients Undergoing Percutaneous Coronary Intervention (PCI)[10]

COR	RECOMMENDATION	LOE
I	After PCI, in patients with stable ischemic heart disease, treat with clopidogrel for at least 1 month in patients treated with a BMS.	A
I	After PCI, in patients with stable ischemic heart disease, treat with clopidogrel for at least 6 months in patients treated with a DES.	B-R
IIb	After PCI, in patients with stable ischemic heart disease with no high risk of bleeding and no significant overt bleeding on DAPT, treatment for more than 1 month may be reasonable for patients treated with a BMS, and treatment for more than 6 months may be reasonable for patients treated with a DES.	A
IIB	In patients with stable ischemic heart disease treated with DAPT after DES who develop a high risk of bleeding (e.g., treatment with oral anticoagulant therapy), are at high risk of severe bleeding complication (e.g., major intracranial surgery), or develop significant overt bleeding, discontinuation of $P2Y_{12}$ inhibitor therapy after 3 months may be reasonable.	C-LD
I	In patients with acute or recent ACS (non–ST-elevation ACS or NSTEMI) treated with PCI with DES or BMS, treat with at least 12 months of clopidogrel, prasugrel, or ticagrelor.	B-R
IIa	In patients with acute or recent ACS (non–ST-elevation ACS or NSTEMI) treated with DAPT after coronary stent implantation, it is reasonable to use ticagrelor in preference to clopidogrel for maintenance $P2Y_{12}$ inhibitor therapy.	B-R
IIa	In patients with acute or recent ACS (non–ST-elevation ACS or NSTEMI) treated with DAPT after coronary stent implantation, who are not at high risk for bleeding complications and who do not have a history of stroke or TIA, it is reasonable to choose prasugrel over clopidogrel for maintenance $P2Y_{12}$ inhibitor therapy.	B-R
IIB	In patients with acute or recent ACS (non–ST-elevation ACS or NSTEMI) treated with DAPT after DES who develop a high risk of bleeding (e.g., treatment with oral anticoagulant therapy), are at high risk of severe bleeding complication (e.g., major intracranial surgery), or develop significant overt bleeding, discontinuation of $P2Y_{12}$ inhibitor therapy after 6 months may be reasonable.	C-LD
IIB	In patients with acute or recent ACS (non–ST-elevation ACS or NSTEMI) treated with PCI (DES or BMS) and not at high bleeding risk (e.g., prior bleeding on DAPT, coagulopathy, oral anticoagulant use), treatment for more than 12 months with clopidogrel, prasugrel, or ticagrelor may be reasonable.	A
III	Prasugrel should not be administered to patients with a prior history of stroke or TIA.	B-R

COR, Class of recommendation; *LOE,* level of evidence (B-R, moderate-quality evidence from one or more randomized clinical trials; *C-LD,* randomized or nonrandomized observational/registry studies or a meta-analysis); *ACS,* acute coronary syndrome; *BMS,* bare-metal stent; *DES,* drug-eluting stent; *NSTEMI,* non–ST-elevation myocardial infarction; *TIA,* transient ischemic attack.

TABLE 62G.5

Dual-Antiplatelet Therapy (DAPT) Score*

CLINICAL PREDICTION SCORE VARIABLE	POINTS
Age ≥75 years	−2
Age 65 to <75 years	−1
Age <65 years	0
Cigarette smoking	1
Diabetes mellitus	1
Myocardial infarction at presentation	1
Prior percutaneous coronary intervention or prior myocardial infarction	1
Paclitaxel-eluting stent	1
Stent diameter <3 mm	1
Congestive heart failure, or left ventricular ejection fraction <30%	2
Vein graft stent	2
Total score range	**−2 to 10**

*Scores of 2 or higher may indicate that extended-duration DAPT is associated with a reduction in MI or stent thrombosis that is greater than the increase in moderate or severe bleeding. Conversely, scores lower than 2 may indicate that extended-duration DAPT is associated with an increase in bleeding that is greater than the reduction in MI or stent thrombosis.

Modified from Levine GN, Bates ER, Bittl JA, et al. ACC/AHA guideline focused update on duration of dual antiplatelet therapy in patients with coronary artery disease. Circulation 2016;134:e123.

TABLE 62G.6

ACC/AHA Recommendations for Antiplatelet and Antithrombin Pharmacotherapy During Percutaneous Coronary Intervention (PCI)[3]

INDICATION	COR	RECOMMENDATION	LOE
Aspirin (ASA)	I	Patients already taking daily long-term ASA therapy should take 81 to 325 mg of ASA before PCI is performed.	B
		Patients not taking ASA therapy should be given nonenteric ASA, 325 mg, before PCI.	B
$P2Y_{12}$ inhibitors Clopidogrel, prasugrel, ticagrelor	I	A loading dose of clopidogrel, generally 600 mg, should be administered before or when PCI is performed.	A
		Clopidogrel: a 600-mg loading dose is recommended.	B
		Prasugrel: generally not recommended in patients >75 years of age; FDA suggests consideration of using a lower maintenance dose in patients weighing <60 kg.	B
		Ticagrelor: issues of patient compliance may be especially important because it is given twice daily.	B
	III	Prasugrel is contraindicated in patients with previous TIA/CVA.	B
Glycoprotein (GP) IIb/IIIa inhibitors	I	If no clopidogrel pretreatment, and UA/NSTEMI with high-risk features.	A
	IIa	If no clopidogrel pretreatment and STEMI, most appropriate with large anterior MI and/or large thrombus burden.	A
		If no clopidogrel pretreatment and stable ischemic heart disease.	B
	IIa	If clopidogrel pretreatment and STEMI, most appropriate with large anterior MI and/or large thrombus burden.	C
	IIa	If clopidogrel pretreatment and UA/NSTEMI with high-risk features.	B
	IIb	If clopidogrel pretreatment and stable ischemic heart disease.	B
	III	Precatheterization laboratory administration of GP inhibitor for STEMI.	B
Unfractionated heparin	I	Dosing based on whether GP inhibitor was given.	C
Bivalirudin	I	The lower bleeding rates associated with bivalirudin are mitigated when used with a GPI	B
Enoxaparin	I	An additional dose of 0.3 mg/kg of IV enoxaparin should be administered at the time of PCI to patients who have received <2 therapeutic SC doses (e.g., 1 mg/kg) or received the last SC enoxaparin dose 8-12 hours before PCI.	B
	IIb	Recommendations for IV enoxaparin during PCI apply to patients who have not received previous antithrombin therapy or who have received "upstream" SC enoxaparin therapy for UA/NSTEMI.	B
	III (harm)	Patients treated with SC enoxaparin within 12 hours of PCI should not receive additional treatment with UFH during PCI.	B
Fondaparinux	III (harm)	PCI should not be performed with fondaparinux as the sole antithrombin agent in patients treated with upstream fondaparinux. An additional anticoagulant with anti–factor IIa activity should be administered.	C

COR, Class of recommendation; *LOE,* level of evidence; *CVA,* cerebrovascular accident; *FDA,* U.S. Food and Drug Administration; *MI,* myocardial infarction; *IV,* intravenous; *NSTEMI,* non–ST-elevation myocardial infarction; *SC,* subcutaneous; *TIA,* transient ischemic attack; *STEMI,* ST-segment elevation myocardial infarction; *UA,* unstable angina; *UFH,* unfractionated heparin.

TABLE 62G.7

ACC/AHA Postprocedure Recommendations for Aspirin and Proton Pump Inhibitor (PPI) Therapy in Patients Undergoing Percutaneous Coronary Intervention[3]

INDICATION	COR	RECOMMENDATION	LOE
Aspirin (ASA)	I	After PCI, use of aspirin should be continued indefinitely.	A
	IIa	After PCI, it is reasonable to use ASA, 81 mg/day, in preference to higher maintenance doses.	B
PPI	IIa	Use of PPIs is reasonable in patients with an increased risk for GI bleeding who require DAPT.	C
	III (no benefit)	Routine use of a PPI is not recommended for patients at low risk for GI bleeding.	C

COR, Class of recommendation; *LOE,* level of evidence; *ACS,* acute coronary syndrome; *BMS,* bare-metal stent; *DAPT,* dual-antiplatelet therapy; *DES,* drug-eluting stent; *GI,* gastrointestinal; *NSTEMI,* non–ST-elevation myocardial infarction; *STEMI,* ST-segment elevation myocardial infarction.

Appropriateness Criteria for Percutaneous Coronary Intervention

An ongoing challenge for the application of guidelines to clinical practice is to construct expert opinion for the appropriateness of revascularization based on integration of the clinical findings, noninvasive testing, coronary anatomy, and the intensiveness of medical therapy. Appropriateness criteria for revascularization based on a consensus opinion of interventionalists, cardiac surgeons, and noninvasive cardiologists were published in 2009[4] and updated in 2012.[5] Risk stratification for cardiac events was established (**Table 62G.8**), and a series of clinical scenarios were graded on a scale of 1 to 9 based on the following appropriateness definitions:

TABLE 62G.8

Noninvasive Risk Stratification

High Risk (>3% Annual Mortality Rate)
1. Severe resting LV dysfunction (LVEF <35%)
2. High-risk treadmill score (−11 or less)
3. Severe exercise-induced LV dysfunction (exercise LVEF <35%)
4. Stress-induced large perfusion defect (particularly if anterior)
5. Stress-induced multiple perfusion defects of moderate size
6. Large, fixed perfusion defect with LV dilation or increased lung uptake (thallium-201)
7. Stress-induced moderate perfusion defect with LV dilation or increased lung uptake (thallium-201)
8. Echocardiographic wall motion abnormality (involving >2 segments) developing with low-dose dobutamine (≤10 mg/kg/min) or at a low heart rate (<120 beats/min)
9. Stress echocardiographic evidence of extensive ischemia
Intermediate Risk (1-3% Annual Mortality Rate)
1. Mild to moderate resting LV dysfunction (LVEF = 35-49%)
2. Intermediate-risk treadmill score (greater than −11 to <5)
3. Stress-induced moderate perfusion defect without LV dilation or increased lung uptake (thallium-201)
4. Limited stress echocardiographic ischemia with a wall motion abnormality only at higher doses of dobutamine involving ≤2 segments
Low Risk (<1% Annual Mortality Rate)
1. Low-risk treadmill score (≥5)
2. Normal or small myocardial perfusion defect at rest or with stress
3. Normal stress echocardiographic wall motion, no change, or limited resting wall motion abnormalities during stress

LV, Left ventricular; *LVEF,* LV ejection fraction.

Modified from Patel MR, Dehmer GJ, Hirshfeld JW, et al. ACCF/SCAI/STS/AATS/AHA/ASNC 2009 appropriateness criteria for coronary revascularization: a report of the American College of Cardiology Foundation Appropriateness Criteria Task Force, Society for Cardiovascular Angiography and Interventions, Society of Thoracic Surgeons, American Association for Thoracic Surgery, American Heart Association, and the American Society of Nuclear Cardiology: Endorsed by the American Society of Echocardiography, the Heart Failure Society of America, and the Society of Cardiovascular Computed Tomography. J Am Coll Cardiol 2009;53:530.

- Score of 7 to 9: *Appropriate* (A) when the expected benefits, in terms of survival or health outcomes (symptoms, functional status, and/or quality of life), exceed the expected negative consequences of the procedure.
- Score of 4 to 6: *Uncertain* (U) for the indication provided, which means that coronary revascularization may be acceptable and may be a reasonable approach for the indication, but with uncertainty implying that more research and/or patient information is needed to further classify the indication.
- Score of 1 to 3: *Inappropriate* (I) for the indication provided, which means that coronary revascularization is not generally acceptable and not a reasonable approach for the indication and is unlikely to improve the patient's health outcomes or survival.

The appropriateness for revascularization in various manifestations of acute coronary syndromes (ACS) is listed in **Table 62G.9**. In general, the guidelines support a very prominent role for revascularization in patients with ACS. The criteria for stable coronary artery disease (CAD) are based on extent of disease in the coronary arteries, complexity of the coronary anatomy, severity of angina, degree of ischemia, and extent of antianginal medical therapy (**Tables 62G.10 to 62G.12**). These key factors must all be weighed before deciding on the appropriateness of revascularization. Patients who have previously undergone coronary artery bypass grafting (CABG) and require repeated revascularization merit special consideration because the risks associated with repeated bypass surgery are higher than with the initial surgery. In patients who have previously undergone CABG, the guidelines recommend revascularization for severe angina (Canadian class III or IV), especially with large areas of ischemia and when medical therapy has already been maximized. The appropriate mode of revascularization by PCI or CABG for various anatomic subsets incorporates the burden of CAD and the presence of total occlusion (which may be measured by the SYNTAX score[6]) into the decision making. Importantly, in the 2012 focused update, two revisions resulted in a higher appropriateness rating for PCI than in the initial 2009 appropriateness criteria, based largely on the positive results of the SYNTAX (Synergy Between PCI with TAXUS and Cardiac Surgery) randomized trial in these subgroups of patients.[7] Three-vessel disease is categorized as *appropriate* for PCI when there are three focal stenoses or a low SYNTAX score, but categorized as *uncertain* in appropriateness for PCI if multiple diffuse lesions or an intermediate to high SYNTAX score is present (**Table 62G.13**).[5] Isolated left main stenosis and left main disease with a low burden of CAD are classified as uncertain appropriateness for treatment by PCI.

TABLE 62G.9

Appropriate Use Criteria for Revascularization in Patients with Acute Coronary Syndromes[4,5]

	INDICATION	APPROPRIATE USE SCORE* (1-9)
1	• STEMI • ≤12 hours from onset of symptoms • Revascularization of the culprit artery	A (9)
2	• STEMI • Onset of symptoms within the previous 12-24 hours • Severe HF, persistent ischemic symptoms, or hemodynamic or electrical instability present	A (9)
3	• STEMI • >12 hours from symptom onset • Asymptomatic; no hemodynamic instability and no electrical instability	I (3)
4	• STEMI with presumed successful treatment by fibrinolysis • Evidence of HF, recurrent ischemia, or unstable ventricular arrhythmias present • One-vessel CAD, presumed to be the culprit artery	A (9)
5	• STEMI with presumed successful treatment by fibrinolysis • Asymptomatic; no HF, no recurrent ischemic symptoms, or no unstable ventricular arrhythmias • Normal LVEF • One-vessel CAD presumed to be the culprit artery	U (5)
6	• STEMI with presumed successful treatment by fibrinolysis • Asymptomatic; no HF, no recurrent ischemic symptoms, or no unstable ventricular arrhythmias at evaluation • Depressed LVEF • Three-vessel CAD • Elective/semielective revascularization	A (8)
7	• STEMI with successful treatment of the culprit artery by primary PCI or fibrinolysis • Asymptomatic; no HF, no evidence of recurrent or provocable ischemia, and no unstable ventricular arrhythmias during the index hospitalization • Normal LVEF • Revascularization of a non–infarct-related artery during the index hospitalization	I (2)
8	• STEMI or NSTEMI and successful PCI of the culprit artery during the index hospitalization • Symptoms of recurrent myocardial ischemia and/or high-risk findings on noninvasive stress testing performed after the index hospitalization • Revascularization of 1 or more additional coronary arteries	A (8)
9	• UA/NSTEMI and low-risk features associated with short-term risk for death or nonfatal MI • Revascularization of the presumed culprit artery	U (6)
10	• UA/NSTEMI and intermediate-risk features associated with short-term risk for death or nonfatal MI • Revascularization of the presumed culprit artery	A (8)
11	• UA/NSTEMI and high-risk features associated with short-term risk for death or nonfatal MI • Revascularization of the presumed culprit artery	A (9)
12	• UA/NSTEMI and high-risk features associated with short-term risk for death or nonfatal MI • Revascularization of multiple coronary arteries when the culprit artery cannot clearly be determined	A (9)
13	• Patients with acute MI (STEMI or NSTEMI) • Evidence of cardiogenic shock • Revascularization of 1 or more coronary arteries	A (8)

**A,* Appropriate; *I,* inappropriate; *U,* uncertain.

CAD, coronary artery disease; *HF,* heart failure; *LVEF,* left ventricular ejection fraction; *MI,* myocardial infarction; *NSTEMI,* non–ST-segment elevation MI; *PCI,* percutaneous coronary intervention; *STEMI,* ST-segment elevation; MI; *UA,* unstable angina.

TABLE 62G.13

Appropriateness of Coronary Artery Bypass Grafting (CABG) and Percutaneous Coronary Intervention (PCI)[5]

ANATOMIC SETTING	CABG*	PCI*
Two-vessel CAD with proximal LAD stenosis	A	A
Three-vessel CAD with low CAD burden (i.e., three focal stenoses, low SYNTAX score)	A	A
Three-vessel CAD with intermediate to high CAD burden (i.e., multiple diffuse lesions, presence of CTO, or high SYNTAX score)	A	U
Isolated left main stenosis	A	U
Left main stenosis and additional CAD with low CAD burden (i.e., additional involvement of one or two vessels or low SYNTAX score)	A	U
Left main stenosis and additional CAD with intermediate to high CAD burden (i.e., three-vessel involvement, presence of CTO, or high SYNTAX score)	A	I

*A, Appropriate; *I,* inappropriate; *U,* uncertain.

CAD, Coronary artery disease; *CTO,* chronic total occlusion; *LAD,* left anterior descending coronary artery; *SYNTAX,* Synergy Between PCI with TAXUS and Cardiac Surgery.

The terms *Appropriate*, *Uncertain,* and *Inappropriate* have been recently updated and replaced with the terms *Appropriate*, *May Be Appropriate,* and *Rarely Appropriate*.

Guidelines for Training

The guidelines recommend that physicians undergo a 3-year comprehensive cardiac training program before dedicated interventional training in an accredited program. Interventional training requires a fourth year of training, including more than 250 interventional procedures, a level that is required for physicians to be eligible for the American Board of Internal Medicine certifying examination in interventional cardiology.[8,9] Maintenance of certification requires that 150 procedures be performed in the 2 years before the 10-year certification lapses (or a procedural log including the outcomes of 25 consecutive cases as the primary operator), in addition to retaking the Added Qualification Examination in Interventional Cardiology.[8,9]

Diseases of the Aorta

Alan C. Braverman, Marc Schermerhorn

The Normal Aorta

Anatomy and Physiology

The aorta, the largest artery in the body, has thoracic and abdominal components (**Fig. 63.1**). The thoracic aorta is divided into the ascending, arch, and descending segments, and the abdominal aorta, into the

suprarenal and infrarenal segments. The ascending aorta has two distinct portions. The *aortic root* begins at the aortic valve and extends to the sinotubular junction. The aortic root supports the bases of the aortic valve leaflets, which bulge outward into the sinuses of Valsalva during systole. The right and left coronary arteries arise from the sinuses of Valsalva. The upper portion of the ascending aorta begins at the sinotubular junction and rises to join the aortic arch. The proximal portion of the ascending aorta lies within the pericardial cavity, anterior to the pulmonary artery bifurcation. The aortic arch gives rise to the innominate, left common carotid, and left subclavian arteries. The descending thoracic aorta begins distal to the left subclavian artery. The ligamentum arteriosum marks the point at which the aortic arch joins the descending aorta, denoted the *aortic isthmus*. The aortic isthmus is vulnerable to deceleration trauma because this site marks the transition between the mobile ascending aorta and arch and the descending aorta, which is relatively fixed to the thoracic cage. The descending aorta gives rise to posterior paired intercostal arteries at multiple levels of the spine. Distally, the thoracic aorta passes through the diaphragm, becoming the abdominal aorta. The abdominal aorta gives rise to the celiac artery and the superior mesenteric artery anteriorly, followed by the typically posterolateral origins of the left and anterolateral right renal arteries. This part of the aorta is called the *suprarenal* or *visceral* segment. The infrarenal aorta lies anterior to the lumbar spine, where paired lumbar artery braches arise posteriorly. The aorta ends by bifurcation into common iliac arteries.

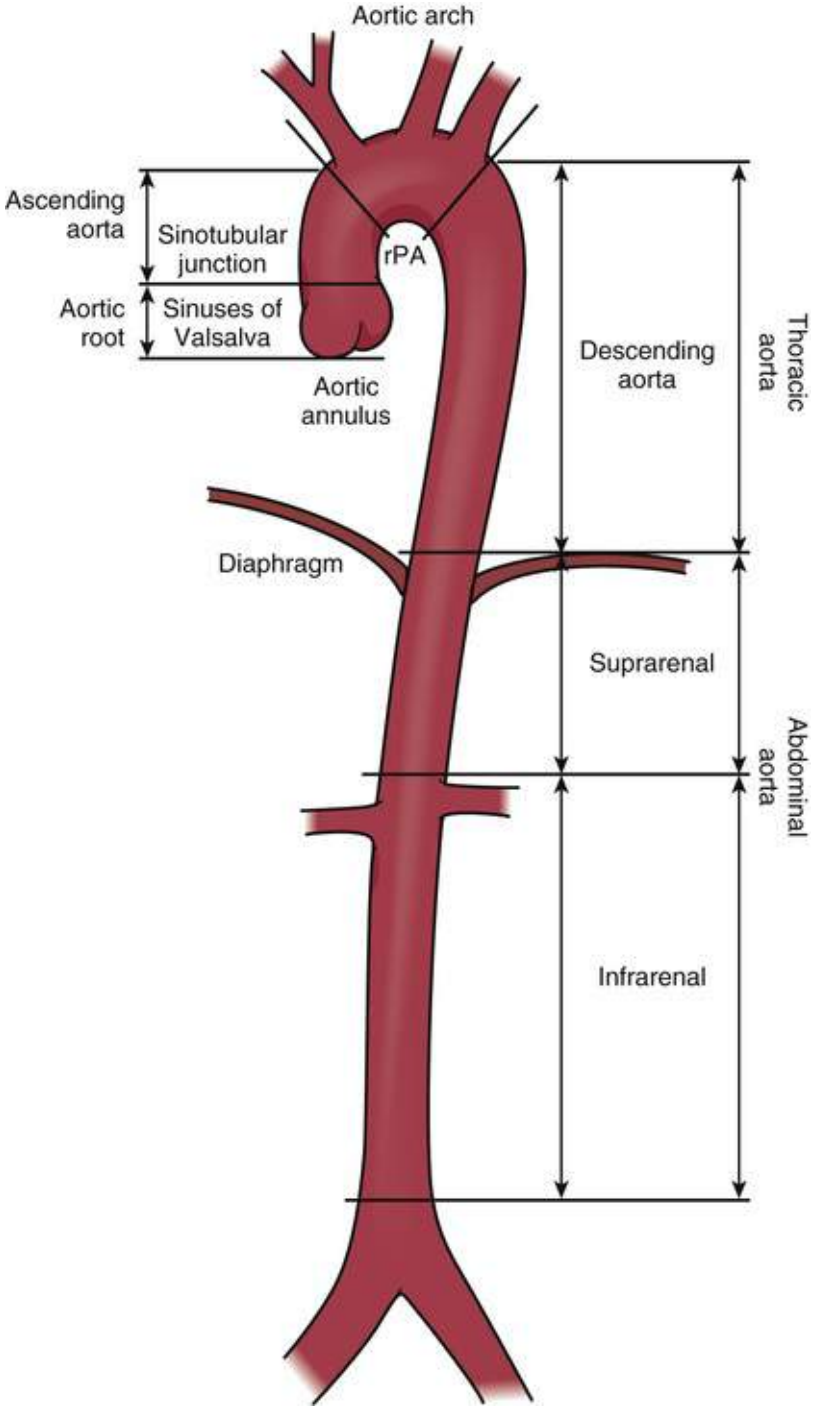

FIGURE 63.1 Anatomic segments of the aorta; *rPA,* right pulmonary artery. (From Erbel R, Aboyans V, Boileau C, et al. 2014 ESC guidelines on the diagnosis and treatment of aortic diseases: document covering acute and chronic aortic diseases of the thoracic and abdominal aorta of the adult. Microscopic Structure.

The aortic wall includes three layers: the *intima*, the *tunica media*, and the *tunica adventitia* (**Fig. 63.2**) (**see Chapter 44**). The internal elastic lamina demarcates the intima, lined by endothelial cells, from the media. The media has concentric layers of elastic fibers alternating with vascular smooth muscle cells (SMCs). Each layer of elastin and SMCs constitutes a "lamellar unit." The media gives the aorta its circumferential resilience (elasticity), which resists hemodynamic stress. The external elastic lamina delineates the abluminal portion of the media from the adventitia. The adventitia contains collagen fibers, fibroblasts, nerves, and vasa vasorum. The adventitial collagen fibers ultimately govern the tensile

strength of the aortic wall.

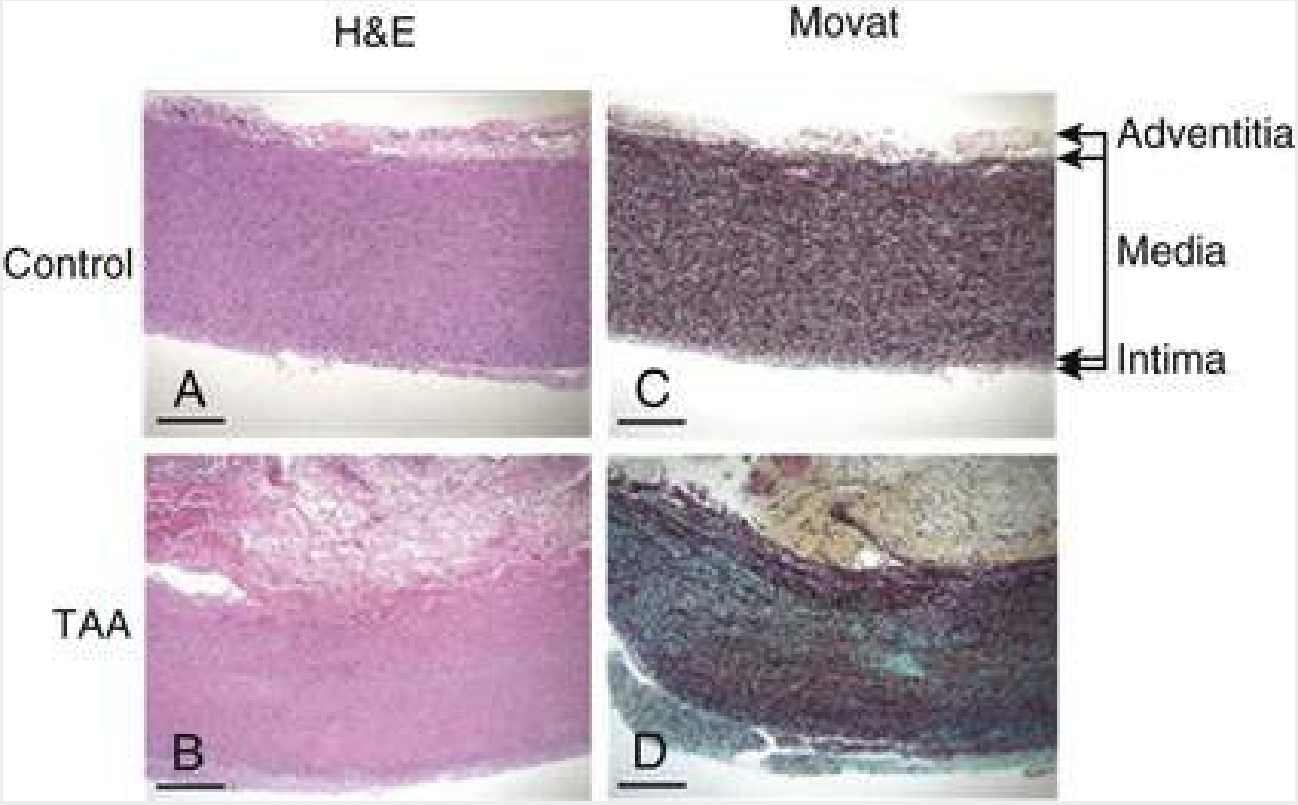

FIGURE 63.2 Aortic histology and pathology associated with thoracic aortic aneurysm (TAA) involving the ascending aorta. All panels are identically oriented with the adventitia at the top and the intima at the bottom. Hematoxylin and eosin (H&E) staining of aortic sections from a control **(A)** and a patient **(B)** with a TAA demonstrates medial degeneration with the fragmentation of elastic fibers, accumulation of proteoglycans, and regions of smooth muscle cell loss. Movat staining of aortic sections from control **(C)** and patient with an aneurysm **(D)** shows fragmentation of elastic fibers (stained *black*), loss of smooth muscle cells (cells stained *red* and nuclei stained *violet*), and accumulation of proteoglycans (stained *blue*) in the medial layer. 40× magnification; *scale bars* represent 500 µg. (Modified from Milewicz DM et al. Genetic basis of thoracic aortic aneurysms and dissections: focus on smooth muscle cell contractile dysfunction. Ann Rev Genomics Hum Genet 2008;9:283-02; and Hiratzka LF et al. 2010 ACCF/AHA/AATS/ACR/ASA/SCA/SCAI/SIR/STS/SVM guidelines for the diagnosis and management of patients with thoracic aortic disease. J Am Coll Cardiol 2010;55:e27-129.)

The ascending aorta normally contains approximately 55 to 60 elastic lamellae, with a gradual decrease in the number of elastic lamellae down the length of the aorta to approximately 26 at the aortic bifurcation. Oxygen and nutrients reach the aortic wall by simple diffusion from the lumen, at least in segments of the aorta that contain up to approximately 29 elastic lamellae. In the proximal aortic segments, the *vasa vasorum* supply additional nutrients to the outer third of the thoracic aortic media. The infrarenal aorta normally lacks an independent microvascular supply.

The compliance of the aortic wall under normal conditions results from reversible extension of the elastic lamellar units in the media. At mechanical strain levels that exceed the extensile capacity of the medial elastic fibers, aortic tensile strength becomes dependent on the collagen fiber meshwork of the media and adventitia. Although not functionally significant under normal circumstances or in systemic hypertension, the dependence on adventitial collagen in accommodating greater hemodynamic stress can contribute to abdominal aortic aneurysms (AAAs), in which the wall tension within the dilated segment may exceed by orders of magnitude higher that in a normal aorta. In AAAs, collagen fibers reorganize to accommodate higher degrees of tensile stress.

Physiology

The aorta as an elastic conduit transmits pulsatile arterial blood pressure (BP) to all points in the arterial tree. The biomechanical properties of the aorta, including resilience to cyclic deformation, derive from the elastin and collagen in the media and adventitia. The aortic wall pressure-diameter relationship is nonlinear; a more distensible component is demonstrated at lower pressures and a stiffer component at higher pressures, with the transition from distensible to stiff behavior occurring at pressures higher than 80 mm Hg.

The pressure-diameter curve of the aorta becomes less steep with increasing age (i.e., aorta stiffens and aortic diameter increases). The aortic diameter is generally less than 40 mm at the root and becomes smaller distally. Aortic diameters depend on age, sex, body size, and BP and increase in size by 0.9 mm in men and 0.7 mm in women per decade.[1]

Evaluation of the Aorta

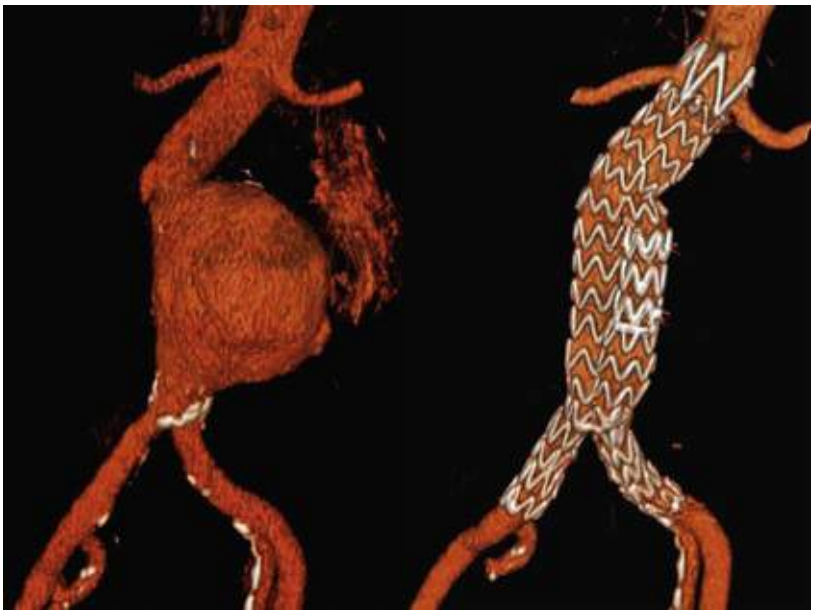
In some nonobese individuals the aorta can be palpated in the midabdominal region. The bifurcation typically occurs at the level of the umbilicus and the fourth lumbar (L4) vertebral body. Plain radiography is insensitive in evaluating the thoracic and abdominal aorta, but much more diagnostic detail regarding the aorta can be obtained with ultrasound (including echocardiography), computed tomography (CT), magnetic resonance imaging (MRI), and less frequently, aortography.

Aortic Aneurysms

The term *aortic aneurysm* refers to a pathologic segment of aortic dilation that expands and can eventually rupture. One criterion for abnormal aortic dilation is an increase in diameter of at least 50% greater than expected for the same aortic segment in unaffected individuals of the same age and sex.[2] Aortic aneurysms are described by their size, location, morphology, and cause. Aortic aneurysms can be either fusiform or saccular. *Fusiform* aneurysms, the more common type, are symmetrically dilated with involvement of the entire aortic circumference. *Saccular* aneurysms exhibit a focal outpouching. These lesions represent “true” aneurysms, with an intact but dilated aortic wall involving all layers. In contrast, in *pseudoaneurysms* (“false” aneurysms), bleeding has occurred through the aortic wall and resulted in a contained periaortic hematoma in continuity with the aortic lumen. Pseudoaneurysms may result from trauma or contained rupture of an aortic aneurysm, dissection, or penetrating ulcer.

Abdominal Aortic Aneurysms

AAAs are defined by an abdominal aorta greater than 3.0 cm in diameter.[3] AAAs occur in 3% to 9% of men older than 50 years and are the most common form of aortic aneurysms. Most AAAs (>80%) arise in the infrarenal aorta (**eFig. 63.1**), but up to 10% may involve the pararenal or visceral aorta and may extend into the thoracoabdominal segment. AAAs are approximately five times more prevalent in men than in women and are strongly associated with age, with most occurring in those older than 60 years.[4] AAAs also are strongly associated with cigarette smoking; current and former smokers have a fivefold increased risk compared to nonsmokers. Other risk factors include emphysema, hypertension, and hyperlipidemia. Up to 20% of patients with AAAs describe a family history of AAA, denoting a heritable component.



EFIGURE 63.1 Three-dimensional computed tomographic angiogram demonstrating a ruptured infrarenal abdominal aortic aneurysm with extravasation managed by way of successful endovascular stent-graft treatment. (From Steuer J, Lachat M, Veith FJ, Wanhainen A. Endovascular grafts for abdominal aortic aneurysm. Eur Heart J 2016;37:145-51. Picture courtesy Kevin Mani, Uppsala, Sweden.)

Pathogenesis

AAA formation is associated with chronic aortic wall inflammation, increased local expression of proteinases, and degradation of structural connective tissue proteins (**Fig. 63.3**). Aneurysmal dilation and rupture result from mechanical failure of medial elastin and adventitial collagen. Inflammatory cells commonly infiltrate the aortic wall. Patients with “inflammatory AAAs” may exhibit extension of this process to the periaortic retroperitoneal tissues. Matrix-degrading enzymes released by inflammatory cells lead to medial degeneration and play a role in dilation and rupture.[5] Inflammatory cells may enter the media in response to signals elaborated by medial SMCs as a result of hemodynamic stress, ischemia, autoimmune processes, or extension of intimal atherosclerosis. Proinflammatory cytokines may play a role. Although a response to both foreign antigens and microbial infection has been postulated in the development of AAAs, evidence shows that the chronic inflammation in aneurysm tissue also exhibits features of an autoimmune response. Destruction of medial elastin and a marked decrease in the concentration of elastin characterize AAAs. Experimental studies have demonstrated that damage to the elastic lamellae leads to aneurysmal dilation, and elastolytic proteinases may play a critical role. The tensile strength of the aortic wall results principally from interstitial collagen, and AAAs generally is associated with increased collagen content. Enzymes such as matrix metalloproteinases (MMPs) and elastolytic cathepsins can degrade the arterial extracellular matrix (ECM) constituents and contribute to aneurysm expansion and rupture.[5] Treatment of animals with tetracyclines and other MMP inhibitors can suppress experimental aneurysm development.[5]

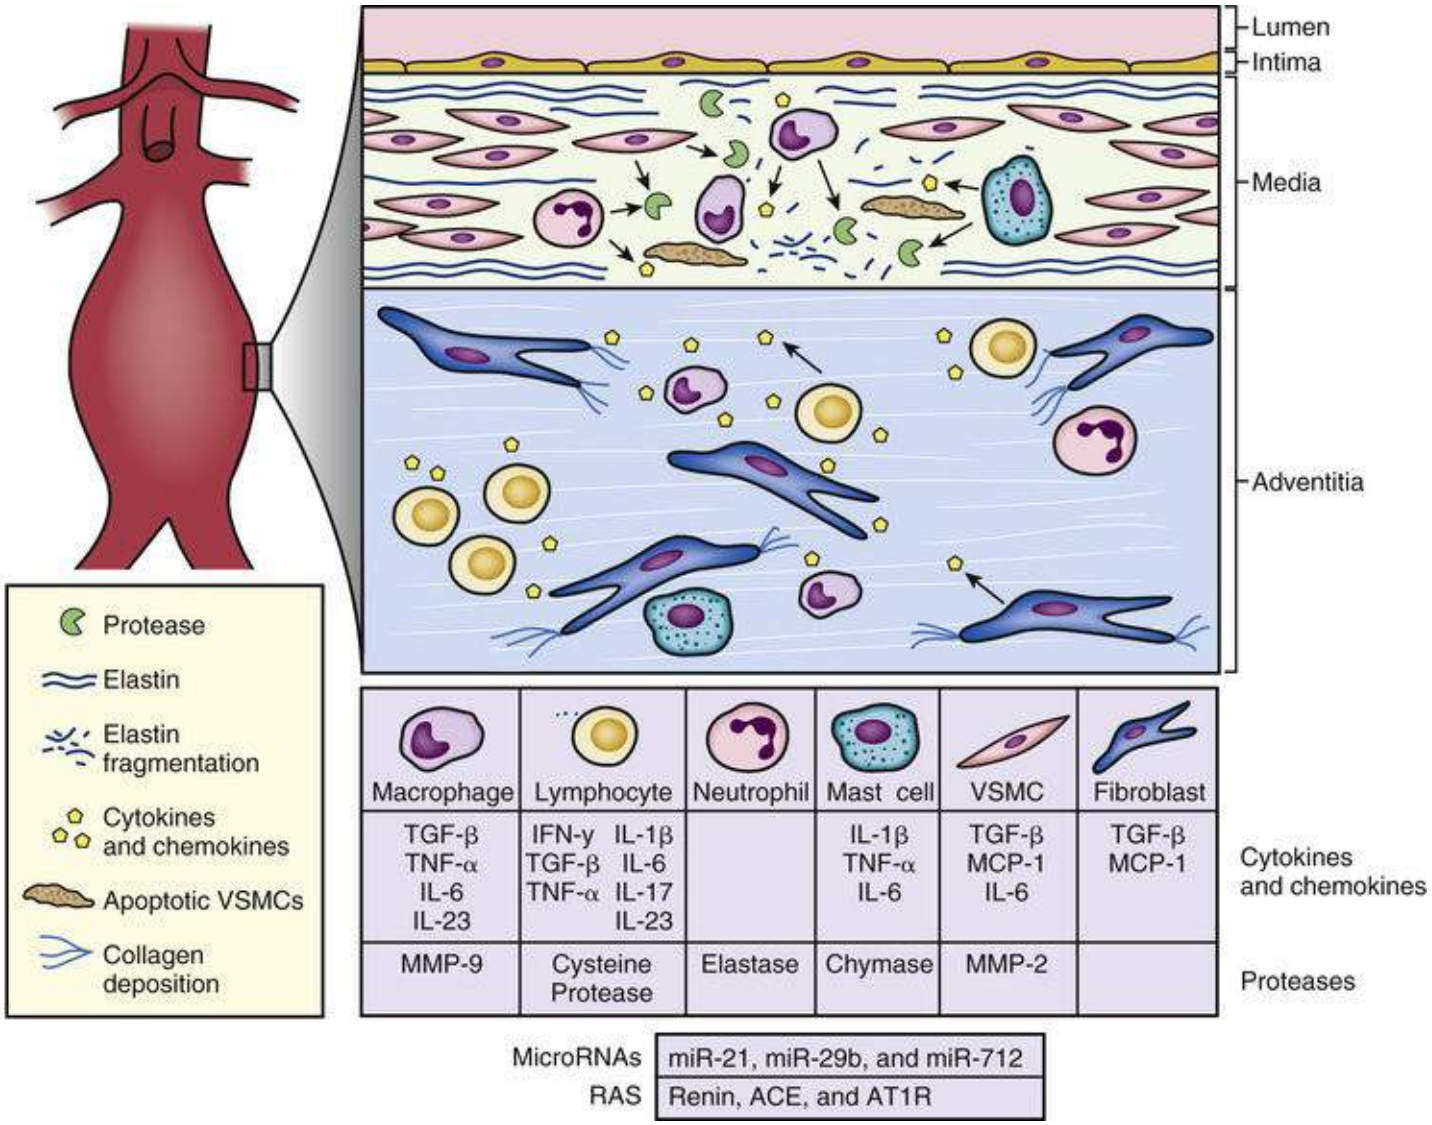


FIGURE 63.3 Pathophysiology and therapeutic targets of abdominal aortic aneurysm (AAA). Progressive dilation of the aortic wall is associated with recruitment of leukocytes, macrophage activation, and production of proinflammatory cytokines. Over years, apoptosis and cellular senescence of smooth muscle cells occurs in conjunction with infiltration of lymphocytes, mast cells, and neutrophils. Macrophages and vascular smooth muscle cells (VSMCs) also produce proenzyme forms of proteases that are activated in the extracellular space and degrade extracellular matrix proteins (elastin and interstitial collagens). Adventitial fibroblasts are presumed to promote structural repair, but the interstitial collagen becomes disorganized. The table legend illustrates major cell types involved in AAA pathogenesis, as well as select examples of future therapeutic targets that are involved in AAA pathogenesis. AT1R, Angiotensin type 1 receptor; IFN, interferon; IL, interleukin; MCP, monocyte chemoattractant protein; MMP, matrix metalloproteinase; miR, microRNA; RAS, renin-angiotensin system; TGF, transforming growth factor; TNF, tumor necrosis factor. (From Davis FM, Rateri DL, Daugherty A. Mechanisms of aortic aneurysm formation: translating preclinical studies into clinical therapies. Heart 2014;100:1498-505.)

The natural history of AAAs involves a balance between degradative and reparative processes. Because vascular SMCs normally produce elastin and collagen during aortic development and SMCs predominate within the elastic media, they may mediate repair of connective tissue within AAAs. Depletion of medial SMCs characterizes AAAs. Mechanisms underlying the loss of SMCs in AAAs include *apoptosis*, which may be initiated by medial ischemia, signaling molecules, or cellular immune responses. In the absence of vasa vasorum, the nutrient supply to the media of the distal aorta depends on diffusion from the lumen, which may be jeopardized by intimal thickening and atherosclerotic plaque.

Clinical Features

AAAs develop insidiously over several years and rarely cause symptoms in the absence of distal

thromboembolism, rapid expansion, or rupture. Although large AAAs are at substantial risk of rupturing, the vast majority of AAAs are small. Most AAAs are detected by screening studies or as an incidental finding on imaging studies performed for another purpose.

Physical examination is insensitive in detecting AAAs, but abdominal palpation may reveal a pulsatile epigastric or periumbilical mass. Only 30% to 40% of AAAs are noted on physical examination, although aneurysms larger than 5 cm are detected in approximately 75% of patients, depending on body habitus.[4] The mural thrombi associated with AAAs may lead to thromboembolism, occurring in 2% to 5% of patients. AAA is present in up to 85% of patients with a femoral artery aneurysm and 60% of patients with a popliteal artery aneurysm.[4] Patients with AAA may have coexisting thoracic aortic aneurysm (TAA) disease (25%) and an increased prevalence of iliac and popliteal aneurysms.[1]

Diagnostic Imaging

Abdominal ultrasound (US) can detect AAAs with high accuracy and is preferred over CT in screening for AAAs because US is inexpensive, noninvasive, and avoids radiation and contrast agents.[4] Because US-derived measurements of AAA diameter are less accurate than by CT or MRI, many use US for follow-up of small AAAs and CT or MRI for larger AAAs. Abdominal CT is accurate in both detection of AAAs and measurement of aneurysm diameter. When combined with radiographic contrast enhancement, thin-slice techniques, and three-dimensional reconstructions with measurements obtained perpendicular to the centerline of the aorta, CT angiography (CTA) is more accurate than US. CTA is especially useful in demonstrating the relationship of the AAA to the renal, visceral, and iliac arteries and patterns of mural thrombus, calcification, or coexisting occlusive atherosclerosis, which might influence AAA repair. Three-dimensional reconstructions enhance visualization of the AAA before endovascular aneurysm repair (EVAR) (**eFig. 63.1**). CT can also assess AAA variants, such as inflammatory AAAs and mycotic aneurysms. Magnetic resonance angiography (MRA) also has high accuracy in detecting AAAs, measuring aneurysm diameter, and planning treatment. MRA avoids exposure to radiation and iodine-based contrast material. CTA has superseded aortography in the evaluation and management of AAAs. In patients undergoing EVAR, aortography is an initial step in the operative procedure. It is also used in subsequent interventions following EVAR, such as embolization of the lumbar or iliac artery branches.

Screening

Screening for AAAs with ultrasound, coupled with repair of AAAs above a size threshold, has reduced AAA-related deaths.[3,4] The incidence of screening-detected AAAs ranges from 1 per 1000 in adults younger than 60 years to 7 per 1000 in those in their mid-60s, but it may be as high as 10% in those with risk factors such as older age, male sex, smoking, family history, history of other aneurysms, hypertension, and atherosclerosis. Aneurysm screening is associated with a 50% reduction in rupture and a 50% decrease in aneurysm-related mortality.[3,4] Despite the cost-effectiveness of AAA screening in men 65 to 74 years of age, routine screening for AAAs in women remains controversial[3] and has not demonstrated a survival benefit.[4] AAAs occur about 10 years later in women than men, and rates of rupture and mortality from rupture are both higher in women. The U.S. Preventive Services Task Force (PSTF) recommended a one-time ultrasound screening for AAAs in men 65 to 75 years of age with a history of smoking.[3,4] The Society for Vascular Surgery (SVS) recommends a one-time screening for AAAs in all men and women 65 or older with a history of tobacco use or a family history of AAA.

Genetics/Molecular Genetics

Several genetic disorders are associated with thoracic aortic aneurysms (TAAs), including Marfan syndrome, Loeys-Dietz syndrome, and vascular Ehlers-Danlos syndrome, but less frequently with aneurysms of the abdominal aorta. Up to 20% of patients with an infrarenal AAA have a family history of AAAs, suggesting an inherited component. Several genetic variants, including *DAB2IP*, *LRP1*, *CDKN2B-AS1*, *CNTN3*, *LAP*, *IL6R*, and the *SORT1* locus, are associated with AAA.[6]

Natural History

AAAs gradually expand over years at an average rate for AAAs 3.0 to 5.5 cm in diameter of 0.2 to 0.3 cm/year, increasing as aortic diameter increases.[3] Not all AAAs follow a linear or consistent rate of expansion. Although the aneurysm diameter is most important in predicting rupture, size alone may not predict risk for rupture. Wall tension, wall stiffness, and peak wall stress may all contribute. Some have suggested that aortic diameter indexed to body surface area (aortic size index) may be a better predictor of rupture for women than diameter alone.[7] The estimated 1-year risk for rupture is 10% to 20% for AAAs 6.0 to 7.0 cm in diameter, 20% to 40% for AAAs 7.0 to 8.0 cm, and 30% to 50% for AAAs larger than 8.0 cm. The 5-year risk for rupture is approximately 5% for AAAs 3.0 to 4.0 cm in diameter, 10% to 20% for AAAs 4.0 to 5.5 cm, 30% to 40% for AAAs 5.5 to 6.0 cm, and greater than 80% for AAAs larger than 7.0 cm.[4]

Ruptured Abdominal Aortic Aneurysm

Symptoms directly attributable to AAAs usually relate to rupture of the aneurysm or rapid expansion and impending rupture. Rupture of AAAs into the peritoneal cavity results in acute hemorrhage, severe abdominal pain, and hypotension caused by exsanguination (**eFig. 63.1**). Rupture into the retroperitoneum may result in a temporarily contained periaortic hematoma, with severe abdominal or back pain that may radiate to the flank or groin. A tender pulsatile abdominal or flank mass may be present, along with hypotension and/or syncope. Approximately 30% to 50% of patients with ruptured AAAs die before hospitalization, and an additional 30% to 40% die after reaching a hospital but before treatment.[4] The operative mortality rate for open surgical repair (OSR) after AAA rupture is 40% to 50%, but may be lower with EVAR.[3,4] Stable patients with symptomatic but apparently unruptured AAAs should undergo CT to determine whether rupture has occurred. Because emergency repair entails a much higher mortality rate, in the absence of rupture, it may be prudent in certain cases to delay surgical repair for 4 to 24 hours to optimize conditions under close monitoring.[4]

Management

Surveillance and Medical Therapy

Patients with small AAAs can be observed safely with imaging surveillance. In general, repair should be considered for asymptomatic aneurysms greater than 5.0 to 5.5 cm in diameter.[3,4] Symptomatic aneurysms and those with rapid growth (>1 cm/yr) require more urgent consideration. In patients with AAAs larger than 4.5 cm, CT is preferred over US for more accurate measurement of AAA size. Surveillance of aneurysms until the diameter exceeds 5.5 cm yields a low rate of rupture (approximately 1% per year).[4] The SVS suggests the following surveillance imaging strategy for AAAs of various sizes: 2.5 to 2.9 cm, every 7 years; 3.0 to 3.9 cm, every 3 years; 4.0 to 4.9 cm, every 12 months; and 5.0 to 5.4 cm, every 6 months. Uncertainty exists regarding the ultimate therapy for AAAs between 4.5 and 5.4 cm, and recommendations must be individualized. Young, healthy patients—especially women—with AAAs

between 5 and 5.4 cm may benefit from early repair.[4]

Several steps are recommended for patients with AAAs to help minimize the risk for expansion of the aneurysm. Smoking cessation is important because ongoing tobacco use is linked to more rapid rates of AAA expansion and rupture. Patients with AAAs and coexisting atherosclerotic disease will likely benefit from statin therapy, which might also slow AAA growth.[5] Patients with small AAAs should exercise regularly because moderate physical activity does not adversely influence the risk for rupture and may limit AAA growth.

Experimental Therapy.

The potential use of pharmacologic therapies to suppress the growth rate of small AAAs is of great interest.[5] One of the earliest approaches suggested was the use of beta-adrenergic receptor–blocking agents (beta blockers) to diminish aortic stress. Although successful in animal models of AAAs, clinical trials demonstrated no benefit of propranolol in patients with small AAAs.[4] Suppression of proteinases involved in ECM degradation is another approach.[5] Further investigation is needed to determine whether MMP inhibitors such as doxycycline can reduce the rate of AAA expansion in humans. Clinical trials have not demonstrated any utility of angiotensin-converting enzyme (ACE) inhibitors in slowing the growth of small AAAs.[8]

Surgery

The decision to undergo elective repair of an asymptomatic AAA depends on life expectancy and the estimated risk for rupture, balanced against the estimated risks associated with AAA repair. Patients with AAAs often have underlying coronary artery disease (CAD), and because postoperative myocardial infarction (MI) increases subsequent perioperative morbidity and mortality, attention is directed toward CAD before elective AAA repair. Current guidelines state that in the absence of an active cardiac condition, further noninvasive testing is indicated only if it will change management. Some patients benefit from preoperative evaluation for coronary ischemia and treatment (**see Chapter 11**). Perioperative medical management to reduce cardiac risk in patients undergoing AAA repair may include continuation of beta blockers, statins, and/or aspirin. AAAs can be treated surgically by OSR or EVAR. Selection of the approach depends on the individual anatomy and on secondary factors such as patient age and estimated risks associated with anesthesia and surgery, with most patients currently undergoing EVAR.[3,4]

Techniques and Outcomes.

For OSR of infrarenal AAAs, the abdominal aorta is approached through a transperitoneal or left retroperitoneal exposure using a tube or bifurcated prosthetic graft. The operative mortality rate for OSR ranges from 1% to 4% in reports from single-institution centers of excellence, and mortality rates in large databases range from 4% to 8%.[4] Operative complication rates range from 10% to 30%, with morbidity related to cardiac, pulmonary, and renal complications and colonic ischemia. Because outcomes with OSR relate to hospital and surgeon volumes, OSR for AAAs should optimally be performed at centers with demonstrable operative mortality rates lower than 5%. Late complications develop in as many as 15% to 30% of patients in long-term follow-up after OSR for AAAs. Such complications include problems related to the abdominal incision (including hernia and bowel obstruction), perianastomotic aneurysms (including false aneurysms secondary to disruption of the suture line and true aneurysms secondary to proximal aortic degeneration), graft infection, graft-enteric fistula, and graft limb occlusions

with lower extremity ischemia. Late aneurysm formation at anastomotic sites after OSR is uncommon and affects 1%, 5%, and 20% of patients, respectively, at 5, 10, and 20 years postoperatively.[4] After open AAA repair, patients should generally have clinical follow-up with CT at 5-year intervals.

Endovascular Abdominal Aortic Aneurysm Repair.

In patients with suitable anatomy, EVAR offers a less invasive alternative to OSR. EVAR requires adequate nonaneurysmal proximal and distal attachment sites.[4] Randomized controlled trials (RCTs) comparing EVAR with OSR for asymptomatic infrarenal AAAs have demonstrated a lower 30-day mortality rate with EVAR than with OSR.[3,9] A significantly higher number of repeated interventions, however, occurred in the EVAR group.[9,10] In an analysis of 79,932 Medicare patients, EVAR had a similar early benefit in perioperative mortality (1.6% versus 5.2%) and complications, demonstrating the generalizability of the RCT data.[9] At long-term (8-year) follow-up, however, AAA-related or all-cause mortality did not differ significantly between EVAR and OSR.[9] EVAR patients had more aneurysm-related reinterventions.[9]

Observational studies report a mortality benefit of EVAR over OSR in ruptured AAA[10] (**eFig. 63.1**). The IMPROVE trial randomized ruptured AAAs to an EVAR-first strategy versus OSR and demonstrated no improvement in 30-day mortality.[10] Although RCTs have yet to demonstrate a survival benefit of EVAR for ruptured AAA, guidelines recommend treatment of ruptured AAA in centers with a protocol for rapid evaluation and management, preferably with EVAR for suitable patients.

Appropriate patient selection permits low perioperative mortality (1% to 2%) and complication (10% to 15%) rates with EVAR for elective AAA repair.[4] Currently, the options of EVAR and OSR are considered in “medically fit” patients with suitable anatomy. Most patients select EVAR because of its early perioperative advantages and the “less invasive” nature of the procedure. At follow-up after 6 and 8 years in the DREAM and EVAR-1 studies, EVAR had more late complications and secondary reinterventions, and the initial reduction in mortality with EVAR did not persist after a few years.[4,9,10]

“Endoleaks” (persistent blood flow in the aneurysm sac outside the endograft) develop in almost 25% of patients at follow-up and can cause of aortic rupture after EVAR.[4] Type I endoleaks, which result from loss of complete sealing at the proximal (type Ia) or distal (type Ib) end of the stent-graft, lead to increased pressure in the aneurysm sac and are associated with increased risk for rupture[3] (**Fig. 63.4**). Type II endoleaks, the most common, result from retrograde filling of the aneurysm sac by the lumbar or inferior mesenteric arteries. Type III endoleaks are caused by separation of components or disruption of the endograft fabric and require treatment, usually by relining with a stent graft. Type IV endoleaks are related to blood seeping through porous graft material and are self-limited. *Endotension,* an enlarging AAA after EVAR without a demonstrated endoleak and with a diameter increased to greater than 10 mm, usually requires repair. Late complications of EVAR (endograft migration, limb thrombosis), implant-related complications, and graft infection can also occur. Monitoring the durability of the clinical results requires long-term radiographic surveillance. Imaging with contrast-enhanced CTA is typically performed at 1 month and annually after implantation of the device.[3] The presence of endoleak may mandate more frequent surveillance. Color duplex ultrasonography to detect endoleaks and AAA enlargement may be used in those with stable imaging findings after 1 year. In conditions that limit the use of contrast material, duplex ultrasound may be combined with non–contrast-enhanced CT.

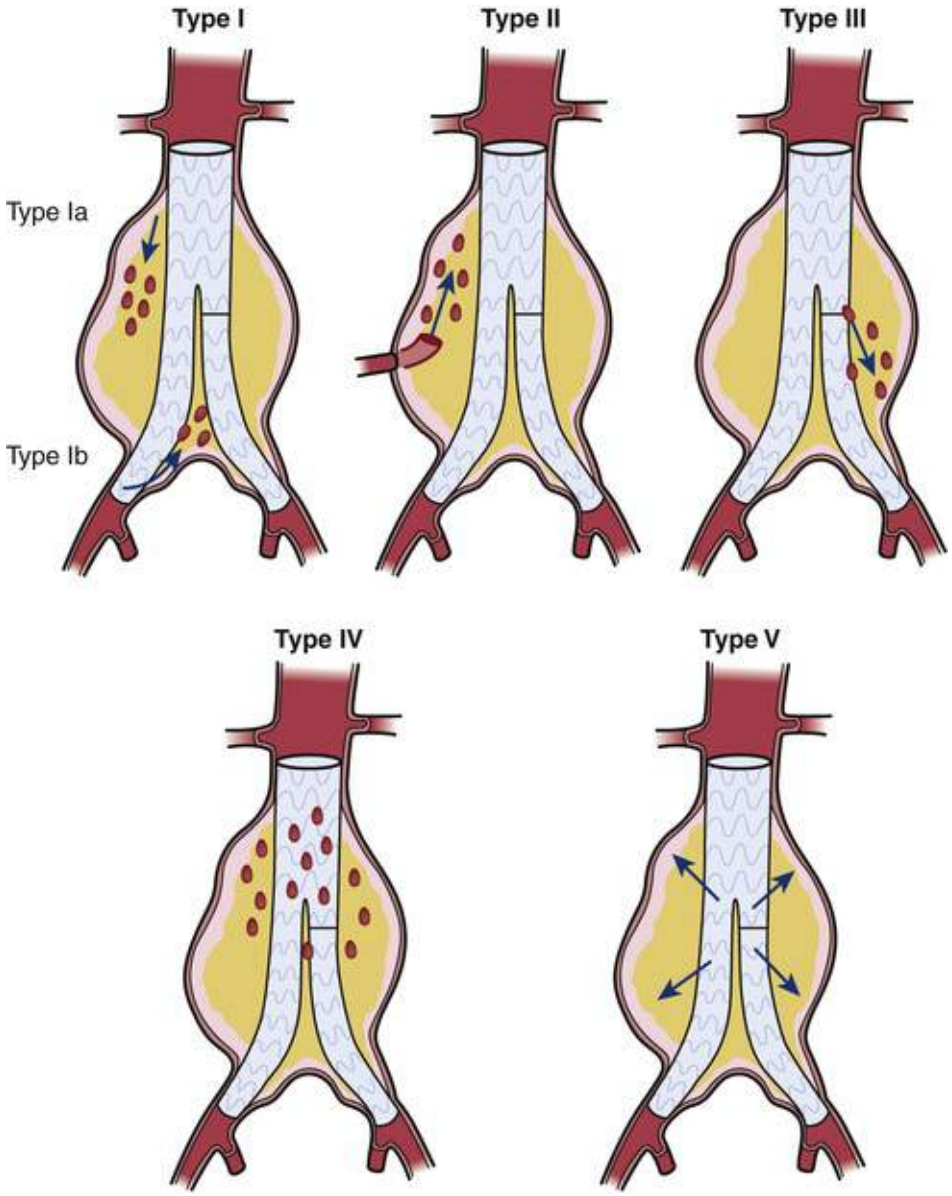

FIGURE 63.4 Classification of endoleaks. **Type I:** Leak at graft attachment site above, below, or between graft components (*Ia*: proximal attachment site; *Ib*: distal attachment site; *Ic*: iliac occluder). **Type II:** Branch leaks without attachment site leaks. Retrograde filling of aneurysm sac through single-branch (*IIa*) or multiple-branch (*IIb*) vessels. **Type III:** Leak through mechanical defect in graft, mechanical failure of the stent-graft by junctional separation of the modular components (*IIIa*), or fractures or fabric holes in the endograft (*IIIb*). **Type IV:** Leak through graft fabric as a result of graft porosity. **Type V:** Continued expansion of aneurysm sac without demonstrable leak on imaging (endotension, controversial). A primary endoleak is present from time of graft placement. A secondary endoleak appears after a prior negative computed tomographic angiogram. (Modified from White GH, May J, Petrasek P. Specific complications of endovascular aortic repair. Semin Interv Cardiol 2000;5:35-46.)

Widespread use of EVAR has demonstrated a reduction in early morbidity and mortality in patients with AAAs, especially in older adults. This advantage does not persist in long-term follow-up, however.[9] EVAR should ideally be performed at centers with very low in-hospital mortality (<3%) and a primary conversion rate to OSR of less than 2% for elective repair.[4] The development of fenestrated and branched endografts is extending EVAR to increasingly challenging aneurysms that extend more proximally to involve the renal and mesenteric vessels.

Thoracic Aortic Aneurysms

TAAs have an estimated incidence of at least 5 to 10 per 100,000 person-years.[11] The cause, natural history, and treatment vary depending on the location of the TAA. Aortic root or ascending aortic

aneurysms are most common (approximately 60%), followed by aneurysms of the descending aorta (approximately 35%) and aortic arch (<10%).[2] *Thoracoabdominal aortic aneurysm* (approximately 10%) refers to descending thoracic aneurysms that extend distally to involve the abdominal aorta.

Cause and Pathogenesis

Causes of TAAs include heritable disorders, genetic (congenital) disorders, and degenerative (formerly known as "atherosclerotic"), mechanical, inflammatory, and infectious diseases. Many of the genetic disorders preferentially involve the aortic root and ascending aorta, but some may involve the arch and descending aorta. Risk factors for TAAs include smoking, hypertension, age, COPD, CAD, and family history. In series of AAA, 20% to 27% of patients had either synchronous or metachronous TAA.[1] *Cystic medial degeneration* (CMD) describes degeneration and fragmentation of elastic fibers, loss of SMCs, increase in deposition of collagen, and replacement with interstitial "cysts" of mucoid-appearing basophilic-staining ECM (**see Fig. 63.2**). Patients with Marfan syndrome and many other genetically triggered TAA diseases have aortic CMD. Aging is associated with some degree of CMD, a process that may be accelerated by hypertension. These changes lead to progressive weakening of the aortic wall and may result in dilation and aneurysm formation.

Genetically Triggered Thoracic Aortic Aneurysm Disorders

Many disorders of the thoracic aorta are related to a genetic or heritable disorder, some of which are associated with multisystem syndromic features and others with thoracic aortic disease and branch vessel disease alone (nonsyndromic)[12] (**Table 63.1**). The phenotype in certain conditions may be subtle, and intrafamilial variability is common, highlighting the importance of a careful physical examination.[13] These disorders are associated with abnormalities in the aortic media, ECM proteins, vascular SMCs, or contractile proteins.[6,12] Such disorders include Marfan syndrome, Loeys-Dietz syndrome, vascular Ehlers-Danlos syndrome, familial thoracic aortic aneurysm and dissection syndrome, bicuspid aortic valve disease, Turner syndrome, and the aortopathy associated with many congenital heart diseases. The timing of prophylactic surgery for aneurysm disease in patients with these conditions depends on the gene defect and other factors, including aortic diameter, rate of aortic growth, family history, age, sex, and patient and physician preferences[12] (**Table 63.2**).

TABLE 63.1

Thoracic Aortic Aneurysm (TAA) Syndromes and Diseases from a Heritable or Genetic Cause

GENE (PROTEIN)	SYNDROME OR DISEASE	CLINICAL FEATURES
Extracellular Matrix Protein Genes		
FBN1 (fibrillin-1)	Marfan syndrome	Aortic root aneurysm, AD, TAA, MVP, long bone overgrowth, scoliosis, pectus deformities, ectopia lentis, myopia, tall stature, PTX
FBN2 (fibrillin-2)	Congenital contractural arachnodactyly, Beals syndrome	MVP, arachnodactyly, marfanoid habitus, digital contractures, mild aortic dilation
COL3A1 (type 3 procollagen)	Vascular Ehlers-Danlos syndrome	TAA, AAA, arterial rupture, AD, MVP, bowel and uterine rupture, PTX, translucent skin, atrophic scars, small joint hypermobility, easy bruising
EFEMP2 (fibulin-4)	Cutis laxa	TAA, arterial tortuosity, arterial stenosis, hypertelorism, arachnodactyly
MFAP5 (microfibrillar-associated protein 5)	FTAAD, AAT9	TAA, AD
TGF-β Signaling Pathway Genes		
TGFBR1 (TGF-β receptor 1)	Loeys-Dietz syndrome type 1, Furlong syndrome, FTAAD, AAT5	TAA, branch vessel aneurysms, AD, arterial tortuosity, craniosynostosis, hypertelorism, bluish sclera, bifid/broad uvula, translucent skin, visible veins, MVP, clubfoot, easy bruising
TGFBR2 (TGF-β receptor 2)	Loeys-Dietz syndrome type 2, FTAAD, AAT3	TAA, branch vessel aneurysms, AD, arterial tortuosity, craniosynostosis, hypertelorism, bluish sclera, bifid/broad uvula, translucent skin, visible veins, MVP, clubfoot, easy bruising
SMAD3 (SMAD3)	Aneurysm-osteoarthritis syndrome, LDS 3	TAA, branch vessel aneurysms, AD, arterial tortuosity, overlapping phenotype with LDS 1 and 2 and marfanoid features, bifid uvula, premature osteoarthritis, osteoarthritis dissecans
TGFB2 (TGF-β 2)	FTAAD, LDS 4	TAA, arterial tortuosity, AD, MVP, PDA, overlapping features of MFS and LDS, bifid uvula, hypertelorism
TGFB3 (TGF-β 3 ligand)	Rienhoff syndrome, LDS 5	TAA, AAA, AD, hypertelorism, bifid uvula, overlapping features of MFS and LDS, MVP
SKI (v-SKI sarcoma oncogene homolog)	Shprintzen-Goldberg syndrome (velocardiofacial syndrome)	TAA, marfanoid habitus, craniosynostosis, intellectual disability, skeletal muscle hypotonia
SLC2A10 (glucose transporter 10)	Arterial tortuosity syndrome	Widespread aortic and branch vessel tortuosity, TAA, aortic and arterial dissection, keratoconus, marfanoid habitus, joint contractures
SMAD2 (SMAD2)	FTAAD	TAA, AD, cervicocranial arterial dissection
SMAD4 (SMAD4)	Juvenile polyposis syndrome, HHT, FTAAD	Telangiectasia, AVMs, TAA, AD
Vascular Smooth Muscle Contraction Components or Cytoskeleton Genes		
ACTA2 (α-smooth muscle actin)	FTAAD, AAT6	TAA, AD, BAV, moyamoya disease, premature CAD and CVD, livedo reticularis, iris flocculi
MYH11 (myosin heavy chain-11)	FTAAD, AAT4	TAA, AD, PDA
MYLK (myosin light chain kinase)	FTAAD, AAT7	AD at relatively small aortic size
PRKG1 (protein kinase cGMP-dependent)	FTAAD, AAT8	Aortic root aneurysm and AD
MAT2A (MAT IIα)	FTAAD	TAA, AD, BAV
FLNA (filamin A)	EDS with periventricular nodular heterotopia and cardiac valve dysplasia	X-linked, TAA, BAV, MV disease, seizures, joint hypermobility
Bicuspid Aortic Valve–Associated Ascending Aortic Aneurysm		
NOTCH1 (NOTCH1)	BAV with TAA	Aortic stenosis, TAA
TGFBR1, TGFBR2, TGFB2, TGFB3, ACTA2, MAT2A, GATA5, SMAD6, LOX	BAV with TAA	Syndromic and nonsyndromic FTAA with increased frequency of BAV
XO, Xp	Turner syndrome	BAV, COA, TAA, AD, short stature, lymphedema, webbed neck, premature ovarian failure; affects 1 in 2500 live-born girls

AAA, Abdominal aortic aneurysm; *AAT,* aortic aneurysm syndrome; *AD,* aortic dissection; *AVM,* arteriovenous malformation; *BAV,* bicuspid aortic valve; *CAD,* coronary artery disease; *COA,* coarctation of the aorta; *CVD,* cerebrovascular disease; *EDS,* Ehlers-Danlos syndrome; *FTAAD,* familial thoracic aortic aneurysm and dissection syndrome; *HHT,* hereditary hemorrhagic telangiectasia; *LDS,* Loeys-Dietz syndrome; *MFS,* Marfan syndrome; *MV,* mitral valve; *MVP,* mitral valve prolapse; *PDA,* patent ductus arteriosus; *PTX,* pneumothorax; *TAA,* thoracic aortic aneurysm; *TGF,* transforming growth factor.

TABLE 63.2

Size Threshold for Prophylactic Aortic Root or Ascending Aortic Aneurysm Resection for Various Conditions

CONDITION	SIZE THRESHOLD*
Degenerative aneurysm	≥5.5 cm
Bicuspid aortic valve	≥5.5 cm
Bicuspid aortic valve with risk factors or low surgical risk†	≥5.0 cm
Bicuspid aortic valve requiring aortic valve replacement	>4.5 cm
Marfan syndrome	≥5.0 cm
Marfan syndrome with risk factors‡	>4.5 cm
Loeys-Dietz syndrome§	4.0 to 4.5 cm
Familial thoracic aortic aneurysm syndromes¶	4.5 to 5.0 cm
Turner syndrome	>2.5 cm/m^2

*Lower thresholds for intervention may be considered according to body surface area in patients of small stature or in the case of rapid growth of the aorta. Age, body size, rapid growth, family history, risk of surgery, and patient and physician wishes may influence aortic size threshold.

†Family history of aortic dissection or aortic growth rate of 0.5 cm or more per year or if the patient is at low surgical risk (<4%) and the surgery is performed by an experienced aortic surgical team in a center with established expertise in these procedures. Other risk factors for aortic dissection include coarctation of the aorta, hypertension, and the root phenotype of bicuspid aortic valve.

‡Family history of aortic dissection or rapid aortic growth (>3 mm/yr), or severe aortic or mitral regurgitation. If pregnancy desired, consider prophylactic aortic surgery for aortic diameter of 4.0 to 4.5 cm.

§It is reasonable to consider surgical repair of the aorta in adults with Loeys-Dietz syndrome or a confirmed *TGFBR1* or *TGFBR2* mutation with aortic diameter of 4.2 cm or more by transesophageal echocardiogram or 4.4 to 4.6 or more by CT or MRI. Aortic surgery at smaller diameters may be recommended when there are severe craniofacial features, rapid growth, or a family history of aortic dissection.

¶Surgical thresholds vary depending on the specific gene mutation involved. TAA caused by *ACTA2*, *SMAD3*, and *MYLK* may lead to aortic dissection at relatively small aortic diameters.

Modified from Erbel R et al. 2014 ESC guidelines on the diagnosis and treatment of aortic diseases: document covering acute and chronic aortic diseases of the thoracic and abdominal aorta of the adult. The Task Force for the Diagnosis and Treatment of Aortic Diseases of the European Society of Cardiology (ESC). Eur Heart J 2014;35:2873-926; Hiratzka LF et al. 2010 ACCF/AHA/AATS/ACR/ASA/SCA/SCAI/SIR/STS/SVM guidelines for the diagnosis and management of patients with thoracic aortic disease. Circulation 2010;121:e266-369; and Hiratzka et al. Surgery for aortic dilatation in patients with bicuspid aortic valves: a statement of clarification from the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. J Am Coll Cardiol 2016;67:724-31.

Marfan syndrome (MFS), an autosomal dominant disorder of connective tissue, results from abnormal fibrillin-1 caused by mutations in the *FBN1* gene.[12] Aortic dilation in MFS affects most prominently the sinuses of Valsalva (**Fig. 63.5**) (Video 63.1), but distal aortic aneurysms and dissections may occur. In addition to directing elastogenesis and providing structural support to tissues, fibrillin-1 interacts with latent transforming growth factor beta (TGF-β)–binding proteins and controls the activation and signaling of TGF-β. The abnormal fibrillin-1 in MFS leads to excess free TGF-β, which promotes aortic disease (**Fig. 63.6**). Angiotensin interacts with TGF-β signaling, and blocking TGF-β, whether by neutralizing antibody or by the angiotensin receptor blocker (ARB) losartan, attenuates or prevents aortic aneurysm formation in MFS mice.[12] In children with MFS and aggressive aortic disease, ARB therapy stabilized aortic root size.[14] However, in randomized trials, there was no significant difference in rate of aortic dilation in Marfan patients treated with atenolol or losartan[14,15] (**eFig. 63.2**). In the Dutch Marfan trial comparing the addition of losartan to standard care (using beta blocker in >70%), losartan therapy did reduce aortic growth rate.[1,16] At present, maximal-dose beta-blocker therapy or ARB treatment in MFS is recommended to lessen aortic growth rate. An upcoming meta-analysis will explore subsets of patients who may benefit from a specific treatment.[14,15]

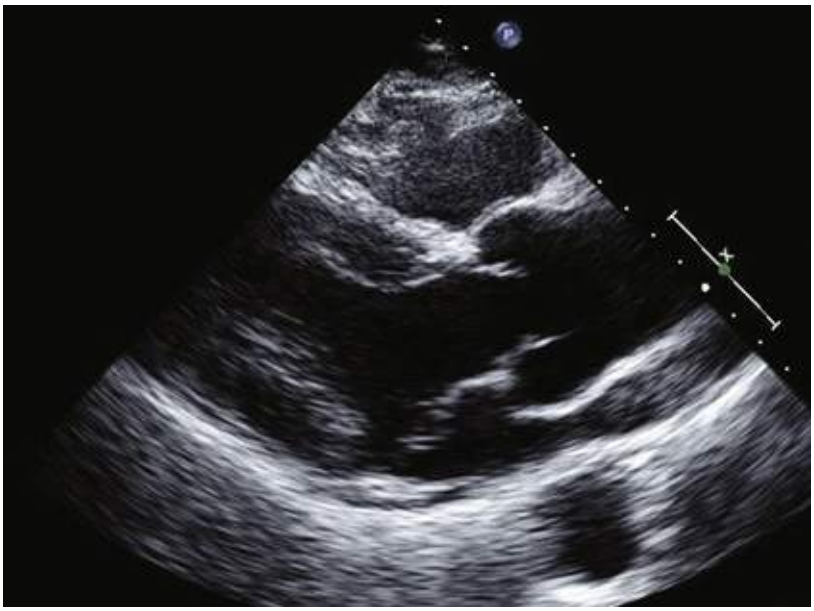

FIGURE 63.5 Transthoracic echocardiogram of a dilated aortic root in a patient with Marfan syndrome. The dilation is most pronounced in the sinuses of Valsalva, and the aorta narrows above the sinotubular junction.

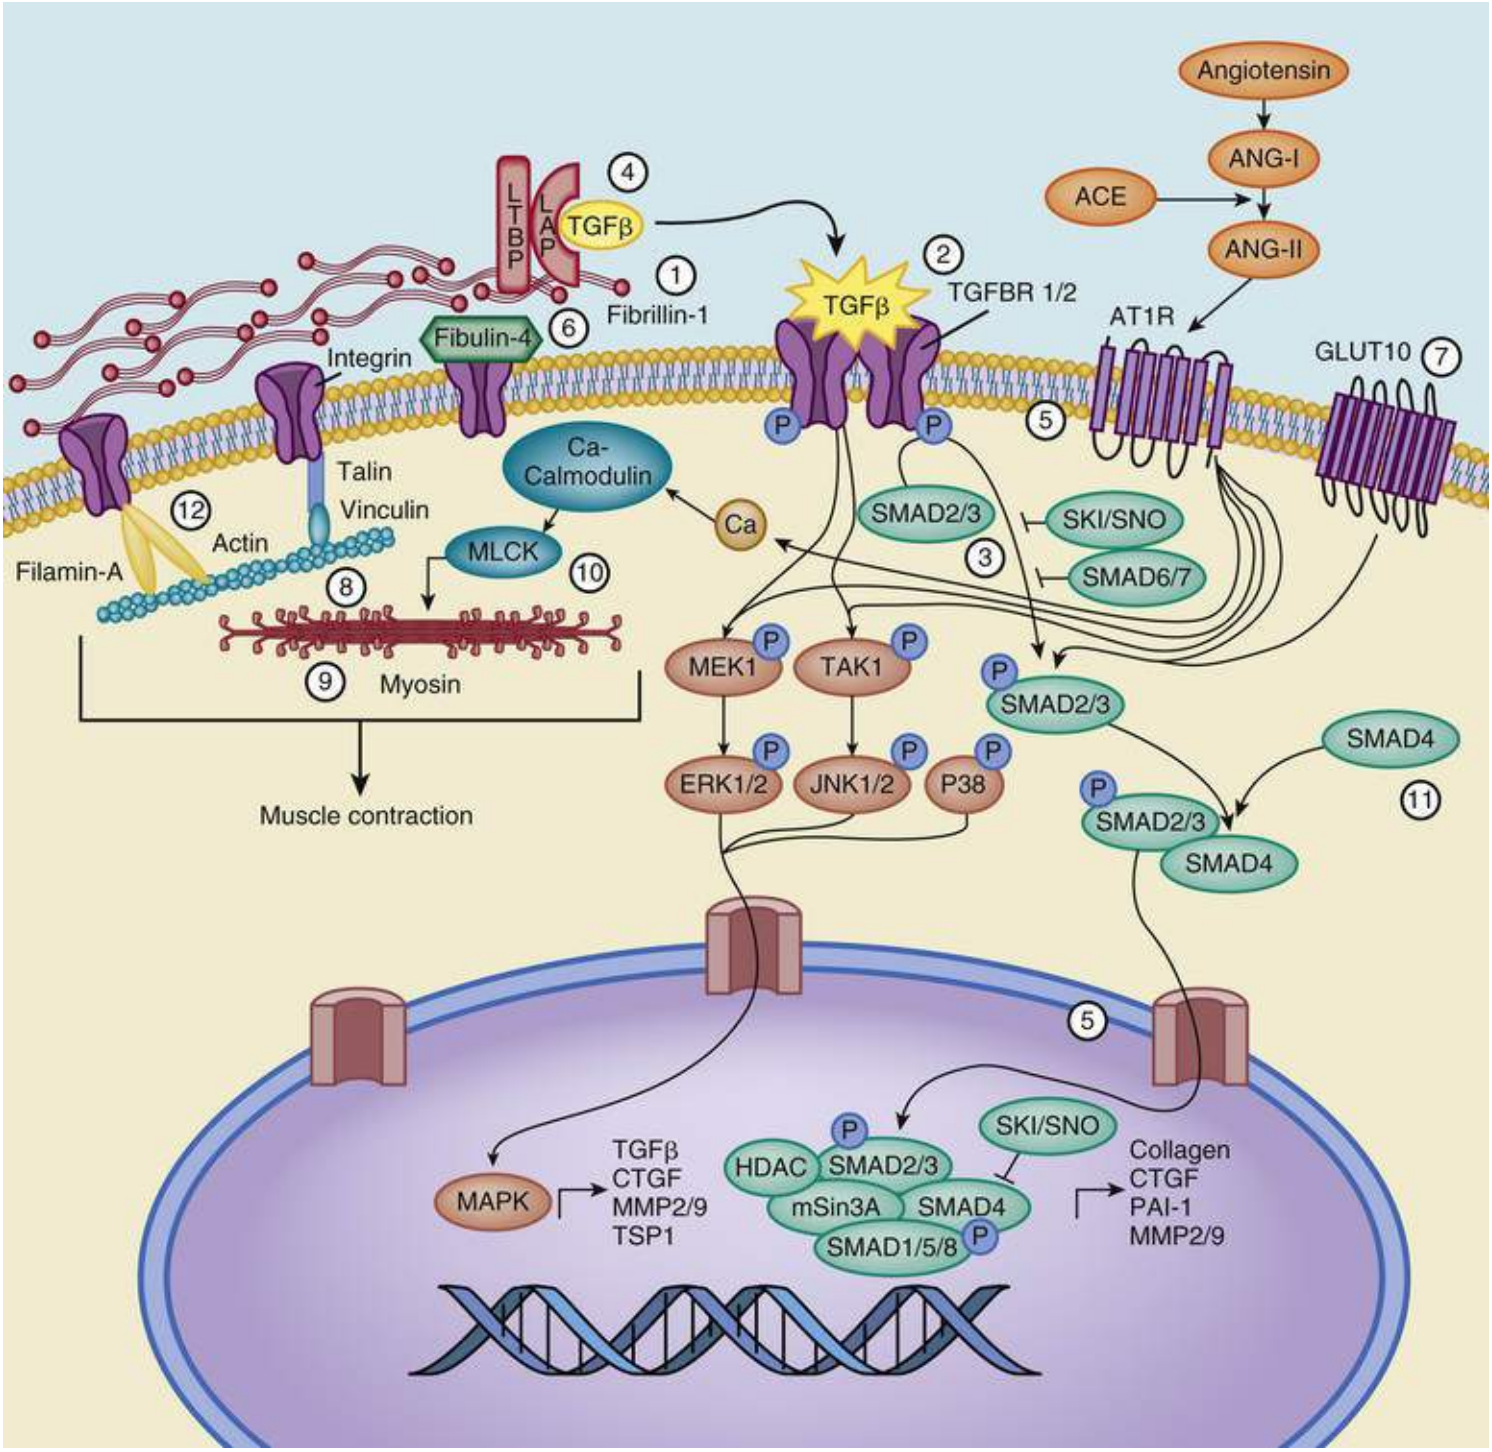

FIGURE 63.6 Pathways implicated in heritable thoracic aortic aneurysm diseases (**see also Table 63.1**). *Numbers* indicate the corresponding syndrome caused by mutations in the protein: *1,* Marfan syndrome; *2,* Loeys-Dietz syndrome type 1 or 2; *3,* Loeys-Dietz syndrome type 3; *4,* Loeys-Dietz syndrome type 4; *5,* Shprintzen-Goldberg syndrome; *6,* cutis laxa type 1B; *7,* arterial tortuosity syndrome; *8, 9,* and *10,* familial thoracic aortic aneurysms and dissections; *11,* Myhre syndrome, juvenile polyposis syndrome, and hemorrhagic telangiectasia syndrome; *12,* Ehlers-Danlos–related syndrome with periventricular nodular heterotopia. *ACE,* Angiotensin-converting enzyme; *ANG,* angiotensin; *ERK,* extracellular signal–regulated kinase; *HDAC,* histone deacetylase; *JNK,* Jun N-terminal kinase; *MAPK,* mitogen-activated protein kinase; *MEK,* mitogen-activated protein kinase/extracellular signal–regulated kinase; *MLCK,* myosin light chain kinase; *MMP,* matrix metalloproteinase; *PAI,* plasminogen activator inhibitor; *TAK,* transforming growth factor-β–activated kinase; *TGF,* transforming growth factor; *TGFBR,* transforming growth factor-β receptor; *TSP,* thrombospondin. (From Gillis E, Van Laer L, Loeys BL. Genetics of thoracic aortic aneurysm: at the crossroads of transforming growth factor-beta signaling and vascular smooth muscle contractility. Circ Res 2013;113:327-40.)

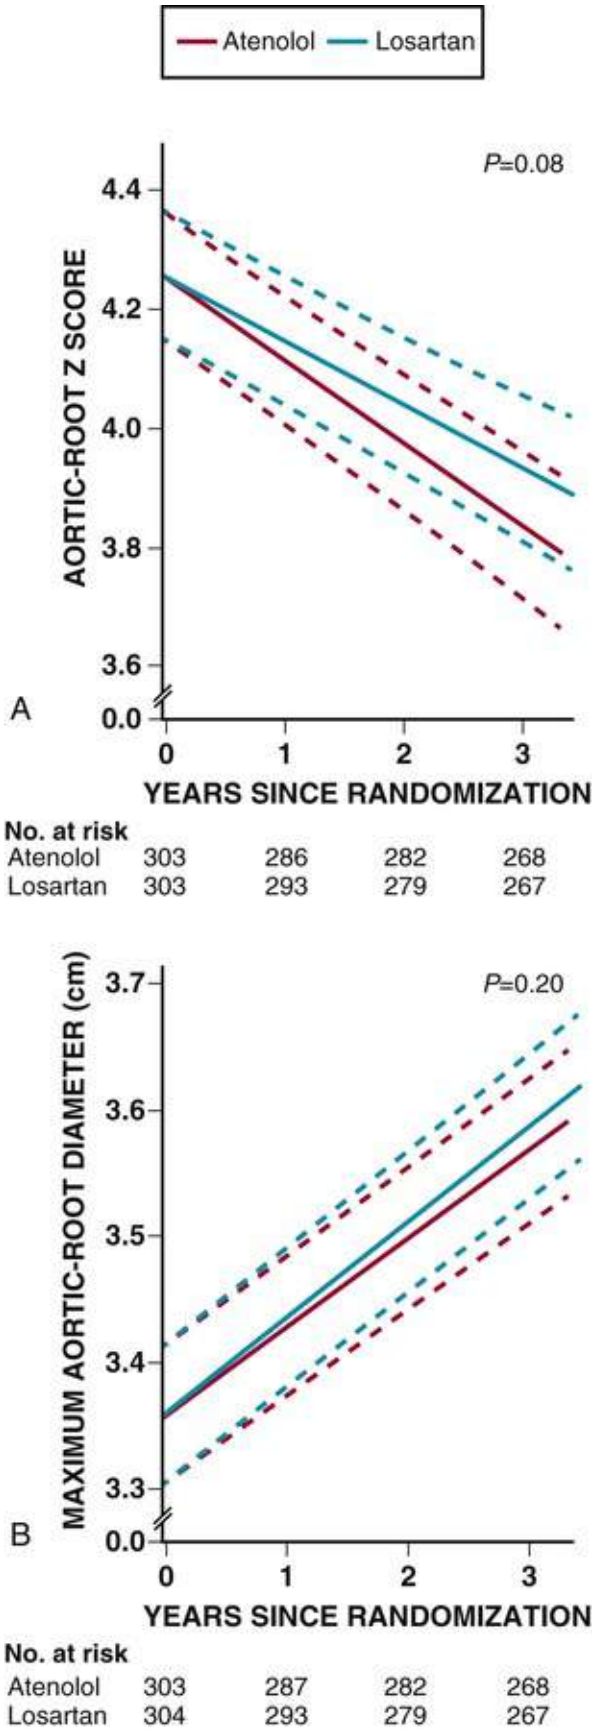


EFIGURE 63.2 Atenolol versus losartan in Marfan syndrome trial. Change in aortic-root *z* score **(A)** and aortic-root diameter **(B),** according to treatment group. Both treatment arms demonstrated a reduction in aortic-root *z* scores over time, consistent with a reduction in aortic growth rate relative to body growth.
(From Lacro RV, Dietz HC, Sleeper LAet al. Atenolol versus losartan in children and young adults with Marfan's syndrome. N Engl J Med 2014;371:2061-71.)

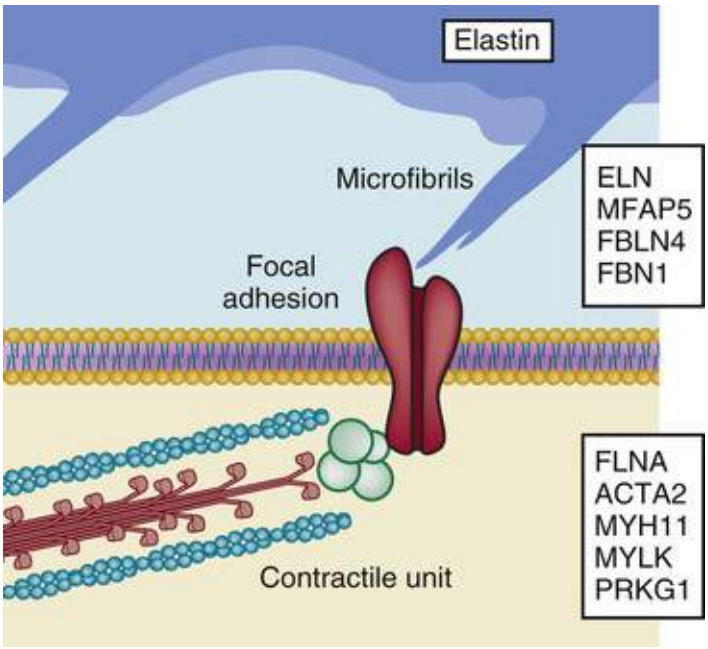
Loeys-Dietz syndrome (LDS), caused by mutations in *TGFBR1* and *TGFBR2*, has craniofacial abnormalities (hypertelorism, bifid/broad uvula, cleft palate, craniosynostosis), arterial tortuosity, and aneurysms and dissections of the aorta and branch vessels.[1,12,17] Patients with LDS may have cutaneous

features, including easy bruisability, hyperlucent skin with easily visible veins, and facial milia. The diseased tissues of patients with LDS exhibit excess TGF-β signaling[12] (**Fig. 63.6**). LDS has a more aggressive vascular phenotype than MFS, with dissections occurring at smaller sizes and younger ages. *TGFBR2* mutations may have a more aggressive phenotype than *TGFBR1* mutations, especially in men.[12] Aortic surgery is recommended at aortic root dimensions of 4 to 4.5 cm, especially when more severe craniofacial features are present.[1,17]

Aneurysms-osteoarthritis syndrome (AOS), also called *LDS3* and familial thoracic aortic aneurysm and dissection syndrome (FTAAD), results from *SMAD3* mutations and involves early severe osteoarthritis and osteochondritis dissecans, skeletal and cutaneous features of LDS, and arterial tortuosity, aneurysms, and dissections of the aorta and branch vessels.[1,17] AOS also may have an aggressive aortic phenotype and may merit aortic surgery at smaller aortic root dimensions.[1,12]

Vascular Ehlers-Danlos syndrome (vEDS) is caused by mutations in *COL3A1* that result in abnormal type III procollagen synthesis and is associated with aortic aneurysms and dissection. Individuals with vEDS have risk for spontaneous arterial dissection and rupture, often involving medium-sized arteries. Aortic root disease is less common, with more frequent involvement of the descending and abdominal aorta and branch vessels. Unlike MFS and LDS, the abnormal arteries in patients with vEDS are friable, thus making surgical repair more difficult. vEDS significantly reduces life span because of arterial disease and rupture of visceral organs.

In the absence of other phenotypic features (nonsyndromic), TAAs may be familial, with up to 20% of patients having an affected first-degree relative.[1,6,12,17] This disorder, *familial thoracic aortic aneurysm and dissection* (TAAD), is inherited as an autosomal dominant trait with decreased penetrance and variable expression (especially in women).[6] An ever-increasing number of genes have been identified that can cause familial TAAD, some of which are also associated with AAA and cerebral aneurysm[1,6,17] (**see Table 63.1**). Although TGF-β signaling abnormalities underlie the pathogenesis in certain aneurysm syndromes, defects in SMC contractile function leading to aortic aneurysm and dissection are related to *ACTA2*, *MYH11*, *MYLK*, *FLNA*, and *PRKG1* mutations[12] (**Fig. 63.6 and eFig. 63.3**). Fibrillin-1 microfibrils may participate in mechanotransduction in vascular SMCs, thereby linking fibrillin-1 in the matrix to intracellular actin filaments. *ACTA2* encodes smooth muscle alpha-actin, and mutation of this gene is the most common cause of familial TAAD; *ACTA2* mutations account for 14% of familial TAAD and is associated with livedo reticularis, iris flocculi, premature coronary and cerebrovascular disease, patent ductus arteriosus (PDA), and bicuspid aortic valves.[12,18] Aortic dissection at diameters or less than 5 cm are described, and approximately 50% of *ACTA2* patients have aortic events, with cumulative risk estimated at 76% by age 85 years.[18] First-degree relatives of individuals with unexplained TAA or dissection should undergo aortic imaging or genetic testing with mutation analysis when a known mutation is present in the family.[1,6,17]



EFIGURE 63.3 Elastin-contractile unit in smooth muscle cells. The altered genes that predispose to thoracic aortic aneurysms and acute aortic dissections are indicated (**see Table 63.1**). The location of the gene indicates where its protein product is located in the elastin-contractile unit. (From Karimi A, Milewicz D. Structure of the elastin-contractile units in the thoracic aorta and how genes that cause thoracic aortic aneurysms and dissections disrupt this structure. Can J Cardiol 2016;32:26-34.)

Bicuspid aortic valve (BAV) *disease* affects approximately 1% of the population and may be associated with ascending aortic aneurysm, coarctation of the aorta, and aortic dissection[19] (Video 63.2). The BAV exhibits abnormal leaflet folding, wrinkling, and increased leaflet doming, which can result in turbulence even in the absence of a stenotic or regurgitant lesion. Abnormal aortic wall shear stress due to helical flow patterns in the setting of bicuspid aortic valves may underlie the aortopathy of BAV disease[20,21] (**Fig. 63.7**). Ascending TAAs associated with BAVs may develop independent of valve function and may develop late after aortic valve replacement (AVR) (Video 63.3). There are multiple aortic phenotypes in BAV aortopathy, and the root phenotype (present in 10%) may have a higher aortic risk[21] (Video 63.4). The aortic dilation in BAV disease occurs most often in the proximal to middle ascending aorta, making imaging of the entire ascending aorta important in patients with BAVs.[17] CMD underlies the aortic aneurysm and risk for dissection associated with BAVs.[21] When BAV and TAA coexist, there is more CMD associated with the regurgitant than with the stenotic BAV.[21] Compared with tricuspid aortic valve (TAV) aneurysms, BAV aneurysms exhibit increased apoptosis, increased MMP-2 activity, and abnormalities in TGF-β and protein kinase C–signaling pathways.[19] The lifetime risk of aortic dissection for the BAV patient is four to eight times higher than the risk in the general population.[21] However, the risk of dissection in BAV patients followed longitudinally and undergoing elective aneurysm surgery is relatively low. Of 416 patients with BAV (age at diagnosis, 35 ±12 years) followed for a mean of 16 years, aortic dissection incidence was 3.1 cases per 10,000 patient-years, with an age-adjusted relative risk of 8.4 compared with the general population.[21] Higher rates were observed in patients age 50 or older at baseline (17.4 cases per 10,000 patient-years) and in patients with ascending aortic aneurysm at baseline (44.9 cases per 10,000 patient-years, versus age matched population risk of 0.31 per 10,000 person-years). The risk of aortic dissection in patients with BAV and an ascending aorta aneurysm of 5.3 cm is approximately 4%.[22] BAVs and ascending aortic aneurysm may be familial, inherited as an autosomal dominant disorder with variable expressivity and incomplete penetrance.[12] Gene mutations associated with BAV and TAA are listed in **Table 63.1**. Genetic heterogeneity, complexity of the trait, noncoding sequence variants, and epigenetic factors may explain the lack of an underlying

genetic pathogenesis in BAV TAA disease.[12] First-degree relatives of a patient with BAV, especially with aortopathy, should undergo evaluation for BAVs and ascending TAA.[17]

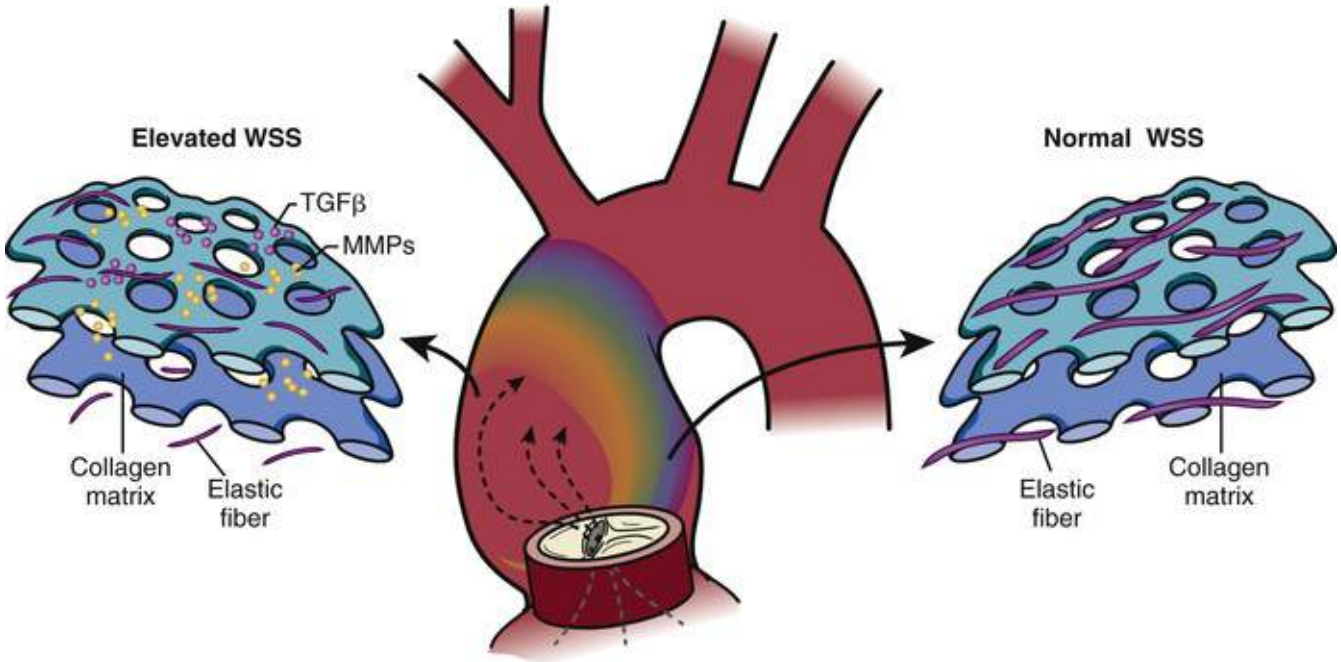


FIGURE 63.7 Bicuspid aortic valve (BAV) aortopathy is related to abnormal aortic flow and elevated wall shear stress. Four-dimensional flow cardiac magnetic resonance imaging (4D flow CMR) is used to assess the relation between wall shear stress (WSS) and regional aortic tissue remodeling in BAV patients. Elevated aortic WSS generated by aberrant flow from cusp fusion corresponds to more severe extracellular matrix (ECM) dysregulation than adjacent regions of normal WSS in the same patient's aorta. Elastic fiber degeneration is more severe in regions of elevated WSS (less elastin, thinner fibers, and greater distances between laminae), where higher concentrations of mediators of ECM dysregulation (matrix metalloproteinases [MMPs] and transforming growth factor beta [TGFβ]) are also observed. These data implicate valve-related hemodynamics as a contributing factor to BAV aortopathy. (From Guzzardi DG, Barker AJ, van Ooij P, et al. Valve-related hemodynamics mediate human bicuspid aortopathy insights from wall shear stress mapping. J Am Coll Cardiol 2016;66:892-900.)

Turner syndrome (TS), which affects 1 in 2000 live-born girls, results from complete or partial loss of a second sex chromosome (XO, Xp). Approximately 50% to 75% of patients with TS have cardiovascular (CV) defects, including BAVs in 30%, coarctation of the aorta in 12%, elongation of the transverse arch in 30%, and ascending aortic dilation 33%.[23] Abnormal TGF-β signaling may contribute to the aortic disease in TS. Patients with TS have an estimated 100-fold greater risk for aortic dissection than do age-matched controls.[23] Most women with TS who develop aortic dissection have risk factors, including aortic dilation, BAV, coarctation of the aorta, and systemic hypertension[23] (**eFig. 63.4**). Women with TS but without risk factors for aortic dissection should undergo reevaluation of the aorta every 5 to 10 years or when clinically indicated (e.g., contemplating pregnancy).[17] Women with risk factors or known CV defects require more frequent imaging. Because patients with TS have short stature, ascending aortic dimensions should be evaluated in relation to body surface area (BSA). TS patients have increased aortic diameter relative to BSA and a higher risk for dissection at smaller absolute aortic diameters.[23,24]

EFIGURE 63.4 Contrast-enhanced computed tomography scan in 47-year-old woman with Turner syndrome demonstrating an elongated aortic arch, coarctation of the aorta (*white arrow*), dilated proximal descending aorta, and acute type B aortic dissection (*black arrow*).

Aortic enlargement and CMD are associated with other congenital heart diseases, including coarctation of the aorta, transposition of the great vessels, ventricular septal defect, and tetralogy of Fallot.

Degenerative Aneurysms

Degenerative ("atherosclerotic") aneurysms are less common in the ascending aorta and are associated with diffuse aortic atherosclerosis. Isolated arch aneurysms may be degenerative or related to penetrating aortic ulcers, CMD, and rarely, syphilis or other infections. Most descending TAAs are degenerative but may also result from genetic disorders. These aneurysms tend to originate just distal to the origin of the left subclavian artery, may be either fusiform or saccular, and may extend into the abdominal aorta or coexist with AAAs.

Aortic Dissection

Dissection is a common cause of aneurysm of the descending thoracic aorta and the arch. Frequently, aneurysm formation develops during the chronic stage of dissection and thus involves the ascending aorta less often, since this segment is almost always surgically replaced during the acute stage (see later).

Syphilis and Aortitis

Cardiovascular syphilis occurs in the tertiary stage and typically involves the ascending aorta and arch. Aortitis rarely occurs today because of antibiotic treatment of syphilis early in its course. CV *syphilis* becomes evident after a latent period of at least 10 to 25 years. Pathologic features include lymphocytic and plasma cell inflammation in the adventitia, with the classic appearance of a "tree bark" or wrinkled appearance of the aortic intima. Ascending aortic aneurysm formation occurs in 40% of cases. Tertiary syphilis may cause aortic valvulitis, aortic regurgitation (AR), and coronary ostial stenosis.

Infectious *aortitis* (typically bacterial, less often fungal) is discussed later (**see also Chapter 73**). Other causes of TAAs include noninfectious aortitis such as giant cell arteritis, other vasculitides, and idiopathic aortitis and IgG4 disease. Noninfectious aortitis may underlie aortic aneurysms in 2% to 8% of TAAs.

Clinical Manifestations

Most TAAs are asymptomatic and are discovered incidentally. Physical findings such as AR may suggest TAA. Symptoms of TAAs usually are related to a local mass effect, progressive AR, or systemic embolization caused by mural thrombus or atheroembolism. Obstruction of the superior vena cava or innominate vein may result from ascending aorta or arch aneurysms. TAAs may compress the trachea, bronchus, or esophagus. Persistent chest or back pain may occur because of a direct mass effect from the TAA, with compression of intrathoracic structures or erosion into bones. The most serious complications of TAAs are rupture and dissection (**Fig. 63.8 and eFig. 63.5**). Aortic rupture leads to sudden severe chest or back pain. Rupture into the pleural cavity (usually left) or into the mediastinum is associated with hypotension; rupture into the esophagus leads to hematemesis; and rupture into the bronchus or trachea results in hemoptysis. Infected TAAs are associated with pain, fever, and fistulas. Acute aortic expansion, contained rupture, and pseudoaneurysm can cause severe chest or back pain. Thoracic aortic dissection (see later) is more common than rupture.

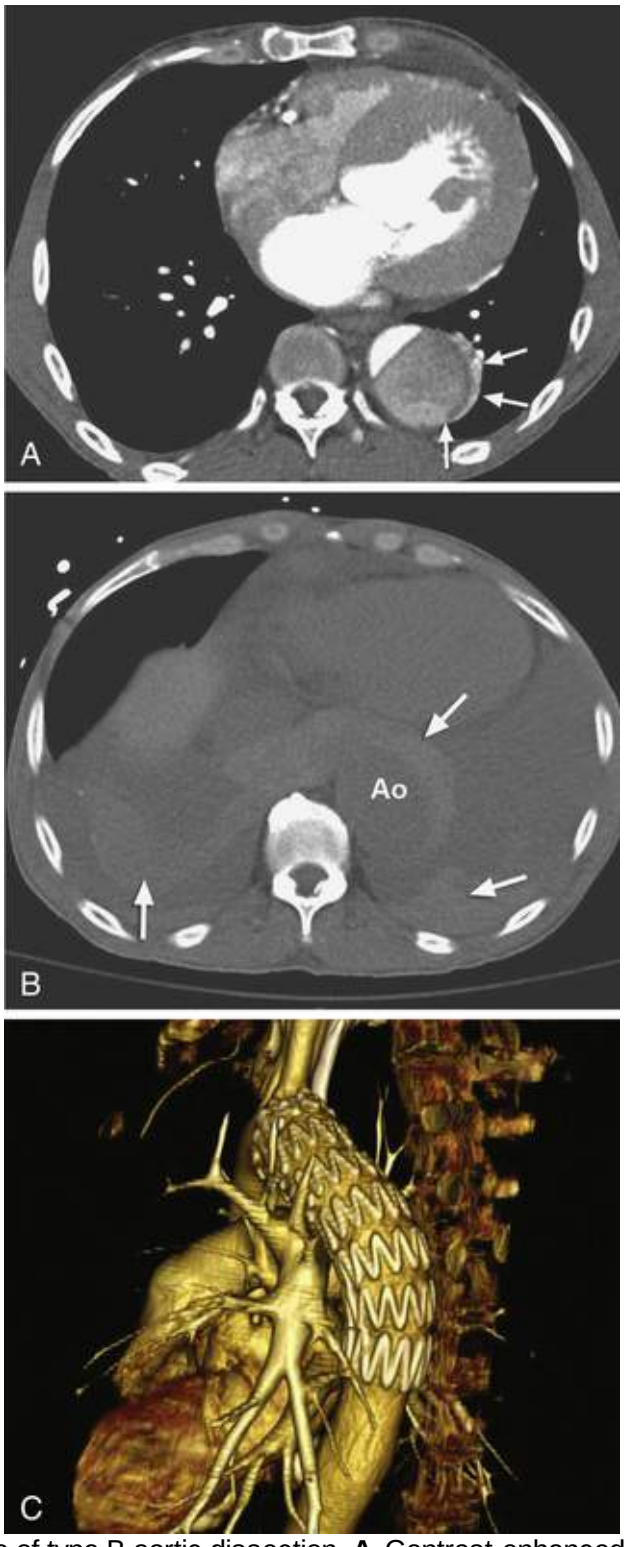

FIGURE 63.8 Rupture of type B aortic dissection. **A,** Contrast-enhanced computed tomography demonstrating early leakage of blood from the dilated false lumen (*arrows*). The small true lumen is densely opacified with contrast material. **B,** Non–contrast-enhanced CT demonstrating acute hemorrhage from the ruptured type B dissection (*arrows*); *Ao,* aorta. **C,** Three-dimensional reconstruction of the descending thoracic aorta after emergency endovascular repair of the ruptured aortic dissection.

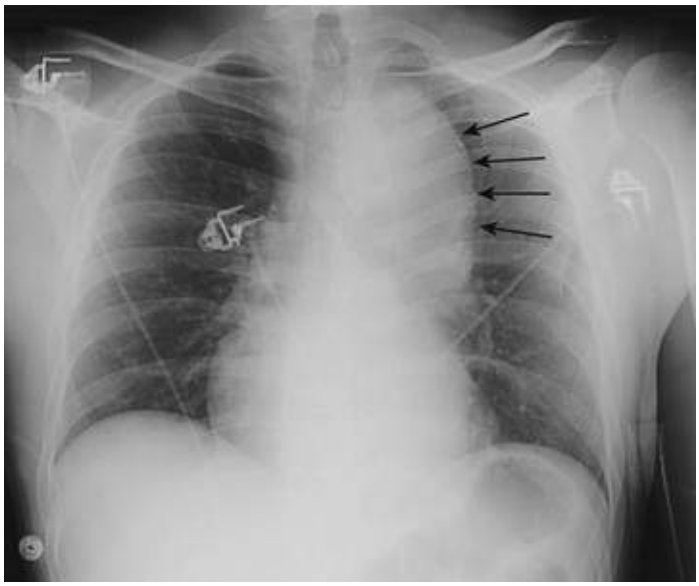
EFIGURE 63.5 Contrast-enhanced computed tomography scan in a patient with acute type A aortic dissection complicated by acute rupture of the aortic arch and active mediastinal bleeding (*arrow*). The dissection flap is visualized in the arch. (From Braverman AC. Aortic dissection. In Levine GN, editor. Color Atlas of Cardiovascular Disease. New Delhi, India: Jaypee Brothers Medical Publishers; 2015, pp 895-903.)

Diagnosis

Many TAAs are evident on chest radiographs (**eFig. 63.6**), with features including a widened mediastinum, prominent aortic knob, or displaced trachea. Smaller aneurysms may not be visible on x-ray films. Aneurysms involving the sinuses of Valsalva and aortic root may not be seen on chest radiographs, being "hidden" behind the sternum, mediastinal structures, and vertebrae. Aortic tortuosity and unfolding in older adults may also mimic or mask TAAs. Thus, chest radiography cannot exclude the diagnosis of TAA.



EFIGURE 63.6 Chest radiograph demonstrating a large descending thoracic aortic aneurysm (*black arrows*).

Transthoracic echocardiography (TTE) can visualize TAAs involving the sinuses of Valsalva and often the proximal ascending aorta, aortic arch, and proximal descending aorta[2] (**see Fig. 63.5** and Videos 63.1

and 63.4). Aortic root size varies with age, height or BSA, and sex, and nomograms provide normal ranges.[2,17] Although TTE does not thoroughly characterize the aortic arch and descending TAAs, transesophageal echocardiography (TEE) can image most of the thoracic aorta (Video 63.5).

Contrast-enhanced CT and MRA provide outstanding detail of aortic and branch vessel anatomy in TAA disease. In the setting of a tortuous aorta, axial images alone can be misleading and may "overstate" the true dimension of the aorta.[2] When the axial images cut through the descending aorta at a plane that is off-axis, it results in a falsely large aortic diameter. Multidetector CTA and MRA allow reconstruction of the axial data into three-dimensional images, permitting aortic measurement in a true cross section to obtain an accurate diameter[2] (**Fig. 63.9 and eFig. 63.7**). The echocardiogram generally measures the internal diameter, whereas CT and MRI measure the external diameter of the aorta, which is expected to be 0.2 to 0.4 cm larger than the internal diameter.[2,17]

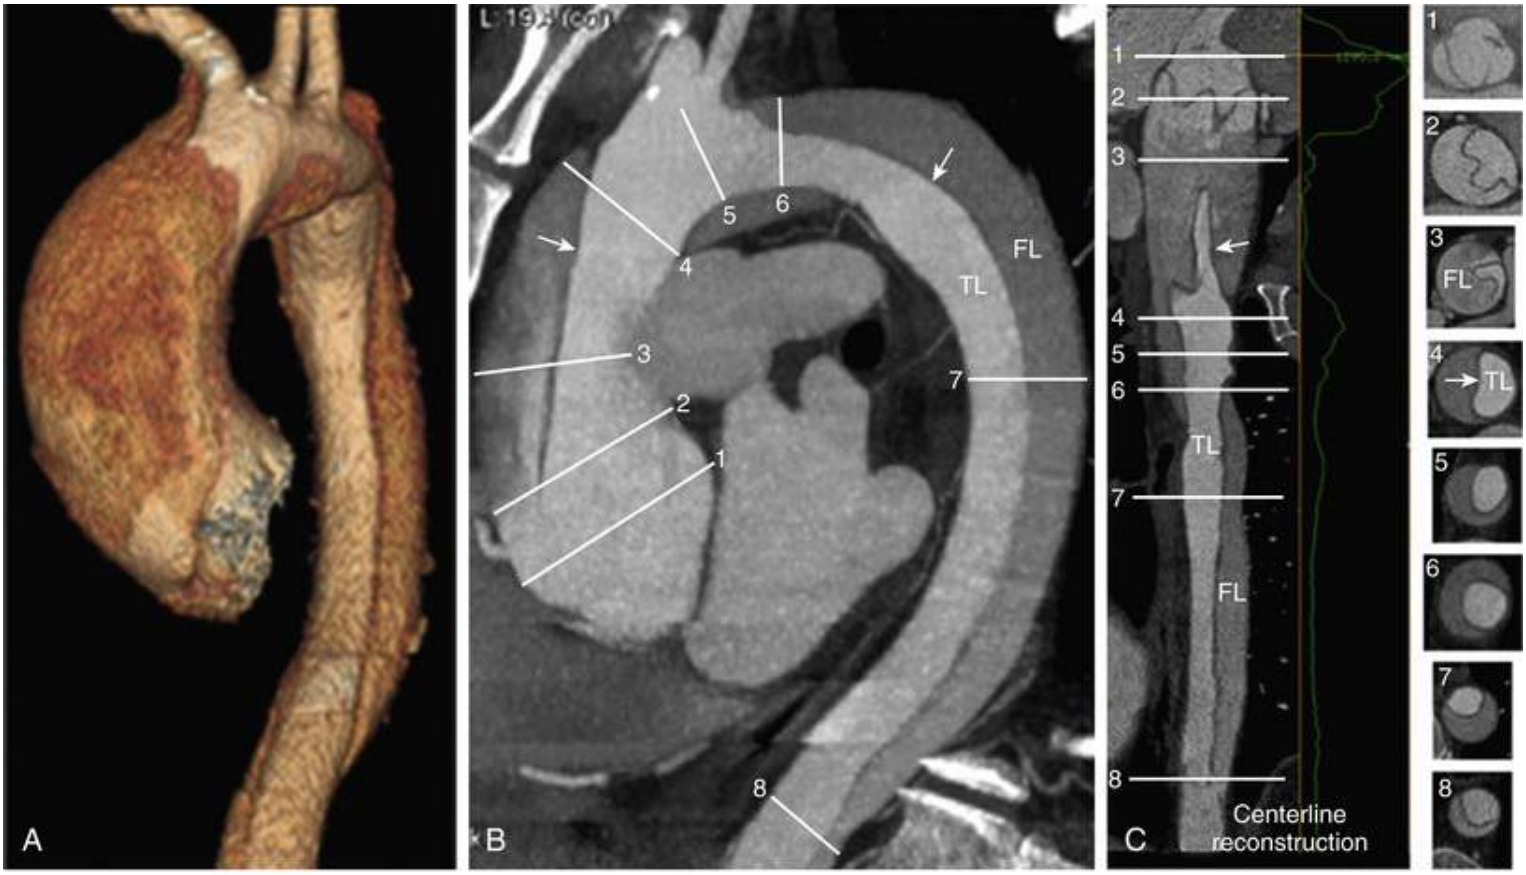


FIGURE 63.9 Computed tomographic angiography (CTA) of the thoracic aorta. **A,** Three-dimensional volume rendering. **B,** Oblique coronal view of the aorta. Note linear gating artifacts. **C,** Centerline reconstruction of the aorta as a straight vessel, eliminating tortuosity and allowing for measurement in true short axis (*right panel*). Corresponding levels of measurements are shown on **B** and **C:** *1,* sinuses of Valsalva; *2,* sinotubular junction; *3,* proximal ascending aorta; *4,* distal ascending aorta; *5,* aortic arch; *6,* aortic isthmus; *7,* mid–descending aorta; *8,* distal descending aorta at diaphragm. Type A aortic dissection flap (*arrows*), true lumen (*TL*), and false lumen (*FL*) are shown in **B** and **C.** (From Mongeon FP, Marcotte F, Terrone DG. Multimodality noninvasive imaging of thoracic aortic aneurysms: time to standardize? Can J Cardiol 2016;32:48-59.)

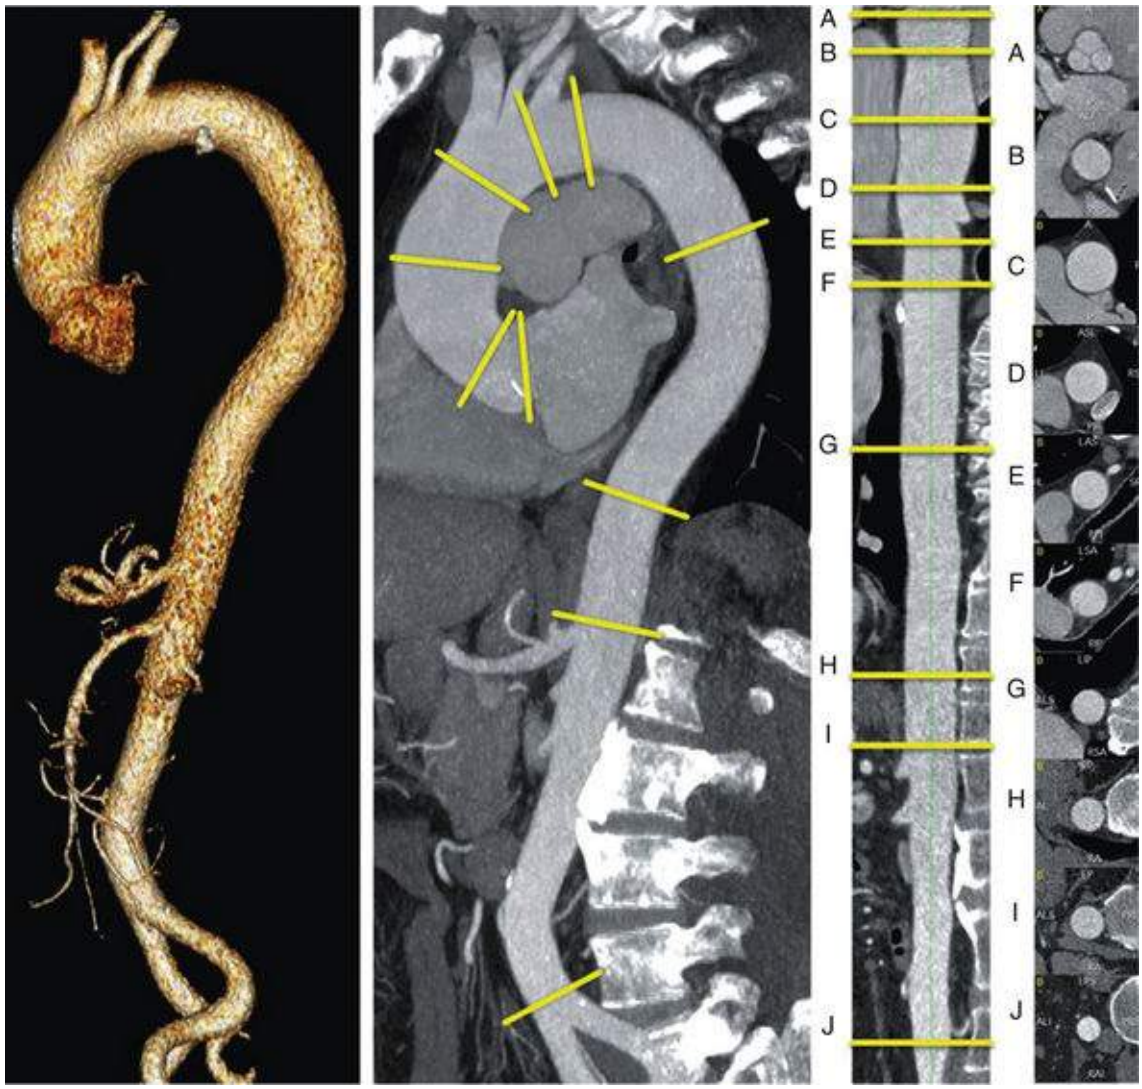


EFIGURE 63.7 Thoracic and abdominal aorta in a three-dimensional reconstruction **(left),** parasagittal multiplanar reconstruction (MPR) along the centerline **(middle),** and straightened MPR along the centerline with given landmarks (*A* to *J*) **(right),** orthogonal to the centerline-orientated cross sections at the landmarks. Landmarks *A* to *J* should be used to report aortic diameters: *A,* sinuses of Valsalva; *B,* sinotubular junction; *C,* mid–ascending aorta (as indicated); *D,* proximal aortic arch (aorta at the origin of the brachiocephalic trunk); *E,* mid–aortic arch (between left common carotid and subclavian arteries); *F,* proximal descending thoracic aorta (approximately 2 cm distal to left subclavian artery); *G,* mid–descending aorta (level of the pulmonary arteries as easily identifiable landmarks, as indicated); *H,* at diaphragm; *I,* at the celiac axis origin; *J,* right before aortic bifurcation. (Provided by F. Nensa, Institute of Diagnostic and Interventional Radiology, Essen. From Erbel R, Aboyans V, Boileau C, et al. 2014 ESC guidelines on the diagnosis and treatment of aortic diseases. The Task Force for the Diagnosis and Treatment of Aortic Diseases of the European Society of Cardiology (ESC). Eur Heart J 2014;35:2873-926.)

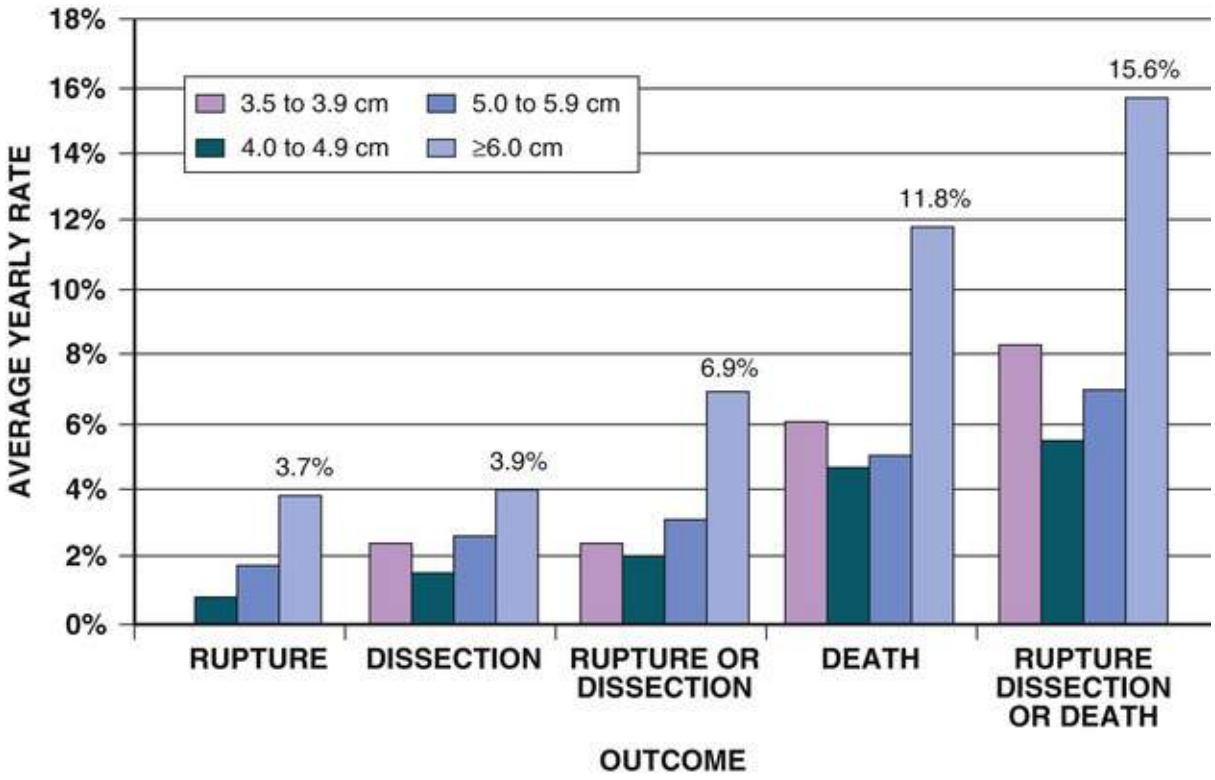
Natural History

Many factors influence the natural history of TAAs. Patients with MFS and BAV disease have a more rapid aneurysm growth rate than those with degenerative aneurysms.[11] The location and size of the TAA also affect its rate of growth and likelihood of rupture or dissection. TAAs are relatively indolent, with a growth rate of approximately 1 to 2 mm/yr and marked individual variability.[1,11] Larger aneurysms grow faster than smaller ones. Aneurysms of the descending aorta have a greater growth rate (approximately 2 mm/year) than those of the ascending aorta (1 mm/yr), and dissected TAAs grow more rapidly than those without dissection.[11]

Rupture and acute dissection are the major complications of TAAs (**see Figs. 63.8 and 63.9 and eFigs. 63.4 and 63.5**). Less than half of patients with rupture arrive at the hospital alive; mortality at 24 hours

reaches 75%. Aortic diameter and the underlying disease determine risks of aortic complications. For ascending aortic aneurysms larger than 6 cm, the risk for rupture, dissection, or death is 15.6%.[1,25] A series of patients with MFS had a risk of aortic dissection of 0.3% per year at an aortic root diameter 4.5 to 4.9 cm and 1.33% per year at 5.0 to 5.4 cm.[26] Among BAV patients, the risk of aortic dissection was approximately 3.8% for those with an ascending aortic diameter of 5.3 cm and 10% when the ascending aorta is 6 cm.[22] For LDS, certain familial TAA syndromes, and vEDS, the aortic diameter is less predictive, and dissection may occur at smaller aortic sizes. In patients with degenerative descending or thoracoabdominal aortic aneurysms, the estimated risks of definite aortic events (dissection, rupture, or death) were 5.5%, 7.2%, 9.3%, and 15.4% at aortic diameters of 50, 55, 60, and 70 mm, respectively.[27]

Risk factors for increased growth and rupture of TAAs include older age, chronic obstructive pulmonary disease (COPD), hypertension, cigarette smoking, rapid aneurysm growth, aortic dissection, and a positive family history.[17] Aortic diameter is the most important risk factor for aneurysm complications (**eFig. 63.8**). Sex and BSA may also predict complications of aneurysms.[17,25,27] Some have proposed using aortic cross-sectional area and body height,[17] and the Aortic Risk Calculator uses height, weight, and aortic diameter to calculate a yearly risk for rupture or dissection.[25]



EFIGURE 63.8 Yearly rates of rupture, dissection, or death related to aortic size. Note that the likelihood of rupture, dissection, or death within the coming year also jumps sharply for aneurysms that reach 6 cm or larger. (The rates indicated for rupture or dissection and for rupture, dissection, or death are lower than the sum of the rates in individual categories because patients with multiple complications were counted only once in the combined categories). (From Elefteriades JA, Farkas EA. Thoracic aortic aneurysm: clinically pertinent controversies and uncertainties. J Am Coll Cardiol 2010;55:841-57. Illustration by Rob Flewell.)

Surgical thresholds for TAA repair depend on the disease present and patient-specific factors (**Table 63.2**). For degenerative aneurysms, surgical replacement of the aorta is recommended when the aortic root or ascending aortic diameter reaches 5.5 cm; the arch >5.5 to 6 cm; and the descending or thoracoabdominal aorta reaches >5.5 to 6 cm.[1,17,27] Surgery is recommended in MFS when the aortic root diameter is 50 mm or larger, with a lower threshold for those with rapid aortic growth or a family history

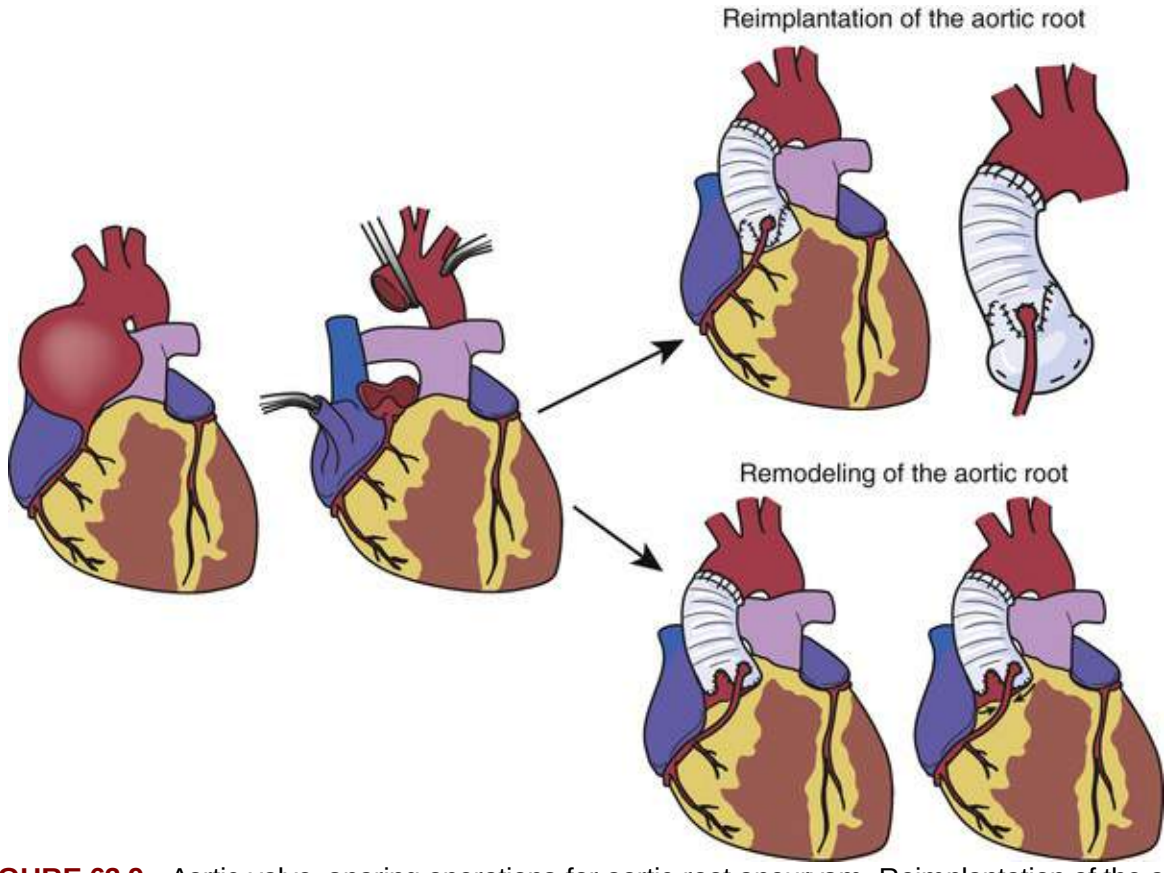
of aortic dissection;[1,17] in familial TAA syndromes at 4.5 to 5 cm;[1] in BAV aneurysm at 5.5 cm or larger, and at 5.0 cm or larger if there are risk factors for aortic dissection (family history of dissection, rapid aortic growth (>3 to 5 mm/year), coarctation of the aorta, or hypertension) or if the patient is at low surgical risk.[1,24] If surgery is being performed on the BAV, aortic aneurysm surgery may be performed in acceptable candidates at aortic diameter greater than 4.5 cm.[24] Adults with LDS should have surgery when the aortic root measures 4.0 to 4.5 cm, although some recommend surgery in patients with LDS once the aortic root is larger than 4 cm, especially when accompanied by a high craniofacial index.[1,12,17] In TS, prophylactic surgery should be considered when the ascending aortic size index is 2.5 cm/m^2 or greater.[23,24] Surgical timing also depends on the family history, sex, rate of aneurysm growth, body size, coexisting aortic valve disease, need for other heart surgery, comorbid conditions, and patient and physician preference. Because aortic complications occur at diameters lower than surgical thresholds, physicians must individualize management based on surgical risk and other factors. Endovascular approaches for some conditions may lead to earlier therapy for appropriate candidates, but genetically triggered aneurysm disease generally limits thoracic endovascular aortic repair to emergencies or hybrid procedures involving surgical grafts as landing zones.

Management

Surgical Treatment

Ascending Thoracic Aortic Aneurysms.

Treatment of ascending TAAs involves opening the ascending aorta and placement of a prosthetic graft with or without concomitant AVR. A composite graft consisting of a Dacron tube with a prosthetic aortic valve sewn into one end (the modified Bentall procedure) is generally the method of choice in treating ascending TAAs involving the root and associated with significant aortic valve disease. The valve and graft are sewn directly into the aortic annulus, and the coronary arteries are reimplanted into the Dacron graft. For elective aneurysm repair, the risk for death or stroke ranges from 1% to 5% depending on the disease, patient population, and surgical experience.[1,17] The risk for morbidity and mortality increases with the need for arch dissection. Emergency operations on the proximal aorta carry much higher risk. Patients with structurally normal aortic valve leaflets and those whose AR is secondary to dilation of the sinotubular junction or aortic annulus may be able to undergo a valve-sparing root replacement—reimplanting the native valve within a Dacron graft (David procedure) or by remodeling the aortic root (Yacoub procedure) (**eFig. 63.9**). The reimplantation technique is preferable to the remodeling technique because it stabilizes the annulus and limits aortic dilation and late AR.[28]



EFIGURE 63.9 Aortic valve–sparing operations for aortic root aneurysm. Reimplantation of the aortic valve is performed with a tubular graft or with tailored graft to recreate the aortic sinuses, whereas remodeling of the aortic root was performed by tailoring a tubular polyester fabric graft in such a way as to recreate the aortic sinuses and suturing it to the remnants of aortic sinuses and aortic annulus. (From David TE, David CM, Manlhiot C, et al. Outcomes of aortic valve-sparing operations in Marfan syndrome. J Am Coll Cardiol 2015;66:1445-53.)

A pulmonary autograft (the Ross procedure) is an alternative to a composite aortic graft in appropriate candidates. This procedure involves replacing the native aortic valve and root with the patient's own pulmonary root, inserted into the aortic position. The pulmonary root is replaced with a cryopreserved homograft root. The Ross procedure carries risks of late autograft aneurysm formation and should not be used in patients with genetically triggered aortic root diseases; its use is controversial in the setting of BAV and aortic disease. Another alternative is the use of cryopreserved aortic allografts (cadaveric aortic root and proximal ascending aorta), but durability issues and late aortic calcification limit this choice. Estimates of risk for mortality for thoracic aortic elective repair follow: composite valve graft, 1% to 5%; separate AVR and ascending aortic repair, 1% to 5%; valve-sparing root replacement, less than 1% to 1.5%; and BAV and ascending aortic repair, 1.5%.[17]

Aortic Arch Aneurysms.

Aortic arch aneurysms are more difficult to treat surgically because reconstruction of the aortic arch vessels requires interruption of blood flow to these vessels.[17] One approach uses a *hemiarch resection*—the arch vessels remain intact, with the descending aorta as a roof, and the remaining arch is replaced. Extended arch resection requires either removing the entire arch and using branched grafts to replace the arch and great vessels, by using bypasses constructed to each great vessel, or reimplanting an island of arch tissue that includes the origins of the great vessel.[17] Cerebral protection during arch surgery can use several methods, traditionally deep hypothermic circulatory arrest. If the aneurysm extends partially into the descending thoracic aorta, the polyester graft is extended as an elephant trunk into the descending portion of the aneurysm, necessitating a second procedure to complete the repair.[17,29] In this procedure the

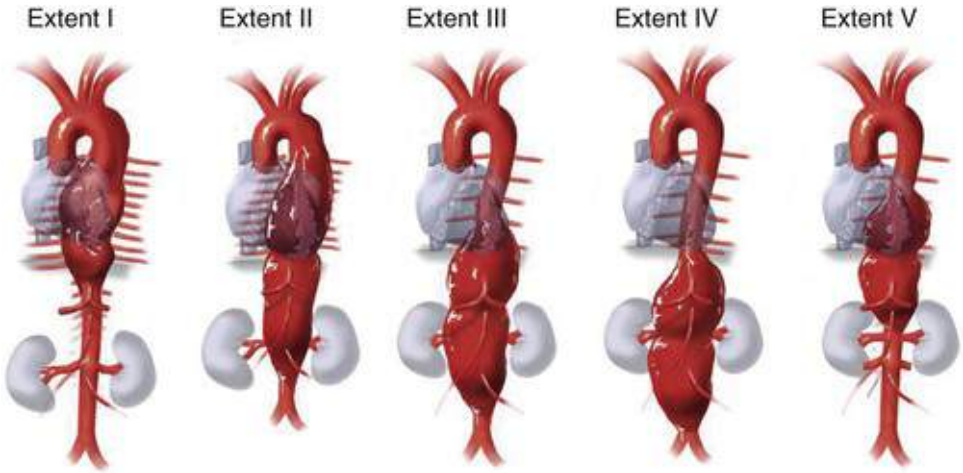
distal anastomosis is created to the midportion of a graft and the distal graft is within the lumen of the aorta and thus can be retrieved without manipulation of the arch. A recent modification of this procedure uses a covered endovascular stent-graft attached to a vascular graft to allow fixation of the stent-graft within the descending aorta and vascular graft reconstruction of the aortic arch.[30] This “frozen elephant trunk” procedure allows total replacement of the arch and descending aortic in a single stage for complex aneurysms, as well as treatment of acute type A dissection.[29] Spinal cord injury occurs in 9% of frozen elephant trunk procedures performed for extensive chronic aortic dissection.[29] Arch aneurysm surgery has a morbidity and mortality rate of 2% to 7% risk for both death and stroke.[1,17] Endovascular techniques and extra-anatomic reconstructions can treat complex aortic arch aneurysms and complete elephant trunk procedures.[17,29] Surgery for arch aneurysms is considered when aneurysm diameter is greater than 55 mm. Increased operative risk merits consideration of debranching procedures with thoracic endovascular aortic repair (TEVAR) as a hybrid approach. However, this approach involves higher risk of a retrograde type A aortic dissection.[1]

Descending Thoracic Aneurysms.

Treatment paradigms for descending TAAs have changed because of the rapid development of TEVAR.[1] Mortality for descending TAA repair is lower early after TEVAR compared to OSR, whereas midterm survival rates are similar.[1] The European Society of Cardiology (ESC) guidelines suggest consideration of TEVAR for descending TAA at diameter greater than 55 mm, and OSR at greater than 60 mm when it is the only option for an appropriate candidate.[1] Lower thresholds for may apply to connective tissue disorders, including MFS and LDS. TEVAR has a higher risk of complications in MFS and other connective tissue disorders and is typically reserved for urgent complications, very-high-risk patients, or with proximal and distal hand-sutured grafts to “land” the endograft.[1] Treatment of descending TAAs involves replacement of the aneurysmal segment with a polyester graft. The procedures are performed with partial femorofemoral bypass or atriofemoral bypass to maintain retrograde perfusion to critical arterial branches; these procedures are associated with a perioperative mortality of 10% or less and a paraplegia rate of approximately 2%, depending on the extent of repair.[17] Five-year survival rates after descending TAA resection approach 70%. TEVAR is discussed later.

Thoracoabdominal Aneurysms.

Thoracoabdominal aortic aneurysms (TAAAs) can extend from the subclavian artery to the iliac vessels. The Crawford classification (modified by Safi) describes the extent of the aneurysm, and this predicts morbidity, mortality, and risk for paralysis with repair[31] (**eFig. 63.10**). Surgical therapy and outcomes with TAAA are further discussed in the online supplement for this chapter.



EFIGURE 63.10 Schematic representation of the modified Crawford classification scheme for thoracoabdominal aortic aneurysm extents. (From Frederick JR, Woo YJ. Thoracoabdominal aortic aneurysm. Ann Cardiothorac Surg 2012;1:277-85.)

Endovascular Repair of Thoracic Aneurysms.

TEVAR is a much less invasive alternative to OSR of descending TAAs, with lower morbidity and mortality rates, but the aorta must have adequate proximal and distal landing zones of at least 20 to 25 mm in length and diameters that accommodate the endograft and adequate vascular access.[1,17] Stent-graft trials in the TEVAR arms reported rates of 1.9% to 2.1% for mortality, 2.4% to 4% for stroke, 4.4% to 7.2% for paraparesis, and 1.3% to 3% for paralysis.[32] In the OSR groups, mortality and neurologic morbidity rates ranged from 5.7% to 11.7% for mortality, 4.3% to 8.6% for permanent stroke, 5.7% for paraparesis, and 3.4% to 8.5% for paralysis.[32]

The anatomic configuration of the ascending aorta and transverse arch makes applying these techniques and devices challenging in these proximal segments. Hybrid techniques using extra-anatomic bypass procedures can create an appropriate proximal landing zone for the endovascular graft in the aorta without the need for major open thoracic surgery. In up to 50% of TEVAR procedures, the stent-graft intentionally covers the left subclavian artery.[17] Transposition of the left subclavian artery or a left carotid-to-subclavian bypass can be performed to allow attachment and seal of an endovascular graft across the takeoff of the subclavian artery. Subclavian artery occlusion without reconstruction is associated with an increased risk for cerebrovascular complications, including stroke, which can be mitigated by reconstruction before endovascular exclusion of the subclavian artery.[1]

If all the branches of the aortic arch need to be excluded for appropriate endovascular repair of an arch aneurysm, other options are available. Complete extra-anatomic aortic arch debranching can be performed, with reconstruction of the arch branches and subsequent carotid and subclavian bypasses as necessary. Another option is to perform an elephant trunk procedure under cardiopulmonary arrest; a prosthetic graft is sutured to the healthy portion of the ascending aorta and aortic arch, and branches of the aortic arch are left intact. This approach creates a proximal attachment zone that can be extended distally with an endovascular graft to complete the aneurysm repair. Bypasses to all the aortic arch branches can also be performed from the proximal ascending aortic arch in select patients, with a healthy portion left in the ascending aorta for attachment and seal of an endovascular graft. Branched devices developed to manage patients with complex thoracic and thoracoabdominal aneurysms are undergoing early evaluation. Debranching procedures involving visceral vessels may be performed before proceeding with endograft implantation, although the morbidity and mortality of this hybrid approach have not been found to be lower than standard OSR for the visceral aorta.[17] Open and endovascular repair of TAAs is associated

with a variety of significant risks, including cardiac, pulmonary, renal, and cerebrovascular complications. Spinal cord dysfunction with the development of paraparesis or paraplegia is a major source of morbidity. Drainage of cerebrospinal fluid (CSF) has been used in combination with a mean arterial pressure (MAP) of at least 70 mm Hg to lessen spinal cord complications.[17]

Rupture of a descending TAA is often fatal before hospital admission. TEVAR of ruptured descending TAAs is associated with a lower in-hospital mortality rate (19%) than OSR (33%).[33] Up to 10% of device-related complications occur in the first 30 days after TEVAR.[17] Endoleaks are the most common complication of endovascular repairs and occur in 10% to 20% of patients.[17] Serial imaging surveillance is required after TEVAR. Over a 5-year follow-up, the mean aortic diameter after TEVAR decreased from 61 to 55 mm.[33] The rate of freedom from reintervention on the aortic segment treated was 85% at 10 years.

Medical Management

Treating hypertension and smoking cessation are important because they are risk factors for TAA development, expansion, and rupture.[17] Patients with degenerative TAAs should receive cholesterol-lowering therapy. Beta blockers or ARBs are recommended for patients with MFS.[12,15] Despite the absence of data from randomized trials, many use beta blockers in non-MFS patients with TAAs and in patients after aneurysm repair. Because TGF-β signaling is related to the pathogenesis of some heritable TAA disorders, drugs affecting this signaling pathway, such as ARBs, may provide benefit.[17]

Long-term imaging surveillance of the aorta is imperative. After discovery of an aneurysm, patients should be reevaluated in 6 months to assess the aneurysm status. In general, for degenerative TAAs, annual imaging is recommended when the aorta is between 4.0 and 4.5 cm, and imaging at 6- to 12-month intervals for aneurysms of 4.5 to 5.4 cm, depending on size and growth rate. For relatively small aneurysms that are stable from year to year, imaging may be performed every 2 to 3 years.[17] In patients with MFS and familial TAAD, annual imaging is recommended for aortic sizes of 3.5 to 4.4 cm and annual or biannual imaging for 4.5 to 5 cm. For BAV with aortic dilation, annual imaging is recommended depending on size. In LDS and in some familial TAA diseases, imaging from the head to the pelvis is recommended because of the potential for widespread aneurysms.[6,12,17]

Lifestyle modification is necessary for patients with TAAs, including awareness of the condition and the risk for aortic dissection and rupture. Avoidance of strenuous physical activity, especially isometric exercise and weightlifting, is important and may impact work-related recommendations.[34,35] Pregnancy is associated with an increased risk for aortic dissection in those with MFS and other heritable aneurysm diseases, and management strategies must encompass this risk.[17] Because many diseases that lead to TAAs are familial, aortic imaging is recommended for first-degree relatives of patients with TAAs or aortic dissection to identify those with asymptomatic disease. If a patient has a mutant gene (**see Table 63.1**), first-degree relatives should undergo counseling and mutation testing.[17] Then, only relatives with the genetic mutation should undergo aortic imaging. In the absence of an identified mutation, first-degree relatives should have evaluation and imaging. If a first-degree relative has thoracic aortic disease, second-degree relatives should also be screened.[17]

Aortic Dissection

Acute aortic syndromes include classic aortic dissection, aortic intramural hematoma (IMH), and penetrating atherosclerotic aortic ulcer (PAU)[1,2,17] (**Fig. 63.10**). In 80% to 90% of acute aortic syndromes, classic aortic dissection is present, with intimal disruption leading to a dissection plane in the media that may propagate anterograde (or less often retrograde) throughout the length of the aorta (see Video 63.18). Adventitial disruption may lead to rupture, or more frequently, a distal tear(s) results in blood reentering the aortic lumen. In classic aortic dissection an intimal flap exists between the two lumens (true and false lumens). From 10% to 20% of acute aortic syndromes result from IMH, where bleeding in the aortic wall occurs without evidence of an intimal tear or dissection flap.[1,2] PAUs also lead to acute aortic syndromes in approximately 5% of cases.

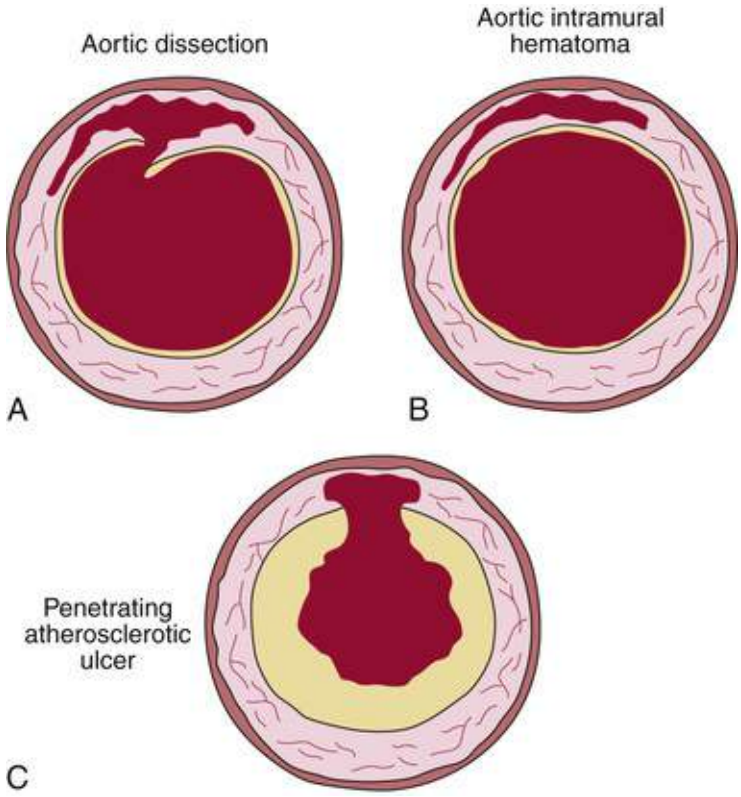


FIGURE 63.10 Acute aortic syndromes. **A,** Classic aortic dissection. There is a tear in the intima with blood entering the media and a dissecting cleavage plane propagating for variable distances anterograde (and occasionally retrograde) throughout the aortic wall. **B,** Aortic intramural hematoma (IMH). A spontaneous hemorrhage of the vasa vasorum leads to bleeding within the media in the absence of an intimal tear or intimal flap. **C,** Penetrating atherosclerotic aortic ulcer (PAU). An ulcerated aortic plaque ruptures into the media, leading to an outpouching or ulceration in the aortic wall. This may be associated with IMH formation, pseudoaneurysm, or a focal, thick-walled aortic dissection.

Ascertaining the exact incidence of aortic dissection is difficult as many patients die before the condition is recognized. U.S. population studies estimate the incidence of aortic dissection at 2 to 6 cases per 100,000 person-years.[1] In Sweden the incidence of dissection in men is reported to be 16 per 100,000 yearly.[17] In autopsy series the prevalence of aortic dissection ranges from 0.2% to 0.8%. Aortic dissection occurs at least twice as often in males as in females. Patients with acute aortic dissection have very high early mortality, with up to 1% per hour reported in the first 24 hours before surgery for type A dissection.[17,36] Type A aortic dissection occurs most often in individuals age 50 to 60 years, with type B

dissection more at a peak of 60 to 70 years.

There are two main hypotheses for acute aortic dissection: (1) a primary tear in the aortic intima with blood from the aortic lumen penetrating into the diseased media and leading to dissection and creation of the true and false lumens and (2) primary rupture of the vasa vasorum leading to hemorrhage in the aortic wall, with subsequent intimal disruption creating the intimal tear and aortic dissection. Distention of the false lumen with blood causes the intimal flap to compress the true lumen and narrow its caliber and may lead to malperfusion syndromes.

Classification

The two major classification schemes for aortic dissection, DeBakey and Stanford, are based on the location of the dissection (**Fig. 63.11 and Table 63.3**). The ascending aorta is proximal to the brachiocephalic artery, and the descending aorta begins distal to the left subclavian artery. The DeBakey classification divides dissections into types I, II, and III. DeBakey type I dissections originate in the ascending aorta and extend at least to the aortic arch and often to the descending aorta—frequently all the way to the iliac arteries. Type II dissections involve the ascending aorta alone. Type III dissections begin in the descending aorta, usually just distal to the left subclavian artery, and may be classified further according to whether the dissection stops above the diaphragm [IIIa] or extends below the diaphragm [IIIb]. The Stanford classification categorizes dissections into type A and type B based on whether the ascending aorta is involved. Type A dissections involve the ascending aorta, with or without extension into the descending aorta. Type B dissections do not involve the ascending aorta. Thus, dissections that involve the aortic arch but not the ascending aorta are characterized as type B in the Stanford classification. Others classify dissections as “ascending” or “descending.”

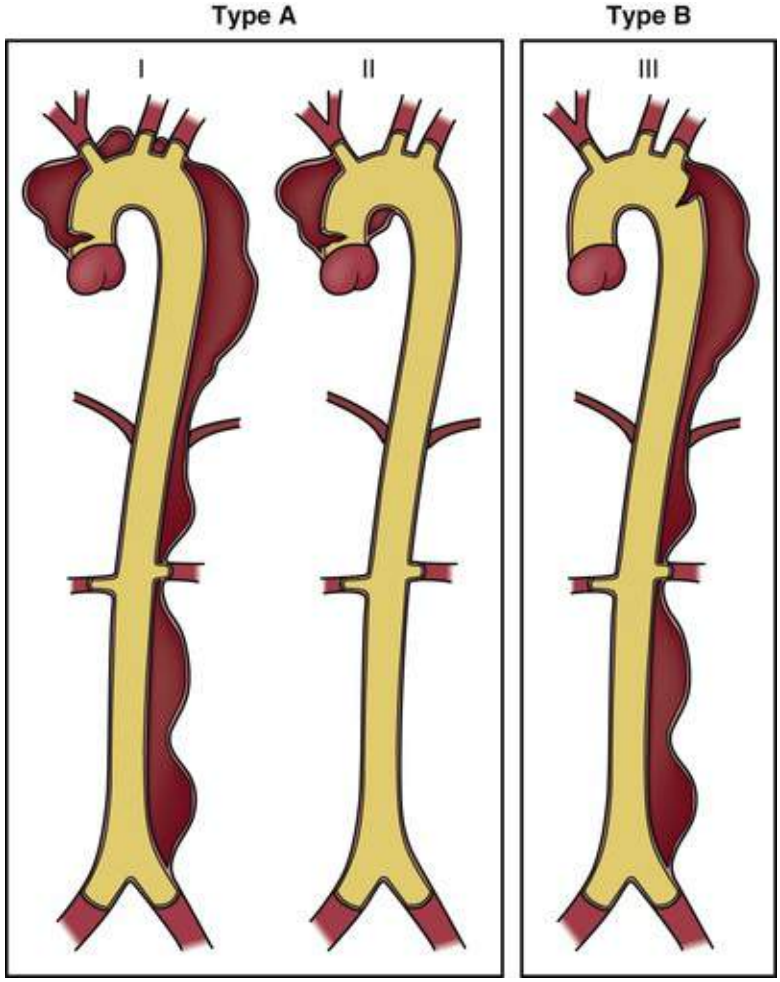

FIGURE 63.11 Classification schemes of acute aortic dissection. **DeBakey classification:** *Type I* dissection originates in the ascending aorta and extends at least to the aortic arch and often to the descending aorta (and beyond). *Type II* dissection originates in the ascending aorta and is confined to this segment. *Type III* dissection originates in the descending aorta, usually just distal to the left subclavian artery, and extends distally. **Stanford classification:** *Type A* dissection involves the ascending aorta (with or without extension into the descending aorta). *Type B* dissection does not involve the ascending aorta.
(From Braverman AC. Aortic dissection. prompt diagnosis and emergency treatment are critical. Cleve Clin J Med 2011;78:1695-704.)

TABLE 63.3

Classification Schemes of Acute Aortic Dissection

TYPE	DESCRIPTION
DeBakey Classification	
I	Dissection originates in the ascending aorta and extends at least to the aortic arch and often to the descending aorta (and beyond).
II	Dissection originates in the ascending aorta and is confined to this segment.
III	Dissection originates in the descending aorta, usually just distal to the left subclavian artery, and extends distally.
Stanford Classification	
A	Dissection involves the ascending aorta (with or without extension into the descending aorta).
B	Dissection does not involve the ascending aorta.

Modified from Braverman AC. Aortic dissection. prompt diagnosis and emergency treatment are critical. Cleve Clin J Med 2011;78:1695-704.

Most type A dissections begin within a few centimeters of the aortic valve, and most type B dissections begin just distal to the left subclavian artery. Approximately 65% of intimal tears occur in the ascending aorta, 30% in the descending aorta, less than 10% in the aortic arch, and approximately 1% in the abdominal aorta. Treatment depends on the site, with emergency surgery being recommended for acute type A dissections and initial medical therapy recommended for type B dissections. Aortic dissection is

also classified according to its duration, with the classic definition of “acute” when present for less than 2 weeks and “chronic” when present for longer than 2 weeks. A new classification system by the International Registry of Acute Aortic Dissection (IRAD) takes into account that the morbidity and mortality associated with acute dissection are highest in the first 2 weeks, especially the first 24 to 48 hours.[1,17,36] The IRAD classification includes hyperacute (<24 hours), acute (2 to 7 days), subacute (8 to 30 days), and chronic (>30 days) (**Fig. 63.12**).[36] Others classify dissections as acute (<2 weeks), subacute (2 to 6 weeks), or chronic (>6 weeks)[17] (**Table 63.4**). The DISSECT system of classification divides patients into subsets of importance for endovascular management.[37]

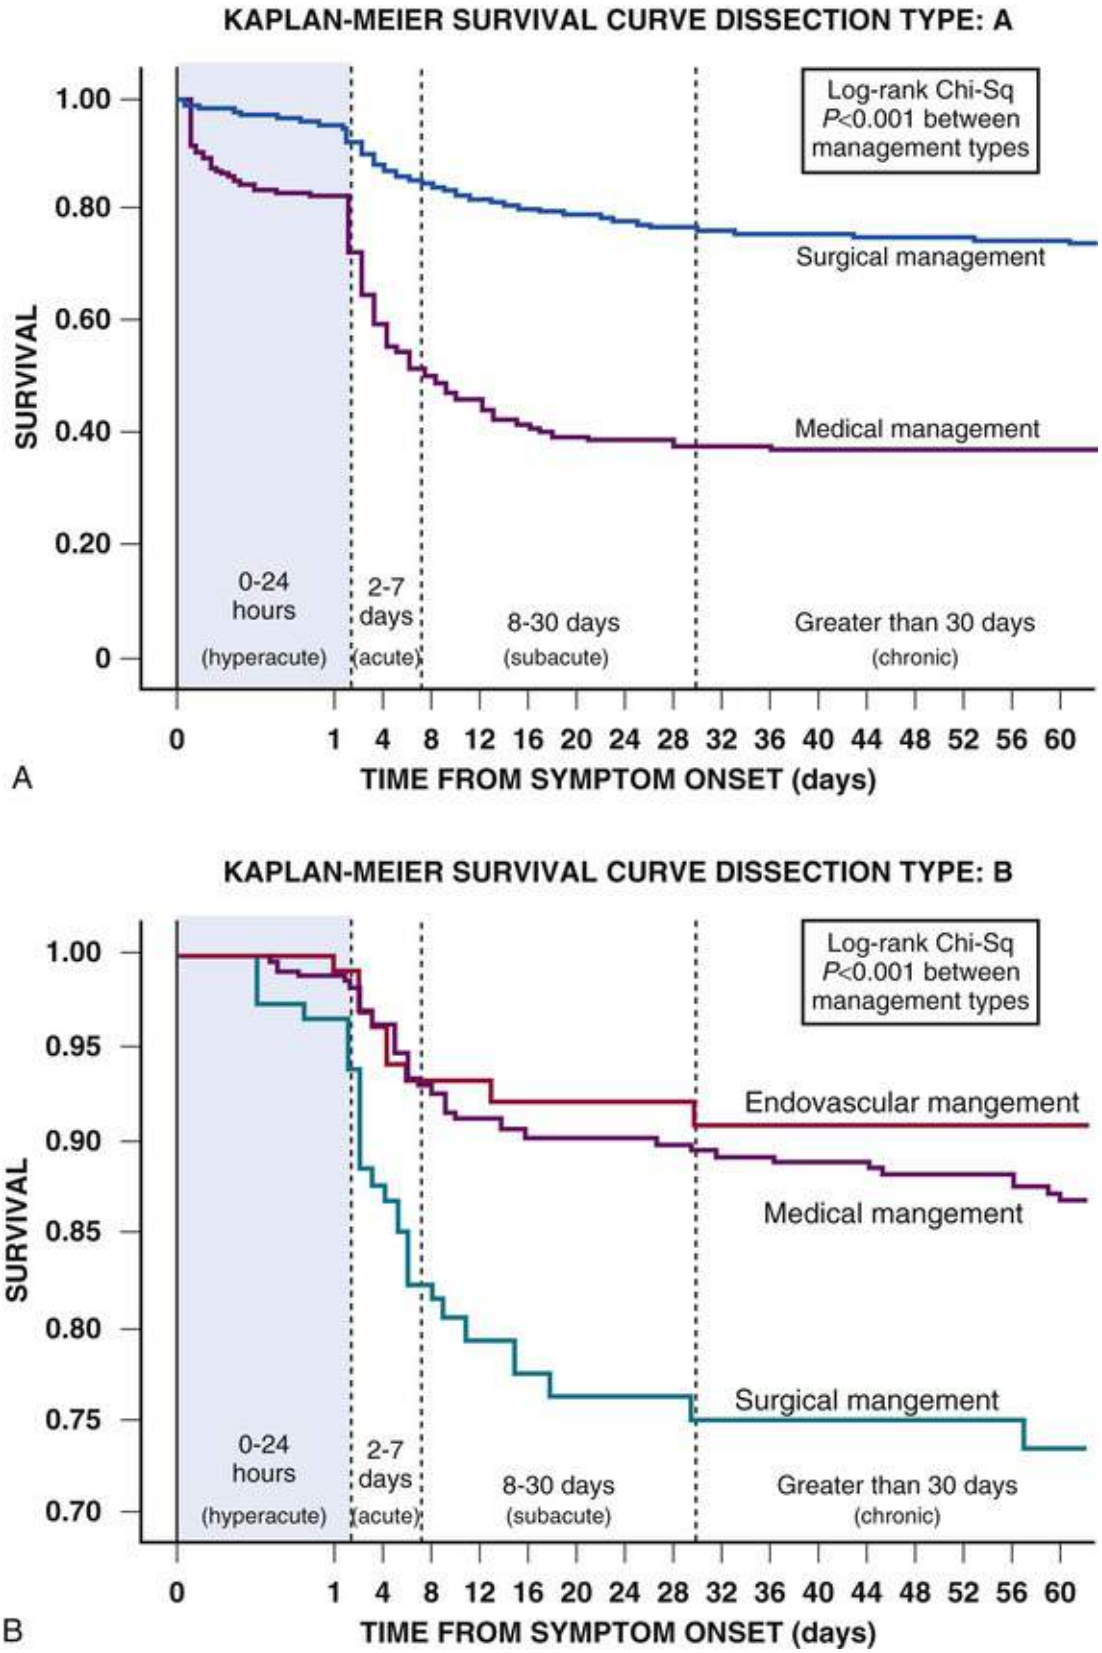

FIGURE 63.12 International Registry of Acute Aortic Dissection (IRAD) classification system of survival after aortic dissection. Kaplan-Meier survival curves for type A dissection **(A)** and type B dissection **(B)** stratified by treatment type. (From Booher AM, Isselbacher EM, Nienaber CA, et al. The IRAD classification system for characterizing survival after aortic dissection. Am J Med 2013;126:730 e19-24.)

Cause and Pathogenesis

Several conditions predispose the aorta to dissection (**Table 63.5**), most from disruption of the integrity of the aortic wall or marked increases in aortic wall circumferential stress (see earlier discussion on TAAs). Approximately 75% of all patients with aortic dissection have hypertension. Hypertension may affect the elastic properties of the arterial wall and increase stiffness, predisposing to aneurysm or dissection. However, hypertension alone is not usually associated with significant aortic dilation, and the vast majority of hypertensive patients never have aortic dissection. In the IRAD registry of 4428 patients, conditions associated with dissection included: hypertension (77%), atherosclerosis (27%), previous cardiac surgery (16%), known aortic aneurysm (16%), MFS (4%), and iatrogenic condition (3%).[38]

TABLE 63.5

Risk Factors for Aortic Dissection

Hypertension
Heritable or genetic thoracic aortic disease and syndromes (**see Table 63.1**)
Marfan syndrome
Loeys-Dietz syndrome
Familial thoracic aortic aneurysm syndromes
Vascular Ehlers-Danlos syndrome
Turner syndrome
Congenital diseases/syndromes
Bicuspid aortic valve
Coarctation of the aorta
Tetralogy of Fallot
Atherosclerosis
Penetrating atherosclerotic ulcer
Trauma, blunt or iatrogenic
Catheter/guidewire
Intra-aortic balloon pump
Aortic/vascular surgery
Motor vehicle accident
Coronary artery bypass grafting/aortic valve replacement/TAVR
Thoracic endovascular aneurysm repair (TEVAR)
Cocaine/methamphetamine use
Inflammatory/infectious diseases
Giant cell arteritis
Takayasu arteritis
Behçet disease
Aortitis
Syphilis
Pregnancy (with underlying aortopathy)
Weightlifting (with underlying aortopathy)

TAVR, Transcatheter aortic valve replacement.

Genetically triggered aortic syndromes, congenital heart diseases, inflammatory vascular diseases, and cocaine and methamphetamine use are also risk factors for aortic dissection. CMD commonly underlies aortic dissection but does not indicate the cause (**see Fig. 63.2**). Excessive signaling in the TGF-β pathway and abnormalities in function of the SMC contractile element may underlie certain aortic aneurysm syndromes[6,12,17] (**see Table 63.1, Fig. 63.6, and eFig. 63.2**). Patients with MFS have a high risk for aortic root aneurysm and especially type A aortic dissection. Despite being present in only 1 in 5000 individuals, MFS accounts for approximately 4% of all aortic dissections and a significant proportion of aortic dissection in young patients.[17,38] After elective root replacement in MFS, there is a 1.5% annual risk of type B aortic dissection.[39] Recognition of genetic mutations as a cause of aortic aneurysms and dissections has increased.[6,12] Variants at the rs2118181 locus on the *FBN1* gene and mutations in the *KIF6* gene also predispose to aortic dissection.[40]

BAV is an important risk factor for ascending aortic aneurysm and dissection[19,21,22] (see Videos 63.2 and 63.3). Aortic dissection is also associated with Noonan syndrome, unicuspid aortic valve, supravalvular aortic stenosis, aberrant right subclavian artery (Kommerell diverticulum), right-sided aortic arch, polycystic kidney disease, and Alport syndrome (in males).[1,17]

Aortic dissection may complicate aortitis, particularly giant cell arteritis. Nonspecific aortitis, Takayasu arteritis, IgG4 disease, and Behçet syndrome all are associated with aortic dissection. Syphilitic aortitis is a rare cause of dissection. Cocaine use accounts for less than 2% of cases of aortic dissection, more often presenting with hypertension and small aortic diameters.[41] Underlying elastic medial abnormalities and the biomechanical stress related to hypertension and tachycardia may play a role. Aortic dissection may also occur with intense weightlifting, but generally in the setting of an underlying aortopathy.

Aortic dissection can occur during late pregnancy or in the early postpartum period.[26] The relationship between pregnancy and aortic dissection is difficult to attribute solely to hemodynamic factors, and

hormonally induced changes in aortic wall composition during pregnancy may contribute. Although most pregnancy-related aortic dissections are caused by underlying aortopathy, the syndrome is not diagnosed in many until after dissection occurs.[42] Women with aortopathy from many disorders, including MFS, LDS, familial TAAD, vEDS, TS, and BAV disease with aneurysm, have increased risk for acute aortic dissection related to pregnancy.[17,26] In MFS the risk for type A dissection is greatest when the aortic root is enlarged, at an estimated 1% when the aortic diameter is less than 40 mm, and 10% in high-risk patients (aortic diameter >40 mm, rapid dilation, or previous aortic dissection).[26] Even after root replacement, pregnancy carries a risk of dissection in women with aortopathy.[43]

Blunt aortic trauma usually leads to localized tears or periaortic or frank aortic transection and only rarely causes classic aortic dissection. Iatrogenic trauma accounts for approximately 3% of aortic dissections.[38] Intra-arterial catheterization and interventions may induce aortic dissection because of disruption of the intima. Iatrogenic type A dissection related to coronary artery interventions are rare, and when limited and stable on imaging, it may often be treated conservatively.[44] Cardiac surgery entails a very small risk for acute aortic dissection related to aortic cannulation, crossclamps, aortic anastomosis, and retrograde dissection as a result of femoral cannulation. Aortic dissection may occur late (months to years) after cardiac surgery, with those undergoing AVR or with a previous aneurysm or dissection having the highest risk. Retrograde ascending aortic dissection occurs in approximately 1% to 2% of patients undergoing TEVAR for acute or chronic type B aortic dissection.

Individuals with TAA have risk for aortic dissection, with risk for dissection and rupture increasing as aneurysm size increases. However, many aortic dissections occur in patients with aortic dimensions that are not greatly dilated.[45] The dissection process leads to an acute increase in aortic diameter during the dissection.[46] Thus, for many with acute dissection, the aortic diameter immediately beforehand was smaller. Of type A aortic dissections in the IRAD registry, aortic diameter averaged 5.3 cm, with approximately 60% smaller than 5.5 cm and 40% smaller than 5.0 cm (**Fig. 63.13**).[45] In addition to aortic diameter, age, sex, body size, and rate of aortic growth, mechanical and hemodynamic factors also play a role. The mechanisms responsible for individual susceptibility to acute dissection at a certain aortic diameter are not well understood.

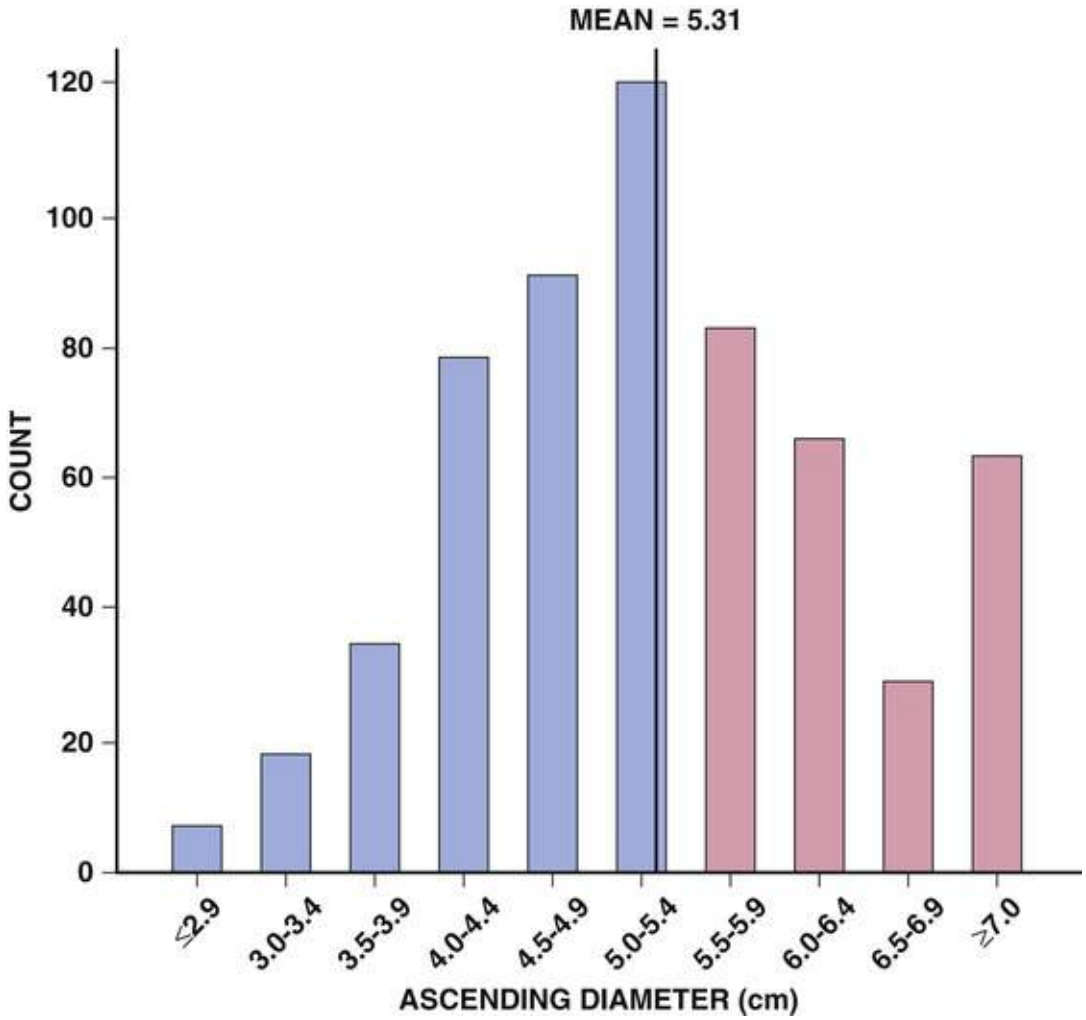

FIGURE 63.13 Distribution of aortic size (in cm) at the time of presentation with acute type A aortic dissection from IRAD. *Blue/purple bars* indicate patients with diameters less than 5.5 cm. (From Elefterades JA, Farkas EA. Thoracic aortic aneurysm: clinically pertinent controversies and uncertainties. J Am Coll Cardiol 2010;55:841-57. Modified from Pape L, Tsai TT, Isselbacher EM, et al. Aortic diameter ≥5.5 cm is not a good predictor of type A aortic dissection: observations from the International Registry of Acute Aortic Dissection (IRAD). Circulation 2007;116:1120-7. Illustration by Rob Flewell.)

Clinical Manifestations

Symptoms

The symptoms of aortic dissection can be variable and may mimic those of more common conditions, thus emphasizing the importance of a high index of suspicion. Abrupt onset of severe chest or back pain is the most classic feature.[1,38] Distinct from the discomfort of coronary ischemia, the pain is described as severe in approximately 90% of patients and usually of sudden onset, with maximum intensity occurring at its inception. The pain may be accompanied by a "sense of doom." The quality of the pain is most commonly described as "sharp," "severe," or "stabbing," and adjectives such as "tearing" or "ripping" are used less often.[1,17,38] Symptoms highly suggestive of aortic dissection, such as a feeling of being "stabbed in the chest with a knife" or "hit in the back with a baseball bat," may be reported, but some describe chest burning, pressure, or pleuritic pain. The pain may lessen or resolve which makes diagnosis even more challenging. In some patients the symptoms related to a complication (e.g., syncope, heart failure, stroke) dominate, and the pain is not mentioned or is downplayed. Factors associated with delay in diagnosis include female gender, transfer from another hospital, fever, and normal BP.[37]

The pain of acute aortic dissection is migratory in approximately 17% of cases and tends to follow the

path of the dissection through the aorta.[1,38] The pain of dissection may radiate from the chest to the back, or vice versa. Pain in the neck, throat, jaw, or head predicts involvement of the ascending aorta (and often the great vessels), whereas pain in the back, abdomen, or lower extremities usually indicates descending aortic involvement.

Other clinical features at presentation include congestive heart failure (CHF) (<10%), syncope (9%), acute stroke (6%), acute MI, paraplegia, and cardiac arrest or sudden death.[47] Acute CHF related to type A dissection may result from acute severe AR. Syncope in patients with type A dissection is usually associated with hemopericardium, rupture, or stroke. Patients with aortic dissection infrequently have predominantly abdominal pain, which may lead to delays in diagnosis. “Painless” aortic dissection occurs in 6% of patients and is more common in those with diabetes, previous aortic aneurysm, and prior cardiac surgery.[47]

Physical Findings

Findings on physical examination and organ system complications in patients with acute aortic dissection are highly variable and range from virtually unremarkable to full cardiac arrest secondary to hemopericardium or rupture. The findings may demonstrate complications related to the dissection, such as AR, abnormal peripheral pulses, stroke, or CHF (**Table 63.6**). The presence of these findings must heighten clinical suspicion for aortic dissection,[17] but their absence does not exclude dissection and should not dissuade pursuit of the diagnosis when suspected. Hypertension occurs in approximately 70% of patients with acute aortic dissection.[38] Although most patients with type B dissection are hypertensive, many with type a dissection are normotensive or hypotensive on initial evaluation.[1,17,38,47] Hypotension complicating acute dissection may result from cardiac tamponade, acute aortic rupture, or CHF related to acute severe AR.

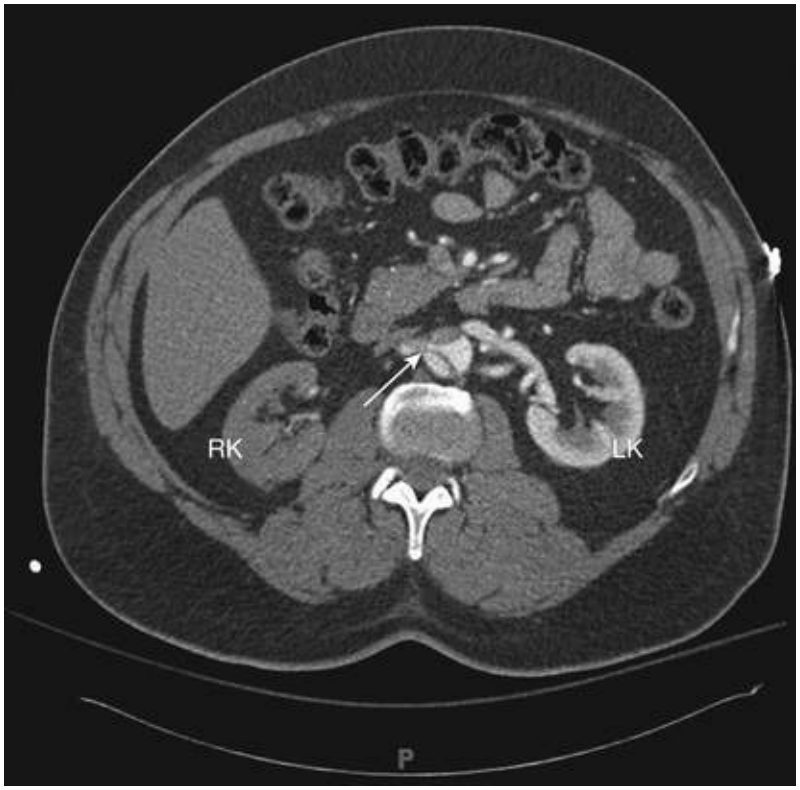
TABLE 63.6

Organ System Complications of Acute Aortic Dissection

Cardiovascular	Cardiac arrest Syncope Aortic regurgitation Congestive heart failure Coronary ischemia Myocardial infarction Cardiac tamponade Pericarditis
Pulmonary	Pleural effusion Hemothorax Hemoptysis (from an aortotracheal or bronchial fistula)
Renal	Acute renal failure Renovascular hypertension Renal ischemia or infarction
Neurologic	Stroke Transient ischemic attack Paraparesis or paraplegia Encephalopathy Coma Spinal cord syndrome Ischemic neuropathy
Gastrointestinal	Mesenteric ischemia or infarction Pancreatitis Hemorrhage (from aortoenteric fistula)
Peripheral vascular	Upper or lower extremity ischemia
Systemic	Fever

The physical findings typically associated with aortic dissection—pulse deficits, AR, and neurologic manifestations—are more characteristic of ascending than descending dissection. A pulse deficit is

reported in 31% of type A dissections and 19% of type B dissections, with frank limb ischemia less common.[1,38] Malperfusion may be dynamic, static, or mixed. Dynamic malperfusion is most common and results from the overpressurized false lumen pushing the septum toward the true lumen, leading to collapse of the true lumen and obstruction of branch vessels. Static malperfusion results from stenosis or occlusion of a branch artery caused by the dissection flap, hematoma, embolism, or thrombosis[17,48] (**eFig. 63.11**).



EFIGURE 63.11 Contrast-enhanced computed tomography scan demonstrating malperfusion of the right kidney (*RK*) because of acute aortic dissection. The dissection flap involves the right renal artery (*arrow*). The left kidney (*LK*) demonstrates normal perfusion and opacification, whereas the RK has poor perfusion with contrast material, consistent with malperfusion.

Aortic regurgitation (AR), a key diagnostic feature of type A dissection, occurs in 41% to 76% of patients[17,38,47] (**Fig. 63.14**) (Video 63.6). The murmur of AR varies in intensity, depending on BP and the degree of heart failure, and may be inaudible in some cases. Potential mechanisms of AR include (1) incomplete coaptation of the aortic leaflets caused by concurrent dilation of the aortic root and annulus or by acute aortic dilation from an expanding false lumen leading to central aortic regurgitation; (2) aortic leaflet prolapse caused by the dissection flap propagating into the aortic leaflets or commissures or by distortion of proper leaflet alignment by an asymmetric dissection flap (**Fig. 63.14**) (Videos 63.7 and 63.8); (3) an extensive or circumferential dehiscing intimal flap prolapsing into the left ventricular outflow tract during diastole and interfering with valve coaptation (Videos 63.9 and 63.10); or (4) preexisting AR resulting from an underlying aortic root aneurysm or BAV disease[17] (Video 63.11).

FIGURE 63.14 Aortic regurgitation complicating acute type A aortic dissection. The dissection flap distorts the normal aortic leaflet alignment, thereby leading to malcoaptation of the aortic valve and subsequent aortic regurgitation. In this example the dissection flap extends into the ostium of the right coronary artery (*arrow*).

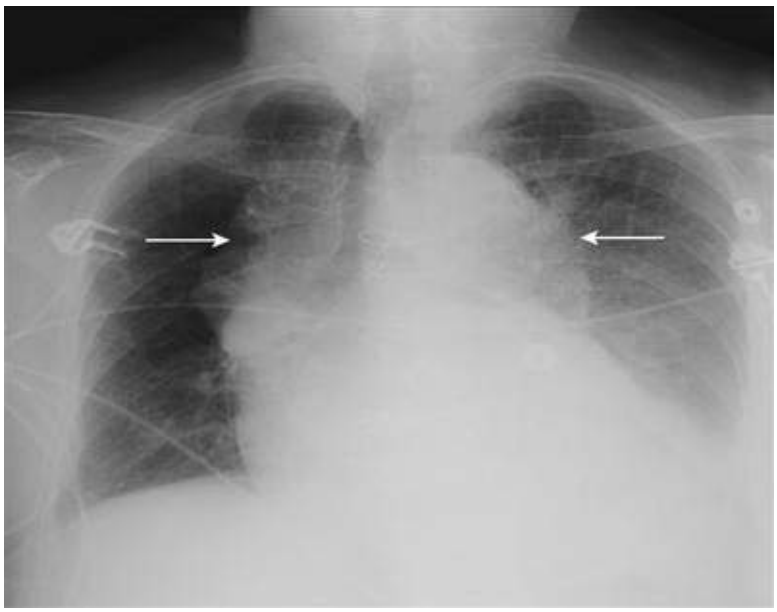
Neurologic manifestations occur in 17% to 40% of patients with aortic dissection and are more common with type A dissections.[49] Neurologic syndromes include persistent or transient ischemic stroke, spinal cord ischemia, ischemic neuropathy, and hypoxic encephalopathy and are related to malperfusion of one or more branches supplying the brain, spinal cord, or peripheral nerves. Ischemic stroke occurs in approximately 6% of patients with type A dissection.[47] Syncope occurs in 19% of type A and 3% of type B aortic dissection and may be related to acute hypotension (caused by cardiac tamponade, severe AR, or aortic rupture), obstruction of a cerebral vessel, or activation of cerebral baroreceptors and carries an increased mortality rate.[17,38,47] Less common neurologic manifestations of dissection include seizures, transient global amnesia, ischemic neuropathy, disturbances in consciousness and coma, and paraparesis or paraplegia related to spinal cord ischemia. Coma and cerebral malperfusion are associated with poor outcomes,[49] but some studies have failed to identify brain malperfusion as an independent risk factor for an adverse outcome after surgical repair.[17,47]

Acute MI related to the false lumen compressing the coronary ostium or the dissection flap involving the coronary artery complicates 1% to 2% of patients with acute type A aortic dissection.[1] It most frequently involves the right coronary artery (**Fig. 63.14**) and leads to acute inferior MI. Troponin elevations and electrocardiographic changes may occur in acute dissection.[1] Aortic dissection may not be suspected as a cause of coronary ischemia, and misdiagnosis may lead to inappropriate therapy and delays in treatment. Considering aortic dissection in the differential diagnosis of patients with acute coronary ischemia or infarction, especially when their risk factors, symptoms, or findings on examination are compatible with this diagnosis, is important. When coronary angiography in a patient with ST-segment elevation myocardial infarction (STEMI) shows no culprit lesion, aortic dissection should be excluded.[17]

Aortic dissection may extend into the abdominal aorta and result in vascular complications and malperfusion. Renal artery involvement occurs in at least 5% to 10% of patients and may lead to renal ischemia, infarction, or renal insufficiency or refractory hypertension (**eFig. 63.11**). Mesenteric ischemia occurs in less than 5% of patients with aortic dissection and is associated with a marked increase in mortality. The symptoms may be insidious, associated with nonspecific abdominal complaints, and a high index of suspicion must be maintained for this complication.[1,17] Aortic dissection may lead to a left-sided pleural effusion, usually related to an inflammatory response. Acute hemothorax may result from rupture. Type A aortic dissection may be accompanied by acute pericarditis but more often is a bland pericardial effusion. Acute cardiac tamponade as a result of rupture with hemopericardium complicates approximately 9% of type A dissections and is related to worse outcomes.[17] Isolated abdominal aortic dissection is rare (approximately 1% of dissections) and is associated with an existing AAA or an iatrogenic cause.

Laboratory Findings

The chest radiograph may be the first clue to the diagnosis of aortic dissection (**eFig. 63.12**), but the findings are nonspecific and in many cases, completely normal. The dissected aorta may not be dilated, and its image may not be displaced or widened on x-ray film. The most common abnormality seen is an abnormal aortic contour or widening of the aortic silhouette, which appears in approximately 80% of cases (83% of type A; 72% of type B).[47] Pleural effusions occur in approximately 20% of dissections. In the most recent IRAD survey, normal chest x-ray findings on presentation were found in 29% of type A and 36% of type B dissections.[38] Thus, a normal chest radiograph cannot exclude the presence of an aortic dissection. Laboratory tests important to obtain when evaluating for complications of aortic dissection include complete blood count, comprehensive metabolic profile, lactic acid, troponin, lactate dehydrogenase, and creatine kinase levels.



EFIGURE 63.12 Chest x-ray film of a patient with acute type A aortic dissection demonstrating a widened mediastinum and enlargement of the ascending and descending aortic shadows (*arrows*).

The electrocardiographic findings in patients with aortic dissection are nonspecific but may indicate acute complications such as myocardial ischemia or infarction related to coronary artery involvement or low-voltage QRS complexes related to hemopericardium. Ten percent of type B dissection patients have

electrocardiographic signs of ischemia.[1] Acute MI occurs in 1% to 2% of patients with type A dissections.

Biomarkers.
Reliable biomarkers for the diagnosis or exclusion of acute aortic dissection have stirred great interest. Release of smooth muscle proteins (calponin), soluble elastin fragments, myosin heavy chain and the BB isoform of creatine kinase, fibrin degradation products, and TGF-β occurs after aortic dissection.[37] These markers have limited usefulness because of sensitivity, specificity, or time delay and are not currently appropriate for clinical use. Patients with acute aortic dissection have elevated D-dimer levels reaching very high levels in many patients, making this a very useful biomarker for classic acute dissection.[1,17,37] In patients seen within the first 24 hours of onset, a D-dimer level lower than 500 ng/mL had a negative likelihood ratio of 0.07 and a negative predictive value of 95%. D-dimer is reported as having a sensitivity of 97% and a specificity of 47%.[37] Notably, normal D-dimer levels can occur with aortic dissection and a thrombosed false lumen, as well as with aortic IMH and PAU.[17] Additionally, patients may initially be seen longer than 24 hours after symptom onset, which affects D-dimer levels. Although a negative D-dimer result in low-suspicion patients may be useful, the negative likelihood ratio provided by the D-dimer assay is not sufficient in high-risk individuals and cannot “rule out” the disease in these patients.[17]

Diagnostic Techniques

When aortic dissection is suspected, expedient and accurate confirmation of the diagnosis is important. Diagnostic methods available to diagnose aortic dissection include contrast-enhanced CT, MRI, TEE, and TTE. TEE, helical CT, and MRI have very high diagnostic accuracy for suspected aortic dissection.[1,2,17] Each modality has advantages and disadvantages with respect to diagnostic ability, speed, convenience, and risk.[2] The choice of imaging study depends on the availability and expertise in the individual institution. If the probability of dissection is high and initial testing is negative or nondiagnostic, a second diagnostic test should be performed. When comparing imaging modalities, one must consider the diagnostic information needed. Besides diagnosing the type and location of dissection, additional useful information includes anatomic features and complications related to the dissection, including its extent, entry sites, and reentry sites; patency of the false lumen; involvement of branch vessels; severity of AR; hemopericardium; coronary artery involvement; malperfusion; and rupture (**eTable 63.1**).

ETABLE 63.1

4. Complications of dissection a. Type A i. Aortic regurgitation ii. Coronary artery involvement iii. Pericardial effusion/hemopericardium b. Aortic rupture or leakage c. Branch vessel involvement d. Malperfusion e. Aneurysmal enlargement

IMH, Intramural hematoma; *PAU,* penetrating atherosclerotic aortic ulcer.

Computed Tomography

Contrast-enhanced computed tomography (CECT) is the modality most often used for evaluating aortic dissection and is best performed with an electrocardiogram (ECG)-gated, multidetector scanner, which may eliminate aortic pulsation motion artifacts.[2] On CECT, aortic dissection is diagnosed by the presence of two distinct lumens with a visible intimal flap or by detection of two lumens by their differing rates of opacification with contrast material (**Fig. 63.15; see also Fig. 63.9 and eFigs. 63.4, 63.5, and 63.11**). If the false lumen is completely thrombosed, it demonstrates low attenuation. The false lumen usually has slower flow and a larger diameter than the true lumen.[1,2] CECT is highly accurate in diagnosing aortic dissection, with a sensitivity and specificity of 98% to 100%.[2,17] Spiral (helical) CECT allows three-dimensional reconstruction for evaluation of the dissection and branch vessels and is critical for planning endovascular repair. CT requires intravenous (IV) contrast material, and without contrast enhancement, aortic dissection may go undetected (**eFig. 63.13**). CT can identify the presence of thrombus in the false lumen and detect hemopericardium, aortic rupture, branch vessel involvement, and blood supply from the true and false lumens. Major limitations of CT include an inability to evaluate the coronary arteries and aortic valve reliably, motion artifact related to cardiac movement, streak artifact related to implanted devices, and complications associated with the use of contrast agents, especially nephropathy (**see Chapter 98**).

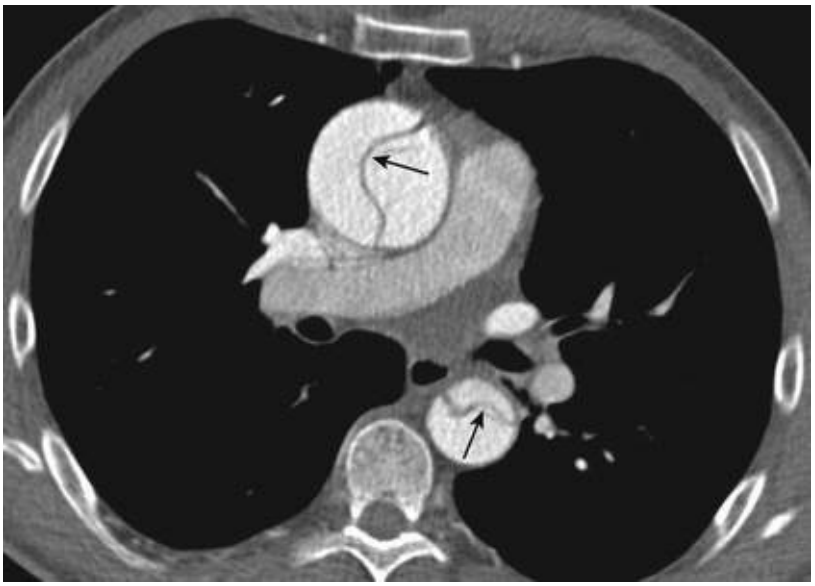

FIGURE 63.15 Contrast-enhanced computed tomography scan of acute type A aortic dissection. The ascending aorta is dilated, and a complex dissection flap is visualized in the ascending aorta (*upper arrow*) and descending aorta (*lower arrow*).

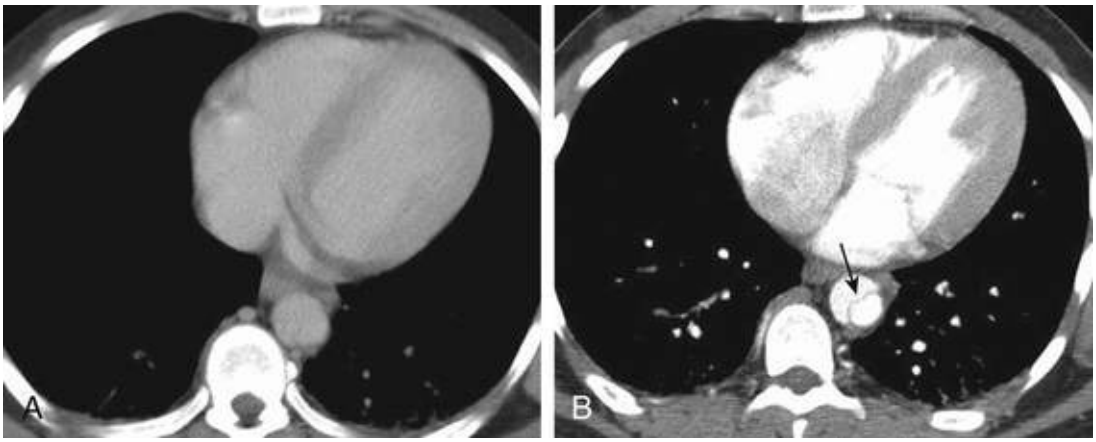

EFIGURE 63.13 Importance of contrast-enhanced computed tomography (CECT) in aortic dissection. CT scan of type B aortic dissection. **A,** Non-CECT fails to identify the dissection or intimal flap. **B,** CECT identifies the intimal flap *(arrow).*

Magnetic Resonance Imaging

MRI is highly accurate in evaluating aortic dissection, with sensitivity and specificity of 98%, and does not require IV iodinated contrast material or ionizing radiation[1,2,17] (**Fig. 63.16**). MRI permits multiplanar imaging with three-dimensional reconstruction and cine-MRI for visualization of blood flow, differentiation of slow flow and clot, evaluation of intimal flap mobility, and detection of AR. MRI can assess branch vessel morphology when combined with contrast-enhanced MRA. MRI may detect pericardial effusion, aortic rupture, entry points, and exit points with a high level of accuracy; MRA may detect and quantify AR. MRI has important limitations in evaluating acute aortic dissection. It is contraindicated in patients with certain implantable devices (pacemaker, defibrillator) and other metallic implants. MRI has limited availability on an emergency basis, and more time is needed to acquire images than with CT. Thus, MRI is infrequently used as the initial test for evaluation of acute dissection, but given its imaging detail and lack of ionizing radiation, it is particularly attractive for the long-term follow-up of aortic dissection.

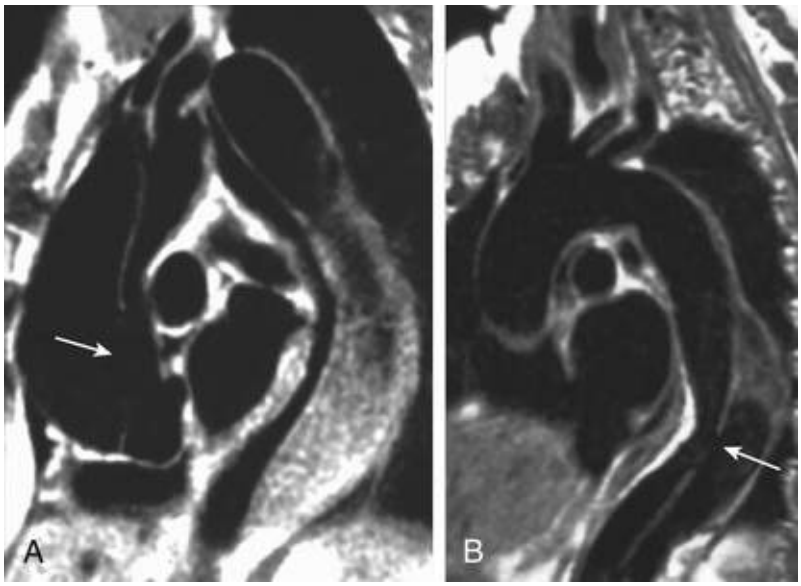

FIGURE 63.16 Spin-echo magnetic resonance images. **A,** Type A dissection. **B,** Type B dissection. The entry site is visualized as focal interruption of the linear image of the intimal flap (*arrows*). (From Baliga RB, Nienaber CA, Bossone E, et al. The role of imaging in aortic dissection and related syndromes. JACC Cardiovasc Imaging 2014;7:406-24.)

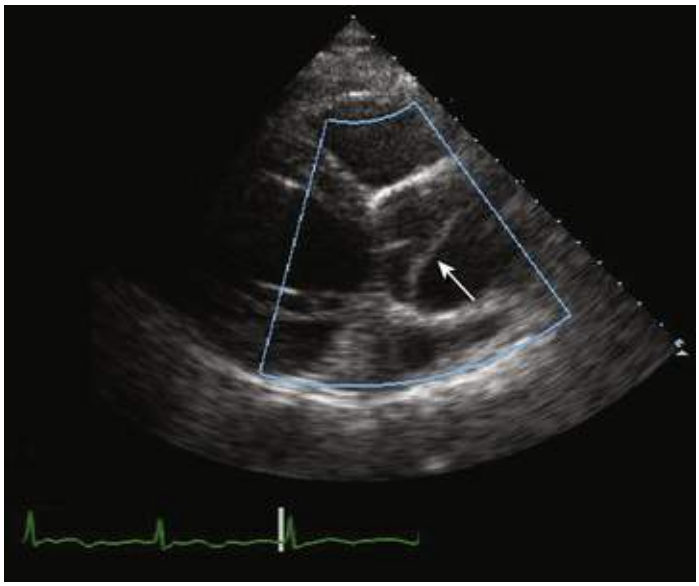
Ultrasound

The sonographic diagnosis of aortic dissection is based on the presence of an undulating intimal flap with independent motion within the aortic lumen that separates the true and false lumens[1,2] (Videos 63.12 to 63.19; also see Videos 63.2, 63.3, and 63.6 to 63.11). Color flow Doppler demonstrates differential flow in the two lumens and can detect intimal tears. When the false lumen is thrombosed, displacement of intimal calcification or thickening of the aortic wall suggests aortic dissection.

Transthoracic Echocardiography

TTE has sensitivity of 70% to 80% and specificity of 93% to 96% for the identification of type A aortic dissection, but it is much less sensitive (31% to 55%) than other modalities for the diagnosis of type B aortic dissection[17] (**eFig. 63.14** and Videos 63.12 to 63.14). Advanced imaging techniques and contrast enhancement can increase the accuracy of TTE for the diagnosis of type A aortic dissection.[1,2] Because TTE has a reduced sensitivity of detecting aortic dissection, negative findings do not exclude acute aortic dissection, but certain clues, including a dilated aorta, AR, or pericardial effusion, may suggest this diagnosis.



EFIGURE 63.14 Transthoracic echocardiogram of a type A aortic dissection. A dissection flap *(arrow)* is present in the dilated aortic root.

Transesophageal Echocardiography

TEE is highly accurate in the evaluation and diagnosis of acute aortic dissection (sensitivity, approximately 98%; specificity, 95%), but its accuracy is operator dependent (**Fig. 63.17**) (see Videos 63.2, 63.3, 63.7 to 63.10, and 63.15 to 63.18). TEE may not completely visualize the distal ascending aorta and proximal aortic arch, but it interrogates the remaining thoracic aortic segments well. TEE may visualize the intimal tear in 75% to 100% of cases, differentiate the true and false lumens, and identify fenestrations in the intimal flap (**eFig. 63.15**) (see Video 63.16). Features of the true lumen on TEE include a smaller lumen, systolic expansion, systolic anterograde flow, communication from the true to the false lumen in systole, and early and fast contrast-enhanced echocardiographic flow.[1,2] TEE is 100% sensitive in detecting AR complicating dissection and may define its mechanism (see Videos 63.6 to 63.11). TEE provides information about left ventricular function, the proximal coronary arteries, and pericardial effusion and may assist with endovascular treatment (see Videos 63.17 and Video 63.18).

EFIGURE 63.15 Transthoracic echocardiogram of a type B aortic dissection demonstrating the dissection flap and a small fenestration *(arrow)*.

Aortography

Aortography is no longer used for the initial diagnosis of suspected acute aortic dissection and is now used mainly during endovascular repair or coronary angiography. Findings of dissection on aortography include two lumens or an intimal flap, an undulating deformation of the aortic lumen, aortic wall thickening, branch vessel involvement, and AR. Compared with other imaging modalities, aortography has less accuracy in diagnosing aortic dissection. A false-negative aortogram may result from thrombosis of the false lumen, from equal opacification of both the true and false lumens, and from IMH.

Selecting an Imaging Modality

Because of its availability on an emergency basis, CECT is usually the first choice for the diagnosis of aortic dissection. The risk for contrast-induced nephropathy may complicate the decision about which test to perform when TEE or MRI is unavailable. Importantly, non–contrast-enhanced CT might fail to diagnose aortic dissection (**eFig. 63.13**). Non–contrast-enhanced MRA may diagnose aortic dissection when gadolinium contrast is contraindicated. TTE may be able to diagnose aortic dissection but does not have sufficient sensitivity to exclude aortic dissection. If TEE or MRI is not available on an urgent basis, the clinician must weigh the risks associated with IV contrast material versus the potential fatal consequences of failing to diagnose aortic dissection.

Role of Coronary Angiography

Routine coronary angiography is not recommended before surgery for acute type A aortic dissection because of concern about delay in emergency surgery.[17] Besides the delay incurred, coronary angiography may be technically difficult in the patient with dissection. Arterial access may fail to gain entry into the true lumen, and injury to the aorta from the catheter or guidewire may cause extension of the dissection or perforation of the aorta. In patients undergoing surgery for acute type A dissection, coronary artery involvement by the dissection can most often be corrected intraoperatively, and angiography is not required.

Evaluation and Management Algorithms

The thoracic aortic disease guidelines provide an algorithm for the management of patients with presentations compatible with acute aortic dissection[17,50] (**Fig. 63.18**). A bedside risk assessment determines whether the patient has any of three high-risk features: (1) *high-risk condition* (MFS or related disorder, familial TAA, family history of aortic disease, known aortic valve disease such as BAV, recent aortic manipulation, or known TAA); (2) *high-risk pain features*, including chest, back, or abdominal pain described as abrupt in onset, severe in intensity, and of ripping/tearing/sharp or stabbing quality; and (3) *high-risk examination features*, including perfusion deficit (pulse deficit, BP differential, focal neurologic deficit), murmur of AR, or hypotension. The presence of two or more high-risk features strongly suggests aortic dissection. Patients considered highly likely to have acute aortic dissection require emergency surgical consultation and expedited imaging. Patients whose features suggest aortic dissection and who do not have an alternative diagnosis require expedited imaging. Those with lower-risk profiles are evaluated for alternative diagnoses, but when none is considered likely or confirmed, aortic imaging is recommended. Further study is needed prospectively to validate the accuracy of this risk score.

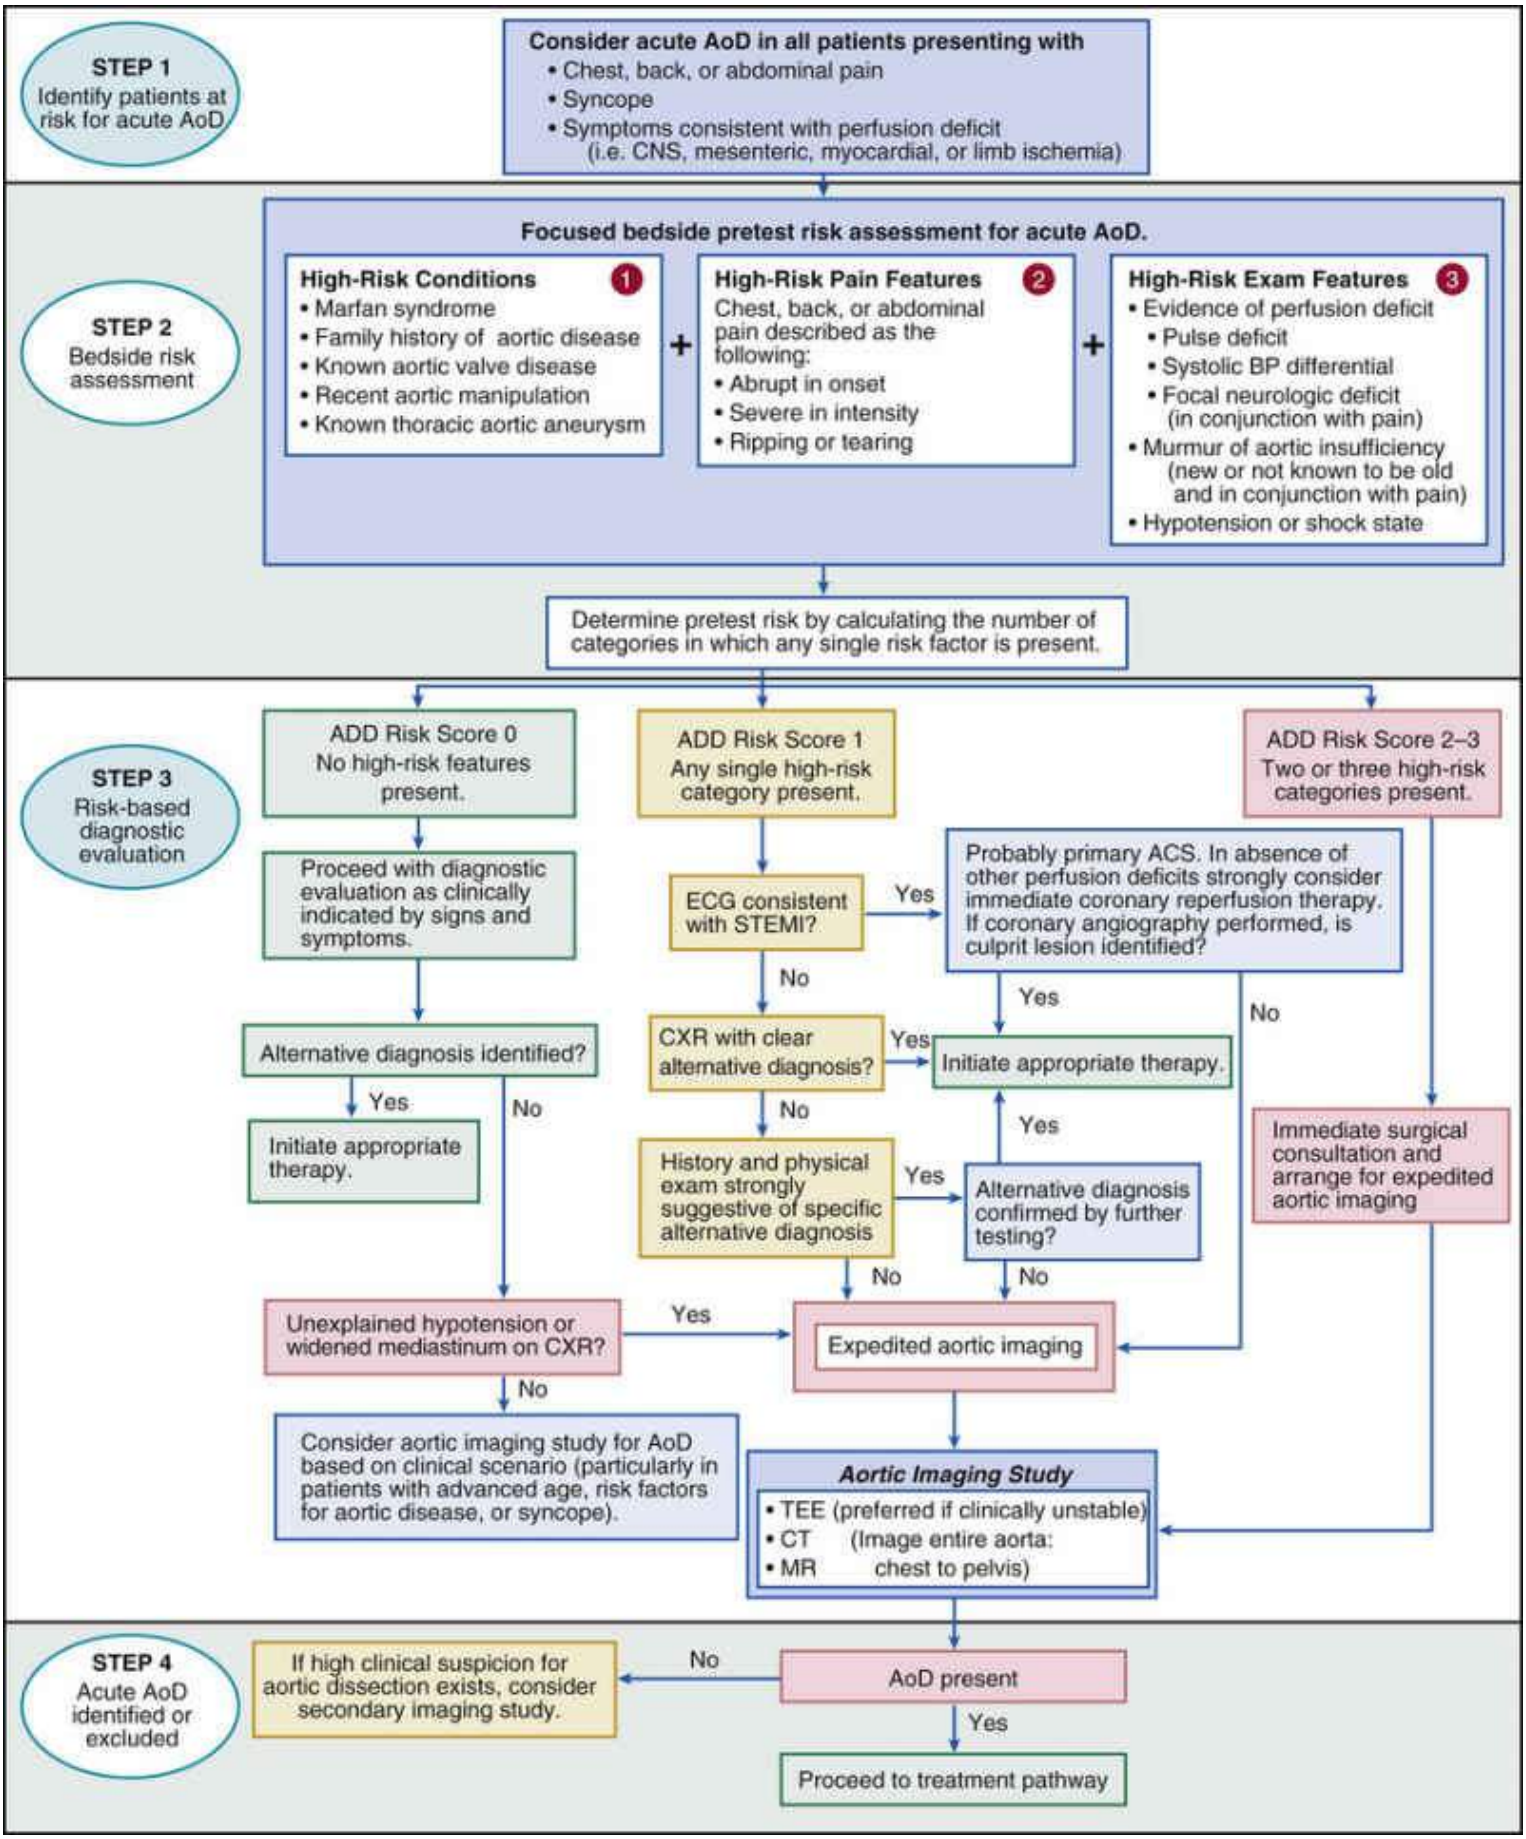

FIGURE 63.18 Evaluation pathway for aortic dissection (AoD). ACS, Acute coronary syndrome; ADD, aortic dissection detection; BP, blood pressure; CNS, central nervous system; CXR, chest x-ray film; STEMI, ST-segment elevation myocardial infarction. (Adapted from Hiratzka LF, Bakris GL, Beckman JA, et al. 2010 ACCF/AHA/AATS/ACR/ASA/SCA/SCAI/SIR/STS/SVM guidelines for the diagnosis and management of patients with thoracic aortic disease: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, American Association for Thoracic Surgery, American College of Radiology, American Stroke Association, Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, Society of Interventional

Management

The thoracic aortic disease guidelines suggest a management pathway for patients with acute aortic dissection (**Fig. 63.19**).[17] Initial medical management includes stabilizing the patient, controlling pain, and lowering BP with beta blockers to reduce the rate of rise in the force (dP/dt) of left ventricular contraction. These measures should commence immediately while the patient is undergoing diagnostic evaluation. Lowering BP may help prevent further propagation of the dissection and lessen the risk for aortic rupture. Aortic dissection has high mortality rate. In the IRAD initial report, medical management of acute type A dissection had a mortality of 20% in the first day and 30% by 48 hours.[47] A recent IRAD update reported survival for medically managed type A dissections to be 82% at 24 hours, 51% at 7 days, 40% at 30 days, and 38% at 60 days.[36] Emergency surgery leads to improved survival in patients with acute type A dissection, with an 18% in-hospital mortality for surgically treated type A dissection and 56% mortality for medically treated patients[38] (**see Fig. 63.12**). Age alone should not be an exclusion criterion for surgical treatment.[1] Initial medical therapy is recommended for acute type B dissections. Patients with acute aortic dissection require urgent multidisciplinary evaluation and management. Emergency transfer to a tertiary medical center with access to cardiovascular surgery, vascular surgery, interventional radiology, and cardiology is recommended for patients with acute dissection.[1,17] Hospitals with higher procedural volumes for surgically managed patients with acute type A and B dissections have lower mortality rates.[1,51]

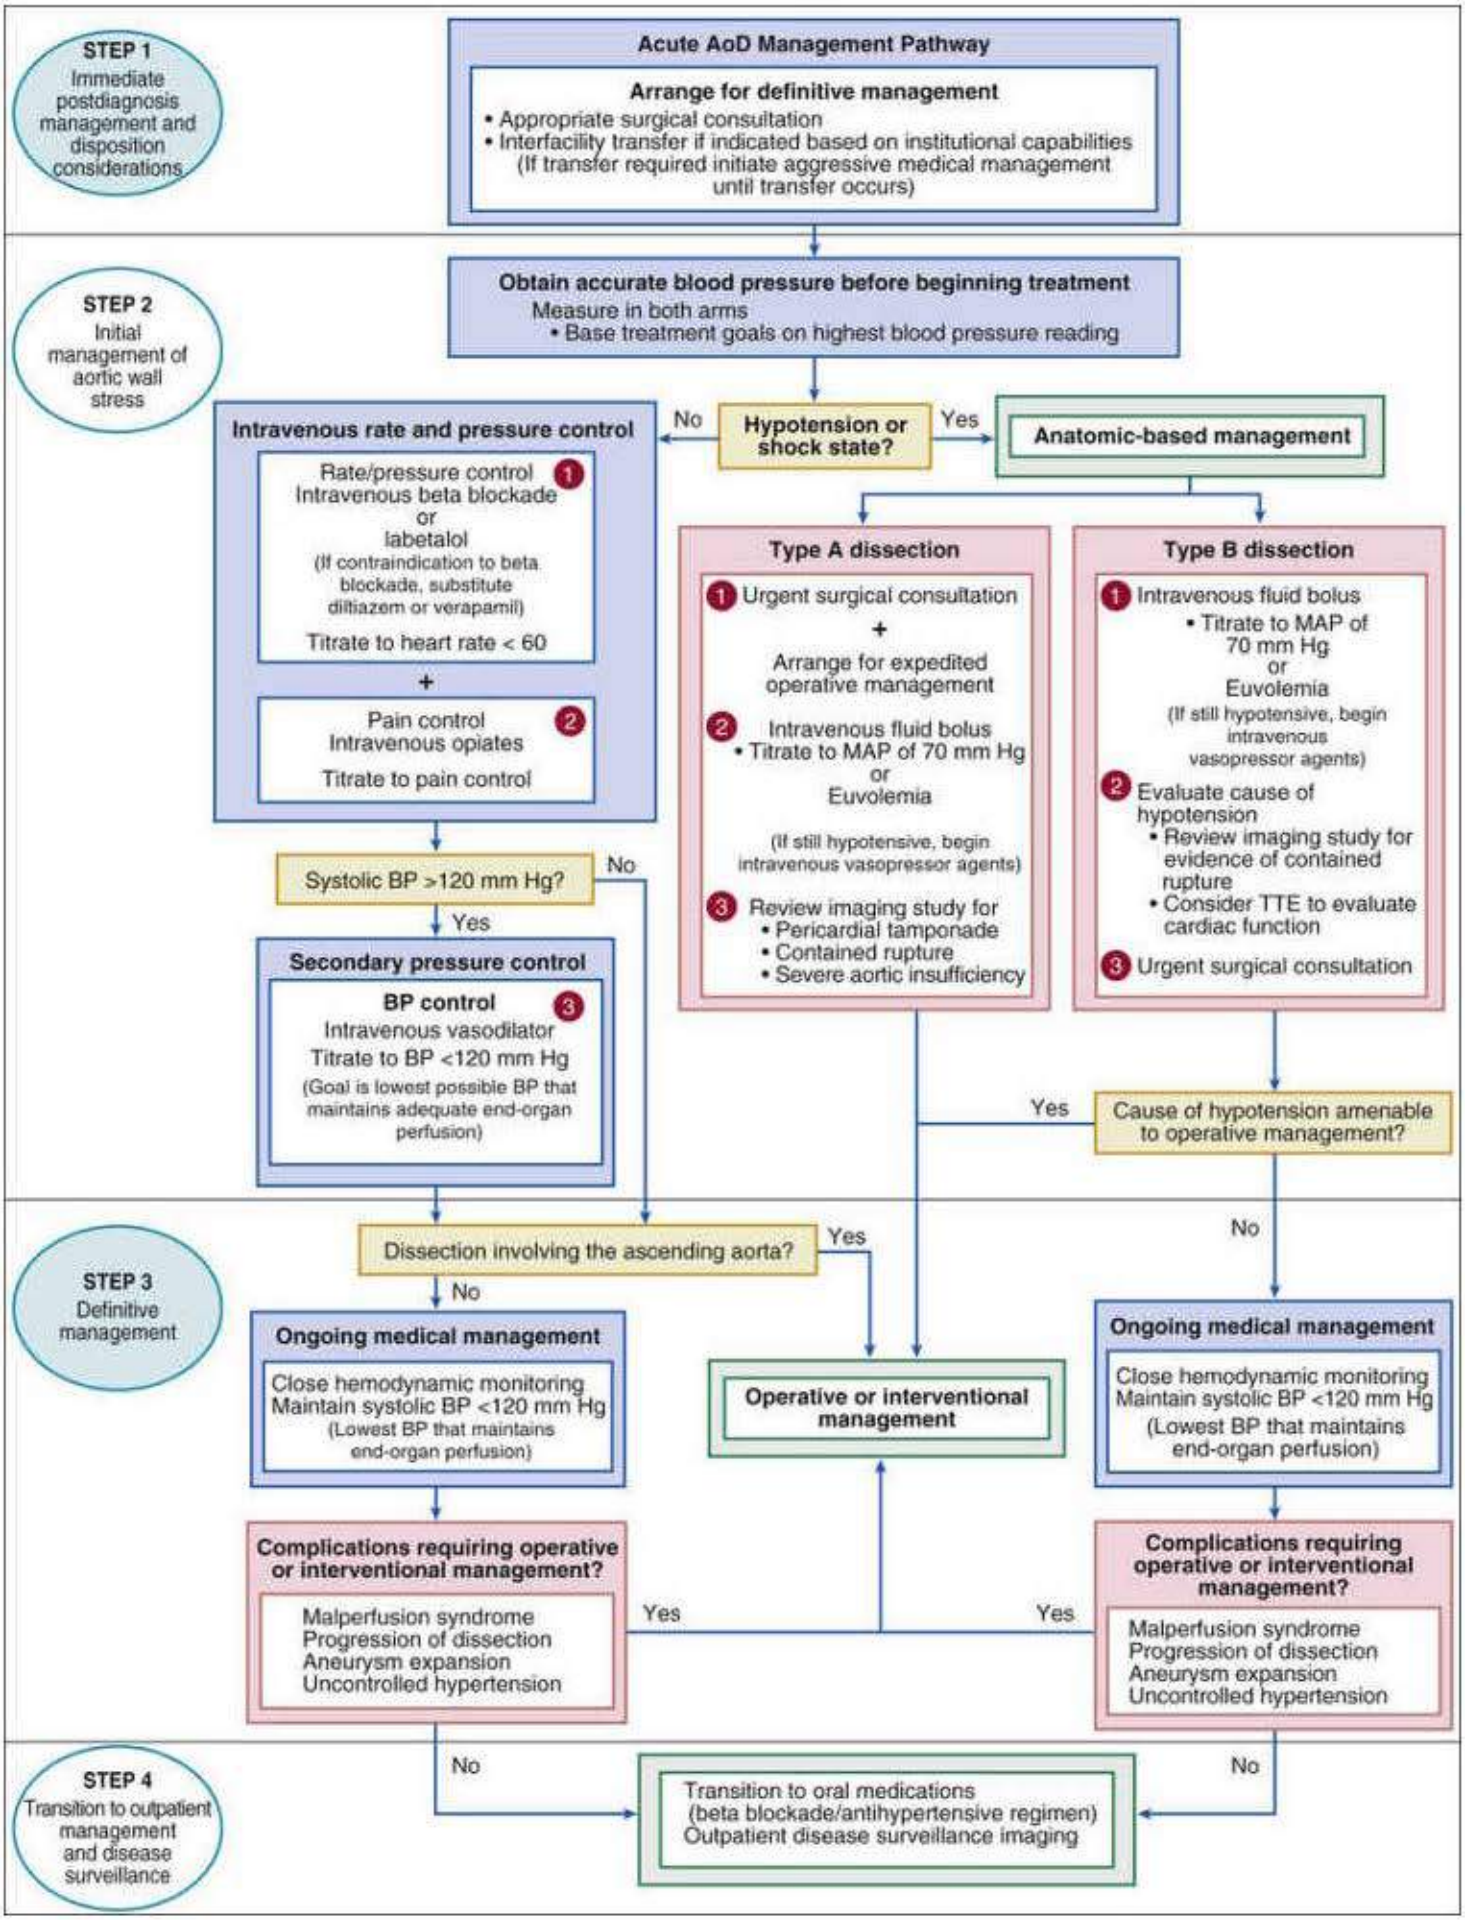

FIGURE 63.19 Management pathway for acute aortic dissection. AoD, Aortic dissection; BP, blood pressure; MAP, mean arterial pressure. (From Hiratzka LF, Bakris GL, Beckman JA, et al. 2010 ACCF/AHA/AATS/ACR/ASA/SCA/SCAI/SIR/STS/SVM guidelines for the diagnosis and management of patients with thoracic aortic disease: executive summary. Stroke Association, Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, Society of Interventional Radiology, Society of Thoracic Surgeons, and Society for Vascular Medicine. Circulation 2010;121:e266.)

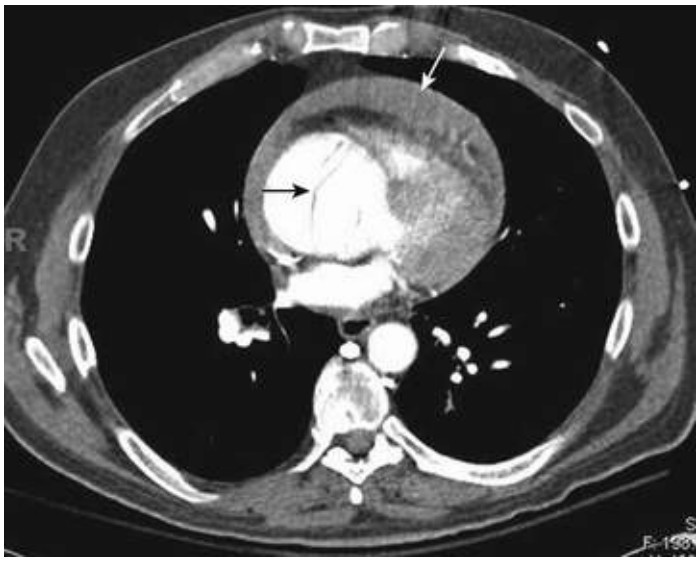
Blood Pressure Reduction

Reduction of systolic BP to levels of approximately 100 to 120 mm Hg or the lowest level necessary for adequate perfusion and a heart rate (HR) of 60 to 80 beats/min is recommended.[37] Beta blockers should be administered even if the patient does not have hypertension. For rapid administration of agents to reduce the rate of rise in ventricular force (dP/dt) and stress on the aorta, IV beta blockers may be given. Esmolol is given as an initial bolus of 1000 µg/kg and then as a continuous infusion of 150 to 300 µg/kg/min. Labetalol is given at an initial IV dose of 20 mg over 2 minutes and then at 40 to 80 mg every 10 minutes (maximum dose, 300 mg) until the desired response is achieved. Labetalol is then administered by continuous infusion at a rate of 2 to 10 mg/min, up to 300 mg total cumulative dose. Sodium nitroprusside leads to rapid reduction of BP but also may result in an increase in dP/dt; thus it must be used together with a beta blocker in the setting of acute aortic dissection. Sodium nitroprusside is initiated at a dose of 0.3 to 0.5 µg/kg/min, uptitrating by 0.5 µg/kg/min as required. Adequate control of BP and HR in patients with acute aortic dissection often requires multiple agents. IV ACE inhibitors and IV nitroglycerin may be useful. Other IV medications for severe hypertension include nicardipine (5 mg/hr, can be increased to a maximum of 15 mg/hr). When evaluating refractory hypertension in acute dissection, the clinician must consider renal artery malperfusion, which may require endovascular therapy (**eFig. 63.11**). The need for multiple antihypertensive agents to control BP acutely may wane after the first several days. Persistence of severe hypertension or signs of renal ischemia should prompt evaluation for renal artery involvement.

Management of Cardiac Tamponade

Cardiac tamponade, which occurs in 8% to 31% of acute type A dissections, is one of the most common mechanisms of death in patients with dissection[1,17,52] (**eFig. 63.16** and Video 63.13). Patients with tamponade may present with hypotension, syncope, or altered mental status and have double the in-hospital mortality rate as those without tamponade (54% versus 25%).[52] Pericardiocentesis for acute hemopericardium in patients with dissection can result in recurrent bleeding and acute hemodynamic collapse, especially if a larger volume of fluid is removed and increased BP leads to further brisk bleeding into the pericardial space. Therefore, in a relatively stable patient with acute type A dissection and cardiac tamponade, the risks associated with pericardiocentesis probably outweigh its benefits. Asian studies report the safety of pericardiocentesis for cardiac tamponade complicating IMH.[17] Hypotension or shock from hemopericardium secondary to ascending dissection requires emergency aortic surgery. However, for patients who will not survive until surgery, pericardiocentesis with aspiration of only enough pericardial fluid to stabilize the patient before surgery may be lifesaving and should be considered a treatment option in this setting.[17,52]



EFIGURE 63.16 Contrast-enhanced computed tomography scan of a dilated ascending aorta with acute type A aortic dissection *(black arrow)* complicated by hemopericardium *(white arrow).*

Definitive Therapy

Definitive therapy for acute aortic dissection includes emergency surgery for type A dissection in patients considered surgical candidates (**eFig. 63.17**). Patients with acute type A aortic dissection are at risk for aortic rupture, AR with heart failure, stroke, cardiac tamponade, and visceral ischemia. Compared to medical therapy, immediate surgical treatment improves survival in patients with acute type A aortic dissection.[17,38,47] In the most recent era of IRAD, the mortality rate of patients with type A aortic dissection undergoing surgery was 18%, versus 56% in those treated medically (typically because of advanced age and comorbid conditions)[36,38] (**see Fig. 63.12**). In experienced centers, 30-day surgical mortality for acute type A dissection is 10% to 35%.[37,38,47,49] Factors increasing mortality included shock, heart failure, cardiac tamponade, MI, renal failure, age, and malperfusion.[17,47,49,53] Type A aortic dissection surgery had a mortality rate of 16% in septuagenarians and 35% in octogenarians.[49] Although shock in type A dissection is associated with a high mortality rate, survivors with or without shock demonstrated a similar long-term mortality.[54] A bedside preoperative and postoperative risk prediction tool for mortality permits estimation of the risks associated with surgery for acute type A aortic dissection[55] (**eFig. 63.18 and eTable 63.2**).

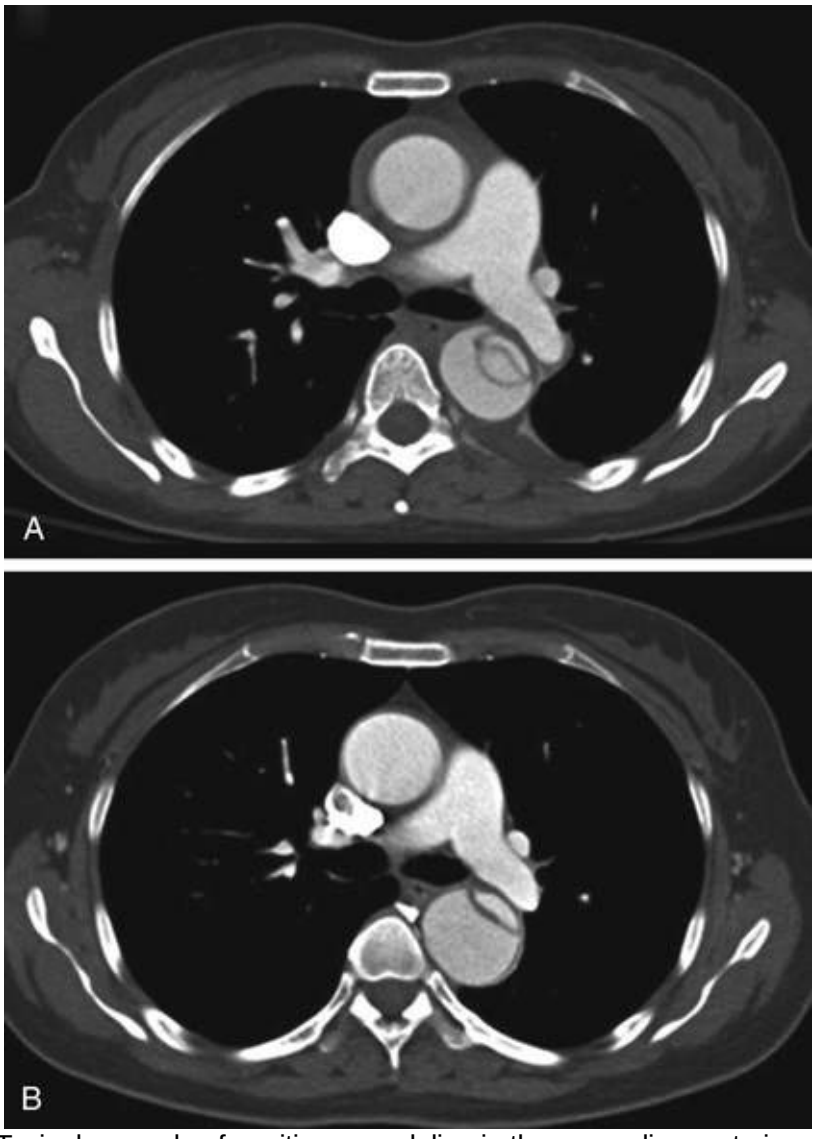
From Rampoldi V, Trimarchi S, Eagle KA, et al. Simple risk models to predict surgical mortality in acute type A aortic dissection: the International Registry of Acute Aortic Dissection score. Ann Thorac Surg 2007;83:55-61.

Select patients with type A dissection have undergone successful TEVAR and hybrid treatment, but more data are required in this area because of technical and anatomic restrictions.[37] Acute retrograde type A dissection with a primary intimal tear in the descending aorta is usually treated surgically. A favorable outcome has been reported for a few carefully selected patients treated with initial medical therapy and timely interventions when the ascending aortic extension is thrombosed and not aneurysmal[56] (**eFig. 63.19**).



EFIGURE 63.19 Typical example of positive remodeling in the ascending aorta is seen in a 48-year-old woman with acute retrograde type A aortic dissection. **A,** At initial presentation, maximal diameter of the ascending aorta was 43.6 mm with the thickness of thrombosed false lumen of 8.7 mm. **B,** After 15.6 months, the thrombosed false lumen in the ascending aorta disappeared, whereas the diameter of the ascending aorta decreased to 36.3 mm. (From Kim JB, Choo SJ, Kim WK, et al. Outcomes of acute retrograde type A aortic dissection with an entry tear in descending aorta. Circulation 2014;130[Suppl 1]:S39-44.)

Patients with acute type B aortic dissection have a lower acute mortality rate than those with acute type A dissection, with overall in-hospital mortality rates of approximately 10%.[38,57] In uncomplicated type B dissection, the in-hospital mortality rate is much lower—as low as 1% to 6% in those requiring only medical therapy[37,38]—but complicated type B dissection carries a much higher mortality rate, especially when accompanied by shock or malperfusion.[57] In the IRAD era, 57% of patients with acute type B dissection were treated medically, 32% received endovascular therapy, and 7% were treated with OSR, with in-hospital mortality rates of 10%, 14%, and 21%, respectively.[38] (**see Fig. 63.12**). National database trends report in-hospital mortality rates of 14.3% for type B dissection treated surgically and 7.9% treated with TEVAR.[51] Increasing age, female sex, hypotension/shock, periaortic hematoma, aortic diameter larger than 5.5 cm, and malperfusion are associated with increased mortality rates. A model using these variables may predict in-hospital mortality.[57] Typical indications for TEVAR in patients with complicated type B aortic dissection include visceral or limb ischemia, rupture or impending rupture, rapid expansion of the aortic diameter, uncontrollable pain, or retrograde extension of the dissection into the ascending aorta (**Table 63.7**). The preferred therapy for most complications is endovascular therapy.[1,37]

Rapid increase in diameter
Recurrent symptoms

*Or open surgical repair if anatomy is unsuitable for TEVAR.

Primary arch dissections are uncommon, and management of this condition must be individualized. Surgical repair of acute arch dissection has a mortality rate between 15% and 29%. If the ascending aorta is involved, the dissection is classified as type A, and emergency surgery is recommended. Many advocate initial medical therapy for primary arch dissections that do not involve the ascending aorta, whereas others recommend emergency surgery for some primary arch dissections, especially if aneurysmal enlargement is present. Type B dissections that extend retrogradely into the transverse arch have been managed variably; initial medical therapy is recommended for most. Isolated abdominal aortic dissections are rare and associated with hypertension, preexisting aneurysm disease, or genetic disorders. Most are spontaneous, but some are related to trauma or iatrogenic causes.

Surgical Management.

Operative therapy for acute aortic dissection is technically very demanding (see Video 63.18). The aortic wall is thin and friable, and Teflon felt and sutures with pledgets are used to buttress the wall and prevent the sutures from tearing the fragile aortic wall.

Type A Aortic Dissection.

OSR, performed as expediently as possible, is the treatment of choice for acute type A aortic dissection to prevent life-threatening complications.[1,17] An inverse relationship exists between hospital/surgeon volume and operative mortality for patients with acute type A dissection.[48] One must weigh the risks of surgery in a low-volume center versus the risk associated with a delay in transfer to a site with expertise. Surgical therapy aims to treat or prevent the common complications of dissection, including cardiac tamponade, AR, aortic rupture, stroke, and visceral ischemia. The immediate surgical goals are to excise the intimal tear; to obliterate the false channel by oversewing the edges of the aorta; and to reconstitute the aorta, directly or more often with placement of an interposition graft. In type A dissection, AR is also treated by resuspension of the aortic valve leaflets or by prosthetic AVR. Although some controversy surrounds the timing of directly treating malperfusion, the general consensus when this complication accompanies acute type A dissection is to repair the aorta first because this will correct the malperfusion in most patients.[1,17,48] Patient-specific therapeutic decisions must be made depending on the mechanism of malperfusion.[53] When severe malperfusion syndrome due to mesenteric ischemia or descending aortic pseudocoarctation is present, some have proposed that initial TEVAR to the descending aorta be performed.[48] However, this approach is associated with delay in definitive surgery and interim rupture rates of 5% to 23%.[48]

A median sternotomy is performed, and cannulation for cardiopulmonary bypass generally involves the axillary artery (**eFig. 63.20**) or less often the femoral approach (**eFig. 63.21**), to avoid trauma to the

weakened aortic wall.[48,58] A woven polyester vascular graft replaces the ascending aorta, and surgeon-specific methods to support the anastomosis are used[58] (**Fig. 63.20**). Most patients can be treated by obliteration of the false lumen by placement of Teflon felt as a neomedia and resuspension of the native aortic valve (**eFigs. 63.22 and 63.23**). Intraoperative aortic valve inspection and TEE guidance assist in managing the aortic valve in patients with proximal aortic dissection.[58] When AR complicates dissection, repair of the aortic wall, decompression of the false lumen, and resuspension of the commissures to the aortic wall will usually restore valve competence. In approximately 20% to 25% of patients who undergo conservative valve management, root dilation or progressive AR may develop late and require AVR or root replacement.[58] When aortic leaflet disease precludes repair, AVR plus associated ascending aortic replacement is indicated. When the sinuses are dilated, composite valve and root replacement is often performed via the modified Bentall procedure. If the sinus of Valsalva is involved by dissection, it is preferable to replace the aortic root to prevent late AR.[1] When the aortic root is dilated but the aortic leaflets are normal, many have achieved success by performing a reimplantation with valve-sparing root replacement[17,48] (**Fig. 63.20 and eFig. 63.9**). This complex process requires a longer procedure and surgical expertise, and for many, composite valve and root replacement is more appropriate. For dissections with a tear localized to the ascending aorta, with a normal-size arch without distal malperfusion, surgical repair involves a hemiarch replacement with an open distal anastomosis under circulatory arrest[48,58] (**eFig. 63.24**).

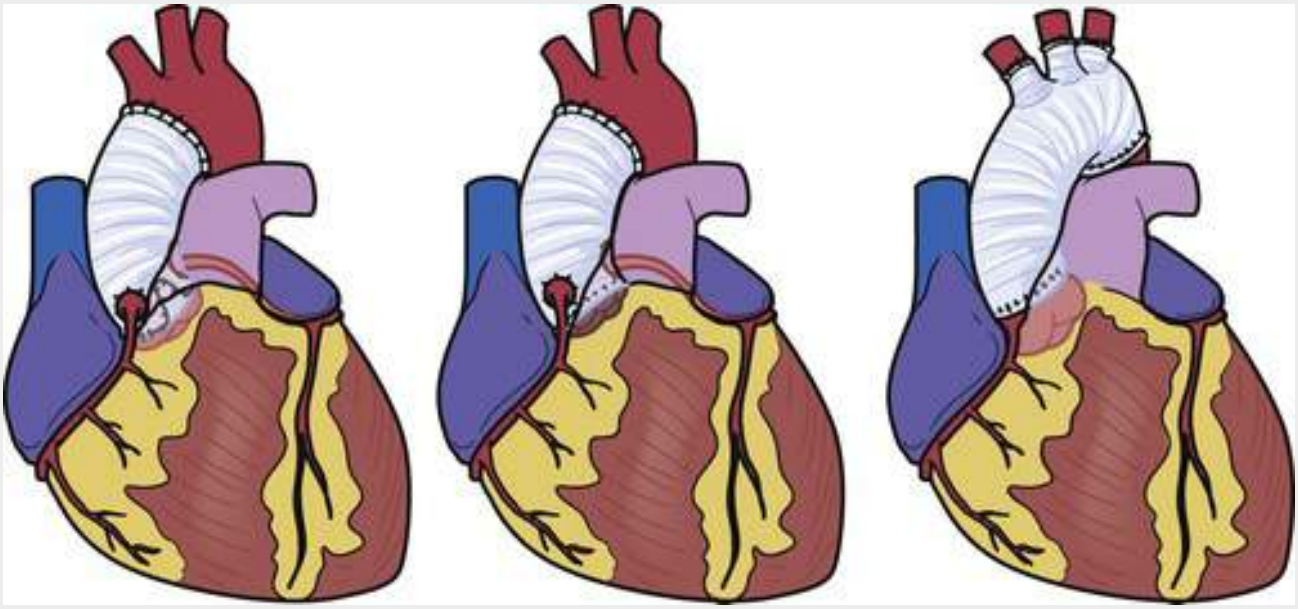

FIGURE 63.20 Different surgical procedures to repair proximal aortic dissection (type A). **Left to right,** DAVID procedure with reinsertion of coronary arteries and preservation of native aortic valve, replacement as both the ascending aorta and the native aortic valve, and total arch replacement with anastomoses to all head vessels. (From Nienaber CA, Divchev D, Palisch H, et al. Early and late management of type B aortic dissection. Heart 2014;100:1491-7.)

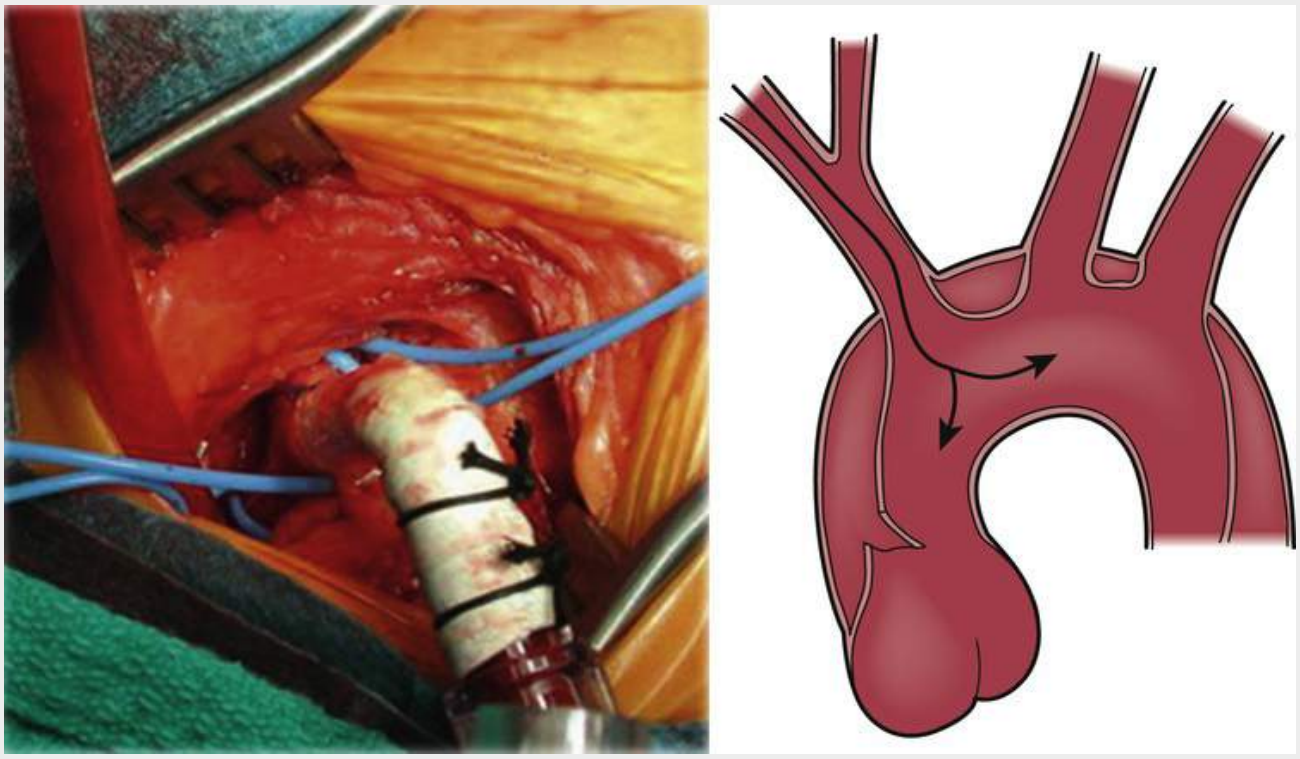
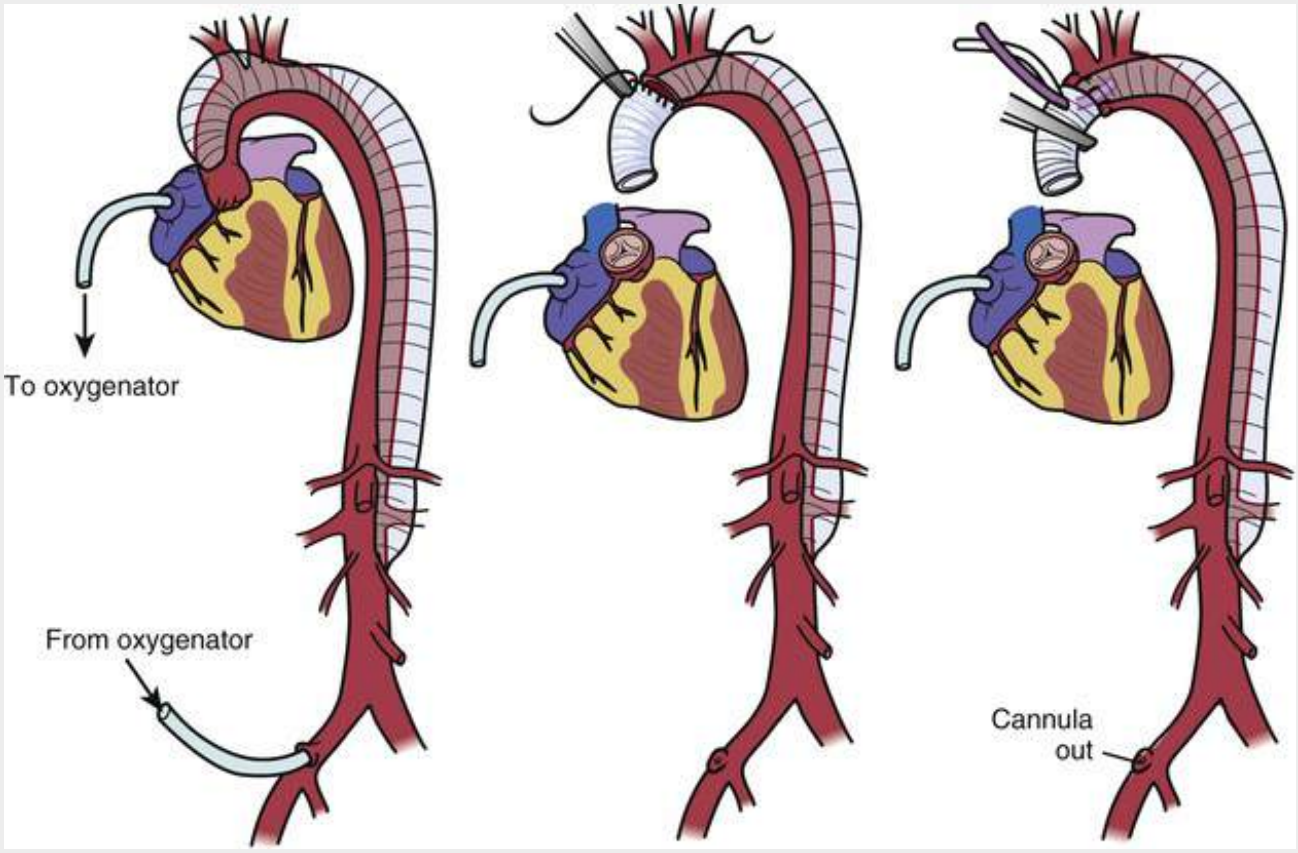


EFIGURE 63.20 Axillary artery perfusion in acute type A aortic dissection. Axillary artery perfusion may prevent malperfusion because blood is pumped into the true lumen. With this type of arterial return during cardiopulmonary bypass, the ascending aorta may be clamped without increasing the risk of malperfusion. (From David TE. Surgery for acute type A aortic dissection. J Thorac Cardiovasc Surg 2015;150:279-83.)



EFIGURE 63.21 Surgery for acute type A aortic dissection. Femoral artery perfusion reverses the flow in the false lumen, and aortic clamping should be avoided to reduce the risk of malperfusion. The distal anastomosis should be performed under circulatory arrest. The femoral cannula should be removed and inserted into the polyester fabric graft for antegrade perfusion after completion of the distal anastomosis.
(From David TE. Surgery for acute type A aortic dissection. J Thorac Cardiovasc Surg 2015;150:279-83.)

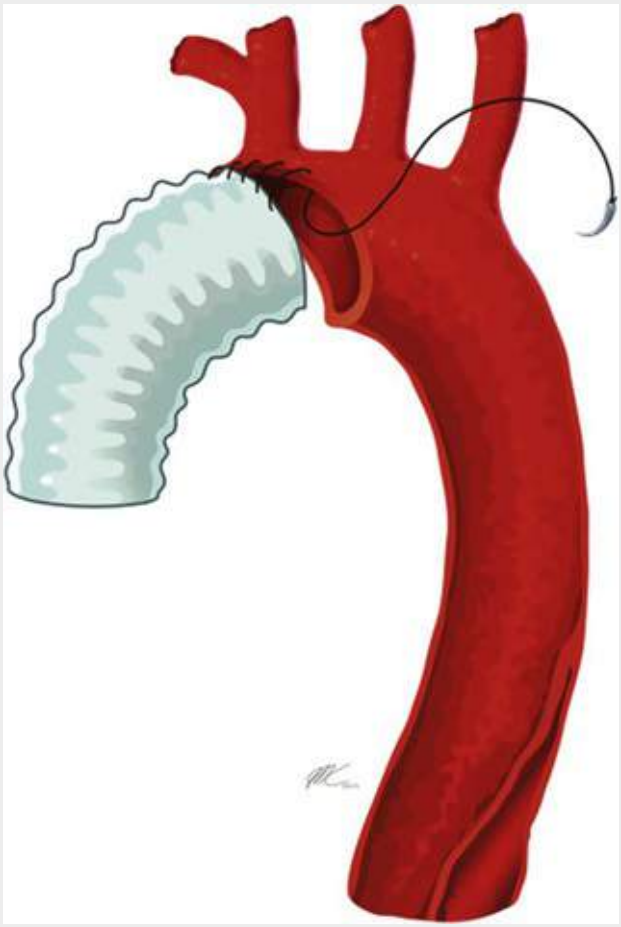
EFIGURE 63.23 Surgical repair of acute type A aortic dissection. **A,** Intraoperative photograph of surgical repair of acute type A aortic dissection. The aorta has been transected above the aortic commissures, and the inner (*white arrow*) and outer (*black arrow*) layers are approximated after removal of thrombus from the false lumen. **B,** The aortic valve has been suspended by three sutures placed at the top of each commissure (*black arrow*). A strip of polytetrafluoroethylene felt is placed within the true aortic lumen (*lower white arrow*), and another strip is placed outside the aorta (*upper white arrow*). A polyester graft will be sutured to the aorta, incorporating the two layers of the aorta and the two strips of felt. (Photograph courtesy Dr. Nicholas Kouchoukos.)



EFIGURE 63.24 Standard surgical repair involving hemiarch replacement and open distal anastomosis under circulatory arrest for patients with tears localized to the ascending aorta, a normal-caliber aortic arch, and no evidence of distal malperfusion. (From El-Hamamsy I, Ouzounian M, Demers P, et al. State-of-the-art surgical management of acute type Aaortic dissection. Can J Cardiol 2016;32:100-9. Image courtesy Dr. Jehangir Appoo.)

The aortic arch is dissected in more than 70% of type A dissections, and arch vessel involvement in the dissection process is reported in 28% to 73%.[1,17,49,58] Arch replacement, with the patient under deep hypothermic circulatory arrest, is also performed if the intimal tear is extensive throughout the arch and arch vessels and is not amenable to primary resection, if the aortic arch is aneurysmal or ruptured, if a primary arch tear is identified at surgery, and in some patients with hereditary aneurysm syndromes. Prolonged circulatory arrest times increase morbidity and mortality. Branched-graft techniques are preferred in managing arch vessels involved.[48] Although more complex procedures in which the entire aortic arch is replaced may reduce patency of the false lumen, this complex procedure carries higher risk than hemiarch or ascending aortic surgery. However, the German Registry for Acute Aortic Dissection Type A (GERAADA) study reported no difference in 30-day mortality comparing hemiarch and total arch versus no arch procedures.[49]

Extended distal repair may be performed to seal tears extending to the descending aorta and to improve obliteration of the false lumen distally.[48] The elephant trunk and the frozen elephant trunk procedures (see earlier section on TAAs) may be performed in acute type A dissection requiring extensive distal repair with multiple techniques available, including open, closed, and hybrid procedures[48,58] (**Fig. 63.21**).

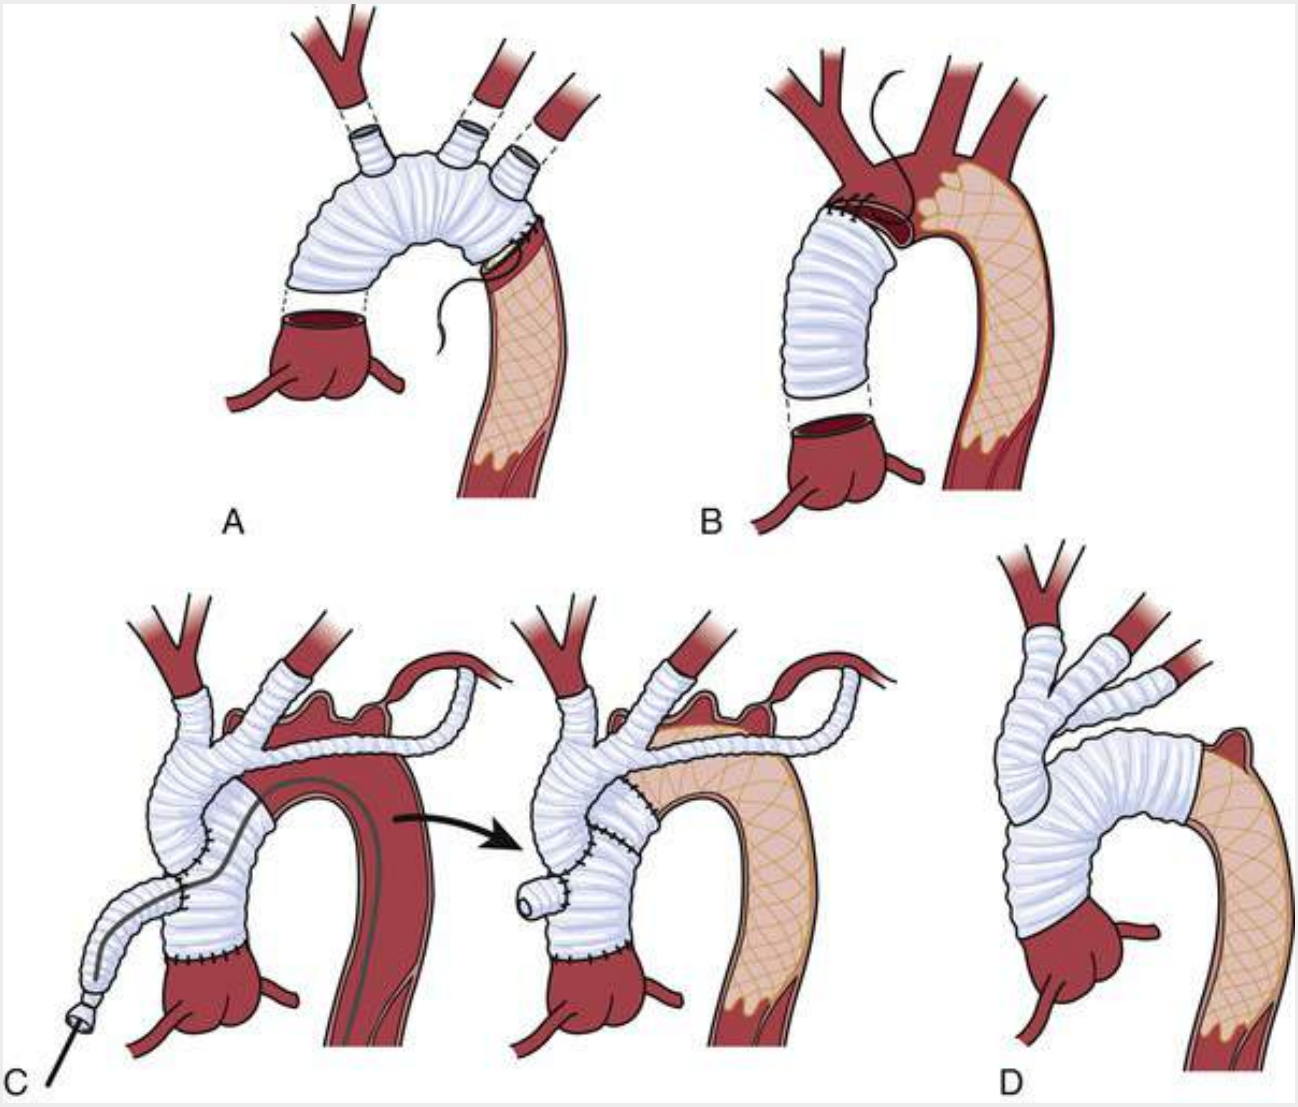


FIGURE 63.21 Approaches to extended distal repair for acute type A aortic dissection. **A,** Open stent graft and total arch replacement with antegrade stent-graft placed in descending thoracic aorta at circulatory arrest. **B,** Open stent-graft and hemiarch replacement with antegrade stent-graft placed in the descending thoracic aorta at circulatory arrest. **C,** Closed stent-graft with hybrid arch. Proximal rerouting of arch vessels to sinotubular junction and endovascular stent graft deployment into ascending aortic graft with fluoroscopy after weaning from cardiopulmonary bypass. **D,** Closed stent-graft with hybrid arch replacement. Arch replaced surgically to level of left subclavian artery and polyester proximal landing zone created for stent-graft in transverse arch. (From El-Hamamsy I, Ouzounian M, Demers P, et al. State-of-the-art surgical management of acute type A aortic dissection. Can J Cardiol 2016;32:100-9. Images courtesy Dr. Jehangir Appoo.)

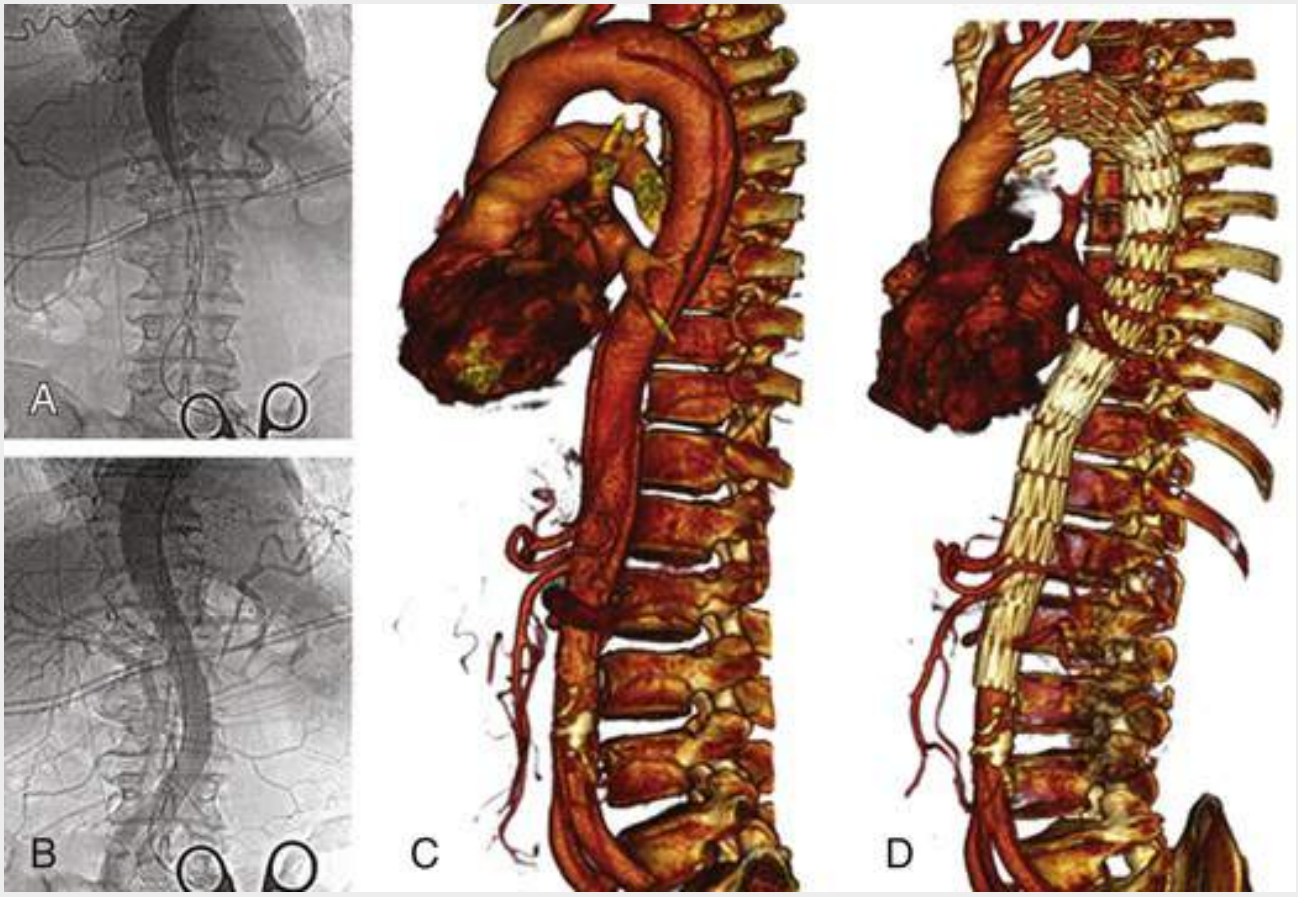
Type B Aortic Dissection.

Treatment of patients with type B aortic dissections is evolving with the increased use of endovascular devices. Because of the high mortality rates associated with OSR, stable patients with uncomplicated type B dissection usually receive nonoperative treatment.[1,17,37] Patients with complicated type B aortic dissection secondary to aortic rupture, intractable pain, aneurysmal enlargement, or end-organ ischemia as a result of aortic branch vessel involvement should receive TEVAR, which entails lower morbidity and mortality than OSR[1,37] (**see Fig. 63.8**) (**eFig. 63.25**). Of 1476 patients with type B dissection in the IRAD registry, 63% were treated medically, with mortality rate of 8.7%; 23% received endovascular repair, with mortality of 12%; and 13% underwent OSR, with mortality of 17%.[38] Other large registries report a mortality rate of approximately 32% for OSR in acute type B dissection.[37] The STABLE trial is evaluating the treatment of complicated type B dissection with endovascular grafts compiling a 30-day mortality rate of 4.7%. Favorable aortic remodeling occurred and follow-up through 5-years is ongoing.[59] The DISSECTION trial treated complicated type B dissection with TEVAR, reporting a 30-

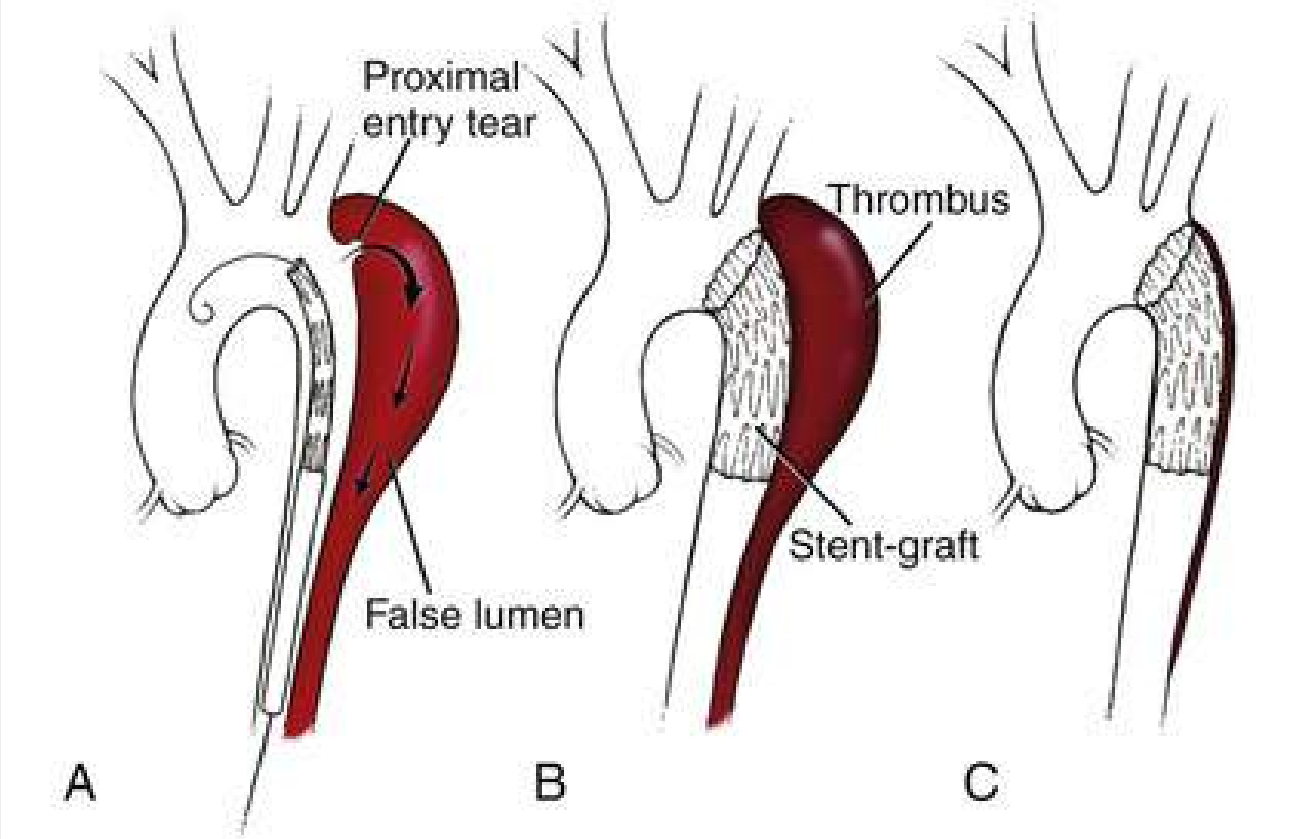
day mortality of 8% and 12-month mortality of 15%.[60]



EFIGURE 63.25 Complicated acute type B aortic dissection with aortic malperfusion above the renal arteries before and after emergency stent-graft implantation. **A,** Aortogram with no-flow to the abdominal aorta. **B,** Aortogram demonstrating markedly improved distal flow after stent-graft placement. **C,** Three-dimensional reconstruction of the complicated type B dissection before thoracic endovascular aneurysm repair (TEVAR). **D,** After stent-graft placement. (From Akin I, Kische S, Tehders TC, et al. TEVAR, the solution to all aortic problems? Herz 2011;36:539.)

When a dead-end false lumen leads to dynamic compression of the true lumen, balloon fenestration of the intimal flap allows blood to flow from the false into the true lumen, decompressing the distended false lumen. However, fenestration and branch vessel stenting alone may not relieve malperfusion, and TEVAR may be required.[1]

TEVAR covers the area of the primary intimal tear and redirects flow to the true lumen, promoting thrombosis of the false lumen and allowing aortic remodeling (**eFig. 63.26**). This treatment often corrects malperfusion syndromes and branch vessel ischemia (**eFig. 63.25**) and is useful in the treatment of enlarging symptomatic dissections and ruptured aortas. At present, endovascular devices are approved for the treatment of type B dissections (acute, chronic, complicated, or uncomplicated). Up to two thirds of patients so treated have persistence of a perfused false lumen, which can require reintervention and surgical conversion. If malperfusion of a branch vessel persists, branch vessel stenting or the technique of *provisional extension to induce complete attachment* (PETTICOAT)—in which the entry point is sealed with an endograft and the remaining thoracic aorta, abdominal aorta, and/or branch vessels are stented open—may correct the problem.[37] Hybrid approaches (TEVAR and OSR) of dissections involving the arch and descending aorta may have lower risk than OSR. Retrograde ascending dissection is a potentially lethal complication that may occur during TEVAR for type B dissection, emphasizing the requirement for an OSR team at institutions performing endografts for aortic dissection.[17]



EFIGURE 63.26 Thoracic endovascular aneurysm repair (TEVAR) after aortic dissection in the setting of aneurysmal enlargement of the false channel. **A,** Endograft is advanced to cover the proximal entry tear into the false channel. **B,** Sealing of the entry tear promotes thrombosis in the false lumen. **C,** Remodeling of the aorta occurs with expansion of the true lumen and a smaller, thrombosed false lumen.

Patients with uncomplicated type B aortic dissection have a risk for long-term complications, including aneurysm formation and late rupture (**eFig. 63.27**). Whether early TEVAR of uncomplicated type B dissection changes the morbidity and mortality of uncomplicated type B dissection is under investigation. The INSTEAD trial reported no difference in all-cause mortality between patients with uncomplicated chronic type B dissection treated with TEVAR versus medical therapy.[61] Patients treated with TEVAR had a significantly higher rate of aortic remodeling, including false lumen thrombosis and true lumen expansion (91% versus 19% for TEVAR versus medical therapy) (**Fig. 63.22**). The 5-year all-cause mortality was not different between groups, but aorta-related mortality was significantly less in TEVAR treated patients, as was progressive aneurysmal enlargement[61] (**Fig. 63.23**). The ADSORB trial comparing TEVAR with medical therapy in uncomplicated type B dissection found that TEVAR improved aortic remodeling compared to medical therapy, but with no difference in rupture or in dissection-related or overall mortality after 1 year;[62] 3-year data are forthcoming. Typical indications for TEVAR (or OSR) in chronic type B aortic dissection include progressive aortic enlargement (>10 mm/yr), aneurysmal enlargement (>55 mm), malperfusion syndromes, and recurrent pain.[1,37] Management of chronic type B aortic dissection is complex because data from a recent meta-analysis demonstrates high rates of operative mortality (OSR, 5.6% to 21%; TEVAR, 0 to 14%) and complications (stroke: OSR, 0 to 13%; TEVAR, 0 to 12%; spinal cord ischemia: OSR, 0 to 16%; TEVAR, 0 to 13%; renal failure: OSR, 0 to 33%; TEVAR, 0 to 34%).[63] Reintervention rates were also high (OSR, 6% to 29%; TEVAR, 4% to 47%). Currently, OSR is reserved for patients with aortic diameters larger than 55 mm who are good surgical candidates and at greater than 60 mm for reasonable candidates, whereas those at high surgical risk should be considered for endovascular repair at dedicated centers (European Society for Vascular

Surgery guideline).

Long-Term Therapy and Follow-Up

Short- and long-term survival rates for type A aortic dissection range between 52% and 94% at 1 year and between 45% and 88% at 5 years.[17] Others report that patients with type A dissection who survive surgery have survival rates of approximately 90% at 1 year, 75% at 5 years, and 54% at 10 years.[58] In single-center studies of long-term follow-up after type A aortic dissection, the 10-year survival rate was 55% to 59% and the 20-year survival rate, 24% to 30%.[64,65]

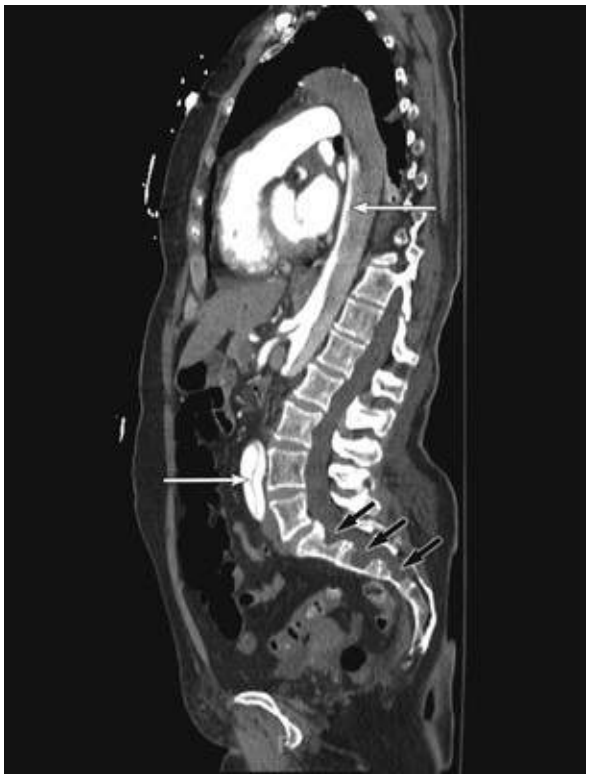
Medically treated patients with type A aortic dissection have a very high mortality rate, in excess of 20% by 24 hours and 50% in the first week after diagnosis.[38,47] Few data exist about the natural history of medically managed chronic type A aortic dissection. Some studies report dismal survival with medical therapy alone, even in patients who survive the initial hospitalization, but IRAD reported a 38% survival rate at 60 days.[36] Of patients with type A dissection surviving hospitalization with medical therapy, the 1-year survival rate has been quite variable, ranging from less than 20% to 88%, and 3-year survival has been reported as high as 68%.[66] A few patients are initially seen in the subacute stage and should undergo surgery. On occasion, patients are incidentally discovered to have a chronic type A dissection during evaluation for AR or a dilated ascending aorta. Surgical treatment is recommended for appropriate candidates with chronic type A dissection, especially those with an ascending aortic aneurysm greater than 5.5 cm, AR, or symptoms.[46]

Long-term survival rates in patients with acute type B dissection range from 56% to 92% at 1 year and

48% to 82% at 5 years.[66] These studies have included single-center reports with heterogeneous enrollment criteria and lack of endovascular therapy. Nonetheless, findings at long-term follow-up after type B aortic dissection are worse than after type A dissection. Previous studies have demonstrated that many deaths in follow-up are related to subsequent aortic complications such as rupture, extension of the dissection, and the risks associated with subsequent aortic and vascular surgery. The 1- to 3-year survival rates of patients discharged after initial hospitalization for acute type B aortic dissection were 78%, 83%, and 77% to 98% for patients treated medically, surgically, or with endovascular therapy, respectively.[36]

Long-term management after aortic dissection includes medical therapy, BP control, screening the patient and first-degree relatives for heritable disorders associated with aortic dissection, serial imaging of the aorta, lifestyle modifications, and education.[34,42] One important long-term management goal after dissection is treating hypertension, with a BP goal of lower than 120/80 mm Hg in most individuals. Poorly controlled hypertension is associated with an increase in late morbidity and mortality.[65,67] There are no randomized trials comparing specific medications after chronic aortic dissection. Beta blockers are the most commonly used drugs after dissection and may be associated with improved survival (specifically with type A dissection).[1,68] Beta blockers are the drugs of first choice because of their effect on aortic stress and dP/dt and are recommended even in patients without hypertension.[17] Beta-blocker therapy is associated with a lower requirement for late surgery in follow-up.[65,67] Calcium channel blockers may improve survival after type B dissection,[68] and ACE inhibitors may be associated with lower rates of late aortic events.[67] Smoking cessation and risk factor modification for degenerative disease are also important.[17]

Many patients with dissection will eventually be found to have an underlying genetic predisposition to aortic disease. Some have syndromic features recognized as MFS or LDS; features of these disorders should be sought on examination.[13] Recognition of *dural ectasia*—widening or enlargement of the dural canal, usually in the lumbosacral spine—on CT or MRI often indicates an underlying genetic aneurysm syndrome (e.g., MFS, LDS) (**eFig. 63.28**). Some patients will have an underlying BAV, a familial condition in 9% of cases; other patients will have nonsyndromic familial TAA or dissection syndromes.[12] Comprehensive family studies recognize that 20% of individuals with a TAA or dissection will have another first-degree relative with thoracic aortic disease, and thus the importance of family screening, as previously described.[17]



EFIGURE 63.28 Dural ectasia as a sign of underlying connective tissue disease in aortic dissection. A sagittal computed tomography scan demonstrates acute aortic dissection (*white arrows*) and dural ectasia (*black arrows*) in the lumbosacral spine of a woman with previously undiagnosed Marfan syndrome.

Long-term management after dissection includes regular imaging of the aorta and its branches for complications, especially aneurysmal enlargement (**eFig. 63.27**). The distal arch and the proximal descending aorta are the areas at highest risk for late aneurysm formation after acute aortic dissection. Between 2% and 13% of patients require reoperation within 5 years, and the risk associated with repeated surgery or intervention 10 years after type A aortic dissection ranges from 16% to 25%.[58] Typical protocols for follow-up after acute dissection include imaging with CT or MRA at 1 to 3, 6, 12, 18, and 24 months and yearly thereafter, with intervals depending on the size of the aorta and changes in aortic dimension over time.[1,17] MRA should be considered for long-term follow-up to avoid repeated radiation exposure.

Risk factors for late aneurysm formation include aortic dilation, hypertension, nonresection of the false lumen, larger false lumen diameter (>22 mm), entry tear diameter larger than 10 mm, and partial false lumen thrombosis.[37] A patent false lumen and a dilated descending aorta (>45 mm) are risk factors for aneurysm and reintervention.[2] Patients with partial false-lumen thrombosis have higher mortality at follow-up than those with a completely patent or completely thrombosed false lumen.[66] Increased pressure may occur in the false lumen in the setting of partial thrombosis because of the lack of distal reentry tears and may lead to subsequent expansion and increased risk for rupture.[66] Ulcerlike projections (localized blood-filled pouches) protruding into the thrombosed false lumen on CT are associated with late aortic events. MRI using four-dimensional phase-contrast imaging may identify patients at risk for aortic dilation.[37]

Many late deaths following surgery for aortic dissection result from rupture of the aorta at the site of previous dissection or from rupture of another aneurysm at a remote site. Aneurysms related to expansion of the false lumen have relatively thin walls and are at higher risk for rupture than degenerative aneurysms. Rapid aortic growth (>5 mm/yr) or aortic diameter greater than 60 mm are risk factors for rupture.[2] The timing of repair for aneurysmal involvement of the residual aorta depends on several factors, including the patient's age and general medical condition, comorbid conditions, underlying

disease process, rate of aneurysmal enlargement, and absolute size of the aorta. In general, patients with a descending aorta diameter after dissection that exceeds 5.5 to 6 cm, or if the rate of aortic expansion exceeds 1 cm/yr, should have evaluation for repair.[1,17] In patients at relatively lower risk and in those with certain genetically triggered TAA diseases, open surgical repair at a smaller aortic diameter is appropriate.

Lifestyle modifications are necessary after aortic dissection. Isometric activities, including weightlifting, lead to increased BP and aortic wall stress.[34] Many need to change jobs, modify their work activities, or be considered disabled as a result of aortic dissection and/or underlying aortic disease, because of limitations placed on physical activity. However, low to moderate levels of many types of physical activity, including sex, are considered safe, and participation in exercise may lessen depression and lower BP.[34]

Aortic Dissection Variants

In addition to acute aortic dissection, aortic IMH and PAU are included in the acute aortic syndromes (**see Fig. 63.10**). These disorders may be identical to classic aortic dissection in their manifestations and may cause acute chest or back pain, but they have important differences in their imaging and management. IMH is associated with many of the same risk factors as classic aortic dissection, whereas PAU is more common in the descending aorta and is associated with heavy calcification and atherosclerosis.

Aortic Intramural Hematoma

Aortic IMH is a type of acute aortic syndrome in which a hematoma develops in the medial layer of the aortic wall with no evidence of an intimal flap or false lumen.[1,2,17,69] Imaging studies demonstrate a circular or crescentic thickening of 5 mm or more in the aortic wall. From 10% to 20% of acute aortic syndromes are caused by an IMH, with higher incidence in Asian studies than Western cohorts.[70-72] IMH involves the ascending aorta in 30%, the arch in 10%, and the descending aorta in 60% to 70% of cases. IMH may result from rupture of the vasa vasorum and subsequent mural hemorrhage. Supporting this theory is the location of IMH in the outer aortic media, versus the inner medial location of a classic dissection. Micro–intimal tear may initiate IMH, with the intimal tear too small to detect by routine CT. This feature may lead to negligible reentry into the true lumen and a thrombosed false lumen.[1,71]

IMH is classified as type A or type B as for classic aortic dissection. Symptoms and risk factors of IMH resemble those of aortic dissection, with acute chest and/or back pain predominating. Ascending IMH may lead to AR, hemopericardium, or rupture, but malperfusion is less common. The proximity of the IMH to the adventitia may explain the frequent coexistence of pleural effusion, pericardial effusion, and periaortic hematoma and underlies the higher risk for aortic rupture.[1,72]

Imaging studies useful for the diagnosis of IMH include TEE, CT, and MRI.[2] TTE has a very low sensitivity. TEE features of IMH include focal crescentic or circumferential aortic wall thickening of 5 mm or more, an eccentric aortic lumen, displaced intimal calcification, and areas of echolucency within the aortic wall and no intimal flap or flow in the aortic wall[2] (**Fig. 63.24**) (**eFig. 63.29** and Videos 63.19 to 63.21). On non–contrast-enhanced CT, IMH appears as an area of high attenuation (due to bleeding) in the wall of the aorta (**eFig. 63.30**), whereas on CECT, the aortic wall demonstrates low attenuation, because no contrast material enters the wall (**Fig. 63.24**). MRI demonstrates focal thickening of the aortic wall, with phase-contrast cine and gradient echocardiography demonstrating no-flow in the aortic wall (**eFig. 63.31**). High signal intensity on T2-weighted MR images may be visualized because of blood in the aortic wall with acute IMH. Ulcerlike projections (ULP; localized blood-filled pouch protruding into hematoma in aortic wall that may be caused by micro–intimal defects), focal contrast enhancement within the hematoma, thick hematoma, and a large aortic diameter are associated with a higher risk of complications in IMH[1,69,71] (**eFig. 63.32**).

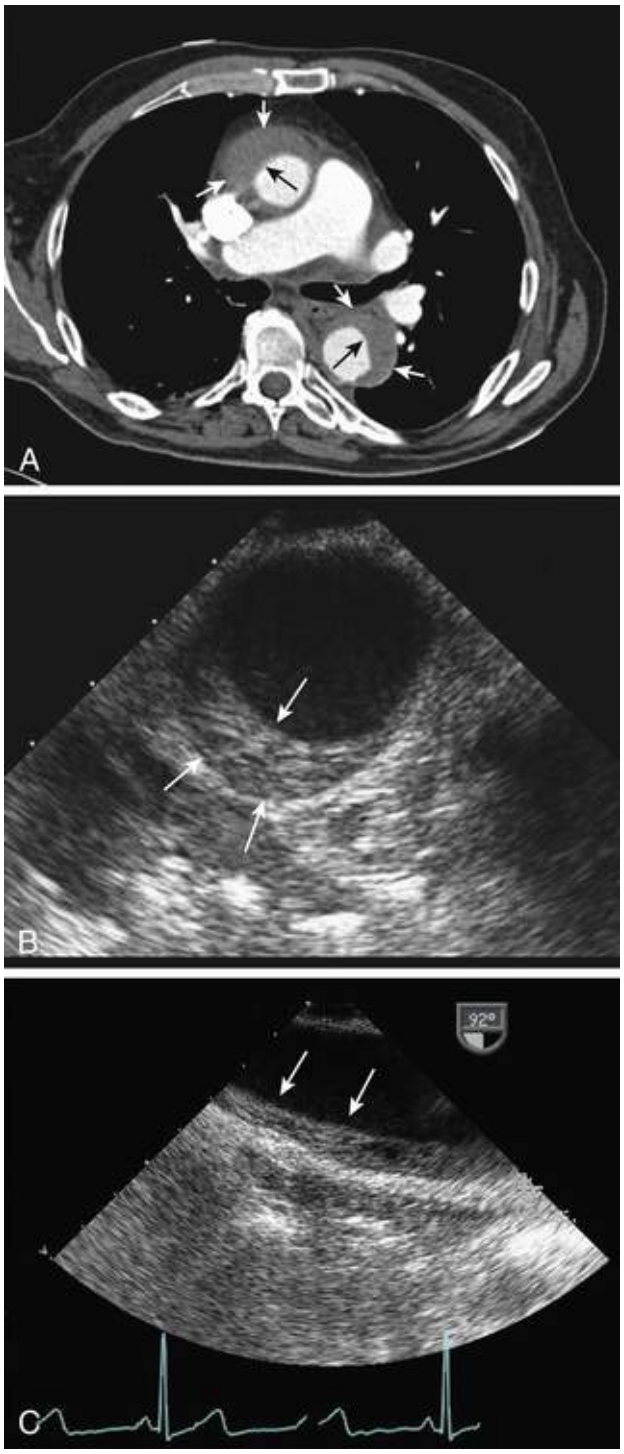


FIGURE 63.24 Intramural hematoma (IMH) of the aorta. **A,** Contrast-enhanced computed tomography scan demonstrating type A IMH of the aorta. Note the circumferential hematoma involving the ascending aorta (*upper arrows*) and the crescentic hematoma involving the descending aorta (*lower* arrows). **B,** Transesophageal echocardiogram short-axis view of the descending aorta demonstrating typical crescentic thickening of the aortic wall (*arrows*) in acute type B IMH. **C,** Transesophageal echocardiogram longitudinal view of the aorta demonstrating IMH (*arrows*).

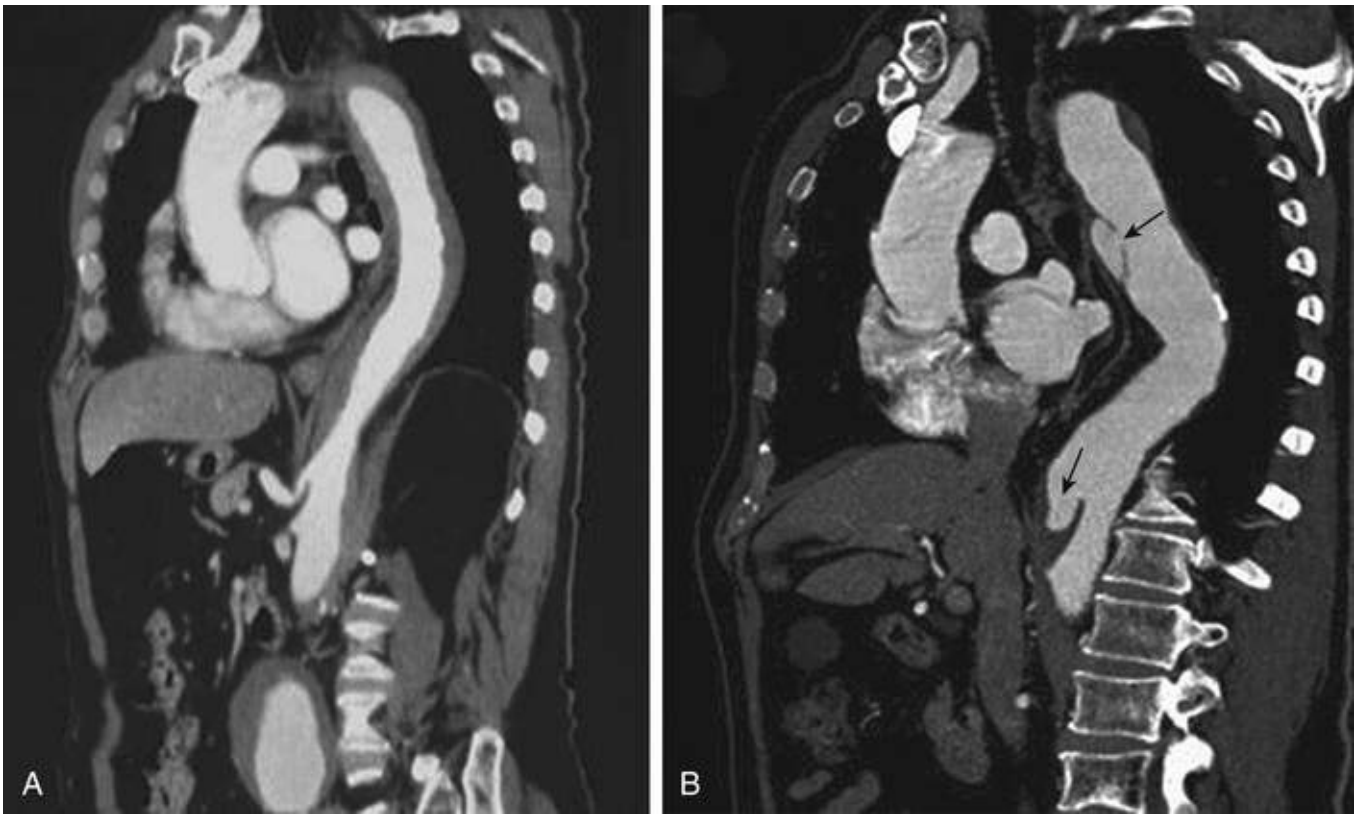
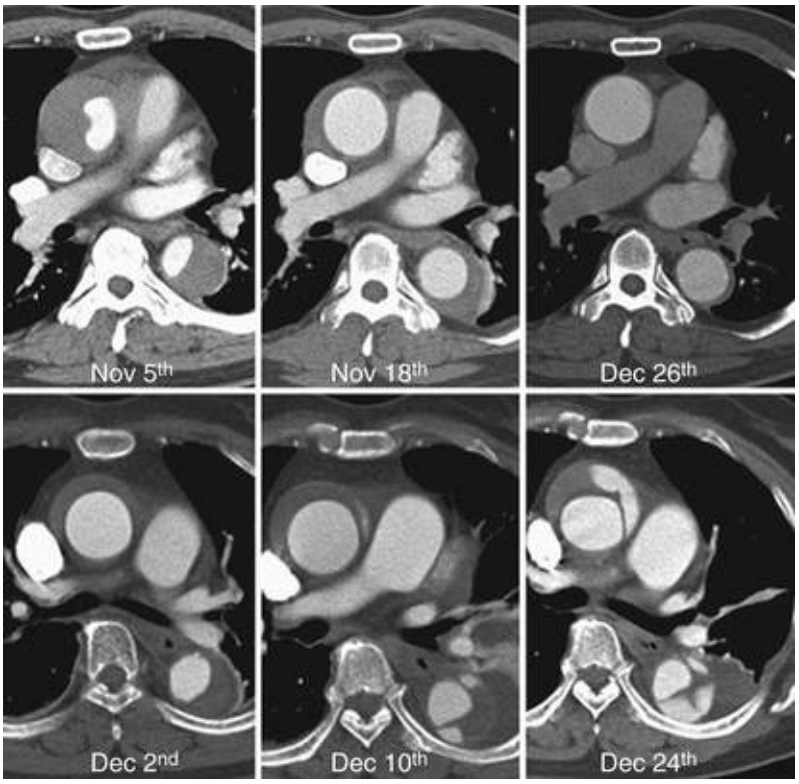
EFIGURE 63.31 Magnetic resonance image of type A intramural hematoma of the aorta. The crescentic thickening of the aortic wall hematoma is denoted by *arrows*.



EFIGURE 63.32 **A,** Computed tomography image of intramural hematoma (IMH) in descending thoracic aorta at diagnosis of acute aortic syndrome. **B,** Development of two ulcerlike projections in the same patient at 6 months (*black arrows*). (From Evangelista A, Czerny M, Nienaber C, et al. Interdisciplinary expert consensus on management of type B intramural haematoma and penetrating aortic ulcer. Eur J Cardiothorac Surg 2015;47:209-17.)

Distinct from an aneurysm with mural thrombus, IMH has a smooth lumen and curvilinear wall (**Fig. 63.24**) (**eFigs. 63.29 to 63.33**). In certain cases, differentiating IMH from aortic dissection with thrombosis of the false lumen, mural thrombus within an aortic aneurysm, or severe aortic atherosclerosis may be difficult. On TEE, identifying the intima—often calcified and echodense—helps in making this distinction. Thickening beneath the intima suggests IMH, whereas thickening above the intima (on the luminal side) occurs with mural thrombus in an aneurysm. In contrast to aortic atherosclerosis, IMH is not typically associated with diffuse irregularities in the aortic intima surface unless related to a penetrating ulcer.



EFIGURE 63.33 Computed tomography images showing complete resorption of a proximal hematoma **(upper panels)** and development of typical aortic dissection during medical treatment **(lower panels).**
(From Song JK. Aortic intramural hematoma: aspects of pathogenesis 2011. Herz 2011;36:488-97.)

Early studies from Europe and the United States reported that patients with type A IMH were at high risk for complications, including aortic dissection (25% to 50%), hemopericardium, and rupture, with mortality in excess of 30% with medical therapy alone.[72] Reports from Asia have suggested a much different approach to the management of type A IMH—medical therapy, serial imaging, and careful observation with prolonged hospitalization as an initial strategy—and have reported low mortality rates for many patients.[71] With this approach, however, many patients with type A IMH have progressed to frank dissection (30% to 40%), hemopericardium, or rupture requiring emergency surgery, complications associated with high mortality[1,2,70,72] (**eFig. 63.33**). Given the potential for unpredictable and catastrophic complications, surgical therapy is recommended for type A IMH and medical management for patients with type B IMH.[1,17,69,72] (See Videos 63.20 and 63.21.)

Descending IMH may progress to frank dissection and late aneurysm formation or may be reabsorbed completely. Predictors of complications from IMH are listed in **eTable 63.3**. Management of localized arch IMH must be individualized, with some advocating initial medical therapy for this group. The average 30-day mortality rate in type B IMH is 4% in medically treated patients and 16% in those requiring surgery. Mortality at 3 years was 14% in medically treated patients and 23% for surgically treated patients.[1] Patients with type B IMH require continued surveillance after surgery and while receiving medical therapy. Complete resolution of type B IMH has been described in more than 50% in some series, whereas others have progressed to frank dissection (5%), localized dissection or ULP (25%), rupture (4%), or late aneurysm formation (27%).[1] Frequent imaging follow-up is recommended when ULP is visualized. Predictors of resolution of type B IMH have included younger age, smaller aortic diameter (<4 to 4.5 cm), hematoma thickness less than 1 cm, and postoperative use of beta blockers.[1,69,72] Surgery or TEVAR for type B IMH is reserved for complications such as persistent pain, aortic aneurysm, progression, impending rupture, or rupture.[1,69] The role of TEVAR is unclear in this disorder because there is no intimal defect or patent false lumen, although midterm results for select patients has been favorable.[69,70]

ETABLE 63.3

High-risk Features of Type B Intramural Hematoma (IMH)

HIGH-RISK FEATURE	CUTOFF OR SIGN OF COMPLICATED EVOLUTION
Age (years)	>70
Initial aortic diameter (mm)	>45
Mean aortic diameter growth rate (mm/yr)	≥5
Wall thickness of involved segment (mm)	≥10
Pleural effusion	Presence
Aortic ulcer	Presence
Ulcerlike projection	Presence

Modified from Evangelista A, Czerny M, Nienaber C et al. Interdisciplinary expert consensus on management of type B intramural haematoma and penetrating aortic ulcer. Eur J Cardiothorac Surg 2015;47:209-17.

Penetrating Atherosclerotic Aortic Ulcer

In PAU, an atherosclerotic lesion penetrates through the internal elastic lamina into the media, often associated with a variable degree of IMH formation.[1,2,17,69] PAUs may lead to pseudoaneurysm, aortic rupture, or late aneurysm. Aortic ulcers may be single or multiple and range from 5 to 25 mm in diameter and 4 to 30 mm in depth. PAUs are more common in the middle to distal descending aorta than in the arch or ascending or abdominal aorta.[1,2] PAUs occur in 2% to 7% of symptomatic patients with acute aortic syndrome.[1,69,73] Patients with PAUs are typically elderly and have coexisting vascular disease and many have concomitant aneurysmal dilation of the aorta elsewhere, especially in the abdominal aorta. Even though up to 25% of PAUs are found incidentally on imaging studies, typical symptoms of PAUs include acute chest or back pain, similar in description to that of classic aortic dissection. Although PAUs may lead to aortic dissection, most patients do not have AR, pulse deficits, or visceral ischemia.

Imaging techniques for PAUs include CT, MRI, TEE, and aortography. Findings on CT include focal aortic ulceration, associated IMH, and a calcified, displaced intima[1,2] (**Fig. 63.25**). Typically, a craterlike outpouching with irregular edges occurs in the setting of heavy atherosclerosis. In some cases, it may be difficult to differentiate PAU with an IMH from an IMH with ulcerlike projection.[1,2] CT may also demonstrate pleural effusions, mediastinal hemorrhage, coexisting aneurysms, contained rupture, pseudoaneurysm, and frank rupture. Most patients have some degree of IMH formation. When a PAU is associated with aortic dissection, the dissection often involves a short segment of aorta and has a thick intimal flap. MRI findings in patients with PAUs include localized areas of high signal intensity in the aorta wall consistent with IMH, focal intimal thickening, and ulcerlike projections.[2] TEE demonstrates aortic atherosclerosis with focal ulceration of the intima, often with hematoma.[2]

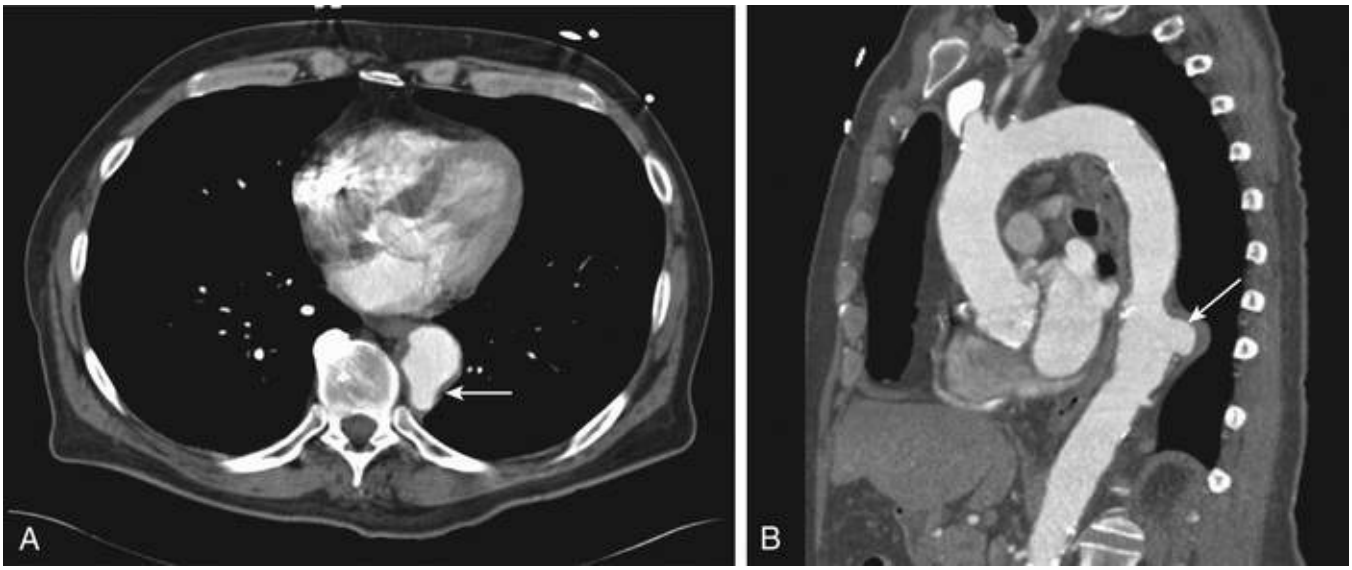


FIGURE 63.25 Contrast-enhanced computed tomography scan demonstrating an acute penetrating atherosclerotic aortic ulcer (PAU). **A,** Axial image demonstrating the typical focal outpouching of the aortic ulcer (*arrow*). **B,** Sagittal image demonstrating the PAU (*arrow*) with associated intramural hematoma. Symptomatic PAU has an increased risk of aortic rupture and is often amenable to endovascular repair. (From Braverman AC. Aortic dissection. In Levine GN, editor. Color Atlas of Cardiovascular Disease. New Delhi, India: Jaypee Brothers Medical Publishers; 2015, pp 895-903.)

PAUs have an uncertain natural history, with variability in the literature depending on patient selection. A PAU may "stabilize" or lead to complications, including IMH, distal embolization, aortic rupture, pseudoaneurysm (contained rupture), aortic dissection, or development of a saccular or fusiform aneurysm.[1] In one study the annual growth rate of PAUs was 0.31 cm/yr. Some studies report gradual aortic enlargement and a low incidence of life-threatening complications, whereas others report a high incidence of acute complications.[69,73] In general, patients with ascending PAUs undergo surgical resection. Stable patients with type B PAUs may be managed medically, with close follow-up and serial imaging. When an asymptomatic PAU is discovered, serial imaging studies are required to document stability.[69] Patients with refractory or recurrent pain, overlying IMH or periaortic hemorrhage, or rapid increase in size are at increased risk of rupture and should undergo invasive treatment.[1,17,69,73] Indications for TEVAR or surgery may include the development of hemorrhage, periaortic hematoma, expanding pseudoaneurysm, saccular aneurysm formation, continued pain, or rupture.[69] Predictors of disease progression include increasing aortic wall thickness, ulcer craters greater than 15 to 20 mm in diameter or 10 mm in depth, increasing aortic hematoma, and increasing pleural effusion.[69,74] The short segment involved and the high-risk patient population make TEVAR preferable to OSR.[69,73] Of 310 patients with PAU treated with TEVAR, the 30-day mortality was 5% and 1-year survival, 91%.[73] Endoleaks may complicate TEVAR for PAU in 5% to 20% of cases, with more recent studies reporting lower risk.[69,73,74] In-hospital mortality for PAU requiring TEVAR is estimated at 4% to 11%,[74] and aortic-related mortality of 4% at 18 months is reported.[73] Others report a 5-year survival of 65% after TEVAR for PAU.[1,69]

Aortoarteritis Syndromes

Bacterial Infections of the Aorta

Infected aortic aneurysms (*mycotic aneurysms*) are a rare but lethal condition and account for less than 1% of all aneurysms undergoing surgery.[75] Infection may result from contiguous spread from adjacent thoracic tissues, such as mediastinitis, abscess, infected lymph nodes, empyema, or paravertebral

abscess. Other causes include septic emboli from endocarditis and hematogenous dissemination of bacteria in the setting of sepsis or IV drug abuse. Infection most often arises in a diseased aorta, whether aneurysmal, atherosclerotic, or traumatized as a result of previous aortic cannulation or suturing.[75] Even though the disease may be insidious in onset, it may also have a fulminant course with frequent aneurysm rupture (>50%) and a high mortality rate (>25% to 50%). Standard treatment has involved resection of the aneurysm, débridement of infected soft tissue, antibiotics, and arterial reconstruction. Most patients undergo in situ aortic grafting, whereas others undergo extra-anatomic bypass. TEVAR is feasible and for many patients, especially those at high risk, may be a reasonable option.[75-77]

The classic triad of an infected aortic aneurysm includes fever; abdominal, back, or chest pain; and a pulsatile tender mass. Most patients, however, do not have these pathognomonic findings. Patients are febrile and have markers of inflammation. Bacteremia is common, but blood cultures may be negative in more than 25% of cases, especially after antibiotic therapy, and in some patients the organism is established only during surgery by culture and Gram stain of the aortic wall.[76,77] Patients often have a comorbid condition (e.g., diabetes, other chronic disease) or an immunocompromised state or may be receiving chronic corticosteroid therapy. Many have recently undergone gastrointestinal operations or invasive procedures. Infected aneurysms typically involve the infrarenal aorta. Infected TAAs are less common, usually affecting the descending aorta and accompanied by rupture or pseudoaneurysm.[77] Infections of prosthetic aortic grafts occur in 1% to 2% of patients. Aortic graft–enteric erosion and fistula are common complications.

The most common microorganisms associated with infected aortic aneurysms include *Staphylococcus aureus* and *Streptococcus* and *Salmonella* species, but infections with gram-negative bacilli and fungi can occur.[75] Even though *Salmonella* can infect an underlying atherosclerotic aortic aneurysm, this microbe may directly penetrate an intact intima of a normal aortic wall and lead to arteritis and aneurysm formation. Thus the clinician should always suspect underlying aortic seeding when *Salmonella* bacteremia occurs.

CT, MRI, and aortography may be diagnostic in patients with infected aortic aneurysms. Saccular aneurysms resulting from rapid focal arterial wall degeneration are most common[75] (**Fig. 63.26 and eFig. 63.34**). Features on CT include disruption of calcification, irregular wall thickening, periaortic mass, rim enhancement, and periaortic stranding. The presence of gas and vertebral body erosion is highly suggestive of infection. Aortocaval or aortoenteric fistulas may complicate infected aneurysms. Infected aneurysms may expand rapidly and have a propensity to rupture. Because most descending or abdominal aneurysms are atherosclerotic, lack of calcium in an involved aorta may suggest infection. MRI features of infected aneurysms include a soft tissue mass, stranding, and rim enhancement. Nuclear imaging studies with ^{111}In-labeled white blood cell scans have also been used. Fluorodeoxyglucose positron emission tomography (FDG-PET) may assist in diagnosing mycotic aneurysms and graft infections by detecting hypermetabolic activity and can monitor response to antibiotic therapy.[2,75]

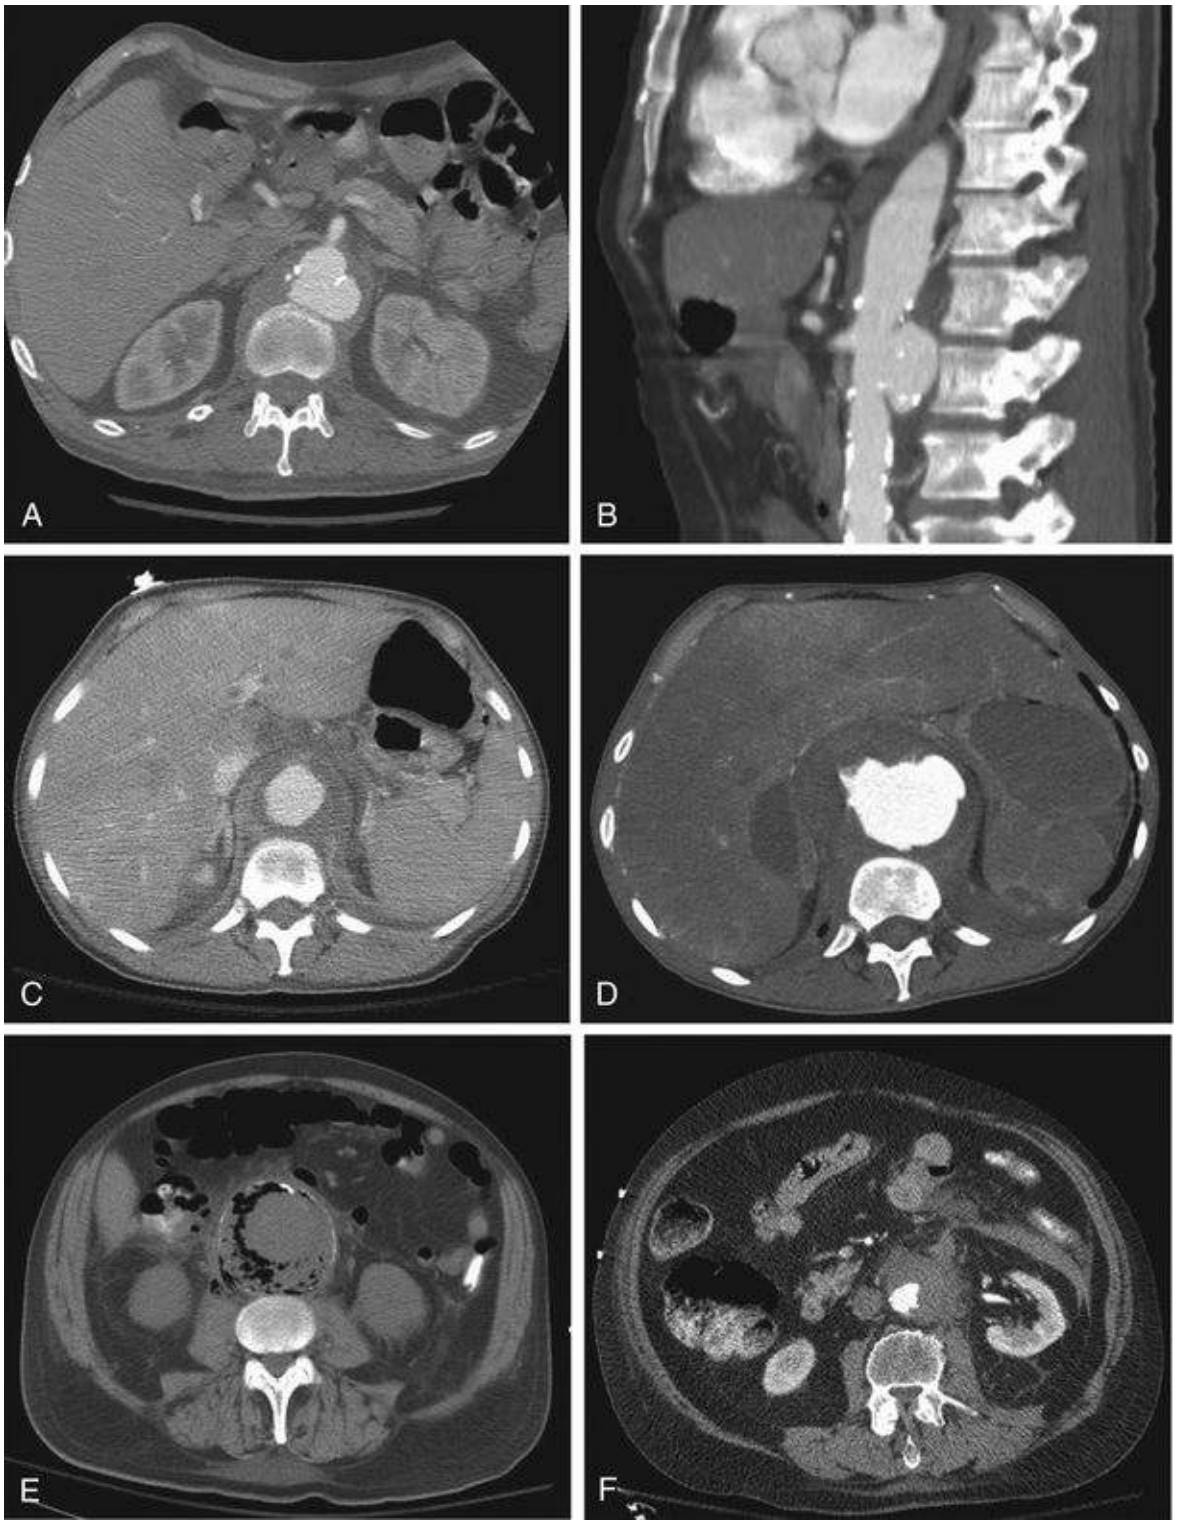

FIGURE 63.26 Typical features of mycotic aneurysms (MAs) on computed tomography. **A, B,** MAs classically present as focal outpouchings of the vascular wall, as seen on axial **(A)** and sagittal **(B)** images. In this case, there is calcification of the aortic wall, which may have been a nidus for infection. **C, D,** MAs tend to grow rapidly, as in this case, with images at initial presentation **(C)** and 2 weeks later **(D).** Also noted is irregularity of the aortic wall and mural thrombus. **E,** Inflammatory changes are common, as in this case with gas in the aortic wall in an MA due to infection by adjacent diverticulitis. **F,** MAs are prone to rupture. (From Deipolyi AR, Rho J, Khademhosseini A, Oklu R. Diagnosis and management of mycotic aneurysms. Clin Imaging 2016;40:256-62.)

EFIGURE 63.34 Example of mycotic aortic aneurysm (MA) treated with endovascular repair. Axial **(A)** and coronal **(B)** contrast-enhanced computed tomography images demonstrate a focal saccular outpouching, with surround inflammatory changes and rupture. **C,** Positron emission tomography demonstrates uptake in the aortic wall and in an adjacent vertebral body, concerning for extension of infection. **D,** Sagittal T2-weighted magnetic resonance image shows high signal in the adjacent vertebrae and discs, consistent with associated discitis/osteomyelitis. Again, MA is shown as a focal saccular outpouching with inflammatory changes. **E,** Aortogram demonstrates filling of the focal outpouching in the distal thoracic aorta. A stent graft is in position, just prior to being deployed. **F,** The covered stent has been deployed and postdilated. **G,** Completion aortogram demonstrates exclusion of the aneurysm by the stent. (From Deipolyi AR, Bailin A, Khademhosseini A, Oklu R. Imaging findings, diagnosis, and clinical outcomes in patients with mycotic aneurysms: single center experience. Clin Imaging 2016;40:512-6.)

Untreated infected aortic aneurysms generally expand and eventually rupture, often with rapid progression. *Salmonella* and other gram-negative infections have a greater tendency for early rupture and death.[77] Overall mortality from infected aortic aneurysms exceeds 50% with medical therapy alone. Treatment of infected AAAs involves excision or exclusion of the infected aortic tissue, in situ or extra-anatomic bypass of the aorta and branches, débridement of infected periaortic tissue, and prolonged antibiotic therapy. Many infected aneurysms are in locations not amenable to conventional extra-anatomic reconstruction. When infrarenal AAAs are associated with extensive aortic and periaortic purulence, extra-anatomic bypass is performed. In situ bypass is more often performed in the patient with suprarenal aneurysms or infrarenal aneurysms with minimal purulence. Recent surgical series have reported a short-term mortality of 10% to 40%, and higher mortality with OSR of thoracic aortic mycotic aneurysm.[75-77] Two-year survival is reported at 60%.[77] Subsequent graft infections complicate approximately 10% of patients, with extra-anatomic bypass resulting in worse outcomes compared to in situ repair.[77] Because many patients have a high risk for complications of surgery for infected aortic aneurysms, some advocate endovascular repair for select patients who are not suitable for OSR, either as a bridge to open repair or

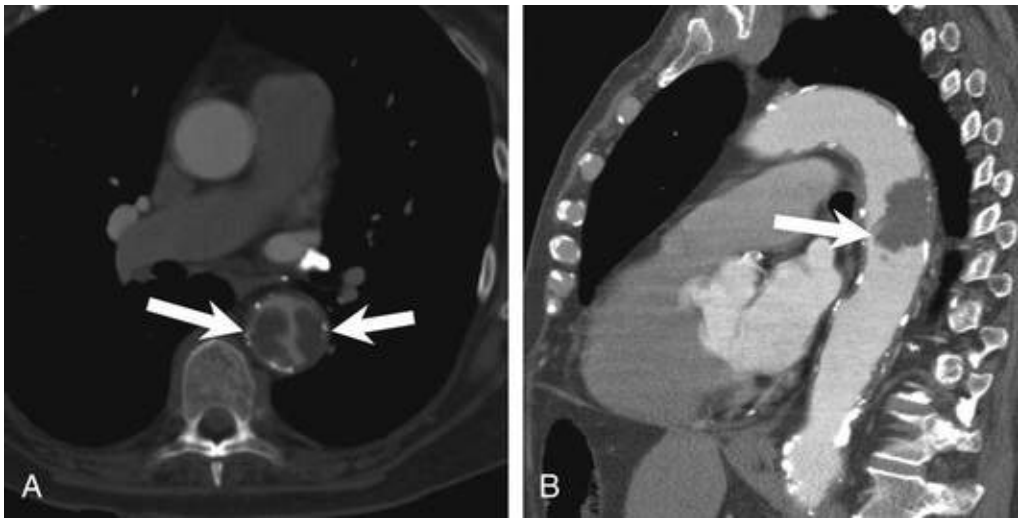
as definitive therapy[77] (**eFig. 63.34**). In a series of 130 aortic mycotic aneurysms treated with endovascular repair, infection-related mortality was 19%, with survival of 91%, 75%, 55%, and 41% after 1 month, 12 months, 60 months, and 120 months, respectively.[77]

Endovascular abdominal stent-graft infections are uncommon, with an incidence of 0.05% to 5%.[78] Pseudoaneurysm and aneurysm expansion and rupture may occur. Treatment includes removal of the infected stent-graft. Antibiotic-soaked in situ grafting is most frequently used, and some patients require axillofemoral bypass with total graft excision and oversewing of the aorta stump.[78]

Primary Tumors of the Aorta

Tumors that affect the thoracic aorta usually arise secondarily from direct invasion by adjacent cancer or metastases, especially from the lung and esophagus. Primary aortic sarcomas are very rare and are usually unsuspected until histologic analysis reveals malignancy. The average age at diagnosis is 60 years, with a male preponderance.[79] High-grade tumors (87%), arterial embolization (47%), and metastatic disease at diagnosis (45%) are common.[79] These tumors most often localize in the descending thoracic and abdominal aorta. Symptoms include pain, embolism, claudication, visceral ischemia, or constitutional symptoms. Less frequently, these tumors may cause hemorrhage or invade adjacent structures. Three categories of tumors have been described: *intraluminal* (polypoid), *intimal* (derived from endothelial cells or myofibroblasts), and *adventitial* (mural, fibrosarcomas). Intraluminal and intimal tumors are the most common and spread along the inner wall of the aorta, appearing polypoid on imaging. They may be accompanied by acute arterial embolization, with the embolus a mixture of tumor and thrombus, or may lead to arterial obstruction or involvement of visceral arteries. Widely metastatic emboli may occur. Adventitial (mural) tumors are rare and grow to involve periaortic tissue and adjacent organs.

Aortic tumors are of mesenchymal origin and include angiosarcoma (37%), leiomyosarcoma (13%), fibrous tumor (7%), and undifferentiated sarcoma (39%). CT may detect intimal tumors (**eFig. 63.35**), but the findings may mimic protruding atheroma. MRI is considered the most reliable imaging modality and may differentiate between tumor and atheromatous material. If no metastases are present, resection with prosthetic graft replacement is recommended. Because of difficulty in achieving wide margins, tumors may recur locally. Palliative treatment of obstructive tumors includes endarterectomy, endovascular grafts, and extra-anatomic bypass. Chemotherapy and radiation therapy have been used in some cases with limited success. The median survival is 11 months, with 1-, 3-, and 5-year survival rates of 47%, 17%, and 9%, respectively.[79]



EFIGURE 63.35 Intimal sarcoma of the descending thoracic aorta in a 70-year-old woman. Contrast-enhanced computed tomography shows an irregular low-density mass (*arrows*) partially filling the aortic lumen in the axial **(A)** and sagittal **(B)** planes. Extensive atherosclerotic calcifications appear throughout the aortic wall. (From Restrepo CS, Betancourt SL, Martinez-Jimenez S, et al. Aortic tumors. Semin Ultrasound CT MR 2012;33:265.)

Future Perspectives

Aortic disease has witnessed remarkable advances through discoveries in basic science, animal experimentation, genetics, clinical consortiums and registries, and translational research. Multiple trials of pharmacotherapy in degenerative AAA disease and heritable TAA disorders have advanced translational science and stimulated new proposals into pathogenesis, identifying potential targets for therapy. Partnerships with patient advocacy organizations have improved awareness of aortic disease. Recent management guidelines for thoracic aortic disease have furthered the evaluation and treatment of these disorders. Large registries, including IRAD, GERAADA, and GenTAC, provide important clinical and translational platforms for understanding aortic disease.

Advances in imaging the aorta structurally and functionally, with techniques to understand the biomechanical forces, four-dimensional flow characteristics, and biologic activity in the aortic wall, hold promise in understanding and managing patients with aortic disease. Remarkable advances in endovascular, hybrid, and open surgical repair have reduced morbidity and mortality for many aortic diseases. The role of endovascular therapy for aneurysm disease and acute and chronic dissection is likely to evolve over time as branched grafts and lower-profile delivery systems become available. Treatment of uncomplicated type B dissection with TEVAR may change the natural history of this disorder.

Surgical Therapy and Outcomes with Thoracoabdominal Aortic Aneurysms

Crawford type I involves the entire thoracic aorta and the upper abdominal aorta extending from the proximal descending aorta above the T6 vertebra to the level of the renal arteries (~25 of TAAAs); type II is the highest risk group, with the aneurysm involving the entire thoracic and most or all of the abdominal aorta extending from the proximal descending aorta above T6 to below the renal arteries, often to the iliac bifurcation (30% of TAAAs); type III aneurysms involve the distal half of the descending thoracic aorta below T6 and extend into the abdominal aorta (<25% of TAAAs); and type IV extends from the diaphragm and involves most of the abdominal aorta to the aortic bifurcation (<25% of TAAAs).

Crawford type V aneurysms arise in the distal half of the descending aorta (below T6) and extend into the abdominal aorta, but are limited to the visceral segment.[1] Repair of Crawford types I-III aneurysms is complex and usually performed through an extensive thoracoabdominal incision. The procedure requires bypass to maintain perfusion of the lower extremities and the mesenteric vessels. Spinal fluid drainage and other techniques, as for thoracic aneurysms, may diminish the risk for paraplegia and paraparesis. The mortality rate in low-risk patients is 3% to 10%, with a paraplegia rate of 3% to 5%, depending on the extent of the repair. Morbidity and mortality with repair of Crawford type IV aneurysms is intermediate between AAA and type I-III TAAA. Emergency surgery for rupture or leak carries a mortality rate of 80%.[1]

Guidelines

Diseases of the Aorta

Alan C. Braverman and Marc Schermerhorn

Recommendations on Imaging of the Aorta[2]

Class I

1. It is recommended that diameters be measured at prespecified anatomic landmarks, perpendicular to the longitudinal axis. (*Level of evidence: C*)
2. In the case of repetitive imaging of the aorta over time, to assess change in diameter, it is recommended that the imaging modality with the lowest iatrogenic risk be used. (*Level of evidence: C*)
3. In the case of repetitive imaging of the aorta over time to assess change in diameter, it is recommended that the same imaging modality be used, with a similar method of measurement. (*Level of evidence: C*)

Class IIb

Aortic diameters may be indexed to the body surface area, especially for the outliers in body size.

(*Level of evidence: B*)

Recommendation in Patients with Aortic Aneurysm[2]

Class IIa

In cases of abdominal aortic aneurysm (AAA), duplex ultrasound for screening for peripheral artery disease and peripheral aneurysms should be considered. (*Level of evidence: C*)

Evaluation and Management of Acute Thoracic Aortic Disease

Recommendations for Screening Tests

Class I

1. An electrocardiogram (ECG) should be obtained in all patients with symptoms that may represent acute aortic dissection.[1]
    a. Given the relative infrequency of dissection-related coronary artery occlusion, the presence of ST-segment elevation suggestive of myocardial infarction (MI) should be treated as a primary cardiac event without delay for definitive aortic imaging unless the patient is at high risk for aortic dissection. *(Level of evidence: B)*
2. Urgent and definitive imaging of the aorta with transesophageal echocardiography (TEE), computed tomography (CT), or magnetic resonance imaging (MRI) is recommended to identify or exclude aortic dissection in patients determined to be at high risk for the disease by initial screening.[1] *(Level of evidence: B)*

Class IIa

1. In case of suspicion of acute aortic syndrome (AAS), the interpretation of biomarkers should always be considered along with the pretest clinical probability.[2] (*Level of evidence: C*)
2. In case of low clinical probability of AAS, negative D-dimer levels should be considered as ruling out the diagnosis.[2] (*Level of evidence: B*)
3. In case of intermediate clinical probability of AAS with positive (point-of-care) D-dimer test, further imaging tests should be considered.[2] (*Level of evidence: B*)

Class III

1. A negative finding on chest radiography should not delay definitive aortic imaging in patients determined to be high risk for aortic dissection by initial screening.[1] *(Level of evidence: C)*
2. In patients with high probability (risk score 2 or 3) of aortic dissection, testing of D-dimers is not recommended.[2] (*Level of evidence: C*)

Recommendations for Diagnostic Imaging Studies

Class I

1. Selection of a specific imaging modality (CT, MRI, TEE, TTE[2]) to identify or exclude aortic dissection should be based on patient variables and institutional capabilities, including immediate availability.[1,2] *(Level of evidence: C)*
2. If high clinical suspicion exists for acute aortic dissection but the findings on initial aortic imaging are negative, a second imaging study should be obtained.[1,2] (*Level of evidence: C*)
3. In case of uncomplicated type B aortic dissection treated medically, repeated imaging (CT or MRI) during the first days is recommended.[2] (*Level of evidence: C*)

Recommendations for Intramural Hematoma (IMH) Without Intimal Defect or Penetrating Aortic Ulcer (PAU)

Class I

1. In all patients with IMH or PAU, medical therapy including pain relief and blood pressure control is recommended.[2] (*Level of evidence: C*)
2. In cases of type A IMH or PAU, urgent surgery is indicated.[2] (*Level of evidence: C*)
3. In cases of type B IMH or PAU, initial medical therapy under careful surveillance is recommended.[2] (*Level of evidence: C*)

Class IIa

1. It is reasonable to treat IMH similar to aortic dissection in the corresponding segment of the aorta.[1] *(Level of evidence: C)*
2. In complicated type B IMH or PAU, thoracic endovascular aortic repair (TEVAR) should be considered.[2] (*Level of evidence: C*)

Class IIb

In complicated type B IMH or PAU, surgery may be considered.[2] (*Level of evidence: C*)

Surgical and Endovascular Treatment by Location of Disease

Ascending Aorta and Aortic Sinuses

Recommendations for Asymptomatic Patients with Ascending Aortic Aneurysms

Class I

1. Asymptomatic patients with a degenerative thoracic aortic aneurysm (TAA), chronic aortic dissection, IMH, PAU, mycotic aneurysm, or pseudoaneurysm who are otherwise suitable

candidates and in whom the diameter of the ascending aorta or aortic sinus is 5.5 cm or greater should be evaluated for surgical repair.[1] *(Level of evidence: C)*

2. Surgery is indicated in patients who have aortic root aneurysm, with maximal aortic diameter of 50 mm or more for patients with Marfan syndrome.[2] (*Level of evidence: C*)
3. Patients undergoing aortic valve repair or replacement and who have an ascending aorta or aortic root larger than 4.5 cm should be considered for concomitant repair of the aortic root or replacement of the ascending aorta.[1] *(Level of evidence: C)*

Class IIa

1. Elective aortic replacement is reasonable for patients with Marfan syndrome, other genetic diseases, or bicuspid aortic valve (BAV) when the ratio of maximal ascending or aortic root area in square centimeters divided by the patient's height (in meters) exceeds 10.[1] *(Level of evidence: C)*
2. It is reasonable for patients with Loeys-Dietz syndrome or a confirmed *TGFBR1* or *TGFBR2* mutation to undergo aortic repair when the aortic diameter reaches 4.2 cm or greater by TEE (internal diameter) or 4.4 to 4.6 cm or greater by CT or MRI (external diameter).[1] *(Level of evidence: C)*
3. In short-statured patients with Turner syndrome and BAV disease, absolute measurement of aortic root or ascending aortic diameter may not predict the risk of aortic dissection, as well as aortic diameter index greater than 2.5 cm/m^2. In addition, in a study of patients with BAV disease, a maximum aortic cross-sectional area-to-height ratio greater than 10 cm^2/m was also a predictor of aortic dissection.[1] (*Level of evidence: B-NR*)

Recommendations for Aortic Arch Aneurysms

Class IIa

For patients with low operative risk in whom an isolated degenerative aneurysm of the aortic arch is present, operative treatment is reasonable for asymptomatic patients when the diameter of the arch exceeds 5.5 cm.[1,2] *(Level of evidence: B)*

Descending Thoracic Aorta and Thoracoabdominal Aorta

Recommendations for Descending Thoracic Aorta and Thoracoabdominal Aortic Aneurysms

Class I

1. For patients with chronic dissection, particularly if associated with a connective tissue disorder, no significant comorbid disease, and a descending thoracic aortic diameter greater than 5.5 cm, open repair is recommended.[1] *(Level of evidence: B)*
2. For patients with degenerative or traumatic descending TAAs exceeding 5.5 cm, saccular aneurysms, or postoperative pseudoaneurysms, TEVAR should be strongly considered when

feasible.[1] *(Level of evidence: B)*

3. For patients with thoracoabdominal aneurysms in whom TEVAR options are limited and surgical morbidity is elevated, elective surgery is recommended if the aortic diameter exceeds 6.0 cm—or less if a connective tissue disorder such as Marfan or Loeys-Dietz syndrome is present.[1] *(Level of evidence: C)*

Class IIa

1. TEVAR should be considered in patients who have descending TAA with maximal diameter of 55 mm or more.[2] *(Level of evidence: C)*
2. When TEVAR is not technically possible, surgery should be considered in patients who have descending TAA with maximal diameter of 60 mm or more. *(Level of evidence: C)*

Counseling and Management of Chronic Aortic Diseases in Pregnancy

Recommendations for Counseling and Management of Chronic Aortic Diseases in Pregnancy[1]

Class I

1. Women with Marfan syndrome and aortic dilation, as well as patients without Marfan syndrome who have known aortic disease, should be counseled about their risk for aortic dissection, in addition to the heritable nature of the disease, before pregnancy. *(Level of evidence: C)*
2. For pregnant women with known thoracic aortic dilation or a familial or genetic predisposition to aortic dissection, strict blood pressure control, specifically to prevent stage II hypertension, is recommended. *(Level of evidence: C)*
3. For all pregnant women with known aortic root or ascending aortic dilation, monthly or bimonthly echocardiographic measurement of ascending aortic dimensions until birth is recommended to detect aortic expansion. *(Level of evidence: C)*
4. Pregnant women with aortic aneurysms should undergo delivery at locations where cardiothoracic surgery is available. *(Level of evidence: C)*

Class IIa

Fetal delivery via cesarean section is reasonable for patients with significant aortic enlargement, dissection, or severe aortic valve regurgitation. *(Level of evidence: C)*

Class IIb

If progressive aortic dilation or advancing aortic valve regurgitation is documented, prophylactic surgery may be considered. *(Level of evidence: C)*

Recommendations for Surveillance of Thoracic Aortic Disease or Previously Repaired Patients[1]

Class IIa

1. CT or MRI of the thoracic aorta is reasonable after a type A or B aortic dissection or after prophylactic repair of the aortic root/ascending aorta. *(Level of evidence: C)*
2. CT or MRI of the aorta is reasonable at 1, 3, 6, and 12 months after dissection and, if stable, annually thereafter so that any threatening enlargement can be detected in timely fashion. *(Level of evidence: C)*

Diagnosis and Management of Patients With Thoracic Aortic Disease: Genetic Syndromes Associated with Thoracic Aortic Aneurysms and Dissection

Recommendations for Genetic Syndromes[1]

Class I

1. An echocardiogram is recommended at diagnosis of Marfan syndrome to determine aortic root and ascending aortic diameters, and at 6 months thereafter to determine the rate of enlargement of the aorta. *(Level of evidence: C)*
2. Annual imaging is recommended for patients with Marfan syndrome if stability of the aortic diameter is documented. If the maximal aortic diameter is 4.5 cm or greater or if the aortic diameter shows significant growth from baseline, more frequent imaging should be considered. *(Level of evidence: C)*
3. Patients with Loeys-Dietz syndrome or a confirmed genetic mutation known to predispose to aortic aneurysms and aortic dissections (e.g., *TGFBR1*, *TGFBR2*, *FBN1*, *ACTA2*, *MYH11*) should undergo complete aortic imaging at initial diagnosis and 6 months thereafter to establish whether enlargement is occurring. *(Level of evidence: C)*

Class IIa

For women with Marfan syndrome contemplating pregnancy, it is reasonable to replace prophylactically the aortic root and ascending aorta if the diameter exceeds 4.0 cm. *(Level of evidence: C)*

Class IIb

In patients with Turner syndrome and additional risk factors, including a BAV, coarctation of the aorta, or hypertension, and in patients who attempt to become pregnant or who become pregnant, it may be reasonable to perform imaging of the heart and aorta to help determine the risk for aortic

dissection. *(Level of evidence: C)*

Recommendations on Genetic Testing in Aortic Diseases

Class I

1. Aortic imaging is recommended for first-degree relatives of patients with TAA and/or dissection to identify those with asymptomatic disease.[1] *(Level of evidence: B)*
2. If the mutant gene associated with aortic aneurysm or dissection is identified in a patient, first-degree relatives should undergo counseling and testing. Then, only relatives with the genetic mutation should undergo aortic imaging.[1] *(Level of evidence: C)*
3. It is recommended to investigate first-degree relatives of a patient with thoracic aortic aneurysm and dissection syndrome (TAAD) to identify a familial form in which relatives all have a 50% chance of carrying the familial mutation.[2] *(Level of evidence: C)*
4. Once a familial form of TAAD is highly suspected, it is recommended to refer the patient to a geneticist for family investigation and molecular testing.[2] *(Level of evidence: C)*

Variability of age of onset warrants screening every 5 years of “healthy” at-risk relatives until diagnosis (clinical or molecular) is established or ruled out.[2] *(Level of evidence: C)*

Class IIa

1. If one or more first-degree relatives of a patient with known TAA and/or dissection are found to have thoracic aortic dilation, aneurysm, or dissection, imaging of second-degree relatives is reasonable.[1] *(Level of evidence: B)*
2. In familial nonsyndromic TAAD, screening for aneurysm should be considered, not only in the thoracic aorta, but also throughout the arterial tree, including cerebral arteries.[2] *(Level of evidence: C)*

Class IIb

Sequencing of genes known to cause familial TAAs and/or dissection may be considered in patients with a family history and clinical features associated with mutations in these genes.[1] *(Level of evidence: B)*

Recommendations for Bicuspid Aortic Valve and Associated Congenital Variants in Adults[1]

Class I

1. First-degree relatives of patients with a BAV, premature onset of thoracic aortic disease with minimal risk factors, or a familial form of TAA and dissection should be evaluated for the

presence of a BAV and asymptomatic thoracic aortic disease. *(Level of evidence: C)*

2. All patients with a BAV should have both the aortic root and ascending thoracic aorta evaluated for evidence of aortic dilation. *(Level of evidence: B)*

Recommendation for Employment and Lifestyle in Patients with Thoracic Aortic Disease[1]

Class IIa

For patients with a current TAA or dissection or previously repaired aortic dissection, employment and lifestyle restrictions are reasonable, including avoidance of strenuous lifting, pushing, or straining that would require a Valsalva maneuver. *(Level of evidence: C)*

Peripheral Artery Diseases

Marc P. Bonaca, Mark A. Creager

Peripheral artery disease (PAD) generally refers to acute or chronic obstruction of the arteries supplying the lower or upper extremities that, when severe, results in downstream ischemia and potentially tissue loss.[1] Most often caused by atherosclerosis, PAD may also result from thrombosis, embolism, vasculitis, fibromuscular dysplasia, or entrapment. The term *peripheral vascular disease* is less specific because it encompasses a group of diseases affecting blood vessels that include other atherosclerotic conditions, such as renal artery disease and carotid artery disease, as well as vasculitides, vasospasm, venous thrombosis, venous insufficiency, and lymphatic disorders.

Atherosclerotic PAD correlates strongly with risk for major adverse cardiovascular events (MACE) because it is frequently associated with coronary and cerebral atherosclerosis.[1] Patients with PAD and concomitant symptomatic cerebrovascular or coronary disease are at particularly high risk. Patients with PAD also have limb morbidity, including intermittent claudication, chronic critical limb ischemia, acute limb ischemia, and tissue loss.[2,3] The limb morbidity impacts quality of life and independence and, in its severe forms, is associated with increased mortality.[4]

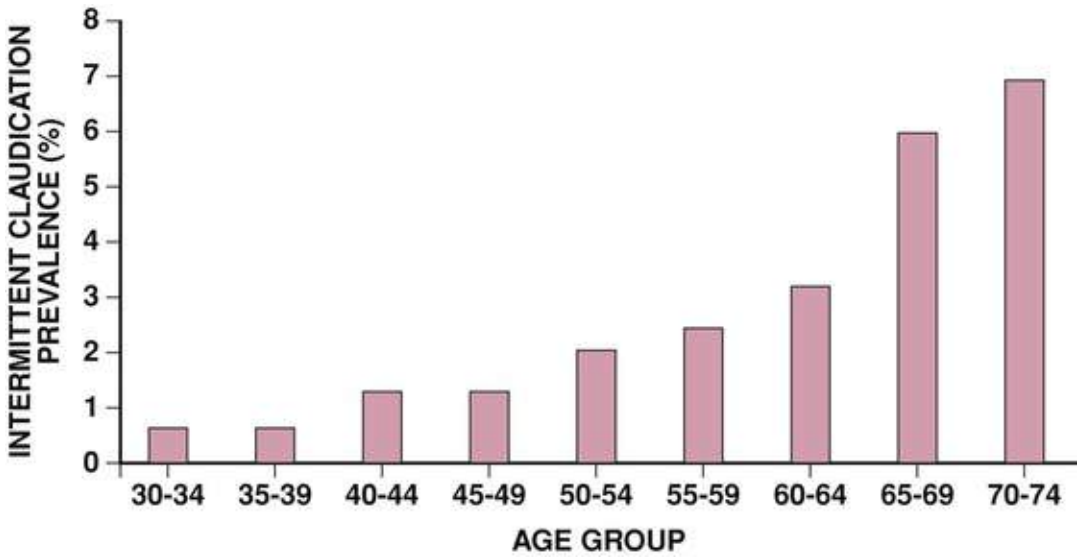
PAD is underdiagnosed, and use of indicated therapies is low.[5] As a manifestation of atherosclerosis associated with increased cardiovascular risk, cardiologists have increasing interest in its diagnosis and management. Clinicians treating patients with PAD not only must be skilled in application of strategies to reduce systemic ischemic risk, but also must know how to characterize the severity of limb disease and use therapies to optimize function and reduce the risk of tissue loss. This chapter provides a framework for the diagnosis and management of patients with PAD.

Epidemiology

The prevalence of PAD varies according to the population studied, the diagnostic method used, and

whether symptoms are included to derive estimates. Most epidemiologic studies have used a noninvasive measurement, the *ankle-brachial index* (ABI), to diagnose PAD. The ABI is the ratio of ankle to brachial systolic blood pressure (see later). The prevalence of PAD based on abnormal ABI values ranges from approximately 6% in persons 40 years and older to 15% to 20% in those 65 years and older.[6,7] PAD affects 8 to 10 million individuals in the United States and more than 200 million people worldwide.[8] The prevalence of PAD is greater in men than in women in most studies. Taking into consideration the total number of women and men in the U.S. population, however, there are more women than men with PAD.[9] Blacks have a higher prevalence of PAD than non-Hispanic whites.[10]

Questionnaires specifically designed to elicit symptoms of *intermittent claudication* can serve to assess the prevalence of symptomatic disease in these populations. Overall, the estimated prevalence of claudication ranges from 1.0% to 4.5% in a population older than 40 years.[1,6] The prevalence and incidence of claudication increase with age and are greater in men than in women in most studies[10] (**eFig. 64.1**). Estimates vary by age and sex but generally indicate that 10% to 30% of patients with PAD have claudication. The incidence of *critical limb ischemia* (CLI) is approximately 22 per 100,000 per year, affecting 1% to 2% of patients with PAD.[1,11] Less information is available on the prevalence and incidence of *acute limb ischemia* (ALI), with estimates among patients with symptomatic PAD of approximately 1% to 2% per year.[3,12] The incidence of *amputation* ranges from 112 to 250 per million per year.



EFIGURE 64.1 Age-related prevalence of intermittent claudication derived from large population-based studies. (From Norgren L, Hiatt WR, Dormandy JA, et al. Inter-Society Consensus for the Management of Peripheral Arterial Disease [TASC II]. Eur J Vasc Endovasc Surg 2007;33:S1.)

Risk Factors for Peripheral Artery Disease

The well-known modifiable risk factors associated with coronary atherosclerosis also contribute to atherosclerosis of the peripheral circulation (**see Chapter 45**). The risk factors most strongly associated with the greatest risk of PAD are cigarette smoking and diabetes mellitus (DM); dyslipidemia, hypertension, chronic kidney disease, and inflammation, as measured by C-reactive protein (CRP) concentration, are also associated with increased risk for PAD (**Table 64.1**). Data from several observational studies indicate a twofold to fourfold increase in the prevalence of PAD in current smokers

in comparison to never smokers, with smoking cessation associated with better outcomes.[13,14] A dose-response relationship exists between lifetime exposure to cigarettes and the incidence of symptomatic PAD. In the Women's Health Study the hazard ratio for incident symptomatic PAD in smokers of more than 15 cigarettes per day was 17 (95% confidence interval [CI] 11 to 27); the risk decreased following smoking cessation.[13] Patients with DM often have extensive and severe PAD and a greater propensity for arterial calcification.[15] Metabolic syndrome is also associated with PAD.[16] Involvement of the femoral and popliteal arteries resembles that in nondiabetic persons, but distal disease affecting the tibial and peroneal arteries occurs more frequently. Among patients with PAD, diabetic patients are more likely than nondiabetic patients to have critical limb ischemia or to undergo an amputation.[15] Abnormalities in lipid metabolism are associated with PAD. Elevations in total or low-density lipoprotein (LDL) cholesterol increase the risk for PAD and claudication in most studies. Hypertriglyceridemia predicts risk for PAD when considered as an independent variable, but its effect diminishes when considered in the context of other lipid fractions.[11,17] In addition, hypertension increases the risk for PAD by 1.3- to 2.2-fold.[17,18] The risk for development of PAD and intermittent claudication increases progressively with the number of risk factors.

TABLE 64.1

Odds Ratio of Peripheral Artery Disease in Persons With Risk Factors

RISK FACTOR	ODDS RATIO (95% CI)
Cigarette smoking	4.46 (2.25-8.84)
Diabetes mellitus	2.71 (1.03-7.12)
Hypertension	1.75 (0.97-3.13)
Hypercholesterolemia	1.68 (1.09-2.57)
Hyperhomocysteinemia	1.92 (0.95-3.88)
Chronic kidney disease	2.00 (1.08-3.70)
Insulin resistance	2.06 (1.10-4.00)
C-reactive protein	2.20 (1.30-3.60)

Data derived from reports of the National Health and Nutrition Examination Survey (NHANES): Selvin E, Erlinger TP. The pathobiology of PAD involves inflammation, as does atherosclerosis in other tissue beds.[19] High concentrations of fibrinogen are associated with an increased risk of developing PAD, most likely a reflection of increased inflammation rather than a procoagulant effect. Levels of leukocyte adhesion molecules and characteristics of leukocyte-platelet aggregates correlate with the development and extent of PAD.[20,21] Levels of CRP, monocytes, and lipoprotein-associated phospholipase A_2 in peripheral blood are independently associated with PAD, consistent with a role of innate immunity and chronic inflammation in its pathogenesis.[19,22] Conversely, serum bilirubin, an endogenous antioxidant with anti-inflammatory properties, is associated with reduced PAD prevalence. Inflammation provides the mechanistic link between many of the common risk factors for atherosclerosis and the pathophysiologic processes in the arterial wall that lead to PAD.

Pathophysiology of Peripheral Artery Disease

Intermittent claudication results from an oxygen (O_2) supply-demand mismatch analogous to angina in

patients with stable angina. Impairment in O_2 delivery capacity coupled with dysfunction in O_2 extraction and utilization at the muscular level result in ischemic pain through activation of local sensory receptors by accumulation of lactate or other metabolites (**Fig. 64.1**). Patients with intermittent claudication may have single or multiple occlusive lesions in the arteries supplying the limb. Blood flow and leg O_2 consumption are normal at rest, but the obstructive lesions limit blood flow and O_2 delivery during exercise such that the metabolic needs of the exercising muscle outstrip the available supply of O_2 and nutrients. Patients with critical limb ischemia typically have multiple occlusive lesions such that even the resting blood supply cannot meet the nutritional needs of the limb, leading to rest pain and tissue loss.

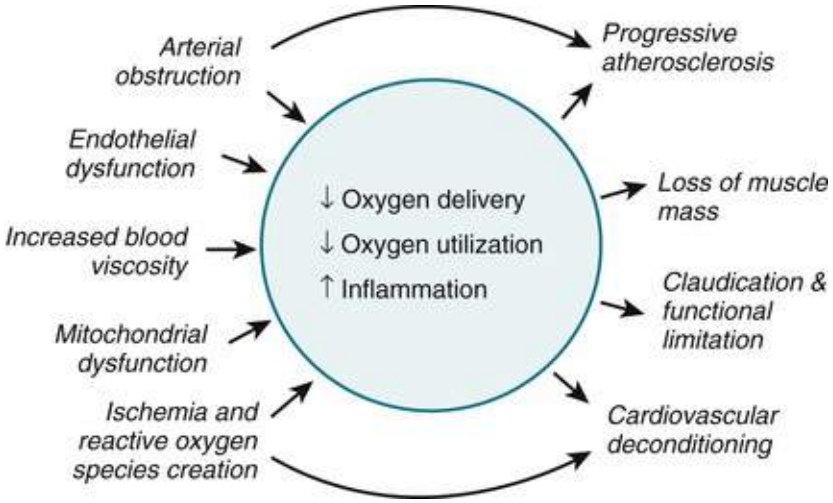

FIGURE 64.1 Mechanisms for functional limitations in peripheral artery disease (PAD). (Modified from Bonaca MP, Creager MA. Pharmacological treatment and current management of peripheral artery disease. Circ Res 2015;116:1579-98.)

Factors Regulating Blood Supply

Flow through an artery is directly related to perfusion pressure and inversely related to vascular resistance (**see Chapter 57**). Stenoses reduce flow through the artery (**Fig. 64.2**), as described in the Poiseuille equation:

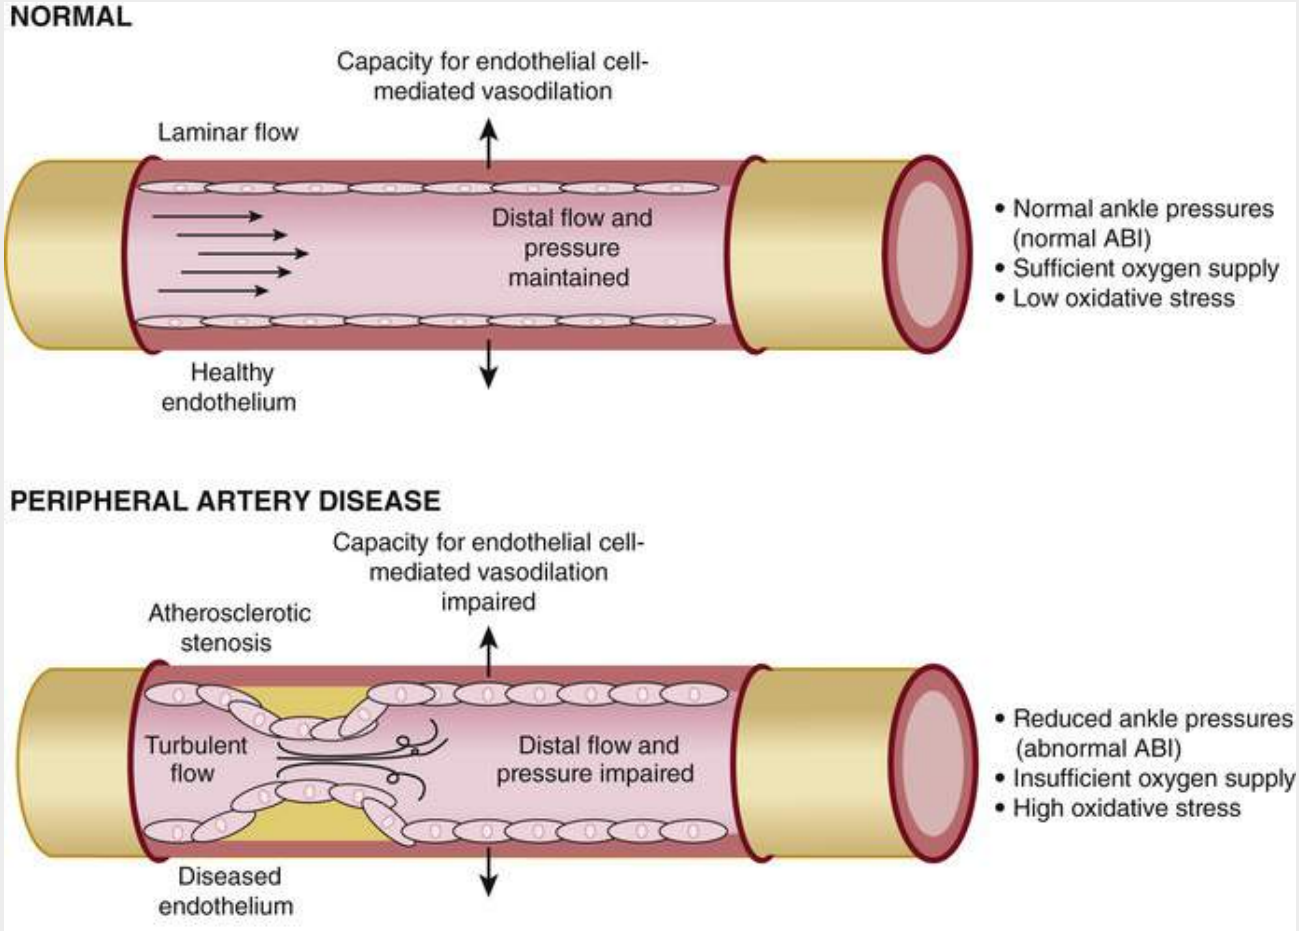

FIGURE 64.2 Pathophysiology of intermittent claudication. In healthy arteries **(top)**, flow is laminar, and endothelial function is normal; therefore blood flow and oxygen delivery match muscle metabolic demand at rest and during exercise. Muscle metabolism is efficient and results in low oxidative stress. In contrast, in PAD **(bottom)**, arterial stenosis results in disturbed flow, and the loss of kinetic energy results in a drop in pressure across the stenosis. Collateral vessels have high resistance and only partially compensate for the arterial stenosis. In addition, endothelial function is impaired, thereby resulting in further loss of vascular function. These changes limit the blood flow response to exercise and result in a mismatch of oxygen delivery to muscle metabolic demand. Changes in skeletal muscle metabolism further compromise the efficient generation of high-energy phosphates. Oxidant stress, the result of inefficient oxidation, further impairs endothelial function and muscle metabolism. ABI, Ankle-brachial index.

$$Q = \frac{\Delta P \pi r^4}{8 \eta l}$$

where ΔP is the pressure gradient across the stenosis, *r* is the radius of the residual lumen, η is blood viscosity, and *l* is the length of the vessel affected by the stenosis. As the severity of a stenotic lesion increases, flow falls progressively. The pressure gradient across the stenosis increases in a nonlinear manner, thus emphasizing the importance of a stenosis at high blood flow rates. Usually, a blood pressure gradient exists at rest if the stenosis reduces the diameter of the lumen by more than 50% because as distorted flow develops, kinetic energy is lost. A stenosis that does not cause a pressure gradient at rest may cause one during exercise when blood flow increases because of the higher cardiac output and decreased vascular resistance. Consequently, as flow through a stenosis increases, distal perfusion pressure drops. As the metabolic demand of exercising muscle outstrips its blood supply, local metabolites (including adenosine, nitric oxide [NO], potassium [K^+]), and hydrogen ion [H^+]) accumulate, and peripheral resistance vessels dilate. Perfusion pressure then drops further because the

stenosis limits flow. In addition, intramuscular pressure rises during exercise and may exceed the arterial pressure distal to an occlusion and halt blood flow. Flow through collateral blood vessels can usually meet the resting metabolic needs of skeletal muscle tissue at rest but does not suffice during exercise.

Functional abnormalities in vasomotor reactivity may also interfere with blood flow. Patients with peripheral atherosclerosis have reduced vasodilator capability of both conduit and resistance vessels. Normally, arteries dilate in response to pharmacologic and biochemical stimuli, such as acetylcholine, serotonin, thrombin, and bradykinin, as well as in response to shear stress induced by increases in blood flow. This vasodilator response results from the release of biologically active substances from the endothelium, particularly NO. The vascular relaxation of a conduit vessel that occurs after a flow stimulus, such as that induced by exercise, may facilitate the delivery of blood to exercising muscles in healthy persons. The atherosclerotic femoral arteries and calf resistance vessels of patients with PAD have impaired endothelium-dependent vasodilation in response to flow or pharmacologic stimuli. This failure of vasodilation might prevent an increase in nutritive blood supply to exercising muscle because endothelium-derived NO can contribute to hyperemic blood flow after an ischemic stimulus.

Abnormalities in the microcirculation also contribute to the pathophysiology of CLI. Patients with severe limb ischemia have a reduced number of perfused skin capillaries. Other potential causes of decreased capillary perfusion in CLI include reduced red blood cell deformability, increased leukocyte adhesiveness, platelet aggregates, fibrinogen, microvascular thrombosis, excessive vasoconstriction, and interstitial edema. Intravascular pressure may also decrease because of precapillary arteriolar dilation secondary to locally released vasoactive metabolites.[23]

Skeletal Muscle Structure and Metabolic Function

Electrophysiologic and histopathologic examination has found evidence of partial axonal denervation of skeletal muscle in legs affected by PAD. Type I, oxidative slow-twitch fibers are preserved, but type II, glycolytic fast-twitch fibers are lost in the skeletal muscle of patients with PAD. The loss of type II fibers correlates with decreased muscle strength and reduced exercise capacity. In skeletal muscle distal to PAD, the shift to anaerobic metabolism occurs earlier during exercise and persists longer after exercise. Patients with claudication have increased lactate release and accumulation of acylcarnitines during exercise and slowed O_2 desaturation kinetics, indicative of ineffective oxidative metabolism.[23] Moreover, mitochondrial respiratory activity and phosphocreatine and adenosine triphosphate (ATP) recovery time are delayed in the calf muscles of PAD patients, as assessed after submaximal exercise by ^{31}P magnetic resonance spectroscopy.[23a]

Clinical Features

Symptoms

The cardinal symptoms of PAD include limb pain either with exercise (intermittent claudication) or at rest. The term *claudication* is derived from the Latin *claudicare*, “to limp.” Intermittent claudication refers to a pain, ache, sense of fatigue, or other discomfort that occurs in the affected muscle group with exercise, particularly walking, and resolves with rest. The location of the symptom is often related to the site of the most proximal stenosis. Buttock, hip, or thigh claudication typically occurs in patients with obstruction of the aorta and iliac arteries. Calf claudication is caused by femoral or popliteal artery stenoses. The gastrocnemius muscle consumes more oxygen during walking than other muscle groups in

the leg do and thus causes the most frequent symptoms reported by patients. Ankle or foot claudication occurs in patients with tibial and peroneal artery disease. Similarly, stenoses of the subclavian, axillary, or brachial arteries may cause shoulder, biceps, or forearm claudication, respectively. The symptoms should resolve several minutes after cessation of effort. Episodic calf or thigh pain that occurs during rest, such as nocturnal cramps, should not be confused with claudication and are not symptoms of PAD. The history obtained from persons reporting claudication should note the walking distance, speed, and incline that precipitate claudication. Such baseline assessment serves to evaluate disability and provides an initial qualitative measure with which to determine stability, improvement, or deterioration during subsequent encounters with the patient. PAD may result in functional limitations beyond those caused by pain. Patients with PAD walk more slowly and have less walking endurance than do patients without PAD.[24]

Several questionnaires can be used to assess the presence and severity of claudication. The Rose Questionnaire was developed initially to diagnose both angina and intermittent claudication in epidemiologic surveys. It questions whether pain develops in either calf with walking and whether the pain occurs at rest, while walking at an ordinary or hurried pace, or on walking uphill. Several modifications of this questionnaire have been developed, including the Edinburgh Claudication Questionnaire and the San Diego Claudication Questionnaire,[24] both of which are more sensitive and specific than a physician's diagnosis of intermittent claudication based on walking distance, walking speed, and nature of the symptoms. Another validated instrument, the Walking Impairment Questionnaire, asks a series of questions and derives a point score based on walking distance, walking speed, and nature of the symptoms.[23,25,26]

Symptoms resembling limb claudication occasionally result from nonatherosclerotic causes of artery obstruction (**Table 64.2**), including arterial embolism; vasculitides such as thromboangiitis obliterans, Takayasu arteritis, and giant cell arteritis; aortic coarctation; fibromuscular dysplasia; irradiation; endofibrosis of the external iliac artery; and extravascular compression as a result of arterial entrapment or an adventitial cyst (**see Chapter 94**). Several nonvascular causes of exertional leg pain should be considered in the differential diagnosis of intermittent claudication. Lumbosacral radiculopathy resulting from degenerative joint disease, spinal stenosis, and herniated discs can cause pain in the buttock, hip, thigh, calf, or foot with walking, often after very short distances or even with standing. This symptom has been called *neurogenic pseudoclaudication*. Lumbosacral spine disease and PAD both preferentially affect the elderly population and thus may coexist in the same individual. Positional changes in symptoms or attenuation of pain while walking stooped forward, such as with a shopping cart, are suggestive of a neurogenic rather than a vascular cause of symptoms. Arthritis of the hips and knees also provokes leg pain with walking. Typically, the pain is localized to the affected joint and can be elicited on physical examination by palpation and range-of-motion maneuvers. *Exertional compartment syndrome* most often occurs in athletes with large calf muscles; increased tissue pressure during exercise limits microvascular flow and results in calf pain or tightness. Symptoms improve after cessation of exercise. Rarely, skeletal muscle disorders such as myositis can cause exertional leg pain. *Glycogen storage disease type V,* also known as McArdle syndrome, in which skeletal muscle phosphorylase is deficient, can cause symptoms mimicking the claudication of PAD. Patients with chronic venous insufficiency sometimes report leg discomfort with exertion, a condition designated *venous claudication.* Venous hypertension during exercise increases arterial resistance in the affected limb and limits blood flow. In the case of venous insufficiency, elevated extravascular pressure caused by interstitial edema further diminishes capillary perfusion. Peripheral edema, venous stasis pigmentation, and occasionally venous varicosities demonstrated on physical examination may provide clues for this unusual cause of exertional leg pain.

TABLE 64.2

Differential Diagnosis of Exertional Leg Pain

Vascular Causes
Atherosclerosis
Thrombosis
Embolism
Vasculitis
Thromboangiitis obliterans
Takayasu arteritis
Giant cell arteritis
Aortic coarctation
Fibromuscular dysplasia
Irradiation
Endofibrosis of the external iliac artery
Extravascular compression
Arterial entrapment (e.g., popliteal artery entrapment, thoracic outlet syndrome)
Adventitial cysts
Nonvascular Causes
Lumbosacral radiculopathy
Degenerative arthritis
Spinal stenosis
Herniated disc
Arthritis
Hips, knees
Venous insufficiency
Myositis
Glycogen storage disease type V (McArdle syndrome)

Symptoms or tissue loss occur at rest in patients with CLI. Typically, patients complain of pain or paresthesias in the foot or toes of the affected extremity. This discomfort worsens with leg elevation and improves with leg dependency, as might be anticipated by the effect of gravity on perfusion pressure. The pain can be particularly severe at sites of skin fissuring, ulceration, or necrosis. Frequently, the skin is very sensitive, and even the weight of bedclothes or sheets elicits pain. Patients may sit on the edge of the bed and dangle their legs to alleviate the discomfort. In contrast, patients with neuropathy can experience little or no pain despite the presence of severe ischemia.

Critical limb and digital ischemia can result from arterial occlusions from a variety of etiologies besides atherosclerosis, including conditions such as thromboangiitis obliterans, vasculitides such as systemic lupus erythematosus (SLE) or scleroderma, vasospasm, atheromatous embolism, and acute arterial occlusion secondary to thrombosis or embolism (see later). Acute gouty arthritis, trauma, and sensory neuropathy such as that caused by DM, lumbosacral radiculopathies, and complex regional pain syndrome (previously known as “reflex sympathetic dystrophy”) can cause foot pain. Leg ulcers also occur in patients with venous insufficiency or sensory neuropathy, particularly that related to diabetes. These ulcers appear to be distinct from those caused by PAD. The ulcer of venous insufficiency usually localizes near the medial malleolus and has an irregular border and a pink base with granulation tissue. In general, they produce milder pain than those caused by PAD. *Neurotrophic ulcers* occur at sites of pressure or trauma, usually on the sole of the foot. These ulcers are deep, frequently infected, and not generally painful because of the loss of sensation.

Physical Findings

A complete cardiovascular examination includes palpation of the peripheral pulses, inspection of the extremities, including the feet, and auscultation of accessible arteries for bruits. Pulse abnormalities and bruits increase the likelihood of PAD.[23,24] Readily palpable pulses in healthy individuals include the brachial, radial, and ulnar arteries in the upper extremities and the femoral, popliteal, dorsalis pedis, and posterior tibial arteries in the lower extremities. The aorta can also be palpated in thin people. A

decreased or absent pulse indicates diminished pressure from a more proximal stenosis. For example, a normal right femoral pulse but absent left femoral pulse suggests the presence of left iliofemoral arterial stenosis. A normal femoral artery pulse but absent popliteal artery pulse would indicate a stenosis in the superficial femoral artery or proximal popliteal artery. A palpable popliteal artery pulse with absent dorsalis pedis or posterior tibial artery pulses indicates disease of the anterior and posterior tibial arteries, respectively.

Bruits are often a sign of accelerated blood flow velocity and flow disturbance at sites of stenosis. A stethoscope should be used to auscultate the supraclavicular and infraclavicular fossae for evidence of subclavian artery stenosis; the abdomen, flank, and pelvis for evidence of stenoses in the aorta and its branch vessels; and the inguinal region for evidence of femoral artery stenoses. Pallor can be elicited on the soles of the feet of some patients with PAD by performing a maneuver in which the feet are elevated above the level of the heart and the calf muscles are exercised by repeated dorsiflexion and plantar flexion of the ankle. The legs are then placed in the dependent position, and the time until the onset of hyperemia by evident rubor and venous distention is measured. Each of these variables depends on the rate of blood flow, which in turn reflects the severity of stenosis and adequacy of collateral vessels.

The legs of patients with chronic aortoiliac disease may show muscle atrophy. Additional signs of chronic low-grade ischemia include hair loss, dystrophic, thickened and brittle toenails, smooth and shiny skin, and atrophy of the subcutaneous fat of the digital pads. Patients with severe limb ischemia have cool skin and may also have petechiae, persistent cyanosis or pallor, dependent rubor, pedal edema resulting from prolonged dependency, skin fissures, ulceration, or gangrene. The ulcers caused by PAD typically have a pale base with irregular borders and usually involve the tips of the toes or the heel of the foot or develop at sites of pressure (**Fig. 64.3**). These ulcers vary in size and may be as small as 3 to 5 mm.

FIGURE 64.3 Typical arterial ulcer. It is a discrete, circumscribed, necrotic ulcer located on the great toe.

Categorization

Classification of patients with PAD depends on the severity of the symptoms and abnormalities detected on physical examination. Categorization of the clinical manifestations of PAD helps to characterize risk

and provides a basis for the types and intensity of therapeutic intervention. Fontaine described one widely used scheme that classifies patients into one of four stages, progressing from asymptomatic to CLI (**Table 64.3**). Several professional vascular societies have adopted the Rutherford scale, a contemporary, more descriptive classification that includes asymptomatic patients, three grades of claudication, and three grades of CLI ranging from rest pain alone to minor and major tissue loss[23,24,27] (**Table 64.4**).

TABLE 64.3

Fontaine Classification of Peripheral Artery Disease

STAGE	SYMPTOMS
I	Asymptomatic
II	Intermittent claudication
IIa	Pain free, claudication walking >200 m
IIb	Pain free, claudication walking <200 m
III	Rest and nocturnal pain
IV	Necrosis, gangrene

TABLE 64.4

Clinical Categories of Chronic Limb Ischemia

GRADE	CATEGORY	CLINICAL DESCRIPTION
	0	Asymptomatic
I	1	Mild claudication
	2	Moderate claudication
	3	Severe claudication
II	4	Ischemic rest pain
	5	Minor tissue loss: nonhealing ulcer, focal gangrene with diffuse pedal ulcer
III	6	Major tissue loss extending above the transmetatarsal level, functional foot no longer salvageable

Modified from Rutherford RB, Baker JD, Ernst C, et al. Recommended standards for reports dealing with lower extremity ischemia: revised version. J Vasc Surg 1997;26:517.

Testing for Peripheral Artery Disease

Patients with signs or symptoms suggestive of PAD should have testing to confirm the diagnosis and to characterize the distribution and severity of disease. In patients with risk factors, clinicians should be aware of atypical symptoms, perform a vascular physical examination, and perform diagnostic testing in those with a history or examination suggestive of PAD.

Segmental Pressure Measurement

Measurement of systolic blood pressure (SBP) along sequential segments of each extremity is one of the simplest noninvasive measures for ascertaining the presence and severity of stenoses in the peripheral arteries. In the lower extremities, pneumatic cuffs are placed on the upper and lower portions of the thigh, on the calf, above the ankle, and often over the metatarsal area of the foot. Similarly, for the upper extremities, pneumatic cuffs are placed on the upper part of the arm over the biceps, on the forearm below the elbow, and at the wrist. SBP at each respective limb segment is measured by first inflating the pneumatic cuff to suprasystolic pressure and then determining the pressure at which blood flow occurs during deflation of the cuff. The onset of flow is assessed by placing a Doppler ultrasound flow probe over an artery distal to the cuff. In the lower extremities, it is most convenient to place the Doppler probe

on the foot over the posterior tibial artery, because it courses inferior and posterior to the medial malleolus, or over the dorsalis pedis artery on the dorsum of the metatarsal arch. In the upper extremities the Doppler probe can be placed over the brachial artery in the antecubital fossa or over the radial and ulnar arteries at the wrist.

Left ventricular contraction imparts kinetic energy to blood, which is maintained throughout the large and medium-sized vessels. SBP may be higher in the more distal vessels than in the aorta and proximal vessels because of amplification and reflection of blood pressure (BP) waves. A stenosis can cause loss of pressure energy because of increased frictional forces and disturbance of flow at the site of the stenosis. Approximately 90% of the cross-sectional area of the aorta must be narrowed before a pressure gradient develops. In smaller vessels, such as the iliac and femoral arteries, a 70% to 90% decrease in cross-sectional area will cause a resting pressure gradient sufficient to decrease SBP distal to the stenosis. Taking into consideration the precision of this noninvasive method and the variability in BP during even short periods, a BP gradient in excess of 20 mm Hg between successive cuffs is generally used as evidence of arterial stenosis in the lower extremity, whereas a gradient of 10 mm Hg indicates a stenosis between sequential cuffs in the upper extremity. SBP in the toes and fingers is approximately 60% of SBP at the ankle and wrist, respectively, because pressure diminishes further in the smaller distal vessels. **Fig. 64.4** provides examples of leg segmental BP measurements in a patient with left calf claudication. In the right leg, there are no pressure gradients between the upper and lower parts of the thigh or between the calf and ankle. In the left leg, pressure gradients between the upper and lower parts of the thigh, between the lower part of the thigh and calf, and between the calf and ankle indicate stenoses in the superficial femoral and popliteal arteries and in the tibioperoneal arteries.

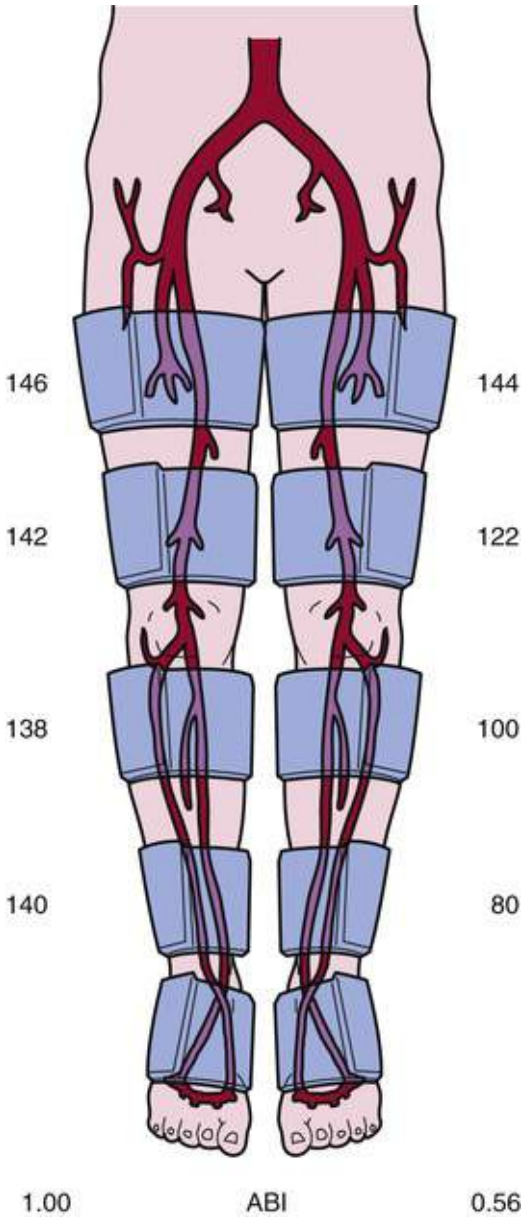

FIGURE 64.4 Segmental pressure measurements in a patient with intermittent claudication of the left calf. A pressure gradient is present between the left upper and lower thigh cuffs, lower thigh and calf cuffs, and calf and ankle cuffs, consistent with multisegmental disease affecting the femoral-popliteal and tibial arteries. The left ankle-brachial index (ABI) is 0.56, which is abnormal. Segmental pressure measurements and the ABI in the right leg are normal.

Ankle-Brachial Index

Determination of the ABI is a simplified application of leg segmental BP measurements that can readily be used at the bedside. This index is the ratio of SBP measured at the ankle to SBP measured at the brachial artery.[28] A pneumatic cuff placed around the ankle is inflated to suprasystolic pressure and subsequently deflated while the onset of flow is detected with a Doppler ultrasound probe placed over the dorsalis pedis and posterior tibial arteries, thus denoting ankle SBP. Brachial artery SBP can be assessed in a routine manner with either a stethoscope to listen for the first Korotkoff sound or a Doppler probe to listen for the onset of flow during cuff deflation. The *normal* ABI range is 1.00 to 1.40. An ABI value of 0.91 to 0.99 is *borderline*, and an ABI of 0.90 or less is *abnormal*.[28,29] An ABI of 0.90 or lower has a specificity of 83% to 99% and a sensitivity of 69% to 73% in detecting stenoses greater than 50%.[28] The sensitivity of an ABI less than 1.0 approaches 100%. The ABI is often used to gauge the severity of PAD. Patients with symptoms of leg claudication often have an ABI ranging from 0.5 to 0.8, and patients

with CLI usually have an ABI lower than 0.5. A low ABI is associated with shorter walking distance and lower speed. Less than 40% of patients whose ABI is lower than 0.40 can complete a 6-minute walk.[24,30] In patients with skin ulcerations, an ankle SBP less than 55 mm Hg predicts poor ulcer healing. Leg BP recordings are not reliable in patients with calcified vessels, as might occur in those with DM or renal insufficiency. Inflation of the pneumatic cuff cannot compress the calcified vessel; the Doppler probe consequently indicates continuous blood flow, even when the pressure exceeds 250 mm Hg. An ABI higher than 1.40 indicates a noncompressible artery, and the test is not informative for either confirming or excluding PAD. In this case, a *toe-brachial-index* (TBI) may be informative, with a ratio of 0.70 or higher reflecting normal perfusion pressure.

Treadmill Exercise Testing

Treadmill exercise testing can be used to evaluate the clinical significance of peripheral artery stenoses and provide objective evidence of the patient's walking capacity. The *claudication onset time* is when symptoms of claudication first develop, and the *peak walking time* occurs when the patient can no longer continue walking because of severe leg discomfort. This standardized and more objective measure of walking capacity supplements the patient's history and provides a quantitative assessment of the patient's disability, as well as a metric for monitoring therapeutic interventions. Treadmill exercise protocols use a motorized treadmill that incorporates fixed or progressive speeds and angles of incline. A fixed workload test usually maintains a constant grade of 12% and a speed of 1.5 to 2.0 mph. A progressive, or graded, treadmill protocol typically maintains a constant speed of 2 mph while the grade gradually increases by 2% every 2 to 3 minutes. Repeated treadmill test results have better reproducibility with progressive than with constant-grade protocols.

Treadmill testing can determine whether arterial stenoses contribute to the patient's symptoms of exertional leg pain. During exercise, blood flow through a stenosis increases as vascular resistance falls in the exercising muscle. According to the Poiseuille equation, described previously, the pressure gradient across the stenosis increases in direct proportion to flow. Thus, ankle and brachial SBP is measured during resting conditions before treadmill exercise, within 1 minute after exercise, and repeatedly until baseline values are reestablished. Normally, the BP increase that occurs during exercise should be the same in both the upper and the lower extremities, with a constant ABI of 1.0 or greater being maintained. In the presence of peripheral artery stenoses, however, the ABI decreases because the BP increase observed in the arm is not matched by a comparable increase in ankle BP. A 25% or greater decrease in the ABI after exercise in a patient whose walking capacity is limited by claudication is considered diagnostic and implicates PAD as a cause of the patient's symptoms. This provocative test should be considered in patients with risk factors and symptoms suggestive of vascular claudication but with normal resting ABI, as may occur in those with proximal disease.[31]

Pulse Volume Recording

The pulse volume recording graphically illustrates the volumetric change in a segment of the limb that occurs with each pulse. Plethysmographic instruments, typically using strain gauges or pneumatic cuffs, can transduce volumetric changes in the limb, which can be displayed on a graphic recorder. These transducers, placed strategically along the limb, record the pulse volume in its different segments, such as the thigh, calf, ankle, metatarsal region, and toes, or the upper part of the arm, forearm, and fingers. The normal pulse volume contour depends on both local arterial pressure and vascular wall distensibility and

resembles a BP waveform. It consists of a sharp systolic upstroke rising rapidly to a peak, a dicrotic notch, and a concave downslope that drops off gradually toward the baseline. The contour of the pulse wave changes distal to a stenosis, with loss of the dicrotic notch, a slower rate of rise, a more rounded peak, and a slower descent. The amplitude becomes lower with increasing severity of disease, and the pulse wave may not be recordable at all in a critically ischemic limb. Segmental analysis of the pulse wave may indicate the location of an arterial stenosis, which probably resides in the artery between a normal and an abnormal pulse volume recording. The pulse volume wave also provides information about the integrity of blood flow when BP measurements cannot be obtained accurately because of noncompressible vessels.

Doppler Ultrasonography

Continuous-wave and pulsed-wave Doppler systems transmit and receive high-frequency ultrasound signals. The Doppler frequency shift caused by moving red blood cells varies directly with the velocity of blood flow. Typically, the perceived frequency shift is between 1 and 20 kHz and is within the audible range of the human ear. Therefore, placement of a Doppler probe along an artery enables the examiner to hear whether blood flow is present and the vessel is patent. Processing and graphic recording of the Doppler signal permit a more detailed analysis of the frequency components.

Doppler instruments can be used without or with gray-scale imaging to evaluate an artery for the presence of stenoses. The Doppler probe is positioned at approximately a 60-degree angle over the common femoral, superficial femoral, popliteal, dorsalis pedis, and posterior tibial arteries. The normal Doppler waveform has three components: a rapid forward-flow component during systole, a transient flow reversal during early diastole, and a slow anterograde component during late diastole. The Doppler waveform becomes altered if the probe is placed distal to an arterial stenosis and is characterized by deceleration of systolic flow, loss of the early diastolic reversal, and diminished peak frequencies. Arteries in a limb with critical ischemia may not show any Doppler frequency shift. As with pulse volume recordings, change from a normal to an abnormal Doppler waveform as the artery is interrogated more distally suggests the location of a stenosis.

Duplex Ultrasound Imaging

Duplex ultrasound imaging provides a direct, noninvasive means of assessing both the anatomic characteristics of peripheral arteries and the functional significance of arterial stenoses. The methodology incorporates gray-scale B-mode ultrasound imaging, pulsed Doppler velocity measurements, and color coding of the Doppler shift information (**Fig. 64.5**). Real-time ultrasonographic scanners emit and receive high-frequency sound waves, typically ranging from 2 to 10 MHz, to construct an image. The acoustic properties of the vascular wall differ from those of the surrounding tissue, thus enabling them to easily be imaged. Atherosclerotic plaque may be present and visible on gray-scale images. Pulsed-wave Doppler systems emit ultrasound beams at precise times and can therefore sample the reflected ultrasound waves at specific depths to enable the examiner to determine blood cell velocity within the lumen of the artery. By positioning the pulsed Doppler beam at a known angle; the examiner can calculate blood flow velocity according to the following equation:

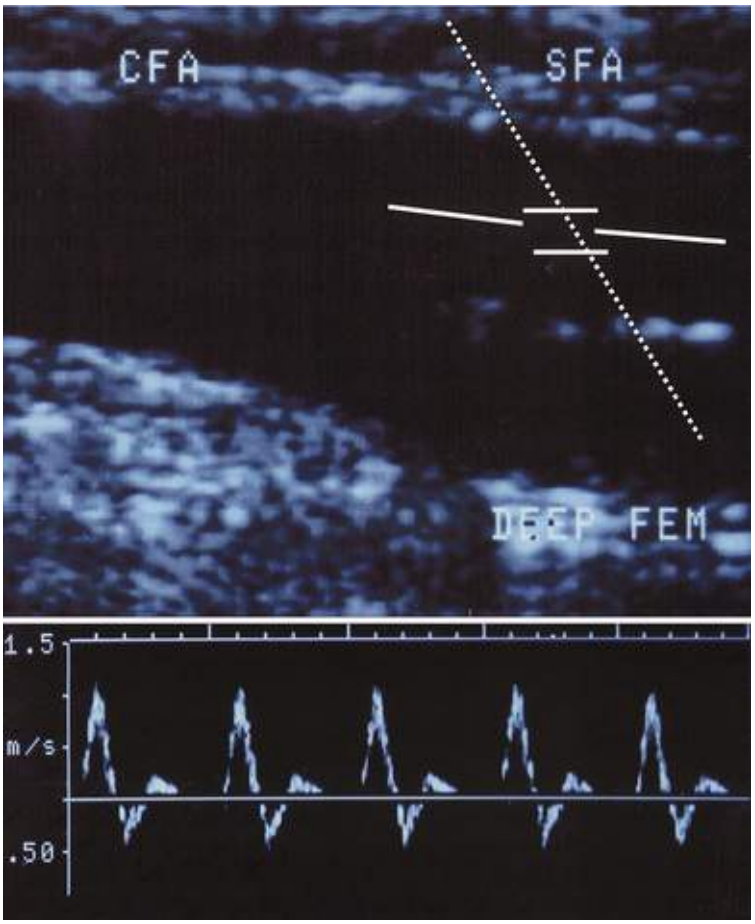

FIGURE 64.5 Duplex ultrasonogram of the common femoral artery (CFA) bifurcation into the superficial femoral artery (SFA) and deep femoral artery. The **upper image** shows a normal gray-scale image of the artery in which the intima is not thickened and the lumen is widely patent. The **lower image** is a recording of the pulse Doppler velocity sampled from the superficial femoral artery. The triphasic profile is apparent, the envelope is thin, and peak systolic velocity is within normal limits.

$$\mathrm{Df} = 2\mathrm{VF}\cos\theta/C$$

where Df is the frequency shift, V is the velocity, F is the frequency of the transmitted sound, θ is the angle between the transmitted sound and the velocity vector, and C is the velocity of sound and tissue. For optimal measurements, the angle of the pulsed Doppler beam should be less than 60 degrees. With color Doppler, the frequency shift information within the entire field sampled by the ultrasound beam can be superimposed on the gray-scale image. This approach provides a composite real-time display of flow velocity within the vessel.

Color-assisted duplex ultrasound imaging is an effective means of localizing peripheral arterial stenoses (**Fig. 64.6**). Normal arteries have laminar flow, with the highest velocity occurring at the center of the artery. The corresponding color image is usually homogeneous with relatively constant hue and intensity. In the presence of an arterial stenosis, blood flow velocity increases through the narrowed lumen. As the velocity increases, there is progressive desaturation of the color display, and flow disturbance distal to the stenosis causes changes in hue and color. Pulsed Doppler velocity measurements can be made along the length of the artery and particularly at areas of flow abnormalities suggested by the color images. A twofold or greater increase in peak systolic velocity at the site of an atherosclerotic plaque indicates a 50% or greater stenosis (**Fig. 64.6**). A threefold increase in velocity suggests a 75% or greater stenosis. An occluded artery generates no Doppler signal. Duplex ultrasound imaging for

identification of sites of arterial stenosis has approximately 89% to 99% specificity and 80% to 98% sensitivity.[32] Measurement of sequential peak systolic velocities enables evaluation of restenosis of peripheral stents or bypass grafts and to determine the need to consider reintervention to preserve vessel patency.

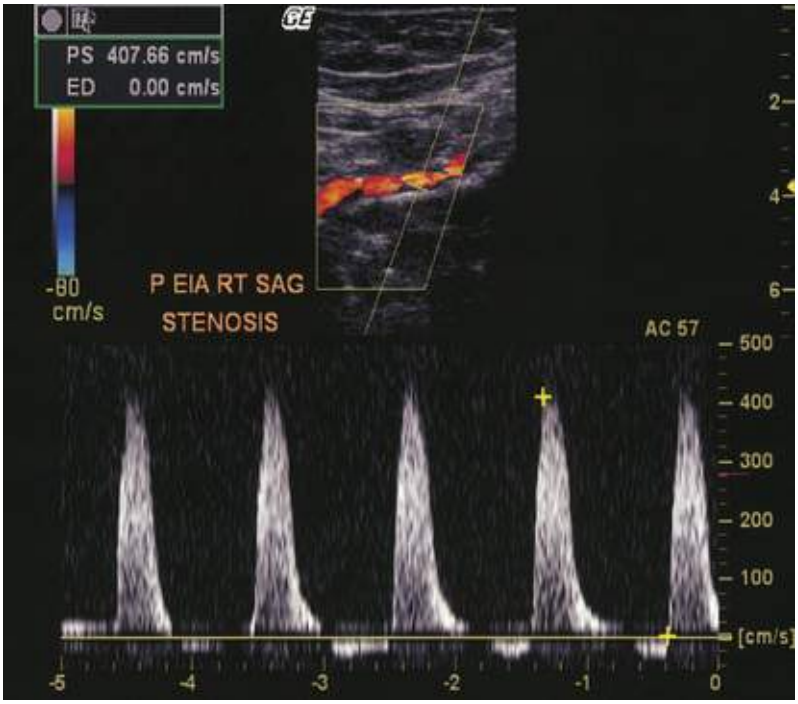

FIGURE 64.6 Duplex ultrasonogram of the external iliac artery. The **upper image** is a color image of the artery in which there is heterogeneity and desaturation of color, indicative of high-velocity flow through a stenosis. The **lower image** is a recording of the pulse Doppler velocity sampled from the right external iliac artery. The peak velocity of 350 cm/sec is elevated. These features are consistent with a significant stenosis.

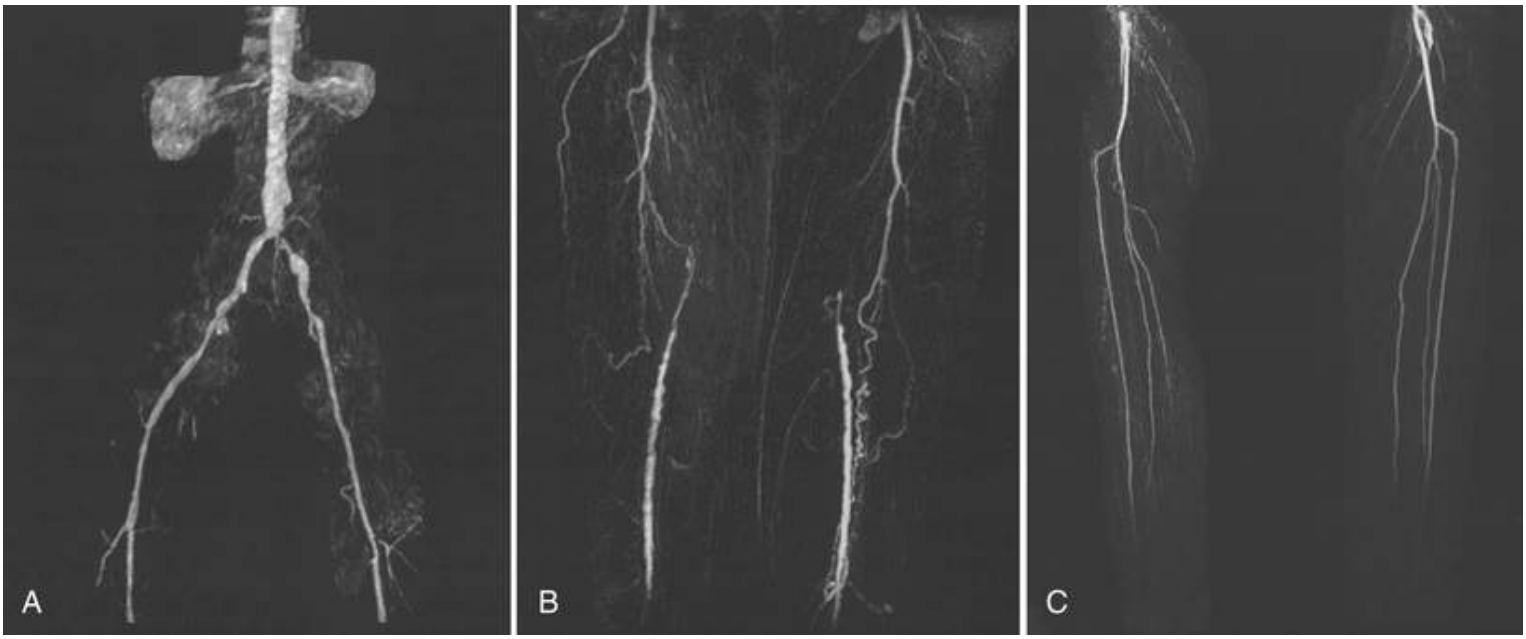
Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) can be used to noninvasively visualize the aorta and peripheral arteries (**see Chapters 17 and 66**). Resolution of the vascular anatomy with gadolinium-enhanced MRA approaches that of conventional contrast-enhanced digital subtraction angiography (DSA) (**eFig. 64.2**). A meta-analysis of 32 studies comparing MRA with intra-arterial DSA found a sensitivity of 95% and a specificity of 96% for detecting segmental stenotic and occlusive lesions.[33] MRA currently has its greatest usefulness in the evaluation of symptomatic patients to assist in decision making before endovascular and surgical intervention or in patients at risk for renal, allergic, or other complications during conventional angiography.



EFIGURE 64.2 Gadolinium-enhanced two-dimensional magnetic resonance angiography (MRA) of the aorta and both legs extending from the thighs to above the ankle. **A,** Aortoiliac atherosclerosis with a stenosed left common iliac artery. **B,** Bilateral superficial femoral artery occlusion with reconstitution of the distal portion of the right and left superficial femoral arteries. **C,** Anterior tibial, posterior tibial, and peroneal arteries, which are patent in each leg.

Computed Tomographic Angiography

Computed tomography (CT) scanners use multidetector technology to acquire cross-sectional images (**see Chapter 18**). This permits imaging of peripheral arteries with excellent spatial resolution during a relatively short time and with a reduced amount of radiocontrast material (**Fig. 64.7**). Image reconstructions in three dimensions permit rotation to optimize visualization of arterial stenoses. Compared with conventional contrast-enhanced angiography, the sensitivity and specificity for stenoses greater than 50% or occlusion reported for computed tomographic angiography (CTA) using multidetector technology are 95% and 96%, respectively.[34] CTA offers advantages over MRA because it can be used in patients with stents, metal clips, and pacemakers, although it has the disadvantage of requiring radiocontrast material and ionizing radiation.

FIGURE 64.7 Computed tomographic angiogram (CTA) in a patient with complete occlusion of the aorta and both iliac arteries. The common femoral arteries have been reconstituted. (Courtesy 3D and Image Processing Center of Brigham and Women's Hospital, Boston.)

Contrast-Enhanced Angiography

Conventional angiography can aid in evaluation of the arterial anatomy before a revascularization procedure. It still has occasional usefulness when the diagnosis is in doubt. Most contemporary angiography laboratories use digital subtraction techniques after intra-arterial administration of contrast material to enhance resolution. Injection of the contrast material into the aorta permits visualization of the aorta and iliac arteries, and injection of contrast material into the iliofemoral segment of the involved leg permits optimal visualization of the femoral, popliteal, tibial, and peroneal arteries (**Fig. 64.8**).

FIGURE 64.8 Angiogram of a patient with disabling left calf claudication. **A,** The aorta and bilateral common iliac arteries are patent. **B,** The left superficial femoral artery has multiple stenotic lesions (*arrows at left*). Significant stenosis of the left tibioperoneal trunk and left posterior tibial artery (*arrows at right*) is present.

Prognosis

Patients with PAD have increased risk for adverse cardiovascular (CV) events, as well as for limb loss and impaired quality of life[2,7] (**Fig. 64.9 and eFig. 64.3**). Such patients frequently have concomitant coronary artery disease (CAD) and cerebrovascular disease.[35] Patients with an abnormal ABI are twofold to fourfold more likely than those with a normal ABI to have a history of myocardial infarction (MI), angina, congestive heart failure, or cerebrovascular ischemia.[36] Angiographically significant CAD occurs in approximately 60% to 80% of patients with PAD, and 15% to 25% of patients with PAD have significant carotid artery stenoses, as detected by duplex ultrasonography. In the REACH (Reduction of Atherothrombosis for Continued Health) Registry, 62% of the patients with PAD had either or both coronary and cerebrovascular disease. The specificity of an abnormal ABI in predicting future CV events is approximately 90%.[28] The risk for death from CV causes increases 2.5- to 6-fold in patients with PAD,

and their annual mortality rate is 4.3% to 4.9%.[17,36] Patients with PAD and prior MI have a particularly poor CV prognosis, with a 3-year risk of CV death, MI, or stroke approaching 20%, reflecting a 60% increase in risk relative to those with prior MI but no PAD[37,38] (**eFig. 64.4**). Those with the most severe PAD have the greatest risk for death, and mortality correlates with decreasing ABI (**Fig. 64.10**).[7] Approximately 25% of patients with CLI die within 1 year, and the 1-year mortality rate in patients who have undergone amputation for PAD may be as high as 45%.[39]

Ticagrelor for prevention of ischemic events after myocardial infarction in patients with peripheral artery disease. J Am Coll Cardiol 2016;67:2719-28.)

Worsening symptoms develop in approximately 25% of patients with claudication, and over 3 years, approximately 20% will require an intervention to improve lower extremity perfusion (**see Fig. 64.9 and eFig. 64.3**). Moreover, loss of mobility occurs more often in patients with PAD than in those without PAD, even in patients without classic symptoms of claudication.[24] Both smoking and DM independently predict progression of disease.[15,40] Those with DM have at least a 12-fold higher likelihood of amputation than nondiabetic persons.[7] The risk for limb loss is higher in PAD patients with CLI in whom revascularization fails or is not feasible and approximates 40% by 6 months.[11]

Treatment

Treatment of PAD aims to reduce CV morbidity and mortality, as well as improve quality of life by decreasing symptoms of claudication, eliminating rest pain, and preserving limb viability. Therapeutic considerations therefore include modification of risk factors by alterations in lifestyle and use of pharmacologic therapy to reduce the risk for adverse CV events such as MI, stroke, and death, as well as to decrease limb morbidity. Symptoms of claudication can improve with pharmacotherapy or exercise rehabilitation. Optimal management of CLI often includes endovascular interventions or surgical reconstruction to improve blood supply and maintain limb viability. Revascularization can aid some patients with disabling symptoms of claudication that persist despite exercise therapy and pharmacotherapy.[1]

Risk Factor Modification

Lipid-lowering therapy reduces the risk of CV events (**see Chapters 45 and 48**). The Heart Protection Study found that lipid-lowering therapy with simvastatin reduced the risk for adverse CV outcomes by 25% in patients with atherosclerosis, including more than 6700 patients with PAD.[41] Pooled results from 17 trials found that lipid-lowering therapy reduced the risk for CV events in patients with PAD by 26%.[41] Recent lipid-lowering guidelines recommend high- or moderate-intensity statin therapy for all patients with PAD, depending on age.[42,43] Proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors have shown promising preliminary results in reducing CV risk in patients with atherosclerosis and are under investigation in large CV outcomes trials that include patients with symptomatic PAD.[44]

Smoking Cessation

Prospective trials examining the benefits of smoking cessation are lacking, but observational evidence unequivocally shows that cigarette smoking increases the risk for atherosclerosis and its clinical sequelae. Nonsmokers with PAD have lower rates of MI and mortality than those who have smoked or continue to smoke, and PAD patients who discontinue smoking have approximately twice the 5-year survival rate of those who continue to smoke. In addition to frequent physician advice, pharmacologic interventions that effectively promote smoking cessation include nicotine replacement therapy, bupropion, and varenicline.[14,41]

Treatment of Diabetes

Aggressive treatment of diabetes decreases the risk for microangiopathic events such as nephropathy and retinopathy (**see Chapter 51**), but most classes of glucose-lowering drugs have not shown a reduction of macrovascular events.[45] In several trials, intensive glucose control versus standard therapy has not reduced ischemic risk associated with increased mortality.[45] Long-term follow-up of the UKPDS (United Kingdom Prospective Diabetes Study) of patients with type 2 DM, however, did find that intensive treatment was associated with a 15% reduction in MI, suggesting a positive glycemic legacy in patients with newly diagnosed diabetes and without prior CV events.[46] Recent studies have shown that certain glucose-lowering agents can reduce CV risk in patients with atherosclerosis. In the EMPA-REG trial, the sodium-glucose transporter 2 (SGLT2) inhibitor inhibitor *empagliflozin* reduced all-cause mortality by 32% in patients with type 2 DM at increased risk of CV events, including more than 600 patients with PAD.[47] The observations of increased rates of leg and foot amputation in ongoing studies with a related agent, however, indicate caution and warrant further study for limb risk in patients with PAD.[48] The glucagon-like protein (GLP)-1 agonists liragulitide and semaglutide improved macrovascular outcomes in patients with type 2 DM and either established CV disease or at heightened CV risk.[49,50] Selection of specific agents may supersede glucose targets in high-risk populations where treating to lower targets alone has associated with harm.[45]

Blood Pressure Control

Antihypertensive therapy reduces the risk for stroke, CAD, and vascular death (**see Chapters 46 and 47**). In patients with PAD, the intensity of antihypertensive treatment must take into consideration benefits of reduced risk of CV events and the potential to exacerbate limb symptoms. Although several studies have suggested that intensive BP control (versus moderate BP control) reduce CV events in diabetic patients with PAD, data with regard to specific targets are mixed.[15] A post hoc analysis of the International

Verapamil-SR/Tandolapril study found that PAD associated with higher ischemic risk, but there appeared to be a J-shaped relationship between SBP and outcome, suggesting that patients with PAD might require specific targets.[51] In the SPRINT trial, a target SBP of 120 mm Hg or less resulted in a significant reduction in CV events, but outcomes specific to patients with PAD were not reported.[52] There are no comparative studies of specific antihypertensive agents in patients with PAD, but findings from several clinical trials support the use of angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) in patients with atherosclerosis, including those with PAD. In the HOPE (Heart Outcomes Prevention Evaluation) study, the ACE inhibitor ramipril decreased the risk for vascular death, MI, or stroke by 22%, with 44% having PAD.[41] Other ACE inhibitors as well as ARBs have shown similar benefits.[41] Although in theory, beta blockers could worsen lower extremity symptoms in PAD, a systematic review that included six studies of beta blocker therapy found no significant impairment of walking capacity.[53] Thus, if clinically indicated for other conditions, these drugs should not be withheld in patients with PAD.

Antiplatelet Therapy

Substantial evidence supports the use of antiplatelet agents to reduce ischemic risk in patients with atherosclerosis (**see Chapter 93**). The Antithrombotic Trialists' (ATT) Collaboration Meta-analysis of more than 9000 patients with symptomatic PAD showed a 23% reduction in vascular death, MI, or stroke with antiplatelet monotherapy.[54] Although the findings are often taken as evidence supporting the use of aspirin, the trials included several classes of antiplatelet agents (e.g., aspirin, thienopyridines, dipyridamole, picotamide). The benefits were counterbalanced by a 60% increase in major extracranial bleeding. Moreover, any conclusions regarding aspirin therapy from this analysis cannot be extrapolated to patients who have asymptomatic PAD. Both the POPADAD (Prevention of Progression of Arterial Disease And Diabetes) and AAA (Aspirin for Asymptomatic Atherosclerosis) trials found no difference in CV outcomes with long-term aspirin in otherwise healthy patients with an abnormal ABI but no symptoms of PAD.[55,56] A meta-analysis including 18 randomized trials comprising 5269 patients with PAD (including asymptomatic patients) found that aspirin did not reduce the risk of CV mortality or MI versus placebo.[41,56]

The CAPRIE (Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events) trial compared clopidogrel with aspirin in reducing ischemic events in patients with recent MI, recent ischemic stroke, or PAD. Overall, clopidogrel reduced vascular death, MI or stroke by 8.7% versus aspirin.[41,56] Notably, among the 6452 patients in the PAD subgroup, clopidogrel treatment appeared to be associated with a greater 23.8% relative risk reduction. Recently, in the EUCLID (Examining Use of Ticagrelor in PAD) trial, ticagrelor, a novel potent $P2Y_{12}$ inhibitor, did not reduce CV death, MI, or stroke versus clopidogrel in patients with symptomatic PAD, including those with prior peripheral revascularization.[57,58] Taken together, these data demonstrate that antiplatelet monotherapy reduces CV risk in patients with symptomatic PAD, but it is of uncertain benefit in those with a marginally low ABI and no symptoms.

The efficacy of dual or more antiplatelets in PAD has been studied in several trials. The CHARISMA (Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance) trial evaluated the addition of clopidogrel to aspirin (DAPT) vs. aspirin alone in patients with established CAD, cerebrovascular disease, or PAD, as well as in patients with multiple risk factors. Overall, dual-antiplatelet therapy (DAPT) produced no significant benefit over aspirin, although a post hoc analysis suggested benefit in those with established CV disease, particularly prior MI.[41] The TRA2°P-TIMI 50 trial studied vorapaxar, an antagonist of protease-activated receptor 1 (PAR-1), in addition to aspirin

and/or clopidogrel, in stable patients with established atherosclerosis. PAR-1 localizes on platelets, endothelium, and vascular smooth muscle. Overall, vorapaxar reduced the risk of MI, stroke, and CV death but was associated with an increase in moderate or severe bleeding.[59,60] Benefit was greatest in patients with MI or PAD, whereas there was overall harm in patients with prior stroke. In the PEGASUS-TIMI 54 trial (Prevention of Cardiovascular Events in Patients with Prior Heart Attack Using Ticagrelor Compared to Placebo on a Background of Aspirin) the addition of ticagrelor, 60 mg, to aspirin resulted in a 5.2% absolute risk reduction in CV death, MI, or stroke, with significant reductions in both CV and all-cause mortality in patients with PAD and prior MI.[37] The PRODIGY trial, which investigated prolonged DAPT after coronary stenting, showed consistent benefits in the PAD subgroup.[38]

Anticoagulant Therapy

The WAVE (Warfarin Antiplatelet Vascular Evaluation) trial compared combination antiplatelet and oral anticoagulant therapy with antiplatelet therapy alone in patients with PAD.[61] Anticoagulation with warfarin did not reduce the primary composite endpoint of MI, stroke, or CV death, but there was a greater than threefold increase in life-threatening bleeding. Trials investigating direct non–vitamin K–dependent oral anticoagulants at various doses alone or in combination with antiplatelet therapy are in progress and should provide information regarding the efficacy and safety of these agents in patients with PAD.

Treatment of Symptoms and Prevention of Limb Vascular Events

Limb morbidity adversely affects quality of life. Treatment strategies should include those measures that improve functional capacity, alleviate symptoms, preserve limb viability, and reduce the risk of limb loss.

Exercise Training

Exercise training is the most effective noninvasive intervention for improving limb-related symptoms. Postulated mechanisms of benefit include the formation of collateral vessels and improvement in endothelium-dependent vasodilation, hemorheology, muscle structure and metabolism, and walking efficiency[25] (**Fig. 64.11**). Exercise increases the expression of angiogenic factors, particularly in hypoxic tissue. Exercise training also improves endothelium-dependent vasodilation. Improvement in calf blood flow has not been demonstrated consistently in patients with claudication; however, some studies have found that exercise training increased capillary density in calf muscle and that this change preceded the improvement in maximal O_2 consumption.[62,63] To date, no imaging studies have demonstrated increased collateral blood vessels after exercise training in patients with PAD.

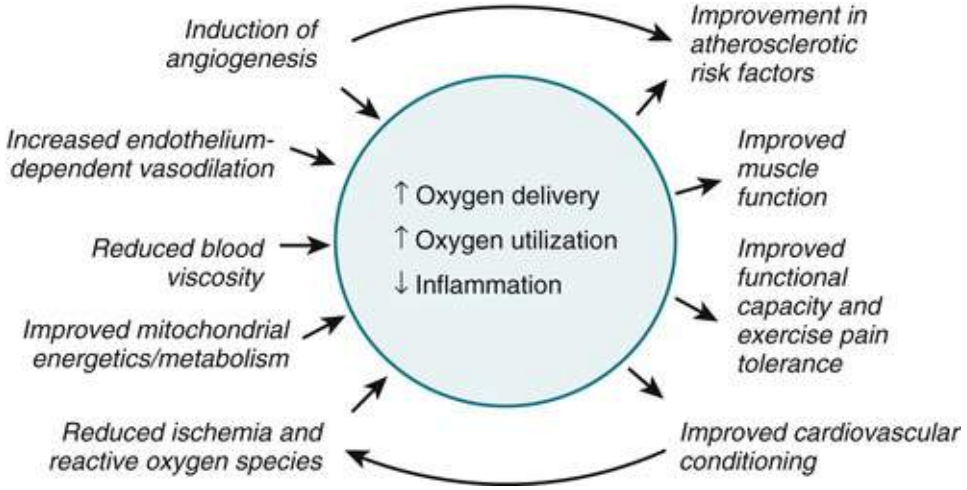

FIGURE 64.11 Mechanisms underlying the benefit of exercise in PAD. (Modified from Bonaca MP, Creager MA. Pharmacological treatment and current management of peripheral artery disease. Circ Res 2015;116:1579-98.)

Much of the benefit of exercise training likely results from changes in skeletal muscle structure or function, such as increased muscle mitochondrial enzyme activity, oxidative metabolism, and ATP production rate (**Fig. 64.11**). Improvement in exercise performance is associated with a decrease in plasma and skeletal muscle short-chain acylcarnitine concentrations, which indicates improvement in oxidative metabolism and increased peak O_2 consumption. Higher physical activity levels are associated with greater calf muscle area and density.[23,24] Training may also enhance biomechanical performance and enable patients to walk more efficiently with less energy expenditure. Supervised exercise training increases maximal walking time by 50% to 200%.[64] Exercise therapy is effective and durable, with the best results achieved with supervised exercise followed by home-based programs (**Fig. 64.12**). The greatest benefit occurs when sessions are at least 30 minutes in duration, when sessions take place at least three times per week for 6 months, and when walking is the mode of exercise. Home-based exercise training, when governed with a step-activated monitor, also improves walking time in patients with claudication[65,66] (**Fig. 64.12**). Leg strength training improves walking time, although not as much as does treadmill exercise training.[24] Arm ergometry also improves walking performance.[67] In the CLEVER (Claudication Exercise versus Endoluminal Revascularization) trial of patients with iliac artery stenosis, supervised exercise training improved mean walking time more than endovascular intervention, and both were more effective than optimal medical therapy; however, quality-of-life measures improved more in the endovascular intervention group[65] (**eFig. 64.5**). In the ERASE (Endovascular Revascularization and Supervised Exercise) trial, the combination of endovascular revascularization and exercise in selected patients was shown to be superior to exercise alone and may be considered a therapeutic strategy for select patients with aortoiliac or femoropopliteal disease.[68] Current guidelines recommend that patients with intermittent claudication undergo supervised exercise rehabilitation as initial therapy.[1,43]

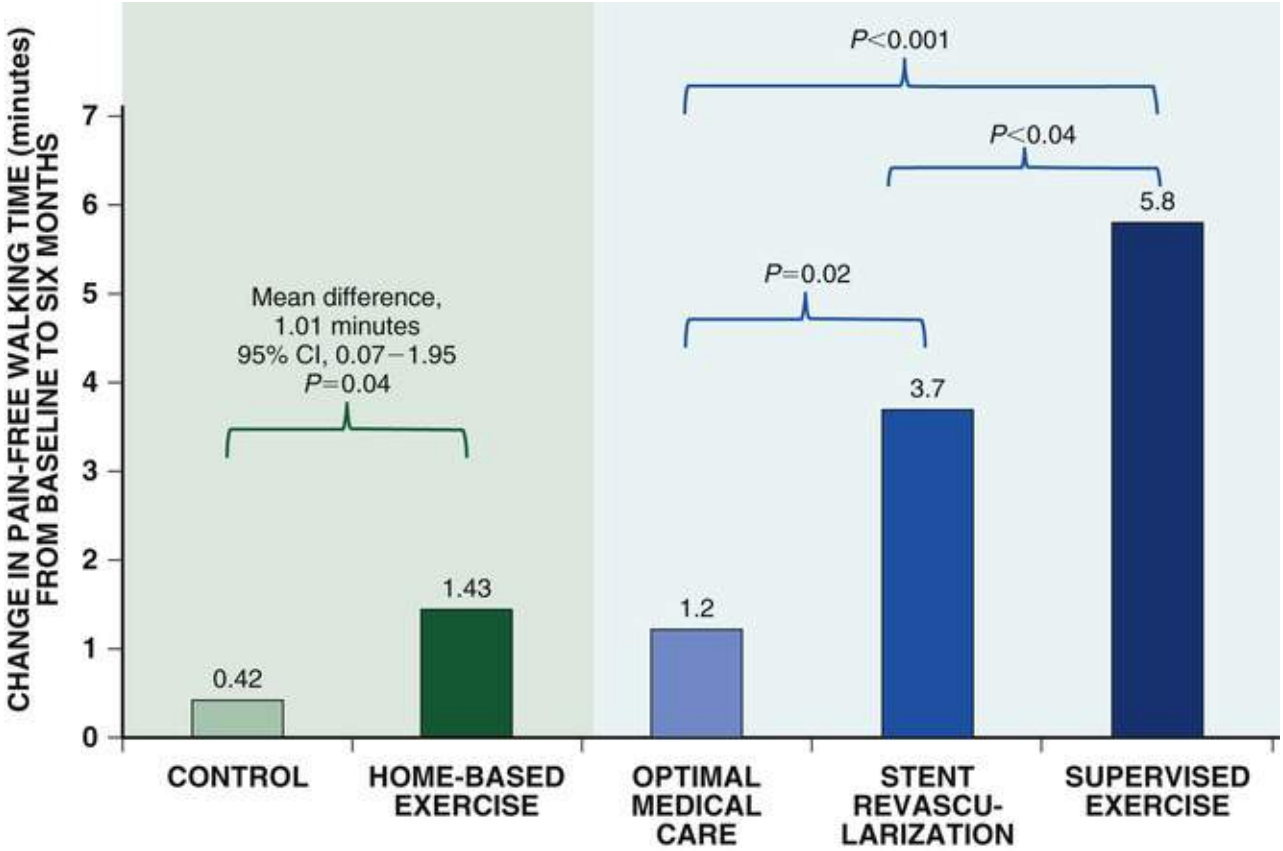

FIGURE 64.12 The relative efficacy of medical care alone, home based exercise, supervised exercise, and stent revascularization in patients with PAD. (Modified from McDermott MM et al. Home-based walking exercise intervention in peripheral artery disease: a randomized clinical trial. JAMA 2013;310:57-65; and Murphy TP et al. Supervised exercise versus primary stenting for claudication resulting from aortoiliac peripheral artery disease: six-month outcomes from the claudication: exercise versus endoluminal revascularization (CLEVER) study. Circulation 2012;125:130-9.)

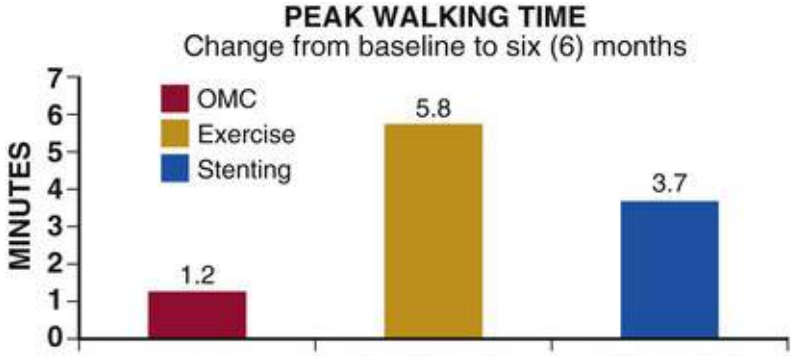

PAIR-WISE COMPARISONS

	Difference (minutes)	*P* value
Exercise vs. OMC	4.6 (95% CI, 2.7–6.5)	<0.001
Stenting vs. OMC	2.5 (95% CI, 0.6–4.4)	0.02
Exercise vs. Stenting	2.1 (95% CI, 0.0–4.2)	0.04

EFIGURE 64.5 Effect of optimal medical care (OMC), exercise training, and endovascular intervention on peak walking time at 6 months in patients with iliac artery stenosis. Supervised exercise training improved mean walking time more than endovascular intervention, and both were more effective than OMC. (Modified from Murphy TP, Cutlip DE, Regensteiner JG, et al. Supervised exercise versus primary stenting for claudication resulting from aortoiliac peripheral artery disease: six-month outcomes from the Claudication: Exercise Versus Endoluminal Revascularization [CLEVER] study. Circulation 2012;125:130.)

Smoking Cessation

Smoking cessation reduces the risk for developing symptomatic PAD and lessens the risk of progression to CLI and amputation in those with PAD.[40,41]. Smoking before limb bypass is associated with early graft failure, and smoking cessation reduces this risk.[69]

Pharmacotherapy to Improve Claudication

Both pentoxifylline and cilostazol are available for the treatment of claudication in patients with PAD (**Table 64.5**). *Pentoxifylline* is a xanthine derivative with benefits thought to be mediated through its hemorheologic properties, including its ability to decrease blood viscosity and to improve erythrocyte flexibility.[41] It has marginal efficacy.[41] *Cilostazol* is a quinolinone derivative that inhibits phosphodiesterase 3 (PDE3), thereby decreasing degradation of cyclic adenosine monophosphate and increasing its concentration in platelets and blood vessels. Although cilostazol inhibits platelet aggregation and causes vasodilation in experimental animals, its mechanism of action in patients with PAD is not known. Meta-analyses have found that cilostazol improves absolute claudication distance by 40% to 50% in comparison to placebo[70] (**eFig. 64.6**). Quality-of-life measures, as assessed by the 36-Item Short-Form Medical Outcomes Scale (SF-36) and Walking Impairment Questionnaire, also demonstrate improvement. A U.S. Food and Drug Administration (FDA) advisory states that cilostazol should not be used in patients with congestive heart failure because other PDE3 inhibitors decrease survival in these patients. A long-term safety trial found that cilostazol (versus placebo) did not increase the risk for total or CV mortality, but the study was limited because more than 60% of the patients discontinued treatment before completion of the study.[71]

TABLE 64.5

Approved Medical Therapies for Patients With Peripheral Artery Disease (PAD)

INDICATIONS						
Therapy	**Mechanism of Action**	**Key Clinical Trials**	**European Medicines Agency**	**European Society of Cardiology**	**FDA**	**ACC/AHA**
Statin (Class effect)	Cholesterol lowering HMG-CoA reductase inhibitor	Heart Protection Study 13% RRR with simvastatin 40 mg daily vs. placebo in all-cause mortality, 18% RRR in coronary heart death Approval for PAD based on subgroup of 6748 patients, 2700 had PAD and no CHD	Reduction in MACE and mortality	Class I for lipid lowering with LDL <2.5 mmol/L, optimally <1.8 mmol/L	Reduction in MACE and mortality	Class I, LOE A
ACEI or ARB (Class effect)	Blood pressure lowering and other vascular effects Renin-angiotensin system inhibition	HOPE 22% RRR with ramipril 10 mg daily vs. placebo for composite of MI, stroke, or CV death Approval for PAD based on subgroup of 4051 patients, 1725 with "clinical PAD"	Reduction in MACE	Class I for blood pressure lowering to ≤140/90 mm Hg	Reduction in MACE	Class I, LOE A for antihypertensive therapy Class IIa, LOE A for ACEI/ARB specifically
Clopidogrel	Antiplatelet $P2Y_{12}$ inhibitor	CAPRIE 8.7% RRR vs. aspirin for composite of ischemic stroke, MI, or vascular death Approval for PAD based on subgroup of 6452 patients	As monotherapy Reduction in MACE	Class I monotherapy for risk reduction Class I added to ASA after lower extremity stenting	As monotherapy Reduction in MACE	Class I, LOE A for monotherapy Class IIb, LOE B-R, C-LD, when added to aspirin as DAPT
Vorapaxar	Antiplatelet PAR-1 antagonist	TRA2P-TIMI 50 20% RRR vs. placebo for composite of MI, stroke, or CV death Approval for PAD based on subgroup of 3787 patients	Added to aspirin or clopidogrel Reduction in MACE, limb benefits mentioned	Approved after most recent guidelines	Added to aspirin and/or clopidogrel Reduction in MACE	Class IIb, LOE B-R added to aspirin and/or clopidogrel
Pentoxifylline	Decreases blood viscosity Mechanism not fully understood	Meta-analysis of six studies including 788 patients showed minimal increase in maximal walking distance with (+59 m)	Improve function and symptoms in patients with intermittent claudication	Described but no clear recommendation	Improve function and symptoms in patients with intermittent claudication	Class III, LOE B-R
Cilostazol	Antiplatelet and vasodilator Mechanism not fully understood	50 mg bid (n = 303), 100 mg bid (n = 998), and placebo (n = 973) Improvement in maximal walking distance with 100 mg bid, expressed as the percent mean change from baseline, 28% to 100% vs. placebo, which were −10% to 41%	Reduction of symptoms of intermittent claudication, as indicated by an increased walking distance	Class I for symptoms	Reduction of symptoms of intermittent claudication, as indicated by an increased walking distance	Class I, LOE A

FDA, U.S. Food and Drug Administration; *ACC/AHA,* American College of Cardiology/American Heart Association; *ACEI,* angiotensin-converting enzyme inhibitor; *ARB,* angiotensin receptor blocker; *bid,* twice daily; *CHD,* coronary heart disease; *CV,* cardiovascular; *DAPT,* dual-antiplatelet therapy; *LDL,* low-density lipoprotein; *LOE,* level of evidence *(B-R,* moderate-quality evidence from one or more randomized clinical trials; *C-LD,* randomized or nonrandomized observational/registry studies or a meta-analysis); *MACE,* major adverse cardiovascular events; *MI,* myocardial infarction; *PAR-1,* protease-activated receptor 1; *RRR,* relative risk reduction.

A pooled analysis of the durability and predictors of treatment response of cilostazol in patients with intermittent claudication. Vasc Med 2010;15:181.)

Antithrombotic Therapy

Studies evaluating the benefits of antithrombotic therapy in patients with atherosclerosis, including patients with PAD, have generally focused on outcomes of MI, stroke, and vascular death, with limb-vascular outcomes variably reported.[54] Two studies in stable patients with asymptomatic PAD showed no benefit of aspirin in reducing incident CLI or amputation.[41,56] A trial of ticlopidine, a $P2Y_{12}$ inhibitor, versus placebo in patients with PAD showed that it reduced limb events and mortality.[41] In CAPRIE, clopidogrel reduced CV risk relative to aspirin, but there were more amputations with clopidogrel (52 versus 47).[41] EUCLID showed no reduction in ALI or limb events with ticagrelor versus clopidogrel in patients without prior revascularization.[57,58] It is therefore unclear whether aspirin or clopidogrel as monotherapy provides limb-vascular benefit.

Many patients with PAD receive DAPT after intervention. Randomized trials to support this practice are lacking. In the CASPAR (Clopidogrel and Acetylsalicylic Acid in Bypass Surgery for Peripheral Artery Disease) trial, DAPT versus aspirin did not reduce the primary composite endpoint of graft occlusion, revascularization, amputation, or death in patients undergoing below-knee bypass surgery for PAD.[72] In TRA2°P-TIMI 50, vorapaxar, added to aspirin, clopidogrel, or DAPT, decreased ALI by 42%, with associated reductions in risk of graft thrombosis, stent thrombosis, and de novo thrombosis.[73] In PEGASUS-TIMI 54, ticagrelor added to aspirin reduced acute adverse limb events including ALI by 35%.[37] In the WAVE trial, there was no reduction in limb ischemia with warfarin.[61] The Dutch Bypass Oral Anticoagulants or Aspirin Study similarly found no benefit for limb outcomes with warfarin after infrainguinal bypass surgery.[41] Several ongoing trials of direct oral anticoagulants at lower doses are ongoing and include ALI in the primary or secondary endpoints.

Statins

In addition to systemic CV risk reduction, statins may improve symptoms of claudication and reduce the risk of tissue loss.[2,41] In the TREADMILL (Treatment of Peripheral Atherosclerotic Disease with Moderate or Intensive Lipid Lowering) trial, atorvastatin (80 mg) increased pain-free walking distance by more than 60% versus a 38% increase with placebo, and additional trials support these findings.[41] A propensity-adjusted analysis from the REACH Registry observed a reduction in amputations with statin use in patients with PAD.[2] The Heart Protection Study reported that simvastatin reduced the risk of a first

acute peripheral vascular event, defined retrospectively as the first occurrence of a noncoronary revascularization, aneurysm repair, major amputation, or death from PAD.[41]

Vasodilators

Most studies of vasodilators have failed to demonstrate any efficacy in patients with intermittent claudication. Several pathophysiologic explanations may account for the failure of vasodilator therapy in patients with PAD. During exercise, resistance vessels distal to a stenosis dilate in response to ischemia. Vasodilators would have minimal if any effect on these endogenously dilated vessels, but would decrease resistance in other vessels and create a relative steal phenomenon, thereby reducing blood flow and perfusion pressure to the affected leg. Moreover, in contrast to their effects on myocardial O_2 consumption in patients with CAD (because of afterload reduction), vasodilators do not reduce skeletal muscle O_2 demand.

Other Medical Therapies

Other classes of drugs, including serotonin (5-HT_2) antagonists, alpha-adrenergic antagonists, L-arginine, carnitine derivatives, vasodilator prostaglandins, antibiotics, and angiogenic growth factors, have been studied for the treatment of either claudication or CLI.[41] Overall, these therapies have not proved useful in improving PAD symptoms.[1] Angiogenic growth factors yielded encouraging preliminary findings in patients with CLI. However, large phase 3 clinical trials did not demonstrate improvement in the rate of amputation-free survival in patients with CLI or improvement in walking time in patients with intermittent claudication[74,75] In initial reports, stem cell–based therapies for PAD improved ABI, rest pain, and pain-free walking time and prevented amputation in some patients with chronic limb ischemia.[76,77] The response to cell therapy, however, may depend on patient selection, with some suggestion that patients with advanced CLI are poor candidates.[78] The findings from these preliminary trials require confirmation with additional clinical trials.

Percutaneous Transluminal Angioplasty and Stents

Peripheral catheter–based interventions are indicated for patients with lifestyle-limiting claudication despite a trial of exercise rehabilitation or pharmacotherapy[79] (**see Chapter 66**). Patients with CLI with anatomy amenable to catheter-based therapy may also be candidates for endovascular intervention. A large clinical trial is comparing the efficacy of endovascular intervention with surgical revascularization on limb outcomes in patients with critical limb ischemia.[80]

Peripheral Artery Surgery

Surgical revascularization improves symptoms in patients with disabling claudication and is indicated to relieve rest pain and preserve limb viability in patients with critical limb ischemia that is not amenable to percutaneous interventions. The specific operation must take into account the anatomic location of the arterial lesions and the presence of comorbid conditions. Planning for surgical procedures requires identification of the arterial obstruction by imaging to ensure sufficient arterial inflow to and outflow from the graft to maintain patency. *Aortobifemoral bypass* is the most frequent operation performed in patients with aortoiliac disease. Typically, a knitted or woven prosthesis made of Dacron or polytetrafluoroethylene (PTFE) is anastomosed proximally to the aorta and distally to each common

femoral artery.[81] On occasion the iliac artery is used for the distal anastomosis to maintain anterograde flow into at least one hypogastric artery. A systematic review of 29 studies from 1970 to 2007 that compared 5738 patients who underwent aortobifemoral bypass surgery found an operative mortality rate of 4%,[82] although high-volume centers in the United States report lower mortality rates. Five-year patency rates for aortobifemoral bypass grafts exceed 80%.[83]

Extra-anatomic surgical reconstructive procedures for aortoiliac disease include axillobifemoral bypass, iliobifemoral bypass, and femoral-femoral bypass. These bypass grafts circumvent the aorta and iliac arteries and are generally used in high-risk patients with CLI. Five-year patency rates range from 50% to 70% for axillobifemoral bypass operations and from 70% to 80% for femoral-femoral bypass grafts.[83] The operative mortality rate for extra-anatomic bypass procedures is 3% to 5% and reflects, in part, the serious comorbid conditions and advanced atherosclerosis in many of the patients who undergo these procedures.

Reconstructive surgery for infrainguinal arterial disease includes femoral-popliteal and femoral-tibial or femoral-peroneal artery bypass. Infrainguinal bypass uses in situ or reversed autologous saphenous veins or synthetic grafts made of PTFE as conduits. Patency rates for autologous saphenous vein bypass grafts exceed those with PTFE grafts,[83] Grafts with the distal anastomosis placed in the popliteal artery above the knee have better patency rates than those placed below the knee. Five-year primary patency rates for femoral-popliteal reconstruction in patients with claudication are approximately 80% and 75% for autogenous vein grafts and PTFE grafts, respectively, and approximately 65% and 45%, respectively, in patients with CLI. For femoral below-knee bypass, including tibioperoneal artery reconstruction, the 5-year patency rates for saphenous vein grafts in patients with claudication or CLI are similar to those for femoral-popliteal above-knee grafts (60% to 80%). The 5-year patency rate for PTFE grafts in the infrapopliteal position is considerably lower, approximately 65% in patients with claudication and 33% in patients with CLI. The operative mortality rate for infrainguinal bypass operations is 2% to 3%.

Graft stenoses can result from technical errors at surgery, such as retained valve cuffs or intimal flap or valvotome injury; from fibrous intimal hyperplasia, usually within 6 months of surgery; or from atherosclerosis, which usually occurs within the vein graft at least 1 to 2 years after surgery. Institution of graft surveillance protocols with the use of color-assisted duplex ultrasonography has enabled the identification of graft stenoses, thereby prompting graft revision and avoiding complete graft failure.[1] Routine ultrasonographic surveillance improves graft outcome.

Fig. 64.13 provides an overview of medical therapy for patients with PAD. **Table 64.5** details medical therapies approved for PAD patients.

Vasculitis

See Chapter 94.

Thromboangiitis Obliterans

Thromboangiitis obliterans (TAO), a segmental vasculitis that involves the distal arteries, veins, and nerves of the upper and lower extremities, typically affects younger persons who smoke.[84,85]

Pathology and Pathogenesis

TAO primarily affects the medium and small vessels of the arms, including the radial, ulnar, palmar, and digital arteries, and their counterparts in the legs, including the tibial, peroneal, plantar, and digital arteries. Involvement can extend to the cerebral, coronary, renal, mesenteric, aortoiliac, and pulmonary arteries.[85] Pathologic findings include an occlusive, highly cellular thrombus that incorporates polymorphonuclear leukocytes, microabscesses, and occasionally multinucleated giant cells. The inflammatory infiltrate can also affect the vascular wall, but the internal elastic membrane remains intact. In the chronic phase of the disease, the thrombus becomes organized and the vascular wall becomes fibrotic.

The precise cause of TAO is not known. Tobacco use or exposure is present in virtually every patient. Hypercoagulability, immunologic mechanisms, and endothelial dysfunction may contribute to the pathogenesis of TAO. Potential immunologic mechanisms include increased cellular sensitivity to types I and III collagen and the presence of antiendothelial cell antibodies. $CD4^+$ T cells have been identified in the cellular infiltrates of vessels of patients with TAO.[84] Decreased endothelium-dependent vasodilation can occur in both the affected and the unaffected limbs of patients with TAO. Some reports have found increased frequency of a prothrombin gene mutation, elevated plasma homocysteine concentration, or increased levels of anticardiolipin antibodies in patients with TAO.

Clinical Features

The prevalence of TAO is greater in Asia than in North America or Western Europe. In the United States, TAO occurs in approximately 13 per 100,000. Symptoms develop in most before 45 years of age, and 75%-90% are men. Patients can have claudication of the hands, forearms, feet, or calves. Most patients with TAO have pain at rest and digital ulcerations; frequently, more than one extremity is affected. Raynaud phenomenon occurs in approximately 45% of patients, and superficial thrombophlebitis, which may be migratory, develops in approximately 40%. The risk for amputation within 5 years is approximately 25%.[85] The radial, ulnar, dorsalis pedis, and posterior tibial pulses may be absent. Two thirds of patients have abnormal Allen test results. The distal aspects of the extremities may have discrete, tender, erythematous subcutaneous cords, indicative of superficial thrombophlebitis.

Diagnosis

No specific laboratory tests, other than biopsy, can diagnose TAO. Most tests therefore aim to exclude other diseases that might have similar clinical features, including autoimmune diseases such as scleroderma or SLE, hypercoagulable states, DM, and acute arterial occlusion secondary to embolism. Acute-phase indicators, such as the erythrocyte sedimentation rate (ESR) or CRP, are usually normal. Serum immunologic markers, including antinuclear antibodies and rheumatoid factor, should not be present, and serum complement levels should be normal. If clinically indicated, a proximal source of embolism should be excluded by imaging. Arteriography of an affected limb supports the diagnosis of TAO if there is segmental occlusion of small and medium arteries, absence of atherosclerosis, and corkscrew collateral vessels circumventing the occlusion (**Fig. 64.14**). These same findings, however, can occur in patients with scleroderma, SLE, mixed connective tissue disease, and antiphospholipid antibody syndrome. The conclusive test is a biopsy specimen showing the classic pathologic findings. This procedure is rarely indicated, however, and biopsy sites may fail to heal because of severe ischemia. The diagnosis therefore usually depends on an age at onset of younger than 45 years, a history of tobacco use, physical examination demonstrating distal limb ischemia, exclusion of other diseases, and if necessary, angiographic demonstration of typical lesions.

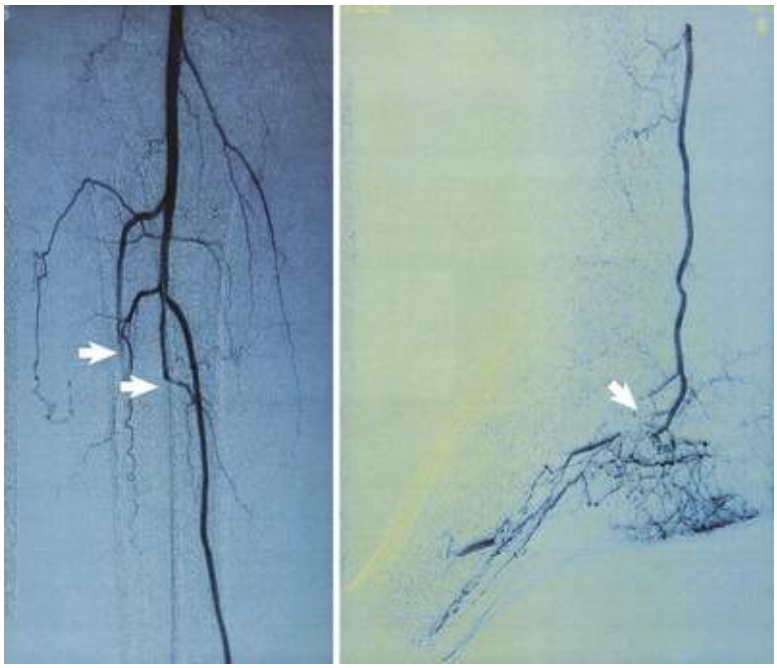

FIGURE 64.14 Angiograms of a young woman with thromboangiitis obliterans. **Left,** Occlusion of anterior tibial and peroneal arteries (*arrows*). **Right,** Occlusion of distal portion of posterior tibial artery (*arrow*) with bridging collateral vessels.

Treatment

The cornerstone of TAO treatment is cessation of tobacco use. Patients without gangrene who stop smoking rarely require amputation.[84] In contrast, one or more amputations may ultimately be required in 40%-45% of those who continue to smoke. No definitive drug therapy is available for TAO. Intravenous iloprost, a prostacyclin analogue, may be more effective than aspirin for rest pain and ischemic ulcers, but oral iloprost is not effective.[86] There is insufficient evidence to support the use of other vasodilator prostaglandin analogues in this setting.[86] Vascular reconstructive surgery is not usually a viable option because of the segmental nature of this disease and the involvement of distal vessels. An autogenous saphenous vein bypass graft can be considered if a target vessel for the distal anastomosis is available.

Takayasu Arteritis and Giant Cell Arteritis

See Chapter 94.

Fibromuscular Dysplasia

Fibromuscular dysplasia (FMD) is a noninflammatory disorder that affects medium and large arteries, typically the renal, carotid, and vertebral arteries. It also may involve the arteries supplying the leg, particularly the iliac arteries and less often the femoral, popliteal, tibial, and peroneal arteries.[87] FMD rarely causes intermittent claudication or CLI. It most often affects women but can occur at any age in both sexes. Although traditionally thought to occur in young women, recent registries have described occurrence primarily in middle-aged women.[87] In addition, while historically described as affecting the renal arteries with the highest frequency, registries describe similar involvement of the carotid, vertebral, and renal arteries, with approximately 65% of patients having multivessel involvement. Aneurysm or dissection is present in more than 40% of patients at diagnosis.[88] Spontaneous coronary artery dissection

(SCAD) is an uncommon presentation of FMD. The most frequent presenting signs and symptoms are hypertension, headache, pulsatile tinnitus, and dizziness illustrating clinical scenarios that should prompt consideration of FMD (**Table 64.6**).[87]

TABLE 64.6

Clinical Circumstances Prompting Consideration of Fibromuscular Dysplasia

Hypertension <35 years old or resistant hypertension at any age
Epigastric bruit and hypertension
Transient ischemic attack, stroke, or cervical bruit in a patient <60 years old
Symptomatic PAD in a woman < 60 years old without atherosclerotic risk factors
Subarachnoid hemorrhage
Pulsatile tinnitus
Severe and recurrent headaches
Peripheral artery dissection or spontaneous coronary artery dissection
Visceral or intracranial aneurysm
Aortic aneurysm in a patient <60
Renal infarction

Modified from Olin JW, Froehlich J, Gu X, et al. The United States Registry for Fibromuscular Dysplasia: results in the first 447 patients. Circulation 2012;125:3182-90.

In patients with suspected FMD, the diagnosis is confirmed by imaging including CT, MRI, and Duplex ultrasound. DSA is generally reserved for patients with a high clinical suspicion and nondiagnostic noninvasive imaging. FMD can be distinguished from atherosclerosis by imaging and patient characteristics (younger, lack of atherosclerosis risk factors) and from vasculitis by the absence of clinical signs, symptoms, or testing suggesting inflammation (e.g., elevated ESR or CRP).

Histopathologic examination shows fibroplasia most often affecting the media, but it can involve the intima or adventitia. The histologic classification of FMD includes the medial subtypes (medial fibroplasia, perimedial fibroplasia, and medial hyperplasia), as well as intimal fibroplasia and adventitial hyperplasia.[89] Depending on the histopathologic type, stenosis results from hyperplasia of the fibrous or muscular components of the vessel wall. Angiography can be classified into two subtypes. The first, *multifocal* FMD, is more common and presents with the classic “string of beads” and has been pathologically associated with intimal fibroplasia, medial hyperplasia, and to perimedial fibroplasia. The second, *focal* FMD, appears as a tubular stenosis, is less common, and is pathologically associated with medial hyperplasia and periarterial hyperplasia (**Fig. 64.15**). As many as one third of cases cannot be classified using angiographic criteria, and the pathologic subtypes overlap considerably. The lack of routine histopathology in the clinical setting and limitations of angiographic criteria have prompted consideration of alternative classification systems.[87]

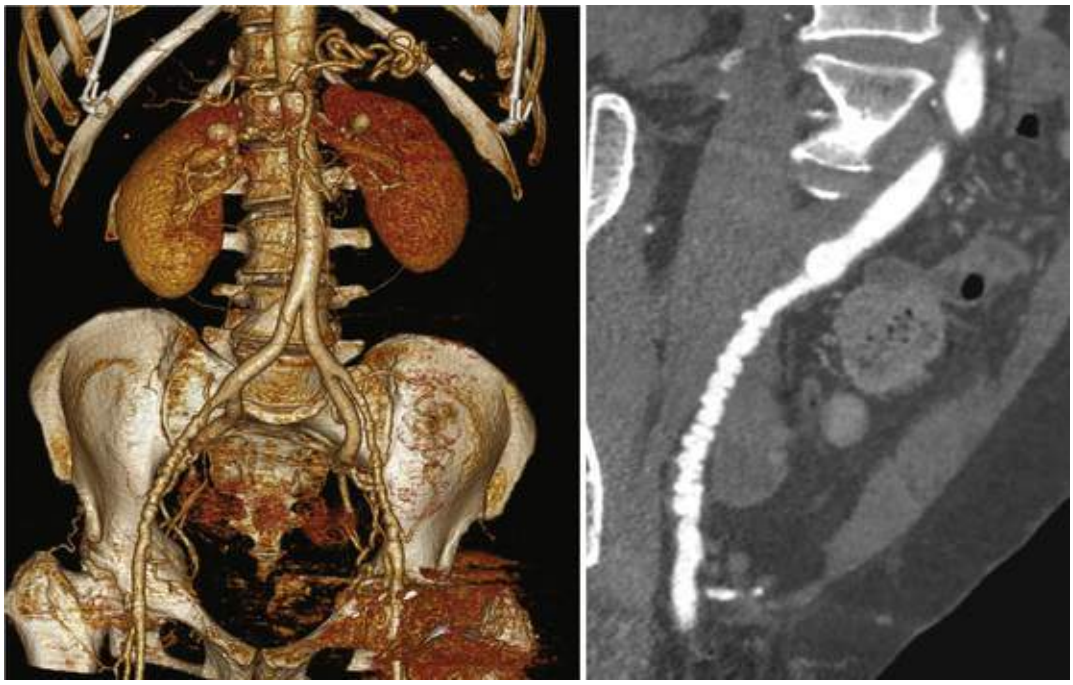

FIGURE 64.15 Angiograms of a patient with fibromuscular dysplasia (FMD). **Left,** Three-dimensional volume-rendered angiogram demonstrating bilateral external iliac FMD. **Right,** Maximum intensity projection of the external iliac artery . (Images courtesy Jeffrey Olin, MD.)

Symptomatic FMD patients can undergo angioplasty. All patients should receive medical therapy to treat any conventional risk factors (e.g., antihypertensive medications) and should have serial clinical evaluations with laboratory testing and/or imaging when indicated, based on clinical assessment. In general, medication use varies based on vascular bed involvement.[90] Smoking is associated with worse outcomes, underscoring the importance of cessation.[91]

Popliteal Artery Entrapment Syndrome

Popliteal artery entrapment syndrome is an uncommon cause of intermittent claudication. It occurs when an anatomic variation in the configuration or insertion of the medial head of the gastrocnemius muscle compresses the popliteal artery.[92] The popliteus muscle also can compress the popliteal artery and cause this syndrome. Popliteal artery entrapment is bilateral in approximately one third of affected patients. It should be suspected when a young, typically athletic, usually male person is evaluated for claudication. Potential consequences include popliteal artery thrombosis, embolism, and aneurysm formation.

Findings on peripheral pulse examination may be normal unless provocative maneuvers are performed. Walking or repeated ankle dorsiflexion and plantar flexion maneuvers may cause attenuation or disappearance of the pedal pulses and a decrease in the ABI in patients with popliteal artery entrapment. Imaging studies such as duplex ultrasonography, CTA, MRA, or conventional angiography, performed at rest and during ankle flexion maneuvers, can confirm the diagnosis. Treatment of popliteal artery entrapment syndrome involves release of the popliteal artery, which may require division and reattachment of the medial head of the gastrocnemius muscle. On occasion, occlusion of the popliteal artery requires surgical bypass. Five-year patency rates for surgical treatment exceed 80%.[93]

Acute Limb Ischemia

Acute limb ischemia (ALI) occurs when an arterial occlusion suddenly reduces blood flow to the arm or

leg.[94] The metabolic needs of the tissue outstrip perfusion, thereby jeopardizing limb viability. Pain may develop quickly and affect the part of the extremity distal to the site of obstruction. It is not necessarily confined to the foot or toes or the hand or fingers, as is usually the case with chronic limb ischemia (CLI). Concurrent ischemia of peripheral nerves causes sensory loss and motor dysfunction. Findings on physical examination can include absence of pulses distal to the occlusion, cool skin, pallor, delayed capillary return and venous filling, diminished or absent sensory perception, and muscle weakness or paralysis. This constellation of symptoms and signs is often recalled as the “six Ps”: pain, paresthesias, pallor, pulselessness, poikilothermia, and paralysis.

Prognosis

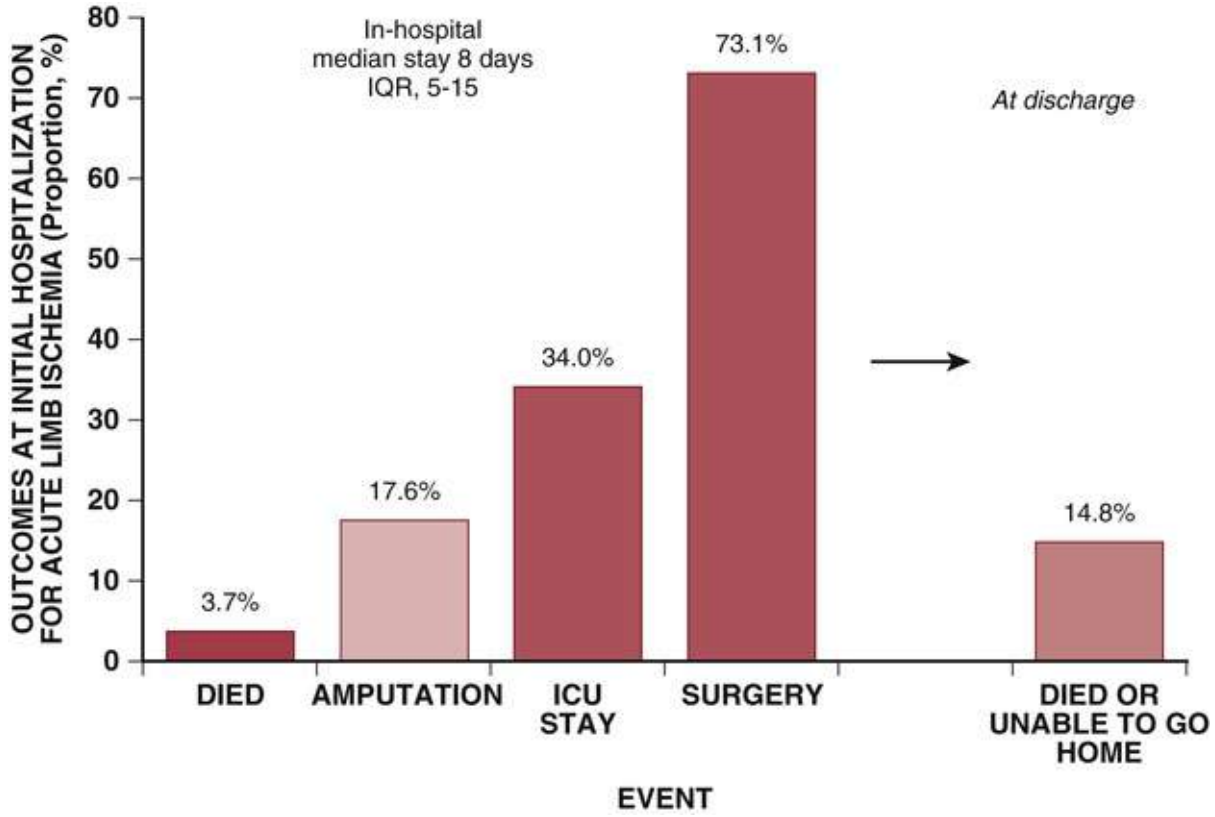
Patients with ALI usually have comorbid CV disorders, which may even be responsible for the ischemia. The risk for limb loss depends on the severity of the ischemia and the time elapsed before revascularization. Among patients with atherosclerosis presenting with ALI in a recent study, approximately 18% required amputation, and 15% either died or were unable to return home after hospitalization[73] (**eFig. 64.7**). The Society for Vascular Surgery and the International Society for Cardiovascular Surgery developed a classification that takes into consideration the severity of ischemia and the viability of the limb, along with related neurologic findings and Doppler signals[95] (**eTable 64.1**).

ETABLE 64.1

Clinical Categories of Acute Limb Ischemia

CATEGORY	DESCRIPTION, PROGNOSIS	FINDINGS		DOPPLER SIGNALS	
		Sensory Loss	Muscle Weakness	Arterial	Venous
I. Viable	Not immediately threatened	None	None	Audible	Audible
II. Threatened					
A. Marginally	Salvageable if treated promptly	Minimal (toes) or none	None	(Often) inaudible	Audible
B. Immediately	Salvageable with immediate revascularization	More than toes, rest pain	Mild, moderate	(Usually) inaudible	Audible
III. Irreversible	Major tissue loss or permanent nerve damage inevitable	Profound, anesthetic	Profound, paralysis (rigor)	Inaudible	Inaudible

Modified from Rutherford RB, Baker JD, Ernst C, et al. Recommended standards for reports dealing with lower extremity ischemia: revised version. J Vasc Surg 1997;26:517. Erratum in J Vasc Surg 2001;33:805.



EFIGURE 64.7 Outcomes in patients presenting with acute limb ischemia. *ICU,* Intensive care unit; *IQR,* interquartile range. (Modified from Bonaca MP, Gutierrez JA, Creager MA, et al. Acute limb ischemia and outcomes with vorapaxar in patients with peripheral artery disease: results from the Trial to Assess the Effects of Vorapaxar in Preventing Heart Attack and Stroke in Patients with Atherosclerosis–Thrombolysis in Myocardial Infarction 50 (TRA2°P-TIMI 50). Circulation 2016;133:997-1005.)

Pathogenesis

Causes of ALI include embolism, thrombosis in situ, dissection, and trauma. A large proportion are embolic[96,97] (**Fig. 64.16**). Most arterial emboli arise from thrombotic sources in the heart, as occurs in atrial fibrillation, or other sources such as prosthetic cardiac valves, paradoxical embolism, and cardiac tumors such as left atrial myxomas. Aneurysms of the aorta or peripheral arteries may lead to embolization of thrombus to more distal arterial sites and usually lodge at branch points where the artery decreases in size. In patients with established PAD, causes of ALI include in-situ atherothrombosis, graft thrombosis, or stent thrombosis[73] (**Fig. 64.16**). Thrombosis in situ occurs in atherosclerotic peripheral arteries, infrainguinal bypass grafts, peripheral artery aneurysms, and normal arteries of patients with hypercoagulable states. In patients with PAD, thrombosis in situ may complicate plaque rupture and cause acute arterial occlusion and limb ischemia, as occurs in the coronary arteries of patients with acute MI. One of the most common causes of ALI in patients with PAD is thrombotic occlusion of an infrainguinal bypass graft. Acute thrombotic occlusion of a normal artery is unusual but may occur in patients with acquired thrombophilic disorders such as antiphospholipid antibody syndrome, heparin-induced thrombocytopenia, disseminated intravascular coagulation, and myeloproliferative diseases. There is limited evidence that inherited thrombophilic disorders such as activated protein C resistance (factor V Leiden), prothrombin *G20210* gene mutation, or deficiencies of antithrombin III and protein C and S increase the risk for acute peripheral arterial thrombosis.

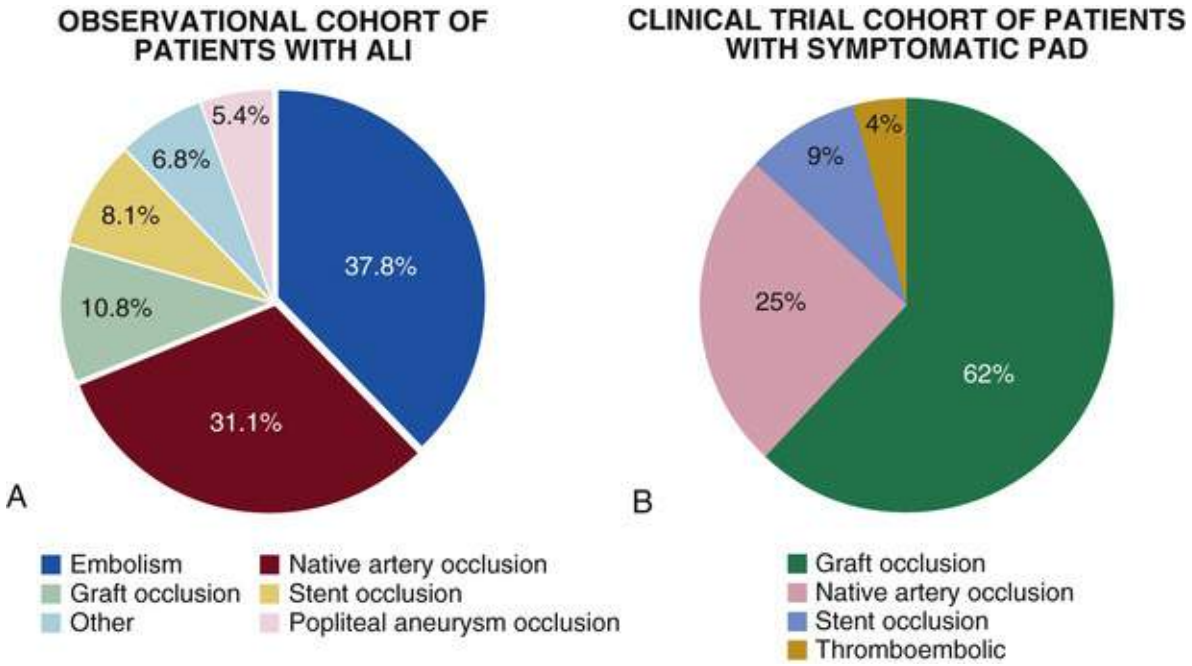


FIGURE 64.16 Etiologies of acute limb ischemia (ALI) in an All Comers registry **(A)** and in patients with symptomatic peripheral artery disease (PAD) not requiring anticoagulation **(B).** (**A,** Modified from Duval S et al. The impact of prolonged lower limb ischemia on amputation, mortality, and functional status: the FRIENDS registry. Am Heart J 2014;168:577-87; **B,** modified from Bonaca MP et al. Acute limb ischemia and outcomes with vorapaxar in patients with peripheral artery disease: results from the Trial to Assess the Effects of Vorapaxar in Preventing Heart Attack and Stroke in Patients with Atherosclerosis–Thrombolysis in Myocardial Infarction 50 (TRA2°P-TIMI 50). Circulation 2016;133:997-1005.)

Diagnostic Tests

The history and physical examination usually establish the diagnosis of ALI. Tests should not delay urgent revascularization procedures to rescue a limb with threatened viability. Pressure in the affected limb and corresponding ABI can be measured if flow is detectable by Doppler ultrasonography. A Doppler probe can assess the presence of blood flow in peripheral arteries, even when pulses are not palpable. Color-assisted duplex ultrasonography can determine the site of occlusion, particularly to evaluate the patency of infrainguinal bypass grafts. MRA, CTA, and conventional arteriography can demonstrate the site of occlusion and provide an anatomic guide for revascularization.

Treatment

For patients with acute leg ischemia, the bed should be positioned such that the feet are lower than chest level, thereby increasing limb perfusion pressure by hydrostatic effects. Effort should be made to reduce pressure on the heels, on bone prominences, and between the toes by appropriate placement of soft material on the bed (e.g., sheepskin) and between the toes (e.g., lamb's wool). Heparin should be administered intravenously immediately.[94] The dose should maintain the partial thromboplastin time at 2.0 to 2.5 times control values to prevent propagation of thrombi or recurrent embolism.

Revascularization is indicated when the viability of the limb is threatened or when symptoms of ischemia persist (**Fig. 64.17**). Options for restoration of blood flow include endovascular revascularization, intra-arterial thrombolytic therapy, and surgical revascularization. Catheter-directed intra-arterial thrombolysis plus thrombectomy is an initial treatment option for patients with either category I or II acute limb ischemia if they have no contraindication to thrombolysis.[94] Identification and repair of a graft stenosis after successful thrombolysis improve long-term graft patency. The thrombolytic regimens currently used include the recombinant tissue plasminogen activators alteplase, reteplase, and

tenecteplase. Catheter-based thrombolytic therapy should generally be continued for 24 to 48 hours to achieve optimal benefit and to limit the risk for bleeding. Adjuvant use of platelet glycoprotein IIb/IIIa inhibitors shortens thrombolysis time but does not improve outcome. Percutaneous, catheter-based mechanical thrombectomy, with devices that remove thrombus via aspiration, fragmentation, or high-energy ultrasound, can be used alone or in addition to pharmacologic thrombolysis to treat patients with ALI. Surgical revascularization, including thromboembolectomy and bypass of the occluded area, is an option for restoration of blood flow to an ischemic limb. Five prospective randomized trials have compared the benefits and risks of thrombolysis and surgical reconstruction in ALI patients. Overall, the two interventions did not differ in the rate of death or amputation during the 1 year between, although patients undergoing thrombolysis had a greater risk for major bleeding. Findings from the individual trials suggest that catheter-based thrombolysis is an appropriate initial option in patients with viable or marginally threatened limbs and when the ischemia is of less than 14 days' duration, whereas surgical revascularization is more appropriate in those with immediately threatened limbs and in those whose symptoms have lasted for more than 14 days. Patients with irreversible injury require amputation (**Fig. 64.17**).

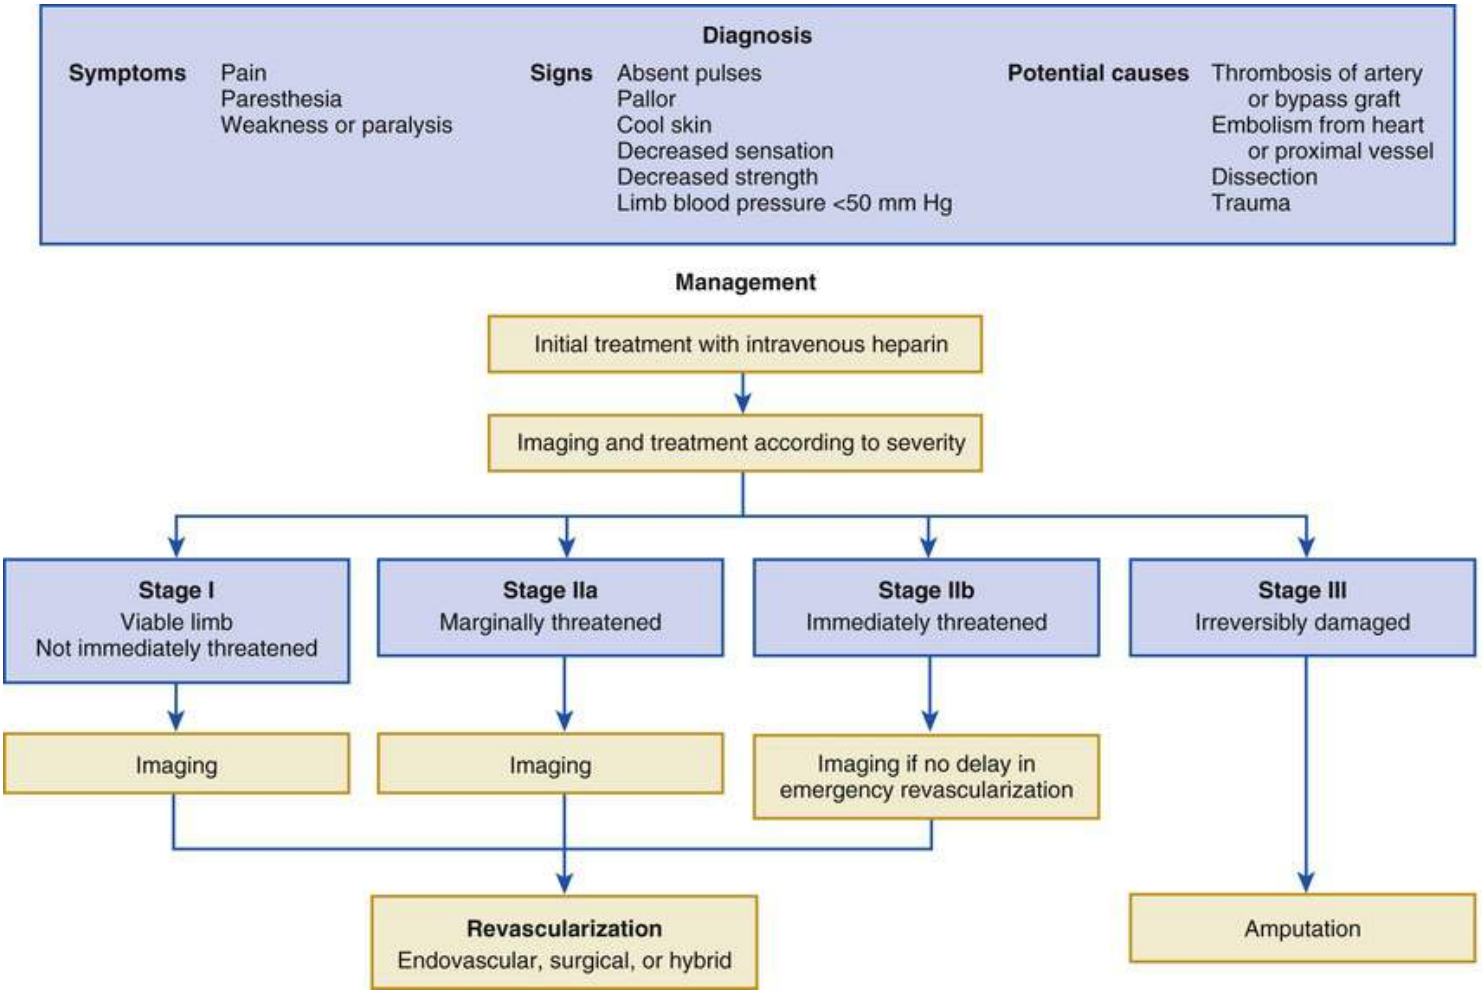

FIGURE 64.17 Diagnostic and treatment approach for patients presenting with acute limb ischemia.

The optimal long-term antithrombotic strategy in patients with ALI remains uncertain. Long-term anticoagulant therapy is usually indicated for patients with an embolic source, such as atrial fibrillation. For patients with symptomatic PAD who develop ALI from thrombotic complications in the limbs (e.g., graft occlusion, stent thrombosis, in situ thrombosis), intensive antiplatelet therapy may be more effective

than aspirin alone in reducing recurrent events.[3,37] Warfarin has not proved beneficial in secondary prevention of nonembolic ALI and is generally only indicated based on the underlying etiology (e.g., atrial fibrillation).

Atheroembolism

Atheroembolism refers to occlusion of arteries resulting from detachment and embolization of atheromatous debris, including fibrin, platelets, cholesterol crystals, and calcium fragments. Other terms include *atherogenic embolism* and *cholesterol embolism.* Atheroemboli originate most frequently from "shaggy," protruding atheroma of the aorta and less frequently from atherosclerotic branch arteries (**eFig. 64.8**). The atheroemboli typically occlude small downstream arteries and arterioles of the skin, extremities, brain, eyes, kidneys, or mesentery. Most affected individuals are men older than 60 years with clinical evidence of atherosclerosis.

EFIGURE 64.8 Atherosclerotic aorta of a patient with atheroemboli. Multiple, protruding, shaggy atheromas with superimposed mural thrombi are present. (Courtesy R.N. Mitchell, MD, PhD, Department of Pathology, Brigham and Women's Hospital, Boston.)

Pathogenesis

Patients with aortic atherosclerosis characterized by large complex atheromas have the greatest risk for atheroembolism. Identification of large, protruding atheromas by transesophageal ultrasound predicts future embolic events. Catheter manipulation may also cause atheroemboli, in approximately 1% to 2% of patients undergoing endovascular procedures. Similarly, surgical manipulation of the aorta during cardiac or vascular operations may precipitate atheroembolism. Controversy remains whether anticoagulants or thrombolytic drugs contribute to atheroembolism. Recent clinical trials of anticoagulants have found a relatively low incidence of atheroembolism in patients with large aortic plaques.

Clinical Features

The most notable clinical features of atheroembolism involving the extremities include painful cyanotic toes, called “blue toe syndrome” (**Fig. 64.18**). Livedo reticularis occurs in approximately 50% of patients. Local areas of erythematous or violaceous discoloration may be present on the lateral aspects of the feet and the soles, as well as on the calves. Other findings include digital and foot ulcerations, nodules, purpura, and petechiae. Pedal pulses are typically present because the emboli tend to lodge in the more distal digital arteries and arterioles. Symptoms and signs indicating additional organ involvement with atheroemboli should be sought. Renal involvement, manifested by increased BP and azotemia, typically occurs in patients with peripheral atheroemboli. Patients also sometimes show evidence of mesenteric or bladder ischemia and splenic infarction.

FIGURE 64.18 Atheroemboli involving the foot, or “blue toe syndrome.” There is cyanotic discoloration of the toes along with localized areas of violaceous discoloration. (Modified from Beckman JA, Creager MA. Peripheral artery disease: clinical evaluation. In Creager MA, Beckman JA, Loscalzo J, editors. Vascular Medicine: A Companion to Braunwald's Heart Disease. 2nd ed. Philadelphia: Elsevier; 2013, p 231.)

The clinical setting and findings usually suffice for the diagnosis of atheroembolism, but other diseases may have some of the manifestations of atheroemboli. Hypersensitivity vasculitides secondary to connective tissue diseases, infections, drugs, polyarteritis nodosa, or cryoglobulinemia generally involve multiple organ systems and cause cutaneous findings of purpura, ulcers, and digital ischemia, similar to those resulting from atheroemboli (**see Chapter 94**). Procoagulant disorders such as antiphospholipid antibody syndrome, heparin-induced thrombocytopenia, and myeloproliferative disorders such as essential thrombocythemia can cause digital artery thrombosis with resultant digital ischemia, cyanosis, and ulceration.

Diagnostic Tests

Laboratory findings consistent with atheroembolism include an elevated ESR, eosinophilia, and eosinophiluria. Other findings may include anemia, thrombocytopenia, hypocomplementemia, and

azotemia. Imaging of the aorta with TEE, MRA, or CTA may identify sites of severe atherosclerosis indicating a source of the atheroemboli. The only definitive test for atheroembolism is pathologic confirmation on skin or muscle biopsy specimens. Pathognomonic findings include elongated needle-shaped clefts in small arteries caused by cholesterol crystals and often accompanied by inflammatory infiltrates composed of lymphocytes and possibly giant cells and eosinophils, intimal thickening, and perivascular fibrosis.

Treatment

No definitive treatment has been established for atheroembolism. Local foot care should be provided as with acute limb ischemia. It may be necessary to excise or amputate necrotic areas.

Risk factor modification, such as lipid-lowering therapy with statins and smoking cessation, can favorably affect the overall outcome of atherosclerosis, but whether such intervention will prevent recurrent atheroembolism is unknown. The efficacy of antiplatelet therapy in preventing recurrence is unknown, although antiplatelets are generally indicated in patients with atherosclerosis. The use of warfarin is controversial, and some have even suggested that anticoagulants precipitate atheroemboli, whereas others have found that warfarin reduces atheroembolic events, particularly in patients with mobile aortic atheroma. The use of corticosteroids to treat atheroembolism is also controversial.

Surgical removal of the source should be considered in patients with atheroembolism, particularly in those with recurrence. Surgical procedures include excision and replacement of affected portions of the aorta, endarterectomy, and bypass operations. Operative intervention targets the site of the aorta and iliac or femoral arteries with aneurysm formation or evidence for mobile atherosclerotic plaque. Frequently, diffuse aortic disease makes it difficult to identify the precise segment responsible for the atheroembolism. Several small case series have reported endovascular placement of stents and stent grafts to prevent recurrent atheroembolism.

Guidelines

Peripheral Artery Diseases

Marc P. Bonaca and Mark A. Creager

The American College of Cardiology Foundation/American Heart Association (ACCF/AHA) Task Force on Practice Guidelines published its most recent guidelines for the management of patients with peripheral artery disease (PAD) in 2016.[1] This summary presents salient features and important recommendations from these guidelines. We omit some recommendations superseded by more recent statements or data.

Vascular History and Physical Examination

The ACCF/AHA guidelines state that practitioners should query patients at risk for PAD about limitations in walking caused by symptoms of fatigue, aching, numbness, or pain in the buttocks, thighs, calves, or feet and about leg discomfort associated with exertion and rest. Additional questions can determine whether the patient has pain even at rest or poorly healing or nonhealing wounds of the legs or feet. The guidelines recommend performance of a comprehensive pulse examination and careful inspection of the

feet. This includes measurement of blood pressure in both arms; auscultation of the carotid arteries, abdomen, and femoral arteries for bruits; and palpation of the brachial, radial, ulnar, femoral, popliteal, dorsalis pedis, and posterior tibial artery pulses. The feet are inspected to assess skin color, temperature, integrity, and the presence of ulcerations (**Tables 64G.1 and 64G.2; see also Table 64G.6**).

TABLE 64G.1

ACCF/AHA Guidelines for Vascular History and Physical Examination of Patients With Peripheral Artery Disease (PAD)

COR	INDICATION	LOE
I	1. Patients at increased risk of PAD should undergo a comprehensive medical history and a review of symptoms to assess for exertional leg symptoms.	B-NR
	2. Patients at increased risk of PAD should undergo vascular examination, including palpation of lower extremity pulses (i.e., femoral, popliteal, dorsalis pedis, and posterior tibial), auscultation for femoral bruits, and inspection of the legs and feet.	B-NR
	3. Patients with PAD should undergo noninvasive blood pressure measurement in both arms at least once during the initial assessment.	B-NR

COR, Class of recommendation; *LOE,* level of evidence; *B-NR,* moderate-quality evidence from one or more nonrandomized clinical trials.

TABLE 64G.2

ACCF/AHA Guidelines for Longitudinal Follow-Up in Patients With Peripheral Artery Disease

COR	INDICATION	LOE
I	1. Patients with PAD should be followed up with periodic clinical evaluation, including assessment of cardiovascular risk factors, limb symptoms, and functional status.	C-EO
	2. Patients with PAD who have undergone lower extremity revascularization (surgical and/or endovascular) should be followed up with periodic clinical evaluation and ABI measurement.	C-EO
IIa	1. Duplex ultrasound can be beneficial for routine surveillance of infrainguinal, autogenous vein bypass grafts in patients with PAD.	B-R
	2. Duplex ultrasound is reasonable for routine surveillance after endovascular procedures in patients with PAD.	C-LD
IIb	The effectiveness of duplex ultrasound for routine surveillance of infrainguinal prosthetic bypass grafts in patients with PAD is uncertain.	B-R

COR, Class of recommendation; *LOE,* level of evidence; *B-R,* moderate-quality evidence from one or more randomized clinical trials; *C-EO,* consensus of expert opinion; *C-LD,* randomized or nonrandomized observational/registry studies or a meta-analysis.

Diagnostic Tests

Noninvasive vascular diagnostic techniques provide adjunctive diagnostic information to the history and physical examination. Such tests include physiologic measurements and imaging studies. Noninvasive physiologic assessment may include the ankle-brachial and toe-brachial indices, segmental pressure measurements, Doppler waveform analysis, pulse volume recordings, and exercise testing (**Table 64G.3; see Chapter 64**).

TABLE 64G.3

ACCF/AHA Guidelines for Diagnostic Testing, Anatomic Assessment and Screening of Other Arterial Beds in Patients With Peripheral Artery Disease

COR	INDICATION	LOE
I	1. In patients with history or physical examination findings suggestive of PAD, the resting ankle-brachial index (ABI), with or without segmental pressures and waveforms, is recommended to establish the diagnosis.	B-NR
	2. Resting ABI results should be reported as abnormal (ABI ≤0.90), borderline (ABI 0.91 to 0.99), normal (1.00 to 1.40), or noncompressible (ABI >1.40).	C-LD
	3. Toe-brachial index (TBI) should be measured to diagnose patients with suspected PAD when the ABI is greater than 1.40.	B-NR
	4. Patients with exertional non–joint-related leg symptoms and normal or borderline resting ABI (>0.90 and ≤1.40) should undergo exercise treadmill ABI testing to evaluate for PAD.	B-NR
	5. Duplex ultrasound, CTA, or MRA of the lower extremities is useful to diagnose anatomic location and severity of stenosis for patients with symptomatic PAD in whom revascularization is considered.	B-NR
	6. Invasive angiography is useful for patients with CLI in whom revascularization is considered.	C-EO
IIa	1. In patients at increased risk of PAD but without history or physical examination findings suggestive of PAD, measurement of the resting ABI is reasonable.	B-NR
	2. In patients with PAD and an abnormal resting ABI (≤0.90), exercise treadmill ABI testing can be useful to objectively assess functional status.	B-NR
	3. In patients with normal (1.00 to 1.40) or borderline (0.91 to 0.99) ABI in the setting of nonhealing wounds or gangrene, it is reasonable to diagnose CLI by using TBI with waveforms, $TcPO_2$, or SPP.	B-NR
	4. In patients with PAD with an abnormal ABI (≤0.90) or with noncompressible arteries (ABI >1.40 and TBI ≤0.70) in the setting of nonhealing wounds or gangrene, TBI with waveforms, $TcPO_2$, or SPP can be useful to evaluate local perfusion.	B-NR
	5. Invasive angiography is reasonable for patients with lifestyle-limiting claudication with an inadequate response to GDMT for whom revascularization is considered.	C-EO
	6. A screening duplex ultrasound for AAA is reasonable in patients with symptomatic PAD.	B-NR
III	1. In patients not at increased risk of PAD (**see Table 64.1**) and without history or physical examination findings suggestive of PAD, the ABI is not recommended.	B-NR
	2. Invasive and noninvasive angiography (CTA, MRA) should not be performed for the anatomic assessment of patients with asymptomatic PAD.	B-R

COR, Class of recommendation; *LOE,* level of evidence; *AAA,* abdominal aortic aneurysm; *CLI,* critical limb ischemia; *CTA,* computed tomographic angiography; *GDMT,* guideline-directed medical therapy; *MRA,* magnetic resonance angiography.

Medical Management of Patients With Peripheral Artery Disease

Medical treatment of patients with PAD is directed toward reducing adverse cardiovascular events and improving symptoms of intermittent claudication. Drugs, other risk factor–modifying measures, and antiplatelet agents can decrease the risk for myocardial infarction (MI), stroke, and cardiovascular death (**Table 64G.4**). Exercise and cilostazol both improve walking distance in patients with claudication (**Table 64G.5**). Medical therapies have not been demonstrated to preserve limb viability in patients once they develop critical limb ischemia, and these patients should undergo urgent evaluation for revascularization (**Tables 64G.6 to 64G.8**).

TABLE 64G.4

ACCF/AHA Guidelines for Medical Therapy for Patients With Peripheral Artery Disease

COR	INDICATION	LOE
I	1. Antiplatelet therapy with aspirin alone (range, 75 to 325 mg/day) or clopidogrel alone (75 mg/day) is recommended to reduce MI, stroke, and vascular death in patients with symptomatic PAD.	A
	2. Treatment with a statin medication is indicated for all patients with PAD.	A
	3. Antihypertensive therapy should be administered to patients with hypertension and PAD to reduce the risk of MI, stroke, heart failure, and cardiovascular death.	A
	4. Patients with PAD who smoke cigarettes or use other forms of tobacco should be advised at every visit to quit.	A
	5. Patients with PAD who smoke cigarettes should be assisted in developing a plan for quitting that includes pharmacotherapy (varenicline, bupropion, and/or nicotine replacement therapy) and/or referral to a smoking cessation program.	A
	6. Patients with PAD should avoid exposure to environmental tobacco smoke at work, at home, and in public places.	B-NR
	7. Management of diabetes mellitus in the patient with PAD should be coordinated between members of the health care team.	C-EO
	8. Cilostazol is an effective therapy to improve symptoms and increase walking distance in patients with claudication.	A
	9. Patients with PAD should have an annual influenza vaccination.	C-EO
IIa	1. In asymptomatic patients with PAD (ABI ≤0.90), antiplatelet therapy is reasonable to reduce the risk of MI, stroke, or vascular death.	C-EO
	2. The use of angiotensin-converting enzyme inhibitors or angiotensin receptor blockers can be effective to reduce the risk of cardiovascular ischemic events in patients with PAD.	A
	3. Glycemic control can be beneficial for patients with CLI to reduce limb-related outcomes.	B-NR
IIb	1. In asymptomatic patients with borderline ABI (0.91 to 0.99), the usefulness of antiplatelet therapy to reduce the risk of MI, stroke, or vascular death is uncertain.	B-R
	2. The effectiveness of dual-antiplatelet therapy (aspirin and clopidogrel) to reduce the risk of cardiovascular ischemic events in patients with symptomatic PAD is not well established.	B-R
	3. Dual-antiplatelet therapy (aspirin and clopidogrel) may be reasonable to reduce the risk of limb-related events in patients with symptomatic PAD after lower extremity revascularization.	C-LD
	4. The overall clinical benefit of vorapaxar added to existing antiplatelet therapy in patients with symptomatic PAD is uncertain.	B-R
	5. The usefulness of anticoagulation to improve patency after lower extremity autogenous vein or prosthetic bypass is uncertain.	B-R
III	1. Anticoagulation should not be used to reduce the risk of cardiovascular ischemic events in patients with PAD.	A
	2. Pentoxifylline is not effective for treatment of claudication.	B-R
	3. Chelation therapy (e.g., ethylenediaminetetraacetic acid) is not beneficial for treatment of claudication.	B-R
	4. B-complex vitamin supplementation to lower homocysteine levels for prevention of cardiovascular events in patients with PAD is not recommended.	B-R

COR, Class of recommendation; *LOE,* level of evidence; *ABI,* ankle-brachial index; *CLI,* critical limb ischemia; *MI,* myocardial infarction.

TABLE 64G.5

ACCF/AHA Guidelines for Exercise Therapy in Patients With Peripheral Artery Disease

COR	INDICATION	LOE
I	1. In patients with claudication, a supervised exercise program is recommended to improve functional status and quality of life and to reduce leg symptoms.	A
	2. A supervised exercise program should be discussed as a treatment option for claudication before possible revascularization.	B-R
IIa	1. In patients with PAD, a structured community- or home-based exercise program with behavioral change techniques can be beneficial to improve walking ability and functional status.	A
	2. In patients with claudication, alternative strategies of exercise therapy, including upper-body ergometry, cycling, and pain-free or low-intensity walking that avoids moderate to maximum claudication while walking, can be beneficial to improve walking ability and functional status.	A

COR, Class of recommendation; *LOE,* level of evidence.

TABLE 64G.6

ACCF/AHA Guidelines for Minimizing Tissue Loss in Patients With Peripheral Artery Disease

COR	INDICATION	LOE
I	1. Patients with PAD and diabetes mellitus should be counseled about self–foot examination and healthy foot behaviors.	C-LD
	2. In patients with PAD, prompt diagnosis and treatment of foot infection are recommended to avoid amputation.	C-LD
IIa	1. In patients with PAD and signs of foot infection, prompt referral to an interdisciplinary care team can be beneficial.	C-LD
	2. It is reasonable to counsel patients with PAD without diabetes mellitus about self–foot examination and healthy foot behaviors.	C-EO
	3. Biannual foot examination by a clinician is reasonable for patients with PAD and diabetes mellitus.	C-EO

COR, Class of recommendation; *LOE,* level of evidence.

TABLE 64G.7

ACCF/AHA Guidelines for Revascularization of Patients With Peripheral Artery Disease

COR	INDICATION	LOE
I	1. In patients with CLI, revascularization should be performed when possible to minimize tissue loss.	B-NR
	2. An evaluation for revascularization options should be performed by an interdisciplinary care team before amputation in the patient with CLI.	C-EO
	3. Endovascular procedures are recommended to establish in-line blood flow to the foot in patients with nonhealing wounds or gangrene.	B-R
	4. Surgical procedures are recommended to establish in-line blood flow to the foot in patients with nonhealing wounds or gangrene.	C-LD
	5. When surgery is performed for CLI, bypass to the popliteal or infrapopliteal arteries (i.e., tibial, pedal) should be constructed with suitable autogenous vein.	A
	6. Endovascular procedures are effective as a revascularization option for patients with lifestyle-limiting claudication and hemodynamically significant aortoiliac occlusive disease.	A
	7. When surgical revascularization is performed, bypass to the popliteal artery with autogenous vein is recommended in preference to prosthetic graft material.	A
IIa	1. Revascularization is a reasonable treatment option for the patient with lifestyle-limiting claudication with an inadequate response to GDMT.	A
	2. Endovascular procedures are reasonable as a revascularization option for patients with lifestyle-limiting claudication and hemodynamically significant femoropopliteal disease.	B-R
	3. Surgical procedures are reasonable as a revascularization option for patients with lifestyle-limiting claudication with inadequate response to GDMT, acceptable perioperative risk, and technical factors suggesting advantages over endovascular procedures.	B-NR
	4. A staged approach to endovascular procedures is reasonable in patients with ischemic rest pain.	C-LD
	5. Evaluation of lesion characteristics can be useful in selecting the endovascular approach for CLI.	B-R
	6. In patients with CLI for whom endovascular revascularization has failed and a suitable autogenous vein is not available, prosthetic material can be effective for bypass to the below-knee popliteal and tibial arteries.	B-NR
	7. A staged approach to surgical procedures is reasonable in patients with ischemic rest pain.	C-LD
IIb	1. The usefulness of endovascular procedures as a revascularization option for patients with claudication due to isolated infrapopliteal artery disease is unknown.	C-LD
	2. Use of angiosome-directed endovascular therapy may be reasonable for patients with CLI and nonhealing wounds or gangrene.	B-NR
III	1. Endovascular procedures should *not* be performed in patients with PAD solely to prevent progression to CLI.	B-NR
	2. Surgical procedures should *not* be performed in patients with PAD solely to prevent progression to CLI.	B-NR
	3. Femoral-tibial artery bypasses with prosthetic graft material should not be used for the treatment of claudication.	B-R

COR, Class of recommendation; *LOE,* level of evidence; *CLI,* critical limb ischemia; *GDMT,* guideline-directed medical therapy.

TABLE 64G.8

ACCF/AHA Guidelines for Wound Healing Therapies for Patients With Critical Limb Ischemia (CLI)

COR	INDICATION	LOE
I	1. An interdisciplinary care team should evaluate and provide comprehensive care for patients with CLI and tissue loss to achieve complete wound healing and a functional foot.	B-NR
	2. In patients with CLI, wound care after revascularization should be performed with the goal of complete wound healing.	C-LD
IIb	1. In patients with CLI, intermittent pneumatic compression (arterial pump) devices may be considered to augment wound healing and/or ameliorate severe ischemic rest pain.	B-NR
	2. In patients with CLI, the effectiveness of hyperbaric oxygen therapy for wound healing is unknown.	C-LD
III	Prostanoids are not indicated in patients with CLI.	B-R

COR, Class of recommendation; *LOE,* level of evidence.

Revascularization Strategies for Patients With Peripheral Artery Disease

Revascularization procedures can improve symptoms and preserve limb viability. These procedures are broadly categorized as endovascular interventions and surgical reconstruction, although hybrid procedures consisting of both endovascular and surgical revascularization are also used. In determining the type of revascularization procedure, one important consideration is the location of the obstruction, which is broadly categorized as *inflow,* involving the aorta and iliac arteries; *outflow,* including the femoral and popliteal arteries; or *run-off,* affecting the tibial and peroneal arteries. The decision to perform endovascular or surgical procedures also depends on the clinical context and the morphologic features and distribution of the stenotic and occlusive lesions. Endovascular interventions may involve percutaneous transluminal angioplasty (PTA) with balloon dilation, stents, atherectomy, and thrombolysis. Surgical procedures include aortobifemoral bypass; iliac endarterectomy; extra-anatomic bypass, such as

femoral-femoral and axillobifemoral bypass; and infrainguinal bypass procedures, such as femoral-popliteal and femoral-tibial bypass. Infrainguinal bypass procedures generally use saphenous veins for the bypass conduit, but other veins or synthetic material may also be used, such as polytetrafluoroethylene (PTFE) (**Table 64G.7**).

Management of Acute Limb Ischemia

The ACCF/AHA guidelines state that patients with symptoms and signs of acute limb ischemia should undergo emergency evaluation and treatment to preserve viability in a salvageable extremity. Revascularization strategies include catheter-based thrombolysis/thrombectomy or surgical revascularization. Considerations for determining the type of revascularization procedure used to treat acute limb ischemia include the cause of acute arterial occlusion, the duration of time since the onset of symptoms, and the severity of limb ischemia (**Table 64G.9**).

TABLE 64G.9

ACCF/AHA Guidelines for Management of Patients With Acute Limb Ischemia (ALI)

COR	INDICATION	LOE
I	1. Patients with ALI should be emergently evaluated by a clinician with sufficient experience to assess limb viability and implement appropriate therapy.	C-EO
	2. In patients with suspected ALI, initial clinical evaluation should rapidly assess limb viability and potential for salvage and does not require imaging.	C-LD
	3. In patients with ALI, systemic anticoagulation with heparin should be administered unless contraindicated.	C-EO
	4. In patients with ALI, the revascularization strategy should be determined by local resources and patient factors (e.g., etiology, degree of ischemia).	C-LD
	5. Catheter-based thrombolysis is effective for patients with ALI and a salvageable limb.	A
	6. Amputation should be performed as the first procedure in patients with a nonsalvageable limb.	C-LD
	7. Patients with ALI should be monitored and treated (e.g., fasciotomy) for compartment syndrome after revascularization.	C-LD
	8. In the patient with ALI, a comprehensive history should be obtained to determine the cause of thrombosis and/or embolization.	C-EO
IIa	1. In patients with ALI with a salvageable limb, percutaneous mechanical thrombectomy can be useful as adjunctive therapy to thrombolysis.	B-NR
	2. In patients with ALI due to embolism and with a salvageable limb, surgical thromboembolectomy can be effective.	C-LD
	3. In the patient with a history of ALI, testing for a cardiovascular cause of thromboembolism can be useful.	C-EO
IIb	The usefulness of ultrasound-accelerated catheter-based thrombolysis for patients with ALI with a salvageable limb is unknown.	C-LD

COR, Class of recommendation; *LOE,* level of evidence.

Prevention and Management of Ischemic Stroke

Larry B. Goldstein

Each year, more than 795,000 Americans have strokes (cerebrovascular accidents), and more than 150,000 die. In 2013, stroke fell from the fourth to the fifth leading cause of death in the United States.[1] Approximately 6.6 million Americans age 20 years or older have had a stroke, a leading cause of severe, long-term disability. Stroke disproportionately affects minority populations. In 2013, 58% of stroke-related deaths occurred in women, and women are less than half as likely as men to be able to live independently after stroke. Although age is a major risk factor for stroke, approximately 10% of strokes occur in persons 18 to 50 years of age.[1] Risk factors for stroke overlap with those for coronary artery disease (CAD) and peripheral artery disease (PAD), yet stroke can reflect diverse pathophysiologic processes, and therapies can confer different levels of benefit and risk than for other vascular diseases.[2] This discussion focuses on therapeutic interventions that have particular relevance for cardiologists. The American Heart Association/American Stroke Association (AHA/ASA) provides detailed, current evidence-based guidelines for prevention of a first stroke,[2] prevention of recurrent stroke,[3] and emergency management of patients with ischemic stroke.[4-6]

This chapter reviews various aspects of medical therapy for ischemic stroke. Readers are directed to AHA guidelines reviewing the use of carotid endarterectomy and angioplasty/stenting for primary and secondary prevention of stroke[2,3,7] and to **Chapter 66**.[7]

Medical Therapy for Prevention of Stroke

Approximately 78% of strokes are first events, which makes primary prevention of paramount importance.[1] Approximately 18% of survivors will have a second stroke within 4 years. After a transient ischemic attack (TIA), patients have a risk for ischemic stroke of approximately 11% over 90 days, with the highest risk in the first week.[1] TIA is a frequently misdiagnosed condition defined as a transient episode of neurologic dysfunction caused by focal brain, spinal cord, or retinal ischemia, without acute infarction. A study that used systems dedicated to the urgent evaluation and management of patients with TIA found a much lower 90-day risk (3.7%).[8] The ABCD2 score was developed to help assess the short-term risk for stroke in patients with TIA[9] (**Table 65.1**). The risk for stroke within 2 days is low (1%) in those with a score of 0 to 3, moderate (4%) in those with a score of 4 to 5, and high (8%) in those with a score of 6 to 7.[9] Even those at apparent low risk, however, may require urgent treatment.[10] Indeed, 22% of strokes occur in patients with an ABCD2 score of less than 4.[8]

TABLE 65.1

ABCD2 Score

FACTOR	POINTS

Blood pressure >140/90 mm Hg	1
Clinical Features	
Speech deficit, no weakness	1
Unilateral weakness	2
Diabetes	1
Duration	
10-59 minutes	1
>60 minutes	2

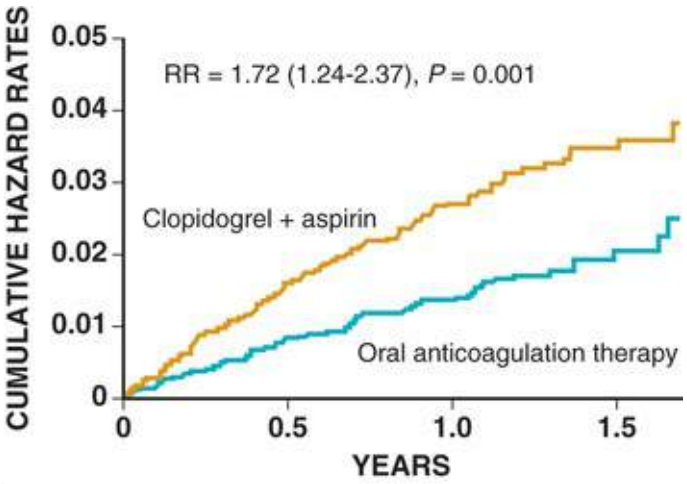
Platelet Antiaggregants

Primary Prevention

The use of platelet antiaggregants for preventing a first stroke depends on the patient's global risk for cardiovascular (CV) events and stroke, as assessed by any of several instruments (**see Chapter 45**). The benefit of aspirin for primary CV prophylaxis outweighs its associated risk for bleeding complications in persons with a 10-year risk greater than 10%. There is no evidence that platelet antiaggregants reduce the risk for stroke in persons at low risk, or in those with diabetes in the absence of other major risk factors, and aspirin is not recommended for these purposes[2] (**see Chapter 45**).

The Women's Health Study found no reduction in its prespecified primary endpoint (nonfatal myocardial infarction [MI], nonfatal stroke, or CV death) with aspirin (100 mg on alternate days), but there was a 17% reduction in stroke, although with an increase in the risk for bleeding.[11] This benefit occurred primarily in women who had stroke risk factors (e.g., hypertension, diabetes). Thus, aspirin may be considered for primary stroke prevention in women whose risk for stroke outweighs its associated bleeding risk.[2]

Patients with atrial fibrillation (AF) should generally receive anticoagulation for prevention of stroke.[3,12] In addition to warfarin, additional agents are available for prevention of a first and recurrent stroke in patients with nonvalvular AF[3] (see later and **Chapters 38 and 93**). Aspirin or the combination of aspirin and clopidogrel is inferior to warfarin for stroke prevention in patients with AF and should only be considered in those who cannot take anticoagulants[13] (**eFig. 65.1**).

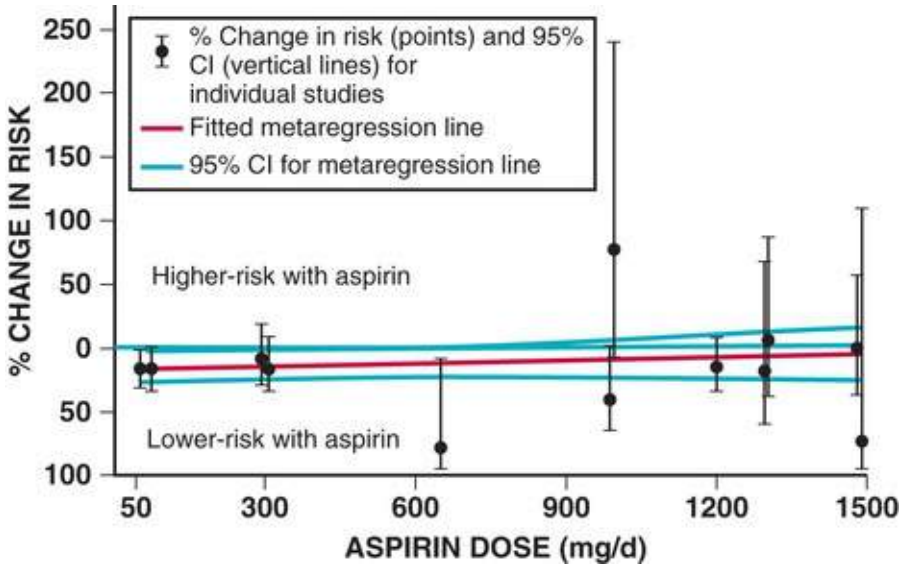


No. at risk				
Clopidogrel + aspirin	3335	3168	2419	941
Oral anticoagulation therapy	3371	3232	2466	930

EFIGURE 65.1 Clopidogrel plus aspirin versus anticoagulation in patients with atrial fibrillation and risk for stroke. RR, Risk ratio (relative risk). (From Connolly S, Pogue J, Hart R, et al. Clopidogrel plus aspirin versus oral anticoagulation for atrial fibrillation in the Atrial Fibrillation Clopidogrel Trial with Irbesartan for Prevention of Vascular Events (ACTIVE W): a randomised controlled trial. Lancet 2006;367:1903.)

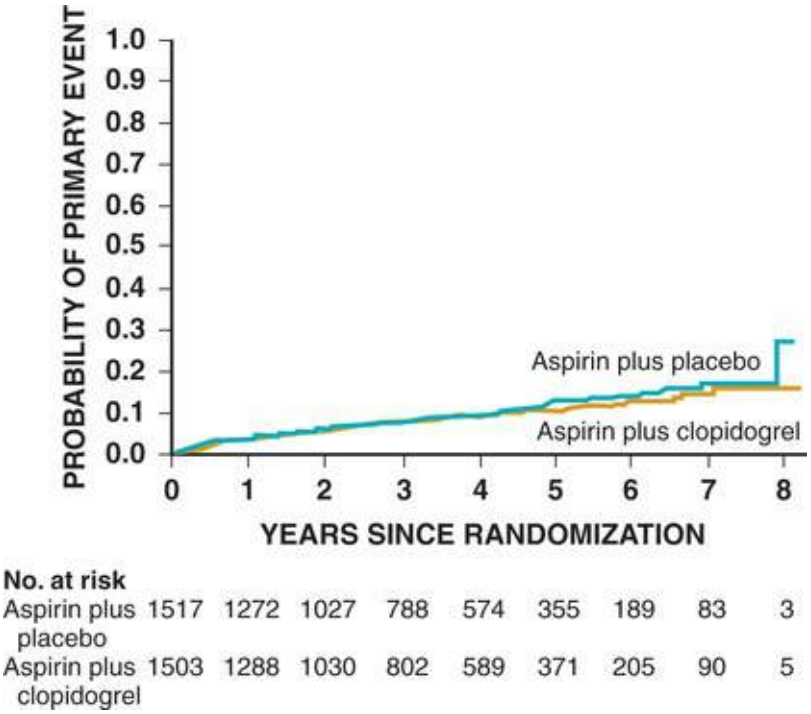
Secondary Prevention

Aspirin (lowest efficacious dose in comparison to placebo, 50 mg/day) lowers the risk of recurrent stroke by approximately 15% (95% confidence interval [CI] 6% to 23%) in persons with noncardioembolic ischemic stroke with little or no increase in stroke recurrence with higher doses[3,14] (**eFig. 65.2**). Sustained-release (SR) *dipyridamole* (200 mg twice daily) is as efficacious as aspirin in reducing the risk for recurrent stroke, with a further reduction (37%) when the two drugs are combined; the combination reduces the risk of stroke by 23% compared to aspirin alone.[3,15] Cardiologists are often concerned that dipyridamole might increase the risk of cardiac ischemia, but clinical trials have not substantiated this reservation.



EFIGURE 65.2 Megaregression analysis showing no difference in the effect of aspirin in reducing stroke risk for doses ranging between 50 and 1500 mg daily. (From Johnson ES, Lanes SF, Wentworth CE, et al. A metaregression analysis of the dose-response effect of aspirin on stroke. Arch Intern Med 1999;159:1248.)

Clopidogrel monotherapy given to patients with a history of MI, stroke, or symptomatic PAD reduces the combined risk of MI, stroke, or vascular death by 8.7% (95% CI 0.3% to 16.5%; $P = 0.043$) compared with aspirin.[3] Although based on a potentially underpowered subgroup analysis, there is no evidence of a significant reduction in stroke in those with previous stroke. The combination of clopidogrel and aspirin does reduce the rate of myocardial infarction, stroke, or death from CV causes more than aspirin alone in patients with cardiovascular disease (CVD, including stroke) or multiple risk factors.[16] When tested specifically in patients with a history of stroke, the combination of clopidogrel and aspirin was associated with an increase in bleeding complications without a reduction in ischemic stroke.[17] SPS3 (Stroke Prevention Study 3) similarly found a higher risk for hemorrhage with no reduction in ischemic events after lacunar stroke in those treated with the combination versus aspirin alone[18] (**Fig. 65.1**).



No. at risk									
Aspirin plus placebo	1517	1272	1027	788	574	355	189	83	3
Aspirin plus clopidogrel	1503	1288	1030	802	589	371	205	90	5

FIGURE 65.1 Aspirin plus clopidogrel versus aspirin for secondary prevention of stroke in patients with lacunar stroke. Probability of the primary outcome is shown. The hazard ratio for the primary outcome, recurrent stroke, was 0.92 (95% CI 0.72 to 1.2). (From SPS3 Investigators. Effects of clopidogrel added to aspirin in patients with recent lacunar stroke. N Engl J Med 2012;367:817.)

The Clopidogrel in High-Risk Patients with Acute Nondisabling Cerebrovascular Events (CHANCE) trial, conducted in China, compared clopidogrel plus aspirin versus aspirin alone starting within 24 hours of minor ischemic stroke or high-risk TIA, with the combination continued for 21 days.[19] The combination reduced the risk of stroke (8.2% versus 11.7%; hazard ratio [HR], 0.68; 95% CI 0.57 to 0.81; $P < 0.001$) with no difference in hemorrhage (**Fig. 65.2**). Pending the results of similar trial in the United States, a short course of clopidogrel and aspirin started within 24 hours can be considered in patients with noncardioembolic minor stroke or high-risk TIA.[3] Long-term clopidogrel plus aspirin should not be used for stroke prophylaxis in patients at high risk or in patients with recent major stroke.[3]

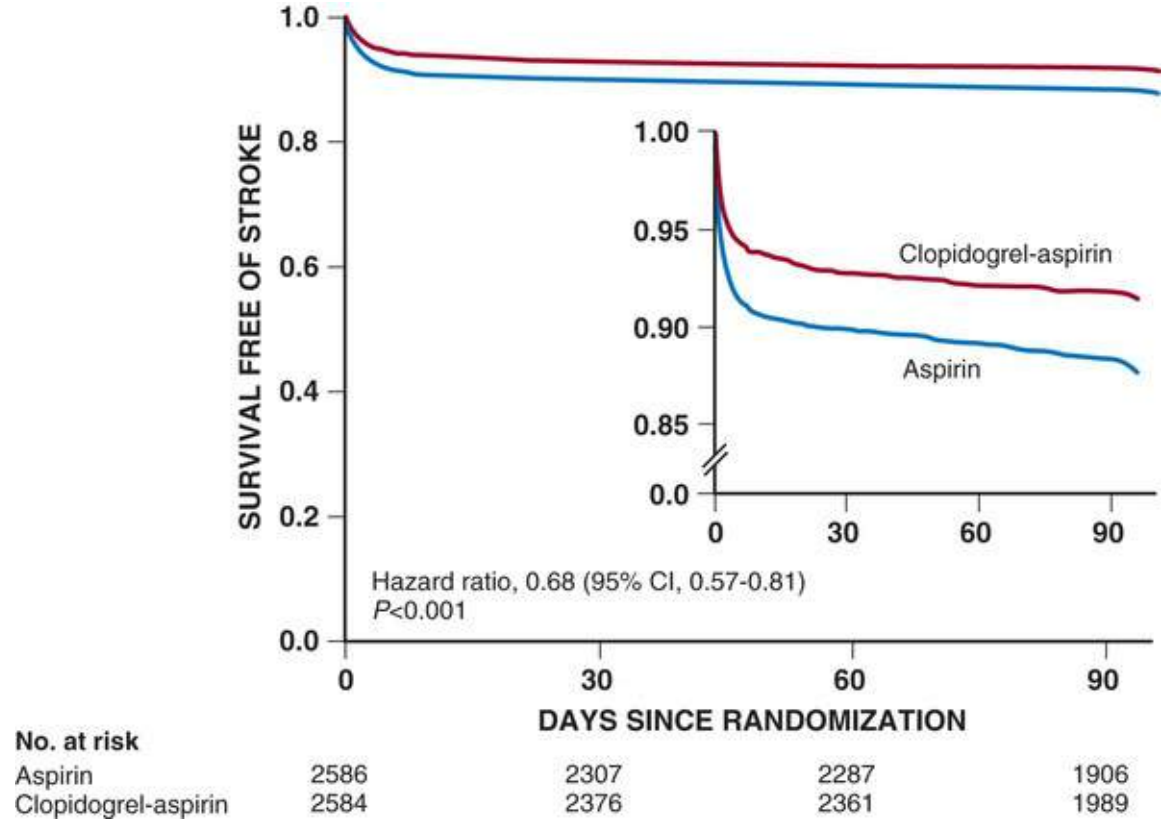


FIGURE 65.2 Effect of clopidogrel at an initial dose of 300 mg, followed by 75 mg/day for 90 days, plus aspirin (75 mg/day for first 21 days), versus placebo plus aspirin (75 mg/day for 90 days), on 90-day stroke risk in patients with minor stroke or TIA, with therapy started within 24 hours. (From Wang Y, Wang Y, Zhao X, et al. Clopidogrel with aspirin in acute minor stroke or transient ischemic attack. N Engl J Med 2013;369:11.)

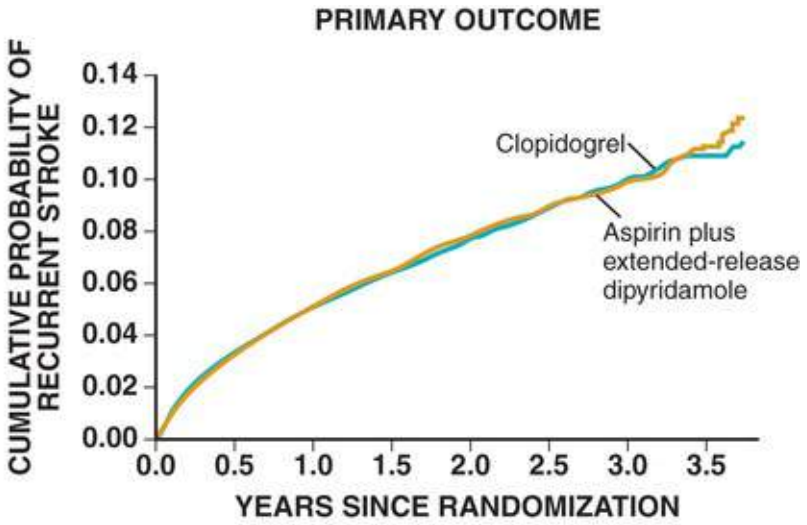
A direct comparison found that aspirin plus dipyridamole was comparable to clopidogrel monotherapy for secondary stroke prevention in patients with noncardioembolic stroke[20] (**eFig. 65.3**). Aspirin, aspirin plus SR dipyridamole, and clopidogrel are reasonable options for secondary stroke prevention in these patients.[3]



No. at risk								
Aspirin plus extended-release dipyridamole	10,181	9715	9431	9146	6970	4426	2332	1060
Clopidogrel	10,151	9677	9371	9137	6934	4435	2331	1037

EFIGURE 65.3 Clopidogrel versus aspirin plus extended-release dipyridamole (ERDP) for secondary stroke prevention. The primary outcome is time to first recurrent stroke. (From Sacco RL, Diener HC, Yusuf S, et al. Aspirin and extended-release dipyridamole versus clopidogrel for recurrent stroke. N Engl J Med 2008;359:1238.)

No prospective randomized trials available have assessed different antithrombotic regimens in patients who have a recurrent event while receiving an antiplatelet drug. A prospective registry study found a reduced composite of stroke, MI, and vascular death in patients who had a stroke while taking aspirin who were either switched to a different antiplatelet drug or who had a second antiplatelet added to aspirin[21] (**Fig. 65.3**)

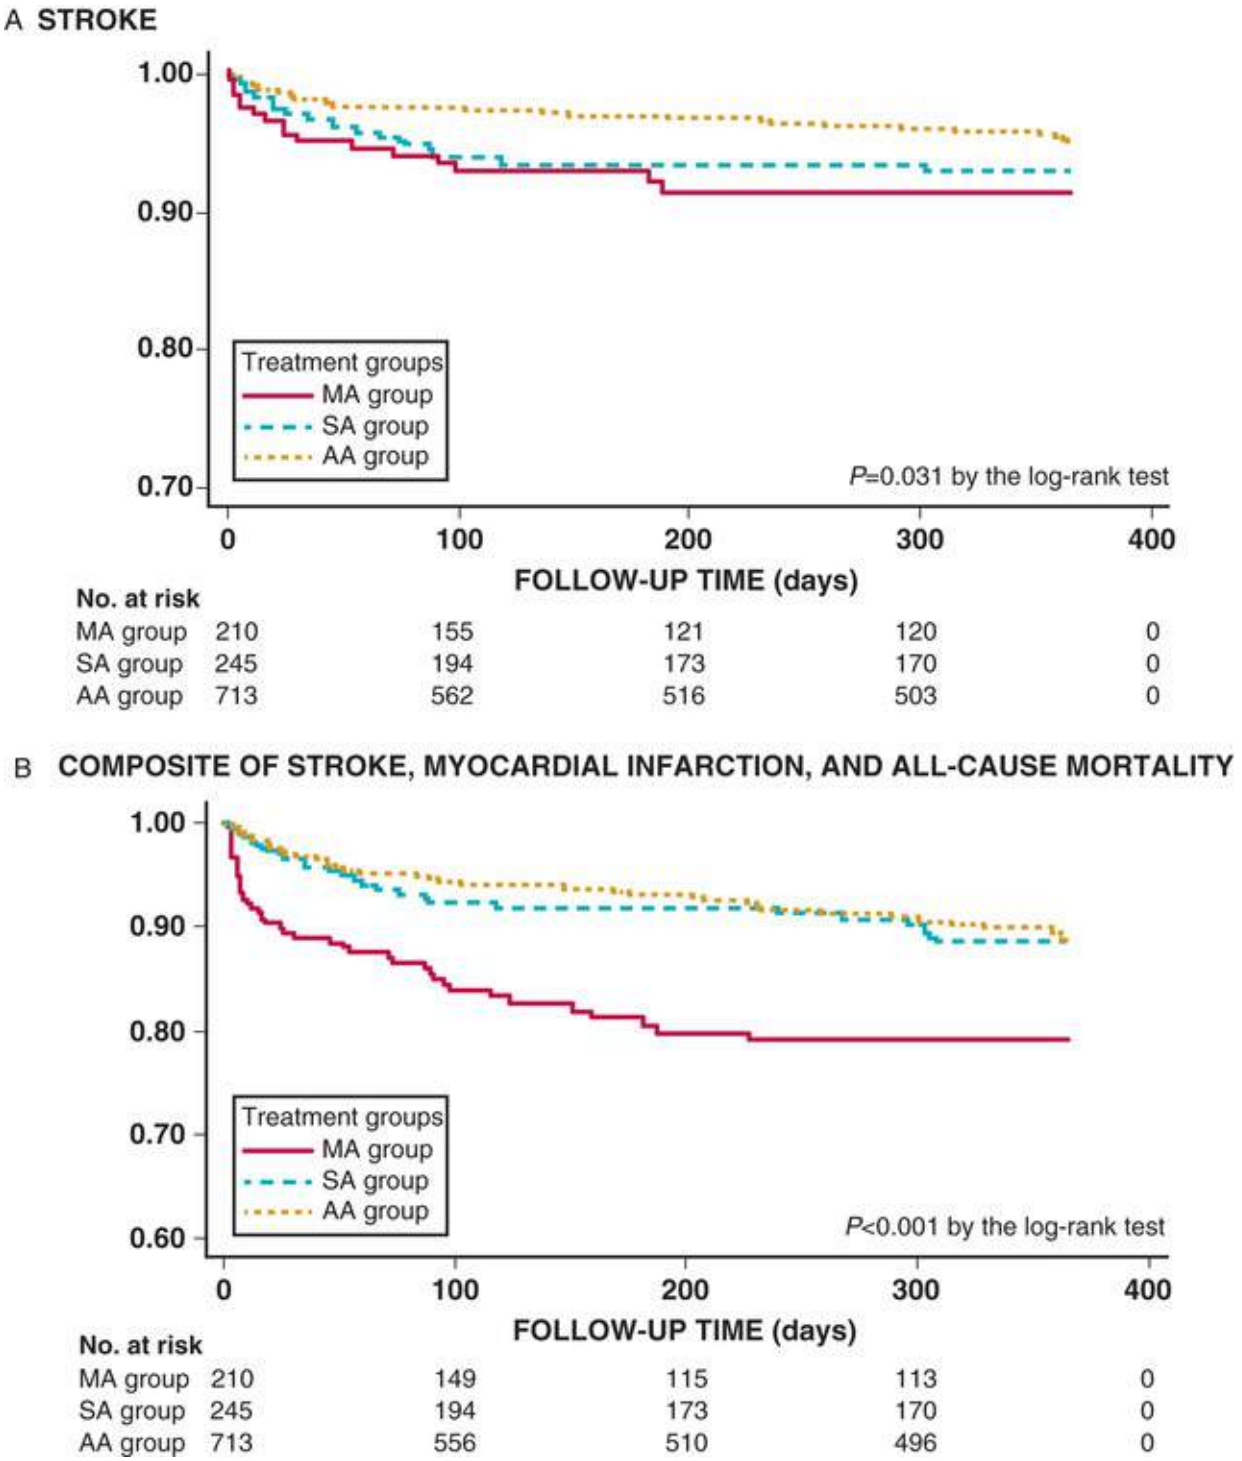


FIGURE 65.3 Effect of maintaining aspirin versus changing antiplatelet therapy in patients who had an ischemic stroke while on aspirin therapy, based on analysis of data from a prospective registry. **A,** Primary endpoint of stroke. **B,** Composite endpoint of stroke, myocardial infarction, and all-cause mortality. AA, Add another antiplatelet agent; MA, Maintain aspirin therapy; SA, Switch aspirin to a different anti-platelet agent. (From Kim JT, Park MS, Choi KH, et al. Different antiplatelet strategies in patients with new ischemic stroke while taking aspirin. Stroke 2016;47:128.)

Anticoagulation

Primary Prevention

The use of long-term anticoagulation to reduce the risk for a first cardiogenic embolism in patients at increased risk because of conditions such as mechanical heart valves, AF, and cardiomyopathy is addressed in **Chapters 25, 38, 63, and 93** and in **Part VIII**.

Secondary Prevention

Evidence supporting the use of anticoagulation for prevention of recurrent stroke in patients without AF or other high-risk cardiogenic sources is uncertain, or the evidence suggests that the benefit does not outweigh the risk for warfarin-associated bleeding complications. Thus, patients who have had a noncardioembolic ischemic stroke or TIA should receive antiplatelet agents rather than oral anticoagulation to reduce the risk for recurrent stroke and other CV events.[3]

Although based on a post hoc analysis, data from Warfarin-Aspirin Recurrent Stroke Study (WARSS) addressed "aspirin nonresponders." This term is used variably to refer to patients taking aspirin who have no measurable platelet antiaggregant effect or to patients who have a recurrent ischemic event such as stroke despite treatment. The WARSS analysis used the latter definition. Despite a high rate of recurrent stroke in patients failing aspirin therapy who were subsequently treated with aspirin, there was no advantage to switching from aspirin to warfarin (and as previously reviewed, no randomized trials have assessed the benefit of switching to an alternative platelet antiaggregant regimen in this setting).

The WASID (Warfarin-Aspirin Symptomatic Intracranial Disease) trial compared warfarin (international normalized ratio [INR] of 2 to 3) with aspirin (1300 mg/day).[22] The rate of recurrent ischemic stroke, intracerebral hemorrhage, or non–stroke-related vascular death did not differ between the two treatment regimens (22% with warfarin versus 21% with aspirin; $P = 0.83$), but the rate of major hemorrhage was higher with warfarin (8.3% versus 3.2%; $P = 0.01$). Because of a lack of efficacy and a higher rate of bleeding complications, warfarin should not generally be used for patients with symptomatic large-vessel intracranial steno-occlusive disease.[3] The SAMMPRIS (Stenting and Aggressive Medical Management for Preventing Recurrent Stroke in Intracranial Stenosis) trial further showed superiority of aggressive medical management to angioplasty/stenting in patients with symptomatic, large-vessel intracranial steno-occlusive disease because of a high, early risk for stroke with endovascular treatment[23] (**Fig. 65.4**). Further work shows that intracranial atherosclerotic stenosis can regress with modern medical therapy.[24]

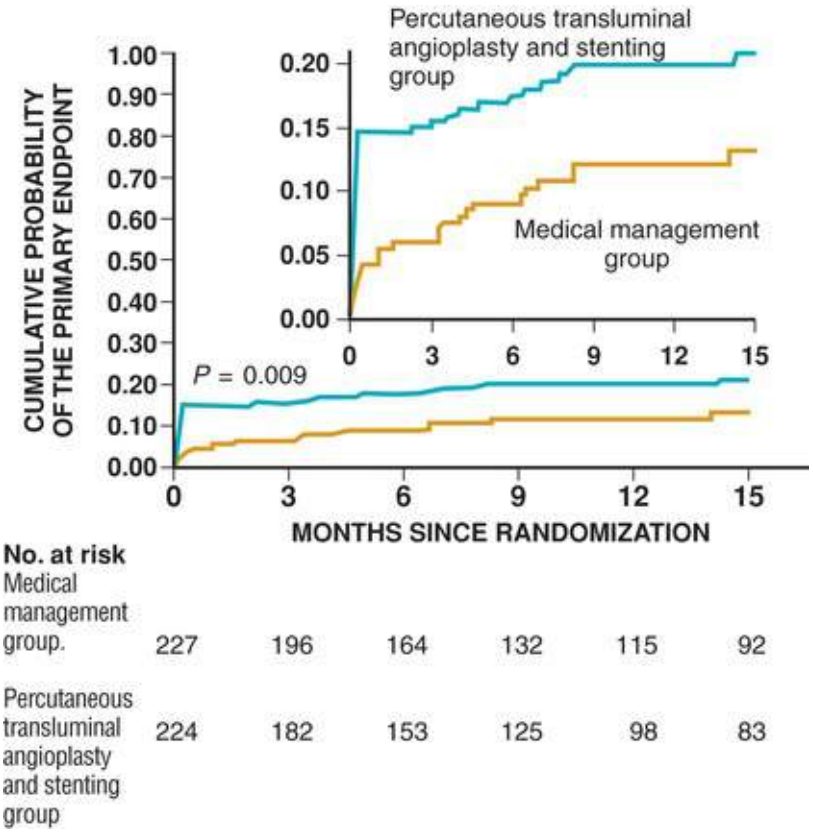

FIGURE 65.4 Percutaneous transluminal angioplasty and stenting plus medical therapy versus medical therapy alone in patients with symptomatic, high-grade intracranial stenosis. Kaplan-Meier curves for the cumulative probability of the primary endpoint according to treatment assignment are shown. The primary endpoint was stroke or death within 30 days after enrollment or after a revascularization procedure for the qualifying lesion during the follow-up period, or stroke in the territory of the qualifying artery beyond 30 days. The curves were truncated at 15 months, because relatively few patients have been followed beyond this time, and only two primary endpoint events have occurred beyond 15 months, both in the group receiving percutaneous transluminal angioplasty and stenting (PTAS) (one at 26.1 months and one at 26.2 months). The maximum duration of follow-up is 28.9 months for the group receiving medical management only and 28.1 months for the PTAS group. The **inset** shows the same data on an enlarged segment of the *y* axis. (From Chimowitz MI, Lynn MJ, Derdeyn CP, et al. Stenting versus aggressive medical therapy for intracranial arterial stenosis. N Engl J Med 2011;365:993.)

Angioplasty and stenting in patients with an intracranial stenosis who "fail" medical therapy may still be considered under the U.S. Food and Drug Administration (FDA) Humanitarian Device Exemption with local institutional review board approval. The use of the procedure is restricted to those who have had a recurrent stroke in the territory of the stenosed artery despite medical therapy and should be avoided in the setting of an acute stroke.

Although a patent foramen ovale (PFO, with or without an atrial septal aneurysm) is found more frequently in young patients with cryptogenic stroke, optimal therapy for secondary stroke prophylaxis is uncertain. Indeed, the relationship between the presence of a PFO (whether large or small and with or without an atrial septal aneurysm) and the risk for *recurrent* stroke and death is not clear. A systematic literature review of 129 articles identified four meeting the minimal quality criteria and found, compared to those without a PFO, no significant increase in recurrent stroke or death for those with a PFO (odds ratio [OR], 0.95; 95% CI 0.62 to 1.44), a small PFO (OR, 1.23; 95% CI 0.76 to 2.00), a large PFO (OR, 0.59; 95% CI 0.28 to 1.24), or a combined PFO and atrial septal aneurysm (OR, 2.10; 95% CI 0.86 to 5.06).[25] This finding agrees with the results of the subsequently reported PICSS (PFO in Cryptogenic Stroke Study), which found almost identical rates of recurrent stroke or death regardless of the presence of a PFO.[26] An index was developed to help identify patients with cryptogenic stroke in whom a PFO is more likely pathogenic than incidental.[27]

Essentially no prospective randomized trials have compared antiplatelet and anticoagulant therapy in patients with cryptogenic stroke in the setting of PFO. In an exploratory analysis, PICSS investigators reported almost identical rates of recurrent stroke or death with aspirin or warfarin in those with and without a PFO.[26] Patients with a cryptogenic ischemic stroke or TIA and a PFO who do not have a venous source of paradoxical embolism or other indication for anticoagulation should receive antiplatelet therapy.[27]

Several randomized trials have assessed the potential benefits of endovascular PFO closure versus medical therapy and found no statistical benefit of closure (**see Chapter 75**). No individual trial of endovascular PFO closure to prevent recurrent stroke met its primary, prespecified endpoint, and meta-analysis did not show superiority of PFO closure to medical therapy for secondary prevention of cryptogenic stroke in patients with PFO[28] (**Fig. 65.5**). Transcatheter PFO closure is not recommended for secondary stroke prevention.[27] The current FDA Humanitarian Device Exemption for endovascular PFO closure with a device designed for that purpose requires the patient to have failed best medical therapy. Whether endovascular PFO closure benefits even this population is uncertain.

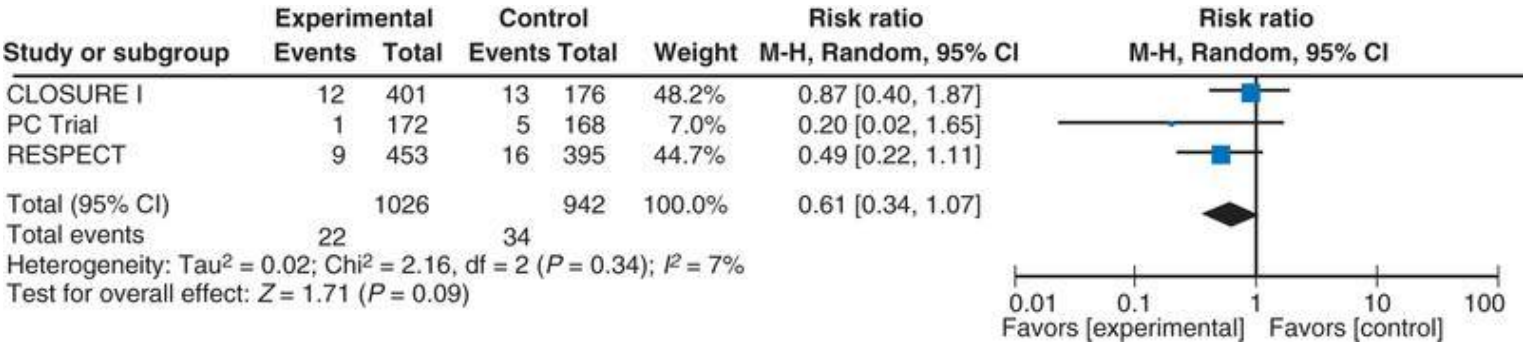

FIGURE 65.5 Meta-analysis of the risk of nonfatal ischemic stroke with patent foramen ovale closure versus medical therapy in patients with cryptogenic stroke. M-H, Mantel-Haenszel method. (From Spencer FA, Lopes LC, Kennedy SA, Guyatt G. Systematic review of percutaneous closure versus medical therapy in patients with cryptogenic stroke and patent foramen ovale. BMJ Open 2014;4:e004282.)

Patients with low–ejection fraction (EF) congestive heart failure (CHF) also have risk for systemic embolization, but data from large prospective randomized trials have not identified the optimal antithrombotic therapy for these patients. The WATCH (Warfarin and Antiplatelet Therapy in Chronic Heart Failure) trial compared open-label warfarin (target INR of 2.5 to 3.0) and double-blind treatment with either clopidogrel or aspirin in patients in sinus rhythm who had chronic CHF (EF <35%).[29] No differences were found between warfarin and aspirin (HR, 0.98; 95% CI 0.86 to 1.12; $P = 0.77$), between warfarin and clopidogrel (HR, 0.89; 95% CI 0.68 to 1.16; $P = 0.39$), or between clopidogrel and aspirin (HR, 1.08; 95% CI 0.83 to 1.40; $P = 0.57$) for the primary outcome (time until nonfatal stroke, nonfatal MI, or death). No evidence shows superiority of warfarin over aspirin or of clopidogrel over aspirin for prevention in stroke in patients with low-EF CHF. The WARCEF (Warfarin versus Aspirin in Reduced Cardiac Ejection Fraction) trial compared warfarin (target INR of 2.0 to 3.5) with aspirin (325 mg/day) in patients in normal sinus rhythm who had a reduced left ventricular (LV) EF.[30] Ischemic stroke, intracerebral hemorrhage, or death from any cause (primary outcome) occurred at a rate of 7.47 events per 100 patient-years with warfarin versus 7.93 with aspirin (HR with warfarin, 0.93; 95% CI 0.79 to 1.10; $P = 0.40$). A reduction in ischemic stroke with warfarin was balanced by an increase in intracranial hemorrhage (**Fig. 65.6**). Taken together, WATCH and WARCEF found no reduction in stroke with warfarin versus aspirin in patients with CHF or low LVEF.

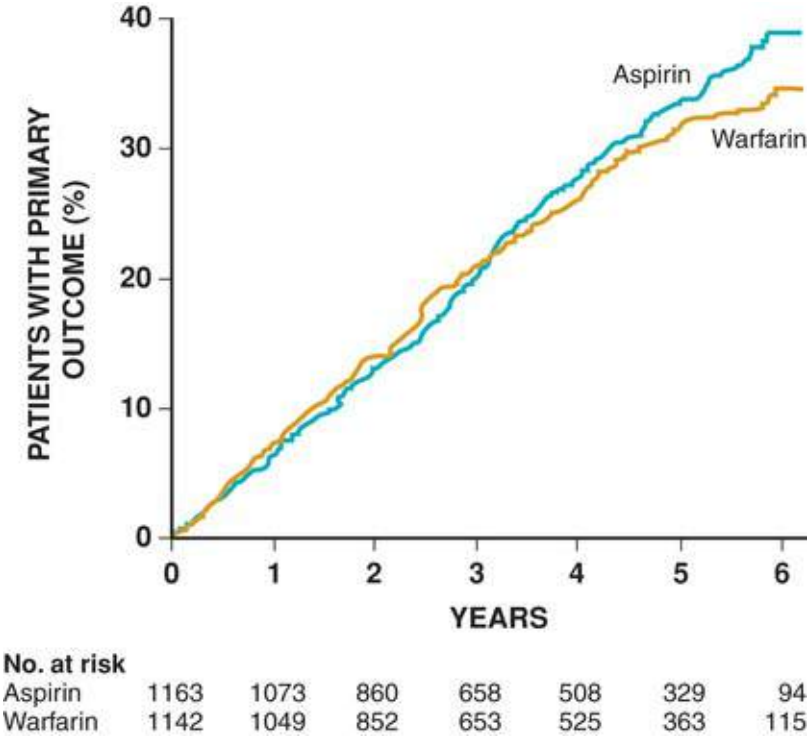

FIGURE 65.6 Warfarin versus aspirin in patients with heart failure and no atrial fibrillation. Cumulative incidence of the primary outcome is shown. The primary outcome was time to the first event in the composite endpoint of ischemic stroke, intracerebral hemorrhage, or death from any cause. (From Homma S, Thompson JLP, Pullicino PM, et al. Warfarin and aspirin in patients with heart failure and sinus rhythm. N Engl J Med 2012;366:1859.)

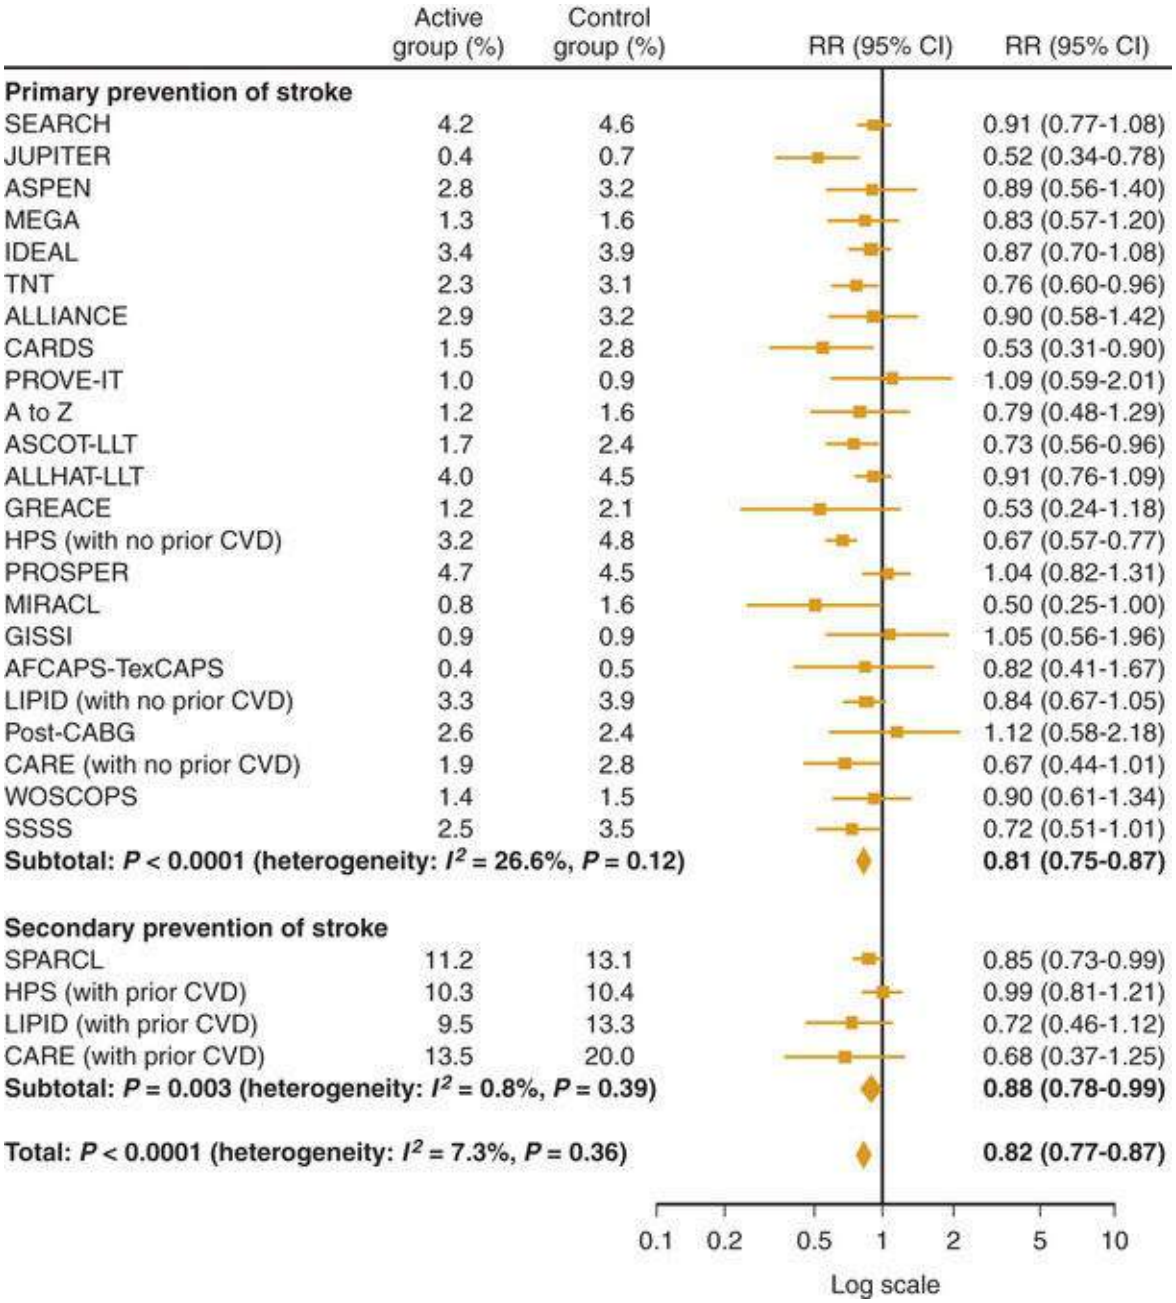
The various inherited (e.g., protein C, protein S, or antithrombin III deficiency; factor V Leiden; prothrombin G20210A mutation) and acquired (e.g., lupus anticoagulant, anticardiolipin or antiphospholipid antibodies) coagulopathies are more often associated with venous than with arterial thrombosis[31,32] (**see also Chapter 93**). Despite clear instances in which these types of disorders associate with ischemic stroke, particularly in children or young adults, causal relationships remain controversial. For example, in APASS (Antiphospholipid Antibody Stroke Study), another substudy of WARSS, 41% of 1770 participants were positive for one or more antiphospholipid antibody.[33] Rates of recurrent thromboembolic events were somewhat higher in those positive for antiphospholipid antibody, but outcomes did not differ between antibody-positive patients treated with warfarin or with aspirin. Patients with venous thromboembolic events who have an underlying coagulopathy or those with stroke or TIA otherwise fulfilling the criteria for antiphospholipid antibody syndrome (venous and arterial occlusive disease in multiple organs, miscarriages, and livedo reticularis) appropriately receive warfarin. Because thrombophilias (especially the genetic forms previously listed) are more frequently associated with venous thrombosis, cryptogenic stroke in this setting should prompt an evaluation for potential sources of paradoxical embolism. The yield of magnetic resonance imaging (MRI) of the pelvis and lower extremities is higher than that of Doppler ultrasound, and MRI should be considered in patients with a presumed paradoxical embolus.[34] In the absence of antiphospholipid antibody syndrome, those with arterial stroke who are found to have only elevated antiphospholipid antibody levels may reasonably be treated with antiplatelet therapy.[27]

Statins (See Chapters 45 and 48)

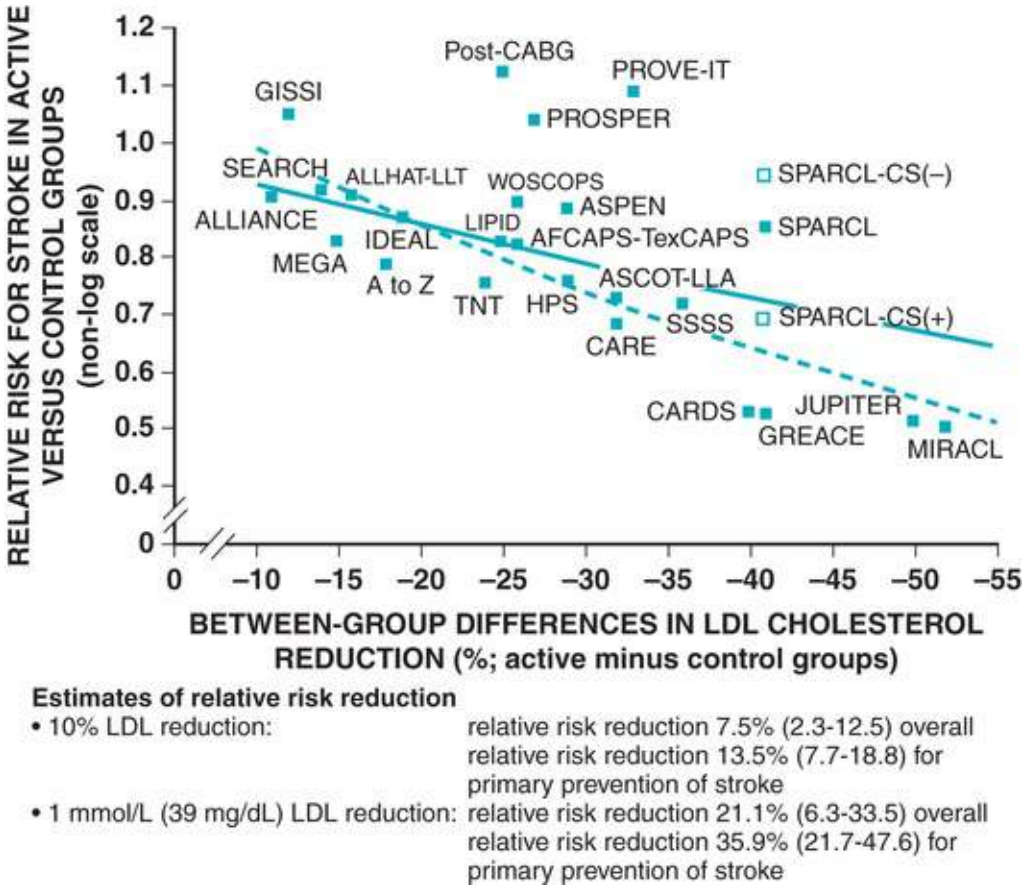
Primary Prevention

Treatment of patients with coronary heart disease (CHD) or those at elevated risk for CHD with

hydroxymethylglutaryl–coenzyme A (HMG-CoA) reductase inhibitors (statins) reduces not only cardiac events, but also the risk for a first stroke[35] (**eFig. 65.4**). A meta-analysis of randomized trials of statins that included 165,792 participants found that each 40-mg/dL decrease in low-density lipoprotein (LDL) cholesterol was associated with a 21.1% (95% CI 6.3% to 33.5%; $P = 0.009$) reduction in the risk for a first stroke[35] (**eFig. 65.5**). Specific studies show a reduction in the risk for first stroke with statin treatment in patients with diabetes,[36,37] those with hypertension,[38] and older adults.[39]

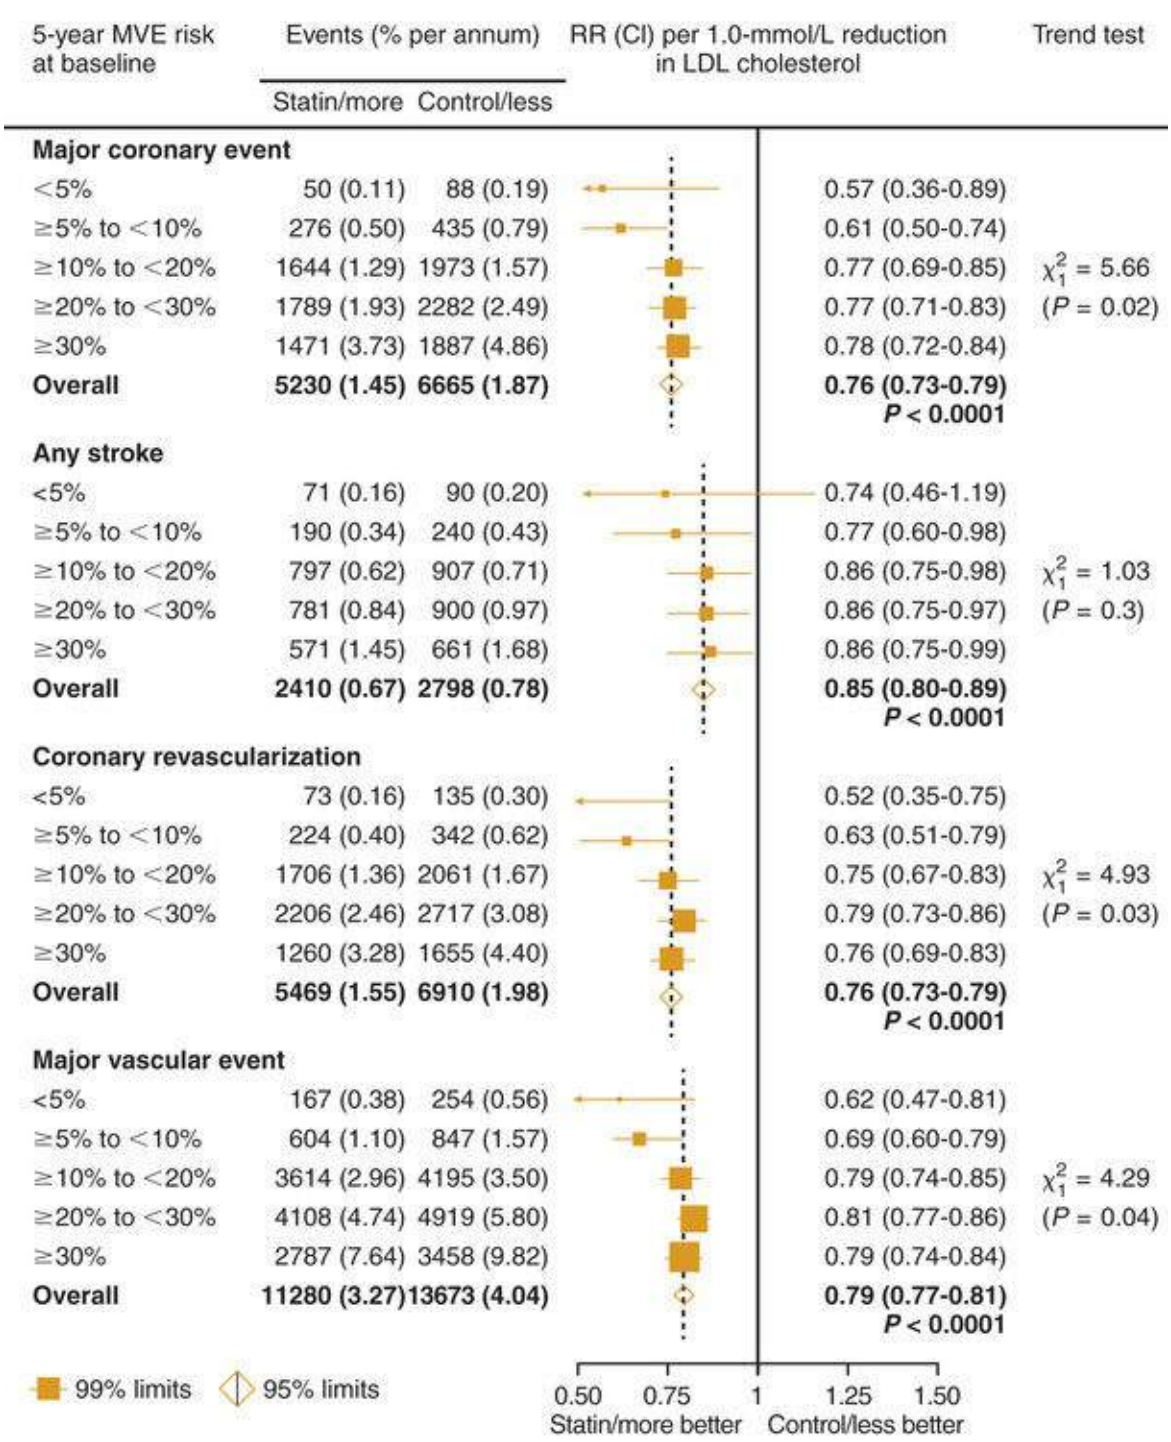


EFIGURE 65.4 Meta-analysis of the effects of statins on stroke prevention. Results are from 24 trials that included 165,792 patients with fatal and nonfatal stroke. CVD, Cardiovascular disease; RR, risk ratio. (From Amarenco P, Labreuche J. Lipid management in the prevention of stroke: review and updated meta-analysis of statins for stroke prevention. Lancet Neurol 8:453, 2009; data on LIPID and CARE with or without prior CVD from Vergouwen MD, de Haan RJ, Vermeulen M, Roos YB: Statin treatment and the occurrence of hemorrhagic stroke in patients with a history of cerebrovascular disease. Stroke 2008;39:497.)



EFIGURE 65.5 Cholesterol lowering with statins and risk for stroke. Inverse variance-weighted regression lines have been plotted after including all 24 trials (165,792 patients; *solid line*) and excluding those with clearly identified groups of patients in secondary stroke prevention (SPARCL; HPS, LIPID, and CARE subgroups with previous cerebrovascular disease; *dashed line*). The underlying causes of stroke are important when considering the association between lipid and stroke risk, so the SPARCL results are also shown in accordance with the presence or absence of documented CS. Data for the SEARCH trial were presented at the 2008 American Heart Association meeting. CS, Carotid stenosis; LDL, low-density lipoprotein. (From Amarenco P, Labreuche J. Lipid management in the prevention of stroke: review and updated meta-analysis of statins for stroke prevention. Lancet Neurol 2009;8:453.)

JUPITER (Justification for the Use of Statin in Prevention: An Intervention Trial Evaluating Rosuvastatin) evaluated the effect of a statin in persons with higher than median (>2 mg/dL) level of high-sensitivity C-reactive protein who were not otherwise candidates for statin treatment.[40] In this group, statin treatment reduced stroke by approximately 50%. The benefit of stroke reduction with statin therapy may extend to those at lower (5% to 10% 5-year) risk for vascular events[41] (**eFig. 65.6**). The Heart Outcomes Prevention Evaluation (HOPE)–3 trial assessed the effect of rosuvastatin (10 mg daily) in CVD-free patients at intermediate (approximately 1% per year) risk.[42] Over 5.6 years, randomization to treatment led to a reduction death from CV causes, nonfatal MI, or nonfatal stroke from 4.8% to 3.7% (HR, 0.76; 95% CI 0.64 to 0.9; $P = 0.002$). Revascularization procedures, heart failure, and resuscitated cardiac arrest were reduced from 5.7% to 4.4% (HR, 0.75; 95% CI 0.64 to 0.88; $P < 0.001$). Stroke was reduced from 1.6% to 1.1% (HR, 0.70; range, 0.52 to 0.95). The AHA/American College of Cardiology (ACC) global risk calculator can be used to identify patients who are most likely to benefit from statin treatment.[43,44]



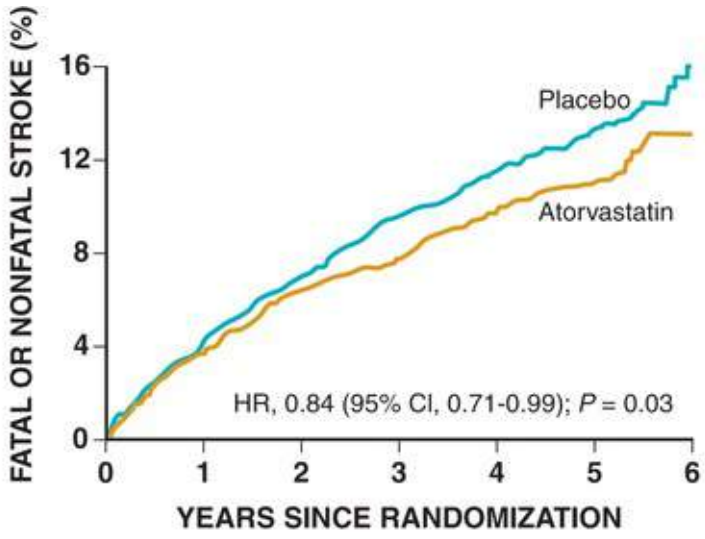
EFIGURE 65.6 Effects on major coronary events, strokes, coronary revascularization procedures, and major vascular events per 1.0-mmol/L reduction in low-density lipoprotein (LDL) cholesterol at different levels of risk. MVE, Major vascular event; RR, relative risk. (From Cholesterol Treatment Trialists' [CTT] Collaborators: The effects of lowering LDL cholesterol with statin therapy in people at low risk of vascular disease: meta-analysis of individual data from 27 randomised trials. Lancet 2012;380:581.)

Secondary Prevention

The HPS (Heart Protection Study) included 3280 patients with a history of stroke (including 1820 with stroke and no history of CHD) who were treated with either a statin or placebo.[45] In those with a previous history of stroke, statin treatment reduced the frequency of major vascular events (MVEs: MI, stroke, revascularization procedure, or vascular death) by 20%, but did not lower the risk for recurrent stroke (occurring in 10.5% of placebo versus 10.4% of statin group). The most important explanation might be that patients were randomized an average of approximately 4 years after the index event. Most recurrent strokes occur soon (within the first few years), so those randomized in the HPS had a relatively low risk

for recurrent stroke.

The SPARCL (Stroke Prevention with Aggressive Reduction in Cholesterol Levels) trial randomly assigned more than 4700 patients within 6 months of a noncardioembolic stroke or TIA and no known CHD to high-dose statin or placebo for a primary endpoint of the first occurrence of a nonfatal or fatal stroke.[46] Those randomized to high-dose statin treatment had a 16% relative reduction in nonfatal or fatal stroke, as well as a 35% relative reduction in major coronary events. Added to the previous data on prevention of a first stroke, SPARCL showed that treatment with a high-dose statin can reduce the risk for recurrent stroke after stroke or TIA (**eFig. 65.7**). On the basis of this trial, patients with atherosclerotic ischemic stroke or TIA and without known CHD should receive high-intensity statin therapy to reduce the risk for stroke and other CV events.[3]



EFIGURE 65.7 Effect of statin therapy on stroke in patients with a recent stroke or TIA. The Kaplan-Meier curve for stroke or TIA in SPARCL is shown. The data report an intention-to-treat analysis with prespecified adjustments for geographic region, entry event, time since the entry event, sex, and baseline age for the first occurrence of a fatal or nonfatal stroke or TIA. HR, Hazard ratio. (From Amarenco P, Bogousslavsky J, Callahan AIII, et al. High-dose atorvastatin after stroke or transient ischemic attack. N Engl J Med 2006;355:549.)

Antihypertensives (See Chapters 46 and 47)

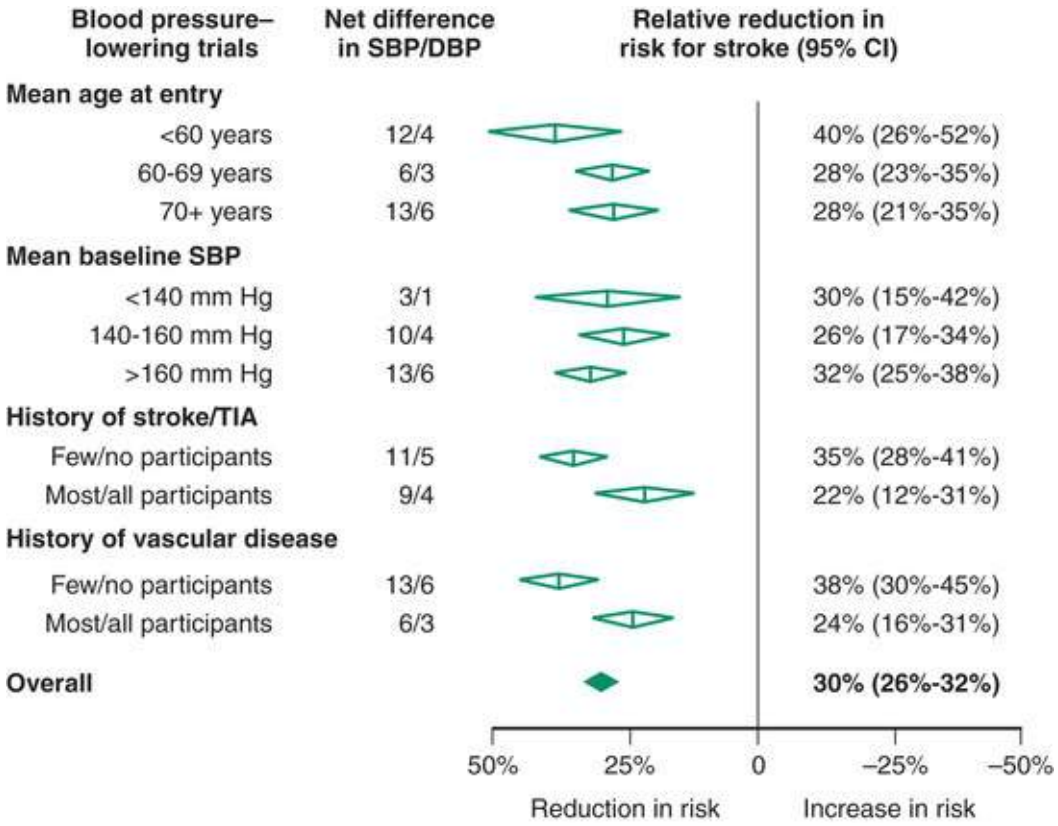
Primary Prevention

Hypertension is one of the most important treatable risk factors for both ischemic stroke and parenchymal intracerebral hemorrhage. Although a specific antihypertensive regimen must be individualized, reduction in blood pressure (BP) is generally more important than the specific agent or agents used.[31,47]

The Systolic Blood Pressure Intervention Trial (SPRINT) compared the benefit of treatment of systolic blood pressure (SBP) to a target of lower than 120 mm Hg with treatment to a target of lower than 140 mm Hg in patients at increased risk of CV events who had SBP of 130 to 180 mm Hg.[48] Stroke fell from 1.5% to 1.3% annually, but the difference was not significant (HR, 0.89; 95% CI 0.63 to 1.25; $P = 0.50$). The HOPE-3 trial also evaluated an antihypertensive regimen in people at intermediate risk without CVD and showed no overall benefit.[49] Explanations for this neutral result include the choice of

antihypertensives (candesartan and hydrochlorothiazide) and the small reduction in BP with treatment (mean, 6/3 mm Hg).

An earlier meta-analysis of randomized controlled trials (RCTs) comparing antihypertensive drugs with placebo or no treatment with more than 73,500 participants who had almost 2900 stroke events found similar risk reductions with angiotensin-converting enzyme (ACE) inhibitors (28%), beta-adrenergic receptor blockers (beta blockers) or diuretics (35%), and calcium channel antagonists (39%), with average BP reduction of 5/2, 13/6, and 10/5 mm Hg, respectively[50] (**eFig. 65.8**). Subsequent work suggests that stroke reduction may be less in the setting of higher BP variability.[51,52] Beta blockers are associated with greater BP variability than other classes of antihypertensives and may be less effective.[53] Chlorthalidone may be more effective than hydrochlorothiazide in reducing CV events.[54]



EFIGURE 65.8 Randomized controlled trials comparing antihypertensive drugs with a placebo (or no treatment) by subgroup. The meta-analyses of blood pressure–lowering trials were stratified into subgroups on the basis of mean age of trial participants at entry, baseline systolic blood pressure (SBP) level, and whether trial participants predominantly had a history of stroke/transient ischemic attack (TIA) or vascular disease. The *diamonds* are centered on the pooled estimate of effect and represent 95% CIs. The *solid diamond* represents the pooled relative risk and 95% CI for all contributing trials. DBP, Diastolic blood pressure. (From Lawes CM, Bennett DA, Feigin FL, Rodgers A. Blood pressure and stroke: an overview of published reviews. Stroke 2004;35:1024.)

Secondary Prevention

A meta-analysis including 16 RCTs of BP lowering for secondary prevention of stroke in 40,292 participants found an 18% (95% CI 9% to 26%) relative risk reduction in recurrent stroke with treatment[55] (**Fig. 65.7**). Each 10–mm Hg reduction in SBP is associated with a 33% (95% CI 9% to 51%) reduction in recurrent stroke. Data on the relative benefits of specific antihypertensive regimens for secondary prevention of stroke are sparse. Another meta-analysis found a reduction in recurrent stroke with diuretics (32%) and with diuretics plus ACE inhibitors (45%), but not with beta blockers or ACE

inhibitors used alone.[56] The overall reductions in both stroke and all vascular events were related to the degree of BP lowering.

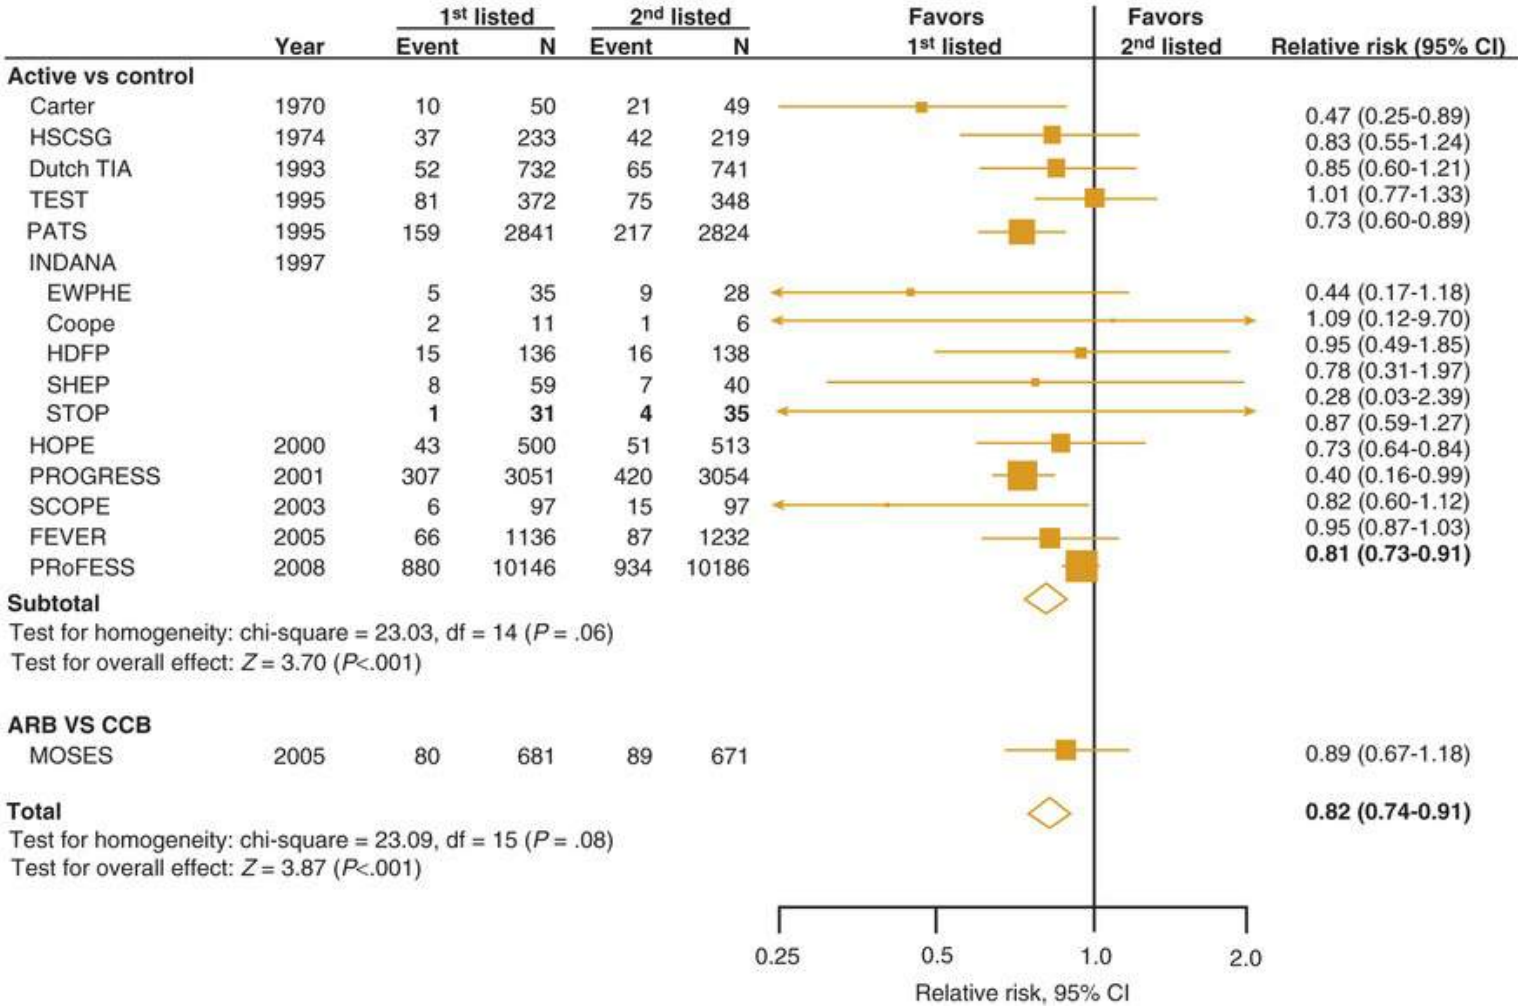


FIGURE 65.7 Meta-analysis of randomized controlled trials of blood pressure lowering for secondary prevention of stroke. ARB, Angiotensin receptor blocker; CCB, calcium channel blocker. (From Arima H, Chalmers J. PROGRESS: prevention of recurrent stroke. J Clin Hypertens 2011;13:693.)

Whether ACE inhibitors have a specific benefit in reducing recurrent stroke risk also remains uncertain. The HOPE study compared the effects of an ACE inhibitor and placebo in high-risk persons and found a 24% reduction in the risk for stroke, MI, or vascular death in 1013 patients with a history of stroke or TIA.[57] PROGRESS (Perindopril Protection Against Recurrent Stroke Study) tested the effects of a BP-lowering regimen, including an ACE inhibitor, in 6105 patients with stroke or TIA within the previous 5 years.[3] Randomization was stratified by intention to use single (ACE inhibitor) or combination (ACE inhibitor plus diuretic indapamide) therapy in hypertensive (>160 mm Hg systolic or >90 mm Hg diastolic) and in nonhypertensive patients. The combination, which reduced BP by an average of 12/5 mm Hg, led to a 43% reduction in recurrent stroke and a 40% reduction in MVEs, with the effect present in both hypertensive and normotensive groups. Monotherapy with either agent showed no significant benefit. Specific patient characteristics and comorbid conditions should guide the choice of a specific antihypertensive regimen.

Diabetes and Glucose Intolerance

There remains no evidence that tight control of diabetes decreases stroke risk in primary or secondary prevention settings. As previously reviewed, management of BP and use of statins reduce stroke risk in patients with diabetes.

The Insulin Resistance Intervention after Stroke (IRIS) trial tested the hypothesis that pioglitazone reduces the rates of stroke and MI after ischemic stroke or TIA in patients without diabetes who have insulin resistance.[58] Over 4.8 years, stroke or MI occurred in 9.0% of the pioglitazone group and 11.8% of the placebo group (HR in pioglitazone group, 0.76; 95% CI 0.62 to 0.93; $P = 0.007$) (**Fig. 65.8**). The primary complications of treatment were a greater frequency of more than 4.5 kg of weight gain (52.2% versus 33.7%; $P < 0.001$), edema (35.6% versus 24.9%; $P < 0.001$), and bone fracture requiring surgery or hospitalization (5.1% versus 3.2%; $P = 0.003$).

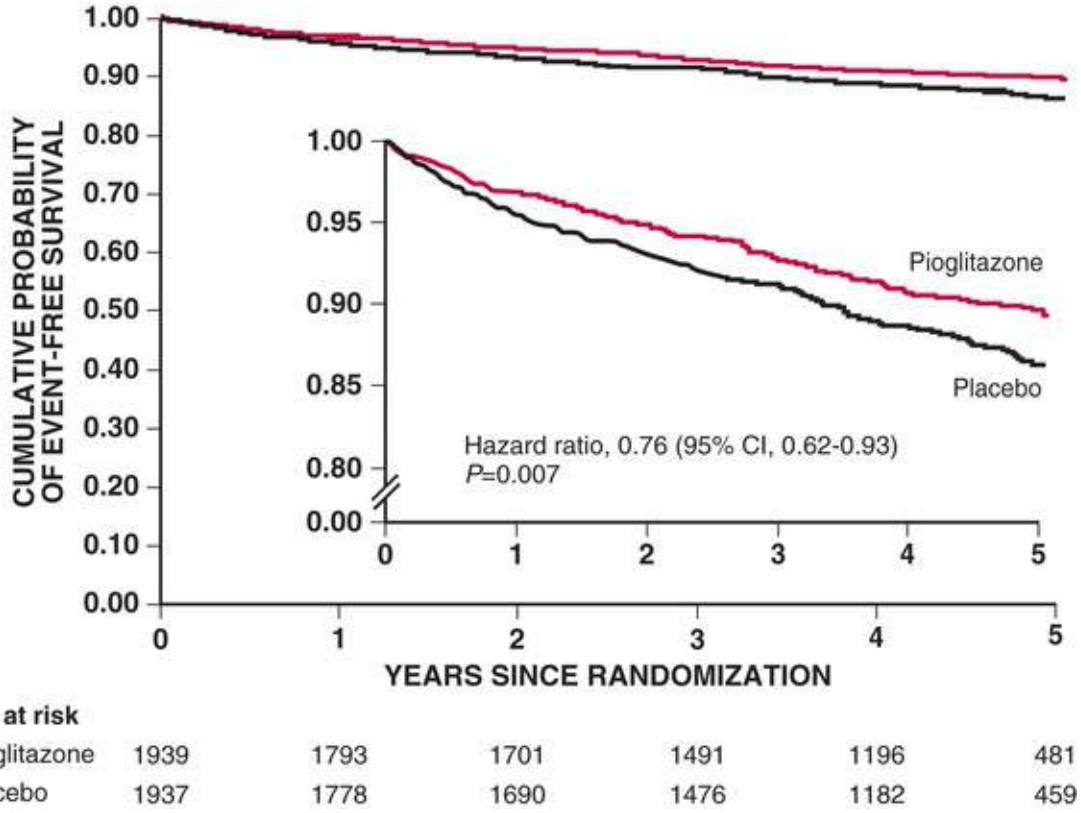

FIGURE 65.8 Effect of pioglitazone on the risk of stroke and myocardial infarction in patients with insulin resistance but no diabetes who had a recent stroke or transient ischemic attack. (From Kernan WN, Viscoli CM, Furie KL, et al. Pioglitazone after ischemic stroke or transient ischemic attack. N Engl J Med 2016;374:1321.)

Management of Acute Ischemic Stroke

In patients presenting with a neurologic deficit suggesting an acute ischemic stroke, we use the approach shown in **Fig. 65.9**. As with acute coronary syndromes (ACS), time is of the essence in the treatment of patients with acute ischemic stroke. Stroke has numerous causes and potential pathophysiologic mechanisms that provide the rationale for tailoring secondary preventive therapies. A variety of conditions may cause symptoms and signs that can be mistaken for those of a stroke. The onset of ischemic symptoms mandates a prompt evaluation of whether the patient should receive reperfusion therapy (**Fig. 65.9**).

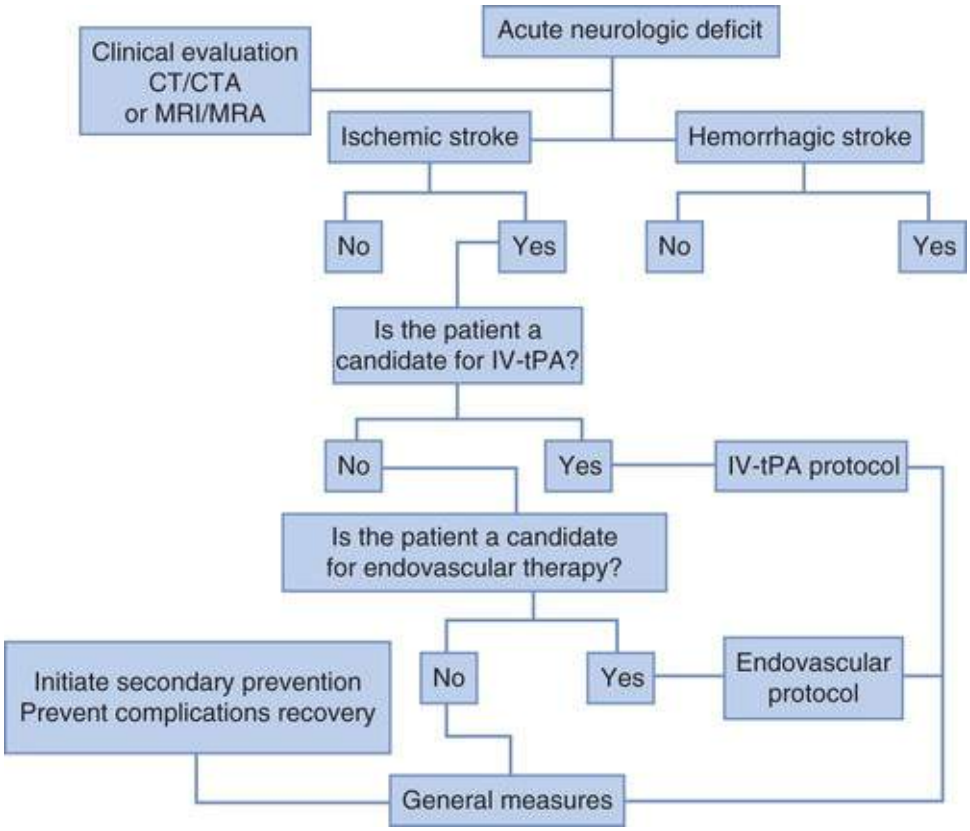

FIGURE 65.9 Example of approach to patients with symptoms suggestive of acute ischemic stroke. Patients presenting with an acute neurologic deficit are first rapidly evaluated to exclude other conditions and brain hemorrhage. This includes neuroimaging, as well as vascular imaging to guide further intervention and management, particularly in those with suspected large artery occlusion who might be candidates for endovascular therapy. CT, Computed tomography; CTA, CT angiography; IV-tPA, intravenous tissue plasminogen activator; MRI, magnetic resonance imaging; MRA, MR angiography. (Modified from Goldstein LB. Modern medical management of acute ischemic stroke. Methodist DeBakey Cardiovasc J 2014;10:39.)

The reliable and valid National Institutes of Health Stroke Scale (NIHSS) serves as a measure of stroke severity. It is used to monitor stroke patients for clinical worsening or improvement and to help determine a patient's candidacy for intravenous tissue plasminogen activator (IV t-PA).[59]

Intravenous Recombinant Tissue Plasminogen Activator

Only IV recombinant t-PA (rt-PA, alteplase) has received FDA approval for pharmacologic treatment of acute ischemic stroke. Treatment of appropriate patients with rt-PA thrombolytic therapy is associated with an approximate 13% absolute (32% relative) increase in the proportion of patients who are free of disability 3 months later.[4] Benefits are similar in those with ischemic stroke involving small penetrating arteries and in those with occlusion of larger intracranial arteries. Although this treatment is also associated with an increased risk for hemorrhage (6.4% risk for symptomatic intracerebral hemorrhage with treatment versus 0.6% with placebo; 2.9% risk for fatal hemorrhage versus 0.3% with placebo), the strategy yields net clinical benefit (improvement in outcomes previously cited includes adverse bleeding effects). Based on national guidelines, alteplase must be given within 4.5 hours of the onset of symptoms, which means that the patient must generally arrive at a properly equipped and organized hospital within 3.5 hours of symptom onset to have the necessary evaluations completed, including brain computed tomography (CT) to exclude hemorrhage or other conditions (**Fig. 65.9**). Within this “window,” the sooner treatment can be initiated, the greater the likelihood of a favorable response[60] (**Fig. 65.10**). Although there is a trend toward an increased risk of intracerebral hemorrhage with IV t-PA within this period, the effect

is not significant.

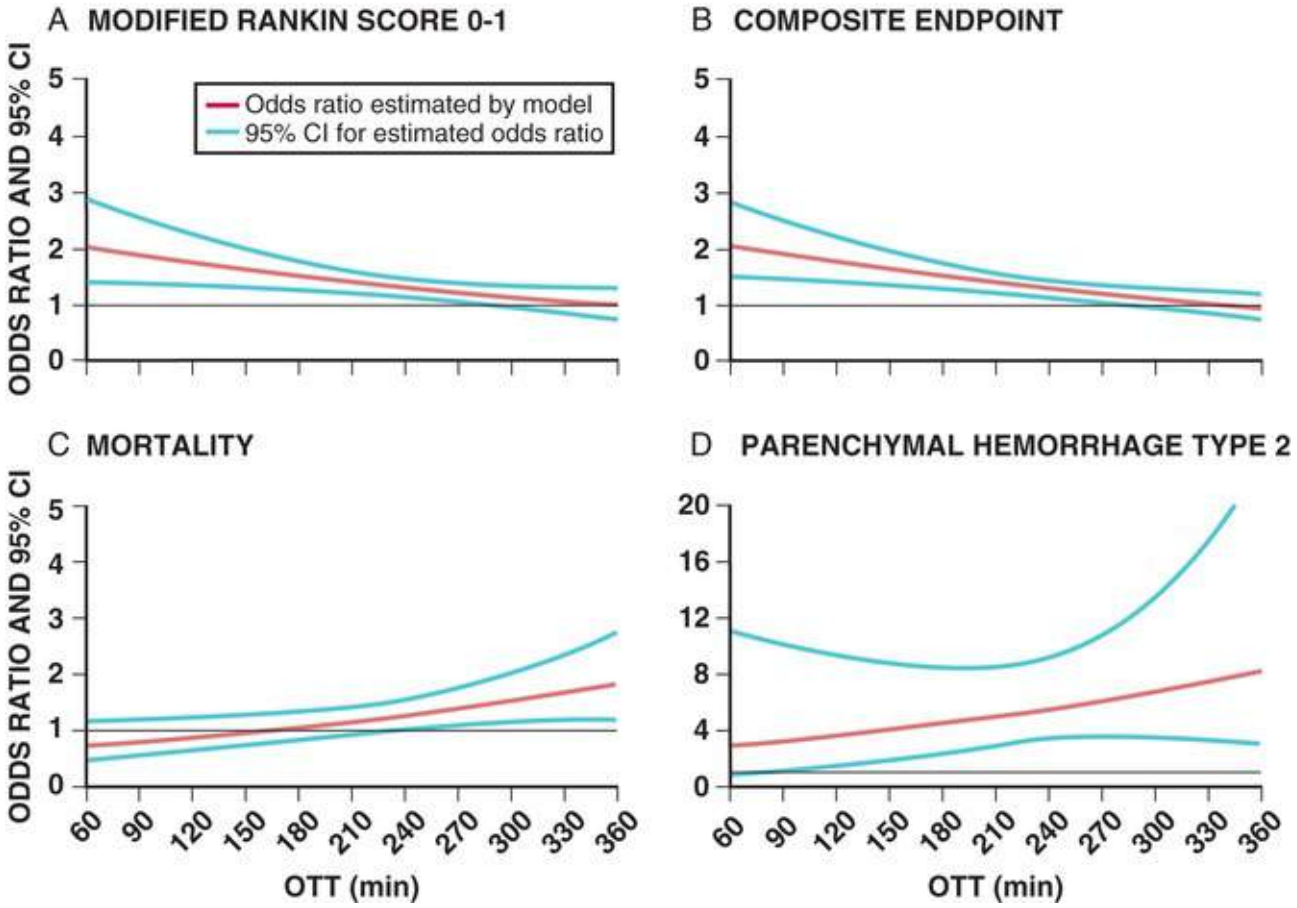

FIGURE 65.10 Pooled clinical trial analysis of the relationship between lag between stroke onset to start of treatment (OTT) with intravenous tissue plasminogen activator (t-PA) on the treatment effect after adjustment for prognostic variables. (From Lees KR, Bluhmki E, von Kummer R, et al. Time to treatment with intravenous alteplase and outcome in stroke: an updated pooled analysis of ECASS, ATLANTIS, NINDS, and EPITHET trials. Lancet 2010;375:1695.)

Clinical guidelines for treatment with IV t-PA initially reflected a strict protocol that closely followed those used in the clinical trials on which the use of alteplase was based.[61] These guidelines were revised based on subsequent data and extensive clinical experience[6] (**Tables 65.2 and 65.3**). Many of decisions rely on clinical judgment. Furthermore, guideline-based recommendations do not align completely with the FDA product labeling. For example, although AHA/ASA guidelines endorse treatment of selected patients up to 4.5 hours after symptom onset, the FDA approval is limited to those who can be treated within 3 hours (**Table 65.2**). The development of organized systems of stroke care should optimize prompt clinical evaluations, minimize delays in treatment, ensure institution of other interventions that improve outcomes, and ensure that patients receive appropriate secondary prevention.[62]

TABLE 65.2

Comparison of Recommendations for Treatment with Intravenous Alteplase (T-PA)

2013 AHA/ASA GUIDELINE[61]	2016 AHA/ASA REVISION[6]	2016 FDA LABELING
Inclusion		
Ischemic stroke causing measurable neurologic deficit	Ischemic stroke causing measurable neurologic deficit. (Class I, LOE A)	Acute ischemic stroke; exclude acute ICH
Onset of symptoms <4.5 hr before beginning treatment	<3 hr (Class I, LOE A) 3-4.5 hr (Class I, LOE B)	Onset of symptoms <3 hr before beginning treatment
Age ≥18 yr	For patients ≥18 years old, treatment equally recommended for	Pediatric use not established; age

	those <80 and >80 years; older patients have poorer outcomes, higher mortality, and higher rates of sICH than those <80 years, but compared with controls, treatment provides a better chance of being independent at 3 mo across all age-groups. (Class I, LOE A) The efficacy and risk of treatment in neonates, children, and adolescents <18 yo are not well established. (Class IIb, LOE B)	>77 yr is one of several interrelated baseline characteristics associated with increased risk of ICH; data suggest a reduced but still favorable clinical outcome.
Exclusions		
Previous stroke <3 mo	Treatment may be harmful. (Class III, LOE B) The potential for increased risk of sICH and associated morbidity and mortality exists but is not well established. (Class IIb, LOE B)	None
Significant head trauma <3 mo	Contraindicated	Contraindicated
Major trauma <14 days	Treatment may be considered; weigh the risks of bleeding from trauma-related injuries against the severity and potential disability from the stroke. (Class IIb; LOE C)	None
Symptoms suggesting SAH	Contraindicated (Class III; LOE C)	Contraindicated
Arterial puncture at noncompressible <7 days	Safety and efficacy are uncertain. (Class IIb, LOE C)	None
History of ICH	Treatment in setting of cerebral microbleeds is reasonable. (Class IIa, LOE B) Treatment of patients with a history of ICH is potentially harmful. (Class III, LOE C)	None
Intracranial neoplasm, AVM, or aneurysm	Treatment is reasonable and probably recommended in patients with a <10 mm unruptured and unsecured intracranial aneurysm. (Class IIa, LOE C) Usefulness and risks with larger aneurysms are not well established. (Class IIb, LOE C) Usefulness and risks with AVM are not well established (Class IIb, LOE C); treatment may be considered in setting of severe deficits and high likelihood of morbidity and mortality that would outweigh anticipated risk of ICH. (Class IIb, LOE C) Probably recommended in setting of extra-axial intracranial neoplasm. (Class IIa, LOE C) Potentially harmful in setting of an intra-axial intracranial neoplasm. (Class III, LOE C)	Contraindicated in the presence of intracranial conditions that may increase the risk of bleeding
Intracranial or intraspinal surgery <3 mo	Potentially harmful (Class III, LOE C)	Contraindicated
Elevated blood pressure (systolic >185 mm Hg or diastolic >110 mm Hg)	Treat if BP can be lowered to <185/110 mm Hg with antihypertensive agents with assessment of stability of BP before starting treatment. (Class I, LOE B) BP should be maintained <180/105 mm Hg for at least the first 24 hours after treatment. (Class I, LOE B)	Contraindicated in setting of current severe uncontrolled hypertension; no specific BP values; warning for BP >175/110 mm Hg
Active internal bleeding	-	Contraindicated
Acute bleeding diathesis, including but not limited to: platelets <100,000/mm^3, heparin <48 hr with APTT greater than ULNl, anticoagulant with INR >1.7 or PT >15 sec; current use of direct thrombin inhibitors or direct factor Xa inhibitors with elevated sensitive laboratory tests (APTT, INR, platelet count, and ECT; TT; or appropriate factor Xa activity assays)	Treatment not recommended if platelets <100,000/mm^3, INR >1.7, APTT >40 sec, or PT >15 sec. (Class III, LOE C) Treatment in patients who received dose of LMWH (prophylactic or therapeutic) <24 hr is not recommended. (Class III, LOE B) Treatment of patients taking direct thrombin inhibitors or direct factor Xa inhibitors is not recommended unless laboratory tests such as APTT, INR, platelet count, ECT, TT, or appropriate direct factor Xa activity assays are normal, or patient has not received dose of these agents for >48 hr (assuming normal renal function). (Class III, LOE C) It is reasonable not to delay treatment pending hematologic or coagulation testing if there is no reason to suspect abnormal test. (Class IIa, LOE B)	Contraindicated for bleeding diathesis (no laboratory values or specific examples)
Blood glucose concentration <50 mg/dL or >400 mg/dL	Hypoglycemia and hyperglycemia may mimic acute stroke; blood glucose should be checked before treatment, (Class III, LOE B) Recommended with initial glucose levels >50 mg/ dL. (Class I, LOE A) Treatment may be reasonable if initial glucose is >400 mg/dL and subsequently normalizes. (Class IIb, LOE C)	None
CT demonstrating multilobar infarction (hypodensity > 1/3 cerebral hemisphere)	Recommended in the setting of mild to moderate early ischemic changes (other than frank hypodensity). (Class I, LOE A) Evidence is insufficient to identify a threshold of hypoattenuation severity or extent that affects treatment response; however, treatment in the setting CT brain imaging showing extensive regions of clear hypoattenuation is not recommended. (Class III, LOE A)	None
Severe stroke	Benefit remains despite increased risk of hemorrhagic transformation. (Cass I, LOE A)	None
Relative Exclusions		
Minor symptoms	No exclusion for mild but disabling stroke symptoms. (Cass I, LOE A) Treatment for nondisabling symptoms can be considered. (Class IIb, LOE C)	None
Rapidly improving symptoms	Reasonable in setting of moderate to severe stroke and early improvement, but with continued moderate and potentially disabling symptoms. (Class IIa, LOE A) Delaying treatment to monitor for continued improvement not recommended. (Class III, LOE C)	None

Pregnancy	May be treated when anticipated benefits of treating moderate to severe stroke outweigh anticipated increased risks of uterine bleeding. (Class IIb, LOE C) Safety and efficacy <14 days after delivery have not been well established. (Class IIb, LOE C)	Pregnancy category C
Seizure at onset with postictal residual neurologic impairments	Treatment is reasonable if the residual impairments are thought secondary to stroke and not a postictal phenomenon. (Class IIa, LOE C)	None
Major surgery or serious trauma <14 days	The potential increased risk of surgical site hemorrhage should be weighed against anticipated benefits of reduced stroke-related neurologic deficits. (Class IIb, LOE C)	None
GI or urinary tract hemorrhage <21 days	Patients with structural GI malignancy or bleeding <21 days should be considered high risk; treatment is potentially harmful. (Class III, LOE C) Treatment of patients with past GI/GU bleeding may be reasonable. (Class IIb, LOE C)	Warning for GI or GU bleeding
Acute MI <3 months)	Reasonable if the recent MI was non-STEMI. (Class IIa, LOE C) Reasonable if the recent MI was STEMI involving right or inferior myocardium. (Class IIa, LOE C) May be reasonable if the recent MI was STEMI involving left anterior myocardium. (Class IIb, LOE C) For patients with concurrent acute ischemic stroke and acute MI, treatment with IV t-PA at the dose appropriate for stroke, followed by PTCA and stenting if indicated, is reasonable. (Class IIa, LOE C)	None
Additional Relative Exclusions 3 to 4.5 Hours*		
Aged >80 years	Treatment is safe and can be as effective as in younger patients. (Class IIa, LOE B)	NA
NIHSS >25	Benefit is uncertain. (Class IIb, LOE C)	NA
Taking oral anticoagulant regardless of INR	Safe and may be beneficial if taking warfarin with an INR<1.7. (Class IIb, LOE B)	NA
History of both diabetes and prior ischemic stroke	May be as effective as treatment in the 0- to 3-hr window and may be a reasonable option. (Class IIb, LOE B)	NA

*Treatment not FDA approved between 3 and 4.5 hours.

AHA/ASA, American Heart Association/American Stroke Association; *FDA,* US Food and Drug Administration; *LOE,* Level of evidence; *APTT,* activated partial thromboplastin time; *AVM,* arteriovenous malformation; *CT,* computed tomography; *ECT,* ecarin clotting time; *GI,* gastrointestinal; *GU,* genitourinary; *ICH,* intracranial/cerebral hemorrhage; *sICH,* subdural ICH; *INR,* international normalized ratio; *IV t-PA,* intravenous tissue plasminogen activator; *LMWH,* low-molecular-weight heparin; *MI,* myocardial infarction; *NA,* not applicable; *NIHSS,* National Institutes of Health Stroke Scale; *PT,* prothrombin time; *PTCA,* percutaneous transluminal coronary angioplasty; *SAH,* subarachnoid hemorrhage; *sICH,* symptomatic intracerebral hemorrhage; *STEMI,* ST-segment elevation MI; *TT,* thrombin time.

TABLE 65.3

Treatment with Intravenous Alteplase (t-PA) in Other Settings

Intracardiac Thrombus
Treatment may be reasonable for patients with major acute ischemic stroke likely to produce severe disability and known left atrial or ventricular thrombus. (Class IIb, LOE C) Treatment is of uncertain benefit for patients with moderate acute ischemic stroke likely to produce mild disability and known left atrial or ventricular thrombus. (Class IIb, LOE C)
Infective Endocarditis
Treatment is not recommended because of the increased risk of intracranial hemorrhage. (Class III, LOE C)
Serious Comorbid Conditions
End-Stage Renal Disease
Treatment is recommended in patients with end-stage renal disease on hemodialysis and a normal APTT. (Class I, LOE C)
Dementia
Patients with preexisting dementia may benefit treatment; individual considerations such as life expectancy and premorbid level of function are important to determine whether treatment may offer a clinically meaningful benefit. (Class IIb, LOE B)
Current Malignancy
Treatment of patients with current malignancy and reasonable (>6 mo) life expectancy may benefit from treatment if other contraindications such as coagulation abnormalities, recent surgery, or systemic bleeding do not coexist. (Class IIb, LOE C)
Preexisting Disability
Preexisting disability does not independently increase the risk of sICH but may be associated with less neurologic improvement and higher mortality; treatment with preexisting disability (mRS score ≥2) may be reasonable, but decisions should take into account quality of life, social support, place of residence, need for a caregiver after treatment, patient and family preferences, and goals of care. (Class IIb, LOE B)
Hemorrhagic Retinopathy
Treatment in patients with a history of diabetic hemorrhagic retinopathy or other hemorrhagic ophthalmic conditions is reasonable, but the potential increased risk of visual loss should be weighed against the anticipated benefits of reduced stroke-related neurologic deficits. (Class IIa; LOE B)
Intracardiac Mass
Treatment may be reasonable for patients with major acute ischemic stroke likely to produce severe disability and cardiac myxoma. (Class IIb, LOE C) Treatment may be reasonable for patients with major acute ischemic stroke likely to produce severe disability and papillary fibroelastoma. (Class IIb, LOE C)
Sickle Cell Disease
Treatment is not well established. (Class IIb, LOE C)
Wake-up Stroke
Treatment is not recommended if time last known to be at baseline is >4.5 hr or unknown. (Class III, LOE B) Use of imaging criteria to select patients who awoke with stroke or have unclear time of symptom onset to guide treatment is not recommended outside a clinical trial. (Class III, LOE B)
Menstruation and Menorrhagia: Recommendations
Treatment is probably indicated in women who are menstruating and do not have a history of menorrhagia; however, women should be warned that treatment could increase the degree of menstrual flow. (Class IIa, LOE C) Treatment may be considered in women with recent or active history of menorrhagia without clinically significant anemia or hypotension because the potential benefits of treatment probably outweigh the risks of serious adverse effects. (Class IIb, LOE C) Emergent consultation with a gynecologist is probably indicated before a decision about treatment is made in the setting of a history of recent or active vaginal bleeding causing clinically significant anemia. (Class IIa, LOE C) Women who are menstruating or have active vaginal bleeding who are treated with IV t-PA should be monitored for vaginal bleeding for 24 hr. (Class I, LOE C)
Aortic Arch and Cervicocephalic Arterial Dissection
Treatment of patients with known or suspected aortic arch dissection is not recommended and is potentially harmful. (Class III, LOE C) Treatment of patients with known or suspected extracranial cervical arterial dissection is reasonably safe within 4.5 hr and is probably recommended. (Class IIa, LOE C) The usefulness and hemorrhagic risk of treatment in the setting of known or suspected intracranial arterial dissection is not well established. (Class IIb, LOE C)
Dural Puncture Within 7 Days
Treatment may be considered in patients who had a lumbar dural puncture in the preceding 7 days. (Class IIb, LOE C)
Psychogenic/Conversion/Malingering
The risk of symptomatic intracranial hemorrhage is quite low and treatment is probably recommended in preference over delaying treatment to pursue additional diagnostic studies. (Class IIa, LOE B)
Catheterization Laboratory Environment/ Endovascular Complications
Treatment is reasonable depending on the usual eligibility criteria. (Class IIa, LOE A)
Cocaine Use
Treatment is reasonable in instances of illicit drug use–associated acute ischemic stroke in patients with no other exclusions. (Class IIa, LOE C)

APTT, Activated partial thromboplastin time; *sICH,* subdural intracranial hemorrhage; *IV t-PA,* intravenous tissue plasminogen activator; *mRS,* modified Rankin scale.

Up to one third of patients may have arterial reocclusion early after IV thrombolysis. One study suggested facilitation of clot lysis by concomitant exposure to the ultrasound waves provided by transcranial Doppler, which also serves to monitor clot dissolution.[63] None of a variety of adjunctive neuroprotective strategies has proved effective.[64]

Endovascular Therapy

Catheter-based endovascular approaches for acute reperfusion of patients with large-vessel occlusions (LVOs) yield proven benefit in patients with acute ischemic stroke.[5] Early trials used either intra-arterial t-PA and first-generation clot retriever devices, alone or in combination, and failed to show an overall

benefit of the approach. More recent trials employing stent retrievers reported improved patient outcomes; almost all patients first received IV t-PA, and the majority had proximal middle cerebral artery (MCA) or internal carotid artery (ICA) occlusions. The stent retriever-based studies found benefit despite differences in patient selection and imaging protocols; several used the Alberta Stroke Program Early CT Score (ASPECTS) to exclude patients with large, established areas of infarction deemed unlikely to benefit from reperfusion.[5,65,66] Regardless of mode of treatment, as with IV-tPA, reestablishing circulation to ischemic tissue as soon as possible confers a greater likelihood of achieving improved patient outcomes.[66] The AHA has issued guidelines for endovascular therapy[5] (**Table 65.4**).

TABLE 65.4

AHA Recommendations for Endovascular Therapy in Patients with Acute Ischemic Stroke[5]

Patients should receive endovascular therapy with a stent retriever if they meet all the following criteria (class I; level of evidence, A):

1. Prestroke modified Rankin Score 0 to 1 (functionally independent).
2. Acute ischemic stroke receiving intravenous recombinant tissue plasminogen activator within 4.5 hours of onset according to guidelines from professional medical societies.
3. Causative occlusion of the internal carotid artery or proximal middle cerebral artery.
4. Age 18 years or older.
5. National Institutes of Health Stroke Scale (NIHSS) score of 6 or greater.
6. Alberta Stroke Program Early CT Score (ASPECTS) of 6 or greater.
7. Treatment can be initiated (groin puncture) within 6 hours of symptom onset

Other Measures for Treatment of Stroke

Several other important questions often arise in the management of patients with acute ischemic stroke, as well as regarding the use of other interventions that lack definitive supporting data.

Anticoagulation and Platelet Antiaggregant Therapy

The indications for the acute anticoagulation of patients with ischemic stroke are extremely limited. The most recent AHA guidelines reflect this view and specifically advise against emergency anticoagulation with the goal of improving neurologic outcomes or preventing early recurrent stroke in patients with acute ischemic stroke, because of a high risk for intracranial bleeding complications, and discourage the initiation of anticoagulant therapy within 24 hours of treatment with IV rt-PA.[61] Patients with AF-associated stroke benefit from long-term anticoagulation, unless contraindicated because of high bleeding risk (e.g., previous intracerebral hemorrhage).[3] The risk for early recurrence in patients with stroke related to AF is generally low (0.3% to 0.5%/day for first 2 weeks), so the timing of initiation of anticoagulation needs to be balanced against the risk for bleeding. Those with large strokes and those with uncontrolled hypertension generally have the highest risk for spontaneous hemorrhagic transformation of an ischemic stroke.

The use of anticoagulants in patients with stroke related to infective endocarditis is problematic (**see Chapter 73**). Systemic embolization occurs in 22% to 50% of patients with infective endocarditis, with up to 65% of emboli affecting the central nervous system, most of which (90%) involve the MCA.[67] Anticoagulation has shown no benefit in patients with native valve endocarditis, and it is not generally recommended for at least the first 2 weeks of antibiotic therapy in patients with stroke related to *Staphylococcus aureus* prosthetic valve endocarditis.[67] Of particular concern is the possible development of *mycotic intracranial aneurysms*. These aneurysms are often multiple and can be either asymptomatic, associated with focal neurologic signs, or because they most commonly affect distal branches of the

MCA, associated with signs and symptoms of subarachnoid hemorrhage or a sterile meningitis.[67] Although CT angiography (CTA) or MR angiography (MRA) can screen patients with symptoms suggesting the presence of a mycotic aneurysm, because distal portions of the artery are most commonly affected, catheter angiography remains the definitive modality for detection of these lesions (distal portions of MCA can be difficult to visualize with CTA or MRA). Many intracranial mycotic aneurysms regress with antibiotic treatment. Surgical clipping or endovascular obliteration can also be considered. Anticoagulation should be generally avoided in these patients, as mycotic aneurysms have propensity to rupture.

As noted earlier, platelet antiaggregants reduce the risk for recurrent stroke in patients with a history of ischemic stroke or TIA. In the acute setting, aspirin initiated within 48 hours of acute ischemic stroke may provide benefit (platelet antiaggregants are prohibited for first 24 hours in patients treated with IV rt-PA). A combined analysis of two relevant trials found that treatment with aspirin (160 mg or 325 mg daily) was associated with a small but statistically significant benefit, with 9 (±3) fewer deaths or nonfatal strokes per 1000 treated patients.[68] The CHANCE trial, conducted in China, suggests that a short course of aspirin plus clopidogrel decreases the risk of early recurrent stroke in patients with minor ischemic stroke or high-risk TIA compared to aspirin alone.[19] Whether these results extend to other populations is uncertain. A secondary analysis of data from CHANCE found that the benefit of clopidogrel (a prodrug) was limited to those who were not carriers of the *CYP2C19* loss-of-function allele (i.e., could metabolically activate clopidogrel).[69] Population-based differences in allele frequency could lead to different trial results in different regions.

Blood Pressure Management

Management of BP in the setting of acute ischemic stroke remains largely empiric. Treatment of elevated BP in patients who might otherwise be candidates for IV t-PA differs from that in patients who are not thrombolytic candidates and follows a specific protocol[4] (**Tables 65.5 and 65.6**). Patients who have been treated with a thrombolytic merit relatively aggressive treatment of elevated BP because of an increased risk for bleeding complications associated with uncontrolled hypertension.

TABLE 65.5

Potential Approaches to Arterial Hypertension in Patients with Acute Ischemic Stroke Who Are Potential Candidates for Acute Reperfusion Therapy

Patient otherwise eligible for acute reperfusion therapy except that BP is >185/110 mm Hg:
Labetalol, 10-20 mg IV over 1-2 min, may repeat once, *or*
Nicardipine, 5 mg/hr IV, titrate up by 2.5 mg/hr every 5-15 min, maximum 15 mg/hr; when desired BP reached, lower to maintain BP in proper limits, *or*
Other agents (e.g., hydralazine, enalaprilat) may be considered when appropriate.
If BP is not maintained at or below 185/110 mm Hg, do not administer rt-PA.
Management of BP during and after rt-PA or other acute reperfusion therapy:
Monitor BP every 15 min for 2 hr from start of rt-PA therapy; then every 30 min for 6 hr and then every hour for 16 hr.
If systolic BP 180-230 mm Hg or diastolic BP 105-120 mm Hg:
Labetalol, 10 mg IV, followed by continuous IV infusion 2-8 mg/min, *or*
Nicardipine, 5 mg/hr IV; titrate up to desired effect by 2.5 mg/hr every 5-15 min (max, 15 mg/hr).
If BP not controlled or diastolic BP >140 mm Hg, consider sodium nitroprusside

BP, Blood pressure; *IV,* intravenous(ly); *rt-PA,* recombinant tissue plasminogen activator.

TABLE 65.6

Approach to Arterial Hypertension in Patients with Acute Ischemic Stroke Who Are *Not* Potential Candidates for Acute Reperfusion Therapy

Consider lowering BP in patients with acute ischemic stroke if systolic BP >220 mm Hg or diastolic BP >120 mm Hg.
Consider BP reduction as indicated for other concomitant organ system injury:
Acute myocardial infarction
Congestive heart failure
Acute aortic dissection
A reasonable target is to lower BP by 15% to 25% within the first day.

BP, Blood pressure.

From Jauch EC, Saver JL, Adams HP, et al. Guidelines for the early management of patients with acute ischemic stroke. Stroke 2013;44:870-947.

Several lines of evidence suggest cautious BP management in non–thrombolytic-treated patients with acute ischemic stroke who do not have malignant hypertension (i.e., in patients with hypertensive encephalopathy, aortic dissection, acute renal failure, acute pulmonary edema, acute MI, or high BP >220/120 mm Hg).[4] Abruptly lowering BP may further compromise an already ischemic brain and potentially increase the size of the stroke. If treatment is necessary, precipitous drops should be avoided. In a single-blind study with blinded outcome assessments, the China Antihypertensive Trial in Acute Ischemic Stroke (CATIS) randomly assigned over 4000 patients to receive antihypertensive treatment (target reduction of 10% to 25% within first 24 hours) or to discontinue all antihypertensive medications during hospitalization.[70] BP reduction did not reduce death or major disability at 14 days or hospital discharge.

Stroke After Percutaneous Coronary Interventions and Thrombolytic Treatment of Myocardial Infarction

Although infrequent, stroke can complicate percutaneous coronary interventions (PCIs). The same principles outlined for the management of acute stroke in other settings apply. The patient could receive IV rt-PA and could be evaluated for endovascular therapy, provided that all the other inclusion criteria are met and the patient has no other contraindications to the therapy. It is important to establish systems to ensure the rapid evaluation and treatment of patients with stroke after PCI.

Intracerebral hemorrhage following administration of a thrombolytic for acute MI or pulmonary embolism is another serious treatment-related complication. The infusion should be stopped and heparin discontinued in any patient in whom acute neurologic symptoms develop. Because these symptoms might result from either hemorrhage or ischemia, a brain-imaging study is mandatory before proceeding with further treatment. Treatments to reduce the amount of thrombolytic-associated intracerebral hemorrhage once it has occurred are not well established. Administration of cryoprecipitate and/or fresh-frozen plasma has been advocated. Those with brainstem compression related to cerebellar hemorrhage may benefit from surgical evacuation of the hematoma. Such patients require prompt transfer to a setting with expertise in neurologic intensive care.

Future Perspectives

Much of the greater than 40% reduction in stroke mortality that has occurred in the United States over the last decade is associated with more effective prevention. One analysis found that 10 potentially

modifiable risk factors account for 90% of the population-attributable risk of stroke.[71] Continued emphasis on prevention promises to have the greatest impact on further improvements. Establishing the clinical usefulness of advanced neuroimaging to optimize selection of patients for acute reperfusion interventions requires additional work. New approaches to poststroke recovery offer the potential of improved outcomes in those with functional deficits that persist after the acute period.

Treatment of Noncoronary Obstructive Vascular Disease

Scott Kinlay, Deepak L. Bhatt

Peripheral vascular disease is a general term that includes pathologic processes affecting arteries, veins, and lymphatics (**see Chapter 64**). This chapter focuses on catheter-based endovascular treatment of large

and medium-sized arteries predominantly affected by atherosclerosis, as well as large-vein obstruction secondary to chronic disease. Although *peripheral artery disease* (PAD) refers to lower limb arterial disease, sometimes the term is used to describe disease in the large and medium arteries of the upper limbs, neck, and aortomesenteric arteries. The incidence and prevalence of PAD increase with age and with other risk factors for atherosclerosis. Thus, these two demographic forces will likely lead to a global increase in PAD (**see Chapter 1**).

Increasing awareness of PAD, the impact that PAD has on cardiovascular (CV) risk and quality of life, and the rapid development of percutaneous techniques for revascularization continue to accelerate the number of endovascular procedures for PAD. Appropriate use of this expensive technology requires a clear understanding of the goals of medical and revascularization therapies.

Approach to the Patient With Peripheral Artery Disease

Chronic PAD may be asymptomatic or may manifest as claudication, critical limb ischemia, or embolic infarction of a distal organ (e.g., stroke). Asymptomatic disease is common. In the lower extremities, asymptomatic disease occurs in at least half and in as many as 80% of patients with abnormal functional test results indicative of obstructive arterial disease (e.g., abnormal ankle-brachial index [ABI]). Even asymptomatic disease indicates elevated CV risk.[1-5] These considerations warrant intensive modification of atherosclerosis risk factors as a prime goal of therapy to reduce the risk for myocardial infarction (MI) and stroke, the most common causes of death in patients with PAD.[1,4-8]

Claudication classically refers to leg discomfort or pain related to exercise and relieved by rest, but it also describes discomfort in the upper limbs caused by effort-related ischemia. Claudication affects function (the ability to walk or use a limb) and quality of life. Therefore, treatment of claudication aims to improve function and reduce discomfort at the maximum level of activity desired by a patient. Stopping cigarette smoking and starting a regular walking regimen are the two most important lifestyle interventions for claudication. Together, these interventions reduce the mechanisms responsible for the progression of disease and favorably change arterial biologic state, including vasodilator function, muscle metabolism, and angiogenesis.[1,5,6,8] It is important to tell patients that the pain or discomfort associated with claudication is not harmful, and that once this discomfort abates with rest, they should continue to push their activity again to improve endurance. Revascularization strategies aim to improve arterial blood flow in obstructed large and medium-sized arteries when noninvasive therapies fail. Catheter-based interventions, when indicated, should be deployed together with lifestyle and medical treatment.[9]

Critical limb ischemia (CLI) refers to PAD with ischemic pain at rest or tissue loss (e.g., ulcer or gangrene).[1,4,5,10] This scenario has clinical urgency because of near-term risk for limb jeopardy requiring major amputation. *Major* amputation in the lower limbs refers to amputation at or above the level of the ankle and requires a prosthesis for the patient to walk.[10] Amputation is disfiguring and at higher levels has greater impact on functional independence of the patient. In contrast, *minor* amputations (e.g., toe or transmetatarsal) usually have little impact on the patient's ability to walk. Catheter-based therapies for CLI are used to improve blood flow and heal ischemic tissue, to salvage the limb (prevent major amputation), or to enable a lower level of amputation that might have less impact on the patient's ability to walk.

Cervical carotid, vertebral, and subclavian disease, although often asymptomatic, can lead to artery-to-artery embolism with transient ischemic attack (TIA) and stroke. The risk for major stroke is high shortly

after a symptomatic event but less so several months after an event or with asymptomatic disease.[11] Mesenteric and renal artery disease affects organ function. Chronic ischemia of the gut causes postprandial abdominal discomfort and food avoidance leading to weight loss, but it may progress to frank mesenteric infarction with a high mortality rate.[12] Renal artery stenosis can precipitate hypertensive crises associated with pulmonary edema, hypertension resistant to treatment, and rapidly worsening renal dysfunction.[13]

Symptomatic disease that threatens a distal organ (e.g., CLI, TIA, mesenteric angina) justifies a more aggressive approach because these manifestations entail the highest risk for functional loss and death without treatment. PAD associated with less-threatening clinical scenarios (e.g., claudication) may allow a less aggressive approach, with more time to assess the response to lifestyle and medical therapies (**Fig. 66.1**). There is rarely justification for catheter-based or surgical revascularization of asymptomatic lower or upper limb PAD, mesenteric disease, or subclavian or vertebral artery disease. Revascularizing asymptomatic extracranial carotid disease beyond medical therapy has uncertain value, although recent guidelines support such interventions for patients at higher risk for stroke and low risk for periprocedural adverse events.[11]

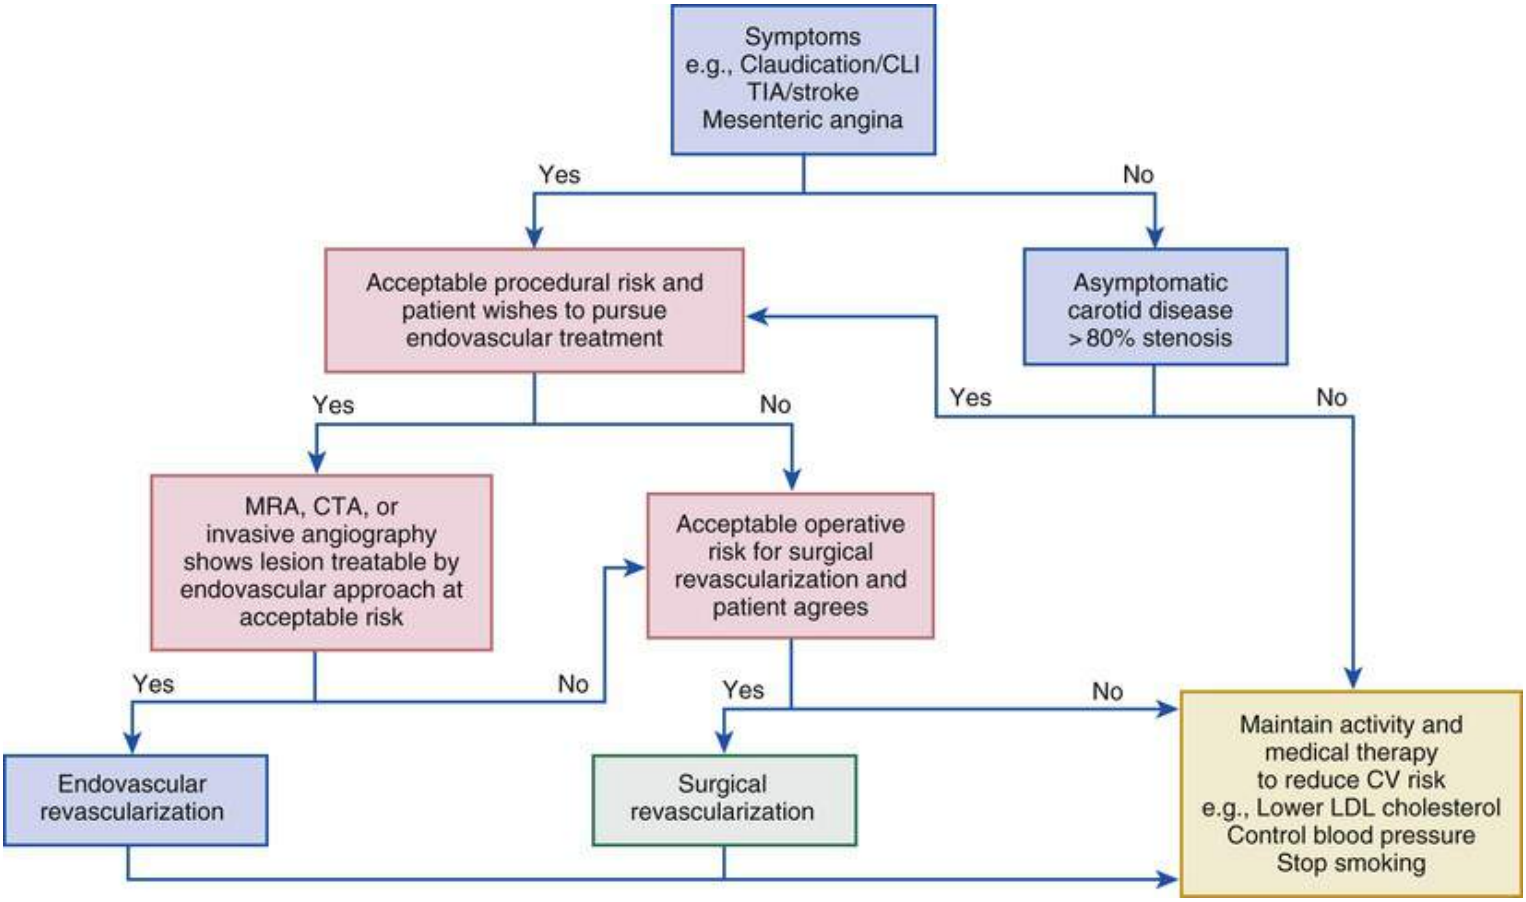

FIGURE 66.1 Approach to a patient with peripheral artery disease. This strategy is based on assessment of the risk for adverse events with and without treatment by taking into consideration procedural or operative risks and the patient's informed decision to proceed with revascularization. CLI, Critical limb ischemia; CTA, computed tomographic angiography; CV, cardiovascular; LDL, low-density lipoprotein; MRA, magnetic resonance angiography; TIA, transient ischemic attack.

Quality of Evidence Evaluating Endovascular Treatments

In contrast to coronary disease, few well-controlled studies have evaluated endovascular treatment of PAD and venous disease. Many studies are single arm, and most focus on patency (lack of restenosis) and repeated revascularization over a relatively short period. Although these endpoints provide information on the mechanisms likely to lead to improved control of symptoms, function, quality of life, and tissue preservation, they do not provide direct guidance on symptoms and function in patients with claudication or CLI. Interventionalists should recognize the limitations in many studies and encourage future studies to address patient-oriented endpoints and adjudicated CV outcomes.[14-16]

Endovascular Technologies

Balloon Angioplasty

Balloon angioplasty remains the mainstay of endovascular intervention for PAD and venous disease[17,18] (**Fig. 66.2**). Angioplasty remodels the artery by expansion and accommodates the atherosclerotic plaque to expand the vessel lumen. This procedure usually causes dissection of the plaque that may or may not impair blood flow. Angioplasty is limited in the short term by acute recoil of the artery and flow-limiting dissections, which may cause abrupt closure of the artery. In the intermediate time frame, overexuberant neointimal hyperplasia and negative remodeling of the artery may lead to symptomatic restenosis. Despite these limitations, balloon angioplasty can achieve durable results, particularly with shorter lesions, and is less likely than stenting to obstruct side branches associated with the lesion. Most operators use prolonged inflations (at least 1 minute or more). Both rapid-exchange and over-the-wire platforms are available, as well as short and long shaft lengths for lesions close to or farther from the access site.

FIGURE 66.2 Treatment of a mid–superficial femoral artery stenosis **(A),** with balloon angioplasty alone **(B),** with an excellent final result **(C).**

Bare-Metal Stents

Bare-metal stents (BMSs) come in two types: balloon-expandable stents (**Fig. 66.3**) and self-expanding stents[17,18] (**Fig. 66.4**). Stent implantation requires aspirin therapy and an adenosine receptor antagonist (i.e., clopidogrel), although the evidence for dual-antiplatelet therapy (DAPT) is largely derived by extrapolation from the coronary stent literature.

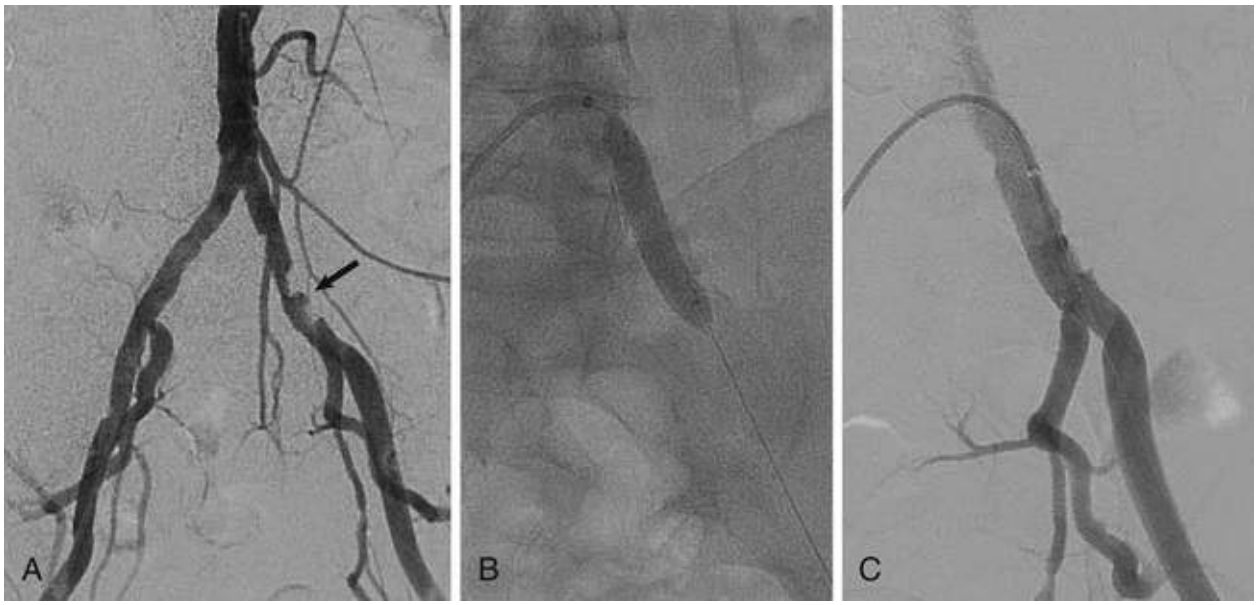

FIGURE 66.3 Treatment of left common iliac stenosis with a balloon-expandable stent from the contralateral right femoral artery. **A,** Serial stenoses in the left common iliac artery (*arrow*). **B,** Balloon-expandable stent deployment. **C,** Final angiogram.

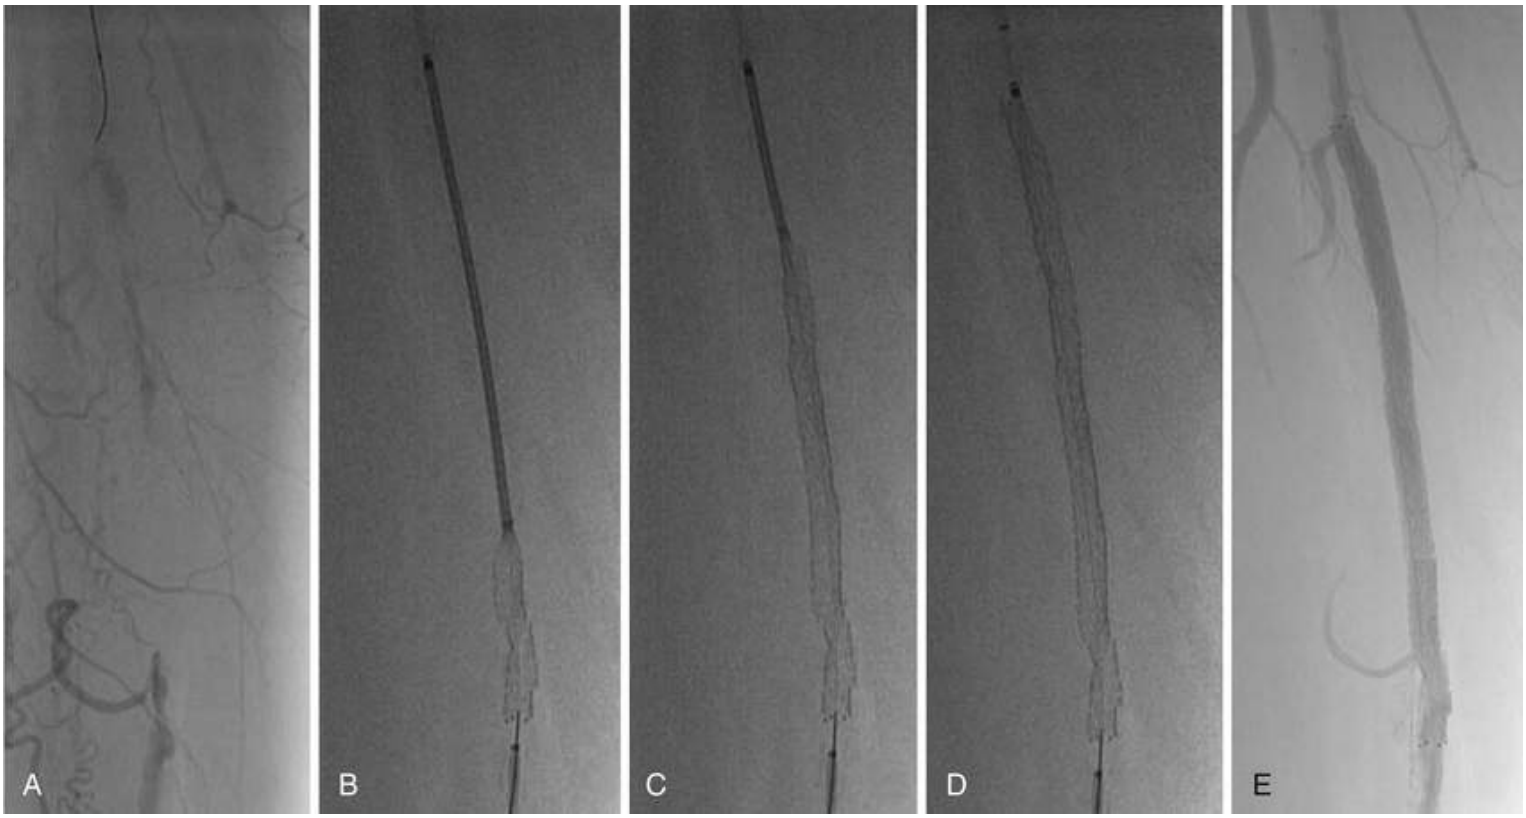

FIGURE 66.4 Treatment of a superficial femoral artery occlusion with a self-expandable nitinol stent. **A,** A wire approaches the occluded segment. **B-D,** The delivery catheter is pulled back to release the self-expanding stent. **E,** Final angiogram.

Balloon-expandable stents have greater radial strength and are less likely to move on deployment, which is important for ostial placement. Such stents can be crushed by external compression and are therefore avoided outside the torso. They are sometimes used to treat tibial disease, but only for critical limb ischemia, for which long-term patency may be less of an issue once tissue healing has occurred.

Self-expanding stents were originally made of stainless steel but are now usually made of nitinol.[17] Nitinol stents reexpand on compression and are therefore used outside the torso, where external compression is more likely to occur. They may also be used in tortuous arteries, where they probably conform better than balloon-expandable stents. Their lower radial strength, however, increases the risk for recoil. More recent self-expanding stent designs are more durable and less likely to fracture.[17,18] Nitinol stents cannot be overdilated if the stent is undersized for the artery, which may lead to stent malapposition or even embolization.

Drug-Eluting Peripheral Stents

Earlier attempts at coating peripheral self-expanding stents were initially associated with less restenosis in the short term but were unsuccessful in longer follow-up, partly because of inferior stent platforms prone to fracture. More durable stent designs[17-19] and drug elution with everolimus[20] or paclitaxel[21] offer lower rates of restenosis. The 5-year follow-up of the Zilver PTX study demonstrated a sustained benefit from self-expanding drug-eluting stents (DESs) over balloon angioplasty and BMSs on freedom from clinical symptoms of ischemia (80% versus 59%) and repeat revascularization (66% versus 43%) in femoral-popliteal arteries.[22] The duration of DAPT required for these stents is uncertain, but recent randomized trials have generally used 2 to 6 months of treatment with an adenosine receptor antagonist.[20,21]

Covered Stents

Stents covered with or sandwiching a polymer such as polytetrafluoroethylene (PTFE) have proved very useful for treating perforations related to endovascular treatment or excluding aneurysms (**Fig. 66.5**). Results from randomized trials are inconsistent; some studies show no benefit over BMSs,[23] and others suggest lower restenosis at 12 months when treating femoral and iliac artery disease.[24,25] In one series, covered stents that cross the knee joint were associated with higher rates of occlusion and major amputation than those deployed above the knee (34% versus 10%).[26] Disadvantages of covered stents include unintentional[21] occlusion of important branch vessels, concerns about the risk for late stent thrombosis, and whether restenosis was merely delayed rather than prevented.

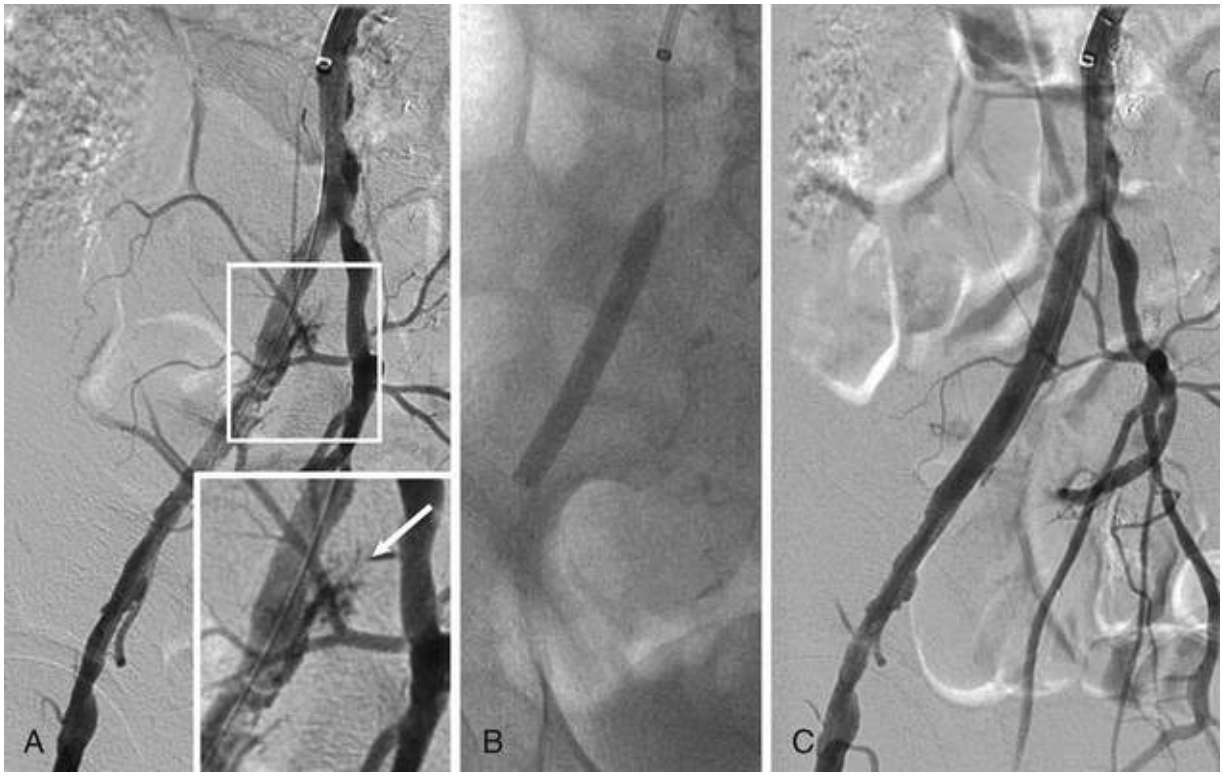

FIGURE 66.5 Treatment of a perforated external iliac artery with a covered stent. **A,** Perforation after directional atherectomy shown enlarged in the lower right box (*arrow*). **B,** Deployment of a balloon-expandable covered stent. **C,** Final angiogram with the perforation sealed.

Drug-Coated Balloons

Balloons coated with antirestenosis agents (drug-eluting balloons) represent an exciting development. This technology uses a non–stent-related method to deliver drugs such as paclitaxel into the arterial wall after conventional angioplasty treatments. Compared with plain balloon angioplasty, drug-coated balloons have less restenosis and repeat revascularization in the femoral-popliteal arteries.[27-30] Drug-coated balloons also offer a lower risk of restenosis compared with plain balloon angioplasty for treating in-stent restenosis lesions.[31] Late follow-up of two randomized trials at 2 and 5 years shows a sustained benefit on patency and repeat revascularization with drug-coated versus plain balloon angioplasty in femoral-popliteal arteries, without safety concerns of aneurysm or late stenoses.[30,32] The duration of DAPT with drug-coated balloons in the femoral-popliteal arteries is uncertain but varies between 1 and 6 months in most randomized trials.

The effect of drug-coated balloons in below-knee angioplasty, primarily for CLI, is less certain. Compared to plain balloon angioplasty, one randomized trial showed a lower risk for repeat revascularization but no effect on major amputation or mortality.[33] The only other randomized trial, the IN.PACT DEEP study, showed no difference in restenosis and a trend to increasing risk of amputation, leading the sponsor to withdraw that drug-coated balloon from the market.[34] Differences in drug-coating techniques and eluting agents could explain the lackluster results of drug-coated balloons below the knee, and the question of their value requires further evaluation.[18]

Thrombolysis and Thrombectomy

Catheter-directed thrombolysis is an important adjunctive therapy for arterial thrombosis, stent thrombosis, and occlusive thrombotic venous disease. Thrombolysis may be indicated for acute thrombosis with a threatened but viable extremity, but an immediately threatened limb (e.g., with sensory or early motor deficits) is more often treated by surgical revascularization,[35] which offers more rapid reperfusion, the ability to débride devitalized tissue, and the opportunity to relieve compartment syndromes. Much of the experience with catheter-based thrombolysis comes from its use for acute limb ischemia (ALI), venous thrombosis, or pulmonary embolism. It serves as an adjunctive treatment of semiacute manifestations such as peripheral stent thrombosis. Long-term results tend to be better when thrombolysis reveals an anatomic stenosis that probably precipitated the thrombosis and is treatable, for example, by repeated angioplasty.

Catheter-directed thrombolysis is more effective than intravenous thrombolysis only if an infusion catheter (with multiple infusion holes) is inserted into the thrombosed vessel. It is also less effective if given more than 14 days after thrombosis.[5,18] Typically, the infusion continues for 12 to 24 hours, because treatment over 48 hours is associated with depletion of circulating fibrinogen and a higher risk for major bleeding.[36] Catheter-based thrombolysis with or without angioplasty or stenting also reduces the incidence of post-thrombotic syndrome in patients with proximal (iliac) deep venous thrombosis,[35,37] and it is used as adjunctive therapy for massive pulmonary emboli[38,39] (**see Chapter 84**).

Any thrombolysis regimen increases risk for fatal or major bleeding. Absolute contraindications to thrombolysis[38] include (1) a cerebrovascular event less than 2 months previously, (2) active bleeding, (3) gastrointestinal bleeding less than 10 days previously, and (4) neurosurgery (intracranial or spinal surgery) or trauma less than 3 months previously. Relative contraindications include (1) cardiopulmonary resuscitation less than 10 days previously, (2) nonvascular surgery or trauma less than 10 days previously, (3) uncontrolled hypertension (sustained systolic blood pressure >180 mm Hg or diastolic blood pressure >110 mm Hg), (4) puncture of a noncompressible vessel, (5) intracranial tumor, and (6) recent eye surgery.

Catheter aspiration thrombectomy uses catheters with a rapid-exchange port to direct the catheter to the thrombus and a large aspiration port to aspirate the catheter with a large syringe. These catheters can aspirate smaller thrombi but are generally inadequate for a large burden of thrombus (e.g., long femoral stent thrombosis).

Mechanical thrombectomy uses a variety of devices that may include thrombolytic agents to help break up thrombus before suction by an aspiration catheter or catheters using the Venturi effect.[39] Although mechanical thrombectomy is a more rapid treatment than catheter-directed thrombolysis, embolization

can occlude the distal arterial bed and lead to infarction and tissue loss, although combination with an embolic protection device might theoretically reduce this risk.

Atherectomy and Other Treatments

Atherectomy devices, although conceptually attractive, have not proved better than angioplasty in direct comparisons in most arterial beds.[17,18] A recent Cochrane review of four trials comparing atherectomy to established treatments for PAD found no evidence to support atherectomy as an alternative to balloon angioplasty.[40] Atherectomy is one of several niche tools and serves best in heavily calcified arteries to improve balloon and stent expansion or in regions where vessels encounter repetitive flexion or torsion, such as over joints, and where stents are avoided (because of kinking and increased fracture). In these settings, atherectomy may improve the distensibility of an artery to permit adequate expansion by balloon angioplasty without flow-limiting dissection. Drug-eluting balloons have renewed interest in this technology because they may reduce the contribution of excessive intimal hyperplasia to restenosis. This strategy needs formal testing in clinical trials.

Coronary rotational atherectomy devices (Rotablator) are generally too small for the larger peripheral arteries, and it is uncertain how a large amount of plaque ablated from a long peripheral lesion would affect the downstream microcirculation (**Fig. 66.6**). *Peripheral rotational* atherectomy devices include the Jetstream, which has a 2.0-, 3.1-, and 3.5-mm cutting profile (**Fig. 66.7**), and the Diamondback, which uses an eccentric location to achieve a larger cutting arc.[17,18] *Directional* atherectomy devices include the Silverhawk device[17,18] (**Fig. 66.8**). All the peripheral devices have a tendency to embolize plaque into microvessels. Distal embolic protection devices may reduce this complication.

Cryoplasty involves the use of proprietary balloon and inflation technology to inflate the balloon with nitrous oxide, which chills on expansion to −10°C (**Fig. 66.9**). One pilot study suggested lower rates of restenosis in the femoral arteries when used with nitinol stents compared to balloon angioplasty,[41] but longer-term outcomes are uncertain and larger studies are needed.

Planning an Intervention

Vascular Imaging

Vascular imaging is the first stage of planning an endovascular intervention[4,5,10,18] (**Fig. 66.10**). Traditionally, invasive angiography served to determine the extent and severity of obstructive disease. Conventional angiography can use lower frame rates than needed for coronary angiography because most peripheral arteries are relatively static. Digital subtraction angiography (DSA) images remove bone and soft tissue from the image while leaving the contrast-enhanced image of the artery for more clarity, provided that the limb remains still during acquisition.

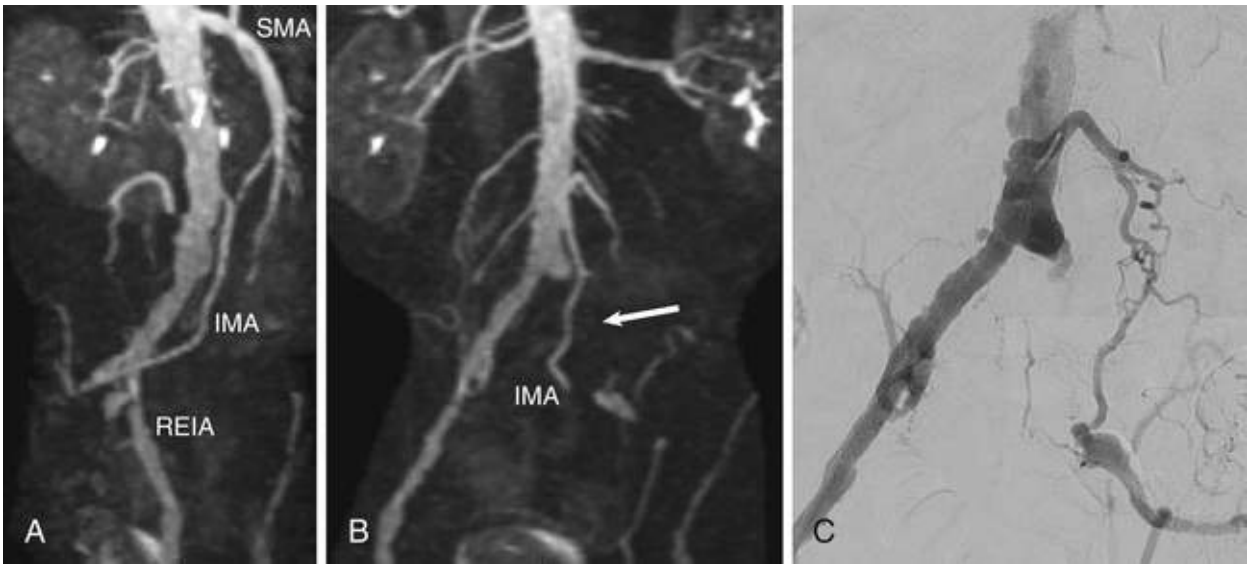

FIGURE 66.10 Comparison of magnetic resonance angiography (MRA) and digital subtraction angiography (DSA). **A,** Lateral rotation of a maximum intensity projection (MIP) image of the lower aorta and iliac arteries; *IMA,* Inferior mesenteric artery; *REIA,* right external iliac artery; *SMA,* superior mesenteric artery. **B,** Anterior-posterior rotation from a MIP showing the left common iliac occlusion (*arrow*) and the IMA supplying collaterals to the left external iliac artery. **C,** Corresponding image from conventional angiography with DSA.

Noninvasive imaging is used to plan the vascular access and the tools probably required for the procedure.[10,18,42] Magnetic resonance imaging (MRI) uses gadolinium or other contrast agents or time-of-flight techniques, which rely on laminar blood flow and have the advantage of not requiring contrast material, which can rarely cause serious adverse effects in patients with renal insufficiency (e.g., nephrogenic sclerosing fibrosis). However, time-of-flight techniques may overestimate the severity of disease in regions of disturbed flow near obstructive or nonobstructive plaque. Computed tomographic angiography (CTA) using iodinated contrast material provides more rapid imaging, but heavy calcification can mask stenoses and make interpretation of lesion severity more difficult. Iodinated contrast agents can cause reactions or impair renal function.

MRI cannot be used in patients who have retained ferric metals (e.g., most pacemakers, shrapnel). Most contemporary stents are compatible with MRI but leave a flow void that does not allow interpretation of obstructive disease. High-resolution contrast-enhanced computed tomography (CT) scans offers advantages for assessing stent patency. Both MRI and CT tend to overestimate the severity of stenosis compared with conventional invasive angiography.

Duplex ultrasound is very useful for imaging arteries in the limbs and the cervical arteries and veins. This modality does require considerable time to map out large arterial systems, however, explaining the more common use of magnetic resonance angiography (MRA) and CTA as noninvasive techniques to plan endovascular interventions.

Vascular Access

Vascular access can use either antegrade or retrograde approaches (**Fig. 66.11**).[10] The contralateral common femoral artery (CFA) furnishes the most common vascular access for the lower limb. A catheter enters the access side over the bifurcation of the aorta and into the target iliac arteries through a support wire. A sheath is directed up and over the aortic bifurcation and pointed into the target iliac artery (**Fig. 66.12**). This approach is familiar to many operators and provides access to the CFA at its most superficial location. It also allows compression of the artery against the femoral head to aid in manual

hemostasis after removal of the sheath.

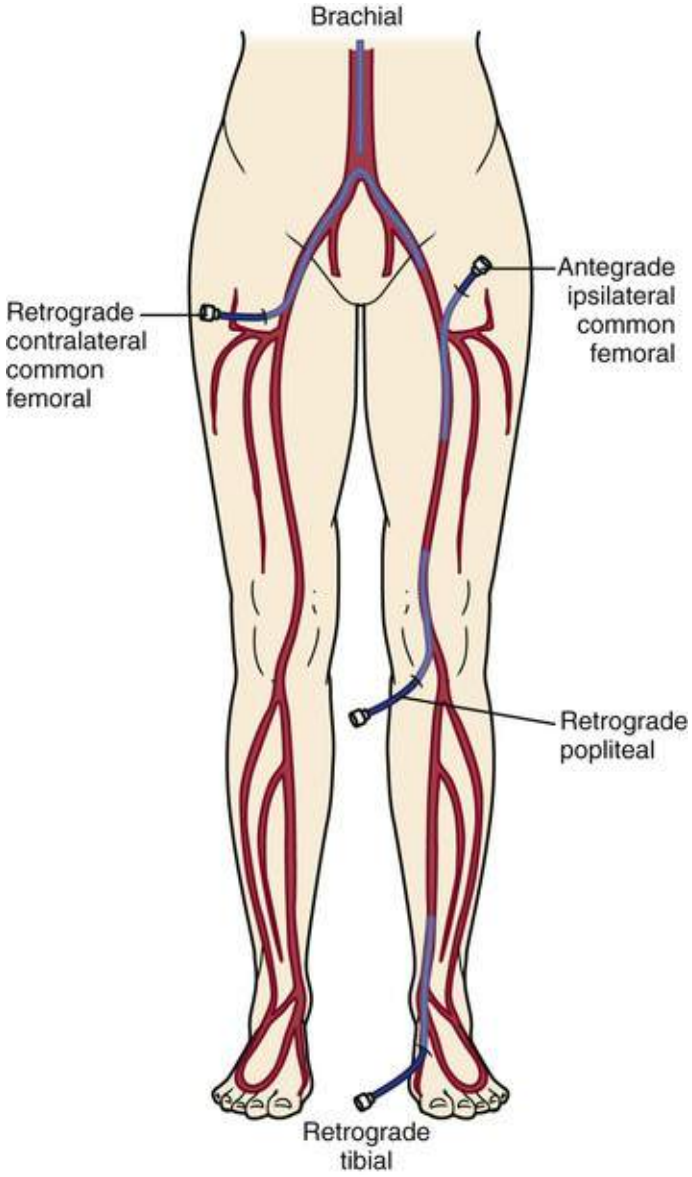

FIGURE 66.11 Antegrade and retrograde arterial access for lower extremity interventions. (From Kinlay S. Management of critical limb ischemia. Circ Cardiovasc Interv 2016;9:e001946.)

FIGURE 66.12 **A-C,** Access to a left iliac stenosis via the right common femoral artery. **A,** Access of the right femoral artery. The *arrow* indicates the access site of the femoral sheath. **B,** An Omniflush catheter is directed from the right iliac artery into the origin of the left iliac artery. **C,** A support wire is used to direct a sheath into the left common iliac artery for the intervention. **D,** Anterograde access of the common femoral artery with the tip of the sheath directed into the superficial femoral artery.

The anterograde femoral approach involves skin access several centimeters cranial to the CFA and angles toward the femoral head (**Fig. 66.12**). This approach offers greater pushability for total occlusions and is closer to distal tibial lesions, but it is difficult in overweight patients, in whom the access needle must traverse a large depot of subcutaneous fat.

Rarely, retrograde access from the popliteal artery or from a tibial artery can assist in crossing a total occlusion that cannot be crossed from an anterograde approach[10,18,43] (**Figs. 66.13 and 66.14**). Retrograde access has the disadvantages of the potential to cause injury to the distal access site because of the smaller artery size (tibial arteries) or more difficult hemostasis from a deeper location (popliteal). Techniques that combine retrograde and anterograde approaches can assist in crossing difficult total occlusions. An unsuccessful procedure from a retrograde access site, however, could lead to a nonhealing ulcer and CLI, and thus it is generally used as a "last resort."

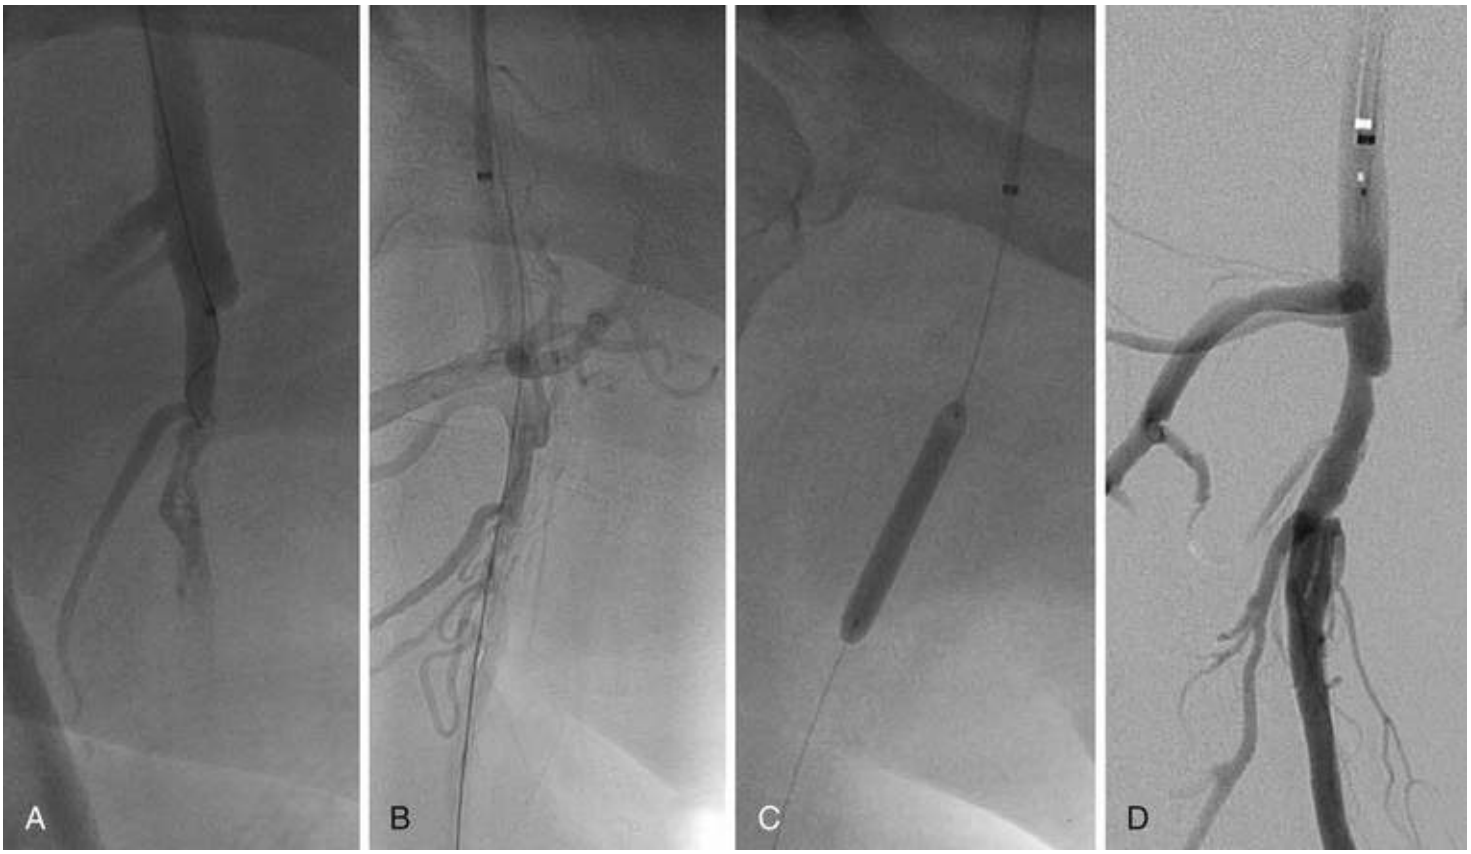

FIGURE 66.13 Anterograde and retrograde approach to a brachial artery stenosis. **A,** Unable to cross the stenosis from the anterograde approach, with a shuttle sheath directed into the brachial artery from the femoral approach. **B,** Successful wire crossing retrogradely from the radial approach. The wire was snared into the shuttle sheath. **C,** Balloon angioplasty performed anterogradely from the shuttle sheath. **D,** Final angiogram with an excellent long-term functional result.

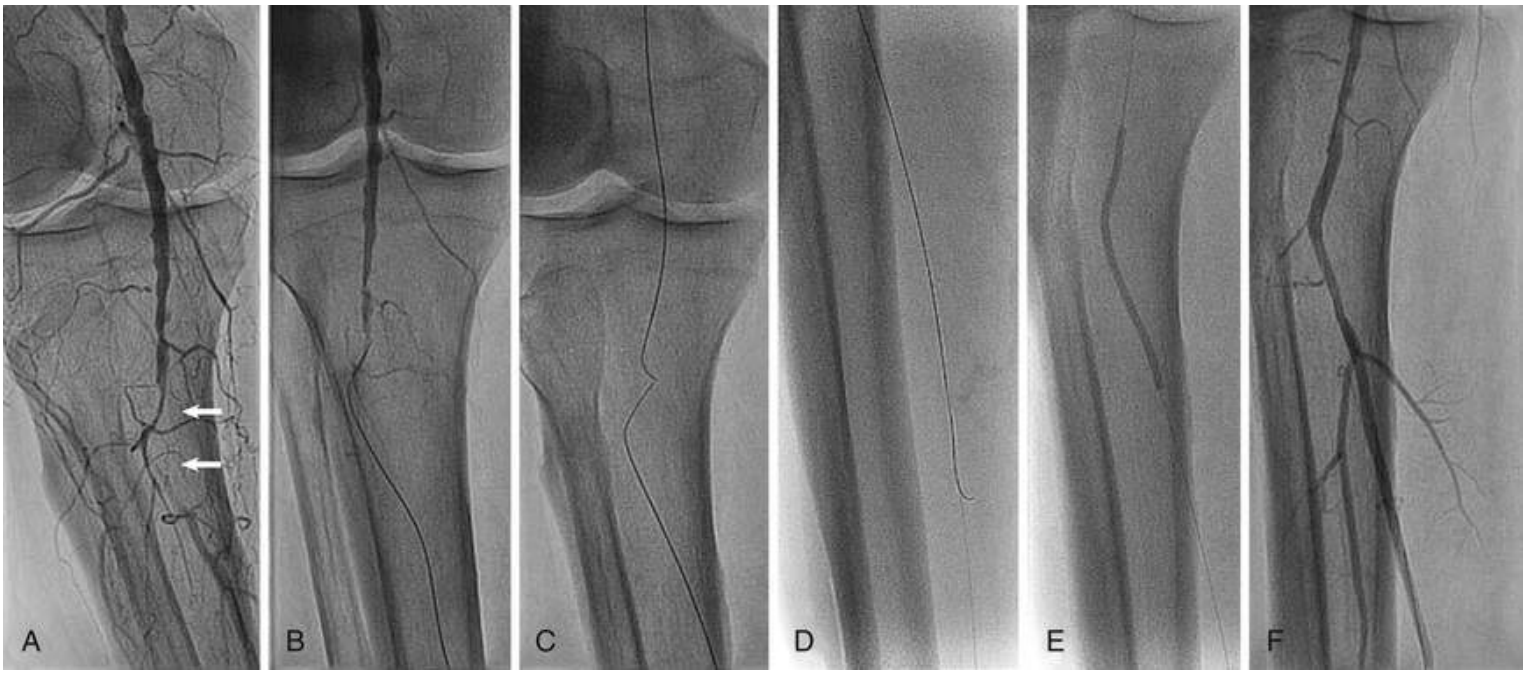

FIGURE 66.14 Anterograde and retrograde approach to an occluded below-knee popliteal and posterior tibial artery. **A,** Occluded segment (*arrows*). **B,** Retrograde wire from the posterior tibial artery accessed at the ankle. **C,** Anterograde and retrograde wires crossing the occlusion. **D,** The anterograde wire crossed the occlusion into the distal posterior tibial artery. **E,** Balloon angioplasty was followed by a short stent in the occluded segment. **F,** Final angiogram.

The brachial artery approach can permit access to the iliac arteries, but it is usually too far a distance from the superficial femoral arteries for most balloons and stent delivery devices. A shuttle sheath from the femoral approach or retrograde access from the radial or brachial approach can be used to access upper limb lesions. Brachial or radial artery access often provides better support for the mesenteric and renal arteries because these arteries typically angulate caudally.

Endovascular Treatment of Arterial Disease

Peripheral Artery Disease of the Lower Extremities

The clinical history and physical examination can generally differentiate PAD from other causes of leg discomfort. Physiologic tests such as the ABI are quick and easy to perform, but segmental leg pressures can indicate the level of obstructive disease. Infrainguinal disease usually diminishes distal pulses and impairs the resting ABI. Typical symptoms of PAD with a normal resting ABI should raise suspicion for iliac or aortic disease, in which case an exercise ABI is generally abnormal (**see Chapter 64**). More advanced imaging such as MRA, CTA, or invasive angiography is generally indicated only if revascularization is being considered. MRI or CT can help identify the level, extent, and severity of PAD and help indicate the likelihood of endovascular success versus surgical treatment, as well as access site and adjunctive endovascular technologies. In general, treatment of proximal disease offers higher long-term durability than does treatment of distal disease.

Aortoiliac Disease

Aortoiliac disease is approached from the ipsilateral femoral artery, contralateral femoral artery, or brachial artery. An ipsilateral femoral approach is more direct and associated with greater wire pushability through an occlusion. Many operators will often gain contralateral femoral access with a small sheath, because this will provide quick access to the aorta or proximal iliac artery for temporary balloon occlusion in the event of perforation and rapid hemorrhage. Although plain balloon angioplasty produces a very durable result, balloon-expandable stents are now preferred for their better long-term durability, particularly with long lesions.[3-5] “Kissing stents” are a well-described option for disease involving the distal aorta, but in many cases of iliac disease, landing stents at the ostium of the iliac artery yields a good response and preserves contralateral access if arterial interventions are required for a leg in the future. Balloon-expandable stents are usually preferable for most lesions involving ostia because of their greater radial strength and precision of placement, but self-expanding stents may be better in more tortuous lesions (**Fig. 66.15**). Although covered stents prevent plaque prolapse, they have uncertain added value and the potential disadvantage of occluding the opposite iliac artery if deployed too high or occluding the ipsilateral internal iliac artery if deployed too low. They also appear to have a higher risk of thrombosis. Covered stents are useful for treating aneurysms and potentially lifesaving for treating vessel rupture or perforation.[17,18] Occlusions involving the distal aorta generally undergo surgical treatment, although percutaneous transluminal angioplasty and stenting offer an option to patients with prohibitive surgical risk and CLI.

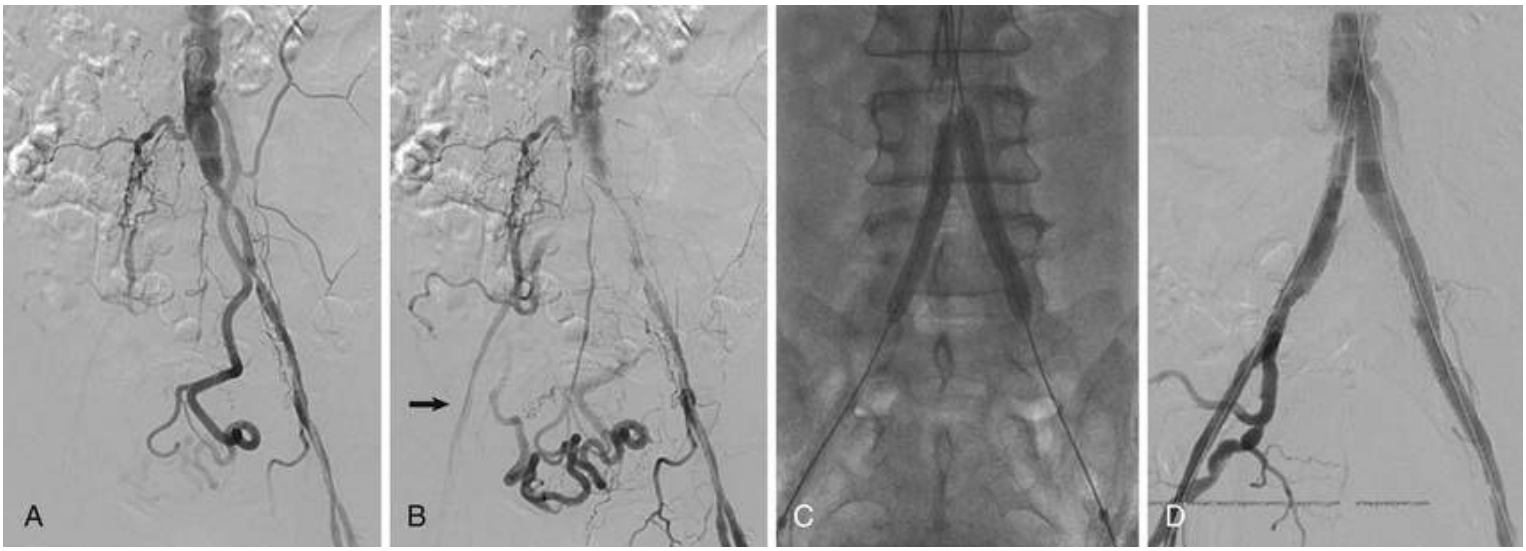

FIGURE 66.15 Aortoiliac intervention for an occluded right common iliac artery and serial stenoses in the left iliac artery. **A,** Early-phase angiogram showing occlusion of the right common iliac artery. **B,** Late-phase angiogram showing a patent right external iliac artery (*arrow*). **C,** Bilateral kissing balloon-expandable stents in the common iliac arteries. **D,** Composite angiogram showing the final result.

The external iliac artery rises out of the pelvis and joins the CFA just above the femoral head. This ascent out of the pelvis is deceptive on angiography, which may be related to the higher risk for perforation or dissection with endovascular treatment. Once the artery leaves the pelvis, it can undergo external compression, prompting consideration of self-expanding stents. Endovascular angioplasty and stenting, particularly for shorter and common iliac lesions, has very good technical success with excellent durability (>80% patency) over a 5-year period, similar to results with surgical revascularization.[3,4,17]

Femoral-Popliteal Artery Disease

Obstructive atherosclerosis is more common in the superficial femoral than the popliteal or common femoral arteries. Usually, the profunda femoris serves as an important source of collateral blood flow to the leg in patients with obstructive superficial femoral artery disease. The CFA is more difficult to treat because it is subject to greater flexion and extension with movement of the hip, and complications that occlude the CFA are likely to lead to an acutely threatened limb as a result of obstruction of the profunda and superficial femoral arteries. Even though balloon angioplasty can successfully treat obstructive CFA disease secondary to atherosclerosis or complications of CFA access for other procedures, surgical repair with patch angioplasty is the standard of care for most patients with acceptable surgical risk. Balloon-expandable stents should not be used in this location because of repetitive compression during movement of the hip, and self-expanding stents should be avoided because of concerns of durability and loss of a site of potential future vascular access. The profunda femoris is a smaller artery with a thinner wall than the superficial femoral artery, and the risk for complications and evidence of long-term success with catheter-based intervention are uncertain.

Most percutaneous femoral interventions involve the superficial femoral and popliteal arteries, and interventional techniques are similar with both arteries. PAD typically involves these arteries, which are subject to torsion and stretch with movement of the leg. The popliteal artery is particularly subject to torsion and kinking, and stents are generally avoided below the level of the top of the patella and above the tibial metaphyseal plate when viewed with the leg straight (**Fig. 66.16**). Stenting between this region subjects stents to extreme flexion, compression, and torsion and is associated with stent fracture, restenosis, and poor long-term durability. As a result, stenting across the knee should be considered only in patients with CLI and a poor angioplasty result and in those with prohibitive surgical risk.

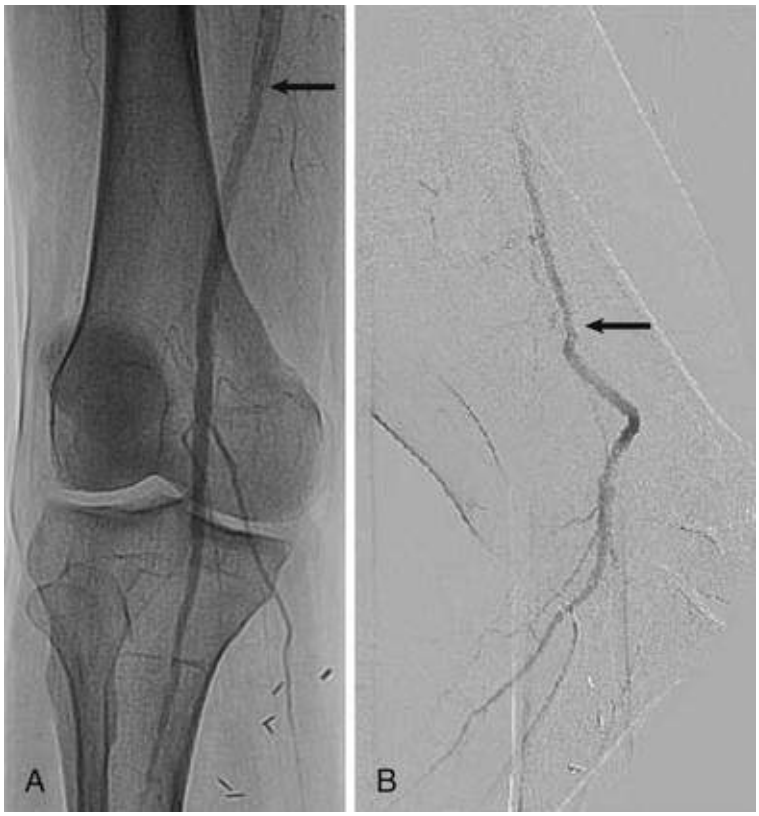

FIGURE 66.16 The popliteal artery is subject to torsion and kinking on bending the knee. **A,** Popliteal angiogram in the anteroposterior view with the knee straight. **B,** Popliteal artery showing increased tortuosity in a rotated view with the knee flexed to 90 degrees. The *arrows* indicate the distal margin of a superficial femoral self-expanding stent.

Acute procedural success rates with catheter-based interventions now approach 90%, in part because of a wide variety of wires, crossing catheters, and reentry catheters for total occlusions. Restenosis rates are higher than in the iliac artery and may require repeated interventions. Catheter-based therapies should be considered part of a long-term strategy of surveillance for recurrent and new disease and repeated interventions when needed.[44-46] Balloon angioplasty alone has durability similar to that of primary stenting for short lesions (<50 to 100 mm in length),[3,8,17] and in this setting, provisional stenting for abrupt closure, flow-limiting dissection, or poor expansion (residual stenosis >30% to 50%) is an acceptable strategy. For longer lesions (>100 mm), primary stenting with self-expanding nitinol stents offer better durability and walking function than balloon angioplasty with provisional stenting[3,8,17] (**Fig. 66.17; see also Fig. 66.4**) (see Videos 66.1 through 66.10). Drug-eluting nitinol self-expanding stents offer less restenosis than does balloon angioplasty with and without provisional stenting with nitinol BMSs.[22] Further studies with longer drug-eluting nitinol stents and comparisons to routine bare-metal stenting with or without drug-coated balloons will determine their value.

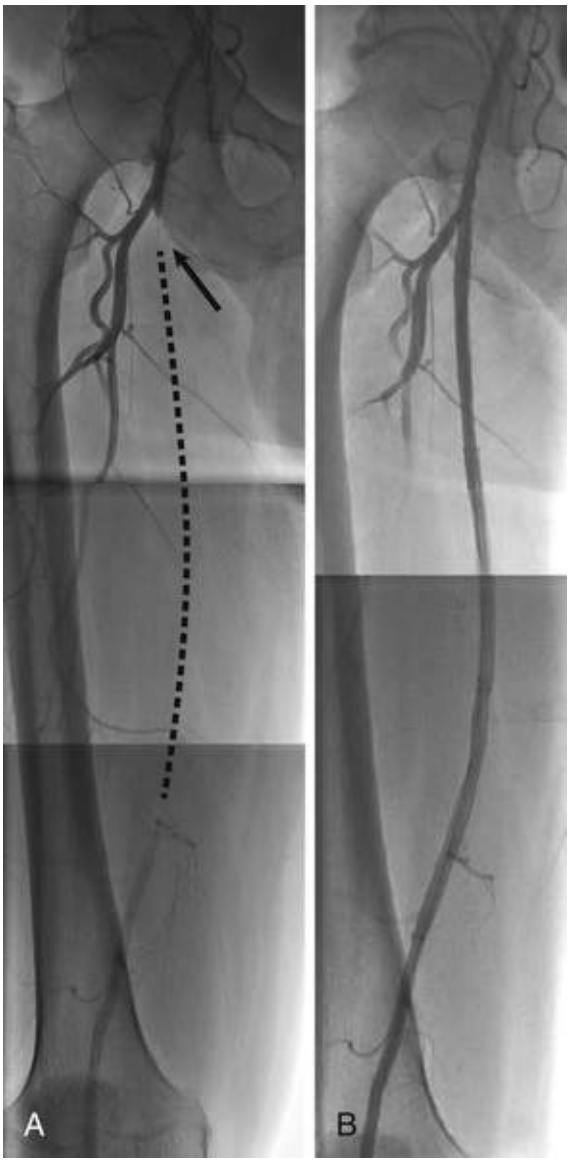

FIGURE 66.17 Composite angiograms showing a long occlusion of the right superficial femoral artery (*arrow* and *dashed line* in **A**). **B,** Three nitinol self-expanding stents were deployed in the superficial femoral artery to restore flow in this artery.

Atherectomy (directional, rotational, or laser), cutting balloons, and cryotherapy offer little routine advantage despite their theoretical value.[3,5,18,40] However, atherectomy may permit greater luminal expansion with balloons and stents in calcified disease. Emboli occur in some cases with atherectomy, and many operators recommend embolic protection devices, but without evidence from randomized controlled trials (RCTs). There are no randomized direct comparisons of adjunctive techniques to balloon angioplasty or stenting in the femoral artery, but based on the evidence available and extrapolation from the coronary experience, their routine use does not reduce long-term risks for restenosis. Drug-eluting balloons offer lower restenosis rates than balloon angioplasty[27-29,31,47] and may provide a durable result with or without atherectomy in regions where stents should be avoided, such as over joints. Interventionalists need to establish systems to monitor patients for recurrent or new disease and treat atherosclerosis risk factors intensively. Collaboration with surgical colleagues and vascular medicine specialists should improve outcomes.

Tibial Disease

The popliteal artery divides into three tibial arteries: the anterior tibial, which becomes the dorsalis pedis in the foot; the posterior tibial, which forms the pedal arcade with the anterior tibial artery; and the

peroneal artery, which usually ends just above the ankle but can be an important collateral to the foot. In general, claudication is rare with loss of even two of the three tibial arteries. Catheter-based interventions have high rates of restenosis, in part because of the small diameter and long lesion length, and are rarely justified in patients with claudication. Frequently, correction of obstructive proximal disease will resolve the claudication even with extensive residual tibial disease.

In contrast, treating severe tibial disease in patients with CLI can promote wound healing, resolve pain at rest, and prevent major amputation (**Fig. 66.18**). Vascular access is more limited for distal tibial disease, because a contralateral femoral approach or a brachial approach (**see Fig. 66.11**)[10] is often too distant for most equipment based on 130- to 150-mm shaft lengths. Antegrade CFA access can allow equipment to reach to foot if needed and often gives greater pushability to drive through long occlusions. The retrograde pedal approach (**see Fig. 66.11**)[10] uses noninvasive ultrasound and a micropuncture needle to access one of the tibial arteries at the foot or ankle. Access from above (e.g., antegrade CFA) allows a retrograde wire from the foot to be snared and exteriorized and provides a rigid rail for angioplasty balloons (**see Fig. 66.14**). A pedal access site may become a nonhealing ulcer if the intervention is unsuccessful, so this approach is often used as a last resort.[10]

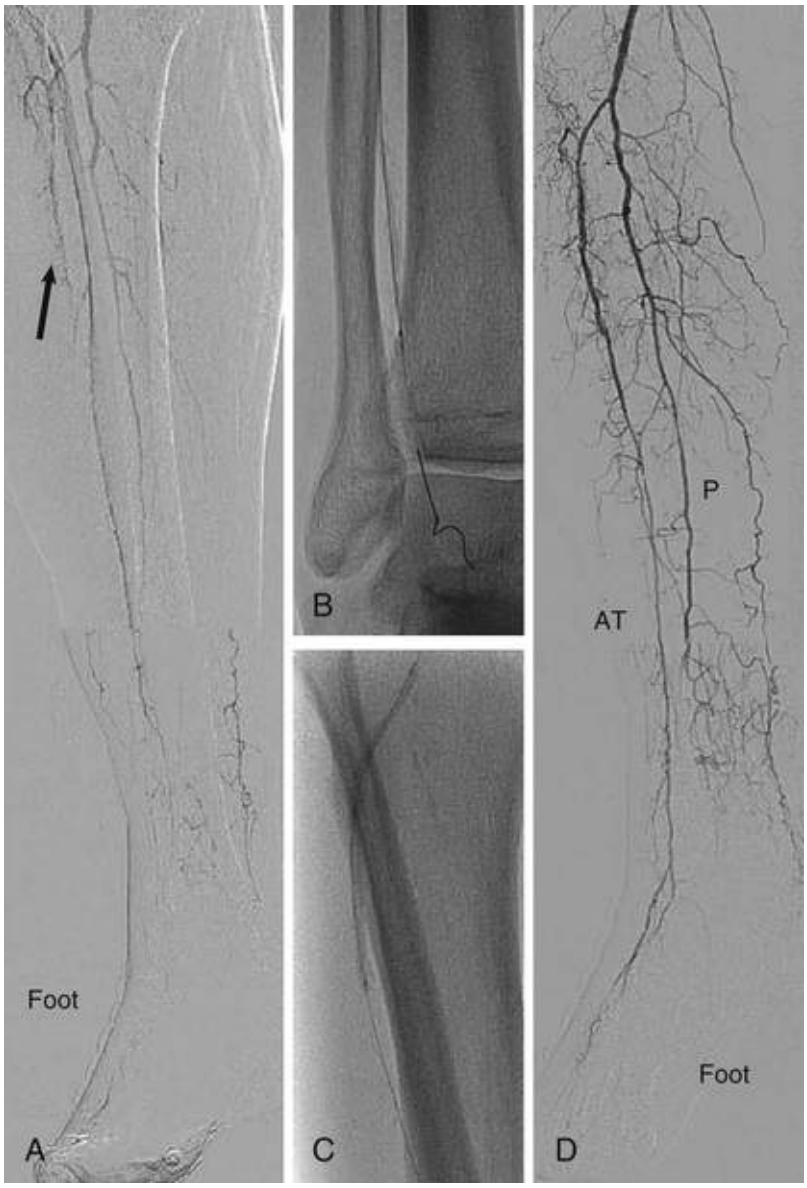

FIGURE 66.18 Revascularization of a totally occluded anterior tibial artery in a patient with a nonhealing ulcer on the right big toe. **A,** Proximal occlusion of the anterior tibial artery (*arrow*) with no flow into the foot. **B,** Wire traversing the anterior tibial artery at the ankle. **C,** Balloon angioplasty of the whole anterior tibial artery (the image shows a balloon at the proximal anterior tibial artery). **D,** Final angiogram. *AT,* Anterior tibial artery; *P,* peroneal artery.

Angiosome-directed revascularization refers to revascularization of a tibial artery that supplies the area of a nonhealing ulcer or gangrene (**Fig. 66.19**).[10] The value of angiosome-directed revascularization versus restoring any straight flow to the foot is debated. In observational studies, wound healing was better and amputation lower with angiosome-directed rather than indirect (nonangiosome) tibial revascularization.[48] These observations may be confounded, however, because indirect revascularization may be a marker for more complex tibial disease and poorer limb outcomes.[10] In one study, changes in foot microcirculation assessed by skin perfusion pressures improved to a similar degree in angiosome and nonangiosome tibial revascularization.[49]

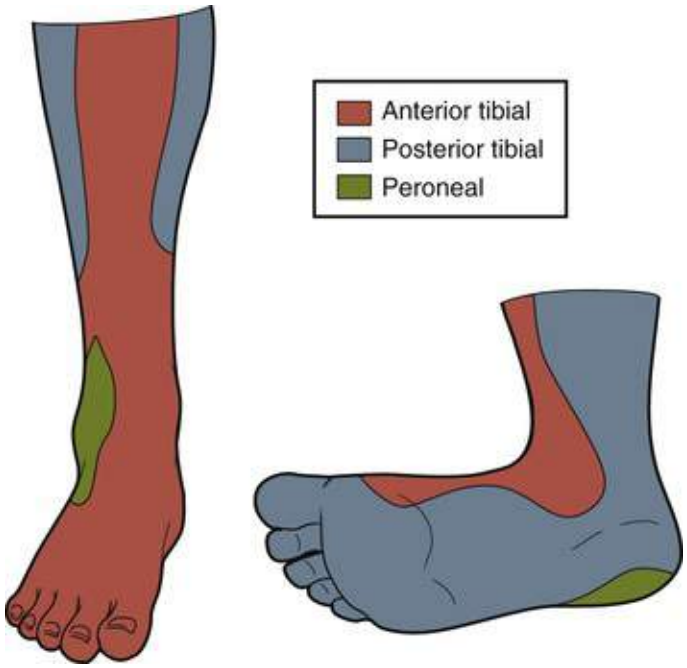

FIGURE 66.19 Angiosome distributions showing regions supplied by the three below-knee arteries. (From Kinlay S. Management of critical limb ischemia. Circ Cardiovasc Interv 2016;9:e001946.)

Tibial disease is most often treated by prolonged balloon inflation, but stents are used as bail-out treatment of flow-limiting dissection[10,18] (**Fig. 66.20; also see Fig. 66.14**). Although balloon-expandable coronary stents are used, they are prone to external compression. Randomized trials of coronary DESs offer greater patency and less reintervention for restenosis than BMSs,[50,51] plain balloon angioplasty,[52] or drug-coated balloon angioplasty.[53] Most of these studies do not show an effect on major amputation or survival, but they may be underpowered for these endpoints. As mentioned, newer drug-coated balloons are under development and testing for tibial interventions.

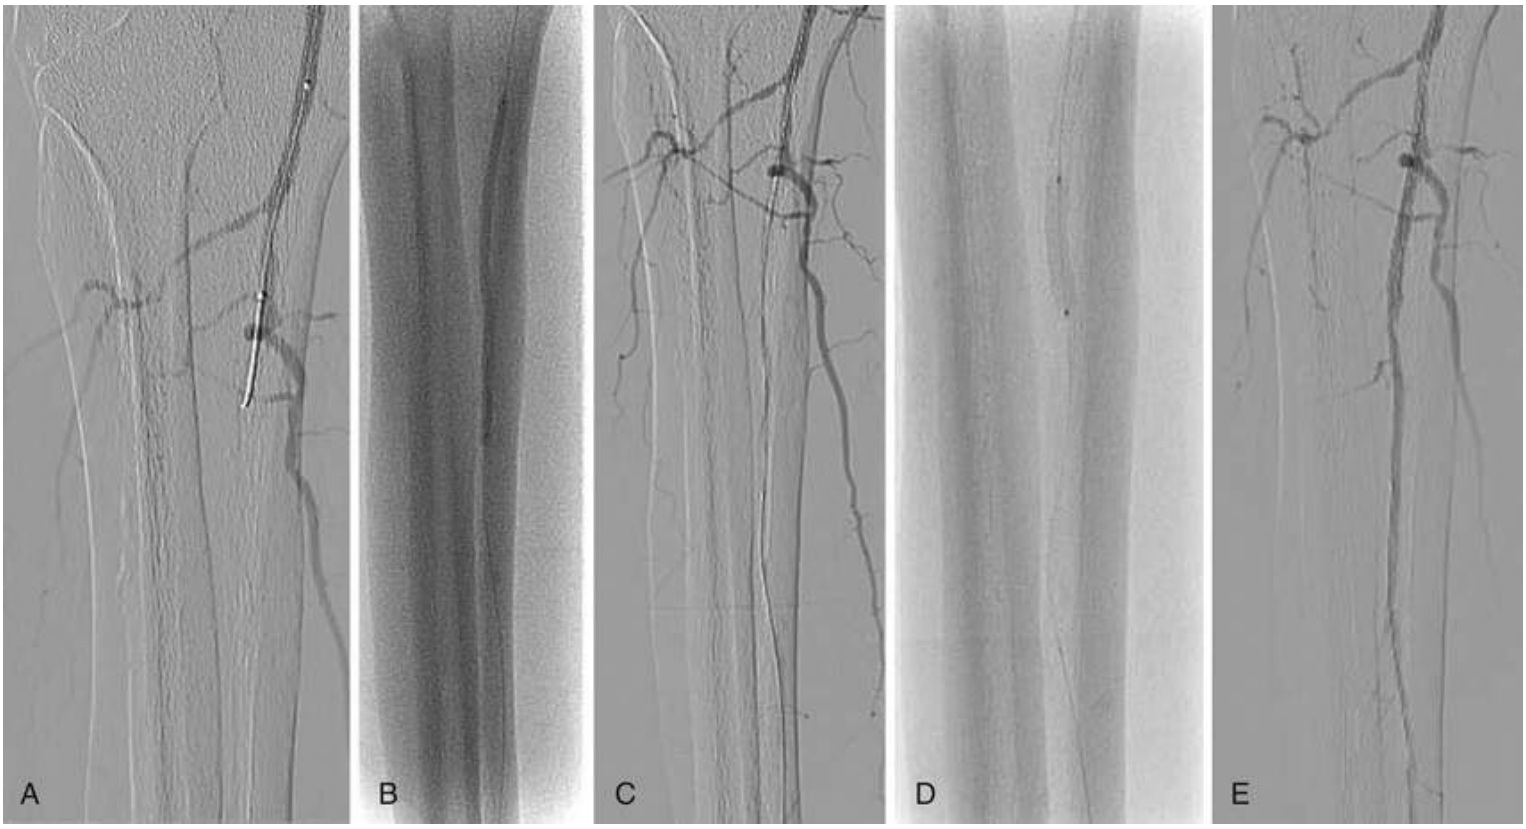

FIGURE 66.20 Bail-out stenting in patient with critical limb ischemia and gangrene of the toes. **A,** Wire traversing occluded peroneal artery. Anterior tibial and posterior tibial arteries were occluded. **B,** Balloon angioplasty of peroneal artery. **C,** Dissection and recoil of proximal peroneal artery. **D,** Stent deployment. **E,** Final angiogram of peroneal artery.

Multiple catheter-based interventions over several months may be required to heal an ulcer because restenosis slows healing. Once healed, however, restenosis may be less of an issue, given the use of adequate foot care and protection to prevent skin breakdown. Managing CLI with ulceration or gangrene requires close follow-up to débride dead tissue in ulcerated areas and aid healing. Gangrenous toes can be left dry until they mummify and autoamputate or can be surgically amputated once viable and devitalized tissue are clearly demarcated. Infected gangrene does require surgical amputation to avoid osteomyelitis. These complexities mandate a team approach to care that includes wound specialists, podiatrists, surgeons, and prosthesis specialists for optimum management.

Cervical Artery Disease

Extracranial Carotid Disease

Extracranial disease of the internal and common carotid artery is a potential source of artery-to-artery embolism, one of the causes of ischemic stroke (**see Chapter 65**). Over the last two decades, improvements in catheter-based techniques have enabled patients at increased risk for stroke from this cause to be treated with outcomes similar to those of traditional carotid endarterectomy.[11]

Symptoms are the most important factor related to the risk for disabling stroke and the indication for revascularization. “Symptomatic disease” refers to patients with a minor stroke or TIA. In the carotid circulation, symptoms are typically dysphasia, contralateral hemiparesis or hemiparesthesia, or ipsilateral transient monocular blindness (amaurosis fugax).[54] Symptoms lasting less than 24 hours and without infarction noted on imaging are classified as TIAs. Minor strokes are classified as “mild clinical deficits” or “no clinical residual deficits” with evidence of infarction on imaging.[54] The higher sensitivity of newer imaging techniques (e.g., diffusion-weighted MRI) compared with older technologies may have

increased the likelihood of finding small infarcts with no residual clinical deficits.[54]

The second factor related to stroke risk is the *severity of stenosis* of the extracranial internal carotid artery. For patients with recent symptoms and stenosis greater than 70%, the risk for stroke over the subsequent 5 years is up to 30%, with a risk of approximately 10% within the first 3 months.[5,11,54] After 3 months, however, the risk for stroke declines and approaches the risk in asymptomatic patients with a similar degree of stenosis (2% to 3% per year).[55]

Carotid endarterectomy and stenting both entail a small procedural/operative risk for stroke, and this limits their benefit to patients at low risk for perioperative events but at higher risk for stroke in the long term without revascularization (**Tables 66.1 and 66.2**). Based on trials of surgery versus medical therapy from 20 years ago, carotid endarterectomy is recommended for symptomatic patients with greater than 50% to 99% stenosis by invasive angiography or greater than 70% stenosis by noninvasive imaging and with a periprocedural risk for stroke and death of less than 6%.[5,11,54] For asymptomatic patients, indications include 80% to 99% stenosis in those with a periprocedural risk for stroke or death of less than 3%.[5,11]

TABLE 66.1

Factors Associated with Increased Risk for Complications with Carotid Artery Stent Placement

Tortuous aortic arch
Platelet or clotting disorder
Difficult vascular access
Lesion or heavy vessel calcification
Visible thrombus
Advanced age (>75-80 yr)*

*The risk for a cerebrovascular accident (stroke) with carotid artery stent placement is increased, and the risk for myocardial infarction with carotid endarterectomy is increased.

TABLE 66.2

Factors Associated with Increased Risk from Carotid Artery Surgery

Anatomic Criteria
High cervical or intrathoracic lesion
Previous neck surgery or radiation therapy
Contralateral carotid artery occlusion
Previous ipsilateral carotid endarterectomy
Contralateral laryngeal nerve palsy
Tracheostomy
Medical Comorbidities
Age >80 yr*
Class III or IV congestive heart failure
Class III or IV angina pectoris
Left main coronary disease
Two- or three-vessel coronary artery disease
Need for open heart surgery
Ejection fraction ≤30%
Recent myocardial infarction
Severe chronic obstructive lung disease

*The risk for a cerebrovascular accident (stroke) with carotid artery stent placement is increased, and the risk for myocardial infarction with carotid endarterectomy is increased.

Carotid stenting with embolic protection has evolved as a treatment that is equivalent to surgical carotid endarterectomy based on direct comparisons in randomized trials of patients with high and average risk for periprocedural CV events from surgery.[56-59] Long-term follow-up of randomized trials show no difference in outcomes over 5 to 10 years between surgical endarterectomy and carotid stenting

for symptomatic and asymptomatic patients with carotid disease.[56,57] Acceptably low periprocedural risk depends on adequate training of operators and selection of patients at low risk for complications.[5,55,60] Potential indications for carotid stenting are the same as those listed earlier for endarterectomy. As with endarterectomy, several factors determine the success of carotid stenting. Patient selection is very important in asymptomatic patients or those several months after symptoms, who have a lower absolute benefit from surgical endarterectomy or stenting than those with recent symptoms.[5,11]

In asymptomatic patients, the reduction in risk with revascularization accrues slowly over the long term and needs to offset the small but important periprocedural/operative risk. This benefit usually takes several years to accrue, and asymptomatic patients need to have reasonable 5-year survival for a realistic chance of achieving a net benefit from revascularization. Patients with a low risk for periprocedural stroke, MI, or death are also selected to maximize the net long-term benefit. For carotid stenting, this includes patients without severe vessel tortuosity, heavy calcification, or significant cognitive deficits.[55] Patients older than 80 years have a higher risk for perioperative adverse events with stenting or surgery. The primary outcome of the CREST study of patients at average surgical risk suggested no difference in outcomes at 2.5 years[61] or 10 years with stenting versus surgery.[57]

Carotid stenting starts with access to the common carotid artery with a diagnostic catheter and then a delivery sheath. Embolic protection consists of distal protection using filters or obstructive balloons deployed distal to the carotid stenosis or proximal occlusion devices deployed proximal to the stenosis. Filters allow blood flow to the brain to continue and theoretically lead to less brain ischemia if the circle of Willis is incomplete. Self-expanding stents using delivery systems on a 0.014-inch platform can avoid external compression (**Figs. 66.21 and 66.22**).

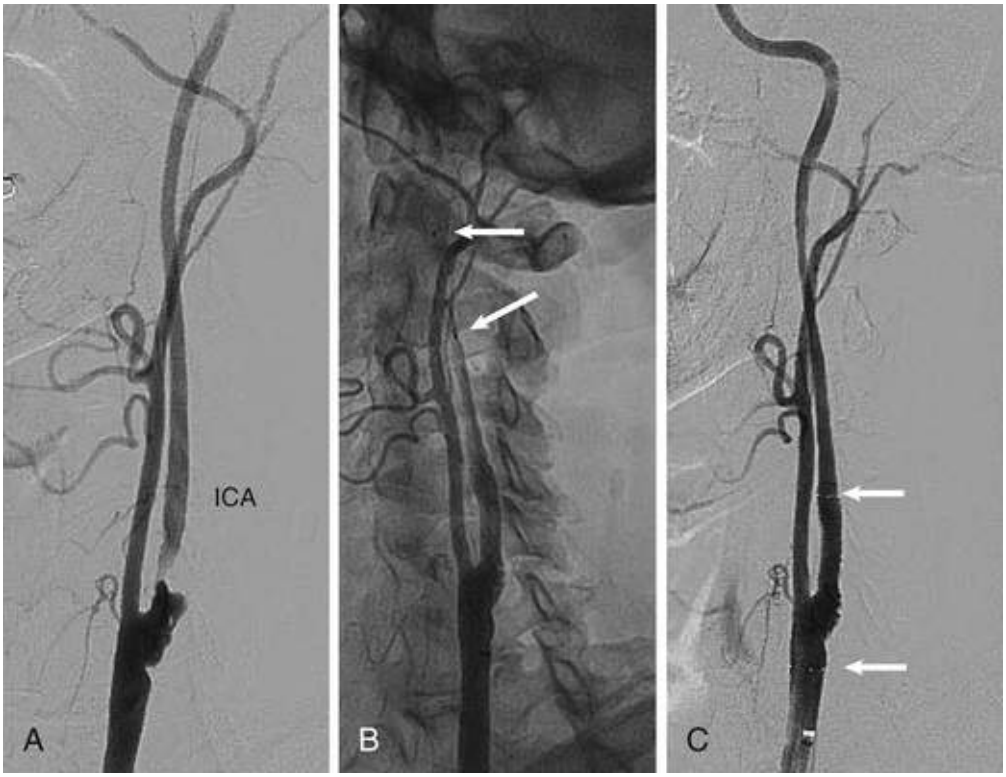

FIGURE 66.21 Carotid stenting for symptomatic carotid stenosis. **A,** Stenosis at origin of left internal carotid artery. **B,** Stent deployed. *Arrows* indicate markers of embolic protection filter. **C,** Final angiogram with *arrows* indicating the margins of the stent.

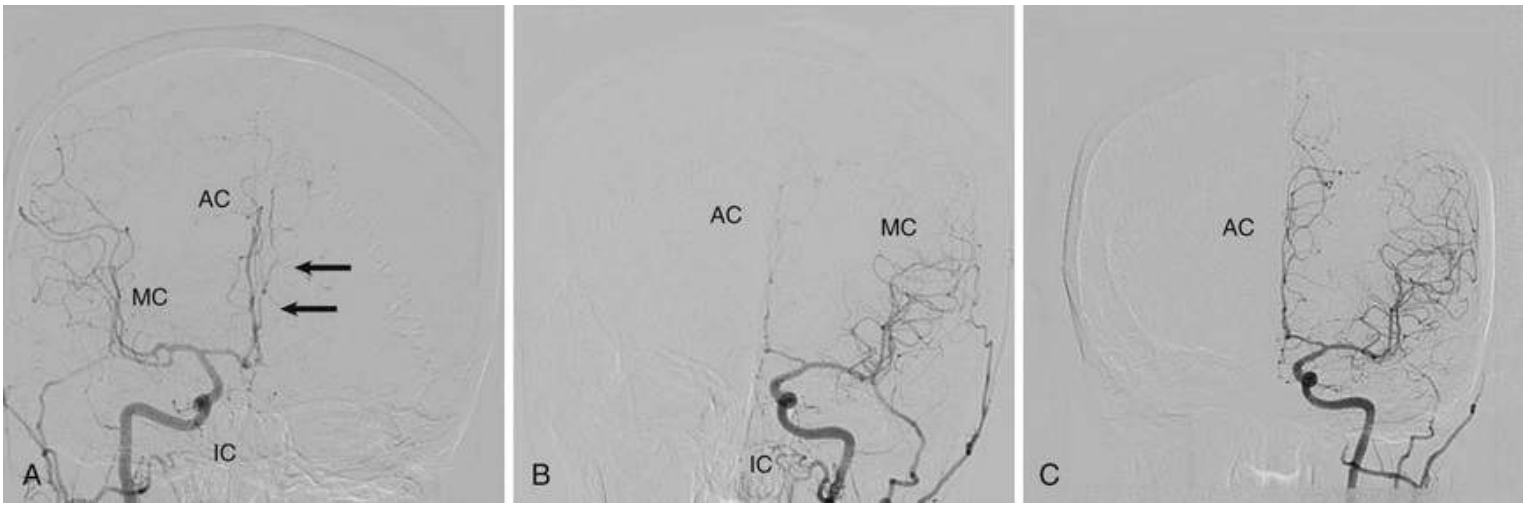

FIGURE 66.22 Intracranial angiograms from the patient in Fig. 66.21. **A,** Right carotid angiogram showing the right internal carotid artery (*IC*), middle cerebral artery (*MC*), and anterior cerebral artery (*AC*). There is crossover filling through the anterior communicating artery into the left anterior cerebral artery because of poor left-sided perfusion from the left cervical internal carotid stenosis. **B,** Left carotid angiogram showing poor filling of the left AC relative to the MC. **C,** Improved perfusion of the left AC after stenting the left internal carotid artery.

Vertebral and Subclavian Disease

The left and right vertebral arteries usually arise from the left and right subclavian arteries, course through the upper vertebrae into the posterior of the skull, and join together as the basilar artery. One vertebral artery is often larger (dominant) than the other, and loss of one such artery is usually well tolerated. Diagnosis of vertebrobasilar insufficiency is clinical with symptoms affecting the brainstem and cerebellum, including dizziness, ataxia, diplopia, and syncope.[5,54] Atherosclerosis usually affects the proximal vertebral arteries, but more extensive proximal disease in the subclavian or brachiocephalic arteries can cause vertebrobasilar insufficiency. Patients with vertebrobasilar insufficiency have a 5-year risk for stroke of approximately 30% without any treatment.

Medical treatment of vertebral artery disease includes antiplatelet agents and 3-hydroxy-3-methylglutaryl–coenzyme A (HMG-CoA) reductase inhibitors. Blood pressure (BP) control to reduce ischemic stroke requires careful titration to avoid hypotension and hypoperfusion, which can precipitate symptoms. Surgical therapy consisting of transection and reimplantation into an adjacent subclavian artery entails considerable morbidity, including Horner syndrome (2%), lymphocele (10% to 15%), chylothorax (<1%), and thrombosis (5% to 10%), as well as high mortality (5%). Extracranial percutaneous treatment, particularly with stenting, has much lower morbidity and short-term mortality, and long-term mortality resembles that of surgery (10% to 20% at 3 years), partly related to the high prevalence of other comorbid conditions.[62]

Subclavian stenosis more often affects the left subclavian origin than the brachiocephalic or right subclavian arteries. This predilection may result from more disturbed blood flow at the origin of the left subclavian artery. Subclavian stenosis usually causes a 15 mm Hg or greater difference in noninvasive brachial BP between the two arms,[5] in the absence of significant bilateral disease. Most subclavian stenosis, however, is asymptomatic and does not need investigation or revascularization. Symptoms from subclavian stenosis include arm claudication with activity, angina in patients with a left internal mammary/thoracic artery graft from previous coronary artery bypass surgery (**Fig. 66.23**), vertebrobasilar insufficiency with arm activity because of vertebral steal, or ischemic (hand) steal syndrome in patients with a dialysis fistula. Although noninvasive imaging can identify reverse flow in the vertebral artery

distal to a subclavian stenosis, this physiologic abnormality does not always lead to symptoms, particularly if it involves a nondominant vertebral artery or blood flow in the contralateral vertebral artery is not impeded. Thus, physiologic reversal of flow in the vertebral artery without symptoms is not an indication for revascularization.

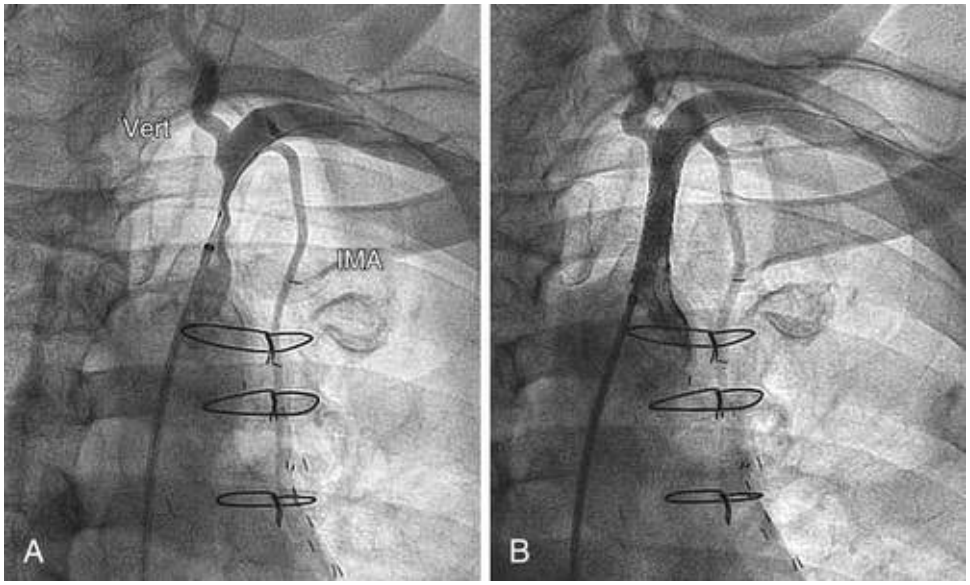

FIGURE 66.23 Stenting a left subclavian stenosis in a patient with angina and ischemia of the anterior left ventricular wall noted on stress testing. **A,** Shuttle sheath placed at the origin of the subclavian artery and stenosis. *IMA,* Internal mammary artery; *Vert,* vertebral artery. **B,** Stent deployed to improve blood flow to the IMA.

Medical therapy targets the progression of atherosclerosis (e.g., antiplatelet agents, HMG-CoA reductase inhibitors, BP control). Because most subclavian disease is proximal or ostial, surgical revascularization usually involves subclavian-to-common carotid bypass, a procedure associated with a 5% risk for morbidity, including stroke. This explains the more common use of percutaneous revascularization with stents to treat symptomatic subclavian disease. Balloon-expandable stents are generally used because they allow more precise placement to cover the ostium of the artery and avoid the vertebral and left internal mammary artery origins. In the event that these distal branches are covered by "snowplowing" of plaque into the branch vessel, balloon-expandable stents permit dilation through the stent struts into the branch vessel. Embolic stroke is rare, possibly because of reverse flow down the vertebral artery during balloon dilation and stenting. Thus, embolic protection is infrequently used for vertebral and subclavian artery stenting. The long-term results of stenting subclavian and brachiocephalic disease are excellent (>90% overall patency).[5]

Mesenteric and Renal Artery Disease

Mesenteric Artery

Three arteries supply the mesenteric viscera: the celiac artery, superior mesenteric artery, and inferior mesenteric artery. Although advanced atherosclerosis of the aorta is common, mesenteric angina or infarction is very uncommon, probably because of the multiple collateral networks in the mesentery. Acute mesenteric ischemia with infarction is a surgical emergency because it is usually associated with infarction of the small or large intestine.[12] An embolus (e.g., from thrombus in the heart associated with atrial fibrillation) is a common cause and typically lodges in the proximal mesenteric artery (usually the

superior mesenteric artery). Urgent surgery within 24 hours is required to resect dead bowel and revascularize ischemic bowel, with death in virtually all cases treated beyond this time.

Chronic mesenteric ischemia is a more insidious syndrome that causes discomfort or frank abdominal pain on eating and substantial weight loss because of food avoidance.[12] Classically, more than two mesenteric arteries are stenosed or occluded. The disease is usually adjacent and involves advanced atherosclerosis of the aorta and origins of the mesenteric arteries. Asymptomatic disease of the mesenteric arteries does not require revascularization.

Bowel endoscopy can detect changes associated with ischemia, but noninvasive arterial imaging with duplex ultrasound or MRA or CTA generally identifies the extent of disease. Invasive angiography usually requires a lateral aortogram to identify clearly the origins of the mesenteric arteries. Surgical revascularization with reimplantation of the arteries has high mortality and morbidity (10% to 15%) because of the advanced age and other vascular comorbid conditions. Percutaneous angioplasty with stenting has lower mortality (<5%) and morbidity and achieves good resolution of symptoms in about 70% to 80% of patients over several years (**Fig. 66.24**).[12] Restenosis may require further intervention and can be identified by duplex ultrasound and CTA or MRA.

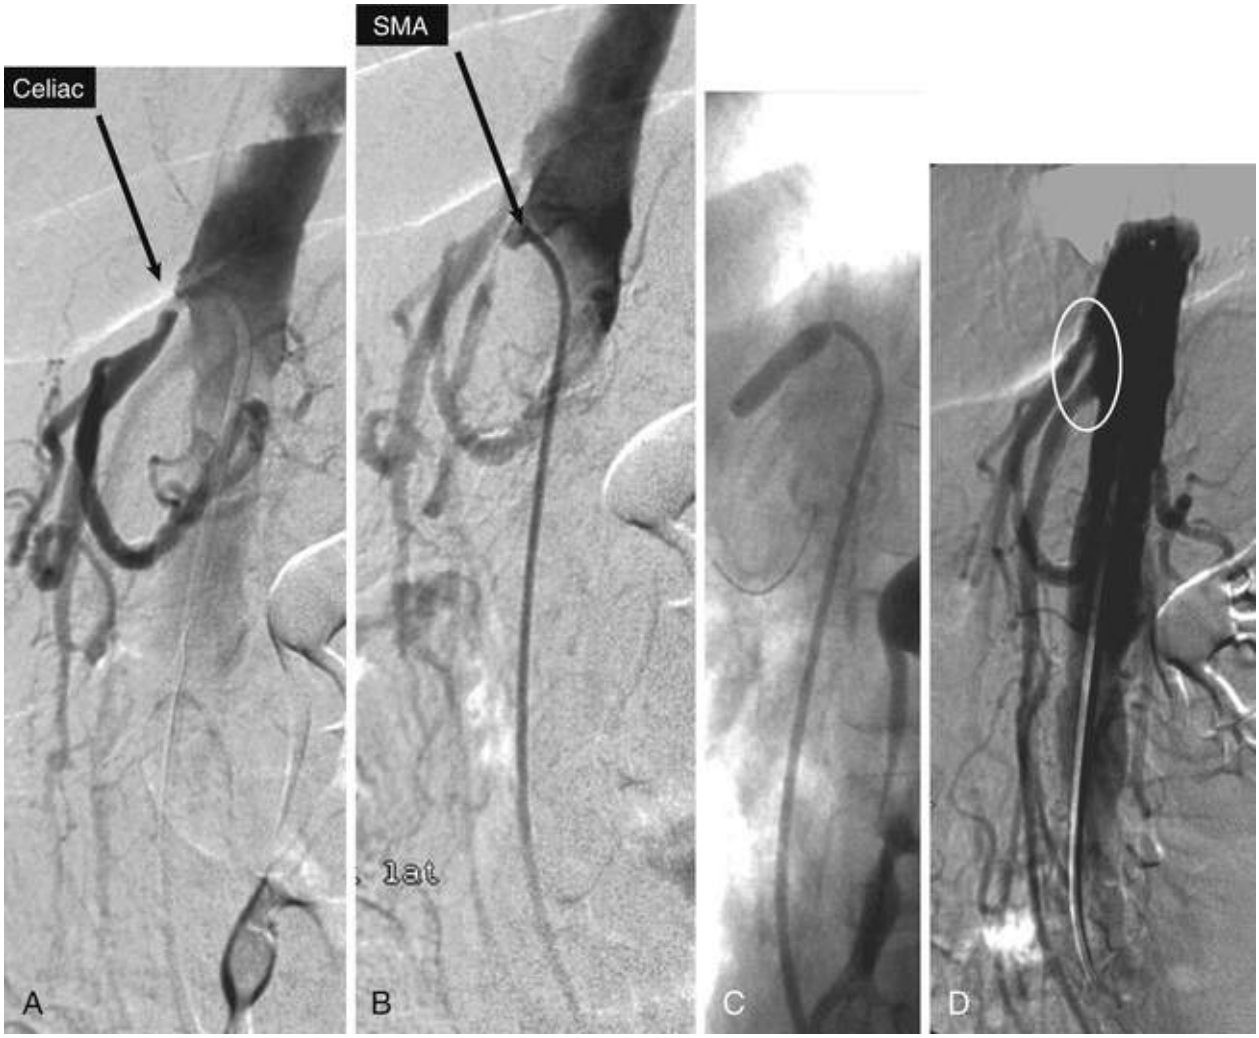

FIGURE 66.24 Mesenteric stenosis. **A, B,** Both these vessels proved to be critically stenosed. *SMA,* Superior mesenteric artery. **C,** The celiac artery and SMA were treated interventionally to restore wide patency in both, as outlined in **D.** The patient's symptoms abated, and she began to gain weight.

Renal Artery

Renal artery stenosis can cause secondary hypertension or rapidly deteriorating renal function. Clinical clues to the diagnosis of renal artery stenosis include onset of hypertension before 55 years of age, resistant or malignant hypertension (particularly in a previously well-controlled patient), rapidly increasing creatinine level over a several-month period or earlier, and sudden pulmonary edema without a clear cardiac cause (e.g., because of sudden hypertension with or without acute mitral regurgitation). Imaging with duplex ultrasound or with MRA, CTA, or invasive angiography can identify renal artery stenosis.

Although renal artery stenosis is relatively common, determining whether it is a reversible cause of hypertension or declining renal function is difficult. Screening outside the aforementioned clinical scenarios probably offers low yield and justification because treatment does not usually impact BP control or renal function.[63,64] Although some patients with renal impairment and significant stenosis may have improved renal function with stenting, approximately one third of patients see no improvement, and in another 20% to 30% of patients, renal function worsens, possibly because of atheroembolization. Even though many operators use embolic protection devices during renal stenting, these devices have unknown value in preventing atheroemboli or worsening renal function.

Three randomized trials of stenting renal arteries with greater than 40% to 60% stenosis by angiography to control resistant hypertension or preserve renal function showed no effect on BP control, preservation of renal function, or CV events.[63,65] In the CORAL study, even the subgroup of participants with a renal artery stenosis of at least 80% did not benefit from renal artery stenting.[65] As a result, the enthusiasm for renal artery stenting has waned considerably, although there is still some support for stenting renal artery stenosis in the presence of “flash” pulmonary edema without cardiac causes, rapidly decreasing renal function, and some cases of accelerating or resistant hypertension, based mainly on case reports and case series (**Fig. 66.25**).[66] In particular, there may still be value for stenting in bilateral renal artery stenosis and unilateral stenosis to a sole remaining kidney.

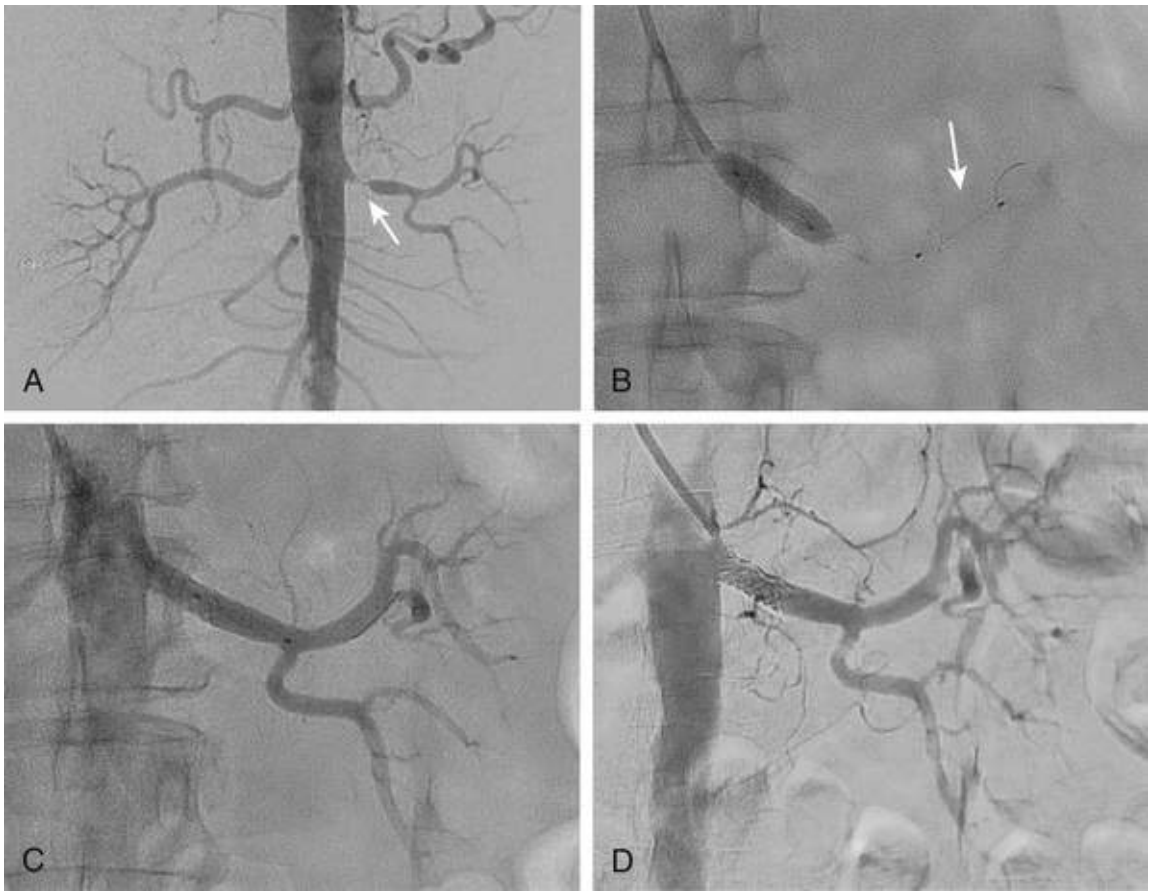

FIGURE 66.25 Left renal artery stent for rapid deterioration in renal function associated with hypertension. **A,** Aortogram showing left renal artery stenosis (*arrow*) with delayed filling of the left kidney compared to the right kidney. **B,** Stent deployment with some overhang into the aorta using an embolic protection filter (*arrow*). **C,** Post-stent deployment angiogram. **D,** Final angiogram after removal of filter.

Fibromuscular dysplasia (FMD) is a rarer cause of renal artery stenosis and hypertension more often seen in younger patients, with a higher prevalence in women.[67] Although defined histologically in the past, a recent classification based on imaging (multifocal "beading" versus unifocal) disease has some prognostic value.[68] FMD typically involves the middle or distal renal artery, whereas atherosclerosis usually involves the ostium or proximal renal artery. FMD often accompanies similar disease in other arterial beds (e.g., carotid arteries).[67] This diagnosis has particular importance in that balloon angioplasty without stenting often very effectively controls BP with a durable response.

Resistant hypertension despite multiple antihypertensive agents is a marker of elevated CV risk.[69] Recognition that the rich plexus of sympathetic nerves in the adventitia of renal arteries may contribute to resistant hypertension led to a number of catheter-based technologies to ablate the sympathetic nerves to lower BP and CV risk (**see Chapters 46 and 47**.) Although early uncontrolled studies suggested marked BP lowering in selected patients, the large sham-controlled SYMPLICITY HTN-3 trial showed no significant effect of renal artery denervation on BP or CV events.[70]

Endovascular Treatment of Venous Disease

Extremity Deep Venous Thrombosis

Upper and lower extremity deep venous thrombosis (DVT) results from multiple factors often encompassed in the Virchow triad: abnormalities in coagulation, hemodynamic flow, and endothelial injury (**see Chapter 84**). Such factors include hypercoagulable states, venous stasis, external obstruction, scarring or congenital abnormalities of veins, or injury to veins.

Lower extremity DVT is treated primarily medically with anticoagulation, but endovascular treatment is an option for patients with proximal venous thrombosis defined as being at the level of the common femoral vein or higher. Thrombosis at this site occurs in about one third of all cases of lower extremity DVT[38] and obstructs venous return from the lower limb. Proximal DVT occurs more frequently in the left leg as a result of compression of the left iliac vein by the overlying right iliac artery (May-Thurner syndrome). Acute severe proximal deep venous occlusion, characterized by a blue limb, pain, and limb ischemia (phlegmasia cerulea dolens) is often associated with malignancy. Chronic post-thrombotic syndrome occurs over several years in about half the patients with iliofemoral DVT[37] and involves limb swelling, heaviness, and pain. Medical treatment includes compression stockings and anticoagulation. Endovascular treatment of proximal DVT by catheter-directed thrombolysis with or without balloon angioplasty and self-expanding stents reduces the incidence of post-thrombotic syndrome by about 20%[37] (**Fig. 66.26**).

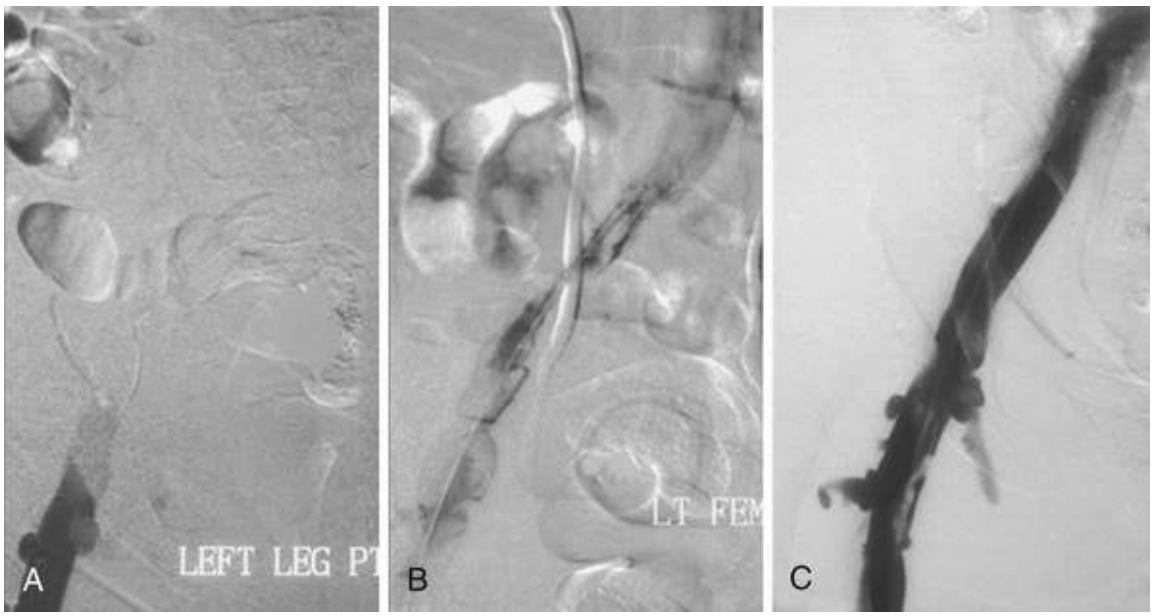

FIGURE 66.26 Venogram and intervention. A venogram of the left femoral vein was obtained after gaining access to the popliteal vein under ultrasound guidance. The patient is lying face down on the table to allow access to the popliteal vein. **A,** Baseline showing occlusion of the left femoral vein. **B,** Multihole catheter across the venous occlusion; administration of lytic agents is started. **C,** Four hours after lysis following percutaneous transluminal angioplasty and placement of a self-expanding stent to restore patency.

Upper extremity DVT is related to effort-related proximal vein thrombosis in athletes (Paget-Schroetter syndrome), venous thoracic outlet syndrome, catheter-related thrombosis, or malignancy.[71] Effort-related thrombosis is usually associated with vigorous arm exercise (e.g., weightlifting). *Venous thoracic outlet syndrome* is related to compression of the subclavian vein as it exits the thoracic cage between the clavicle, first rib, costoclavicular ligament, and subclavian and anterior scalene muscles. Catheter-related thrombosis is associated with indwelling catheters, ports, and pacemaker or defibrillator leads. Malignancy with external obstruction is more frequently associated with superior vena cava syndrome (see next). Anticoagulation is the most common treatment of upper extremity DVT, but endovascular therapy can provide relief from post-thrombotic syndrome. Endovascular therapy includes catheter-directed thrombolysis and treatment of any precipitating cause. For example, thoracic outlet syndrome generally requires surgical decompression (resection of the first rib or other structures) and venoplasty soon after thrombolysis because stents usually crush or fracture in this location. Central venous catheters

should be removed if they are no longer required, or the patient should be maintained on a long-term anticoagulation regimen.

Superior Vena Cava Syndrome

Superior vena cava syndrome results from obstruction of the superior vena cava with impairment of venous return from the head and upper limbs (**see Chapters 81 and 84**). Typical causes include external compression, invasion from a tumor, or thrombosis related to an indwelling central catheter (e.g., for chemotherapy) or leads from pacemakers or defibrillators. Symptoms include swelling and fullness in the head, headache, dyspnea, and a sense of choking. Angioplasty alone rarely relieves this condition successfully because of vessel recoil, but stenting very effectively reduces symptoms. Thrombosis often accompanies stenosis and requires catheter-directed thrombolytic therapy before balloon and stent therapy (**Fig. 66.27**). The stent usually needs to be oversized and extended well above and partly below the lesion so that it remains anchored and less likely to embolize. Anticoagulation is generally prescribed, often indefinitely for superior vena cava obstruction or thrombosis associated with malignancy. Symptoms usually respond rapidly within 24 hours. Ideally, indwelling catheters and pacemaker leads should be removed before stenting and reimplanted afterward if required. Long-term outcomes depend more on the cause of the superior vena cava obstruction, but in nonmalignant cases, high patency rates (>80%) over several years prevail.[72,73]

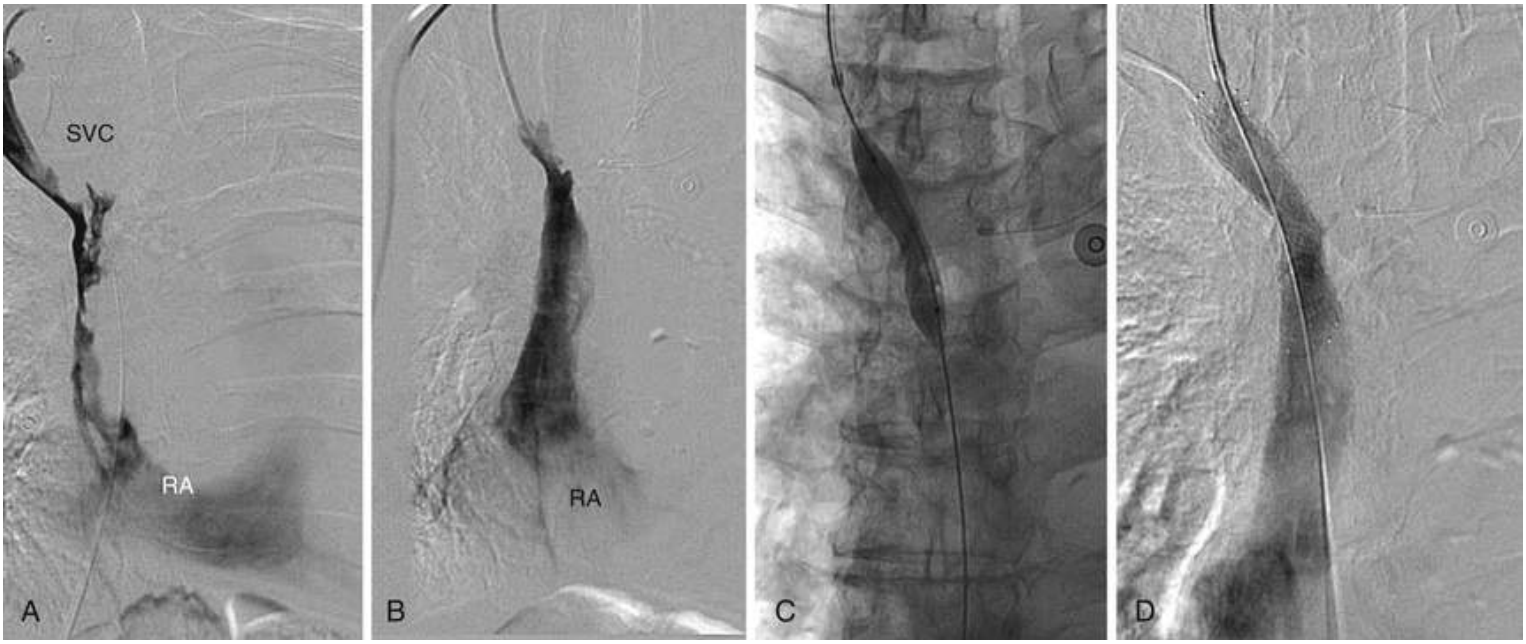

FIGURE 66.27 Superior vena cava syndrome secondary to external compression of the SVC by a lung tumor and thrombosis of the SVC. **A,** Initial venogram showing compression of the superior vena cava (*SVC*) and filling defects because of thrombus; *RA,* right atrium. **B,** Venogram after 24 hours of catheter-directed thrombolysis with resolution of the thrombus but residual stenosis. **C,** Balloon venoplasty. **D,** Final angiogram after deployment of a self-expanding stent.

Future Perspectives

New technologies have advanced endovascular treatment of noncoronary vascular disease into the mainstream. In many cases, adapting techniques from interventional cardiology has revolutionized the

ability to treat patients with complex peripheral vascular disease through minimally invasive endovascular means. In coming years, an even greater proportion of peripheral vascular disease may be treated in the angiography suite instead of in the operating room.

PART VIII
Diseases of the Heart Valves

OUTLINE

67

Approach to the Patient with Valvular Heart Disease

Catherine M. Otto, Robert O. Bonow

Over the lifetime of a patient with valvular heart disease (VHD), the most important aspects of medical care are

1. An accurate diagnosis of the cause and severity of VHD
2. Measures to prevent further valve dysfunction through prevention of rheumatic fever and endocarditis
3. Education about the natural history of disease, including anticipated type and timing of symptom

onset
4. Primary and secondary prevention of atherosclerotic cardiovascular disease (CVD)
5. Interval medical evaluation and imaging to monitor disease progression
6. Prompt recognition and treatment of associated cardiac conditions, including atrial fibrillation (AF), hypertension, coronary artery disease (CAD), endocarditis, and aortic dilation
7. Optimal timing of surgical or transcatheter intervention to correct or ameliorate valve dysfunction.

Although much attention is focused on the timing and type of intervention, the other aspects of standard medical care in these patients likely have comparable or greater benefit in improving quality and length of life. As clinicians, we follow patients with VHD for many years before and after intervention; a surgical or transcatheter intervention is only one (although major) episode in each patient's medical journey. We also need to consider that most of our interventions leave the patient with a new disease: a prosthetic valve. Surgical and transcatheter interventions are transformative technologies that prevent premature death and disability, but patients still have VHD after intervention and continue to require medical therapy, as discussed in this chapter.

The Heart Valve Clinic

The clinical presentation, diagnosis, natural history, and optimal timing of interventions for patients with VHD depend on the specific valve lesion (**see Chapters 68 to 70**). However, many of the principles of patient evaluation and medical therapy are common to all VHD patients. Patients with VHD now are classified by disease stage as follows[1,2]:

Stage A: Patients at risk for development of VHD
Stage B: Asymptomatic patients with progressive VHD (mild to moderate severity)
Stage C: Asymptomatic patients with severe VHD with *either*
Normal right or left ventricular systolic function (stage C1) *or*
Decompensated ventricular function (stage C2)
Stage D: Symptomatic patients with severe VHD

Patients with significant VHD are best evaluated in a heart valve clinic, functioning as part of the heart valve team (**Fig. 67.1**), given the complexity of diagnosis and clinical decision making in these patients.[3,4] However, the initial diagnosis of VHD relies on detection by the primary care provider or general cardiologist. VHD patients may present with new cardiac symptoms, but often the diagnosis is made in asymptomatic patients based on the presence of a murmur on physical examination or findings on echocardiography requested for other reasons.

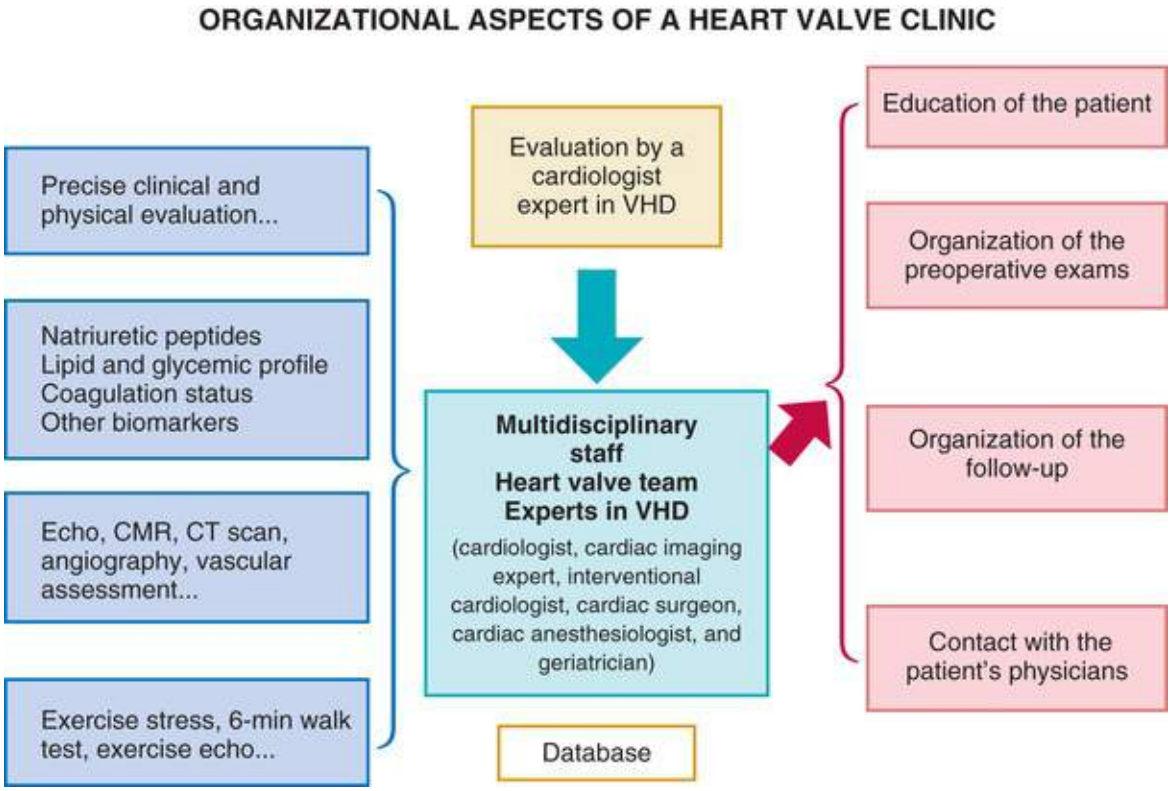

FIGURE 67.1 Functioning of the advanced heart valve clinic. CMR, Cardiac magnetic resonance imaging; CT, computed tomography; Echo, echocardiography; VHD, valvular heart disease. (From Lancellotti P, Rosenhek R, Pibarot P, et al: ESC Working Group on Valvular Heart Disease position paper. Heart valve clinics: organization, structure, and experiences. Eur Heart J 2013;34:1597.)

Clinical History

In a patient with suspected or known VHD, the clinical history is the most important element for diagnosis and clinical decision making (**see Chapter 10**). Patient demographics provide important clues about the likelihood and type of VHD based on the epidemiology of these conditions. For example, the asymptomatic young man with a diastolic murmur most likely has a bicuspid aortic valve; the pregnant patient with heart failure (HF) who is from an area with endemic rheumatic heart disease most likely has rheumatic mitral stenosis (MS); a middle-aged man with a loud systolic murmur and decreased exercise tolerance likely has mitral valve prolapse (MVP); and the elderly man with a systolic murmur and HF likely has calcific aortic stenosis (AS).

Risk Factors.

Potential risks for VHD include genetic, clinical, and infectious factors. Although specific genetic causes have not yet been identified, a positive family history often is present in patients with a bicuspid aortic valve or MVP, as well as in patients with VHD secondary to a connective tissue disorder, such as Marfan syndrome. Clinical factors associated with calcific valve disease include older age, male gender, hypertension, hyperlipidemia, smoking, diabetes, and renal insufficiency.[5] Only approximately 50% of those with rheumatic valve disease are aware of having had rheumatic fever in the past, so rheumatic valve disease should be considered in any patient who has resided in an area with a high prevalence of rheumatic fever[6] (**see Chapter 74**).

Symptoms.

Symptoms caused by VHD include frank HF, angina, and syncope, although the initial symptoms typically

are subtler with decreased exercise tolerance, exertional dizziness, or dyspnea. Because VHD typically progresses slowly over many years with adaptive cardiac changes, patients may gradually reduce activities without recognizing that limitation is caused by a medical condition and thus may deny symptoms, even when exercise capacity is severely reduced. In contrast, acute valve regurgitation from endocarditis, chordal rupture, or aortic dissection presents acutely with cardiogenic shock, pulmonary edema, or HF.

Exercise Capacity.
Clinicians should specifically ask patients to compare their current level of physical activity to activity levels in the past, in order to detect decreased exercise capacity in the apparently "asymptomatic" patient.[7] With careful questioning and education of the patient about the expected symptoms of VHD, many patients then will realize that symptoms are present and will report this at the next follow-up visit. If in doubt about symptom status, exercise testing may be helpful (**see Chapters 68 and 69**).

Other Considerations.
Clinical decision making in the VHD patients involves numerous factors other than the presence and severity of VHD. Thus the clinical history also should include comorbid cardiac and noncardiac conditions, functional status, cognitive function, family and social support, and a discussion of patient preferences and values.

Physical Examination

Physical examination is important in patients with known or suspected VHD (**see Chapter 10**). A cardiac murmur is a defining characteristic of VHD and the most common reason for making the initial diagnosis. In addition, discrepancies between physical examination findings and diagnostic testing may prompt additional evaluation. However, reliability of physical examination is low for determining the exact cause and severity of VHD. Thus, although it is an intellectual challenge to listen to the murmur, evaluate changes with maneuvers, and so on, the real value of physical examination is for monitoring the patient's general appearance; looking for signs of HF; evaluating frailty, physical activity levels, and cognitive function; and detecting findings to suggest a systemic disease process associated with VHD. In clinical practice the wide availability of echocardiography ensures that a correct diagnosis of valve anatomy and function is possible in every patient (**see Chapter 14**).

Cardiac Murmurs

The murmur characteristics, loudness, radiation, and associated findings provide useful clues about which valve is involved and whether the valve is stenotic or regurgitant. However, with a few exceptions, clinical studies have demonstrated that physical examination is unreliable for evaluation of the severity of VHD and remains unreliable even with higher levels of education and training. Thus, echocardiography is recommended for (1) any murmur associated with cardiac symptoms, (2) a grade 3 or louder systolic murmur, and (3) any diastolic murmur.

Murmur Location

The location on the chest wall where the murmur is loudest, the direction of radiation, the timing of the murmur and associated changes in the first and second heart sounds all are closely related to the anatomy and hemodynamics of the valve lesion (**Fig. 67.2**). Systolic murmurs are caused by stenosis of a semilunar

(aortic or pulmonic) valve or regurgitation of an atrioventricular (mitral or tricuspid) valve, with a differential diagnosis that includes other abnormal systolic cardiac flows (e.g., ventricular septal defect) (**Table 67.1**). Diastolic murmurs are caused by regurgitation of a semilunar (aortic or pulmonic) valve or stenosis of an atrioventricular (mitral or tricuspid) valve.

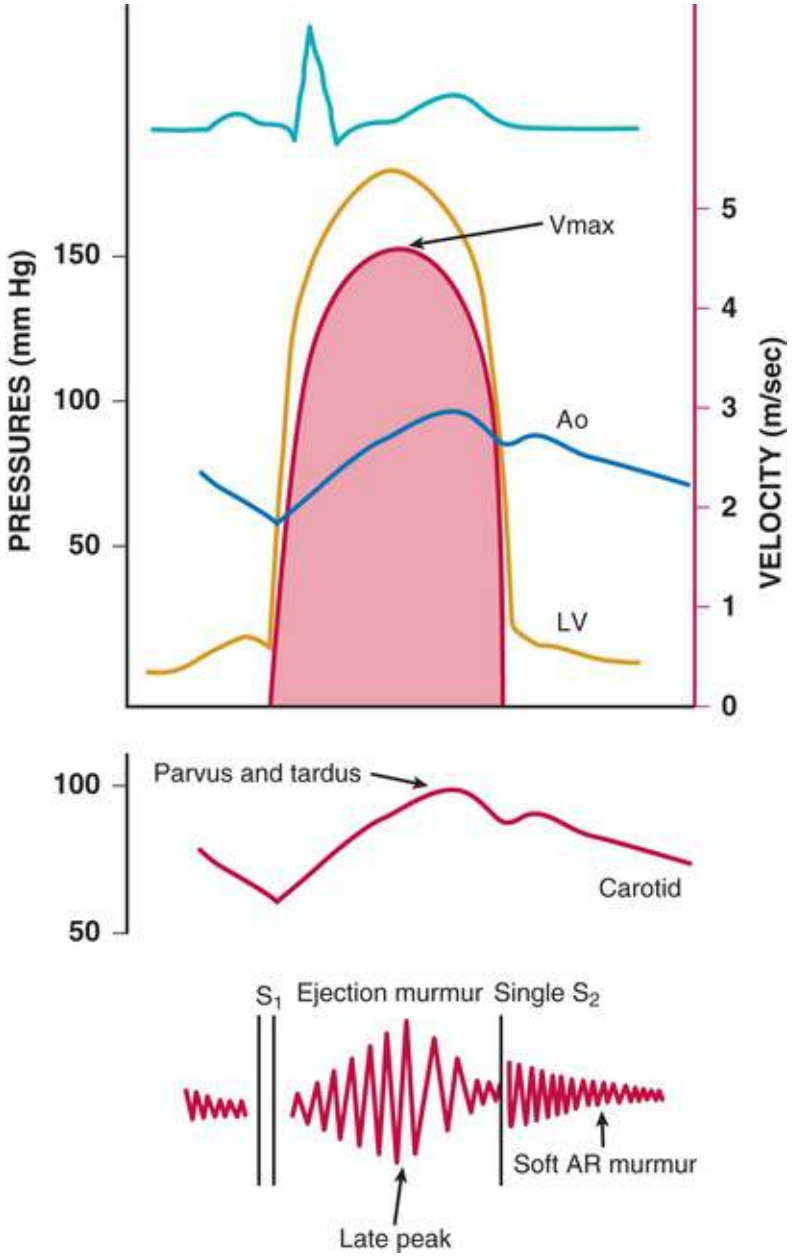

FIGURE 67.2 The close relationship among cardiac hemodynamics, Doppler flow velocities, and physical examination findings is evident in this diagram of the ECG (*top*), aortic (Ao) and left ventricular (LV) pressure tracings, aortic flow velocity (*red shaded area*), carotid pulse contour, and auscultatory findings (*bottom*) in valvular aortic stenosis. AR, Aortic regurgitation; Vmax, Maximum velocity.

TABLE 67.1

Physical Examination Characteristics of Murmurs Caused by Valve Disease

CONDITION	CHARACTERISTICS AND TIMING	LOCATION	RADIATION	EFFECTS OF MANEUVERS	ASSOCIATED FINDINGS	DIFFERENTIAL DIAGNOSIS
Innocent flow murmur	Soft midsystolic	Base	Variable or none	No change	None	A flow murmur is common during pregnancy and in patients with a high output state (e.g., fever, anemia).
Aortic stenosis (AS)	Crescendo-decrescendo systolic	Base (right second ICS)	Usually to carotid arteries but sometimes to apex in older adults	Decrease with handgrip or standing	Single S_2, delayed and decreased carotid upstroke, midsystolic click with congenital AS	HCM murmur peaks in late systole and increases with standing or strain phase of Valsalva maneuver.
Mitral regurgitation (MR)	Holosystolic	Apex	Radiation to back or axilla with posteriorly directed jet, to LSB or head with anteriorly directed jet	Increase with handgrip	Hyperdynamic apical impulse	Ventricular septal defect murmur usually loudest (with palpable thrill) at LSB and does not change with handgrip. Acute MR may have a very soft or inaudible murmur.
Tricuspid regurgitation (TR)	Holosystolic with respiratory variation	Left lower sternal border	Right lower sternal border	Increase with inspiration	Prominent v waves in JVP, pulsatile liver	—
Pulmonic stenosis (PS)	Crescendo-decrescendo systolic	Left second ICS	None	No change	Ejection click if mobile valve leaflets	A pulmonic flow murmur due to increased flow volume may be present with ASD in the absence of PS.
Aortic regurgitation (AR)	High-pitched diastolic decrescendo	Best heard at LSB with patient sitting up and leaning forward at end-expiration	None	Increase with handgrip	Wide pulse pressure, displaced and enlarged apical impulse	Acute AR murmur may be harsh and short in duration and the pulse pressure may be narrow with a normal size apical impulse.
Mitral stenosis (MS)	Low-pitched diastolic rumble, presystolic accentuation	Apex Murmur best heard with patient in steep left lateral position with stethoscope bell on apical impulse	None	Best heard in left lateral decubitus position	Loud S_1 with opening snap in early to middle diastole	—
Pulmonic regurgitation (PR)	Soft decrescendo diastolic	Left second ICS	LSB	May increase with inspiration	RV heave if severe PR has resulted in RV dilation	—
Tricuspid stenosis (TS)	Low-pitched diastolic rumble	Right sternal border	Right upper abdomen	Increase with inspiration	Increased JVP, peripheral edema, ascites	—

ASD, Atrial septal defect; *HCM,* hypertrophic cardiomyopathy; *ICS,* intercostal space; *JVP,* jugular venous pressure; *LSB,* left sternal border; *RV,* right ventricular.

Murmur Timing

The timing of onset and offset and the changing loudness of the murmur over the cardiac cycle reflect valve hemodynamics. A murmur of AS starts after the first heart sound (S_1), increases and then decreases in loudness with a peak in midsystole to late systole, and ends before the second heart sound (S_2). The visual analogy for this crescendo-decrescendo murmur is a diamond-shaped or ejection-type murmur. In contrast, the murmur of mitral regurgitation (MR) obscures S_1 and S_2 because backflow across the mitral valve starts sooner and ends later than flow across the aortic valve. An MR murmur typically is uniform in loudness from onset to offset, a pattern called *holosystolic.* In patients with MVP, the MR murmur may be only late systolic, and S_1 is clearly audible.

Murmur Loudness

Murmurs tend to be loudest over the anatomic location of the affected valve, for example, the upper right second intercostal space at the cardiac base for the aortic valve and the left ventricular (LV) apex for the

mitral valve. Right-sided, but not left-sided, valve lesions vary in loudness with respiration. In general, the loudness of a murmur correlates with severity; more severe AS is associated with a louder murmur in many patients, but this relationship is not a reliable indicator of disease severity. For example, a MR murmur may be loud with only mild valve leakage, and conversely, severe AS may be present with a soft murmur if cardiac output is low or sound transmission to the chest wall is poor.

Murmur Radiation

Murmurs can also be heard distal to the valve lesion, usually with a reduced loudness. The “radiation” of a murmur follows the blood flow direction: AS murmurs radiate to the carotid arteries; MR murmurs radiate to the axilla. However, there is wide variation in physical examination findings. The murmur of AS radiates to the apex in some, often elderly, patients (the Gallavardin phenomenon). The MR murmur may radiate to the back with a posteriorly directed MR jet or superiorly, if the jet is aimed in that direction.

Changes in First and Second Heart Sounds

The relationship of the murmur to S_1 and S_2 and the sounds themselves also provide information about the presence of valve disease. With AS, the aortic component of S_2 is reduced; an absent aortic closure sound is a relatively sensitive and specific finding in patients with severe AS. With MS, an opening snap precedes the diastolic murmur, with the interval between S_2 and the opening snap reflecting the severity of valve obstruction. Other valve lesions are associated with other changes (**see Table 67.1**).

Other Cardiac Findings

Examination of the neck veins is helpful for estimating right atrial filling pressure and for detection of abnormal venous pulsations, such as the *v* wave caused by tricuspid valve regurgitation, which can be associated with a lateral motion of the head with each heart beat in severe cases. The carotid artery impulse is bounding in patients with severe aortic regurgitation (AR) and may be associated with a rhythmic bobbing of the head in synchrony with the heart beat due to the increased pulse pressure (de Musset sign). A delayed onset of the carotid upstroke with a slow rate of rise in systole is specific for severe aortic valve obstruction. However, this finding is not sensitive for detection of AS because carotid pulsations may be brisk if there is concurrent increased vessel stiffness or AR, even when severe AS is present. Other standard components of the cardiovascular examination in patients with VHD include examination of the lungs, abdomen, and extremities.

Diagnostic Testing

Cardiac imaging is central to diagnosis and management of patients with VHD. Chest radiography is used for evaluation of acute decompensation but is not routinely used for diagnosis or monitoring. The 12-lead electrocardiogram (ECG) and various types of ambulatory monitoring are used for diagnosis and management of arrhythmias, as in any patient with heart disease, but ECG diagnosis of chamber hypertrophy or dilation largely has been replaced by direct imaging.[8]

Imaging

Echocardiography (See Chapter 14)

Echocardiography is the primary modality for diagnosis of the cause of VHD, severity of valve dysfunction, LV size and systolic function, and associated findings such as pulmonary hypertension and left atrial enlargement.[9] Standard echocardiographic approaches are appropriate for the initial diagnosis of VHD, but more precise evaluation and quantitation of valve disease require special expertise. Not all echocardiography laboratories or echocardiographers have the training and experience to perform these measurements reliably, and thus imaging is best performed at the heart valve center. Advanced imaging approaches, including three-dimensional imaging and strain rate imaging, as well as transesophageal echocardiography (TEE), have further expanded clinical indications for echocardiography. Echocardiography is essential both for optimal timing of surgical or transcatheter intervention (**see Chapter 72**), and for monitoring progressive disease (**Table 67.2**).

TABLE 67.2

Frequency of Echocardiograms in Asymptomatic Patients with Valvular Heart Disease and Normal Left Ventricular Function*

Stage	VALVE LESION			
	Aortic Stenosis†	Aortic Regurgitation	Mitral Stenosis	Mitral Regurgitation
Stage B (progressive)	Mild (V_{max} 2.0-2.9 m/sec) Every 3-5 yr	Mild Every 3-5 yr depending on valve and sinus anatomy	Mild (MVA >1.5 cm^2) Every 3-5 yr	Every 3-5 yr (mild severity)
	Moderate (V_{max} 3.0-3.9 m/sec) Every 1-2 yr	Moderate Every 1-2 yr	—	Every 1-2 yr (moderate severity)
Stage C (severe)	Every 6 mo to 1 yr (V_{max} ≥4 m/sec)	Every 6-12 mo More frequently if LV dilation present.	Every 1-2 yr (MVA 1.0-1.5 cm^2) Every 1 yr (MVA <1 cm^2)	Every 6-12 mo More frequently if LV dilation present.

*Patients with mixed-valve disease may require serial evaluations at intervals earlier than recommended for single-valve lesions.

†With normal stroke volume.

LV, Left ventricle; *MVA,* mitral valve area; V_{max}, maximum aortic jet velocity.

Modified from Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACC guideline for the management of patients with valvular heart disease: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2014;63:e57-185.

Cardiac Magnetic Resonance Imaging (See Chapter 17)

Cardiac magnetic resonance imaging (CMR) provides more accurate and reproducible measures of LV volumes and ejection fraction (EF), but few use this approach for prediction of outcomes in VHD patients. CMR also allows quantitation of AR and MR, which may be helpful if echocardiography is nondiagnostic or when the degree of LV dilation seems out of proportion to regurgitant severity. CMR is less helpful for evaluation of AS because maximum velocity may be underestimated. However, CMR evaluation of LV myocardial fibrosis provides insights into the disease process and may be clinically relevant in the future.

Computed Tomography (See Chapter 18)

Both CMR and computed tomography (CT) are useful in VHD patients who have associated aortic dilation. In patients with a bicuspid aortic valve, a baseline CMR or CT aortic study is recommended, unless the ascending aorta is well visualized on echocardiography, and is the primary modality for

following progressive aortic dilation in affected patients[1,10] (**see Chapters 63 and 68**). CT also has value for evaluating prosthetic valve dysfunction, allowing accurate visualization of mechanical leaflet occluder motion and detection of thrombus or pannus formation (**see Chapter 71**). CT also is useful in patients with endocarditis for visualizing the full extent of aortic or ventricular pseudoaneurysms and other complications. Combined positron emission tomography (PET) and CT have also been used in assessing the site of ongoing inflammatory changes in endocarditis (**see Chapters 16 and 73**).

Stress Testing

Stress testing is used in patients with VHD for several reasons[7,11] (**Table 67.3**):

TABLE 67.3

Primary Indications for Stress Testing in Valvular Heart Disease

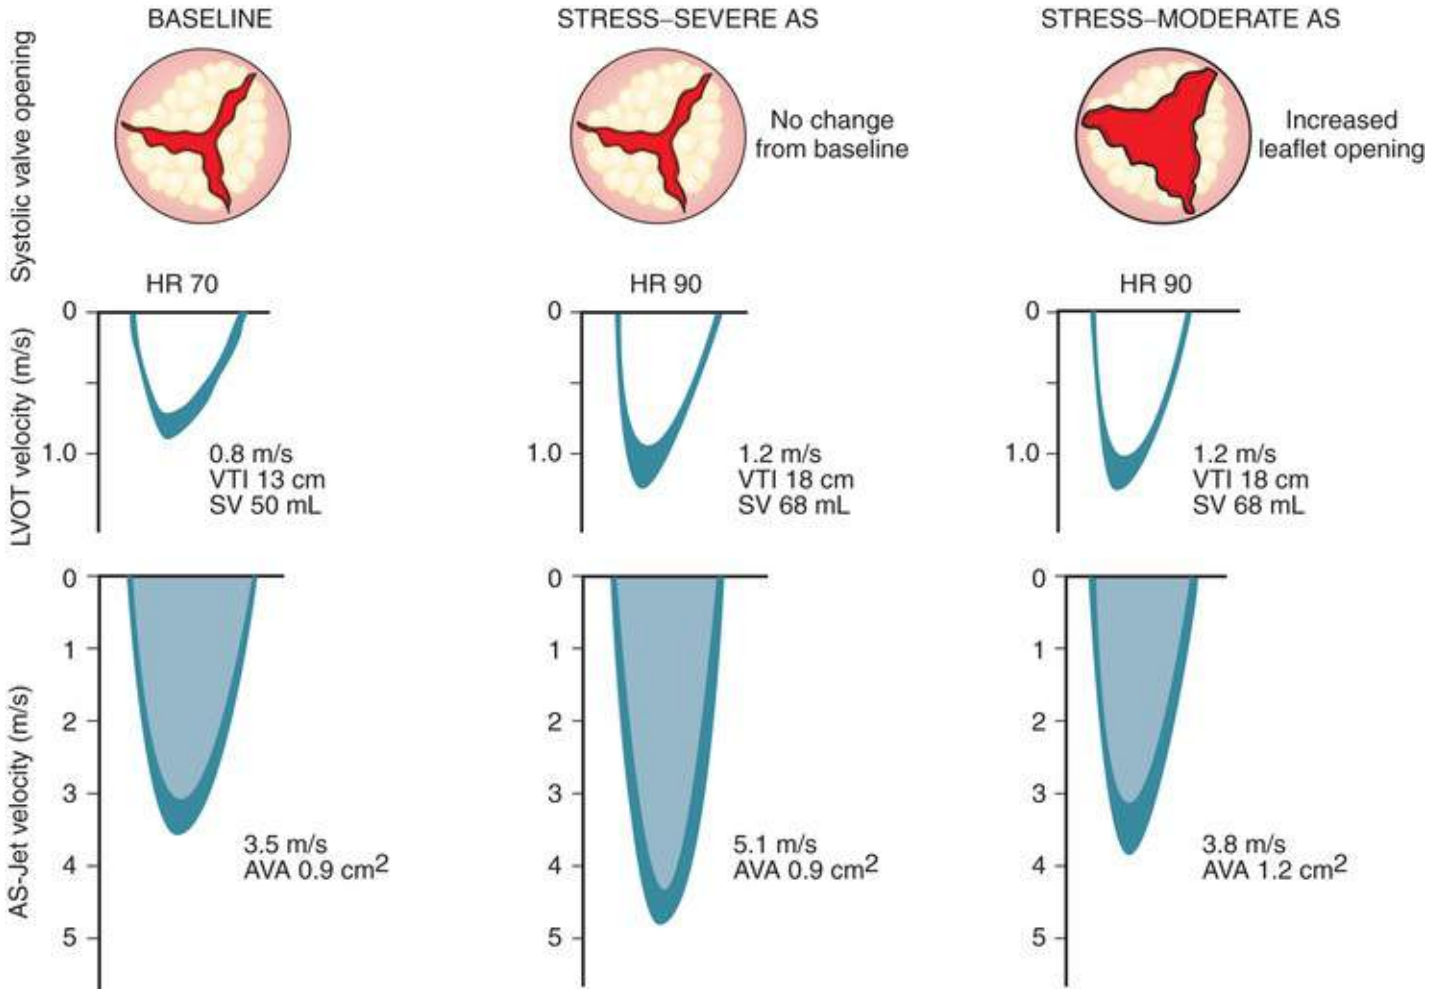
INDICATION	STRESS TYPE	ECHO DATA ACQUISITION	PARAMETERS USED IN CLINICAL DECISION MAKING	COMMENTS
Aortic stenosis (AS): symptom status	Exercise treadmill	Optional	Exercise duration Symptoms Blood pressure response	—
Low-output, low-gradient AS*	Low-dose dobutamine	Aortic jet velocity (CWD) LV outflow velocity (PDE) Ejection fraction (2D)	Severe AS is present if: V_{max} >4.0 m/sec or mean ΔP >40 mm Hg with AVA ≤1.0 cm^2 at any flow rate	Contractile reserve is defined as ↑ejection fraction or ↑transaortic stroke volume >20%
Mitral stenosis	Exercise treadmill or supine bicycle	TR jet velocity (CWD)	PA systolic pressure > 60 mm Hg with exercise	—
Mitral regurgitation	Exercise treadmill or supine bicycle	TR jet velocity (CWD)	PA systolic pressure > 60 mm Hg with exercise	—

*Defined as AVA <1.0 cm^2 with LV ejection fraction <40% and mean ΔP <30-40 mm Hg with stroke volume index 35 ml/m^2 or less.

2D, Two-dimensional imaging; *AVA,* aortic valve area; *CWD,* continuous-wave Doppler; *LV,* left ventricular; *ΔP,* pressure gradient; *PA,* pulmonary artery; *PDE,* pulsed Doppler echocardiography; *TR,* tricuspid regurgitation; *Vmax,* maximum aortic jet velocity.

Modified from Otto CM, Owens DS: Stress testing for structural heart disease. In Gillam LD, Otto CM, editors. Advanced Approaches in Echocardiography: Practical Echocardiography Series. Philadelphia: Saunders; 2012.

1. Treadmill exercise testing is used for evaluation of exercise capacity, blood pressure response, and symptoms when symptom status is unclear on the clinical history (**see Chapter 13**).
2. Low-dose dobutamine stress echocardiography is used for evaluation of AS severity when concurrent LV dysfunction is present (**eFig. 67.1; see Chapters 14 and 68**).
3. Bicycle or treadmill stress testing, with Doppler echocardiographic evaluation of pulmonary pressures, is used in patients with mitral valve disease and exertional symptoms despite only moderate disease at rest (**see Chapter 69**).



EFIGURE 67.1 Changes in aortic valve opening and Doppler flows with dobutamine stress echocardiography for low-output low-gradient aortic stenosis (AS). The baseline data show a hypothetical patient with an ejection fraction (EF) of 35% and limited aortic valve systolic opening, an aortic jet velocity (AS-jet) of 3.5 m/sec, and aortic valve area (AVA) of 0.9 cm^2. If true severe AS is present **(middle panel),** as EF increases from 35% to 45%, the transaortic flow rate increases but the aortic opening is fixed, resulting in a marked increase in aortic velocity (and pressure gradient) with no change in valve area. In a patient with the same baseline data but "pseudosevere AS," the increase in EF and transaortic stroke volume (SV) "push" the aortic leaflets to open more so that there is a smaller increase in aortic velocity in association with an increase in AVA. Current diagnostic testing relies on Doppler data with dobutamine stress testing because direct imaging of valve anatomy is not adequate for the visualization of the exact systolic orifice. LVOT, Left ventricular outflow tract; HR, heart rate, VTI, velocity-time integral. (From Otto CM, Owens DS: Stress testing for structural heart disease. In Gillam LD, Otto CM, editors. Advanced Approaches in Echocardiography: Practical Echocardiography Series. Philadelphia: Saunders; 2012.)

Caution is needed in using any type of stress testing for diagnosis of CAD in patients with VHD. Coronary blood flow is abnormal in patients with significant VHD, and the accuracy of stress testing for diagnosis of CAD in this population has not been well established. For example, myocardial oxygen supply-demand mismatch in patients with AS may result in "balanced ischemia" without evidence of regional dysfunction, even when significant epicardial CAD is present. Coronary angiography is recommended when CAD is suspected in patients with VHD.

Cardiac Catheterization

Concomitant CAD frequently is present in patients with VHD. Coronary angiography is recommended before surgical or transcatheter valve intervention in the following groups[1]:

1. In patients with symptoms of angina, objective evidence of ischemia, decreased LV systolic

function, history of CAD, or coronary risk factors (including men age >40 years and postmenopausal women)

2. In patients with chronic severe secondary MR (**see Chapter 69**)
3. In select patients undergoing surgical valve procedures with a low or intermediate pretest probability of CAD, CT coronary angiography is a reasonable alternative to invasive angiography (**see Chapter 18**). An abnormal coronary CT angiogram (the presence of any epicardial CAD) mandates further evaluation by cardiac catheterization.
4. When emergency surgery is needed for acute valve regurgitation, disease of the aortic sinuses or ascending aorta, or infective endocarditis, it is appropriate to proceed directly to surgery without coronary angiography.

Basic Principles of Medical Therapy

Medical therapy in all patients with VHD includes prevention of progressive valvular dysfunction, primary and secondary prevention for atherosclerotic CVD, and treatment of concurrent cardiac conditions.

Prevention of Rheumatic Valve Disease

On a worldwide basis, primary and secondary prevention of rheumatic valve disease is key to reducing the overall burden of VHD (**see Chapter 74**). Even though less common in developed countries because of primary prevention by treatment of streptococcal pharyngitis, secondary prevention is important for all patients with a diagnosis of rheumatic valve disease.[6]

Endocarditis Prophylaxis

Optimal dental hygiene and regular dental care are critical for prevention of infective endocarditis (**see Chapter 73**); all patients should be educated about the importance of endocarditis prevention, the signs and symptoms of early endocarditis, and the need to report promptly any unexplained fever or other symptoms.[12-15] Patients should be encouraged to request blood cultures first when a primary care provider recommends antibiotic therapy for any indication. In addition, antibiotic prophylaxis at the time of dental procedures is recommended in patients with all types of prosthetic heart valves and valve repairs, as well as other high-risk conditions.[15,16]

Prevention and Treatment of Coronary Artery Disease

Risk factors for development of calcific valve disease are similar to the risk factors for atherosclerotic CVD (**see Chapter 45**). Thus, appropriate evaluation and management of conventional CVD risk factors is important in management of patients with VHD. CAD is common in patients with VHD and should be treated with guideline-based medical, interventional, and surgical therapy (**see Chapter 61**). Revascularization at the time of surgical or interventional procedures for VHD should be considered to relieve symptoms and improve long-term outcomes.

Atrial Fibrillation

Atrial fibrillation often accompanies mitral valve disease, presumably related to increased pressure and size and of the left atrium, and may herald symptom onset. Medical management of AF associated with mitral valve disease may include transcatheter or surgical ablation procedures to restore sinus rhythm is some patients as an alternative to medical therapy for rate or rhythm control (**see Chapter 38**). Anticoagulation to prevent embolic events is recommended in all patients with AF and mitral valve

disease (**Table 67.4**). When rheumatic disease is present, particularly MS, vitamin K antagonist therapy is needed given the extremely high embolic risk, whereas current guidelines suggest direct oral anticoagulation (**see Chapter 93**) is reasonable in patients with MR and AF.[17-20] AS often is accompanied by AF, particularly in older adults. Management focuses on rate control and prevention of embolic events, although select patients may be considered for ablation procedures.

TABLE 67.4

Anticoagulation for Atrial Fibrillation in Patients with Valvular Heart Disease (VHD)

PATIENT GROUP	RECOMMENDATION	RATIONALE
VHD plus atrial fibrillation (AF)	Anticoagulant therapy should be individualized using shared decision making after discussion of benefits and risks, and taking into account patient preferences and values.	With new data showing equivalence of direct oral anticoagulant versus vitamin K antagonist therapy for patients with AF and VHD in prevention of embolic events, a shared decision-making approach should be followed to determine the anticoagulation therapy for each individual patient.
Mitral stenosis (MS)	Anticoagulation (vitamin K antagonist or heparin) is indicated for patients with MS and AF (paroxysmal, persistent, or permanent).	Patients with MS and AF are at the highest risk of embolic events with a high prevalence of left atrial thrombi, even when in sinus rhythm. Clinical trials of direct oral anticoagulants versus warfarin excluded patients with MS.
Other native valve disease	In patients with native aortic valve disease, tricuspid valve disease, or mitral valve regurgitation, antithrombotic therapy for AF should follow standard AF guidelines.	Randomized clinical trials of direct oral anticoagulants versus warfarin, which included subgroups of patients with native valve disease (except MS), showed equivalence of these therapies.
Bioprosthetic valves	In patients with a bioprosthetic valve, antithrombotic therapy for AF should follow standard AF guidelines, as well as recommendations for management after valve implantation (**see Chapter 71**).	Randomized clinical trials of direct oral anticoagulants versus warfarin, which included subgroups of patients with bioprosthetic valves, showed equivalence of these therapies.
Mechanical valves	Patients with a mechanical prosthetic valve should be treated with vitamin K antagonists or heparin as recommended for the prosthetic valve regardless of the presence of AF.	Patients with mechanical valves require warfarin therapy (or heparin) for prevention of thromboembolic events. Guidelines for prosthetic valves address whether the goal INR should be increased when concurrent AF is present (**see Chapter 72**).

INR, International normalized ratio.

Hypertension

Hypertension also typically is present in patients with VHD and should be treated using guideline-based medical therapy[21] (**see Chapter 47**). In patients with AS, medical therapy may need to be initiated at lower doses and titrated upward slowly but usually is well tolerated. It is especially important to measure transvalvular velocity, gradient, and area when the patient is normotensive because hypertension can result in underestimation of AS severity (**see Chapter 68**).

Left Ventricular Dysfunction

Left ventricular dysfunction caused by VHD is an indication for intervention. However, many patients have LV dysfunction from CAD or a primary cardiomyopathy in conjunction with mild or moderate VHD. In particular, amyloid heart disease may be present in elderly adults with calcific valve disease (**see Chapter 77**). Thus a complete evaluation for other causes of LV dysfunction is recommended, particularly when the degree of LV systolic dysfunction, hypertrophy, or diastolic dysfunction seems out of proportion to the severity of VHD. This evaluation helps guide decision making in predicting the likely effects of interventions on recovery of LV function. Management of HF with preserved or reduced EF in patients with valve disease follows the same general principles as for other patients (**see Chapters 25 and 26**), with the caveat that management of volume status may be challenging because there is only a narrow range of LV filling volumes/pressures that allow an adequate forward cardiac output without an excessive rise in filling pressures, often referred to as a “narrow preload window.” Patients often rapidly swing back and forth between pulmonary congestion and low-output symptoms. Meticulous outpatient medical management is needed in these patients.

Aortic Disease

Aortic dilation frequently accompanies aortic valve disease (**see Chapter 68**). Bicuspid aortic valve disease is accompanied by an aortopathy in many patients with progressive aortic dilation and an increased risk of aortic dissection (**see Chapter 63**). Additional imaging and monitoring of aortic anatomy and size is needed in these patients. Some patients with calcific aortic valve disease also have aortic dilation, often in conjunction with systemic hypertension, again with the need for additional imaging and follow-up in select patients.

Aortic Valve Disease

Brian R. Lindman, Robert O. Bonow, Catherine M. Otto

Aortic Stenosis

Epidemiology

In recent population-based echocardiographic studies, 1% to 2% of persons age 65 or older and 12% of persons 75 or older had calcific aortic stenosis (AS)[1,2] (**see Chapter 88**). Among those older than 75, 3.4% (95% confidence interval [CI] 1.1% to 5.7%) have severe AS.[2] The prevalence of aortic valve sclerosis without stenosis, defined as irregular thickening or calcification of the aortic valve leaflets, increases with age and ranges from 9% in populations with a mean age of 54 years to 42% in populations with a mean age of 81 years.[1,3] The rate of progression from aortic sclerosis to stenosis is 1.8% to 1.9% per year.[3] With the aging of the population, the number of individuals with AS is expected to increase twofold to threefold in developed countries in the coming decades.[1,3,4]

Causes and Pathology

Valvular AS has three principal causes: a congenital bicuspid valve with superimposed calcification, calcification of a normal trileaflet valve, and rheumatic disease (**Fig. 68.1**). In a U.S. series of 933 patients undergoing aortic valve replacement (AVR) for AS, a bicuspid valve was present in more than 50%, including two thirds of those younger than 70 years and 40% of those older than 70 (see Classic References, Roberts and Ko).

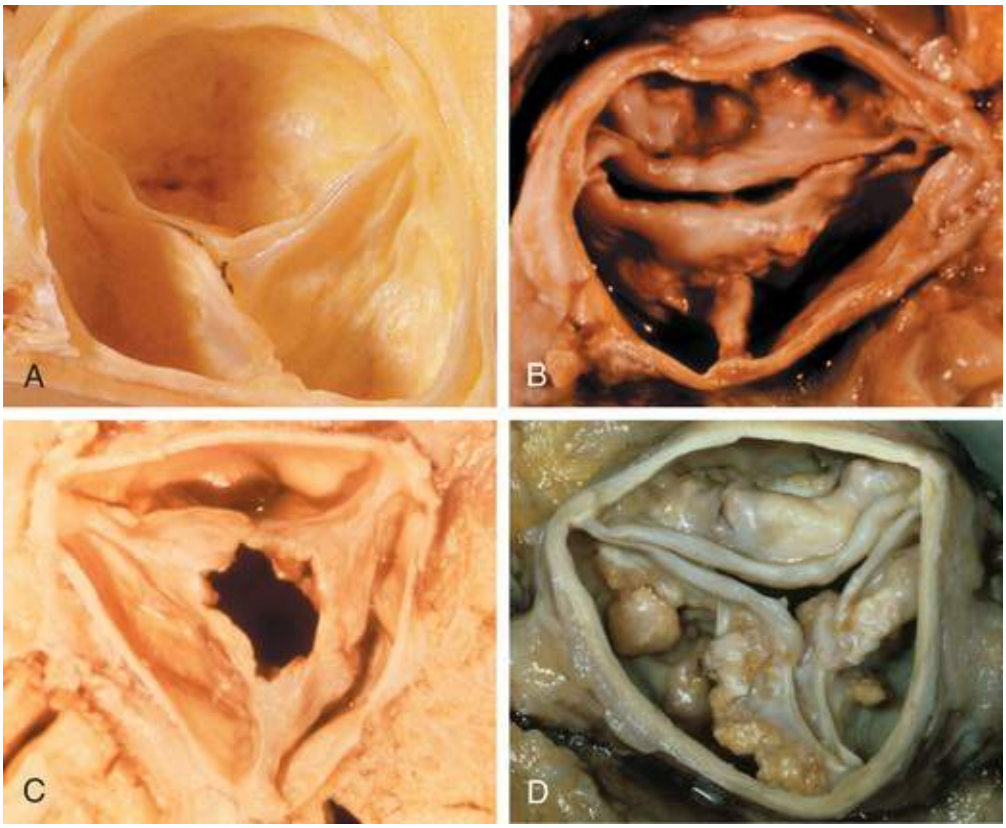

FIGURE 68.1 Major types of aortic valve stenosis. **A,** Normal aortic valve. **B,** Congenital bicuspid aortic stenosis. A false raphe is present at 6 o'clock. **C,** Rheumatic aortic stenosis. The commissures are fused with a fixed central orifice. **D,** Calcific degenerative aortic stenosis. (**A,** From Manabe H, Yutani C, editors. Atlas of Valvular Heart Disease. Singapore: Churchill Livingstone; 1998, pp 6, 131; **B-D,** courtesy Dr. William C. Roberts, Baylor University Medical Center, Dallas.)

In addition, AS may be caused by a congenital valve stenosis manifesting in infancy or childhood. Rarely, AS is caused by severe atherosclerosis of the aorta and aortic valve; this form of AS occurs most

frequently in patients with severe hypercholesterolemia and is observed in children with homozygous type II hyperlipoproteinemia. Rheumatoid involvement of the valve is a rare cause of AS and results in nodular thickening of the valve leaflets and involvement of the proximal portion of the aorta. Ochronosis with alkaptonuria is another rare cause of AS.

Fixed obstruction to left ventricular (LV) outflow also may occur above the valve (supravalvular stenosis) or below the valve (discrete subvalvular stenosis; **see Fig. 14.45**) (Video 68.1A and 68.1B). Dynamic subaortic obstruction may be caused by hypertrophic cardiomyopathy (**see Chapter 78**).

Congenital Aortic Valve Disease.

Congenital malformations of the aortic valve may be unicuspid, bicuspid, or tricuspid, or the anomaly may manifest as a dome-shaped diaphragm (**see Fig. 14.44** and **Chapter 75**). Unicuspid valves typically produce severe obstruction in infancy and are the most common malformations found in fatal valvular AS in children younger than 1 year, but also may be seen in young adults with an anatomy that mimics bicuspid valve disease. Congenitally bicuspid valves rarely are responsible for serious narrowing of the aortic orifice during childhood,[5] but do cause significant aortic regurgitation (AR) requiring valve surgery in young adulthood in a subset of patients. Most affected patients, however, have normal valve function until late in life, when superimposed calcific changes result in valve obstruction (see later, Bicuspid Aortic Valve Disease).

Calcific Aortic Valve Disease.

Calcific (formerly “senile” or “degenerative”) aortic valve disease affecting a congenital bicuspid or normal trileaflet valve is now the most common cause of AS in adults. Aortic sclerosis, identified by either echocardiography or computed tomography (CT), is the initial stage of calcific valve disease and, even in the absence of valve obstruction or known cardiovascular disease, is associated with an increased risk of myocardial infarction (MI) and cardiovascular and all-cause mortality.[3,6] Epidemiologic associations have been documented between cardiovascular risk factors and calcific aortic valve disease, suggesting that treating or preventing these risk factors may lessen the risk of developing AS (**Table 68.1**).

TABLE 68.1

Strength of Associations in Observational and Epidemiologic Studies of Clinical Risk Factors and Calcific Aortic Valve Disease (CAVD)

Risk Factor	CAVD ANALYSIS		
	Cross-Sectional	Incident	Progression
Age	+++	+++	+++

Although calcific AS once was considered to represent the result of years of normal mechanical stress on an otherwise normal valve (“wear and tear”), it is now clear that an active biology underlies the initiation and progression of calcific aortic valve disease (**Fig. 68.2**).[7] Differences in the biology driving the initiation and progression phases of calcific aortic valve disease could have important implications for medical therapies aimed at preventing, slowing, or reversing the path from aortic sclerosis to severe stenosis, both in terms of which pathways are relevant to target and when along the disease spectrum drugs targeting them are most likely to be effective.

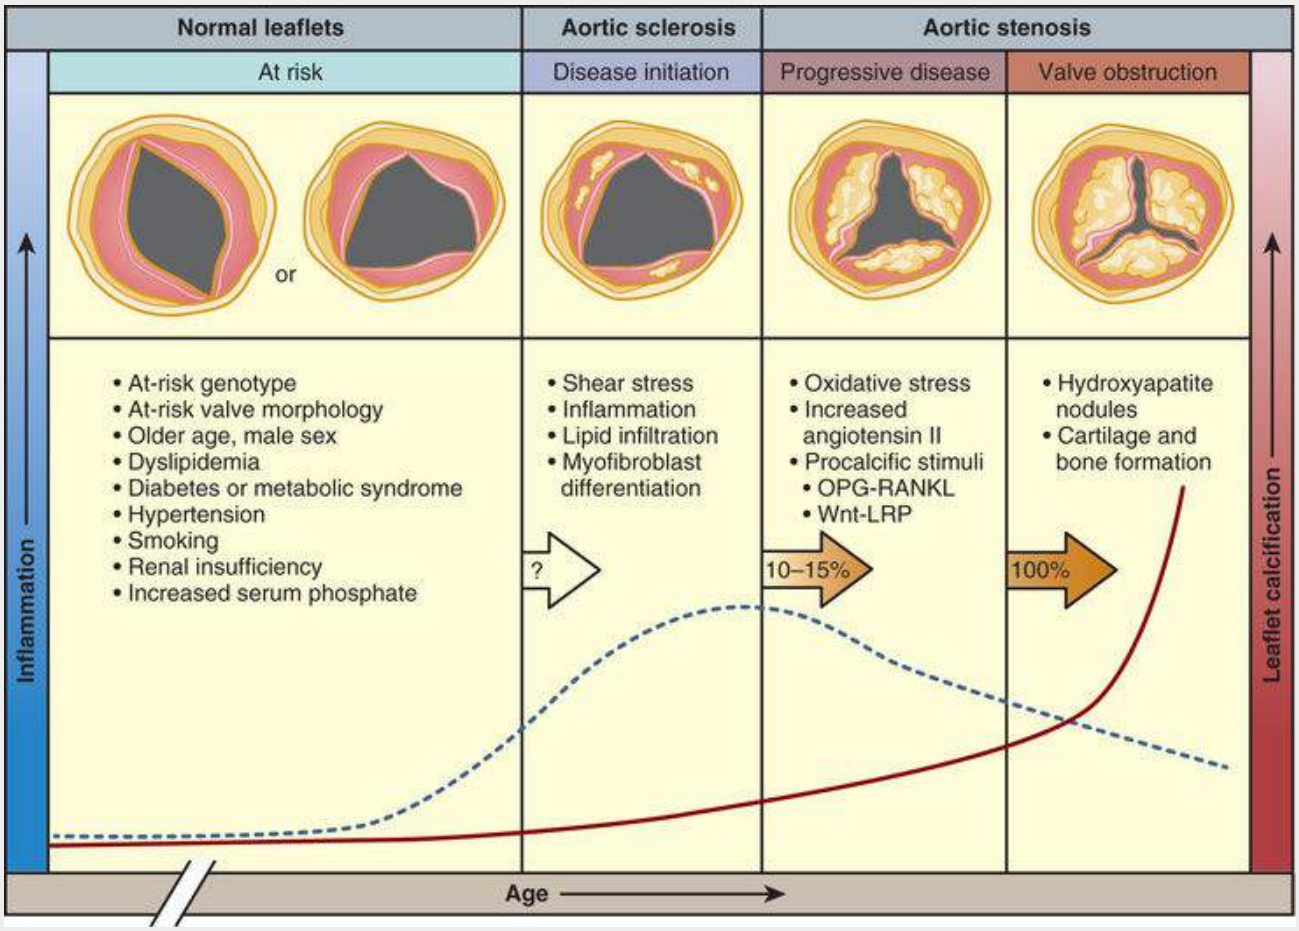

FIGURE 68.2 Disease mechanisms and time course of calcific aortic stenosis (AS): relationship among disease stage, valve anatomy, clinical risk factors, mechanisms of disease, and patient's age. Endothelial disruption with inflammation (*dashed line*) and lipid infiltration are key elements in the initiation of disease. There are few data on the prevalence of disease initiation in at-risk patients, and progressive disease develops in only a subgroup of these patients. Progressive leaflet disease, which is associated with several disease pathways, develops in approximately 10% to 15% of patients with AS. Once these disease mechanisms are activated, leaflet calcification results in severe AS in almost all patients. With end-stage disease, tissue calcification (*red line*) is the predominant tissue change, resulting in valve obstruction. Current imaging approaches are reliable only when substantial leaflet changes are present (in patients with progressive disease or valve obstruction), which limits clinical studies of interventions to prevent or slow the progression of early disease. LRP, Lipoprotein receptor–related protein complex; OPG, osteoprotegerin; RANKL, receptor activator of nuclear factor-κB ligand. (From Otto CM, Prendergast B. Aortic-valve stenosis: from patients at risk to severe valve obstruction. N Engl J Med 2014;371:744-56.)

Normal valve leaflets are comprised of the fibrosa (facing the aorta), ventricularis (facing the ventricle), and spongiosa (located between the fibrosa and ventricularis). *Valve interstitial cells* (VICs) are the most predominant cell type; endothelial and smooth muscle cells are also present. Through a complex interplay of molecular events, the pliable, flexible valve becomes stiff and immobile, characterized grossly by fibrosis and calcification. The process is initiated by lipid infiltration and oxidative stress, which attract and activate inflammatory cells and promote the elaboration of cytokines (**Fig. 68.3**).[4] VICs undergo osteogenic reprogramming that promotes the mineralization of the extracellular matrix and the progression of fibrocalcific remodeling of the valve.

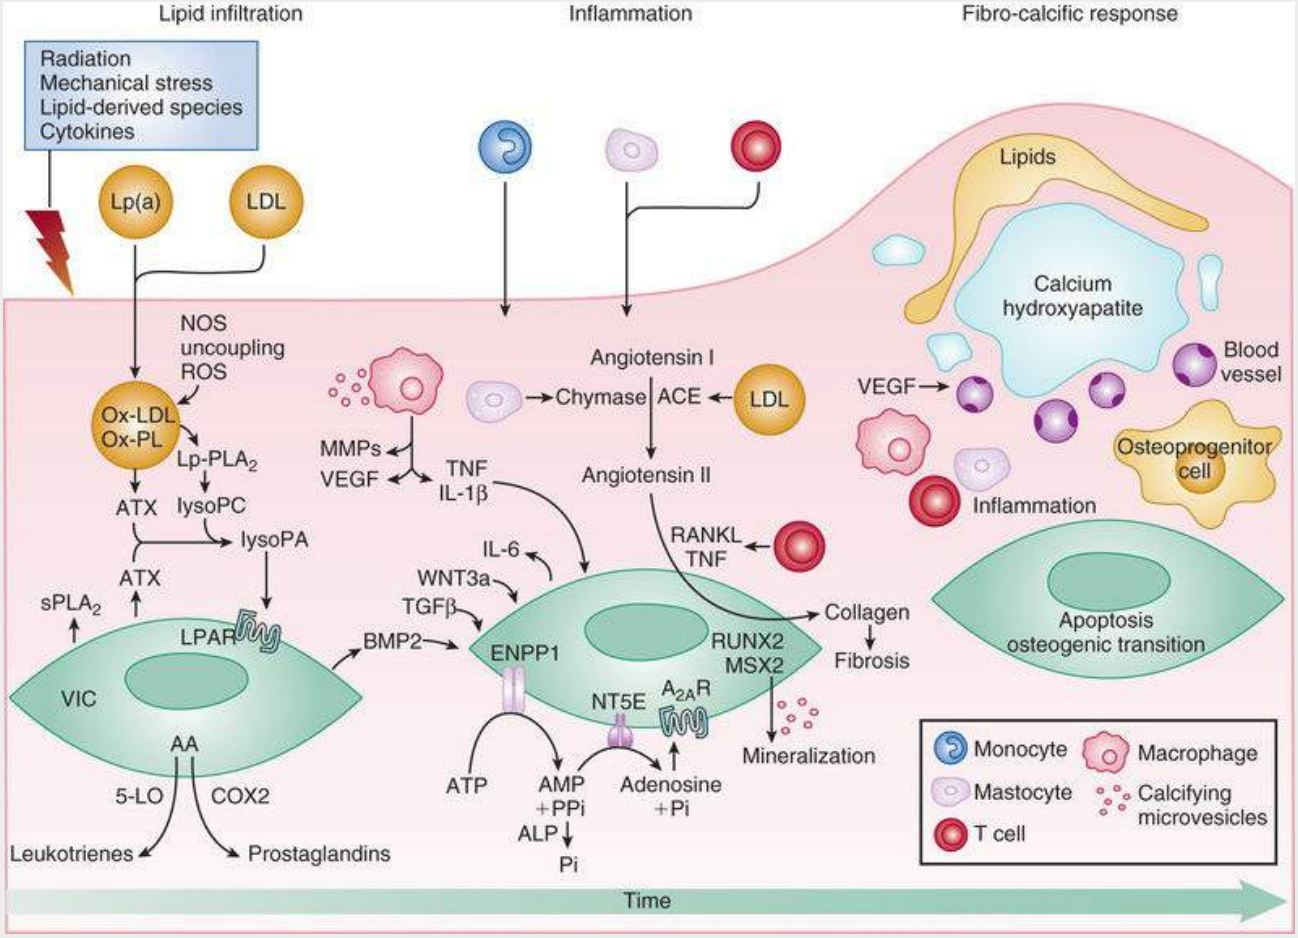

FIGURE 68.3 Pathogenesis of calcific aortic stenosis. Endothelial damage allows infiltration of lipids, specifically low-density lipoprotein (*LDL*) and lipoprotein(a) [*Lp(a)*], into the fibrosa and triggers the recruitment of inflammatory cells into the aortic valve. Endothelial injury can be triggered by several factors, including lipid-derived species, cytokines, mechanical stress, and radiation injury. The production of reactive oxygen species (*ROS*) is promoted by the uncoupling of nitric oxide synthase (*NOS*), which increases the oxidation of lipids and further intensifies the secretion of cytokines. Enzymes transported in the aortic valve by lipoproteins (i.e., LDL, Lp[a]) such as lipoprotein-associated phospholipase A_2 (*Lp-PLA*$_2$) and ectonucleotide pyrophosphatase/phosphodiesterase 2 (ENPP2), also known as autotoxin (*ATX*), produce lysophospholipid derivatives. ATX, which is also secreted by valve interstitial cells (*VIC*), transforms lysophosphatidylcholine (*lysoPC*) into lysophosphatidic acid (*lysoPA*). Several factors, including lysoPA, the receptor activator of nuclear factor-κB ligand (*RANKL*; also known as TNFSF11), and WNT3a, promote the osteogenic transition of VIC. Arachidonic acid (*AA*) generated by cytosolic PLA_2 promotes the production of eicosanoids such as prostaglandins and leukotrienes through prostaglandin G/H synthase 2 (PTGS2; also known as cyclooxygenase 2 [*COX2*]) and 5-lipoxygenase (*5-LO*) pathways, respectively. In turn, eicosanoids promote inflammation and mineralization. Chymase and angiotensin-converting enzyme (*ACE*) promote production of angiotensin II, which increases synthesis and secretion of collagen by VIC. Because of increased production of matrix metalloproteinases (*MMPs*) and decreased synthesis of tissue inhibitors of metalloproteinases (TIMPs), disorganized fibrous tissue accumulates within the aortic valve. Microcalcification begins early in the disease, driven by microvesicles secreted by VIC and macrophages. In addition, overexpression of ectonucleotidases—ENPP1, 5′-nucleotidase ecto (*NT5E*), and alkaline phosphatase (*ALP*)—promotes both apoptosis and osteogenic-mediated mineralization. Bone morphogenetic protein 2 (*BMP2*) leads to osteogenic transdifferentiation, which is associated with the expression of bone-related transcription factors (e.g., runt-related transcription factor 2 [*RUNX2*] and homeobox protein MSX2). Osteoblast-like cells subsequently coordinate calcification of the aortic valve as part of a highly regulated process analogous to skeletal bone formation. Deposition of mineralized matrix is accompanied by fibrosis and neovascularization, which is abetted by vascular endothelial growth factor (*VEGF*). In turn, neovascularization increases the recruitment of inflammatory cells and bone marrow–derived osteoprogenitor cells. *$A_{2A}R$,* Adenosine A_{2A} receptor; *$sPLA_2$,* secreted phospholipase A_2; *LPAR,* lysophosphatidic acid receptor; *Ox-PL,* oxidized phospholipid; *Ox-LDL,* oxidized LDL; *TGFβ,* transforming growth factor beta; *TNF,* tumor necrosis factor. (From Lindman BR, Clavel M-A, Mathieu P, et al. Calcific aortic stenosis. *Nat Rev Dis Primers*. 2016;2:16006.)

Familial clustering of calcific AS also has been described, suggesting a possible genetic

predisposition to valve calcification.[8,9] Genetic polymorphisms have been linked to the presence of calcific AS, including those involving the vitamin D receptor, interleukin (IL)-10 alleles, estrogen receptor, transforming growth factor (TGF)-ß receptor, and the apolipoprotein E4 allele.[10] In a genome-wide association study (GWAS) based on a meta-analysis of data on nearly 7000 patients from three population-based cohorts, a single-nucleotide polymorphism (SNP) in the locus for low-density lipoprotein (LDL) was associated with aortic valve calcification, serum lipoprotein(a) [Lp(a)] levels, and incident AS (hazard ratio [HR], 1.68; CI 1.32 to 2.15).[11] This correlation was confirmed by review of a large Danish registry of more than 77,000 patients in whom two Lp(a) genotypes were significantly associated with incident AS.[12] Recent evidence suggests a potential link between Lp(a) and AS through lipoprotein-associated phospholipase A_2 (Lp-PLA_2) and ectonucleotide pyrophosphatase/phosphodiesterase family member 2 (ENPP2), also known as *autotaxin*.[13-17] Lp(a) transports both Lp-PLA_2 and autotaxin, and each of these is found in increased abundance in stenotic aortic valves.[15,16,18] Lp-PLA_2 transforms oxidized phospholipids species into lysophosphatidylcholine (lysoPC); in turn, autotaxin transforms lysoPC into lysophosphatidic acid (lysoPA), which appears to play a role in the osteogenic reprogramming of VICs.[16,17]

Rheumatic Aortic Stenosis.

Rheumatic AS results from adhesions and fusions of the commissures and cusps and vascularization of the leaflets of the valve ring, leading to retraction and stiffening of the free borders of the cusps. Calcific nodules develop on both surfaces, and the orifice is reduced to a small, round or triangular opening (**Fig. 68.1C**). As a consequence, the rheumatic valve often is regurgitant as well as stenotic. Patients with rheumatic AS invariably have rheumatic involvement of the mitral valve (**see Chapter 74**). With the decline in rheumatic fever in developed nations, rheumatic AS is decreasing in frequency, although it continues to be a major problem on a worldwide basis.

Pathophysiology

Valve Obstruction

In adults with calcific AS, a significant burden of leaflet disease is present before obstruction to outflow develops. However, once even mild obstruction is present, hemodynamic progression occurs in almost all patients, with the interval from mild to severe obstruction ranging from less than 5 to more than 10 years (**Fig. 68.4**). In infants and children with congenital AS, the valve orifice shows little change as the child grows, thereby contributing to the relative obstruction over time. **Table 68.2** provides the clinical stages reflecting the progression of aortic stenosis.

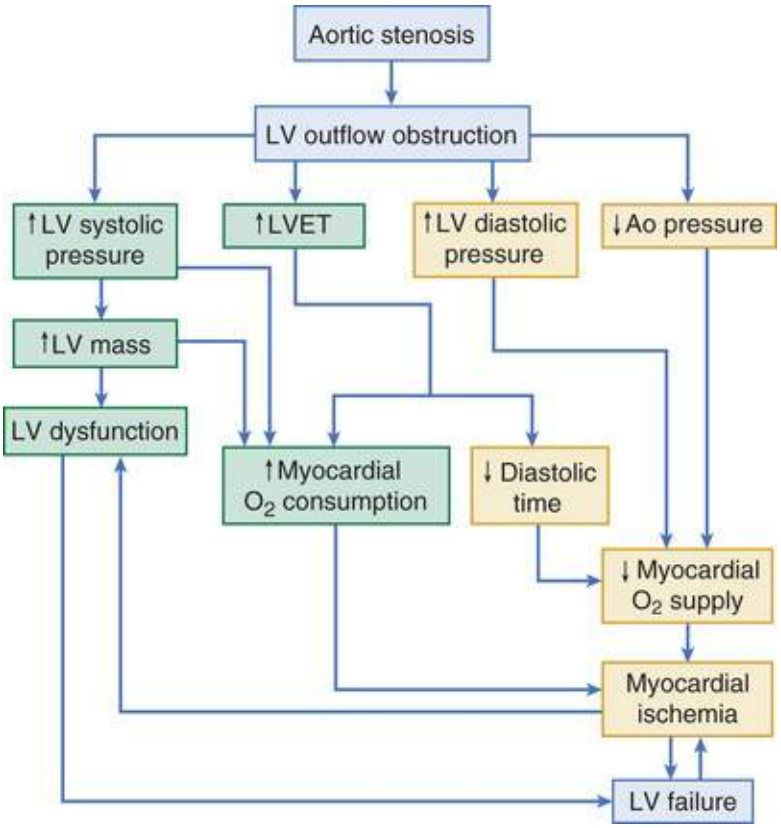

FIGURE 68.4 Pathophysiology of aortic stenosis. Left ventricular (LV) outflow obstruction results in an increased LV systolic pressure, increased LV ejection time (LVET), increased LV diastolic pressure, and decreased aortic (Ao) pressure. Increased LV systolic pressure with LV volume overload increases LV mass, which may lead to LV dysfunction and failure. Increased LV systolic pressure, LV mass, and LVET increase myocardial oxygen (O_2) consumption. Increased LVET results in a decrease of diastolic time (myocardial perfusion time). Increased LV diastolic pressure and decreased Ao diastolic pressure decrease coronary perfusion pressure. Decreased diastolic time and coronary perfusion pressure decrease myocardial O_2 supply. Increased myocardial O_2 consumption and decreased myocardial O_2 supply produce myocardial ischemia, which further deteriorates LV function. (From Boudoulas H, Gravanis MB: Valvular heart disease. In Gravanis MB, editor. Cardiovascular Disorders: Pathogenesis and Pathophysiology. St Louis; Mosby; 1993, p 64.)

TABLE 68.2

Stages of Valvular Aortic Stenosis (AS)

STAGE	DEFINITION	VALVE ANATOMY	VALVE HEMODYNAMICS	HEMODYNAMIC CONSEQUENCES	SYMPTOMS
A	**At risk of AS**	Bicuspid aortic valve (or other congenital valve anomaly) Aortic valve sclerosis	Aortic Vmax <2 m/sec	None	None
B	**Progressive AS**	Mild to moderate leaflet calcification of a bicuspid or trileaflet valve with some reduction in systolic motion *or* Rheumatic valve changes with commissural fusion	***Mild AS:*** Aortic Vmax 2.0-2.9 m/sec or mean ΔP <20 mm Hg ***Moderate AS:*** Aortic Vmax 3.0-3.9 m/sec or mean ΔP 20-39 mm Hg	Early LV diastolic dysfunction may be present. Normal LVEF	None
C	**Asymptomatic severe AS**				
C1	Asymptomatic severe AS	Severe leaflet calcification or congenital stenosis with severely reduced leaflet opening	***Severe AS:*** Aortic Vmax ≥4 m/sec or mean ΔP ≥40 mm Hg AVA typically is ≤1 cm^2 (or AVAi ≤0.6 cm^2/m^2) Very severe AS is an aortic Vmax ≥5 m/sec, or mean ΔP ≥ 60 mm Hg	LV diastolic dysfunction Mild LV hypertrophy Normal LVEF	None Exercise testing is reasonable to confirm symptom status
C2	Asymptomatic severe AS with LV dysfunction	Severe leaflet calcification or congenital stenosis with severely reduced leaflet opening	Aortic Vmax ≥4 m/sec or mean ΔP ≥40 mm Hg AVA typically is ≤1 cm^2 (or AVAi ≤0.6 cm^2/m^2)	LVEF <50%	None
D	**Symptomatic severe AS**				
D1	Symptomatic severe high-gradient AS	Severe leaflet calcification or congenital stenosis with severely reduced leaflet opening	***Severe AS:*** Aortic Vmax ≥4 m/sec, or mean ΔP ≥40 mm Hg AVA typically is ≤1 cm^2 (or AVAi ≤0.6 cm^2/m^2), but may be larger with mixed AS/AR	LV diastolic dysfunction LV hypertrophy Pulmonary hypertension may be present.	Exertional dyspnea or decreased exercise tolerance Exertional angina Exertional syncope or presyncope
D2	Symptomatic severe low-flow, low-gradient AS with reduced LVEF	Severe leaflet calcification with severely reduced leaflet motion	AVA ≤1 cm^2 with resting aortic Vmax <4 m/sec, or mean ΔP <40 mm Hg Dobutamine stress echo shows AVA ≤1 cm^2 with Vmax ≥4 m/sec at any flow rate	LV diastolic dysfunction LV hypertrophy LVEF <50%	HF Angina Syncope or presyncope
D3	Symptomatic severe low-gradient AS with normal LVEF or paradoxical low-flow severe AS	Severe leaflet calcification with severely reduced leaflet motion	AVA ≤1 cm^2 with aortic Vmax ≤4 m/sec, or mean ΔP <40 mm Hg AVAi ≤0.6 cm^2/m^2 Stroke volume index <35 mL/m^2 Measured when patient is normotensive (systolic BP <140 mm Hg)	Increased LV relative wall thickness Small LV chamber with low stroke volume Restrictive diastolic filling LVEF ≥50%	HF Angina Syncope or presyncope

AVA, Aortic valve area; *AVAi,* AVA indexed to body surface area; *BP,* blood pressure; *HF,* heart failure; *LVEF,* left ventricular ejection fraction; Δ*P,* pressure gradient; *Vmax,* maximum aortic jet velocity.

From Nishimura RA, Otto CM, Bonow RO, et al, 2014 AHA/ACCF guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2014;63:e57.

Severe obstruction to LV outflow usually is characterized by the following: (1) an aortic jet velocity of 4 m/sec or greater; (2) a mean transvalvular pressure gradient at least 40 mm Hg in the presence of a normal flow; or (3) an effective aortic orifice (calculated by the continuity equation; **see Fig. 14.48**) no greater than 1.0 cm^2 in an average-sized adult (i.e., ≤0.6 cm^2/m^2 of body surface area), which is approximately 25% of the normal aortic orifice of 3.0 to 4.0 cm^2.[19] *Moderate* AS is characterized by an aortic jet velocity of 3.0 to 3.9 m/sec or mean transvalvular pressure gradient of 20 to 39 mm Hg, usually with an aortic valve orifice area (AVA) of 1.0 to 1.5 cm^2. *Mild* AS is characterized by an aortic jet velocity of 2.0 to 2.9 m/sec or mean transvalvular pressure gradient less than 20 mm Hg, usually with

aortic orifice of 1.5 to 2.0 cm^2 (**Table 68.2**).[4,19-21]

The degree of stenosis associated with symptom onset varies among patients, however, and no single number defines severe or critical AS in an individual patient. Clinical decisions are based on consideration of symptom status and the LV response to chronic pressure overload, in conjunction with hemodynamic severity. In some cases, additional measures of hemodynamic severity, such as the energy loss index, valvular impedance, or evaluation with changing loading conditions (e.g., dobutamine stress) or with exercise, are necessary for full evaluation of disease severity.[22-26]

Hypertrophic Myocardial Remodeling

Maintenance of cardiac output in the face of an obstructed aortic valve imposes a chronic increase in LV pressure. In response, the ventricle typically undergoes hypertrophic remodeling characterized by myocyte hypertrophy and increased wall thickness (**Fig. 68.5**). LV remodeling may manifest as concentric remodeling, concentric hypertrophy, or eccentric hypertrophy. Based on LaPlace law, LV remodeling reduces wall stress (afterload) and is considered one of the important compensatory mechanisms to maintain LV ejection performance, which is directly affected by afterload (see Classic References, Grossman).

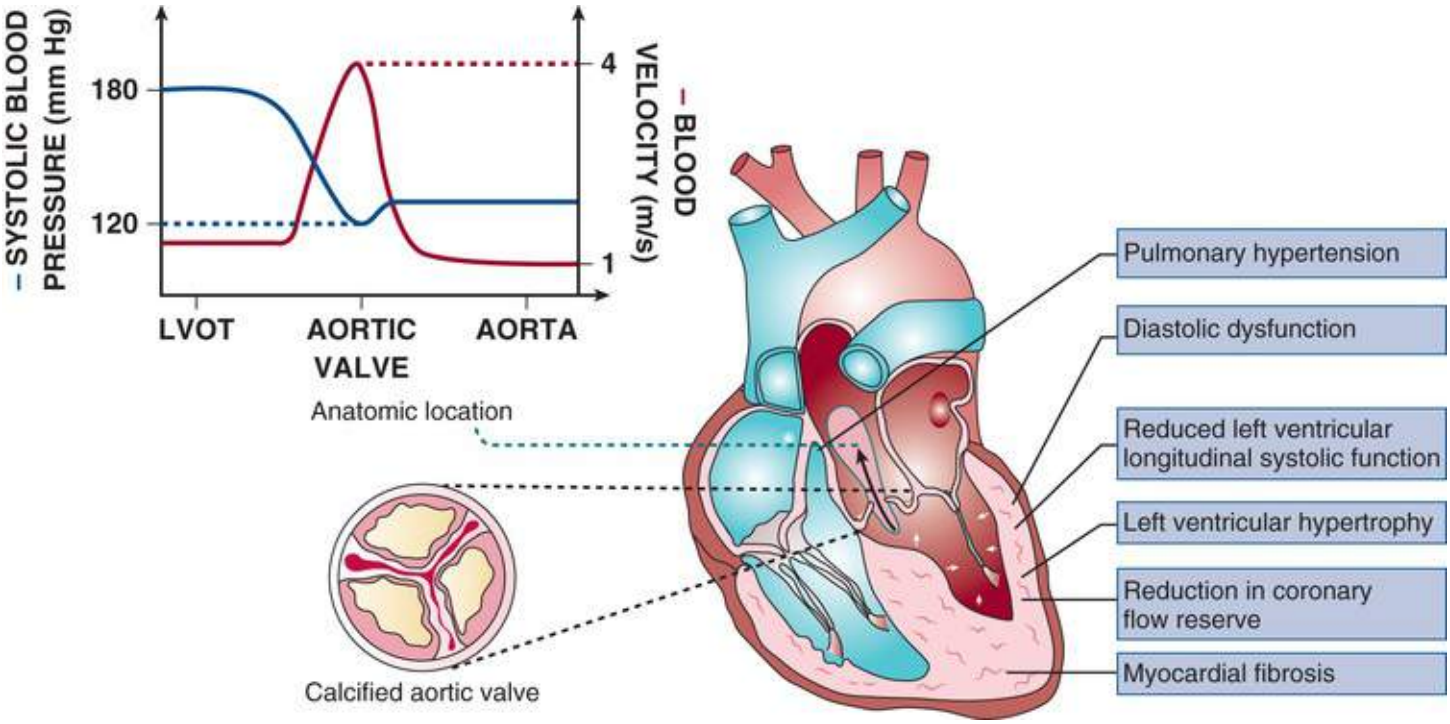

FIGURE 68.5 Maladaptive remodeling and impaired function of the left ventricle in response to pressure overload from aortic stenosis. The narrowing of the aortic valve orifice causes an acceleration of the blood flow velocity with a concomitant decrease in systolic blood pressure between the left ventricular outflow tract (LVOT) and the aorta. The increased LV pressure imposed by AS results in LV hypertrophy (augmentation of LV myocardial mass), reduced coronary flow reserve, myocardial fibrosis, diastolic dysfunction, and decreased longitudinal systolic shortening, although the ejection fraction remains normal in most patients. Left atrial enlargement is common because of elevated LV filling pressures, which often lead to secondary pulmonary hypertension and right ventricular dysfunction in the more advanced stages of the disease. (From Lindman BR, Clavel M-A, Mathieu P, et al. Calcific aortic stenosis. Nat Rev Dis Primers 2016;2:16006.)

However, LV hypertrophy is not simply related to increased afterload. Preclinical studies have demonstrated that blocking the hypertrophic response to pressure overload did not have deleterious

effects on LV performance despite increased wall stress (see Classic References, Hill). In patients with AS, several studies have now documented that increased LV hypertrophic remodeling is associated with more severe ventricular dysfunction and heart failure (HF) symptoms, as well as higher mortality.[27-29] Thus, while it may reduce wall stress, LV hypertrophic remodeling also may have longer-term deleterious effects that translate into impaired ventricular performance and worse clinical outcomes.

Cardiac hypertrophy in response to pressure overload involves both adaptive and maladaptive processes.[30] In addition, hypertrophic remodeling in patients with AS is determined by several factors other than the severity of valve obstruction, including sex, genetics, vascular load, and metabolic abnormalities.[31,32] Moreover, the degree to which LV hypertrophic remodeling is maladaptive versus adaptive and the resulting functional and clinical effects is not simply an issue of total LV mass and geometry; composition and energetics of the myocardium also are important.[30]

Left Ventricular Diastolic Function

Hypertrophic remodeling also impairs diastolic myocardial relaxation and increases stiffness,[33,34] as modulated by cardiovascular and metabolic comorbidities.[35] Higher cardiomyocyte stiffness, increased myocardial fibrosis, advanced-glycation end products, and metabolic abnormalities each contribute to increased chamber stiffness and higher end-diastolic pressures.[33] Atrial contraction plays a particularly important role in filling of the left ventricle in AS because it increases LV end-diastolic pressure without causing a concomitant elevation of mean left atrial pressure. This “booster pump” function of the left atrium prevents the pulmonary venous and capillary pressures from rising to levels that would produce pulmonary congestion, while maintaining LV end-diastolic pressure at the elevated level necessary for effective contraction of the hypertrophied left ventricle. Loss of appropriately timed, vigorous atrial contraction, as occurs in atrial fibrillation (AF) or atrioventricular dissociation, may result in rapid clinical deterioration in patients with severe AS. After surgical relief of AS, diastolic dysfunction may revert toward normal with regression of hypertrophy, but some degree of long-term diastolic dysfunction typically persists.

Left Ventricular Systolic Function

Left ventricular systolic function, as measured by the ejection fraction (EF), remains normal until late in the disease process in most patients with AS.[4] Nonetheless, more subtle systolic dysfunction can be detected as reduced longitudinal systolic strain before a reduction in the EF[36,37] (**see Chapter 14**). The development and severity of systolic dysfunction is the result of a complex interplay of factors, including the severity of valve obstruction, metabolic abnormalities, vascular load, inadequate hypertrophy (given the inverse correlation between wall stress and systolic performance), maladaptive hypertrophy (resulting in impaired contractility), ischemia, and fibrosis.[4,32,38] Eventually, a subset of patients develop overt systolic dysfunction manifested by a reduced LVEF. In these patients, systolic function usually improves after the ventricle is unloaded by AVR; the amount of recovery depends on many factors, including the degree to which systolic dysfunction was affected by afterload mismatch versus altered contractility.[39,40]

Myocardial Fibrosis.

Cardiac fibrosis is an emerging risk factor for adverse clinical outcomes in patients with AS.[41-44] As a part of the hypertrophic remodeling process, diffuse and replacement myocardial fibrosis (not fibrosis from prior MI) may develop,[41] although the incidence and extent of fibrosis are variable and

unpredictable and the underlying biologic mechanisms not yet clarified. Importantly, patients with severe fibrosis, despite a normal EF, are more likely to have worse preoperative HF symptoms and less likely to experience improvement in symptoms midterm after valve replacement, compared to those with no or minimal fibrosis before valve replacement.[42]

Pulmonary and Systemic Vasculature.

The hypertrophied and pressure overloaded left ventricle transmits increased pressure to the pulmonary vasculature, which leads to pulmonary hypertension in many patients with AS, becoming severe in 15% to 20%.[45] While patients may initially manifest pulmonary venous hypertension alone, some will go on to develop increased pulmonary vascular resistance, perhaps influenced by specific comorbidities and chronicity of pulmonary venous hypertension.[46-48] Among asymptomatic patients, exercise induced pulmonary hypertension is associated with decreased event-free survival.[49] Among patients undergoing surgical or transcatheter AVR, the presence and severity of pulmonary hypertension is associated with increased postoperative mortality.[46,48,50]

The systemic vasculature also makes an important contribution to total LV afterload. Hemodynamic studies with agents that dilate the systemic vasculature show an acute increase in LV stroke volume, underscoring that changes in vascular properties can unload the left ventricle despite no change in the valvular obstruction[47,51] (see Classic References, Khot). Measures of increased vascular load, including vascular stiffness, global load (integrating both valvular and vascular load), and systolic blood pressure, have been associated with adverse LV remodeling, impaired LV function, and worse clinical outcomes.[38,52-54]

Myocardial Ischemia.

In patients with AS, the hypertrophied left ventricle, increased systolic pressure, and prolongation of ejection all elevate myocardial oxygen (O_2) consumption. At the same time, even in the absence of epicardial coronary disease, decreased myocardial capillary density in the hypertrophied ventricle, increased LV end-diastolic pressure, and a shortened diastole all serve to decrease the coronary perfusion pressure gradient and myocardial blood flow. Together, this creates an imbalance between myocardial O_2 supply and demand, with the ischemia most pronounced in the subendocardium (**see Fig. 68.4**). As valve obstruction becomes more severe, coronary flow reserve progressively decreases.[55] Exercise or other states of increased O_2 demand may exacerbate this imbalance and cause angina indistinguishable from that caused by epicardial coronary obstruction.

Clinical Presentation

Symptoms

The cardinal manifestations of acquired AS are exertional dyspnea, angina, syncope, and ultimately HF.[20,56] Most patients now are diagnosed before symptom onset on the basis of the finding of a systolic murmur on physical examination, with confirmation of the diagnosis by echocardiography. Symptoms typically begin at age 50 to 70 years with bicuspid aortic valve stenosis and in those older than 70 with calcific stenosis of a trileaflet valve, although even in this age group approximately 40% of patients with AS have a congenital bicuspid valve (see Roberts and Ko).

The most common clinical presentation in patients with a known diagnosis of AS who are followed prospectively is a gradual decrease in exercise tolerance, fatigue, or dyspnea on exertion. The mechanism of exertional dyspnea may be LV diastolic dysfunction, with an excessive rise in end-diastolic pressure leading to pulmonary congestion. Alternatively, exertional symptoms may be a result of the limited ability

to increase cardiac output with exercise. More severe exertional dyspnea, with orthopnea, paroxysmal nocturnal dyspnea, and pulmonary edema, reflects various degrees of pulmonary venous hypertension. These are relatively late symptoms in patients with AS, and in current practice, intervention typically is undertaken before this disease stage.

Angina is a frequent symptom of patients with severe AS and usually resembles the angina observed in patients with coronary artery disease (CAD) in that it is usually precipitated by exertion and relieved by rest (**see Chapters 56 and 61**). In patients without CAD, angina results from the combination of the increased O_2 needs of hypertrophied myocardium and reduction of O_2 delivery secondary to the excessive compression of coronary vessels. In patients with CAD, angina is caused by a combination of epicardial coronary artery obstruction and the O_2 imbalance characteristic of AS. Very rarely, angina results from calcific emboli to the coronary vascular bed.

Syncope most often is caused by the reduced cerebral perfusion that occurs during exertion when arterial pressure declines because of systemic vasodilation and an inadequate increase in cardiac output related to valvular stenosis. Syncope also has been attributed to malfunction of the baroreceptor mechanism in severe AS (**see Chapter 99**), as well as to a vasodepressor response to a greatly elevated LV systolic pressure during exercise. Premonitory symptoms of syncope are common. Exertional hypotension also may be manifested as “graying-out spells” or dizziness on effort. Syncope at rest may be caused by transient AF with loss of the atrial contribution to LV filling, which causes a precipitous decline in cardiac output, or to transient atrioventricular (AV) block caused by extension of the calcification of the valve into the conduction system.

Gastrointestinal (GI) bleeding may develop in patients with severe AS, often associated with angiodysplasia (most frequently of the right colon) or other vascular malformations. This complication arises from shear stress–induced platelet aggregation with a reduction in high-molecular-weight multimers of von Willebrand factor and increases in proteolytic subunit fragments.[57] These abnormalities correlate with the severity of AS and are correctable by AVR.

An increased risk of infective endocarditis has been documented in patients with aortic valve disease, particularly in younger patients with a bicuspid valve (**see Chapter 73**). Cerebral emboli resulting in stroke or transient ischemic attacks (TIAs) may be caused by microthrombi on thickened bicuspid valves. Calcific AS rarely may cause embolization of calcium to various organs, including the heart, kidneys, and brain.

Physical Examination.

The key features of the physical examination in patients with AS are palpation of the carotid upstroke, evaluation of the systolic murmur, assessment of splitting of the second heart sound (S_2), and examination for signs of HF (**see Chapters 10 and 67**).

The carotid upstroke directly reflects the arterial pressure waveform. The expected finding with severe AS is a slow-rising, late-peaking, low-amplitude carotid pulse, the *parvus and tardus* carotid impulse. When present, this finding is specific for severe AS. However, many adults with AS have concurrent conditions, such as AR or systemic hypertension, that affect the arterial pressure curve and the carotid impulse. Thus an apparently normal carotid impulse is not reliable for excluding the diagnosis of severe AS. Also with severe AS, radiation of the murmur to the carotid arteries may result in a palpable thrill or carotid shudder.

Auscultation.

The ejection systolic murmur of AS typically is late-peaking and heard best at the base of the heart, with radiation to the carotids. Cessation of the murmur before A_2 is helpful in differentiation from a pansystolic mitral murmur. In patients with calcified aortic valves, the systolic murmur is loudest at the base of the heart, but high-frequency components may radiate to the apex—the so-called *Gallavardin phenomenon,* in which the murmur may be so prominent that it is mistaken for the murmur of mitral regurgitation (MR). In general, a louder and later-peaking murmur indicates more severe stenosis. However, although a systolic murmur of grade 3 intensity or greater is relatively specific for severe AS, this finding is insensitive, and many patients with severe AS have only a grade 2 murmur. When the left ventricle fails and stroke volume falls, the systolic murmur of AS becomes softer; rarely, it disappears altogether.

Splitting of S_2 is helpful in excluding the diagnosis of severe AS, because normal splitting implies the aortic valve leaflets are flexible enough to create an audible closing sound (A_2). With severe AS, S_2 may be single because (1) calcification and immobility of the aortic valve make A_2 inaudible, (2) closure of the pulmonic valve (P_2) is buried in the prolonged aortic ejection murmur, or (3) prolongation of LV systole makes A_2 coincide with P_2.

Dynamic Auscultation.

The intensity of the systolic murmur varies from beat to beat when the duration of diastolic filling varies, as in AF or after a premature contraction. This characteristic is helpful in differentiating AS from MR, in which the murmur usually is unaffected. The murmur of valvular AS is augmented by squatting, which increases stroke volume. It is reduced in intensity during the strain of the Valsalva maneuver and on standing, both of which reduce transvalvular flow.

Diagnostic Testing

Echocardiography

Echocardiography is the standard approach for evaluating and following patients with AS and selecting them for operation (**see Chapter 14** and **Figs. 14.46 to 14.49**). Echocardiographic imaging allows accurate definition of valve anatomy, including the cause of AS and the severity of valve calcification, and sometimes allows direct imaging of the orifice area using three-dimensional imaging.[58-60] Echocardiographic imaging also is invaluable for the evaluation of LV hypertrophy and systolic function, with calculation of EF, measurement of aortic sinus dimensions, and detection of associated mitral valve disease.[60] Longitudinal systolic strain imaging has emerged as a more sensitive measure of LV function and predicts adverse clinical events, including mortality.[36,61-63]

Doppler echocardiography allows measurement of *transaortic jet velocity,* which is the most useful measure for following disease severity and predicting clinical outcome. The stenotic orifice area is calculated using the continuity equation, and mean transaortic pressure gradient is calculated using the modified Bernoulli equation[60] (**see Fig. 14.48**). Both AVA and pressure gradient calculations from Doppler data have been well validated compared with invasive hemodynamics and in terms of their ability to predict clinical outcome. However, the accuracy of these measures requires an experienced laboratory with meticulous attention to technical details.

The combination of pulsed, continuous-wave, and color flow Doppler echocardiography is helpful in detecting and determining the severity of AR (which coexists in approximately 75% of patients with predominant AS) and in estimating pulmonary artery pressure. In some patients, additional measures of AS severity may be necessary, such as correction for poststenotic pressure recovery or three-dimensional

transesophageal echocardiography (TEE) of valve anatomy. Evaluation of AS severity is affected by the presence of systemic hypertension, and reevaluation after blood pressure (BP) control may be necessary.[64] In patients with LV dysfunction and low cardiac output, assessing the severity of AS can be enhanced by assessing hemodynamic changes during dobutamine infusion (see later).

Exercise Stress Testing

Because patients may tailor their lifestyle to minimize symptoms or may ascribe fatigue and dyspnea to deconditioning or aging, they may not recognize early symptoms as important warning signals, although these symptoms often can be elicited by a careful history. Exercise testing may be helpful in apparently asymptomatic patients to unmask symptoms or demonstrate limited exercise capacity or an abnormal BP response.[65] Exercise stress testing should be absolutely avoided in symptomatic patients.

Cardiac Computed Tomography

The use of CT is expanding in patients with calcific aortic valve disease (**see Chapter 18**). CT is useful for evaluating aortic dilation in patients with evidence or suspicion of aortic root disease on echocardiography or chest radiography, particularly those with a bicuspid valve. Measurement of aortic dimensions at several levels, including the sinuses of Valsalva, sinotubular junction, and ascending aorta, is necessary for clinical decision making and surgical planning. Beyond this, CT is increasingly used to assess valve calcification to predict the rate of disease progression or, more often, when the severity of the stenosis is in doubt, particularly in those with low-flow, low-gradient AS.[66,67] CT is also a routine part of the preprocedural evaluation of patients having AVR, principally to look for a porcelain aorta, as well as determine appropriate valve sizing and assess aortic and peripheral vascular anatomy when a transcatheter approach is considered[68] (**see Figs. 18.15 and 72.5**).

Cardiac Catheterization

In almost all patients, the echocardiographic examination provides the important hemodynamic information required for patient management. Cardiac catheterization is now recommended only when noninvasive tests are inconclusive, when clinical and echocardiographic findings are discrepant, and for coronary angiography before surgical intervention[19,69-71] (**see Chapters 19 and 20**).

Other Imaging Modalities

Cardiac Magnetic Resonance Imaging (see Chapter 17).

CMR is useful for assessing LV volume, function, and mass, especially in settings where this information cannot be obtained readily from echocardiography.[72] CMR is also excellent for assessing aortic dimensions in patients with a bicuspid valve, particularly to avoid radiation when serial imaging is needed over many years. Given the adverse prognosis associated with the presence and severity of myocardial fibrosis, CMR with late gadolinium enhancement (LGE) may be used to risk-stratify patients with AS (**Fig. 68.6**). CMR is also sometimes used instead of CT to assess valve morphology, vascular anatomy, and annular dimensions in preparation for transcatheter aortic valve replacement, although MRI is not recommended for assessment of stenosis severity because of underestimation of transvalvular velocities.[73]

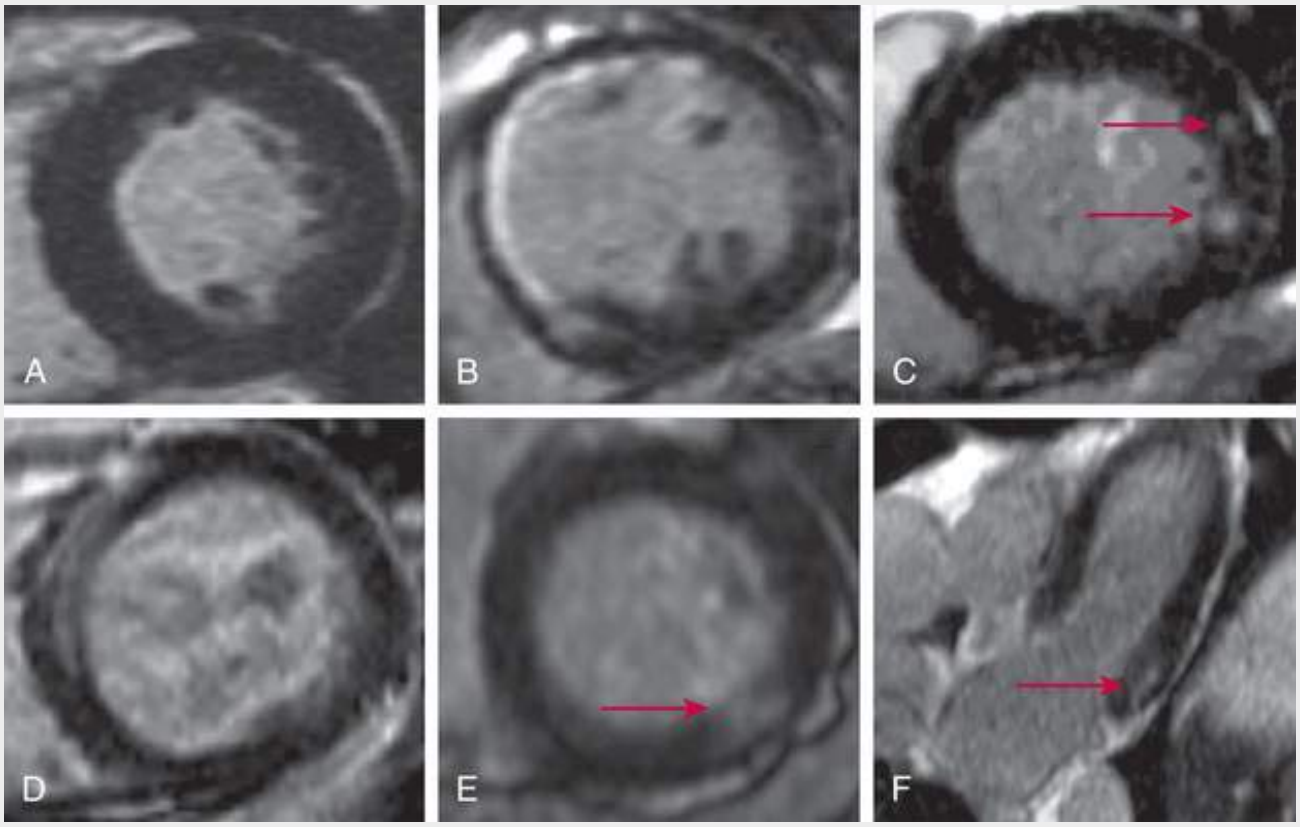

FIGURE 68.6 Cardiac magnetic resonance images showing different patterns of late gadolinium enhancement (LGE) observed in patients with aortic stenosis. **A,** No LGE. **B,** Infarct LGE with subendocardial pattern observed in septum and anterior wall. **C,** Two focal areas of midwall LGE in lateral wall of left ventricle (*red arrows*). **D,** Midwall LGE in a more linear pattern, affecting the septum. **E,** Short-axis view, and **F,** long-axis view, of midwall LGE (*red arrows*) of the inferolateral wall in the same patient. (Dweck MR, Joshi S, Murigu T, et al. Midwall fibrosis is an independent predictor of mortality in patients with aortic stenosis. J Am Coll Cardiol 2011;58:1271-9.)

Positron Emission Tomography (see Chapter 16).

Active uptake of ^{18}F–sodium fluoride in the aortic valve on positron emission tomography (PET) identifies active tissue calcification and predicts change in aortic valve calcification on follow-up CT 1 to 2 years later.[74-76] The new calcification is observed in a similar distribution as the baseline uptake of ^{18}F–sodium fluoride (**Fig. 68.7**). This may become a useful surrogate endpoint for trials testing therapies to slow the progression of calcific aortic valve disease, but further studies are needed.

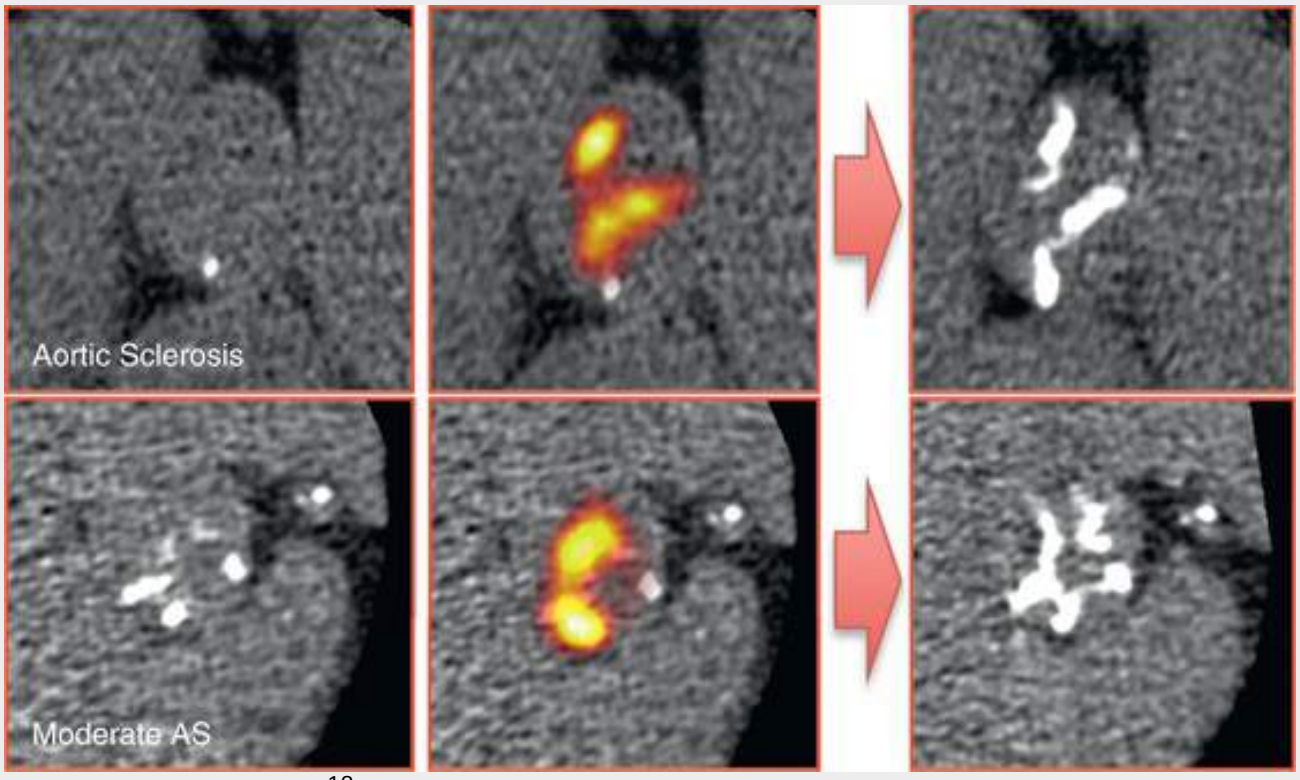

FIGURE 68.7 Valvular ^{18}F-fluoride uptake predicts the progression of calcification in aortic stenosis (AS). Two patients with calcific aortic valve disease. **Left,** Baseline computed tomography (CT) images. **Middle,** Fused positron emission tomography (PET)/CT images showing increased ^{18}F-fluoride valvular uptake (*red/yellow areas*). **Right,** Repeat CT scans after 2 years with new areas of macroscopic calcium (*white areas*) in a similar distribution to that of baseline PET uptake. (Jenkins WS, Vesey AT, Shah AS, et al. Valvular (18)F-fluoride and (18)F-fluorodeoxyglucose uptake predict disease progression and clinical outcome in patients with aortic stenosis. J Am Coll Cardiol 2015;66:1200-1.)

Disease Course

Asymptomatic Patients

The diagnosis of AS is most often made on auscultation of a murmur suggestive of AS, followed by confirmation with echocardiography. When AS is not severe and symptoms are absent, patients are reevaluated clinically and with echocardiography based on the AS severity. Generally, repeat imaging is performed every 6 to 12 months for severe AS, every 1 to 2 years for moderate AS, and every 3 to 5 years for mild AS, unless a change in signs or symptoms prompts repeat imaging sooner.[19,69]

The severity of outflow tract obstruction gradually increases over 10 to 15 years, so the clinical course includes a long latent period during which stenosis severity is only mild to moderate and clinical outcomes are similar to those for age-matched normal patients.[77,78] The rate of progression of AS is highly variable and difficult to predict. In clinical studies the factors associated with more rapid hemodynamic progression included older age, more severe leaflet calcification, renal insufficiency, hypertension, obesity, metabolic syndrome, smoking, hyperlipidemia, and elevated circulating levels of Lp(a) and increased activity of Lp-PLA_2.[4,13,14]

Of patients with mild valve thickening but no obstruction to outflow (e.g., aortic sclerosis), 16% will have valve obstruction at 1 year of follow-up, but only 2.5% will develop severe valve obstruction at an average of 8 years after the diagnosis of aortic sclerosis. Disease progression may be related to different factors than for initiation of disease.[79]

Once moderate to severe AS is present, prognosis remains excellent provided the patient remains

asymptomatic.[80] The progressive nature of the disease, however, warrants close follow-up. Although stenosis is on average more severe in symptomatic than in asymptomatic patients, marked overlap is evident in all measures of severity between these two groups. Prospective studies evaluating the rate of progression to symptomatic AS in initially asymptomatic patients are summarized in **eTable 68.1**. The strongest predictor of progression to symptoms is the Doppler aortic jet velocity.[20,81,82] Survival free of symptoms is 84% at 2 years when aortic velocity is less than 3 m/sec, compared with only 21% when velocity is greater than 4 m/sec (**Fig. 68.8**). In adults with severe AS (Doppler velocity >4 m/sec), outcome can be further predicted by the magnitude of the Doppler velocity (**Fig. 68.8B**), as well as by the severity of aortic valve calcification.[63,83,84] In such studies, most events consisted of the development of symptoms prompting AVR and not sudden death in otherwise asymptomatic patients. However, retrospective studies have reported some cases of sudden death in apparently asymptomatic adults with severe AS. A prospective observational study of initially asymptomatic Japanese patients with severe AS compared outcome in those who underwent early surgery versus a "watchful waiting" strategy.[85] With propensity matching to adjust for baseline differences between the two groups, the survival rate was significantly higher in the 291 patients with early surgery compared to the 291 initially followed conservatively. However, it is noteworthy that 31% of patients in the conservative group who developed symptoms did not undergo AVR, and this accounted for 17% of the deaths during "watchful waiting." Thus the role of early surgical intervention in asymptomatic patients remains unresolved and can only be determined with a prospective randomized controlled trial (RCT).

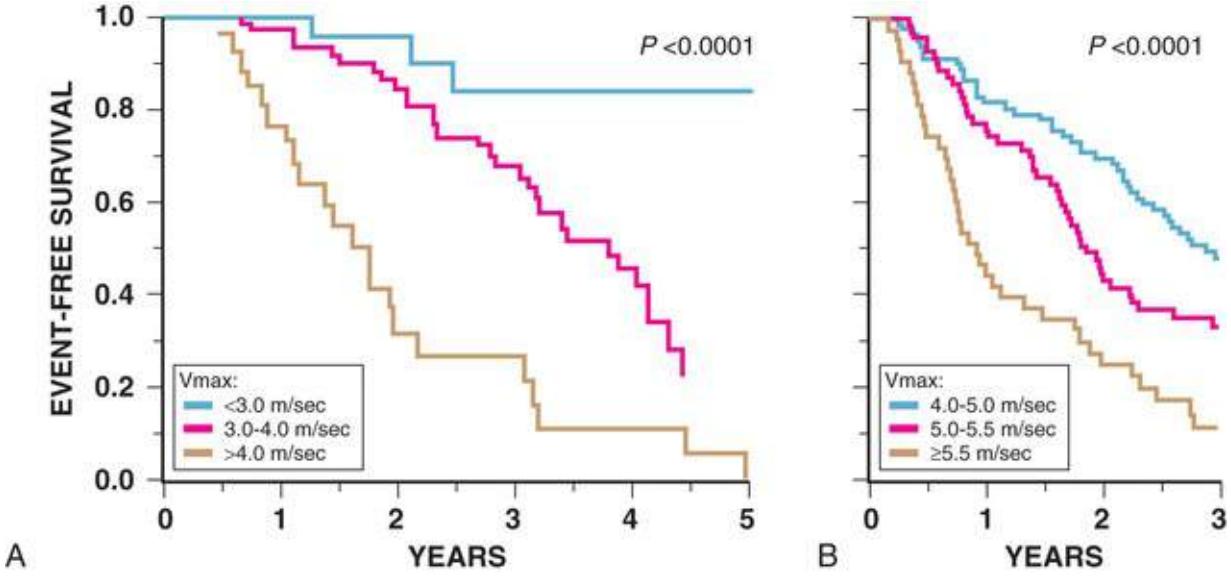

FIGURE 68.8 **A,** Natural history as reflected by event-free survival in asymptomatic patients with aortic stenosis. Initial peak aortic jet velocity (Vmax) stratifies patients according to the likelihood that symptoms requiring valve replacement will develop over time. **B,** Outcomes with very severe AS. Kaplan-Meier event-free survival rate for patients with Vmax of 4.0 m/sec or greater. In both **A** and **B,** most "events" consisted of the onset of symptoms warranting aortic valve replacement. Because of the variability in hemodynamic severity at symptom onset, and because many patients fail to recognize symptom onset resulting from the insidious rate of disease progression, both exercise testing and serum B-type natriuretic peptide (BNP) levels have been evaluated as measures of disease progression and predictors of symptom onset. Exercise testing monitored by a physician is safe in adults with severe AS when symptom status is unclear, and patients who develop symptoms or exhibit a decrease in blood pressure with exertion should be considered to have symptomatic disease.[65] An elevated BNP level may be helpful when symptoms are equivocal or when stenosis severity is only moderate, but the role of BNP monitoring in the evaluation of disease progression has not been fully defined.[86] **Table 68.3** lists other factors that are useful for risk stratification to predict symptom onset and event-free survival.

TABLE 68.3

Risk Stratification of Patients with Severe Aortic Stenosis (AS)

ASYMPTOMATIC PATIENTS*	SYMPTOMATIC PATIENTS†
Abnormal exercise test	Lack of contractile reserve in patients with low-flow, low-gradient, low-EF AS
Elevated BNP	Very low mean gradient (<20 mm Hg)
Moderate to severe valve calcification	Very elevated BNP
Very high aortic velocity (>5 or 5.5 m/sec)	Severe ventricular fibrosis
Rapid increase in aortic velocity	O_2-dependent lung disease
Increased hypertrophic LV remodeling	Frailty
Reduced LV longitudinal systolic strain	Advanced renal dysfunction
Myocardial fibrosis	Very high STS score
Pulmonary hypertension	

*Markers of increased rate of disease progression and/or decreased event-free survival.

†Markers of increased risk and/or potential futility.

BNP, Brain (B-type) natriuretic peptide; *EF,* ejection fraction; *LV,* left ventricular; *STS,* Society of Thoracic Surgeons.

Symptomatic Patients

Once even mild symptoms are present, survival is poor unless outflow obstruction is relieved. Expected survival for patients with severe symptomatic AS will differ somewhat based on the age, number of comorbidities, and severity of HF of the cohort examined, but average survival without AVR is only 1 to 3 years after symptom onset.[87,88] In the PARTNER (Placement of Transcatheter Aortic Valves) study, outcomes were very poor for patients with severe symptomatic AS deemed unsuitable candidates for surgery who were randomly assigned to conventional therapy (e.g., medical therapy without transcatheter AVR), with a 1-year mortality of 50.9% and a 2-year mortality of 68%.[88,89] Among symptomatic patients with severe AS, the outlook is poorest when the left ventricle has failed and the cardiac output and transvalvular gradient are both low. The risk of sudden death is high with symptomatic severe AS, so these patients should be promptly referred for AVR. In patients who do not undergo AVR, recurrent hospitalizations for angina and decompensated HF are common, associated with significant consumption of health care resources.[90]

Classification of Severe Aortic Stenosis.

Severe AS is defined as AVA of 1.0 cm^2 or greater, mean gradient of 40 mm Hg or higher, or a peak jet velocity of 4 m/sec or more (**see Table 68.2**). When aortic velocity or gradient meet this criteria, severe AS is present and classified as stage C in asymptomatic patients and stage D1 in symptomatic patients. Classification of stenosis severity is more complex when AVA is 1.0 cm^2 or less, but mean pressure gradient is less than 40 mm Hg and peak jet velocity less than 4 m/sec. Many patients with these apparently "discordant" data have moderate AS. However, it is important to consider the diagnosis of low-gradient severe AS, particularly if symptoms consistent with AS are present. First, measurement errors should be excluded, particularly an undermeasured LV outflow tract dimension, since this will yield a calculated AVA that is smaller than the actual AVA (**see Chapter 14**). Indexing AVA for body size may be helpful in small patients but is not recommended in normal-size and larger adults. The next steps are to measure LVEF and stroke volume, evaluate valve anatomy and degree of leaflet calcification, and then consider further testing.

Severe Low-Flow, Low-Gradient Aortic Stenosis with Reduced LVEF.

Classic low-flow, low-gradient AS (stage D2) is defined as AVA of 1.0 cm^2 or less with an aortic velocity less than 4.0 m/sec or mean gradient less than 40 mm Hg, and LVEF less than 50% (**see Table 68.2**). Patients with HF symptoms and stage D2 AS often create a diagnostic dilemma for the clinician because their clinical presentation and hemodynamic data may be indistinguishable from those of patients with a dilated cardiomyopathy and a calcified valve that is not severely stenotic.[91,92] Severe AS can be distinguished from moderate AS with primary LV dysfunction based on the changes in valve hemodynamics during transient increases in flow, usually by increasing cardiac output with dobutamine[92,93] (**see Chapter 14**). Severe AS is present if there is an increase in aortic velocity to at least 4 m/sec at any flow rate, with AVA that remains less than 1.0 cm^2.[58] Dobutamine echocardiography also provides evidence of myocardial contractile reserve (increase in stroke volume >20% from baseline), which is an important predictor of operative risk and survival after AVR in these patients.[92,94-96] However, even in patients with a lack of contractile reserve, AVR should be considered if the mean gradient is greater than 20 mm Hg, because survival after AVR is better (approximately 50% at 5 years) than with medical therapy.[96,97] In those without contractile reserve, the projected AVA at a transvalvular flow rate of 250 mL/sec, or cardiac CT to assess valve calcification, may be useful to improve discrimination between truly severe AS versus moderate AS with myocardial dysfunction.[95]

Severe Low-Flow, Low-Gradient Aortic Stenosis with Preserved LVEF.

Low-flow, low-gradient AS also can occur with a normal LVEF (≥50%) (**see Table 68.2**), typically in elderly patients with a small, hypertrophied left ventricle or those with concurrent hypertension. This is often referred to as "paradoxical" low-flow, low-gradient AS (ACC/AHA stage D3; AVA ≤1.0 cm^2 with aortic velocity <4.0 m/sec or mean gradient <40 mm Hg, and LVEF ≥50%) because despite a normal EF, transaortic flow is low (stroke volume index <35 mL/m^2).[19,98] Distinguishing truly severe AS from moderate AS can be challenging. Measurement errors should be ruled out and small body size accounted for (an indexed AVA ≤0.6 cm^2/m^2 is consistent with severe AS). Dobutamine has been used to augment flow to distinguish truly severe AS from pseudosevere AS, but is less preferred in these patients with a hypertrophied ventricle, small LV cavity, and marked diastolic dysfunction.[99] Evaluation of valve hemodynamics after the treatment of hypertension can be helpful and, increasingly, CT assessment of valve calcification is being used to identify patients with a severely calcified valve.[64,66]

Treatment

Medical Management

Medical therapy has not been shown to affect disease progression in patients with AS.[4,7,20] Furthermore, both observational studies and RCTs convincingly demonstrate that AVR is superior to medical therapy in patients with severe symptomatic AS.[88,100] The risk of sudden death increases dramatically once symptoms are present, and patients should be advised to report promptly the development of any symptoms possibly related to AS. In asymptomatic patients with AS of any degree, evaluation and treatment for conventional cardiovascular risk factors is recommended in accordance with established guidelines (**see Chap. 45**).

Hypertension accompanies AS in a majority of patients.[101] Because of traditional teaching that AS is a disease with fixed afterload, there has often been reluctance to treat hypertension because of concerns that vasodilation would not be offset by an increase in stroke volume. However, several studies have demonstrated that vasodilation is accompanied by increases in stroke volume, even in patients with severe AS[47] (see Classic References, Khot). Hypertension imposes an additional load on the left ventricle and is associated with more adverse hypertrophic LV remodeling.[53] Although treatment of hypertension may not reduce AS-related events, it should be treated according to established guidelines (**see Chapter 47**) because of the known adverse association between hypertension and vascular events and mortality.[53,54] There is no one class of medicines established as the preferred treatment of hypertension in patients with AS, but because the renin-angiotensin system is upregulated in the valve and ventricle of patients with AS, angiotensin-converting-enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) may preferentially considered. Small studies have demonstrated their safety, and some suggest a clinical benefit, but larger-scale randomized studies are needed.[20]

The presence of concomitant CAD is related to the patient's age but is common in patients with AS. Primary and secondary prevention guidelines should be followed and the decision of whether to prescribe a statin medication should not be influenced by the presence of AS. RCTs testing the use of statins in patients with mild AS to more advanced disease were adequately powered and showed no improvement in mortality, time to AVR, or rate of AS progression in the treatment versus placebo groups.[102]

Atrial fibrillation (AF) or atrial flutter may also develop in up to one third of older patients with AS, perhaps exacerbated by left atrial enlargement related to diastolic dysfunction. When such an arrhythmia is observed in a patient with AS, the possibility of associated mitral valvular disease should be considered. When AF occurs, the rapid ventricular rate may cause angina pectoris. The loss of the atrial contribution to LV filling and a sudden fall in cardiac output may cause serious hypotension. If this occurs, AF should be treated promptly, usually with cardioversion. New-onset AF in a previously asymptomatic patient with severe AS may be a marker of impending symptom onset.[103]

In patients with heart failure (HF) and volume overload, AVR is indicated, but diuretics may reduce congestion and provide some symptomatic relief prior to valve replacement. Patients with decompensated HF may benefit from medical therapy as a bridge to definitive therapy with valve replacement. Nitroprusside has been used during hemodynamic monitoring in the intensive care unit to unload the left heart, reduce congestion, and improve forward flow. Similarly, phosphodiesterase type 5 inhibition has been shown to provide acute improvements in pulmonary and systemic hemodynamics resulting in biventricular unloading.[47] These medications may improve the patient's hemodynamic status, allowing the AVR procedure to be performed more safely.

Balloon Aortic Valvuloplasty

AVR is the procedure of choice for relief of outflow obstruction in adults with valvular AS. Balloon aortic valvuloplasty has only a modest hemodynamic effect in patients with calcific AS. It can provide

short-term improvement in survival and quality of life, but these benefits are not sustained.[104] Accordingly, balloon aortic valvuloplasty is not recommended as an alternate to valve replacement for calcific AS. In selected cases, it might be reasonable as a bridge to definitive treatment with AVR in unstable patients or as a palliative procedure in patients who are not candidates for AVR.[105]

Aortic Valve Replacement

AVR is recommended for adults with symptomatic severe AS, even if symptoms are mild (**Fig. 68.9**). Despite this clear guideline recommendation,[19,69] many patients with symptomatic AS are not referred appropriately for surgery, even when the operative risk is low.[87] AVR also is recommended for severe AS with a LVEF less than 50% and for patients with severe asymptomatic AS who are undergoing coronary bypass grafting (CABG) or other forms of heart surgery.[19,20,69] In addition, AVR is appropriate for apparently asymptomatic patients with severe AS when exercise testing provokes symptoms or a fall in BP. Outcomes are similar in patients with mixed AS and AR, and standard criteria for intervention are applicable in this patient group.[106,107] In asymptomatic patients with severe AS and a low operative risk, AVR may be considered when markers of rapid disease progression are present (e.g., severe valve calcification) or when AS is very severe, depending on patient preferences regarding the risk of earlier intervention versus careful monitoring with intervention promptly at symptom onset. Once a decision is made that AVR is indicated, a surgical approach or transcatheter approach may be considered (**see Fig. 68.9**).[108]

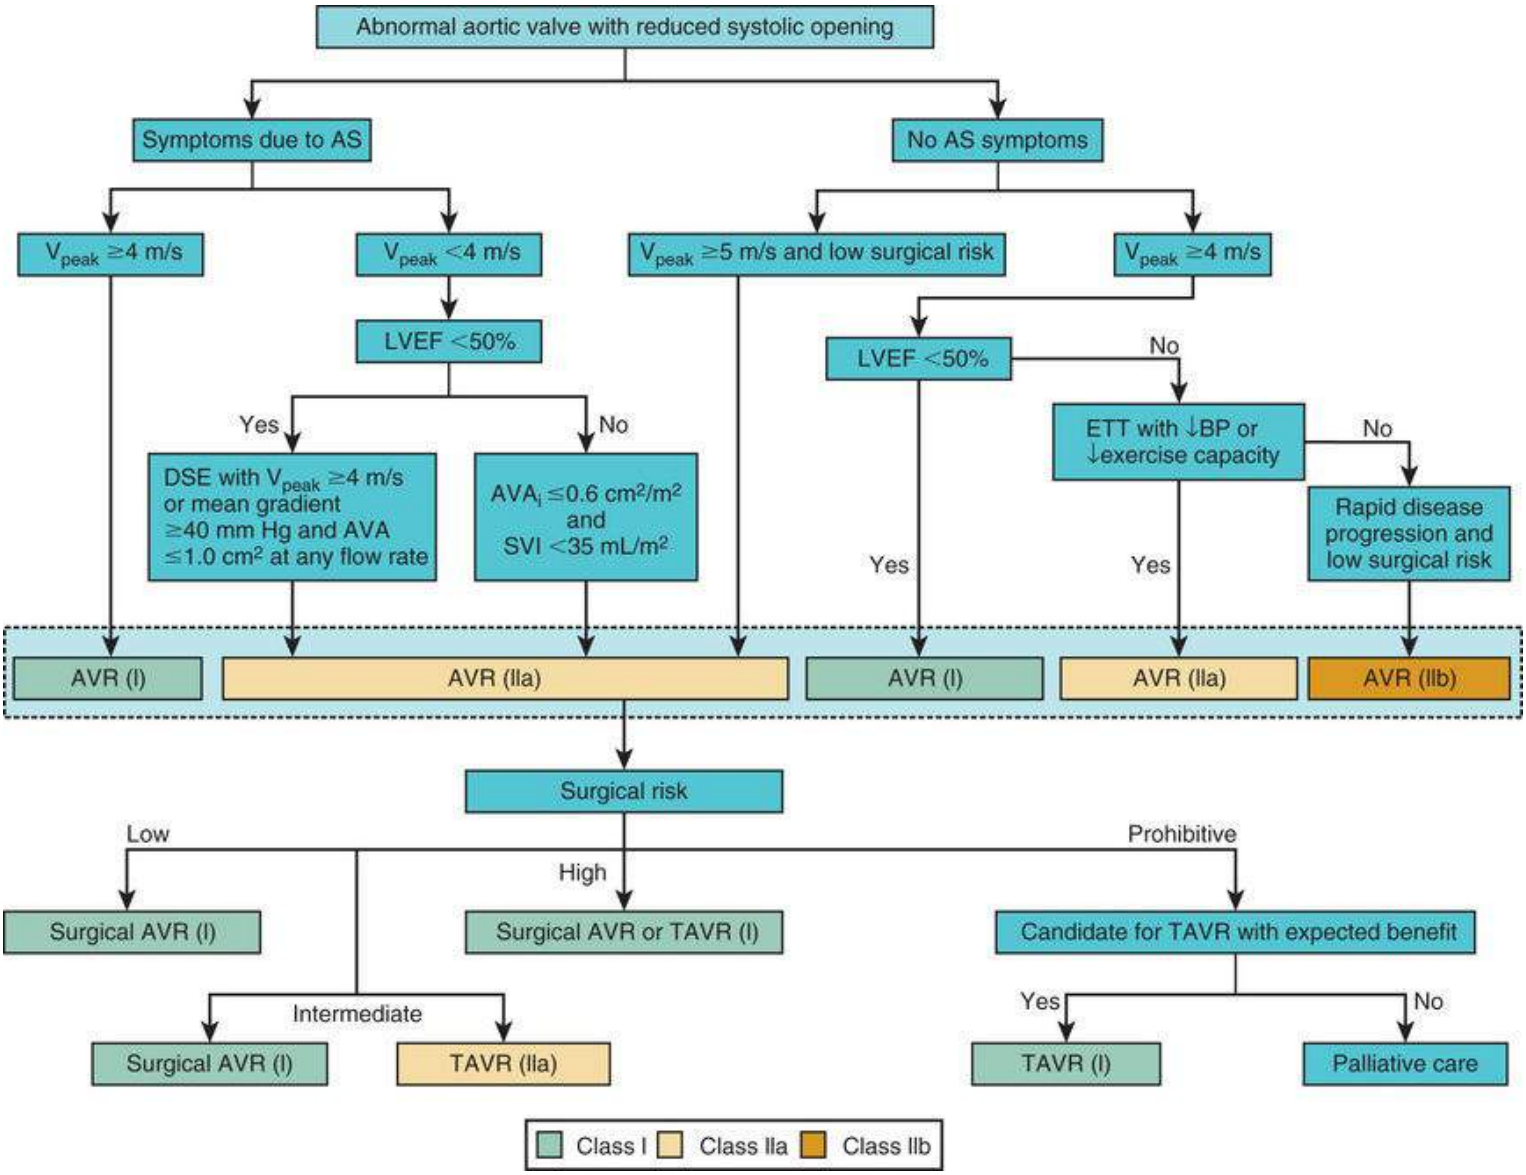

FIGURE 68.9 Algorithm for management of aortic stenosis (AS) recommended by 2014 American College of Cardiology/American Heart Association guidelines for indications for aortic valve replacement (AVR) for severe AS, including the 2017 update for considerations for surgical AVR and transcatheter AVR (TAVR). AVA, Aortic valve area; AVAi, AVA indexed for body surface area; BP, blood pressure; DSE, dobutamine stress echocardiography; ETT, exercise treadmill test; LVEF, left ventricular ejection fraction; SVI, stroke volume index; V_{peak}, peak aortic jet velocity. (Modified from Lindman BR, Clavel M-A, Mathieu P, et al. Calcific aortic stenosis. Nat Rev Dis Primers 2016;2:16006.)

After AVR, symptoms of pulmonary congestion (exertional dyspnea) and myocardial ischemia (angina pectoris) are relieved in almost all patients, and most patients will exhibit an improvement in exercise tolerance, even if it was only mildly reduced before surgery. A reduced EF often improves and even normalizes after AVR, but impaired longitudinal strain may still be evident.[109] LV hypertrophy tends to regress after AVR, but the rate and extent of reversal varies and is often incomplete. Myocardial fibrosis regresses more slowly than myocyte hypertrophy, and thus diastolic dysfunction may improve but still persist for years after successful valve replacement.

Surgical Aortic Valve Replacement

Since the first successful surgical AVR (SAVR) in 1960, improvements in valve design, surgical techniques, and perioperative management have decreased surgical morbidity and mortality despite the increasing age and comorbidities of patients treated. The Society of Thoracic Surgeons (STS) National Database Committee reported an overall operative mortality rate of 3.2% in 67,292 patients undergoing

isolated AVR and 5.6% in 66,074 patients undergoing AVR and CABG.[110-112] In patients younger than 70 with minimal comorbidities, the operative risk of mortality is less than 1% in many centers. Medicare data from the past decade indicate that the 30-day mortality after surgical AVR in patients age 65 and older in the United States has decreased, from 7.6% in 1999 to 4.2% in 2011, with the most marked decrease in patients age 85 and older, in whom the 30-day mortality has decreased from 12.3% to 5.8%.[113] Therefore, advanced age should not be considered a contraindication to operation.[114] The 30-day mortality rate also is significantly related to the number of AVR procedures performed at each hospital. Risk factors associated with a higher mortality rate include a high New York Heart Association (NYHA) functional class, impaired LV function, advanced age, the presence of associated CAD, and other comorbidities.[115-118]

Transcatheter Aortic Valve Replacement

Over the last decade, transcatheter AVR (TAVR) has transformed the treatment of patients with calcific AS.[119] First, it was shown to be superior to medical therapy (usually accompanied by balloon aortic valvuloplasty) in patients who were not candidates for surgery.[88-100] Subsequently, in patients deemed high risk for surgery, TAVR was shown to be noninferior and perhaps superior to SAVR.[120-122] More recently, in intermediate-risk patients, TAVR has been shown to compare favorably to SAVR.[123-125] Randomized trials are ongoing to compare TAVR and SAVR in low-risk patients. The most common approach to valve implantation is *transfemoral*, particularly as sheath size progressively decreases. The long-term durability of transcatheter valves remains to be determined, which is particularly relevant as we move toward treating younger, lower-risk patients (**see Chapter 72**).

Patient Selection for TAVR or SAVR.

The choice of SAVR versus TAVR should come after a decision that AVR is indicated (**see Fig. 68.9**).[108] Given the complexity of issues to consider, it is recommended that these decisions occur through a heart valve team of cardiac surgeons, interventional cardiologists, clinical and imaging experts in valve disease, as well as nurses, anesthetists, and geriatricians as needed.[126] The overall procedural risk for the patient for SAVR or TAVR depends on multiple factors, including age, comorbidities, frailty, LV function, and anatomic issues (**Table 68.4**). The landscape for these decision pathways is rapidly changing as successive trials are reported (**see Chapter 72**). Currently, TAVR is approved in the United States for patients at extreme, high, or intermediate risk for surgery, as reflected in the 2017 update of the American College of Cardiology/American Heart Association (ACC/AHA) guidelines for the management of patients with valvular heart disease;[127] results from low-risk trials are anticipated in the next few years. In a novel approach to developing a clinical practice guideline, recommendations were recently provided for transcatheter versus surgical valve replacement[128-131] (**Fig. 68.10**). For patients at higher risk, the potential benefit versus futility of TAVR needs careful consideration[132] (**Fig. 68.11**). Although TAVR reduces mortality compared to medical therapy, a sizable subgroup of patients dies soon after TAVR or has no improvement in their quality of life.[133] If poor health status is driven more by comorbidities and frailty than by symptomatic AS, AVR may yield no clinical benefit, and palliative care should be considered.

TABLE 68.4

Factors to Consider for Patient Selection for Transcatheter versus Surgical Aortic Valve Replacement

Age (both in terms of procedural risk and anticipated postprocedure survival with implanted prosthesis)
Left ventricular function
Valve anatomy (bicuspid versus tricuspid)
Number of comorbidities
Pulmonary function
Renal function
Liver function
Frailty
Disability
Anatomy (e.g., porcelain aorta, septal bulge, femoral vessel size, aortic atheroma, “hostile chest,” graft anatomy)
Coronary disease: need for revascularization, optimal strategy
Concomitant significant mitral or tricuspid valve disease and likelihood of improvement if only aortic stenosis is treated
Likelihood of particular complications (e.g., paravalvular leak, coronary obstruction, heart block, stroke, acute kidney injury)

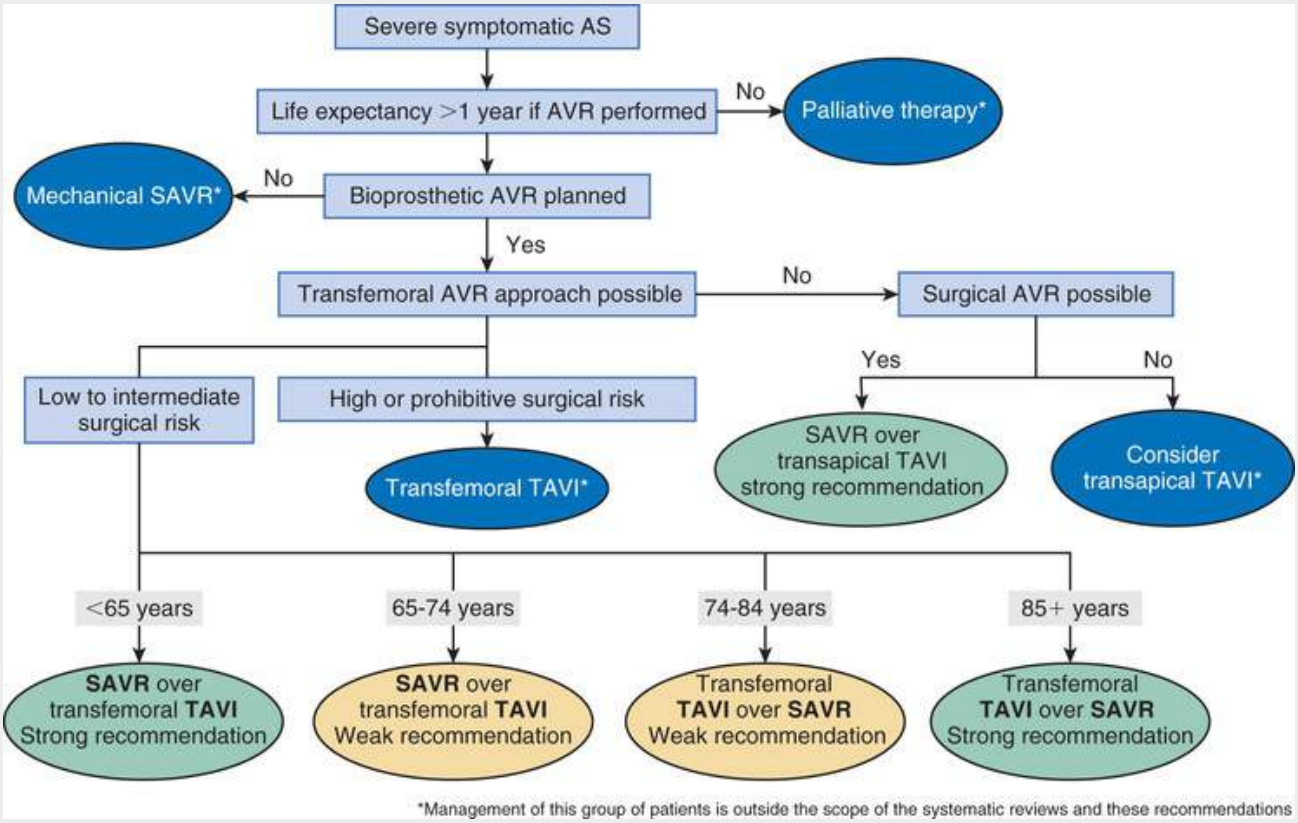

FIGURE 68.10 Algorithm for management of severe aortic stenosis (AS). *Colored boxes* represent the recommendations covered by this study. AVR, Aortic valve replacement; SAVR, surgical aortic valve replacement; TAVI, transcatheter aortic valve insertion. (From Vandvik PO, Otto CM, Siemieniuk RA, et al. Transcatheter or surgical aortic valve replacement for patients with severe, symptomatic, aortic stenosis at low to intermediate surgical risk: a clinical practice guideline. BMJ 2016;354:i5085.)

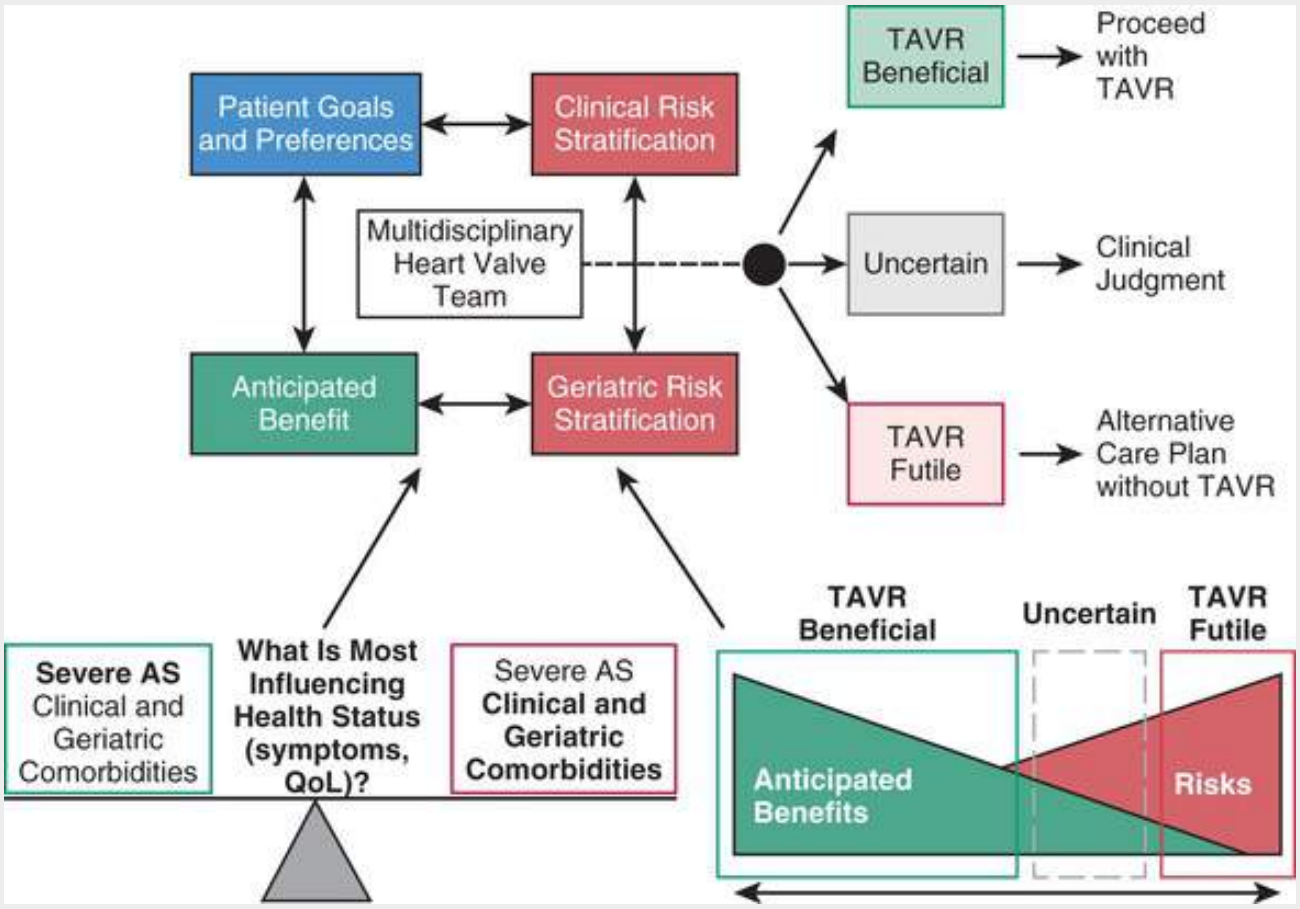

FIGURE 68.11 Decision making by multidisciplinary heart valve team on patients referred for transcatheter aortic valve replacement (TAVR). The team considers and weighs the various factors shown and makes a decision regarding whether TAVR will likely be beneficial or futile. Areas of uncertainty require clinical judgment. The factors thought most to influence the patient's current health status affect assessment of the anticipated benefit of TAVR. Anticipated benefits or risks may clearly outweigh each other, but in some cases, there is uncertainty when patient goals and preferences are especially important to incorporate into decision making regarding whether to perform TAVR. AS, Aortic stenosis; QoL, quality of life. (From Lindman BR, Alexander KP, O'Gara PT, Afilalo J. Futility, benefit, and transcatheter aortic valve replacement. JACC Cardiovasc Interv 2014;7:707-16.)

Aortic Regurgitation

Causes and Pathology

Aortic regurgitation may be caused by primary disease of the aortic valve leaflets and/or the wall of the aortic root[106] (**Fig. 68.12**). Among patients with isolated AR who undergo AVR, the percentage with aortic root disease has been increasing steadily during the past few decades; it now represents the most common cause and accounts for more than 50% of all such patients in some series.

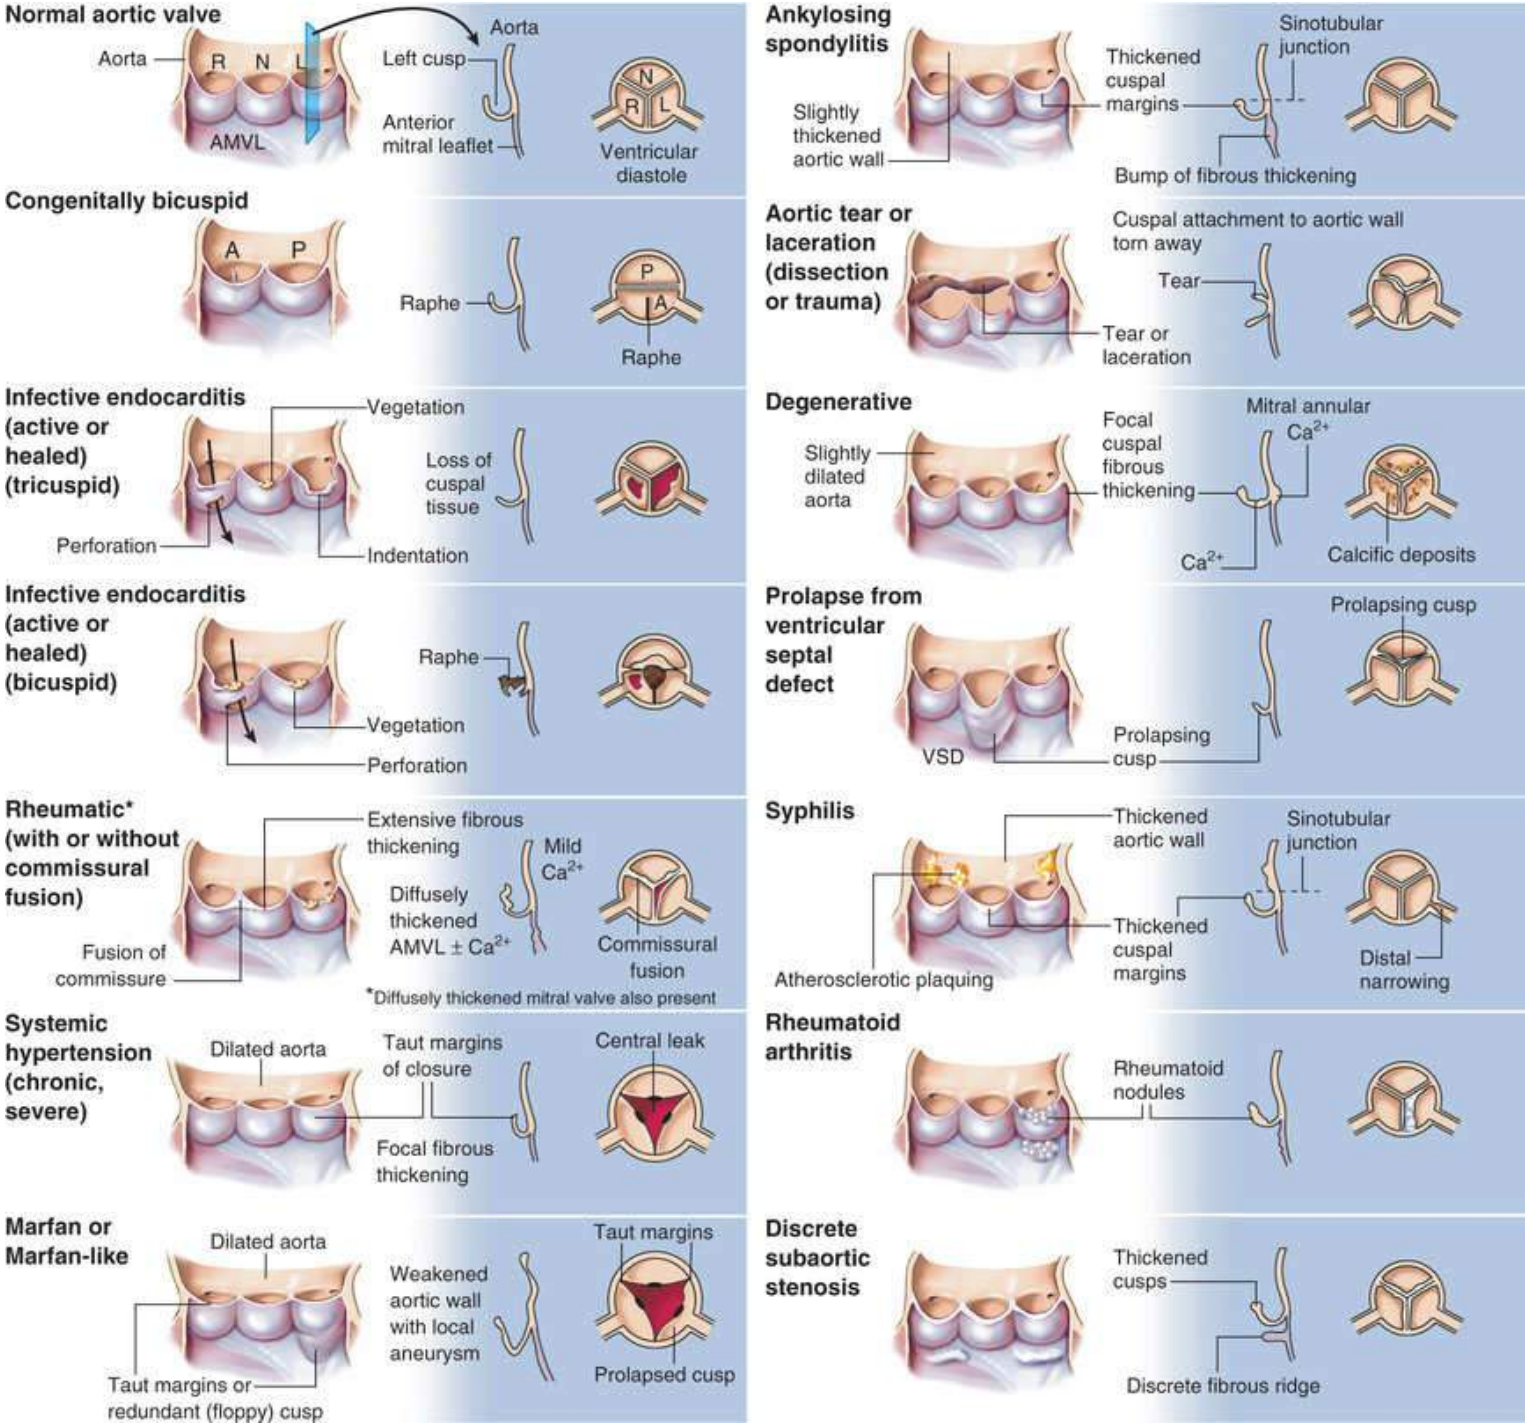

FIGURE 68.12 Diagram of various causes of pure aortic regurgitation. *A,* Anterior; *AMVL,* anterior mitral valve leaflet; *Ca^{2+},* calcification; *L,* left coronary cusp; *N,* noncoronary cusp; *P,* posterior; *R,* right coronary cusp; *VSD,* ventricular septal defect. (From Waller BF. Rheumatic and nonrheumatic conditions producing valvular heart disease. Cardiovasc Clin 1986;16:30.)

Valvular Disease

Primary valvular causes of AR include (1) calcific AS in older patients, who have some degree (usually mild) of AR (75% of patients); (2) infective endocarditis (**see Chapter 73**), in which the infection may destroy or cause perforation of a leaflet, or the vegetations may interfere with proper coaptation of the cusps; and (3) trauma that results in a tear of the ascending aorta, in which loss of commissural support can cause prolapse of an aortic cusp. Although the most common complication of a congenitally bicuspid valve in adults is stenosis, incomplete closure or prolapse of a bicuspid valve may also cause isolated AR or a combination of AS and AR.[5] Rheumatic fever remains a common cause of AR worldwide. The

cusps become infiltrated with fibrous tissue and retract, which prevents cusp apposition during diastole; this usually leads to AR through a defect in the center of the valve (**see Fig. 68.1C**). The associated fusion of the commissures may restrict the opening of the valve, resulting in combined AS and AR; associated mitral valve involvement is also common (**see Chapter 74**). Progressive AR may occur in patients with a large ventricular septal defect, as well as in patients with membranous subaortic stenosis (**see Chapter 75**), and as a complication of percutaneous balloon aortic valvuloplasty. Progressive AR also may occur in patients with myxomatous proliferation of the aortic valve. An increasingly common cause of valvular AR is structural deterioration of a bioprosthetic valve (**see Chapter 71**).

Less common valvular causes of AR include various forms of congenital AR, such as unicommissural and quadricuspid valves, or rupture of a congenitally fenestrated valve, particularly in the presence of hypertension. Other, less common causes of AR occur in association with systemic lupus erythematosus, rheumatoid arthritis, ankylosing spondylitis, Jaccoud arthropathy, Takayasu disease, Whipple disease, Crohn disease, and in the past the use of certain anorectic drugs. Isolated congenital AR is an uncommon lesion on necropsy studies but, when present, is usually associated with a bicuspid valve.

Aortic Root Disease

Aortic regurgitation secondary to marked dilation of the ascending aorta is now more common than primary valve disease in patients undergoing AVR for isolated AR[134] (**see Chapter 63**). The conditions responsible for aortic root disease include age-related (degenerative) aortic dilation, cystic medial necrosis of the aorta (either isolated or associated with classic Marfan syndrome), aortic dilation related to bicuspid valves,[5] aortic dissection, osteogenesis imperfecta, syphilitic aortitis, ankylosing spondylitis, Behçet syndrome, psoriatic arthritis, arthritis associated with ulcerative colitis, relapsing polychondritis, reactive arthritis, giant cell arteritis, and systemic hypertension, as well as exposure to some appetite-suppressant drugs.

When the aortic annulus becomes greatly dilated, the aortic leaflets separate and AR may ensue. Dissection of the diseased aortic wall may occur and aggravate the AR. Dilation of the aortic root also may have secondary effects on the aortic valve because dilation causes tension and bowing of the individual cusps, which may thicken and retract. This defect leads to intensification of the AR, further dilating the ascending aorta and leading to a vicious cycle in which, as for MR, more regurgitation leads to more regurgitation (**see Chapter 69**).

Pathophysiology of Chronic Aortic Regurgitation

Left Ventricular Remodeling and Function.

In contrast to MR, in which a fraction of the LV stroke volume is ejected into the low-pressure left atrium, in AR the entire LV stroke volume is ejected into a high-pressure chamber (i.e., the aorta), although the low aortic diastolic pressure does facilitate ventricular emptying during early systole (**Fig. 68.13**). In MR, especially acute MR, the reduction of wall tension (i.e., reduced afterload) allows more complete systolic emptying; in AR, the increase in LV end-diastolic volume (i.e., increased preload) provides hemodynamic compensation.

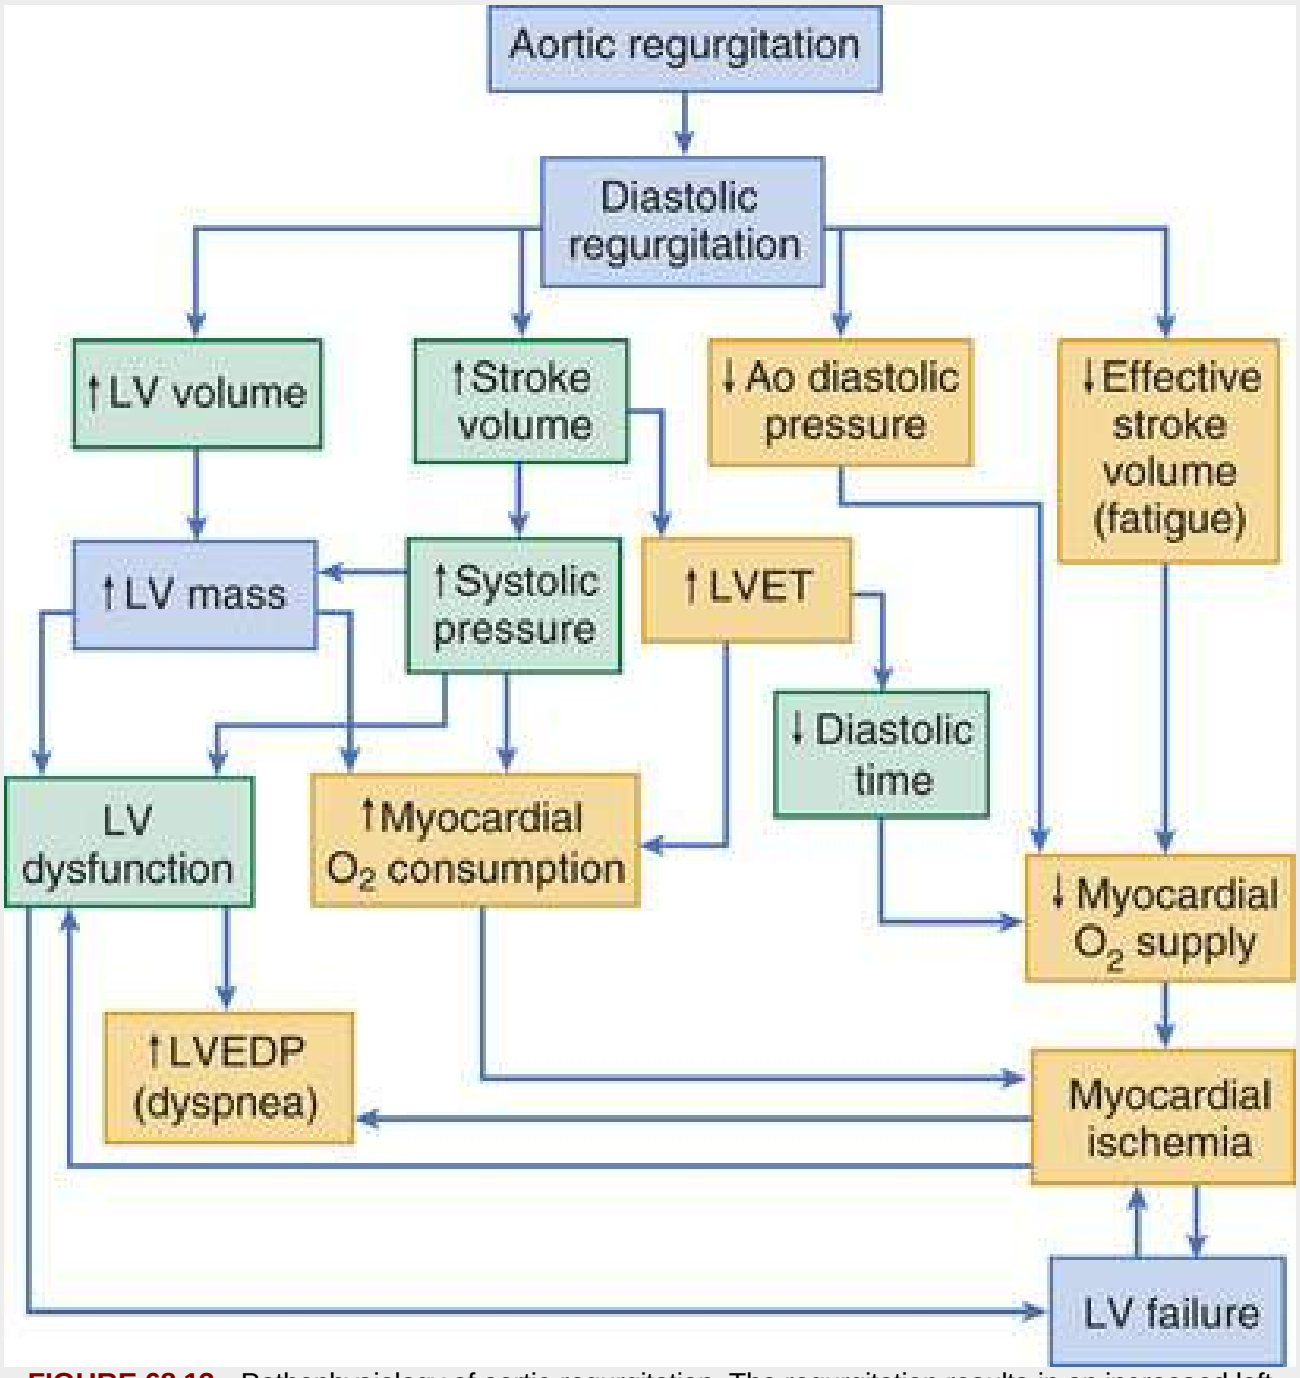

FIGURE 68.13 Pathophysiology of aortic regurgitation. The regurgitation results in an increased left ventricular (LV) volume, increased stroke volume, increased aortic (Ao) systolic pressure, and decreased effective stroke volume. Increased LV volume results in an increased LV mass, which may lead to LV dysfunction and failure. Increased LV stroke volume increases systolic pressure and prolongation of LV ejection time (LVET). Increased LV systolic pressure results in a decrease in diastolic time. Decreased diastolic time (myocardial perfusion time), diastolic aortic pressure, and effective stroke volume lead to reduced myocardial O_2 supply. Increased myocardial O_2 consumption and decreased myocardial O_2 supply produce myocardial ischemia, which further impairs LV function. LVEDP, LV end-diastolic pressure. (From Boudoulas H, Gravanis MB: Valvular heart disease. In Gravanis MB, editor. Cardiovascular Disorders: Pathogenesis and Pathophysiology. St Louis: Mosby; 1993, p 64.)

Severe AR may occur with a normal effective forward stroke volume and a normal LVEF (forward + regurgitant stroke volume/end-diastolic volume), together with an elevated LV end-diastolic volume, pressure, and stress[106] (**Fig. 68.14**). In accord with Laplace law—wall tension is related to the product of the intraventricular pressure and radius divided by wall thickness (**see Chapter 22**)—LV dilation also increases the LV systolic tension required to develop any level of systolic pressure. Thus, in AR, there is an increase in both preload and afterload. LV systolic function is maintained through the combination of chamber dilation and hypertrophy. This leads to eccentric hypertrophy, with replication of sarcomeres in

series and elongation of myocytes and myocardial fibers (see Classic References, Grossman). In compensated AR, sufficient wall thickening results in a normal ratio of LV wall thickness to cavity radius. Under these conditions, end-diastolic wall stress is maintained at or returns to normal levels. In AS, by contrast, changes include pressure overload (concentric) hypertrophy with replication of sarcomeres, largely in parallel, and an increased ratio of wall thickness to radius, but in both AR and AS, an increase in interstitial connective tissue develops. In AR, LV mass usually is greatly increased, often to levels even higher than in isolated AS. As AR persists and increases in severity over time, however, wall thickening fails to keep pace with the hemodynamic load, and end-systolic wall stress rises. At this point, the afterload mismatch results in a decline in systolic function, and the LVEF falls (**see Fig. 68.14**).

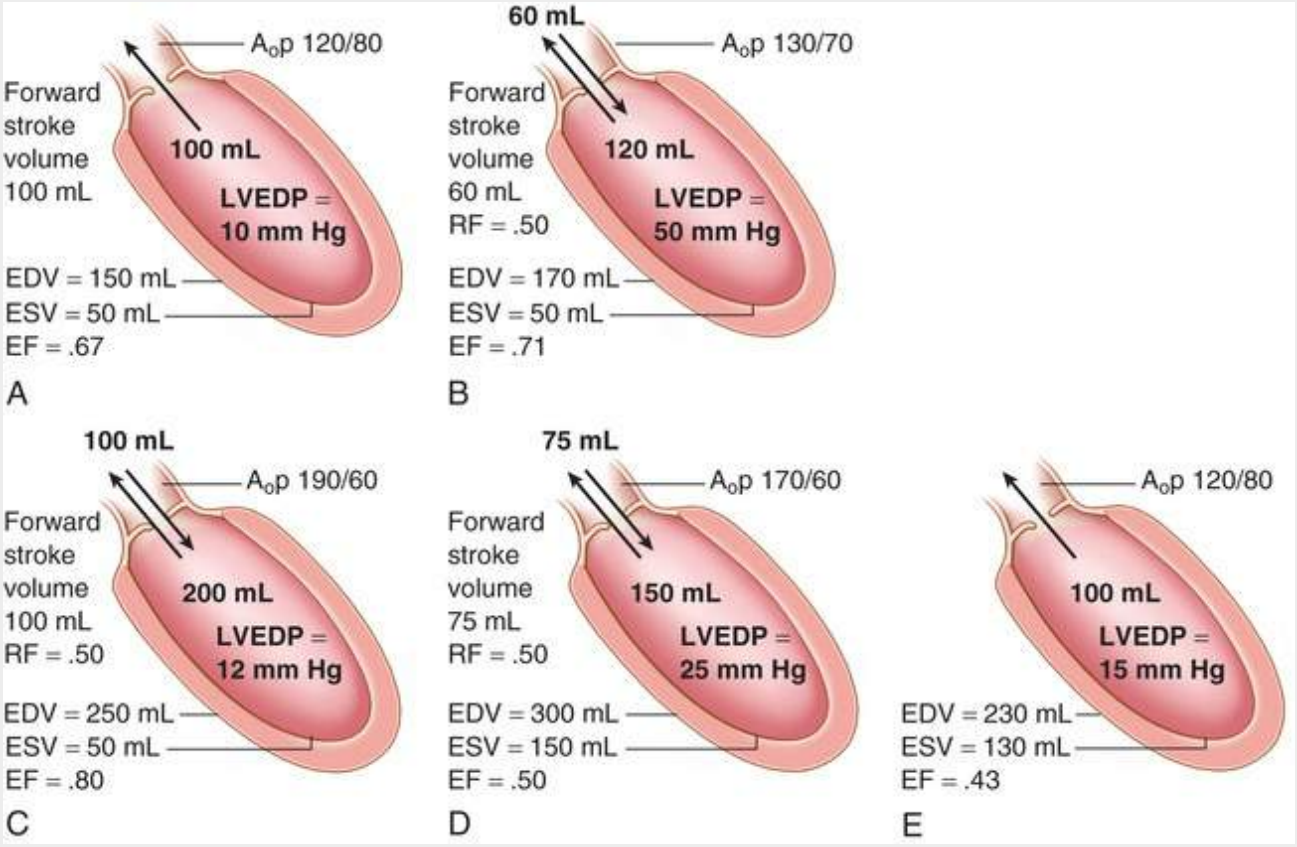

FIGURE 68.14 Hemodynamics of aortic regurgitation (AR). **A,** Normal conditions. **B,** The hemodynamic changes that occur in severe acute AR. Although total stroke volume is increased, forward stroke volume is reduced. Left ventricular end-diastolic pressure (LVEDP) rises dramatically. **C,** Hemodynamic changes occurring in chronic compensated AR. Eccentric hypertrophy produces increased end-diastolic volume (EDV), which permits an increase in total, as well as forward, stroke volume. The volume overload is accommodated, and LV filling pressure is normalized. Ventricular emptying and end-systolic volume (ESV) remain normal. **D,** In chronic decompensated AR, impaired LV emptying produces an increase in ESV and a fall in ejection fraction (EF), total stroke volume, and forward stroke volume. Further cardiac dilation and reelevation of LV filling pressure occur. **E,** Immediately after valve replacement, preload estimated by EDV decreases, as does filling pressure. ESV also is decreased, but to a lesser extent. The result is an initial fall in EF. Despite these changes, elimination of AR leads to an increase in forward stroke volume, and with time, EF increases. A_oP, Aortic pressure; RF, regurgitant fraction. (From Carabello BA. Aortic regurgitation: hemodynamic determinants of prognosis. In Cohn LH, DiSesa VJ, editors. Aortic Regurgitation: Medical and Surgical Management. New York: Marcel Dekker; 1986, pp 99-101.)

Patients with severe chronic AR have the largest LV end-diastolic volumes of any form of heart disease, resulting in so-called cor bovinum. However, end-diastolic pressure is not uniformly elevated (i.e., LV compliance often is increased; **see Fig. 68.14**). The adaptive response to gradually increasing,

chronic AR permits the ventricle to function as an effective high-compliance pump, handling a large stroke volume, often with little increase in filling pressure. During exercise, peripheral vascular resistance declines and, with an increase in heart rate, diastole shortens and the regurgitation per beat decreases, facilitating an increment in effective (forward) cardiac output without substantial increases in end-diastolic volume and pressure. The EF and related ejection phase indices are often within normal limits, both at rest and during exercise, even though MI, as reflected in the slope of the end-systolic pressure-volume relationship, is depressed.

As the left ventricle decompensates, interstitial fibrosis increases, compliance declines, and LV end-diastolic pressure and volume rise (**see Fig. 68.14**). In advanced stages of decompensation, left atrial, pulmonary artery wedge, pulmonary arterial, right ventricular (RV), and right atrial pressures rise, and the effective (forward) cardiac output falls, at first during exercise and then at rest. The normal decline in LV end-systolic volume or the rise in EF fails to occur during exercise. Symptoms of HF develop, particularly those secondary to pulmonary congestion.

Myocardial Ischemia.

When acute AR is induced experimentally, myocardial O_2 requirements rise substantially, secondary to an increase in wall tension. In patients with chronic severe AR, total myocardial O_2 requirements also are augmented by the increase in LV mass. Because the major portion of coronary blood flow occurs during diastole, when aortic pressure is lower than normal in AR, coronary perfusion pressure is reduced. Studies in experimentally induced AR have shown a reduction in coronary flow reserve, with a change in forward coronary flow from diastole to systole. The result—a combination of increased O_2 demands and reduced supply—sets the stage for the development of myocardial ischemia, especially during exercise. Thus, patients with severe AR exhibit a reduction of coronary reserve, which may be responsible for myocardial ischemia, which may in turn play a role in the deterioration of LV function.

Clinical Presentation of Chronic Aortic Regurgitation

The clinical stages of chronic AR demonstrate the progressive nature of the disease (**Table 68.5**).

TABLE 68.5

Stages of Chronic Aortic Regurgitation (AR)

STAGE	DEFINITION	VALVE ANATOMY	VALVE HEMODYNAMICS	HEMODYNAMIC CONSEQUENCES	SYMPTOMS
A	**At risk of AR**	Bicuspid aortic valve (or other congenital valve anomaly) Aortic valve sclerosis Diseases of the aortic sinuses or ascending aorta History of rheumatic fever or known rheumatic heart disease IE	AR severity none or trace	None	None
B	**Progressive AR**	Mild to moderate calcification of a trileaflet valve or bicuspid aortic valve (or other congenital valve anomaly) Dilated aortic sinuses Rheumatic valve changes Previous IE	***Mild AR:*** Jet width <25% of LVOT Vena contracta <0.3 cm RVol <30 mL/beat RF <30% ERO <0.10 cm^2 Angiography grade 1+ ***Moderate AR:*** Jet width 25-64% of LVOT Vena contracta 0.3-0.6 cm RVol 30-59 mL/beat RF 30-49% ERO 0.10-0.29 cm^2 Angiography grade 2+	Normal LV systolic function Normal LV volume or mild LV dilation	None
C	**Asymptomatic severe AR**	Calcific aortic valve disease Bicuspid valve (or other congenital abnormality) Dilated aortic sinuses or ascending aorta Rheumatic valve changes IE with abnormal leaflet closure or perforation	***Severe AR:*** Jet width ≥65% of LVOT Vena contracta >0.6 cm Holodiastolic flow reversal in proximal abdominal aorta RVol ≥60 mL/beat RF ≥50% ERO ≥0.3 cm^2 Angiography grade 3+ to 4+ In addition, diagnosis of chronic severe AR requires evidence of LV dilation.	*C1:* Normal LVEF (≥50%) and mild-to-moderate LV dilation (LVESD ≤50 mm) *C2:* Abnormal LV systolic function with depressed LVEF (<50%) or severe LV dilation (LVESD >50 mm or indexed LVESD >25 mm/m^2)	None; exercise testing is reasonable to confirm symptom status
D	**Symptomatic severe AR**	Calcific valve disease Bicuspid valve (or other congenital abnormality) Dilated aortic sinuses or ascending aorta Rheumatic valve changes Previous IE with abnormal leaflet closure or perforation	***Severe AR:*** Doppler jet width ≥65% of LVOT Vena contracta >0.6 cm Holodiastolic flow reversal in the proximal abdominal aorta RVol ≥60 mL/beat RF ≥50% ERO ≥0.3 cm^2 Angiography grade 3+ to 4+ In addition, diagnosis of chronic severe AR requires evidence of LV dilation.	Symptomatic severe AR may occur with normal systolic function (LVEF ≥50%), mild to moderate LV dysfunction (LVEF 40-50%), or severe LV dysfunction (LVEF <40%). Moderate to severe LV dilation is present.	Exertional dyspnea or angina, or more severe HF symptoms

ERO, Effective regurgitant orifice; *HF,* heart failure; *IE,* infective endocarditis; *LVEF,* left ventricular ejection fraction; *LVESD,* left ventricular end-systolic dimension; *LVOT,* left ventricular outflow tract; *RF,* regurgitant fraction; *RVol,* regurgitant volume.

From Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACCF guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2014;63:e57.

Symptoms

In chronic severe AR, the left ventricle gradually enlarges while the patient remains asymptomatic.[134,135] Symptoms of reduced cardiac reserve or myocardial ischemia develop, most often in the fourth or fifth decade of life, and usually only after considerable cardiomegaly and myocardial dysfunction have occurred. The principal manifestations—exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea—usually develop gradually. Angina pectoris is prominent late in the course; nocturnal angina may be troublesome and often is accompanied by diaphoresis, which occurs when the heart rate slows and arterial diastolic pressure falls to extremely low levels. Patients with severe AR often complain of an uncomfortable awareness of the heartbeat, especially on lying down, and thoracic discomfort caused by pounding of the heart against the chest wall. Tachycardia, occurring with emotional stress or exertion, may cause palpitations and head pounding. Premature ventricular contractions (PVCs) are particularly distressing because of the great heave of the volume-loaded left ventricle during the postextrasystolic beat. These complaints may be present for many years before symptoms of overt LV dysfunction develop.

Physical Examination.

In patients with chronic, severe AR, the head may bob with each heartbeat (Musset sign), and water-hammer pulses, with abrupt distention and quick collapse (Corrigan pulse), are evident. The arterial pulse often is prominent and can be best appreciated by palpation of the radial artery with the patient's arm elevated (**see Chapters 11 and 67**). A bisferiens pulse may be present and is more readily recognized in the brachial and femoral arteries than in the carotid arteries. A variety of auscultatory findings provide confirmation of a wide pulse pressure. The Traube sign (also known as “pistol shot” sounds) refers to booming systolic and diastolic sounds heard over the femoral artery, the Müller sign consists of systolic pulsations of the uvula, and the Duroziez sign is a systolic murmur heard over the femoral artery when it is compressed proximally and a diastolic murmur when it is compressed distally. Capillary pulsations (Quincke sign) can be detected by transmitting a light through the patient's fingertips or exerting gentle pressure on the tip of a fingernail.

Systolic arterial pressure is elevated, and diastolic pressure is abnormally low. Korotkoff sounds often persist to zero even though the intra-arterial pressure rarely falls below 30 mm Hg. The point of change in Korotkoff sounds (i.e., the muffling of these sounds in phase IV) correlates with the diastolic pressure. As HF develops, peripheral vasoconstriction may occur and arterial diastolic pressure may rise, even though severe AR is present.

The apical impulse is diffuse and hyperdynamic and is displaced laterally and inferiorly. A rapid ventricular filling wave often is palpable at the apex. The augmented stroke volume may create a systolic thrill at the base of the heart or suprasternal notch and over the carotid arteries. In many patients, a carotid shudder is palpable.

Auscultation.

The diastolic murmur, the principal physical finding in AR, is of high frequency and begins immediately after A_2. It may be distinguished from the murmur of pulmonic regurgitation by its earlier onset (i.e., immediately after A_2 rather than after P_2) and usually by the presence of a widened pulse pressure. The murmur is heard best with the diaphragm of the stethoscope while the patient is sitting up and leaning forward, with the breath held in deep exhalation. In severe AR, the murmur reaches an early peak and then shows a dominant decrescendo pattern throughout diastole.

The severity of AR correlates better with the duration than with the intensity of the murmur. In mild AR, the murmur may be limited to early diastole and typically is high-pitched and blowing. In severe AR

the murmur is holodiastolic and may have a rough quality. When the murmur is musical ("cooing dove" murmur), it usually signifies eversion or perforation of an aortic cusp. In patients with severe AR and LV decompensation, equilibration of aortic and LV pressures in late diastole abolishes the late diastolic component of the regurgitant murmur. When AR is caused by primary valvular disease, the diastolic murmur is heard best along the left sternal border in the third and fourth intercostal spaces. However, when it is caused mainly by dilation of the ascending aorta, the murmur often is more readily audible along the right sternal border.

Many patients with chronic AR have a harsh systolic outflow murmur caused by the increased total LV stroke volume and ejection rate, which often radiates to the carotid vessels. The systolic murmur often is more readily audible than the diastolic murmur. It may be higher-pitched and less rasping than the murmur of AS but often is accompanied by a systolic thrill. Palpation of the carotid pulses will elucidate the cause of the systolic murmur and differentiate it from the murmur of AS.

A third heart sound (S_3) correlates with an increased LV end-diastolic volume. Its development may be a sign of impaired LV function, which is useful in identifying patients with severe AR who are candidates for surgical treatment. A mid-diastolic and late diastolic apical rumble, the *Austin Flint murmur*, is common in severe AR and may occur in the presence of a normal mitral valve. This murmur appears to be created by severe AR impinging on the anterior leaflet of the mitral valve or the free LV wall; convincing evidence for obstruction to mitral inflow in these patients is lacking.

Diagnostic Testing

Echocardiography

Echocardiography is helpful in identifying the cause of AR (**Fig. 68.15**) and may demonstrate a bicuspid valve, thickening of the valve cusps, other congenital abnormalities, prolapse of the valve, a flail leaflet, or vegetation (**see Chapter 14**). In addition to leaflet anatomy and motion, the size and shape of the aortic root can be evaluated, although visualization of the ascending aorta is not always adequate, necessitating additional imaging tests in some cases. Transthoracic echocardiography (TTE) usually is satisfactory, but transesophageal echocardiography (TEE) often provides more detail, particularly of the aortic root. TTE is useful for the measurement of LV end-diastolic and end-systolic dimensions and volumes, EF, and mass[59,134] (Videos 68.2A and 68.2B). Two-dimensional image–guided M-mode measurements of LV dimensions are recommended when possible, because the high temporal resolution of this modality allows more accurate identification of endocardial borders. Care is needed to ensure that measurements are not oblique and are at the same site on subsequent studies. When the M-line is oblique, two-dimensional measurements are made in conjunction with the calculation of biplane ventricular end-diastolic and end-systolic volumes. Recent studies have suggested that LV end-systolic volume is a strong predictor of adverse clinical outcomes.[135-138] These measurements, when made serially, are of great value in selecting the optimal time for surgical intervention.

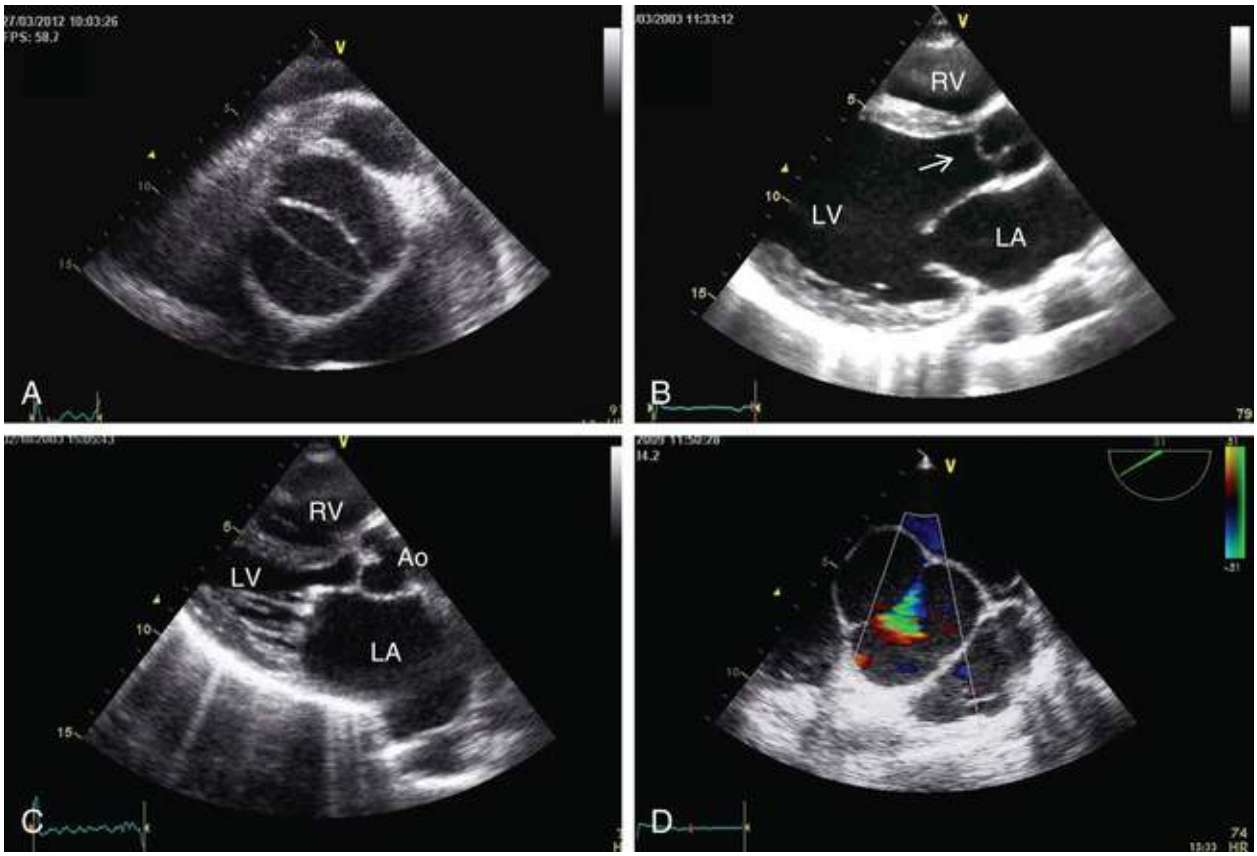

FIGURE 68.15 Role of echocardiography in etiologic investigation of aortic regurgitation. **A,** Transthoracic parasternal short-axis view showing a bicuspid aortic valve. **B,** Myxomatous aortic valve with a prolapse of the right coronary cusp (*arrow*). **C,** Rheumatic valvular disease with mitral and aortic involvement. **D,** Transesophageal image showing a central regurgitant orifice secondary to annuloaortic ectasia. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *RV,* right ventricle. (From Tornos P, Evangelista A, Bonow RO. Aortic regurgitation. In Otto CM, Bonow RO, editors. Valvular Heart Disease: A Companion to Braunwald's Heart Disease. 4th ed. Philadelphia: Saunders; 2013, pp 163-78.)

High-frequency fluttering of the anterior leaflet of the mitral valve during diastole may be seen in acute and chronic AR. However, it does not develop when the mitral valve is rigid, as occurs with rheumatic involvement. This sign, unlike the Austin Flint murmur, is present even in mild AR and results from the movement imparted to the anterior leaflet of the mitral valve by the jet of blood regurgitating from the aorta.

Doppler echocardiography and color flow Doppler imaging are the most sensitive and accurate noninvasive techniques for the diagnosis and evaluation of AR. They readily detect mild degrees of AR that may be inaudible on physical examination. Both aortic regurgitant orifice size and aortic regurgitant flow can be estimated quantitatively[59,139] (**see Fig. 14.50** and Video 68.3A and 68.3B), and such determinations are strongly recommended.[19,140] These quantitative data provide the basis for the definitions of mild, moderate, and severe AR (**see Table 68.5** and Videos 68.4, 68.5A and 68.5B, and 68.6A and 68.6B). Serial studies permit determination of the progression of AR and its effect on the left ventricle.

Cardiac Magnetic Resonance Imaging.

CMR provides accurate measurements of regurgitant volumes and the regurgitant orifice in AR (**Fig. 68.16**). It is the most accurate noninvasive technique for assessing LV end-systolic volume, diastolic volume, and mass (**see Chapter 17**). CMR accurately quantifies the severity of AR on the basis of the antegrade and retrograde flow volumes in the ascending aorta and is recommended when

echocardiographic evaluation of regurgitation is suboptimal.[73,141-143]

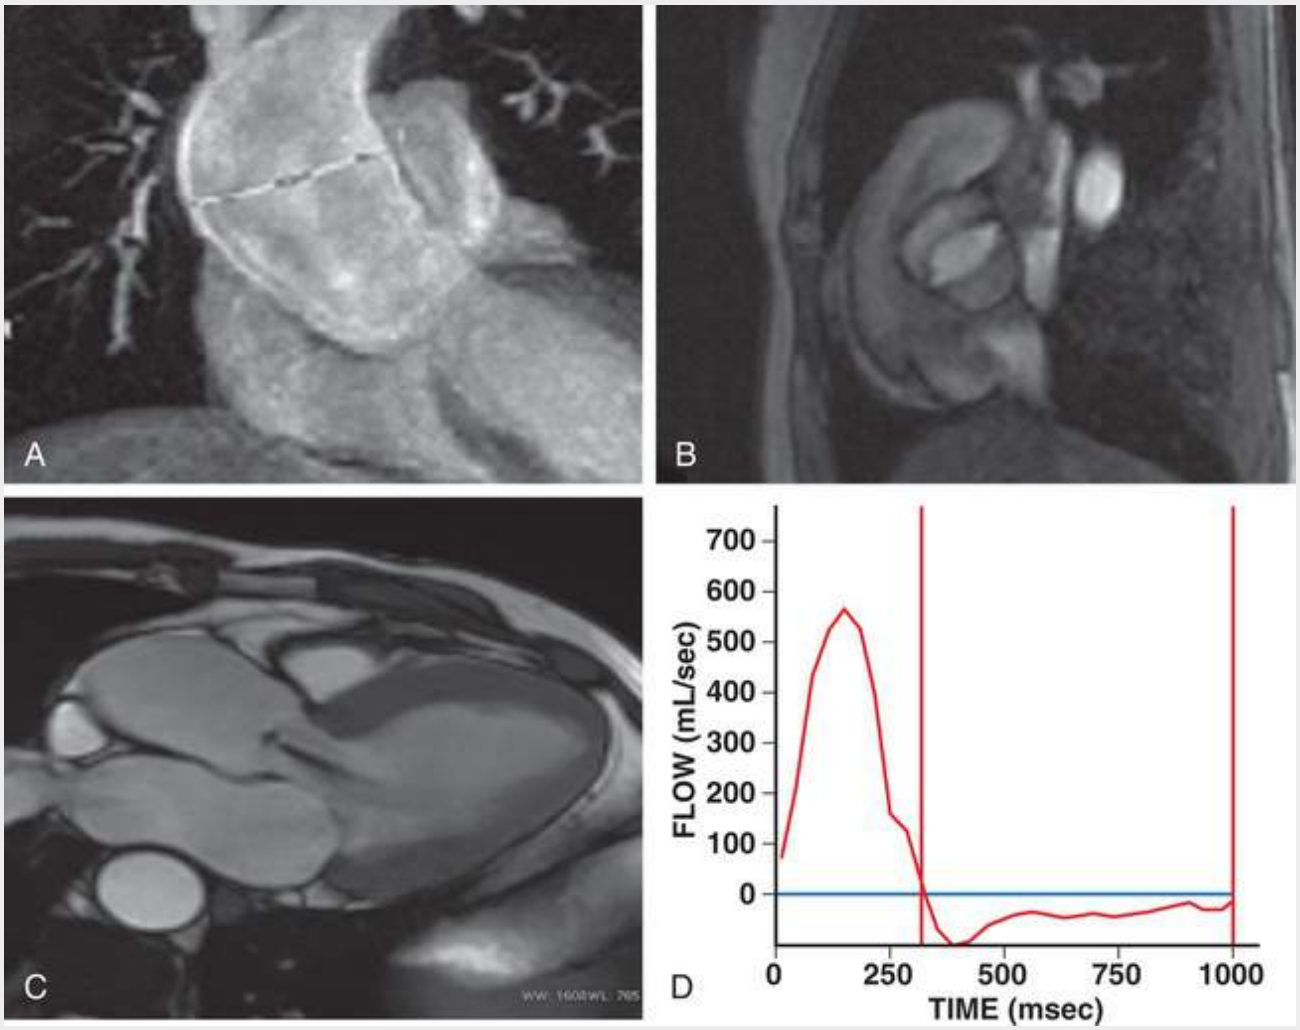

FIGURE 68.16 Cardiac magnetic resonance images showing a bicuspid aortic valve with aortic regurgitation and ascending aorta dilation. **A,** Fast single-shot steady-state free precession (SSFP) image in a coronal view. **B,** Retrospectively reconstructed magnitude image from a phase-contrast sequence showing a bicuspid aortic valve. **C,** Balanced SSFP image. Oblique axial left ventricle inflow-outflow view, showing grade 2 AR. **D,** Flow-versus-time plot for the ascending aorta. Antegrade flow was calculated at 140 mL/beat, retrograde flow at 40 mL/beat, and aortic regurgitant fraction of 33%. (From Tornos P, Evangelista A, Bonow RO. Aortic regurgitation. In Otto CM, Bonow RO, editors. Valvular Heart Disease: A Companion to Braunwald's Heart Disease. 4th ed. Philadelphia: Saunders; 2013, pp 163-78.)

Angiography.

For angiographic assessment of AR, contrast material should be injected rapidly (i.e., at 25 to 35 mL/sec) into the aortic root, and filming should be carried out in the right and left anterior oblique projections (**see Chapter 19**). Opacification may be improved by filming during a Valsalva maneuver.

Disease Course

Asymptomatic Patients with Chronic Aortic Regurgitation

Patients with mild or moderate AR who are asymptomatic with normal or only minimally increased cardiac size require no therapy but should be followed clinically and by echocardiography every 12 or 24 months. Asymptomatic patients with chronic severe AR and normal LV function should be examined at intervals of approximately 6 months. In addition to clinical examination, serial echocardiographic

assessments of LV size and EF should be made. CMR usually is not necessary but may be useful in patients whose noninvasive test results are inconclusive or discordant with clinical findings or when further evaluation of aortic size is needed (**Fig. 68.16**). Patients with mild to moderate AR and those with severe AR with a normal LVEF and only mild ventricular dilation may engage in aerobic forms of exercise. However, patients with AR who have limitations of cardiac reserve and evidence of declining LV function should not engage in competitive sports or strenuous activities.[144]

Moderately severe or even severe chronic AR often is associated with a generally favorable prognosis for many years. Quantitative measures of AR severity predict clinical outcome, and LV size and systolic function also are strong predictors of clinical outcome. In a study of 251 asymptomatic patients (mean age, 61 years), the 10-year survival was 94% ±4% in those with mild AR, compared with 69% ±9% in those with severe AR (**Fig. 68.17**).[137] By contrast, in series involving younger asymptomatic patients (mean age, 39 years) with severe AR and a normal LVEF, the mortality rate was less than 1% per year,[19,135] and more than 45% of the patients remained asymptomatic with normal LV function at 10 years. The average rate of developing symptoms or LV systolic dysfunction in these latter series was less than 6% per year (**Fig. 68.18**; **see eTable 68.2**).

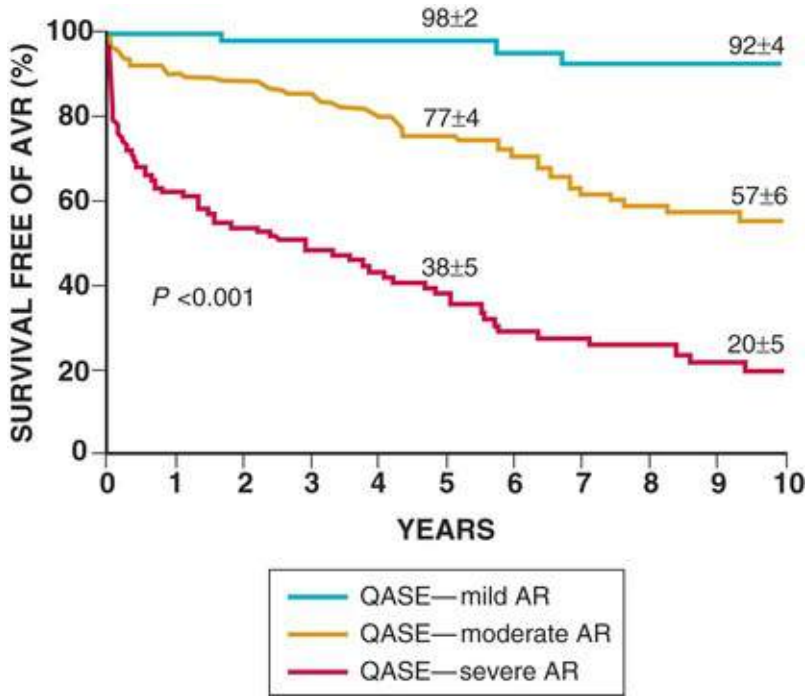

FIGURE 68.17 Composite endpoint of survival free of surgery for aortic regurgitation after diagnosis in asymptomatic patients; AVR, aortic valve replacement. Patients are stratified according to quantitative criteria of the American Society of Echocardiography (QASE) for AR grading. The QASE–severe AR is defined as regurgitant volume (RV) greater than 60 mL/beat or effective regurgitant orifice (ERO) greater than 30 mm^2. The QASE–mild AR is defined as RV less than 30 mL/beat and ERO less than 10 mm^2, and QASE–moderate AR as greater than mild but not reaching QASE–severe criteria. The 5- and 10-year rates of the endpoint (± standard error) are indicated. Note the wide difference in outcomes according to QASE grading at baseline. (From Detaint D, Messika-Zeitoun D, Maalouf J, et al. Quantitative echocardiographic determinants of clinical outcome in asymptomatic patients with aortic regurgitation: a prospective study. J Am Coll Cardiol Imaging 2008;1:1.)

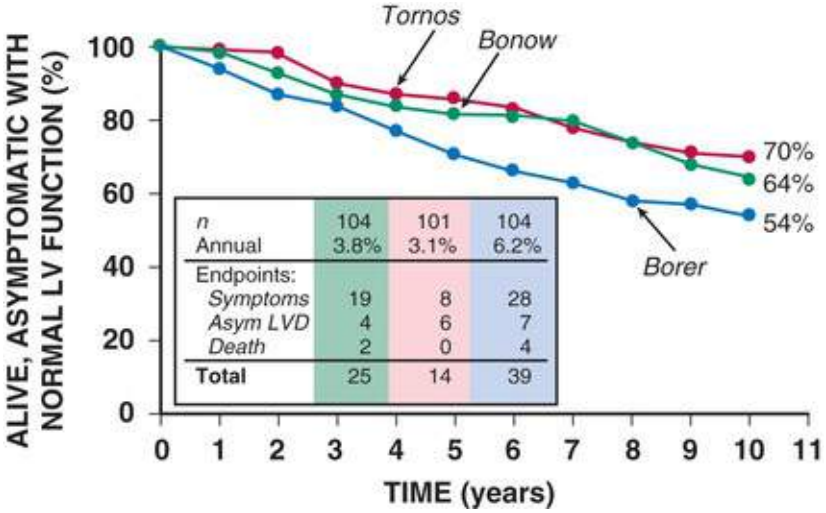

FIGURE 68.18 Three series examining the natural history of chronic asymptomatic aortic regurgitation in patients with normal LV ejection fraction at rest, each comprising more than 100 patients. At 10 years, 54% to 70% of patients remained asymptomatic with normal left ventricular (LV) function, such that the risk of developing symptoms, LV dysfunction (LVD), or death is approximately 3% to 6% per year. The endpoints encountered in these series are indicated. Most patients who deteriorated developed symptoms leading to aortic valve replacement. However, 25% to 30% of the endpoints, either asymptomatic LVD (Asym LVD) or death, occurred without warning symptoms. (From Bonow RO. Chronic mitral regurgitation and aortic regurgitation: have indications for surgery changed? J Am Coll Cardiol 2013;61:693. Data modified from Bonow RO et al. Gradual deterioration of LV function may occur even during the asymptomatic period, and some patients may incur significant impairment of systolic function before the onset of symptoms (**see Table 68.5**). Numerous surgical series over the past two decades have indicated that depressed LVEF is among the most important determinants of mortality after AVR, particularly since LV dysfunction may become

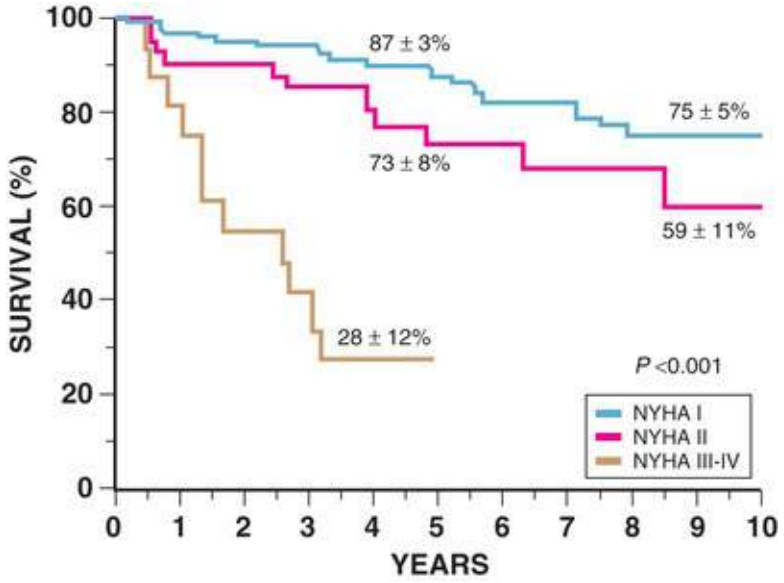
irreversible and may not improve after AVR.[19,69,135] LV dysfunction is more likely to be reversible if detected early, before EF becomes severely depressed, before the left ventricle becomes markedly dilated, and before significant symptoms develop. It is therefore important to intervene surgically before these changes have become irreversible.[134] Measures of LV systolic volume and systolic function are the most important predictors of clinical course in asymptomatic patients[135-137] (**see eTable 68.2**). Biomarkers such as BNP[145] and assessment of myocardial strain[146] also may play a role in the future in identifying high-risk patients, based on small series published to date, but more work is necessary before these additional measures are recommended for routine management.

Symptomatic Patients with Chronic Aortic Regurgitation

As with AS, however, once the patient with AR becomes symptomatic, the downhill course becomes rapidly progressive. Congestive heart failure, punctuated by episodes of acute pulmonary edema, and sudden death may occur, usually in previously symptomatic patients who have considerable LV dilation. Data compiled in the presurgical era indicate that without surgical treatment, death usually occurred within 4 years after the development of angina pectoris and within 2 years after the onset of HF. Even in the current era, 4-year survival without surgery in patients with NYHA Class III or IV symptoms is only approximately 30% (**see eFig. 68.1**).



EFIGURE 68.1 Survival without surgery in 242 patients with chronic aortic regurgitation, demonstrating the importance of symptoms in determining outcome. Patients with New York Heart Association (NYHA) Class III or IV symptoms had a survival of only 28% at 4 years. By contrast, the 10-year survival in patients in NYHA Class I was 75%, which was identical to that for an age-matched normal population. (From Dujardin KS, Enriquez-Sarano M, Schaff HV, et al. Mortality and morbidity of aortic regurgitation in clinical practice: a long-term follow-up study. Circulation 1999;99:1851.)

Treatment of Chronic Aortic Regurgitation

Medical Therapy

No specific therapy to prevent disease progression in chronic AR is currently available. Uncertainty remains about whether patients with chronic AR and evidence of significant volume overload (increased end-diastolic dimension or volume) should be considered for vasodilator therapy to alter the natural

history of chronic LV volume overload.[147] Short-term studies spanning 6 months to 2 years have demonstrated beneficial hemodynamic effects of oral hydralazine, nifedipine, felodipine, and ACE inhibitors. However, prospective RCTs have not shown consistent clinical benefit in terms of LV function or delay in need for AVR. In view of this equipoise, definitive recommendations regarding the indications for long-active nifedipine or ACE inhibitors are not possible.[134]

It is conceivable that blockade of the renin-angiotensin system may provide additional myocardial benefits beyond peripheral vasodilation by direct mechanisms to reduce interstitial fibrosis and remodeling. Such promising effects have been demonstrated in animal models[148] but are yet to be tested in prospective RCTs. A retrospective Scottish registry study of 2266 patients with at least moderate AR reported a 44% reduction in all-cause mortality (HR, 0.56; 95% CI 0.64 to 0.89; $P < 0.01$) over a mean 4.4-year period in the 876 patients taking ACE inhibitors or ARBs compared with the 1390 patients who did not receive these drugs.[149] Patients taking ACE inhibitors/ARBs were younger, however, with significantly greater use of other drugs (including aspirin, statins, beta blockers, and calcium channel blockers) that might affect outcome, because most events were considered cardiovascular and not directly related to AR. Nevertheless, ACE inhibitor/ARB therapy was associated with a 32% reduction in AR events (AVR, HF hospitalization, HF death) ($P < 0.01$). Another retrospective study reported beneficial effects of beta-blocker therapy on survival in patients with AR.[150] However, patients receiving beta blockers were younger than those not taking beta blockers and also more frequently had concomitant therapy with ACE inhibitors, statins, aspirin, and calcium channel blockers that might have influenced outcome. More than two thirds of patients in this study had HF and 25% had AF, so extrapolation to asymptomatic patients is difficult. Moreover, interpretation of the survival results is complicated by greater intervention with AVR and CABG in those taking beta blockers. Thus, these studies are not definitive and indicate the need for prospectively designed RCTs before ACE inhibitor or beta-blocker therapy can be considered in asymptomatic patients with chronic AR.

Although there is no specific therapy to improve clinical outcomes in patients with chronic AR, it is recommended to treat hypertension (systolic BP >140 mm Hg), CAD, atrial arrhythmias, and any other cardiovascular comorbidities according to established guidelines. For symptomatic patients, chronic medical therapy may be necessary for some patients who refuse surgery or who are considered to be inoperable because of comorbid conditions. These patients should receive an aggressive HF regimen (**see Chapter 25**) with ACE inhibitors (and perhaps other vasodilators), diuretics, and salt restriction; beta blockers may also be beneficial.[150] Even though nitroglycerin and other nitrates are not as helpful in relieving anginal pain in patients with AR as in patients with CAD or AS, these are reasonable therapies to try. In patients who are surgical candidates but who have severely decompensated LV dysfunction, vasodilator therapy may be particularly helpful to stabilize them before AVR.

Surgical Aortic Valve Replacement

Indications for Valve Replacement

Fig. 68.19 shows a proposed management strategy for patients with chronic severe AR.[19] Because of their excellent prognosis in the short and medium term, surgical correction should be deferred in patients with chronic severe AR who are asymptomatic, exhibit good exercise tolerance, and have an EF greater than 50% without severe LV dilation (i.e., end-systolic diameter ≤50 mm) or progressive LV dilation on serial echocardiograms. In the absence of obvious contraindications or serious comorbidity, surgical treatment is advisable for symptomatic patients with severe AR and for asymptomatic patients either with EF of

50% or less or with severe LV dilation (end-systolic diameter >50 mm or 25 mm/m^2 when indexed to body size).[19,69] Between these ends of the clinical-hemodynamic spectrum are many patients in whom it may be difficult to balance the immediate risks of AVR and the continuing risks of an implanted prosthetic valve against the hazards of allowing a severe volume overload to damage the left ventricle.[134,135]

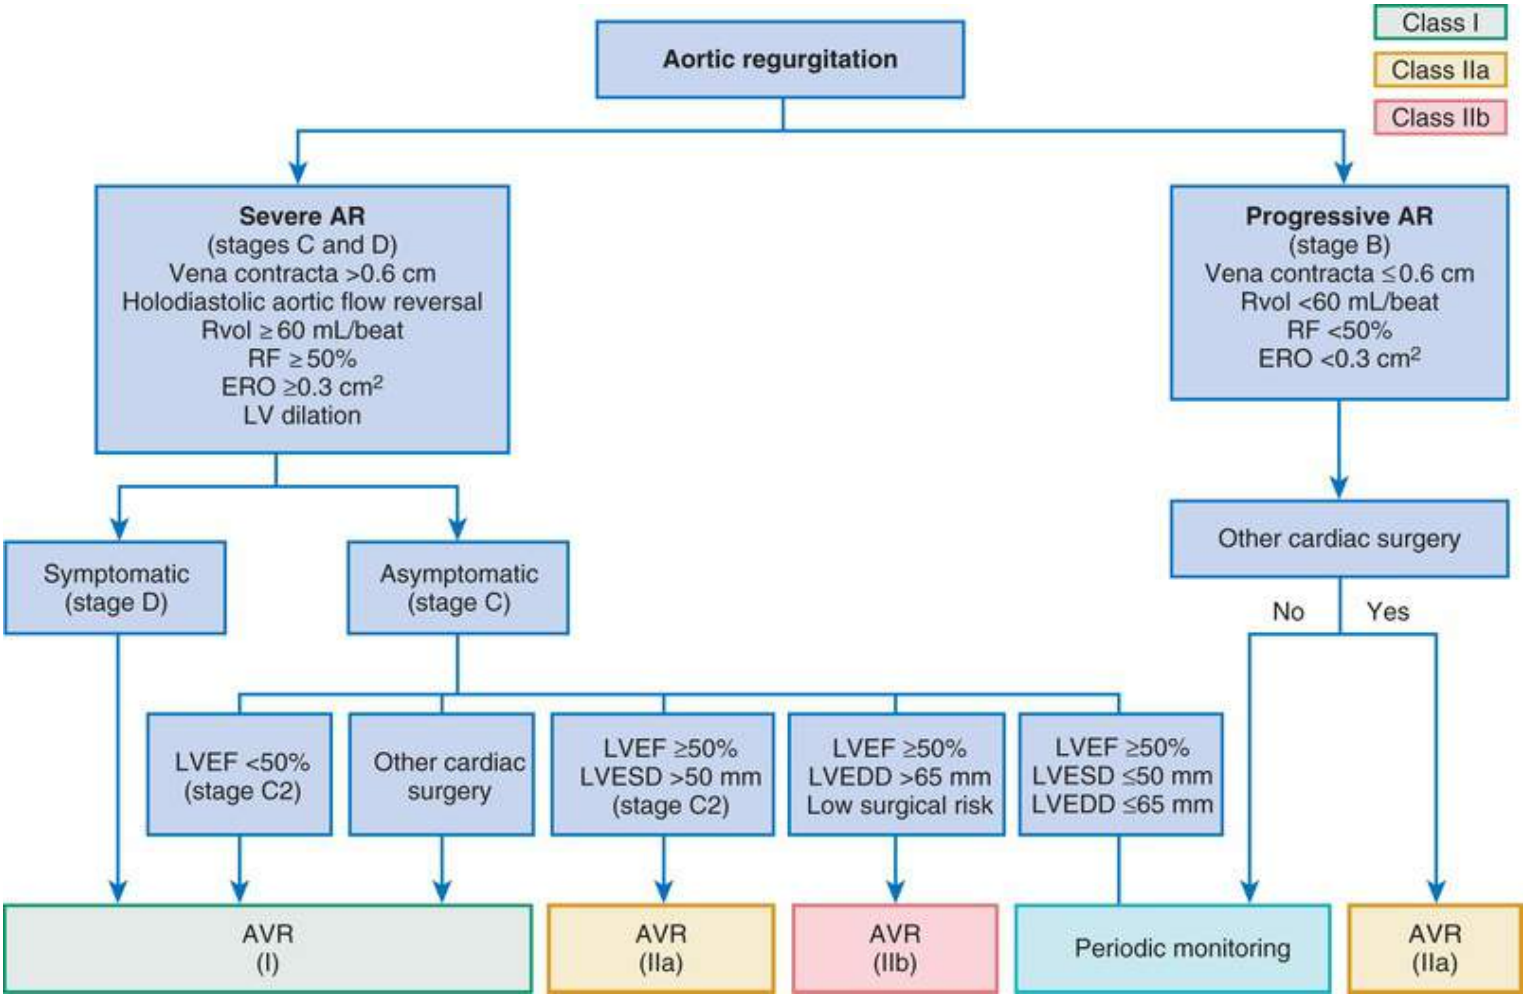


FIGURE 68.19 Management strategy for patients with chronic severe aortic regurgitation. AVR, Aortic valve replacement (valve repair may be appropriate in selected patients); ERO, effective regurgitant orifice; LVEDD, left ventricular end-diastolic dimension; LVEF, left ventricular ejection fraction; LVESD, left ventricular end-systolic dimension; RF, regurgitant fraction; RVol, regurgitant volume. (From Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACCF guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2014;63:e57.)

Because severe symptoms (NYHA Class III or IV) and LV dysfunction with an EF less than 50% are independent risk factors for poor postoperative survival (**Fig. 68.20**), surgery should be carried out in patients with even mild symptoms (NYHA Class II) before severe LV dysfunction has developed.[19,70,134,135] Even after successful correction of AR, patients with severe LV dysfunction may have persistent cardiomegaly and depressed LV function. Such patients often exhibit persistent histologic changes in the left ventricle, including massive fiber hypertrophy and increased interstitial fibrous tissue. Therefore, surgery is highly desirable for patients before irreversible LV changes have occurred.

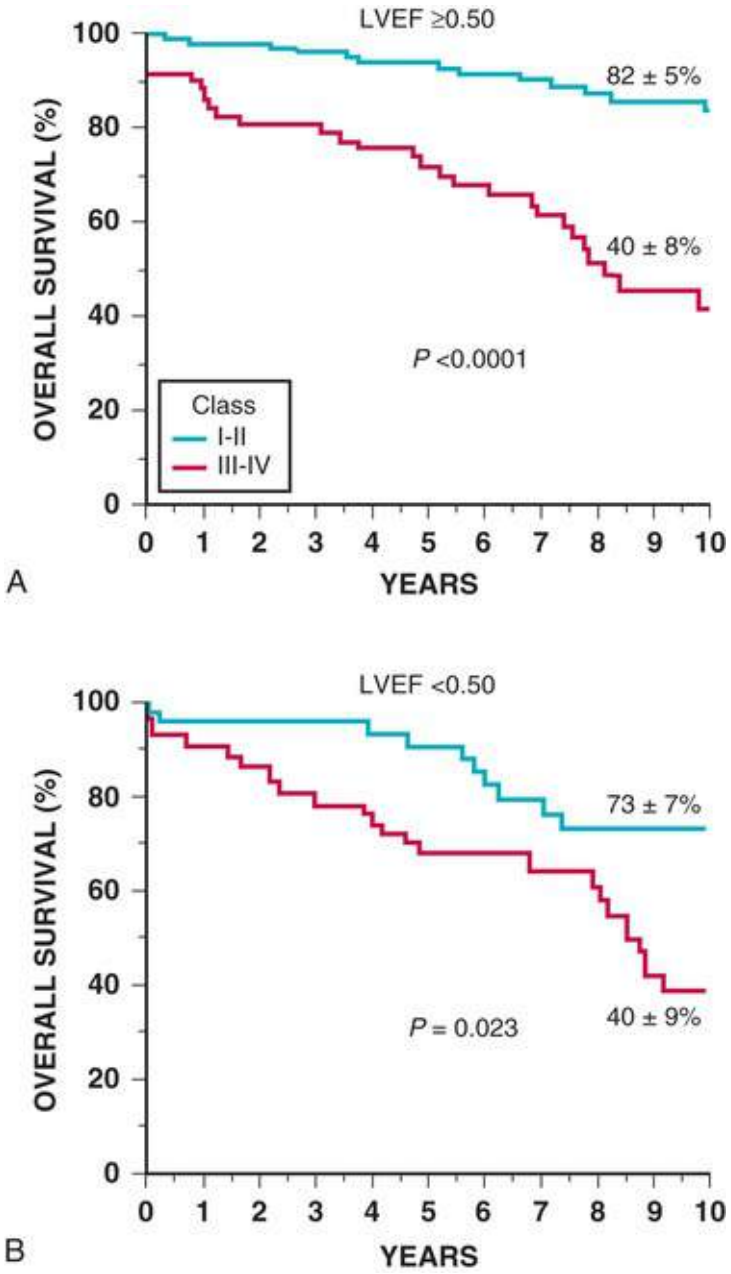

FIGURE 68.20 Long-term postoperative survival in patients with aortic regurgitation, stratified according to the severity of preoperative symptoms and preoperative left ventricular ejection fraction (LVEF). Patients with NYHA Class III or IV symptoms experienced significantly worse survival than those with Class I or II symptoms, whether the echocardiographic LVEF was higher than 0.50 **(A)** or less than 0.50 **(B),** without associated coronary artery disease. (From Klodas E, Enriquez-Sarano M, Tajik AJ, et al. Optimizing timing of surgical correction in patients with severe aortic regurgitation: role of symptoms. J Am Coll Cardiol 1997;30:746.)

Because AR has complex effects on preload and afterload, the selection of appropriate indices of ventricular contractility to identify patients for operation is challenging. The relationship between end-systolic wall stress and LVEF or percentage of fractional shortening is a useful measurement,[56] as are more load-independent measures of LV contractility. However, in the absence of such complex measurements, serial changes in LV end-diastolic and end-systolic volumes or dimensions can be used to detect the relative deterioration of LV function.[134] Although strongly influenced by loading conditions, LV end-diastolic and end-systolic volumes and ejection phase indices (e.g., EF, fraction shortening) are still useful empiric predictors of postoperative function.

Serial echocardiograms should be obtained to detect changes in LV size and function in asymptomatic patients with severe AR (**see Fig. 68.19**). Impaired LV function at rest is the basis for selecting patients for operation; normal LV function at rest with failure of the EF to rise normally with exercise is not considered an indication for surgery, but it is an early warning sign of impaired function at rest.

Echocardiographic measurements of LV size also are important, with M-mode LV end-diastolic and end-systolic dimensions, when possible, and with biplane apical calculations of the end-systolic volume index. Echocardiographic measurements should be made with side-by-side comparison of previous serial studies. A consistent change in dimensions or volumes, greater than measurement variability, must be ensured before recommending AVR for asymptomatic patients on the basis of these numbers alone.

Asymptomatic patients with severe AR but normal LV function have an excellent prognosis and do not require prophylactic operation (**see eTable 68.2**). On average, less than 6% of patients each year require surgery because of the development of symptoms or of LV dysfunction (**see Fig. 68.18**), although the rate of symptom development is higher in patients older than 60 years.[137] The LV end-systolic dimension determined by echocardiography is valuable in predicting outcome in asymptomatic patients. Patients with severe AR and an end-systolic diameter less than 40 mm almost invariably remain stable and can be followed without need for surgery in the near term. However, patients with an end-systolic diameter of more than 50 mm have a 19% likelihood per year of developing symptoms of LV dysfunction, and those with an end-systolic diameter more than 55 mm are at increased risk for development of irreversible LV dysfunction if they do not undergo AVR. Postoperative function and survival in this latter group are determined by the severity of symptoms and degree and duration of LV dysfunction.[134,135] Indexed end-systolic dimension (ESDI) or volume (ESVI) may be a more robust indicator for timing of surgical intervention.[136,137] Patients with an ESDI of 2.5 cm/m^2 or ESVI of 45 mL/m^2 or greater are at higher risk for adverse outcomes.[19,137] Further data on the use of EDVI and ESVI are needed before this approach becomes standard. Recent findings suggest that lower thresholds of EDVI should be considered to optimize long-term survival after AVR.[138]

In summary, the following considerations apply to the selection of patients with chronic AR for surgical treatment.[19,69] Operation should be deferred in asymptomatic patients with normal and stable LV function and should be recommended for symptomatic patients (**see Fig. 68.19**). In asymptomatic patients with LV dilation or dysfunction, a decision should be based not on a single abnormal measurement but rather on several observations of depressed performance and impaired exercise tolerance, carried out at intervals of 2 to 4 months. If evidence of LV dysfunction is borderline or inconsistent, continued close follow-up is indicated. If abnormalities are progressive and consistent (i.e., LVEF <50% or LV end-systolic diameter rises to >50 mm), AVR should be strongly considered, even in asymptomatic patients. Symptomatic patients with severe AR who have normal, mildly depressed, or moderately depressed LV function should undergo AVR. Even patients with severely depressed LV function have acceptable operative and long-term survival.[151] Ventricular assist device or transplant may also be considered as an alternative, particularly in those with longstanding severe LV dysfunction, but medical therapy is associated with a dismal prognosis.

The indications for AVR for patients with severe AR secondary to aortic sinus or ascending aortic disease are similar to those for patients with primary valvular disease. In addition, concomitant surgery to repair the aortic sinuses or replace the ascending aorta is indicated if the amount of aortic dilation is greater than 45 mm.[19,152] As for patients with other valvular lesions, adult surgical candidates who may have underlying CAD, based on symptoms, age, sex, and risk factors, should undergo preoperative coronary angiography. Those with significant coronary artery stenoses should undergo revascularization at the time of AVR.

Operative Procedures

The standard surgical approach for chronic AR is AVR. Concurrent aortic root replacement is performed when aortic dilation is the cause of or accompanies valve dysfunction. However, experience is

accumulating with surgical aortic valve repair, which is a viable option for select patients in experienced centers.[153-156] Occasionally, when a leaflet has been torn from its attachments to the aortic annulus by trauma, surgical repair may be possible, and in patients with AR secondary to prolapse of an aortic leaflet, aortic cusp resuspension or cusp resection may be used. When AR is caused by leaflet perforation resulting from healed infective endocarditis, a pericardial patch can be used for repair. However, unlike patients with chronic MR, the large majority of patients with pure AR will require AVR rather than repair. Transcatheter AVR for AR is under investigation but is not an established approach.[157,158]

Because an increasing proportion of patients with severe isolated AR coming to operation now have primary aortic root rather than primary valvular disease, an increasing number can be treated surgically by correcting the dilated aortic root.[155,156] Aneurysmal dilation of the ascending aorta requires excision, replacement with a graft that includes a prosthetic valve, and reimplantation of the coronary arteries. In some patients with aortic root disease, the native valve can be spared when the aortic root is replaced or repaired (**Fig. 68.21**).

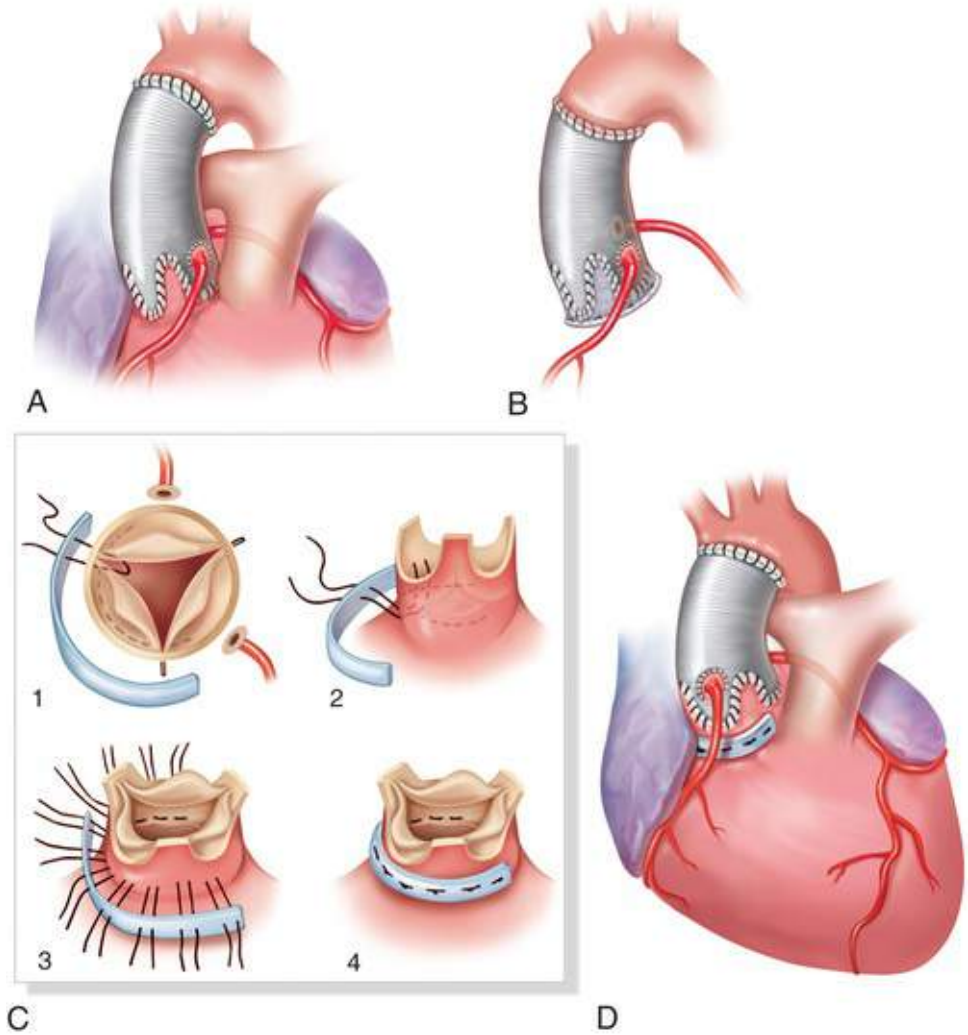

FIGURE 68.21 Repair of aortic regurgitation caused by aortic root dilation. **A,** Remodeling of the aortic root with replacement of all three aortic sinuses. **B,** Reimplantation of the aortic valve in patients with annuloaortic ectasia and aortic root aneurysm. **C, D,** Aortic annuloplasty in patients with annuloaortic ectasia. (From David TE. Aortic root aneurysms: remodeling or composite replacement? Ann Thorac Surg 1997;64:1564.)

When AVR is performed in patients with severe AR, the aortic annulus often is larger than in patients with AS. Thus a larger prosthetic valve can be inserted, and mild postoperative obstruction to LV outflow is less of a problem than it is in some patients with AS. In general, the associated risks and results of AVR

in patients with AR are similar to those in patients with AS, with a large proportion of patients exhibiting striking relief of symptoms. Substantial reductions in heart size and in LV diastolic volume and mass occur in most patients. Exceptions are seen in patients with NYHA Class III or IV HF and patients with severe LV dysfunction preoperatively. As for patients with AS, the operative risk of AVR for patients with AR depends on the general condition of the patient, the state of LV function, and the skill and experience of the surgical team. Mortality ranges from 3% to 8% in most medical centers. A late mortality of approximately 5% to 10%/year is observed in survivors who had marked cardiac enlargement and/or prolonged LV dysfunction preoperatively. Follow-up studies have shown both early rapid and then slower, long-term reductions in LV mass, EF, myocyte hypertrophy, and ventricular fibrosis content after surgical relief of AR. By extending the indications for operation to symptomatic patients with normal LV function, as well as to asymptomatic patients with LV dysfunction, early and late results are improving. With the continued improvement of surgical techniques and results, it probably will become possible to extend the surgical recommendation to asymptomatic patients with severe AR, normal LV systolic function, and only mild LV dilation. However, in view of the risks of operation and the long-term complications of currently available prosthetic valves, we do not believe that the time for such a policy has yet arrived.

Acute Aortic Regurgitation

Pathophysiology and Clinical Presentation.

Acute AR is caused most often by infective endocarditis, aortic dissection, or trauma[159] (**see Chapters 63 and 73**). The characteristic features of acute AR are tachycardia and an increase in LV diastolic pressure. In contrast with the pathophysiologic events in chronic AR just described, in which the left ventricle can adapt over time to the increased hemodynamic load, in acute AR the regurgitant volume fills a ventricle of normal size that cannot accommodate the combined large regurgitant volume and inflow from the left atrium. Because the ability of total stroke volume to rise acutely is limited, forward stroke volume declines. The sudden increase in LV filling causes the LV diastolic pressure to rise rapidly above left atrial pressure during early diastole (**see Fig. 68.14**), causing the mitral valve to close prematurely in diastole. The tachycardia may compensate for the reduced forward stroke volume, and the LV and aortic systolic pressures may exhibit little change. However, acute severe AR may cause profound hypotension and cardiogenic shock. In light of the limited ability of the left ventricle to tolerate acute severe AR, patients with this valvular lesion often develop clinical manifestations of sudden cardiovascular collapse, including weakness, severe dyspnea, and profound hypotension secondary to the reduced stroke volume and elevated left atrial pressure. In some patients, the aortic diastolic pressure equilibrates with the elevated LV diastolic pressure.

Physical Examination.

Patients with acute severe AR characteristically appear gravely ill, with tachycardia, severe peripheral vasoconstriction, cyanosis, and sometimes pulmonary congestion and edema. Depending on the etiology of the acute AR, signs suggestive of endocarditis or aortic dissection may be present. The peripheral signs of AR are often not impressive and certainly not as dramatic as in patients with chronic AR. The normal or only slightly widened pulse pressure may lead to significant underestimation of the severity of the valvular lesion. The LV impulse is normal or almost normal, and the rocking motion of the chest characteristic of chronic AR is not apparent. S_1 may be soft or absent because of premature closure of the mitral valve, and the sound of mitral valve closure in mid- or late diastole occasionally is audible.

Closure of the mitral valve may be incomplete, however, and diastolic MR may occur.

The early diastolic murmur of acute AR is lower-pitched and of shorter duration compared with that of chronic AR, because as LV diastolic pressure rises, the (reverse) pressure gradient between the aorta and left ventricle is rapidly reduced. A systolic murmur is common, resulting in to-and-fro sounds. The Austin Flint murmur often is present but is of brief duration and ceases when LV pressure exceeds left atrial pressure in diastole. With premature diastolic closure of the mitral valve, the presystolic portion of the Austin Flint murmur is eliminated.

Echocardiography.

In acute AR, the echocardiogram reveals a dense, diastolic Doppler signal with an end-diastolic velocity approaching zero and premature closure and delayed opening of the mitral valve. Diastolic MR may be seen. LV size and EF are usually normal, although contractility may be enhanced and EF increased because of the compensatory adrenergic surge. These findings contrast with those in chronic AR, in which end-diastolic dimensions and wall motion are increased. Occasionally, with equilibration of aortic and LV pressures in diastole, premature opening of the aortic valve may be detected. TEE is often useful to clarify the underlying reason for the acute regurgitation, particularly to identify an ascending aortic dissection or endocarditis.

Electrocardiography.

In acute AR, the ECG will usually show sinus tachycardia. If endocarditis is a possible etiology, progressive severity of heart block on serial ECGs may indicate the presence and expansion of an accompanying aortic root abscess.

Radiography.

In acute AR, radiographic examination often reveals evidence of marked pulmonary edema. The cardiac silhouette usually is remarkably normal, although left atrial enlargement may be present, and depending on the cause of the AR, enlargement of the ascending aorta may be seen.

Management.

Because early death caused by LV failure is common in patients with acute severe AR, prompt surgical intervention is indicated. Even a normal ventricle cannot sustain the burden of acute, severe volume overload. Therefore the risk of acute AR is much greater than that of chronic AR. While the patient is being prepared for surgery, treatment with an intravenous positive inotropic agent (dopamine or dobutamine) and/or a vasodilator (nitroprusside) often is necessary. The agent and dosage should be selected on the basis of arterial pressure (**see Chapter 24**). Beta blockers and intra-aortic balloon counterpulsation are contraindicated, because either lowering the heart rate or augmenting peripheral resistance during diastole can lead to rapid hemodynamic decompensation. In hemodynamically stable patients with acute AR secondary to active infective endocarditis, operation may be deferred to allow 5 to 7 days of intensive antibiotic therapy (**see Chapter 73**). However, AVR should be undertaken at the earliest sign of hemodynamic instability, or if there is any evidence of abscess formation. If an acute aortic dissection is the cause for the AR, the aorta will also need to be fixed during surgery.

Bicuspid Aortic Valve Disease

Epidemiology

A congenital bicuspid aortic valve (BAV) is present in approximately 1% to 2% of the population and is more prevalent in men, accounting for 70% to 80% of cases. In a subset of patients with BAV, familial

clustering consistent with an autosomal dominant inheritance with incomplete penetrance has been documented.[5] In some families with BAV and associated congenital anomalies, a mutation in the *NOTCH1* gene has been described.

Pathophysiology

The most prevalent anatomy for a bicuspid valve is two cusps with a right-left systolic opening, consistent with congenital fusion of the right and left coronary cusps, seen in 70% to 80% of patients (**Fig. 68.22**; **see also Figs. 68.15 and 14.44**) (Videos 68.7A, 68.7B, and 68.7C). An anterior-posterior orientation, with fusion of the right and noncoronary cusps, is less common, seen in approximately 20% to 30% of patients.[160,161] Fusion of the left and noncoronary cusps is rarely seen. A prominent ridge of tissue or raphe may be present in the larger of the two cusps so that the closed valve in diastole may mimic a trileaflet valve. Echocardiographic diagnosis relies on imaging the systolic leaflet opening with only two aortic commissures (Videos 68.8A and 68.8B). Unicuspid valves are distinguished from a bicuspid valve by having only one aortic commissure.

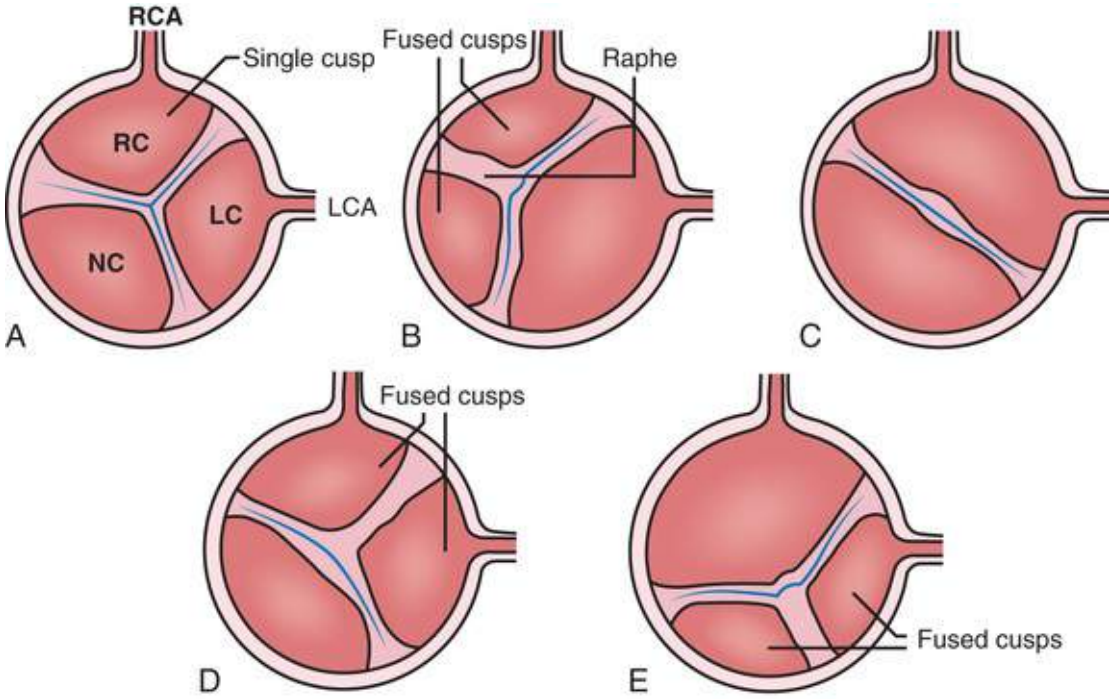

FIGURE 68.22 Comparison of tricuspid and bicuspid aortic valve structures. **A,** Schematic representation of a normal tricuspid aortic valve with the three cusps. *LC,* Left coronary; *LCA,* left coronary artery; *NC,* noncoronary; *RC,* right coronary; *RCA,* right coronary artery. **B,** Bicuspid valve with right noncoronary cusp fusion and one raphe (the line of union between the fused cups). **C,** Bicuspid valve with fusion of the right and left coronary cusps and no raphe. **D,** Bicuspid valve with right-left coronary cusp fusion and one raphe. **E,** Bicuspid valve with fusion of the left and noncoronary cups and one raphe. (From Lindman BR, Clavel M-A, Mathieu P, et al. Calcific aortic stenosis. Nat Rev Dis Primers 2016;2:16006.)

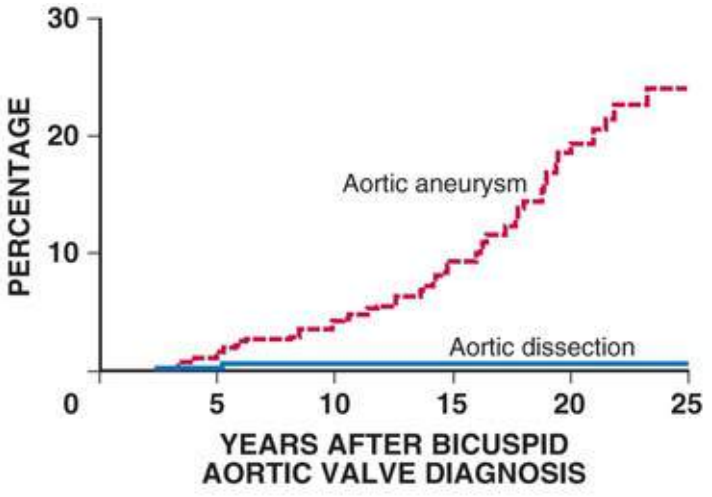
Bicuspid aortic valve disease is associated with an aortopathy, with dilation of the ascending aorta related to accelerated degeneration of the aortic media[5,161-163] (**see Chapter 63**). The presence, location, and severity of aortic dilation are related to valve morphology (**see Fig. 17.16**), but do not appear to be related to the severity of valve dysfunction.[164,165] The risk of aortic dissection in patients with BAV is five to nine times higher than the general population, but the absolute risk is still quite low (**Fig. 68.23**).[5,166,167] Some studies have also suggested an association between BAV disease (anterior-posterior leaflet

opening) and mitral valve prolapse (MVP).[168]



No. at risk						
Aortic aneurysm	384	352	309	186	88	39
Aortic dissection	416	387	348	209	110	53

FIGURE 68.23 Risk of aneurysm formation and aortic dissection after definite bicuspid aortic valve diagnosis. Kaplan-Meier risk of aortic aneurysm (*dashed red line*) 25 years after echocardiographic diagnosis in 384 patients (32 patients with baseline aneurysm excluded) and risk of aortic dissection (*blue bar*) 25 years after echocardiographic diagnosis in 416 patients. (From Michelena HI, Khanna AD, Mahoney D, et al. Incidence of aortic complications in patients with bicuspid aortic valves. JAMA 2011;306:1104-12.)

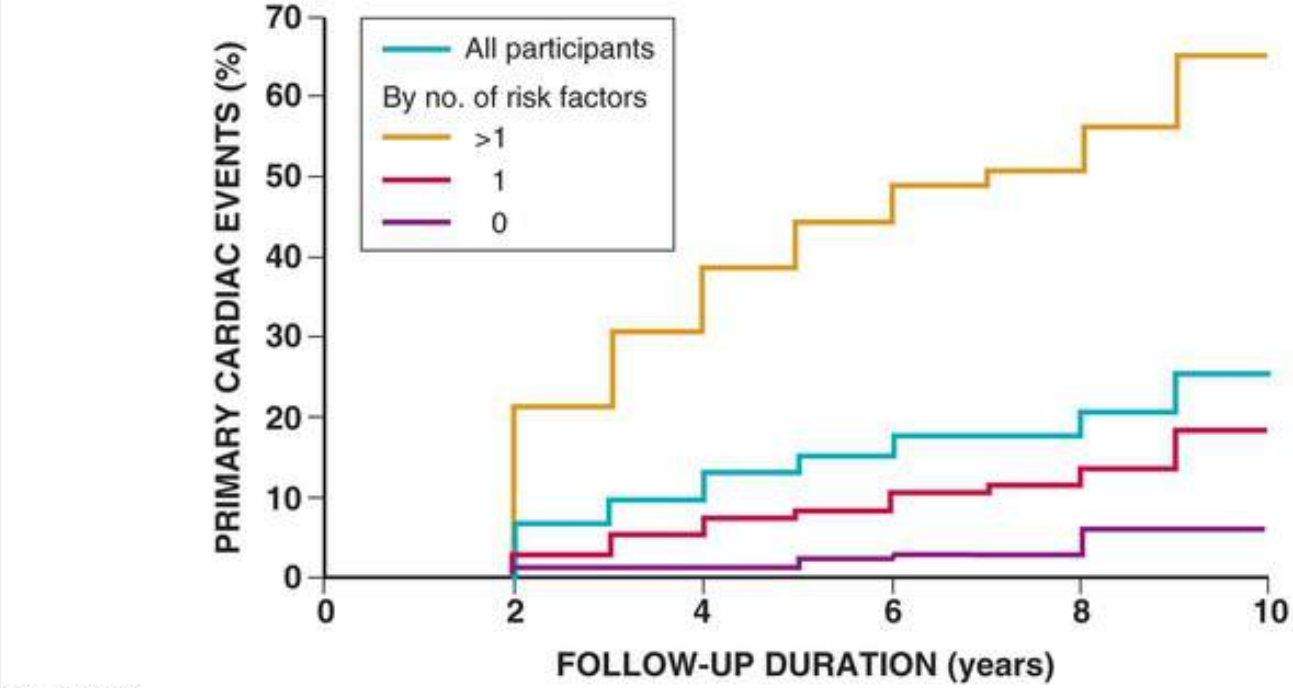
Clinical Presentation

Patients with BAV may be diagnosed at any age on the basis of the presence of an aortic ejection sound or a systolic or diastolic murmur. Some patients, however, are initially diagnosed on echocardiography requested for other reasons, and others are diagnosed through a family history of BAV disease.[169] Often, the diagnosis is unknown until the physical examination reveals manifestations of valve dysfunction or the patient develops symptoms.

Disease Course

Most bicuspid valves function normally until late in life, although a subset of patients present in childhood or adolescence with valve dysfunction. Overall, survival is no different from population estimates.[167,170,171] Over a mean follow-up of 9 years, primary cardiac events occurred in 25% of 642 ambulatory adults with BAV. Events included aortic valve or root replacement (22%), hospitalization for HF (2%), and cardiac death (3%). Risk factors for cardiac events were age greater than 30 years, and moderate or severe AR or AS (**Fig. 68.24**). In another series of 212 patients with BAV and no or mild valve dysfunction at diagnosis, aortic valve surgery, ascending aortic surgery, or any cardiovascular surgery occurred in 24%, 5%, and 27%, respectively, over 20 years of follow-up.[171] Patients with BAV also are at increased risk for endocarditis (0.4 per 100,000), accounting for approximately 1200 deaths per year in the United States. However, most patients with BAV develop calcific valve stenosis later in life, typically presenting with severe AS after the age of 50 years. Although the histopathologic features of calcific stenosis of a BAV are no different from those of a trileaflet valve, the turbulent flow and increased leaflet stress caused by the abnormal architecture are postulated to result in accelerated valve

changes, explaining the earlier average age at presentation in patients with a bicuspid, compared with trileaflet, stenotic valve. BAV disease accounts for greater than 50% of AVRs in the United States and is a common cause of calcific AS, even in older persons.



No. at risk						
All participants	642	639	533	413	309	198
By no. of risk factors						
>1	142	141	95	66	51	36
1	306	305	261	204	153	93
0	194	193	177	143	105	69

FIGURE 68.24 Outcome of patients with bicuspid aortic valves. The frequency of primary cardiac events in patients with more than one risk factor at baseline (*n* = 142) was 65% (standard deviation [SD], 5%); in all participants (*n* = 642), 25% (SD, 2%); in patients with one risk factor at baseline (*n* = 306), 18% (SD, 3%); and in patients with no risk factors at baseline (*n* = 194), 6% (SD, 2%). The risk factors for primary cardiac events were age older than 30 years, moderate or severe aortic regurgitation, and moderate or severe aortic stenosis. (From Tzemos N, Therrien J, Yip J, et al. Outcomes in adults with bicuspid aortic valves. JAMA 2008;300:1317.)

The aortopathy associated with BAV disease often results in aortic dilation and carries an increased risk of aortic dissection. The magnitude of risk appears to vary depending on valve and aortic morphology and on a family history of aortic involvement.[162,172,173]

Management

The management of BAV disease is directed toward the hemodynamic consequences of valve dysfunction—AS or AR—as discussed earlier. Currently, there are no effective medical therapies to prevent progressive valve deterioration when a bicuspid valve is diagnosed. In addition to appropriate follow-up for valve dysfunction, evaluation of the ascending aorta is needed, often with CT or CMR to ensure adequate visualization and accurate measurement of the aortic sinuses and ascending aorta (**see Fig. 68.16**).[174] If AVR is needed for stenosis or regurgitation, concurrent aortic root replacement is recommended if the maximum aortic dimension (measured at end-diastole) exceeds 45 mm.[152] Even in the

absence of aortic valve disease, aortic root replacement is recommended when the aortic dimension is 55 mm or greater in adults with BAV and may be considered with an aortic diameter of 50 mm if there is a family history of dissection or evidence of rapid progression.[152]

Mitral Valve Disease

James D. Thomas, Robert O. Bonow

Mitral Stenosis

Causes and Pathology

The predominant cause of mitral stenosis (MS) is rheumatic fever,[1] with rheumatic changes present in 99% of stenotic mitral valves excised at the time of mitral valve replacement. Approximately 25% of all patients with rheumatic heart disease have isolated MS, and approximately 40% have combined MS and mitral regurgitation (MR). Multivalve involvement is seen in 38% of patients with MS, with the aortic valve affected in approximately 35% and the tricuspid valve in approximately 6%. The pulmonic valve is rarely affected. Two thirds of all patients with rheumatic MS are female. The interval between the initial episode of rheumatic fever (**see Chapter 74**) and clinical evidence of mitral valve obstruction is variable, ranging from a few years to more than 20 years.

Rheumatic fever results in characteristic changes of the mitral valve; diagnostic features are thickening at the leaflet edges, fusion of the commissures, and chordal shortening and fusion[2] (**Fig. 69.1**). With acute rheumatic fever, the changes include inflammation and edema of the leaflets, with small fibrin-platelet thrombi along the leaflet contact zones. Subsequent scarring leads to the characteristic valve deformity, with obliteration of the normal leaflet architecture by fibrosis, neovascularization, and increased collagen and tissue cellularity. *Aschoff bodies*, the pathologic hallmark of rheumatic disease, are seen most frequently in the myocardium, not the valve tissue, with Aschoff bodies identified in only 2% of autopsied patients with chronic valve disease.

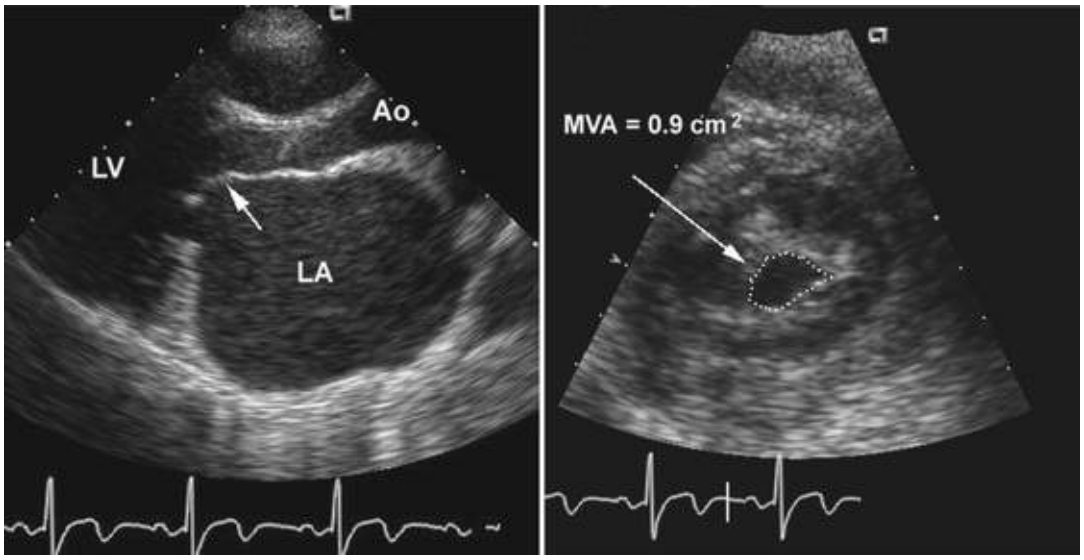

FIGURE 69.1 Parasternal long-axis **(left)** and short-axis **(right)** two-dimensional echocardiographic views showing the characteristic findings in rheumatic mitral stenosis. Note the commissural fusion that results in doming of the leaflets in the long-axis view and in a decrease in the width of the mitral orifice in the short-axis view. The patient has relatively thin, flexible leaflets with little subvalvular involvement. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *MVA,* mitral valve area. (From Otto CM. Valvular Heart Disease. Philadelphia: Saunders; 2004.)

These anatomic changes lead to a typical functional appearance of the rheumatic mitral valve. In earlier stages of the disease, the relatively flexible leaflets snap open in diastole into a curved shape because of restriction of motion at the leaflet tips (**see Fig. 69.1**; **see also Fig. 14.36**). This sudden restriction of leaflet opening in diastole is responsible for the characteristic opening snap (OS) on auscultation, and the interval between the second heart sound (S_2) and OS bears an inverse relationship with left atrial (LA) pressure. This "diastolic doming" is most evident in the motion of the anterior leaflet and becomes less prominent as the leaflets become more fibrotic and calcified, which also muffles the OS. The symmetric fusion of the commissures results in a small, central oval orifice in diastole that on pathologic specimens is shaped like a fish mouth or buttonhole because the anterior leaflet is not in the physiologic open position (**Fig. 69.2**; **see also Fig. 69.1, right, and Fig. 14.37**). With end-stage disease, the thickened leaflets may be so adherent and rigid that they cannot open or shut, with consequent reduction in or, rarely, even abolition of the first heart sound (S_1), and leading to combined MS and MR. When rheumatic fever results exclusively or predominantly in contraction and fusion of the chordae tendineae, with little fusion of the valvular commissures, dominant MR results.

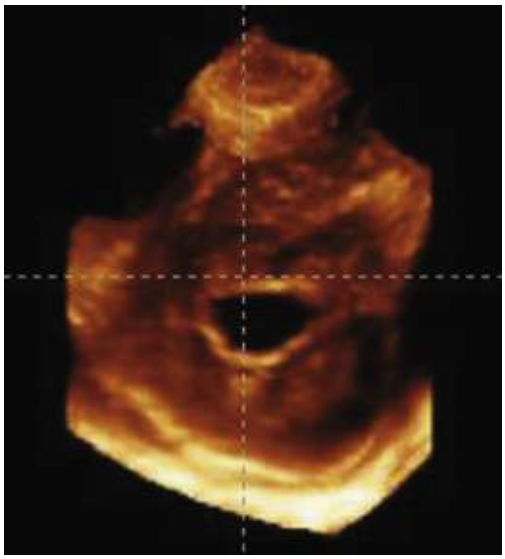

FIGURE 69.2 Three-dimensional imaging of rheumatic mitral stenosis, obtained by intraoperative epicardial echocardiography. Commissural fusion leaves the mitral valve with a small, circular orifice that has been likened to a fish mouth.

Debate continues about whether the anatomic changes of severe MS result from recurrent episodes of rheumatic fever or from a chronic autoimmune process caused by cross-reactivity between a streptococcal protein and valve tissue (**see Chapter 74**), or whether calcific valve disease is superimposed. Evidence supporting recurrent infection as an important factor in disease progression includes the correlation between the geographic variability in the prevalence of rheumatic heart disease and the age when patients present with severe MS. In North America and Europe, with approximately 1 case per 100,000 population, patients present with severe valve obstruction in the sixth decade of life. By contrast, in Africa, with a disease prevalence of 35 per 100,000, severe disease often is seen in teenagers. Conversely, evidence favoring superimposed calcific valve disease is the observation that restenosis after mitral valvuloplasty is caused by leaflet thickening and fibrosis, rather than representing recurrent commissural fusion.[3]

Congenital MS is uncommon and typically is diagnosed in infancy or early childhood (**see Chapter 75**), often as part of the Shone complex. MS is a rare complication of malignant carcinoid disease, generally seen only with pulmonary metastases or right-to-left shunting, systemic lupus erythematosus (SLE), rheumatoid arthritis, and mucopolysaccharidoses of the Hunter-Hurler phenotype, Fabry disease, and Whipple disease. Methysergide therapy is an unusual but documented cause of MS, as was the association with the diet drug fenfluramine (most notoriously in the combination drug Fen-Phen). The association of atrial septal defect with rheumatic MS is called Lutembacher syndrome.

Other conditions may result in obstruction to left ventricular (LV) inflow, including an LA tumor, particularly myxoma (**see Chapter 95**), ball valve thrombus in the left atrium (usually associated with MS), infective endocarditis with large vegetations (**Chapter 73**), or a congenital membrane in the left atrium (i.e., cor triatriatum; **Chapter 75**). In older patients, extensive mitral annular calcification may result in restriction of the size and motion of the annulus and may extend onto the base of the mitral leaflets, resulting in functional MS, although obstruction rarely is severe.[4] Mitral annular calcification often develops in patients with calcific aortic valve disease.[5] A particularly troublesome form of MS is seen following radiotherapy for chest or breast cancer. Characterized by heavy calcification and thickening of the aortomitral curtain,[6] it often requires multimodality imaging for full characterization.[7]

Pathophysiology

The most useful descriptor of the severity of mitral valve obstruction is the degree of valve opening in diastole, or the mitral valve orifice area. In normal adults the cross-sectional area of the mitral valve orifice (MVA) is 4 to 6 cm^2 (**Table 69.1**). When the orifice is reduced to approximately 2 cm^2, which is considered to represent mild MS, blood can flow from the left atrium to the left ventricle only if propelled by a small, although abnormal, pressure gradient. When the mitral valve opening is reduced to 1 cm^2, which is considered to represent severe MS,[8] a left atrioventricular (AV) pressure gradient of approximately 20 mm Hg (and therefore, with normal LV diastolic pressure, a mean LA pressure >25 mm Hg) is required to maintain normal cardiac output at rest (**Fig. 69.3**; **see also Fig. 19.13**).

TABLE 69.1

Stages of Mitral Stenosis (MS)

STAGE	DEFINITION	VALVE ANATOMY	VALVE HEMODYNAMICS*	HEMODYNAMIC CONSEQUENCES	SYMPTOMS
A	**At risk for MS**	Mild valve doming during diastole	Normal transmitral flow velocity	None	None
B	**Progressive MS**	Rheumatic valve changes with commissural fusion and diastolic doming of mitral valve leaflets Planimetered MVA >1.5 cm^2	Increased transmitral flow velocities MVA >1.5 cm^2 Diastolic pressure half-time <150 msec	Mild to moderate LA enlargement Normal pulmonary pressure at rest	None
C	**Asymptomatic severe MS**	Rheumatic valve changes with commissural fusion and diastolic doming of mitral valve leaflets Planimetered MVA ≤1.5 cm^2 (MVA ≤1 cm^2 with very severe MS)	MVA ≤1.5 cm^2 (MVA ≤1 cm^2 with very severe MS) Diastolic pressure half-time ≥150 msec (Diastolic pressure half-time ≥220 msec with very severe MS)	Severe LA enlargement Elevated PASP >30 mm Hg	None
D	**Symptomatic severe MS**	Rheumatic valve changes with commissural fusion and diastolic doming of mitral valve leaflets Planimetered MVA ≤1.5 cm^2	MVA ≤1.5 cm^2 (MVA ≤1 cm^2 with very severe MS) Diastolic pressure half-time ≥150 msec (Diastolic pressure half-time ≥220 msec with very severe MS)	Severe LA enlargement Elevated PASP >30 mm Hg	Decreased exercise tolerance Exertional dyspnea

*The transmitral mean pressure gradient should be obtained to determine the full hemodynamic effect of the MS and usually is greater than 5 to 10 mm Hg in severe MS; however, because of the variability of the mean pressure gradient with heart rate and forward flow, it has not been included in the criteria for severity.

LA, Left atrial; *MVA,* mitral valve area; *PASP,* pulmonary artery systolic pressure.

From Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACCF guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2014;63:e57-185.

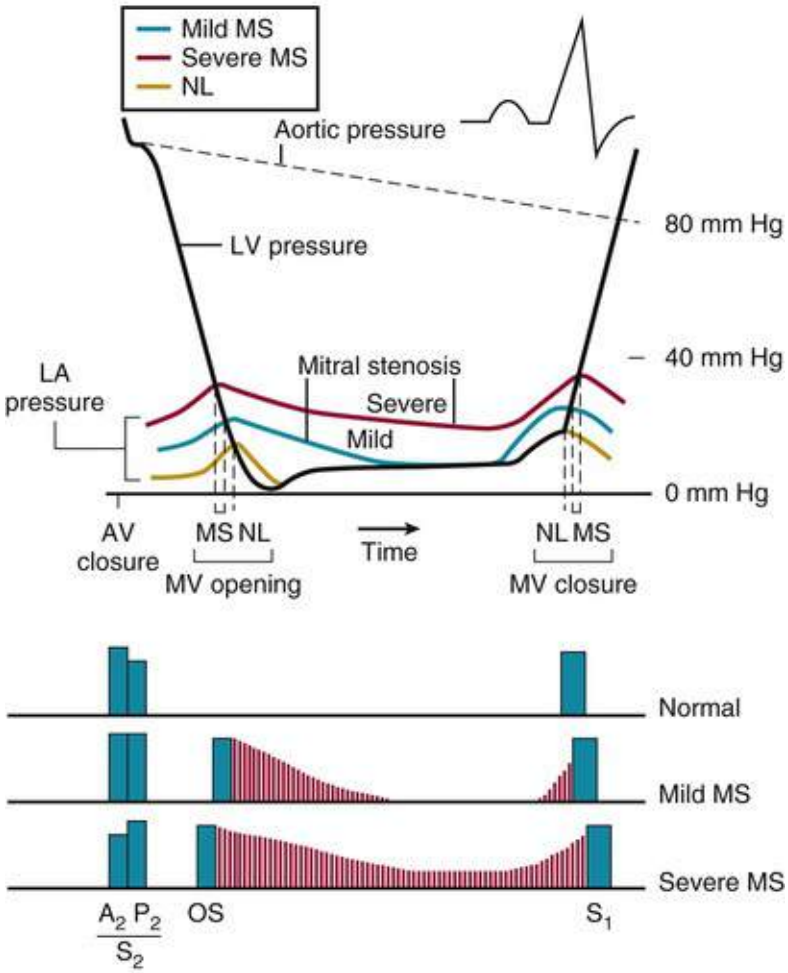

FIGURE 69.3 Schematic representation of left ventricular (LV), aortic, and left atrial (LA) pressures, showing normal (NL) relationships and alterations with mild and severe mitral stenosis (MS). Corresponding classic auscultatory signs of MS are shown at the *bottom* of the diagram. The higher left atrial *v* wave of severe MS causes earlier pressure crossover and earlier mitral valve (MV) opening, leading to a shorter interval between aortic valve (AV) closure and the opening snap (OS). The higher LA end-diastolic pressure with severe MS also results in later closure of the MV. With severe MS, the diastolic rumble becomes longer, and there is accentuation of the pulmonic component (P_2) of the second heart sound (S_2) in relation to the aortic component (A_2).

The transvalvular pressure gradient for any given valve area is a function of the square of the transvalvular blood velocity (v) in the simplified Bernoulli equation, balancing the potential energy of pressure with the kinetic energy of $\frac{1}{2}\rho v^2$, where ρ is blood density. Given that velocity is approximately equal to the instantaneous flow rate Q divided by MVA, the pressure gradient clearly is proportional to the square of the flow and inversely proportional to the square of valve area.[8] Thus a doubling of flow rate quadruples the pressure gradient, and any further reduction in valve area only exacerbates this. The elevated LA pressure in turn raises pulmonary venous and capillary pressures, resulting in exertional dyspnea. The first bouts of dyspnea in patients with MS usually are precipitated by tachycardia resulting from exercise, pregnancy, hyperthyroidism, anemia, infection, or atrial fibrillation (AF). All these (1) increase the rate of blood flow across the mitral orifice, resulting in further elevation of the LA pressure, and (2) decrease the diastolic filling time, resulting in a reduction in forward cardiac output. Because diastole shortens proportionately more than systole as heart rate increases, the time available for flow across the mitral valve is reduced at higher heart rates. At any given stroke volume, therefore, tachycardia results in a higher instantaneous volume flow rate and higher transmitral pressure gradient, which elevates LA pressures further. This higher transmitral gradient, often in combination with inadequate LV filling (because of the shortened diastolic filling time), explains the sudden occurrence of dyspnea and

pulmonary edema in previously asymptomatic patients with MS who develop AF with a rapid ventricular rate. It also accounts for the equally rapid clinical improvement in these patients when the ventricular rate is slowed. Compounding the direct impact of LA pressure on pulmonary capillary wedge pressure (PCWP) is the development of reflex pulmonary arterial vasospasm, which may further elevate pulmonary arterial pressure, leading to right-sided heart failure (HF).[9]

Atrial contraction augments the presystolic transmitral valvular gradient by approximately 30% in patients with MS (**Fig. 69.3**). AF is common in patients with MS, with an increasing prevalence with age. In patients with severe MS younger than 30 years, only approximately 10% are in AF, compared with approximately 50% of those older than 50s. Withdrawal of atrial transport when AF develops reduces cardiac output by approximately 20%, often resulting in symptom onset.

Obstruction at the mitral valve level has other hemodynamic consequences, which account for many of the adverse clinical outcomes associated with MS. Elevated LA pressure results in pulmonary artery hypertension, with secondary effects on the pulmonary vasculature and right-sided cardiac chambers. In addition, LA enlargement and stasis of blood flow are associated with an increased risk of thrombus formation and systemic embolism. Typically, the left ventricle is relatively normal or even small, unless there is coexisting MR, with the primary LV abnormalities being a small, underfilled chamber and paradoxical septal motion caused by right ventricular (RV) enlargement and dysfunction.

Hemodynamic Consequences of Mitral Stenosis

Pulmonary Hypertension.

In patients with MS and sinus rhythm, mean LA pressure is elevated (**see Fig. 69.3**), and the LA pressure curve shows a prominent atrial contraction (*a* wave), with a gradual pressure decline after mitral valve opening (*y* descent). In patients with mild to moderate MS without elevated pulmonary vascular resistance (PVR), pulmonary artery pressure (PAP) may be normal or only minimally elevated at rest but rises during exercise (**see eFig. 19.12**). However, in patients with severe MS and those with significantly increased PVR, PAP is elevated when the patient is at rest. Rarely, in patients with extremely elevated PVR, PAP may exceed systemic arterial pressure. Further elevations of LA and pulmonary vascular pressures occur during exercise and tachycardia, particularly with the onset of AF.

Pulmonary hypertension in patients with MS results from (1) passive backward transmission of the elevated LA pressure; (2) pulmonary arteriolar constriction, which presumably is triggered by LA and pulmonary venous hypertension (reactive pulmonary hypertension); and (3) organic obliterative changes in the pulmonary vascular bed, which may be considered a complication of longstanding and severe MS (**see Chapter 85**). With moderately elevated PAP (systolic pressure 30 to 60 mm Hg), RV performance is usually maintained. In time, severe pulmonary hypertension results in right-sided HF, with dilation of the right ventricle and its annulus, secondary tricuspid regurgitation, and sometimes pulmonic regurgitation. These changes in the pulmonary vascular bed may also exert a protective effect; the elevated precapillary resistance makes the development of symptoms of pulmonary congestion less likely by tending to prevent blood from surging into the pulmonary capillary bed and damming up behind the stenotic mitral valve. This protection, however, occurs at the expense of a reduced cardiac output. In patients with severe MS, pulmonary vein–bronchial vein shunts occur. Their rupture may cause hemoptysis. Patients with severe MS exhibit a reduction in pulmonary compliance, increase in the work of breathing, and redistribution of pulmonary blood flow from base to apex.

Left Ventricular Function.

The LV chamber typically is normal or small, with normal systolic function and normal LV end-diastolic pressure. However, coexisting MR, aortic valve lesions, systemic hypertension, ischemic heart disease, and cardiomyopathy all may be responsible for elevations of LV diastolic pressure.

Exercise Hemodynamics.

At any given severity of stenosis, the clinical picture is dictated largely by the levels of cardiac output and PVR with exertion. The response to a given degree of mitral obstruction may be characterized at one end of the hemodynamic spectrum by a normal cardiac output and high left AV pressure gradient or, at the opposite end of the spectrum, by a greatly reduced cardiac output and low transvalvular pressure gradient. Thus, in some patients entering the *severe* range of MS (with MVA of 1.0 to 1.5 cm^2), cardiac output may be normal at rest and rises normally during exertion. However, the high transvalvular pressure gradient with exertion elevates LA and pulmonary capillary pressures, leading to pulmonary congestion during exertion. By contrast, in other patients with MS in this range, there is an inadequate rise in cardiac output during exertion, resulting in a smaller rise in pulmonary venous pressure. In these patients, symptoms are caused by a low cardiac output rather than by pulmonary congestion. In patients with *critical* MS (MVA <1 cm^2), particularly when PVR is elevated, cardiac output usually is depressed at rest and may fail to rise at all during exertion. These patients frequently have resting weakness and fatigue secondary to a low cardiac output, with low-output and pulmonary congestion symptoms with exercise.

Left Atrial Changes.

The combination of mitral valve disease and atrial inflammation secondary to rheumatic carditis causes (1) LA dilation, (2) fibrosis of the atrial wall, and (3) disorganization of the atrial muscle bundles. These changes lead to disparate conduction velocities and inhomogeneous refractory periods. Premature atrial activation, caused by an automatic focus or reentry, may stimulate the left atrium during the vulnerable period, thereby precipitating AF. The development of this arrhythmia correlates independently with the severity of the MS, degree of LA dilation, and height of the LA pressure. However, in most studies of patients with severe MS undergoing percutaneous balloon mitral valvotomy (BMV), the strongest predictor of AF is older age. AF often is episodic at first but then becomes more persistent. AF causes diffuse atrophy of atrial muscle, further atrial enlargement, and further inhomogeneity of refractoriness and conduction (**see Chapter 38**). These changes lead in turn to irreversible AF.

Clinical Presentation

Symptoms

Dyspnea

The most common presenting symptoms of MS are dyspnea, fatigue, and decreased exercise tolerance.[3] Symptoms may be caused by a reduced ability to increase cardiac output normally with exercise or elevated pulmonary venous pressures and reduced pulmonary compliance. Dyspnea may be accompanied by cough and wheezing. Vital capacity is reduced, presumably because of the presence of engorged pulmonary vessels and interstitial edema. Patients who have critical obstruction to LA emptying and dyspnea with ordinary activity (New York Heart Association [NYHA] Functional Class III) generally have orthopnea as well and are at risk for attacks of frank pulmonary edema. The latter may be precipitated by effort, emotional stress, respiratory infection, fever pregnancy, or AF with a rapid ventricular rate or other tachyarrhythmia. Pulmonary edema may be caused by any condition that increases

the flow rate across the stenotic mitral valve, either because of an increase in total cardiac output or a reduction in the time available for blood flow across the mitral orifice to occur. In patients with a markedly elevated PVR, RV function often is impaired, and the presentation also may include symptoms and signs of right-sided HF.

MS is a slowly progressive disease, and many patients remain seemingly asymptomatic merely by readjusting their lifestyles to a more sedentary level. Usually, symptom status can be accurately assessed by a directed history, asking the patient to compare current levels of maximum exertion with those at specific times in the past. Interviewing the family may reveal limitations that the patient does not acknowledge. Exercise testing may be useful for selected patients to determine functional status objectively and may be combined with Doppler echocardiography (see later) to assess exercise hemodynamics.

Hemoptysis

Hemoptysis is rare in patients with a known diagnosis of MS because intervention usually is performed before severe obstruction becomes chronic. When hemoptysis does occur, it can be sudden and severe, caused by rupture of thin-walled, dilated bronchial veins, usually because of a sudden rise in LA pressure, or it may be milder, with only blood-stained sputum associated with attacks of paroxysmal nocturnal dyspnea. The pink, frothy sputum characteristic of acute pulmonary edema with rupture of alveolar capillaries also may develop in these patients. Hemoptysis also may be caused by pulmonary infarction, a late complication of MS associated with HF.

Chest Pain

Chest pain is not a typical symptom of MS, but a small proportion, perhaps 15%, of patients with MS experience chest discomfort that is indistinguishable from that of angina pectoris. This symptom may be caused by severe RV hypertension secondary to the pulmonary vascular disease or by concomitant coronary atherosclerosis. Rarely, chest pain may be secondary to coronary obstruction caused by coronary embolization. In many patients, however, a satisfactory explanation for the chest pain cannot be uncovered, even after complete hemodynamic and angiographic studies.

Palpitations and Embolic Events

Patients with MS often are initially diagnosed when they present with AF or an embolic event.

Other Symptoms

Compression of the left recurrent laryngeal nerve by a greatly dilated left atrium, enlarged tracheobronchial lymph nodes, and dilated pulmonary artery may cause hoarseness (Ortner syndrome). A history of repeated hemoptysis is common in patients with pulmonary hemosiderosis. Systemic venous hypertension, hepatomegaly, edema, ascites, and hydrothorax are all signs of severe MS with elevated PVR and right-sided HF.

Physical Examination

The most common findings on physical examination in patients with MS are an irregular pulse caused by AF and signs of left- and right-sided HF (**see Chapter 10**). The classic diastolic murmur and loud S_1 often are difficult to appreciate. Patients with severe chronic MS, a low cardiac output, and systemic

vasoconstriction may exhibit the so-called mitral facies, characterized by pinkish purple patches on the cheeks. The arterial pulse is usually normal, but in patients with a reduced stroke volume, the pulse may be low in volume. The jugular venous pulse (JVP) usually exhibits a prominent *a* wave in patients with sinus rhythm and elevated PVR. In patients with AF, the *x* descent of the JVP disappears, and there is only one crest, a prominent *v* or *c-v* wave, per cardiac cycle. Palpation of the cardiac apex usually reveals an inconspicuous left ventricle; the presence of a palpable presystolic expansion wave or an early diastolic rapid filling wave speaks strongly against serious MS. A readily palpable, tapping S_1 suggests that the anterior mitral valve leaflet is pliable. When the patient is in the left lateral recumbent position, a diastolic thrill of MS may be palpable at the apex. Often, a RV lift is felt in the left parasternal region in patients with pulmonary hypertension. A greatly enlarged right ventricle may displace the left ventricle posteriorly and produce a prominent RV apex beat that can be confused with a LV lift. A loud P_2 may be palpable in the second left intercostal space in patients with MS and pulmonary hypertension.

Auscultation

The auscultatory features of MS (**see Fig. 69.3**) include an accentuated S_1 with prolongation of the Q-S_1 interval, correlating with the level of the LA pressure. Accentuation of S_1 occurs when the mitral valve leaflets are flexible. It is caused in part by the rapidity with which LV pressure rises at the time of mitral valve closure, as well as by the wide closing excursion of the leaflets. Marked calcification and/or thickening of the mitral valve leaflets reduce the amplitude of S_1, probably because of diminished motion of the leaflets. As PAP rises, P_2 at first becomes accentuated and widely transmitted and often can be readily heard at both the mitral and the aortic areas. With further PAP elevation, splitting of S_2 narrows because of reduced compliance of the pulmonary vascular bed, with earlier pulmonic valve closure. Lastly, S_2 becomes single and accentuated. Other signs of severe pulmonary hypertension include a nonvalvular pulmonic ejection sound that diminishes during inspiration, because of dilation of the pulmonary artery, a systolic murmur of tricuspid regurgitation, a Graham Steell murmur of pulmonic regurgitation, and an S_4 originating from the right ventricle. An S_3 gallop originating from the left ventricle is absent in patients with MS unless significant MR or aortic regurgitation coexists.

Opening Snap.

The mitral OS is caused by a sudden tensing of the valve leaflets after the valve cusps have completed their opening excursion. The OS occurs when the movement of the mitral dome into the left ventricle suddenly stops. It is most readily audible at the apex, using the diaphragm of the stethoscope. The OS usually can be differentiated from P_2 because the OS occurs later, unless right bundle branch block is present. In addition, the OS usually is loudest at the apex, whereas S_2 is best heard at the cardiac base. The mitral valve cannot be totally rigid if it produces an OS, so an OS usually is accompanied by an accentuated S_1. Calcification confined to the tip of the mitral valve leaflets does not preclude an OS, although calcification of the body and tip does. The mitral OS follows A_2 by 0.04 to 0.12 second; this interval varies inversely with the LA pressure (**see Fig. 69.3**). A short A_2-OS interval is a reliable indicator of severe MS, but accurate estimation of this time interval requires considerable experience.

Diastolic Murmur.

The diastolic, low-pitched, rumbling murmur of MS is best heard at the apex, with the bell of the stethoscope (low-frequency mode on electronic stethoscopes) and with the patient in the left lateral

recumbent position. When this murmur is soft, it is limited to the apex but, when louder, may radiate to the left axilla or the lower left sternal area. Although the intensity of the diastolic murmur is not closely related to the severity of stenosis, the pitch and duration of the murmur are a guide to the severity of mitral valve narrowing. The murmur persists for as long as the left AV pressure gradient exceeds approximately 3 mm Hg, and it is higher in pitch for higher-velocity (and higher-gradient) transmitral jets. The murmur usually commences immediately after the OS. In mild MS the early diastolic murmur is brief but, in the presence of sinus rhythm, resumes in presystole. In severe MS the murmur persists until end-diastole, with presystolic accentuation while sinus rhythm is maintained (**see Fig. 69.3**).

Other Auscultatory Findings.

A pansystolic murmur of tricuspid regurgitation and a S_3 originating from the right ventricle may be audible in the fourth intercostal space in the left parasternal region in patients with severe MS. These signs, which are secondary to pulmonary hypertension, may be confused with the findings of MR. However, the inspiratory augmentation of the murmur and of the S_3 and the prominent *v* wave in the jugular venous pulse aid in establishing that the murmur originates from the tricuspid valve. A high-pitched decrescendo diastolic murmur along the left sternal border in patients with MS and pulmonary hypertension may be audible pulmonic regurgitation (Graham Steell murmur) but more often is caused by concomitant aortic regurgitation.

Diagnosis and Evaluation

Differential Diagnosis

Mitral stenosis is a rare diagnosis in developed countries, and most apical diastolic murmurs have other causes. In older patients, an apical diastolic rumble is most likely to be caused by mitral annular calcification, and 90% of patients with a diastolic apical murmur have no significant stenosis on echocardiography. In patients with a normally functioning mitral prosthesis, a diastolic murmur is a frequent finding. In severe MR—indeed, in any condition in which flow across a nonstenotic mitral valve is increased (e.g., a ventricular septal defect)—there may also be a short diastolic murmur following an S_3. LA myxoma (**see Chapter 95**) may produce auscultatory findings similar to those in rheumatic valvular MS. A diastolic rumble may also be present in some patients with hypertrophic cardiomyopathy (HCM), caused by early diastolic flow into the hypertrophied, nondistensible left ventricle (**see Chapter 78**).

Echocardiography

Echocardiography is the most accurate approach to the diagnosis and evaluation of MS[8,10] (**see Chapter 14**). It is recommended for all patients with MS at initial presentation, for reevaluation of changing symptoms or signs, and at regular intervals (depending on disease severity) for monitoring disease progression (**see Table 69.1**). Imaging shows the characteristic anatomy with leaflet thickening and restriction of opening caused by symmetric fusion of the commissures, resulting in "doming" of the leaflets in diastole (**see Fig. 69.1**; **see also Fig. 14.36** and Videos 69.1A and 69.2A). As disease becomes more severe, thickening extends from the leaflet tips toward the base, with further restriction of motion and less curvature of the leaflet in diastole. The mitral chords are variably thickened, fused, and shortened, with superimposed calcification of the valve apparatus in many cases.

Mitral valve area is measured by direct planimetry from two-dimensional short-axis images (**see Fig.**

69.1, right, and Fig. 14.38; Videos 69.1B and 69.2B) and calculated by the Doppler pressure half-time and proximal isovelocity surface area (PISA) methods (**see Figs. 14.39 and 14.40**; Video 69.3), each of which has technical challenges.[11] The transmitral gradient also is calculated and any coexisting MR quantitated on the basis of the accepted guidelines.[12,13] Three-dimensional echocardiography is playing an increasing role in assessing mitral valve morphology and quantifying severity of MS[14-18] (**see Fig. 69.2**; **see also Fig. 14.38**; Videos 69.4 and 69.5). Evaluation of the morphology of the valve is helpful for predicting the hemodynamic results and outcome of percutaneous BMV. The Wilkins score consists of four components summed together, graded 0 to 4+ for leaflet thickness, mobility, calcification, and chordal involvement to provide an overall score that is favorable (low) or unfavorable (high) for valvuloplasty (**see Table 14.9**). Confirming earlier reports, the Wilkins score continues to predict long-term outcome after BMV[19] (**see Fig. 72.7**). Other important anatomic features of the valve are the degree of anterior leaflet doming, symmetry of commissural fusion, and distribution of leaflet calcification.[8]

Other key features on echocardiography are LA size, PAP, LV size and systolic function, and RV size and systolic function. When pulmonary hypertension is present, the right ventricle frequently is dilated, with reduced systolic function. Tricuspid regurgitation may be secondary to RV dysfunction and annular dilation or may be caused by rheumatic involvement of the tricuspid valve (**see Chapter 70**). Complete evaluation of aortic valve anatomy and function also is important because the aortic valve is affected in approximately one third of patients with MS. When transthoracic images are suboptimal, transesophageal echocardiography (TEE) is appropriate. TEE also is necessary to exclude LA thrombus and to evaluate MR severity when percutaneous BMV is considered.

Exercise Testing with Doppler Echocardiography

Exercise testing is useful for many patients with MS to ascertain the level of physical conditioning and elicit covert cardiac symptoms. The exercise test can be combined with Doppler echocardiography to assess exercise pulmonary pressure,[20] usually with the Doppler examination performed at rest after termination of treadmill exercise, but sometimes performed during bicycle exercise (**see Chapter 14**). Exercise Doppler testing is recommended when a discrepancy exists between resting echocardiographic findings and severity of clinical symptoms.[21] Useful parameters on exercise testing include exercise duration, blood pressure and heart rate response, change in mitral peak and (especially) mean gradient, and increase in pulmonary pressures with exercise, compared with the expected normal changes. An exercise pulmonary systolic pressure greater than 60 mm Hg can be a key data point in the management of these patients.

Other Diagnostic Evaluation Modalities

Electrocardiography.

The electrocardiogram (ECG) is relatively insensitive for detecting mild MS but does show characteristic changes in moderate or severe obstruction (**see Chapter 12**). LA enlargement (P wave duration in lead II >0.12 second and/or a P wave axis between +45 and −30 degrees) is a principal ECG feature of MS and is found in 90% of patients with significant MS and sinus rhythm. The ECG signs of LA enlargement correlate more closely with LA volume than with LA pressure and often regress after successful valvotomy. AF is common with longstanding MS, as noted.

ECG evidence of RV hypertrophy correlates with RV systolic pressure. When RV systolic pressure is 70 to 100 mm Hg, approximately 50% of patients exhibit ECG criteria for RV hypertrophy, including a

mean QRS axis greater than 80 degrees in the frontal plane and R:S ratio greater than 1 in lead V_1. Other patients with this degree of pulmonary hypertension have no frank evidence of RV hypertrophy, but the R:S ratio fails to increase from the right to the midprecordial leads. When RV systolic pressure is greater than 100 mm Hg in patients with isolated or predominant MS, ECG evidence of RV hypertrophy is consistently found.

Radiography.

Patients with hemodynamically significant MS almost invariably have evidence of LA enlargement on the lateral and left anterior oblique views (**see Fig. 15.3**), although the cardiac silhouette may be normal in the frontal projection. Extreme LA enlargement rarely occurs in isolated MS; when present, MR usually is severe. Enlargement of the pulmonary artery, right ventricle, and right atrium (as well as the left atrium) is commonly seen in patients with severe MS causing pulmonary hypertension. Occasionally, calcification of the mitral valve is evident on the chest radiograph, but more often fluoroscopy is required to detect valvular calcification.

Radiologic changes in the lung fields indirectly reflect the severity of MS. Interstitial edema, an indication of severe obstruction, is manifested as Kerley B lines (dense, short, horizontal lines most frequently seen in costophrenic angles) (**see Fig. 15.5**). This finding is present in 30% of patients with resting PCWP less than 20 mm Hg and in 70% with pressure greater than 20 mm Hg. Severe longstanding mitral obstruction often results in Kerley A lines (straight, dense lines up to 4 cm in length, running toward the hilum), as well as the findings of pulmonary hemosiderosis and rarely, parenchymal ossification.

Cardiac Computed Tomography and Magnetic Resonance Imaging.

Cardiac CT scanning can provide MVA estimates in MS by planimetry after multiplanar reconstruction, although these typically are somewhat larger than those obtained by echocardiography or catheterization.[22,23] Cardiac magnetic resonance imaging (CMR) can also estimate the stenotic valve area, either by planimetry or continuity, with closer agreement to echocardiographic values than CT.[23,24] These tomographic techniques can also provide information on LA cavity and appendage thrombi.

Cardiac Catheterization.

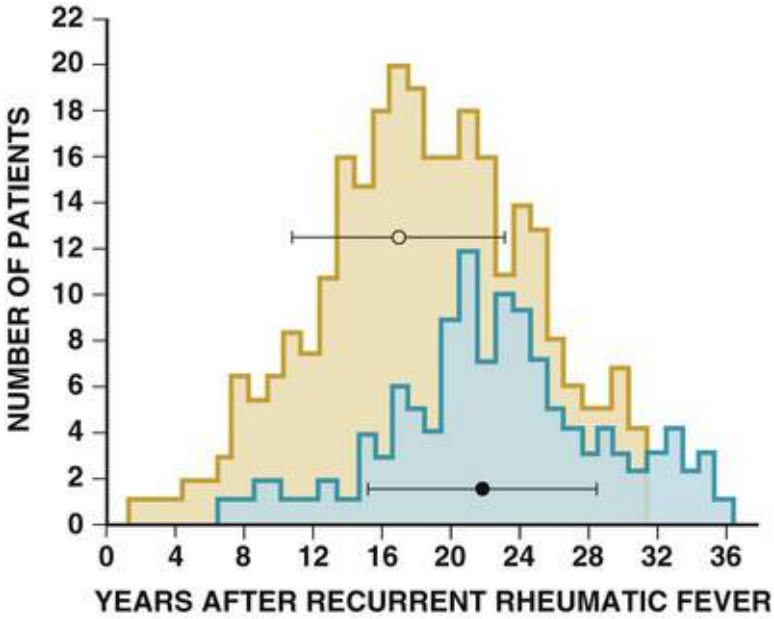
Catheter-based measurement of LA and LV pressures shows the expected hemodynamics (**see Fig. 19.13**) and allows measurement of the mean transmitral pressure gradient and, in conjunction with measurement of transmitral volume flow rate, calculation of the valve area using the Gorlin formula. Occasionally, diagnostic cardiac catheterization is necessary when echocardiography is nondiagnostic or results are discrepant with clinical findings. More often, these measurements now are recorded for monitoring before, during, and after percutaneous BMV. Routine diagnostic cardiac catheterization is not recommended for the evaluation of MS.

Disease Course

Interval Between Acute Rheumatic Fever and Mitral Valve Obstruction

In temperate zones, such as the United States and Western Europe, patients who develop acute rheumatic fever have an asymptomatic period of approximately 15 to 20 years before symptoms of MS develop (**see eFig. 69.1**). It then takes approximately 5 to 10 years for most patients to progress from mild disability (i.e., early NYHA Class II) to severe disability (NYHA Class III or IV). The progression is much more rapid in patients in tropical and subtropical areas, in Polynesians, and in Native Alaskans. In India, critical MS may be present in children as young as 6 to 12 years of age. In North America and Western

Europe, however, symptoms develop more slowly, with onset usually between ages 45 and 65 years. The most likely causes for these differences are the relative prevalence of rheumatic fever and lack of primary and secondary prevention in developing countries, resulting in recurrent episodes of valve scarring (**see Chapter 74**).



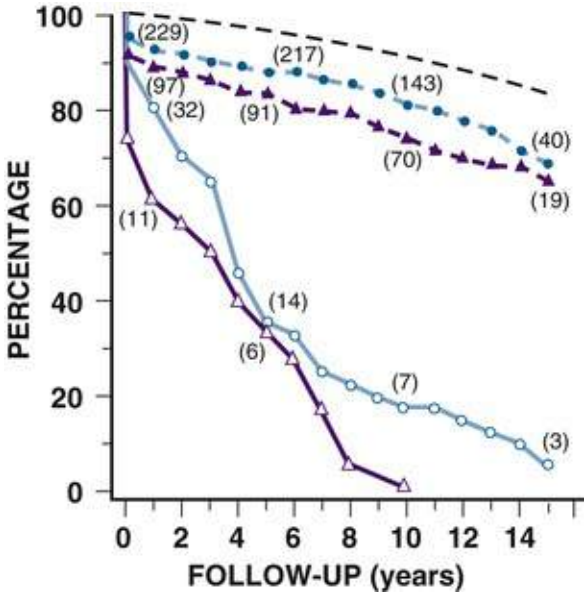
EFIGURE 69.1 Interval between active rheumatic fever and clinical symptoms of valve disease in 177 patients with mitral stenosis (*yellow bars*) and 121 with aortic stenosis (*blue bars*). (From Horstkotte D, Niehues R, Strauer BE. Pathomorphological aspects, aetiology, and natural history of acquired mitral valve stenosis. Eur Heart J 1991;12[Suppl B]:55-60.)

Hemodynamic Progression

Serial echocardiographic data have described the rate of hemodynamic progression in patients with mild MS.[3,8] The two largest series had a combined total of 153 adults, with a mean age of approximately 60 years, with an average follow-up of slightly more than 3 years. As in most series of patients with MS, 75% to 80% were women. The initial MVA was 1.7 ±0.6 cm^2, and the overall rate of progression was a decrease in valve area of 0.09 cm^2/yr. Approximately one third of patients showed rapid progression, defined as a decrease in MVA of more than 0.1 cm^2/yr. These data apply to the older patients with MS seen in developed countries. Few data are available on the rate of hemodynamic progression of rheumatic MS in underdeveloped countries, where the age at symptom onset is much younger.

Clinical Outcomes

Natural history data obtained in the presurgical era indicate that symptomatic patients with MS have a poor outlook, with 5-year survival rates of 62% for MS patients in NYHA Class III but only 15% in Class IV. Data from unoperated patients in the surgical era still reported a 5-year survival rate of only 44% in patients with symptomatic MS who refused valvotomy (**eFig. 69.2**).



EFIGURE 69.2 Natural history of the respective valvular lesion in 159 patients with isolated mitral stenosis (MS) (*solid blue line*) or mitral regurgitation (MR) (*solid purple line*) who did not have surgery, even though operation was indicated, compared with patients treated with valve replacement for MS (*dashed blue line*) or MR (*dashed purple line*). The expected survival rate in the absence of mitral valve disease is indicated by the *upper curve* (*dashed black line*). (From Horstkotte D, Niehues R, Strauer BE. Pathomorphological aspects, aetiology, and natural history of acquired mitral valve stenosis. Eur Heart J 1991;12[Suppl B]:55-60.)

Overall clinical outcomes are greatly improved in patients who undergo surgical or percutaneous relief of valve obstruction on the basis of current guidelines.[21,25] However, longevity is still shortened compared with that expected for age, largely because of complications of the disease process (AF, systemic embolism, pulmonary hypertension) and side effects of therapy (e.g., prosthetic valves, anticoagulation).

Complications

Atrial Fibrillation

The most common complication of MS is AF (**see Chapter 38**).[3] The prevalence of AF in patients with MS is related to the severity of valve obstruction and patient age. In historical series, AF was present in 17% of patients age 21 to 30 years, 45% age 31 to 40 years, 60% age 41 to 50, and 80% older than 51. Even when MS is severe, the prevalence of AF is related to age. In more recent BMV studies, prevalence of AF ranged from 4% in a series of 600 patients from India (mean age, 27 years) to 27% in 4832 patients from China (mean age, 37) to 40% in 1024 patients from France (mean age, 49).

AF may precipitate or worsen symptoms caused by loss of the atrial contribution to filling and to a short diastolic filling period when the ventricular rate is not well controlled. In addition, AF predisposes affected patients to LA thrombus formation and systemic embolic events. AF conveys a worse overall prognosis in MS patients than in the general population. In patients with AF and MS, 5-year survival is only 64%, compared with 85% in patients with AF but without MS.

Systemic Embolism

Systemic embolism in patients with MS is caused by LA thrombus formation. Although systemic embolization most often occurs in patients with AF, 20% of patients with MS and a systemic embolic event are in sinus rhythm. When embolization occurs in patients in sinus rhythm, the possibility of transient AF or underlying infective endocarditis should be considered. However, up to 45% of patients with MS who are in normal sinus rhythm demonstrate prominent spontaneous LA contrast (a marker of

embolic risk; Video 69.6) on TEE (**see Chapter 14**). Atrial thrombi have been documented in a few patients with MS in sinus rhythm, and many patients with new-onset AF have LA thrombi. It is postulated that the loss of atrial appendage contractile function, despite electrical evidence of sinus rhythm, leads to blood flow stasis and thrombus formation. Additional evidence implicates inflammatory markers, endothelial dysfunction, and platelet activation as inciting mechanisms for thromboembolism.[26,27]

The risk of embolism correlates directly with patient age and LA size[28] and inversely with the cardiac output. Before the advent of surgical treatment, this serious complication of MS developed in at least 20% of patients at some time during the course of their disease. Before the era of anticoagulant therapy and surgical treatment, approximately 25% of all fatalities in patients with MS were secondary to systemic embolism.

Approximately half of all clinically apparent emboli are found in the cerebral vessels. Coronary embolism may lead to myocardial infarction (MI) and angina pectoris, and renal emboli may be responsible for the development of systemic hypertension. Emboli are recurrent and multiple in approximately 25% of patients who develop this complication. Rarely, massive thrombosis develops in the left atrium, resulting in a pedunculated ball-valve thrombus, which may suddenly aggravate obstruction to LA outflow when a specific body position is assumed or may cause sudden death. Similar consequences occur in patients with free-floating thrombi in the left atrium. These two conditions usually are characterized by variability in the physical findings, often on a positional basis. They are very hazardous and necessitate surgical treatment, often on an emergency basis.

Infective Endocarditis

MS is a predisposing factor for endocarditis in less than 1% of cases in clinical series of bacterial endocarditis (**see Chapter 73**). The estimated risk of endocarditis in patients with MS is 0.17 per 1000 patient-years, which is much lower than the risk in patients with MR or aortic valve disease.

Medical Management

Drug Treatment

The medical management of MS is directed primarily toward (1) prevention of recurrent rheumatic fever, (2) prevention and treatment of complications of MS, and (3) monitoring disease progression to allow intervention at the optimal time.[3] Patients with MS caused by rheumatic heart disease should receive penicillin prophylaxis for beta-hemolytic streptococcal infections to prevent recurrent rheumatic fever, per established guidelines (**see Chapter 74**). Prophylaxis for infective endocarditis is no longer recommended (**Chapter 73**). Anemia and infections should be treated promptly and aggressively in patients with valvular heart disease. Of note, however, blood cultures should always be considered before initiation of antibiotic therapy in patients with valve disease, because the presentation of endocarditis often is mistaken for a noncardiac infection.

Anticoagulation with vitamin K antagonists (VKAs) for prevention of systemic embolism is warranted in any patient with MS and AF, prior embolism, or known thrombus in the LA cavity or appendage.[21] Anticoagulation also may be considered for patients with severe MS and sinus rhythm when there is severe LA enlargement (diameter >55 mm) or spontaneous contrast on echocardiography. Treatment with warfarin is used to maintain the international normalized ratio (INR) between 2 and 3.[29] Few data address the safety and utility of novel oral anticoagulants (NOACs) in MS, because such patients were generally excluded from all NOAC trials (**see Chapter 93**), although there has been a recent publication calling for

a randomized trial to test VKAs and NOACs in patients with MS.[30]

Asymptomatic patients with mild to moderate rheumatic mitral valve disease should have a history and physical examination annually, with echocardiography every 3 to 5 years for mild stenosis, every 1 to 2 years for moderate stenosis, and annually for severe stenosis. More frequent evaluation is appropriate for any change in signs or symptoms. All patients with significant MS should be advised to avoid occupations requiring strenuous exertion.

In patients with severe MS, with persistent symptoms after intervention or when intervention is not possible, medical therapy with oral diuretics and the restriction of sodium intake may improve symptoms. Digitalis glycosides do not alter the hemodynamics and usually do not benefit patients with MS and sinus rhythm, but these drugs are of value in slowing the ventricular rate in patients with AF and in treating patients with right-sided HF. Hemoptysis is managed by measures designed to reduce pulmonary venous pressure, including sedation, assumption of the upright position, and aggressive diuresis. Beta-adrenergic blocking agents and rate-slowing calcium antagonists may increase exercise capacity by reducing heart rate in patients with sinus rhythm, especially in patients with AF.

Treatment of Arrhythmias.

AF is a frequent complication of severe MS. Management of AF for patients with MS is similar to management for AF of any cause (**see Chapter 38**). However, it typically is more difficult to restore and maintain sinus rhythm because of pressure overload of the left atrium in conjunction with effects of the rheumatic process on atrial tissue and the conducting system.

Immediate treatment of AF includes administration of intravenous (IV) heparin followed by oral warfarin. The ventricular rate should be slowed, as stated in the American College of Cardiology/American Heart Association (ACC/AHA) guidelines for the management of AF,[29] initially with an IV beta blocker or nondihydropyridine calcium channel antagonist, followed by long-term rate control with oral doses of these agents. When these medications are ineffective or when additional rate control is necessary, digoxin or amiodarone may be considered. Digoxin alone for long-term management of AF may be considered in patients with concurrent LV dysfunction or a sedentary lifestyle. An effort should be made to reestablish sinus rhythm by a combination of pharmacologic treatment and cardioversion. If cardioversion is planned in a patient who has had AF for more than 24 hours before the procedure, anticoagulation with warfarin for more than 3 weeks is indicated. Alternatively, if TEE results show no atrial thrombus, immediate cardioversion can be carried out provided the patient is effectively anticoagulated with IV heparin before and during the procedure and with warfarin chronically thereafter. Paroxysmal AF and repeated conversions, spontaneous or induced, carry the risk of embolization. In patients who cannot be converted or maintained in sinus rhythm, beta blockers or digitalis should be used to maintain the ventricular rate at rest at approximately 60 beats/min. Beta blockers are particularly helpful in preventing rapid ventricular responses that develop during exertion. Multiple repeat cardioversions are not indicated if the patient fails to sustain sinus rhythm while receiving adequate doses of an antiarrhythmic.

Patients with chronic AF who undergo surgical mitral valve repair or replacement may undergo the maze procedure. More than 80% of patients undergoing this procedure can be maintained in sinus rhythm postoperatively and can regain normal atrial function, including a satisfactory success rate in those with significant LA enlargement. Early intervention with percutaneous valvotomy may prevent the development of AF.

Mitral Valvotomy

Percutaneous Balloon Mitral Valvotomy

Patients with mild to moderate MS who are asymptomatic frequently remain so for years, and clinical outcomes are similar to those in age-matched normal individuals. Severe or symptomatic MS, however, is associated with poor long-term outcomes if the stenosis is not relieved mechanically (**see eFig. 69.2**). Percutaneous BMV is the procedure of choice for the treatment of MS; surgical intervention is now reserved for patients who require intervention and are not candidates for a percutaneous procedure[8] (**see Chapter 72**).

BMV is recommended for symptomatic patients with moderate to severe MS (i.e., MVA <1 cm^2/m^2 of body surface area [BSA] or <1.5 cm^2 in normal-sized adults) and with favorable valve morphology, no or mild MR, and no evidence of LA thrombus (**Fig. 69.4**). Even mild symptoms, such as a subtle decrease in exercise tolerance, are an indication for intervention because the procedure relieves symptoms and improves long-term outcome with a low procedural risk. In addition, BMV is a reasonable option for asymptomatic patients with very severe MS (<1 cm^2) with favorable valve anatomy or when mitral valve obstruction has resulted in AF.[21] Of note, AF precipitates symptoms in most patients with significant MS.

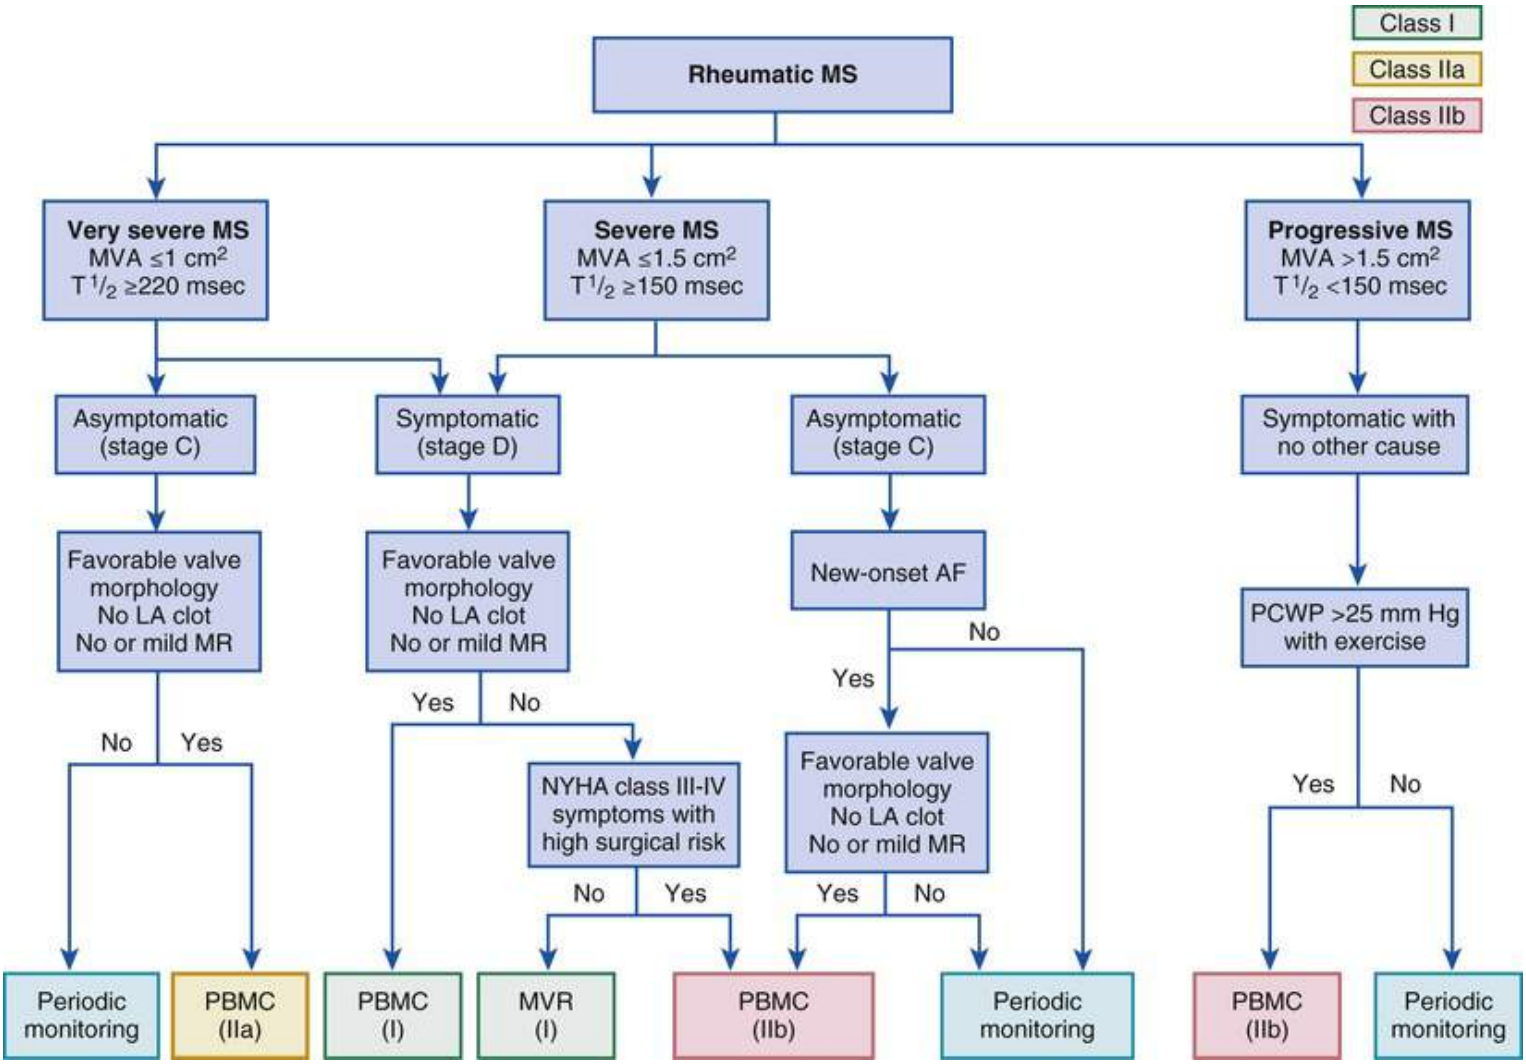


FIGURE 69.4 Indications for intervention for rheumatic mitral stenosis (MS). AF, Atrial fibrillation; LA, left atrial; MR, mitral regurgitation; MVA, mitral valve area; MVR, mitral valve surgery (repair or replacement); PBMC, percutaneous balloon mitral commissurotomy; PCWP, pulmonary capillary wedge pressure; $T_{1/2}$, pressure half-time. (From Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACCF guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2014;63:e57-185.)

BMV also may be considered in symptomatic patients in whom surgery carries high risk for adverse events or outcomes, even when valve morphology is not ideal, including patients with restenosis after a previous BMV or previous surgical commissurotomy who are unsuitable candidates for surgery because of very high risk. These include very old, frail patients; patients with associated severe ischemic heart disease; patients in whom MS is complicated by pulmonary, renal, or neoplastic disease; women of childbearing age in whom mitral valve replacement is undesirable; and pregnant women with MS.

BMV may be further considered for patients with mild MS in whom symptoms cannot be explained by other causes and who experience pulmonary hypertension (PCWP >25 mm Hg) with exercise (**see Fig. 69.4**). In this last group, it is likely that valve obstruction is the cause of pulmonary hypertension, even when stenosis severity does not meet the valve area criteria for severe obstruction.

This percutaneous technique consists of advancing a small balloon flotation catheter across the interatrial septum (after transseptal puncture), enlarging the opening, advancing a large (23- to 25-mm) hourglass-shaped (Inoue) balloon, and inflating it within the orifice[19,31] (**Fig. 69.5**; **see also Fig. 72.6**; Video 69.7). Alternatively, two smaller (15- to 20-mm) side-by-side balloons across the mitral orifice may be used. A third technique involves retrograde, nontransseptal dilation of the mitral valve, in which the balloon is positioned across the mitral valve using a steerable guidewire.

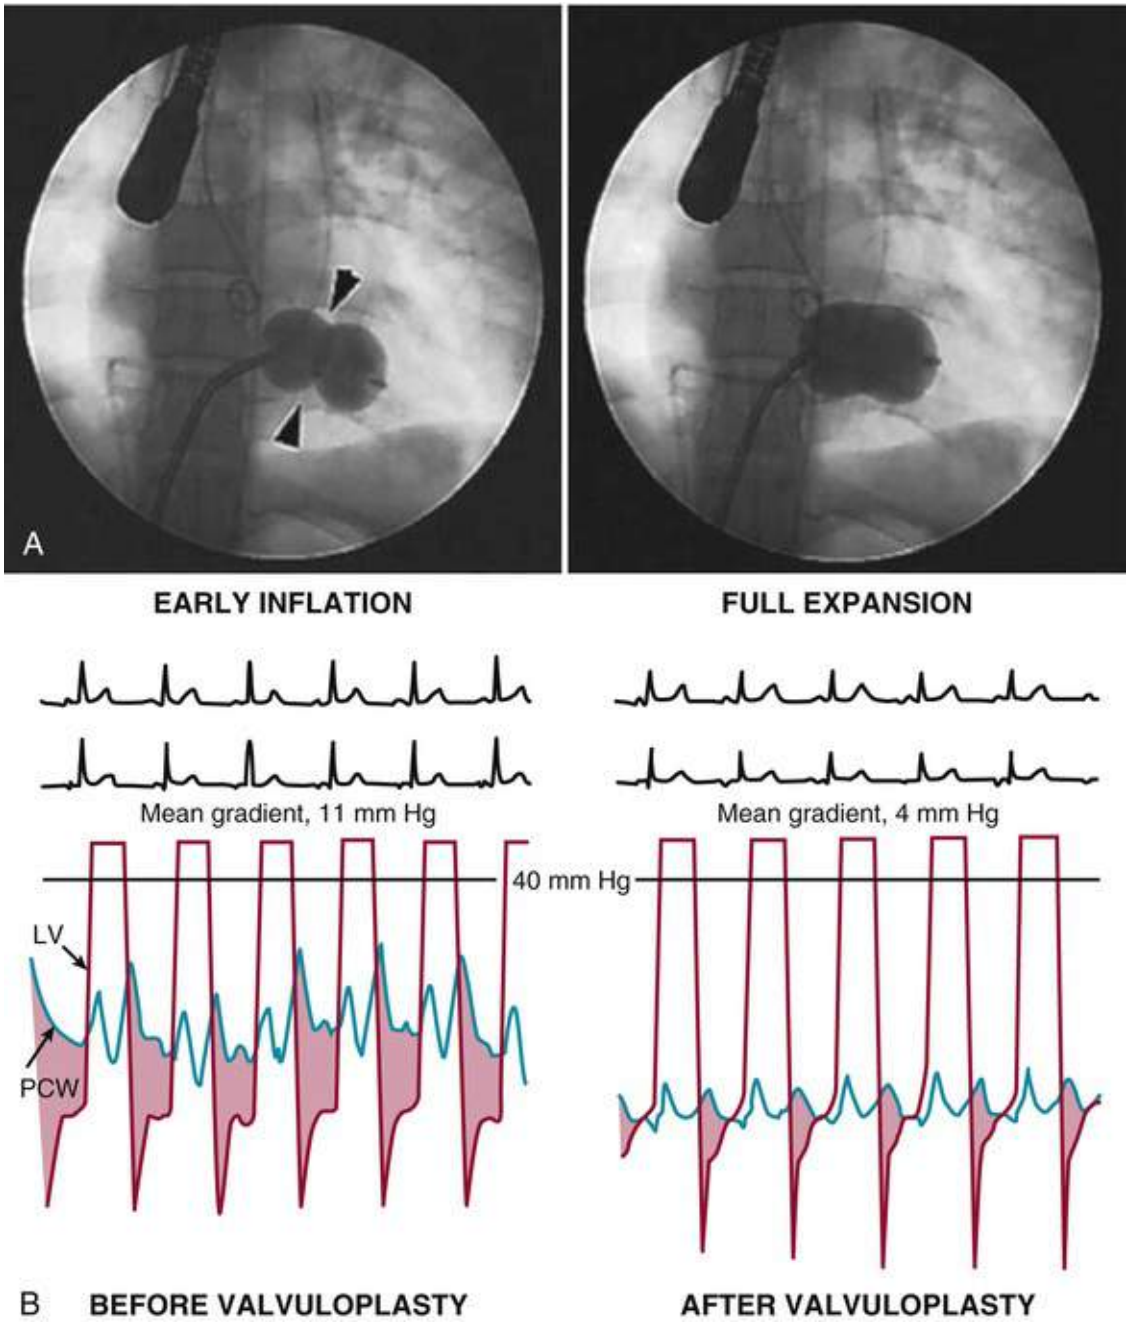

FIGURE 69.5 Percutaneous balloon mitral valvotomy (BMV) for mitral stenosis using the Inoue technique (**see Chapter 72**). **A,** The catheter is advanced into the left atrium using the transseptal technique and guided in antegrade fashion across the mitral orifice. As the balloon is inflated, its distal portion expands first; this is pulled back so that it fits snugly against the orifice (*arrowheads*). With further inflation, the proximal portion of the balloon expands to center the balloon within the stenotic orifice **(left).** Further inflation expands the central "waist" portion of the balloon **(right),** resulting in commissural splitting and enlargement of the orifice. **B,** Successful BMV results in significant increase in mitral valve area, as reflected by a reduction in the diastolic pressure gradient between left ventricle (*magenta*) and pulmonary capillary wedge (PCW) (*blue*) pressure, as indicated by the *shaded* area. (From Delabays A, Goy JJ. Images in clinical medicine: percutaneous mitral valvuloplasty. N Engl J Med 2001;345:e4.)

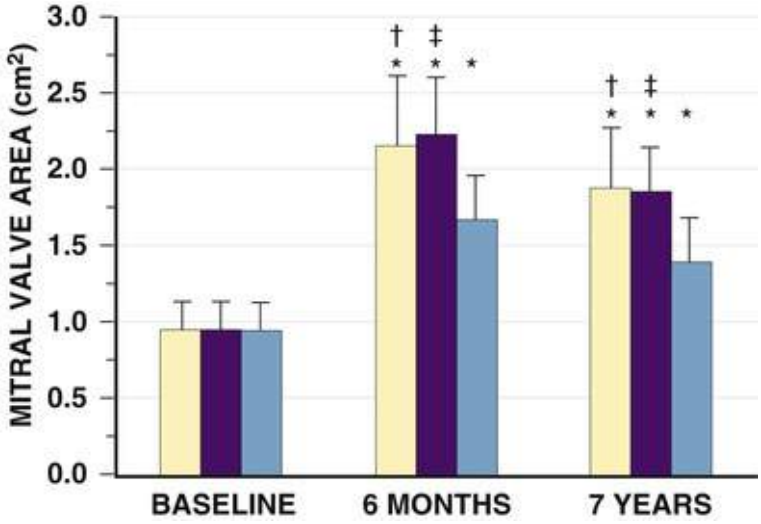
Commissural separation and fracture of nodular calcium appear to be the mechanisms responsible for improvement in valvular function. In several series, the hemodynamic results of BMV have been favorable (**eFig. 69.3**), with reduction of the transmitral pressure gradient from an average of approximately 18 to 6 mm Hg (**see Chapter 72**), a small (average, 20%) increase in cardiac output, and an average doubling of the calculated MVA, from 1 to 2 cm^2.[8,19,31] Results are especially impressive in younger patients without severe valvular thickening or calcification (**see Fig. 69.1**). Elevated PVR declines rapidly, although usually not completely. The reported mortality rate has ranged from 1% to 2%. Complications include cerebral emboli and cardiac perforation, each in approximately 1% of patients,

and development of MR severe enough to require operation in another 2% (approximately 15% develop lesser, but still undesirable, degrees of MR).[32] Approximately 5% of patients are left with a small, residual atrial septal defect (ASD), but this closes or decreases in size in most. Rarely, the ASD is large enough to cause right-sided HF; this complication most often is seen in conjunction with an unsuccessful mitral valvotomy.



EFIGURE 69.3 Mitral valve area before and 6 months and 7 years after valvotomy in a prospective, randomized trial of balloon mitral valvotomy (BMV) (*yellow bars*), open surgical mitral commissurotomy (OMC) (*purple bars*), and closed mitral commissurotomy (CMC) (*blue bars*). At 6 months and 7 years, results with BMV were equivalent to those with OMC and superior to those with CMC. *P < 0.001 compared to baseline value; †*P* < 0.001 for BMV versus CMC; ‡*P* < 0.001 for OMC versus CMC. (From Ben Farhat B, Ayari M, Maatouk F, et al. Percutaneous balloon versus surgical closed and open mitral commissurotomy: seven-year follow-up results of a randomized trial. Circulation 1998;97:245-50.)

The likelihood of hemodynamic benefit and the risk of complication with BMV are predicted by anatomic features of the stenosed valve (Video 69.8). Rigid thickened valves with extensive subvalvular fibrosis and calcification lead to suboptimal results. One echocardiographic scoring system divides patients into three groups: those with a pliable, noncalcified anterior leaflet and minimal chordal disease (group 1); those with a pliable, noncalcified anterior leaflet but with chordal thickening and shortening (<10 mm long) (group 2); and those with fluoroscopic evidence of calcification of any extent of the valve apparatus (group 3).[8] Event-free survival at 3 years is highest for group 1 (89%), compared with group 2 (78%) or group 3 (65%). With an alternate echocardiographic scoring system (Wilkins score), leaflet rigidity, leaflet thickening, valvular calcification, and subvalvular disease are each scored from 0 to 4 (**see Table 14.9**).[3,19,21] A score of 8 or lower usually is associated with an excellent immediate- and long-term result, whereas scores exceeding 8 are associated with less impressive results (**Fig. 69.6**; **see also Fig. 72.7**), including increased risk of development of MR. Commissural calcification also is a predictor of poor outcomes.

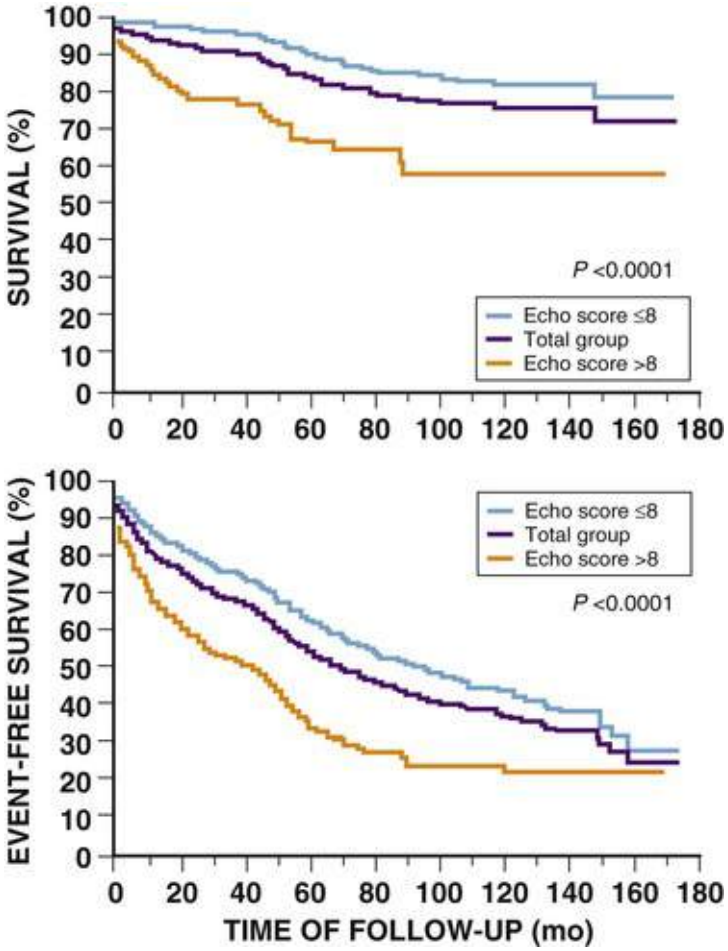


FIGURE 69.6 Long-term survival **(top)** and event-free survival **(bottom)** after balloon mitral valvotomy (BMV) for 879 patients who were stratified by baseline echocardiographic (Echo) morphology score of 8 or less (*blue line*) or more than 8 (*gold line*). Events include death, repeat BMV, and surgical mitral valve replacement. Patients with the lower Echo score had a significantly better outcome initially and over the next 12 to 13 years. (From Palacios IF, Sanchez PL, Harrell LC, et al. Which patients benefit from percutaneous mitral balloon valvuloplasty? Prevalvuloplasty and postvalvuloplasty variables that predict long-term outcome. Circulation 2002;105:1465-71.)

TEE should be performed just before BMV to exclude LA thrombus and confirm that MR is not moderate or severe. TEE also is appropriate for evaluating MS severity and mitral valve morphology when transthoracic images are suboptimal, although the chordal apparatus on TEE is less well visualized compared with transthoracic imaging. During the procedure, transthoracic, transesophageal, or intracardiac echocardiography is used to monitor placement of the catheters and balloon, assess hemodynamic results after each inflation, and detect complications such as MR.

In patients with suitable anatomic findings, long-term results are favorable, with excellent survival rates without functional disability or need for surgery or repeat BMV.[3,31] Patients with severe MS randomly assigned to undergo BMV, closed surgical valvotomy, or open surgical valvotomy had similar clinical outcomes for BMV and open surgery that were superior to closed surgical valvotomy. After 7 years, MVA was equivalent in the BMV and open surgery groups, both significantly greater than in the closed valvotomy group (**eFig. 69.3**). In another randomized study that included older patients with less favorable valve morphology, compared with open surgical commissurotomy, patients randomly assigned to undergo BMV had a smaller increase in MVA and higher likelihood of restenosis (28% versus 18% at 4 years). Excellent results also have been reported in children and adolescents in developing nations, where patients tend to be younger. These young patients usually have pliable valves, which are ideal for BMV. It has also been shown that suitable candidates who have restenosed after prior commissurotomy can still be effectively treated with BMV.[33]

Surgical Valvotomy

Three operative approaches are available for the treatment of rheumatic MS: (1) closed mitral valvotomy (CMV) using a transatrial or transventricular approach; (2) open valvotomy (i.e., valvotomy done under direct vision with the aid of cardiopulmonary bypass [CPB]), which may be combined with other repair techniques, such as leaflet resection or augmentation, chordal procedures, and annuloplasty when MR is present; and (3) mitral valve replacement (**Table 69.2**).[34] Surgical intervention for MS is recommended for patients with severe MS and significant symptoms (NYHA Class III or IV) when BMV is not available, when BMV is contraindicated because of persistent LA thrombus or moderate to severe MR, or when the valve is calcified and surgical risk is acceptable. The preferred surgical approach is valve repair (open valvotomy, with or without additional procedures) whenever possible, although since patients referred for surgery often have poor morphology for BMV, valve replacement is often the best choice. Surgery also is reasonable for patients with severe MS and severe pulmonary hypertension when BMV is not possible and may be considered for patients with moderate to severe MS with recurrent embolic events despite anticoagulation.

TABLE 69.2

Approaches to Mechanical Relief of Mitral Stenosis

APPROACH	ADVANTAGES	DISADVANTAGES
Closed surgical valvotomy	Inexpensive Relatively simple Good hemodynamic results in selected patients Good long-term outcome	No direct visualization of valve Only feasible with flexible, noncalcified valves Contraindicated with MR grade higher than 2+ Surgical procedure with general anesthesia
Open surgical valvotomy	Visualization of valve allows directed valvotomy. Concurrent annuloplasty for MR is feasible.	Best results with flexible, noncalcified valves Surgical procedure with general anesthesia
Valve replacement	Feasible in all patients regardless of extent of valve calcification or severity of MR	Surgical procedure with general anesthesia Effect of loss of annular-papillary muscle continuity on LV function Prosthetic valve Chronic anticoagulation
Balloon mitral valvotomy	Percutaneous approach Local anesthesia Good hemodynamic results in selected patients Good long-term outcome	No direct visualization of valve Only feasible with flexible noncalcified valves Contraindicated with MR grade higher than 2+

LV, Left ventricular; *MR,* mitral regurgitation.

Closed Mitral Valvotomy.

CMV is rarely used now in the United States, having been replaced by BMV, which is more effective in patients who are CMV candidates. CMV is more popular in developing nations, where the expense of open heart surgery and even of balloon catheters for BMV is an important factor, and where patients with MS are younger and therefore have more pliable valves. However, even in these nations, CMV is being replaced by BMV, with balloon resterilization to keep the procedure economical.

CMV is performed without CPB but with the aid of a transventricular dilator. It is an effective operation, provided that MR, atrial thrombosis, or valvular calcification is not serious and that chordal fusion and shortening are not severe. Echocardiography is useful for selecting suitable candidates for CMV by identifying patients without valvular calcification or dense fibrosis. If possible, CMV should be carried out with pump standby; if the surgeon is unable to achieve a satisfactory result, the patient can be placed on CPB and the valvotomy performed under direct vision or the valve replaced.

On average, MVA is increased by 1 cm^2, with only 20% to 30% of patients requiring mitral valve

replacement within 15 years. The hospital mortality rate is 1% to 2% in experienced centers. Marked symptomatic improvement occurs in most patients, and those selected with low echocardiographic scores have excellent long-term survival. Long-term follow-up has shown that the results are best if the operation is carried out before chronic AF, severe pulmonary hypertension, or HF has occurred,[34] and complication rates are higher when valves are calcified or severely thickened.

Open Mitral Valvotomy.

Most surgeons now prefer to carry out direct-vision or open valvotomy. This operation is most frequently performed in patients with MS whose mitral valves are too distorted or calcified for BMV. CPB is established and, to obtain a dry, quiet heart, body temperature is usually lowered, the heart is arrested, and the aorta is occluded intermittently. Thrombi are removed from the left atrium and its appendage, and the latter often is amputated to remove a potential source of postoperative emboli. The commissures are incised, and when necessary, fused chordae tendineae are separated, the underlying papillary muscle is split, and the valve leaflets are débrided of calcium. Mild or even moderate MR may be corrected using similar repair approaches as for primary MR. Intraoperative echocardiography (or, if not available, LA and LV pressures) is used after bypass has been discontinued to confirm that the valvotomy has been effective. When it has not been effective, another attempt can be made. If repair is not possible—usually because of severe distortion and calcification of the valve and subvalvular apparatus, with accompanying MR that cannot be corrected—mitral valve replacement (MVR) should be done. In patients with AF, an LA maze or AF ablation procedure typically is done at surgery to increase the likelihood of maintaining long-term sinus rhythm. Open valvotomy is feasible and successful in more than 80% of patients referred for this procedure, with an operative mortality of 1%, rate of reoperation for MVR of 0% to 16% at 36 to 53 months, and 10-year actuarial survival rates of 81% to 100%.

Restenosis After Valvotomy

Mitral valvotomy, whether percutaneous or operative and open or closed, is palliative rather than curative and, even when successful, there is some degree of residual mitral valve dysfunction. Because the valve is not normal postoperatively, turbulent flow usually persists in the paravalvular region, and the resultant trauma may play a role in restenosis. These changes are analogous to the gradual development of obstruction in a congenitally bicuspid aortic valve and are not usually the result of recurrent rheumatic fever. It is likely that the process of superimposed leaflet calcification and increased stiffness superimposed on the rheumatic valve is similar to the calcific changes seen in aortic valve stenosis.

On clinical grounds alone, based on the reappearance of symptoms, the incidence of restenosis has been estimated to range widely, from 2% to 60%. Recurrence of symptoms is often not caused by restenosis but may be caused by one or more of the following conditions: (1) an inadequate first procedure with residual stenosis; (2) increased severity of MR, either at operation or developing consequently, sometimes from infective endocarditis; (3) progression of aortic or tricuspid valve disease; or (4) development of coronary artery disease (CAD). True restenosis occurs in less than 20% of patients who are followed for 10 years.[3]

Thus, in properly selected patients, mitral valvotomy, however performed—percutaneous BMV, closed or open surgical valvotomy—is a low-risk procedure that results in a significant increase in the size of the mitral orifice and favorably alters the clinical course of an otherwise progressive disease. PAP falls promptly and decisively when mitral obstruction is effectively relieved. Most patients maintain clinical improvement for 10 to 15 years of follow-up. When a second procedure is required because of symptomatic deterioration, the valve is usually calcified and more seriously deformed than at the first

operation, and adequate reconstruction may not be possible. Accordingly, MVR often is necessary at that time, although in suitable patients, repeat commissurotomy can be quite effective.[33]

Mitral Valve Replacement

MVR is recommended for symptomatic patients with severe MR when BMV or surgical mitral valve repair is not possible. Usually, MVR is required for patients with combined MS and moderate or severe MR, those with extensive commissural calcification, severe fibrosis, and subvalvular fusion, and those who have undergone previous valvotomy. The operative mortality rate for isolated MVR ranges from 3% to 8% in most centers and averaged 6.04% in 16,105 such operations for patients with MS and/or MR reported in the Society of Thoracic Surgeons (STS) National Database.[35] Prosthetic valves are associated with increased risk because of valve deterioration and chronic anticoagulation, so the threshold for operation should be higher in patients in whom preoperative evaluation suggests that MVR may be required than in patients in whom valvotomy alone appears to be indicated.

Generally, a mechanical valve is preferred when MVR for MS is necessary and AF is present because of the need for chronic anticoagulation. In patients younger than 65 years who are in sinus rhythm, a mechanical valve is reasonable because of the risk of tissue valve deterioration and likely need for a second operation in the future. However, some younger patients may choose a bioprosthetic valve for lifestyle considerations, despite the risk of valve deterioration. A bioprosthetic valve is appropriate in patients who cannot take warfarin and is reasonable in all patients older than 65 years. The development of percutaneous options for MVR, particularly valve-in-valve insertion into dysfunctional mitral bioprostheses,[36] has complicated decision making in the initial operation, with some younger patients preferring bioprostheses.

MVR is indicated in patients with MS and MVA smaller than 1.5 cm^2 in NYHA Class III or IV whose valves are not suitable for valvotomy (**see Fig. 69.4**). Because the operative mortality risk may be high (10% to 20%) in NYHA Class IV patients, surgery should be carried out before patients reach this stage if possible. On the other hand, even such high-risk patients should not be denied this option unless they have comorbid conditions that preclude surgery or a satisfactory outcome.

Percutaneous Mitral Valve Replacement in Mitral Stenosis

Unlike the dramatic progress seen in the application of transcatheter aortic valve replacement (TAVR) for treatment of aortic stenosis, the development of percutaneous valve repair or replacement for MS is still in the early stages (**see Chapter 72**). Mitral clipping, approved for high-risk patients with organic MR, has no role in mitral stenosis, since the clipping only makes the valve area smaller. There have been a few case reports published where balloon-expandable transcutaneous aortic prostheses have been inserted into stenotic mitral valve, either transapically[37] or transseptally,[38] with reasonable results, but utility on a broader scale is unproved as yet.

Mitral Regurgitation

Causes and Pathology

The mitral valve apparatus involves the mitral leaflets, chordae tendineae, papillary muscles, and mitral annulus (**Fig. 69.7** and Video 69.9). Abnormalities of any of these structures may cause MR.[12,39-41] The major causes of MR include myxomatous degeneration (mitral valve prolapse [MVP] and ruptured mitral chordae), rheumatic heart disease, infective endocarditis, HCM, annular calcification, dilated cardiomyopathy (DCM), and ischemic heart disease (**eTable 69.1**). Less common causes of MR include collagen vascular diseases, trauma, the hypereosinophilic syndrome, carcinoid, and exposure to certain drugs.

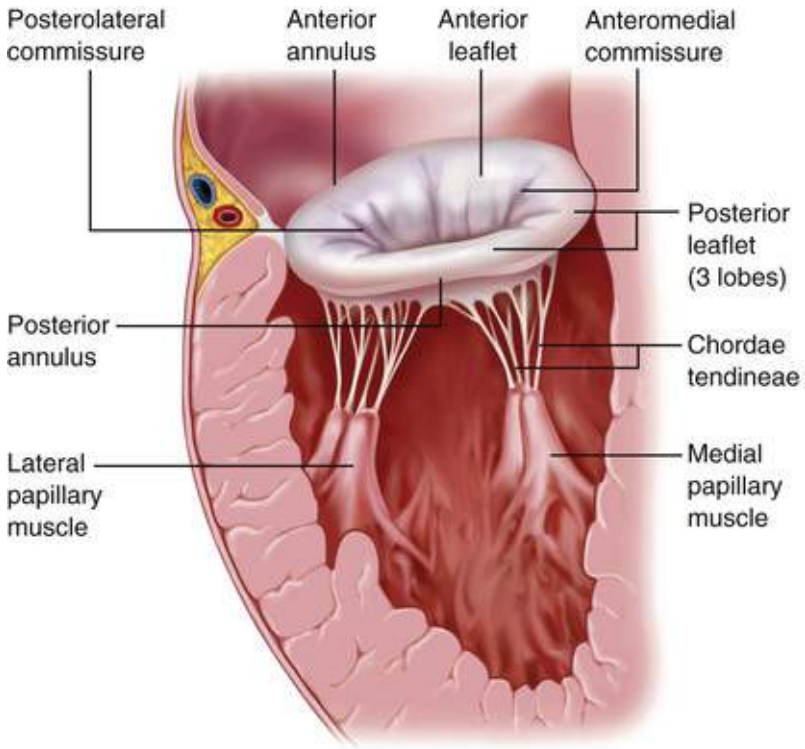

FIGURE 69.7 Continuity of the mitral apparatus and the left ventricular (LV) myocardium. Mitral regurgitation (MR) may be caused by any condition that affects the leaflets or the structure and function of the left ventricle. Similarly, a surgical procedure that disrupts the mitral apparatus in an attempt to correct MR will have adverse effects on LV geometry, volume, and function. (From Otto CM. Evaluation and management of chronic mitral regurgitation. N Engl J Med 2001;345:740-6.)

ETABLE 69.1

Causes of Acute and Chronic Mitral Regurgitation

Acute
Mitral Annulus Disorders
• Infective endocarditis (abscess formation) • Trauma (valvular heart surgery) • Paravalvular leak caused by suture interruption (surgical technical problems or infective endocarditis)
Mitral Leaflet Disorders
• Infective endocarditis (perforation or interfering with valve closure by vegetation) • Trauma (tear during percutaneous balloon mitral valvotomy or penetrating chest injury) • Tumors (atrial myxoma) • Myxomatous degeneration • Systemic lupus erythematosus (Libman-Sacks lesion)
Rupture of Chordae Tendineae
• Idiopathic (e.g., spontaneous) • Myxomatous degeneration (mitral valve prolapse, Marfan syndrome, Ehlers-Danlos syndrome) • Infective endocarditis • Acute rheumatic fever • Trauma (percutaneous balloon valvotomy, blunt chest trauma)
Papillary Muscle Disorders
• Coronary artery disease (causing dysfunction and rarely rupture) • Acute global left ventricular dysfunction • Infiltrative diseases (amyloidosis, sarcoidosis) • Trauma
Primary Mitral Valve Prosthetic Disorders
• Porcine cusp perforation (endocarditis) • Porcine cusp degeneration • Mechanical failure (strut fracture) • Immobilized disc or ball of the mechanical prosthesis
Chronic
Inflammatory
• Rheumatic heart disease • Systemic lupus erythematosus • Scleroderma
Degenerative
• Myxomatous degeneration of mitral valve leaflets (Barlow click-murmur syndrome, prolapsing leaflet, mitral valve prolapse) • Marfan syndrome • Ehlers-Danlos syndrome • Pseudoxanthoma elasticum • Calcification of mitral valve annulus
Infective
• Infective endocarditis affecting normal, abnormal, or prosthetic mitral valves
Structural
• Ruptured chordae tendineae (spontaneous or secondary to myocardial infarction, trauma, mitral valve prolapse, endocarditis) • Rupture or dysfunction of papillary muscle (ischemia or myocardial infarction) • Dilation of mitral valve annulus and left ventricular cavity (congestive cardiomyopathies, aneurysmal dilation of left ventricle) • Hypertrophic cardiomyopathy • Paravalvular prosthetic leak
Congenital
• Mitral valve clefts or fenestrations • Parachute mitral valve abnormality in association with: Endocardial cushion defects Endocardial fibroelastosis Transposition of great arteries Anomalous origin of left coronary artery

Data from Jutzy KR, Al-Zaibag M. Acute mitral and aortic valve regurgitation. In Al-Zaibag M, Duran CMG, editors. Valvular Heart Disease. New York: Marcel Dekker; 1994, pp 345-62; and Haffajee CI. Chronic mitral regurgitation. In Dalen JE, Alpert JS, editors. Valvular Heart Disease. 2nd ed. Boston: Little, Brown; 1987, p 112.

The many potential causes of MR can be broadly categorized by the type of leaflet motion abnormality proposed by Carpentier (**Fig. 69.8**), because these mechanisms also suggest strategies for surgical correction.[39] Leaflet motion is normal in type I, increased in type II, and restricted in type III (restricted opening in IIIa and restricted closure in IIIb). In general, types II and IIIa usually are caused by primary disorders of the valve leaflets, whereas types I and IIIb have relatively normal leaflets, which are distorted by LV and annular remodeling causing secondary MR. The surgeon's view of the mitral valve in classic views of these four conditions is shown in **Fig. 69.9**. For clinical purposes, MR is classified as *primary* (or organic or degenerative) MR, caused by intrinsic disease of the mitral leaflets, and *secondary* (or functional) MR, caused by diseases of the left ventricle and/or mitral annulus. *Ischemic*

MR is a subset of secondary MR caused by regional ventricular dysfunction from prior MI. Primary and secondary MR are two distinctly different disease conditions, with different pathophysiologies, outcomes, and management considerations.

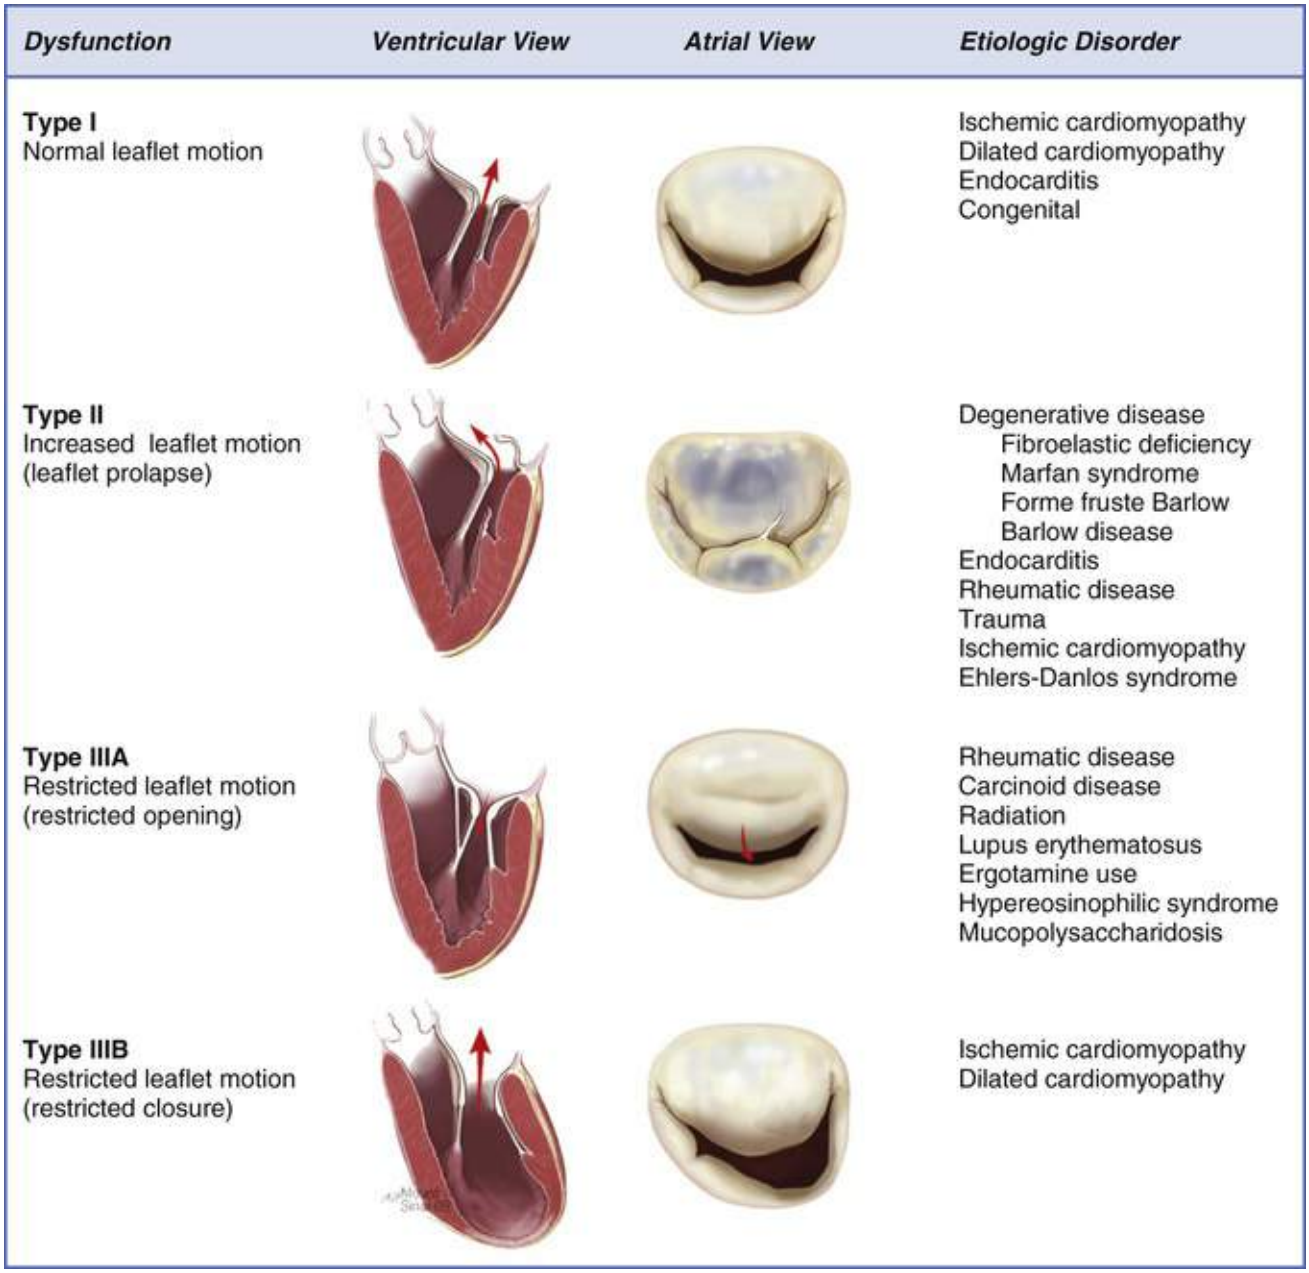

FIGURE 69.8 Pathophysiologic triad approach to mitral regurgitation (MR) and its multifactorial etiology. The mechanism of leaflet dysfunction defines the three types of MR. (From Castillo JG, Adams DH. Mitral valve repair and replacement. In Otto CM, Bonow RO, editors. Valvular Heart Disease: A Companion to Braunwald's Heart Disease. Philadelphia: Saunders; 2013, pp 327-340.)

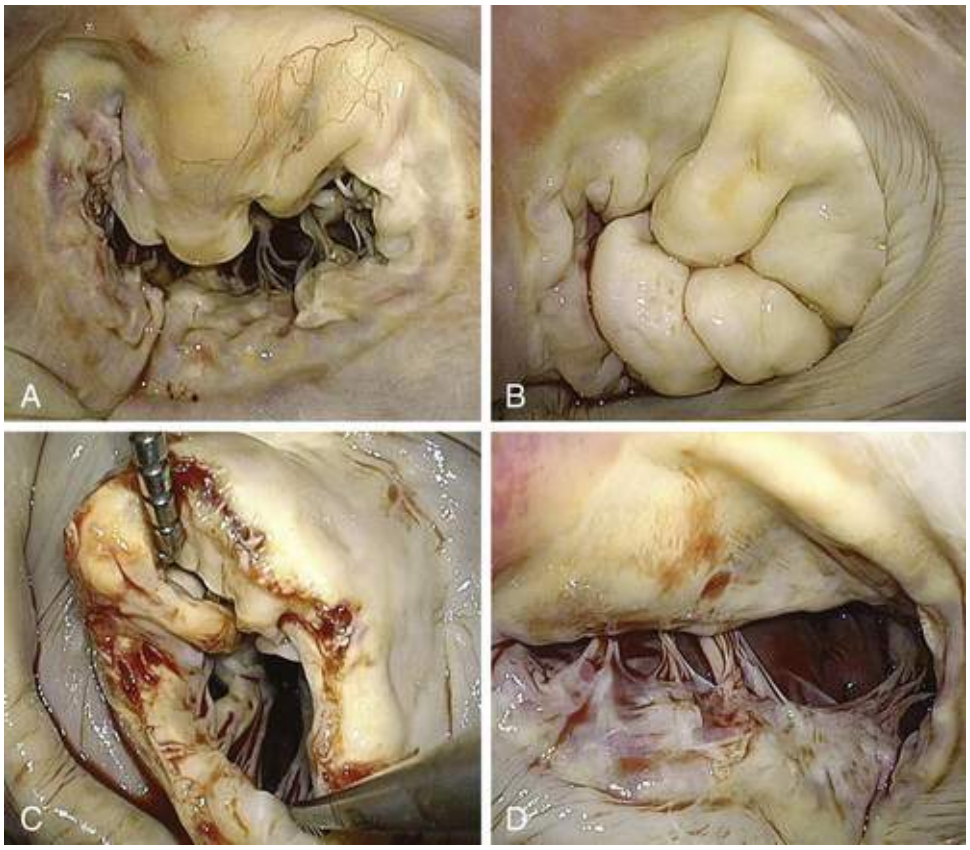

FIGURE 69.9 Valve lesions in mitral regurgitation. **A,** Severe annular dilation leading to type I dysfunction. **B,** Severe myxomatous changes with redundant, thick, and bulky segments in a patient with Barlow disease and type II dysfunction. **C,** Rheumatic mitral valve disease with classic "fish mouth" appearance and type IIIA dysfunction. **D,** Ischemic mitral valve disease caused by severe tethering of the P_3 scallop leading to type IIIB dysfunction. (From Castillo JG, Adams DH: Mitral valve repair and replacement. In Otto CM, Bonow RO, editors. Valvular Heart Disease: A Companion to Braunwald's Heart Disease. Philadelphia: Saunders; 2013, pp 327-340.)

Abnormalities of Valve Leaflets.

MR caused by primary abnormalities of the valve leaflets occurs in many situations.[39,42] In the developed world, myxomatous degeneration is the leading cause of organic MR. Intensive work in the past decade has demonstrated the mitral valve to be a dynamic structure with protein turnover and remodeling continuing throughout life. The normal mitral valve is a thin (<3 mm) endothelium-lined bileaflet structure with dense collagen on the ventricular side (fibrosa), a less stiff layer of collagen and elastin on the atrial side (atrialis), and in between a loose connective tissue layer with abundant glycosaminoglycans (spongiosa). Interspersed among the spongiosa are valvular interstitial cells (VICs), derived from endocardial endothelium, which normally are inactive.[42] In myxomatous degeneration, these VICs can be transformed to myofibroblasts, which secrete excess glycosaminoglycans and matrix metalloproteinases, leading to fragmentation of the fibrosa and atrialis and thickening of the spongiosa (**Fig. 69.10**). In turn, this reduces the tensile strength of the MV, making it prone to prolapse into the left atrium with repetitive application of ventricular pressure.[43]

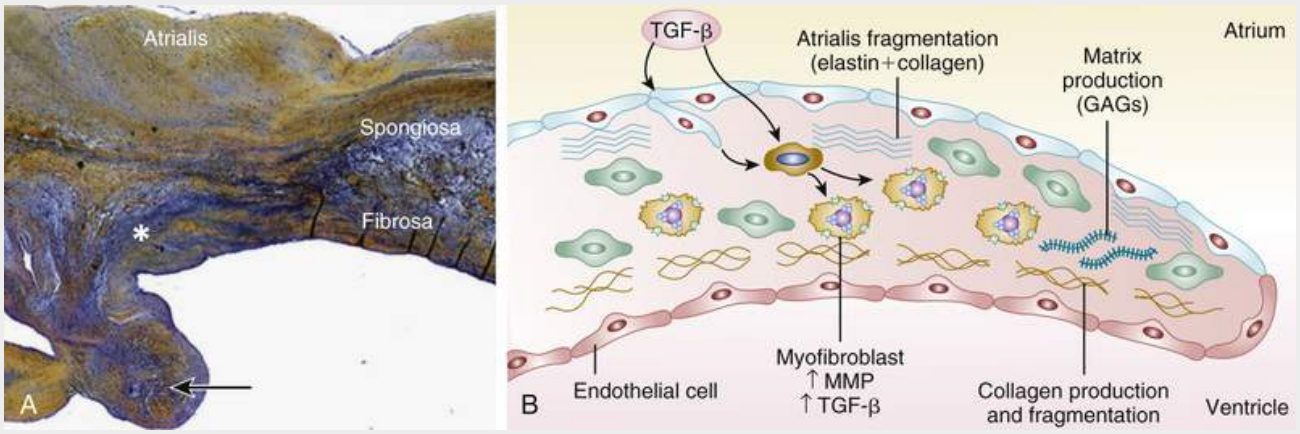

FIGURE 69.10 Mechanisms of mitral valve prolapse (MVP). **A,** Mitral valve stained with hematoxylin and eosin to define the lesion of MVP as disruption of the fibrosa by myxoid extracellular matrix (*), which also infiltrates the collagen core of the chordae tendineae, one of which was ruptured (*arrow*). The elastin lamina beneath the atrialis is also disrupted. **B,** Schematic showing the mechanism of myxomatous degeneration, with activation of valve interstitial cells to myofibroblasts that increase matrix production and turnover, secrete MMPs that drive collagen and elastin fragmentation, and release transforming growth factor (TGF)-β, which in turn promotes further cell proliferation and myofibroblast differentiation. GAGs, Glycosaminoglycans; MMP, matrix metalloproteinase. (From Levine RA, Hagege AA, Judge DP, et al. Mitral valve disease: morphology and mechanisms. Nat Rev Cardiol 2015;12:689-710.)

A minority of myxomatous degeneration cases have a clear genetic component, with MVP frequently seen in connective tissue disorders such as Marfan, Loeys-Dietz, and Ehlers-Danlos syndromes and pseudoxanthoma elasticum (**see Chapter 7**).[44] A common thread in these syndromes appears to be excessive transforming growth factor beta (TGF-β) stimulation. The more common, nonsyndromic MVP can have a genetic component, with familial clustering demonstrated in the Framingham study, but this likely involves many genes with incomplete penetrance. Although parental MVP conveyed a fivefold increased risk of MVP, the overall prevalence in the offspring was only 5.4%.[45]

Myxomatous disease occurs on a spectrum that depends on the relative degree of leaflet thickening and redundancy versus weakness in the chordae tendineae. On one extreme is *Barlow syndrome* (**see Fig. 69.9B**), with gross leaflet thickening and redundancy, multiscalloped deep prolapse, and severe regurgitation arising from multiple points along the valve closure line. At the other extreme is *fibroelastic deficiency,* with relatively thin leaflets, presenting with isolated flail of a single scallop and very focal regurgitation, which still may be severe. Intermediate forms may lie between these two extremes.[46]

Infective endocarditis can cause MR by perforating valve leaflets (**see Chapter 73**). Vegetations can prevent leaflet coaptation, and valvular retraction during the healing phase of endocarditis can cause MR. Destruction of the mitral valve leaflets can also occur in patients with penetrating and nonpenetrating trauma.

In the developing world, chronic rheumatic heart disease remains a common cause of MR. In contrast with MS, rheumatic MR is more frequent in men than in women. It is a consequence of shortening, rigidity, deformity, and retraction of one or both mitral valve cusps and is associated with shortening and fusion of the chordae tendineae and papillary muscles.

MR can also occur with exposure to certain drugs, which cause fibrotic changes in the valve leaflets.[47] Drugs associated with MR include the ergot alkaloids methysergide and ergotamine, the anorexigens (dex)fenfluramine and benfluorex, the dopamine agonists pergolide and cabergoline; and 3,4-methylenedioxymethamphetamine (MDMA, “Ecstasy”). The thickened, rigid leaflets are similar to those usually seen in the right heart in patients with carcinoid and suggest a common pathophysiologic cause of overstimulation of the serotonin 2B receptor. In carcinoid confined to the gastrointestinal tract, the excess

serotonin is metabolized in the lungs, and mitral involvement is not seen. However, with lung metastases or right-to-left shunting, mitral and aortic thickening and regurgitation may develop.

Abnormalities of the Mitral Annulus

Dilation.

In normal adults the mitral annulus measures approximately 10 cm in circumference. It is soft and flexible, and contraction of the surrounding LV muscle during systole causes the annular constriction that contributes importantly to valve closure.[2] Smooth muscle cells within the annulus and mitral leaflets themselves can also exert a sphincter action on the valve.[48] MR secondary to dilation of the mitral annulus can occur in any form of heart disease characterized by dilation of the left ventricle and/or atrium, especially DCM and longstanding AF.[49,50] LV submitral aneurysm has been reported as a cause of annular MR in sub-Saharan Africa and appears to result from a congenital defect in the posterior portion of the annulus. In addition, primary diseases of the leaflets, such as myxomatous disease, are associated with annular dilation and abnormal annular motion, which may aggravate severity of MR.[51,52]

Calcification.

Idiopathic (degenerative) calcification of the mitral annulus is often found at autopsy, generally of little functional consequence. However, when severe (**see eFig. 15.7**), it may cause MR and may even encroach on the orifice enough to cause significant MS. Mitral annular calcification shares common risk factors with atherosclerosis, including systemic hypertension, hypercholesterolemia, and diabetes; is associated with coronary and carotid atherosclerosis, as well as aortic valve calcification; and identifies patients at higher risk for cardiovascular morbidity and mortality. Annular calcification may also be accelerated by an intrinsic defect in the fibrous skeleton of the heart, as in Marfan and Hurler syndromes, where annular dilation further contributes to MR. The incidence of mitral annular calcification is also increased in patients who have chronic renal failure with secondary hyperparathyroidism, as well as with rheumatic involvement.

Abnormalities of the Chordae Tendineae.

Abnormalities of the chordae tendineae are important causes of MR (**see Fig. 14.30**). Lengthening and rupture of the chordae tendineae are cardinal features of the MVP syndrome (**see Fig. 14.40**), particularly fibroelastic deficiency. The chordae may be congenitally abnormal; rupture may be spontaneous (primary) or may result from infective endocarditis, trauma, rheumatic fever, or rarely, osteogenesis imperfecta or relapsing polychondritis. In most patients, no cause for chordal rupture is apparent other than increased mechanical strain on thin, myxomatous chordae. Chordae to the posterior leaflet rupture more frequently than those to the anterior leaflet. Depending on the number of chordae involved in rupture and the rate at which rupture occurs, the resultant MR may be mild, moderate, or severe and acute, subacute, or chronic. Chordal rupture may also occur secondary to trauma from percutaneous circulatory support devices.[53]

Involvement of the Papillary Muscles.

Diseases of the LV papillary muscles can also cause MR. Because these muscles are perfused by the terminal portion of the coronary vascular bed, they are particularly vulnerable to ischemia, and any disturbance in coronary perfusion may result in papillary muscle dysfunction. When transient, ischemia results in temporary papillary muscle dysfunction and may cause transient episodes of MR that are sometimes associated with attacks of angina pectoris or pulmonary edema. When severe and prolonged, ischemia causes papillary muscle dysfunction and scarring, as well as chronic MR. The posterior papillary muscle, which is supplied by the posterior descending branch of the right coronary artery, becomes ischemic and infarcted more frequently than the anterolateral papillary muscle; the latter is

supplied by diagonal branches of the left anterior descending coronary artery and often by marginal branches from the left circumflex artery as well. Ischemia of the papillary muscles usually is caused by coronary atherosclerosis but also may occur in patients with severe anemia, shock, coronary arteritis of any cause, or an anomalous left coronary artery. MR occurs frequently in patients with healed myocardial infarcts and most frequently is caused by regional dysfunction of the LV myocardium at the base of a papillary muscle, usually in the right coronary or left circumflex territories, resulting in tethering of the mitral leaflets and incomplete leaflet coaptation.[54,55] Although necrosis of a papillary muscle is a frequent complication of MI, frank rupture of the full papillary muscle is much less common and is often fatal because of the extremely severe MR that it produces (**see Chapters 58 and 59**). However, rupture of one or two of the apical heads of a papillary muscle can result in a flail leaflet (**see Fig. 14.29A**) with a lesser degree of MR (but still usually severe), which makes survival possible, usually with prompt surgical therapy,[56,57] although percutaneous repairs have also been reported.[58]

Various other disorders of the papillary muscles also may be responsible for the development of MR (**see Chapters 23, 61, and 77**). These disorders include congenital malposition of the muscles; absence of one papillary muscle, resulting in the so-called parachute mitral valve syndrome; and involvement or infiltration of the papillary muscles by a variety of processes, including abscesses, granulomas, neoplasms, amyloidosis, and sarcoidosis.

Left Ventricular Dysfunction.

Ischemic LV dysfunction and DCM are important causative factors in the development of MR and represent the second leading cause of MR after MVP in the United States.[55] LV dilation from any cause, including ischemia, can alter the spatial relationships between the papillary muscles and chordae tendineae and thereby result in functional MR (**see Fig. 69.6**; **see also Figs. 14.31B and 14.41**). In general, for a given amount to LV dilation, MR is greater when there is asymmetric tethering of the mitral valve from inferior and inferolateral ventricular scarring than from symmetric dilation in DCM (**Fig. 69.11**).[54]

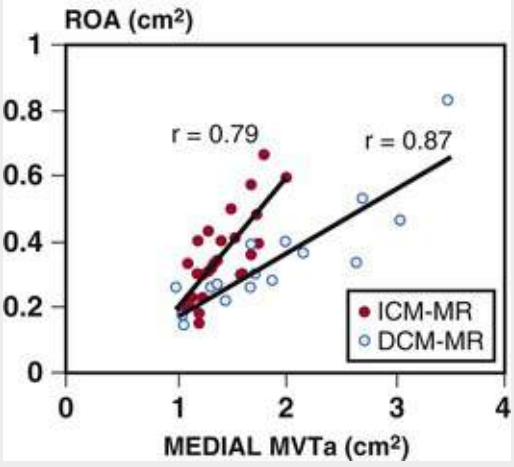

FIGURE 69.11 Significant correlations between mitral valve tethering area (MVTa) and effective regurgitant orifice area (ROA) in patients with secondary mitral regurgitation related to ischemic cardiomyopathy (ICM-MR) versus dilated cardiomyopathy (DCM-MR). For a given MVTa, patients with ICM have more severe MR than patients with DCM. (From Kwan J, Shiota T, Agler DA, et al. Geometric differences of the mitral apparatus between ischemic and dilated cardiomyopathy with significant mitral regurgitation: real-time three-dimensional echocardiography study. Circulation 2003;107:1135-40.)

Some degree of MR is found in approximately 30% of patients with CAD being considered for coronary artery bypass graft surgery (CABG). In most of these patients, MR develops from tethering of

the posterior leaflet because of regional LV dysfunction. The outlook for the patient with ischemic MR is substantially worse than for the patient with MR from other causes, because of the associated CAD, LV remodeling, and systolic dysfunction. Other pathologic changes may include additional ischemic damage to the papillary muscles, dilation of the mitral valve ring, and loss of systolic annular contraction, contributing further to MR. In most of these patients, MR is mild; however, any degree of MR is associated with a worse prognosis than in patients without MR. The incidence and severity of regurgitation vary inversely with the LV ejection fraction (EF) and vary directly with the LV end-systolic volume. MR occurs in approximately 20% of patients after acute MI and, even when mild, is associated with a higher risk of adverse outcomes.[55,59,60]

Other causes of MR include obstructive HCM (**see Chapter 78**), the hypereosinophilic syndrome, endomyocardial fibrosis, trauma affecting the leaflets and papillary muscles, Kawasaki disease, LA myxoma, and various congenital anomalies, including cleft anterior leaflet and ostium secundum ASD (**Chapters 75 and 94**).

Chronic Primary Mitral Regurgitation

Pathophysiology

Because the regurgitant mitral orifice is functionally in parallel with the aortic valve, the impedance to ventricular emptying is reduced in patients with MR. Consequently, MR enhances LV emptying. A significant proportion of the regurgitant volume is ejected into the left atrium before the aortic valve opens and after it closes. The volume of MR flow depends on a combination of the instantaneous size of the regurgitant orifice and the (reverse) pressure gradient between the left ventricle and left atrium.[61] Both the orifice size and the pressure gradient are labile. LV systolic pressure, and therefore the LV-LA gradient, depends on SVR, and LA pressure may rise dramatically with severe MR, sometimes reducing the LV-LA gradient to zero by end-systole. For patients in whom the mitral annulus has normal flexibility, the cross-sectional area of the mitral annulus may be altered by many interventions. Thus, increases in preload and afterload and depression of contractility increase LV size and enlarge the mitral annulus and thus the regurgitant orifice. When LV size is reduced by treatment with positive inotropic agents, diuretics, and particularly vasodilators, the regurgitant orifice size decreases, and the volume of regurgitant flow declines, as reflected in the height of the *v* wave in the LA pressure pulse and in the intensity and duration of the systolic murmur. Conversely, LV dilation, regardless of cause, may increase MR.

Left Ventricular Compensation

The left ventricle initially compensates for the development of acute MR by emptying more completely and by increasing preload (i.e., through Frank-Starling principle). Because acute MR reduces late systolic LV pressure and radius, LV wall tension declines markedly (and proportionately to a greater extent than LV pressure), permitting a reciprocal increase in the extent and velocity of myocardial fiber shortening and leading to a reduced end-systolic volume (ESV) (**Fig. 69.12**). When MR, particularly severe MR, becomes chronic, the LV end-diastolic volume (EDV) increases and the ESV returns to normal. By means of the Laplace principle, which states that myocardial wall tension is related to the product of intraventricular pressure and radius divided by wall thickness, the elevated LVEDV increases wall tension to normal or supranormal levels in the “chronic compensated stage” of severe MR. The resultant increase in LVEDV and mitral annular diameter may create a vicious circle in which MR leads to more MR. In patients with chronic MR, LVEDV and LV mass are increased; that is, typical volume overload

(eccentric) hypertrophy develops. However, the degree of hypertrophy is often not proportional to the degree of LV dilation, so the ratio of LV mass/EDV may be less than normal, increasing wall stress. Nonetheless, the reduced afterload permits maintenance of EF in the normal to supranormal range, giving false reassurance, as the "effective ejection fraction" (EFE, forward stroke volume divided by LVEDV) may be quite depressed, often unmasked after mitral surgery.[62,63] The reduced LV afterload allows a greater proportion of the contractile energy of the myocardium to be expended in shortening than in tension development, and explains how the left ventricle can adapt to the load imposed by MR.

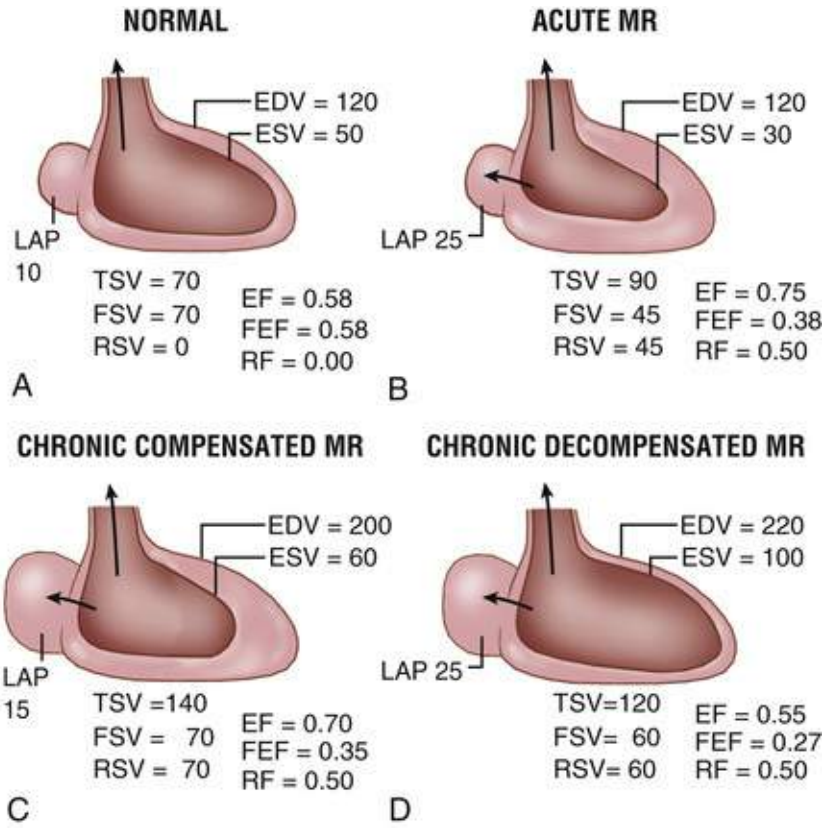

FIGURE 69.12 Three phases of mitral regurgitation are depicted and compared with **A,** normal physiology. **B,** In acute MR an increase in preload and a decrease in afterload cause an increase in end-diastolic volume (EDV) and a decrease in end-systolic volume (ESV), producing an increase in total stroke volume (TSV). Forward stroke volume (FSV) is diminished, however, because 50% of the TSV regurgitates as the regurgitant stroke volume (RSV), resulting in an increase in left atrial pressure (LAP). Although the left ventricular (LV) ejection fraction (EF) appears preserved at 0.75, in reality the forward or "effective" EF (FEF, defined as FSV/EDV) is only 0.38 with a regurgitant fraction (RF, defined as RSV/TSV) of 0.50. **C,** In the chronic compensated phase, eccentric hypertrophy has developed and EDV is now increased substantially. Afterload has returned toward normal as the radius term of the Laplace relationship increases with the increase in EDV. Normal muscle function and a large increase in EDV permit a substantial increase in TSV from the acute phase. This in turn permits a normal FSV. Left atrial enlargement now accommodates the regurgitant volume at lower LAP. EF remains greater than normal, but FEF demonstrates the inefficiency of the cardiac function. **D,** In the chronic decompensated phase, muscle dysfunction has developed, impairing EF, diminishing both TSV and FSV. The EF, although still normal, has decreased to 0.55, with FEF even lower at 0.27, and LAP is reelevated because less volume is ejected during systole, causing a higher ESV. RF has remained at 0.50 in all three regurgitation scenarios. (Illustration modified to show FEF and RF.) (Modified from Carabello BA. Progress in mitral and aortic regurgitation. Curr Probl Cardiol 2003;28:553-82.)

The eccentric LV hypertrophy that accompanies the elevated EDV of chronic MR is secondary to new sarcomeres laid down in series. A shift to the right (greater volume at any pressure) occurs in the LV diastolic pressure-volume curve in patients with chronic MR. With decompensation, chamber stiffness increases, raising the diastolic pressure at any volume.
